Abstract

In this paper, we consider the class $\mathcal{C}^d$ of sphere intersection graphs in $\mathbb{R}^d$ for $d \geq 2$. We show that for each integer t, the class of all graphs in $\mathcal{C}^d$ that exclude $K_{t,t}$ as a subgraph has strongly sublinear separators. We also prove that $\mathcal{C}^d$ has asymptotic dimension at most $2d + 2$.

1 Introduction

We write $\mathcal{C}^d$ for the class of intersection graphs of spheres in $\mathbb{R}^d$ for $d \geq 2$. The *sphere dimension* of a graph G is the smallest integer so that G is contained in $\mathcal{C}^d$. This notion of dimension is analogous to the *boxicity*, *cubicity*, or *sphericity*[1] of a graph. These "dimensionality" parameters were introduced by Roberts [47], further studied by Maehara [42], and have since become a topic of much research; see for instance [7, 23, 49, 52]. We formulate an equivalent definition of $\mathcal{C}^d$ utilising an appealing application of stereographic projection, allowing us to think of $\mathcal{C}^d$ as a higher-dimensional generalisation of the class of circle graphs. (See [5, 29, 45] for some classical work on circle graphs and [16, 48] for surveys.) It will, therefore, become natural to let $\mathcal{C}^1$ denote the class of circle graphs, which then have sphere dimension 1. Thus, $\mathcal{C}^d$ simultaneously generalises various well-studied graph classes.

Of particular note, graphs with low dimension often satisfy strong separator theorems along the lines of Lipton and Tarjan's [38] famous separator theorem for planar graphs. Formally, a *balanced separator* in an n-vertex graph G is a set $S \subseteq V(G)$ so that each

[1] We note that sphericity is more restrictive than sphere dimension as it only considers unit spheres.

component of $G - S$ has at most $\frac{2}{3}n$ many vertices[2]. Lipton and Tarjan showed that every n-vertex planar graph has a balanced separator of size $\mathcal{O}(\sqrt{n})$. These separator theorems have many applications as they can be combined with divide-and-conquer techniques [9, 12, 39, 50].

Planar graphs are intersection graphs of internally disjoint circles by the Circle Packing Theorem of Andreev [1], Koebe [35], and Thurston [51]. So Miller, Teng, Thurston, and Vavasis [44] generalised the planar separator theorem by proving that the intersection graph of any sphere packing of size n in $\mathbb{R}^d$ has a balanced separator of size $\mathcal{O}(n^{1-\frac{1}{d}})$. In fact, their results hold for any collection of balls of bounded ply; the *ply* of a collection of geometric objects is the maximum number of objects with a non-empty common intersection. The ply of a collection of balls in $\mathbb{R}^d$ is closely related to the clique number of its intersection graph.

Many other geometric generalisations of Lipton and Tarjan's theorem have been proven, including some very recently [13, 14, 17, 30, 34, 50]. Some of these results, such as [13, 14, 34], consider relaxations of separators and allow for more general geometric objects that way. However, if we keep the original notion of balanced separators, then two main improvements have been made. First, instead of considering balls, we can consider compact convex subsets of $\mathbb{R}^d$ of bounded aspect ratio (the ratio of their diameter to their height) by [30, Lemma 2.21]. Second, it is enough that for any pair of objects under consideration, we can "move one of them around inside the other to roughly trace its boundary"; see [17, Theorem 2].

All the results discussed above are for convex subsets of $\mathbb{R}^d$. We prove a new separator theorem for the intersection graphs of spheres in $\mathbb{R}^d$. Instead of bounding the ply, there is a different natural obstruction which we must bound the size of: the class of all complete bipartite graphs has bounded sphere dimension, but does not admit small balanced separators. Our first result is that this is the only obstruction. For any integers $t, d \geq 2$, we write $\mathcal{C}_t^d$ for the class of all graphs that have sphere dimension at most d and do not contain the complete bipartite graph $K_{t,t}$ as a subgraph. (This subgraph need not be induced.)

▶ **Theorem 1.** *For any integers $t, d \geq 2$, the class $\mathcal{C}_t^d$ has strongly sublinear separators. More precisely, every n-vertex graph $G \in \mathcal{C}_t^d$ has a balanced separator of size $\widetilde{\mathcal{O}}_d(t^{10}n^{1-\frac{1}{2d+8}})$.*

To the best of our knowledge, this is the first high-dimensional separator theorem that applies to classes that contain large induced complete bipartite graphs. In two dimensions, Lee [37] proved that every string graph with m edges has a balanced separator of size $\mathcal{O}(\sqrt{m})$. This implies a separator theorem for string graphs with a forbidden $K_{t,t}$-subgraph by the Kővári-Sós-Turán Theorem [36]. This theorem of Lee was conjectured by Fox and Pach [24], and a slightly weaker version with an extra $\log(m)$ factor was proven by Matoušek [43]. As far as we know, the same bound could hold for graphs with sphere dimension at most d; maybe every graph with m edges and sphere dimension d has a balanced separator of size $\mathcal{O}_d(\sqrt{m})$. If so, a theorem of Fox, Pach, Sheffer, Suk, and Zahl [25] about semi-algebraic graphs could then be used to obtain a strong separator theorem for $\mathcal{C}_t^d$.

Next, we turn our attention to the asymptotic dimension of our graphs. Gromov [28] introduced the notion of asymptotic dimension of a metric space as a coarse version of the classical topological dimension. This was part of his coarse-geometric approach, which has tremendously impacted geometric group theory. For instance, Yu [53] showed that (any Cayley graph of) every finitely generated group G with finite asymptotic dimension embeds coarsely into Hilbert space, and therefore G satisfies a seminal conjecture of Novikov. Roughly speaking, asymptotic dimension corresponds to the number of colours needed to colour a graph, or family of graphs, with certain restrictions on the diameters and spacing of monochromatic components; the precise definition is given in Section 2.

[2] The exact constant does not matter much; we could replace $\frac{2}{3}$ by any constant $c \in (0, 1)$.

Although asymptotic dimension was originally introduced to study spaces of infinite diameter, the notion can be applied to classes of finite graphs, and it is gaining popularity in this setting [4, 15, 17, 26, 27, 33, 40]. This popularity is partly motivated by a connection to sparse partition schemes in algorithm development, as we discuss in Section 6. It is also motivated by connections to graph colouring, as discussed in [20].

Thus, understanding how the asymptotic dimension of a graph class interacts with other geometric properties is important. In this spirit, Bonamy et al. [4] proved that planar graphs have asymptotic dimension at most 2, and asked if every class with strongly sublinear separators has bounded asymptotic dimension [4]. (We note that this question was phrased in terms of classes of polynomial expansion; however, a class has polynomial expansion if and only if it has strongly sublinear separators [18, 46]. Formally, a class has *strongly sublinear separators* if there exists $\delta > 0$ so that every n-vertex graph that is an induced subgraph of some graph in the class admits a balanced separator of size $\mathcal{O}(n^{1-\delta})$.) We prove that the answer is positive for graphs of bounded sphere dimension.

▶ **Theorem 2.** *For any integer $d \geq 1$, the class of graphs of sphere dimension at most d has asymptotic dimension at most $2d + 2$.*

This theorem generalises and also uses a theorem of Dvořák and Norin [19], at the cost of increasing the dimension by 1. In fact, we prove a more general result by considering intersection graphs of shapes other than spheres (Theorem 18).

Paper structure. We introduce some preliminaries in Section 2. In Section 3, we discuss basic properties of sphere dimension, particularly the connection to circle graphs. In Section 4, we prove our main result that $\mathcal{C}_t^d$ has strongly sublinear separators. We prove that $\mathcal{C}^d$ has bounded asymptotic dimension in Section 5. We conclude with some open problems in Section 6.

2 Preliminaries

All graphs in this paper can be assumed to be finite and simple, although some of our results extend verbatim to the infinite case. We use $\widetilde{\mathcal{O}}_d$ for the version of big-$\mathcal{O}$ notation where we view d as being fixed and suppress polylogarithmic factors. (In fact it will be clear from our proof of Theorem 1 that we only suppress a single $\log n$ factor and a constant factor of the form c^d for c a universal constant.)

Geometric intersection graphs. Let $\mathcal{G}$ be a class of geometric objects in a given space, for example, unit squares in the plane. Then an *intersection graph of* $\mathcal{G}$ is a graph G whose vertices can be identified with objects in $\mathcal{G}$ such that there is an edge between two vertices in G if and only if the two corresponding objects intersect. Similarly, we write $G(\mathcal{G})$ for the graph with vertex-set $\mathcal{G}$ where two vertices are adjacent if they have a non-empty intersection. The *ply* of $\mathcal{G}$ is the maximum size of a set of objects in $\mathcal{G}$ with a non-empty common intersection.

Shallow minors. Our proof of Theorem 1 relies on a theorem of Plotkin, Rao, and Smith [46] and Dvořák and Norin [18] which characterises classes that admit strongly sublinear separators in terms of forbidden shallow minors. We give some relevant definitions.

Given a positive integer r, we say that a graph H is an *r-shallow minor* of a graph G if there is a function $\varphi : V(H) \to 2^{V(G)}$ such that:

- for every $x \in V(H)$, the subgraph of G induced by $\varphi(x)$ contains a rooted spanning tree of height at most r,
- for all distinct $x, y \in V(H)$, the sets $\varphi(x)$ and $\varphi(y)$ are disjoint, and
- for every $xy \in E(H)$, there is an edge in G with one end in $\varphi(x)$ and the other in $\varphi(y)$.

We call φ an *r-shallow minor model* of H in G. For $v \in V(H)$, we call $\varphi(v)$ the *bag of v*.

Strongly sublinear separators. Recall that a *balanced separator* in an n-vertex graph G is a set $S \subseteq V(G)$ so that each component of $G - S$ has at most $\frac{2}{3}n$ vertices. A graph class $\mathcal{C}$ has *strongly sublinear separators* if there exist $\varepsilon > 0$ so that for any n-vertex graph H which is an induced subgraph of a graph in $\mathcal{C}$, the graph H has a balanced separator of size $\mathcal{O}(n^{1-\varepsilon})$. (The big-$\mathcal{O}$ notation can hide a constant factor that depends on $\mathcal{C}$.) Note that to obtain strongly sublinear separators, it suffices to show that there exists $\delta > 0$ so that there are balanced separators of size $\widetilde{\mathcal{O}}(n^{1-\delta})$. In order to provide this, we show that there exists $\delta > 0$ so that there are separators of size $\widetilde{\mathcal{O}}(n^{1-\delta})$. Plotkin, Rao, and Smith [46] proved that any graph with a forbidden shallow minor has a small balanced separator.

▶ **Theorem 3** (Plotkin, Rao, and Smith [46]). *For any $r, h \in \mathbb{N}$, any n-vertex graph without an r-shallow K_h minor has a balanced separator of size $\mathcal{O}(rh^2 \log n + \frac{n}{r})$.*

We apply this theorem with r being a small power of n and h being a polynomial in r. With this choice of parameters, Theorem 3 yields a sufficiently small balanced separator.

Strong colouring number. Let G be a graph, $r \in \mathbb{N}$, and $\leq$ be an ordering of the vertices of G. For a vertex $v \in V(G)$, we call a vertex $u \in V(G)$ *strongly r-reachable from v* if $u \leq v$ and there exists a v-u-path P of length at most r in G such that u is the only vertex in P that is smaller than v with respect to $\leq$. The *r-width* of $\leq$ is the maximum over all $v \in V(G)$ of the number of vertices which are strongly r-reachable from v. Finally, the *r-strong colouring number* of a graph G, denoted $\mathsf{scol}_r(G)$, is the minimum r-width over all possible vertex orderings of G. We require the observation that intersection graphs of balls of bounded ply have bounded strong colouring numbers.

▶ **Lemma 4** ([21, Lemma 1]). *Let $\mathcal{B}$ be a finite collection of balls in $\mathbb{R}^d$ of ply at most t. Then the intersection graph $G(\mathcal{B})$ has r-strong colouring number at most $t(2r+2)^d$.*

We also use the following well-known observation that graphs with large shallow clique minors have large strong colouring numbers.

▶ **Observation 5.** *If a graph G contains an r-shallow K_h-minor, then $\mathsf{scol}_{4r+1}(G) \geq h - 1$.*

Asymptotic and Assouad–Nagata dimension. Let G be a graph, and let $\mathsf{dist}_G(\cdot,\cdot)$ denote its usual graph metric. If the graph is clear from the context, we drop the index. Let $\mathcal{U}$ be a family of subsets of $V(G)$. We say that $\mathcal{U}$ is *D-bounded* if each set $U \in \mathcal{U}$ has diameter at most D. We say that $\mathcal{U}$ is *r-disjoint* if for any a, b belonging to different elements of $\mathcal{U}$ we have $\mathsf{dist}(a, b) > r$.

We say that $D : \mathbb{R}_+ \to \mathbb{R}_+$ is an *n-dimensional control function* for a graph class $\mathcal{C}$, if for any $G \in \mathcal{C}$ and $r > 0$, $V(G)$ has a cover $\mathcal{U} = \bigcup_{i=1}^{n+1} \mathcal{U}_i$ such that each $\mathcal{U}_i$ is r-disjoint and each element of $\mathcal{U}$ is $D(r)$-bounded. The *asymptotic dimension* of $\mathcal{C}$ denoted by $\mathsf{asdim}(\mathcal{C})$, is the least integer n such that $\mathcal{C}$ has an n-dimensional control function. If no such integer n exists, then $\mathsf{asdim}(\mathcal{C})$ is infinite. The *Assouad–Nagata dimension* of $\mathcal{C}$, denoted by $\mathsf{ANdim}(\mathcal{C})$, is defined similarly, except that we insist that $D(r) \in \mathcal{O}(r)$.

3 Sphere graphs and sphere dimension

In this section, we show that the graph classes $\mathcal{C}^d$ can be thought of as a higher-dimensional analogue of the well-studied class of circle graphs. Recall that a *circle graph* is an intersection graph of a family of chords of $\mathbb{S}^1$. We generalise this definition as follows. A *d-sphere graph* is an intersection graph of a subfamily of

$$\mathcal{H}_d := \{\mathbb{D}^d \cap H \mid H \text{ is a hyperplane of } \mathbb{R}^{d+1}\},$$

where the d-disc $\mathbb{D}^d$ is the set $\{x \in \mathbb{R}^{d+1} \mid |x,0| \leq 1\}$, and $\mathbb{S}^d$ is its boundary. In particular, $\mathcal{H}_1$ consists of all chords of the circle $\mathbb{S}^1$, and $\mathcal{H}_2$ consists of the flat discs with boundary on $\mathbb{S}^2$. Thus, 1-sphere graphs are exactly the circle graphs, which by definition are the graphs in $\mathcal{C}^1$. We observe that the class of d-sphere graphs coincides with $\mathcal{C}^d$:

▶ **Observation 6.** *For every $d \geq 1$, a countable graph G is a d-sphere graph if and only if it belongs to $\mathcal{C}^d$.*

Proof. For $d = 1$ this is so by definition. For $d \geq 2$, suppose $\Theta = \{H_v \mid v \in V(G)\}$ is a d-sphere representation of G, i.e. a family of elements of $\mathcal{H}_d$ witnessing that G is a d-sphere graph. Assume that no H_v contains the *north pole* $\{0,\dots,0,1\}$ of $\mathbb{S}^d$, which we can since G is countable (which is a much stronger assumption than we actually need). Notice that $H_v \cap \mathbb{S}^d$ is homeomorphic to $\mathbb{S}^{d-1}$ for every v. Letting f be the stereographic projection of $\mathbb{S}^d$ onto $\mathbb{R}^d$, we observe that $f(H_v \cap \mathbb{S}^d) =: H'_v$ is also homeomorphic to $\mathbb{S}^{d-1}$, where we use the well-known property of stereographic projection that it preserves spheres not containing the north pole [44, Lemma 4.2]. Then G is isomorphic to the intersection graph of the family $\Theta' = \{H'_v \mid v \in V(G)\}$ by construction.

Conversely, we use f^{-1} to stereographically project a representation of G as an intersection graph of spheres in $\mathbb{R}^d$ (avoiding the origin) to a d-sphere graph representation. ◀

We now give some other observations about sphere graphs and sphere dimension. As a warm-up, we observe that if G is planar, then it has sphere dimension 2. This is because the Circle Packing Theorem [35] asserts that every finite[3] planar graph admits a sphere packing in $\mathbb{R}^2$. (A *sphere packing* of a graph G is an arrangement of closed euclidean spheres $\{S_v : v \in V(G)\}$ in $\mathbb{R}^d$ or $\mathbb{S}^d$ such that $S_v \cap S_w$ is empty whenever $vw \notin E(G)$ and $S_v \cap S_w$ is a single point whenever $vw \in E(G)$. In other words, G is the tangency graph of the family $\{S_v : v \in V(G)\}$.) It is known that every finite graph G admits a sphere packing in $\mathbb{R}^d$ for $d \leq |V(G)| - 1$ [22], and so $G \in \mathcal{C}^{|V(G)|-1}$. This proves the following observation.

▶ **Observation 7.** *Every graph G with $|V(G)| \geq 3$ has sphere dimension at most $|V(G)| - 1$.*

Conversely, we prove the following.

▶ **Observation 8.** *For every $d \in \mathbb{N}$, there is a finite graph which is not a d-sphere graph.*

Proof. We may assume that $d \geq 2$ since it is well known that not every graph is a circle graph; see [5]. Let n be an integer; we think of n as being large in comparison to d.

Let G_n be a graph of minimum degree n that does not contain a triangle as a subgraph, and such that G_n remains connected after removing the closed neighbourhood $N[y] := N(y) \cup \{y\}$ of any $y \in V(G_n)$; for example, G_n could be a portion of the n-dimensional cubic lattice.

[3] More generally, this applies to any connected, locally finite, planar graph; see [31] and references therein.

Suppose G_n can be realised as a d-sphere graph, and therefore as an intersection graph of spheres $\{S_v \mid v \in V(G_n)\}$ in $\mathbb{R}^d$ by Observation 6. Pick a sphere of minimum radius among the S_v. Then, the spheres representing the neighbours of v intersect S_v and are mutually disjoint since G_n is triangle-free. Moreover, there is no triple S_x, S_y, S_z of such spheres such that S_y lies in the interior of S_x and S_z lies in the interior of S_y because $N[y]$ would separate x from z in this case. Thus, after deleting any such spheres lying in the interior of others, we are left with at least $n/2$ spheres with disjoint interiors intersecting S_v, each of radius at least that of S_v. By a volume argument, the number of such spheres is bounded by a function of d. Thus G_n is not a d-sphere graph when n is large enough. ◀

It is possible to strengthen Observation 8 by providing cubic graphs of arbitrarily high sphere dimension. Indeed, this is a corollary of Theorem 1, as we now discuss. Let $\{G_n^d : n \in \mathbb{N}\}$ be a family of cubic expander graphs with $\lim_{n\to\infty} |V(G_n^d)| = \infty$. Then, since expanders do not have small separators, at most finitely many members of this family can have sphere dimension at most d by Theorem 1 and by Lee's [37] separator theorem for circle graphs. Alternatively, we can let $\{G_n^d : n \in \mathbb{N}\}$ be a family of finite cubic graphs of asymptotic dimension more than $2d+1$; for instance, such graphs can be obtained from a portion of the $(2d+2)$–dimensional hypercubic lattice by replacing each vertex with a subcubic tree. Then at most finitely many members of this family can have sphere dimension at most d by the result of [19] that our Theorem 18 generalises.

4 Strongly sublinear separators

In this section, we prove Theorem 1, the separator theorem for the class $\mathcal{C}_t^d$ of all graphs which have sphere dimension at most d and do not have $K_{t,t}$ as a subgraph.

We need some additional notation. Given a sphere S in $\mathbb{R}^d$, we write $\mathsf{ball}(S)$ for the (closed) ball with boundary S. We say that a sphere S' *contains* a different sphere S if $\mathsf{ball}(S')$ contains $\mathsf{ball}(S)$. Given a collection $\mathcal{S}$ of spheres in $\mathbb{R}^d$, we say that a sphere $S \in \mathcal{S}$ is *maximal* if there is no $S' \in \mathcal{S} \setminus \{S\}$ such that S' contains S. Likewise, a sphere $S \in \mathcal{S}$ is *minimal* if there is no $S' \in \mathcal{S} \setminus \{S\}$ such that S contains S'. We call $\mathcal{S}$ *nested* if for any two spheres in $\mathcal{S}$, one contains the other. In this section, every collection of spheres is finite.

We start by noting that excluding $K_{t,t}$ provides a bound on the number of short paths between the "inside" and the "outside" of a large set of nested spheres.

▶ **Lemma 9.** *Let $r, t \in \mathbb{N}$, let $\mathcal{S}$ be a collection of spheres in $\mathbb{R}^d$, and let $\mathcal{N} \subseteq \mathcal{S}$ be a set of $t(r+1)$-many nested spheres. Suppose that the intersection graph $G(\mathcal{S} \setminus \mathcal{N})$ contains a collection $\mathcal{P}$ of $t^2(r+1)$-many pairwise vertex-disjoint paths such that for each path $P \in \mathcal{P}$,*

- *one end of P intersects the minimal sphere in $\mathcal{N}$,*
- *the other end of P intersects the maximal sphere in $\mathcal{N}$, and*
- *P has length at most r.*

Then, $G(\mathcal{S})$ contains a $K_{t,t}$ as a subgraph.

Proof. We sort the vertices in $\mathcal{N}$ by containment and consider $\leq$ to be this ordering. For every path $P \in \mathcal{P}$ and every vertex $x \in V(P)$, the neighbourhood of x in $\mathcal{N}$ is an interval with respect to $\leq$. We denote this interval by I_x. The first two conditions of the lemma guarantee that every sphere in $\mathcal{N}$ is a neighbour of at least one vertex in P. Thus, since $|\mathcal{N}| = t(r+1)$ and P has length at most r, every $P \in \mathcal{P}$ contains a vertex x_P with $|I_{x_P}| \geq t$. Also, there are at most $t(r+1)$ choices for the first vertex (according to $\leq$) inside I_{x_P}. Therefore, there are t vertices of the form x_P (on different paths) such that their intervals all start in the same vertex. These t vertices, plus the first t vertices in their intervals, yield the desired $K_{t,t}$-subgraph. ◀

Using this insight, we next prove that "minimal" graphs that contain a certain shallow clique minor cannot be represented by spheres with too much nesting.

▶ **Lemma 10.** *Let $t, d, r, h \in \mathbb{N}$ with $t, d \geq 2$, and suppose that $G \in \mathcal{C}_t^d$ has as few vertices as possible subject to containing an r-shallow K_h-minor. Let $\mathcal{S}$ be a collection of spheres in $\mathbb{R}^d$ such that $G = G(\mathcal{S})$. Then every nested subset of $\mathcal{S}$ has size at most $36t^4(3r+1)^3$.*

Proof. Suppose towards a contradiction that there is a nested set $\mathcal{N} \subseteq \mathcal{S}$ of size at least $36t^4(3r+1)^3$. Let φ be an r-shallow minor model of K_h in G. For each vertex $x \in V(K_h)$, we fix some rooted spanning tree T_x of the subgraph of G induced on $\varphi(x)$ of height at most r. Note that, as G is minimal with respect to containing an r-shallow K_h-minor, every vertex of G is in a bag of φ. Similarly, for every vertex $x \in V(K_h)$, every leaf of T_x has an edge to some other bag which has no other neighbours in T_x. We now break into cases based on whether many vertices in $\mathcal{N}$ lie in the same bag or in different bags.

First, consider the case that at least $6t^2(3r+1)^2$ vertices of $\mathcal{N}$ lie in a single bag, say the bag of $x \in V(K_h)$. As T_x has height at most r, at least a $\frac{1}{(r+1)}$ proportion of these elements all have the same distance to the root of T_x. Thus, there exists a set $\mathcal{X} \subseteq \mathcal{N}$ of size at least $6t^2(3r+1)$ such that all vertices in $\mathcal{X}$ are not only in T_x but also have the same distance to the root of T_x. So, no vertex in $\mathcal{X}$ lies on the path between the root of T_x and another vertex in $\mathcal{X}$. For each $X \in \mathcal{X}$, we fix an arbitrary leaf vertex $\ell(X)$ of T_x that is a descendent of X in T_x. (It is possible that $\ell(X) = X$.) Let us denote the path of T_x joining X and $\ell(X)$ by $P(X)$. Since all of the vertices in $\mathcal{X}$ have the same distance to the root, the paths $\{P(X) \mid X \in \mathcal{X}\}$ are pairwise vertex-disjoint. Additionally, for each of these leaves $\ell(X)$, there is a vertex $y(X) \in V(K_h)$ such the bag of $y(X)$ has an edge to $\ell(X)$ and does not have an edge to any other vertex in $\varphi(x)$. Thus, since the leaves $\{\ell(X) \mid X \in \mathcal{X}\}$ are all distinct, the vertices $\{y(X) \mid X \in \mathcal{X}\}$ are also all distinct.

Now we sort the elements of $\mathcal{X}$ by containment as $X_1, \ldots, X_{|\mathcal{X}|}$. We pair up the first $t^2(6r+2)$ elements of $\mathcal{X}$ with the last $t^2(6r+2)$ elements of $\mathcal{X}$. So we consider the pairs $(X_1, X_{|\mathcal{X}|})$, $(X_2, X_{|\mathcal{X}|-1})$, and so on. As K_h is the complete graph, for every pair $(X_i, X_{|\mathcal{X}|-i+1})$ there is a path between X_i and $X_{|\mathcal{X}|-i+1}$ whose vertex-set is contained in $P(X_i) \cup \varphi(y(X_i)) \cup \varphi(y(X_{|\mathcal{X}|-i+1})) \cup P(X_{|\mathcal{X}|-i+1})$. The two paths $P(X_i)$ and $P(X_{|\mathcal{X}|-i+1})$ have length at most $r-1$ since no vertex in $\mathcal{X}$ is the root of T_x. In each of the two bags $\varphi(y(X_i))$ and $\varphi(y(X_{|\mathcal{X}|-i+1}))$, we can choose paths of length at most $2r$. Finally, we need 3 edges to join the parts together. So overall, this path between X_i and $X_{|\mathcal{X}|-i+1}$ has length at most $2(r-1)+2(2r)+3 = 6r+1$ (see Figure 1). Note that $|\mathcal{X}| \geq 6t^2(3r+1) = 3t^2(6r+2) \geq 2t^2(6r+2) + t(6r+2)$. So at least $t(6r+2)$ spheres lie between any two paired spheres in $\mathcal{X}$. Thus, by Lemma 9, G contains $K_{t,t}$ as a subgraph, a contradiction.

Second, consider the case that there exists a set $\mathcal{X} \subseteq \mathcal{N}$ of size at least $6t^2(3r+1)$ so that every pair of vertices in $\mathcal{X}$ lie in different bags of φ. So for every $X \in \mathcal{X}$, there exists a vertex $y(X) \in V(K_h)$ such that X lies in $\varphi(y(X))$. Again, we sort the elements of $\mathcal{X}$ by containment as $X_1, \ldots, X_{|\mathcal{X}|}$ and pair the first and last elements. This time, we pair the first $t(4r+2)$ elements of $\mathcal{X}$ with the last $t(4r+2)$ elements of $\mathcal{X}$. So for $1 \leq i \leq t(4r+2)$, the sphere X_i is paired to the sphere $X_{|\mathcal{X}|-i+1}$. As K_h is the complete graph, there exists a path between X_i and $X_{|\mathcal{X}|-i+1}$ of length at most $4r+1$ in the subgraph of G induced by $\varphi(y(X_i)) \cup \varphi(y(X_{|\mathcal{X}|-i+1}))$ (see Figure 2). Additionally, $|\mathcal{X}| \geq 6t^2(3r+1) = 3t^2(6r+2) \geq 2t(4r+2) + t^2(4r+2)$. Thus, at least $t^2(4r+2)$ spheres lie between any two paired spheres in $\mathcal{X}$. Thus, again by Lemma 9, G contains $K_{t,t}$ as a subgraph, a contradiction.

One of the two cases must occur, and so this completes the proof of Lemma 10. ◀

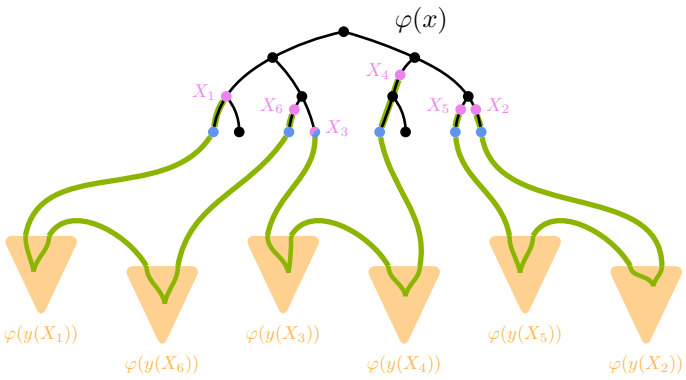

Figure 1 This illustrates the case that many vertices of $\mathcal{N}$ lie in a single bag. The set $\mathcal{X} = \{X_1, \ldots, X_6\}$ is depicted together with the corresponding leaves (note that X_3 is equal to its leaf). Using two paired bags, the green paths are of length at most $6r + 1$ and pairwise disjoint.

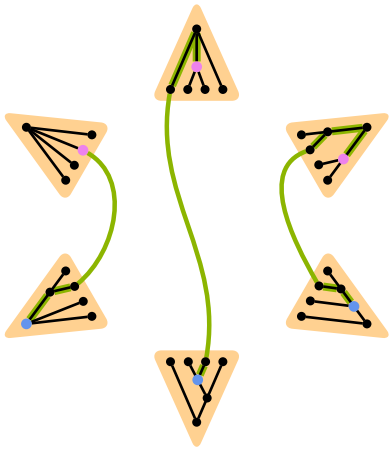

Figure 2 This illustrates the case that many vertices of $\mathcal{N}$ lie in different bags. The outermost spheres are mapped to the innermost spheres such that the green paths (all of length at most $4r + 2$) have to cross the spheres lying in between.

It is known, as seen in Lemma 4, that intersection graphs of balls of small ply have bounded strong colouring number. We make use of this to show that we can obtain a similar result for sphere intersection graphs excluding a $K_{t,t}$-subgraph, assuming they can be represented without a large set of nested spheres.

▶ **Lemma 11.** *Let $\mathcal{S}$ be a collection of spheres in $\mathbb{R}^d$ whose intersection graph $G = G(\mathcal{S})$ does not contain $K_{t,t}$ as a subgraph. Suppose that every nested subset of $\mathcal{S}$ has size at most k. Then for every $r \in \mathbb{N}$, the r-strong colouring number of G is at most $2kt(2r + 2)^d$.*

Proof. We claim that the collection $\{\mathsf{ball}(S) \mid S \in \mathcal{S}\}$ of balls in $\mathbb{R}^d$ has ply at most $2kt$. This yields the desired statement by Lemma 4.

So, let $\mathcal{X} \subseteq \mathcal{S}$ be a collection of spheres such that their common intersection as balls is non-empty, that is, such that $\bigcap_{X \in \mathcal{X}} \mathsf{ball}(X) \neq \emptyset$. Let us consider the poset $\preceq$ on $\mathcal{X}$ where for any spheres $X, X' \in \mathcal{X}$, we have $X \preceq X'$ if X is contained in X'. Every chain in this poset has size at most k by the assumption about nested sets. Next, note that a single point in

$\mathbb{R}^d$ lies in at most $2t$ pairwise incomparable (according to $\preceq$) spheres in $\mathcal{X}$, as otherwise, G would contain a clique of size $2t$ and therefore have $K_{t,t}$ as a subgraph. Thus, every antichain in this poset has size at most $2t$, and the lemma follows. ◀

The penultimate step is to combine lemmata 10 and 11 with Observation 5 in order to exclude shallow minors from the class $\mathcal{C}_t^d$.

▶ **Lemma 12.** *For any integers $t, d \geq 2$ and any $r \in \mathbb{N}$, no graph $G \in \mathcal{C}_t^d$ has a clique of size $72t^5(3r+2)^{d+3}$ as an r-shallow minor.*

Proof. For convenience, we set $h = 72t^5(3r+2)^{d+3}$. Suppose for a contradiction that there is a graph $G \in \mathcal{C}_t^d$ which contains K_h as an r-shallow minor. Choose such a graph G with as few vertices as possible. Let $\mathcal{S}$ be a collection of spheres in $\mathbb{R}^d$ such that $G = G(\mathcal{S})$. Then by Lemma 10, every nested subset of $\mathcal{S}$ has size at most $36t^4(3r+1)^3$. So by Lemma 11, the $(4r+1)$-strong colouring number of G is at most $2(36t^4(3r+1)^3)t(2r+2)^d$. Note that

$$2(36t^4(3r+1)^3)t(2r+2)^d = 72t^5(3r+1)^3(2r+2)^d \leq 72t^5(3r+2)^{d+3} - 2 = h - 2.$$

Finally, by Observation 5, the $(4r+1)$-strong colouring number of G is at least $h-1$. So $h - 1 \leq \mathsf{scol}_{4r+1}(G) \leq h - 2$, a contradiction. ◀

Now we can combine our results with the theorem of Plotkin, Rao, and Smith [46] (stated as Theorem 3) to obtain strongly sublinear separators in graphs of sphere dimension at most d which exclude a $K_{t,t}$-subgraph. We restate the theorem below for convenience.

▶ **Theorem 1.** *For any integers $t, d \geq 2$, the class $\mathcal{C}_t^d$ has strongly sublinear separators. More precisely, every n-vertex graph $G \in \mathcal{C}_t^d$ has a balanced separator of size $\widetilde{\mathcal{O}}_d(t^{10}n^{1-\frac{1}{2d+8}})$.*

Proof. Let $G \in \mathcal{C}_t^d$. For convenience, set $r = n^{\frac{1}{2d+8}}$. (We omit floors and ceilings for the sake of readability when they do not affect the proof.) By Lemma 12, G does not have a clique of size $72t^5(3r+2)^{d+3}$ as an r-shallow minor. Since $72t^5(3r+2)^{d+3} \in \mathcal{O}_d(t^5r^{d+3})$, by Theorem 3 we have that G contains a balanced separator of size

$$\mathcal{O}_d\left(rt^{10}r^{2d+6}\log n + \frac{n}{r}\right) = \widetilde{\mathcal{O}}_d\left(t^{10}r^{2d+7} + n^{1-\frac{1}{2d+8}}\right) = \widetilde{\mathcal{O}}_d\left(t^{10}n^{1-\frac{1}{2d+8}}\right).$$ ◀

5 Asymptotic dimension

In this section, we prove that $\mathcal{C}^d$ has bounded asymptotic dimension. In fact, we prove that the following more general class of graphs has bounded asymptotic dimension. Let $\mathcal{C}_\alpha^d$ be the class of connected intersection graphs of systems of path-connected sets in $\mathbb{R}^d$, each of which is obtained from a compact convex set of aspect ratio at most α by removing some subset of its interior. Clearly, the class $\mathcal{C}^d$ of intersection graphs of spheres in $\mathbb{R}^d$ is a subclass of $\mathcal{C}_\alpha^d$. If the sets are restricted so that none of their interiors is removed, then this subclass was proved to have bounded asymptotic dimension by Dvořák and Norin [19]. This theorem shall be one of our main tools.

▶ **Theorem 13** ([19])**.** *For every positive integer d and every $\alpha \geq 1$, the class of intersection graphs of systems of compact convex sets of aspect ratio at most α in $\mathbb{R}^d$ has asymptotic dimension at most $2d+1$.*

We introduce some notations similar to those used for spheres as in Section 4. For a graph $G \in \mathcal{C}^d_\alpha$ and a vertex $x \in V(G)$ we refer by $\mathsf{ccl}(x)$ to the convex closure of x. We say that a vertex y *contains* a different vertex x if $\mathsf{ccl}(y)$ contains $\mathsf{ccl}(x)$. We say the vertex x is *maximal* if there is no $y \in V(G)\backslash\{x\}$ such that y contains x.

The *height* of a bounded convex set $X \subset \mathbb{R}^d$ is the infimum $h \geq 0$ such that X is contained between two parallel hyperplanes at distance h. The *aspect ratio* of X is the ratio of the diameter of X over its *height*. Let $\mathcal{B}^d_\alpha$ denote the class of intersection graphs of systems of compact convex sets of aspect ratio at most α in $\mathbb{R}^d$. If $G \in \mathcal{C}^d_\alpha$ contains no pair of distinct vertices x, y with y containing x, then G belongs to $\mathcal{B}^d_\alpha$, i.e. Theorem 13 applies.

Our next main tool is a theorem of Bonamy, Bousquet, Esperet, Groenland, Liu, Pirot, and Scott [4] that shall allow us to apply Theorem 13. Before introducing this theorem, we require some further definitions.

A *weighted graph* (G, λ) consists of a graph G and a function $\lambda : E(G) \to \mathbb{R}^+$. We call $\lambda(e)$ the *weight* of e for each $e \in E(G)$. The length in (G, λ) of a path P in G is the sum of the weights of the edges of P. Given two vertices $x, y \in V(G)$, we define $\mathsf{dist}_{(G,\lambda)}(x, y)$ to be the infimum of the length in (G, λ) of a path between x and y; we define $\mathsf{dist}_{(G,\lambda)}(x, y) = \infty$ if there exists no path between x and y. We remark that all the weighted graphs we consider are actually graphs whose edges have weights 1 or 2. Given $A \subseteq V(G)$, we let $G[A]$ denote the *induced subgraph* of G on vertex set A. In other words, $G[A]$ is the subgraph of G obtained by restricting to the vertex set A. For weighted graphs, we define $(G, \lambda)[A]$ similarly.

A *real projection* of a (weighted) graph (G, λ) is a function $p : V(G) \to \mathbb{R}$ such that $|p(x) - p(y)| \leq \mathsf{dist}(x, y)$ for every pair of vertices $x, y \in V(G)$. Given $S > 0$ and a real projection p of a weighted graph G, we say that a vertex set $A \subseteq V(G)$ is (p, S)-*bounded* if $\max_{x,y\in A} |p(x) - p(y)| \leq S$. Given a class $\mathcal{C}$ of weighted graphs and a sequence $\mathcal{L} = (\mathcal{L}^1, \mathcal{L}^2 \ldots)$ of classes of weighted graphs with $\mathcal{L}^1 \subseteq \mathcal{L}^2 \subseteq \cdots$, we say that $\mathcal{C}$ is $\mathcal{L}$-*layerable* if there is a function $f : \mathbb{R}^+ \to \mathbb{N}$ such that any weighted graph $(G, \lambda) \in \mathcal{C}$ has a real projection $p : V(G) \to \mathbb{R}$ such that for any $S > 0$, any maximal (p, S)-bounded set in (G, λ) induces a (weighted) subgraph that belongs to $\mathcal{L}^{f(S)}$.

▶ **Theorem 14** ([4, Theorem 4.3]). *Let $\mathcal{L} = (\mathcal{L}_1, \mathcal{L}_2, \ldots)$ be a sequence of classes of weighted graphs of asymptotic dimension at most n. Let $\mathcal{C}$ be an $\mathcal{L}$-layerable class of weighted graphs. Then the asymptotic dimension of $\mathcal{C}$ is at most $n + 1$.*

We use the well-known fact that quasi-isometric classes of graphs have equal asymptotic dimension. A (Π, Σ)-*quasi-isometry* between (weighted) graphs (G, λ) and (H, ψ) is a map $f : V(G) \to V(H)$ such that the following hold for fixed constants $\Pi \geq 1$, $\Sigma \geq 0$:

1. $\Pi^{-1}\mathsf{dist}(x, y) - \Sigma \leq \mathsf{dist}(f(x), f(y)) \leq \Pi\mathsf{dist}(x, y) + \Sigma$ for every $x, y \in V(G)$, and
2. for every $z \in V(H)$, there is a $x \in V(G)$ such that $\mathsf{dist}(z, f(x)) \leq \Sigma$.

We say that classes of weighted graphs $\mathcal{G}$ and $\mathcal{H}$ are *quasi-isometric*, if there exist fixed constants $\Pi \geq 1$, $\Sigma \geq 0$ such that for every $G \in \mathcal{G}$ there exists a $H \in \mathcal{H}$ and a (Π, Σ)-*quasi-isometry* between G and H. It is well known that quasi-isometric classes of (weighted) graphs have equal asymptotic dimension (see for instance [4]).

▶ **Lemma 15.** *If classes of weighted graphs $\mathcal{G}_1, \mathcal{G}_2$ are quasi-isometric, then they have equal asymptotic dimension.*

Instead of working with $\mathcal{C}^d_\alpha$, we shall define an essentially equivalent (we only add edges of weight 2 between some vertices at distance 2) class of weighted graphs $\widehat{\mathcal{C}}^d_\alpha$ that is layerable by a class of weighted graphs that are quasi-isometric to graphs in $\mathcal{B}^d_\alpha$.

For $G \in \mathcal{C}^d_\alpha$, choose some maximal $v \in V(G)$. We call v the *pivot* vertex of G. Now, for each non-negative integer i, let D_i be the vertices in G at distance i from v. Let $(\widehat{G}, \lambda)$ be the weighted graph obtained from G by adding, for each pair $x, y \in V(G)$ with $x, y \in D_i$ for some i, an edge of weight 2 between x and y if x is contained in y (all the edges $(E(G))$ have weight 1 in $(\widehat{G}, \lambda)$). The following observation is key.

▶ **Lemma 16.** *Let $G \in \mathcal{C}^d_\alpha$. Then for every pair $x, y \in V(G)$ holds $\mathsf{dist}_G(x, y) = \mathsf{dist}_{(\widehat{G},\lambda)}(x, y)$.*

Proof. It is enough to show that if there is an edge of weight 2 between vertices x, y in $(\widehat{G}, \lambda)$, then in G, there is a vertex adjacent to both x and y. Since there is an edge of weight 2 between vertices x, y in $(\widehat{G}, \lambda)$, there exists some positive integer i such that $x, y \in D_i$, and without loss of generality, we may assume that x is contained in y. Let P be a path of length i between x and v, and let z be the unique vertex of $D_{i-1} \cap V(P)$. Then z intersects x and $\bigcup_{u \in V(P)} u$ contains a curve C from x to a point in v not contained in w for any $w \in V(G)$. Since the curve C starts in the interior of y and ends in its exterior, C must intersect y. Therefore, y is adjacent to a vertex of P. However, y is non-adjacent to x in G and cannot be adjacent to any vertex of $D_0 \cup \cdots \cup D_{i-2}$ since $y \in D_i$. Therefore, y must be adjacent to z in G. Hence, the distance between x and y in G is equal to 2, as desired. ◀

Let $\mathcal{L}^i_{d,\alpha}$ be the class of weighted graphs that are $(i, 1)$-quasi-isometric to a graph in $\mathcal{B}^d_\alpha$. Note that $\mathcal{L}^1_{d,\alpha} \subseteq \mathcal{L}^2_{d,\alpha} \subseteq \cdots$. Let $\mathcal{L}_{d,\alpha} = (\mathcal{L}^1_{d,\alpha}, \mathcal{L}^2_{d,\alpha}, \ldots)$. We show that $\widehat{\mathcal{C}}^d_\alpha$ is $\mathcal{L}_{d,\alpha}$-layerable.

▶ **Lemma 17.** *The class of weighted graphs $\widehat{\mathcal{C}}^d_\alpha$ is $\mathcal{L}_{d,\alpha}$-layerable.*

Proof. Let $(\widehat{G}, \lambda) \in \widehat{\mathcal{C}}^d_\alpha$, let $G \in \mathcal{C}^d_\alpha$ be the graph obtained from $(\widehat{G}, \lambda)$ by removing its edges of weight 2, and let v be the pivot-vertex of $(\widehat{G}, \lambda)$. For $x \in V(\widehat{G})$, let $p(x) \coloneqq d_{\widehat{G}}(v, x)$. Then, p is a real projection of $(\widehat{G}, \lambda)$. Let $S > 0$, and let $A \subseteq V(\widehat{G})$ be some maximal (p, S)-bounded set in $(\widehat{G}, \lambda)$. Then, there exists some non-negative integer t such that A is the set of vertices in $(\widehat{G}, \lambda)$ (or equivalently G) whose distance from v is between t and $t + \lceil S \rceil$; indeed, we can let $t \coloneqq \min\{p(x) \mid x \in A\}$.

Let M be the set of maximal vertices of $G[A]$. Observe that $(\widehat{G}, \lambda)[M] = G[M]$ contains no edge of weight 2 and furthermore that it is a graph in $\mathcal{B}^d_\alpha$. Let $f : A \to M$ be such that for every $u \in A$, $f(u)$ is some maximal vertex containing u. We shall show that f is a $(2\lceil S \rceil + 4, 1)$-quasi-isometry from $(\widehat{G}, \lambda)[A]$ to $G[M]$, which implies that $(\widehat{G}, \lambda)[A] \in \mathcal{L}^{2\lceil S \rceil + 4}_{d,\alpha}$ and therefore that $\widehat{\mathcal{C}}^d_\alpha$ is $\mathcal{L}_{d,\alpha}$-layerable as we desire.

If there is an edge of weight 1 or 2 between vertices x and y of $(\widehat{G}, \lambda)[A]$, then $f(x)$ and $f(y)$ intersect or coincide, and therefore $\mathsf{dist}_{G[M]}(f(x), f(y)) \leq 1$. It follows that $\mathsf{dist}_{G[M]}(f(x), f(y)) \leq \mathsf{dist}_{(\widehat{G},\lambda)[A]}(x, y)$ for every pair of vertices $x, y \in A$.

Consider some $m \in M$. Note that $f^{-1}(m)$ is non-empty since $f(m) = m$, and so f is surjective. We aim to show that each vertex x of $f^{-1}(m)$ has distance at most $S + 2$ from m in $(\widehat{G}, \lambda)[A]$. Let $x_0 x_1 \ldots x_\ell$ be a v–x geodesic in $(\widehat{G}, \lambda)$ (or G), i.e. a path with $x_0 = v$, $x_\ell = x$ and $p(x_i) = \mathsf{dist}_{(\widehat{G},\lambda)}(v, x_i) = i$ for each i. Then $\bigcup_{i=0}^{\ell} x_i$ contains a curve C from x to a point in v not contained in the interior of z for any $z \in V(G) \backslash v$. Since the curve C starts in the interior of $\mathsf{ccl}(m)$ and ends outside the interior of $\mathsf{ccl}(m)$, it follows that m is adjacent in G to some vertex of $\{x_0, \ldots, x_\ell\}$. We further have that m must be adjacent to one of $x_{p(m)-1}, x_{p(m)}, x_{p(m)+1}$. Note that $t \leq p(m) \leq p(x) = \ell \leq t + \lceil S \rceil$ since $m, x \in A$. If either $p(m) > t$ or m is adjacent to one of $x_{p(m)}$ or $x_{p(m)+1}$, then there is a path in $G[A]$ (and thus in $(\widehat{G}, \lambda)[A]$) between m and x of length at most $\lceil S \rceil + 1$. So, we may assume now that $p(m) = t$ and that m is non-adjacent to both $x_{p(m)}$ and $x_{p(m)+1}$. It follows that $x_{p(m)}$

is contained in $\mathsf{ccl}(m)$ and that m is adjacent to $x_{p(m)-1}$ in G. Therefore, there is an edge of weight 2 in $(\widehat{G},\lambda)$ between m and $x_{p(m)}$. Hence, there is a path of length at most $\lceil S\rceil+2$ in $(\widehat{G},\lambda)[A]$ between m and x. Thus, x has distance at most $\lceil S\rceil+2$ from m in $(\widehat{G},\lambda)[A]$.

So $f^{-1}(m)$ has radius at most $\lceil S\rceil+2$ in $(\widehat{G},\lambda)[A]$ and therefore diameter at most $2\lceil S\rceil+4$. Thus, as $G[M]$ is a graph, for every $x,y\in A$, we have that $(2\lceil S\rceil+4)^{-1}\mathsf{dist}_{(\widehat{G},\lambda)[A]}(x,y)-1\leq \mathsf{dist}_{G[M]}(f(x),f(y))$. Hence f is a $(2\lceil S\rceil+4)$-quasi-isometry between $(\widehat{G},\lambda)[A]$ and $G[M]$. ◀

We have assembled all the ingredients to prove the main result of this section:

▶ **Theorem 18.** *For every positive integer d and every $\alpha\geq 1$, the class $\mathcal{C}^d_\alpha$ of intersection graphs of systems of path-connected sets in $\mathbb{R}^d$, each of which is obtained from a compact convex set of aspect ratio at most α by removing some subset of its interior, has asymptotic dimension at most $2d+2$.*

Proof. By Lemma 16, the asymptotic dimension of $\mathcal{C}^d_\alpha$ and $\widehat{\mathcal{C}}^d_\alpha$ is equal. By Lemma 17, $\widehat{\mathcal{C}}^d_\alpha$ is $\mathcal{L}_{d,\alpha}$-layerable. The graph classes $\mathcal{L}^1_{d,\alpha},\mathcal{L}^2_{d,\alpha},\ldots$ all have asymptotic dimension at most $2d+1$ by Lemma 15 and Theorem 13. Therefore, by Theorem 14, $\widehat{\mathcal{C}}^d_\alpha$ has asymptotic dimension at most $2d+2$. Hence $\mathcal{C}^d_\alpha$ has asymptotic dimension at most $2d+2$. ◀

6 Final remarks and open problems

As we have seen, every graph G with at least three vertices has sphere dimension at most $|V(G)|-1$ by Observation 7. Can this be improved? Providing a bound with respect to the number of edges is also interesting.

▶ **Problem 19.** *What is the maximum sphere dimension of a graph on n vertices?*

In light of other known separator theorems for ball intersection graphs [44], it seems likely that the exponent in Theorem 1 is not optimal. We conjecture the following.

▶ **Conjecture 20.** *For any integers $t,d\geq 1$, every n-vertex graph $G\in\mathcal{C}^d_t$ has a balanced separator of size $\mathcal{O}_{t,d}(n^{1-\frac{1}{d+1}})$.*

This conjecture is true for $d=1$ since every n-vertex circle graph with a forbidden $K_{t,t}$ subgraph has a separator of size $\mathcal{O}_t(\sqrt{n})$ due to [37] and [24, Theorem 3].

It is also likely possible to improve the asymptotic dimension bound in Theorem 18 for graphs of bounded sphere dimension as follows.

▶ **Conjecture 21.** *For any integer $d\geq 1$, the class of graphs with sphere dimension at most d has asymptotic dimension at most d.*

This conjecture would be tight since the hypercubic lattice $\mathbb{Z}^d$ has asymptotic dimension and sphere dimension equal to d. For the latter claim, the sphere dimension is at most d because of the standard sphere packing centred at the integers. The fact that the sphere dimension is at least d follows from a deep result by Benjamini and Schramm [2, 3] stating that $\mathbb{Z}^d$ cannot be quasi-sphere packed in $\mathbb{R}^{d-1}$, with a little additional work. The case $d=2$ of the conjecture (furthermore for Assouad–Nagata dimension and in the more general class of string graphs) will be proved in separate work [10]. It is also easy to deduce the $d=1$ case for circle graphs from known results [8, 26]. Recently Liu and Norin [41] independently, using different methods, proved an improved asymptotic dimension bound of $d+1$. It might be possible to reduce Conjecture 21 via quasi-isometry to the class of intersection graphs of balls in $\mathbb{R}^d$ (this is the case for $d=2$ [10]).

▶ **Conjecture 22.** *For any integer $d \geq 2$, the class of graphs with sphere dimension at most d is quasi-isometric to the class of intersection graphs of balls in $\mathbb{R}^d$.*

Recall that an *induced minor* of a graph is obtained by deleting vertices and contracting edges. Let $\mathrm{Forb}_{\mathrm{ind}}(H)$ denote the class of graphs that do not contain a graph H as an induced minor.

▶ **Problem 23.** *Do the graphs in $\mathrm{Forb}_{\mathrm{ind}}(H)$ have bounded sphere dimension for every finite graph H? If not, is each graph in $\mathrm{Forb}_{\mathrm{ind}}(H)$ uniformly quasi-isometric to a graph with bounded sphere dimension?*

The same questions can be asked for minors instead of induced minors. These two versions of Problem 23 are related via the following problem, which is a special case of [27, Conjecture 1.1] (which has been disproven [11], but special cases remain open):

▶ **Problem 24.** *For every finite graph H, each graph in $\mathrm{Forb}_{\mathrm{ind}}(H)$ is uniformly quasi-isometric to a graph with no H minor.*

For $d \geq 3$, it is not possible to replace asymptotic dimension by Assouad–Nagata dimension in Theorem 18, even for the subclass of ball intersection graphs. This was observed by Dvořák and Norin [17]. Assouad–Nagata dimension is closely related to a concept in computer science called sparse partition schemes. Roughly speaking, if a graph class has bounded Assouad–Nagata dimension, and the colourings witnessing this can be computed, then certain universal versions of classical optimisation problems such as TSP, Steiner Tree and Set Cover allow approximations of bounded ratio. These approximate solutions are computed using sparse partition schemes; see, for instance, [4, 32, 6]. As mentioned above, graphs of bounded sphere dimension have unbounded Assouad–Nagata dimension, and so we cannot hope for sparse partition schemes. Still, it would be interesting to obtain bounds on these parameters as a function of the size of the graph. Our proof of Theorem 18 utilises Theorem 14, which has a strengthening preserving boundedness of Assouad–Nagata dimension. Thus, the bottleneck lies in the proof of Theorem 13 in [17].

Nearest Neighbor Searching in a Dynamic Simple Polygon

Department of Information and Computing Sciences, Utrecht University, The Netherlands

Abstract

In the nearest neighbor problem, we are given a set S of point sites that we want to store such that we can find the nearest neighbor of a (new) query point efficiently. In the dynamic version of the problem, the goal is to design a data structure that supports both efficient queries and updates, i.e. insertions and deletions in S. This problem has been widely studied in various settings, ranging from points in the plane to more general distance measures and even points within simple polygons. When the sites do not live in the plane but in some domain, another dynamic problem arises: what happens if not the sites, but the domain itself is subject to updates?

Updating sites often results in local changes to the solution or data structure, while updating the domain may incur many global changes. For example, in the closest pair problem, inserting a point only requires us to check if this point is in the new closest pair, while updating the domain might change the distances between most pairs of points in our set. Presumably, this is the reason that this form of dynamization has received much less attention. Only some basic problems, such as shortest paths and ray shooting, have been studied in this setting.

Here, we tackle the nearest neighbor problem in a dynamic simple polygon. We allow insertions into both the set of sites and the polygon. An insertion in the polygon is the addition of a line segment starting at the boundary of the polygon. We present a near-linear size –in both the number of sites and the complexity of the polygon– data structure with sublinear update and query time. This is the first nearest neighbor data structure that allows for updates to the domain.

1 Introduction

The nearest neighbor problem is a fundamental problem in computer science: given a set of n point sites S in some domain P, the goal is to store S so that given a query point $q \in P$ we can efficiently find the point in S closest to q [5, 19]. In case P is the two-dimensional Euclidean plane, such queries can be answered in $O(\log n)$ time by computing the Voronoi diagram of S, and storing it for efficient point location queries. In many applications, the domain however may contain obstacles (e.g. buildings, cars, rivers, lakes etc.) that are impassible. Hence, we may want to model P as a simple polygon, or even a polygonal domain (i.e. a polygon with holes), and measure the distance between two points by the length of their shortest obstacle avoiding path. In this setting, it is also possible to build the Voronoi diagram. Aronov [3] showed that the so called *geodesic Voronoi diagram* in a simple polygon with m vertices has complexity $O(n + m)$, and gave an $O((n + m) \log(n + m) \log m)$ time algorithm to construct it. This then allows for $O(\log(n + m))$ time nearest neighbor queries. Finding an optimal algorithm to construct the geodesic Voronoi diagram remained elusive for

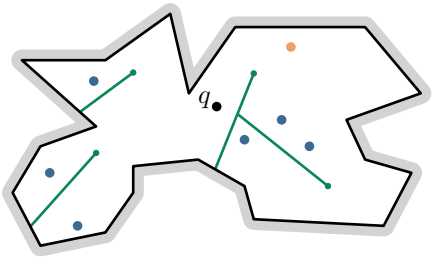

Figure 1 After inserting the green segments, the orange site is the nearest neighbor of q.

quite a while. Only a few years ago, after a series of improvements [21, 24, 26], Oh showed an optimal $O(m + n \log n)$ time algorithm [22]. When P is a polygon with holes, the Voronoi diagram has the same complexity, and can be computed in $O((n + m) \log(n + m))$ time [16].

Nearest neighbor searching is a *decomposable search problem*, meaning that to find the nearest neighbor in the set $A \cup B$, we can compute the nearest neighbor in set A, separately compute the nearest neighbor in set B, and return the closest of these two candidates [4]. Therefore, supporting efficient insertions of new point sites in $\mathbb{R}^2$ (while still answering queries in polylogarithmic time) is relatively simple using, for example, the logarithmic method [25]. However, supporting both insertions and deletions in polylogarithmic time, turned out to be quite challenging. Chan [5] presented the first such results, achieving $O(\log^2 n)$ query time while supporting insertions in $O(\log^3 n)$ and deletions in $O(\log^6 n)$ amortized expected time. Kaplan et al. [19] and later Chan [7] further improved the update times to $O(\log^2 n)$ for insertions, and $O(\log^4 n)$ for deletions. Kaplan et al. also generalized these results to other (constant complexity) distance functions [19]. Agarwal, Arge, and Staals [1] showed that these techniques can be extended to efficiently answer nearest neighbor queries in a simple polygon P. De Berg and Staals even presented a data structure that can report efficiently report the k-nearest neighbors, for some query parameter $k \in [n]$, in this setting [11].

The above results thus support applications in which the set of input points may change over time. However, in such applications, the obstacles are also likely to change. Unfortunately, none of the approaches above support updates to the domain P, e.g. by inserting or deleting an obstacle. Even more generally, there is relatively little work in which the input domain P may change while maintaining some non-trivial structure on P or S. Results of this type are mostly restricted to general purpose range or intersection searching [2, 17] or point location [14]. The most prominent work that we are aware of that specifically maintains some data structure on top of a dynamic polygonal domain is the work by Goodrich and Tamassia [13]. They support ray shooting and shortest path queries in a dynamic connected planar subdivision $\hat{P}$ in $O(\log^2 n)$ time. Ishaque and Tóth show how to maintain the (geodesic) convex hull of S in $\hat{P}$ while supporting the insertion of barriers (non-crossing segments such that all faces are simply connected) and site deletions in $O(\text{polylog}(n + m))$ time [18]. Oh and Ahn generalize this result to supporting both insertions and deletions (of barriers and sites) [23]. They achieve update times of $\tilde{O}((n + m)^{2/3})$, where the $\tilde{O}(\cdot)$ notation hides logarithmic factors in n and m. A recent result of Choudhury and Inkulu [10] shows how to maintain the visibility graph inside a dynamic simple polygon P using $\tilde{O}(\Delta)$ time per update, where Δ is the number of changes.

Challenges. A possible explanation for the lack of work in this dynamic domain setting is that the problems seem extremely challenging: even just adding a single line segment to the boundary of the polygon may significantly change the distances between the sites in the

polygon. This severely limits what information (i.e. which distances) the data structure can store. An insertion may also structurally change the triangulation of the polygon (which is the foundation upon which, e.g., the data structure of Agarwal, Arge, and Staals [1] is built).

Our results. We overcome these challenges, and present the first dynamic data structure for the geodesic nearest neighbor problem that allows updates to both the sites S and the simple polygon P containing S. Our data structure achieves sublinear query and update time and allows the following updates on P and S (Fig. 1): **1.** inserting a segment (barrier) between points u and v, where u on the boundary ∂P of P and $v \in P$ an arbitrary point, provided that the interior of this segment does not intersect ∂P, and **2.** inserting a site $s \in P$ into S.

This type of barrier insertion is similar to the insertion operation considered by Ishaque and Tóth [18] and Oh and Ahn [23]. Note that in case v also lies on the boundary of P, this actually splits the polygon into two subpolygons, which can no longer interact. Hence, we can essentially treat these subpolygons independently. In the remainder of the paper, we thus focus on the more interesting case in which v lies strictly in the interior of P. This also slightly simplifies our presentation, since P then remains an actual simple polygon.

Our data structure uses $O(n(\log\log n + \log m) + m)$ space, supports the above updates in amortized $\tilde{O}(n^{3/4} + m^{3/4})$ time, and answers queries in expected $\tilde{O}(n^{3/4} + n^{1/4}m^{1/2})$ time. While these query and update times are still far off from the polylogarithmic query and update times for a static domain, they are comparable to, for example, the result of Oh and Ahn for maintaining the geodesic hull in a dynamic polygon [23].

We believe it should be possible to extend our data structure to support deleting sites as well. In particular, by further incorporating the results of Agarwal, Arge, and Staals [1]. However, for ease of exposition we defer site deletions for now. Supporting deleting vertices of the polygon seems more interesting, however also much more complicated. Further ideas are likely required to support deletions of vertices as well.

Organization. Our data structure essentially consists of two independent parts, both of which critically build upon balanced geodesic triangulations [9]. So, we first review some of their useful properties in Section 2. We then give an overview of the data structure in Section 3. Section 4 describes the first part of our data structure, which can be regarded as an extension of the dynamic two-point shortest path data structure of Goodrich and Tamassia [13]. Our main technical contribution is in Section 5, which describes the second main part: a (static) data structure that can answer nearest neighbor queries in a subpolygon Q of P that can be specified at query time. This result may be of independent interest. Omitted proofs as well as the generalization of some of the results of Agarwal, Arge, and Staals [1] that we need for our data structure, can be found in the full version [12].

2 Preliminaries

Let P be a simple polygon with m vertices, let ∂P be the boundary of P, and let S be a set of n point sites inside P. We denote the shortest path that is fully contained within P between two point $p, q \in P$ by $\pi_P(p, q)$, or simply $\pi(p, q)$ if the polygon is clear from the context. Similar to earlier papers about geodesic Voronoi diagrams, we will use the general position assumptions that no point is (ever) equidistant to four sites in S, and no vertex of P is equidistant to three sites.

A *geodesic triangulation* of P is a triangulation-like decomposition of P into geodesic triangles. A *geodesic triangle* with corners $u, v, w \in P$ is formed by the three shortest paths $\pi(u, v)$, $\pi(v, w)$, $\pi(w, u)$. In general, such a geodesic triangle consists of a simple polygon

bounded by three concave chains, and three polygonal chains emanating from the vertices where the the concave chains join. The interior of the simple polygon region is called the *deltoid* region, and the polygonal chains are called the *tails* of the geodesic triangle. Note that the deltoid region may be empty, for example if w lies on $\pi(u, v)$.

Similar to a triangulation, a geodesic triangulation decomposes P into $O(m)$ geodesic triangles with corners that are vertices of P whose boundaries do not cross. This triangulation induces a dual tree $\mathcal{T}$, where two nodes are connected if their respective geodesic triangles share two corners. We root this tree at a node whose geodesic triangle shares a side with an edge of P. A geodesic triangulation is called *balanced* if the height of this tree is $O(\log m)$. A balanced geodesic triangulation can be constructed in $O(m)$ time [9].

A dynamic shortest path data structure. Here we shortly discuss the data structure of Goodrich and Tamassia for dynamic planar subdivisions [13]. This data structure supports both shortest-path and ray-shooting queries in $O(\log^2 m)$ time. Updates to the subdivision, such as inserting or deleting a vertex or edge, also take $O(\log^2 m)$ time. The main component is a balanced geodesic triangulation with dual tree $\mathcal{T}$. A secondary dynamic point location data structure [14] is build for this geodesic triangulation. A tertiary data structure stores, for each deltoid Δ, the three concave chains bounding Δ in balanced tree structures. To support shortest path queries, they store for each node in $\mathcal{T}$ the tail of its geodesic triangle that is not shared by its parent in a balanced tree structure. The size of the data structure is $O(m)$. Using rotations, insertions and deletions can be performed in $O(\log^2 m)$ time.

3 Overview of the data structure

Our dynamic nearest neighbor data structure for a dynamic simple polygon consists of two independent data structures: a Dynamic Shortest Path data structure, which remains up-to-date, and a Cone Query data structure, which is static and is rebuild after a number of updates. We denote by P the current polygon with m vertices and by S the current set of n sites in P. Furthermore, we denote by $\tilde{P}$ and $\tilde{m}$ the polygon and number of vertices and by $\tilde{S}$ and $\tilde{n}$ the set of sites and its size at the last rebuild of the Cone Query data structure. Let k be the number of updates (insertions) since the last rebuild, i.e. $k = m + n - \tilde{m} - \tilde{n}$.

The main purpose of the two data structures is the following. When given a query point q, we first use the Dynamic Shortest Path data structure to compute the distance from q to each of the newly inserted sites, i.e. in $S \setminus \tilde{S}$. This gives us the nearest neighbor of q among these sites. To find the nearest neighbor of q among $\tilde{S}$, we first use the Dynamic Shortest Path data structure to find $O(k)$ regions in P, where each region R is paired with an apex point v_R on ∂R. Each regions has the property that the shortest path $\pi_P(p, q)$ from a point $p \in R$ to q is given by $\pi_{\tilde{P}}(p, v_R) \cup \pi_P(v_R, q)$. This means that the nearest neighbor of q in P of the sites $\tilde{S} \cap R$ is the same as the nearest neighbor of v_R in $\tilde{P}$ of the same sites $\tilde{S} \cap R$.

This is where the Cone Query query data structure comes into play. This data structure allows us the answer such a nearest neighbor query for some region R with apex v_R in $\tilde{P}$. After querying the Cone Query data structure for each of the $O(k)$ regions generated by the Dynamic Shortest Path data structure, we return the nearest neighbor of q among $\tilde{S}$, which is the closest of these $O(k)$ sites. Next, we define the queries for the Cone Query data structure more precisely. We refer to these queries as *bounded nearest neighbor queries*.

▶ **Definition 1** (Figure 2). *A* bounded nearest neighbor query (R, v_R) *in* $\tilde{P}$ *consists of a region* R *and an point* $v_R \in \partial R$ *and asks for the nearest neighbor of* v_R *in* $\tilde{S} \cap R$*, where* R *is of one of the following two types:*

- *a* geodesic triangle*: a region bounded by three shortest paths in* $\tilde{P}$*, or*
- *a* geodesic cone*: a region bounded by two shortest paths in* $\tilde{P}$ *and part of* $\partial\tilde{P}$*.*

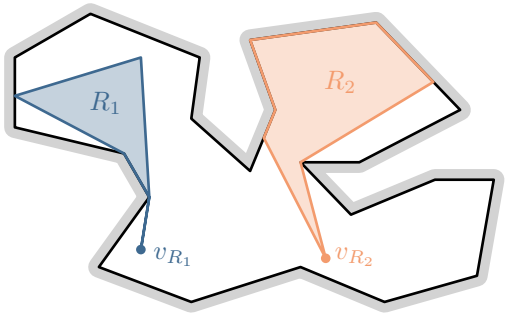

Figure 2 Two bounded nearest neighbor queries: a geodesic triangle (R_1) and a geodesic cone (R_2).

The Dynamic Shortest Path data structure that finds these geodesic triangle and geodesic cone regions is based on the data structure of Goodrich and Tamassia [13] for ray shooting and shortest path queries in a dynamic planar subdivision. We augment this data structure to distinguish between "old" and "new" vertices, i.e. the vertices in $\tilde{P}$ and in $P \setminus \tilde{P}$. In Section 4, we discuss this data structure in more detail, and obtain the following result.

▶ **Theorem 2.** *A Dynamic Shortest Path data structure maintains a dynamic simple polygon with $O(\log^2 m)$ update time using $O(m)$ space such that for a query point q a set of $O(k)$ bounded nearest neighbor queries that together find the nearest neighbor of q in P among $\tilde{S}$ in P can be computed in $O(k \log^2 m)$ time.*

The Cone Query data structure is the main data structure we present. We give a short overview of the data structure here, illustrated in Figure 3, and discuss the details and proofs in Section 5. The data structure is based on a balanced geodesic triangulation $\mathcal{T}$, augmented with three auxiliary data structures. We call the geodesic triangulation the first level data structure, and the three auxiliary data structures the second level data structures. The second level data structures are the following. First, for each node in $\mathcal{T}$, we store a partition tree [6] on the sites that lie in the corresponding deltoid. Furthermore, we store several third level data structures for each node of the partition tree. This allows us to find the nearest neighbor of v_R for (a subset of) the sites contained in the deltoid. Second, for each node in $\mathcal{T}$, we store the sites that lie on the boundary of the geodesic triangle in a binary search tree. This allows us the find the nearest neighbor of v_R for a subset of the sites that lie on the boundary of the geodesic triangle. Third, for each edge in $\mathcal{T}$, which corresponds to a shortest path between two points on $\partial\tilde{P}$, we store a nearest neighbor data structure that allows us to compute the nearest neighbor of v_R among the sites in one of the subpolygons defined by this shortest path, provided that v_R lies in the other subpolygon. We show that we can answer a bounded nearest neighbor query by querying $O(\log \tilde{m})$ of these level two data structures. This results in the following theorem.

▶ **Theorem 3.** *For a static polygon $\tilde{P}$ with $\tilde{m}$ vertices and a set $\tilde{S}$ of $\tilde{n}$ sites in $\tilde{P}$, the Cone Query data structure can be constructed in $O(\tilde{m} \log\log \tilde{n} + \tilde{n} \log \tilde{n} \log\log \tilde{n} + \tilde{n} \log \tilde{n} \log^2 \tilde{m}))$ time and $O(\tilde{n} \log\log \tilde{n} + \tilde{n} \log \tilde{m} + \tilde{m})$ space, such that a bounded nearest neighbor query can be answered in $O(\sqrt{\tilde{n}} \log^{3/2} \tilde{m} + \log \tilde{n} \log^2 \tilde{m})$ expected time.*

To obtain our final result, we rebuild the Cone Query data structure once k becomes larger than $\tilde{n}^{1/4} + \tilde{m}^{1/4}$. This results in update and query times that are $\tilde{O}(n^{3/4} + m^{3/4})$. Note that by rebuilding the Cone Query data structure earlier (or later), we can increase (or decrease) the update time and decrease (or increase) the query time, respectively.

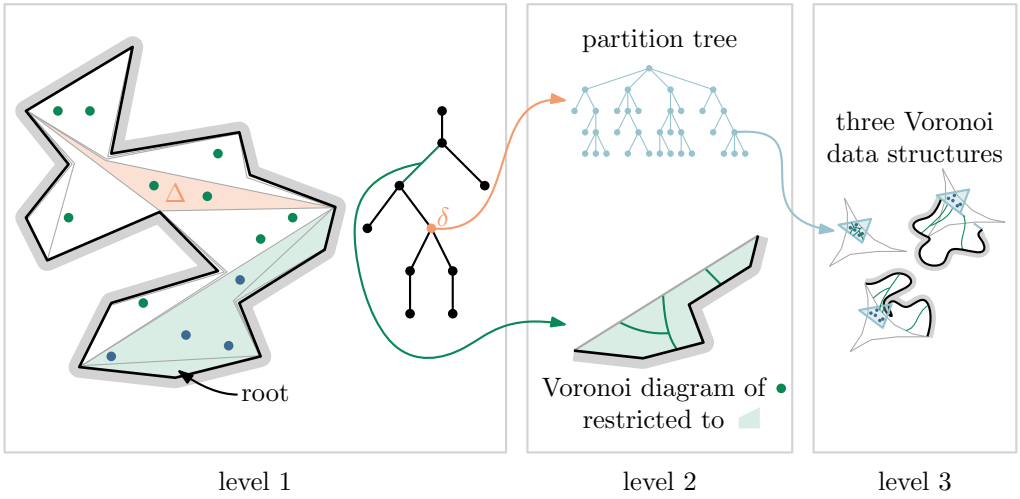

Figure 3 Overview of the Cone Query data structure. For each node in the geodesic triangulation (level 1) we store a partition tree and for each edge we store some restricted Voronoi diagram (level 2). For each node in the partition tree we store three Voronoi based data structures (level 3). Nodes of the geodesic triangulation whos deltoid is empty are omitted.

▶ **Theorem 4.** *We can build an insertion-only data structure for a dynamic simple polygon P with m vertices and a dynamic set S of n sites in P using $O(n(\log\log n + \log m) + m)$ space with $O(n^{3/4}\log n(\log\log n + \log^2 m) + m^{3/4}\log\log n)$ amortized update time that can answer nearest neighbor queries in $O(n^{3/4}\log^{3/2} m + m^{1/4}(n^{1/2}\log^{3/2} m + \log n \log^2 m))$ expected time.*

4 Dynamic shortest path data structure

The Dynamic Shortest Path data structure is an extension of the dynamic data structure of Goodrich and Tamassia [13], discussed in Section 2. We first explain how we adapt it to support efficient access to our newly inserted vertices. Then, we show how to use the Dynamic Shortest Path data structure to generate $O(k)$ bounded nearest neighbor queries that can together answer a nearest neighbor query, thus proving Theorem 2.

Extending the dynamic shortest path data structure. We extend the dynamic shortest path data structure of Goodrich and Tamassia [13] so that we have efficient access to the vertices and edges that were inserted since the last rebuild. We call these *marked* vertices and edges. In the data structure of [13], each polygonal chain is stored in a *chain tree*: a balanced binary tree where leaves correspond to the edges in the chain and internal nodes to the vertices of the chain. Each internal node also corresponds to a subchain and stores its length. We additionally store a boolean in each node that that is true whenever its subchain contains a marked edge, and false otherwise. Next to this dynamic data structure, we keep a list of all marked vertices. For this list, we consider the endpoint of an inserted edge to be marked, even if the vertex already existed in $\tilde{P}$.

▶ **Lemma 5.** *The Dynamic Shortest Path data structure maintains a dynamic simple polygon with $O(\log^2 m)$ update time using $O(m)$ space.*

▶ **Lemma 6.** *Given two points $p, q \in P$, the Dynamic Shortest Path data structure can find the first (or last) marked vertex on $\pi(p, q)$ in $O(\log^2 m)$ time.*

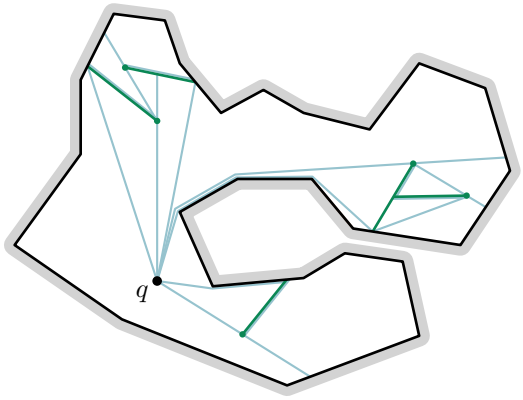

Figure 4 The bounded nearest neighbor query regions that are obtained for the query point q. The green segments are the segments inserted after the last rebuild.

Computing the bounded nearest neighbor queries. Next, we explain how to use the Dynamic Shortest Path data structure to find for a query point $q \in P$ a set of bounded nearest neighbor queries such that the nearest neighbor of q is the result of one of these queries. For each bounded nearest neighbor query we return the apex v_R, the two other endpoints s, t of the shortest paths bounding R, and a boolean indicating whether R is a geodesic triangle or geodesic cone. In case R is a geodesic cone, we order s, t such that the part of ∂P in R is given by the clockwise traversal from s to t along ∂P. We will choose our region R in such way that the paths bounding R are shortest paths in both P and $\tilde{P}$. In other words, there are no marked vertices (that are reflex vertices) on these shortest paths.

▶ **Lemma 7.** *We can compute a set of $O(k)$ bounded nearest neighbor queries in $\tilde{P}$ that allows us to find the nearest neighbor of a point $q \in P$ among the sites in $\tilde{S}$ in $O(k \log^2 m)$ time.*

Proof. We first describe the partition of P that will result in the $O(k)$ bounded nearest neighbor queries, and then discuss how to compute them. We partition P into $O(k)$ maximal regions such that for every point in a region R, the path to q uses the same *marked* vertices, see Figure 4. This can be viewed as a shortest path map for q, where we only consider marked vertices. Each region in this map will be a bounded nearest neighbor query together with its apex, i.e. the first marked vertex on the path from any point in the region to q.

To find these regions, we keep track of all points on ∂P that define the boundary between two such regions in a balanced binary tree T based on the order along ∂P. Observe that all marked vertices define such a boundary point. We thus insert all $O(k)$ marked vertices into T. Then, for each marked vertex v, we:

1. Compute the shortest path $\pi(v, q)$.
2. Perform a ray shooting query in the direction of the last segment of $\pi(v, q)$ to find the point x where the extension of this segment hits ∂P.
3. Insert x into T.

The Dynamic Shortest Path data structure supports shortest path queries in $O(\log^2 m)$ time. We can also obtain the last segment on the shortest path using the chain trees representing the path. The ray shooting query that follows again takes $O(\log^2 m)$ time. Finally, inserting x into T takes just $O(\log k)$ time. As there are $O(k) = O(m)$ marked vertices, this takes $O(k \log^2 m)$ time in total.

What remains is to find the bounded nearest neighbor queries using T. Each pair s, t of consecutive points in T defines such a query. If s and t are endpoints of the same marked edge, then their query region R is a geodesic triangle, otherwise R is a geodesic cone. The apex v_R of the bounded nearest neighbor is the last marked vertex on $\pi(q, s) \cap \pi(q, t)$, or q if there is no such vertex. We distinguish the following cases:

- If s (or t) is a marked, then v_R is the first (other) marked vertex on $\pi(s, q)$ (or $\pi(t, q)$).
- If both s and t are not marked, and thus included in T in the ray shooting step, then v_R is the second marked vertex on $\pi(s, q)$, i.e. the first vertex after the vertex used in the ray shooting step.

Note that in both cases v_R is also on $\pi(t, q)$, as otherwise the ray shooting step on v_R would add some point x between s and t on ∂P to T. Lemma 6 implies that we can find v_R in $O(\log^2 m)$ time (to find the second marked vertex we can search the corresponding chain tree from the first marked vertex in $O(\log m)$ time). ◀

5 Static cone query nearest neighbor data structure

In this section, we present the static Cone Query data structure. Throughout this section, let P be a *static* simple polygon with m vertices and S a *static* set of n sites in P. We want our data structure to answer bounded nearest neighbor queries for a region R and a query point q on ∂R, which in our case will be the apex point v_R, as in Definition 1. We assume that the region R is given as endpoints of the (at most three) shortest paths bounding it, and in case R is a geodesic cone, an indication which part of ∂P is in R.

The base of our data structure is a geodesic triangulation $\mathcal{T}$. We construct several data structures for the nodes and edges of $\mathcal{T}$. We assign each site $s \in S$ to the highest node in $\mathcal{T}$ whose geodesic triangle contains s. Note that there is only one node whose geodesic triangle contains s if s lies in some deltoid region, but there may be more if s is on the boundary of a geodesic triangle. For a geodesic triangle $\delta \in \mathcal{T}$, we denote the set of sites assigned to δ by S_δ. For the deltoid Δ of δ, we define $S_\Delta := S_\delta \cap \Delta$.

As a preprocessing step, we triangulate P [8] and construct the shortest path data structure of Guibas and Hershberger [15]. We also construct a point location data structure [20] on the geodesic triangulation. Each face in this subdivision is associated with its node in $\mathcal{T}$, and each edge is associated with the highest node in $\mathcal{T}$ that has this edge on its boundary. The geodesic triangulation can also be used to answer ray shooting queries in $O(\log m)$ time [9].

Next, we define two fundamental queries for a node in $\mathcal{T}$.

▶ **Definition 8.** *Let δ be a node in $\mathcal{T}$. Let (R, q) be a bounded nearest neighbor query, then we define the following subqueries.*

- Type (a)*: return the nearest neighbor of q in $S_\delta \cap R$.*
- Type (b)*: let $\mathcal{T}_x$ be the subtree of $\mathcal{T}$ rooted at a child x of δ and P_x the corresponding subpolygon, i.e. $P_x := \bigcup_{y \in \mathcal{T}_x} y$. For $q \notin P_x$, return the nearest neighbor of q in $S \cap P_x$.*

For each node $\delta \in \mathcal{T}$, we store two data structures that together can answer type (a) queries. One that finds the nearest neighbor of q among the sites on the boundary of the geodesic triangle, and one that finds the nearest neighbor of q among the sites in the deltoid region. For each edge $(\delta, x) \in \mathcal{T}$ we store a data structure that can answer type (b) queries.

Next, we show that we can answer bounded nearest neighbor queries using $O(\log m)$ type (a) and (b) queries. We first state two lemmas that prove useful in finding these queries.

▶ **Lemma 9.** *Let p, r be two points on ∂P, and let $s \in P$. In $O(\log m)$ time we can test if s lies right of the shortest path $\pi(p, r)$.*

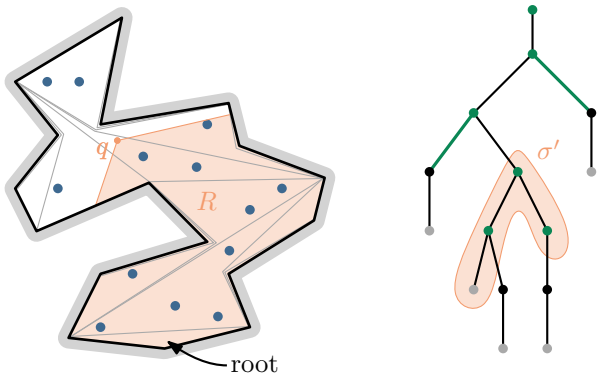

Figure 5 A geodesic triangulation and its dual tree. Nodes with empty deltoid regions are gray. We perform a type (a) query for all green nodes, and a type (b) query for all green edges.

▶ **Lemma 10.** *Let p, r be two points on ∂P, and let $s, t \in P$. We can determine in $O(\log^2 m)$ time the first and last point of $\pi(s,t) \cap \pi(p,r)$, or conclude the paths are disjoint.*

▶ **Lemma 11.** *A bounded nearest neighbor query can be answered using $O(\log m)$ type (a) and (b) queries. We can determine these $O(\log m)$ queries in $O(\log^2 m)$ time.*

Proof. We first prove the first part of the lemma, and then show how to find these type (a) and (b) queries efficiently. Figure 5 illustrates which nodes and edges we query. Let (R, q) be a bounded nearest neighbor query. The region R is either bounded by three shortest paths, or by two shortest path and part of ∂P. We first consider one of these shortest path that bounds R. Let $\pi(s,t)$ be this shortest path, and let $v(s)$ and $v(t)$ be geodesic triangles in $\mathcal{T}$ that contain s and t respectively. Let σ be the subset of nodes of $\mathcal{T}$ on the paths from $v(s)$ and $v(t)$ to the root of $\mathcal{T}$. Furthermore, let P_σ be the union of the geodesic triangles in σ, i.e. $P_\sigma = \bigcup_{\delta \in \sigma} \delta$. We claim that $\pi(s,t)$ is contained P_σ. Indeed, consider a deltoid region Δ that is entered by $\pi(s,t)$ of a geodesic triangle $\delta \notin \sigma$. Let $\pi(a,b)$ be the shortest path that is the boundary of δ through which $\pi(s,t)$ enters Δ. Note that by definition a and b are on ∂P. So, because $\pi(s,t)$ starts and ends in P_σ, it should at some point reenter P_σ by crossing $\pi(a,b)$ again. This contradicts $\pi(s,t)$ being a shortest path.

Let σ' be the the union of the σ sets for the shortest paths bounding R, excluding any geodesic triangles that intersect none of the shortest paths bounding R. Observe that for any point $p \in P$ the subgraph of nodes in $\mathcal{T}$ whose geodesic triangle contains p is connected. As each pair of shortest paths bounding R has a common endpoint, the subgraph of σ' is also connected. For each $\delta \in \sigma'$, we perform a type (a) query. Because $\mathcal{T}$ has height $O(\log m)$, we perform $O(\log m)$ of these queries. Together, these queries find the nearest neighbor of q in R for all geodesic triangles whose intersection with one of the shortest paths bounding R is non-empty. Clearly, any node whose deltoid region is intersected by such a shortest path is in σ'. Any site that is on the boundary of a geodesic triangle intersected by such a shortest path is stored in the highest node in $\mathcal{T}$ that contains the site. As this subset of nodes is connected, some node in σ' must contain this site.

What remains is to query the geodesic triangles that are fully contained in R. If R is a geodesic triangle, no node in $\mathcal{T}$ can be contained in the interior of R, as there are no vertices of P in its interior, and the corners of the geodesic triangle are vertices of P. If R is a geodesic cone, there might be $O(m)$ nodes in $\mathcal{T}$ contained inside R that do not intersect the two bounding paths. Because R is connected, there is an edge (δ, x) in $\mathcal{T}$, with δ the parent of x, whose removal splits $\mathcal{T}$ into two subtrees, one of which contains exactly the

geodesic triangles that are fully contained in R. If this subtree is $\mathcal{T}_x$ (recall that $\mathcal{T}_x$ is the subtree rooted at x), then we perform a type (b) query on (δ, x). If the subtree is $\mathcal{T} \setminus \mathcal{T}_x$, then for each node on the path from δ to the root, we perform a type (a) query and a type (b) query for the incident edge not on this path.

Finally, we prove the second part of the lemma. We first compute the set σ'. Consider one of the shortest paths $\pi(s,t)$ that bounds R. We first perform a point location query for both s and t. This gives us two nodes $v(s), v(t)$ in $\mathcal{T}$ that contain s and t. We then find the lowest common ancestor w of $v(s)$ and $v(t)$ in $O(\log m)$ time. All nodes on the paths from $v(s)$ and $v(t)$ to w are in σ'. Note that the previous argument that $\pi(s,t)$ cannot cross a geodesic triangle boundary and return even implies that $\pi(s,t)$ is contained in the subpolygon correspoding to these nodes. However, there may be more nodes on the path from w to the root of $\mathcal{T}$ whose boundary intersects $\pi(s,t)$. Let $\pi(p,r)$ be the shortest path that is the boundary between w and its parent geodesic triangle. Lemma 10 implies that we can find the first point a and the last point b of $\pi(s,t) \cap \pi(p,r)$, or conclude the paths are disjoint, in $O(\log^2 m)$ time. Any geodesic triangle in $\mathcal{T}$ above w that intersects $\pi(s,t)$ intersects either a or b (or both). It follows we can find the highest node of $\mathcal{T}$ that intersects $\pi(s,t)$ by a point location query on a and b, and choosing the highest node of the returned nodes. All nodes on the path in $\mathcal{T}$ from w and to this node are in σ'. By following the same procedure for all shortest path bounding R, we can compute σ' in $O(\log^2 m)$ time.

If R is a geodesic triangle, we are finished. If R is instead a geodesic cone, we need to find the edge whose removal splits off the fully contained geodesic triangles as described earlier. Note that this edge must be incident to σ'. Let s and t be the endpoints other than q of the shortest paths that bound R. We first find the subsequence of polygon vertices contained in R by a point location query for s and t. By storing the boundary of P in a balanced tree, we can then find the subsequence of vertices between the edges containing s and t in $O(\log m)$ time. For each node in σ', we check whether the incident edge that is not in σ' is contained in R by checking whether its endpoints are contained in the subsequence in $O(\log m)$ time. We thus find the desired edge of $\mathcal{T}$ in $O(\log^2 m)$ time. The required type (a) and (b) queries can then be found by traversing the tree as described before in $O(\log m)$ time. ◀

5.1 Second level data structures

For each node $\delta \in \mathcal{T}$, we store two data structures that together can answer type (a) queries, and for each edge (δ, x) we store a data structure that can answer type (b) queries.

Data structures for type (a) queries. Fix a node $\delta \in \mathcal{T}$ and let Δ be its deltoid. For each shortest path bounding δ, we store the sites of S_δ that are on the path in a binary search tree based on the order along the path. Together, these trees contain the sites in $S_\delta \setminus S_\Delta$.

On the sites in S_Δ we construct Chan's partition tree [6]. Each leaf node stores a constant number of sites, and each site is stored in exactly one leaf. For each node μ in the partition tree, let $S(\mu)$ denote the sites stored in the leaves below μ and let $\blacktriangle(\mu)$ denote the triangular cell of μ that contains $S(\mu)$. We store the following data structures for μ, see Figure 6:

1. The geodesic Voronoi diagram of the sites $S(\mu)$ with respect to the polygon $\blacktriangle(\mu) \cap \Delta$.
2. For each segment bounding $\blacktriangle(\mu)$: the forest representing the Voronoi diagram of $S(\mu)$ restricted to the subpolygon bounded by ∂P and the chord that contains the segment that does not contain $S(\mu)$.
3. For each shortest path π bounding δ: the forest representing the Voronoi diagram of $S(\mu)$ restricted to the subpolygon bounded by ∂P and π that does not contain $S(\mu)$.

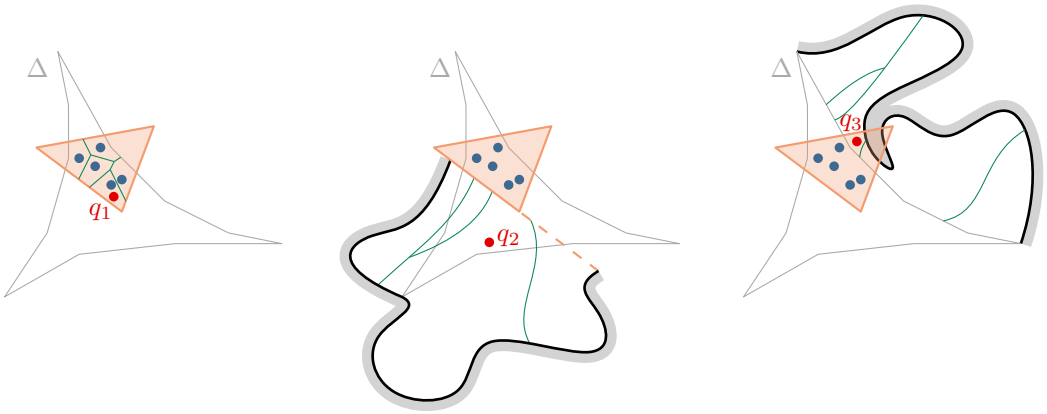

Figure 6 The three data structures stored for the orange cell $\blacktriangle(\mu)$ for answering type (a) queries. The first is used for a query point inside $\blacktriangle(\mu) \cap \Delta$, the second for a query point outside $\blacktriangle(\mu)$, and the third for a query point that is in $\blacktriangle(\mu)$ but outside of Δ.

The first data structure is simply the standard geodesic Voronoi diagram [22]. For the second and third data structure, we adapt a data structure that Agarwal, Arge, and Staals [1] use in their dynamic nearest neighbor data structure. They essentially prove that when a polygon is partitioned into two subpolygons P_ℓ, P_r by a line segment, the forest representing the Voronoi diagram of the sites in P_ℓ restricted to P_r can be stored and queried efficiently. In the full version [12], we generalize this result to the case where the polygon is partitioned using an arbitrary shortest path instead of a line segment, and obtain the following result.

▶ **Theorem 12.** *Let P be a polygon with m vertices appropriately preprocessed for two-point shortest path and ray-shooting queries. Let P_ℓ, P_r be a partition of P into two subpolygons by a shortest path between two points on ∂P. Given a set of n sites S in P_ℓ, there is an $O(n)$ size data structure storing the combinatorial representation of the Voronoi diagram of S in P_r so that given a query point $q \in P_r$, we can find the site in S closest to q in $O(\log n \log m)$ time. Building the data structure takes $O(n \log^2 m + n \log n)$ time.*

Data structure for type (b) queries. Let δ be a node in $\mathcal{T}$ and x be a child of δ. To be able to answer type (b) queries we store Voronoi diagram of the sites in $S \cap P_x$ restricted to $P \setminus P_x$, for P_x as in Definition 8, in the forest data structure of Theorem 12, as the boundary between the two geodesic triangles is a shortest path.

5.2 Analysis

Next, we prove that the Cone Query data structure achieves the bounds in Theorem 3. We use the following lemma about multilevel data structures using Chan's partition tree.

▶ **Lemma 13** (Corollary 6.2 of [6]). *Given n points in $\mathbb{R}^2$, for any fixed $\gamma < 1/2$, we can form $O(n)$ canonical subsets of total size $O(n \log\log n)$ in $O(n \log n)$ time, such that the subset of all points inside any query triangle can be reported as a union of disjoint canonical subsets C_i with $\sum_i |C_i|^\gamma \leq O(\sqrt{n})$ in time $O(\sqrt{n})$ w.h.p.(n).*

Query time. Let (R, q) be a bounded nearest neighbor query. Lemma 11 states that we can answer the query using $O(\log m)$ type (a) and (b) queries and that we can compute these queries in $O(\log^2 m)$ time. What remain is to analyze the time of a type (a) and (b) query.

First, consider a type (a) query. Recall that this asks for the nearest neighbor of q in $S_\delta \cap R$ for a geodesic triangle $\delta \in \mathcal{T}$ with deltoid Δ. To answer this query we have to query the three binary trees storing the sites in $S_\delta \setminus S_\Delta$ and the partition tree on S_Δ. For a shortest path of $\partial\delta$, the sites on this path that are contained in R form a contiguous subsequence. We can thus obtain this subset of sites in a binary tree in $O(\log n)$ time. Because the distance from q to a shortest path is a convex function, we can then binary search in this subtree to find the site closest to q in $O(\log n \log m)$ time.

To find the closest site of q in S_Δ, we query the partition tree. However, we cannot apply Lemma 13 directly, as this requires the query region to be a triangle instead of a geodesic triangle or cone. Oh and Ahn [23] essentially prove that seven triangles can cover a geodesic triangle without including any sites of S_Δ outside of the geodesic triangle in their interior. Here, we need a slightly more general statement that also includes geodesic cones.

▶ **Lemma 14.** *We can construct in $O(\log^2 m)$ time a constant number of interior disjoint triangles whose union contains $\Delta \cap R$ but does not contain any sites in $S_\Delta \setminus R$.*

For each of the $O(1)$ triangles given by Lemma 14 we query the partition tree. Lemma 13 states that the partition tree gives us a set of disjoint canonical subsets C_i. For each canonical subset, which corresponds to some node μ in the partition tree, we perform a nearest neighbor query using one of the data structures stored in the node. Which data structure we query depends on the location of q in relation to Δ and $\blacktriangle(\mu)$, see Figure 6.

- If q is inside both the deltoid Δ and the cell $\blacktriangle(\mu)$, i.e. $q \in \Delta \cap \blacktriangle(\mu)$, we query the geodesic Voronoi diagram of $\Delta \cap \blacktriangle(\mu)$.
- If q is outside the cell $\blacktriangle(\mu)$, i.e. $q \notin \blacktriangle(\mu)$, we query the forest constructed for the segment of $\blacktriangle(\mu)$ whose extension separates q from $\blacktriangle(\mu)$.
- If q is inside the cell $\blacktriangle(\mu)$ but outside the deltoid Δ, i.e. $q \in \blacktriangle(\mu)$ and $q \notin \Delta$, we query the forest constructed for side of δ that separates q from Δ.

Consider a canonical subset C_i for which the complexity of Δ restricted to the cell of C_i is m_i. The first type of query, which is in the (regular) geodesic Voronoi diagram, takes $O(\log(|C_i| + m_i))$ time [22]. The second and third type of query take $O(\log |C_i| \log m)$ time by Theorem 12. The query time thus becomes

$$\begin{aligned}\sum_i (\log |C_i| \log m + \log(|C_i| + m_i)) &= \log m \sum_i \log |C_i| + \sum_i \log(|C_i| + m_i) \\ &\leq \log m \sum_i \log |C_i| + \sum_i (\log |C_i| + \log m_i) \\ &= (\log m + 1) \sum_i \log |C_i| + \sum_i \log m.\end{aligned}$$

Here we used that for $|C_i|, m_i \geq 2$ it holds that $\log(|C_i| + m_i) \leq \log(|C_i| m_i)$. Choosing any $\gamma \in (0, 1/2)$ in Lemma 13 implies that $\sum_i \log |C_i| = O(\sqrt{|S_\Delta|})$. The number of terms in the sum $\sum_i \log m$ is bounded by $O(\sqrt{|S_\Delta|})$ as well. A type (a) query can thus be answered in $O(\sqrt{|S_\Delta|} \log m)$ time.

Finally, we note that the $O(\log m)$ type (a) queries we perform are on distinct deltoids. Thus, if we sum over all deltoids Δ_i that we query, we have $\sum_i |S_{\Delta_i}| = O(n)$. To bound the sum of square roots over these set sizes, we use the HM-GM-AM-QM inequalities, which states that for positive reals $x_1, \ldots, x_a$, we have $x_1 + \cdots + x_a \leq \sqrt{a(x_1^2 + \cdots + x_a^2)}$. It then follows that the total query time of all type (a) queries is $\sum_{i=0}^{O(\log m)} \sqrt{|S_{\Delta_i}|} \log m = O(\sqrt{n} \log^{3/2} m)$.

A type (b) query requires only a single query of the data structure of Theorem 12, and thus takes $O(\log n \log m)$ time. The total query time of the type (b) queries is $O(\log n \log^2 m)$.

Construction time. As preprocessing, we build the shortest path data structure of Guibas and Hershberger in $O(m)$ time [8, 15]. We then build the level one data structure: a balanced geodesic triangulation together with a point location data structure, in $O(m)$ time [9].

There are three level two data structures: one for each edge of $\mathcal{T}$ (for the type (b) queries), and two for each node of $\mathcal{T}$ (for the type (a) queries). Let δ be a node in $\mathcal{T}$ and Δ the corresponding deltoid.

First, consider the data structure on each edge of $\mathcal{T}$. This is the forest data structure of Theorem 12. For a child x of δ this data structure can be build in $O(|S \cap P_x| \log^2 m + |S \cap P_x| \log |S \cap P_x|)$ time, with P_x as in Definition 8. Note that each site in S can occur in at most $O(\log m)$ polygons P_x, once for each level of $\mathcal{T}$. It follows that constructing the data structure for each edge of $\mathcal{T}$ takes $O(n \log^3 m + n \log n \log m)$ time in total.

Second, consider the two data structures on the nodes of $\mathcal{T}$. For each shortest path bounding δ, we store the sites on the path in a binary search tree. These trees can be constructed in $O(n_\delta(\log n_\delta + \log m))$ time. Furthermore, we store the sites in the deltoid Δ in a partition tree. The partition tree (excluding auxiliary data structures) can be build in $O(n_\Delta \log n_\Delta)$ time (Lemma 13).

For each node μ of the partition tree, we store three third level Voronoi data structures for the sites $S(\mu)$. Let $m(\mu)$ be the number of vertices of $\blacktriangle(\mu) \cap \Delta$. The first level three data structure is a (regular) geodesic Voronoi diagram restricted to μ, including a point location data structure, and can be constructed in $O(m(\mu) + |S(\mu)| \log |S(\mu)|)$ time [22]. The second and third data structures are the forest data structure of Theorem 12 on each segment bounding the cell of μ and each shortest path bounding δ. These can be constructed in $O(|S(\mu)| \log^2 m + |S(\mu)| \log |S(\mu)|)$ time (Theorem 12). The total construction time for a node μ of the partition tree is then $O(m(\mu) + |S(\mu)| \log |S(\mu)| + |S(\mu)| \log^2 m)$. To bound the total construction time for all nodes of the partition tree, observe that the cells in each of the $O(\log \log n_\Delta)$ levels of the partition tree are disjoint. So, $\sum_\mu |m(\mu)| = O(m_\Delta \log \log n_\Delta)$. Furthermore, $\sum_\mu |S(\mu)| = O(n_\Delta \log \log n_\Delta)$. The total construction time over all nodes is then $O(m_\Delta \log \log n_\Delta + n_\Delta \log \log n_\Delta (\log n_\Delta + \log^2 m))$.

Together, the level two and three data structures on a node $\delta \in \mathcal{T}$ are constructed in $O(m_\delta \log \log n_\delta + n_\delta \log \log n_\delta (\log n_\delta + \log^2 m))$ time. This implies that the total construction time for all nodes in $\mathcal{T}$ is $O(m \log \log n + n(\log n \log \log n + \log^2 m \log \log n))$.

The total construction time of all first, second, and third level data structures then becomes $O(m \log \log n + n \log n \log \log n + n \log^3 m + n \log n \log^2 m + n \log n \log m) = O(m \log \log n + n \log n \log \log n + n \log n \log^2 m)$.

Space usage. The space of the shortest path data structure on P is $O(m)$. For a node $\delta \in \mathcal{T}$ and Δ the corresponding deltoid, the trees for $\partial\delta$ have size $O(n_\delta)$. As for the partition tree, Lemma 13 states that the total size of the canonical subsets is $O(n_\Delta \log \log n_\Delta)$. The three data structures that are built for each node of the partition tree use just linear space in the number of sites, thus the total size of the partition tree including its auxiliary data structures remains $O(n_\Delta \log \log n_\Delta)$. The total space over all nodes in $\mathcal{T}$ is thus $O(n \log \log n)$. What remains is to analyze the space of the data structures for type (b) queries. Theorem 12 states that this forest data structure for a child x of δ uses $O(|S \cap P_x|)$ space. As before, each site in S can occur in at most $O(\log m)$ polygons P_x, once for each level of $\mathcal{T}$. Thus the total space of these data structures is $O(n \log m)$.

Abstract

Quantum topology provides various frameworks for defining and computing invariants of manifolds inspired by quantum theory. One such framework of substantial interest in both mathematics and physics is the Turaev-Viro-Barrett-Westbury state sum construction, which uses the data of a spherical fusion category to define topological invariants of triangulated 3-manifolds via tensor network contractions. In this work we analyze the computational complexity of state sum invariants of 3-manifolds derived from Tambara-Yamagami categories. While these categories are the simplest source of state sum invariants beyond finite abelian groups (whose invariants can be computed in polynomial time) their computational complexities are yet to be fully understood. We first establish that the invariants arising from even the smallest Tambara-Yamagami categories are #P-hard to compute, so that one expects the same to be true of the whole family. Our main result is then the existence of a fixed parameter tractable algorithm to compute these 3-manifold invariants, where the parameter is the first Betti number of the 3-manifold with $\mathbb{Z}/2\mathbb{Z}$ coefficients.

Contrary to other domains of computational topology, such as graphs on surfaces, very few hard problems in 3-manifold topology are known to admit FPT algorithms with a topological parameter. However, such algorithms are of particular interest as their complexity depends only polynomially on the combinatorial representation of the input, regardless of size or combinatorial width. Additionally, in the case of Betti numbers, the parameter itself is computable in polynomial time. Thus while one generally expects quantum invariants to be hard to compute classically, our results suggest that the hardness of computing state sum invariants from Tambara-Yamagami categories arises from classical 3-manifold topology rather than the quantum nature of the algebraic input.

1 Introduction

Quantum physics – especially quantum field theory – is a profuse source of invariants in low-dimensional topology, and these invariants often provide information about manifolds beyond the reach of classical topology. For example, on one hand, the Alexander polynomial of a knot is determined "classically" (from the first homology of the knot's universal abelian cover) and infinitely many different knots have trivial Alexander polynomial; on the other hand, the Jones polynomial (the prototypical example of a quantum invariant) has never been shown to be trivial on any non-trivial knot. However, the native paradigm for (approximately) computing quantum invariants is manifestly quantum computational, so that in general one should expect them to be hard to compute on a classical computer [19]. Naturally then we seek to understand the full landscape of the computational complexities of quantum invariants. From the point of view of computational topology we are particularly interested in a middle ground where there may be interesting invariants that are not too hard to compute, and to develop algorithms to compute them as efficiently as possible.

In this work, we investigate the complexity landscape of a specific class of quantum invariants of 3-manifolds, namely, the *Turaev-Viro-Barrett-Westbury (TVBW) state sum construction* [30, 2]. Unlike other quantum invariants (e.g. Donaldson invariants), the TVBW construction is *a priori* algorithmically computable, combining a finite amount of algebraic data in the form of a *(skeletalized) spherical fusion category* $\mathcal{C}$ with a triangulation $\mathfrak{T}$ of a closed, oriented 3-manifold M to generate a complex algebraic number $|M|_{\mathcal{C}} \in \mathbb{C}$ that is an orientation-preserving homeomorphism invariant of M. The invariant $|M|_{\mathcal{C}}$ is defined as the contraction of a certain tensor network built by decorating $\mathfrak{T}$ with the data of $\mathcal{C}$, and can be formally described via a combinatorial *state sum formula*. We refer the reader to the full version of this article [8] for a brief review of the TVBW construction (in the case of multiplicity-free, pseudo-unitary spherical categories) and [32] for more background.

As we review at the end of this introduction, it is desirable to understand the computational complexity of evaluating the TVBW invariant $|\cdot|_{\mathcal{C}}$ on a given triangulated 3-manifold

$$|\cdot|_{\mathcal{C}} : \{\text{triangulations of closed, oriented 3-manifolds}\} \to \mathbb{C}$$
$$\text{triangulation } \mathfrak{T} \text{ of } M \mapsto |M|_{\mathcal{C}}.$$

More precisely, we would like to understand how the computation of these invariants depends on the choice of spherical fusion category $\mathcal{C}$, since there are countably infinitely many equivalence classes of such categories, and their classification is at least as hard as the classification of finite groups. As usual, we aim to understand the complexity of computing $|M|_{\mathcal{C}}$ as a function of the size of a triangulation $\mathfrak{T}$ used to encode M.

We approach this complexity-theoretic classification problem from the perspective that fusion categories are "quantum" generalizations of (the representation theory of) finite groups. While this perspective has not been made explicitly overt in the computational topology literature, it is common in quantum algebra, where the extent to which a fusion category deviates from a finite group G can be made precise in various ways. For the sake of space, we will not review these notions here, but will note that anyway one cuts it, the simplest spherical fusion categories are of the type $\mathrm{Vec}(A)$ – where A is an abelian group – consisting of A-graded finite-dimensional vector spaces, with a tensor product that comes from the group operation in A. In fact, for any finite group G, the category of G-graded vector spaces $\mathrm{Vec}(G)$ forms a spherical fusion category, but if G is non-abelian, we consider this category to be more "complicated" than $\mathrm{Vec}(A)$. One reason for this is that $|\cdot|_{\mathrm{Vec}(A)}$ is always polynomial-time computable, whereas $|\cdot|_{\mathrm{Vec}(G)}$ is often $\#P$-hard for non-abelian groups [21].

Arguably, after $\mathrm{Vec}(A)$, the next simplest family of fusion categories consists of the Tambara-Yamagami categories $\mathrm{TY}(A,\chi,\nu)$. Such a category is determined by a finite abelian group A, together with a small amount of additional data: a *bicharacter* (*i.e.*, a non-degenerate symmetric bilinear pairing) $\chi : A \times A \to U(1)$, and a choice of square root $\nu = \pm 1/\sqrt{|A|} = \pm |A|^{-1/2}$ [28]. (See [8] for a complete description of these categories using this data.) And yet, in the full version of this article [8], we show that already in the simplest non-trivial case with $A = \mathbb{Z}/2\mathbb{Z}$, the invariants $|\cdot|_{\mathrm{TY}(\mathbb{Z}/2\mathbb{Z},\chi,-1/\sqrt{2})}$ are $\#P$-hard to compute. This is more-or-less a restatement of known results about the Turaev-Viro invariant TV_4 [14, 23], since $|\cdot|_{\mathrm{TY}(\mathbb{Z}/2\mathbb{Z},\chi,1/\sqrt{2})} = \mathrm{TV}_4(\cdot)$. However, as we shall explain, our approach offers a conceptual clarification by placing TV_4 within the broader taxonomy of spherical fusion categories. In particular, we conjecture that the TVBW state sum invariant of *every* non-trivial Tambara-Yamagami category $\mathrm{TY}(A,\chi,\nu)$ is #P-hard.

Our main result is a parameterized algorithm to compute the TVBW state sum invariants $|M|_{\mathrm{TY}(A,\chi,\nu)}$ associated to Tambara-Yamagami categories, where our parameter is the first $\mathbb{Z}/2\mathbb{Z}$ Betti number β_1.

▶ **Main Result** (Informal; see Theorem 4). *Fix an integer $B \geq 0$ and a Tambara-Yamagami category $\mathrm{TY}(A,\chi,\nu)$. Then there exists a polynomial time algorithm to evaluate $|M|_{\mathrm{TY}(A,\chi,\nu)}$ for triangulated 3-manifolds with $\beta_1(M) \leq B$.*

While the hardness of general Tambara-Yamagami invariants is still conjectural, we interpret our main result as showing that any such hardness is explainable by a simple classical topological fact: there exist triangulations $\mathfrak{T}$ of 3-manifolds M with n simplices where $\beta_1(M)$ can be as large as $\Theta(n)$.

Our algorithm succeeds by converting the natively quantum topological computational problem of computing a TVBW state sum invariant of a triangulated 3-manifold – which *a priori* requires an expensive tensor network contraction – into a sequence of other much more efficient classical computational problems in algebraic number theory and combinatorial-algebraic topology. Prior to our work, to the best of our knowledge, the only published algorithm in 3-manifold topology directly parameterized by an efficiently computable *topological* quantity (whose value is independent of the presentation of the input) is the algorithm of Maria and Spreer to compute the Turaev-Viro quantum invariant TV_4 of 3-manifolds [30] at a 4th root of unity in $O(2^{\beta_1} n^3)$ operations [23].

The technical underpinnings of our algorithm are explained in Section 3; the algorithm itself is precisely described and analyzed in Section 4. At the heart of our algorithm is a (non-obvious!) observation: $|M|_{\mathrm{TY}(A,\chi,\nu)}$ can be identified with a (normalized) sum of $|H^1(M,\mathbb{Z}/2\mathbb{Z})| = 2^{\beta_1}$ many *Gauss sums of $\mathbb{Q}/\mathbb{Z}$-valued quadratic forms* on certain finite abelian groups derived from A and the given triangulation of M.

$$

spherical category $\mathcal{C}$	complexity of $\lvert M\rvert_{\mathcal{C}}$	FPT in β_1?	Reference
$\mathrm{Vec}(A)$ for A abelian	in fP	Yes	well-known, e.g. [20]
$\mathrm{TY}(\mathbb{Z}/2\mathbb{Z}, \exp(\pi iab), -1/\sqrt{2})$	$\#\mathsf{P}$-hard	Yes	[14, 23], long version [8]
$\mathrm{TY}(A, \chi, \nu)$	unknown in general	Yes	this work
$\mathrm{Vec}(G)$ for G non-abelian solvable	unknown	unknown	
$\mathrm{Vec}(G)$ for G non-abelian simple	$\#\mathsf{P}$-complete	No (unless $\mathsf{fP} = \#\mathsf{P}$)	[20]
$U_q\mathfrak{sl}_2$-mod (q a non-lattice root of 1)	$\#\mathsf{P}$-hard	No (unless $\mathsf{fP} = \#\mathsf{P}$)	[13, 19]

Figure 1 State of the art for computing TVBW invariants based on "simple" spherical fusion categories.

The second and third equalities above follow for a rather general reason: $\mathrm{TY}(A, \chi, \nu)$ possesses the structure of a $\mathbb{Z}/2\mathbb{Z}$-*grading* and so by general facts related to *homotopy quantum field theory* [31], we are able to reduce $\lvert M\rvert_{\mathrm{TY}(A,\chi,\nu)}$ to a sum of 2^{β_1} terms in a manner similar in spirit to [23]. Notably, however, the concept of *graded fusion categories* is absent from [23], and this structure enables us to analyze the state sum invariant of M directly from *any* simplicial triangulation, without having to pass to a one-vertex triangulation via the crushing algorithm of Jaco and Rubinstein [12] (as in [23]).

The bulk of Section 3 is then concerned with explaining and justifying ($\star$), and our methods here diverge substantially from [23]. The efficient algorithmic evaluation of quadratic Gauss sums appears to be well-known to experts in algebraic number theory, although we were unable to find specific references for this fact, the closest apparently being [3]; see Section 2.1 and [8] for further discussion.

The general nature of our main result allows us to establish new conceptual insight into the complexity-theoretic landscape of TVBW invariants, a portion of which we summarize in Figure 1. It is known that TVBW 3-manifold invariants are often #P-hard to compute exactly, and sometimes hard even just to approximate [13, 14, 18, 19, 20, 21]; moreover, in many of these cases, it is known that there can be no tractable algorithm in β_1. Thus the existence of a parametrized algorithm in a topological and efficiently computable parameter for the Tambara-Yamagami invariants is an interesting counterpoint to their expected hardness. This suggests that the hardness of computing the invariants is due to some intrinsic hardness in 3-manifold topology, rather than the Tambara-Yamagami category alone, whose construction is only a small modification of $\mathrm{Vec}(A)$.

After scrutinizing Figure 1, it seems sensible to expect that there should be a dichotomy theorem for TVBW invariants. A naïve conjecture would be that $\lvert\cdot\rvert_{\mathcal{C}}$ is in fP if and only if $\mathcal{C} \simeq \mathrm{Vec}(A)$, and otherwise $\lvert\cdot\rvert_{\mathcal{C}}$ is $\#\mathsf{P}$-hard. However, this cannot be correct, as there are "twisted" versions of A-graded vector spaces $\mathrm{Vec}(A, \eta)$, $\eta \in H^3(A, U(1))$, for which $\lvert\cdot\rvert_{\mathrm{Vec}(A,\eta)}$ is also known to be polynomial-time computable. More subtly, if G is any 2-step nilpotent group, then $\lvert M\rvert_{\mathrm{Vec}(G)} = \#\{\pi_1(M) \to G\}/\#G$ should also be in fP.

A systematic understanding of the computational complexity of state sum invariants is significant because they fit into the larger framework of a fully-extended 3D TQFT. Indeed, this connection endows the invariants with important applications to *fault-tolerant quantum computation* and the characterization of *topologically ordered phases of matter*, e.g. via *topological quantum computing* [16, 17, 26, 34], as well as to the developing paradigm of "non-invertible" or "categorical" symmetries and dualities present in *quantum field theories* and *lattice models* [1, 6, 9, 10, 29]. Of course, there is plenty of motivation from low-dimensional topology as well, where these invariants can be used in practice to distinguish non-homeomorphic 3-manifolds. TVBW invariants are heuristically strong, with a typical category $\mathcal{C}$ capable of distinguishing "most" pairs of non-homeomorphic manifolds.

2 Background

In this section we introduce the TVBW invariants of 3-manifolds derived from Tambara-Yamagami categories, as well as some of the basic components necessary for our algorithm.

2.1 Elements of algorithmic number theory

Finite abelian groups. Let $(A,+)$ be a *finite abelian group* with $|A|$ elements, denoted additively. The fundamental theorem of finitely generated abelian groups shows that A admits a unique *primary decomposition* of the form:

$$A \cong \bigoplus_{p \text{ prime}} \bigoplus_{k_i,n_i \,:\, i\in I_p} \left(\mathbb{Z}/p^{k_i}\mathbb{Z}\right)^{n_i}$$

for finitely many primes p, and positive integers $k_i, n_i > 0$. For a finite abelian group A, we denote by $d(A)$ the number of non-trivial summands in its primary decomposition. We use $A_{(p)}$ to denote the subgroup elements whose order is a power of p. Hence,

$$A = \bigoplus_{p \text{ prime}} A_{(p)}, \quad \text{where } A_{(p)} = \bigoplus_{k_i,n_i \,:\, i\in I_p} \left(\mathbb{Z}/p^{k_i}\mathbb{Z}\right)^{n_i}.$$

The following is a standard algorithmic result for finite abelian groups, formulated according to our needs in this article; see for example [25, Chap. 1.11].

▶ **Theorem 1.** *Let H be a finite abelian group presented via a primary decomposition with generators $h_1,\dots,h_{d(H)}$ for each of its prime summands. If $G \subseteq H$ is a subgroup of H specified via a set of generators $g_1,\dots,g_{d(G)}$ (each of which is encoded by a list of integers n_{ij} such that $g_i = \sum_j n_{ij}h_j$), then there exists a polynomial time algorithm using $O(d(|H|)^3)$ operations in H that finds a presentation of the primary decomposition of G – that is, a new* minimal *set of generators of G denoted $g'_1,\dots,g'_{d(G)}$ (each of which is, as before, represented by a list of integers n'_{ij} such that $g'_i = \sum_j n'_{ij}h_j$) together with relations of the form $(g'_i)^{p_i^{k_i}}$ for primes p_i and positive integers k_i.*

Pairings and forms on finite abelian groups. We now quickly review the basics of quadratic forms on finite abelian groups. We refer the reader to [27] for more background.

Let $(A,+)$ be a finite abelian group, denoted additively. A *symmetric bilinear pairing* $b\colon A\times A\to G$ into the (not necessarily finite) abelian group $(G,+)$ is a map satisfying

$$b(x,y) = b(y,x), b(x+y,z) = b(x,z)+b(y,z), \text{ and } b(x,y+z) = b(x,y)+b(x,z) \text{ for all } x,y,z.$$

A pairing is *non-degenerate* if for every $x\in A$, $x\neq 0$, there exists some $y\in A$ such that $b(x,y)$ is not trivial in G. When the symmetric bilinear pairing takes value in $(G,+) = (\mathbb{Q}/\mathbb{Z},+)$, where $(\mathbb{Q}/\mathbb{Z},+)$ is the additive group of rational numbers modulo the integers, we call the pair (A,b) a *discriminant pairing*. For any real number $x\in\mathbb{R}$, denote by $\mathbf{e}(x)$ the quantity $\exp(2\pi i x)$. Let $(U(1),\times)$ be the multiplicative group of complex numbers $\{\mathbf{e}(x) : x\in\mathbb{R}/\mathbb{Z}\}$ on the unit circle. There is a natural group isomorphism $\mathbb{Q}/\mathbb{Z}\to U(1), x\mapsto \mathbf{e}(x)$. When a symmetric bilinear pairing b is non-degenerate and takes value in $(U(1),\times)$, we call it a *bicharacter*. Note that (A,b) is a non-degenerate discriminant pairing if and only if $(A,\mathbf{e}(b(\cdot,\cdot)))$ is a bicharacter. If (A,b) is a discriminant pairing and $e_1,\dots,e_k\in A$, then the *Gram matrix* of $(e_1,\dots,e_k)$ is the $k\times k$ matrix $(b(e_i,e_j))_{i,j}$.

For a map $q\colon A\to G$, define $\partial q\colon A\times A\to G$ by $\partial q(x,y) := q(x+y)-q(x)-q(y)$ for any $x,y\in A$. The map q is a *(homogeneous) quadratic form* if, for any $x\in A$ and $u\in\mathbb{Z}$, $q(ux) = u^2q(x)$ and the map ∂q is bilinear. For a quadratic form q, we call ∂q the *bilinear*

pairing associated to q. A quadratic form q is *non-degenerate* if the bilinear pairing ∂q is non-degenerate. If q takes value in $\mathbb{Q}/\mathbb{Z}$, the pair (A, q) is called a *pre-metric group*, and if moreover q is non-degenerate, (A, q) is a *metric group*.

Gauss sums on pre-metric groups. If $\gamma \in \mathbb{Q}/\mathbb{Z}$, let $\mathbf{e}(\gamma) := \exp(2\pi i\gamma)$. To every pre-metric group (G, q) we associate a complex number $\Theta(G, q)$ called the *Gauss sum*:

$$\Theta(G, q) := \frac{1}{|\sqrt{|G|}|} \sum_{x \in G} \mathbf{e}(q(x)).$$

Our next theorem is one of the central tools in our algorithm for computing the TVBW invariants of Tambara-Yamagami categories.

▶ **Theorem 2.** *Let G be a finite abelian group presented via a primary decomposition with $d(G)$ summands. If oracle access to a quadratic form $q : G \to \mathbb{Q}/\mathbb{Z}$ is provided, then the Gauss sum $\Theta(G, q)$ can be evaluated in polynomial time using $O(d(G)^3 \operatorname{poly}(\log |G|))$ operations, $O(d(G)^2)$ oracle accesses, and $O(d(G)^2 \operatorname{poly}(\log |G|))$ memory words.*

Theorem 2 is seemingly folklore in the algebraic number theory literature, but we were unable to find any references proving it. We understand it as a consequence of a scattered collection of works on pre-metric groups and algorithms. Wall [33] abstractly classifies metric groups by showing how to decompose them into direct sums of elementary pieces; Basak and Johnson [3] later provide an algorithmic formulation of the decomposition theorem and explain that the Gauss sum of a metric group can be computed readily from the decomposition. We have however not found a complexity analysis of this construction anywhere in the literature. The closest we are aware of is [5, Thm. 1.1], which shows that Gauss sums of (not-necessarily-homogeneous) quadratic forms on cyclic groups $\mathbb{Z}/N\mathbb{Z}$ are computable in polynomial time; however, even if A itself is cyclic, the Gauss sums we will need to compute in our algorithm for $|M|_{\mathrm{TY}(A,\chi,\nu)}$ are on non-cyclic pre-metric groups of the form (A^n, q). In order to fill this gap, we prove Theorem 2 in the full version of the paper [8] by supplementing the algorithm of [3] with a detailed complexity analysis.

2.2 Combinatorial and algebraic topology

(Co)homology. Throughout this article we employ the simplicial cohomology of simplicial complexes with $\mathbb{Z}/2\mathbb{Z}$ coefficients. We assume the reader is familiar with the basic definitions (see [11] for an introduction to the topic). The following well-known fact can be understood as an application of Theorem 1.

▶ **Theorem 3.** *Let $\mathfrak{T}$ be a simplicial complex with n simplices. For any dimension $d = 0, 1, 2, \ldots$, the following can be computed in polynomial time using $O(n^3)$ operations: a basis of $Z^d(\mathfrak{T}, \mathbb{Z}/2\mathbb{Z})$; a basis of $B^d(\mathfrak{T}; \mathbb{Z}/2\mathbb{Z})$; a set of elements in $Z^d(\mathfrak{T}; \mathbb{Z}/2\mathbb{Z})$ that represent a basis of $H^d(\mathfrak{T}; \mathbb{Z}/2\mathbb{Z})$. In particular, the dimension of each of these spaces can be computed in polynomial time.*

Triangulated 3-manifolds. The most common data type in computational 3-manifold topology is that of a generalized triangulation; e.g., see [24]. However, strictly speaking, the TVBW invariants are only defined for *simplicial (or PL)* triangulations. It is possible to extend the definition to "polytope decompositions" (including generalized triangulations) [15], but we will not need to work at this level of generality.

Thus, throughout this work, we make the following conventions: a 3-manifold M is always closed and oriented, and presented by a simplicial triangulation, denoted $\mathfrak{T}$, together with an orientation of $\mathfrak{T}$. The orientability of M is reflected in the fact that the simplicial homology group $H_3(\mathfrak{T};\mathbb{Z})$ is isomorphic to $\mathbb{Z}$ (this can be checked quickly from $\mathfrak{T}$), and then an *orientation* of $\mathfrak{T}$ is encoded by labeling each tetrahedron in $\mathfrak{T}$ with a sign $+1$ or -1 in a way that gives rise to a $\{+1,-1\}$-valued cellular 0-cocycle on the cellulation dual to $\mathfrak{T}$.

Later, it will also be convenient to decorate each *edge* of an oriented triangulation with an arbitrarily chosen orientation. We stress that these edge orientations are arbitrary, and have nothing to do with the orientation of the manifold's tetrahedra. Going forward, by a small abuse of language, if we say *triangulation*, then we will usually mean an oriented triangulation equipped with such an edge orientation. We denote the set of vertices of $\mathfrak{T}$ by V, the set of edges by E, the set of triangular faces by F, and the set of tetrahedra by T.

2.3 Tambara-Yamagami quantum invariants

The *quantum invariants* we consider in this article are $\mathbb{C}$-valued topological invariants of closed 3-manifolds derived from algebraic data (a *spherical fusion category*) attached to a combinatorial presentation of the 3-manifold (a *simplicial triangulation*), together with evaluation rules described in the works of Turaev and Viro [30] and Barrett and Westbury [2]. We now give an extremely brief introduction to *Tambara-Yamagami quantum invariants*, which are the TVBW invariants produced by a particular infinite family of spherical fusion categories called *Tambara-Yamagami categories* [28]. For the sake of space, here we provide only the details necessary to follow the proofs of our main results. We refer the reader to [8] for the full details of the combinatorial description of spherical fusion categories in general and for Tambara-Yamagami categories in particular, as well as the general construction of TVBW invariants (for unitary and multiplicity-free categories).

Let $(A,+)$ be a finite abelian group with $|A|$ elements, $\chi : A \times A \to U(1)$ a bicharacter on A, and ν a choice of square root $\nu = \pm 1/\sqrt{|A|} = \pm |A|^{-1/2}$. The *Tambara-Yamagami category* $\mathrm{TY}(A,\chi,\nu)$ is an algebraic object which gives rise to the following data:

- a set of *colors* $L \stackrel{\text{def}}{=} A \sqcup \{m\}$ (where m is some symbol not in A), together with a *duality* operation * defined by $a^* \stackrel{\text{def}}{=} -a$ and $m^* \stackrel{\text{def}}{=} m$.
- scalars d_a and d_m associated to every color in L called *quantum dimensions*, as well as the *(global) quantum dimension* scalar D. These scalars are defined as follows:

$$d_a \stackrel{\text{def}}{=} 1 \text{ for all } a \in A, \qquad d_m \stackrel{\text{def}}{=} +|A|^{1/2}, \qquad D \stackrel{\text{def}}{=} \sum_{x \in L} d_x^2 = 2|A|.$$

- a set of *admissible triples* of colors

$$\{(a,b,-a-b),(a,m,m),(m,a,m),(m,m,a) : a,b \in A\} \subset L \times L \times L,$$

- and a system of $\mathbb{C}$-valued *tetrahedron weights* defined below.

A *coloring* $\theta\colon E \to L$ of a triangulation $\mathfrak{T}$ is an assignment of a color to each edge of $\mathfrak{T}$. Given an edge e_0 on the boundary of a face f, the orientation of e_0 determines a direction along which to traverse the three boundary edges of f; call these edges e_0, e_1 and e_2, according to the order in which we first see them while doing this traversal. Now associate a triple of colors $(\theta(e_0), \theta(e_1)^{(*)}, \theta(e_2)^{(*)})$, where $\theta(e_i)^{(*)}$ means we apply the duality operation * to the label $\theta(e_i)$ if the direction of traversal around f disagrees with the orientation of e_i. The coloring θ is called *admissible* if every such triple associated to an edge-face pair is admissible. The set of *admissible colorings* is denoted by $\mathrm{Adm}_L(\mathfrak{T})$.

We now describe the tetrahedral weights involved in the definition of the Tambara-Yamagami invariants. Let θ be a coloring of $\mathfrak{T}$ and let $\theta_e := \theta(e) \in L$ denote the label of an edge $e \in E$. For each tetrahedron $t \in T$ with edges $e_1, e_2, \dots e_6$ and orientation $O(t) \in \{+, -\}$, we assign a *tetrahedral weight* $|t|_\theta^{O(t)} \in \mathbb{C}$. If θ is inadmissible, then $|t|_\theta^{O(t)} \stackrel{\text{def}}{=} 0$. Otherwise, θ is admissible and so, as described in [8], takes on one of four possible types; taking $O(t)$ into account we then assign the tetrahedral weights as follows:

m-empty

$$\begin{vmatrix} a & b & a+b \\ b-c & a+c & c \end{vmatrix}^{+} = 1 \qquad \begin{vmatrix} a & b & a+b \\ c-b & a+c & c \end{vmatrix}^{-} = 1$$

m-triangle

$$\begin{vmatrix} m & m & a \\ a & a+b & m \end{vmatrix}^{+} = d_m \qquad \begin{vmatrix} a & b & a+b \\ m & m & m \end{vmatrix}^{-} = d_m$$

flat m-quad

$$\begin{vmatrix} a & m & m \\ b & m & m \end{vmatrix}^{+} = d_m \chi(a,b) \qquad \begin{vmatrix} a & m & m \\ b & m & m \end{vmatrix}^{-} = d_m \overline{\chi(a,b)}$$

crooked m-quad

$$\begin{vmatrix} m & m & a \\ m & m & b \end{vmatrix}^{+} = \nu d_m^2 \overline{\chi(a,b)} \qquad \begin{vmatrix} m & m & a \\ m & m & b \end{vmatrix}^{-} = \nu^{-1} d_m^2 \chi(a,b),$$

where a, b, c are arbitrary elements in A.

Finally, the Tambara-Yamagami quantum invariant $|M|_{\mathrm{TY}(A,\chi,\nu)}$ of a 3-manifold M with triangulation $\mathfrak{T}$ is defined via the following "state sum formula:"

$$|M|_{\mathrm{TY}(A,\chi,\nu)} \stackrel{\text{def}}{=} \sum_{\theta \in \mathrm{Adm}_L(\mathfrak{T})} \frac{\prod_{t \in T} |t|_\theta^{O(t)} \prod_{e \in E} d_{\theta e}}{\prod_{f \in F} \sqrt{d_{\theta e_1} d_{\theta e_2} d_{\theta e_3}} \prod_{v \in V} D}.$$

We note that for a fixed coloring θ and tetrahedron t, testing its admissibility on t and determining its type can be carried out in constant time. Thus, there is a naïve algorithm to compute $|M|_{\mathrm{TY}(A,\chi,\nu)}$ directly from this definition with running time exponential in the size of $\mathfrak{T}$. In fact, this is true of $|M|_{\mathcal{C}}$ for any spherical fusion category $\mathcal{C}$. We now turn to showing that we can do much better when $\mathcal{C} = \mathrm{TY}(A, \chi, \nu)$ if we bound the $\mathbb{Z}/2\mathbb{Z}$ Betti number $\beta_1(M)$.

3 The role of the Betti number in Tambara-Yamagami invariants

We are interested in the following algorithmic problem:

$\mathrm{TY}(A, \chi, \nu)$-INVARIANT COMPUTATION
Input: $\mathfrak{T}$ a triangulation of an oriented closed 3-manifold M
Output: $\lvert M\rvert_{\mathrm{TY}(A,\chi,\nu)}$

Since we are not working uniformly in the data A, χ, ν, there is no harm in assuming we have full "explicit" access to it. Our main result is

▶ **Theorem 4.** *For a fixed Tambara-Yamagami category $\mathrm{TY}(A, \chi, \nu)$, there is a deterministic algorithm that, given as input a triangulation of an orientable closed 3-manifold M with n tetrahedra, computes the quantum invariant $|M|_{\mathrm{TY}(A,\chi,\nu)}$ in $O(2^{\beta_1} n^3)$ operations and using $O(n^2)$ memory words.*

In this section we expound the ideas introduced in Section 1 that lead to this algorithm; its proof is deferred until Section 4. Hereafter A, χ, and ν are fixed.

3.1 Admissible colorings induce simplicial 1-cocycles

We begin by noting that each admissible coloring determines a $\mathbb{Z}/2\mathbb{Z}$-valued simplicial 1-cocycle. More precisely, consider the function

$$\phi\colon \mathrm{Adm}_L(\mathfrak{T}) \to C^1(\mathfrak{T}, \mathbb{Z}/2\mathbb{Z}), \qquad \phi(\theta)(e) = \begin{cases} 1 & \text{if } \theta(e) = m \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

that assigns to an admissible coloring of $\mathfrak{T}$ a $\mathbb{Z}/2\mathbb{Z}$-valued simplicial 1-cochain of the triangulation (that is, a function $E \to \mathbb{Z}/2\mathbb{Z}$).

▶ **Lemma 5.** *For any admissible coloring θ of a triangulation $\mathfrak{T}$, $\phi(\theta)$ is a 1-cocycle.*

In the case of $\mathrm{TY}(\mathbb{Z}/2\mathbb{Z}, \exp(i\pi ab), -1/\sqrt{2}) = \mathrm{TV}_4$, this lemma was proved in [4, 22] and used in the algorithm of [23]. It can be proved easily in the general case by examining the definition of admissible triples in $\mathrm{TY}(A, \chi, \nu)$ – the calculation boils down to the simple observation that in any admissible coloring, the number of edges around any face of $\mathfrak{T}$ colored by m is either 0 or 2. More conceptually, this lemma follows from the fact that $\mathrm{TY}(A, \chi, \nu)$ is a spherical $\mathbb{Z}/2\mathbb{Z}$-*graded* fusion category, and a similar result holds for any spherical G-graded fusion category, cf. [31].

3.2 The partial state sum at a 1-cocycle

Fix a 1-cocycle $\alpha \in Z^1(\mathfrak{T}, \mathbb{Z}/2\mathbb{Z})$ and consider the *partial state sum at* α, defined by only summing over the admissible labelings associated to α:

$$|\mathfrak{T}, \alpha|_{\mathrm{TY}(A,\chi,\nu)} \overset{\text{def}}{=} \sum_{\theta \in \phi^{-1}(\alpha)} \frac{\displaystyle\prod_{t \in T} |t|_\theta^{O(t)} \prod_{e \in E} d_{\theta e}}{\displaystyle\prod_{f \in F} \sqrt{d_{\theta e_1} d_{\theta e_2} d_{\theta e_3}} \prod_{v \in V} D}.$$

By definition, all admissible colorings of $\phi^{-1}(\alpha)$ have the same set of edges colored by the object m. We partition E, F, and T, such that for every coloring in $\phi^{-1}(\alpha)$:

1. $E = E_\emptyset \sqcup E_\bullet$ where $E_\emptyset$ is the set of edges colored by an element of A, and $E_\bullet$ is the set of edges colored by m,
2. $F = F_\emptyset \sqcup F_{\bullet\bullet}$ where $F_\emptyset$ is the set of faces whose edges are colored exclusively by elements of A, and $F_{\bullet\bullet}$ is the set of faces with exactly two edges colored by m,
3. $T = T_\emptyset \sqcup T_\triangle \sqcup T_\boxplus \sqcup T_\boxminus \sqcup T_\diamondsuit \sqcup T_\diamond$, where $T_\emptyset$ is the set of m-empty faces, $T_\triangle$ is the set of m-triangles, $T_\boxplus$ and $T_\boxminus$ are respectively the set of positively and negatively oriented flat m-quads, and $T_\diamondsuit$ and $T_\diamond$ are respectively the set of positively and negatively oriented crooked m-quads (see end of Section 2.3 for conventions).

Replacing $|t|_\theta^{O(t)}$ by the appropriate values and factorizing, we now rewrite the partial state sum at the 1-cocycle α.

For an admissible coloring θ and an m-quad tetrahedron t in θ (either flat or crooked), define $\chi_{\theta(t)}$ to be the value $\chi(a, b)$ where a, b are the colors in θ assigned to the two opposite edges not colored by m in the (flat or crooked) m-quad tetrahedron t. One can then check:

$$|\mathfrak{T}, \alpha|_{\mathrm{TY}(A,\chi,\nu)} = D^{-|V|} \cdot d_m^{C_\alpha} \cdot \nu^{|T_\diamondsuit| - |T_\diamond|} \sum_{\theta \in \phi^{-1}(\alpha)} \left(\prod_{t \in T_\boxplus} \chi_{\theta(t)} \cdot \prod_{t \in T_\boxminus} \overline{\chi_{\theta(t)}} \cdot \prod_{t \in T_\diamondsuit} \overline{\chi_{\theta(t)}} \cdot \prod_{t \in T_\diamond} \chi_{\theta(t)} \right) \tag{2}$$

where $C_\alpha = |E_\bullet| - |F_{\bullet\bullet}| + |T_\boxplus| + |T_\boxminus| + 2|T_\diamondsuit| + 2|T_\diamond|$.

In Section 3.4 we prove:

▶ **Theorem 6.** *Fix a category* $\mathrm{TY}(A,\chi,\nu)$*. Let* $e_1,\dots,e_{|E|}$ *be an arbitrary ordering of the edges of* $\mathfrak{T}$*. For any collections* $\mathcal{P},\mathcal{Q}$ *of pairs of indices* (i,j)*,* $1\le i,j\le|E|$*, with potentially repeated pairs, such that* $|\mathcal{P}|,|\mathcal{Q}|\in O(n)$*, there is an algorithm to evaluate the sum:*

$$\sum_{\theta\in\phi^{-1}(\alpha)}\prod_{(i,j)\in\mathcal{P}}\chi(\theta_{e_i},\theta_{e_j})\prod_{(r,s)\in\mathcal{Q}}\overline{\chi(\theta_{e_r},\theta_{e_s})} \tag{3}$$

in $O(n^3)$ *operations, using* $O(n^2)$ *memory words.*

Using the theorem, we arrive at a key step towards our main result.

▶ **Corollary 7.** *Fix a category* $\mathrm{TY}(A,\chi,\nu)$*. Given as input a 3-manifold triangulation* $\mathfrak{T}$ *with* n *tetrahedra, and a 1-cocycle* α *in* $\mathfrak{T}$*, the sum (2) can be evaluated in* $O(n^3)$ *operations, using* $O(n^2)$ *memory words.*

Proof. By definition of the projection ϕ (Equation (1)), the 1-cocycle α gives a description of the edges colored by the object m in all admissible colorings of $\phi^{-1}(\alpha)$. Additionally, the multiplicative constant $D^{-|V|}\cdot d_m^{C_\alpha}\cdot\nu^{|T_{\diamondsuit}|-|T_{\diamondsuit}|}$ in front of the sum (Equation (2)) depends exclusively on the set of edges colored by m. In consequence, the multiplicative constant can be evaluated in linear time by checking the set of m-colored edges of each tetrahedron. Using the notations of Theorem 6, we consider the pairs $\mathcal{P}$ (resp. $\mathcal{Q}$) of indices (i,j) of opposite edges (e_i,e_j) not colored by m in tetrahedra of type $T_{\boxplus}\sqcup T_{\diamondsuit}$ (resp. $T_{\boxminus}\sqcup T_{\diamondsuit}$), in order to evaluate the sum $\sum_{\theta\in\phi^{-1}(\alpha)}\left(\prod_{t\in T_{\boxplus}}\chi_{\theta(t)}\cdot\prod_{t\in T_{\boxminus}}\overline{\chi_{\theta(t)}}\cdot\prod_{t\in T_{\diamondsuit}}\overline{\chi_{\theta(t)}}\cdot\prod_{t\in T_{\diamondsuit}}\chi_{\theta(t)}\right)$ in cubic time. ◀

3.3 Efficiently characterizing colorings over a 1-cocycle

For a given 1-cocycle $\alpha\in Z^1(\mathfrak{T};\mathbb{Z}/2\mathbb{Z})$, we now characterize the set $\phi^{-1}(\alpha)\subseteq\mathrm{Adm}(\mathfrak{T})$. Recall that $E_\emptyset$ is the set of edges not colored by m and $F_\emptyset$ is the set of faces with no edge colored by m.

▶ **Lemma 8.** *If the finite abelian group* A *is given by its primary decomposition with* $d(A)$ *summands, and the triangulation* $\mathfrak{T}$ *has* $n=|\mathfrak{T}|$ *tetrahedra, then the set* $\phi^{-1}(\alpha)$ *is in bijection with the elements of a finite abelian group* G *with* $O(d(A)n)$ *generators.*

Proof. Fix an arbitrary orientation of the edges of the triangulation. The admissibility constraints for colorings in a Tambara-Yamagami category imply that the set $\phi^{-1}(\alpha)$ is in bijection with the set of assignments $\theta\colon E_\emptyset\to A$ satisfying the following linear equations: for any m-empty face with edges e_1,e_2,e_3,

$$\varepsilon_1\theta(e_1)+\varepsilon_2\theta(e_2)+\varepsilon_3\theta(e_3)=0,$$

where $\varepsilon_i\in\{\pm1\}$ depending whether the orientations of edges e_1,e_2,e_3 agree or not with an arbitrarily chosen orientation of the triangular face. Consider the group homomorphism $\lambda\colon A^{|E_\emptyset|}\to A^{|F_\emptyset|}$ where the $|F_\emptyset|$-many values are the relations $\varepsilon_1\theta(e_1)+\varepsilon_2\theta(e_2)+\varepsilon_3\theta(e_3)$ above. The set $\phi^{-1}(\alpha)$ is in bijection with the kernel of this application. Because $A^{|E_\emptyset|}$ is a finite abelian group with $d(A)|E_\emptyset|$ summands in its primary decomposition, with $|E_\emptyset|\le|E|\in O(n)$, then $\ker\lambda$ is a finite abelian group with $O(d(A)n)$ generators. ◀

Additionally, a minimal family of generators $(y_1,\dots,y_\ell), y_i\in A^{|E_\emptyset|}$, for $\ker\lambda$ can be computed in polynomial time.

▶ **Lemma 9.** *For a fixed abelian group A, with the notations above, a minimal family of generators for* $\ker\lambda$ *can be computed in $O(n^3)$ operations, using $O(n^2)$ memory words.*

Proof. The proof is standard linear algebra over $\mathbb{Z}$ using Smith normal form, see the proof of [8, Lemma 3.0] for details. ◀

In conclusion, any generator of the kernel $\ker\lambda \subseteq A^{|E_\emptyset|}$ can be interpreted as an assignment of colors to the empty edges of the triangulation $E_\emptyset \to A$. For a fixed 1-cocycle α of the triangulation, any admissible coloring in $\phi^{-1}(\alpha)$ can be expressed as a sum (with integer coefficients) of elements of the kernel (where the sum of colors is edge-wise) following the rule of addition in A.

3.4 Partial state sums are (normalized) Gauss sums

The goal of this subsection is to prove Theorem 6. Consider a finite abelian group $(A,+)$ with $d := d(A)$ generators $x_1,\dots,x_d$ for the summands of its primary decomposition, its product A^k with generators $(x_{ij})_{i=1\dots d, j=1\dots k}$, and a subgroup $(G,+)$ with $g := d(G)$.

For a group element $y \in G$, we express $y = \sum_{i,j} n_{ij}(y)x_{ij}$, for integer coefficients $n_{ij}(y)$, in the set of generators for A^k. We also write $y^{(j)} := \sum_{i=1\dots d} n_{ij}(y)x_i \in A$ for the projection of y into the j-th component of the product A^k.

Let $\mathcal{P},\mathcal{Q}$ be arbitrary sets of pairs of indices (i,j), with $1 \le i,j \le k$, and possible multiplicities $p_{ij} \ge 1$ for the pair $(i,j) \in \mathcal{P}$, and q_{ij} for the pair $(i,j) \in \mathcal{Q}$. Consider the product:

$$\psi\colon G \to U(1), \qquad y \mapsto \prod_{(i,j)\in\mathcal{P}} \chi(y^{(i)},y^{(j)})^{p_{ij}} \prod_{(r,s)\in\mathcal{Q}} \chi(y^{(r)},y^{(s)})^{-q_{rs}}. \tag{4}$$

and define the complex valued sum:

$$\Omega(\mathcal{P},\mathcal{Q}) := \frac{1}{|\sqrt{|G|}|} \sum_{y\in G} \psi(y). \tag{5}$$

▶ **Lemma 10.** *The sum $\Omega(\mathcal{P},\mathcal{Q})$ in Equation (5) is a* quadratic Gauss sum *over G,* i.e.*, there exists a quadratic form $q\colon G \to \mathbb{Q}/\mathbb{Z}$ s.t.,*

$$\Omega(\mathcal{P},\mathcal{Q}) = \Theta(G,q) = \frac{1}{|\sqrt{|G|}|} \sum_{x\in G} \mathbf{e}(q(x)).$$

Proof. Define the pairing $b\colon A\times A \to \mathbb{Q}/\mathbb{Z}$ satisfying, for any $x,y \in A$, the equality $\chi(x,y) = \mathbf{e}(b(x,y))$. The map b is a bilinear pairing. This follows from the definition of a bicharacter. For any $x,y,z \in A$,

$$\chi(x+y,z) = \mathbf{e}(b(x+y,z)) = \chi(x,z)\chi(y,z) = \mathbf{e}(b(x,z)+b(y,z)),$$

and in consequence $b(x+y,z) = b(x,z)+b(y,z) \mod \mathbb{Z}$. By symmetry of χ, bilinearity follows. Define $q\colon G \to \mathbb{Q}/\mathbb{Z}$ by:

$$q(y) := \sum_{(i,j)\in\mathcal{P}} p_{ij}\cdot b(y^{(i)},y^{(j)}) - \sum_{(r,s)\in\mathcal{Q}} q_{rs}\cdot b(y^{(r)},y^{(s)}),$$

such that $\left|\sqrt{|G|}\right| \Omega(\mathcal{P},\mathcal{Q}) = \sum_{x\in G} \mathbf{e}(q(x))$. The map q is a quadratic form. Indeed, first notice that, for any integer u, $q(uy) = u^2 q(y)$ follows from the fact that $b(uy^{(i)},uy^{(j)}) = u^2 b(y^{(i)},y^{(j)})$. Second, the form $\partial q : (y,y') \mapsto q(y+y') - q(y) - q(y')$ is bilinear, as it can be expressed as a sum of evaluations of the bilinear pairing b on $(y^{(i)},y'^{(j)})$ for some i,j. ◀

Proof of Theorem 6. Using the notation of Theorem 6, we identify the following sum on the triangulation:

$$\sum_{\theta\in\phi^{-1}(\alpha)} \prod_{(i,j)\in\mathcal{P}} \chi(\theta_{e_i},\theta_{e_j}) \prod_{(r,s)\in\mathcal{Q}} \overline{\chi(\theta_{e_r},\theta_{e_s})} \tag{6}$$

with the quantity $\left|\sqrt{|G|}\right| \Omega(\mathcal{P},\mathcal{Q})$ in Equation (5), where the group G is the subgroup $\ker\lambda$ of the product $A^{|E_\emptyset|}$, whose presentation we identify in polynomial time via Lemma 9. The pairs of indices $\mathcal{P}$ and $\mathcal{Q}$ represent indices of edges in Equation (6), and particular copies of A in the product $A^{|E_\emptyset|}$ in Equation (4), with a natural correspondence induced by the fact that copies of A in $A^{|E_\emptyset|}$ are in bijection with edges not colored by m (once the 1-cocycle α is fixed). The order of the finite group $G=\ker\lambda$ can be evaluated by finding the primary decomposition of G, which can be done in polynomial time (Theorem 1). Let q be the quadratic form defined in the proof of Theorem 10. We can compute the Gram matrix of a minimal family of generators of $\ker\lambda$ (computed in Lemma 9) for the discriminant pairing $(G,\partial q)$ by evaluating ∂q, and compute the Gauss sum $\Omega(\mathcal{P},\mathcal{Q})$ in polynomial time (by virtue of Theorem 2), with the expected complexity. ◀

3.5 Cohomologous 1-cocycles have equal partial state sums

The tools introduced so far in this section would only be enough to construct a parameterized algorithm in terms of the number of 1-cocycles $Z^1(\mathfrak{T};\mathbb{Z}/2\mathbb{Z})$. The final ingredient necessary to further reduce the parameter to $\beta_1(M)$ follows from a general statement about TVBW invariants of spherical G-graded fusion categories (for any finite group G) first described by Turaev and Virelizier [31, Thm. 7.1], specialized to our situation: $\mathrm{TY}(A,\chi,\nu)$ is a spherical $\mathbb{Z}/2\mathbb{Z}$-graded fusion category.

▶ **Theorem 11** (special case of Thm. 7.1 in [31]). *If α and β are cohomologous elements of the group of cocycles $Z^1(\mathfrak{T};\mathbb{Z}/2\mathbb{Z})$, then $|\mathfrak{T},\alpha|_{\mathrm{TY}(A,\chi,\nu)} = |\mathfrak{T},\beta|_{\mathrm{TY}(A,\chi,\nu)}$.*

4 Fixed parameter tractable algorithm in the first Betti number

Fix the data of $\mathrm{TY}(A,\chi,\nu)$. Given as input an arbitrary triangulation $\mathfrak{T}$ of a closed oriented 3-manifold M, our algorithm to compute the TVBW invariant $|M|_{\mathrm{TY}(A,\chi,\nu)}$ is as follows:

1. Compute a set of 1-cocycles $\{\alpha_1,\dots,\alpha_{\beta_1}\}\subset Z^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})$ such that $\{[\alpha_1],\dots,[\alpha_{\beta_1}]\}$ forms a basis of the 1-cohomology vector space $H^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})$.

   Compute a basis for $B^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})$; the cardinality $\#B^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})$ of the set of 1-coboundaries is equal to $2^{\dim B^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})}$. [Theorem 3]

2. For each of the 2^{β_1} distinct 1-cohomology classes $[\alpha]$ of $H^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})$, construct a representative $\alpha\in Z^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})$ by enumerating all 2^{β_1} $\mathbb{Z}/2\mathbb{Z}$-combinations of elements in $\{\alpha_1,\dots,\alpha_{\beta_1}\}$, *i.e.*, all $\alpha=\varepsilon_1\alpha_1+\ldots+\varepsilon_{\beta_1}\alpha_{\beta_1}$, for $\varepsilon_i\in\mathbb{Z}/2\mathbb{Z}$.

   Now, for each such α, apply Corollary 7 to compute the partial state sum $|\mathfrak{T},\alpha|_{\mathrm{TY}(A,\chi,\nu)}$, with the following steps:

   a. Compute a minimal family of generators for $\ker\lambda=\langle x_1,\dots,x_g\rangle$, [Lemma 9]

   b. Compute the primary decomposition of $\ker\lambda$ with generators $\ker\lambda=\langle x'_1,\dots,x'_g\rangle$ for the summands, [Theorem 1]

   c. Compute the Gram matrix of $x'_1,\dots,x'_g$ for the pre-metric form $(\ker\lambda,q)$, by evaluating ∂q on all pairs (x'_i,x'_j). [defined in Lemma 10]

d. Evaluate the Gauss sum of $(\ker\lambda, q)$, [Theorem 2]
and multiply by $\left|\sqrt{|G|}\right|$. [proof of Theorem 6]
Normalize to get the state sum $|\mathfrak{T},\alpha|_{\mathrm{TY}(A,\chi,\nu)}$, with multiplicative factor as in Equation (2). [Corollary 7]

3. Sum over all α:

$$|M|_{\mathrm{TY}(A,\chi,\nu)} = \sum_{\substack{\alpha=\varepsilon_1\alpha_1+\ldots\varepsilon_{\beta_1}\alpha_{\beta_1}\\ \text{with } \varepsilon_i\in\mathbb{Z}/2\mathbb{Z}, \text{ and s.t.,}\\ \langle[\alpha_1],\ldots,[\alpha_{\beta_1}]\rangle = H^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})}} \#B^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})\cdot|\mathfrak{T},\alpha|_{\mathrm{TY}(A,\chi,\nu)}.$$

Our main Theorem 4 follows readily from the following:

▶ **Theorem 12.** *Fix a Tambara-Yamagami category* $\mathrm{TY}(A,\chi,\nu)$*. Given a triangulation* $\mathfrak{T}$ *of a closed 3-manifold* M *with* n *tetrahedra, the above algorithm computes* $|M|_{\mathrm{TY}(A,\chi,\nu)}$ *in* $O(2^{\beta_1}n^3)$ *operations and using* $O(n^2)$ *memory words.*

Proof. Computing a basis for $B^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})$, as well as a set of generators $\{\alpha_1,\ldots,\alpha_{\beta_1}\}$ whose cohomology classes form a basis of $H^1(\mathfrak{T},\mathbb{Z}/2\mathbb{Z})$, in step (1) is a standard procedure in computer algebra (Theorem 3), done by normalizing a $O(n)\times O(n)$ matrix with $\mathbb{Z}/2\mathbb{Z}$ coefficients. This can be done in $O(n^3)$ operations in $\mathbb{Z}/2\mathbb{Z}$ with Gaussian eliminations, where an arithmetic operation in $\mathbb{Z}/2\mathbb{Z}$ has constant complexity.

Given the 1-cocycles $\{\alpha_1,\ldots,\alpha_{\beta_1}\}$, we can enumerate every combination $\alpha=\varepsilon_1\alpha_1+\ldots+\varepsilon_{\beta_1}\alpha_{\beta_1}$ in (amortized) $O(n)$ operations per α. Indeed, enumerating all $\{\varepsilon_1,\ldots,\varepsilon_{\beta_1}\}$ is akin to incrementing a β_1-bits binary counter from $0\ldots0$ to $1\ldots1$, which induces an (amortized) change of $O(1)$ bits per increment [7, Chapter 16]. The 1-cocycles are represented by formal sums of $O(n)$ edges, and computing the sum of two 1-cocycles takes $O(n)$ operations.

For each α as above, we compute the partial state sum using Corollary 7 in polynomial time. Specifically, step (2a) is solved by computing a Smith normal form, together with transformation matrices, of a particular $O(d(A)n)\times O(d(A)n)$-integer matrix, which has complexity $O(n^3)$ (Lemma 9) with (modular) Gaussian eliminations, once A is fixed.

We can read-off the generators $x_1,\ldots,x_g$ of $\ker\lambda$ from the transformation matrices, and compute the generators $x'_1,\ldots,x'_g$ of step (2b) by computing the primary decomposition of the subgroup $\ker\lambda$ (Theorem 1). Computing the Gram matrix in step (2c) is done by evaluating the bilinear pairing ∂q, defined in Lemma 10, on all pairs (x'_i,x'_j). The quadratic form q is defined as a sum of $O(n)$ terms of the form $b(x'_i,x'_j)$, and the overall Gram matrix can be computed in $O(g^2n)$ operations. Recall that we have an oracle access to the function $b(\cdot,\cdot)$ (see beginning of Section 3). By Theorem 2, the Gauss sum of $(\ker\lambda,q)$ can be evaluated from the Gram matrix of $x'_1,\ldots,x'_g$ in $O(g^3)$ operations in $\mathbb{Q}/\mathbb{Z}$, where the arithmetic complexity of operations in $\mathbb{Q}/\mathbb{Z}$ depend solely on the maximal order of an element of A (independently of the size of the Gram matrix). See the full version [8] for details.

Finally, the invariant $|M|_{\mathrm{TY}(A,\chi,\nu)}$ computed in step (3) is the sum of 2^{β_1} complex numbers represented with a constant number of memory words each for a fixed group A (with $\beta_1\leq n$). In consequence, the overall complexity of the algorithm, knowing $g\in O(d(A)n)$ and considering $d(A),|A|$ constant for a fixed group A, is $O(2^{\beta_1}n^3)$. The memory complexity is bounded by the size of the matrices, which is $O(n^2)$, since we have a fixed A (coefficients are represented with a constant number of memory words, and $d(A)$ is a constant). ◀

Tiling with Three Polygons Is Undecidable

Erik D. Demaine

Stefan Langerman
Computer Science Department, Université libre de Bruxelles, Belgium

Abstract

We prove that the following problem is co-RE-complete and thus undecidable: given three simple polygons, is there a tiling of the plane where every tile is an isometry of one of the three polygons (either allowing or forbidding reflections)? This result improves on the best previous construction which requires five polygons.

1 Introduction

A ***tiling*** of the plane [9] is a covering of the plane by nonoverlapping polygons called ***tiles***, isometric copies of one or more geometric shapes called ***prototiles***, without gaps or overlaps. In this paper, we study the most fundamental computational problem about tilings:

▶ **Problem 1** (Tiling). *Given one or more prototiles, can they tile the plane?*

The tiling problem is ***undecidable*** – solved by no finite algorithm. Golomb [6] was first to prove this result, by building n polyominoes that simulate n ***Wang tiles*** [15] – unit squares with edge colors that must match – by adding color-specific bumps and dents to each edge. Four years earlier, Berger [1] proved that tiling with Wang tiles is undecidable (disproving Wang's original conjecture [15]) by showing how they can simulate a Turing machine. Robinson [13] later simplified Berger's proof. The worst-case number n of tiles (Wang or polyomino) is $\Theta(|Q| \cdot |\Sigma|)$, where $|Q|$ and $|\Sigma|$ are the number of states and symbols in the simulated Turing machine, respectively.

Constant Number of Prototiles. The first constant and previously best upper bound on the number of prototiles required to make the tiling problem undecidable is 5, as proved by Ollinger fifteen years ago [11]. Our main result, proved in Section 3, is an improvement of this upper bound to 3:

▶ **Theorem 1.1.** *Given three simple-polygon prototiles, determining whether they tile the plane is undecidable.*

It remains open whether tiling with one or two given prototiles is decidable. ***Periodic*** tilings (tilings with two translational symmetries) can be found algorithmically by enumerating fundamental domains, as we show in the full paper. (Surprisingly, this intuitive fact does not seem to have been explicitly proved before, except in special settings like Wang tiles [15].) Thus a necessary condition for undecidability is the existence of prototile(s) with only aperiodic tilings. Recently, Smith, Myers, Kaplan, and Goodman-Strauss [14] found a single prototile with this property, so there are no obvious obstacles to undecidability.

Tiling by Translation. Our construction relies on rotation of the prototiles (but works independent of whether we allow reflections). If we restrict to tiling by translation only, then Ollinger's construction can be modified to use 11 prototiles, by adding some rotations of the five polyominoes [11]. This upper bound was improved to 10 by Yang [17] and to 8 by Yang and Zhang [18]. All of these constructions use polyominoes. In higher dimensions, Yang and Zhang [19] improved the upper bound to five polycube prototiles in 3D, and four polyhypercube prototiles in 4D.

The tiling-by-translation problem also has a lower bound of 2 for undecidability: any single polygon that tiles the plane by translation can do so by periodic (even isohedral) tiling [5]. This result also holds for disconnected polyominoes [2]. If we generalize to tiling a specified periodic subset of d-dimensional space, where d is part of the input, then Greenfeld and Tao [8] recently proved tiling to be undecidable with a single disconnected polyhypercube.

Periodic Target. We show that Greenfeld and Tao's generalization to tiling a specified periodic subset [8] changes the best known results also for undecidability of tiling the plane. Our 3-polygon construction and Ollinger's 5-polyomino construction [11], and Yang and Zhang's 8-polyomino translation-only construction [18] all have one prototile (our shurikens, and their jaws) that appear periodically in any tiling of the plane. Thus, if we remove that pattern from the target, we obtain a periodic subset of the plane which can be tiled using a reduced number of prototiles of 2, 4, and 7, respectively. In particular, we prove

▶ **Corollary 1.2.** *Given two simple-polygon prototiles, and given a periodic subset of the plane, determining whether the two prototiles tile the periodic subset is undecidable.*

Logical Undecidability. Algorithmic undecidability implies ***logical undecidability*** (as explained in [7] in the context of tilings). In particular, our result implies that there are three polygon prototiles that cannot be proved or disproved to tile the plane, for any fixed set of axioms (e.g., ZFC). Otherwise, we would obtain a finite algorithm to decide tileability, by enumerating all proofs.

▶ **Corollary 1.3.** *For any fixed set of axioms, there are three fixed simple-polygon prototiles such that both "these prototiles tile the plane" and "these prototiles do not tile the plane" have no proof.*

Tiling Completion. Undecidability of tiling requires the set of prototiles to depend on the Turing machine simulation. To obtain undecidability with a fixed set of prototiles, we can generalize the tiling problem as follows [13]:

▶ **Problem 2** (Tiling Completion)**.** *Given one or more prototiles, and given some already placed tiles, can this placement be extended to a tiling of the plane?*

Robinson [13] gave the first result on this problem: a set of 36 prototiles (Wang tiles or polygons) for which tiling completion is undecidable. This result applies the general Turing machine simulation to Minsky's 4-symbol 7-state universal Turing machine, so only a finite number of tiles need to be preplaced to represent the Turing machine to simulate. Likely this result could be improved using newer smaller universal Turing machines [16]. If we allow for (countably) infinitely many tiles to be preplaced, we can use semi-universal Turing machines and simulate Rule 110, enabling undecidability with just six supertiles (Wang tile or polygons) [20]. Our main result reduces this upper bound to 3, in the stronger model of finitely many preplaced tiles:

▶ **Corollary 1.4.** *There are three fixed simple-polygon prototiles such that, given a finite set of already placed tiles, determining whether this placement can be extended to a tiling of the plane is undecidable.*

Co-RE-completeness. While past results on tiling and tiling completion have focused on undecidability, all such proofs actually show ***co-RE-hardness***: the simulated Turing machine halts if and only if the prototiles fail to tile. Co-RE-hardness is a more precise statement than undecidability, so we use that phrasing here. But it raises the question: are tiling and tiling completion in co-RE? Surprisingly, this question does not seem to have been solved (or even asked) in the literature before. In Section 4, we prove the answer is "yes":

▶ **Theorem 1.5.** *Given a finite set of polygon prototiles, and given a (possibly empty) connected set of already placed tiles, determining whether this placement can be extended to a tiling of the plane is in co-RE.*

This result holds in a very general model for polygons: the angles and edge lengths can be represented as ***computable*** numbers (meaning that a Turing machine can output the first n bits, given n). Our three-polygon construction uses a more restricted model, where the angles are rational multiples of π and the edge lengths are constant-size radical expressions, showing the problem to be co-RE-complete for every model in between.

▶ **Corollary 1.6** (Stronger form of Theorem 1.1)**.** *Given three simple-polygon prototiles, where the edge lengths and angles in degrees are specified by computable numbers or by constant-size radical expressions, determining whether they tile the plane is co-RE-complete.*

2 Wang Tiling: Signed and Unsigned

We reduce from Wang tiling, which is known to be undecidable. A ***Wang tile*** is a square with a ***glue*** on each edge. Classically, Wang tiles are ***unsigned***, meaning that glues match if they are equal, and ***translation-only***, meaning they have a specified orientation of which edge is north, east, south, and west. In 1966, Berger proved unsigned Wang tiling undecidable:

▶ **Theorem 2.1** ([1])**.** *Given a set of Wang tiles, it is co-RE-hard to determine whether they tile the plane by translation only, matching glues of equal value.*

Our first reduction converts unsigned Wang tiling to a variant that is ***signed***, meaning every glue has a sign ($+$ or $-$) and value, and glues match if they have opposite sign and equal value, and ***free***, meaning the tile can be rotated and/or reflected. This result was proved by Robinson [13, p. 179]. Figure 1 sketches the reduction; the full paper gives the details for completeness.

▶ **Lemma 2.2** ([13]). *Given a set of unsigned translation-only Wang tiles T, we can construct a set of signed free Wang tiles T' that has the same tilings as T up to global isometry, allowing or forbidding reflection.*

(a) 11 unsigned translation-only Wang tiles T that tile only aperiodically, the minimum possible [10].

(b) Equivalent 11 signed free Wang tiles T'. Bumps/dents denote signs.

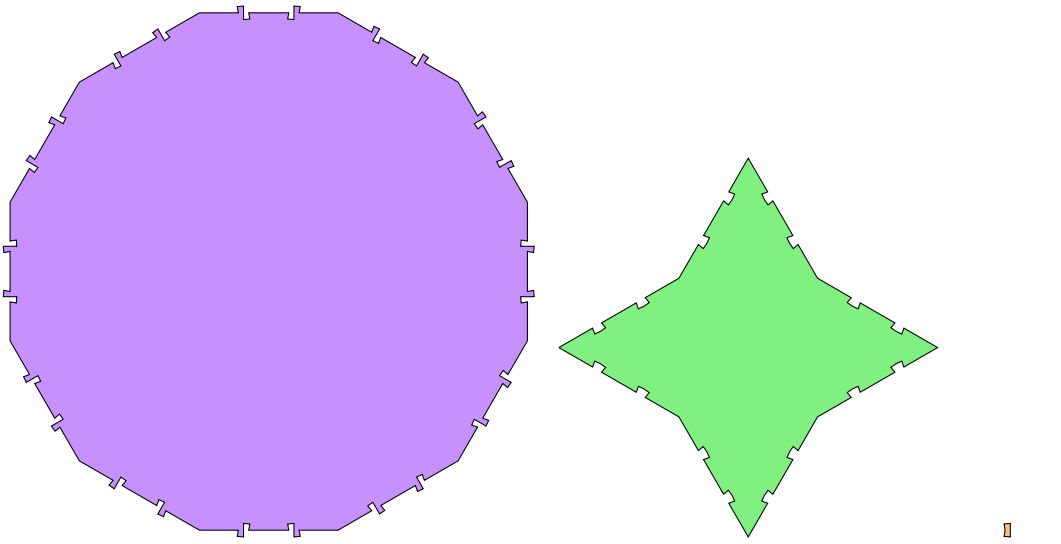
Figure 1 Example of converting unsigned translation-only Wang tiles to signed free Wang tiles.

Henceforth when we say "Wang tiles" we mean signed free Wang tiles.

3 Three Tiles That Simulate n Signed Wang Tiles

We implement any set of n Wang tiles with three tiles, illustrated in Figure 2:

1. the *wheel* which encodes all of the Wang tiles,
2. the *staple* which covers the unused Wang tiles of each wheel, and
3. the *shuriken* which fills in the remaining gaps.

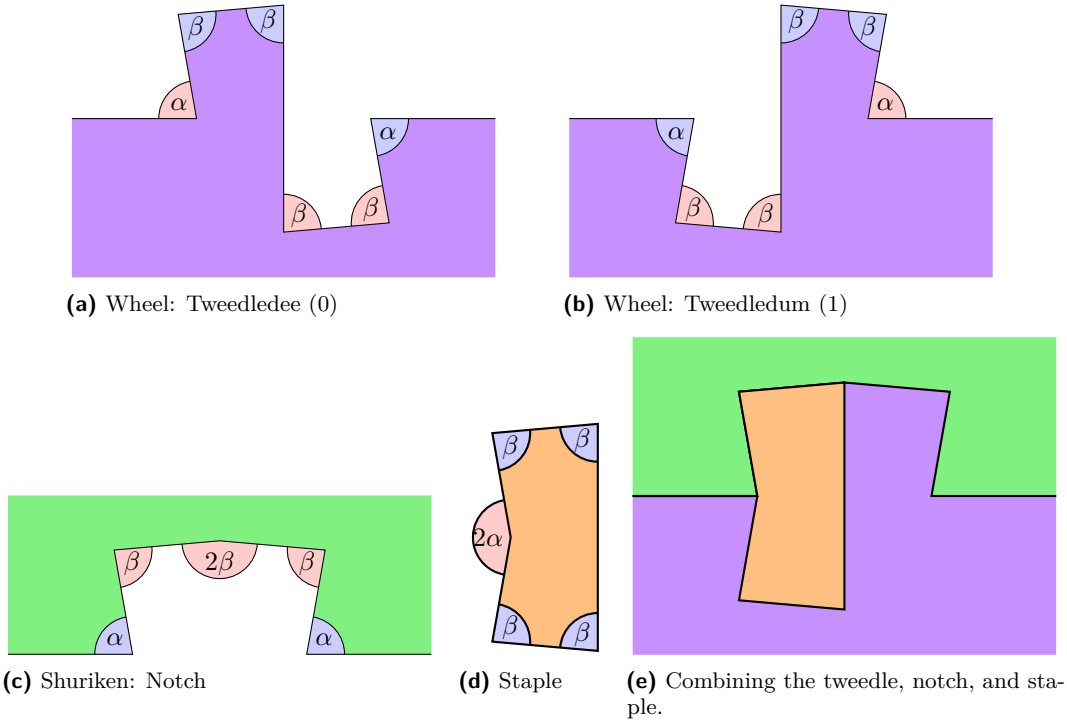


(a) Wheel **(b)** Shuriken **(c)** Staple

Figure 2 The three tiles in our construction, to scale; Figure 3 shows zoomed details of the construction. The wheel is just an example; it depends on the n Wang tiles being simulated. The shuriken depends (only) on n.

3.1 Construction and Intended Tiling

Suppose we are given a set of n Wang tiles, where the ith tile ($1 \le i \le n$) has signed glues n_i, e_i, s_i, w_i on its north, east, south, and west edges respectively. Assume n is an odd integer ≥ 5 by possibly adding duplicate tiles.



(a) Wheel: Tweedledee (0)

(b) Wheel: Tweedledum (1)

(c) Shuriken: Notch

(d) Staple

(e) Combining the tweedle, notch, and staple.

Figure 3 Zoomed views of portions of the three tiles in our construction (15× scale vs. Figure 2).

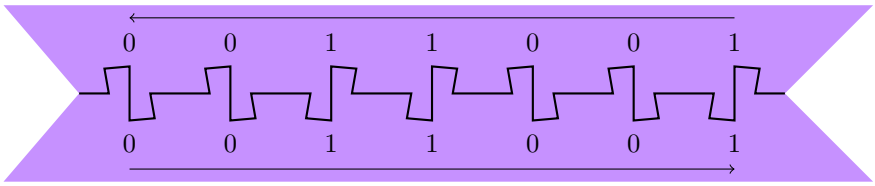


Figure 4 Matching a glue (top) and its negative (bottom) between two wheels.

The ***wheel*** is a regular $4n$-gon with each edge adorned by bumps and notches representing the $4n$ glues. For tile i, the glues n_i, e_i, s_i, w_i adorn sides $i, n+i, 2n+i, 3n+i$ of the $4n$-gon, respectively. To encode a glue, we encode its value in binary using $b = O(\log n)$ bits, prepend a 00 at the beginning, and append 01 at the end. For negative glues, we reverse the order of the bits, which puts a 10 at the beginning and a 00 at the end. Then we represent each bit with a ***tweedledee*** (0) or ***tweedledum*** (1) gadget, which are rotationally symmetric zig-zags shown in Figures 3a and 3b. Both follow the sequence of angles $\alpha, \beta, \beta, \beta, \beta, \alpha$ (where α and β are defined below); for tweedledee, this sequence measures defect, angle, angle, defect, defect, angle, respectively; while for tweedledum, this measures the opposite (angle, defect, defect, angle, angle, defect).[1] As shown in Figure 4, two adjacent glues match exactly if and only if they have the same value and opposite sign (where the opposite sign is enforced by the 00 and 01 at either end). This representation also ensures that reflecting a wheel will produce reflected glues that do not match unreflected glues: a reflection causes the bits of a

[1] It is also possible to use two different convex angles β_1, β_2 in place of each repetition β, β, but the notation is messier, so we opt for this simpler construction.

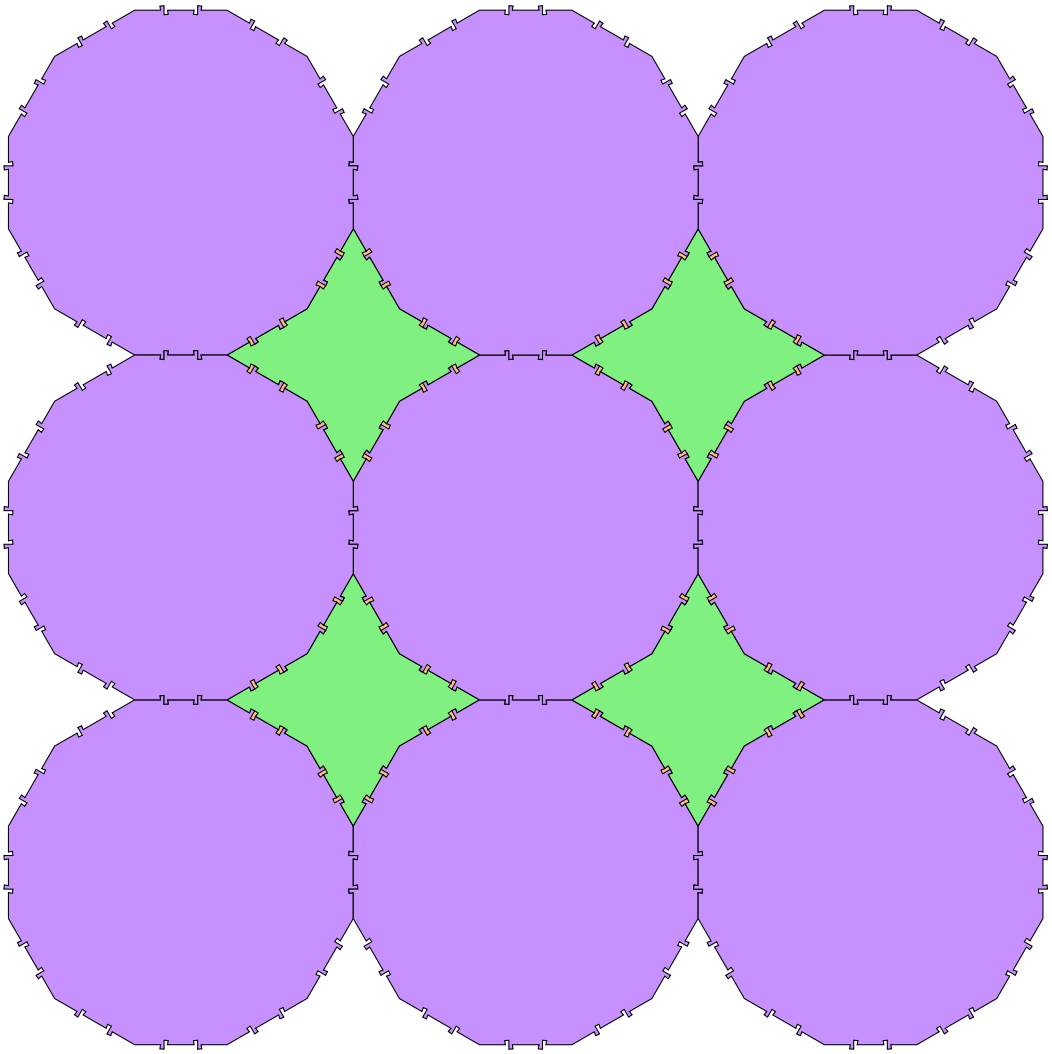

Figure 5 Example tiling with the wheel, shuriken, and staple.

glue to be reversed and negated, so the reflection of a positive glue starts with 01 and ends with 11, and the reflection of a negative glue starts with 11 and ends with 10, both of which are incompatible with unreflected glues.

By this construction, rotating the wheel so that its ith side is horizontal and at the top will have its north, east, south, and west sides represent the glues n_i, e_i, s_i, w_i of tile i. Given a tiling of the plane using this set of Wang tiles, we can place copies of the rotated wheel exactly as in the Wang tiling, and the glues will match exactly. Some space remains between the wheels, which we fill with "staples" and "shurikens". See Figure 5.

The ***shuriken*** is composed of four regular concave chains of $n-1$ sides, matching the lengths and complementary to the angles of the regular $4n$-gon. Each side is adorned with b reflectionally symmetric ***notches***, shown in Figure 3c, each consisting of convex angle α; reflex deficits $\beta, 2\beta, \beta$; and convex angle α. As shown in Figure 3e, each notch can fit a tweedle of either kind, leaving a space that is filled exactly by a ***staple*** (shown in Figure 3d, and consisting of convex angles $\beta, \beta, \beta, \beta$ and reflex deficit 2α). Thus each side of the shuriken can exactly match any glue, effectively hiding the unused tiles of each wheel (the glues that are not on the north, east, south, or west sides). Thus we have shown:

▶ **Lemma 3.1.** *Given a set of n Wang tiles and a tiling of the plane with them, we can construct a tiling of the plane with the wheel, the shuriken, and the staple constructed above.*

It remains to show that this is the only way our three tiles can tile the plane.

3.2 Angle Structure

We start with a few definitions and observations on the angles of the tiles.

Call an angle ***clean*** (and color it purple) if it is an integer multiple of $\frac{\pi}{2n}$. The sum of clean angles is clean, and the sum of clean angles and one nonclean angle is not clean.

The vertices of the convex $4n$-gon, which we call ***corners***, have clean convex angle $\pi(1-\frac{1}{2n})$. The matching shuriken reflex ***anticorners*** have a matching defect $\pi(1-\frac{1}{2n})$, and each of the four concave chains are connected at the convex ***tip*** vertices, which have a clean convex angle of $\frac{\pi}{n}$.

Define angles $\alpha = \frac{\pi}{2} - 2\varepsilon$ and $\beta = \frac{\pi}{2} - \varepsilon$, and pick $\varepsilon = \frac{\pi}{16}$.[2] These angles and their combinations are not clean:

▶ **Property 1.** *For any $\theta_1, \theta_2 \in \{\alpha, \beta\}$, neither θ_1 nor $\theta_1 + \theta_2$ is clean.*

Proof. The relevant angles are $\alpha = \frac{\pi}{2} - 2\varepsilon = \frac{3\pi}{8}$, $\beta = \frac{\pi}{2} - \varepsilon = \frac{7\pi}{16}$, $2\alpha = \frac{3\pi}{4}$, $2\beta = \frac{7\pi}{8}$, and $\alpha + \beta = \frac{13\pi}{16}$, which all have a doubly even denominator (divisible by 4). Because n is odd, these numbers cannot be equal to $\frac{i\pi}{2n}$ for any integer i, so none of these angles are clean. ◀

Table 1 Angles used in the wheel, shuriken, and staple. For convex vertices, we give the interior angle, while for reflex vertices, we give the defect (2π minus the interior angle).

Shape	angle of convex vertices	defect of reflex vertices
staple	β	2α
shuriken	$\alpha, \frac{\pi}{n}$	$\beta, 2\beta, \pi(1-\frac{1}{2n})$
wheel	$\alpha, \beta, \pi(1-\frac{1}{2n})$	α, β

Table 1 lists the angles used by each polygon, colored to indicate which are clean. Angles α, β are all a bit less than 90°, so a sum of two of them is a bit less than 180°, and a sum of three of them is a bit less than 270°. More precisely:

▶ **Lemma 3.2.** *For any $\theta_1, \theta_2, \theta_3 \in \{\alpha, \beta\}$, $\theta_1 \in (\frac{3}{8}\pi, \frac{7}{16}\pi)$, $\theta_1 + \theta_2 \in (\frac{3}{4}\pi, \frac{7}{8}\pi)$ which is $< \pi$, and $\theta_1 + \theta_2 + \theta_3 \in (\frac{9}{8}\pi, \frac{21}{16}\pi)$ which is $> \pi$. Note that these intervals are disjoint, so the value of a sum $\sum_i \theta_i$ with at most three terms determines the number of terms in the sum.*

3.3 Edge Lengths

We design the edge lengths of the tweedledee and tweedledum in Figures 3a and 3b so that the near-vertical and near-horizontal edges all have the same length, which we call 1, and the total horizontal traversal is exactly 4. Equivalently, we choose the sequence of edge lengths for either tweedle to be

$$\begin{aligned}&\langle 2 - \sin\beta + \cos\alpha,\ 1,\ 1,\ 2(\sin\alpha + \cos\beta),\ 1,\ 1,\ 2 - \sin\beta + \cos\alpha\rangle \\ &= \langle 2 - \cos\varepsilon + \sin 2\varepsilon,\ 1,\ 1,\ 2(\cos 2\varepsilon + \sin\varepsilon),\ 1,\ 1,\ 2 - \cos\varepsilon + \sin 2\varepsilon\rangle.\end{aligned}$$

[2] Other choices of ε also work; the choice here is so that all edge lengths can be expressed by radical expressions, and all angles are rational multiples of π (or equivalently, rational numbers of degrees).

Given our choice of $\varepsilon = \frac{\pi}{16}$,

$$\cos\varepsilon = \frac{1}{2}\sqrt{2+\sqrt{2+\sqrt{2}}}, \qquad \sin\varepsilon = \frac{1}{2}\sqrt{2-\sqrt{2+\sqrt{2}}},$$
$$\cos 2\varepsilon = \frac{1}{2}\sqrt{2+\sqrt{2}}, \qquad \sin 2\varepsilon = \frac{1}{2}\sqrt{2-\sqrt{2}}$$

are all radical expressions, so all our edge lengths can be expressed by radical expressions.

To prevent the notches from intersecting each other at the tip of the shuriken (with the sharp angle of π/n), we place the notches of the shuriken and the tweedles of the wheel at a distance of n from the anticorners of the shuriken and the corners of the wheel respectively. That is, each side of the shuriken is composed of an edge of length n, followed by the b notches, followed by an edge of length n; and each side of the wheel is composed of an edge of length n, followed by the b tweedles composing the glue, followed by an edge of length n.

3.4 Forced Tiling Structure

▶ **Lemma 3.3.** *The staple does not tile the plane (even allowing reflections).*

Proof. The staple has convex vertices just of angle β and one reflex vertex of defect 2α. In any tiling of staples, every reflex vertex must have its defect 2α filled by some convex angles. But $2\alpha = \frac{3}{4}\pi$, so by Lemma 3.2, it must be filled by exactly two convex angles. But $2\beta = \frac{7}{8}\pi > 2\alpha$, so two of the convex angles do not fit. Thus it is impossible to exactly fill the deficit. ◀

▶ **Lemma 3.4.** *The staple and shuriken do not tile the plane (even allowing reflections).*

Proof. By Lemma 3.3, any tiling with staples and shurikens has a shuriken. Any shuriken has a reflex anticorner of defect $\pi(1-\frac{1}{2n})$, which is clean and less than π. This defect must be filled by some convex angles, of which we have three: $\alpha, \beta, \frac{\pi}{n}$. By Lemma 3.2, this defect can be filled by at most two angles $\in \{\alpha, \beta\}$. But by Property 1, summing one or two of these angles is not clean, while the remaining convex angle $\frac{\pi}{n}$ and the target sum $\pi(1-\frac{1}{2n})$ are. Thus we cannot use any angles $\in \{\alpha, \beta\}$ to fill the deficit, leaving only the convex angle $\frac{\pi}{n}$. But $\frac{\pi}{n}$ is an even multiple of $\frac{\pi}{2n}$, while the target sum is an odd multiple of $\frac{\pi}{2n}$. Thus it is impossible to exactly fill the deficit. ◀

▶ **Lemma 3.5.** *Any tiling of the plane with staples, shurikens, and wheels (even allowing reflections) must consist of an infinite square grid of wheels corresponding to a Wang tiling.*

Proof. By Lemma 3.4, any tiling with staples, shurikens, and wheels has a wheel. Any wheel has a convex corner of angle $\pi(1-\frac{1}{2n})$, which has a deficit of $\pi(1+\frac{1}{2n})$, which is clean. We claim that this deficit can be filled in exactly two ways: one reflex anticorner of a shuriken of deficit $\pi(1-\frac{1}{2n})$, or one convex tip vertex of a shuriken of angle $\frac{\pi}{n}$ and one convex corner of a wheel of angle $\pi(1-\frac{1}{2n})$.

Because the target deficit is $> \pi$, we need to consider both convex and reflex angles as well as flat edges (of angle π) for possible fillings. First consider the unclean angles starting with reflex angles of deficit $\alpha, \beta, 2\alpha, 2\beta$. But $\alpha < \beta < 2\alpha < 2\beta = \frac{7}{8}\pi = \pi(1-\frac{1}{8}) < \pi(1-\frac{1}{2n})$ for any $n \geq 5$. Thus none of the unclean reflex angles can be used to fill the deficit. The only remaining reflex angle that can fill the deficit is a shuriken anticorner of deficit $\pi(1-\frac{1}{2n})$, and if we use that angle, we are done.

Next consider the unclean convex angles α and β. Because $\pi(1+\frac{1}{2n}) < \frac{9}{8}\pi$ for any $n \geq 5$, by Lemma 3.2 this deficit can be filled by at most two angles $\in \{\alpha, \beta\}$. But by Lemma 1, summing one or two of these angles is not clean, while the remaining convex angles $\frac{\pi}{n}, \pi(1-\frac{1}{2n})$, flat edge of angle π, and the target sum $\pi(1+\frac{1}{2n})$ are all clean. Thus we cannot use any angles $\in \{\alpha, \beta\}$ to fill the deficit.

This leaves only the flat edge of angle π and two convex angles: the shuriken tip of angle $\frac{\pi}{n}$ and the wheel corner of angle $\pi(1-\frac{1}{2n})$. If we used only copies of the tip $\frac{\pi}{n}$, we would get an even multiple of $\frac{\pi}{2n}$, but the target sum $\pi(1+\frac{1}{2n})$ is an odd multiple of $\frac{\pi}{2n}$. Using a flat edge π would leave a gap of angle $\frac{\pi}{2n}$, which is too small to fill with any of the available angles. Finally, using the wheel corner $\pi(1-\frac{1}{2n})$ (gluing a second wheel to the first) will leave a gap of angle $\frac{\pi}{n}$, which can only be filled by the tip angle $\frac{\pi}{n}$.

Thus we have shown that, in all cases, the wheel's convex angle $\pi(1-\frac{1}{2n})$ has to be matched with an anticorner or a tip of the shuriken. Furthermore, an edge of the wheel adjacent to a corner must be glued to an edge of the concave chain adjacent to a tip or anticorner of the shuriken. We can follow the path of both the wheel and the concave chain of the shuriken and observe that the $n-2$ anticorners and the two tips of that concave chain will be glued to consecutive corners of the wheel.

At the end of the concave chain of the shuriken, we find a tip glued to the corner of a wheel, leaving a deficit of $\pi(1-\frac{1}{2n})$ to fill. As shown in Lemma 3.4, this can only be filled by another wheel corner. Therefore, the surround of a wheel must be filled by an alternating sequence of wheels and shurikens (omitting the small gaps left between the tweedles and the notches, which are filled by staples).

Pick one wheel T in the tiling, translate the tiling so that its center[3] is at the origin $(0,0)$, and rotate the plane so that edge i of its $4n$-gon is glued to another wheel at a horizontal edge of the $4n$-gon, with T below that edge. Also rescale so that the width of a wheel's $4n$-gon (the distance between parallel edges, without adornments) is 1. Then the wheel adjacent to edge i of T will have its center at coordinate $(0,1)$. Following the boundary of T clockwise, we find a shuriken glued to the edges $i+1, \ldots, i+n-1$ of T, and a wheel glued to the edge $i+n$ of T. The wheel glued to edge $i+n$ has its center at coordinates $(1,0)$. Continuing this reasoning, we find that the tiling is a grid of wheels with centers on all integer lattice points. The shurikens and staples ensure that all spaces are filled, and the tweedles ensure that the tiles are compatible as in a Wang tiling. Therefore, for any tiling with the three tiles, we can produce a tiling of the plane with the original Wang tiles. ◀

3.5 Undecidability

The angles of the polygons, as listed in Table 1, are all rational multiples of π. The edge lengths of the polygons, as listed in Section 3.3, can all be expressed as radical expressions. We call polygons with such angles and edge lengths ***nice***.

▶ **Theorem 3.6.** *Given n Wang tiles, we can construct three nice polygons that can tile the plane (allowing or forbidding reflections) if and only if the Wang tiles can tile the plane.*

Proof. Combine Lemma 3.1 (if) and Lemma 3.5 (only if). ◀

Combining this with membership of the tiling problem in co-RE (to be proved in the next section), we obtain:

[3] Define the ***center*** of a wheel to be the center of gravity of its $4n$-gon, without adornments.

▶ **Corollary 3.7** (Nice form of Corollary 1.6). *Given three nice polygons in the plane, deciding whether they tile the plane is co-RE-complete and thus undecidable.*

In a recent paper, Greenfeld and Tao [8] consider a generalized version of the tiling problem, where only a periodic subset of space needs to be covered by the tiles. In our reduction, the union of the shurikens form a periodic subset of $\mathbb{R}^2$, and so does its complement. Thus, tiling the complements of the shurikens with the two remaining tiles is undecidable:

▶ **Corollary 3.8** (Stronger form of Corollary 1.2). *Given two nice polygons, deciding whether they tile a periodic subset of the plane is co-RE-complete and thus undecidable.*

By plugging in Wang tiles that simulate a universal Turing machine, such as Robinson's 36 Wang tiles [13], we also obtain undecidability of tiling completion with three specific tiles:

▶ **Corollary 3.9** (Stronger form of Corollary 1.4). *There exist three fixed tiles for which completing a given finite partial tiling is co-RE-complete and thus undecidable.*

We implemented our construction in an open-source web application [4], where the user can input any set of Wang tiles and see the resulting polygons. Figure 6 shows the output for the 11 Wang tiles from Figure 1.

4 Membership in Co-RE

The previous sections show the co-RE-hardness of the tiling problem for three given tiles, and the tiling completion problem for three fixed tiles. We counterbalance these intractability results by showing that the tiling problem and tiling completion problem are in co-RE, for any finite set of prototiles. Refer to the full paper for omitted proofs in this section.

4.1 Model: Computable Polygons

To make these positive results as strong as possible, we use the weakest possible model of computation. We use a standard Turing machine, and represent polygons by their sequences of angles and edge lengths (equivalently, instructions in the Logo/Turtle graphics language), which need not be given explicitly but can be computed to any desired precision. More precisely, we assume the input polygons are "computable" in the following sense:

▶ **Definition 4.1.** *A real number a is **computable** [3] if there is a Turing machine T_a that, given a natural number n, outputs an integer $T_a(n)$ such that $\frac{T_a(n)-1}{n} \le a \le \frac{T_a(n)+1}{n}$. A polygon is **computable** if it is promised to be simple and closed, and its n angles and edge lengths are computable.*

Computability is likely the most general representation of real numbers that is still usable for our problem. Computable numbers include all rational numbers, algebraic numbers, and transcendental numbers that can be computed to any desired precision. In particular they are closed under addition, subtraction, multiplication, division, integer roots and even trigonometric functions:

▶ **Theorem 4.2** ([3, Theorem 4.14]). *If x, y, and z are computable real numbers with $z > 0$, then $x + y$, $x - y$, xy, x/z, $|x|$, $\min(x, y), \max(x, y)$, $\exp(x), \sin(x), \cos(x)$, $\log(z)$, and $\sqrt{z}$ are computable as well.*

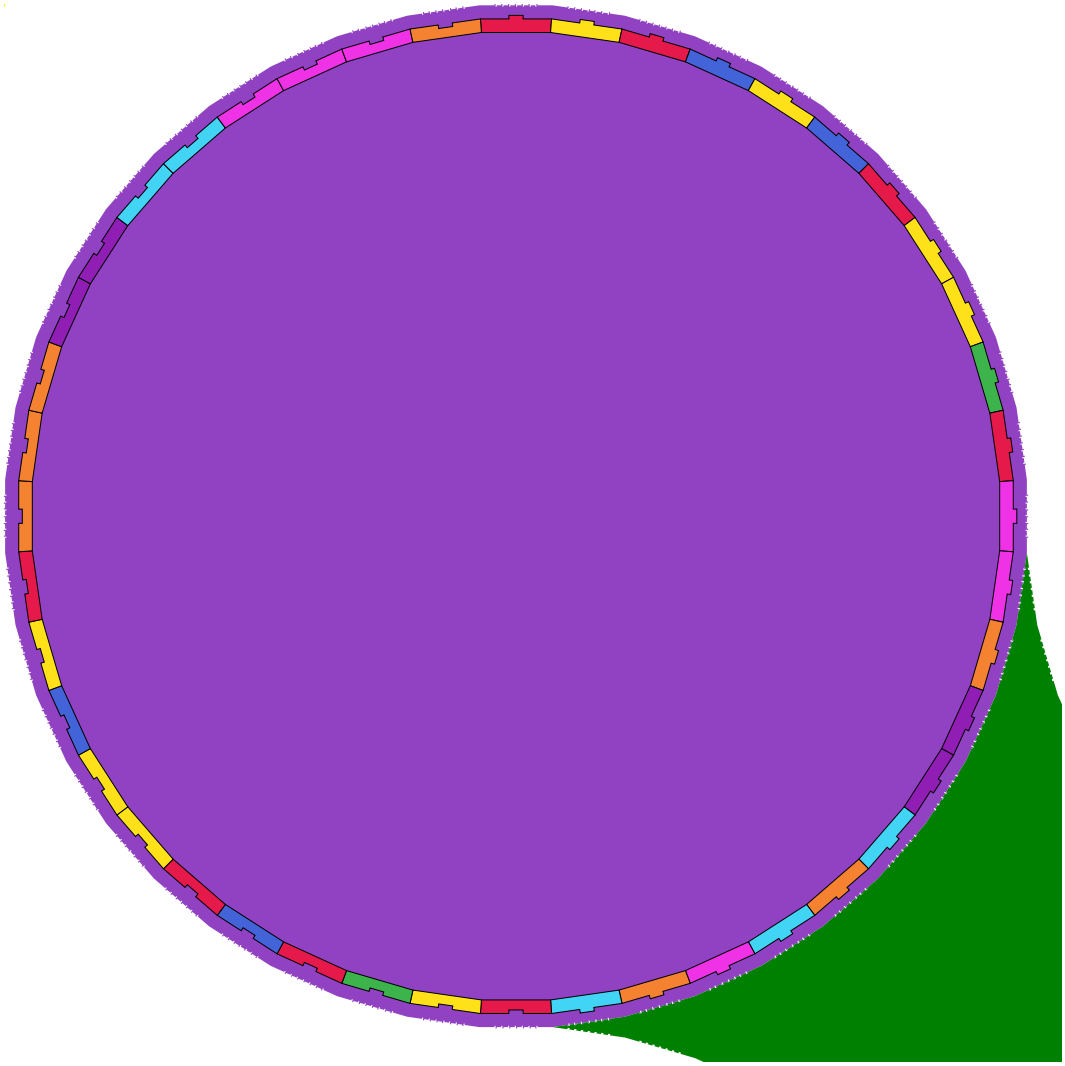

Figure 6 Output of our implemented reduction [4] for the 11 Wang tiles from Figure 1, focusing on the wheel and how the shuriken fits around the bottom-right corner. The wheel is annotated with edge colors from Figure 1b.

Note that some basic operations can be intractable for computable numbers. For instance, determining whether a computable number is zero, or the equality between two computable numbers, is undecidable (in fact, co-RE-complete). To see this, given a Turing machine T, define a number a_T to have its nth bit after the binary point be 1 if T halts after n steps, and 0 otherwise. The number a_T is computable, and is zero if and only if T does not halt. For our problem, we can show a similar undecidability:

▶ **Theorem 4.3.** *Given a single computable pentagon, determining whether it tiles the plane is co-RE-hard and thus undecidable.*

Proof. Pick a generic quadrilateral, and glue a very flat isosceles triangle to one of its edges, where the apex angle is $180° - r/100$ for a given constructible number $r \in [0, 1]$. The other angles and edge lengths of the triangle are constructible via trigonometric functions.

The resulting pentagon tiles the plane only in the degenerate case where the triangle is degenerate, i.e., a line segment, which happens exactly when the obtuse angle of the triangle is exactly 180°. Thus the tiling problem is equivalent to testing whether $r = 0$ for a given constructible number $r \in [0, 1]$, which is co-RE-hard as shown above. ◀

Of course, this result is quite unsatisfying, as the reason for undecidability stems from the extreme weakness of the model and generality of the representation of the polygons, and the inability to even check locally that a tiling is valid. Yet surprisingly, in this same model, we are able to show membership in co-RE.

4.2 Co-RE Algorithm

The high-level idea of our algorithm is to try to build partial tilings that cover a larger and larger disk. If we ever fail to cover a disk, then we know that the plane cannot be tiled; and if we never fail, the well-known Extension Theorem (Theorem 4.11 below) guarantees that the plane can be tiled. To determine whether we can tile enough to cover a disk, we bound the number of tiles that could possibly intersect the disk, then enumerate all possible combinatorial ways for these tiles to fit together, and for each, check whether the tiles fit together properly. Checking fit is limited to tiles that share vertices, however, so we need to take care to handle the case that there are seam lines in the tiling where no tiles on opposite sides of the line share a vertex (as in, e.g., the classic brick tiling). We also avoid checking for global intersection between tiles (because doing so is tricky in our model), opting instead to check just locally that angles add up correctly at vertices and that edge lengths add up correctly along edges. Our notion of "neat carpet" handles both of these issues by forbidding only local self-overlap, and guaranteeing that every boundary vertex is either outside the specified disk or has total angle 180° so potentially forms a seam boundary. We are then able to show that arbitrarily large neat carpets imply the existence of a plane tiling.

Our co-RE algorithm will in particular need to repeatedly test for equality among constructible numbers, a co-RE-complete problem. Thus we need a way to compose co-RE decisions. We use the following standard result (mentioned, e.g., in [12]):

▶ **Lemma 4.4.** *Finite disjunctions and recursively enumerable conjunctions of co-RE decision problems are in co-RE.*

Let $\mathcal{T}$ be a set of prototiles, where each tile is a (simple closed) computable polygon. Define a ***carpet*** to be a topological disk produced by gluing together a finite collection of tiles from $\mathcal{T}$, where every interior vertex has 360° total angle from incident tiles. We assume that the carpet is laid out in the Euclidean plane, that is, every point in a tile has real coordinates, but we allow the surface to be self-overlapping, that is, a point of the plane might be covered by more than one tile. A ***patch*** is a carpet whose embedding in the plane is not self-overlapping.

A carpet can be described by its ***combinatorial gluing***, which specifies (1) the set of tiles, each of which is an instance of a prototile; (2) a partition of the tile vertices into coincident (glued together) points; and (3) for each tile edge, the sequence of other tile edges and/or boundary that the edge has positive-length overlap with, in order along the edge. Call a carpet or a patch ***seamless*** if the position of all tiles in the carpet is fully determined by the combinatorial gluing and the position of its first tile. This notion forbids carpets whose tiles can be separated by a line along which the two sides could slide (causing an uncountable infinity of solutions). To verify seamlessness, build the ***incidence graph*** on the tiles of the carpet, where two tiles are connected by an edge if they share a vertex, and

check that the graph is connected. For the case of tiling completion, we can ensure that the given patch is seamless by adding a vertex along each seam, common to both adjacent tiles; as this modification to the preplaced tiles does not change their shape, it does not change the outcome of the decision.

First we show how to verify that a carpet is valid:

▶ **Lemma 4.5.** *Given a combinatorial gluing of a possible seamless carpet, deciding whether it corresponds to a seamless carpet is co-RE-complete.*

Define the ***distance*** between two points in a carpet to be the Euclidean distance between those two points when the carpet is laid out in the Euclidean plane (note that this embedding may be self-overlapping, and this distance is no larger than the intrinsic distance within the carpet). Call a vertex of a carpet ***neat*** if it is either interior to the carpet and surrounded by tiles summing up to an angle of 2π, or is on the boundary of the carpet and is surrounded by contiguous tiles summing up to an angle of π. A carpet is ***neat within radius $< r$*** if every vertex at distance $< r$ from the origin is neat. In an ***anchored*** carpet, we assume one ***anchored*** tile in the combinatorial gluing has been chosen to be placed with its center of gravity at the origin, and with a canonical rotation (say, matching its prototile).

▶ **Lemma 4.6.** *Given an anchored carpet and a computable positive number r, deciding whether it is neat within radius $< r$ is in co-RE.*

Let ρ be the maximum "radius" of tiles in $\mathcal{T}$, meaning that a disk of radius ρ centered at the center of gravity of each tile in $\mathcal{T}$ covers that tile. Let $A_{\min}$ be the minimum area of a tile in $\mathcal{T}$. Let D_r denote the disk of radius r centered at the origin.

▶ **Lemma 4.7.** *If $\mathcal{T}$ can tile the plane, then for any $r > 0$, (a) there is an anchored patch with a finite number $N(r)$ of tiles that covers the disk D_r, and (b) there is an anchored seamless patch with $\leq N(r)$ tiles that is neat within radius $< r$.*

If a seamless patch P can be extended to tile the plane, then for any $r > 0$, (a) there is an anchored patch containing P with a finite number $|P| + N(r)$ of tiles that covers the disk D_r, and (b) there is a seamless patch containing P with $\leq |P| + N(r)$ tiles that is neat within radius $< r$.

Proof. For the (a) statements, translate (and rotate) the tiling so that one of its tiles is anchored; and if we are given a seamless patch P, choose to anchor one of its tiles. Consider the disk $D_{r+2\rho}$ of radius $r + 2\rho$ centered at the origin (the anchored tile's center of gravity). Take all the tiles in the plane tiling that are fully inside $D_{r+2\rho}$, and take all the tiles of P (if given). Because the tiles do not overlap and are each of area $\geq A_{\min}$, there are at most $\pi(r + 2\rho)^2/A_{\min}$ tiles inside $D_{r+2\rho}$. Take the connected component that contains the origin (and thus the tiles of P, if given), which only decreases the number of tiles. This is an anchored patch that covers the smaller disk D_r.

For the (b) statements, build the incidence graph on the tiles of the carpet, where two tiles are connected by an edge if they share a vertex. If this graph is connected, then the patch is seamless. If this graph is disconnected, it is because of seams. Seam lines cannot intersect: otherwise, their intersection point is a vertex common to both sides of the seams. Thus, cutting the patch along all seams, or equivalently taking one connected component of the incidence graph, will create neat vertices on the new boundary, where the seams were. Take the component that contains a tile covering the origin. This is a seamless patch that is neat within radius $< r$. ◀

▶ **Lemma 4.8.** *Given prototiles $\mathcal{T}$ and a computable radius r, deciding whether there is an anchored carpet that is neat within radius $< r$ is in co-RE. If there is no such carpet, then $\mathcal{T}$ cannot tile the plane.*

Given prototiles $\mathcal{T}$, a seamless patch P, and a computable radius r, deciding whether P can be extended to a carpet that is neat within radius $< r$ is in co-RE. If there is no such carpet, then P cannot be extended to tile the plane.

▶ **Lemma 4.9.** *If an anchored carpet is neat within radius $< r + 2\rho$, then the carpet contains an anchored patch that is neat within radius $< r$.*

Proof. Consider the intersection between the carpet C and the disk $D_{r+2\rho}$, which might have multiple connected components and/or be self-overlapping. Pick the component S that contains the anchored tile. The boundary of S is composed of straight lines (the edges of the tiles connected by neat vertices) and circular arcs (portions of the boundary of $D_{r+2\rho}$), connected together at convex angles. Thus S is convex, so non-self-overlapping.

Back in the carpet, remove all tiles that are not entirely contained in $D_{r+2\rho}$. Again, this possibly results in several connected components. Retain the component C' that contains the anchored tile, where connectivity is defined by interior paths, so that C' does not have pinch points. By construction, this component is contained in S and thus is not self-overlapping. Also C' is a topological disk: a hole in C' could only come from a removed tile, which must touch the outside of $D_{r+2\rho}$, contradicting that it is surrounded by C' (by planarity). Therefore, C' is a patch.

Finally, because all tiles removed have diameter $\leq 2\rho$, none of the deleted tiles intersect the disk D_r, and therefore all vertices within radius $< r$ remain untouched. Therefore the patch C' is neat within radius $< r$. ◀

▶ **Lemma 4.10.** *If there exists an anchored carpet C that is neat within radius $< r + 2\rho$, then there exists a patch that covers the disk $D_{r/2}$. Furthermore, that patch contains all tiles of C that intersect $D_{r/2}$.*

Proof. Suppose we have a carpet that is neat within radius $< r + 2\rho$. By Lemma 4.9, we have a patch that is neat within radius $< r$. The intersection of the patch and the disk D_r is a disk cut by noncrossing chords; refer to Figure 7. Note that any chord of D_r that intersects $D_{r/2}$ cuts off an arc of angle $\frac{2}{3}\pi$ from D_r. Because the chords defined by the patch do not intersect in D_r, at most two of them intersect $D_{r/2}$.

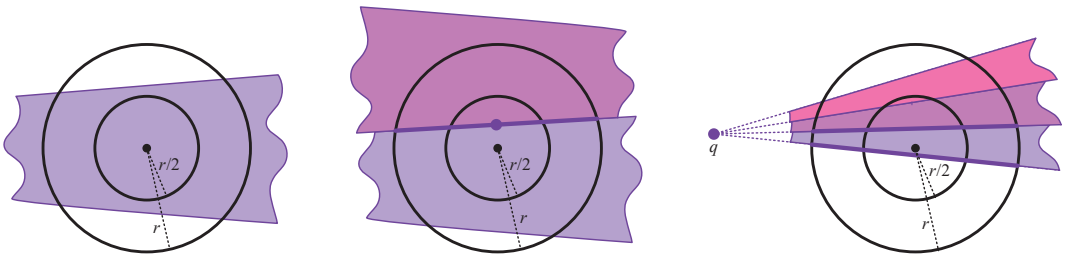

Figure 7 A neat patch within $< r$, and how it can interact with the smaller disk $D_{r/2}$. From left to right: no chords, one chord, and two chords.

If no chord intersects $D_{r/2}$, then the patch covers $D_{r/2}$, and we are done.

If exactly one chord intersects $D_{r/2}$, then the patch is contained in a half-plane that contains the origin and is bounded by the extension of the cord. Rotate a copy of the patch by 180° about the center of the cord, and glue the two pieces together. This produces a patch that covers $D_{r/2}$.

If two chords intersect $D_{r/2}$, then the patch is contained in a wedge defined by the extensions of the two chords. Let q be the apex of the wedge, and assume q is on the x axis, with one of the chords above the x axis and the other chord below. Assume without loss of generality that the chord below is the longest one. Repeatedly stitch copies of the patch by rotating it about q, upward, gluing the longer chord of the previous copy to the shorter chord of the next copy, until the upper half of $D_{r/2}$ is covered. Now repeat the procedure for a single chord. The resulting patch covers the disk of radius $r/2$. ◀

▶ **Theorem 4.11** (Extension Theorem [9, p. 151])**.** *Given a finite collection $\mathcal{T}$ of prototiles, if they tile arbitrarily large disks, then they admit a tiling of the plane.*

Given a finite collection $\mathcal{T}$ of prototiles and patch P using tiles of $\mathcal{T}$, if P can be extended to cover arbitrarily large disks centered in P, then P can be completed to tile the plane.[4]

We translate the above theorem to seamless anchored patches.

▶ **Lemma 4.12.** *Given a collection $\mathcal{T}$ of prototiles, if there exist anchored carpets that are neat within radius $< r$ for arbitrarily large r, then $\mathcal{T}$ admits a tiling of the plane.*

Given a collection $\mathcal{T}$ of prototiles, and given an anchored patch P using tiles of $\mathcal{T}$, if P can be extended to a carpet that is neat within radius $< r$ for arbitrarily large r, then P can be completed to tile the plane.

▶ **Theorem 4.13** (Precise form of Theorem 1.5)**.** *Given a set $\mathcal{T}$ of k polygons in our model, deciding whether they tile the plane is in co-RE. Also given a patch P of tiles from $\mathcal{T}$, deciding whether P can be completed to tile the plane is in co-RE.*

Proof. For every positive integer k, set $r = k\rho$ and use Lemma 4.8 to determine whether there exists an anchored carpet that is neat within radius $< r$, or whether P can be completed to produce such a carpet. This is a recursively enumerable disjunction of co-RE problems, so by Lemma 4.4 is in co-RE. By Lemma 4.12, if all of these problems output true, then the polygons tile the plane or complete P to tile the plane. By Lemma 4.8, if any of these problems outputs false, then the polygons do not tile or complete P to tile the plane. ◀

Abstract

Given a zigzag filtration, we want to find its barcode representatives, i.e., a compatible choice of bases for the homology groups that diagonalize the linear maps in the zigzag. To achieve this, we convert the input zigzag to a levelset zigzag of a real-valued function. This function generates a Mayer–Vietoris pyramid of spaces, which generates an infinite strip of homology groups. We call the origins of indecomposable (diamond) summands of this strip their apexes and give an algorithm to find representative cycles in these apexes from ordinary persistence computation. The resulting representatives map back to the levelset zigzag and thus yield barcode representatives for the input zigzag. Our algorithm for lifting a p-dimensional cycle from ordinary persistence to an apex representative takes $O(p \cdot m \log m)$ time. From this we can recover zigzag representatives in time $O(\log m + C)$, where C is the size of the output.

1 Introduction

In topological data analysis, one often wants to not only describe the distribution of topological features in data, but also to identify individual features directly in the input. For persistent homology, a natural starting point are the cycle representatives of homology classes. Specifically, one wants to find *barcode representatives*, a consistent choice of bases for the input sequence of homology groups. For ordinary persistence, this comes directly from the computation: a representative at the start of the bar includes into every consecutive space and therefore remains a valid choice of the basis element.

For zigzag persistence, the situation is more complicated. Because simplices can enter and leave the complex, a representative cycle at one step in the zigzag filtration may not exist at a later step. So even though zigzag persistence algorithms keep track of representative cycles, the specific choices that they make do not always produce compatible barcode representatives. To cope with this problem, Dey et al. [9] introduced an algorithm that keeps track of additional information that allows it to report consistent barcode representatives. For a zigzag filtration with m insertions and deletions, the algorithm requires $O(m^3)$ preprocessing and $O(m^2)$ time to report one or all representatives for any single bar, and $O(m^3)$ time to report all representatives.

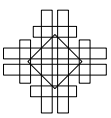

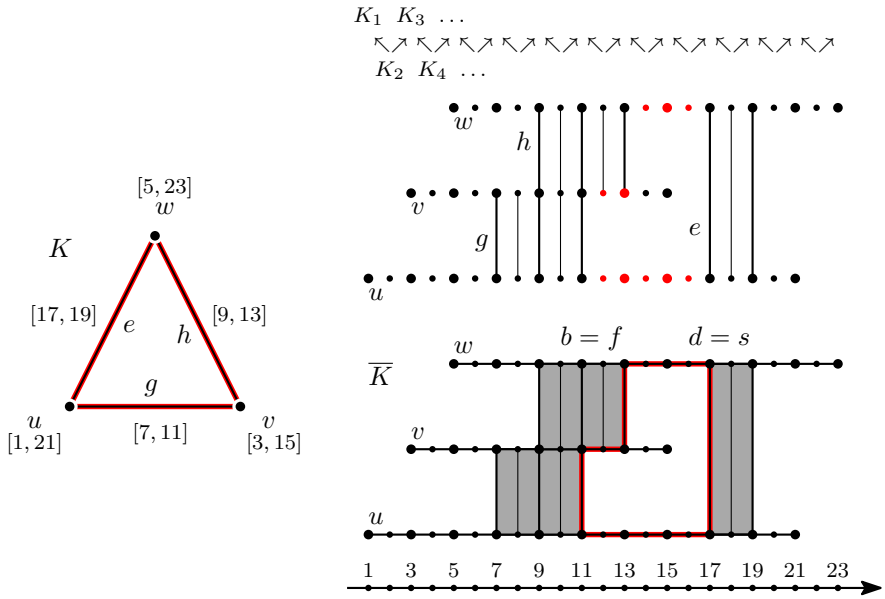

Figure 1 A zigzag on the top. A total complex K on the left. The support of each simplex in a zigzag, $T(\sigma)$, shown as an interval. The corresponding prism $\overline{K}$ on the bottom. A 1-cycle in $K[11, 17]$ and its lift in $\overline{K}[11, 17]$ are highlighted in red. The lifted cycle is an apex representative; its slices (pairs of vertices in red) are representatives of a bar in the original zigzag.

On the surface, this is as well as one can hope to do: there are $O(m)$ bars, over $O(m)$ spaces, with each representative consisting of $O(m)$ simplices. But we can do better. Every zigzag filtration is isomorphic to a levelset zigzag filtration of some function. The function generates the Mayer–Vietoris pyramid [5], which decomposes into diamond summands [2]. Each diamond has a single space as its origin, its apex: this space maps into every other space in the diamond. By finding the diamond's representative in the apex – an apex representative – we can quickly recover its representative in every other space, including those that fall in the levelset zigzag, and therefore in the original zigzag; see Figure 1. All the information can be recovered from an ordinary persistence computation. It takes matrix multiplication time, $O(m^\omega)$, to compute persistence [16], and an extra $O(p \cdot m \log m)$ time to recover a p-dimensional apex representative of size $O(p \cdot m)$. After the preprocessing, zigzag representatives can be recovered in $O(\log m + C)$ time, where C is the size of the output.

2 Background

We assume familiarity with simplicial and cell complexes, homology, persistent homology, including zigzag persistence. We only recap select topics to establish notation. Any gaps can be filled with the standard literature [14, 12, 13].

Throughout the paper, we take care to work with arbitrary field coefficients, but abuse notation as follows. Cell $\sigma \in z$ means the coefficient of σ in z is non-zero, $\langle \sigma, z \rangle \neq 0$. If α is a chain in some cell complex K, then $\alpha \subseteq L$ means that α is supported on the subcomplex $L \subseteq K$, i.e., $\forall \sigma \in (K - L), \langle \sigma, \alpha \rangle = 0$. Similarly, $z \cap L$ refers to the restriction of chain z to L, i.e., $z \cap L = \sum_{\sigma \in L} \langle \sigma, z \rangle \cdot \sigma$.

Persistence. Given a filtered cell complex K, let D be a matrix that represents its boundary operator, with rows and columns ordered according to the filtration. To find ordinary persistence pairing, one can compute a decomposition, $R = DV$, where matrix R is reduced, meaning its pivots – lowest non-zero elements in its columns – appear in unique rows, and matrix V is full-rank upper-triangular. We index the columns and rows of the matrices by the (totally ordered) cells of the input complex. The persistence pairing is given by the pivots of matrix R: a p-dimensional homology class created by the addition of simplex σ is destroyed by the addition of simplex τ iff $\operatorname{low} R[\tau] = \sigma$, where $\operatorname{low} R[\tau]$ returns the pivot in the column $R[\tau]$. By definition, the corresponding column $V[\tau]$ stores a $(p+1)$-dimensional chain whose boundary is the cycle $R[\tau]$.

The decomposition $R = DV$ is not unique: multiple matrices R and V satisfy it. However, the original persistence algorithm [10] performs operations in a lazy fashion, subtracting columns from left to right only if their pivots collide. We call this a *lazy reduction*. It has the following special properties that simplify our algorithms.

▶ **Lemma 1** (Lemma 1 in [17]). *Assume decomposition $R = DV$ is obtained via the lazy reduction, and $\sigma_i = \operatorname{low} R[\tau_i]$ and $\sigma_j = \operatorname{low} R[\tau_j]$ are such that $\tau_i < \tau_j$. If $\sigma_i < \sigma_j$, then entry $V[\tau_i, \tau_j] = 0$.*

Proof. Induction on V; see [17]. ◀

▶ Remark 2. The authors of [17] simplify the statement of the preceding lemma by abusing the notation. They assume that if $R[\tau] = 0$, then $\operatorname{low} R[\tau] = \bar{\sigma}$, a special imaginary cell that precedes every cell in the complex. In particular, it follows that in a lazy reduction, entry $V[\tau_i, \tau_j] = 0$ if $R[\tau_i] = 0$.

The contrapositive of the lemma is the following corollary.

▶ **Corollary 3.** *Assume decomposition $R = DV$ is obtained via the lazy reduction, and $\sigma_i = \operatorname{low} R[\tau_i]$ and $\sigma_j = \operatorname{low} R[\tau_j]$ are such that $\tau_i < \tau_j$. If $V[\tau_i, \tau_j] \neq 0$, then $\sigma_j < \sigma_i < \tau_i < \tau_j$.*

Zigzag persistence. We start with a zigzag of simplicial complexes,

$$K_0 \to K_1 \leftarrow K_2 \to K_3 \leftarrow K_4 \to \ldots \leftarrow K_n, \tag{1}$$

where every consecutive pair of complexes vary by at most one simplex, i.e., K_i can be equal to K_{i+1} in the sequence. It is convenient to assume that every simplex σ appears and disappears exactly once in this sequence, and therefore is present during some interval $T(\sigma) = [i, j]$, i.e., $\sigma \in K_k$ iff $k \in T(\sigma)$. This assumption can be made without loss of generality by assuming that the union K of all simplices across all times, $K = \bigcup_i K_i$ forms a Δ-complex. The full definition of this object is too verbose – we refer the reader to [7], which adapts the classical concept of Δ-complexes in [14, p. 103] to our case of zigzag filtration – but informally it relaxes the requirement that in a simplicial complex two simplices intersect in a common face. All the familiar notions of simplicial homology work the same, but now instead of having a simplex supported over multiple intervals in the zigzag, we can have multiple simplices, with the same boundary, each supported on a single interval. We use $m = |K|$ to denote the size of the input complex.

▶ Remark. To simplify the notation we let $\min(\sigma) = \min T(\sigma)$ and $\max(\sigma) = \max T(\sigma)$.

▶ Remark 4. We assume that $\max(\sigma) > \min(\sigma)$, i.e., $T(\sigma)$ is not a single point. We can assume this without loss of generality because we can always pad the zigzag with extra copies of a space.

Applying homology, we get a zigzag of homology groups, where we suppress dimension for simplicity,

$$\mathsf{H}(K_0) \to \mathsf{H}(K_1) \leftarrow \mathsf{H}(K_2) \to \mathsf{H}(K_3) \leftarrow \mathsf{H}(K_4) \to \ldots \leftarrow \mathsf{H}(K_n). \tag{2}$$

Just like with ordinary persistence, this zigzag decomposes into k bars or persistence intervals [3]. Let $\{\alpha_i^1, \ldots, \alpha_i^k\}$ be a choice of elements in $\mathsf{H}(K_i)$ such that the non-zero elements form a basis for $\mathsf{H}(K_i)$. We say that such bases are *compatible* across the zigzag if the maps in Equation (2) diagonalize, i.e., $\alpha_{2i-1}^j \leftarrow\!\shortmid\, \alpha_{2i}^j \mapsto \alpha_{2i+1}^j$. For every j, α_*^j are non-zero over a single persistence interval $[b^j, d^j]$. Cycles z_i^j that give a set of compatible bases $\alpha_i^j = [z_i^j]$ are called *zigzag representatives*, with z_*^j being the representatives of the j-th bar in the zigzag barcode.

Real-valued function. A convenient setting for persistence is that of a Morse-like [4] real-valued function $f : \mathbb{X} \to \mathbb{R}$. We denote with $\mathbb{X}_a^b = f^{-1}[a, b]$ the preimage of an interval and allow the endpoints to be infinite, $a, b = \pm\infty$, in which case the interval is understood to be open at the infinite ends. We denote the following pairs of spaces:

$$\mathbb{X}[b, d] = (\mathbb{X}_b^d, \emptyset), \qquad \mathbb{X}(b, d] = (\mathbb{X}_{-\infty}^d, \mathbb{X}_{-\infty}^b),$$
$$\mathbb{X}[b, d) = (\mathbb{X}_b^\infty, \mathbb{X}_d^\infty), \qquad \mathbb{X}(b, d) = (\mathbb{X}, \mathbb{X}_{-\infty}^b \cup \mathbb{X}_d^\infty).$$

Let $a_1 < \ldots < a_n$ be the critical values of the function f. Let s_i be regular values interleaved with the critical values: $s_0 < a_1 < s_1 < a_2 < \ldots < s_{n-1} < a_n < s_n$. The following constructions play an important role in the theory of persistent homology:

- Extended persistence (EP):

$$\begin{aligned} 0 \to \mathsf{H}(\mathbb{X}[-\infty, s_0]) \to \ldots \to \mathsf{H}(\mathbb{X}[-\infty, s_n]) = \mathsf{H}(\mathbb{X}) \\ \to \mathsf{H}(\mathbb{X}[-\infty, s_n)) \to \ldots \to \mathsf{H}(\mathbb{X}[-\infty, s_1)) \to \mathsf{H}(\mathbb{X}[-\infty, s_0)) = 0. \end{aligned}$$

- Levelset zigzag (LZZ):

$$0 \leftarrow \mathsf{H}(\mathbb{X}[s_0, s_0]) \to \mathsf{H}(\mathbb{X}[s_0, s_1]) \leftarrow \mathsf{H}(\mathbb{X}[s_1, s_1]) \to \ldots \to \mathsf{H}(\mathbb{X}[s_{n-1}, s_n]) \leftarrow \mathsf{H}(\mathbb{X}[s_n, s_n]) \to 0.$$

Carlsson et al. [5] showed that these two sequences contain the same information by arranging the four types of spaces into a *Mayer–Vietoris Pyramid*, see Figure 2(left). Once homology is applied, the pyramid unrolls into an infinite Mayer–Vietoris strip of homology groups, where every diamond belongs to the Mayer–Vietoris long exact sequence, making it *exact* in the terminology of [3], see Figure 2(right). This allows one to translate the decomposition between any two paths that differ by a single diamond (and therefore between any pair of paths via composition).

Bendich et al. [2] further showed that the translation rules in [5] hold at the level of the basis elements of the individual paths, which means the entire pyramid decomposes as a direct sum of (indecomposable) pointwise 1-dimensional diamond summands, flush with its boundaries, shown in blue in Figure 2(right). The decomposition of the levelset zigzag and extended persistence are simply slices through these flush diamond summands. Bauer et al. [1] study the Mayer–Vietoris Pyramid in the cohomological setting.

We call the bottom-most space in the support of a diamond its *apex*. The homology class assigned to the diamond in that space, an *apex class*, and any cycle that belongs to such a class, an *apex representative*. We note that just like the choice of the basis for

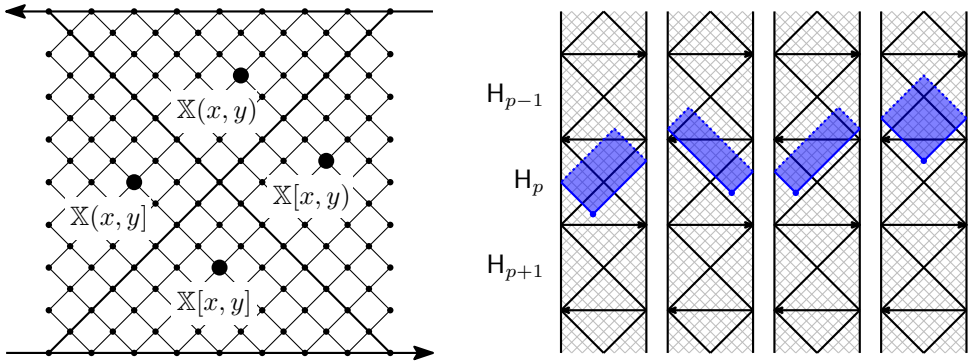

Figure 2 Left: Mayer–Vietoris Pyramid arranges spaces $\mathbb{X}[b,d], \mathbb{X}(b,d], \mathbb{X}[b,d), \mathbb{X}(b,d)$ in a way where every diamond in the pyramid belongs to the Mayer–Vietoris long exact sequence. Right: Four types of flush diamond indecomposables in the infinite strip of homology groups; the apex of each diamond is marked.

ordinary persistence is not unique, neither is the choice of the apex classes. An apex class is characterized by lying outside the image of the maps into the apex; specifically, for the four types of apexes their classes satisfy:

$$
\begin{aligned}
&[z] \in \mathsf{H}(\mathbb{X}[b,d]) \text{ s.t. } [z] \notin \operatorname{im}(\mathsf{H}(\mathbb{X}[b+\varepsilon,d]) \to \mathsf{H}(\mathbb{X}[b,d])) \text{ and } [z] \notin \operatorname{im}(\mathsf{H}(\mathbb{X}[b,d-\varepsilon]) \to \mathsf{H}(\mathbb{X}[b,d]))\\
&[z] \in \mathsf{H}(\mathbb{X}(b,d]) \text{ s.t. } [z] \notin \operatorname{im}(\mathsf{H}(\mathbb{X}(b-\varepsilon,d]) \to \mathsf{H}(\mathbb{X}(b,d])) \text{ and } [z] \notin \operatorname{im}(\mathsf{H}(\mathbb{X}(b,d-\varepsilon]) \to \mathsf{H}(\mathbb{X}(b,d]))\\
&[z] \in \mathsf{H}(\mathbb{X}[b,d)) \text{ s.t. } [z] \notin \operatorname{im}(\mathsf{H}(\mathbb{X}[b+\varepsilon,d)) \to \mathsf{H}(\mathbb{X}[b,d))) \text{ and } [z] \notin \operatorname{im}(\mathsf{H}(\mathbb{X}[b,d+\varepsilon)) \to \mathsf{H}(\mathbb{X}[b,d)))\\
&[z] \in \mathsf{H}(\mathbb{X}(b,d)) \text{ s.t. } [z] \notin \operatorname{im}(\mathsf{H}(\mathbb{X}(b+\varepsilon,d)) \to \mathsf{H}(\mathbb{X}(b,d))) \text{ and } [z] \notin \operatorname{im}(\mathsf{H}(\mathbb{X}(b,d-\varepsilon)) \to \mathsf{H}(\mathbb{X}(b,d)))
\end{aligned}
$$

Because there is a map from the apex to every space in the diamond, we can recover a representative in any space by simply mapping an apex representative forward. All the maps in the pyramid are inclusions, except for the boundary homomorphism connecting two consecutive dimensions of homology in the strip. We say more about this translation in Section 7, but the overarching point is that given an apex representative, it is straightforward to recover every other representative, and levelset zigzag representatives in particular.

3 Setup

Prism. Given a zigzag in Equation (1), we define a larger cell complex $\overline{K}$, called a *prism*:

$$\overline{K} = \{\sigma \times [i,i+1] \mid [i,i+1] \subseteq T(\sigma), i \in \mathbb{Z}\} \cup \{\sigma \times i \mid i \in T(\sigma), i \in \mathbb{Z}\}, \tag{3}$$

together with a function $\overline{f} : |\overline{K}| \to \mathbb{R}$ on its underlying space, defined by the projection onto the second component, $\overline{f}(x \times t) = t$. See Figure 3. We observe that the prism consists of two types of cells: *horizontal cells* $\sigma \times [i,i+1]$ and *vertical cells* $\sigma \times i$.

We define an integer interlevel set, for $i,j \in \mathbb{Z}$, $\overline{K}_i^j = \{\sigma \times T \in \overline{K} \mid T \subseteq [i,j]\}$. We note that its underlying space $|\overline{K}_i^j| = \overline{f}^{-1}[i,j]$. Then for any pair of integers b,d, we get four types of pairs of subspaces,

$$\overline{K}[b,d] = \overline{K}_b^d, \quad \overline{K}(b,d] = (\overline{K}_{-1}^d, \overline{K}_{-1}^b), \quad \overline{K}[b,d) = (\overline{K}_b^{n+1}, \overline{K}_d^{n+1}), \quad \overline{K}(b,d) = (\overline{K}, \overline{K}_{-1}^b \cup \overline{K}_d^{n+1}).$$

Applying homology to each pair, we get relative homology groups that appear in the four quadrants of the Mayer–Vietoris pyramid: $\mathsf{H}(\overline{K}[b,d]), \mathsf{H}(\overline{K}(b,d])), \mathsf{H}(\overline{K}[b,d)), \mathsf{H}(\overline{K}(b,d))$.

Because even-indexed spaces in Equation (1) include into odd-indexed spaces, $K_{2i-1} \leftarrow K_{2i} \to K_{2i+1}$, we have an isomorophism of homology groups $\mathsf{H}(\overline{K}[2i,2i+1]) \simeq \mathsf{H}(\overline{K}[2i+1,2i+1]) \simeq \mathsf{H}(\overline{K}[2i+1,2i+2])$, induced by deformation retractions. It follows that the

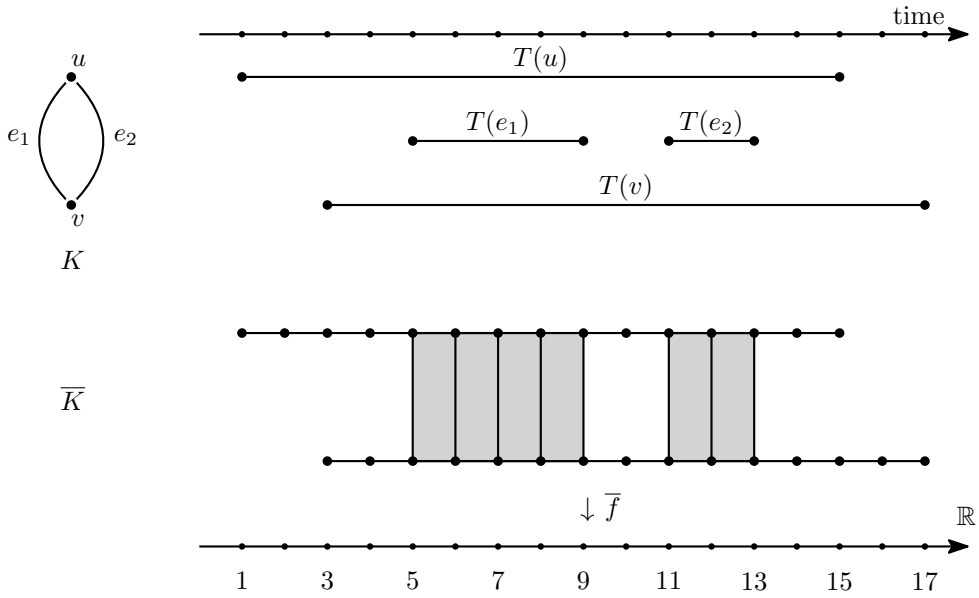

Figure 3 A Δ-complex K, with the times $T(\sigma)$ of its simplices illustrated, together with the corresponding prism $\overline{K}$ and its projection $\overline{f}$ onto the second coordinate.

levelset zigzag [5] of function $\overline{f}$,

$$\underbrace{\mathsf{H}(\overline{K}[0,0])}_{\mathsf{H}(K_0)} \to \underbrace{\mathsf{H}(\overline{K}[0,1]) \xleftarrow{\simeq} \mathsf{H}(\overline{K}[1,1]) \xrightarrow{\simeq} \mathsf{H}(\overline{K}[1,2])}_{\mathsf{H}(K_1)} \leftarrow \underbrace{\mathsf{H}(\overline{K}[2,2])}_{\mathsf{H}(K_2)} \to \ldots \leftarrow \underbrace{\mathsf{H}(\overline{K}[n,n])}_{\mathsf{H}(K_n)}$$

is isomorphic to our starting zigzag in Equation (2). Explicitly, the isomorphism is given by the following bijection between the four types of intervals:

$$\begin{array}{lcll}
(\mathsf{H}(K_{2i}), \mathsf{H}(K_{2j})) & \leftrightarrow & (\mathsf{H}(\overline{K}[2i,2i]), \mathsf{H}(\overline{K}[2j,2j])) & \text{(open-open)} \\
(\mathsf{H}(K_{2i}), \mathsf{H}(K_{2j+1})) & \leftrightarrow & (\mathsf{H}(\overline{K}[2i,2i]), \mathsf{H}(\overline{K}[2j+1,2j+2])) & \text{(open-closed)} \\
(\mathsf{H}(K_{2i+1}), \mathsf{H}(K_{2j})) & \leftrightarrow & (\mathsf{H}(\overline{K}[2i,2i+1]), \mathsf{H}(\overline{K}[2j,2j])) & \text{(closed-open)} \\
(\mathsf{H}(K_{2i+1}), \mathsf{H}(K_{2j+1})) & \leftrightarrow & (\mathsf{H}(\overline{K}[2i,2i+1]), \mathsf{H}(\overline{K}[2j+1,2j+2])) & \text{(closed-closed)}
\end{array}$$

Intervals. Because we perform computation on the input complex K, rather than the prism, we need a notation for different intervals and pairs of intervals. The connection between these and the corresponding intervals in $\overline{K}$ will be made clear in Section 6. We denote the sub- and super-level sets:

$$K^i_{-1} = \{\sigma \in K \mid \min(\sigma) \le i\}, \qquad K^{n+1}_j = \{\sigma \in K \mid \max(\sigma) \ge j\},$$

and define four pairs of spaces:

$$\begin{array}{ll}
K[b,d] = K^{n+1}_b \cap K^d_{-1}, & K(b,d] = (K^d_{-1}, K^b_{-1}), \\
K[b,d) = (K^{n+1}_b, K^{n+1}_d), & K(b,d) = (K, K^b_{-1} \cup K^{n+1}_d).
\end{array}$$

Because every step of the input zigzag is a simplicial complex, it follows that for any $\sigma, \tau \in K$,

$$\sigma \in \partial\tau \Rightarrow \min(\sigma) < \min(\tau) < \max(\tau) < \max(\sigma). \tag{4}$$

The following relationships between sub- and super-levelsets follow immediately:

$$\alpha \subseteq K^x_{-1} \Rightarrow \partial\alpha \subseteq K^x_{-1} \tag{5}$$

$$\alpha \subseteq K - K^{n+1}_x \Rightarrow \alpha \subseteq K^x_{-1} \tag{6}$$

Cone. To compute the persistence decomposition of the zigzag, we follow the algorithm of Dey and Hou [7], who use a construction similar to extended persistence [6] on the cone $\hat{K} = \omega * K$ over the input complex K, where $*$ indicates a join with the cone vertex ω. Every simplex σ in the base space K gets value $\min(\sigma)$ from the input zigzag. Every simplex $\hat{\sigma}$ in the cone $\hat{K} - K$ gets value $\max(\sigma)$ from the input zigzag. We then define a filtration, where the base space simplices come first, ordered by increasing value, and the cone simplices come second, ordered by decreasing value. Specifically,

$$0 \to \mathsf{H}(K^1_{-1}) \to \ldots \to \mathsf{H}(K^n_{-1}) = \mathsf{H}(K) \to \mathsf{H}(K, K^{n+1}_n) \to \ldots \to \mathsf{H}(K, K^{n+1}_1) \to \mathsf{H}(K, K) = 0,$$

which in reduced homology is isomorphic to

$$0 \to \mathsf{H}(K^1_{-1}) \to \ldots \to \mathsf{H}(K) \to \mathsf{H}(K \cup \omega * K^{n+1}_n) \to \ldots \to \mathsf{H}(K \cup \omega * K^{n+1}_1) \to \mathsf{H}(\hat{K}) = 0. \tag{7}$$

The latter is an ordinary filtration and we compute its persistence via the $R = DV$ decomposition of the boundary map of the cone $\hat{K}$. Crucially, the resulting bars are in one-to-one correspondence with the bars in the decomposition of the input zigzag in Equation (2).

4 Lifting

Because prism $\overline{K}$ has so many cells, it is expensive to process directly. We want to perform computation on the cone $\hat{K}$ instead. To recover the apex representatives for the prism, we need to lift cone cycles in $\hat{K}$ to prism cycles in $\overline{K}$. In Section 6, we explain what exact cycles to lift to get different apex representatives. Meanwhile, we first describe an algorithm that given a (relative) cycle z in KI produces a cycle $\overline{z}$ in $\overline{K}I$, where I is one of the four types of intervals, $(b, d]$, $[b, d)$, (b, d), $[b, d]$. Algorithm 1 in this section is a reinterpretation of an inefficient, but easier-to-understand Lift-Cycle-easy algorithm in the full version of this paper [8]. We encourage the reader to go through through that algorithm first.

▶ Remark. A p-chain $\overline{z}$ in $\overline{K}$ consists of two types of p-cells: $\tau \times t$, where τ is a p-simplex, and $\sigma \times [t_1, t_2]$, where σ is a $(p-1)$-simplex.

▶ Remark. We use an abridged notation, $c \cdot \sigma \times [i, j]$, to represent the chain $\sum_{k \in [i, j-1]} c \cdot \sigma \times [k, k+1]$. This choice is guided by computational efficiency: the former requires constant space vs. the $O(j - i)$ space required for the latter.

Algorithm 1 takes a p-cycle z, a direction expressed as a pair of values (s, f), and an initial $(p-1)$-cycle w_{init}. We call the pair (s, f) a direction because the order of the values specifies whether we process the cycle in increasing ($s < f$) or decreasing ($f < s$) order. The algorithm stretches the cycle from $\overline{K}[s, s]$ to $\overline{K}[f, f]$, covering $\overline{K}I$; see Figure 1.

Correctness. The correctness of Algorithm 1 follows from the following claim about the boundary structure, which will be important in Section 6. We let z^y_x be the restriction of cycle z to the simplices τ whose times t_τ lie in the interval $[x, y]$, i.e., $z^y_x = \sum_{\tau \in z, t_\tau \in [x,y]} \langle \tau, z \rangle \cdot \tau$.

▷ Claim 5. Given input cycle $z \in K$, the boundary of the lifted cycle $\overline{z}$ satisfies $\partial\overline{z} = w_{\text{init}} \times s + w_{\text{final}} \times f$, where $w_{\text{final}} = w_{\text{init}} + \partial z^d_b$.

Algorithm 1 LIFT-CYCLE(z, (s, f), w_{init}.)

Input:
- relative p-cycle z in $H(KI)$, where I is one of $(b, d]$, $[b, d)$, (b, d), $[b, d]$;
- direction from start to finish, s, f $(= b, d$ or $d, b)$;
- initial boundary $w_{\text{init}} = -\partial z \cap K[s, s] \subseteq K[s, s]$

Output:
- relative p-cycle $\overline{z}$ in $H(\overline{K}I)$

1: **for** *each* $\tau \in z$ **do**
2: $\quad t_\tau \leftarrow$ a value in $T(\tau) \cap [b, d]$ ▷ if $T(\tau) \cap [b, d] = \emptyset$, ignore τ
3: $\quad \overline{z} \leftarrow \overline{z} + \langle \tau, z \rangle \cdot (\tau \times t_\tau)$
4: **for** *each* σ s.t. $\exists \tau \in z, \sigma \in \partial\tau$ **do** ▷ each face of some simplex in z
5: $\quad c \leftarrow \langle \sigma, w_{\text{init}} \rangle$
6: $\quad l \leftarrow s$
7: $\quad$ **for** $(t_\tau, \tau) \in \{(t_\tau, \tau) \mid \tau \in \delta\sigma\}$ in order of t_τ from s to f **do**
8: $\quad\quad$ **if** $l \neq t_\tau$ **then**
9: $\quad\quad\quad \overline{z} \leftarrow \overline{z} + c \cdot (\sigma \times [l, t_\tau])$
10: $\quad\quad c \leftarrow c + \langle \tau, z \rangle \cdot \langle \sigma, \partial\tau \rangle$
11: $\quad\quad l \leftarrow t_\tau$
12: $\quad$ **if** $l \neq f$ **then**
13: $\quad\quad \overline{z} \leftarrow \overline{z} + c \cdot (\sigma \times [l, f])$

Proof. Simplex σ generates a cell $\sigma \times [s, l] \in \overline{z}$ iff $\langle \sigma, w_{\text{init}} \rangle \neq 0$ (Line 5). This cell contributes $\sigma \times s$ to the boundary of $\overline{z}$. Simplex σ generates a cell $\sigma \times [l', f] \in \overline{z}$ iff $\langle \sigma, w_{\text{init}} \rangle + \sum_{\tau \in \delta\sigma \cap z_b^d} \langle \sigma, \tau \rangle \neq 0$. By definition this is the case only for simplices in $w_{\text{final}} = w_{\text{init}} + \partial z_b^d$. ◁

It follows that if $w_{\text{init}} \subseteq K[s, s]$, then $\overline{z}$ is a cycle in $\overline{K}I$. What is not immediate is why the chains $\sigma \times [l, t_\tau]$ and $\sigma \times [l, f]$ in Lines 9 and 13 are in the prism $\overline{K}$.

▷ Claim 6. Chains $\sigma \times [l, t_\tau]$ and $\sigma \times [l, f]$ added in Lines 9 and 13 of Algorithm 1 are present in $\overline{K}$.

Proof. Without loss of generality, assume $s < f$. There are three types of chains:

1. $\sigma \times [s, t_{\tau_1}]$. σ has a non-zero coefficient on this interval iff $\langle \sigma, w_{\text{init}} \rangle \neq 0$ (Line 5), in which case $\sigma \in K[s, s]$. Existence of coface τ_1 implies $\min(\sigma) \leq s \leq t_{\tau_1} < \max(\sigma)$.
2. $\sigma \times [t_{\tau_i}, t_{\tau_{i+1}}]$. From Equation (4), $\min(\sigma) < t_{\tau_i} \leq t_{\tau_{i+1}} < \max(\sigma)$.
3. $\sigma \times [t_{\tau_i}, f]$. Suppose that this chain is not in $\overline{K}$. This means $x = \max(\sigma) \in [t_{\tau_i}, f)$. Equation (4) implies that σ has no cofaces in $[x, f]$. Therefore, $\sigma \in w_{\text{init}} + \partial z_s^x$ and $\sigma \notin \partial z_x^f$. Therefore, $\sigma \in \partial z$. Since we assumed z is a relative cycle in KI, it cannot have any boundary inside the interval itself – a contradiction. ◁

▶ Remark. It may seem strange that we state nothing about the relationship between z and $\overline{z}$. This is because we exploit additional properties of the algorithm in Section 6.

Running time. Let m be the size of the input p-cycle z. Algorithm 1 requires $O(p \cdot m \log m)$ time. It goes through all simplices σ that are faces of some simplex $\tau \in z$; there are at most $(p+1) \cdot m$ such $(p-1)$-simplices. For each one, the algorithm sorts its cofaces by their times t_τ. Although there is no bound on the number of cofaces of one simplex, the total number of

the cofaces to sort is again at most $(p+1)\cdot m$. Individual operations in the update take constant time, so the overall running time of Algorithm 1 is $O(p \cdot m \log m)$. The size of the lifted cycle is $O(p \cdot m)$.

5 Apex Representatives

We give a characterization of apex representatives in the prism.

▶ **Lemma 7** (Closed endpoint).

1. *If a relative cycle $\overline{z}$, with $[\overline{z}] \in \mathsf{H}(\overline{K}(b,d])$, contains $\tau \times d$ with $\min \tau = d$, then*

$$[\overline{z}] \notin \operatorname{im}\left(\mathsf{H}(\overline{K}(b,d-1]) \to \mathsf{H}(\overline{K}(b,d])\right).$$

2. *If a relative cycle $\overline{z}$, with $[\overline{z}] \in \mathsf{H}(\overline{K}[b,d))$, contains $\tau \times b$ with $\max \tau = b$, then*

$$[\overline{z}] \notin \operatorname{im}\left(\mathsf{H}(\overline{K}[b+1,d)) \to \mathsf{H}(\overline{K}[b,d))\right).$$

3. *If an absolute cycle $\overline{z}$, with $[\overline{z}] \in \mathsf{H}(\overline{K}[b,d])$, contains $\sigma \times b$ and $\tau \times d$ with $\max \sigma = b$ and $\min \tau = d$, then*

$$[\overline{z}] \notin \operatorname{im}\left(\mathsf{H}(\overline{K}[b+1,d]) \to \mathsf{H}(\overline{K}[b,d])\right) \quad \textit{and} \quad [\overline{z}] \notin \operatorname{im}\left(\mathsf{H}(\overline{K}[b,d-1]) \to \mathsf{H}(\overline{K}[b,d])\right).$$

Proof. All the statements follow the same proof, except for the endpoints of the intervals, so we only show the first. Suppose there is some class $[\alpha] \in \mathsf{H}(\overline{K}(b,d-1])$ that maps to $[\overline{z}] \in \mathsf{H}(\overline{K}(b,d])$. Then $\overline{z} = \alpha + \partial\beta$ for some chain β. Since $\tau \in \overline{z}$ and $\tau \notin \alpha$ (since $\min \tau = d > d-1$), τ must be in $\partial\beta$. But from Equation (4), τ has no cofaces in K^d_{-1} – a contradiction. ◀

▶ **Lemma 8** (Open endpoint).

1. *If the boundary $\partial\overline{z}$ of a relative cycle $\overline{z}$, with $[\overline{z}] \in \mathsf{H}(\overline{K}(b,d])$, contains $\sigma \times b$ with $\min \sigma = b$, then $[\overline{z}] \notin \operatorname{im}\left(\mathsf{H}(\overline{K}(b-1,d]) \to \mathsf{H}(\overline{K}(b,d])\right)$.*
2. *If the boundary $\partial\overline{z}$ of a relative cycle $\overline{z}$, with $[\overline{z}] \in \mathsf{H}(\overline{K}[b,d))$ contains $\sigma \times d$ with $\max \sigma = d$, then $[\overline{z}] \notin \operatorname{im}\left(\mathsf{H}(\overline{K}[b,d+1)) \to \mathsf{H}(\overline{K}[b,d))\right)$.*
3. *If the boundary $\partial\overline{z}$ of a relative cycle $\overline{z}$, with $[\overline{z}] \in \mathsf{H}(\overline{K}(b,d))$, contains $\sigma \times b$ with $\min \sigma = b$ and $\tau \times d$ with $\max \tau = d$, then*

$$\overline{z} \notin \operatorname{im}\left(\mathsf{H}(\overline{K}(b-1,d)) \to \mathsf{H}(\overline{K}(b,d))\right) \quad \textit{and} \quad \overline{z} \notin \operatorname{im}\left(\mathsf{H}(\overline{K}(b,d+1)) \to \mathsf{H}(\overline{K}(b,d))\right).$$

Proof. All the statements follow the same proof, except for the endpoints of the intervals, so we only show the first. From the long exact sequence of the triple [14, p. 118], $K^{b-1}_{-1} \subseteq K^b_{-1} \subseteq K^d_{-1}$, we know that the image in the claim is equal to the kernel of the map induced by the boundary,

$$\operatorname{im}\left(\mathsf{H}_*(\overline{K}(b-1,d]) \to \mathsf{H}_*(\overline{K}(b,d])\right) = \ker\left(\mathsf{H}_*(\overline{K}(b,d]) \xrightarrow{\partial^*} \mathsf{H}_{*-1}(\overline{K}(b-1,b])\right).$$

For $[\overline{z}]$ to be in the kernel, $\partial\overline{z}$ needs to be a relative boundary in $\overline{K}(b-1,b]$, i.e., $\partial\overline{z} = \partial\beta + \gamma$ for some $\beta \subseteq K^b_{-1}$ and $\gamma \subseteq K^{b-1}_{-1}$. Since $\sigma \in \partial\overline{z}$ and $\sigma \notin \gamma$, σ must be in $\partial\beta$. But from Equation (4), σ has no cofaces in K^b_{-1} – a contradiction. ◀

Putting Lemmas 7 and 8 together, we get the following theorem.

▶ **Theorem 9.**

1. *If a relative cycle $\overline{z}$, with $[\overline{z}] \in \mathsf{H}(\overline{K}(b,d])$, contains $\tau \times d$ with $\min \tau = d$, and its boundary $\partial\overline{z}$ contains $\sigma \times b$ with $\min \sigma = b$, then $\overline{z}$ is an apex representative.*

2. *If a relative cycle* $\overline{z}$*, with* $[\overline{z}] \in \mathsf{H}(\overline{K}[b,d))$*, contains* $\tau \times b$ *with* $\max \tau = b$*, and its boundary* $\partial\overline{z}$ *contains* $\sigma \times d$ *with* $\max \sigma = d$*, then* $\overline{z}$ *is an apex representative.*
3. *If an absolute cycle* $\overline{z}$*, with* $[\overline{z}] \in \mathsf{H}(\overline{K}[b,d])$*, contains* $\sigma \times b$ *and* $\tau \times d$ *with* $\max \sigma = b$ *and* $\min \tau = d$*, then* $\overline{z}$ *is an apex representative.*
4. *If the boundary* $\partial\overline{z}$ *of a relative cycle* $\overline{z}$*, with* $[\overline{z}] \in \mathsf{H}(\overline{K}(b,d))$*, contains* $\sigma \times b$ *with* $\min \sigma = b$ *and* $\tau \times d$ *with* $\max \tau = d$*, then* $\overline{z}$ *is an apex representative.*

6 Four Intervals

We assume $R = DV$ is the decomposition of the boundary matrix D of the cone $\hat{K}$ filtration in Equation (7). We use σ, τ to refer to simplices in the base space K, and $\hat{\sigma}, \hat{\tau}$ for the simplices in the cone $\hat{K} - K$.

Summary. The main content of this section is summarized in Table 1: lifting the stated cycles z in K, derived from the lazy reduction, with the given arguments to the algorithm Lift-Cycle, produces apex representatives in $\overline{K}$. The results of the section are more general, but also more verbose; they derive the expression for the cycles for any reduction.

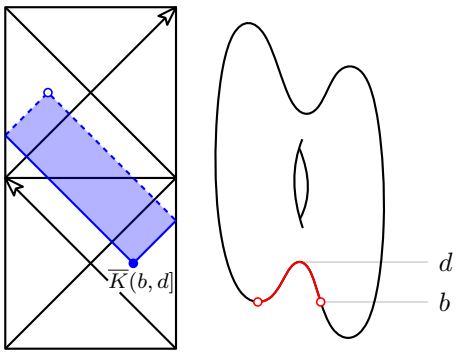
Table 1 Summary of the chains and arguments used in different cases of the Lift-Cycle algorithm, derived from the lazy reduction.

EP type	LZZ type	Apex	z	(s,f)	w_{init}
Ordinary	closed-open	$K(b,d]$	$V[\tau]$	(d,b)	0
Relative	open-closed	$K[b,d)$	$R[\hat{\tau}] \cap K$	(b,d)	0
Extended (d,b)	open-open	$K[b,d]$	$R[\hat{\tau}]$	(d,b)	0
Extended (b,d)	closed-closed	$K(b,d)$	$V[\hat{\tau}] \cap K$	(b,d)	$-R[\hat{\tau}]$

6.1 Ordinary (closed-open)

Throughout this subsection, we assume the following **setting**:

a pair (σ, τ) in the cone filtration, born at b and dying at d, i.e., $\min(\sigma) = b < d = \min(\tau)$.



▷ Claim 10. Let $z = V[\tau]$. Then $[z] \in \mathsf{H}(K(b,d])$. Furthermore, $\tau \in z$ and $\sigma \in \partial z = R[\tau]$.

Proof. Since V is upper-triangular with all diagonal entries non-zero, τ is the latest simplex in $V[\tau]$, i.e., $\max\{\min(\tau') \mid \tau' \in V[\tau]\} = \min(\tau) = d$. Therefore, $V[\tau] \subseteq K^d_{-1}$. By definition, the boundary $\partial V[\tau] = R[\tau]$. σ is its latest simplex, i.e., $\max\{\min(\sigma') \mid \sigma' \in R[\tau]\} = \min(\sigma) = b$. Therefore, $\partial V[\tau] \subseteq K^b_{-1}$. It follows that if $z = V[\tau]$, then $[z] \in \mathsf{H}(K^d_{-1}, K^b_{-1}) = \mathsf{H}(K(b,d])$. ◁

▷ Claim 11. Relative cycle $\overline{z}$ produced by the call Lift-Cycle$(V[\tau], (d,b), 0)$ is an apex representative in $\mathsf{H}(\overline{K}(b,d])$.

Proof. Let $z = V[\tau]$.

1. $\sigma \times b \in \partial\overline{z}$, $\min(\sigma) = b$.
   Because $\sigma \in \partial z$ (Claim 10) and $\min(\sigma) = b$, its coboundary $\delta\sigma \subseteq K^{n+1}_b$. Meanwhile, $z \subseteq K^d_{-1}$. Therefore, all cofaces of σ in z intersect $[b,d]$. Therefore, $\sigma \in \partial(z \cap [b,d])$. It follows from Claim 5 that

   $$\sigma \times b \in \partial\overline{z} = w_{\text{final}} \times b = \partial(z \cap [b,d]) \times b.$$

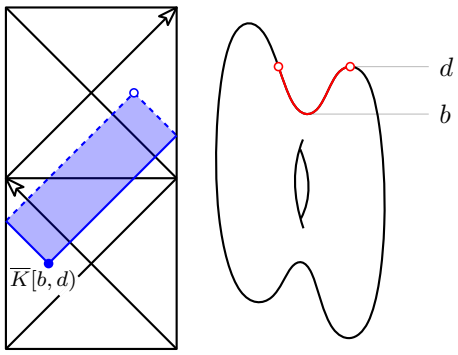
2. $\tau \times d \in \overline{z}$, $\min(\tau) = d$.
   This follows immediately since $\tau \in z$ (Claim 10) and $T(\tau) \cap [b,d] = \{d\}$.

It follows from Theorem 9 that $\overline{z}$ is an apex representative in $\mathsf{H}(\overline{K}(b,d])$. ◁

6.2 Relative (open-closed)

Throughout this subsection, we assume the following **setting**:

a pair $(\hat{\sigma}, \hat{\tau})$ in the cone filtration, born at d and dying at b, i.e., $\max(\sigma) = d > b = \max(\tau)$.



▷ Claim 12. Let chain z consist of the boundary of the cone simplices in $V[\hat{\tau}]$ restricted to the base space,

$$z = \partial\left(V[\hat{\tau}] \cap (\hat{K} - K)\right) \cap K.$$

Then $[z] \in \mathsf{H}(K[b,d))$. Furthermore, $\tau \in z$ and $\sigma \in \partial z$.

Proof. Let $\gamma = V[\hat{\tau}] \cap (\hat{K} - K)$, i.e., $z = (\partial\gamma) \cap K$.

1. $z \subseteq K^{n+1}_b$, $\tau \in z$.
   Because γ consists of only cone simplices, every simplex $\tau' \in z$ is in the boundary of some cone simplex $\hat{\tau}'$. Because $\hat{\tau}$ is the latest simplex in $V[\hat{\tau}]$, we have that $\hat{\tau}'$ is added before $\hat{\tau}$. Therefore, $\max(\tau') \geq \max(\tau) = b$. Because $\hat{\tau}$ is the only simplex in γ with τ in its boundary, $\tau \in \partial\gamma \cap K = z$.

2. $\partial z \subseteq K_d^{n+1}$.
   Let
   $$\alpha = \partial z = -\partial\left(\partial\gamma \cap (\hat{K} - K)\right)$$
   be the shared boundary between the base space and the cone parts of $\partial\gamma$. We note that because cone simplices can only be in the boundary of cone simplices, $(\partial V[\hat{\tau}]) \cap (\hat{K} - K) = \partial\gamma \cap (\hat{K} - K)$. Therefore, all the cone simplices $\hat{\sigma}' \in \partial\gamma \cap (\hat{K} - K))$ are such that $\max(\sigma') \geq \max(\sigma) = d$. Therefore, any simplex in the shared boundary α is in K_d^{n+1}. Putting the first two sub-claims together, $[z] \in \mathsf{H}(K_b^{n+1}, K_d^{n+1}) = \mathsf{H}(K[b,d))$.
3. $\sigma \in \partial z$.
   $(\hat{\sigma}, \hat{\tau})$ is a persistence pair, therefore, $\hat{\sigma} \in \partial V[\hat{\tau}]$. Because cone simplices can only be in the boundaries of cone simplices, $\hat{\sigma} \in \partial\gamma$. Because $\hat{\sigma}$ is the only simplex in $(\partial\gamma) \cap (\hat{K} - K)$ that has σ in its boundary, it follows that
   $$\sigma \in \partial z = \partial\left((\partial\gamma) \cap K\right) = \partial\left((\partial\gamma) \cap (\hat{K} - K)\right). \qquad \triangleleft$$

▶ Remark 13 (Lazy reduction). If $R = DV$ is obtained by lazy reduction, it follows from Corollary 3 that $V[\hat{\tau}]$ consists only of cone simplices. In other words, the chain in the prior claim simplifies to

$$z = (\partial V[\hat{\tau}]) \cap K = R[\hat{\tau}] \cap K.$$

▷ Claim 14. Relative cycle $\overline{z}$ produced by the call Lift-Cycle$(R[\hat{\tau}] \cap K, (b,d), 0)$ is an apex representative in $\mathsf{H}(\overline{K}[b,d))$.

Proof. Let $z = R[\hat{\tau}] \cap K$.

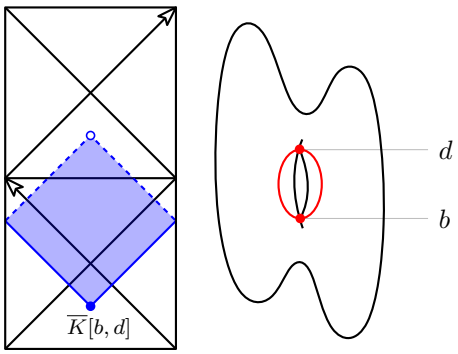
1. $\sigma \times d \in \partial\overline{z}$, $\max(\sigma) = d$.
   Because $\sigma \in \partial z$ (Claim 12) and $\max(\sigma) = d$, its coboundary $\delta\sigma \subseteq K_{-1}^d$. Meanwhile, $z \subseteq K_b^{n+1}$. Therefore, all cofaces of σ in z intersect $[b,d]$. Therefore, $\sigma \in \partial\left(z \cap [b,d]\right)$. It follows from Claim 5 that
   $$\sigma \times d \in \partial\overline{z} = w_{\text{final}} \times d = \partial\left(z \cap [b,d]\right) \times d.$$
2. $\tau \times b \in \overline{z}$, $\max(\tau) = b$.
   This follows immediately since $\tau \in z$ (Claim 12) and $T(\tau) \cap [b,d] = \{b\}$.

It follows from Theorem 9 that $\overline{z}$ is an apex representative in $\mathsf{H}(\overline{K}[b,d))$. $\triangleleft$

6.3 Extended (open-open)

Throughout this subsection, we assume the following **setting**:

a pair $(\sigma, \hat{\tau})$ in the cone filtration born at d, dying at b, i.e., $\min(\sigma) = d > b = \max(\tau)$.



▷ Claim 15. Let chain c consist of those simplices in $V[\hat{\tau}]$ that are either in the cone, or in K_b^{n+1}, i.e.,

$$c = V[\hat{\tau}] \cap (\hat{K} - K) + V[\hat{\tau}] \cap K_b^{n+1}.$$

Let $z = \partial c$; then $[z] \in \mathsf{H}(K[b,d])$. Furthermore, $\sigma, \tau \in z$.

Proof. We split the chain $V[\hat{\tau}]$ into three parts:

$$\alpha = V[\hat{\tau}] \cap (K - K_b^{n+1}), \qquad \beta = V[\hat{\tau}] \cap K_b^{n+1}, \qquad \gamma = V[\hat{\tau}] \cap (\hat{K} - K),$$

and re-write its boundary accordingly: $R[\hat{\tau}] = \partial V[\hat{\tau}] = \partial\alpha + \partial\beta + \partial\gamma$. $c = (\beta + \gamma) = V[\hat{\tau}] - \alpha$.

1. $z = \partial c \subseteq K_{-1}^d$, $\sigma \in z$.
   $\partial V[\hat{\tau}] \subseteq K_{-1}^d$ because σ is the latest simplex in $R[\hat{\tau}]$. Putting together Equations (5) and (6), $\alpha \subseteq K - K_b^{n+1}$ implies $\partial\alpha \subseteq K_{-1}^b \subseteq K_{-1}^d$. Therefore, $z = \partial V[\hat{\tau}] - \partial\alpha \subseteq K_{-1}^d$.
   Because $\sigma \in \partial V[\hat{\tau}]$, but $\sigma \notin \partial\alpha$, $\sigma \in z$.
2. $z \subseteq K_b^{n+1}$, $\tau \in z$.
   Since chain $\beta \subseteq K_b^{n+1}$, its boundary $\partial\beta \subseteq K_b^{n+1}$. Since boundaries $\partial V[\hat{\tau}], \partial\alpha, \partial\beta \subseteq K$, so is $\partial\gamma$. Every simplex in γ has the form $\omega * \tau$, where $\tau \in K_b^{n+1}$. Therefore, $\partial\gamma \subseteq K_b^{n+1}$. It follows that $z = \partial\beta + \partial\gamma \subseteq K_b^{n+1}$.
   Because $\max(\tau) = b$, it has no cofaces in K_b^{n+1}. Therefore, $\tau \notin \partial\beta$. Because $\hat{\tau}$ is the only simplex in γ that has τ in its boundary, $\tau \in \partial\gamma$. Therefore, $\tau \in z = \partial\beta + \partial\gamma$.

   Therefore, $[z] \in \mathsf{H}(K_b^{n+1} \cap K_{-1}^d) = \mathsf{H}(K[b,d])$. ◁

▶ Remark 16 (Lazy reduction). Furthermore, if $R = DV$ comes from the lazy reduction, then the next claim proves that in the previous claim, chain $c = V[\hat{\tau}]$. In other words, we can use $z = R[\hat{\tau}] = \partial V[\hat{\tau}]$ directly.

▷ Claim 17 (Lazy reduction). If $R = DV$ is obtained from the lazy reduction, then all the base space simplices in $V[\hat{\tau}]$ are in K_b^{n+1}, i.e., $V[\hat{\tau}] \cap K \subseteq K_b^{n+1}$.

Proof. Let τ' be a simplex in $V[\hat{\tau}] \cap K$. In this case, for the lazy reduction, because $V[\tau', \hat{\tau}] \neq 0$, from Corollary 3, taking $\sigma_j = \sigma$ and $\tau_i = \tau'$, we get

$$\max(\tau') > \min(\tau') > \min(\sigma) = d > b.$$ ◁

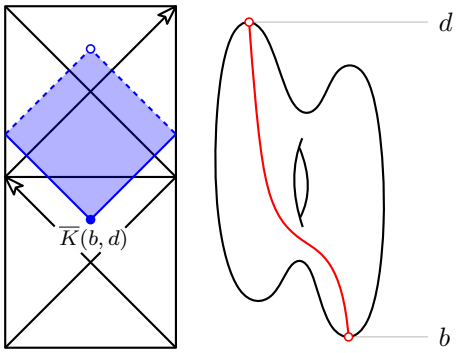
▷ Claim 18. Absolute cycle $\overline{z}$ produced by the call Lift-Cycle$(R[\hat{\tau}], (d,b), 0)$ is an apex representative in $\mathsf{H}(\overline{K}[b,d])$.

Proof. Let $z = R[\hat{\tau}]$. Because $\sigma, \tau \in z$ (Claim 15) and $\min(\sigma) = d$ and $\max(\tau) = b$, both simplices $\sigma \times d$ and $\tau \times b$ are in the lifted cycle $\overline{z}$. It follows from Theorem 9 that $\overline{z}$ is an apex representative in $\mathsf{H}(\overline{K}[b,d])$. ◁

6.4 Extended (closed-closed)

Throughout this subsection, we assume the following **setting**:

a pair $(\sigma, \hat{\tau})$ in the cone filtration, born at b, dying at d, i.e., $\min(\sigma) = b < d = \max(\tau)$.



▷ Claim 19. Let $z = V[\hat{\tau}] \cap K_b^{n+1}$. Then $[z] \in \mathsf{H}(K(b,d))$. Furthermore,

$$\sigma \in w_{\text{init}} = -\partial\left(V[\hat{\tau}] \cap (\hat{K} - K) + V[\hat{\tau}] \cap K_b^{n+1}\right) \subseteq K[b,b]$$

and $\tau \in (w_{\text{init}} + \partial z) = -\partial\left(V[\hat{\tau}] \cap (\hat{K} - K)\right)$.

Proof. We split the chain $V[\hat{\tau}]$ into three parts:

$$\alpha = V[\hat{\tau}] \cap (K - K_b^{n+1}), \qquad z = \beta = V[\hat{\tau}] \cap K_b^{n+1}, \qquad \gamma = V[\hat{\tau}] \cap (\hat{K} - K),$$

and re-write its boundary accordingly: $R[\hat{\tau}] = \partial V[\hat{\tau}] = \partial\alpha + \partial\beta + \partial\gamma$.

1. $\partial z \subseteq K_{-1}^b \cup K_d^{n+1}$.
   Putting together Equations (5) and (6), $\alpha \subseteq K - K_b^{n+1}$ implies $\partial\alpha \subseteq K_{-1}^b$. Because σ is the latest simplex in $R[\hat{\tau}]$ and $\min(\sigma) = b$, $R[\hat{\tau}] \subseteq K_{-1}^b$. It follows that $\partial(\beta+\gamma) = R[\hat{\tau}] - \partial\alpha \subseteq K_{-1}^b$. Since $\partial\gamma \subseteq K_d^{n+1}$, we have $\partial z = \partial(\beta+\gamma) - \partial\gamma \subseteq K_{-1}^b \cup K_d^{n+1}$. Therefore, $[z] \in \mathsf{H}(K(b,d))$.
2. $\sigma \in w_{\text{init}} = \partial(\beta+\gamma) \subseteq K[b,b]$.
   We already saw that $\partial(\beta+\gamma) \subseteq K_{-1}^b$. To show that it is also in K_b^{n+1}, we note that since $\beta \subseteq K_b^{n+1}$, its boundary $\partial\beta \subseteq K_b^{n+1}$. $\partial\gamma \subseteq K_d^{n+1} \subseteq K_b^{n+1}$. Therefore, $\partial(\beta+\gamma) \subseteq K_b^{n+1}$. Because $\min(\sigma) = b$, Equation (4) implies that σ cannot be in the boundary of any simplex $\tau \in \alpha$ since $\max(\tau) < b$. Since $\sigma \in R[\hat{\tau}]$ and $w_{\text{init}} = \partial(\beta+\gamma) = R[\hat{\tau}] - \partial\alpha$, it follows that $\sigma \in w_{\text{init}}$.
3. $\tau \in -\partial\gamma$.
   Because $\hat{\tau}$ is the only simplex in γ that has τ in its boundary, $\tau \in -\partial\gamma$. ◁

▷ Claim 20 (Lazy reduction). If $R = DV$ is obtained from the lazy reduction, then $z = V[\hat{\tau}] \cap K$ is in $K(b,d)$, $\sigma \in w_{\text{init}} = -R[\hat{\tau}] = -\partial V[\hat{\tau}] \subseteq K[b,b]$, and $\tau \in (w_{\text{init}} - \partial z)$.

Proof. We only need to show that, in the case of the lazy reduction, $\alpha = V[\hat{\tau}] \cap (K - K_b^{n+1}) = 0$, i.e., $V[\hat{\tau}] \cap K = V[\hat{\tau}] \cap K_b^{n+1}$. Then the claim follows from the previous Claim 19.

The proof is analogous to the proof of Claim 17. Let τ' be a simplex in $V[\hat{\tau}] \cap K$. In this case, for the lazy reduction, because $V[\tau', \hat{\tau}] \neq 0$, from Corollary 3, taking $\sigma_j = \sigma$ and $\tau_i = \tau'$, we get $\max(\tau') > \min(\tau') > \min(\sigma) = b$. ◁

▶ Remark 21. $V[\hat{\tau}] \cap K$ can be empty. For example, if K is a single vertex that appears at b and then disappears at d. This is the reason why we need to bootstrap Algorithm 1 with an initial cycle w_{init}.

▷ Claim 22. Relative cycle $\overline{z}$ produced by the call Lift-Cycle$(V[\hat{\tau}] \cap K, (b,d), -R[\hat{\tau}])$ is an apex representative in $\mathsf{H}(\overline{K}(b,d))$.

Proof.

1. $\sigma \times b \in \partial\overline{z}$, $\min(\sigma) = b$.
   Simplex σ, with $\min(\sigma) = b$, is in the initial cycle w_{init} (Claim 19). Therefore, $\sigma \times b$ is in the boundry $\partial\overline{z}$ of the lifted cycle.
2. $\tau \times d \in \partial\overline{z}$, $\max(\tau) = d$.
   Simplex τ, with $\max(\tau) = d$, is in $w_{\text{init}} + \partial z$ (Claim 19). Its coboundary $\delta\tau \subseteq K^d_{-1}$. Meanwhile, $z \subseteq K^{n+1}_b$ (Claim 19). Therefore, all cofaces of τ in z intersect $[b, d]$. Therefore, $\tau \in w_{\text{init}} + \partial\left(z \cap [b, d]\right) = w_{\text{final}}$. It follows from Claim 5 that

$$\tau \times d \in w_{\text{final}} \times d \subseteq \partial\overline{z}.$$

It follows from Theorem 9 that $\overline{z}$ is an apex representative in $\mathsf{H}(\overline{K}(b, d))$. ◁

7 Zigzag Representatives

To solve our original problem – to find zigzag representatives – all that remains is to map an apex representative into an appropriate space in the zigzag. Because we assumed in Remark 4 that no simplex is supported on a single space, the death and the birth for any given interval are distinct. Suppose we want to map an apex representative $\overline{z}$, with $[\overline{z}] \in \mathsf{H}(\overline{K}I)$, into a zigzag representative in $\mathsf{H}(\overline{K}[i, i]) \simeq \mathsf{H}(K_i)$.

If i is odd, then the p-cycle $\overline{z}$ may contain a vertical cell $\tau \times i$, which does not map into $(p-1)$-cells in the levelset. To sidestep this complication, we perturb i. Let $x = i \pm \varepsilon \in I$ be a real value near i that lies inside our birth-death interval. We assume $x = i + \varepsilon$; the other case is symmetric. We implicitly subdivide $\overline{K}$ at x and extend our previous notation to allow for the interlevel sets ending at x, e.g., $\overline{K}^x_i$. We note that $\overline{K}^x_i$ deformation retracts onto $\overline{K}^i_i$, with the homotopy following the second (time) coordinate, and $\overline{K}^x_x$ includes into $\overline{K}^i_i$ once the cell times are shifted from x to i. We want to compose three maps:

$$\mathsf{H}_p(\overline{K}I) \to \mathsf{H}_p(\overline{K}(i, x)) \xrightarrow{\partial^*} \mathsf{H}_{p-1}(\overline{K}[x, x]) \to \mathsf{H}_{p-1}(K_i).$$

Because $\overline{K}I$ is an apex of a diamond, and $\overline{K}(i, x)$ is a space in the diamond, the first map is an inclusion (of pairs), so $\overline{z}$ remains a relative cycle in $\overline{K}(i, x)$. Let

$$\overline{z} = \sum \alpha_\tau \cdot (\tau \times t_\tau) + \sum \alpha_\sigma \cdot (\sigma \times [t^1_\sigma, t^2_\sigma]),$$

then the second (boundary) map takes $\overline{z}$ to

$$\overline{z}[x, x] = \sum_{\substack{(\sigma \times [t^1_\sigma, t^2_\sigma]) \in \overline{z} \\ x \in [t^1_\sigma, t^2_\sigma]}} \alpha_\sigma \cdot (\sigma \times x),$$

which maps into K_i by dropping the second coordinate,

$$z(i) = \sum_{(\sigma \times x) \in \overline{z}[x,x]} \alpha_\sigma \cdot \sigma.$$

By storing the apex cycle $\overline{z}$ in an interval tree [11, 15], we can retrieve any zigzag representative of size C in time $O(\log m + C)$.

Abstract

Dey and Xin (J.Appl.Comput.Top., 2022) describe an algorithm to decompose finitely presented multiparameter persistence modules using a matrix reduction algorithm. Their algorithm only works for modules whose generators and relations are distinctly graded. We extend their approach to work on *all* finitely presented modules and introduce several improvements that lead to significant speed-ups in practice. Our algorithm is fixed-parameter tractable with respect to the maximal number of relations of the same degree and with further optimisation we obtain an $O(n^3)$ time algorithm for interval-decomposable modules. In particular, we can decide interval-decomposability in this time. As a by-product to the proofs of correctness we develop a theory of parameter restriction for persistence modules. Our algorithm is implemented as a software library AIDA, the first to enable the decomposition of large inputs. We show its capabilities via extensive experimental evaluation.

1 Introduction

Multiparameter Persistence Modules (MPM) as introduced by Carlsson and Zomorodian [21, 22] make it possible to capture topological features of data with respect to more than one parameter. This, for example, allows detection of features in different scale-regions stably with respect to outliers [13]. One of the main challenges of dealing with MPM is that their indecomposable summands do not provide a discrete invariant, as in the case of finitely generated 1-parameter persistence modules, where this decomposition leads to the *barcode*.

In contrast, indecomposable MPM can be arbitrarily complex because the representation theory of the partially ordered set $\mathbb{N}^d$ is wild ([45, 49]). In light of this difficulty, researchers in TDA have come up with various invariants with varying degree of discrimination powers and ease of computability ([16, 24, 27, 32, 48, 51, 52, 58, 60]). Nevertheless, the begging question remains how to compute the indecomposable summands of MPM.

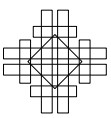

Figure 1 Philippe Chaperon's set design for Giuseppe Verdi's opera Aida, 1880.

A fast algorithm for this task has numerous benefits. Primarily, every additive invariant of persistence module can, by definition, be computed from its indecomposable summands, possibly reducing computation time. For example, the computation of the matching distance [10, 12] becomes more tractable for decomposed modules as the complexity of the barcode template [46] reduces, which we show empirically in Section 7.

Contributions. We present an algorithm inspired by the Dey-Xin algorithm [29], speeding up various steps and lifting the assumption that the module needs to be distinctly graded. Our methods are collected in the software package AIDA (Figure 1), which allows the decomposition of presentations arising from large data within seconds. We demonstrate the usefulness of our improvements in extensive experimental evaluation. Since the methods used in AIDA are of more general interest we implemented them in a stand-alone, header-only C++library PERSISTENCE-ALGEBRA. Both this library and the AIDA code are publicly available.[1]

While the distinctly graded case allows for an incremental column-by-column approach to compute a decompositon, the general case requires to consider all columns of the same degree at once, say k_i many at the i-th step. It does not suffice to consider all permutations of these columns [5]; instead arbitrary changes-of-base within the columns could be part of a correct solution. Our first approach requires a brute-force iteration over these change-of-basis matrices (which is only possible over a finite field) and is therefore not polynomial in k_i. Nevertheless, through a careful analysis, we limit the number of cases and provide a tractable solution if k_i is small. Since we can then use the poly-time strategy of [29], this yields a decomposition algorithm which is fixed-parameter tractable with respect to $k_{\max} := \max_i k_i$.

[1] `https://github.com/JanJend/AIDA` and `https://github.com/JanJend/Persistence-Algebra`

To further reduce the iteration – or even avoid it altogether – we analyse which kinds of matrix operations can actually help in the decomposition. This leads to another FPT-algorithm in a parameter κ_i smaller than k_i which promises to accelerate the computation for modules where k_i is too large. A modification of this idea also yields an algorithm which, for interval-decomposable modules, runs in $\mathcal{O}(n^3)$ time, independent of κ_i.

Related work. Multi-parameter persistent homology is an active research area with many theoretic, computational, and applied results in recent years [15]. In particular, efficient algorithms have been devised for the computation of a presentation of standard bifiltrations [4, 2, 17, 18, 25, 44], for minimizing presentations [29, 33, 47] and for efficient distance computation [10, 12, 28]. Our decomposition algorithm complements this pipeline.

In theory we can decompose any module over a finite dimensional algebra in polynomial time by decomposing its endomorphism algebra [23], but this algorithm is not practical. The algorithms in the C MeatAxe Package ([50], [57]), in the MAGMA system [14], and in the GAP system [34], [54], rely on the Holt-Rees extension [37] of the MeatAxe algorithm [53], both of which are *Las Vegas* algorithms and too slow for the large sparse matrices appearing in TDA. We remark that that the run-time complexity of these algorithms is sometimes not precisely cited in the TDA literature. For example the bounds in [15, Section 8.5] and [29, Introduction]) are a misinterpretation of the usage of the MeatAxe algorithm in this pipeline and use the *lower* bound given in [36] for the non-practical algorithm described in [55].

The only algorithm specifically designed for MPM is the aforementioned Dey-Xin algorithm [29] which has a time complexity of $\mathcal{O}(n^{2\omega+1})$, where $\omega < 2.373$ is the matrix multiplication constant. It only works for uniquely graded modules, a property that is satisfied by some, but not all modules that appear in practice. Moreover, an algorithm to compute graphcodes [43] yields a partial decomposition

It is well known that decompositions are not stable; every persistence module is even arbitrarily close to an indecomposable one in interleaving distance [9], but geometric bifiltrations typically do not create such pathologies. Moreover, Bjerkevik [11, Thm 5.4] constructs a module which captures *all* decompositions of an entire ϵ-interleaving-neighbourhood. His construction creates many generators and relations of the same degree so its decomposition requires an efficient algorithm we provide with AIDA.

Complicated indecomposables can arise already in relatively simple geometric examples [20, 19] and most modules in practice are not interval-decomposable (e.g., most examples from our benchmark set contain non-interval indecomposables; see also [3]). However, we expect that in practice most modules will mainly consist of small or structurally simple indecomposables (see [1]), and we designed our algorithm to work fast in such scenarios.

Outline. We review persistence modules and their presentations in Section 2. The algorithm by Dey and Xin [29], which is the basis of our work, is reviewed and modified in Sections 3 and 4. In Section 5, we describe how to decompose non-distinctly graded modules with an exhaustive approach. In Section 6, we present an algorithm that reduces the potentially restrictive iteration of the exhaustive algorithm. The detailed descriptions of our algorithms and proofs of correctness are deferred to the extended arXiv version [26].

2 Persistence Modules and their Presentations

Consider a simplicial complex S, discretely filtered with respect to d many parameters. That is for each $\alpha \in \mathbb{N}^d$ there is a subcomplex $S_\alpha \subset S$ and for each pair $\alpha \leq \beta$ there is an inclusion $S_\alpha \subset S_\beta$. Applying the simplicial homology functor $H_*(-;\mathbb{K})$, for a field $\mathbb{K}$ results in a commutative diagram of $\mathbb{K}$-vector spaces over $\mathbb{N}^d$. For $d = 2$, it has the following shape:

$$\begin{array}{ccccccc}
\vdots & & \vdots & & \vdots & & \\
\uparrow & & \uparrow & & \uparrow & & \\
H_*(S_{0,1}\,;\mathbb{K}) & \longrightarrow & H_*(S_{1,1}\,;\mathbb{K}) & \longrightarrow & H_*(S_{2,1}\,;\mathbb{K}) & \longrightarrow & \cdots \\
\uparrow & & \uparrow & & \uparrow & & \\
H_*(S_{0,0}\,;\mathbb{K}) & \longrightarrow & H_*(S_{1,0}\,;\mathbb{K}) & \longrightarrow & H_*(S_{2,0}\,;\mathbb{K}) & \longrightarrow & \cdots
\end{array}$$

The maps encode how classes in $H_*(S_\alpha, \mathbb{K})$ *persist* when parameters are increased.

▶ **Definition 1.** *A d-parameter* persistence module X *over $\mathbb{K}$ is a commutative diagram of $\mathbb{K}$-vector spaces over $\mathbb{N}^d$.*

Presentations. A persistence module can be succinctly represented by a *presentation*. This is a set of generators and a set of relations among these generators. If these sets are finite, they form a *presentation matrix*, where the row indices correspond to the generators, the column indices to the relations and an entry at (i, j) tells us which scalar coefficient in $\mathbb{K}$ the i-th generator appears with in the j-th relation.

▶ **Definition 2.** *A* graded matrix *is a matrix $M \in \mathbb{K}^{m\times n}$ together with functions $G\colon [m] \to \mathbb{N}^d$ and $R\colon [n] \to \mathbb{N}^d$ which decorate the rows and columns with degrees such that*

$$\forall (i,j) \in [m] \times [n] : \quad \text{If } R(j) \not\geq G(i) \text{ then } M_{i,j} = 0.$$

Given two functions G, R we write $\mathbb{K}^{G\times R}$ for the corresponding space of graded matrices.

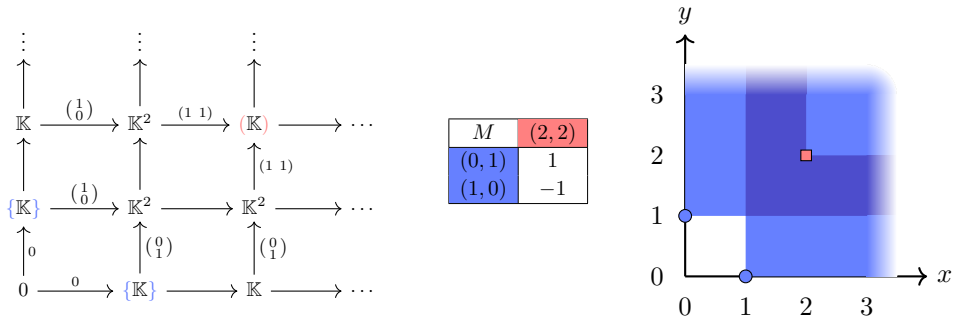

Figure 2 The matrix in the middle presents the module on the left. The location of generators are indicated by blue brackets, the relation by a red bracket. The picture on the right indicates the dimensions of the vector spaces over a continuous plane.

▶ **Definition 3.** *A finite presentation is called* minimal *if there is no presentation of the same module with less generators or less relations.*

▶ Remark 4. Every finitely generated (fg) persistence module has a finite presentation (Hilbert's syzygy theorem [35]). Furthermore, there are efficient algorithms to compute minimal presentations of persistence modules from simplicial bi-filtrations ([8, 42, 47]) and Schreyer's algorithm ([31]) for the general case.

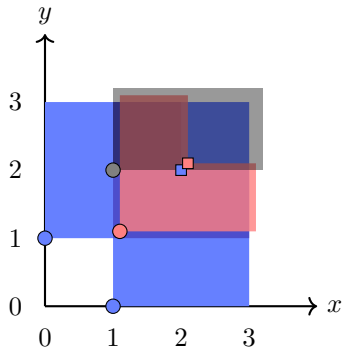
▶ **Theorem 5** (Krull-Remak-Schmidt-Azumaya [6]). *Every fg persistence module X has a finite decomposition into indecomposable submodules, $X = \sum_{i \in I} X_i$, and the isomorphism types of the submodules are independent of the decomposition.*

Decompositions of modules correspond to decompositions of their presentations, but this correspondence is only surjective, see [26, Example 2.30] for details.

▶ **Definition 6.** *Let $M \in \mathbb{K}^{m \times n}$ be a matrix. A* block *b is a pair (b_{rows}, b_{cols}) where $b_{rows} \subset [m]$, $b_{cols} \subset [n]$ and we write M_b for the corresponding submatrix. M is called (block-)* decomposed *if there is a set of blocks $\mathcal{B}$ which partition the row- and column-indices such that M is zero outside of the blocks. We write $M_{\mathcal{B}}$ for a matrix which is block-decomposed and if the matrix is graded, then G_b, R_b denote the corresponding degrees of b.*

▶ **Example 7.** A matrix decomposed over $(b = (\{1,2\},\{1\}),\ c = (\{3\},\{2\}),\ d = (\{4\},\{\}))$

M	$(2,2)$	$(2,2)$
$(0,1)$	1	0
$(1,0)$	1	0
$(1,1)$	0	1
$(1,2)$	0	0



▶ **Definition 8** ([29, Section 4.1]). *For $M \in \mathbb{K}^{G \times R}$, an elementary row- (column-) operation from index i to index j is called* admissible *if $G(i) \geq G(j)$ ($R(i) \leq R(j)$).*

Admissible operations preserve the isomorphism type of the presented module.

▶ **Proposition 9** ([26, Sec.2.1]). *If M, $M' \in \mathbb{K}^{G \times R}$ minimally present isomorphic modules, then there is a sequence of admissible operations transforming M into M'. Equivalently, there are invertible graded matrices $Q \in \mathbb{K}^{G \times G}$, $P \in \mathbb{K}^{R \times R}$ such that $M' = QMP$.*

In particular any decomposition of a module lifts to a change-of-basis between a presentation matrix and a block-decomposed presentation matrix.

▶ Remark 10. Proposition 9 points to the main difficulty in writing a matrix-elimination type algorithm. Assume that we want to bring a presentation M into a certain shape, i.e. with zeroes in a block b. This is equivalent to finding invertible graded matrices Q, P such that $(QMP)_b = 0$. A priori this is a *quadratic* system of equations in the entries of Q and P.

3 The Generalized Persistence Algorithm

The Generalized Persistence (GP) Algorithm introduced by Dey and Xin [29] finds an indecomposable decomposition of a presentation matrix $M \in \mathbb{K}^{G \times R}$ assuming that all relations have pairwise distinct degrees. We review the core functionality of their algorithm.

The GP-Algorithm loops over the relations in an order compatible with the product order on $\mathbb{N}^d$, similarly to the Persistence Algorithm for 1-parameter persistence modules [30, 7]. It manipulates the matrix via admissable row and column operations and maintains the invariant that after having handled the i-th column, the matrix consisting of the first i columns is block-decomposed into indecomposables. We must therefore decompose a graded matrix that is already decomposed except for its last column. This is reflected in the next definition; note that the GP algorithm assumes N to consist of a single column, but we already define the structure for N of arbitrary size to prepare our extension of the algorithm.

▶ **Definition 11.** *Let $\alpha \in \mathbb{N}^d$ and $[M_{\mathcal{B}}\ N] \in \mathbb{K}^{G\times(R\cup k\cdot\alpha)}$ be a presentation, where N contains k columns, all of degree α. It is called* α-decomposed, *if it is* minimal, *$M_{\mathcal{B}}$ is an indecomposable decomposition, and the degree of no column of $M_{\mathcal{B}}$ is larger than α. For $b \in \mathcal{B}$ we denote by N_b the submatrix $N_{b_{rows}\times k\cdot\alpha}$ of N with the row indices of b.*

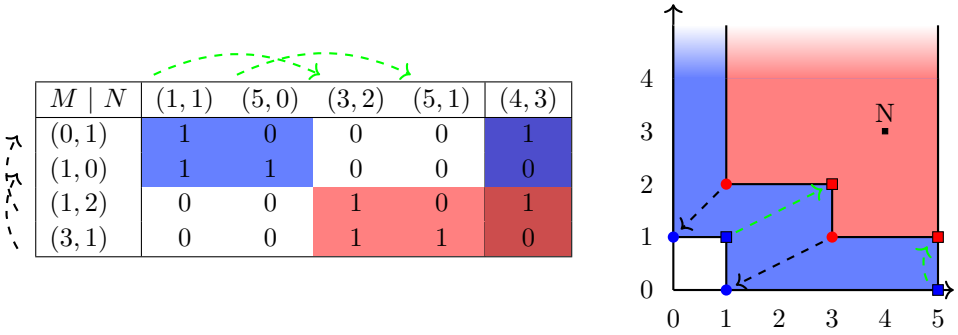


Figure 3 A (4,3)-decomposed presentation. There are two blocks in $M_{\mathcal{B}}$ and they present the interval modules on the right. Some admissible operations have been indicated by arrows both in the matrix and between the corresponding generators and relations.

`BlockReduce`. If we can decompose α-decomposed presentations, then by iterating over the relations we can decompose all finite presentations. If N has only one column this means we have to zero out every sub-column N_b of N whenever possible to reach the block-decomposition with the most blocks. This is done by a subroutine which Dey and Xin called `BlockReduce`, a name we will keep.

▶ **Example 12.** We illustrate `BlockReduce` on the example given in Figure 3. Let us call the (blue) upper block b and the lower (red) block c. We will use two types of admissible operations to try to zero out N_b:

(a) Column operations from M_b to N, e.g. adding the first column to the fifth column.
(b) Row operations from M_c to M_b, e.g. adding the fourth row to the second row.

Adding the third row to the first would delete all entries in N_b, but this would also destroy the block-decomposition of $M_{\mathcal{B}}$, placing a 1 at position $M_{1,3}$:

$M \mid N$	(1,1)	(5,0)	(3,2)	(5,1)	(4,3)
(0,1)	1	0	1	0	0
(1,0)	1	1	0	0	0
(1,2)	0	0	1	0	1
(3,1)	0	0	1	1	0

$M \mid N$	(1,1)	(5,0)	(3,2)	(5,1)	(4,3)
(0,1)	1	0	1	0	0
(1,0)	1	1	1	1	0
(1,2)	0	0	1	0	1
(3,1)	0	0	1	1	0

However, if we also add the fourth to the second row and then use the two column operations indicated by the 2 (green) arrows (right side), we can revert the alteration of $M_{\mathcal{B}}$.
We thus need a third type of admissible operations: **(c)** Column operations from b to c.

The operations of type (a), (b), and (c) have a pleasant feature: their effect on the matrix does not change if the order of their application changes. Dey-Xin call such sets of operations *independent*. In the setting of Remark 10, when restricting the entries of Q and P to those belonging to independent operations, the system of equations becomes *linear*.

Dey and Xin observed that following this strategy, repeated application of the operations (a)–(c) actually suffices to decompose an α-decomposed presentation with $k = 1$, but assumed that the generators are also uniquely graded. We prove a more general statement, which therefore also lifts this assumption from the GP Algorithm.

▶ **Lemma 13** ([26, Lemma 5.10]). *Let $[M_{\mathcal{B}}\ N]$ be α-decomposed, then after a suitable sequence of elementary column operations on N, there is a sequence of independent admissible operations which finds an indecomposable decomposition of $[M_{\mathcal{B}}\ N]$ without altering $M_{\mathcal{B}}$.*

At last assume again that $k = 1$. After having zeroed out as much as possible of N, the blocks b for which N_b are still non-zero must all *merge* into a new block, since their non-zero entries now overlap in this last column. This finishes the loop of the GP Algorithm.

Extending `BlockReduce`. Consider an α-decomposed presentation $[M_{\mathcal{B}}\ N]$ and let $k \geq 1$ now be arbitrary, where we recall that k is the number of columns of N. At first, we are still interested in deleting the entire sub-matrices N_b for every $b \in \mathcal{B}$ wherever this is possible. Consider now *sets* of admissible operations of the types (a)-(c) in Example 12, encoded as graded matrices. Using $M_{b,c} \coloneqq M_{b_{\text{rows}} \times c_{\text{cols}}}$, their effect on $(M_{\mathcal{B}}\ N)$ can be described:

(a) A graded matrix $U \in \mathbb{K}^{R_b \times k\cdot\alpha}$ and $N_b \leftarrow N_b + M_b U$.
(b) A graded matrix $Q \in \mathbb{K}^{G_b \times G_c}$ and $N_b \leftarrow N_b + QN_c, \quad M_{b,c} \leftarrow M_{b,c} + QM_c$.
(c) A graded matrix $P \in \mathbb{K}^{R_b \times R_c}$ and $M_{b,c} \leftarrow M_{b,c} + M_b P$.

Finding Q, P such that after performing (b) and (c) the matrix $M_{\mathcal{B}}$ has not changed is equivalent to demanding that $M_{b,c} = 0$, which is a *linear* system $(*)$. Finding U, Q such that performing (a), (b) zeroes out N_b is another one $(**)$.

`BlockReduce` (General Version). `Input`: $[M_{\mathcal{B}}\ N] \in K^{G \times (R \cup k\cdot\alpha)}$, $b \in \mathcal{B}$.

Find $U \in \mathbb{K}^{R_b \times k\cdot\alpha}$ and $\forall c \neq b \in \mathcal{B}$: $\quad Q_c \in \mathbb{K}^{G_b \times G_c}$, $P_c \in \mathbb{K}^{G_b \times R_c}$, such that

$$Q_c M_c + M_b P_c = 0 \quad (*) \quad \text{and} \quad N_b + \sum Q_c N_c + M_b U = 0 \quad (**) \tag{1}$$

In [29], Dey and Xin write these equations in a large matrix which they call S-matrix.

Run time of `BlockReduce`. Let $(M_{\mathcal{B}}\ N)$ be α-decomposed with M of size $m \times n$, then the size of every block is also bounded by $m \times n$. It follows that $(*)$ contains at most $(m^2 + n^2)$ variables and mn equations and $(**)$ contains at most $m^2 + nk$ variables and mk equations. Let $\omega < 2.373$ denote the exponent for matrix multiplication.

▶ **Proposition 14** (cf. Algorithm 3 in [29]). *The time complexity of solving $(*)$ is in $\mathcal{O}\left((nm)^{\omega-1}\left(m^2+n^2\right)\right)$ and of solving $(**)$ is in $\mathcal{O}\left((mk)^{\omega-1}\left(m^2+nk\right)\right)$.*

4 Modifications

AIDA implements many modifications to `BlockReduce` which make this subroutine much faster and enable the *Automorphism-invariant* α-decomposition in Section 6.

Column-Sweeps. When processing a new set of columns N of degreee α_i, we first try to zero out each N_b only with column-operations (i.e., ignoring row-operations first), which is often sufficient and, if not, will maybe reduce the number of non-zero entries. To this end we reduce the sub-matrix $M_b^{\leq \alpha_i}$ of M_b containing the columns of degree $\leq \alpha_i$. Importantly, this matrix can be stored and sometimes even updated when the next set of columns is considered in the same way as in the standard persistence algorithm for one parameter.

`BlockReduce` (Hom-Variant). The following change is subtle but crucial:

1. Find a basis $(Q_i, -P_i)_{i\in I}$ of the solution-space of $(*)$ for every c and store it.
2. Search for the solution of $(**)$ in the vector spaces spanned by $(Q_i, -P_i)_{i\in I}$ for each c.

This split makes no computational difference asymptotically, and its overhead is negligible. In subsequent algorithms, we will call `BlockReduce` recursively without changing $M_{\mathcal{B}}$ (thanks to Lemma 13). By solving and storing $(*)$, we thus avoid recomputations during the recursion.

Morphisms of Presentations. Let $M_c \in \mathbb{K}^{G_1\times R_1}$, $M_b \in \mathbb{K}^{G_2\times R_2}$ present persistence modules X_c, X_b. Up to sign, the solutions of `BlockReduce` $(*)$ form the $\mathbb{K}$-vector space

$$\operatorname{Hom}(M_c, M_b) \coloneqq \left\{(Q, P) \in \mathbb{K}^{G_2\times G_1} \times \mathbb{K}^{R_2\times R_1} \mid QM_c = M_bP\right\}$$

and there is a natural $\mathbb{K}$-linear surjection $\operatorname{Hom}(M_c, M_b) \twoheadrightarrow \operatorname{Hom}(X_c, X_b)$.

So when solving `BlockReduce` $(*)$ for each pair $c \neq b \in \mathcal{B}$, we are actually computing, akin to elementary matrices, the generators of a subgroup of $\operatorname{Aut}(M_{\mathcal{B}})$. Additionally, the property of a morphism $(Q, P) \in \operatorname{Hom}(M_c, M_b)$ to be part of a solution of `BlockReduce` $(**)$ depends only on the map $\widetilde{Q}\colon X_c \to X_b$ which it induces.

Fast Hom-computation. Let X, Y be persistence modules, then $\operatorname{Hom}(X, Y)$ can be computed faster if Y is pointwise "small". This is because we can restrict the target space of each generator of X. We will explore this thoroughly in future research and also point to the following known result for "smallest" modules, also due to Dey and Xin.

▶ **Proposition 15** ([28], Proposition 16). *Let X and Y be interval modules with n generators and relations, then $\operatorname{Hom}(X, Y)$ can be computed in $\mathcal{O}(n)$ time.*

Furthermore, not all homomorphisms are needed to find a decomposition.

▶ **Observation 16.** *The map $\widetilde{Q}\colon X_c \to X_b$ of persistence modules induces a linear map of vector spaces $\left(\widetilde{Q}\right)_\alpha : (X_c)_\alpha \to (X_b)_\alpha$. If this map is the zero map then, since $\operatorname{Im} N_c$ is generated at α, QN_c is a linear combination of the columns of $M_b^{\leq\alpha}$ (cf. Column-Sweeps).*

▶ **Definition 17.** *For persistence modules X, Y we define the space of α-*homomorphisms

$$\operatorname{Hom}^\alpha(X, Y) \coloneqq \operatorname{Hom}(X, Y) \Big/ \{f\colon X \to Y \mid f_\alpha\colon X_\alpha \to Y_\alpha = 0\}.$$

For presentations M_c, M_b one defines $\operatorname{Hom}^\alpha(M_c, M_b)$ analogously.

Thus, instead of finding a basis for the whole solution space of `BlockReduce` $(*)$ we actually only need to compute a set of solutions which span $\operatorname{Hom}^\alpha(X_c, X_b)$. This is a simple reduction based on Observation 16 and will decrease the size of the system $(**)$, but more importantly for Section 6 it will sometimes reduce this solution space to zero.

Interval Modules. For X, Y interval modules we can describe this reduction precisely. By [28, Proposition 16] the vector space $\mathrm{Hom}(X,Y)$ has a basis consisting of "valid" overlaps:

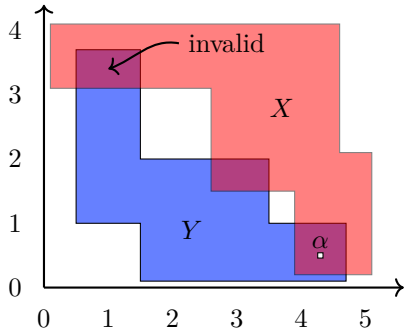

Figure 4 We compute that $\mathrm{Hom}(X,Y) \simeq \mathbb{K}^2$, but $\mathrm{Hom}^{\alpha}(X,Y) \simeq \mathbb{K}$.

At most one of the valid overlaps can contain α and so $\dim_K \mathrm{Hom}^{\alpha}(X,Y) \leq 1$. Define a relation $X \to_{\alpha} Y :\Leftrightarrow \mathrm{Hom}^{\alpha}(X,Y) \neq 0$. This relation is a *partial order* on any set of isomorphism classes of interval modules ([26, Lemma 6.16]). Additionally, an interval module can have at most dimension 1 at α. Therefore, when we consider a set of new relations N in the algorithm, if M_b presents an interval module, we can reduce every sub-column $N_{b,i}$ to have a single non-zero entry. Together with the transitivity of α-maps, this observation allows Gaussian (row-)elimination on N avoiding `BlockReduce` $(**)$ (6, [26, Algorithm B.1]).

5 Decomposing General Presentations

One might hope that we could process the columns of N in some order and just use `BlockReduce`. Unfortunately this does not work: Counterexamples are [5, Example 5.14] and also [26, Example 5.2] where we construct a 2-parameter module over $\mathbb{F}_2$ which is smallest for presentations over $\mathbb{F}_2$ which cannot be decomposed with this method. If on the other hand we allow column operations which do not follow some order, the set of blocks for which N_b can be partially deleted is no long unique up to permutation [26, Example 5.3].

Exhaustive Decomposition. One immediate difference to the distinctly graded case is that a decomposition might introduce several new blocks. Instead of finding all of them at once, we will try to split the presentation into two summands and use recursion. We invoke Lemma 13 again to find invertible matrices, which leave $M_{\mathcal{B}}$ unchanged and such that

$$Q\,[M_{\mathcal{B}}\ N]\begin{bmatrix} P & U \\ 0 & T \end{bmatrix} = [QM_{\mathcal{B}}P \quad Q\,(M_{\mathcal{B}}U + NT)\,] = \begin{bmatrix} M_{\mathcal{B}_1} & 0 & N_1 & 0 \\ 0 & M_{\mathcal{B}_2} & 0 & N_2 \end{bmatrix}.$$

It follows that there is an invertible matrix $T \in \mathbb{K}^{k\times k}$ and a partition $[k] = \{1,\dots,j\} \cup \{j+1,\dots,k\}$ of the columns of N, which allow us to decompose the whole presentation by zeroeing out submatrices with `BlockReduce`: After multiplying N with T from the right, for every block $b \in \mathcal{B}$ we can delete either $N_{b,[j]}$ or $N_{b,[j]^{\complement}}$. Here we see that we would have to solve $(*)$ again, but since we stored its solution this is not necessary and $(**)$ is efficiently solved. Since we work over a finite field, this immediately implies a brute-force algorithm:

Exhaustive α-decomposition. For each invertible matrix T over $\mathbb{F}_q$ and $j \in [k]$ set $N_1 = (NT)_{\{1,\dots,j\}}$, $N_2 = (NT)_{\{j+1,\dots,k\}}$ and decompose each separately with `BlockReduce`.

This is computationally unfeasible even for smaller k: The maximal number of iterations of this loop for $q = 2$ and $k \in \{2, \dots, 6\}$ are 6, 342, 60 822, 40 058 262, 100 833 607 062 and more generally $|\mathbf{GL}_k(\mathbb{F}_q)| \in q^{k^2+\mathcal{O}(k)}$. Fortunately, we can be much smarter about the matrices and partitions we use: Assume that T is as above so that NT decomposes into two parts, supported on $[j]$ and $[j]^{\complement}$, after using `BlockReduce` $(**)$. The two parts also induce a partition of $T = [T_1\ T_2]$. If T_1', T_2' are matrices with the same column-spaces as T_1, T_2 respectively then $N\,[T_1'\ T_2']$ could be brought to the same decomposition with `BlockReduce`. That is, finding a decomposition with this strategy depends only on the *decomposition* of $\mathbb{F}_q^k$ as a vector space which $T = [T_1\ T_2]$ represents. Additionally, once we have deleted as many parts of NT_1 as possible, we can update the block structure and do the same again for NT_2, but now also being able to use column-operations from the columns of NT_1 to those of NT_2 without breaking linearity of the system. That is, we also do not need to consider a decomposition $[T_1\ T_2]$, if a decomposition has been considered already that is of the form $[T_1\ T_2' + T_1 S]$, for any matrix S and any T_2' with the same column-space as T_2. But this is the case for *every* other invertible matrix of the form $[T_1\ T_2']$, so that we only need to iterate over all proper subspaces $\operatorname{span}(T_1)$ of $\mathbb{F}_q^k$, i.e. the Grassmanian $\mathbf{Gr}_l(\mathbb{F}_q^k)$ for every $l < k$. These matrices can be generated fast by leveraging the Schubert cell decomposition [56]:

Algorithm `Generate` $\mathbf{Dec}_q(k, l)$. For each set $P \in \binom{[k]}{l}$ construct a $k \times l$ matrix T_1 in column-echelon form with pivots given by P. Then construct all subspaces in the corresponding cell by changing the entries that are irrelevant for the echelon form and not in the same row as a pivot. For each T_1 generated this way, choose any T_2 with opposite pivots and store the pairs $[T_1\ T_2]$ in a set $\mathbf{Dec}_q(k, l)$.

Avoiding Redundant Counting. Since exchanging T_1 and T_2 in $\mathbf{Dec}_q(k, l)$ would not make a difference for the decomposition we can actually ignore the sets $\mathbf{Dec}_q(k, l)$ for $l > k/2$. In the case where k is even and $l = k/2$ we can avoid double counting even more. Consider the graph on $\mathbf{Gr}_{k/2}(\mathbb{F}_q^k)$ where $U \sim V$ if they form a decomposition (also called the q-Kneser graph). By symmetry we only need to find a minimal vertex cover of this graph and use these subspaces for the computation above. This can be done by considering in `Generate` $\mathbf{Dec}_q(k, k/2)$ only those pivot sets $P \in \binom{[k]}{k/2}$ which contain the first position. Let $\mathbf{Dec}_q(k) \coloneqq \bigcup_{l \le k/2} \mathbf{Dec}_q(k, l)$, then we can iterate over $\mathbf{Dec}_q(k)$ instead of $[k] \times \mathbf{GL}_k(\mathbb{F}_q)$ for the exhaustive decomposition. The first terms of $|\mathbf{Dec}_2(k)|$ are 1, 2, 7, 43, 186, 1965, 14605, 297181, ... and the asymptotic growth is in $q^{k^2/4+\mathcal{O}(k)}$.

At last, when calling the recursion on a sub-matrix we can pull back decompositions we have already tried to the corresponding sub-space to avoid double counting again.

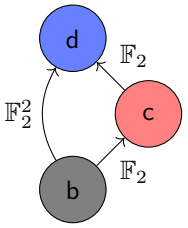
▶ **Theorem 18.** *Let M be a minimal presentation of a persistence module X over $\mathbb{F}_q$ with n generators and relations and at most k relations of the same degree. Then the exhaustive decomposition algorithm has a worst-case running time in $\mathcal{O}\left(n^{2\omega+1} + n^{\omega+2} q^{k^2/4+\mathcal{O}(k)}\right)$.*

Proof. For at most n times we need to compute `BlockReduce` $(*)$ and then solve `BlockReduce` $(**)$ at most $q^{k^2/4+\mathcal{O}(k)}$ many times. Using Proposition 14 gives the term above. ◀

6 Automorphism-invariant α-decomposition

While exhaustive α-decomposition will comfortably work only as long as, say, $k \le 7$, we will encounter presentations where this approach is unsustainable. We will see in the next example that iteration over subspaces as in Section 5 can often be avoided.

▶ **Example 19.** Consider the $(1,3)$-decomposed presentation extending Example 7. We calculate: $\mathrm{Hom}^{\alpha}(M_b, M_c) \simeq \mathbb{K}$, $\mathrm{Hom}^{\alpha}(M_c, M_d) \simeq \mathbb{K}$, and $\mathrm{Hom}^{\alpha}(M_b, M_d) \simeq \mathbb{K}^2$ and all other Hom^{α}-sets are trivial. We depict this information in a digraph structure on $\mathcal{B}$.



M N	$(2,2)$	$(2,2)$	$(1,3)$	$(1,3)$
$(0,1)$	1	0	0	1
$(1,0)$	1	0	0	0
$(1,1)$	0	1	0	1
$(1,2)$	0	0	1	1

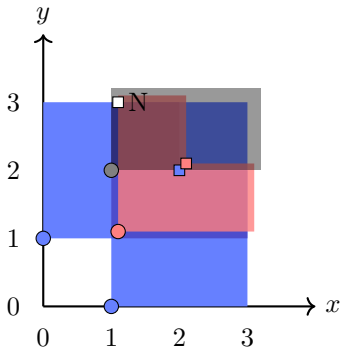


Figure 5 The digraph on $\mathcal{B}$ tells us which sub-modules are *invariant* under α-base-changes. If $\mathcal{B}$ is acyclic, then the group we have computed is *unipotent*.

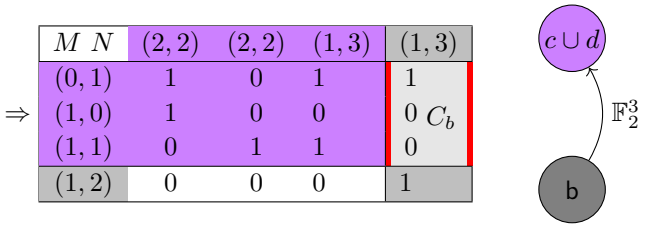
There are no maps to b and so if we want to change N_b then we can only use admissible column operations. If we consider the last row as a presentation itself, it is not decomposed maximally: The two 1s form a block, which can be made smaller by adding the 4th to the 3rd column. That is, we are *minimising* this sub-presentation, reaching the following presentation on the left and the last column index must become a part of the block b.

M N	$(2,2)$	$(2,2)$	$(1,3)$	$(1,3)$
$(0,1)$	1	0	1	1
$(1,0)$	1	0	0	0
$(1,1)$	0	1	1 $N_c^{\{0\}}$	1 C_b
$(1,2)$	0	0	0	1

$\Rightarrow$

M N	$(2,2)$	$(2,2)$	$(1,3)$	$(1,3)$
$(0,1)$	1	0	1 C_c	1
$(1,0)$	1	0	0	0
$(1,1)$	0	1	1	0
$(1,2)$	0	0	0	1

Next we turn to the second block. The subbatch N_c has a part $N_c^{\{0\}}$ sitting above the cleared part of N_b and a part C_b in the new column of b. Now if we were again to add the 4th column to the 3rd, then we could not delete the 1 that would appear at $M_{4,3}$ with any row-operations, because there are no maps to M_b! So the non-existence of maps *to* a block restricts the column operations on N away *from* the block.
This implies that we can not use any operations from outside of c to decompose $\left[M_c \; N_c^{\{0\}}\right]$ and since we cannot reduce $N_c^{\{0\}}$ further, the 3rd column must become part of the block c. Then C_b can be zeroed out using again `BlockReduce` $(**)$ and we reach the presentation above on the right. Next we try to reduce N_d and start with the part C_c in the new column of c, because the column-operation from fourth to third is still impossible. We cannot zero out C_c with admissible operations, so the two blocks c and d need to *merge*:



We update the $\mathrm{Hom}^\alpha(-,-)$ spaces to the new blocks and can continue with C_b.

Extensions concentrated at α. We have seen in Example 19, that if $\mathcal{B}$ is acyclic with respect to $\mathrm{Hom}^\alpha \neq 0$, it is possible to process N in a way so that all admissible operations we need to consider only flow in the direction of the graph. Consequently there is no iteration over subspaces needed. In particular the algorithm would then also work for any field $\mathbb{K}$, not only a finite one. Let us formalise the structure of the matrix we need to decompose:

▶ **Definition 20.** *An α-decomposed presentation* $\begin{bmatrix} M_{\mathcal{C}} & 0 & N_{\mathcal{C}} & C \\ 0 & M_{\mathcal{D}} & 0 & N_{\mathcal{D}} \end{bmatrix}$ *is called* α-decomposed extension *if* $[M_{\mathcal{C}}\ N_{\mathcal{C}}]$ *and* $[M_{\mathcal{D}}\ N_{\mathcal{D}}]$ *are minimal indecomposable decompositions. We denote by κ the number of columns of C.*

When $\mathcal{B}$ is acyclic, we have seen in Example 19 that $\mathcal{C}$ and $\mathcal{D}$ contain just a single block and there are no (α-)maps from $M_{\mathcal{C}}$ to $M_{\mathcal{D}}$. We argued that in this case there are also no column operations from $N_{\mathcal{D}}$ to the left which need to be considered and so we can use `BlockReduce` (**) (on the extended presentations) to decide if C can be zeroed out.

▶ Remark 21. Let X, Y be the persistence modules presented by the two submatrices $[M_{\mathcal{C}}\ N_{\mathcal{C}}]$ and $[M_{\mathcal{D}}\ N_{\mathcal{D}}]$ in Definition 20 and Z the module presented by the entire matrix $[M\ N]$. The inclusion of $[M_{\mathcal{C}}\ N_{\mathcal{C}}]$ into $[M\ N]$ induces a short exact sequence $0 \to X \to Z \to Y \to 0$. To this sequence corresponds a cocycle in $\mathrm{Ext}^1(Y, X)$ which is exactly given by $[C]$.

The correctness of the algorithm follows from our main theorem by lifting isomorphisms:

▶ **Theorem 22.** *Let $0 \to X \xrightarrow{f} Z \xrightarrow{g} Y \to 0$ be induced by an α-decomposed extension. If $\mathrm{Hom}^\alpha(M_{\mathcal{C}}, M_{\mathcal{D}}) = 0$ and Z is decomposable, then so is the entire short exact sequence.*

Proof. [26, Theorem 7.25]. ◀

Notice that the condition means that X is *almost invariant* under the action of $\mathrm{Aut}(Z)$: No automorphism could alter X_α and therefore also not the cocycle $C\colon\ A(-\alpha)^\kappa \to X$.

What if $\mathcal{B}$ is not acyclic? In general there is no order in which we can traverse the blocks, such that maps to the current block come only from parts of the matrix which already form an indecomposable decomposition. The solution here is to contract all strongly connected components of $\mathcal{B}$ forming the *condensation* $\mathcal{T}$ of this digraph.

The α-decomposed extension we need to decompose in each step may then have many blocks in $\mathcal{C}$ and $\mathcal{D}$ and thus cannot be reduced by a linear system anymore. We employ another algorithm `ExtensionDecomp` ([26, Algorithm B.4]) which again loops over subspaces, but of $\mathbb{K}^\kappa$, the column-space of C. The resulting algorithm is FPT in $\kappa_{\max}$, the largest occurrence of κ, and called the Automorphism-invariant Iterative Decomposition Algorithm.

Interval-Decomposables. Assume that the input module is interval-decomposable. Then in Section 4 we have seen that $\mathcal{B}$ is transitive and each $N_{b,i}$ can be assumed to be a single entry. Also, for every α-decomposed extension we need to reduce, the matrices $[M_{\mathcal{C}}\ N_{\mathcal{C}}]$ and $[M_{\mathcal{D}}\ N_{\mathcal{D}}]$ must each present a set of isomorphic intervals. Then all row and column operations on C are possible and we can use normal matrix reduction ([26, Algorithm B.1]).

▶ **Theorem 23.** *The method outlined above decomposes interval decomposable modules in $\mathcal{O}(n^3)$ time where n is the number of generators and relations.*

7 Experiments

We have implemented our decomposition algorithm in a stand-alone C++ library AIDA. AIDA takes as input a minimal presentation in the form of a SCC2020 file[2] which can be generated, for instance, using the MPFREE library [42]. All experiments were performed on a workstation with an Intel(R) Xeon(R) CPU E5-1650 v3 CPU (6 cores, 12 threads, 3.5GHz) and 64 GB RAM, running GNU/Linux (Ubuntu 20.04.2) and gcc 9.4.0.

Test instances. We considered a large collection of data files [41] including chain complex data generated by various bifiltrations, including function-Rips, lower-star bifiltrations, and multi-covers – see [33]. Also included are chain complexes of function-alpha bifiltrations for various choices of point clouds and density functions as described in the paper of Alonso et al. [4]. We additionally generated test cases which are not based on bifiltration data by simple random processes that can create interval-decomposable or random presentation inspired by the Erdös-Renyi-model of random graphs ([26, Appendix A]). In total, the benchmark set contains around 1300 different minimal presentation files. Our benchmarks scripts, the version of AIDA that we have used, and the results of our experiments are available at [40].

Most instances in the above collection are distinctly graded, that is $k_{\max} = 1$. This is perhaps surprising because, for instance, function-alpha bifiltrations are generally not distinctly graded simplex-wise. Yet apparently their homology classes have unique degrees. A few instances also have $k = 2$ or $k = 3$, but the only instances with large values of k are the one coming from multi-cover bilfiltrations as described in [25].

Effectiveness of the speed-ups. We implemented our code such that some optimizations can be disabled to gauge their importance. Our first finding is that the column sweep optimization as described at the beginning of Section 3 has the most visible effect on practical performance. In Table 1, we display the running time for some representative instances. We observe that the improvement factor depends on the instance type and even varies a lot for instances of the same type (as the third and fourth row of the table indicate). However, the improvement was consistent over all considered examples.

We next consider the effect of the optimized computation of the system $(*)$. In many instances, this technique does not speed up the computation or even slightly slows it down, due to the technical overhead of solving $(*)$ first. However, the slow-down was never more than a factor of 2 in the experiments. On the other hand, for some instances, a speed-up is achieved; most significantly, this is the case for the off-datasets, which are triangular meshes in 3D bi-filtered along two of the coordinate axis (bottom half of Table 1). This happens

[2] `https://bitbucket.org/mkerber/chain_complex_format/src/master/`

Table 1 Running times (in seconds) for the algorithm in different configurations: "vanilla" means that no modification is enabaled. "+sweep" means that column sweep is enabled, "+homset" means that the separate and optimized computation of $(*)$ is enabled.

type	#Gens	#Rels	vanilla	+sweep	+homset
fun-alpha (kde)	10000	14014	118	0.39	0.42
fun-alpha (random)	6460	11154	7.64	0.37	0.33
random	800	782	6.85	2.12	3.31
random	800	776	54.0	2.54	3.03
off (hand)	595	596	508	0.96	0.02
off (eros)	2819	2820	>3600	22.7	0.40
off (dragon)	8229	8230	>3600	833	9.4
off (raptor)	7203	7186	>3600	1588	32.7

because this filtration tends to create the large but pointwise low-dimensional summands which we have optimized the computation for.

Empirical complexity. We demonstrate in Table 2 that AIDA is able to decompose presentations with hundreds of thousands of generators and relations within seconds in many practical cases. This is also true for non-distinctly graded cases: the bottom half of the table displays multi-cover instances where $k_{\max}$ is larger than 1 ($k_{\max} = 4$ on the left, $k_{\max} = 6$ on the right of the table). We also display the progression of AIDA's time and memory consumption when the input size (roughly) doubles. We can see that in some cases, AIDA scales almost linearly with the size of the input presentation (the upper-left and lower-right part of the table) whereas in other cases the time grows rather quadratically (the upper-right and lower-left part). We also observed instances with a super-quadratic growth in our experiments; nevertheless, the empirical behavior is much better than what the asymptotic bound predicts. This is not surprising for realistic sparse input matrices, in analogy to the persistence algorithm for one parameter, because matrix reduction is generally faster. Also the summands typically stay small, so that $(*)$ can be solved fast.

Table 2 Running time and memory of AIDA for large data sets. The top half are function-alpha bifiltrations for point clouds of a torus with kde function value, in homology dimension 0 and 1. The bottom half are multi-cover bifiltration of a random point sample, with presentations in homology dimension 2 and 1. All numbers are averaged over 5 instances.

dim	#Gens	#Rels	time	mem	dim	#Gens	#Rels	time	mem
0	5000	7431	0.11	17 MB	1	12410	19890	22.3	108 MB

	154400	308800	17.6	447 MB		74462	148924	1.95	218 MB

Comparison with other software. We are not aware of any other implementation for the special case of multi-graded persistence modules, but there exist some libraries that include a decomposition algorithm for modules over finite dimensional algebras, for example the

algorithm by Lux and Szöke [50] in the C-MeatAxe library. Since using this algorithm would require too many preprocessing steps, we instead used the decomposition algorithm for quiver representations in the QPA pacakge [54] for GAP [34] and implemented (also in the AIDA package) an algorithm to convert MPM to quiver representations. Our tests show that the QPA algorithm already needs several minutes for presentations with around 100 generators and relations and times out for all presentations we have considered for testing AIDA.

Speeding up barcode template computation. We demonstrate how decomposing a module can speed up computational tasks in multi-parameter persistence: barcode templates are a common tool to capture all combinatorial barcodes that arise from a 2-parameter module through restrictions to one parameter. Such a barcode template is computed via the arrangement of lines in the plane, arising from the joins of generators and relations of a module via point-line duality. It is evident that this construction is compatible with decomposition, meaning that if a module $M = M_1 \oplus M_2$ decomposes, the arrangements of M_1 and M_2 can be computed separately and then be overlaid.

We implemented a small test program that computes the barcode template using the arrangement package of CGAL [59] once for the undecomposed modules and once after applying AIDA. Table 3 shows that the arrangement size as well as the computation time drastically reduces when using AIDA. We remark that the variance of the aida arrangement in size was very large, leading to the effect that the average arrangment size even decreases in our sample. In either case, we speculate that incorporating AIDA would speed-up the visualization of persistence modules in RIVET and is a necessary preprocessing step in the exact computation of matching distances in practice.

Table 3 Running time for computing the barcode template of function-alpha bifiltrations of randomly sampled point in the unit square using random function values. The columns show the number of lines generated that define the arrangement, the number of vertices in the final arrangment and the time to compute it. All number are averages of 5 randomly generated instances.

			With AIDA			Without AIDA		
#points	#Gens	#Rels	#lines	V	time	#lines	V	time
20	18.4	28	24.6	210	0.002	176	6639	0.034
40	59	97	144	6295	0.026	1877	692K	3.50
60	99	166	382	39996	0.19	5096	5.076M	27.1
80	137	224	346	33301	0.16	8801	14.3M	81.8

8 Conclusion

AIDA is the first practical algorithm to decompose multi-parameter persistence modules. We emphasise that it works for any number of parameters (although all experiments were on 2 parameters) and should be adaptable to any other poset or acyclic quiver.

Our improvements are a consequence of a better understanding of MPM on the algebraic level. More speed-ups are possible; for instance, the faster computation of $\mathrm{Hom}(X, Y)$ that we employ is not the best possible and we plan to improve it further. We also believe that the algorithm from Section 6 should show improvement over the exhaustive algorithm of Section 5 for sparse input with larger $k_{\max}$ and non-sparse input also for smaller $k_{\max}$.

Abstract

In this paper, we study estimators for geometric optimization problems in the sublinear geometric model. In this model, we have oracle access to a point set with size n in a discrete space $[\Delta]^d$, where queries can be made to an oracle that responds to orthogonal range counting requests. The query complexity of an optimization problem is measured by the number of oracle queries required to compute an estimator for the problem. We investigate two problems in this framework, the Euclidean Minimum Spanning Tree (MST) and Earth Mover Distance (EMD). For EMD, we show the existence of an estimator that approximates the cost of EMD with $O(\log \Delta)$-relative error and $O(\frac{n\Delta}{s^{1+1/d}})$-additive error using $O(s \operatorname{polylog} \Delta)$ range counting queries for any parameter s with $1 \leq s \leq n$. Moreover, we prove that this bound is tight. For MST, we demonstrate that the weight of MST can be estimated within a factor of $(1 \pm \varepsilon)$ using $\tilde{O}(\sqrt{n})$ range counting queries.

1 Introduction

In recent years, the size of data encountered in various applications has grown exponentially. While classical algorithms are designed to process the entire input to get exact or approximate solutions, the increasing demand for *efficiency* in massive datasets necessitates approaches that can provide useful results without examining all of the input data. Motivated by this, a wide range of sublinear-time algorithms has been extensively studied over the past

few decades from various subfields in theoretical computer science. For instance, there are sublinear-time algorithms for the longest increasing subsequence and edit distance problems on strings [32, 34, 29], the triangle counting and vertex cover problems on graphs [10, 26, 38], Earth Mover's Distance on probability distributions [9], and minimum spanning tree on general metric spaces [22]. Moreover, there are sublinear-time algorithms for several fundamental geometric problems [16, 20, 21, 31, 35]. For further information, refer to [24, 39].

To obtain sublinear-time algorithms, we need an *oracle* to access the input data. There are various sublinear-time oracle models in the geometric setting although there are common oracles for strings, graphs and metric spaces. Chazelle et al. [16] presented several geometric algorithms assuming that the input is given without any preprocessing. In the case of point inputs, the only thing one can do is uniform sampling. In the case of polygons, one can also check if two edges are adjacent. Although they showed that several problems admit sublinear-time algorithms in this model, it seems not strong enough to solve a wider range of fundamental geometric problems such as the clustering problems, the Earth Mover's Distance problem, and the minimum spanning problem. Subsequently, many researchers developed sublinear-time algorithms for several different models. Examples are models in which the oracle can answer orthogonal range emptiness queries and cone nearest point queries [20], orthogonal range counting queries [21, 35], or separation queries [31].

In this paper, we study the *range counting oracle model* for geometric optimization problems. Here, we do not have direct access to the input point set, but instead we use an orthogonal range counting data structure for access. More specifically, given an orthogonal range as a query, it returns the number of input points contained in the query range. In fact, many database software systems, such as Oracle[1] and Amazon SimpleDB[2], provide built-in support for such range queries. These queries allow users to compute aggregates, such as the count, sum, or average of records that fall within a specified range of values for a set of attributes, which is crucial for a wide array of applications. For example, in data analytics, range queries are used to calculate the number of sales within a specific date range or determine the total revenue from products within a given price interval. In geographic information systems (GIS), range queries help aggregate spatial data points within certain coordinate bounds, such as counting the number of locations within a specific radius of a given point. Furthermore, in machine learning, range queries are employed during data preprocessing to summarize statistics over selected subsets, which supports tasks such as data filtering and dimensionality reduction.

The following are desirable properties for a reasonable oracle model: the queries to the oracle should be efficient to implement, it is preferable for it to be supported by lots of well-known databases, and it should allow sublinear-time algorithms for fundamental geometric problems. First, this model clearly satisfies the first property; there are numerous works on data structures for range counting queries and their variants [2, 7, 14, 15, 13, 25, 40]. In particular, one can preprocess a set of n points in $\mathbb{R}^d$ in $O(n \log^{d-1} n)$ time to construct a data structure of size $O(n \log^{d-1} n)$ so that the number of points inside a query range can be found in $O(\log^{d-1} n)$ time. Second, range counting queries are already supported by well-known public databases as we mentioned earlier. Therefore, without any special preprocessing, we can apply sublinear-time algorithms designed on the range counting oracle for such databases in sublinear time. Third, we show that several fundamental problems can be solved in sublinear time on the range counting oracle model in this paper.

Table 1 Summary of our results. Here, n denotes the number of points, and Δ denotes the size of the domain. For EMD, a parameter s determines a trade-off between the additive error and the query complexity.

		Additive Error	Multiplicative Error	Query Complexity
EMD	UB	$O(n\Delta/s^{1+1/d})$	$O(\log \Delta)$	$\tilde{O}(s)$
	LB	$\Omega(n\Delta/s^{1+1/d})$	–	$\tilde{O}(s)$
Cell Sampling	UB	–	$1 \pm \varepsilon$	$\tilde{O}(\sqrt{n})$
	LB	–	$O(1)$	$\Omega(\sqrt{n})$
MST	UB	–	$1 \pm \varepsilon$	$\tilde{O}(\sqrt{n})$
	LB	–	$O(1)$	$\Omega(n^{1/3})$

We focus on the following three fundamental geometric problems: the Earth Mover's Distance problem, the minimum spanning tree problem, and the cell sampling problem. The Earth Mover's Distance $\mathsf{EMD}(R, B)$ between two point sets R and B in $\mathbb{R}^d$ and the cost $\mathsf{MST}(P)$ of a minimum spanning tree of a point set $P \in \mathbb{R}^d$ are defined as follows.

$$\mathsf{EMD}(R, B) = \min_{\pi: R \to B} \sum_{r \in R} \|r - \pi(r)\| \quad \text{and} \quad \mathsf{MST}(P) = \min_{T} \sum_{uv \in E(T)} \|u - v\|,$$

where π ranges over all one-to-one matchings between R and B, and T ranges over all spanning trees of P. If we have direct access to the input point set(s), then $\mathsf{EMD}(R, B)$ can be computed exactly in near quadratic time in $\mathbb{R}^2$ [4], and approximately within $(1 + \varepsilon)$-relative error in near linear time [3]. Similarly, $\mathsf{MST}(P)$ can be computed exactly in near quadratic time by computing the complete graph on P and applying Kruskal's algorithm, and computed approximately in near linear time [30]. Note that EMD can be used for measuring the similarity between two point sets, and MST can be used for summarizing the distribution of a point set. Thus these problems have various applications in multiple areas of computer science including computer vision [11], machine learning [27] and document similarity [33].

The cell sampling problem is defined as follows. Let P be a set of points in a discrete space $[\Delta]^d$. Given a value r with $1 \leq r \leq \Delta$, let $\mathcal{G}$ be the grid imposed on $[\Delta]^d$ whose cells have side length r. We say a grid cell is *non-empty* if it contains a point of P. Our goal is to sample one non-empty cell almost uniformly at random from the set of all non-empty cells of $\mathcal{G}$. If we have direct access to P, this problem is trivial as we can compute all non-empty cells explicitly. However, in our sublinear model, we cannot compute all non-empty cells if the number of non-empty cells exceeds our desired query complexity. We believe that cell sampling can be considered as a fundamental and basic primitive in sublinear models as sublinear algorithms rely on efficient sampling to extract meaningful information from large data sets. In fact, this problem has been studied in the dynamic streaming model, and has been used as a primitive for several geometric problems [28, 36] and graph problems [19].

Our results. We present sublinear-time algorithms for EMD, Cell Sampling, and MST in the orthogonal range counting oracle model. Our results are summarized in Table 1.

- For EMD, we present an algorithm for estimating the Earth Mover's Distance between two point sets of size n in $[\Delta]^d$ within a multiplicative error of $O(\log \Delta)$ in addition to an additive error of $O(n\Delta/s^{1+1/d})$. Our algorithm succeeds with a constant probability, and uses $\tilde{O}(s)$ range counting queries for any parameter s. Notice that the optimal solution can be as large as $\Theta(n\Delta)$, and in this case, the additive error is relatively small. Furthermore, we show that this trade-off is tight for any parameter s.

- For Cell Sampling, we present an algorithm that samples a non-empty cell in a grid so that the probability that a fixed non-empty cell is selected is in $[(1-\varepsilon)/m, (1+\varepsilon)/m]$ for any constant $0 < \varepsilon < 1$. Here m denotes the number of non-empty cells. We also show that the query complexity here is tight. Moreover, if we sample $\tilde{O}(\sqrt{n}\log(n))$ non-empty cells, we can estimate the number of non-empty cells within $(1 \pm \varepsilon)$-factor.
- For MST, we present an algorithm for estimating the cost of a minimum spanning tree of a point set of size n in $[\Delta]^2$ within a multiplicative error of $1 \pm \varepsilon$. Our algorithm again succeeds with constant probability, and uses $\tilde{O}(\sqrt{n})$ range counting queries. Also, we show that any randomized algorithm using $o(n^{1/3})$ queries has at least a constant multiplicative error.

Related work. Both EMD and MST have been extensively studied across various sublinear models over the past few decades. The work most closely related to ours is the one by Czumaj et al. [20]. They studied the Euclidean minimum spanning tree problem in a different model. In particular, their oracle supports *cone nearest* queries, *orthogonal range emptiness* queries, and *point sampling* queries.[3] Here, given a cone nearest query consisting of a cone C with apex p, the oracle returns $(1+\delta)$-approximate nearest neighbor of p in $C \cap P$, where P is the set of input points. Using $\tilde{O}(\sqrt{n})$ queries, their algorithm estimates the cost of the MST of n points within a relative error of $(1 \pm \varepsilon)$. Moreover, they showed that if the oracle supports orthogonal emptiness queries only, then any deterministic algorithm for estimating the cost of MST within $O(n^{1/4})$-relative error uses $\Omega(\sqrt{n})$ orthogonal range emptiness queries. Sublinear time algorithms for computing a metric minimum spanning tree problem have also been studied [23]. Here, the oracle supports *distance* queries: Given two points, it returns their distance in the underlying space. The most popular sublinear-*space* model is the streaming model. In this model, the input arrives as data stream, and an algorithm is restricted to using a sublinear amount of memory relative to the input size. Both EMD and MST are studied extensively in this model [5, 18, 28], showcasing the challenges and techniques for processing large datasets in the steaming model.

Although no sublinear algorithms for EMD and MST were known in the range counting oracle model prior to our work, other geometric optimization problems have been studied in this model. Monemizadeh [35] presented an algorithm for the facility location problem using $\tilde{O}(\sqrt{n})$ queries, and Czumaj and Sohler [21] studied clustering problems and map labeling problems. To the best of our knowledge, these are the only work done in the range counting oracle model. However, there are several closely related models such as the range-optimization model. For instance, Arya et al. [8] studied the range MST problem, where the goal is to construct a data structure for computing the cost of MST within a query orthogonal range. In this setting, clustering problems also have been considered [1, 37].

Preliminaries. We make use of quadtrees for both EMD and MST. Consider a discrete space $[\Delta]^2$. For $i \in \{0, 1, \ldots, \log \Delta\}$, we use $\mathcal{G}_i$ to denote a grid over the discrete space $[\Delta]^2$ consisting of cells with side lengths of 2^i. A quadtree $\mathcal{Q}$ on $[\Delta]^2$ is then constructed as follows. The root of the quadtree corresponds to the unique cell of $\mathcal{G}_{\log \Delta}$. For each node v of the quadtree of depth i has four equal sized children, each corresponding to a cell in $\mathcal{G}_{i-1}$ contained in the cell corresponding to v. Note that the depth of $\mathcal{Q}$ is $O(\log \Delta)$. If it is clear from the context, we use a node of the quadtree and its corresponding cell interchangeably.

[3] More precisely, the oracle supports cone nearest queries and orthogonal range queries only, but they are also given the access to the input point set, which allow them to sample a vertex uniformly at random.

Let P be a point set in $[\Delta]^d$. For both EMD and MST we will use binary search in combination with range counting queries to find the k^{th} smallest point in dimension $i \leq d$. Furthermore, we will often want to sample a point from P uniformly at random. We can do so using $O(\log \Delta)$ range counting queries in a procedure called *telescoping sampling* [35].

▶ **Lemma 1** (Telescoping Sampling [35]). *We can select a point of P uniformly at random using $O(\log \Delta)$ range counting queries.*

Throughout this paper, we use $\tilde{O}(f(s))$ to denote $O(f(s) \operatorname{polylog} \Delta)$. Due to space restrictions, some proofs are omitted; they can be found in the full version of the paper.

2 Sublinear algorithms for the Earth Mover's Distance problem

In this section, we present several sublinear-time algorithms that approximate the cost of the Earth Mover's Distance between two point sets in $[\Delta]^d$ for an integer $d \geq 1$. The approximation bounds we obtain are tight up to a factor of $O(\log \Delta)$ for any integer $d \geq 1$.

In a one-dimensional space, we know the configuration of an optimal matching: the kth leftmost red point is matched with the kth leftmost blue point for all $1 \leq k \leq n$. Thus it suffices to estimate the cost of this matching. On the other hand, we do not know the exact configuration of an optimal matching in a higher dimensional space. Thus instead of considering an optimal matching, we consider a matching of cost $O(\mathsf{OPT} \log \Delta)$, where OPT is the Earth Mover's Distance between two point sets. This is where the multiplicative error of $O(\log \Delta)$ comes from. Apart from this, we use the same approach for all dimensions $d \geq 1$.

2.1 A sublinear algorithm for points in 1D

In this section, we present a sublinear algorithm using $\tilde{O}(s)$ range counting queries in a one-dimensional space. More precisely, we prove the following theorem. The optimal solution can be as large as $\Theta(n\Delta)$, and in this case, the additive error is relatively small.

▶ **Theorem 2.** *Given two sets R and B of size n in a discrete space $[\Delta]$ and a parameter $s > 1$, we can estimate the cost of the Earth Mover's Distance between R and B within $O(1)$ multiplicative error in addition to $O(\frac{\Delta n}{s^2})$ additive error with probability at least $2/3$ using $\tilde{O}(s)$ range counting queries.*

If no two points coincide, we have $\mathsf{OPT} \geq n$. Therefore, we have the following corollary.

▶ **Corollary 3.** *Given two sets R and B of size n in a discrete space $[\Delta]$ such that no two points of $R \cup B$ coincide, and a parameter $s > 1$, we can estimate the cost of the Earth Mover's Distance between R and B within $O(\frac{\Delta}{s^2})$ multiplicative error with probability at least $2/3$ using $\tilde{O}(s)$ range counting queries.*

Let $R = \{r_1, r_2, \ldots, r_n\}$ and $B = \{b_1, b_2, \ldots, b_n\}$ be two sets in $[\Delta]$ sorted along the axis. Let M be an optimal matching between R and B. We separate two cases: *long* edges and *short* edges. An edge of M is *long* if its length is at least Δ/s, and it is *short*, otherwise. Let OPT be the Earth Mover's Distance between R and B.

We employ the following *win-win* strategy: For a long edge, a slight perturbation of its endpoints introduces only a constant relative error. Thus, we move its endpoints to the center of a grid, enabling us to estimate the total length efficiently. For short edges, we can disregard cases where the number of such edges is small, as this results in only a small additive error. Consequently, we may assume that the number of short edges is large,

allowing us to estimate their total length using sampling. To further reduce the additive error, we partition the set of short edges into $\log(\Delta/s)$ subsets based on edge length and then consider each subset separately.

Long edges. For long edges, we subdivide $[\Delta]$ into segments each of length $\Delta/(2s)$. For each long edge (r_i, b_i), imagine that we move r_i and b_i to the centers of the segments containing them. Since (r_i, b_i) is long, this introduces an additive error of $O(\Delta/s)$, resulting in a constant relative error. Using this fact, we estimate the total length of all long edges within a constant relative error using $\tilde{O}(s)$ range counting queries. Let L_{long} be the resulting estimator.

▶ **Lemma 4.** *We can estimate the total length of the long edges in M within $O(1)$ multiplicative error using $\tilde{O}(s)$ range counting queries.*

Proof. We subdivide $[\Delta]$ into s segments each of length $\Delta/(2s)$. Here, the number of segments is $O(s)$. Let $\mathcal{S}$ be the set of the resulting segments. Then a long edge contains at least one segment. Imagine that we move every point p incident to a long edge to the center of the segment containing p. For each segment S, we compute the number $n_r(S)$ of red points contained in S and the number $n_b(S)$ of blue points contained in S, respectively, using $O(s)$ queries. Then we construct another point set P' by adding $n_r(S)$ red points to the center of S and adding $n_b(R)$ blue points to the center of S. We can do this without using queries. For a point $p \in R \cup B$, let p' be the its corresponding point in P'. Then consider the matching $M' = \{(r', b') \mid (r, b) \in M\}$. We can compute M' explicitly without using any queries. Let M'_{long} be the set of edges of M' containing at least one segment of $\mathcal{S}$. A long edge of M has its corresponding edge in M'_{long}. However, some short edge of M might have its corresponding edge in M'_{long}. Here, observe that the short edges of M having their corresponding edges in M'_{long} have length at least $\Delta/(2s)$, thus the cost induced by those edges are also within a constant factor of OPT. They will be also counted for short edges, but this also increases the total cost by a constant factor. Therefore, the lemma holds. ◀

Short edges. For short edges, we use random sampling. More specifically, we subdivide the set of short edges into $t = \log(\Delta/s)$ subsets with respect to their lengths: $E_1, E_2, \ldots, E_t$, where E_i is the set of all edges of M of lengths in $[2^{i-1}, 2^i)$. Then we estimate the *number* of edges of E_i for every index i. To do this, we choose a random sample of R of size $x = O(s \log^2 \Delta)$. For each chosen point, we can find its mate. Let S_i denote the set of all edges between the sampled points and their mates. If $|E_i| \geq n/(s \log \Delta)$ then the number of edges in $E_i \cap S_i$ would be a good estimator for $|E_i|$. Otherwise, we can ignore them as E_i induces an additive error of at most $\Delta n/(s^2 \log \Delta)$. This is because every short edges has length at most Δ/s. Let $\ell_i = |E_i \cap S_i| \cdot (n/x)$. Then we have the following lemma.

▶ **Lemma 5.** *If $|E_i| \geq n/(s \log \Delta)$, we have $\ell_i = \Theta(|E_i|)$ with a constant probability. Otherwise, we have $\ell_i \leq O(|E_i|)$ with a constant probability.*

Proof. Let Y_j be the random variable where $Y_j = 1$ if the jth edge in S_i is contained in E_i, and $Y_j = 0$ otherwise. Let $Y = Y_1 + \ldots + Y_x$, where $x = s \log^2 \Delta$ is the number of sampled points. By definition, we have $\mathbb{E}[Y_j] = \frac{|E_i|}{n}$, and $\mathbb{E}[Y] = x \cdot \frac{|E_i|}{n}$. Now we analyze the failure probability. If $|E_i| \geq n/(s \log \Delta)$, we use Chernoff bounds. Then the probability that $|\mathbb{E}[Y] - Y| \geq \varepsilon \mathbb{E}[Y]$ is at most $2\exp(-\varepsilon^2 \cdot p \cdot (s \log^2 \Delta)/3)$, where p is the probability that $Y_j = 1$. In our case, $p = |E_i|/n \geq 1/(s \log \Delta)$. Thus the failure probability is at most $1/\Delta$ in this case. If $|E_i| < n/(s \log \Delta)$, we use Markov's inequality. Then the probability that $Y_i \geq c|E_i|$ is less than a small constant for a large constant c. Therefore, the second part of the lemma also holds. ◀

To amplify the success probability of Lemma 5, we repeat the procedure for computing ℓ_i $O(\log \Delta)$ times. Then we take the minimum, and let $L = \sum_{i=1}^{t} 2^i \cdot \ell_i + L_{\text{long}}$.

▶ **Lemma 6.** *With a constant probability,* $(1/4) \cdot \mathsf{OPT} - n\Delta/s^2 \leq L \leq 4 \cdot \mathsf{OPT} + n\Delta/s^2$.

Proof. Since we can estimate the total length of long edges with an additive error of $2 \cdot \mathsf{OPT}$, it suffices to focus on short edges. For each edge of E_i, we round up its length to 2^i. This induces the additive error of $2 \cdot \mathsf{OPT}$. Now we use Lemma 5. Consider the event that we have the desired bounds for all indices i in Lemma 5. Due to the amplification of success probability we made before, this total success probability is a constant. If $|E_i| \geq (n/(s \log \Delta)$, the estimator ℓ_i has an error of $O(1) \cdot \mathsf{OPT}$ in total for all such indices. If $|E_i| < n/(s \log \Delta)$, we do not have a lower bound guarantee for ℓ_i. However, since the number of such edges is n/s in total, and the length of each such edge is Δ/s, this induces the additive error of $n\Delta/s^2$. Therefore, the total additive error is $n\Delta/s^2$. ◀

2.2 A sublinear algorithm for higher dimensions

In this section, we present a sublinear algorithm that approximates the cost of the Earth Mover's Distance between two point sets in $[\Delta]^d$ for an integer $d \geq 2$. More specifically, we prove the following theorem. Again, notice that the Earth Mover's Distance between two point sets can be as large as $\Theta(\Delta n)$ in the worst case.

▶ **Theorem 7.** *Given two sets R and B of size n in a discrete space $[\Delta]^d$ and a parameter $s > 1$, we can estimate the cost of the Earth Mover's Distance between R and B within $O(\log \Delta)$-relative error in addition to $O(\frac{\Delta n}{s^{1+1/d}})$ additive error with probability at least $2/3$ using $\tilde{O}(s)$ range counting queries.*

If no two points coincide, we have $\mathsf{OPT} \geq n$. Therefore, we have the following corollary.

▶ **Corollary 8.** *Given two sets R and B of size n in a discrete space $[\Delta]^2$ and a parameter $s > 1$ such that no two points in $R \cup B$ coincide, we can estimate the cost of the Earth Mover's Distance between R and B within $O(\max\{\log \Delta, \frac{\Delta}{s^{1+1/d}}\})$-relative error with probability at least $2/3$ using $\tilde{O}(s)$ range counting queries.*

Let OPT be the Earth Mover's Distance between R and B. This algorithm is essentially the same as the algorithm for the one-dimensional case. The only difference is that we do not know the configuration of an optimal matching in a higher dimensional space. Instead, we can use a matching obtained from the quadtree on $[\Delta]^d$, which has cost of $O(\log \Delta) \cdot \mathsf{OPT}$. Then as before, we separate two cases. If an edge has length at least $\Delta/s^{1/d}$, it is *short*. Otherwise, it is *long*. Then we can compute all long edges exactly, and we can estimate short edges using sampling. Details can be found in the full version of this paper.

3 Lower bounds for the Earth Mover's Distance

In this section, we show that for any parameter s, any randomized algorithm that approximates the Earth Mover's Distance between two sets within an additive error of $O(n\Delta/s^{1+1/d})$ requires at least s orthogonal range counting queries. More specifically, we prove:

▶ **Lemma 9.** *For any parameter s and any integers $d \geq 1$ and $\Delta \geq 1$, any randomized algorithm for approximating the Earth Mover's Distance between two point sets of size n in a discrete space $[\Delta]^d$ within additive error $O(n\Delta/s^{1+1/d})$ uses $\Omega(s)$ range counting queries.*

(a) (b)

Figure 1 (a) All segments use the near gadget. The cost of this instance is n. (b) The gray segment uses the far gadget. The cost of this instance is $\Theta(n\Delta/s^2)$.

If points from $B \cup R$ may coincide, achieving any multiplicative approximation factor is impossible. Even when no two points of $B \cup R$ coincide, Lemma 9 shows that no randomized algorithm with a multiplicative error of $O(\Delta/s^{1+1/d})$ uses $o(s)$ range counting queries.

3.1 A lower bound for points in 1D

In this section, we prove Lemma 9 in the one-dimensional space. This will be extended for a higher dimensional space later. To analyze the lower bound on the additive error of a Monte Carlo algorithm, we use the following version of Yao's Minmax Theorem [6]: Assume that there exists a randomized algorithm using s range counting queries with success probability at least $2/3$. Then for any distribution μ of instances, there exists a deterministic algorithm using s range counting queries that returns desired answers on instances chosen from μ with probability at least $2/3$. Here, the success probability of a randomized algorithm is the probability that the output is within our desired bound.

Thus it suffices to construct a distribution μ of instances such that no deterministic algorithm using s range counting queries has success probability at least $2/3$. For this, we define two types of gadgets on a segment S of length $\Delta/(8s)$: the *near* gadget and *far* gadget. See Figure 1. For the far gadget, we put $4n/s$ red points near the left endpoint of S and $4n/s$ blue points near the right endpoint of S. For the near gadget, we put $2n/s$ red points and $2n/s$ blue points alternately starting from the left endpoint of S so that the distance between any two consecutive points is one, and the starting point lies in the left endpoint of S. Additionally, we put $2n/s$ red points and $2n/s$ blue points alternately so that the distance between any two consecutive points is one, and the last point lies in the right endpoint of S. Notice that the cost induced by the near gadget is $\Theta(n/s)$, but the cost induced by the far gadget is $\Theta(n\Delta/s^2)$. Our strategy is to place $O(s)$ copies of the near gadget inside $[\Delta]$ and to hide one far gadget inside $[\Delta]$ with probability $1/2$. In this way, we can construct two types of instances, one with cost n and one with cost $\Theta(n\Delta/s^2)$.

More specifically, we define a distribution μ of instances as follows. We partition $[\Delta]$ into $8s$ segments each of length $\Delta/(8s)$. Let $\mathcal{S} = \{S_1, S_2, \ldots, S_{8s}\}$ be the set of resulting segments along the axis. See Figure 1. With probability $1/2$, we let $t = 0$. Then with probability $1/2$, we choose one index t from $1, 2, \ldots, s$ uniformly at random. That is, the probability that a fixed index i is chosen is $1/(16s)$ for $i = 1, 2, \ldots, 8s$. Then for each index $i \neq t$, we place the near gadget on S_i. For index $i = t$, we place the far gadget on S_i. Notice that we do not place the far gadget anywhere if $t = 0$. Thus it suffices to show that, for any deterministic algorithm using s range counting queries, the probability that it estimates the cost of OPT within an additive error of $O(n\Delta/s^2)$ on the instances chosen from μ is less than $2/3$.

▶ **Lemma 10.** *For any deterministic algorithm using s range counting queries, the probability that it estimates the cost of an instance chosen from μ within an additive error of $O(n\Delta/s^2)$ is less than $2/3$.*

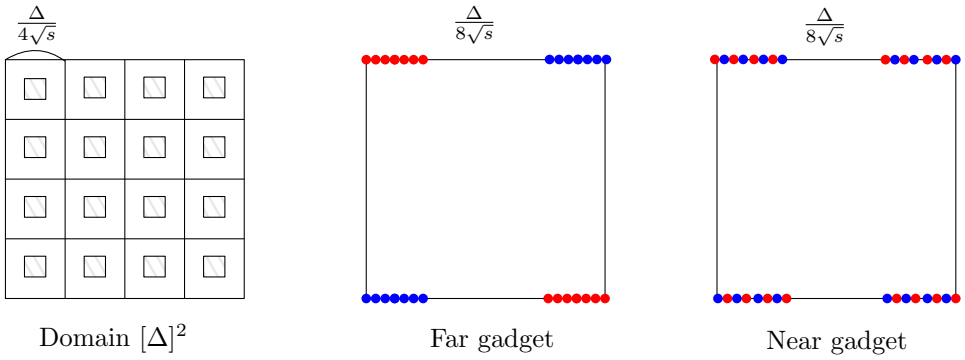

Figure 2 We partition $[\Delta]^2$ into $16s$ squares. In each square, we place either the far gadget or the near gadget. The cost of the far gadget is at least $n\Delta/s^2$, and the cost of the near gadget is $\Theta(n/s)$.

3.2 Lower bounds for dimensions 2 and higher

We now extend the construction of the 1D case to the 2D case. We again use Yao's Minmax Theorem. Thus it suffices to construct a distribution μ of instances such that no deterministic algorithm using s range counting queries has success probability at least $2/3$.

For this, we define two types of gadgets on a square S of side length $\Delta/(8\sqrt{s})$: the *near* gadget and *far* gadget. See Figure 2. For the far gadget, we put two copies of the far gadget constructed from the 1D case, one on the upper side of S and one on the lower side of S, so that a red point comes first in the upper side, and a blue point comes first in the lower side. For the near gadget, we do the same: Put two copies of the near gadget constructed from the 1D case, one on the upper side and one on the lower side, so that a red point comes first in the upper side, and a blue point comes first in the lower side. In this way, every gadget has $8n/s$ red points and $8n/s$ blue points.

Now define a distribution μ of instances as follows. We construct the grid on $[\Delta]^2$ consisting of $16s$ cells each of side length $\Delta/(4\sqrt{s})$. See Figure 2. We choose a cell W as follows. With probability $1/2$, we let $W = \emptyset$. Then with probability $1/2$, we choose one cell from the $16s$ cells uniformly at random, and let it W. Then for each cell in the grid, except for W, we place the near gadget in the middle of the cell. Then we place the far gadget in the middle of W. Notice that we do not place the far gadget anywhere if $W = \emptyset$. Thus it suffices to show that, for any deterministic algorithm using s range counting queries, the probability that it estimates the cost of OPT within an additive error of $O(n\Delta/s^{1.5})$ on an instance chosen from μ is less than $2/3$. We can prove this similarly to Lemma 10.

▶ **Lemma 11.** *For any deterministic algorithm using s range counting queries, the probability that it estimates the cost of an instance chosen from μ within an additive error of $O(n\Delta/s^{1.5})$ is less than $2/3$.*

Extension to a higher dimensional space. The construction of an input distribution used in the two-dimensional case can be easily extended to a higher dimensional space. We again define two gadgets on a d-dimensional cube S of side length $\Delta/(4s^{1/d})$. For the far gadget, we put two copies of the far gadget we constructed from the $(d-1)$-dimensional case, one on one facet of S and one on its parallel facet of S. We do the same for the near gadget using two copies of the near gadget we constructed from the $(d-1)$-dimensional case. Then we can define a distribution of instances as we did for the two-dimensional space. Details can be found in the full version of this paper.

4 Sampling a non-empty cell uniformly at random

In this section, we show how to sample a grid cell (almost) uniformly at random from all grid cells containing points of P. Let $\mathcal{G}$ be a grid of certain side length r imposed on the discrete space $[\Delta]^2$. Let $\mathcal{C} = \{c_1, c_2, \ldots, c_m\}$ denote the set of all grid cells of $\mathcal{G}$ containing points of P. We say such cells are *non-empty*. For each cell c_i, we let n_i denote the number of points contained in c_i. Here, we say sampling is *c-approximate* uniform if the probability that each non-empty cell is chosen is in $[1/(cm), c/m]$ for a constant c with $c > 1$. Or, we simply say sampling is *almost* uniform.

One might want to use the telescoping sampling of Lemma 1 directly: In particular, we choose a point v of P uniformly at random, and return the cell of $\mathcal{G}$ containing v. However, the probability that a cell c_i is chosen in this way is n_i/n, not $1/m$. So, instead, we use a two-step sampling procedure as stated in Algorithm 1. Here, we are required to check if it has at most $\sqrt{n}$ non-empty cells. If so, we need to find all of them explicitly. This can be done $O(\sqrt{n}\log\Delta)$ range counting queries:

▶ **Lemma 12.** *If the number of non-empty cells is $O(\sqrt{n})$ we can compute all of them using $O(\sqrt{n}\log\Delta)$ range counting queries.*

Algorithm 1 CellSampling(r).

1: Let $\mathcal{G}$ be the grid of side length r imposed on the discrete space $[\Delta]^2$.
2: **if** the number of non-empty cells of $\mathcal{G}$ is at most $\sqrt{n}$ **then**
3: Let $\mathcal{C}$ be the set of non-empty cells of $\mathcal{G}$.
4: Return a cell chosen from $\mathcal{C}$ uniformly at random.
5: **else**
6: Select a set T of $x = \sqrt{n}\log n$ points from P uniformly at random.
7: Let n_p be the number of points of P contained in the cell of $\mathcal{G}$ containing p.
8: Assign weight $w(p) = \frac{n}{xn_p}$ to p.
9: Let $m' = \sum_{p\in T} w(p)$ denote the total weight of all points in T.
10: Sample a point p from T with probability $\frac{w(p)}{m'}$.
11: Return the cell of $\mathcal{G}$ containing p.

▶ **Lemma 13.** CellSampling(r) *selects a cell almost uniformly at random from all non-empty cells of $\mathcal{G}$ using $\tilde{O}(\sqrt{n})$ range counting queries.*

▶ **Corollary 14.** *We can estimate the number of non-empty cells within an $O(1)$-relative error using $\tilde{O}(\sqrt{n})$ range counting queries.*

Lower bound. Now, we show that any randomized algorithm that can perform c-approximate uniform sampling for non-empty cells requires at least $\Omega(\sqrt{n}/c)$ range counting queries for any parameter $c \geq 1$. Our lower bound holds even in a discrete one-dimensional space $[\Delta]$ with $\Delta \geq n$. We assume that we have an interval L of length $\Delta \geq n$ consisting of n cells each of length Δ/n. We subdivide L into $\sqrt{n}/(4c)$ segments each of length $4c\Delta/\sqrt{n}$. Let $\mathcal{S}$ be the set of the segments for the line segment L. In this way, each segment in S contains $(4c\Delta/\sqrt{n})/(\Delta/n) = 4c\sqrt{n}$ cells. We construct a set $\mathcal{I}$ of $\sqrt{n}/(4c) + 1$ instances as follows.

We construct one *uniform* instance of L. In this instance, for each segment $S \in \mathcal{S}$, we identify its leftmost cell and place $4c\sqrt{n}$ points in that cell. Therefore, each uniform instance contains $\sqrt{n}/(4c)$ non-empty cells (one corresponding to each segment) while maintaining a total of n points per uniform instance.

Next, we construct $\sqrt{n}/(4c)$ *non-uniform* instances of L. For the i^{th} non-uniform instance, we select the i^{th} segment, which we refer to as the *witness segment*. In the leftmost cell of this witness segment, we place $2c\sqrt{n}$ points. Additionally, in each of the next $2c\sqrt{n}$ cells following the leftmost cell, we place one point per cell. For each of the remaining $\sqrt{n}/(4c)-1$ non-witness segments, we place $4c\sqrt{n}$ points in the leftmost cell of each segment, as we did for the uniform instance. In this way, every non-uniform instance has $2c\sqrt{n}+1+\sqrt{n}/(4c)-1 = 2c\sqrt{n}+\sqrt{n}/(4c)$ non-empty cells and contains $4c\sqrt{n}\cdot(\sqrt{n}/(4c)-1)+2c\sqrt{n}+2c\sqrt{n} = n$ points in total. Thus, the ratio of the number of non-empty cells between a non-uniform instance and a uniform instance is $(2c\sqrt{n}+\sqrt{n}/(4c))/(\sqrt{n}/(4c)) = 8c^2+1$. For both instances see Figure 3.

▶ **Lemma 15.** *Given an instance I from $\mathcal{I}$, any randomized algorithm that determines whether I is uniform with a success probability of at least $2/3$ requires $\Omega(\sqrt{n}/c)$ range counting queries.*

▶ **Lemma 16.** *Any algorithm that can perform c-approximate uniform sampling for non-empty cells requires $\Omega(\sqrt{n}/c)$ range counting queries for any parameter $c \geq 1$.*

5 Estimating the cost of a minimum spanning tree

Let $P \subseteq [\Delta]^2$ be a set of n points. In this section, we present a $(1+\varepsilon)$-approximation algorithm for estimating the cost OPT of a minimum spanning tree of P that uses $\tilde{O}(\sqrt{n})$ range counting queries. The algorithm is randomized and succeeds with a constant probability. We then show that any randomized constant-factor approximation algorithm requires $\Omega(n^{1/3})$ range counting queries.

5.1 Algorithm for the minimum spanning tree problem

For general graphs, Chazelle, Rubinfeld, and Trevisan [17] presented a $(1+\varepsilon)$-approximation algorithm for estimating the cost of a minimum spanning tree of a graph G. This so-called CRT algorithm uses two types of oracles: we need to sample a vertex of G uniformly at random, and we need to access the list of the neighbors of each vertex. If the average degree of G is d, and the edge weights of G come from $\{1,\ldots,w\}$, then the running time of this algorithm is $O(dw\varepsilon^{-2}\log(dw/\varepsilon))$. Our algorithm is based on the CRT algorithm. As it works for graphs with bounded average degree, we use a quadtree-based $(1+\varepsilon)$-spanner S of P

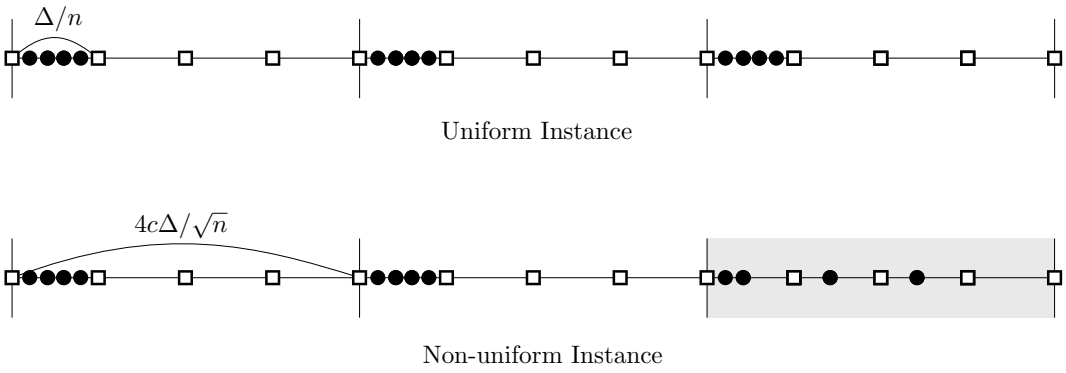

Figure 3 Illustration for the uniform instance and a non-uniform instance. The gray segment is the witness of the non-uniform instance.

introduced by [12]. Here, the maximum degree of S is $O(\log \Delta)$, and the cost of a minimum spanning tree of P is within $(1+\varepsilon)$ to the cost of a minimum spanning tree of S as shown in [30]. Thus it suffices to estimate the cost of a minimum spanning tree of S.

However, a main issue here is that the running time depends on the maximum edge weight, which is Δ in our case. To handle this, we need to look at the CRT algorithm more carefully. As we will see later, the problem reduces to the problem of estimating the number c_i of components of S_i for every $i \in \{0, 1, \ldots, \log_{1+\varepsilon}(2\Delta)\}$, where S_i denotes the subgraph of G induced by edges of length less than $(1+\varepsilon)^i$. To do this, the CRT algorithm samples ε^{-2} vertices from $V(S_i)$, and computes the number of edges contained in the component of S_i containing each sampled vertex v. If v is contained in a small component, we can traverse S_i until we visit all vertices of the component. If v is contained in a large component, we cannot compute this. In this case, we ignore it. This induces the additive error of $\varepsilon(1+\varepsilon)^i \cdot (n/t)$ to the final estimator, where t is the size threshold between large components and small components. To get an approximation factor of $1+\varepsilon$, we need to set $t = \Delta$, which is too large for our purpose. Note that we need to traverse a component of size t, which requires at least t queries. Here, the factor of n/t in the additive error indeed the number of components we cannot traverse using $O(t)$ queries.

Our strategy here is to traverse S_i in a *cell-by-cell* manner. More specifically, we consider a grid $\mathcal{G}$ of side length $(1+\varepsilon)^i/2$, and contract all vertices of S_i in a single cell of $\mathcal{G}$ into a vertex. Then using the same number of queries, we can visit more of the original vertices. By a careful analysis, we can reduce the additive error to $\varepsilon(n/t) \leq \varepsilon \cdot \mathsf{OPT}$. This idea was already used by [28] for maintaining the cost of the minimum spanning tree in the dynamic streaming setting.[4] However, this raises a new issue: we need to sample a *cell containing a point of P* uniformly at random. Here, we can use Lemma 13 to choose a random sample from vertices of S'_i.

Then we have the following lemma. Details can be found in the full version of this paper.

▶ **Theorem 17.** *Given a set P of size n in a discrete space $[\Delta]^2$, we can estimate the cost of a minimum spanning tree of P within a factor of $(1+\varepsilon)$ with a constant probability using $\tilde{O}(\sqrt{n})$ range counting queries.*

5.2 Lower bound for the minimum spanning tree problem

In this section, we show that any randomized constant-factor approximation algorithm for the Euclidean minimum spanning tree problem uses $\Omega(n^{1/3})$ range counting queries. For this, we construct a distribution μ of instances where any randomized algorithm using $o(n^{1/3})$ queries fails to obtain a constant-factor approximate solution with probability at least $1/3$.

Let $[\Delta]^2$ be a discrete domain with $\Delta = O(n)$. We subdivide $[\Delta]^2$ into $16n^{1/3}$ equal-sized cells where each has side length $4n^{5/6}$. See Figure 4. In the middle of each cell, we place either the *strip* gadget or the *uniform* gadget. Each gadget is defined on the domain $[n^{5/6}]^2$ which we further subdivide into $n^{4/3}$ finer cells of side length $n^{1/6}$. For the strip gadget, we put one point to each finer cell on one diagonal of $[n^{5/6}]^2$. For the uniform gadget, we put one point to the cell in the i-th row and the $((i \cdot n^{1/3}) \mod n^{2/3})$-th column for $i = 0, 1, 2, \ldots, n^{2/3}$. In total, each gadget contains $n^{2/3}$ points. Notice that the cost of a

[4] As they did, we can use the Euclidean complete graph on P instead of a spanner S of P. However, this requires additional work: Given two cells c and c' and a value r, we need to check if there are two points $p \in c$ and $p' \in c'$ with $\|p - p'\| = r$. We cannot do this using $O(\log \Delta)$ range counting queries. Instead, we can resolve this by defining another distance function. But we feel that working with spanners makes the analysis simpler.

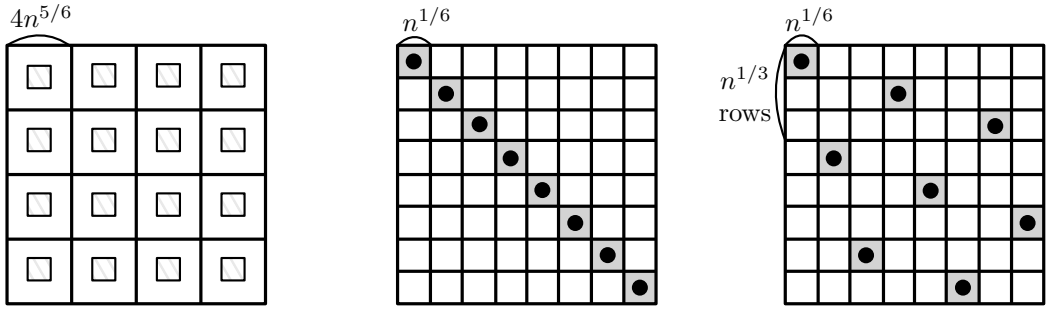

Figure 4 The domain $[\Delta]$ is partitioned into $16n^{1/3}$ cells. Each cell contains the strip gadget or the uniform gadget. The strip gadget has cost $\Theta(n^{5/6})$ while the uniform gadget has cost $\Theta(n^{7/6})$.

minimum spanning tree of the points inside the strip gadget is $\Theta(n^{5/6})$, and the cost of a minimum spanning tree of the points inside the uniform gadget is $\Theta(n^{7/6})$. Now we define a distribution μ of instances. First, with probability $1/2$, we place copies of the strip gadget in all cells of the domain $[\Delta]^2$. Then with probability $1/2$, we pick one cell c of the domain $[\Delta]^2$ uniformly at random. We place a copy of the uniform gadget in c, and place copies of the strip gadget in the other cells. Then we have the following lemma.

▶ **Lemma 18.** *Let I and I' be two instances of μ such that I has the uniform gadget, but I' does not use the uniform gadget. Then $\mathsf{MST}(I') \leq 2 \cdot \mathsf{MST}(I)$, where $\mathsf{MST}(\cdot)$ denotes the cost of a minimum spanning tree.*

Proof. Let M be a minimum spanning tree of I. Observe that the cost of M is at least $2 \cdot n^{7/6}$. This is because M contains at least $n^{1/3}$ edges connecting two points contained different cells in the domain $[\Delta]^2$. Their total length is at least $2 \cdot n^{7/6}$.

Now we analyze an upper bound on the cost of a minimum spanning tree of I'. We can construct a spanning tree of I' from M as follows. The two instances are the same, except that I has a uniform gadget in a cell, say c, and I' has a strip gadget in c. By the cut property, there are at most $O(1)$ edges of M having one endpoint in c and one endpoint lying outside of c. Moreover, such edges have length at most $8n^{5/6}$. For each such edge, we reconnect it with any vertex in c. Then we remove all edges having both endpoints in c from M, and add the edges of the minimum spanning tree of the strip gadget. In total, the cost of M decreases by at most $n^{7/6} - O(1) \cdot n^{5/6}$. Here, the term $n^{7/6}$ is the cost of the uniform gadget. Therefore, we have $\mathsf{MST}(I') - \mathsf{MST}(I) \leq n^{7/6} - O(1) \cdot n^{5/6} \leq (1/2) \cdot n^{7/6} \leq \mathsf{MST}(I)$. ◀

▶ **Lemma 19.** *Any randomized constant-factor approximation algorithm for the minimum spanning tree problem on a point set of size n in a discrete space $[\Delta]^d$ requires $\Omega(n^{1/3})$ range counting queries.*

Abstract

We generalize a classical result by Boris Delaunay that introduced Delaunay triangulations. In particular, we prove that for a locally finite and coarsely dense generic point set A in $\mathbb{R}^d$, every generic point of $\mathbb{R}^d$ belongs to exactly $\binom{d+k}{d}$ simplices whose vertices belong to A and whose circumspheres enclose exactly k points of A. We extend this result to the cases in which the points are weighted, and when A contains only finitely many points in $\mathbb{R}^d$ or in $\mathbb{S}^d$. Furthermore, we use the result to give a new geometric proof for the fact that volumes of hypersimplices are Eulerian numbers.

1 Introduction

In the seminal paper [5], Boris Delaunay (also spelled Delone) introduced the Delaunay triangulation of a finite point sets using simplices with empty circumspheres. His construction can be reformulated as follows: for a (finite and generic) point set, $A \subseteq \mathbb{R}^d$, the simplices with vertices in A that contain no points of A inside their circumspheres cover the convex hull of A in one layer. In this paper, we generalize Delaunay's construction and prove similar properties for simplices with circumspheres that enclose exactly k points of A, for some fixed non-negative integer k. We call these simplices the k-hefty simplices of A.

We introduce the main concepts we will work with. A set $A \subseteq \mathbb{R}^d$ is *locally finite* if every closed ball contains at most a finite number of the points of A, and it is *coarsely dense* if every closed half-space contains at least one and therefore infinitely many of the points of A. If A has both properties, we call it a *thin Delone set*; compare with the more restrictive class of *Delone sets*, which are *uniformly discrete* and *relatively dense*, meaning the smallest inter-point distance is bounded away from 0, and the radius of the largest empty ball is bounded away from ∞. We call A *generic* if no $d+1$ of its points lie on a common hyperplane, and no $d+2$ of its points lie on a common $(d-1)$-sphere. Any $(d-1)$-sphere

bounds a closed d-ball and thus partitions $\mathbb{R}^d$ into points *inside* the sphere (in the interior of the ball), points *on* the sphere, and points *outside* the sphere (in the complement of the ball). Assuming A is generic, there is a unique $(d-1)$-sphere passing through any $d+1$ points of A, which we call the *circumscribed sphere* of the d-simplex spanned by the points.

▶ **Main Definition.** *Let k be a non-negative integer and $A \subseteq \mathbb{R}^d$ a generic thin Delone set or a generic finite set. A d-simplex with vertices in A is* k-hefty *if exactly k points of A lie inside the circumsphere of the d-simplex.*

For example, the 0-hefty simplices are the top-dimensional simplices in the Delaunay triangulation of A, and k-hefty simplices with $k > 0$ are related to the cells in higher-order Delaunay triangulations [2, 7]. Our main result is Theorem 2.2, which we restate here in less technical terms:

▶ **Main Theorem.** *Let k be a non-negative integer and $A \subseteq \mathbb{R}^d$ a generic thin Delone set. Then the k-hefty simplices of A cover $\mathbb{R}^d$ exactly $\binom{d+k}{d}$ times.*

More specifically, almost every point of $\mathbb{R}^d$ is covered by exactly $\binom{d+k}{d}$ k-hefty simplices, while boundary points of k-hefty simplices may be contained in more than this number of such simplices. We also prove versions of this theorem for finitely many points, points on the d-dimensional sphere, and weighted points. In addition, we apply the covering multiplicities to get a new proof that the volumes of hypersimplices are Eulerian numbers, and to get new proofs for some bounds on k-sets.

The paper is organized as follows. In Section 2, we introduce the main definitions, prove the main result for thin Delone sets (Theorem 2.2) and finite sets (Corollary 2.3), and formulate their local versions (Theorem 2.4). In Section 3, we apply the results to obtain a new proof for the fact that volumes of hypersimplices are Eulerian numbers and new proofs for old bounds on k-sets. In the concluding Section 4, we discuss extensions of the results to points in hyperbolic and spherical spaces and to points with real weights in Euclidean space.

2 Hefty Simplices in Euclidean Space

This section presents the main result of this paper, which is stated for infinite and finite point sets in Euclidean space. We begin with the main technical lemma before stating and proving the main theorem.

2.1 Main Technical Lemma

For technical reasons we first show that the k-hefty simplices of a thin Delone set A are "locally uniform" in size. Specifically, we prove an upper bound for the radii of spheres that enclose a fixed point, $x \in \mathbb{R}^d$, as well as at most k points of A. To this end, we write $B(x, R)$ for the closed ball with center x and radius R, and note that the number of points of A in this ball goes to infinity when R goes to infinity.

▶ **Lemma 2.1.** *Let $A \subseteq \mathbb{R}^d$ be coarsely dense, k a non-negative integer, and $x \in \mathbb{R}^d$. Then there exists $R = R(x, A, k)$ such that if x is inside a sphere that is not fully contained in $B(x, R)$, then there are at least $k+1$ point of $A \cap B(x, R)$ inside this sphere.*

Proof. Without loss of generality, assume $x = 0$. For every unit vector, $u \in \mathbb{S}^{d-1}$, the open halfspace of points y that satisfy $(y, u) > 0$ contains infinitely many points of A. It follows that the function $f_u \colon (0, \infty) \to \mathbb{Z}$ that maps $r > 0$ to the number of points of A inside the sphere with center ru and radius r is non-decreasing and unbounded.

We introduce $g\colon \mathbb{S}^{d-1} \to \mathbb{R}$ defined by $g(u) = \inf\{r > 0 \mid f_u(r) \geq k+1\}$ and claim that g is bounded. To derive a contradiction, suppose g is unbounded, and let $u_1, u_2, \ldots$ be a sequence of unit vectors with $g(u_n) \geq n$. Since $\mathbb{S}^{d-1}$ is compact, there is a subsequence that converges to a vector $u_0 \in \mathbb{S}^{d-1}$. Let S be the sphere with radius $g(u_0)+1$ and center $(g(u_0)+1)u_0$. By construction, there are at least $k+1$ points of A inside S. Since these points are (strictly) inside the sphere, there is a sufficiently small $\varepsilon > 0$ such that moving the center of the sphere by at most ε while adjusting its radius so the origin remains on the sphere, retains at least $k+1$ point of A inside the sphere. But this contradicts the unboundedness of g as there are points u_i in the subsequence that are within distance ε from u_0 with $g(u_i)$ much larger than $g(u_0)+1$.

Since g is bounded, $M = \sup\{g(u) \mid u \in \mathbb{S}^{d-1}\}$ is finite and, by construction of g, there are at least $k+1$ points of A inside any sphere with center y and radius $\|y\|$ as long as $\|y\| \geq M$. Setting $R = 2M$, every sphere with center y that encloses the origin and is not contained in $B(0,R)$ has radius $r > M$. This sphere encloses the ball with center $M\frac{y}{\|y\|}$ and radius M, so there are at least $k+1$ points of A inside this sphere that all belong to $B(0,R)$. ◀

As an immediate consequence of Lemma 2.1, the circumsphere of any k-hefty simplex of A that encloses x is completely contained in $B(x,R)$, in which R depends on x, A, and k.

2.2 Global Covering

Our first goal is to generalize the classic result of Delaunay that the 0-hefty simplices of every thin Delone set cover $\mathbb{R}^d$ in one layer; that is: every point of $\mathbb{R}^d$ is contained in at least one 0-hefty simplex and almost every point of $\mathbb{R}^d$ is contained in exactly one 0-hefty simplex. Specifically, we show that for every generic thin Delone set, $A \subseteq \mathbb{R}^d$, the family of k-hefty simplices covers $\mathbb{R}^d$ $\binom{d+k}{d}$ times. We call $\binom{d+k}{d}$ the *k-th covering number* and note that it depends on the dimension, d, and the parameter, k, but not on the set A. We call $x \notin A$ *generic with respect to* A if $A \cup \{x\}$ is generic. Almost every point $x \in \mathbb{R}^d$ is generic with respect to a generic thin Delone set, A. To see this, observe that by local finiteness of A there are only countably many hyperplanes spanned by d points each or spheres spanned by $d+1$ points each, so the union of these hyperplanes and spheres has Lebesgue measure zero.

▶ **Theorem 2.2.** *Let k be a non-negative integer and $A \subseteq \mathbb{R}^d$ a generic thin Delone set. Then any point $x \in \mathbb{R}^d$ that is generic with respect to A belongs to exactly $\binom{d+k}{d}$ k-hefty simplices of A.*

Proof. The case $d = 1$ is obvious since every k-hefty simplex of A is an interval with endpoints in A and exactly k points between the two endpoints. Every point that is generic with respect to A, i.e. in $\mathbb{R} \setminus A$, is contained in exactly $k+1$ such intervals. For $d \geq 2$, the proof splits into three steps.

Step 1. Letting k be a non-negative integer and $A \subseteq \mathbb{R}^d$ a generic thin Delone set, we prove that there is a constant $c = c(k,A)$ such that any point that is generic with respect to A is contained in exactly c k-hefty simplices of A. Write $cover_k(x,A)$ for the number of k-hefty simplices of A that contain x. By Lemma 2.1, $cover_k(x,A)$ is finite. Indeed, every k-hefty simplex of A that contains x must select its vertices from the finitely many points inside the ball $B(x,2M)$. To show that $cover_k(x,A)$ is the same for all generic points, we move x continuously from one point to another. The only time $cover_k(x,A)$ can change is when x passes through the boundary of a k-hefty simplex. It suffices to show that for every $(d-1)$-simplex, Δ, with vertices in A, the number of k-hefty simplices with facet Δ is the same on both sides of Δ.

Consider the line, L, that consists of all points equidistant to the vertices of Δ and mark each point $y \in L$ with the number of points of A inside the sphere with center y that passes through the vertices of Δ. This partitions L into labeled intervals, and since A is generic, the labels of two consecutive intervals differ by exactly one. Fix a *left to right* direction on L, move y in this direction, and observe that the portion of space inside the sphere centered at y that lies to the left of the hyperplane spanned by Δ shrinks, while the portion to the right of this hyperplane grows. The transitions from an interval labeled $k+1$ to another labeled k are in bijection with the k-hefty simplices with facet Δ to the left of Δ. Indeed, as y makes the transition, there is a point of A that passes from inside to outside the sphere centered at y, so this point is to the left of Δ. Similarly, the transitions from an interval labeled k to another labeled $k+1$ are in bijection with the k-hefty simplices with facet Δ to the right of Δ. There are equally many transitions of either kind because the labels go to infinity on both sides. This proves that $cover_k(x, A)$ does not depend on x.

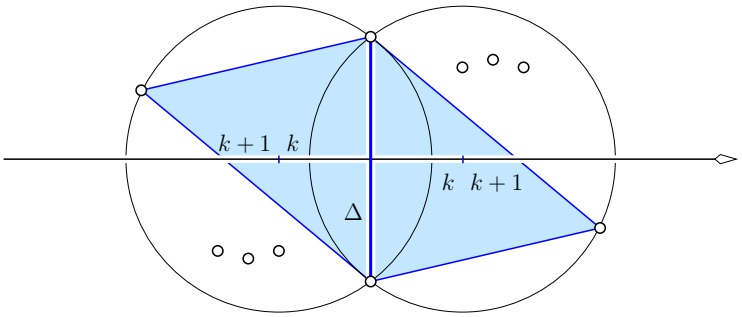

Figure 1 Two circles in the 1-parameter family of circles that pass through the endpoint of the edge Δ. Both are the circumcircles of k-hefty triangles, with $k = 3$ in the case displayed. As we move the center from left to right, every point that leaves the inside of the circle lies to the left of Δ, and every point that enters the inside of the circle lies to the right of Δ.

Step 2. We strengthen the claim proved in Step 1 by showing that the constant depends on d and k but not on A. Specifically, we prove that for every dimension d and non-negative integer k, there exists a number $f(d, k)$ such that for any generic thin Delone set, $A \subseteq \mathbb{R}^d$, any point $x \in \mathbb{R}^d$ generic with respect to A belongs to exactly $f(d, k)$ k-hefty simplices of A.

It suffices to show that for two thin Delone sets, A and A', and two points, $x, x' \in \mathbb{R}^d$, that are generic with repect to both sets, $cover_k(x, A) = cover_k(x', A')$. By Lemma 2.1, there exists $R > 0$ such that if a sphere encloses x and a point outside $B(x, R)$, then there are at least $k+1$ points of $A \cap B(x, R)$ inside this sphere. It follows that the circumspheres of all k-hefty simplices that enclose x are contained in $B(x, R)$. Similarly, let R' be the constant from Lemma 2.1 for x' and A'. We construct a new thin Delone set, A'': picking points y and y' at distance larger than $R + R'$ from each other, we let $A'' \cap B(y, R)$ be a translate of $A \cap B(x, R)$ and $A'' \cap B(y', R')$ a translate of $A' \cap B(x', R')$. We perturb the points if necessary to achieve genericity, and add more points outside $B(y, R)$ and $B(y', R')$ until A'' is thin Delone. By choice of R and R' we have $cover_k(x, A) = cover_k(y, A'')$, because every k-hefty simplex of A whose circumsphere encloses x translates into a k-hefty simplex of A'' whose circumsphere encloses y, and vice versa. Similarly, we have $cover_k(x', A') = cover_k(y', A'')$. Finally, $cover_k(x, A) = cover_k(x', A')$ because $cover_k(y, A'') = cover_k(y', A'')$ as proved in Step 1.

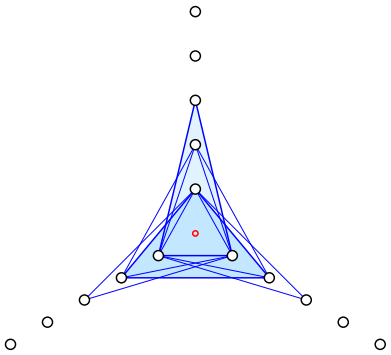

Figure 2 Before perturbation, the points of A lie on three half-lines emanating from the origin. We show six 2-hefty triangles, and emphasize two of them by shading.

Step 3. We provide an explicit example of a generic thin Delone set, $A \subseteq \mathbb{R}^d$, and a point, $x \in \mathbb{R}^d$, with $cover_k(x, A) = \binom{d+k}{d}$. Specifically, we prove that for every dimension d and non-negative integer k, there exists a generic thin Delone set $A \subseteq \mathbb{R}^d$, and a point x generic with respect to A, such that $cover_k(x, A) = \binom{d+k}{d}$.

Let S be a regular d-simplex with vertices $v_0, v_1, \ldots, v_d$ and barycenter $0 = \frac{1}{d+1}\sum_i v_i$, and A the set of points of the form iv_j, for integers $i \geq 1$ and $j = 0, 1, \ldots, d$. We call A a *radial* set and the points with fixed j a *direction* of A; see Figure 2. Set $x = 0$. Every k-hefty simplex of A that contains 0 has exactly one vertex from each direction. Let $i_0v_0, i_1v_1, \ldots, i_dv_d$ be the vertices of such a simplex. The number of points of A inside its circumsphere is $\sum_j(i_j - 1) = k$. Enumerating these simplices is the same as writing k as an ordered sum of $d + 1$ non-negative integers, and there are exactly $\binom{d+k}{d}$ ways to do that. To complete the proof, we perturb A while making sure that $d + 1$ points span a simplex that contains 0 before the perturbation iff they span such a simplex after the perturbation. This completes the proof of our main result. ◀

2.3 The Finite Case

For a finite set, $A \subseteq \mathbb{R}^d$, the covering multiplicity of Theorem 2.2 holds sufficiently deep inside the set but acts only as an upper bound near the fringes. To formalize these claims, we introduce a parametrized generalization of the convex hull: for each integer $k \geq 0$, the *k-hull* of A, denoted $H_k(A)$, is the common intersection of all closed half-spaces that miss at most k of the points in A. Clearly, $H_0(A) = \operatorname{conv} A$, and $H_k(A) \supseteq H_{k+1}(A)$ for every k. It is also easy to see that $H_k(A)$ is contained in the convex hull of A after removing at most k of its points, and indeed $H_k(A)$ *is* the intersection of all such convex hulls. By the Centerpoint Theorem of discrete geometry [6, Section 4.1], $H_k(A) \neq \emptyset$ if $k < \frac{n}{d+1}$, in which $n = \#A$ is the number of points in A.

▶ **Theorem 2.3.** *Let $A \subseteq \mathbb{R}^d$ be finite and generic, $k \geq 0$ an integer, and $x \in \mathbb{R}^d$ generic with respect to A. Then x is covered by at most $\binom{d+k}{d}$ k-hefty simplices of A, with equality iff $x \in H_k(A)$.*

Proof. To prove the upper bound, we add points outside all circumspheres of $d + 1$ points in A to construct a thin Delaunay set $A' \subseteq \mathbb{R}^d$. This is possible because the union of balls bounded by such spheres is bounded. Hence, $A \subseteq A'$, and any k-hefty simplex of A is also a k-hefty simplex of A'. Assuming x is generic with respect to A', Theorem 2.2 implies that

exactly $\binom{d+k}{d}$ k-hefty simplices of A' cover x. If all of them are also k-hefty simplices of A, then x is covered by exactly $\binom{d+k}{d}$ k-hefty simplices of A, but if not, then x is covered by fewer than $\binom{d+k}{d}$ k-hefty simplices of A.

"$\Longleftarrow$". We prove $x \in H_k(A)$ implies that every k-hefty simplex of A' covering x is also a k-hefty simplex of A. Since A' has exactly $\binom{d+k}{d}$ k-hefty simplices that cover x, this will imply that A has the same number of such simplices. Consider such a k-hefty simplex of A', and let $B \subseteq A'$ be the points inside its circumsphere. Since $x \in H_k(A)$, every closed half-space that misses at most k points of A contains x. But $\#B = k$, so x belongs to the convex hull of $A \setminus B$. The top-dimensional simplices of $\mathrm{Del}(A \setminus B)$ cover the convex hull once, hence there is a unique 0-hefty simplex of $A \setminus B$ that covers x. All points of $A' \setminus A$ lie outside its circumsphere, which implies that the same simplex is the unique 0-hefty simplex of $A' \setminus B$ that covers x. Therefore $B \subseteq A$ because the vertices of the simplex are in A, and all vertices we removed must come from A as well. So this is a k-hefty simplex of A.

"$\Longrightarrow$". Assuming $x \notin H_k(A)$, we modify the construction of A' to show that there is a set $A'' \supseteq A$ such that all k-hefty simplices of A are k-hefty simplices of A'' but at least one k-hefty simplex of A'' that covers x is not a k-hefty simplex of A. In contrast to A', the set A'' will be finite. Since $x \notin H_k(A)$, there are d points in A such that the open half-space bounded by the hyperplane passing through these points that contains x contains at most k points of A. Let Δ be the $(d-1)$-simplex spanned by the d points, write Δ^+ for the open half-space that contains x, and let $B \subseteq A$ be the points in Δ^+. By assumption, $\#B \leq k$. We get A'' by adding $1 + k - \#B$ points to A as follows. First, we add $k - \#B$ points in Δ^+ but outside all circumspheres of $d+1$ points in A. After that, we add a point $y \in \mathbb{R}^d$ so that the d-simplex that is the pyramid with apex y and base Δ covers x, and all other k points in Δ^+ are inside the circumsphere of this d-simplex. We also require that y is outside all circumspheres of $d+1$ points in A. It is clear that such a point y exists on a sufficiently large sphere that passes through all vertices of Δ. As proved above, there are at most $\binom{d+k}{d}$ k-hefty simplices of A'' that cover x. The pyramid with apex y and base Δ is such a simplex, but it is not a k-hefty simplex of A. Hence, the number of k-hefty simplices of A that cover x is strictly less than $\binom{d+k}{d}$, as claimed. ◀

▶ Remark. Observe that our arguments in part "$\Longleftarrow$" imply that once we fix a subset $B \subseteq A$ of size k, then the k-hefty simplices of A that have exactly these points inside their circumspheres have disjoint interiors. This is because they are 0-hefty simplices of $A \setminus B$.

2.4 Local Covering

By Theorem 2.2, the k-hefty simplices of a thin Delone set cover $\mathbb{R}^d$ without gap an integer number of times. However, beyond one dimension, it is generally not possible to split such a cover into sub-covers (separate layers) that enjoy the same property. As an example, consider the thin Delone set of which Figure 3 shows one point surrounded by five others. Assuming the remaining points are sufficiently far from the six, the point at the center is incident to five 1-hefty triangles, as shown. Globally, the 1-hefty triangles cover any small neighborhood of this point three times, but it is not possible to decompose this cover into three; see [9] for indecomposable coverings in other contexts. It is however possible to split it locally into two. Such a local split exists for every $k \geq 1$, and we prove that the hefty simplices incident to the point cover any small neighborhood a specific number of times.

▶ **Theorem 2.4.** *Let $A \subseteq \mathbb{R}^d$ be a generic thin Delone set and k a non-negative integer. Then the k-hefty simplices of A incident to a vertex $a \in A$ cover any sufficiently small neighborhood of a exactly $\binom{d+k-1}{d-1}$ times.*

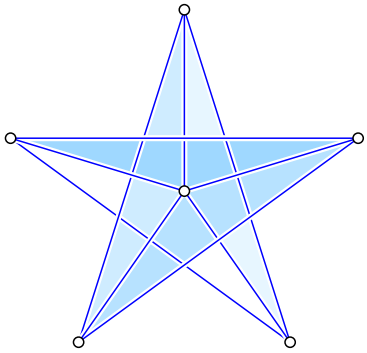

Figure 3 Six points of a Delone set, in which one is surrounded by five others, and the remaining points lie outside the circumcircles defined by these points. The five 1-hefty triangles incident to the surrounded point cover any small neighborhood of that point twice, but they cannot be split into two disjoint covers of such a neighborhood.

Proof. The case $k = 0$ is that of the Delaunay triangulation of A. Its top-dimensional simplices cover $\mathbb{R}^d$ exactly once, and thus also every neighborhood of $a \in A$ exactly once. We therefore assume $k > 0$. Let $A' = A \setminus \{a\}$. Observe that A' is also a generic thin Delone set and a is generic with respect to A'. We can therefore apply Theorem 2.2 to the $(k-1)$-hefty simplices of A' that contain $a \in \mathbb{R}^d$. There are only finitely many such simplices and each of them contains a small neighborhood of a.

Let y be a point in a sufficiently small neighborhood of a that is inside the intersection of all $(k-1)$-hefty simplices of A' that contain a, and assume that y is generic with respect to A. By Theorem 2.2, there are exactly $\binom{d+k}{d}$ k-hefty simplices of A that cover y. They split into simplices incident and not incident to a. The latter are the $(k-1)$-hefty simplices of A' that contain a. Indeed, since y is sufficiently close to a, a k-hefty simplex of A with vertices in A' contains a in its interior iff it contains y in its interior. The circumsphere of each such simplex encloses exactly $k-1$ points of A' as we removed a from A to get A'. This implies that the number of k-hefty simplices of A that contain y and are not incident to a is $\binom{d+k-1}{d}$. Thus, the number of k-hefty simplices of A that contain y and are incident to a is

$$\binom{d+k}{d} - \binom{d+k-1}{d} = \binom{d+k-1}{d-1}, \tag{1}$$

as claimed. ◀

Similar to Theorem 2.3, we establish an inequality for finite sets that follows from Theorem 2.4. We are satisfied with a less refined statement than formulated for the global case in Section 2.3.

▶ **Corollary 2.5.** *Let $A \subseteq \mathbb{R}^d$ be finite and generic and k be a non-negative integer. Then every generic point in a small neighborhood of any point $a \in A$ belongs to at most $\binom{d+k-1}{d-1}$ k-hefty simplices of A incident to a.*

3 Applications

We discuss two applications of Theorem 2.2: its relation to volumes of hypersimplices and Eulerian numbers in Section 3.1, and the connection to k-sets and k-facets in Section 3.2.

3.1 Worpitzky's Identity for Eulerian Numbers

As an application of our covering results, we show how the multiplicities from Theorem 2.2 are related to the volumes of hypersimplices and to Eulerian numbers. Specifically, we show that de Laplace's relation for hypersimplices [4] implies Worpitzky's identity for Eulerian numbers [14], and vice versa.

We begin by introducing the three main concepts we need in this subsection. Letting d be a positive integer, the number of *descents* in a permutation $j_1, j_2, \ldots, j_d$ of $1, 2, \ldots, d$ is the number of indices $1 \leq i \leq d-1$ such that $j_i > j_{i+1}$. For $0 \leq k \leq d-1$, the *Eulerian number* for d and k is the number of permutations of $1, 2, \ldots, d$ with exactly k descents. For example, $A(d,0) = A(d,d-1) = 1$, for every d, and $\sum_{k=0}^{d-1} A(d,k) = d!$. Less obvious is Worpitzky's identity [14] between two polynomials from more than a century ago:

$$\sum\nolimits_{k=0}^{d-1} A(d,k) \binom{x+k}{d} = x^d. \tag{2}$$

Next, let $x_0, x_1, \ldots, x_d$ be $d+1$ affinely independent points and write $\Delta = \operatorname{conv}\{x_0, x_1, \ldots, x_d\}$ for the d-simplex they span. A *p-fold sum* is obtained by selecting p of the $d+1$ points, considering them as vectors, and returning the point that corresponds to the sum of these vectors. For each $1 \leq p \leq d$, the convex hull of the p-fold sums of the $d+1$ points is a d-dimensional convex polytope referred to as a *d-hypersimplex of order p*, denoted $\Delta_d^{(p)}$. Clearly, $\Delta_d^{(1)} = \Delta$, and more generally, $\Delta_d^{(p)}$ is a homothetic copy of the convex hull of the barycenters of all $(p-1)$-dimensional faces of Δ. Since the barycenter of a $(p-1)$-simplex is $1/p$ times the sum of its vertices, the volume of that polytope is $1/p^d$ times the volume of the homothetic hypersimplex. Define the *relative volume* of $\Delta_d^{(p)}$ as $v(d,p) = \operatorname{vol}_d(\Delta_d^{(p)})/\operatorname{vol}_d(\Delta)$, and observe that it does not depend on the choice of Δ. Again more than a century ago, de Laplace [4] proved that these relative volumes are Eulerian numbers:

$$v(d,k+1) = A(d,k); \tag{3}$$

see also the combinatorial proof of the same equation by Stanley [11]. The third concept is the dual of the order-n Voronoi tessellation of a finite set $A \subseteq \mathbb{R}^d$, introduced in 1990 by Aurenhammer [2]. Referring to this dual as the *order-n Delaunay mosaic* of A, denoted $\operatorname{Del}_n(A)$, it is defined by its d-cells, each the convex hull of a collection of averages of n points selected from A. Specifically, for each $1 \leq p \leq d$ and every $(n-p)$-hefty simplex, take all sets of cardinality n that contain all $n-p$ points inside the circumsphere together with any p points on the circumsphere. E.g. for $p=1$, we get $d+1$ averages whose convex hull is a homothetic copy of the original d-simplex, and for $p=2$, we get a homothetic copy of the convex hull of the midpoints of the edges of the d-simplex. Collecting these polytopes, we get $\operatorname{Del}_n(A)$. For $n=1$, we have $\operatorname{Del}_1(A) = \operatorname{Del}(A)$, and more generally $\operatorname{Del}_n(A)$ has a d-cell for every $(n-p)$-hefty simplex in which p varies from 1 to d. Since the vertices are averages of n points, each d-cell in $\operatorname{Del}_n(A)$ has volume $1/n^d$ times the volume of the corresponding hypersimplex. It is now easy to prove the following relation for the relative volumes of the hypersimplices.

▶ **Theorem 3.1.** *For integers $d, n \geq 1$, the relative volumes of the hypersimplices satisfy*

$$\sum\nolimits_{p=1}^{d} v(d,p) \binom{n+d-p}{n-p} = n^d, \tag{4}$$

in which $\binom{n+d-p}{n-p} = 0$ whenever $n-p < 0$.

Proof. Let A be any Delone set – and not just a thin Delone set – in $\mathbb{R}^d$, so that every ball whose radius exceeds some given constant contains at least one point of A. Let $R > 0$ be sufficiently large and consider all d-cells in $\mathrm{Del}_n(A)$ that are contained in $[-R, R]^d$. Setting $n' = \max\{0, n-d\}$, there are $n - n' \leq d$ different types of d-cells to be considered, namely homothetic copies of hypersimplices of orders 1 to $n - n'$ defined by $(n-p)$-hefty simplices for $1 \leq p \leq n - n'$. The total volume of these d-cells is $(2R)^d + \mathcal{O}\left(R^{d-1}\right)$, since we miss only a constant width neighborhood of each facet of the hypercube.

Consider now an $(n-p)$-hefty simplex of A. Generically, its circumsphere passes through $d+1$ points and encloses $n-p$ of the points in A. By definition of Delaunay set, the radius of this circumsphere is bounded from above by a constant times $n-p$. Furthermore, the $(n-p)$-hefty simplex contains every d-cell in $\mathrm{Del}_n(A)$ it may determine since the vertices of the latter are averages of the vertices of the $(n-p)$-hefty simplex. By Theorem 2.2, the $(n-p)$-hefty simplices that define d-cells of $\mathrm{Del}_n(A)$ inside the hypercube therefore cover most of the hypercube exactly $\binom{n+d-p}{n-p}$ times. It follows that the total volume of these p-hefty simplices is $\binom{n+d-p}{n-p}(2R)^d + \mathcal{O}\left(R^{d-1}\right)$. By definition of relative volume, the total volume of the corresponding hypersimplices thus is $v(d,p)\binom{n+d-p}{n-p}(2R)^d/n^d + \mathcal{O}\left(R^{d-1}\right)$. Taking the sum for $1 \leq p \leq n - n'$, dividing by $(2R)^d$, and taking the limit as R goes to infinity, we get the claimed relation. ◀

To see that Theorem 3.1 together with de Laplace's relation implies Worpitzky's identity and together with Worpitzky's identity implies de Laplace's relation, we change the summation index in (4) from p to $k = d - p$ and apply $\binom{n+k}{n-d+k} = \binom{n+k}{d}$ to get

$$\sum_{k=0}^{d-1} v(d, d-k)\binom{n+k}{d} = n^d. \tag{5}$$

Since this relation holds for every positive integer, n, it also holds if we treat $\binom{n+k}{d}$ and n^d as polynomials of degree d in n. Substituting $A(d,k) = A(d, d-k-1)$ for $v(d, d-k)$ using de Laplace's relation (3), we get Worpitzky's identity (2). To see the other direction, we observe that the polynomials given by the binomial coefficients are linearly independent, so there is only one way to write n^d as their linear combination, and it is given by Worpitzky's identity. Comparing (5) with (2), we get $v(d, d-k) = A(d,k) = A(d, d-k-1)$, which is (3).

3.2 *k*-sets and *k*-facets

In this section, we briefly discuss connections between the covering numbers studied in Section 2 and the k-sets and k-facets studied in discrete geometry; see e.g. [8, Chapter 11]. Letting A be a generic set of n points in $\mathbb{R}^d$, a *k-set* is a set of k points, $B \subseteq A$, such that B and $A \setminus B$ can be separated by a hyperplane, and a *k-facet* is a set of d points, $\Delta \subseteq A$, such that the hyperplane passing through these points partitions $A \setminus \Delta$ into k and $n-d-k$ points on its two sides. We refer to [12, Section 2.2] for a discussion of the relation between these two concepts.

We present alternative proofs of two well-established results, which we state in terms of k-facets. Both proofs make use of the *inversion* of A through the unit sphere centered at a point $x \in \mathbb{R}^d \setminus A$, which maps a point $a \in \mathbb{R}^d \setminus \{x\}$ to $\iota_x(a) = x + (a-x)/\|a-x\|^2$. It is not difficult to see that the image under this inversion of a hyperplane that avoids x is a sphere that passes through x. Similarly, the image of the open half-space that does not contain x is the open ball bounded by this sphere. If the hyperplane passes through the points of a k-facet, $\Delta \subseteq A$, and separates x from the k-set on the other side, then the d-simplex spanned by x and the points in $\iota_x(\Delta)$ is a k-hefty simplex of $A' = \iota_x(A) \cup \{x\}$ incident to x.

Write $F_k(A)$ for the number of k-facets of A. We first reprove the following 2-dimensional result by Alon and Győri [1] for k smaller than a third of the number of points.

▶ **Proposition 3.2.** *Let A be a generic set of n points in $\mathbb{R}^2$ and $k < \frac{n}{3}$ a non-negative integer. Then $\sum_{j=0}^{k} F_j(A) \leq (k+1)n$.*

Proof. Recall that the k-hull of A is the intersection of all closed half-spaces that miss at most k points of A, denoted $H_k(A)$. By the Centerpoint Theorem of discrete geometry, $H_k(A)$ has a non-empty interior if $k < \frac{n}{3}$; see e.g. [6, Section 4.1]. Let x be a point in the interior of $H_k(A)$ and set $A' = \iota_x(A) \cup \{x\}$. Let $j \leq k$. As explained above, the inversion through the unit circle centered at x maps every j-facet of A to a j-hefty triangle of A' incident to x. By Corollary 2.5, the j-hefty triangles incident to x cover a small neighborhood of x at most $j+1$ times, so if we consider all j between 0 and k, we get the neighborhood of x covered at most $1 + 2 + \ldots + (k+1) = \binom{k+2}{2}$ times.

To continue, we draw a half-line emanating from x through every point in $\iota_x(A)$, thus splitting the neighborhood of x into n angles. Every hefty triangle incident to x covers a contiguous sequence of these angles, and for each $i \geq 1$, there are at most n triangles that cover exactly i of these angles. Each angle is covered some integer number of times, and we take the sum of these numbers over all angles. If $\sum_{j=0}^{k} F_j(A) > (k+1)n$, then this sum is strictly greater than $n(1 + 2 + \ldots + (k+1)) = n\binom{k+2}{2}$. This implies that one of the angles is covered more than $\binom{k+2}{2}$ times, which contradicts Corollary 2.5. ◀

We continue with Lovász Lemma – see [3] but also [8, Lemma 11.3.2] – which is a crucial ingredient in many arguments about k-sets; see e.g. [10]. This lemma gives an asymptotic upper bound on the number of $(d-1)$-simplices spanned by the points of k-facets a line can intersect. We give a short proof of a more general version by Welzl [13]. To state the lemma, we say a directed line, L, *enters* a k-facet, $\Delta \subseteq A$, if L intersects the $(d-1)$-simplex spanned by Δ at an interior point and moves from the side with k points to the side with $n-d-k$ points as it passes through the $(d-1)$-simplex.

▶ **Proposition 3.3.** *Let $A \subseteq \mathbb{R}^d$ be a generic finite set, k a non-negative integer, and L a directed line. Then L enters at most $\binom{d+k-1}{d-1}$ k-facets of A.*

Proof. We may assume that L passes through the convex hull of A and let $x \in L$ be a point reached after passing through $\operatorname{conv} A$. The inversion through the unit sphere centered at x maps every k-facet entered by L to a k-hefty simplex incident to x such that L passes through this simplex before it reaches x. By Corollary 2.5, there are at most $\binom{d+k-1}{d-1}$ such k-hefty simplices. ◀

Since a line can be directed in two different ways, the number of $(d-1)$-simplices spanned by k-facets of the set A one orientation of this line or the other can enter is at most $2\binom{d+k-1}{d-1}$.

4 Concluding Remarks

The results on covering numbers presented in Section 2 extend to other settings of which we mention three:

- locally finite sets in hyperbolic space;
- finite sets on the sphere;
- weighted points in Euclidean space.

A claim about global covering analogous to Theorem 2.2 holds in all three settings, while one about local covering analogous to Theorem 2.4 holds only for the first two. The first setting is most similar to the situation in Euclidean space studied in Section 2: the proofs are almost verbatim the same, with the main difference being a modified radial set since the design illustrated in Figure 2 is not thin Delone in hyperbolic space. For the second setting, there is an ambiguity in the definition of a k-hefty simplex since any $(d-1)$-sphere on the d-sphere bounds two complementary d-balls. We thus require that the finite set is *k-balanced*, by which we mean that every open hemisphere contains at least $k+1$ points. With this assumption, only the smaller of the two open d-balls has a chance to contain k of the points, so we consider it the inside of the $(d-1)$-sphere. The proofs of the extensions of Theorems 2.2 and 2.4 to k-balanced sets on the sphere are similar to those for thin Delone sets in Euclidean space. Alternatively, we may use stereographic projection to reduce the spherical to the Euclidean setting.

The generalization to points with real weights is akin the generalization of Voronoi to power tessellations or diagrams; see e.g. [6, Chapter 13]. We interpret a point with weight $w \in \mathbb{R}$ as a sphere with squared radius w (which may be negative), and we generalize the circumsphere of a d-simplex to the *orthosphere*, which in the generic case is the unique sphere orthogonal to the $d+1$ spheres that are the vertices of the d-simplex. The orthosphere *encloses* a weighted point if the two centers are strictly closer than required for the two spheres to be orthogonal to each other, and the d-simplex is *k-hefty* if it encloses exactly k of the weighted points. With these adaptations of the definitions, a claim analogous to Theorem 2.2 holds also in the weighted case, provided the weights satisfy a mild condition, which is for example satisfied if the weights are bounded. On the other hand, Theorem 2.4 fails to extend. Indeed, the k-hefty simplices incident to a weighted point cover the neighborhood of the point some integer number of times, but depending on the point and its surrounding, this integer varies between 0 and $\binom{d+k}{d}$.

Abstract

We study a variant of the Coordinated Motion Planning problem on undirected graphs, referred to herein as the Coordinated Sliding-Motion Planning (CSMP) problem. In this variant, we are given an undirected graph G, k robots $R_1, \ldots, R_k$ positioned on distinct vertices of G, $p \leq k$ distinct destination vertices for robots $R_1, \ldots, R_p$, and $\ell \in \mathbb{N}$. The problem is to decide if there is a serial schedule of at most ℓ moves (i.e., of makespan ℓ) such that at the end of the schedule each robot with a destination reaches it, where a robot's move is a free path (unoccupied by any robots) from its current position to an unoccupied vertex. The problem is known to be NP-hard even on full grids. It has been studied in several contexts, including coin movement and reconfiguration problems, with respect to feasibility, complexity, and approximation. Geometric variants of the problem, in which congruent geometric-shape robots (e.g., unit disk/squares) slide or translate in the Euclidean plane, have also been studied extensively.

We investigate the parameterized complexity of CSMP with respect to two parameters: the number k of robots and the makespan ℓ. As our first result, we present a fixed-parameter algorithm for CSMP parameterized by k. For our second result, we present a fixed-parameter algorithm parameterized by ℓ for the special case of CSMP in which only a single robot has a destination and the graph is planar. A crucial new ingredient for both of our results is that the solution admits a succinct representation as a small labeled topological minor of the input graph.

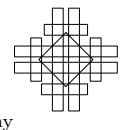
1 Introduction

In the coordinated motion planning problem, we are given an integer $\ell \in \mathbb{N}$, an undirected graph G, k robots $R_1, \ldots, R_k$ positioned on distinct starting vertices of G and $p \leq k$ distinct destination vertices for robots $R_1, \ldots, R_p$. In each step, one robot (or a subset of robots in other variants of the problem in which robots may move in parallel) may move from its

© Eduard Eiben, Robert Ganian, Iyad Kanj, and M. S. Ramanujan;
licensed under Creative Commons License CC-BY 4.0



current vertex to an adjacent unoccupied vertex. The goal is to decide if there is a schedule (i.e., a sequence of moves) of length at most ℓ, at the end of which each robot $R_1, \ldots, R_p$ has reached its destination vertex without colliding with other robots along the way. The problem and its variants (including the common variant where $p = k$) have been extensively studied, with respect to various motion types and graph classes, due to their ubiquitous applications in artificial intelligence (planning), robotics, computational geometry and more generally theoretical computer science [3, 6, 10, 11, 16, 17, 23, 24, 28, 31–38]. Moreover, it generalizes several well-known puzzles, including the famous $(n^2 - 1)$-puzzle and the Rush-Hour puzzle. Most of these variants are NP-hard, including the aforementioned (n^2-1)-puzzle [12,29]. Due to its numerous applications, the coordinated motion planning problem on (full rectangular) grids was posed as the SoCG 2021 Challenge [18].

We consider a variant of the coordinated motion planning problem on undirected graphs in which robots move serially one at a time, and a robot's move consists of a move along a free/unobstructed path (i.e., a path in which no other robot is located at the time of the move) as opposed to a single edge; we refer to such a move as a *sliding* move, analogous to the type of motion in geometric variants of the coordinated motion planning problem, where robots are geometric shapes (e.g., disks or rectangles) that move by translating/sliding in the plane. These geometric variants have been extensively studied since the 1980s [24, 28, 31–33]. The goal of this variant is to decide whether there is a schedule of makespan at most ℓ, where here the makespan of the schedule is simply the number of moves in it. We denote our general problem of interest as CSMP. We will also consider the special case of CSMP where G is planar and $p = 1$ – that is, only a designated robot has a destination and the remaining robots merely act as "blockers". We refer to this special case as Planar-CSMP-1.

Contributions and Techniques. We present a fixed-parameter algorithm for CSMP parameterized by the number k of robots, and a fixed-parameter algorithm for Planar-CSMP-1 parameterized by the makespan ℓ. A crucial common ingredient for both results is showing that the solution to a problem instance admits a succinct representation, whose size is a function of the parameter, as a topological minor of the input graph. To the best of our knowledge, this is a novel approach in the context of coordinated motion planning problems.

CSMP. Showing that the solution admits a succinct representation entails first bounding the makespan in an optimal solution by a function of the number k of robots. Towards this end, we preprocess the graph by shortening (to $\mathcal{O}(k)$) sufficiently long paths comprising degree-2 vertices and focus on two cases. In one case, where the graph has bounded[1] treedepth, we show that the instance can be reduced iteratively without altering the solution. This reduction process ultimately results in an instance of bounded size, implying the existence of a solution with a bounded makespan.

In the other case, we use ideas from [10] to define a notion of *havens*, which are subgraphs of bounded size with the following property: if a robot has to pass through a haven, then with a bounded number of additional steps, we can enable it to pass through the haven regardless of the other robots in the haven (i.e., without collision), effectively "untangling" all the robots' traversals within the haven. Building on this, we construct a schedule in which each robot interacts with only a bounded number of havens, ultimately leading to a bounded-makespan schedule.

[1] In the rest of this description, we simply say *bounded* to refer to values bounded by a function of k.

After bounding the makespan in an optimal solution, we show that it essentially describes a graph H of bounded size as a topological minor in the input graph. Here, we have to work with *rooted* topological minors since all robots have specified starting points and some have specified destinations. For us, the roots are just the starting and ending vertices, as we have boundedly-many roots. Towards our goal, we partition the vertices of the graph induced by the edges participating in an optimal solution into two sets: important and unimportant vertices. We show that the number of important vertices is bounded, and that the unimportant vertices form paths whose internal vertices have degree 2. This structure enables us to show that the graph induced by the edges in the solution (with terminals as roots) is a realization of some rooted graph with a bounded number of vertices as a topological minor in the input graph. We also prove the converse, namely that from *any* realization of H as a topological minor in G, one can obtain an optimal solution for the given instance. Towards proving this, we show that if a robot follows a path that is devoid of important vertices, then it slides on that path without stopping. Finally, we leverage known results on topological minor containment to verify the existence of the correct rooted graph.

Planar-CSMP-1. It is easy to see here that the solution admits a succinct representation since the parameter itself is the makespan. The difficulty is that the number of robots in the instance can be very large compared to the parameter ℓ, and we cannot find a realization of the succinct solution which avoids the "blocker" robots that do not contribute to the realization. To cope with this hurdle, we exploit the planarity of the graph to reduce its diameter, thus reducing the instance to an instance on a graph with bounded treewidth. The fixed-parameter tractability of the problem will then follow from Courcelle's Theorem [2, 8].

The heart of our reduction method is finding an "irrelevant edge" in the graph that can be safely contracted to produce an equivalent instance of the problem. While the method of finding an irrelevant edge and contracting it has been employed in several results in the literature to exclude large grids, thus reducing the treewidth of the graph, in our setting the grid approach seems unworkable. Instead, we show that a sufficiently-large component C of free vertices (i.e., vertices with no blockers on them) must contain an irrelevant edge. We reduce all the cases to one where C is formed by a skeleton consisting of a "long" path of degree-2 vertices (the degree is taken in C), plus a "small" number of additional vertices. We then show that if the instance is a YES-instance of the problem, then it admits a solution that interacts nicely with this skeleton, in the sense that we can identify a subgraph of the representation of the solution, i.e., a topological minor that is essentially a roadmap of the solution, separated from the rest of the solution by a small cut. We can enumerate each possible representation of the part of the solution that interacts with the skeleton, and for each possible representation, test whether it exists near the skeleton; if it does, we mark the vertices in the graph that realize this representation. Since the skeleton is long, the total number of marked vertices on the skeleton is small, and an edge with both endpoints unmarked – and hence can be contracted – must exist.

Related Work. The CSMP problem, with $p = k$, has been studied in [7] on several graph classes, and with respect to various settings, based on whether or not the destinations of the robots are distinguished (referred to as labeled or unlabeled). The graph classes that were considered include trees, grids, planar graphs, and general graphs, and it was shown that the problem is NP-hard even for (full rectangular) grids. Upper and lower bounds on the makespan of a solution, as well as computational complexity and approximation results, were derived for the various settings considered in [7].

A related problem to CSMP is that of moving unit disks (or objects [16]) in the plane, which has been studied in the context of reconfiguring/moving coins in the plane [1, 4], and was shown to be NP-hard [1]. We also mention the related work on coordinated pebble motion on graphs (and permutation groups), which was studied in [25] motivated by the work on the $(n^2 - 1)$-puzzle. The variant of coordinated motion planning in which only one designated robot is required to reach its destination, that is $p = 1$, and each move is along a single edge, was studied as Graph Motion Planning with 1 Robot in [27].

Despite the tremendous amount of work on coordinated motion planning problems, not much work has been done from the parameterized complexity perspective. The work in [10] studied the parameterized complexity of the non-sliding version of CSMP, that is, where each motion step is along a single edge, parameterized by the makespan in the serial setting. Another recent work [17] studied the parameterized complexity of the classical coordinated motion planning problem on grids, presenting parameterized algorithms for various objective measures (makespan, travel length). The work in [20] established the W[1]-hardness of the classical coordinated motion planning problem parameterized by the makespan in the parallel motion setting, and also showed the NP-hardness of this problem on trees, among other results. Finally, the parameterized complexity of a geometric variant of the PSPACE-complete Rush-Hour problem, which itself was shown to be PSPACE-complete [21], was studied [19]; in particular, that problem was shown to be FPT when parameterized by either the number of robots (i.e., cars) or the number of moves.

2 Terminology and Problem Definition

We assume basic familiarity with parameterized complexity theory, including *fixed-parameter tractability*, *parameterized reductions*, and the class W[1] [9, 15]. We also assume knowledge of standard graph-theoretic notions such as planarity, graph diameter and vertex degree [13]. We write $[n]$, where $n \in \mathbb{N}$, for $\{1, \ldots, n\}$.

Treewidth is a fundamental graph parameter which can be seen as a measure of how similar a graph is to a tree; trees have treewidth 1, while the complete n-vertex graph has treewidth $n - 1$. A formal definition of treewidth will not be necessary to obtain our results; we will make use of the fact that every planar graph with diameter r has treewidth at most $3r + 1$ [5, 30] and of Courcelle's Theorem [2, 8], which in particular provides a linear-time procedure to identify vertex subsets satisfying properties definable in *Monadic Second Order Logic* (MSO) on graphs of constant treewidth. We also use the notion of *treedepth* [26].

Rooted graphs. A rooted graph is a graph where some vertices are labeled – formally:

▶ **Definition 1** (Rooted graphs). *A* rooted graph *is a graph G with a set $\partial(G) \subseteq V(G)$ of distinguished vertices called* roots *and a labeling $\lambda_G : \partial(G) \to \mathbb{N}$. The set $\partial(G)$ is the* root set *of G, and the* label set *of G is $\Lambda(G) = \{\lambda_G(v) \mid v \in \partial(G)\}$.*

▶ **Definition 2** (Topological minors of rooted graphs [22]). *Let G and H be two rooted graphs with labelings λ_H and λ_G for their root sets. We say that H is a* topological minor *of G if there exist injective functions $\phi : V(H) \to V(G)$ and $\varphi : E(H) \to \mathsf{paths}(G)$ such that*

- *for every $e = \{h, h'\} \in E(H)$, the endpoints of $\varphi(e)$ are $\phi(h)$ and $\phi(h')$,*
- *for every distinct $e, e' \in E(H)$, the paths $\varphi(e)$ and $\varphi(e')$ are internally vertex-disjoint,*
- *there does not exist a vertex v in the image of ϕ and an edge $e \in E(H)$ such that v is an internal vertex on $\varphi(e)$, and*
- *for every $v \in \partial(H)$, $\lambda_H(v) = \lambda_G(\phi(v))$.*

We say that (ϕ, φ) *is a* realization *of* H *as a topological minor in* G*. Moreover, the subgraph of* G *induced by the union of the edges in the paths in* $\varphi(e)$ *for* $e \in E(H)$ *and the vertices in* $\phi(h)$ *for* $h \in V(H)$ *is called a* topological minor model *of* H*.*

Note that for $\partial(G) = \emptyset$ the above coincides with the usual definition of topological minors.

▶ **Proposition 3.** ([22]) *There is an algorithm that, given two rooted graphs* G *and* H*, runs in time* $f(|H|) \cdot \mathcal{O}(|G|^3)$ *for some computable function* f *and decides whether* H *is a topological minor of* G*.*

Problem Formalizations. In our problems of interest, we are given an undirected graph G and a set $\mathcal{R} = \{R_1, R_2, \ldots, R_k\}$ of k robots where $\mathcal{R}$ is partitioned into two sets $\mathcal{M}$ and $\mathcal{F}$. Each $R_i \in \mathcal{M}$, has a starting vertex s_i and a destination vertex t_i in $V(G)$ and each $R_i \in \mathcal{F}$ is associated only with a starting vertex $s_i \in V(G)$. We refer to the elements in the set $\{s_i \mid i \in [k]\} \cup \{t_i \mid R_i \in \mathcal{M}\}$ as *terminals*. We assume that all the s_i are pairwise distinct and that all the t_i are pairwise distinct. We use a discrete time frame $[0, q]$, $q \in \mathbb{N}$, to reference the sequence of moves of the robots. In each time step $x \in [0, q]$, exactly one robot moves and the rest remain stationary.

In Coordinated Sliding-Motion Planning (CSMP), we are given a tuple $(G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$, where $G, \mathcal{R}$ and k are as described in the last paragraph and $\ell \in \mathbb{N}$. The goal is to decide whether there is a sequence of $q \leq \ell$ moves such that robots move serially one at a time, where a robot's move consists of a move along a free/unobstructed path (i.e., a path in which no other robot is located at the time of the move), and such that each $R_i \in \mathcal{R}$ starts in s_i at time step 0 and each $R_i \in \mathcal{M}$ is positioned on t_i at the end of time step q. The second problem that we consider is a restriction of CSMP to the case where G is planar and $\mathcal{M}$ contains exactly one robot, referred to as the *main* robot. We refer to this restriction as Planar-CSMP-1, and for simplicity represent its instances as tuples of the form $(G, s, t, \ell, \mathcal{R})$, where s and t are the starting and destination vertices of the main robot, respectively, and $\mathcal{R}$ is the set of all robots.

We next introduce some notation that will be used in our technical sections. A *route* for robot R_i is a tuple $W_i = (u_0^i, P_1^i, u_1^i, \ldots, P_q^i, u_q^i)$ where each u_j^i is a vertex in G and each P_j^i is a simple path in G, such that (i) $u_0^i = s_i$ and $u_q^i = t_i$ if $R_i \in \mathcal{M}$ and (ii) $\forall j \in [q]$, P_j^i is a u_{j-1}^i-u_j^i path in G (if $u_{j-1}^i = u_j^i$, then P_j^i is the singleton path comprising the same vertex).

Put simply, each W_i corresponds to a "walk" in G. If vertices of W_i at two consecutive time steps $j-1$ and j are identical, then j is a *waiting time step* for the robot R_i. Moreover, each R_i begins at its starting vertex at time step 0, and if $R_i \in \mathcal{M}$ then R_i is at its destination vertex at time step q. Though we work with undirected graphs and the paths described above are undirected paths, each path P_j^i has a natural *starting vertex* and *ending vertex* designated by the time step j.

▶ **Definition 4.** Two routes $W_i = (u_0^i, P_1^i, \ldots, P_q^i, u_q^i)$ and $W_j = (u_0^j, P_1^j, \ldots, P_q^j, u_q^j)$, where $i \neq j \in [k]$, are *non-conflicting* if $\forall r \in \{0, \ldots, q\}$, the path P_r^i is disjoint from u_{r-1}^j and the path P_r^j is disjoint from u_{r-1}^i. Otherwise, we say that W_i and W_j *conflict*.

In particular, in the above definition, for every $i \neq j \in [k]$ and $\forall r \in \{0, \ldots, q\}$, $u_r^i \neq u_r^j$.

A *schedule* S for $\mathcal{R}$ is a set of pairwise non-conflicting routes $W_i, i \in [k]$, during a time interval $[0, q]$, where exactly one robot moves in each time step. The *number of moves* in a route $W_i = (u_0^i, P_1^i, \ldots, P_q^i, u_q^i)$ or the number of moves of its associated robot is the number of time steps j such that $u_j^i \neq u_{j+1}^i$. The *total number of moves* (or *makespan*) in a schedule is the sum of the number of moves in its routes. A schedule of minimum total moves is called an *optimal schedule*.

A vertex v is *occupied* at time step i if some robot is located at v at time step i; otherwise, v is said to be *free* (or *unoccupied*). If the time step is not specified, it is assumed to be time step 0 (i.e., in the initial state). At each time step, a robot may either move to a different vertex, or stay at its current vertex. Finally, we always assume that the input graph is connected since otherwise, we can work on individual connected components.

Remarks on Feasibility and Constructiveness. When only considering feasibility, CSMP is equivalent to the version where each move is along a single edge instead of an unobstructed path. Hence, feasibility testing is linear-time solvable [10, 39] and we can work under the assumption that every instance of CSMP is feasible (otherwise, we can reject the instance).

3 FPT Algorithm for CSMP Parameterized by the Number of Robots

In this section, we show that CSMP is FPT parameterized by the number k of robots in the input. Note that we do not assume any restrictions on the input graph.

Our strategy has three high-level steps: (i) We first show that if a solution exists, then there is an optimal schedule whose makespan is bounded[2]. (ii) We then show that such a solution is essentially a realization of a rooted graph H of bounded size as a topological minor in a rooted graph G' obtained by assigning unique labels to the terminals in G. We also prove the converse, that is, from any realization of H as a topological minor in G', one can obtain an optimal solution for the given instance. (iii) Finally, we leverage known results on topological minor containment to verify the existence of the correct rooted graph. Let us now give more detail on Steps (i) and (ii).

Step (i): To prove the existence of a solution with boundedly many moves, we preprocess the graph by applying a reduction rule that shortens degree-2 paths to a bounded length. This simplification allows us to focus on two cases for the graph (assuming it is connected):

Case (a): Bounded Treedepth. If the graph has bounded treedepth, we show that instances with bounded treedepth and a bounded number of robots can be reduced iteratively without altering the solution. This reduction process results in an instance of bounded size, implying the existence of a solution with a bounded makespan.

Case (b): Long Paths. Suppose every vertex is the endpoint of a sufficiently long path. We use ideas from [10] to define a suitable notion of *havens* for our setting; in particular, havens are subgraphs of bounded size that can efficiently handle collisions. Here, by the "efficient handling" of collisions, we mean that given any pair of "configurations" of robots in a haven, we can move the robots from one configuration to another without any conflicts using only boundedly many moves. Thus, with a small number of time steps, a robot can pass through a haven without collision, regardless of other robots in the haven. Building on this fact, we construct a schedule where each robot interacts with only a bounded number of havens. Within each haven, the number of moves used by a robot is bounded and we show that outside the havens, the robot only makes boundedly many moves as well. This yields a bound on the makespan of the schedule.

Step (ii): Consider the graph induced by the edges in the solution. We partition the vertices of this graph into two sets: important and unimportant vertices. The important vertices are those with degree at least three, the terminals, and any vertex where a robot waits at any time step. We show that the number of important vertices is bounded by a function of k (say, $\zeta(k)$). Moreover, by definition, the unimportant vertices form paths with only degree-2 vertices as internal vertices. Additionally, every robot that visits a vertex in such a path

[2] We recall that by bounded, we mean "bounded by a function of the parameter" – in this case, k.

slides without stopping on any vertex of this path. This structure enables us to show that the graph induced by the edges in the solution (with terminals as roots) is a realization of some rooted graph with at most $\zeta(k)$ vertices as a topological minor in the input graph.

3.1 Bounding the Makespan in an Optimal Schedule

Our first task is to apply a reduction rule to the given instance that enforces useful structural properties on the graph without affecting the existence of a solution.

▶ **Reduction Rule 1.** *Let $I = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of* CSMP*. If there is a path P in G such that every internal vertex of P is disjoint from the set of terminals and has degree exactly two in G, then shorten P to length $min\{|P|, 2k + 1\}$.*

We say that an instance I is *irreducible* if Reduction Rule 1 cannot be applied. In the rest of this section, we work with such instances. Our goal now is to show that every YES-instance has a schedule in which the makespan is bounded by a function of the number of robots.

▶ **Lemma 5.** *Let $I = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$ be an instance of* CSMP*. If I is a* YES*-instance, then I has an optimal schedule with $2^{\mathcal{O}(k^4)}$ moves.*

The proof strategy of Lemma 5 is as follows. We show that for a YES-instance, either the treedepth of the input graph is bounded or a certain locality property holds (roughly speaking, every vertex is sufficiently close to a vertex of degree at least three). We then show that in either case, there is a solution with boundedly-many moves. Specifically, when the treedepth is bounded, we show how to reduce the graph to a bounded-size graph without affecting the existence of a solution (thus implicitly bounding the makespan of an optimal solution) and otherwise, we show how the aforementioned locality property can be used along with a greedy strategy to produce a schedule with boundedly many moves (again, bounding the makespan of an optimal solution).

3.2 Succinct Representation of a Solution

In what follows, fix an optimal schedule $S = \{W_i \mid i \in [k]\}$ for an instance $I = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$. By Lemma 5, we may assume, without loss of generality, that S has length $2^{\mathcal{O}(k^4)}$. We also assume that no robot moves in two consecutive time steps since otherwise, the movements of such a robot could be done in a single time step while the remaining robots wait. Moreover, we say that an edge e of G is *traversed by* S if there is an $i \in [k]$ and a time step j such that the path P^i_j contains the edge e. That is, some robot R_i uses the edge e in some time step j. We denote by G_S, the subgraph of G induced by the edges traversed by S. For a time step j, we denote by $G_{S,j}$ the subgraph of G_S induced by the edges traversed by S up to time step j. A vertex v in G_S is a *waiting vertex* within time interval $[0, j]$ if there is a robot R_i and a time step $j' \leq j$ such that R_i is at v at time steps $j' - 1$ and j. We say that v is a waiting vertex if it is a waiting vertex within some time interval. A vertex v in G_S is an *intersection* vertex within time interval $[0, j]$ if its degree in $G_{S,j}$ is at least three. We say that v is an intersection vertex if it is an intersection vertex within some time interval. A vertex v in $G_{S,j}$ is an *important* vertex within time interval $[0, j]$ if it is either a terminal vertex, or within time interval $[0, j]$ it is a waiting vertex or an intersection vertex. Otherwise, v is *unimportant* within time interval $[0, j]$. We say that v is an important (unimportant) vertex if it is important (resp. unimportant) within some time interval.

▶ **Observation 6.** *The number of waiting vertices within time interval $[0, j]$ is at most $k + j$.*

▶ **Observation 7.** *The unimportant vertices within any time interval $[0, j]$ induce a disjoint union of paths and any endpoint of any of these paths has degree 2 in $G_{S,j}$.*

For a time step j, we denote by $\mathcal{P}_{S,j}$, the set of all x-y paths P of non-zero length such that x and y are distinct important vertices within time interval $[0, j]$ and every internal vertex of P is an unimportant vertex within time interval $[0, j]$.

For two paths P and P' in G, their *crossing points* are those vertices that have degree at least three in the graph induced by the edges in $E(P) \cup E(P')$.

We say that S is a *special schedule up to time step* j if, for every robot R_i and $j > 0$ such that R_i moves in time step j, the path P^i_j has at most four crossing points with any path in $\mathcal{P}_{S,j'}$ where $j' \leq j - 1$. Note that every schedule is trivially special at time step 1 since only a single path has been taken at this point. Moreover, $\mathcal{P}_{S,1}$ has size at least one because a move has been made and so, $\mathcal{P}_{S,j}$ has size at least one for every j. We say that S is a *special schedule* if it is a special schedule up to the final time step.

We say that two schedules are *equivalent at time step* j if the positions of all the robots at the end of time j is the same in both schedules, that is, robot R_i is on vertex v after time step j in one schedule if and only if the same happens in the other schedule. We say that two schedules are equivalent if they are equivalent at every time step. In particular, two equivalent schedules take the same number of time steps.

▶ **Lemma 8.** *There is a solution* S' *that is a special schedule.*

Henceforth, we assume that the solution S is a special schedule.

▶ **Lemma 9.** *The number of important vertices in* G_{S} *is bounded by* $2^{2^{\mathcal{O}(k^4)}}$.

3.3 Leveraging Succinct Representations and Topological Minor Containment

In what follows, fix a schedule $S = \{W_i \mid i \in [k]\}$ for an instance $I = (G, \mathcal{R} = (\mathcal{M}, \mathcal{F}), k, \ell)$.

We define the *representation* of S to be the rooted graph (denoted by H_S) whose vertices are the important vertices of G_S, and in which there is an edge between two vertices u and v if and only if there is a u-v path in G_S whose internal vertices have degree 2 in G_S and are unimportant. Moreover, the terminals receive unique labels (assume that the terminals are labeled with $[p]$ for some $p \leq 2k$) and the remaining vertices receive the same label which is distinct from those of the terminals, say $p + 1$. An illustration is provided in Figure 1. From Lemma 9, we directly obtain:

▶ **Lemma 10.** *If* S *is a special schedule, then its representation has* $2^{2^{\mathcal{O}(k^4)}}$ *vertices.*

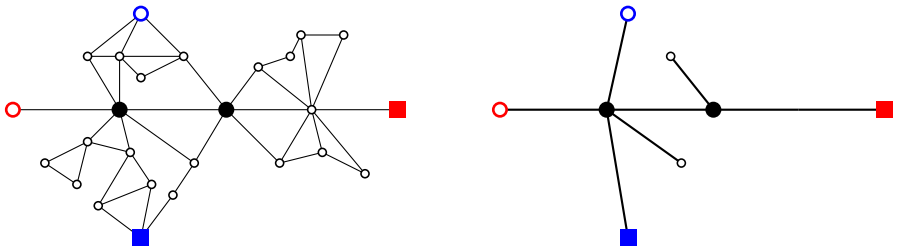


Figure 1 Left: an instance of CSMP with two robots with destinations (red and blue, with destinations marked as squares) and two blocker robots (both marked as solid black circles). Right: A representation of one particular optimal schedule for this instance, where we first move the two blockers and then the remaining two robots.

For the graph G, we let G' denote the rooted graph where the terminals get their unique labels and the rest of the vertices get a specific label $p+1$, where p is the number of terminals.

▶ **Lemma 11.** *H_S is a topological minor of G' and moreover, any realization of H_S as a topological minor in G' implies a schedule with length at most that of* S.

▶ **Theorem 12.** CSMP *is fixed-parameter tractable parameterized by the number of robots.*

Proof. For a hypothetical optimal solution S, we guess (i.e., use brute-force branching to determine) the representation H_S. By Lemmas 8 and 10, there are at most $2^{2^{2^{\mathcal{O}(k^4)}}}$ choices and these can be enumerated in FPT time. For each H_S, we do the following:

1. Decide whether the guess is feasible by brute-forcing over it. More precisely, we guess the configurations of the robots at each time step and verify that this guess corresponds to a set of non-conflicting routes with at most ℓ moves in total. Reject guesses that do not pass this check. Clearly, this step takes time $f(k)$ for some computable function f.
2. If H_S is not rejected, then invoke Proposition 3 to decide whether H_S is a topological minor of G' and return "yes" if and only if at least one of the invocations returns "yes".

Fixed-parameter tractability follows from the fact that Proposition 3 is used at most $f(k)$ times. The correctness follows from Lemma 10 and Lemma 11. ◀

4 An FPT Algorithm for Planar-CSMP-1 Parameterized by the Makespan

We start by giving a high-level description of the result. Our aim is to prove that Planar-CSMP-1 is fixed-parameter tractable parameterized by ℓ. The crux of our technique is showing that a sufficiently large component of free vertices must contain an edge that can be safely contracted. These contractions eventually result in bounding the size of each free component in the graph, and consequently the diameter and hence the treewidth of the graph (due to planarity). The fixed-parameter tractability of the problem will then be established using Courcelle's Theorem [2, 8].

To show that each large component C of free vertices contains an edge that can be safely contracted, we first show that this is the case unless C is formed by a skeleton consisting of a sufficiently long path of degree-2 vertices (the degree is taken in C), plus a sufficiently small number of additional vertices. We then focus on the skeleton of this component. We show that if the instance is a YES-instance of the problem, then it admits a solution S that interacts "nicely" with this skeleton. Recall from the previous section that a solution can be succinctly represented as a rooted topological minor of size $\sigma(\ell)$ for some computable function σ. This is because at most ℓ robots move in the solution. Now, we can identify a subgraph S of the representation of the solution (i.e., a topological minor that is essentially a roadmap of the solution), that is separated from the rest of the solution by a small cut. The realization of this subgraph uses most of the skeleton and the remaining part of this realization consists of small subgraphs that are close to the skeleton. Therefore, we can assume that all edges in these parts of the subgraphs are realized by edges in the graph.

Thus, it suffices to enumerate each possible representation of the part of the solution that interacts with the skeleton (which can be done in FPT-time), and test whether it exists near the skeleton; if it does, we mark the vertices in the graph that realize this representation. Since the skeleton is long, the total number of marked vertices on the skeleton is small, and an edge with both endpoints unmarked that can be contracted must exist. We remark that in many of the arguments that we make, we rely on the crucial fact that, except for the main robot, the robots are "indistinguishable" from each other. We now proceed to the details.

Refer to a vertex on which a robot other than the main robot is located as a *blocker* vertex. Let the *blocker-distance* between a vertex v and a vertex w, denoted $blockd(v, w)$, be the minimum integer p such that there is a v-w path in G containing p blocker vertices. The

reason why the blocker-distance is relevant is that we show that vertices which have high blocker-distance from s and t can be removed from the graph. Observe that, for any two vertices v, w, *blockd*(v, w) can be computed in polynomial time via, e.g., Dijkstra's algorithm.

Let $\mathcal{I} = (G, s, t, \ell, \mathcal{R})$ be an instance and let $F \subseteq V(G)$ be the set of free vertices in G. A *free component* is a connected component of $G[F]$. Free components will be central to our proof – in particular, observe that the blocker-distance between s and t is at most $\ell - 1$ and we can safely remove all vertices from G at blocker distance at least $\ell + 1$ from s. Hence, if there are no large free components, then the diameter of G is bounded. As G is planar, also its treewidth is bounded and we can use Courcelle's Theorem [2, 8] to prove the following:

▶ **Lemma 13.** Planar-CSMP-1 *can be solved in time $f(\ell, \lambda) \cdot |\mathcal{I}|$, where f is a computable function and λ is the size of the largest free component in the input instance $\mathcal{I}$.*

The Structure of Free Components. The following observation is straightforward:

▶ **Observation 14.** *Let Q be a path of free vertices and let x, y be arbitrary vertices on Q such that the subpath of Q between x and y has length at least ℓ. If there exists an x-y path P_{xy} whose internal vertices are disjoint from Q such that the number of blockers on P_{xy} is at most $\ell - \mathrm{blockd}(s, x) - \mathrm{blockd}(y, t) - 1$, then the instance $\mathcal{I}$ is a* YES*-instance and we can output a solution for $\mathcal{I}$ in polynomial time.*

We refer to a path where the above observation does not result in solving the instance as a *resilient* path. In other words, a path Q is resilient if and only if for every pair of vertices x, y in $V(Q)$ whose distance on Q is at least ℓ, there is no x-y path Z in $G - Q$ with at most $\ell - \mathit{blockd}(s, x) - \mathit{blockd}(y, t) - 1$ blockers. Our goal is to show that every "sufficiently large" free component contains a "still sufficiently long" path with certain special properties that, intuitively, allow the path to be "cleanly separated" from a hypothetical solution. This is formalized in the following definition and lemma, where the property of being "still sufficiently long" is given by the function $g(\ell) = 32\ell^6 \cdot 2^{14\ell^2} + 1$.

▶ **Definition 15.** *Let Q be a path in a free component C with endpoints u', v'. We say that Q is* ℓ-clean *if it satisfies the following conditions:*

1. *every vertex in Q has degree precisely 2 in C;*
2. *$|V(Q)| > g(\ell)$;*
3. *if $\mathcal{I}$ admits a solution that intersects $V(Q)$, then there are two vertices $u, v \in V(Q)$, each at distance at most $\ell^2 + 1$ from u' and v', respectively, and a solution S for $\mathcal{I}$ such that: $\{u, v\}$ is a cut in G_{S} between $\{s, t\}$ and the u-v subpath of Q; we denote by Q^{S}_{uv} the connected subgraph of G_{S} that contains u, v and all the connected components of $G_{\mathrm{S}} - \{u, v\}$ that do not contain s or t; and*
4. *Q is resilient.*

▶ **Lemma 16.** *There is a polynomial-time procedure which takes as input a free component C in an instance $\mathcal{I} = (G, s, t, \ell, \mathcal{R})$ such that $|V(C)| \geq (g(\ell) + 1) \cdot (\ell - 1) + 3(\ell + 2)$, and either solves the instance, or outputs an instance equivalent to $\mathcal{I}$ obtained by contracting an edge in C, or outputs an ℓ-clean path Q in C.*

4.1 Finding Irrelevant Edges

For the following considerations, it will be useful to proceed with a fixed choice of C and an ℓ-clean path Q. Next, we will show that we can make an even stronger assumption about the hypothetical solutions "passing through" Q.

▶ **Lemma 17.** *Assume that $\mathcal{I}$ admits a solution that intersects $V(Q)$. Then there exist vertices u, v each at distance at most ℓ^2+1 from u' and v', respectively, and a solution S^* for $\mathcal{I}$ satisfying properties 3-4 in Definition 15, and furthermore satisfying the following property 5: $|V(Q^{S^*}_{uv}) - V(Q)| \leq \ell$.*

For the following, we will refer to a solution satisfying properties 3-5 as (Q,u,v)-*canonical*, or simply Q-canonical in brief when the identities of u and v do not matter. From the properties of canonical solutions, we can directly establish the following:

▶ **Lemma 18.** *Let S^* be a Q-canonical solution. Then there is a $(2\ell^2)$-vertex rooted graph $U^{S^*}_{uv}$ (with roots u, v and* `occupied`*), such that $U^{S^*}_{uv}$ is a rooted topological minor of G (with roots u, v and* `occupied`*) and there is a realization (ϕ,ψ) of $U^{S^*}_{uv}$ that maps $U^{S^*}_{uv}$ to $Q^{S^*}_{uv}$. Moreover, waiting vertices are in $\phi(U^{S^*}_{uv})$ and for every edge $e \in E(U^{S^*}_{uv})$ either $\psi(e)$ is a single edge or a subpath of Q.*

Crucially, below we provide a procedure that can efficiently test for $U^{S^*}_{uv}$ as defined above.

▶ **Lemma 19.** *Let Q be an ℓ-clean u'-v' path and let u, v be the vertices specified in property 3 of Definition 15. Let $p \leq 2\ell$ and U be a connected p-vertex rooted graph with roots u, v and "*`occupied`*" such that U contains at most $\ell - \text{blockd}(s,x) - \text{blockd}(y,t) - 1$ occupied vertices. There is a procedure which runs in time $2^{\mathcal{O}(\ell^2)} \cdot |V(G)||V(Q)|$ and either outputs a realization (ϕ,ψ) of U which results in a subgraph $\Gamma \subseteq G$ such that:*

- *u,v separate Γ from u' and v', and*
- *for every edge $e \in E(U)$ either $\psi(e)$ is a single edge or a subpath of Q, or*

correctly determines that no such $(\Gamma,(\phi,\psi))$ exists.

Proof Sketch. As the first step, we use the ℓ-cleanness of Q to establish that if Γ exists, then it must have a "necklace-like" structure. In particular, such a Γ must consist of the u-v subpath of Q along with at most p connected subgraphs $\Gamma_1,\ldots,\Gamma_j$, each of size $p+p\ell$, each intersecting the u-v subpath of Q but otherwise being pairwise disjoint, and having pairwise distance at least $\ell+1$ on $G[Q]$. We further may assume that $\Gamma_1,\ldots,\Gamma_j$ are ordered based on their distance to u.

With this knowledge, we exhaustively branch to consider every possible choice of rooted subgraphs $\Gamma_1,\ldots,\Gamma_j$ (up to isomorphism) to construct a set of *signatures* of a hypothetical tuple $(\Gamma,(\phi,\psi))$; crucially, the number of such signatures can be upper-bounded by $\ell^{\mathcal{O}(\ell)}$. We can now show that to test whether there exists some tuple $(\Gamma,(\phi,\psi))$, it suffices to consider each signature individually and see if there is a "leftmost" Γ matching that signature, i.e., a Γ where the subgraphs $\Gamma_1,\ldots,\Gamma_j$ are pushed as close to u as possible (while adhering to the properties of the given signature). This then allows us to process the u-v subpath of Q from u to v and test, at each vertex x, whether it could be the "first vertex" of Γ_1. Once we find the leftmost such x, we can jump ahead by $\ell+1$ and proceed to Γ_2, and so forth.

A key point here is that since each of the subgraphs $\Gamma_1,\ldots,\Gamma_j$ has bounded size, it suffices to perform each such test on the $(p+p\ell)$-neighborhood of x. Since this graph is planar and has bounded diameter (by a function of ℓ), it also has bounded treewidth [5,30], thus allowing us to employ well-known subgraph-isomorphism testing algorithms [14] to determine whether each x can indeed be part of a specified subgraph Γ_i. We remark that performing this test on each vertex individually is critical: the subgraph of G induced on the neighborhood of all of Q may have arbitrarily large treewidth. ◀

We call the subgraph Γ identified above a *host* for the *roadmap* U.

▶ **Reduction Rule 2.** *Let Q be a given ℓ-clean u'-v' path. There is a reduction rule which enumerates:*

- *the family $\mathcal{U}$ of all connected rooted graphs (with roots u, v and* `occupied`*) containing at most $(2\ell^2)$-many vertices, and*
- *the set Z of all vertex pairs (u, v) at distance at most $\ell^2 + 1$ from the respective endpoints of Q,*

and then for each choice of $U \in \mathcal{U}$ and $(u, v) \in Z$, applies Lemma 19 to determine whether there is a host of U w.r.t. (u, v) on Q. If there is, we mark *every vertex in $\phi(U) \cap V(Q)$ where (ϕ, ψ) is the computed realization.*

Afterwards, if there is an edge e on Q with two unmarked endpoints, we contract e.

▶ **Lemma 20.** *Reduction Rule 2 is safe. Moreover, for each ℓ-clean path Q, it can be executed in time at most $2^{\mathcal{O}(\ell^2)} \cdot |V(G)| \cdot |V(Q)|$, and is guaranteed to perform a contraction if Q contains more that $32\ell^6 \cdot 2^{14\ell^2} + 1$ many vertices.*

▶ **Theorem 21.** Planar-CSMP-1 *is fixed-parameter tractable parameterized by ℓ.*

Proof. We begin by applying Lemma 16 to each free component in G of size at least $\big(g(\ell) + 1) \cdot (\ell - 1)\big) + 3(\ell + 2)$. If this solves the instance, we are done; otherwise, it is guaranteed to either produce an equivalent instance obtained by an edge contraction (in which case we repeat), or identify an ℓ-clean path Q of length more than $g(\ell) = 32\ell^6 \cdot 2^{14\ell^2} + 1$. In the third case, we apply Reduction Rule 2 to Q to produce an equivalent instance obtained by an edge contraction in Q – as guaranteed by Lemma 20 – and restart.

The exhaustive application of the above procedure either correctly solves the input instance, or results in an equivalent instance such that each free component in G has size at most $\big(g(\ell)+1)\cdot(\ell-1)\big)+3(\ell+2)-1$. At this point, we invoke Lemma 13 to solve the instance. The overall running time is upper-bounded by $2^{\mathcal{O}(\ell^2)} \cdot |\mathcal{I}|^{\mathcal{O}(1)} + \zeta(\ell) \cdot |\mathcal{I}|$, where the former term is the running time of the preprocessing steps and ζ is a computable function that results from the application of Lemma 13 (and specifically of Courcelle's Theorem within that lemma) on an instance with the aforementioned bound on the size of free components. ◀

5 Conclusion

In this paper, we designed FPT algorithms for two important variants of the Coordinated Motion Planning problem on undirected graphs, CSMP and Planar CSMP-1, in which robots move by sliding along unobstructed paths. Our results take a different perspective and contribute new insights to the design of FPT algorithms for coordinated motion planning problems on graphs, developing and employing new techniques that combine topological graph theory, fixed-parameter tractability and computational logic. Our work opens up several interesting questions pertaining to the parameterization by the makespan ℓ.

1. Is CSMP parameterized by the makespan W[1]-hard on general graphs?
2. Can Theorem 21 be generalized to solve CSMP on planar graphs?
3. What is the parameterized complexity of CSMP and CSMP-1 on grids where each sliding-move/path is either horizontal or vertical?

Abstract

Bipartite graphs are a fundamental concept in graph theory with diverse applications. A graph is bipartite iff it contains no odd cycles, a characteristic that has many implications in diverse fields ranging from matching problems to the construction of complex networks. Another key identifying feature is their Laplacian spectrum as bipartite graphs achieve the maximum possible eigenvalue of graph Laplacian. However, for modeling higher-order connections in complex systems, hypergraphs and simplicial complexes are required due to the limitations of graphs in representing pairwise interactions. In this article, using simple tools from graph theory, we extend the cycle-based characterization from bipartite graphs to those simplicial complexes that achieve the maximum Hodge Laplacian eigenvalue, known as disorientable simplicial complexes. We show that a N-dimensional simplicial complex is disorientable if its down dual graph contains no simple odd cycle of distinct edges and no twisted even cycle of distinct edges. Furthermore, we see that in a N-simplicial complex without twisting cycles, the fewer the number of (non-branching) simple odd cycles in its down dual graph, the closer is its maximum eigenvalue to the possible maximum eigenvalue of Hodge Laplacian. Similar to the graph case, the absence of odd cycles plays a crucial role in solving the bi-partitioning problem of simplexes in higher dimensions.

1 Introduction

Bipartite graphs are useful tools in diverse domains, from matching problems and coding theory to social networks and biomedical applications such as cancer detection[1, 18, 15]. Exploring the properties of bipartite graphs, and their applications not only has enriched graph theory but also has opened the door to innovative solutions in challenging applications [1]. In the past few years, there has been a trend in understanding cycles in networks in terms of function, dynamics, and synchronizability [10]. Cycles and bipartite graphs are closely related. A graph is bipartite if and only if it has no odd cycles. Cycle-based characterization of bipartite graphs is essential in various domains, such as clustering, coloring and matching problems as well as complex network construction and analysis where detecting quasi-bipartite clusters, i.e. graphs with a few number of even cycles, is needed [7, 8]. Moreover, this characterization as well as some of its applications have been extended to directed graphs where a strongly connected digraph is bipartite if and only if it has no cycle of odd length [12].

One the other side, one can test for a graph being bipartite by observing the spectrum of the graph Laplacian, a matrix computed based on the incidence relations between vertices and edges of the graph. For the normalized Laplacian, the graph is bipartite if and only if two is the maximum eigenvalue of its Laplacian. Consider the spectrum of the normalized Laplacian of an unweighted graph in increasing order, $0 = \lambda_1 \leq ... \leq \lambda_n \leq 2$; the graph is connected if and only if λ_2 is bigger than zero and is bipartite iff λ_n is equal to two. While the down side of the spectrum tells the number of connected components (i.e. graph's topology), the up side reveals bipartiteness. Both the top and bottom eigenvalues then can help us to partition the vertices of the graph into two sets in two different ways; if λ_2 is positive but small we can partition the vertices into two sets with very few edges connecting the sets while elements of each set are highly connected to each other and they form clusters. And when λ_n is close to two we can partition the set of the vertices into two sets in a way that for each of these sets, there are few connections, and almost all of the edges, connect the vertices of one set to the other.

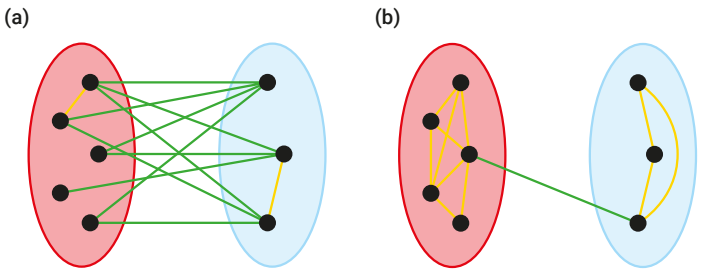

Figure 1 Partitioning vertices based on the Laplacian spectrum. In (a) vertices are partitioned based on λ_n and in (b) based on the λ_2.

Many empirical networks and complex systems however incorporate higher-order relations between elements and therefore are modeled as hypergraphs and/or simplicial complexes, rather than graphs. Simplicial complexes are generalizations of graphs where there are not only vertices and edges but also possibly triangles, tetrahedrons, and so on. To develop a systematic tool for the structural analysis of simplicial complexes, different methods, and theories have been extended from graphs to these higher-order structures. An important

question is that can the graph partitioning scheme that we described, be generalized to simplicial complexes? The main starting point to answer this question is the discrete "Hodge" Laplacian which is a generalization of the graph Laplacian for simplicial complexes. There have been many advances in our understanding of the spectrum of discrete Hodge Laplacian on simplicial complexes in the past few years [17, 11, 9]. Moreover, Laplacian-based methods have become popular for detecting the structure and dynamics of complex networks modeled by simplicial complexes in the past few years [3]. It is well known, due to Eckmann [5], that for any fixed d where $N \geq d \geq 0$ (N is the dimension of the complex), the minimum eigenvalue of the d-Laplacian can tell us about the topology of the complex in dimension d. This theorem has led to many theoretical findings regarding the minimum eigenvalues of the Laplacian on simplicial complexes [11, 9] as well as clustering methods for d-simplexes in such a way that the clusters represent the topology of the complex in dimension d [4, 16]. This is a generalization of what was described at the beginning based on the down side of the Laplacian spectrum for clustering the vertices of a graph. However, there is very little known about the maximum eigenvalue of the Laplacian and specifically the higher dimensional analogues for bipartiteness. A higher-order notion of bipartiteness called "disorientability", was introduced in [14] as a structure that the spectrum of the (up) Hodge Laplacian achieves its maximum possible value; the graph is the simplest setting and a one-dimensional simplicial complex is disoriantable if and only if it is bipartite. It is known that simple random walks on the vertices of a connected bipartite graph are periodic. It has been shown that the same is true when the random walks are on higher dimensional simplexes of a general simplicial complex and such random walks are periodic if and only if the complex is disorientable [14, 13, 6]. Random walks on graphs and simplicial complexes are the main tools in tackling diverse complex real-world problems from ranking web pages in Google page rank algorithm [2] to signal processing and flow network decomposition [16]. Considering the numerous theoretical implications and practical applications that bipartite graphs have, it is very desirable to develop our understanding of disorientability in simplicial complexes not just in terms of the spectrum of the Laplacian, but in terms of the combinatorial structure and shape of the complex and the parity of length of higher order cycles and see if we can have similar simplified characterization for recognizing whether a simplicial complex is disorientable and does disorientability give some kind of bi-portioning of the simplicies of higher dimensions in a similar manner like bipartite graphs? Similarly, can we detect quasi-bipartite clusters in higher dimensions? Since more data sets and some complex problems are nowadays represented by simplicial complexes and not graphs it seems necessary to develop the applied partitioning methods for partitioning the simplexes of dimensions higher than zero and explore further the applications, and devise algorithms. In this manuscript, we state conditions under which the simplicial complex is disorientable, in terms of the length of the higher dimensional cycles in the complex. Consequently, any simplicial complex can become disorientable by a finite number of splittings of some of the maximum dimensional simplexes; note that this is very similar to the graph case where by dividing some of the edges into two, and playing with the parity of the length of their cycles, we can always make the graph bipartite. And the fewer number of splittings needed to make the graph bipartite, the closer the maximum eigenvalue would be to the possible maximum eigenvalue of the graph Laplacian. We elaborate this for graphs and simplicial complexes in more details in the next sections (Lemma 19 and Theorem 20).

To the best of our knowledge, this is the first full characterization of disorientability from the combinatorial structure of the higher-dimensional cycles in simplicial complexes.

First, we recall some preliminary notions.

2 Background

▶ **Definition 1** (Simplicial complex). *A simplicial complex K on a vertex set $V = \{v_1, ..., v_n\}$ consists of a collection of simplices, that is, subsets of V with the requirement that all these subsets are closed under inclusion. A subset that contains $d+1$-vertices, is called a d-simplex. A 0-simplex is simply a vertex, a 1-simplex is an edge, and a 2-simplex is a triangle. The dimension of the complex is the maximum d, where we have at least one d-simplex in K.*

For computational purposes, we need to define an orientation for each d-simplex when $d \geq 1$.

▶ **Definition 2** (Oriented Simplex). *An orientation of a d-simplex is an equivalence class of orderings of its vertices, where two orderings are equivalent if they differ by an even permutation. For simplicity, we can choose the reference orientation of the simplices induced by the ordering of the vertex labels.*

A 0-simplex (a node) can have only one orientation. Hence, issues of orientation do not arise in graph-theoretic settings. Let S_d be the set of all d-simplexes in K with $0 \leq d \leq N$ and $[S_d]$ be the set of all oriented d-simplexes. For any d-simplex σ ($d \neq 0$) we have two opposite orientations, clockwise and counterclockwise (note that both are in $[S_d]$). A face of a d-simplex σ is a subset of σ with cardinality d, i.e., with one element of σ omitted. If ρ is a face of a d-simplex σ_d, then σ_d is called a co-face of ρ_{d-1}. The degree of a d-simplex is the number of its co-faces (i.e., of dimension $d+1$). A d-simplex is called branching if its degree is bigger than 2.

▶ **Definition 3** (Cycle, Simple and twisted Cycles). *A d-cycle of length l ($0 \leq d \leq N-1$) is a chain of d simplexes, $\sigma_d^0 ..., \sigma_d^l$ such that for each i, σ^i and σ^{i+1} are upper adjacent (i. e. they share a co-face) and $\sigma^0 = \sigma^l$. A d-cycle is called non-twisted (or simple) if there exist an assignment of orientations on its $d+1$-simplexes such that the induced orientation of every two $d+1$-simplex on their common d-face cancel each other (namely they are opposite). Otherwise we call it twisted. We call the simplicial complex non-twisting if it does not have a twisted cycle and otherwise, we call it twisting.*

▶ **Example 4.** A discrete cylinder and torus with respectively simple 0-cycle(s) and 1-cycle(s) are examples of non-twisting simplicial complexes and discrete Mobius strip and Klein bottle are twisting as they have respectively a 0-twisting cycle and a 1-twisting cycle (see Fig 4).

Note that graphs can not have twisted cycles and this just can happen in higher dimensions. Twisting cycles do not naturally arise in geometric and topological data analysis (TDA) when constructing Simplicial complexes from a set of data points. However, we present it here for the sake of completeness of our characterization.
We can extend face/co-face relations to the oriented d-simplexes with the help of the boundary/coboundary operators. The d-th chain group $C_d(K)$ of K is a vector space with real coefficients with the basis S_d.

▶ **Definition 5** (Boundary and co-boundary matrices). *The* boundary map $\partial_d : C_d(K) \to C_{d-1}(K)$ *is a linear operator from oriented d-simplices to oriented $(d-1)$-simplices defined by*

$$\partial_d[i_0, ...i_d] = \sum_{j=0}^{d} (-1)^j [i_0, .i_{j-1}, i_{j+1}..i_d]. \tag{1}$$

After choosing a basis for C_d, the boundary operator ∂_d can be represented by a matrix B_d, which enables us to simply perform computations via matrix calculus. For graphs, the matrix B_1 is the node-to-edge incidence matrix. Likewise, the higher-order boundary maps can be interpreted as higher-order incidence matrices between simplices and their (co-)faces for each B_i. The transpose of the boundary matrix B_i denoted by B_i^T represents the co-boundary map $\partial_d^T : C_d \to C_{d+1}$. This enables us to define (higher order) Laplacian:

▶ **Definition 6** (Hodge Laplacian). *We can define the d-th discrete (combinatorial) Hodge Laplacian as*

$$L_d = B_d^T B_d + B_{d+1} B_{d+1}^T. \tag{2}$$

For $d = 0$, $L_0 = B_1 B_1^T$ and for $d = N$, $L_N = B_N^T B_N$. $B_d^T B_d$ and $B_{d+1} B_{d+1}^T$ are respectively called the down and up Laplacians.

▶ Remark 7. For every d the non-zero spectrum of L_d^{up} equals to the non-zero spectrum of L_{d+1}^{down} [9].

We can extend Laplacian definitions and properties to arbitrary positive weight functions on the set of simplices (note that in the above case all the weights are one); another special case is the "normalized Laplacians" where for each simplex σ such that σ is not a facet, the degree of σ equal to its weight and the weights of all the facets are one.
The Laplacian spectrum and in particular its maximum eigenvalue can be obtained using the Rayleigh quotient. For a graph G we have:

$$\lambda_n = Sup_f \frac{\sum_{u \sim v} (f(u) - f(v))^2}{\sum_v f^2(v) d(v)}$$

where λ_n is the maximum eigenvalue of the normalized Laplacian and the supremum is taken over real-valued functions on the vertex set and $d(v)$ is the degree of the vertex v. This formula can be extended to weighted graphs as well as higher dimensions. For a N-dimensional simplicial complex $\lambda_n \leq N + 1$ [11].
We can create dual graphs of simplicial complexes based on the upper adjacency and/or lower adjacency connections between the simplexes. For this purpose, we consider a N-simplicial complex K and we fix a number d ($0 \leq d \leq N$).

▶ **Definition 8** (Dual graphs). *The up-dual graph G of K in dimension d is constructed as follows: each d-simplex in K becomes a vertex in the dual graph G, and there is an edge between two vertices in G if their corresponding d-simplexes in K share a co-face. Similarly, the down-dual graph G of K in dimension d is a graph G that its vertices are the d-simplexes of K but there is an edge between two vertices in G if their corresponding d-simplexes in K share a face. Particularly, the down-dual graph of a graph is called a line graph. We call a N-complex d-connected if the up dual graph in dimension d is connected.*

There are two types of generalizations for bipartiteness for a N-simplicial complex; a notion which has been investigated more, as it is connected to random walks [14], is called disorientability.

▶ **Definition 9** (Higher order bipartiteness). *A disorientation of a N-complex K is a choice of orientations of its N-simplexes, that whenever two arbitrary N-simplexes intersect in a $(N-1)$-simplex, they induce the same orientation on it (see Fig.2.). If K has a disorientation it is said to be disorientable. A graph is disorientable iff it is bipartite [14].*

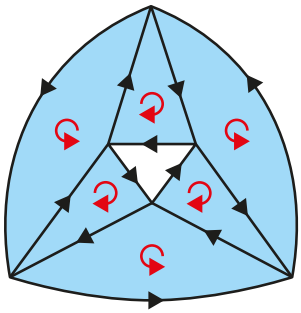

Figure 2 Example of a 2-d disorientable simplicial complex.

Another natural analogue is "$(d+1)$-partiteness": having some partition $A_0, ..., A_d$ of V so that every d-simplex contains one vertex from each A_i. A $(d+1)$-partite complex is seen to be disorientable, but the opposite does not necessarily hold for $d \geq 2$ [14]. Since this second case is not related to the spectrum of the Laplacian and periodicity of random walks and does not have the theoretical implications that disorientability has we will omit it here.

3 Main Results

To explore disorientable N-dimensional simplicial complexes we use their down-dual graphs and we start with graphs as 1-d complexes. As already mentioned in [14] bipartite graphs are disorientable and in fact, these two are equivalent in graphs. We elaborate on this from a signs perspective and the line graph of a graph.
If a graph is disorientable, there is a choice of orientations on its edges that adjacent edges induce the same orientation on their common vertex. Equivalently, there is an assignment of $\pm$ to vertices (note that these are just signs and not orientations) such that no two adjacent vertex have the same sign, namely we have a bipartite graph where each partition is labeled with one of these signs representing the head/tails of the oriented edges. Now let's look at the line graph of a bipartite graph. We have the following simple observation:

When going to line graphs of a general graph, its cycles and the parity of their length are preserved. But we might get some more cycles in the line graph that did not exist before due to the existence of branching vertices, i.e. those vertices that have degree bigger or equal than 3. We call these cycles branching cycles as they correspond to the branching vertices in the original graph. For any such vertex v with degree $\alpha \geq 3$ we would have a sequence of cycles with lengths α, $\alpha - 1$,.., 3 in the line graph. So if there exists no branching vertex, there is a one-to-one correspondence between the cycles in the graphs and its dual (line graph). Therefore if the graph is bipartite and non-branching its line graph is also bipartite.

Therefore a non-branching disoientable graph is a graph where we can assign $+$ and $-$ to the edges of its line graph such that no two adjacent edges have the same sign. But what if the bipartite graph has some branching vertices? In this case, the line graph is not bipartite and has (fundamental) odd cycles that for every such cycle, all of its edges relate to the same corresponding branching vertex. We note that if we consider general (not necessarily fundamental) cycles the existing odd cycles include more than one edge corresponding to that branching vertex. From graph theory, recall that a fundamental cycle is a cycle formed by combining a path within a spanning tree with an edge not in that tree.

Therefore, the graph is disorientable iff it is bipartite or equivalently iff its line graph has no odd cycle of distinct edges, namely they correspond to different vertices in the original graph. In the language of signs, a graph is disorientable iff in its line graph, we can assign $+$ and $-$ to the edges such that no two adjacent edges that correspond to different vertices in the original graph, get the same sign.

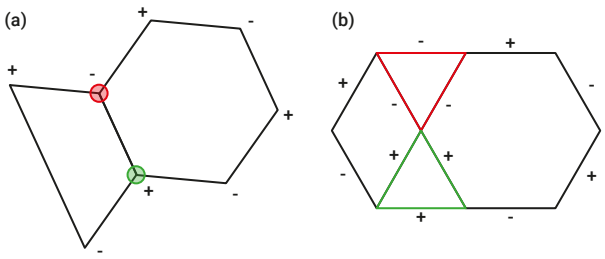

Figure 3 A bipartite graph and its line graph. (a) is bipartite and (b) is the line graph of (a) and has two odd cycles of length 3 corresponding to the branching red and green vertices in (a).

This simple but fundamental change of perspective from graphs to their line graphs helps us to explore bipartiteness in general simplicial complexes. We start with the simplest cases: non-branching and non-twisting simplicial complexes and we gradually develop the idea for the general case.

1. If the simplicial complex is non-branching and non-twisting:

▶ **Lemma 10.** *A non-branching, non-twisting simplicial complex is disorientable if and only if in its down dual graph, we can assign + and - to the edges in such a way that no two adjacent edges have the same sign. We note that this is equivalent to the condition that the down-dual graph has no odd cycle which is the same as bipartiteness.*

Proof. If the simplicial complex is disorientable, by definition there is an assignment of orientations on N-simplexes such that they induce the same orientation on their common face. Therefore, in its corresponding down dual graph, we would be able to have a single assignment of $+/-$ to each edge representing the induced orientations on the common $(N-1)$-faces (in the simplicial complex) such that no two adjacent edges get the same sign. This means that the down-dual graph has no odd cycle. Therefore it is bipartite. For the reverse, if there is such assignment of $+/-$ to the edges of the down-dual graph, by definition the simplicial complex is disorientable as each such sign for each edge can be interpreted as the unique induced sign on the common $(N-1)$-simplex (from its oriented N-simplexes cofaces). ◀

▶ Remark 11. The above lemma can be considered as a higher-dimensional version of the two-coloring problem on graphs. We note that in this case, we can color the max-dimensional simplexes with two colors in such a way that no two adjacent simplexes that share a face have the same color. Recall that a graph can be colored by two colors if and only if it is bipartite. Also planer graphs (graphs that can be drawn without any of their edges crossing) can be colored using at most four colors, such that no two adjacent nodes have the same color.

2. The simplicial complex is branching and non-twisting:
▶ **Lemma 12.** *A branching non-twisting simplicial complex is disorientable if and only in its down dual graph, either all of the edges of an odd cycle correspond to a branching $(N-1)$-simplex and/or that odd cycle includes more than one edge corresponding to that branching simplex.*

Proof. Similar to the branching bipartite graphs that are already described, for every branching $(N-1)$-simple α, in the down dual graph we would have a (branching) cycle of length= degree α, as well as all (branching) cycles with length between three and degree of α, such that all of the edges of these cycles correspond to α. Therefore, all of the edges corresponding to all of these cycles in the down dual graph are adjacent and get the same sign and when moving to another adjacent edge (that corresponds to another $(N-1)$-simple), the sign is changed. Therefore, we might have odd cycles, but they can just be for the branching $(N-1)$-simplexes, and no other fundamental odd cycle will exist. Also, when considering general odd cycles (not necessarily fundamental ones) they might include more than one edge corresponding to that branching simplex. ◀

3. The simplicial complex is non-branching and twisting:
▶ **Lemma 13.** *A non-branching simplicial complex is disorientable if and only if in its down dual graph, all the twisting cycles have odd length and all the non-twisting cycles have even length.*

Proof. As we saw, in non-branching (disoriantable) simplicial complexes, the down dual graph has no simple cycle of odd length. We should show every twisted cycle in the down dual graph should be odd to assure disorientability. We note that twisted cycles, by definition, always include two N-simplexes inducing the same orientation on their common face. We recall that this happens whenever we try to assign orientations on the N-simplexes in such a way that lower-adjacent N-simplexes induce opposite orientation on their common face. We call this three simplexes the twisted part. Lets assume the twisted cycle is as following:
$(N-1)$-cycle of length l, $\sigma^0_{N-1}, \beta^1_N ..., \beta^l_N, \sigma^l_{N-1}$
where $\sigma^0 = \sigma^l$ and $\sigma^0(\sigma^l)$, β^1_N and β^l_N is the twisting part.
If we start assigning orientations on N-simplexes, starting from β^1_N in a compatible manner where every two adjacent N-simplex in the cycle induce the same orientation on their common face, if l is even, due to the twisting part, the induced orientation of β^l_N on σ^l would be opposite of orientation of σ^0 induced by β^1_N (see Fig 4.a). Therefore we need odd number of N-simplexes in the cycle to make compatible induced orientations on all common faces along the cycle and in particular on the $\sigma^0 = \sigma^l$ (see Fig 4.c). Roughly speaking, the twisted part acts as an extra (hidden) N-dimensional simplex where the twisted connection corresponds to two faces of this simplex, with opposite orientations. Therefore, every twisted cycle as opposed to simple cycles should have odd length to induce the dissorientability condition along the cycle. The rest of the proof is as before and we omit it here. ◀

As examples of types 1 and 3, see Figure 4 in Example 17. Also, a single edge which is the face of three triangles is a simple example of a branching and non-twisting complex.

In conclusion, we have the following theorem that enables us to check the dissorientability of a general simplicial complex based on the length of the cycles of its down-dual graph.

▶ **Theorem 14.** *A simplicial complex is dissorientable if and only if in its down dual graph, the (possible) odd cycles only correspond to the branching* $(N-1)$*-simplexes and/or twisted cycles and there is no twisted cycle of even length.*

Proof. This can be simply obtained by combining Lemma 3.1, Lemma 3.3 and Lemma 3.4. ◀

▶ Remark 15. A similar result for the special case of this theorem on the normalized Laplacian in [9] was brought to our attention by the reviewers; there they use a detailed analysis of the spectrum of the up-Laplacian in simplicial complexes, while our approach is fully combinatorial and based on the shape of the down-dual graph where we show the results for the maximum eigenvalue of the Laplacian, independent of the weight function on the simplexes. This approach then helps us to obtain the following main result for general Laplacians.

▶ **Theorem 16.** *Every simplicial complex can become dissorientable by a finite number of splittings of some of the* N*-dimensional simplexes into two* N*-dimensional simplexes.*

Proof. We orient all of N-simplexes one by one in a compatible manner, namely in such a way that the adjacent N-simplexes induce the same orientation on their common face. If we can achieve this goal globally and for all of the lower-adjacent N-simplexes, we are done; i.e., the simplicial complex is disorientable. If not, there are at least two N-simplexes, A and B, such that they induce opposite orientations on their common face. We note that this means A and B are adjacent vertices in the down dual graph and based on the previous theorem both are included in a cycle of odd (even for the twisting cycles) length. We chose one of them arbitrarily (A) and we split it into two N-simplexes A' and A'', where A'' and B have non-empty intersections. We orient A' based on the orientation of A in such a manner that A and A' have exactly the same orientation on the shared face. We then orient A'' in a compatible manner with A' where they induce the same orientation on their common face. Then trivially A'' will have a compatible orientation with B, meaning they induce the same orientation on their common face. If we repeat this process for any two non-compatible N-simplex we get our desired result. We note that by splitting A, we make the length of the simple cycle in the down-dual graph including A', A'', B even, and the length of the twisted cycles will become odd. Also if the incompatibility is happening in a branching $(N-1)$-simplex, we might need to split more than one of the cofaces of such simplex; this splitting of course will not change the number of branching and consequently will not affect the length of its corresponding cycle in the down-dual graph. ◀

▶ Remark 17. Note that if splitting one/some of the N-simplex(es) divides its (their) free $(N-1)$-face(s) into two, then this will not have an effect on the other N-simplexes. But if we split the N-simplex in such a way that it divides its non-free face into two, due to the simplicial structure, this will also affect all other N-dimensional cofaces of the divided $(N-1)$ simplex, namely those which are lower adjacent to the original N-simplex (as shown in the next example).

▶ **Example 18.** In the presented example in Figure 4, we show how to make simplicial complexes disorintable and the effect on the cycles of their corresponding down-dual graphs.

We have two main rows of simplicial complexes (with blue) and the down-dual graph of each example is drawn at the bottom of each complex. The top row is the discrete Mobius strip and the bottom row corresponds to a tetrahedron.

▶ **Lemma 19.** *The fewer odd cycles a graph has, the fewer splittings are required to make the graph bipartite; in other words, the closer the maximum eigenvalue is to 2.*

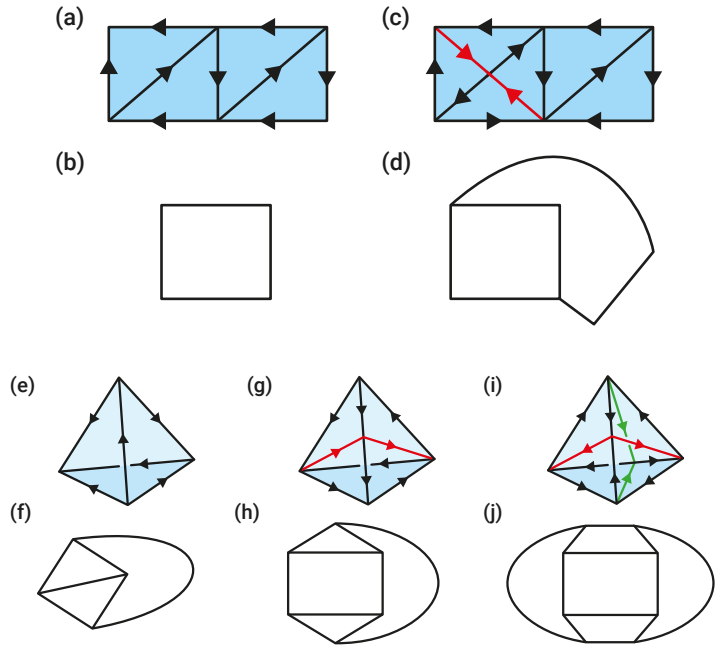

Figure 4 Making simplicial complexes disorintable and the effect on the cycles of their corresponding down-dual graphs for Mobius strip and tetrahedron. The down-dual graph of each complex is drawn in its bottom. (a) is a non-disorientable Mobius strip as (b) has a twisting even cycle. (c) is obtained by splittings of two simplexes of (a), presented by red arrows, which is disorientable as in (d) twisting cycle(s) are even and simple cycle(s) are odd. Similarly, (e) and (g) are non-disorientable as based on respectively (f) and (h) they have odd simple cycles. (i) is obtained from (e) by splitting of all its four 2-simplexes and is disorientable as (j) has no odd simple simple.

Proof. We should show that dividing an edge in an odd cycle of a graph into two by adding a vertex increases the maximum eigenvalue of the graph Laplacian. This can be demonstrated using the Rayleigh quotient, where an arbitrary real-valued function f on the graph's vertex set is considered. If O is an arbitrary odd cycle, there is always an edge xy in the cycle that the function value at x and y has the same sign. By creating a new vertex z (its degree is 2) between x and y with an opposite function sign, the Rayleigh quotient increases, as by adding z the denominator would increase by a factor of $2f^2(z)$ while the nominator increases by a factor of $(f(z) - f(x))^2 + (f(z) - f(y))^2$ which is triviality bigger. Since this happens for any arbitrary real-valued function, the Rayleigh quotient as well as its supremum which is the maximum eigenvalue of the Laplacian increases and it becomes closer to the maximum possible value (i.e. two) and that is obtained by bipartite graphs with no odd cycles. ◀

▶ **Theorem 20.** *In a N-simplicial complex without twisting cycles, the fewer the number of (non-branching) simple odd cycles in its down dual graph, the fewer splittings of N- simplexes are required to make the complex disorientable; namely the closer is its maximum eigenvalue to the possible maximum eigenvalue (which for the Normalized Laplacian is $N + 1$).*

Proof. The proof is very similar to the one of the above Lemma. Here we use the down-dual graph (in dimension N) of the complex and we turn every simple (non-branching) odd cycle to even cycle one by one by adding one vertex as described before. Using Rayleigh quotient of the Laplacian in dimension $N - 1$ and exact argument as above gives the result.

As mentioned before, both of L^{up}_{N-1} and L^{down}_{N} have the same maximum obtained by the supremum of the Rayleigh quotient of functions defined on N-simplexes (i.e. vertices of the down dual graph). ◀

4 Conclusion

We have fully characterized disorientability of general simplicial complexes in terms of the parity of the length of cycles in their down dual graphs. As a direct result, every simplicial complex can become dissorientable by a finite number of splittings of some of the N-dimensional simplexes into two N-dimensional simplexes in a similar manner that any graph can become bipartite by a finite number of splitting of some of its edges into two (i.e. making the odd edges even). Such splittings do not change the topology of the complex and the lower the number of splittings needed to make the complex disoriantable, the closer is the maximum eigenvalue of its Hodge Laplacian spectrum to the possible maximum eigenvalue.

We hope that this new perspective allows the extension of a range of theoretical and applied cycle-based methods from bipartite graphs to higher dimensional disorientable simplicial complexes.

Non-Euclidean Erdős–Anning Theorems

David Eppstein
University of California, Irvine, CA, USA

Abstract

The Erdős–Anning theorem states that every point set in the Euclidean plane with integer distances must be either collinear or finite. More strongly, for any (non-degenerate) triangle of diameter δ, at most $O(\delta^2)$ points can have integer distances from all three triangle vertices. We prove the same results for any strictly convex distance function on the plane, and analogous results for every two-dimensional complete Riemannian manifold of bounded genus and for geodesic distance on the boundary of every three-dimensional Euclidean convex set. As a consequence, we resolve a 1983 question of Richard Guy on the equilateral dimension of Riemannian manifolds. Our proofs are based on the properties of additively weighted Voronoi diagrams of these distances.

1 Introduction

Many incidence properties of lines or curves, seemingly mysterious on their own, become obvious when viewed through the lens of computational geometry, where the curves may be features of Voronoi diagrams or related constructions. Thus, for instance, to see that the three perpendicular bisectors of a triangle's sides meet at a single point, observe that these bisectors contain the edges of the Voronoi diagram of the triangle vertices, and these Voronoi edges meet at the Voronoi vertex. In this work we apply the same principle to the Erdős–Anning theorem on integer distances in the plane, conventionally proven using the algebraic intersection properties of hyperbolae. By reinterpreting these hyperbolae and their intersection points as the cell boundaries and vertices of additively-weighted Voronoi diagrams, and by analyzing these diagrams geometrically and topologically rather than algebraically, we greatly generalize this theorem, to several wide classes of two-dimensional metric spaces. In doing so, we resolve a 1983 question of Richard Guy on the equilateral dimension of Riemannian manifolds, the maximum number of points that can be placed at equal distances from each other in these spaces.

The Erdős–Anning theorem states that every point set in the Euclidean plane with integer distances must be either collinear or finite [1, 9]. More strongly, for any (non-degenerate) triangle of diameter δ, at most $O(\delta^2)$ points can have integer distances from all three triangle vertices. When the whole point set has diameter D, its number of points is $O(D)$ [25], and if in addition it is non-collinear its number of points is $D^{O(1/\log\log D)}$ [11]. In contrast, as Euler already observed, there exist infinite non-collinear point sets of bounded diameter with all distances rational, for instance, dense subsets of a unit circle [10, 13].

There are many metrics other than Euclidean distance for which we might ask similar questions. One obstacle to generalizing the Erdős–Anning theorem to other metrics is that its usual proof is heavily based on algebraic geometry. In the Euclidean plane, the locus of points whose distances to two given points differ by a fixed integer is a branch of a hyperbola.

Therefore, the points with integer distances to three non-collinear points lie at the intersection points of two finite families of hyperbolas. Hyperbolas are algebraic curves of degree two, and by Bezout's theorem two hyperbolas have at most four crossings, so these two finite families have finitely many intersection points. But it is not obvious how to extend this argument to metrics for which the corresponding curves are more complicated or non-algebraic. Erdős and Anning originally used a different argument using trigonometric inequalities [1], but its generalization is also non-obvious.

A second obstacle is that analogous statements are untrue for some metrics. For the L_1 or L_∞ distances in the plane, the integer lattice provides a familiar example of an infinite set that is not collinear and has only integer distances. Thus, generalizations of the theorem to other families of metrics must avoid families that include L_1 or L_∞.

In this paper we prove the following generalized versions of the Erdős–Anning theorem:

> *For any strictly convex distance function on $\mathbb{R}^2$, every point set with integer distances must be either collinear or finite. For any (non-degenerate) triangle of diameter δ, at most $O(\delta^2)$ points can have integer distances from all three triangle vertices. If a set with integer distances has diameter D, it has at most $O(D)$ points.* (Section 3)
>
> *For any two-dimensional complete Riemannian manifold of finite genus g, every point set with integer distances must either be finite or be contained in a geodesic (a locally-shortest curve) that contains every shortest curve between pairs of the points. If some three points do not lie on a single shortest curve, and have diameter δ, at most $O((g+1)\delta^2)$ points can have integer distances from these three points.* (Section 4)
>
> *For geodesic distance on the boundary of a convex set in $\mathbb{R}^3$, every point set with integer distances must either be finite or be contained in a geodesic that contains every shortest curve between pairs of the points. If some three points do not lie on a single shortest curve, and have diameter δ, at most $O(\delta^2)$ points can have integer distances from these three points. If a set with integer distances has diameter D, it has at most $O(D^{4/3})$ points.* (Section 5)

Our proofs replace the intersection properties of low-degree algebraic curves with the geometric and topological properties of additively weighted Voronoi diagrams. Our results for Riemannian manifolds resolve a question posed in 1983 by Richard Guy [12], on the *equilateral dimension* of Riemannian manifolds, the maximum number of points at unit distance from each other in these manifolds. Guy asked whether the equilateral dimension could be bounded by a function of dimension. For complete Riemannian 2-manifolds of bounded genus, we bound the equilateral dimension by a function of the genus (Corollary 12) but for locally Euclidean incomplete Riemannian 2-manifolds, for complete Riemannian 2-manifolds of unbounded genus, and for complete Riemannian metrics on $\mathbb{R}^3$, we show that the equilateral dimension is unbounded (Example 6 and Example 7).

For space reasons we defer many lemmas and other material to the full version at `https://arxiv.org/2401.06328`.

2 Preliminaries: Voronoi diagrams and star-shaped cells

A *Voronoi diagram* of a finite set of point *sites* in a metric space (X, d) subdivides the space according to which site is closest. Each site s_i has a (closed) cell V_i associated with it, where

$$V_i = \left\{ p \in X \;\middle|\; d(p, s_i) \le \min_{j \neq i} d(p, s_j) \right\}$$

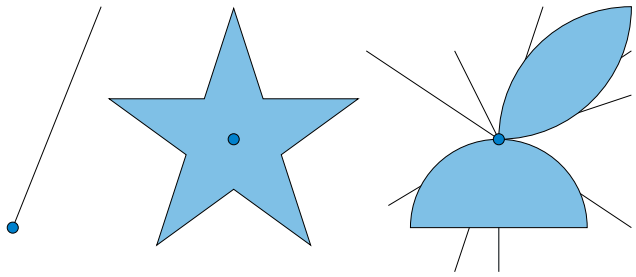

Figure 1 Three star-shaped sets, each shown with a point in its kernel.

is the set of points whose distance to site s_i is less than or equal to the distance to any other site s_j. We will only use Voronoi diagrams of finite sets (in fact, of at most three sites), so we only define and discuss the properties of these diagrams for finite sets of sites.

The intersection of any collection of Voronoi cells is the locus of points having equal distances to their sites. When X has the topology of the plane, the *bisector* of a pair of sites (the intersection of their Voronoi cells) is often (but not always) a curve, and a non-empty intersection of three or more sites is often (but not always) an isolated point or points, called *Voronoi vertices*. We will use *additively weighted* Voronoi diagrams, in which each site s_i has a weight w_i associated with it, and in which the distances in the definition of cells are modified by adding these weights:

$$V_i = \left\{ p \in X \;\middle|\; d(p, s_i) + w_i \le \min_{j \neq i} d(p, s_j) + w_j \right\}.$$

Voronoi diagrams have been the object of intensive study, including Voronoi diagrams for convex distance functions [6, 15, 17], for points on a sphere [3, 21, 23], for points in the hyperbolic plane [4, 8, 24], orbifolds [20], and for more general Riemannian manifolds [18]. Additively weighted Voronoi diagrams are also a standard concept [5, 16], and confusingly, are sometimes called *hyperbolic Dirichlet tessellations* despite their use of Euclidean distance [2], because their cells are bounded by hyperbolas (the same hyperbolas from the Erdős–Anning proof). We did not find works combining additive weights and non-Euclidean distances.

The *kernel* of a subset S of the plane is defined as the set of points p such that, for every point q in S, the line segment pq belongs to S. S is convex if and only if its kernel coincides with S. Weakening this formulation of convexity, S is defined to be *star-shaped* if its kernel is non-empty. (See Figure 1. Note that, according to this definition, star-shaped sets are not required to form topological disks, and the empty set is not star-shaped.) It is known that, for instance, the Voronoi cells of unweighted convex distance functions are star-shaped topological disks [6]. For additively weighted Voronoi diagrams, we should be a little more careful, because of the possibility that a Voronoi cell can degenerate to a line segment, a single point, or the empty set, but in the Euclidean case they are again known to be star-shaped when non-empty [2].

3 Convex distance functions

A *convex distance function* on $\mathbb{R}^d$ can be defined from any centrally symmetric compact convex body K. The resulting function $d_K(p, q)$ is the smallest scale factor s such that a copy of K, scaled by s and centered at p, contains q. Any convex distance function defines a norm on $\mathbb{R}^d$, $||p||_K = d_K(0, p)$. In the reverse direction, the closed unit ball $\{p \mid ||p|| \le 1\}$

of any norm $||\cdot||$ can be used to define a convex distance function. A convex set is *strictly convex* if its boundary does not contain any line segment, and a *strictly convex distance function* is a convex distance function defined from a strictly convex set. Convex distance functions obey all the requirements of a metric space, including the triangle inequality. For strictly convex distance functions and non-collinear triples of points p, q, r, they obey a strict form of the triangle inequality [6]:

$$d_K(p,r) < d_K(p,q) + d_K(q,r).$$

Examples of strictly convex distance functions include the Minkowski L_p distances for $1 < p < \infty$, obtained from the convex body

$$K_p = \left\{ (x_1, x_2, \ldots x_d) \;\middle|\; \sum_{i=1}^{d} x_i^p \le 1 \right\}.$$

For $p = 1$ and for the limiting case $p = \infty$ one obtains distance functions that are convex but not strictly convex. For $p = 2$ we recover the familiar Euclidean distance. Convex distance functions define *geodesic metric spaces* in which the distance between any two points equals the length of a shortest curve between the points. For strictly convex distance functions, this shortest curve is unique: it is just the *line segment* between its two points.

In unweighted Voronoi diagrams of strictly convex distance functions, every cell is a topological disk (or the whole space) with its site in its interior. However, additively weighted Voronoi diagrams may have additional complications, which we examine more carefully in the full version. In brief: A site may have zero or negative distance to another site, and therefore belong to the cell of another site; we call such sites *degenerate*. The Voronoi cell of a degenerate site may be empty, a single point, or a line segment or ray extending away from the site in the direction opposite its nearest non-degenerate neighbor. The cells of non-degenerate sites are strictly star-shaped with respect to their sites, interior-disjoint, and cover the plane. From these properties we prove:

▶ **Lemma 1.** *For the additively weighted Voronoi diagram of three non-collinear points, the three cells have at most two points of common intersection.*

The proof is a case analysis that considers how many sites are degenerate. The two degenerate cells of two degenerate sites lie on rays diverging from the non-degenerate site, and cannot intersect. With one degenerate site, there can be only one point of common intersection, the degenerate site (if its cell is a single point) or the opposite endpoint of its line segment cell. The main case has no degenerate sites. If there could be three points of common intersection, the line segments connecting these points to the three sites would lie entirely within the cells of their sites, and could not cross. Therefore, these segments would form a planar drawing of the nonplanar graph $K_{3,3}$, a contradiction.

3.1 Erdős–Anning theorems for strict convex distance functions

▶ **Theorem 2.** *Let s_1, s_2, and s_3 be three non-collinear points of a 2-dimensional strictly convex distance function d. Then the number of points that can have integer distances to all three of s_1, s_2, and s_3 is $O\big(d(s_1,s_2)\cdot d(s_1,s_3)\big)$.*

Proof. Let p be a point with integer distances to all three of s_1, s_2, and s_3. Consider the additively weighted Voronoi diagram of these three sites, with weights $w_i = d(s_1,p) - d(s_i,p)$. Then at p, the three additively weighted distances all equal $d(s_1,p)$, so all three sites are equal nearest neighbors. This means that p must belong to the triple intersection of Voronoi cells $V_1 \cap V_2 \cap V_3$.

Weight w_1 is identically zero, and by the triangle inequality the remaining two weights have absolute values $|d(s_1,p) - d(s_2,p)|$ and $|d(s_1,p) - d(s_3,p)|$ that are at most $d(s_1,s_2)$ and $d(s_1,s_3)$ respectively. Therefore, there are at most $\big(2d(s_1,s_2)+1\big) \cdot \big(2(d(s_1,s_3)+1\big)$ combinations of weights defining an additively weighted Voronoi diagram for which p might be a triple intersection point, and at most two triple intersection points per diagram by Lemma 1, giving a total of at most $2\big(2d(s_1,s_2)+1\big) \cdot \big(2(d(s_1,s_3)+1\big)$ possible points that can have integer distances to all three of s_1, s_2, and s_3. ◀

The following generalization of the Erdős–Anning theorem follows immediately:

▶ **Theorem 3.** *If a set S of points of a 2-dimensional strictly convex distance function has the property that all distances between points of S are integers, then S is finite or collinear.*

Proof. If S is not collinear, it has three non-collinear points to which we apply Theorem 2. ◀

3.2 Diameter bounds

The number of points in a set with integer distances can also be bounded linearly in the diameter of the set, generalizing a result of Solymosi [25] for Euclidean distance.

▶ **Theorem 4.** *If a set S of points of a 2-dimensional strictly convex distance function has diameter D (measured according to that distance function), and all distances in S are integers, then $|S| = O(D)$, with a constant of proportionality that depends on the distance function.*

Proof. We may assume without loss of generality that the unit ball of the given distance function d is contained in a Euclidean unit circle. For, if it does not, let ξ be the maximum Euclidean distance from the origin to any point of the unit d-ball, and scale both S and d by $1/\xi$, leaving distances between the scaled points unchanged and allowing the d-ball to fit within a Euclidean unit circle. Let ρ be the minimum Euclidean distance from the origin of the unit circle of d; note that, if we treat the distance function as fixed, then ρ is a constant. Then the function measured by d is lower bounded by the Euclidean distance, and upper bounded by $\frac{1}{\rho}$ times the Euclidean distance. From the lower bound on d, the Euclidean diameter of S is at most its d-diameter, D.

Enclose S in a square bounding box of (Euclidean) side length D, and center this within a larger square B of side length $3D$, so that all points of S are at Euclidean distance at least D from the boundary of B. Construct the (Euclidean) Voronoi diagram of S, and let s_1 be the point of S whose Voronoi cell V_1, intersected with B, has the smallest Euclidean area, $\leq 9D^2/n = O(D^2/n)$. Let s_2 be the Euclidean nearest neighbor of s_1 in S, let m be the midpoint of s_1 and s_2, and construct a right triangle ps_1m with right angle at s_1, contained in $V_1 \cap B$, with the largest possible Euclidean area. (See Figure 2 for an example.) We distinguish two cases:

- If p is on the boundary of B, as shown in Figure 2, it is at Euclidean distance $\geq D$ from s_1. In order for right triangle ps_1s_2 to have area $O(D^2/n)$, at most the area of the set $V_1 \cap B$ that contains it, edge s_1s_2 must have Euclidean length $O(D/n)$, and therefore also $d(s_1,s_2) = O(D/n)$ (larger than the Euclidean length by at most the constant factor $\frac{1}{\rho}$). For this distance to be a nonzero integer, n must be $O(D)$.
- Otherwise, p is on the boundary of V_1, and equidistant (in Euclidean distance) from s_1 and some site s_3 which cannot be collinear with s_1s_2. Therefore, the Euclidean distance from s_1 to p is at least half the Euclidean distance from s_1 to s_3. Combining this inequality

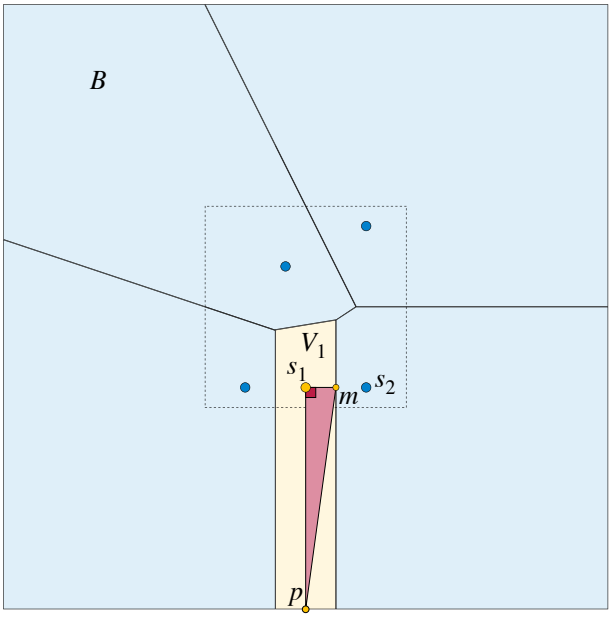

Figure 2 Figure for the proof of Theorem 4: After enclosing the given points in a bounding box B of side length three times the diameter D, s_1 is the point whose Euclidean Voronoi cell V_1 has the smallest intersection with B, s_2 is its nearest neighbor, m is their midpoint, and right triangle ps_1m is chosen to have as large an area as possible within $V_1 \cap B$. In the case shown, p is on the boundary of B, at distance greater than D from s_1, from which it follows that $d(s_1, s_2) = O(D/n)$.

with the area of the triangle and the $\frac{1}{\rho}$ factor by which d can increase over Euclidean distance gives the bound $d(s_1, s_2) \cdot d(s_1, s_3) = O(D^2/n)$. It follows from Theorem 2 that $n = O(D^2/n)$ and therefore that $n = O(D)$. ◀

The examples of $n \times n$ integer grids for the L_1 or L_∞ distance show that the assumption of strict convexity is necessary for this result.

4 Riemannian manifolds

In this section we prove a form of the Erdős–Anning theorem for two-dimensional complete Riemannian manifolds. These can be defined intrinsically (without respect to an embedding) as smooth manifolds equipped with a smoothly varying inner product structure on their tangent space. "Completeness" in this context means that all Cauchy sequences converge; for instance, puncturing the Euclidean plane by removing the origin would produce a space that is not complete. Examples of such spaces include the Euclidean plane itself, the surface of any smooth convex body in three dimensions such as a sphere, and the hyperbolic plane.

One complication in these spaces is that their usual analogues of straight lines, *geodesics*, are only locally shortest curves between their points: two or more points may belong to a common geodesic that does not contain the shortest curve between them. Indeed, in some cases a geodesic may cross itself or form a dense subset of its surface. For this reason, we will generally work with shortest curves (between some two points of the space) rather than geodesics. These curves may not be unique: for instance, for antipodal points on a sphere, there are infinitely many shortest curves, covering the whole sphere. By the Hopf–Rinow theorem [14], every complete Riemannian manifold has a shortest curve between every two points. Thus, these are geodesic metric spaces.

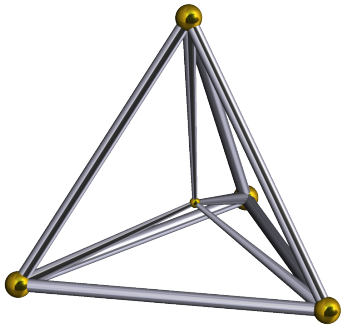

Figure 3 Five small spheres connected in pairs by cylindrical tubes. Smoothing the sphere-cube edges produces a complete Riemannian manifold. Public domain image from `https://commons.wikimedia.org/wiki/File:Schlegel_wireframe_5-cell.png`.

We will not assume that the surfaces we consider are orientable. One way to parameterize a two-dimensional surface, without assuming orientability, is by its *Euler genus*, the number $2 - \chi$ where χ is the Euler characteristic. It is possible for a Riemannian manifold to have infinite genus, but (except for Example 7, which motivates this limitation) we will only work with surfaces of bounded genus.

4.1 Examples

▶ **Example 5.** Consider any finite set of three or more points S on a unit sphere, no three of which belong to a great circle. Then each two points of S have a unique shortest curve which does not pass through other points of S. Perturb the sphere by placing a small smooth bump along each shortest curve, increasing the distance between its two points to a rational number without changing the other distances, and then scale the result to clear the denominators of these rational distances. The result is a complete Riemannian manifold of Euler genus zero with an arbitrary finite number of points at integer distances from each other.

It is necessary to assume that our Riemannian manifolds are complete, because of the following example:

▶ **Example 6.** Consider the points coordinatized by two real numbers r and θ, with r positive and θ arbitrary, and with the standard locally Euclidean geometry of the polar coordinate system. This can be thought of as a cone with an infinite angle at its removed apex [26]. Its Euler genus is zero (topologically it is just an open halfplane). When two of its points have θ-coordinates that differ by at least π, their distance equals the sum of their r-coordinates (distances from the removed apex). Therefore, the points $\{(\frac{1}{2}, i\pi) \mid i \in \mathbb{Z}\}$ form an infinite set at unit distance from each other. They have no shortest curves, because any such curve would pass through the missing apex point.

As the next example shows, to obtain a generalization of the Erdos–Anning theorem to complete Riemannian manifolds, we will also need to assume bounded genus, and our bounds on numbers of points in integer distance sets will need to depend on the genus.

▶ **Example 7.** For any n, one may form a complete Riemannian manifold from n spheres, connected by cutting out disks from pairs of spheres, attaching a cylindrical tube between the boundaries of the two disks, and smoothing the parts of the surface where the disks meet

the tubes. This construction may be performed abstractly as a topological space; it is not necessary to embed the spheres and tubes into three-dimensional space. Let S consist of one point per sphere, for spheres small enough that all distances within one sphere are less than $\frac{1}{3}$; then by adjusting the lengths of all the tubes, all distances between points of S can be made equal to one. This construction produces arbitrarily large finite sets of points at unit distance from each other, with genus $O(n^2)$. Because they all have the same distance, no three of these points belong to a shortest curve.

The connected sum of an infinite sequence of examples of this type for $n = 4, 5, 6, \ldots$, using tubes to connect the example for each n to the examples for $n-1$ and $n+1$, forms a single complete Riemannian manifold of infinite genus in which one can find arbitrarily large (but nevertheless finite) sets of points that are all at unit distance from each other.

Although the topological structure of this example is complicated, it can be embedded in a distance-preserving way into a Riemannian metric on $\mathbb{R}^3$. For each n, choose the spheres and tubes of the n-point example to have a small enough radius that they can all be smoothly embedded within a unit ball of $\mathbb{R}^3$, coiling the tubes to cause them to have the desired lengths. Form the connected sum of these examples as before and embed it smoothly in $\mathbb{R}^3$ using disjoint unit balls for each term in the connected sum. Thicken the resulting smoothly embedded surface S by a small amount (varying smoothly over the surface) chosen to be small enough that the thickened set remains smoothly embedded in $\mathbb{R}^3$, and give the resulting thickened set a Riemannian metric that agrees with the metric on S (and the Euclidean distance of $\mathbb{R}^3$) in directions parallel to S, but that is longer in the direction perpendicular to S by a factor that varies smoothly from very large for points on S to one at the boundary of this thickened set. Then, for the remaining points of $\mathbb{R}^3$, outside the thickened set, use the usual Euclidean distance. By choosing this perpendicular lengthening factor large enough, it is possible to ensure that escaping from S to the boundary of the thickened set takes more than unit distance, and that distances within S are preserved.

Richard Guy asked whether the *equilateral dimension* of Riemannian manifolds, the maximum cardinality of a set of points in the manifold for which all distances are one, can be bounded by a function of the dimension of the manifold [12]. A positive answer was known only for the case of complete Riemannian manifolds of bounded curvature [19]. Example 6 provides a counterexample for locally Euclidean and topologically simple but incomplete Riemannian 2-manifolds. Example 7 provides a counterexample for complete Riemannian 2-manifolds of unbounded genus and for topologically simple complete Riemannian 3-manifolds. On the other hand, our generalization of the Erdős–Anning theorem to complete Riemannian 2-manifolds of bounded genus also provides a bound on the equilateral dimension of these manifolds, as a function of their genus (Corollary 12).

Our proof of the Erdős–Anning theorem for strictly convex distance functions relied on the non-planarity of $K_{3,3}$. For complete Riemannian manifolds of bounded genus we need to reach further for graphs that cannot be embedded, as the following example shows.

In the full version we prove properties of additively weighted Voronoi diagrams for Riemannian manifolds analogous to those of convex distance functions, culminating in a bound of $2g + 2$ on the number of intersections of the cells of three sites with none of the three belonging to a geodesic between the other two.

4.2 Erdős–Anning theorems for Riemannian manifolds

▶ **Theorem 8.** *Let s_1, s_2, and s_3 be three points of a 2-dimensional complete Riemannian manifold of Euler genus g, with distance function d. Suppose also that there is no shortest curve containing all three of these points. Then the number of points that can have integer distances to all three of s_1, s_2, and s_3 is $O\big((g+1)\cdot d(s_1,s_2)\cdot d(s_1,s_3)\big)$.*

Except for the factor of g coming from our bound on triple points of Voronoi diagrams from the full version, the proof is the same as for Theorem 2. For this theorem, the possibility that all triples of points lie on shortest curves (preventing the theorem from being applied) corresponds to the possibility of all points being collinear in the Euclidean plane or for convex distance functions. It is a strengthening of the more obvious generalization of collinearity, that all points of S lie on a common geodesic:

▶ **Lemma 9.** *Let S be a set of three or more points of a complete Riemannian manifold such that each three points of S belong to a shortest curve. Then S is a subset of a geodesic, and every shortest curve between pairs of points in S lies along this geodesic.*

Proof. Let s_1 be any of the points, and consider the system of rays containing shortest curves to all the other points. Suppose for a contradiction that two rays R_2 and R_3 in this system of rays contain shortest curves from s_1 to points s_2 and s_3 in S, and that these two rays are distinct and non-opposite. Then if s_1 were on a shortest path from s_2 to s_3, then a shortest curve from s_2 to s_3 would follow R_2 from s_2 to s_1 and then follow R_3 from s_1 to s_3. This cannot happen, because a shortest curve that turns from one ray to another at s_1 could be shortcut by a different curve in a neighborhood of s_1. Alternatively, if s_2 were on a shortest curve from s_1 to s_3, then we could get a shortest curve from s_1 to s_3 that follows R_2 from s_1 to s_2, turns at s_2, and then continues along the R_3 from s_2 to s_3, again an impossibility. The case that s_3 is on a shortest curve from s_1 to s_2 is symmetric. So none of the three points can be the middle point of a shortest curve containing all three points. This contradiction to the assumption of the lemma implies that rays R_2 and R_3 cannot exist, and that the system of rays contains either a single ray or two opposite rays. In either case, these two rays, and therefore all points of S, lie on a single geodesic.

If some two points s_2 and s_3 had a shortest curve that did not lie along this geodesic, then we could apply this same argument to the rays at s_2 containing the shortest curve to s_1 (along the geodesic through all points of S) and the ray containing the shortest curve from s_2 to s_3 (not along this geodesic), obtaining the same contradiction. Therefore all shortest curves lie on the same geodesic. ◀

The conclusion of this lemma cannot be strengthened to state that each pair of points in S has a unique shortest curve. For instance, consider an even number of points equally spaced on the equator of a sphere. In this example, each point has two shortest curves to its opposite point. A set of points whose shortest curves all lie on a single geodesic might still not have the property that each three points belong to a shortest curve: consider, for instance, three equally spaced points on the equator of a sphere.

Combining Theorem 8 with Lemma 9 gives us the following generalization of the Erdős–Anning theorem:

▶ **Theorem 10.** *If a set S of points of a 2-dimensional complete Riemannian manifold of bounded genus has the property that all distances between points of S are integers, then either S is finite or there is a single geodesic of the manifold containing all points of S and connecting each pair of points by a shortest curve.*

We also have the following diameter bound, weaker than in the Euclidean or convex distance function case:

▶ **Theorem 11.** *If a set S of points of a 2-dimensional complete Riemannian manifold of bounded genus g has integer distances and diameter D, then $|S| = O(gD^2)$.*

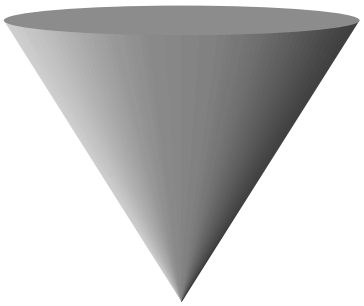

Figure 4 A solid cone.

Proof. If S has three points not all on a single shortest curve, this follows from Theorem 8. Otherwise, the points all have shortest curves along a geodesic. Let C be a shortest curve of length D between some two points of S. If C covers all points of S, there are at most $D+1$ points. Otherwise, let s_1 and s_2 be the two endpoints of C, and let s_3 be any point not covered by C. For s_1, s_2, and s_3 to be part of a shortest curve, the curve must have s_1 and s_2 as endpoints, for otherwise we would have a shortest curve that includes a segment from s_1 to s_2, causing it to be longer than D. In this case, the only possibility is that s_1 and s_2 have two shortest paths, and are at distance D from each other along a geodesic of length $2D$, so there are at most $2D$ points in S. ◀

▶ **Corollary 12.** *The equilateral dimension of a 2-dimensional complete Riemannian manifold of bounded genus g is $O(g)$.*

5 Convex surfaces

In this section we extend our results on Riemann manifolds to non-smooth surfaces of non-negative curvature. The restriction to non-negative curvature is motivated by Example 6, which shows that even a single cone point of negative curvature can be an obstacle to Erdős–Anning theorems. For concreteness, in this section we usually define a *convex surface* to mean the boundary of a convex subset of $\mathbb{R}^3$ with nonempty interior. However, we also allow a special case, which can be thought of as the limit of convex cylinders as the cylinder height goes to zero: the double covering of a convex subset K of $\mathbb{R}^2$, obtained by gluing two copies of K at corresponding boundary points. For instance, the Euclidean plane is a convex surface in the first of these two senses: it is the boundary of a halfspace. By results of Aleksei Pogorelov, a more abstract class of non-smooth convex manifolds, topologically equivalent to a sphere and with total Gaussian curvature 4π, can be characterized as being either boundaries of convex bounded subsets of $\mathbb{R}^3$ or double covers of convex bounded subsets of $\mathbb{R}^2$ [7]. We include double covers in our definition of convex surfaces to be consistent with this result of Pogorelov, but we do not require the convex sets from which they are defined to be bounded. We measure the distance on a convex surface as the infimum of lengths of curves on the surface. By a compactness argument, each pair of points on the surface can be connected by a curve of length equal to this distance, so this is a geodesic metric space [22], and we can apply arguments involving the Lipschitz property of distances. Every convex surface, in the sense described here, is topologically a disk (like the Euclidean plane), a sphere (like a geometric sphere, polyhedron, or double-covered topological disk), or an annulus (like the boundary of an infinite cylinder).

The boundary of a (bounded) solid cone (Figure 4) exhibits several of the common geometric features of a convex surface. The base of the cone is a flat disk; the sides of the cone have a flat surface metric (locally isometric to a subset of the Euclidean plane) even though they are curved in three-dimensional space. The circle where the base meets the sides is non-smooth; each point has a neighborhood that approaches a Euclidean metric (equivalent to that of a folded piece of paper) in the limit. The apex of the cone, however, is not Euclidean, even in the limit: it has a positive angular deficiency that can be measured by comparing the radius and circumference of small metric disks around it. The total curvature of this surface is 4π, by the Gauss–Bonnet theorem, but in this case this curvature is concentrated at the cone point (where it equals the angular deficit of this point) and along the circle where the base and sides meet.

In general, when a shortest curve on a convex surface passes through a locally Euclidean point, it must pass straight through it, in the local Euclidean geometry of a neighborhood of a point. A curve that does not do this could be shortcut to bypass the point. It is not possible for a shortest curve to pass through a cone point (any point of positive angular deficiency): any curve through such a point can be shortcut. Thus, we need only consider such points as endpoints of shortest curves, not as their interior points.

▶ **Lemma 13.** *For every point p on a convex surface, the disks of radius r centered on that point, in the limit as $r \to 0$, approach a cone for which p either has angular deficit zero (p is locally Euclidean) or a well-defined positive angular deficit (p is locally a cone point).*

Proof. For a point p on a convex surface, let $C_r(p)$ denote the cone formed by positive combinations of p with the points at distance r from p on the surface. Then C_r is monotone in r: for $r' < r$, $C'_r(p) \supset C_r(p)$, by convexity. By compactness of the space of cones at a point p, in the limit as r goes to zero, these cones approach a limiting cone; call this limit $C_0(p)$. Let B be the curve obtained by intersecting the boundary of $C_0(p)$ with a unit sphere centered at p. Then B is convex, and lies in a half-sphere, again by convexity of the convex surface. Thus, its length is at most 2π. If it is exactly 2π, then p is locally Euclidean; otherwise, it is locally equivalent to a cone point with deficit equal to the difference between 2π and the length of B. ◀

We defer the detailed analysis of Voronoi diagrams for these metrics to the full version.

5.1 Erdős–Anning theorems for convex surfaces

▶ **Theorem 14.** *Let s_1, s_2, and s_3 be three points of a convex surface, with distance function d. Suppose also that there is no shortest curve containing all three of these points. Then the number of points that can have integer distances to all three of s_1, s_2, and s_3 is $O\big(d(s_1, s_2) \cdot d(s_1, s_3)\big)$.*

Proof. Same as for Theorem 2 and Theorem 8, substituting the properties of additive Voronoi diagrams for convex surfaces in place of the corresponding properties of the diagrams for convex distance functions and Riemannian manifolds. ◀

▶ **Lemma 15.** *Let S be a set of three or more points of a convex surface such that each three points of S belong to a shortest curve. Then S is a subset of a geodesic, and every shortest curve between pairs of points in S lies along this geodesic.*

Proof. Same as for Lemma 9, again substituting the properties of Voronoi diagrams on these surfaces. ◀

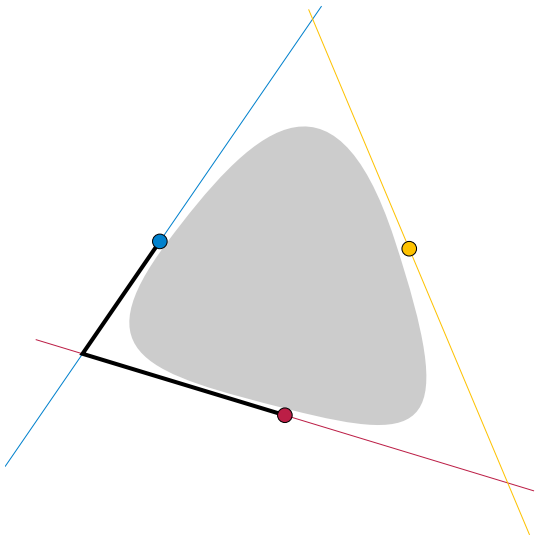

Figure 5 Lemma 17: a short path connecting two of three points separated by a convex set.

▶ **Theorem 16.** *If a set S of points of a convex surface has the property that all distances between points of S are integers, then either S is finite or all triples of points in S are subsets of shortest curves along a single geodesic.*

Proof. Same as for Theorem 10, again substituting the properties of Voronoi diagrams on these surfaces. ◀

Our diameter bound seems unlikely to be tight. It uses the following preliminary lemmas.

▶ **Lemma 17.** *Suppose that three given points in $\mathbb{R}^d$ are disjoint from an open convex set U. Then two of the points can be connected by a curve disjoint from U of length at most twice their Euclidean distance.*

Proof. Consider the plane containing the three points; if U does not intersect this plane then the points can be connected directly. Within this plane draw a line through each point, disjoint from U. The three lines form a triangle or unbounded three-sided region containing U; if all three points lie its sides, one of its internal angles is $\geq 60°$, and the curve connecting two points through this angle has length at most twice the distance between the points (Figure 5; worst case: U is an equilateral triangle and the three points are its edge midpoints). If one of the three points is not on a side of the region containing U, it can see the entire line through another of the points, and be connected directly to that point. ◀

▶ **Lemma 18.** *If n points on a convex surface have diameter D then some two of the points have geodesic distance $O(D/\sqrt{n})$.*

Proof. Let the set of points be S, and let the convex surface be the boundary of a set K (or the double cover of a set K), embedded in $\mathbb{R}^3$. By assumption, S lies within a ball B of radius D in $\mathbb{R}^3$. Subdivide the ball by a grid of cubes, of side length $O(D/\sqrt{n})$, positioned so that none of the given points lies on a cube boundary, and let $\square$ denote the set of cubes in this grid whose intersection with $B \cap K$ is non-empty and includes at least one non-vertex point of the cube. Each point in S is contained in at least one cube $C \in \square$. This cube C must touch (at least at a corner) a grid cube that is outside $\square$, because if all eight cubes corner-adjacent

to C belonged to $\square$, the intersection points of these eight cubes with $B \cap K$ would have a convex hull that entirely encloses C, preventing C from containing any boundary points of K. Therefore, C is within $O(1)$ grid positions of a boundary square of the union of cubes $\cup\square$. But $\cup\square$ is orthogonally convex – any axis-parallel line can cross only two boundary squares (one in each direction) – so it has $O(n)$ boundary squares. Therefore there are also $O(n)$ cubes near these squares that contain points of S. By choosing the grid size appropriately, we can adjust the constant factors in this $O(n)$ bound and ensure that fewer than $n/2$ cubes contain points of S. With this adjustment, some cube $C \in \square$, of side length $O(D/\sqrt{n})$, contains at least three points of S. We consider two cases:

- If the convex surface is non-degenerate (it bounds a convex set with non-empty interior), then by Lemma 17, two of these three points are connected by a path in space, disjoint from the interior of the given convex set, of length $O(D/\sqrt{n})$, and hence are at geodesic distance $O(D/\sqrt{n})$ on the convex surface.
- Otherwise, the convex surface is a double-covered two-dimensional convex set, two of the three points are on the same side of the double cover, and these two points can be connected directly within C by a geodesic segment of length $O(D/\sqrt{n})$.

In either case, we have two points at geodesic distance $O(D/\sqrt{n})$. ◀

The example of a square grid of $\sqrt{n} \times \sqrt{n}$ points on a flat plane, scaled to have diameter D, shows that Lemma 18 is tight.

▶ **Theorem 19.** *If a set S of points of a convex surface has integer distances and diameter D, then $|S| = O(D^{4/3})$.*

Proof. Let n be the size of S, and let its two closest such points be p and q, with distance $O(D/\sqrt{n})$ by Lemma 18. We distinguish two cases:

- Suppose that all triples of points in S that include both p and q belong to shortest curves. Each point in S must belong either to a ray from p through q or a ray from q through p, with the ray containing a shortest curve from p to q. Further, this shortest curve (and hence these two rays) must be unique, for if there were two shortest curves between p and q, one of them could be combined with part of a shortest curve from p or q to a third point r to form a shortest curve that passes through q or p at a non-straight angle, an impossibility. Thus, two rays contain all remaining points in S, and these points lie at integer spacing along these two rays, giving $O(D)$ points in S in total.
- Otherwise, some point r does not lie on a shortest curve with p and q. By Theorem 14, there can be $O(D^2/\sqrt{n})$ points in S. That is, $n = O(D^2/\sqrt{n})$. Multiplying both sides by $\sqrt{n}$ and taking the 2/3 power gives the result. ◀

6 Discussion

We have shown that integer-distance point sets are finite or collinear in three broad classes of metric spaces each generalizing Euclidean distance in the plane. The next natural direction to look for a further extension of these results is in higher dimensions. Erdős and Anning state without proof that their results extend to d-dimensional Euclidean space [1]. However, the obvious attempt to generalize our proof to higher dimensions, by using intersection patterns of $(d+1)$-tuples of Voronoi cells, does not work for convex distance functions: there exist three-dimensional convex distance functions for which some 4-tuple of points is equidistant from arbitrarily many other points [15]. For Riemannian manifolds, the theorem does not generalize, as Example 7 shows. Nevertheless, it would be interesting to study similar questions for higher-dimensional uniform metrics, such as hyperbolic space. It would also be of interest to strengthen the bound on diameter in Theorem 11 and Theorem 19.

Shelling and Sinking Graphs on the Sphere

Jeff Erickson

Abstract

We describe a promising approach to efficiently morph spherical graphs, extending earlier approaches of Awartani and Henderson [*Trans. AMS* 1987] and Kobourov and Landis [*JGAA* 2006]. Specifically, we describe two methods to morph shortest-path triangulations of the sphere by moving their vertices along longitudes into the southern hemisphere; we call a triangulation *sinkable* if such a morph exists. Our first method generalizes a longitudinal shelling construction of Awartani and Henderson; a triangulation is sinkable if a specific orientation of its dual graph is acyclic. We describe a simple polynomial-time algorithm to find a longitudinally shellable rotation of a given spherical triangulation, if one exists; we also construct a spherical triangulation that has no longitudinally shellable rotation. Our second method is based on a linear-programming characterization of sinkability. By identifying its optimal basis, we show that this linear program can be solved in $O(n^{\omega/2})$ time, where ω is the matrix-multiplication exponent, assuming the underlying linear system is non-singular. Finally, we pose several conjectures and describe experimental results that support them.

1 Introduction

A *morph* between two planar straight-line graphs is a continuous deformation from one to the other, such that all edges in all intermediate graphs are interior-disjoint line segments. Planar graph morphing has many applications in graphics, animation, visualization, and geometric modeling, as well as connections to fundamental questions in low-dimensional topology.

There are two state-of-the-art approaches for morphing planar graphs. The first is the barycentric interpolation method of Floater, Gotsman, and Surazhsky [26, 29, 31, 56–58], which is based on an extension by Floater [27, 28] of Tutte's classical spring-embedding theorem [60]. These algorithms compute an implicit representation of a smooth morph, any intermediate stage of which can be constructed in $O(n^{\omega/2}) = O(n^{1.1864})$ time, where $\omega < 2.3728$ is the matrix-multiplication exponent. The second method combines an edge-collapsing strategy originally proposed by Cairns [11,12,35,59] with more recent algorithms for convex hierarchical graph drawing [13, 17, 36, 39, 40]. This method has led to several efficient algorithms for constructing explicit representations of piecewise-linear morphs [2, 25, 39, 40]. Algorithms are also known for several variants of planar morphing [5, 6, 10, 15, 43, 61].

Both planar morphing approaches have recently been generalized to geodesic graphs on the flat torus [14, 25, 44], and very recently, Luo, Wu, and Zhu generalized the barycentric interpolation method to arbitrary negative-curvature surfaces of higher genus [45, 46].

1.1 What about the sphere?

In light of the long history of results for morphing planar graphs and their generalizations to higher-genus surfaces, it is surprising how little is known about morphing graphs on the sphere. Although embeddings on the sphere are *topologically* equivalent to embeddings in the plane, the different geometries of the two surfaces induce significantly different behavior.

In 1944, Cairns [12] proved that any two isomorphic shortest-path triangulations of the sphere are connected by a continuous family of shortest-path triangulations, using essentially the same edge-contraction strategy that he used for planar triangulations (but with more complex case analysis). A direct translation of Cairns's spherical morphing proof leads to an exponential-time algorithm; unlike his planar result, this is still the fastest algorithm known. In fact, as far as we are aware, this is the *only* algorithm known for morphing arbitrary spherical triangulations.

Morphing algorithms are known for a few special cases of spherical triangulations. Almost all of these algorithms operate by moving vertices along longitudes into the southern hemisphere, projecting the resulting "southern" triangulation into the plane, and applying a planar morphing algorithm. Awartani and Henderson [4] describe an algorithm to morph spherical triangulations that satisfy a certain **longitudinal shelling** condition using this strategy. They also prove that any triangulation with a *longitudinal seam*, meaning there is a longitude that does not cross the interior of any edge, satisfies their shelling condition. (We study Awartani and Henderson's shelling condition in more detail in Section 3.) Kobourov and Landis [41] describe an algorithm to morph between *Delaunay* triangulations via longitudinal morphs; their algorithm easily generalizes to **coherent** triangulations, which are central projections of arbitrary convex polyhedra. The same method is also implicit in Richter-Gebert's proof [47, Theorem 13.3.3] of classical theorems of Eberhard [21] and Steinitz [50] describing morphs between isomorphic convex polyhedra.

We call a sphere triangulation **sinkable** if it can be morphed along longitudes into the southern hemisphere. Every coherent triangulation is longitudinally shellable, and every longitudinally shellable triangulation is sinkable. Awartani and Henderson [4] describe an example of an unsinkable triangulation; it is not possible to move the vertices of their triangulation into the southern hemisphere without inverting at least one face. The simplest examples of unsinkable triangulation are the central projections of sufficiently twisted *Schönhardt polyhedra* [48], where the rotated faces are normal to the z-axis; see Figure 1.1. (Supnick proved that Schönhardt triangulations are the simplest non-coherent triangulations [54, 55]; our algorithm in Section 5 can be used to determine which of them are sinkable.)

The definitions of longitudinal shellability and sinkability depend on a specific choice of antipodal points as the north and south poles; neither property is invariant under rotations of the sphere. For example, a 90° rotation around the x-axis makes every Schönhardt triangulation in Figure 1.1 longitudinally shellable, and therefore sinkable.

1.2 Our Results

We describe a promising approach to efficiently morph shortest-path embeddings of graphs on the sphere, extending the previous results of Awartani and Henderson [4] and Kobourov and Landis [41]. At a high level, we propose finding suitable rotations of the sphere that allow the source and target embeddings to be pushed into the southern hemisphere along longitudes, thereby reducing to a planar morphing problem.

We emphasize that we do *not* develop this strategy into a complete algorithm; the existence of an efficient spherical morphing algorithm remains an open problem. We also note that sinking is not *required* to construct spherical morphs; for example, we can directly morph any Schönhardt triangulation into any other by twisting one face.

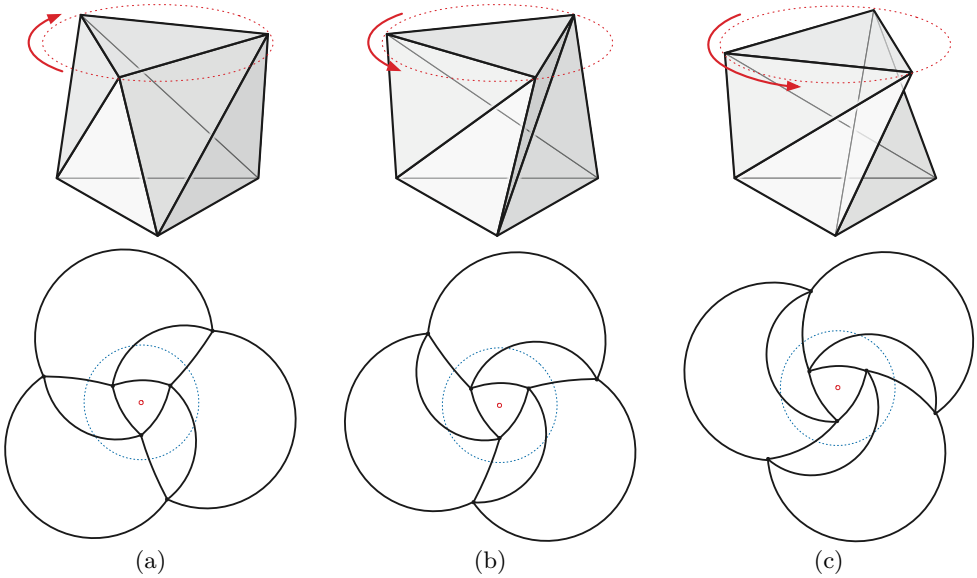

Figure 1.1 Three Schönhardt polyhedra and stereographic projections of the corresponding spherical triangulations. Depending on the twisting angle, these triangulations are (a) coherent and therefore longitudinally shellable, (b) sinkable but not longitudinally shellable, or (c) not sinkable.

We begin in Section 2 by reviewing relevant definitions, describing our proposed morphing strategy in detail, and proving some preliminary results. In Section 3, we formally define the *longitudinal shelling* condition introduced by Awartani and Henderson and provide several combinatorial characterizations, each of which can be tested in $O(n)$ time. We also reiterate Awartani and Henderson's proof that every longitudinally shellable triangulations is sinkable. In Section 4, we present an algorithm that either finds a rotation of a given sphere triangulation Γ that is longitudinally shellable, or reports correctly that no such rotation exists, in $O(n^{5/2}\log^3 n)$ time. We also construct a spherical triangulation that has no longitudinally shellable rotation. In Section 5, we describe an efficient algorithm to determine whether a given sphere triangulation is *sinkable*. First we show that sinkability is equivalent to the feasibility of a certain linear program with $O(n)$ variables and constraints. By identifying the optimal basis for this linear program, we show that it can be solved in $O(n^{\omega/2})$ time, assuming the underlying linear system is non-singular.

Due to space constraints, we defer several proofs and related results to the full version [24]. In particular, we describe the results of lightweight experiments, which suggest that "in practice" one can find a shellable rotation of a spherical triangulation by testing a small number of random rotations. We also present several open problems for further research, including several conjectures suggested by our experimental results.

2 Background and Preliminary Results

2.1 Cartography

We consider drawings of graphs on the unit sphere $S^2 = \{(x, y, z) \mid x^2 + y^2 + z^2 = 1\}$. The **north pole** is the point $(0, 0, 1)$; the **south pole** is the point $(0, 0, -1)$; the **equator** is the intersection of the unit sphere with the plane $z = 0$. A **longitude** is an open great-circular arc whose endpoints are the north and south poles. Every point except the poles lies on a unique longitude.

Throughout the paper, we fix an arbitrary simple maximal planar graph G with $n \geq 4$ vertices, arbitrarily indexed from 1 to n. An **embedding** of G on the sphere is an injective map from G to S^2, or less formally, a drawing of G where edges are arbitrary simple curves that intersect only at their shared endpoints. Every embedding of G on the sphere is a **triangulation**, meaning every face is bounded by a cycle of three distinct edges.

Unless explicitly indicated otherwise, we consider only **generic shortest-path** triangulations, meaning (1) every edge is a great-circular arc with length less than π; (2) no great circle contains more than two vertices, and (3) no great circle through the poles contains more than one vertex. Condition (1) is the natural spherical analogue of straight-line embeddings in the plane. Condition (3) implies that vertices lie on distinct longitudes.

Classical theorems of Steinitz [33, 49, 50] and Whitney [8, 62] imply that G has a unique embedding on the sphere, up to homeomorphism, which is a generic shortest-path triangulation. A **face of G** is a face of this essentially unique embedding. We sometimes identify each face as a triple (i, j, k) of vertices (or their indices) in counterclockwise order around its interior.

Every generic shortest-path triangulation has a unique **north face** whose interior contains the north pole and a unique **south face** whose interior contains the south pole. The remaining **non-polar** faces are of two types: An **up-face** has one vertex (called its **apex**) directly north of its opposite edge (called its **base**); symmetrically, a **down-face** has one vertex (its apex) directly south of its opposite edge (its base). The **legs** of a non-polar face f are the edges of f incident to the apex of f. The faces immediately north and south of any vertex i are respectively denoted $\boldsymbol{f_{\mathsf{above}}(i)}$ and $\boldsymbol{f_{\mathsf{below}}(i)}$. For each vertex i, $f_{\mathsf{above}}(i)$ is either the north face or a down-face, and $f_{\mathsf{below}}(i)$ is either the south face or an up-face. See Figure 2.1.

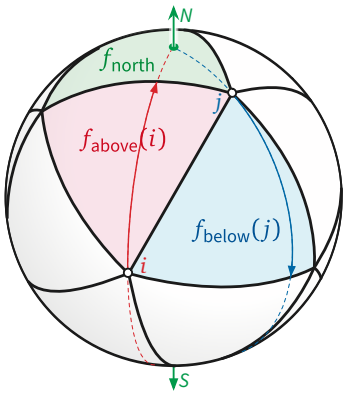

Figure 2.1 An up-face $f_{\mathsf{above}}(i)$, a down-face $f_{\mathsf{below}}(j)$, and the north face $f_{\mathsf{north}} = f_{\mathsf{above}}(j)$ of a spherical triangulation. Edge ij is a leg of both $f_{\mathsf{above}}(i)$ and $f_{\mathsf{below}}(j)$.

A face of a (generic) triangulation is **everted** if it has area greater than 2π, or equivalently, if it contains an open hemisphere. Every triangulation contains at most one everted face. We call a triangulation **full** if no face is everted, and **southern** if every vertex lies below the equator (which implies that the north face is everted).

A connected region R on the sphere is **θ-monotone** if every longitude is either disjoint from R or has connected intersection with R.

2.2 Coordinates

Throughout the paper, we represent spherical triangulations *implicitly* as projections of certain polyhedra onto the unit sphere. Specifically, we represent each vertex using signed homogeneous coordinates [51–53] – for any scalar $\lambda > 0$, the coordinate vectors (x, y, z) and $(\lambda x, \lambda y, \lambda z)$ represent the same point on the sphere. We can freely rescale the vertices, each independently, without changing the underlying spherical triangulation; although it is never actually necessary, this rescaling is sometimes convenient for purposes of discussion and intuition. For example, we can implicitly interpret any southern triangulation as a *planar* triangulation by scaling vertices onto the tangent plane $z = -1$; this scaling is equivalent to the *gnomonic* or *central* projection $(x, y, z) \mapsto (-x/z, -y/z, -1)$. Awartani and Henderson [4] analyze longitudinal morphing (defined below) by implicitly scaling vertices onto the unit cylinder $x^2 + y^2 = 1$.

2.3 Longitudinal Morphing

Two embeddings $\Gamma_0 \colon G \to S^2$ and $\Gamma_1 \colon G \to S^2$ are **isomorphic** if they define the same rotation system, or equivalently, if there is an orientation-preserving homeomorphism $H \colon S^2 \to S^2$ such that $\Gamma_1 = h \circ \Gamma_0$. Two isomorphic embeddings are **θ-equivalent** if each vertex of G lies on the same longitude in both embeddings.

A **homotopy** between two embeddings $\Gamma_0 \colon G \to S^2$ and $\Gamma_1 \colon G \to S^2$ is a continuous function $H \colon [0, 1] \times G \to S^2$ such that $H(0, \cdot) = \Gamma_0$ and $H(1, \cdot) = \Gamma_1$. Any pair of isomorphic embeddings Γ_0 and Γ_1 are connected by an **isotopy**, which is a homotopy H such that every intermediate drawing $\Gamma_t = H(t, \cdot)$ is an embedding. (The edges of these intermediate embeddings can be arbitrary simple curves, not necessarily shortest paths.) A **morph** is an isotopy in which the edges of every intermediate embedding Γ_t are shortest paths. Finally, a **longitudinal morph** is a morph in which vertices move only along their longitudes.

▶ **Lemma 2.1.** *Any two θ-equivalent triangulations are connected by a longitudinal morph.*

Proof sketch. Let Γ_0 and Γ_1 be two θ-equivalent triangulations. By scaling coordinate vectors as described in Section 2.2 if necessary, we can assume that each vertex has the same x- and y-coordinates in both embeddings. We define a longitudinal morph by linearly interpolating the z-coordinates of the vertices. The signed volume spanned by the vertices of any face is a linear function of the interpolation parameter t. Each non-polar face has the same orientation in Γ_0 and Γ_1, and therefore in every intermediate embedding. (See the full version [24] for a more detailed proof.) ◀

▶ **Corollary 2.2.** *A triangulation Γ is sinkable if and only if there is a southern triangulation that is θ-equivalent to Γ.*

We extend this argument slightly by considering **weak triangulations**, which are drawings of G that may include degenerate faces, but no inverted faces or crossing edges. (Weak triangulations are special cases of *weak embeddings* studied by Akitaya, Fulek, and Tóth [1] and Fulek and Kyncl [30].) A weak triangulation Γ_1 is θ-equivalent to a triangulation Γ_0 if vertices lie on the same longitudes in Γ_0 and Γ_1 and every non-degenerate non-polar face of Γ_i has the same orientation as the corresponding face of Γ_0.

▶ **Corollary 2.3.** *A triangulation Γ is sinkable if any only if there is a southern weak triangulation that is θ-equivalent to Γ.*

2.4 Morphing Strategy

Recall that a triangulation is **sinkable** if it can be longitudinally morphed to a θ-equivalent triangulation with all vertices below the equator. A **rotation** of a spherical triangulation Γ is the triangulation $\rho \circ \Gamma$ for some rigid motion $\rho\colon S^2 \to S^2$ of the sphere.[1] Our strategy rests on the following (admittedly optimistic) conjecture:

▶ **Conjecture 2.4.** *Every shortest-path triangulation Γ of the sphere can be rotated to obtain a sinkable triangulation.*

Conjecture 2.4 implies that one can morph any triangulation Γ_0 into any isotopic target triangulation Γ_1 through an intermediate coherent triangulation $\Gamma_{1/2}$. Steinitz's theorem [33, 49, 50] implies that a coherent embedding $\Gamma_{1/2}$ of G exists. Given any coherent triangulation, we can project its underlying convex polyhedron from a point on the positive z-axis just outside the polyhedron to the plane $z = -1$, and then centrally project the resulting planar triangulation back to the southern hemisphere, to obtain a θ-equivalent southern triangulation. It follows that *every* rotation of a coherent triangulation is sinkable.

We construct a morph from Γ_0 to $\Gamma_{1/2}$ in several stages as follows. First, we rotate Γ_0 so that the resulting triangulation Γ'_0 is sinkable (as guaranteed by Conjecture 2.4) and then longitudinally morph Γ'_0 to a southern triangulation Γ''_0.[2] Similarly, we rotate $\Gamma_{1/2}$ so that the resulting triangulation $\Gamma'_{1/2}$ has the same north face as Γ'_0 and Γ''_0, and then longitudinally morph $\Gamma'_{1/2}$ to a southern triangulation $\Gamma''_{1/2}$. Projection from the center of the sphere maps Γ''_0 and $\Gamma''_{1/2}$ to isomorphic straight-line triangulations in the plane $z = -1$, each with the same triangular outer face. We can construct a morph between these planar triangulations using any of several algorithms [2, 7, 11, 25, 29, 34, 40]; lifting this planar morph back to the sphere yields a spherical morph from Γ''_0 to $\Gamma''_{1/2}$. Our final morph is the concatenation of the rotation $\Gamma_0 \rightsquigarrow \Gamma'_0$, the longitudinal morph $\Gamma'_0 \rightsquigarrow \Gamma''_0$, the lifted planar morph $\Gamma''_0 \rightsquigarrow \Gamma''_{1/2}$, the reverse of the longitudinal morph $\Gamma'_{1/2} \rightsquigarrow \Gamma''_{1/2}$, and the reverse of the rotation $\Gamma_{1/2} \rightsquigarrow \Gamma'_{1/2}$. See Figure 2.2 for an example (without the initial and final rotations).

We construct a morph $\Gamma_1 \rightsquigarrow \Gamma_{1/2}$ using the same strategy. The final morph $\Gamma_0 \rightsquigarrow \Gamma_1$ is the concatenation of $\Gamma_0 \rightsquigarrow \Gamma_{1/2}$ and the reverse of $\Gamma_1 \rightsquigarrow \Gamma_{1/2}$.

3 Longitudinal Shelling

A **shelling** of a spherical triangulation Γ is an ordering $f_1, f_2, \ldots, f_{2n-4}$ of the faces of Γ such that the union of any prefix $U_k = \bigcup_{i \le k} f_i$ is either empty ($k = 0$), the entire sphere ($k = 2n - 4$), or a topological disk. We call a shelling **longitudinal** if every disk U_k is θ-monotone. Bruggesser and Mani's line shelling [9] implies that every *coherent* triangulation is longitudinally shellable.

3.1 Characterization

We characterize the shellability of Γ in terms of three directed graphs, which are illustrated in Figure 3.1.

[1] Rotations should not be confused with *rotation systems*, which encodes the cyclic order of edges around each vertex in a planar or spherical embedding.

[2] If the triangulation Γ_0 is not full, we can rotate it directly to a southern triangulation $\Gamma'_0 = \Gamma''_0$.

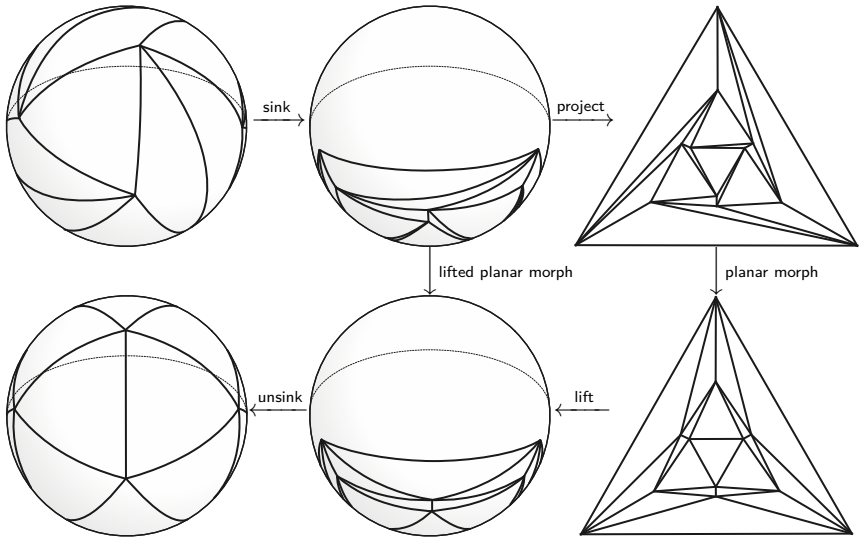

Figure 2.2 Morphing a six-beaked shaddock [19, 38] into a regular icosahedron; compare with Kobourov and Landis [41, Figure 1].

- The directed dual graph $\mathbf{\Gamma^{\downarrow}}$ contains a directed edge from face f_i to face f_j if and only if f_i and f_j share an edge in Γ, and some point in f_i is due north (on the same longitude) of some point in f_j.
- The oriented primal graph $\mathbf{\Gamma^{\rightarrow}}$ is the directed dual of $\Gamma^{\downarrow}$. For every undirected edge ij of Γ, the graph $\Gamma^{\rightarrow}$ contains the directed edge $i{\rightarrow}j$ if and only if vertex j is east of vertex i, or more formally, if the determinant

$$\det \begin{pmatrix} 0 & 0 & 1 \\ x_i & y_i & z_i \\ x_j & y_j & z_j \end{pmatrix} = \det \begin{pmatrix} x_i & y_i \\ x_j & y_j \end{pmatrix}$$

  is positive, where (x_i, y_i, z_i) is the coordinate vector for vertex i.
- Finally, $\mathbf{\Gamma^{\swarrow}}$ is a directed proper subgraph of Γ whose edges are the legs of each down-face, each directed toward its apex.

We defer the proof of the following lemma to the full version [24].

▶ **Lemma 3.1.** *For every generic shortest-path triangulation Γ, the following conditions are equivalent:*

(a) Γ *is longitudinally shellable.*
(b) $\Gamma^{\downarrow}$ *is acyclic.*
(c) $\Gamma^{\rightarrow}$ *is strongly connected.*
(d) $\Gamma^{\rightarrow}$ *contains directed paths from f_{north} to f_{south} and from f_{south} to f_{north}.*
(e) $\Gamma^{\swarrow}$ *is acyclic.*

Each of the conditions (b), (c), (d), and (e) can be tested in $O(n)$ time using textbook graph algorithms. A straightforward extension of Lemma 3.1 to triangulations with vertical edges implies a theorem of Awartani and Henderson [4]: Every triangulation with *longitudinal seam* is longitudinally shellable. See the full version [24] for more details.

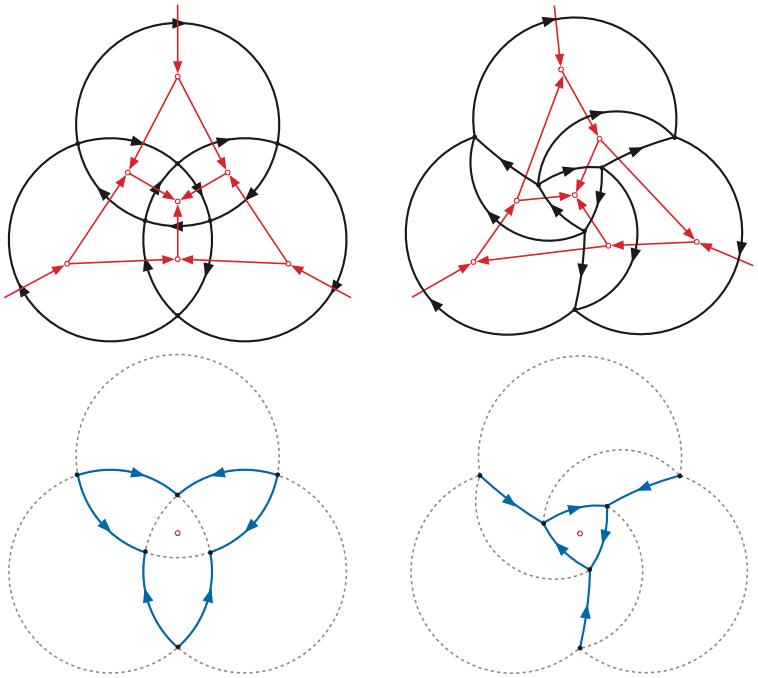

Figure 3.1 Stereographic projections of directed graphs $\Gamma^{\downarrow}$ (red straight edges), $\Gamma^{\rightarrow}$ (black curved edges), and $\Gamma^{\searrow\swarrow}$ (blue, second row) for the Platonic octahedral triangulation (which is longitudinally shellable) and a Schönhardt triangulation (which is not). Compare with Figure 1.1.

3.2 The Awartani–Henderson Embedding

▶ **Theorem 3.2** (Awartani and Henderson [4]). *Every longitudinally shellable triangulation of the sphere is sinkable. Moreover, given any longitudinally shellable triangulation Γ, we can compute a longitudinal morph from Γ to a southern triangulation in $O(n)$ time.*

Proof sketch. Let Γ be a longitudinally shellable triangulation. We construct a southern weak triangulation Γ' that is θ-equivalent to Γ by considering vertices in any topological order of $\Gamma^{\searrow\swarrow}$. The first three vertices lie on the north face and thus can be placed anywhere below the equator on their respective longitudes. For each later vertex i, we make z'_i as large as possible, such that no face induced by vertices 1 through i (except the north face) is inverted. Every down-face in the resulting drawing Γ' is degenerate. The theorem now follows from Corollary 2.3. (We give a more detailed proof, more closely following Awartani and Henderson [4], in the full version [24].) ◀

4 Longitudinally Shellable Rotations

When a given triangulation Γ is not longitudinally shellable, we can still apply our morphing strategy if we can find a rotation of the sphere that transforms Γ into a longitudinally shellable triangulation. In this section, we describe an efficient algorithm that either finds such a rotation or correctly reports that no such rotation exists. Our experimental results (described in the full version [24]) suggest that "in practice", even for triangulations with many long skinny triangles, a significant fraction of rotations of Γ are longitudinally shellable, so it suffices to consider a small number of random rotations. In fact, every one of the thousands of random adversarial triangulations we generated had shellable rotations. Nevertheless, in Section 4.2, we construct a triangulation with no longitudinally shellable rotation.

4.1 Finding a Shelling Direction

Instead of considering different rotations of Γ, it is convenient to keep Γ fixed and consider different locations for the "north pole". We call a unit vector p a **shelling direction** for Γ if any (and therefore every) rotation of the sphere that takes p to the standard north pole $(0, 0, 1)$ also takes Γ to a longitudinally shellable triangulation. We similarly define the directed graphs $\Gamma^{\downarrow}(p)$ and $\Gamma^{\rightarrow}(p)$ and $\Gamma^{\searrow\swarrow}(p)$. For example, for any unit vector $p = (x, y, z)$, the graph $\Gamma^{\rightarrow}(p)$ contains the edge $i{\rightarrow}j$ if and only if

$$\mathrm{vol}(p, i, j) := \det \begin{pmatrix} x & y & z \\ x_i & y_i & z_i \\ x_j & y_j & z_j \end{pmatrix} > 0,$$

and p is a shelling direction for Γ if and only if the graphs $\Gamma^{\downarrow}(p)$ and $\Gamma^{\searrow\swarrow}(p)$ are acyclic.

▶ **Theorem 4.1.** *Given any shortest-path triangulation Γ on the sphere, we can either compute a shelling direction for Γ or report correctly that no such direction exists, in $O(n^{2.5} \log^3 n)$ time.*

Proof. Each edge ij in Γ lies on a unique great circle; let $\mathcal{A}(\Gamma)$ denote the arrangement of all $3n - 6$ such great circles. For any two unit vectors p and q, the graphs $\Gamma^{\rightarrow}(p)$ and $\Gamma^{\rightarrow}(q)$ are identical if and only if p and q lie in the same cell of $\mathcal{A}(\Gamma)$. Thus, for any cell C, we can write $\Gamma^{\rightarrow}(C)$ to denote the graph $\Gamma^{\rightarrow}(p)$ for any $p \in C$. If C and C' are adjacent two-dimensional cells of $\mathcal{A}(\Gamma)$, then $\Gamma^{\rightarrow}(C)$ and $\Gamma^{\rightarrow}(C')$ differ in the direction of exactly one edge.

We can find a shelling direction for Γ in $O(n^3)$ time by constructing the great-circle arrangement $\mathcal{A}(\Gamma)$, and then for each two-dimensional cell C, check whether $\Gamma^{\rightarrow}(C)$ is strongly connected. (This arrangement is centrally symmetric, and the gnomonic projection of either hemisphere to any tangent plane is an arrangement of *lines*. Thus, we can use any classical algorithm to construct line arrangements [16, 22, 23].

We can speed up this naive algorithm using a data structure of Diks and Sankowski for reachability queries in dynamic directed plane graphs [18]. Diks and Sankowski's data structure maintains a directed planar graph with a fixed embedding, supports edge insertions and deletions that do not change the embedding in $O(\sqrt{n} \log^3 n)$ time, and supports queries of the form "Is there a directed path from vertex i to vertex j?" in $O(\sqrt{n} \log^2 n)$ time.

To use this data structure, we traverse the dual graph of the arrangement $\mathcal{A}(\Gamma)$. At each two-dimensional cell C, we perform two reachability queries in $\Gamma^{\rightarrow}(C)$ between the two polar faces. If both reachability queries succeed, then by Lemma 3.1(d), cell c contains a shelling direction. When we move from a cell C to a neighboring cell C', we delete one edge and insert its reversal. Altogether, we perform $O(n^2)$ queries and $O(n^2)$ updates. ◀

4.2 Unshellable From Every Direction

Regard each edge of the undirected dual graph Γ^* as a pair of opposing directed edges or **darts**. For any directed cycle γ^* of darts in Γ^*, the **polar region $P(\gamma^*)$** is the set of all north poles p such that the directed dual graph $\Gamma^{\downarrow}(p)$ contains every dart in γ^*. A unit vector p is a shelling direction for Γ if and only if $p \notin P(\gamma^*)$ for *every* directed dual cycle γ^*.

▶ **Lemma 4.2.** *For every directed cycle γ^* of darts in the dual graph Γ^*, the corresponding polar region $P(\gamma^*)$ is the interior of a convex spherical polygon, that is, the intersection of S^2 with a (possibly empty) open convex polyhedral cone.*

Proof. Let $i{\to}j$ be any dart in Γ, and let f and g be the faces incident to $i{\to}j$ on the left and right, respectively. The directed graph $\Gamma^{\downarrow}(p)$ contains the edge $f{\to}g$ if and only if $\mathrm{vol}(p,i,j) > 0$. The set of all points p satisfying this inequality is an open hemisphere $H(f{\to}g)$ bounded by the great circle through $i{\to}j$. Finally, the polar region $P(\gamma^*)$ of any dual cycle γ^* is the intersection of the hemispheres $H(f{\to}g)$ for all $f{\to}g \in \gamma^*$. ◀

A **rotor** is the subset of faces of Γ dual to any directed cycle γ^* in the dual graph Γ^*. We sketch the construction of a triangulation Γ containing a small number of rotors, whose polar regions cover the entire sphere. We describe our construction in terms of an arbitrary sufficiently small angular parameter $\varepsilon > 0$; in practice, it suffices to set $\varepsilon \approx 0.01 \approx 0.5°$.

First we define a simple *equatorial rotor*, which triangulates a belt of width $O(\varepsilon^2)$ around a great circle using $O(1/\varepsilon)$ isosceles triangles with aspect ratio $O(\varepsilon)$ and with all edges at angle $O(\varepsilon)$ from the great circle. The triangulation edges are consistently oriented so that for any north pole p sufficiently far from the rotor, the rotor defines a cycle in the directed dual graph $\Gamma^{\downarrow}(p)$. The polar region of (one orientation of) the rotor is a convex spherical polygon whose boundary has Hausdorff distance $O(\varepsilon)$ from the rotor itself. In particular, in the limit as ε approaches zero, this polar region approaches an open hemisphere.

Figure 4.1 Local structure of an equatorial rotor.

Our unshellable triangulation contains four modified equatorial rotors, whose central great circles are parallel to the faces of a regular tetrahedron. Let Q denote the arrangement of these four great circles; Q is the central projection of an inscribed semi-regular cuboctahedron; see Figure 4.2. Each pair of great circles meets at an angle of $\arccos(1/3) \approx 70.529°$.

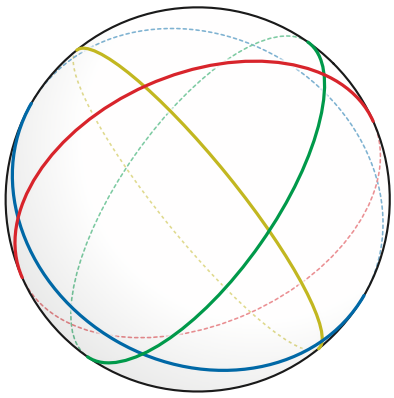

Figure 4.2 Four great circles defining a spherical cuboctahedron.

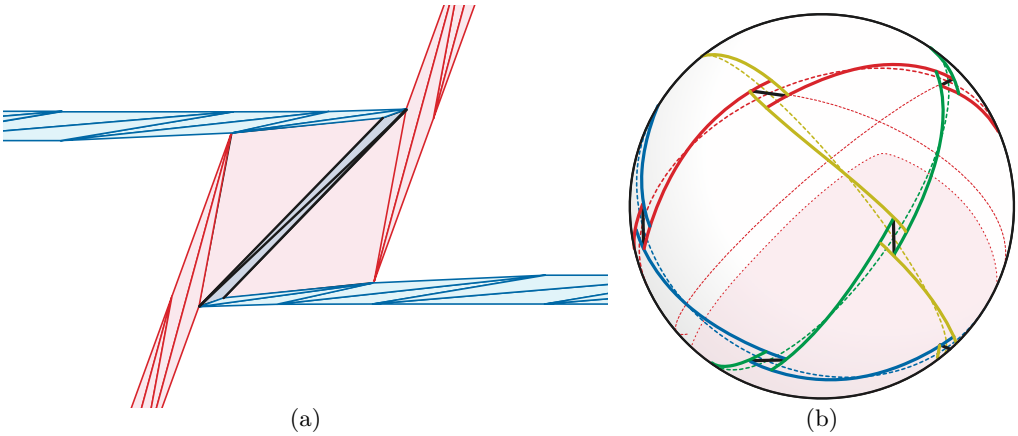
At each vertex of Q, we modify the two equatorial rotors by introducing a *crossing gadget*, illustrated in Figure 4.3(a). Overall the gadget resembles a rhombus with diameter $O(\varepsilon)$ whose edges are parallel to the great circles defining the rotors. Each of the equatorial rotors is broken and offset by $O(\varepsilon)$ to cover two opposite edges of this rhombus. Then three new edges are added to reconnect both rotors; these edges have distance and angle $O(\varepsilon)$ from the long diagonal of the rhombus and the bisector of the smaller angle between the two great circles. The two fat triangles inside the rhombus are incorporated into one of the two rotors (the vertical red rotor in Figure 4.3); the two thin triangles near the diagonal are incorporated into both. Figure 4.3(b) shows a schematic of our overall construction.



(a) (b)

Figure 4.3 (a) A single crossing gadget. (b) Constructing a triangulation with no shelling direction. Each color of broken lines is an equatorial rotor; each short black line is the diagonal of a crossing gadget. The polar region of one (red) equatorial rotor is shaded.

Now let γ^* be a directed cycle in the dual graph Γ^* through the faces of one equatorial rotor. The corresponding polar region $P(\gamma^*)$ nearly fills a triangular region bounded by three bisector circles, each defined by an antipodal pair of crossing gadgets. This polar region completely covers one triangular face and nearly half of three square faces of Q. The reversal of γ^* defines an antipodally symmetric polar region.

Thus, the union of the polar regions defined by all four equatorial rotors covers the entire sphere except for a small "hole" near the center of each square face of Q, which we can make arbitrarily small by choosing ε appropriately. We cover these holes by adding a small rotor, reminiscent of the projection of a Schönhardt polyhedron, inside each square face of Q; see Figure 4.4. Finally, to complete the triangulation Γ, we arbitrarily triangulate the area between the rotors.

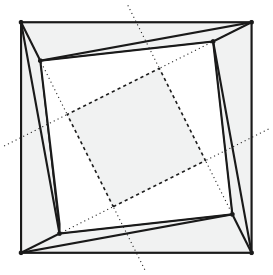


Figure 4.4 A square rotor (solid lines) and its polar region (dashed lines).

▶ **Theorem 4.3.** *There is a shortest-path triangulation of the sphere with no longitudinal shelling direction.*

Proof. By construction, every point $p \in S^2$ lies in the polar region of at least one rotor, and therefore in the polar region of at least one directed cycle in the dual graph Γ^*. Thus, for every $p \in S^2$, the directed dual graph $\Gamma^{\downarrow}(p)$ is not acyclic. The theorem follows immediately from Lemma 3.1. ◀

Nothing in our construction prevents our bad triangulation Γ from being *sinkable*. In particular, just before we add the final rotors to cover the "holes", the partial triangulation is still longitudinally shellable from any direction inside one of those holes. After rotating and sinking this partial triangulation and then projecting to the plane $z = -1$, we can add the final rotors to the resulting planar embedding. Moreover, experimental evidence [24] strongly suggests that every triangulation in which all edges have length less than $\pi/2$ is sinkable; our bad triangulation Γ satisfies this condition.

5 Sinking

Finally, we present an exact characterization of sinkable triangulations. Let Γ be our initial full shortest-path triangulation of the sphere. Recall from Corollary 2.3 that Γ is sinkable if and only if there is a southern weak triangulation Γ' that is θ-equivalent to Γ.

Without loss of generality we can consider only weak triangulations Γ' where each vertex has the same x- and y-coordinates as in Γ. Let (x_i, y_i, z_i) and (x_i, y_i, z'_i) denote the coordinates of vertex i in Γ and Γ', respectively. Then Γ' is θ-equivalent to Γ if and only if $\mathrm{vol}'(i,j,k) \geq 0$ for every non-polar face (i,j,k), where

$$\mathrm{vol}'(i,j,k) := \det \begin{pmatrix} x_i & y_i & z'_i \\ x_j & y_j & z'_j \\ x_k & y_k & z'_k \end{pmatrix}$$

We reiterate that because we have fixed all x- and y-coordinates, the volume determinant $\mathrm{vol}'(i,j,k)$ is a linear function of the vector z'.

▶ **Lemma 5.1.** *A spherical triangulation Γ is sinkable if and only if the following linear program is feasible:*

$$\begin{array}{lrll} \textit{maximize} & \sum_i z'_i & & \\ \textit{subject to} & z'_i = -1 & \textit{for every vertex } i \textit{ of } f_{\textit{north}} & (5.1) \\ & \mathrm{vol}'(i,j,k) \geq 0 & \textit{for every non-polar face } (i,j,k) & \end{array}$$

Proof. Suppose $z' = (z'_1, \ldots, z'_n)$ is the z-coordinate vector of a weak triangulation Γ' that is θ-equivalent to Γ, such that $z'_i < 0$ for all i. We can move the vertices of north face of Γ' to the plane $z = -1$ by applying a linear transformation that preserves the z-axis and all longitudes. The coordinate vector of every other vertex i is a positive linear combination of the north-face coordinate vectors, so $z'_i < 0$ for all i. ◀

Lemma 5.1 immediately implies an algorithm to compute a sinking longitudinal morph, or report correctly that none exists, in weakly polynomial time, provided the input x- and y-coordinates are rational [32]. We obtain a simpler and faster algorithm by identifying the optimal basis of the linear program, subject to a mild technical condition.

First we need a small extension of a result used in many planar morphing algorithms [17, 20, 37, 39, 40]. A polygon is *weakly convex* if its interior is convex and each of its vertices has interior angle *at most* π. Let T be any straight-line plane graph whose outer face is a simple x-monotone polygon and whose inner faces are triangles. A weakly convex polygon W is *compatible* with T if there is a homeomorphism from the boundary of T to the boundary of W that preserves x-coordinates. A weak planar triangulation T' is *x-equivalent* to T if it has the same underlying graph, every nondegenerate face of T' has the same orientation as the corresponding face of T, and corresponding vertices have equal x-coordinates.

▶ **Lemma 5.2.** *Given a triangulation T of an x-monotone polygon in the plane, and a weakly convex polygon W that is compatible with T, there is a weak planar triangulation T' that is x-equivalent to T and whose outer face is W.*

Proof sketch. If W is a *strictly* convex polygon (all interior angles are strictly less than π), the lemma follows immediately from algorithms of Chrobak, Goodrich, Tammassia [17] and Kleist, Klemz, Lubiw, Schlipf, Staals, and Strash [39]; we extend these algorithms to weakly convex W using a limiting argument. See the full version [24] for a complete proof. ◀

We emphasize that our algorithms never *compute* the weak triangulation T'; we only need to prove that it exists.

▶ **Theorem 5.3.** *If $z' = (z'_1, \ldots, z'_n)$ is an optimal solution to linear program* (5.1)*, then z' is also a solution to the following $n \times n$ linear system:*

$$\begin{aligned} z'_i &= -1 && \text{for every vertex } i \text{ of } f_{\mathsf{north}} \\ \mathrm{vol}'(i,j,k) &= 0 && \text{for every down-face } (i,j,k) \end{aligned} \tag{5.2}$$

Proof. Let z' be any feasible solution for linear program; Lemma 5.1 implies that $z'_i < 0$ for all i. Let Γ' be the southern weak triangulation defined by z', and suppose that at least one down-face of Γ' is nondegenerate. We argue that we can construct another southern weak triangulation Γ'' (that is, another feasible solution z'' to (5.1)) by increasing some z-coordinates and leaving all other coordinates fixed, which implies that z' is not an optimal solution to (5.1).

Call a vertex of Γ' *sober* if it is not incident to the north face or to any degenerate face. If any vertex of Γ' is sober, we can construct Γ'' by moving any sober vertex upward slightly and keeping all other vertices fixed. So without loss of generality, we assume that Γ' has no sober vertices. We call a vertex i *upward-free* if i is not a vertex of the north face and $f_{\mathsf{above}}(i)$ is nondegenerate in Γ', *downward-free* if $f_{\mathsf{below}}(i)$ is nondegenerate in Γ', *totally free* if it is both upward- and downward-free, and *trapped* if $f_{\mathsf{above}}(i)$ and $f_{\mathsf{below}}(i)$ are both degenerate.

A *bar* in Γ' is a maximal circular arc that is covered by edges of Γ' and has no totally free vertices in its interior. Each bar is either a single edge or the union of one or more degenerate faces; in the latter case, the corresponding subset of faces in Γ are edge-connected, and their union is a θ-monotone disk. Equivalently, a nontrivial bar is the image in Γ' of a maximal edge-connected subset of faces of Γ that are all degenerate in Γ'. We call the subcomplex of Γ induced by these faces a *pre-bar*. The *endpoints* of a pre-bar are the preimages of the endpoints of its bar. Because no vertex of Γ' is sober, every vertex not incident to the north face is contained in at least one bar.

Every upward-free vertex in Γ' is the image of a vertex on the northern boundary of a pre-bar in Γ. Every downward-free vertex in Γ' is either incident to the north face or the image of a vertex on the southern boundary of a pre-bar in Γ. Each endpoint of a bar can be upward-free, downward-free, or both. Finally, each trapped vertex in Γ' is the image of a vertex in the interior of a pre-bar in Γ, and thus lies on a unique bar in Γ'. See Figure 5.1(a) and (b).

We construct a new weak triangulation Γ'' by defining new coordinates $z''_i \geq z'_i$ for each vertex i. Let $\varepsilon > 0$ be any sufficiently small positive constant. Defining new coordinates for the free vertices of Γ' is straightforward:

- For every vertex i of the north face, we define $z''_i = z'_i$.
- For every upward-free vertex i, we define $z''_i = z'_i/(1+\varepsilon) > z'_i$.
- For every downward-free vertex i that is not also upward free, we define $z''_i = z'_i$.

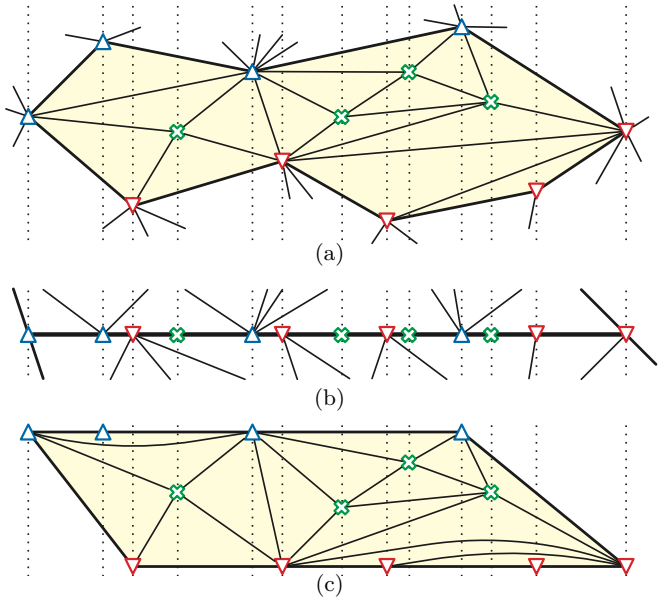

Figure 5.1 Planar projections of (a) a pre-bar in Γ, (b) the corresponding bar in Γ', and (c) the corresponding perturbed bar in Γ'' (with curved edges to show degenerate facets). Triangles indicate upward- and downward-free vertices; X's indicate trapped vertices. Dotted lines indicate longitudes.

Choosing sufficiently small ε already guarantees that any face that is non-degenerate in Γ' is also non-degenerate in Γ''. However, placing the trapped vertices to avoid inverting degenerate faces of Γ' requires more care.

Let β be any nontrivial bar in Γ', and let B be the corresponding pre-bar in Γ. We have already mapped the entire boundary of B to a spherical trapezoid τ in Γ''. Specifically, if β lies on the plane $z = ax + by$, then all upward-free vertices in β lie on the plane $z = (ax + by)/(1 + \varepsilon)$ in Γ''.

Because β projects to a line segment in the plane $z = -1$, it lies inside an open hemisphere bounded by a *vertical* plane through the origin. Without loss of generality, suppose β lies in the hemisphere $y > 0$. Let π_y denote the function $(x, y, z) \mapsto (x/y, z/y)$; we can interpret this function geometrically as the gnomonic projection from S^2 onto the plane $y = 1$. Then $\pi_y(\beta)$ is a non-vertical line segment, $\pi_y(B)$ is a triangulation of an x-monotone polygon, and $\pi_y(\tau)$ is a planar trapezoid whose lower boundary is a subset of $\pi_y(\beta)$ and whose upper boundary lies on a line parallel to $\pi_y(\beta)$. Each longitude ℓ through a trapped vertex i on β defines a *vertical* line $\pi_y(\ell)$ that must contain the point $(x_i/y_i, z_i''/y_i)$. See Figure 5.1.

To summarize, $\pi_y(B)$ is a triangulation of an x-monotone polygon, and $\pi_y(\tau)$ is a weakly convex polygon (specifically, a trapezoid) that is compatible with $\pi_y(B)$. Thus, Lemma 5.2 implies that there is a weak triangulation $\pi_y(T'')$ that is x-equivalent to $\pi_y(B)$ and whose outer face is $\pi_y(\tau)$. Pulling $\pi_y(T'')$ back to the sphere gives us a weak triangulation T'' of the spherical trapezoid τ that is θ-equivalent to B. Each interior vertex i of B maps to a vertex in the closed interior of τ, which implies $z_i' \le z_i'' \le z_i'/(1 + \varepsilon)$.

We assemble the overall weak triangulation Γ'' by applying this construction to every bar in Γ'. (Processing each bar requires projecting to a different vertical tangent plane.) Because $z_i'' \ge z_i'$ for every vertex i, and $z_i'' > z_i'$ for at least one vertex i, the original weak triangulation Γ' cannot be an optimal solution to our linear program (5.1). ◀

▶ **Corollary 5.4.** *Given a shortest-path triangulation* Γ *of the sphere, we can either compute a longitudinal morph from* Γ *to a southern triangulation, or report correctly that no such morph exists, in* $O(n^{\omega/2})$ *time, assuming linear system* (5.2) *is non-singular.*

Proof. The support of linear system (5.2) is precisely the directed planar graph $\Gamma^{\searrow\swarrow}$. Thus, assuming the system is non-singular, it can be solved in $O(n^{\omega/2}) = O(n^{1.1864})$ time (in the real RAM model) via nested dissection and fast matrix multiplication [3,42]. If the solution z' is a feasible point for linear program (5.1), the corresponding drawing Γ' is a weak southern triangulation θ-equivalent to Γ. If the system is non-singular, and the solution z' is not a feasible point for linear program (5.1), then by Theorem 5.3, the linear program is infeasible, so we can correctly report that Γ is not sinkable. ◀

Theorem 5.3 is a strict generalization of the Awartani-Henderson embedding, described in the proof of Theorem 3.2. When Γ is shellable, its support graph $\Gamma^{\searrow\swarrow}$ is acyclic. Thus, we can permute the rows and columns of (5.2) to obtain an upper-triangular system, which we can then solve by back-substitution. Each step of back-substitution assigns one z-coordinate, exactly mirroring one step of the Awartani-Henderson construction.

Michael Perk
Department of Computer Science, TU Braunschweig, Germany

Abstract

We provide a spectrum of new theoretical insights and practical results for finding a Minimum Dilation Triangulation (MDT), a natural geometric optimization problem of considerable previous attention: Given a set P of n points in the plane, find a triangulation T, such that a shortest Euclidean path in T between any pair of points increases by the smallest possible factor compared to their straight-line distance. No polynomial-time algorithm is known for the problem; moreover, evaluating the objective function involves computing the sum of (possibly many) square roots. On the other hand, the problem is not known to be NP-hard.

(1) We provide practically robust methods and implementations for computing an MDT for benchmark sets with up to 30,000 points in reasonable time on commodity hardware, based on new geometric insights into the structure of optimal edge sets. Previous methods only achieved results for up to 200 points, so we extend the range of optimally solvable instances by a factor of 150.

(2) We develop scalable techniques for accurately evaluating many shortest-path queries that arise as large-scale sums of square roots, allowing us to certify exact optimal solutions, with previous work relying on (possibly inaccurate) floating-point computations.

(3) We resolve an open problem by establishing a lower bound of 1.44116 on the dilation of the regular 84-gon (and thus for arbitrary point sets), improving the previous worst-case lower bound of 1.4308 and greatly reducing the remaining gap to the upper bound of 1.4482 from the literature. In the process, we provide optimal solutions for regular n-gons up to $n = 100$.

1 Introduction

Triangulating a set of points is one of the classical problems in computational geometry. On the practical side, it has natural applications in wireless sensor networks [47, 49], mesh generation [4], computer vision [45], geographic information systems [46] and many other areas [15]. On the theoretical side, finding a triangulation that is optimal with respect to

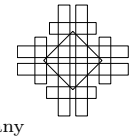

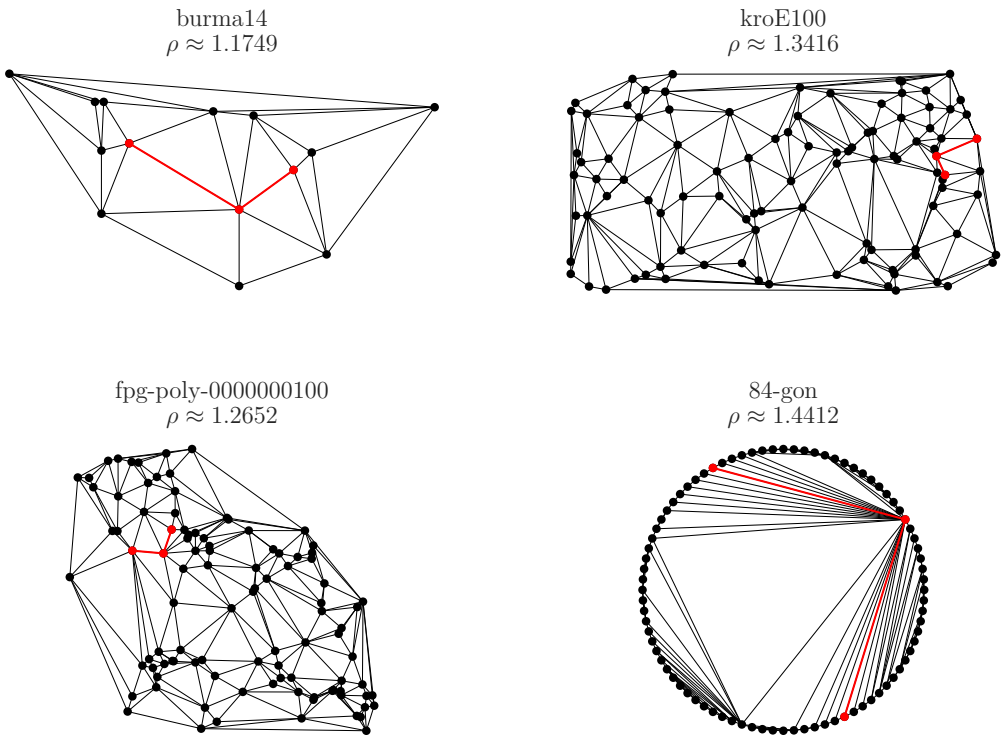

Figure 1 MDT solutions for four instances. The red edges indicate a dilation-defining path.

some objective function has also received considerable attention: The Delaunay triangulation maximizes the minimum angle and minimizes the maximum circumcircle of all triangles. Minimizing the maximum edge length is possible in quadratic time [21]. On the other hand, maximizing the minimum edge length is NP-complete [27]. Famously, Mulzer and Rote [36] showed that computing the Minimum Weight Triangulation (MWT) is NP-hard.

In this paper, we provide new results and insights for another natural objective that considers triangulations as sparse structures with relative low cost for ensuing detours: The *dilation* of a triangulation T of a point set P is the worst-case ratio (among all $s, t \in P$) between the shortest s-t-path in T and the Euclidean distance between s and t. The Minimum Dilation Triangulation (MDT) problem asks for a triangulation that minimizes the dilation ρ, see Figure 1 for examples. This problem is closely related to the concept of a Euclidean t-spanner: a subgraph with dilation (also called *spanning ratio* or *stretch factor* [37]) at most t. Spanners have application in areas as robotics, network design [1, 26], sensor networks [10, 25] and design of parallel machines [3] and have been studied extensively [11]. Computing the MDT amounts to computing a *plane* spanner with smallest spanning ratio, as every plane spanner can be extended into a triangulation. For many types of triangulations, such as the Delaunay triangulation or the MWT, both lower and upper bounds on the worst-case dilation are known. Moreover, a constant upper bound on the worst-case dilation of a triangulation also implies a constant-factor approximation of the MDT. Lower and upper bounds on the worst-case dilation of the MDT have been studied, both for general point sets and for special point sets such as regular polygons or points on a circle; see Section 1.2 for further details.

Despite this importance and attention, actually computing a Minimum Dilation Triangulation is a challenging problem. Its computational complexity is still unresolved, signaling that there may not be a simple and elegant algorithmic solution that scales well. Moreover, actually

computing accurate dilations involves computing shortest paths under Euclidean distances between $\Theta(n^2)$ pairs of points requires dealing with another famous challenge [39, 18, 6, 23], as it corresponds to evaluating and comparing numerous sums of many square roots.

1.1 Our contributions

We provide various new contributions, both to theory and practice.

1. We present practically robust methods and implementations for computing an optimal MDT for benchmark sets with up to 30,000 points in reasonable time on commodity hardware, based on new geometric insights into the structure of optimal edge sets. Previous methods only achieved results for up to 200 points (involving one computational routine of complexity $\Theta(n^4)$ instead of our improved complexity of $O(n^2 \log n)$), so we extend the range of practically solvable instances by a factor of 150.
2. We develop scalable techniques for accurately evaluating many shortest-path queries that arise as large-scale sums of square roots, allowing us to certify exact optimal solutions. This differs from previous work, which relied on floating-point computations, without regard for errors resulting from numerical issues.
3. We resolve an open problem from [20] by establishing a lower bound of 1.44116 on the dilation of the regular 84-gon (and thus for arbitrary point sets). This improves the previous worst-case lower bound of 1.4308 from the regular 23-gon and greatly reduces the remaining gap to the upper bound of 1.4482 from [43]. In the process, we provide optimal solutions for regular n-gons up to $n = 100$.

1.2 Related work

The complexity of finding the MDT is unknown [24]. [28] prove that finding the minimum dilation graph with a limited number of edges is NP-hard. [12] show that finding a spanning tree of given dilation is also NP-hard. Kozma [33] proves NP-hardness for minimizing the expected distance between random points in a triangulation, with edge weights instead of Euclidean distances. For surveys, see Eppstein [24] until 2000 and [38] for more recent results.

On the practical side, the authors of [44] study the problem of finding sparse low dilation graphs for large point sets in the plane. The authors of [9] present an approximation algorithm for the related problem of improving a given graph with a budget of k edges such that the dilation is minimized. Regarding the MDT, all practical approaches in the literature are based on fixed-precision arithmetic. Klein [31] used an enumeration algorithm to find an optimal MDT for up to 10 points. The authors of [19] present heuristics for the MDT and evaluate their performance on instances with up to 200 points. Instances with up to 70 points were solved by the authors of [8] using integer linear programming techniques. In their approach, the edge elimination strategy from Knauer and Mulzer [32] was used to eliminate edges from the complete graph. Recently, Sattari and Izadi [41] presented an exact algorithm based on branch and bound that was evaluated on instances with up to 200 points.

The MDT is closely related to finding a plane t-spanner; see [34] for an overview. Chew [13] first proved an upper bound of $\sqrt{10}$ on plane t-spanners in the L_1-metric, which he later improved [14] to 2 for the triangular-distance Delaunay graph in the plane. [5] proved that any convex point set admits a plane 1.88-spanner. For a centrally symmetric convex point set containing n points, Sattari and Izadi [42] give an upper bound of $n/2 \sin(\pi/n)$. The best known upper bound on the dilation of arbitrary point sets is by Xia [48], who established and upper bound of 1.998 for the dilation of the Delaunay triangulation.

Mulzer [35] studied the MDT for the set of vertices of a regular n-gon and proved an upper bound of 1.48586. Amarnadh and Mitra [2] improved this bound to 1.48454 for any point set that lies on the boundary of a circle. Sattari and Izadi [43] again improved the bound to 1.4482. Dumitrescu and Ghosh [20] show that any triangulation of a regular 23-gon has dilation at least 1.4308, improving upon the bound of 1.4161 by Mulzer [35] and answering a question posed by Bose and Smit [7] as well as Kanj [30]. Dumitrescu and Ghosh [20] also computed dilations of regular 22-gon and regular 24-gon.

2 Preliminaries

Let $P \subset \mathbb{R}^2$ be a set of points in the plane. We denote the Euclidean distance between two points $u, v \in P$ by $d(u, v)$. For a connected geometric graph $G = (P, E)$ with $E \subseteq \binom{P}{2}$, we denote the Euclidean shortest path between two points $u, v \in P$ by $\pi_G(u, v)$ and its length by $|\pi_G(u, v)|$, omitting G if it is clear from context. The dilation $\rho_G(u, v)$ between two points u, v in G is the ratio $\rho_G(u, v) := \frac{|\pi_G(u,v)|}{d(u,v)}$ between the shortest path length and the Euclidean distance. The dilation $\rho(G)$ of the graph G is defined as the maximum dilation between any two points in P, i.e., $\rho(G) := \max\{\rho_G(u, v) \mid u, v \in P, u \neq v\}$.

In the remainder of this work, the graph G we consider is a triangulation, i.e., a maximal crossing-free graph on P. Two edges $e_1 = (p_1, q_1), e_2 = (p_2, q_2)$ are said to *cross* or *intersect* iff the line segments they induce intersect in their interior. Given a point set P, the Minimum Dilation Triangulation problem (MDT) asks to find a triangulation T of P minimizing $\rho(T)$.

3 Candidate edge enumeration

Here we describe a novel and practically efficient scheme for enumerating a set of edges that induces a supergraph of the MDT. We start with the underlying theoretical ideas for this supergraph, followed by an algorithm for computing a supergraph of any triangulation with dilation *strictly less* than a given bound ρ, which we exploit to enumerate a supergraph of the MDT with a (usually) small number of edges. This is further adapted to reductions of the dilation bound ρ. We also discuss the computation of lower bounds on the dilation of the MDT. Some additional implementation details can be found in the full version.

3.1 Theoretical background

Our supergraph is based on the well-known *ellipse property* (used in [8, 28, 32]) that all edges of a triangulation T with dilation below ρ must satisfy.

▶ **Definition 1.** *A pair of points s, t has the* ellipse property *with respect to a point set P and a dilation bound ρ if, for any pair of points $\ell, r \in P \setminus \{s, t\}$ such that ℓr and st intersect,* $\min\{d(\ell, s) + d(s, r), d(\ell, t) + d(t, r)\} < \rho d(\ell, r)$.

Recall that the set of points that have the same sum of distances κ to two points ℓ, r with $\kappa \geq d(\ell, r)$ is an *ellipse* with ℓ, r as its focal points (or *foci*); thus, all paths between ℓ and r with length less than $\kappa = \rho \cdot d(\ell, r)$ must lie strictly inside this ellipse.

If a pair of points s, t does not have the ellipse property, then there is a pair of points ℓ, r such that st cuts through all paths between ℓ and r that could have dilation less than ρ; see Figure 2. We call such a pair of points ℓ, r an *exclusion certificate* for s, t.

▶ **Observation 2.** *Let $\rho \geq 1$ be some dilation bound and let T be a triangulation containing the edge st for points s, t that do not have the ellipse property w.r.t. P and ρ. Then, $\rho(T) \geq \rho$.*

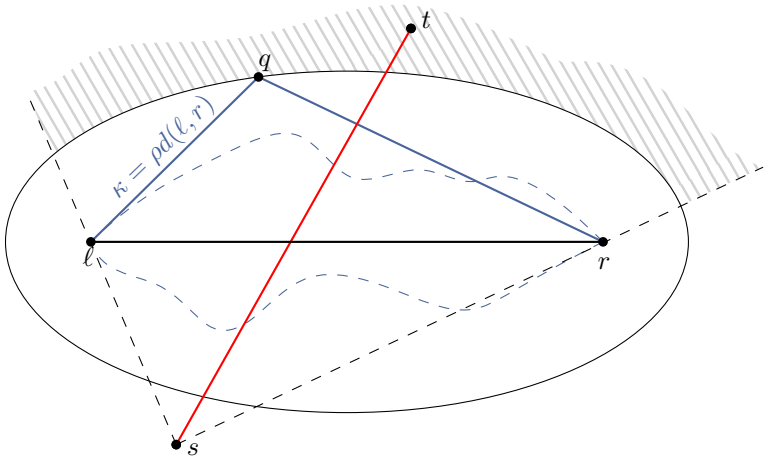

Figure 2 Any path connecting ℓ and r with length below $\kappa = \rho d(\ell, r)$ must lie within the ellipse (dashed black lines). The edge st does not have the *ellipse property* as neither s nor t lie inside the ellipse; therefore, inserting st makes connecting ℓ and r by a sufficiently short path impossible.

3.2 High-level description

Preliminary experiments showed that a brute-force check of each of the $\Theta(n^4)$ pairs of potential edges is impractical for large n, dominating the overall runtime time even for early versions of our solution approach.

We therefore developed a more efficient scheme to enumerate a superset of the edges that satisfy the ellipse property. This scheme performs a *filtered incremental nearest-neighbor search* from each point $p \in P$ to identify all candidate edges of the form pt, i.e., looking for all possible *neighbors* t of p. This search is efficiently implemented on a quadtree containing all points. While enumerating candidates, we construct so-called *dead sectors*, i.e., regions of the plane that cannot contain possible neighbors of p. We exclude all points that lie in dead sectors; we also use dead sectors to prune entire nodes of the quadtree and to terminate the search early if it has become clear that all remaining points must be in a dead sector. This usually avoids considering most points as potential neighbors of p individually. The algorithm has a runtime of $O(nk \log n)$, where k is the average number of points and quadtree vertices considered individually from each point. At worst, this can be $O(n^2 \log n)$; in practice, k is often much lower than n. A related, slightly less complex enumeration algorithm applied to minimum-weight triangulations by Haas [29] scales to 10^8 points. In the following, we describe the components of the enumeration scheme in more detail.

3.3 Dead sectors

We begin by giving a definition of the dead sectors we use.

▶ **Definition 3.** *Given a dilation ρ, a source point p and two points ℓ, r, the* dead sector $\mathcal{DS}_\rho(p, \ell, r) \subset \mathbb{R}^2$ *is the region of all points t such that pt intersects ℓr and neither p nor t lie in the ellipse with foci ℓ, r and focal distance sum $\kappa = \rho d(\ell, r)$.*

Depending on p, ρ, ℓ and r, $\mathcal{DS}_\rho(p, \ell, r)$ is either empty (if p is in the ellipse) or it is bounded by two rays and an elliptic arc; see Figure 3. In that case, it can also be interpreted as an elliptic arc and an interval of polar angles around p.

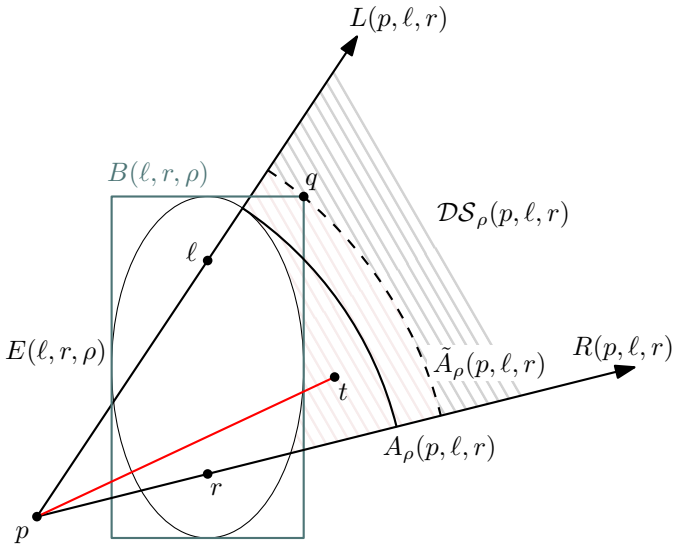

Figure 3 A dead sector $\mathcal{DS}_\rho(p,\ell,r)$, shaded in gray and red with the ellipse $E(\ell,r,\rho)$. We approximate the ellipse by a disk centered at p with radius $\tilde{A}_\rho(p,\ell,r)$ (thereby ignoring the red area), which is the distance from p to the farthest point q of the rectangle $B(\ell,r,\rho)$ in $\mathcal{DS}_\rho(p,\ell,r)$.

During our enumeration we construct many dead sectors, the union of which can become quite complex, making it cumbersome and inefficient to work with directly. We instead chose to simplify the shape of our dead sectors, giving up a small fraction of excluded area in exchange for a simple and efficient representation. We replace the elliptic arc by a single disk centered on p, whose radius is at least the maximum distance from p to any point on the elliptic arc. We can hence represent each non-empty simplified dead sector by a polar angle interval around p and a single radius called *activation distance* $A_\rho(p,\ell,r)$; see Figure 3.

We initially attempted to compute fairly precise upper bounds on the activation distance; however, due to computational and numerical issues described in the full version, we decided to use a more robust and efficient approach. Instead of using the elliptic arc, we compute an upper bound $\tilde{A}_\rho(p,\ell,r)$ using a minimal rectangle $B(\ell,r,\rho)$ containing the ellipse with sides are parallel and perpendicular to ℓr. We only need to check the extreme points of $B(\ell,r,\rho)$ and its intersections with the rays $L(p,\ell,r)$ and $R(p,\ell,r)$ to compute an upper bound $\tilde{A}_\rho(p,\ell,r)$; see Figure 3.

In the worst case, these simplifications may lead to additional candidate edges. While this cannot make the resulting graph exclude any edges that satisfy the ellipse property, it is still undesirable; we use additional checks for further reductions later on.

3.4 Quadtree

We use a quadtree containing all points in P for the filtered incremental search. The points are stored in a contiguous array A_P outside the tree. Each quadtree node v is associated with a contiguous subrange of A_P represented by two pointers. This subrange contains the points in the subtree $\mathcal{T}_v$ rooted at v. Each node also has a bounding box that contains all points in $\mathcal{T}_v$. Each interior node has precisely four children; each leaf node contains at most a small constant number of points. To allow the contiguity of the subranges, points are reordered during tree construction. This has the added benefit of spatially sorting the points, improving the probability that geometrically close points are near each other in memory [29].

3.5 Enumeration process

One can think of the filtered incremental search from p as a process of continuously growing a disk centered at p starting with a radius of 0. As in the sweep-line paradigm, one encounters different types of events at discrete disk radii. We primarily encounter events when the disk first touches a point of P or the bounding box of a quadtree node.

Observe that, during a search from a point p, the dead sectors have two states: either their activation distance is not yet reached, in which case they are *inactive* and do not exclude any points, or they are *active* and exclude all points in a certain polar angle interval around p. We therefore also introduce events when the disk radius reaches the activation distance of a dead sector. This enables efficient management of active dead sectors as a set of polar angle intervals around p; see the full version for a discussion of the ensuing numerical issues.

When we first encounter a point t, we have to determine whether t is in any dead sector by checking the active dead sector data structure. If it is not, we have to report it as potential neighbor of p, adding it to a set of points sorted by polar angle around p. Furthermore, to construct new dead sectors, we combine t with $O(1)$ other points of P; which points we use is decided by a heuristic discussed in the full version.

When we encounter a quadtree node v, we have to determine whether v's bounding box is fully contained in the union of all dead sectors and can thus be pruned; we thus again check the active dead sectors. Otherwise, we have to take v's children, or the points it contains if it is a leaf, into account; they are then considered as future events.

3.6 Initialization and postprocessing

We initially compute the Delaunay triangulation of the point set P and compute its dilation. We also optionally attempt to improve the dilation of the triangulation by a simple improvement heuristic. The heuristic is based on computing constrained Delaunay triangulations, greedily adding shortcut edges as constraints to reduce the length of the path currently defining the dilation. We then use the resulting dilation ρ as bound for the enumeration process outlined in the previous sections, enumerating only edges that could locally be in a triangulation with dilation strictly below ρ.

After the initial enumeration process is complete, we are left with a set of *possible* edges and can safely ignore all other edges. We postprocess these as follows. For each possible edge pq, we compute the set of possible edges intersecting it. We need this information later on to model the problem of finding a triangulation on the set of possible edges. For each pair st, ℓr of intersecting edges, we explicitly check whether either pair is an exclusion certificate for the other. In many cases, this postprocessing gets us very close to the edge set that would be obtained by the trivial $\Theta(n^4)$ edge candidate enumeration algorithm; see the experiment section for details. We mark each edge that does not have intersecting possible edges as *certain*; certain edges must be part of any triangulation with dilation less than ρ.

3.7 Dilation thresholds

We also compute a *dilation threshold* $\vartheta(st)$ for each possible edge st. Let $I(st)$ be the set of possible edges intersecting st. For each $\ell r \in I(st)$, we can compute a lower bound on the dilation of the shortest path connecting ℓ to r, should st be present, as

$$\rho_{st}(\ell r) = \min\{d(\ell, s) + d(s, r), d(\ell, t) + d(t, r)\}/d(\ell, r);$$

see Figure 4. The dilation threshold of st is then $\vartheta(st) = \max_{\ell r \in I(st)} \rho_{st}(\ell r)$.

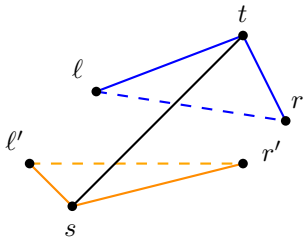

Figure 4 If st (black) is present, the pairs ℓ, r (resp. ℓ', r') can only be connected by paths that have at least the length of the solid blue (resp. orange) path. Hence, the ratio between the solid and dashed blue (resp. orange) paths is a lower bound on the dilation of any triangulation containing st. The maximum of such lower bounds for st is the dilation threshold $\vartheta(st)$ of st.

▶ **Observation 4.** *If an edge st has dilation threshold $\vartheta(st)$, it is not in any triangulation with dilation $\rho < \vartheta(st)$.*

This allows us to quickly exclude further edges if we lower the dilation bound ρ we aim for, without reenumerating edges or recomputing intersections.

3.8 Lower bounds

We use the dilation thresholds to bound the minimum dilation. For each edge st, either st or some edge crossing it must be in any triangulation. Thus, the minimum of all dilation thresholds among $\{st\} \cup I(st)$ is a lower bound on the minimum dilation. Combining all edges, we obtain the following lower bound:

$$\rho(T) \geq \max_{st} \min\{\vartheta(pq) \mid pq \in \{st\} \cup I(st)\}.$$

We use interval arithmetic to compute a safe lower bound on this value in $O(1)$ time per intersection between two edges resulting from our enumeration.

Furthermore, by computing the points on the convex hull, we also know the number of edges g of any triangulation. This also gives us a lower bound on the minimum dilation by considering the g lowest dilation thresholds. We also use Kruskal's algorithm to compute the lowest dilation threshold that admits a connected graph.

4 Exact algorithms

Now we present two exact algorithms: IncMDT is an incremental method that uses a SAT solver for iterative improvement, until it can prove that no better solution exists. BinMDT is based on a binary search for the optimal dilation ρ; once the lower and upper bound are reasonably close, the approach falls back to IncMDT to reach a provably optimal solution.

4.1 Triangulation supergraph

Both algorithms rely on the MDT supergraph mentioned in Section 3. As part of this computation, we also obtain an initial triangulation and its dilation, as well the intersecting possible edges $I(st)$ for each possible edge st. In both algorithms, we may gradually discover triangulations with lower dilation; these are used to exclude additional edges using the precomputed dilation thresholds $\vartheta(e)$. To keep track of the status of each edge, we insert all points and possible edges into a graph data structure we call *triangulation supergraph*. In

this structure, we mark each edge as *possible*, *impossible* or *certain*. Initially, all enumerated edges are *possible*. If, at any point, all edges intersecting an edge e become *impossible*, e becomes *certain*. If an *impossible* edge becomes *certain* or vice versa, the graph does not contain a triangulation any longer. If this happens, we say we encounter an *edge conflict*.

4.2 SAT formulation

Given a triangulation supergraph $G = (P, E)$, we model the problem of finding a triangulation on *possible* and *certain* edges using the following simple SAT formulation. Let $E_p \subseteq E$ be the set of non-*impossible* edges when the SAT formulation is constructed. For each edge $e \in E_p$, we have a variable x_e. We use the following clauses in our formulation.

$$\neg x_{e_1} \vee \neg x_{e_2} \qquad \forall e_1, e_2 \in E_p : e_2 \in I(e_1) \tag{1}$$

$$x_e \vee \bigvee_{e_j \in I(e)} x_{e_j} \qquad \forall e \in E_p \tag{2}$$

Clauses (1) ensure crossing-freeness and clauses (2) ensure maximality. When an edge e becomes certain, we add the clause x_e; similarly, when an edge becomes impossible, we add the clause $\neg x_e$. Both algorithms are based on this simple formulation; in the following, we describe how they use and modify it to find an MDT.

4.3 Clause generation

The following subproblem, which we call *dilation path separation*, arises in both our algorithms: Given a dilation bound ρ, a triangulation supergraph $G = (P, E)$ excluding only edges that cannot be in any triangulation with dilation less than ρ, a current triangulation T and a pair of points $s, t \in P$ such that $|\pi_T(s, t)| \geq \rho \cdot d(s, t)$, find a clause C that is (a) violated by T and (b) satisfied by any triangulation T' with $\rho(T') < \rho$.

▶ **Lemma 5.** *Assuming a polynomial-time oracle for comparing sums of square roots, there is a polynomial-time algorithm that solves the dilation path separation problem.*

Proof. Let Π be the set of all s-t-paths π in G with $|\pi| < \rho \cdot d(s, t)$. We begin by observing that, along every path $\pi \in \Pi$, there is an edge $e \in E$ that is not in T; otherwise, we get a contradiction to $|\pi_T(s, t)| \geq \rho \cdot d(s, t)$. Let $E' \subseteq E \setminus T$ be a set of edges such that for each $\pi \in \Pi$, there is an edge $e \in E'$ on π. Then, $C = \bigvee_{e \in E'} x_e$ is a clause that satisfies the requirements; note that if Π is empty, the empty clause can be returned.

T contains no edge from E', so C is violated by T. Furthermore, if a triangulation T' with $\rho(T') < \rho$ does not contain any of the edges in E', it contains none of the paths in Π. Therefore, $\pi_{T'}(s, t)$ uses an edge that is not in E, which has been excluded from all triangulations with dilation less than ρ; a contradiction. E' can be computed by repeatedly computing shortest s-t-paths π; as long as $\pi < \rho d(s, t)$, we find an edge $e \notin T$ on π, add e to E' and forbid it in future paths. The number of edges bounds the number of iterations of this process; using the comparison oracle, we can efficiently perform each iteration. ◀

For a description of how we compute E' in practice, see the full version.

4.4 Incremental algorithm

Based on the SAT formulation and the algorithm for the dilation path separation problem, IncMDT is simple. Given an initial triangulation T with dilation ρ, we enumerate the set of candidate edges and construct a triangulation supergraph G with bound ρ. We construct the

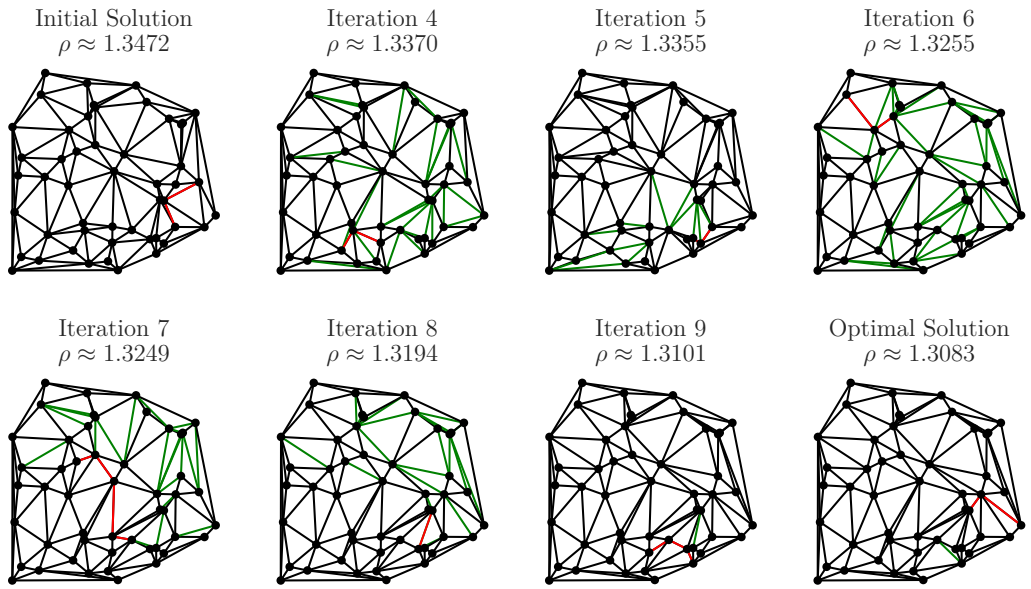

Figure 5 Progress of the incremental algorithm on an instance with $n = 50$ points. Green edges indicate changes in the triangulation, red edges indicate a dilation-defining path.

initial SAT formula M and solve it; if it is unsatisfiable, the initial triangulation is optimal. Otherwise, we repeat the following until the model becomes unsatisfiable or we encounter an edge conflict, keeping track of the best triangulation found, see Figure 5.

We extract the new triangulation T' from the SAT solver and compute the dilation ρ' and a pair s, t of points realizing ρ'. If ρ' is better than the best previously found dilation ρ, we update ρ and mark all edges e with $\vartheta(e) \geq \rho'$ as *impossible*. We then set $T = T'$ and solve the dilation path separation problem for ρ, G, T, s and t. We add the resulting clause to M and let the SAT solver find a new solution.

4.5 Binary search

Preliminary experiments with IncMDT showed that we spend almost all runtime for computing dilations, even for instances for which we could rely exclusively on interval arithmetic, requiring no exact computations. For many instances, most iterations of IncMDT resulted in tiny improvements of the dilation. To reduce the number of iterations (and thus, dilations computed), we considered the binary search-based algorithm BinMDT.

4.5.1 High-level idea

At any point in time, aside from the dilation ρ_{ub} of the best known triangulation, BinMDT maintains a lower bound ρ_{lb} on the dilation, initialized as described in Section 3.

As long as $\rho_{\text{ub}} - \rho_{\text{lb}} \geq \sigma$ for a small threshold value σ, BinMDT performs a binary search. It computes a new dilation bound $\rho = \frac{1}{2}(\rho_{\text{lb}} + \rho_{\text{ub}})$. It then uses the SAT model in a similar way as IncMDT to determine whether a triangulation T with $\rho(T) < \rho$ exists. If it does, it updates $\rho_{\text{ub}} = \rho(T)$; otherwise, it updates $\rho_{\text{lb}} = \rho$.

Once $\rho_{\text{ub}} - \rho_{\text{lb}}$ falls below σ, BinMDT falls back to a slightly modified version of IncMDT to find the MDT, starting from the best known triangulation with dilation ρ_{ub}.

In the following, we describe and motivate the differences between how IncMDT and BinMDT use the SAT formulation; for more details, see the full version.

4.5.2 Dilation sampling

To further reduce the time spent on computing dilations, observe the following. When a node v of some graph G is expanded in Dijkstra's algorithm from source s, we know the shortest path from s to v and thus the dilation $\rho_G(s, v)$. Because $\rho_G(s, v) \leq \rho(G)$, we can compute a lower bound on the dilation much faster than the precise value by only performing a constant number of node expansions from each point $p \in P$. We call this *sampling* of the dilation. Given a bound ρ on the dilation, we can sample a triangulation T for violations, i.e., pairs s, t of points with $\rho_T(s, t) \geq \rho$. We observed that a dilation-defining path usually consisted of few edges; thus, we have a good chance of finding it by sampling.

If it is likely that a new-found triangulation T' violates a given bound ρ, we can thus expect to save time by sampling for violations instead of computing the dilation exactly. Sampling also allows us to use multiple violations to construct multiple clauses in each iteration, potentially further reducing the number of iterations. BinMDT uses sampling after each SAT call with a small constant limit on the number of violations. If violations are found, no full dilation computation is required and violations are used to construct clauses. Only if no violations are found, we compute the exact dilation; ideally, this only happens once for each upper bound reduction in the binary search, namely once we find a triangulation satisfying the current bound. We also sample in the final improvement phase of BinMDT. For an experimental overview on the number of times sampling was sufficient in comparison to the number of times the dilation had to be computed exactly, see the full version.

5 Empirical evaluation

Now we present experiments to evaluate our algorithms. We used Python 3.12, with a core module written in C++20 for all computationally heavy tasks; the code was compiled with GCC 13.2.0 in release mode. We use CGAL 5.6.1 for geometric primitives and exact number types, Boost 1.83 for utility functions and pybind11 2.12 for Python bindings and use the incremental SAT solver CaDiCaL 1.9.5 via the PySAT interface for solving the SAT models. All experiments were performed on Linux workstations equipped with AMD Ryzen 9 7900 CPUs with 12 cores/24 threads and 96 GiB of DDR5-5600 RAM running Ubuntu 24.04.1.

5.1 Research questions

Our experimental evaluation aims to answer the following questions.

Q1 How does the edge enumeration algorithm from Section 3 compare to the brute force enumeration in terms of runtime and the number of edges eliminated? Can we solely rely on this algorithm or should we reconsider using the brute force enumeration?

Q2 What is the quality of the initial solutions computed by the Delaunay triangulation and the constrained Delaunay triangulations from Section 3 compared to the optimal solution?

Q3 How do our approaches compare to existing algorithms for the MDT w.r.t. runtime and solution quality? Can we solve instances with thousands of points to provable optimality?

Q4 How do BinMDT and IncMDT compare? Which should be used for large instances?

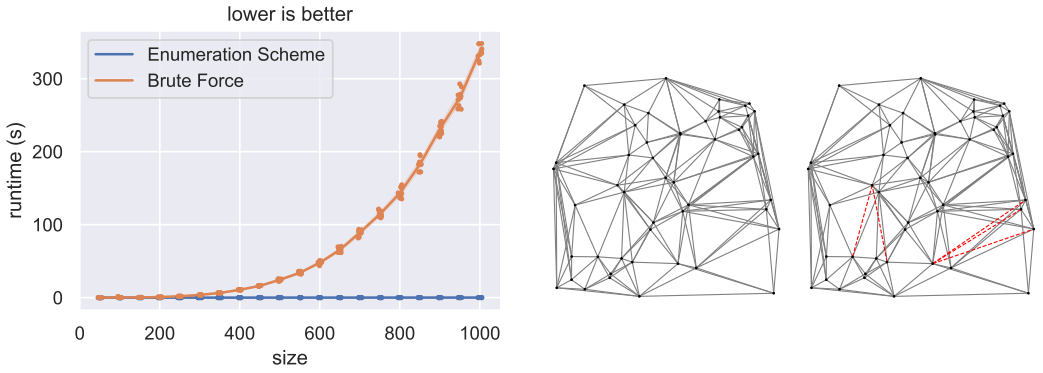

Figure 6 Comparison of our approach from Section 3 and the $\Theta(n^4)$ brute force elimination on the *random* instance set. **(Left)** The $\Theta(n^4)$ elimination is infeasible for larger instances. **(Right)** In all cases, only a small number of (red) edges were not eliminated by our approach.

5.2 Experiment design

To answer our questions, we collected and generated a large set of instances, consisting of instances from the following instance classes. In all cases, the coordinates of points in the instances are either integers or double precision floating-point numbers.

random-small We include instances from the work of [8]. The 210 instances have fixed sizes $n \in \{10, 20, \ldots, 70\}$ and were generated by placing uniformly random points inside a 10×10 square. For each size a total of 30 instances were generated.

random We include two sets of randomly generated instances. These encompass a set of instances with points with float coordinates chosen uniformly between 0 and 10^3, ranging from 50 to 10,000 points. This resulted in a total of 800 instances.

public We include instances from all well-known publicly available benchmark instance sets we could locate. These include point sets previously used in the CG:SHOP challenges [17, 16], TSPLIB instances [40], instances from a VLSI dataset[1] and point sets from the Salzburg Database of Polygonal Inputs [22]. In total, we collected 486 instances with up to 10,000 points and an additional 38 with up to 30,000 points.

5.3 Q1: Edge enumeration

We first compare the edge enumeration algorithm from Section 3 to the $\Theta(n^4)$ brute force enumeration of all possible edges on the *random* instance set. Both preprocessing options include finding all pairwise intersections between the enumerated segments. Due to the $\Theta(n^4)$ runtime, we only consider instances with up to 1000 points; see Figure 6.

The $\Theta(n^4)$ algorithm precisely identifies all edges that have the ellipse property; it can hence only eliminate more edges than the edge enumeration algorithm from Section 3. However, for our test instances, the number of edges that can be eliminated by our approach is almost identical to the $\Theta(n^4)$ algorithm; see Figure 6 for an example. The runtime makes the $\Theta(n^4)$ algorithm infeasible for larger instances; it takes more than 250 s for instances with only 1000 points, compared to < 1 s for our more efficient approach.

[1] `https://www.math.uwaterloo.ca/tsp/vlsi/index.html`

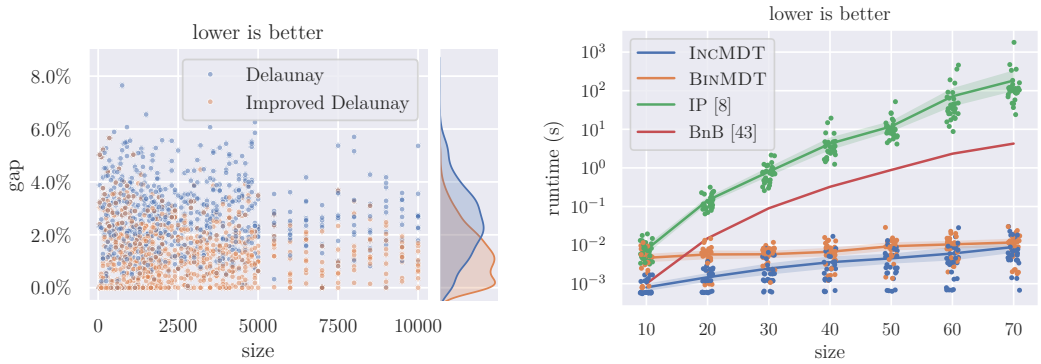

Figure 7 (Left) Initial solution comparison on the *random* set with up to 10,000 points. Delaunay triangulations can be improved by shortcut edges, but are often close to the optimal solution. **(Right)** Runtime comparison with the approaches from [8] and [41] on the *random-small* set.

5.4 Q2: Initial solutions

Better initial solutions can reduce the number of candidate edges further than bad ones and thus affect the runtime of the overall algorithm. Delaunay triangulations are a natural choice for the initial solution, but we suspect that they can be improved by adding shortcut edges. Figure 7 shows that the relative dilation gap between the Delaunay triangulation and the optimal solution for the *random* instance set. It can be seen that the introduction of shortcut edges can indeed reduce the gap to the MDT to around 1.5 %.

5.5 Q3: Comparison to state-of-the-art

We compare our approaches to two exact state-of-the-art algorithms for the MDT. Note that both of these use floating-point arithmetic and are not guaranteed to find the optimal solution. However, we can confirm that all previous solutions are within a small relative error of our optimal solution. The first approach is an integer programming (IP) approach by [8] that used the commercial software CPLEX to solve the MDT. The second comparison is with the most recent exact algorithm (BnB) from Sattari and Izadi [41]. For both approaches the source code is no longer available, so we cannot compare our results on the same hardware. Also for BnB [41] the instance data and results are no longer available. For both approaches we therefore use the data the authors published in their papers. Note that the drastic runtime difference that we see in our experiments cannot be attributed to improved hardware alone.

For *random-small*, both IncMDT and BinMDT outperform the IP and BnB approach by a large margin (up to four orders of magnitude), see Figure 7. All instances were solvable in less than 0.1 s. Additionally, Sattari and Izadi [41] provided results for TSPLIB [40] instances (part of our *public* instance set) with up to 200 points. Our approach is significantly faster than theirs, solving each of these instances to provable optimality in less than 1 s instead of up to 1248 s; a table with all instances and runtimes can be found in the full version.

5.6 Q4: Algorithm comparison

We now compare IncMDT to BinMDT. Recall that BinMDT aims to reduce the time spent on dilation computations by reducing the number of dilation computations and merely sampling the dilation whenever that suffices. The first experiment was conducted on the

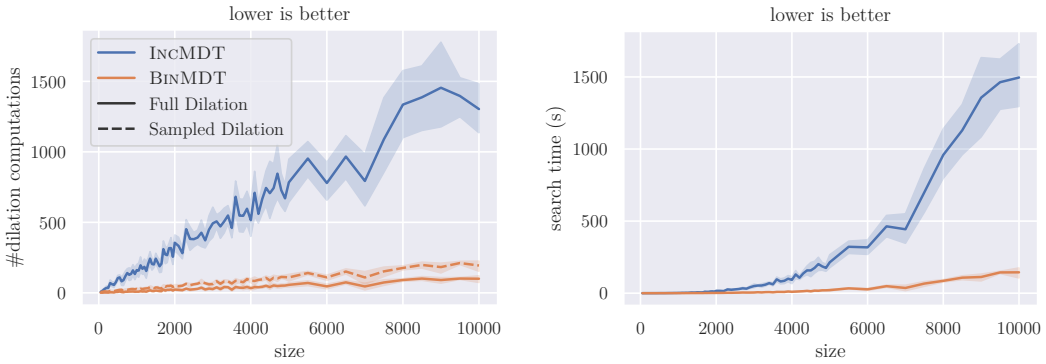

Figure 8 Experiments on the *random* benchmark set. **(Left)** The number of dilation computations of BinMDT is significantly reduced compared to the incremental algorithm. **(Right)** BinMDT is significantly faster than the incremental algorithm.

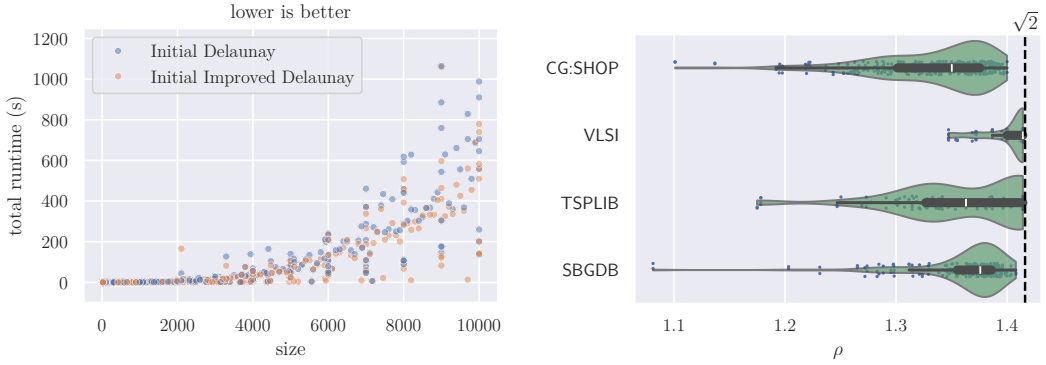

Figure 9 Experiments on the *public* benchmark set. **(Left)** Using the improved Delaunay triangulation as an initial solution significantly improved the performance. **(Right)** The dilation of the MDTs is at most $\sqrt{2}$ for all instances.

random instances with up to 10,000 points; this experiment confirms that BinMDT indeed achieves a significantly lower runtime, requires fewer dilation computations, and that sampling is sufficient in most cases, see Figure 8.

After we confirmed that BinMDT is superior, we conducted an additional experiment with two different initial solution strategies on the *public* instances up to 10,000 points, see Figure 9. The first strategy uses the Delaunay triangulation as an initial solution; the second strategy uses the improved Delaunay triangulation with shortcut edges. The improved Delaunay triangulation significantly reduces the runtime of BinMDT for almost all instances. Detailed results for all *public* instances, as well as an additional experiment on the *public* instance set showing that BinMDT can solve instances with up to 30,000 points in less than 17 h to provable optimality, can be found in the full version.

6 Improved bounds for regular n-gons

Vertex sets of regular n-gons are particularly challenging, as there are no points in the interior to serve as Steiner points for shortcuts, making local heuristics less successful. They are also natural candidates for worst-case dilation, as each diagonal constitutes an obstacle for the

separated points. Thus, they have received considerable attention [35, 20, 43], with a lower bound of 1.4308 (see [20]) and an upper bound of 1.4482 (see [43]) on their worst-case dilation. Improving this gap is an open question posed by [20, Problem 1], originating from [7, 30]. With the help of our exact algorithm (see the full version), we were able to compute bounds for $n \in \{4, 5, \ldots, 100\}$, answering the problem by Dumitrescu and Ghosh.

Our implementation currently uses floating-point precision to represent the coordinates of the input points. Thus, we cannot exactly represent the necessarily irrational points of any regular n-gon ($n \geq 5$) in our solver. However, we can compute the MDT of a rational point set that is a good approximation of a regular n-gon. We can then bound the error and thus obtain a rigorous lower bound on the dilation of the regular n-gon.

▶ **Theorem 6.** *Let P be a set of $n = 84$ points placed at the vertices of a regular n-gon. Then the dilation of the MDT of P is $\rho \geq 1.44116645381$.*

Proof. Let P be the point set of a regular 84-gon and Q be a point set that contains floating-point approximations of the points of P. There is a bijection $f : P \to Q$ with inverse f^{-1} that maps each point in P to the closest point in Q. For a given triangulation or path of P, we write $f(\cdot)$ to denote the triangulation or path where the points are transformed by pointwise application of f. Neither P nor Q contain collinear points and all points are in convex position, therefore T is a triangulation of P iff $f(T)$ is a triangulation of Q.

Let $\epsilon \geq \max_{p_i,p_j \in P} |d(p_i, p_j) - d(f(p_i), f(p_j))|$ be a bound on the maximum absolute error on distances and let δ be a chosen such that

$$\forall p_i, p_j \in P : (1-\delta)d(p_i, p_j) \leq d(f(p_i), f(p_j)) \leq (1+\delta)d(p_i, p_j).$$

Let T be the MDT of P with dilation ρ. Let $f(p_i), f(p_j)$ be a dilation-defining pair in $f(T)$ with path $\pi \subset Q$. Because T has dilation ρ, we have (i) $|f^{-1}(\pi)|/d(p_i,p_j) \leq \rho$. As π has at most $n-1$ edges, we have (ii) $|\pi| - (n-1)\epsilon \leq |f^{-1}(\pi)| \leq |\pi| + (n-1)\epsilon$ and thus the following upper bound on the MDT of Q.

$$\begin{aligned}\frac{|\pi|}{d(f(p_i), f(p_j))} &= \frac{|\pi| - (n-1)\epsilon}{d(f(p_i), f(p_j))} + \frac{(n-1)\epsilon}{d(f(p_i), f(p_j))} \overset{(ii)}{\leq} \frac{|f^{-1}(\pi)|}{(1-\delta)d(p_i,p_j)} + \frac{((n-1)\epsilon)}{d(f(p_i), f(p_j))} \\ &\overset{(i)}{\leq} \frac{1}{1-\delta}\rho + \frac{(n-1)\epsilon}{d(f(p_i), f(p_j))} \leq \frac{1}{1-\delta}\rho + \frac{(n-1)\epsilon}{\min_{q_i,q_j \in Q} d(q_i, q_j)}.\end{aligned}$$

Using exact calculations done with *sympy*, we computed $\epsilon \leq 2.730751 \cdot 10^{-16}$ and $\delta \leq 6.458762 \cdot 10^{-16}$, which, combined with the lower bound on the dilation of Q from our solver gives us $\rho \geq 1.44116645381$. ◀

7 Conclusion

We have presented exact algorithms for minimum dilation triangulations, greatly outperforming previous methods from the literature. This has also yielded insights into the intricate structure of optimal solutions for regular n-gons, together with new lower bounds on the worst-case dilation of triangulations. This demonstrates the value of computational tools for gaining analytic insights that seem out of reach with purely manual analysis.

On the theoretical side, one tantalizing open question remains the complexity of the MDT; here the intricate structure of solutions for regular n-gons may show the way for hardness constructions even for convex arrangements. An equally fascinating problem is the worst-case dilation of triangulations; here we conjecture that the asymptotic dilation for regular n-gons corresponds to the worst-case dilation for general point sets, implying a value between 1.44116 and 1.4482, with a better lower bound achievable via even larger n-gons.

On the practical side, the runtime of our algorithms is dominated by repeatedly computing the dilation of a triangulation. With sums of square roots handled as described, this does not appear to be a difficult problem per se, so appropriately tailored algorithms or data structures for carrying out huge numbers of dilation queries would be extremely helpful.

On Sparse Covers of Minor Free Graphs, Low Dimensional Metric Embeddings, and Other Applications

Arnold Filtser
Department of Computer Science, Bar-Ilan University, Ramat-Gan, Israel

Abstract

Given a metric space (X, d_X), a (β, s, Δ)-sparse cover is a collection of clusters $\mathcal{C} \subseteq P(X)$ with diameter at most Δ, such that for every point $x \in X$, the ball $B_X(x, \frac{\Delta}{\beta})$ is fully contained in some cluster $C \in \mathcal{C}$, and x belongs to at most s clusters in $\mathcal{C}$. Our main contribution is to show that the shortest path metric of every K_r-minor free graphs admits $(O(r), O(r^2), \Delta)$-sparse cover, and for every $\epsilon > 0$, $(4+\epsilon, O(\frac{1}{\epsilon})^r, \Delta)$-sparse cover (for arbitrary $\Delta > 0$). We then use this sparse cover to show that every K_r-minor free graph embeds into $\ell_\infty^{\tilde{O}(\frac{1}{\epsilon})^{r+1} \cdot \log n}$ with distortion $3+\epsilon$ (resp. into $\ell_\infty^{\tilde{O}(r^2) \cdot \log n}$ with distortion $O(r)$). Further, among other applications, this sparse cover immediately implies an algorithm for the oblivious buy-at-bulk problem in fixed minor free graphs with the tight approximation factor $O(\log n)$ (previously nothing beyond general graphs was known).

1 Introduction

Given a metric space (X, d_X) a (β, s, Δ)-sparse cover is a collection of clusters $\mathcal{C} \subseteq P(X)$ all with diameter at most Δ, such that every point belongs to at most s clusters, and every ball $B_X(x, \frac{\Delta}{\beta})$ is fully contained in some cluster $C \in \mathcal{C}$. Sparse covers are very useful for algorithmic design, and in particular for divide and concur. Since their introduction by Awerbuch and Peleg [14], sparse covers found numerous applications. A partial list of which includes: compact routing schemes [81, 80, 86, 8, 7, 3, 23], distant-dependent distributed directories [15, 79, 80, 23], network synchronizers [11, 12, 73, 80, 23], distributed deadlock prevention [13], construction of spanners and ultrametric covers [55, 50, 70, 56, 48, 44], metric embeddings [82, 67], universal TSP and Stiner tree constructions [61, 22, 41, 24], and Oblivious buy-at-bulk [84].

We will study sparse covers in weighted graphs, where we distinguish between two different types of diameter. The *weak* diameter of a cluster $A \subseteq V$ in a weighted graph $G = (V, E, w)$ is the maximum pairwise distance $\max_{u,v \in A} d_G(u, v)$ w.r.t. the original shortest path distance, while the *strong* diameter is the maximum pairwise distance $\max_{u,v \in A} d_{G[A]}(u, v)$ in the induced subgraph. We continue with a formal definition:

▶ **Definition 1** (Sparse Cover). *Given a weighted graph $G = (V, E, w)$, a collection of clusters $\mathcal{C} = \{C_1, ..., C_t\}$ is called a weak/strong (β, s, Δ) sparse cover if the following conditions hold.*
1. *Bounded diameter: The weak/strong diameter of every cluster $C_i \in \mathcal{C}$ is bounded by Δ.*

© Arnold Filtser;
licensed under Creative Commons License CC-BY 4.0

2. *Padding: For each $v \in V$, there exists a cluster $C_i \in \mathcal{C}$ such that $B_G(v, \frac{\Delta}{\beta}) \subseteq C_i$.*
3. *Sparsity: For each $v \in V$, there are at most s clusters in $\mathcal{C}$ containing v.*
If the clusters $\mathcal{C}$ can be partitioned into s partitions $\mathcal{P}_1, \ldots, \mathcal{P}_s$ s.t. $\mathcal{C} = \cup_{i=1}^{s} \mathcal{P}_i$, then $\{\mathcal{P}_1, \ldots, \mathcal{P}_s\}$ is called a weak/strong (β, s, Δ) sparse partition cover. We say that a graph G admits a weak/strong (β, s) sparse (partition) cover scheme, if for every parameter $\Delta > 0$ it admits a weak/strong (β, s, Δ) sparse (partition) cover that can be constructed in expected polynomial time. Sparse partition cover scheme is abbreviated SPCS .

The notion of sparse cover scheme is the more common in the literature. However, SPCS provides additional structure that is crucial for different applications. [1] Obtaining strong diameter guarantee is also considerably more challenging, however it is frequently required in "subgraph based" applications. [2]

Sparse covers were introduced by Awerbuch and Peleg [14] who showed that for every $k \in \mathbb{N}$, every n vertex graph admits a strong $(4k-2, 2k \cdot n^{\frac{1}{k}})$-SPCS . Klein, Plotkin, and Rao [65] constructed a celebrated weak padded decomposition [3] for K_r-minor free graphs with padding parameter $O(r^3)$ (later improved to $O(r^2)$ [36]). It is folklore that padded decomposition with padding parameter ρ implies a $(\rho, O(\log n))$-SPCS (by taking the union of $O(\log n)$ independent partitions). Thus [65, 36] implied a weak $(O(r^2), O(\log n))$-SPCS for K_r-minor free graphs. Krauthgamer et al. [67] observed that one can use [65, 36] padded decomposition to construct a weak $(O(r^2), 2^r)$-SPCS for K_r-minor free graphs (see [41] for an explicit proof). This was the first sparse cover where all the parameters are independent from the cardinality of the vertex set n. Busch et al. [23] used shortest path separators to obtain a strong $(8, f(r) \cdot \log n)$-SPCS . [4] Abraham et al. [3] constructed a strong sparse cover. Specifically, they made some adaptations to [65] to obtain a strong $(O(r^2), 2^{O(r)} \cdot r!)$-sparse cover scheme (not a SPCS). The final major piece in our story is a weak padded decomposition for K_r-minor free graphs with padding parameter $O(r)$ by Abraham et al. [6]. Which was later improved to strong padded decomposition with the same parameter by Filtser [38]. In particular, this implies a strong $(O(r), O(\log n))$-sparse cover scheme. Interestingly, it was unknown how to turn this padded decomposition into a sparse cover with sparsity independent of n. Indeed, Filtser explicitly asked whether it is possible to construct $(O(r), g(r))$-sparse cover scheme [38] . The main result of this paper is an affirmative answer to this question. A decade after the publication of [2] we finally managed to turn this padded decomposition into a sparse cover.

▶ **Theorem 2** (Cover for Minor Free Graphs). *Every K_r-minor free graph admits the following:*
- *Strong $\big(O(r), O(r^2)\big)$-SPCS .*
- *For $\epsilon \in (0, \frac{1}{2})$, strong $\big(4+\epsilon, O(\frac{1}{\epsilon})^r\big)$-SPCS .*

The first bullet in Theorem 2 improves over the previous SPCS state of the art [36, 67, 41] in a threefold manner: (1) the padding is improved quadratically from $O(r^2)$ to $O(r)$, (2)

---

[1] In this paper we require the partition property of SPCS for metric embeddings into ℓ_∞, and for the oblivious buy-at-bulk. This property is also crucial in the construction of ultrametric covers [48, 42, 44].
[2] In this paper we use the strong diameter guarantee for routing, buy-at-bulk, and path reporting distance oracle.
[3] Roughly, padded decomposition with padding parameter ρ is a random partition into clusters of diameter at most Δ such that every ball of radius $\frac{\Delta}{\rho}$ is fully contained in a single cluster with probability at least $\frac{1}{2}$. See [38].
[4] $f(r)$ is the enormous constant hiding in the Robertson Seymour [83] structure theorem. Johnson [62] estimated $f(r) \geq 2 \Uparrow (2 \Uparrow (2 \Uparrow \frac{r}{2})) + 3)$ where $2 \Uparrow t$ is the exponential tower function ($2 \Uparrow 0 = 1$ and $2 \Uparrow t = 2^{2 \Uparrow (t-1)}$) .

Table 1 Summary of new and previous work on sparse covers.

Family	Padding	Sparsity	SPCS ?	Diameter	Ref
General	$4k-2$	$2k \cdot n^{\frac{1}{k}}$	yes	strong	[14]
Planar	32	18	yes (implicit)	strong	[23]
K_r-minor free	$O(r^3)$	$O(\log n)$	yes	weak	[65]
	$O(r^2)$	$O(\log n)$	yes	weak	[36]
	$O(r)$	$O(\log n)$	yes	weak	[6]
	$O(r)$	$O(\log n)$	yes	strong	[38]
	8	$f(r) \cdot \log n$ (4)	yes (implicit)	strong	[23]
	$O(r^2)$	2^r	yes	weak	[36, 67]
	$O(r^2)$	$2^{O(r)} \cdot r!$	no	strong	[3]
	$O(r)$	$O(r^2)$	yes	strong	Theorem 2
	$4+\epsilon$	$O(\frac{1}{\epsilon})^r$	yes	strong	

the sparsity is improved exponentially from 2^r to $O(r^2)$, (3) the diameter guarantee is now strong. Alternately, the second bullet improves the padding parameter from $O(r^2)$ to $O(1)$ while keeping a similar sparsity. See Table 1 for a comparison of ours and previous work.

1.1 Low dimensional metric embeddings into ℓ_∞

Metric embedding is a map between two metric spaces that approximately preserves pairwise distances. Given a (finite) metric space (X, d_X), a map $\phi : V \to \mathbb{R}^k$, and a norm $\|\cdot\|$, the *contraction* and *expansion* of the map ϕ are the smallest $\xi, \rho \geq 1$, respectively, such that for every pair $x, y \in X$,

$$\frac{1}{\xi} \cdot d(x,y) \leq \|\phi(x) - \phi(y)\| \leq \rho \cdot d(x,y) \quad .$$

The *distortion* of the map is then $\xi \cdot \rho$. The expansion ρ is also called the Lipschitz constant of the embedding ϕ. Metric embeddings into norm spaces were thoroughly studied [21, 72, 74, 4], and have a plethora of applications.

There is a special interest for metric embeddings into ℓ_∞. From an algorithmic viewpoint, there is a significant advantage in the additional structure the norm space is providing. One example being nearest neighbor search (NNS) [58, 19], where ℓ_∞ enjoys succinct data structures. NNS for many other spaces works by first embedding the space into ℓ_∞, and then using the ℓ_∞ NNS data structure to answer queries in the original metric space (see e.g. [37, 59]). From a geometric view point, ℓ_∞ is a special norm as it is a universal host metric space. That is, every finite metric spaces embeds isometrically (that is with distortion 1) into ℓ_∞ (the so called Fréchet embedding). However, there are n-point metric spaces of which every isometric embedding into ℓ_∞ requires $\Omega(n)$ dimensions [72]. It is desirable to have low dimensional metric embeddings, as these are much more useful for algorithmic design. Matoušek [74] showed that for every integer $t \geq 2$, every metric space embeds with distortion $2t-1$ into ℓ_∞ of dimension $O(n^{1/t} \cdot t \cdot \log n)$ (which is almost tight assuming the Erdős girth conjecture [34]). For distortion $O(\log n)$, Abraham et al. [4] later improved the dimension to $O(\log n)$.

For more restrictive metric spaces better results are known. Linial et al. [72] showed that every n-point tree metric embeds isometrically into $\ell_\infty^{O(\log n)}$, while Neiman [75] showed that every metric space with doubling dimension d embeds into $\ell_\infty^{\epsilon^{-O(d)} \cdot \log n}$ with distortion $1+\epsilon$. Krauthgamer et al. [67] showed that every n-point K_r-minor free graph G embeds

Table 2 Summary of new and previous work on metric embeddings into ℓ_∞.

Family	Distortion	Dimension	Ref
General Metric	1	$n-1$	Fréchet
	$2k-1$	$O(k \cdot n^{1/k} \cdot \log n)$	[74]
	$O(\log n)$	$O(\log n)$	[4]
Tree	1	$\Theta(\log n)$	[72]
K_r-Minor Free	$O(r^2)$	$\tilde{O}(3^r) \cdot \log n$	[67]
	$O(r)$	$\tilde{O}(r^2) \cdot \log n$	Corollary 3
	$3+\epsilon$	$\tilde{O}(\frac{1}{\epsilon})^{r+1} \cdot \log n$	Theorem 4

into $\ell_\infty^{\tilde{O}(3^r \cdot \log n)}$ with distortion $O(r^2)$. Their embedding follows from a SPCS based on [65, 36]. However, their construction uses additional properties of that cover, and we cannot simply plug in our SPCS to get an improved embedding. We show that under very general conditions,[5] one can use SPCS in a black box manner to obtain a metric embedding into ℓ_∞ (see full version [43]). As a corollary, we improve both the distortion and dimension compared to [67]. We than slightly tailor the embedding for minor free graphs to push the distortion down all the way to $3+\epsilon$. See Table 2 for a comparison of new and old results.

▶ **Corollary 3.** *Every n vertex K_r-minor free graph embeds into $\ell_\infty^{O(r^2 \cdot \log r \cdot \log n)}$ with distortion $O(r)$.*

▶ **Theorem 4.** *For every $\epsilon \in (0, \frac{1}{2})$, every n vertex K_r-minor free graph G can be embedded into $\ell_\infty^{O(\frac{1}{\epsilon})^{r+1} \cdot \log \frac{1}{\epsilon} \cdot \log \frac{n}{\epsilon}}$ with distortion $3+\epsilon$.*

1.2 Oblivious Buy-at-Bulk

Given a weighted graph $G = (V, E, w)$ and a *canonical fusion function* $f : \mathbb{N} \to \mathbb{R}_{\geq 0}$ (see full version [43] for a definition), in the oblivious buy-at-bulk problem, the goal is to pick a route P_i for every possible demand pair $\delta_i = (s_i, t_i) \in \binom{V}{2}$. Then, given a specific set of demands $A = \{\delta_1, \ldots, \delta_k\}$, the cost of our oblivious solution $\mathcal{P} = \{P_1, \ldots, P_k\}$ is $\text{cost}(\mathcal{P}) = \sum_{e \in E} f(\varphi_e) \cdot w(e)$, where φ_e is the number of paths in $\mathcal{P}$ using e. The solution is said to have approximation ratio ρ if for every subset of demands, the induced cost of the oblivious solution is at most ρ times the optimal solution. Due to the concavity of the canonical fusion function f, it is advantageous for the chosen paths to intersect as much as possible. The best known approximation for general graphs is $O(\log^2 n)$ [53], while for planar graphs $O(\log n)$ approximation is known [84], which is tight [57]. Srinivasagopalan et al. [84] left it as an explicit open problem to "obtain efficient solutions to other related network topologies, such as minor-free graphs." More than a decade later, compared with general graphs, nothing better for K_r-minor free graphs is known. Using our sparse covers on top of a black box reduction from [84], we obtain the following tight result ([57]):

▶ **Corollary 5.** *For every n-vertex weighted K_r-minor free graph $G = (V, E, w)$ admits an efficiently commutable solution to the oblivious buy-at-bulk problem with approximation ratio $O(r^6 \cdot \log n)$. Furthermore, the solution is also oblivious to the concave faction f.*

[5] In fact the reduction hold in general with no condition, while the dimension slightly increases. See full version [43].

1.3 Further Applications

Sparse partition and universal TSP / Steiner tree

Given a weighted graph $G = (V, E, w)$, a (α, τ, Δ)-sparse partition is a partition $\mathcal{C}$ of V into clusters with weak diameter at most Δ, such that every ball of radius $\frac{\Delta}{\alpha}$ intersects at most τ clusters from $\mathcal{C}$. G admits a (α, τ)-sparse partition scheme if it admits (α, τ, Δ)-sparse partition for every $\Delta > 0$. Using our Theorem 2, we construct $\big(O(r), O(r^2)\big)$-sparse partition scheme for K_r minor free graphs, improving over the previous state of the art of $\big(O(r^2), 2^r\big)$-sparse partition scheme [61, 41]. For further details, see full version [43].

In the universal TSP problem, we are given a metric space (X, d_X) and the goal is to choose a single permutation π (a universal TSP) of X, such that given a subset $S \subseteq X$, we visit the points in S w.r.t. the order in π. This is the induced TSP tour by π. The permutation π has stretch ρ, if the length of the induced tour for every subset S is at most ρ times larger than the optimal tour for S. There is a general reduction from sparse partition scheme to universal TSP. Using this reduction and our sparse partitions, given a shortest path metric of an n point K_r minor free graph, we construct universal TSP with stretch $O(r^4) \cdot \log n$, exponentially improving the dependence on r compared with previous results $(O(1)^r \cdot \log n)$. The same phenomena occurs also for the universal Steiner tree problem. See full version [43] for further details.

Name Independent Routing

Here we are given an unweighted graph $G = (V, E)$ where the names (and ports) of all nodes are fixed. The goal is to design a compact routing scheme that will allow sending packages in the network, where routing decisions are made using small local routing tables, and the resulting routing paths are approximate shortest paths. This regime is considered more challenging and practical from the regime where nodes names and ports could be chosen by the routing scheme designer. Given a hereditary graph family that has α-orientation (see full version [43] for a definition), where each graph possess strong (τ, β)-sparse cover scheme, Abraham et al. [3] constructed name independent compact routing scheme with stretch $O(\beta)$, $O(\log n + \log \tau)$-bit headers and tables of $O(\frac{\log^3 n}{\log \log n} + \alpha \cdot \log n) \cdot \tau \cdot \log D$ bits. We use our strong sparse covers (Theorem 2) to construct name independent compact routing scheme significantly improving over previous work. See full version [43] for a comparison.

Path reporting distance oracle

A path reporting distance oracle (PRDO) for a weighted graph $G = (V, E, w)$ is a succinct data structure that given a query $\{x, y\}$, efficiently returns an approximate x-y shortest path P. We say that a PRDO has stretch k and query time t, if for every query (x, y), the oracle returns a path P of weight at most $k \cdot d_G(x, y)$ in $O(|P|) + t$ time. PRDO were first studied for general graphs. Later, Elkin et al. [33] constructed a PRDO for K_r-minor free graphs based on strong sparse covers. We plug in our strong sparse cover from Theorem 2 to obtain improvements in both space and stretch, see full version [43] for details.

1.4 Related Work

We provided background on sparse covers in the introduction. We refer to the cited papers for additional background on sparse partitions, UTSP, UST, routing and distance oracles. Here we provide additional background on metric embeddings in order to put our results (Corollary 3, Theorem 4) in a wider context. We begin with metric embeddings into ℓ_p spaces.

Every n point metric space embeds into $\ell_2^{O(\log n)}$ with distortion $O(\log n)$ [21], which is also tight [72]. Planar graphs, and more generally fixed minor free graphs, embed into $\ell_2^{O(\log n)}$ with distortion $O(\sqrt{\log n})$ [82, 5], which is also tight [76]. The big open question here is regarding the embedding of such graphs into ℓ_1. The upper bounds are the same as for ℓ_2, while the only lower bound is 2 [71]. A long standing conjecture by Gupta et al. [54] states that every graph family excluding a fixed minor, and in particular planar graphs, can be embedded into ℓ_1 with constant distortion. Some partial progress for planar graph was made in the cases where we care only about vertices laying on a small number of faces [68, 40], or only about vertex pairs laying on the same face [78, 69].

Refined notion of distortion in metric embeddings were studied, such as scaling distortion [4, 18], and terminal/prioritized distortion [30, 31]. In particular, there been study of prioritized low dimensional embeddings into ℓ_∞ [45, 32]. Online metric embeddings into normed spaces were also studied [60, 77, 20].

A different venue of research is metric embeddings into trees, or more generally low treewidth graphs. Every n-point metric space stochastically embeds into trees with expected distortion $O(\log n)$ [16, 35]. This result is tight even when the metric is the shortest path metric of a planar graph [9]. Every planar graph with diameter Δ can be (deterministically) embedded into a graph with treewidth $\tilde{O}(\epsilon^{-3})$ with additive distortion $\epsilon \cdot \Delta$ [51, 49, 25]. Every K_r-minor free graphs stochastically embeds into graphs with treewidth $f(r) \cdot O(\frac{\log\log n}{\epsilon})^2$ with expected additive distortion $\epsilon \cdot \Delta$ [28, 49]. Clan embeddings and Ramsey-type embeddings of K_r-minor free graphs were also studied [48]. Finally, recently it was shown that every K_r-minor free graphs stochastically embeds into graphs with treewidth $f(r) \cdot \tilde{O}(\frac{1}{\epsilon}) \cdot \mathrm{poly}(\log(n \cdot \Phi))$ with multiplicative expected distortion $1 + \epsilon$ [29] (here Φ is the aspect ratio).

2 Preliminaries

$\tilde{O}$ notation hides poly-logarithmic factors, that is $\tilde{O}(g) = O(g) \cdot \mathrm{polylog}(g)$. All logarithms are at base 2 (unless specified otherwise), ln stand for the natural logarithm. Given a set A, $\binom{A}{2} = \{\{x, y\} \mid x, y \in A, x \neq y\}$ denotes all the subsets of size 2. For a number $k \in \mathbb{N}$, $[k] = \{1, 2, \ldots, k\}$.

We consider connected undirected graphs $G = (V, E, w)$ with edge weights $w : E \to \mathbb{R}_{\geq 0}$. We say that vertices v, u are neighbors if $\{v, u\} \in E$. Let d_G denote the shortest path metric in G. $B_G(v, r) = \{u \in V \mid d_G(v, u) \leq r\}$ is the closed ball of radius r around v. For a vertex $v \in V$ and a subset $A \subseteq V$, let $d_G(x, A) := \min_{a \in A} d_G(x, a)$, where $d_G(x, \emptyset) = \infty$. For a subset of vertices $A \subseteq V$, $G[A]$ denotes the induced graph on A, and $G \setminus A := G[V \setminus A]$. The *diameter* of a graph G is $\mathrm{diam}(G) = \max_{v,u \in V} d_G(v, u)$, i.e. the maximal distance between a pair of vertices. Given a subset $A \subseteq V$, the *weak*-diameter of A is $\mathrm{diam}_G(A) = \max_{v,u \in A} d_G(v, u)$, i.e. the maximal distance between a pair of vertices in A, w.r.t. to d_G. The *strong*-diameter of A is $\mathrm{diam}(G[A])$, the diameter of the graph induced by A.

The *aspect ratio* of a metric space (X, d_X) is usually defined as the ratio between the maximum and minimum distances. However, here we mainly work with the shortest path distance in graphs, where we allow 0-weights. Formally, here the shortest path metric is actually a pseudometric. Accordingly, we will define aspect ratio of a graph $G = (V, E, w)$ as the ratio between the maximum distance to the minimum non zero distance: $\Phi(G) = \frac{\max_{u,v \in V} d_G(u,v)}{\min_{u,v \in V \text{ s.t. } d_G(u,v) > 0} d_G(u,v)}$.

A graph H is a *minor* of a graph G if we can obtain H from G by edge deletions/-contractions, and isolated vertex deletions. A graph family $\mathcal{G}$ is *H-minor-free* if no graph $G \in \mathcal{G}$ has H as a minor. Some examples of minor free graphs are planar graphs (K_5 and $K_{3,3}$ minor-free), outer-planar graphs (K_4 and $K_{3,2}$ minor-free), series-parallel graphs (K_4 minor-free) and trees (K_3 minor-free).

The ℓ_∞-norm of a vector $x = (x_1, \ldots, x_k) \in \mathbb{R}^k$ is $\|x\|_\infty := \max_{i\in[k]} |x_i|$. An embedding from a metric space (X, d_X) into ℓ_∞ is a function $f : X \to \mathbb{R}^k$. The embedding f has distortion $c \cdot t$ if for every $x, y \in X$, $\frac{1}{c} \cdot d_X(x, y) \leq \|f(x) - f(y)\|_\infty \leq t \cdot d_X(x, y)$. t is the *expansion* (also known as a *Lipschitz* constant) of f, while c is that *contraction* of f. An embedding with distortion 1 (where $c = t = 1$) is called *isometric*. Embedding $f : X \to \ell_\infty^k$ can be viewed as a collection of embeddings $\{f_i\}_{i=1}^k$ into the line $\mathbb{R}$, where $f_i(x)$ equals to the i'th coordinate of $f(x)$. We will also denote $(f(x))_i = f_i(x)$. Using this notation, f has expansion t if for every $x, y \in X$ and $i \in [k]$, $|f_i(x) - f_i(y)| \leq t \cdot d_X(x, y)$. Similarly, f has contraction c if for every $x, y \in X$ there is some $i \in [k]$ such that $|f_i(x) - f_i(y)| \geq \frac{1}{c} \cdot d_X(x, y)$. In this case, we will say that the pair x, y is *satisfied* by the coordinate i.

3 Technical Overview

Cop Decomposition

Abraham et al. [6] constructed a padded decomposition for K_r-minor free graphs based on the cops-and-robbers game [10]. Fix the scale parameter $\Delta > 0$. The process works as follows: pick arbitrary x_1, and let the ball $B_G(x_1, r_1)$ be the first cluster η_1, where $r_1 \in [0, \Delta]$ is sampled using truncated exponential distribution. To construct the second cluster, pick an arbitrary connected component C_2 of $G \setminus \eta_1$, and arbitrary $x_2 \in C_2$. Let T_2 be a shortest path from x_2 to some vertex y with a neighbor in η_1. Then the second cluster $\eta_2 = B_{G[C_2]}(T_2, r_2)$ is a ball around T_2 in the graph induced by the connected component, where the radius $r_2 \in [0, \Delta]$ is sampled using truncated exponential distribution. In general, suppose that we already constructed clusters $\eta_1, \ldots, \eta_{k-1}$. Let C_k be an arbitrary connected component of $G \setminus \cup_{i<k}\eta_i$, and $x_k \in C_k$ arbitrary vertex. Let $\mathcal{K}_{C_k} \subseteq \{\eta_1, \ldots, \eta_{k-1}\}$ be all the previously created clusters η_i, such that there is an edge from η_i to C_k. Let T_k be a shortest path tree in C_k, with x_k as a root, and such that for every $\eta_i \in \mathcal{K}_{C_k}$, there is an edge from a vertex in T_k to η_i. In particular, T_k will have at most $|\mathcal{K}_{C_k}|$ leaves. The k'th cluster $\eta_k = B_{G[C_k]}(T_k, r_k)$ is a ball around T_k in the induced graph $G[C_k]$, where $r_k \in [0, \Delta]$ is sampled using truncated exponential distribution. See Figure 1 for illustration.

One can run the cop decomposition on general graphs without getting any interesting structure. What makes it particularly interesting for K_r-minor free graphs is the fact that the size of the set $\mathcal{K}_{C_k}$ of neighboring previously created clusters is always bounded by $r - 2$. Indeed, one can argue that if $|\mathcal{K}_{C_k}| \geq r - 1$, than one can contract all the internal edges inside each cluster in $\mathcal{K}_{C_k}$, and the connected component C_k, and obtain K_r as a minor. Thus T_k is a shortest path tree (w.r.t. $G[C_k]$) with at most $r - 2$ leaves, and the cluster C_k is a ball of radius at most Δ around this tree. We will call each such cluster a *supernode*, and the shortest path tree T_k it's *skeleton*. In addition, we construct a tree $\mathcal{T}$ over the supernodes. Here each supernode η_k will be the child in $\mathcal{T}$ of the last created supernode $\eta_i \in \mathcal{K}_{C_k}$. Note that the only outgoing edges from η_k are either to its descendants or ancestors in $\mathcal{T}$. Furthermore, η_k have at most $r - 2$ "neighbor" ancestors. We will call the connected component C_k where we constructed the supernode η_k (with skeleton T_k) the *domain* of η_k, denoted $\mathrm{dom}(\eta_k)$. Note that the vertices in $\mathrm{dom}(\eta_k)$ will either belong to η_k, or to the descendants of η_k w.r.t. $\mathcal{T}$. See Figure 1 for illustration.

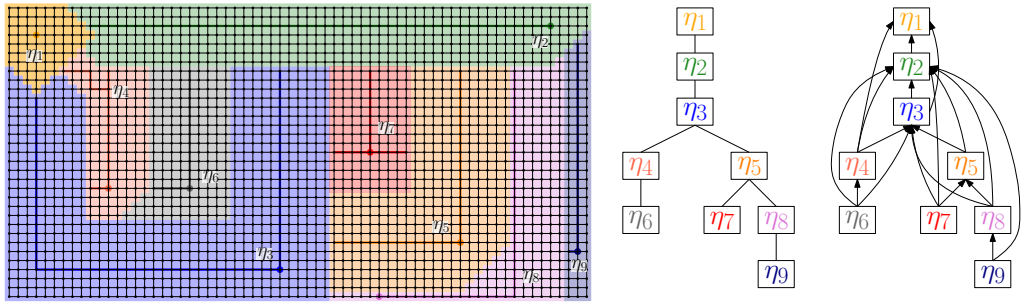

Figure 1 (a) Illustration of an (Δ, γ, w)-buffered cop decomposition of the unweighted grid graph together with (b) - the associated tree $\mathcal{T}$. There are 9 different supernodes $\eta_1, \ldots, \eta_9$, all colored with different colors. Each supernode η contains a shortest path tree T_η (the bold lines) with at most 3 leaves, where all the vertices $x \in \eta$ in the super node are at distance at most $\Delta = 6$ from T_η. The domain of each supernode consist of all the supernodes in its subtree. For example $\mathrm{dom}(\eta_5) = G[\eta_5 \cup \eta_7 \cup \eta_8 \cup \eta_9]$, and $\mathrm{dom}(\eta_3) = G[V \setminus (\eta_1 \cup \eta_2)]$. As η_3 and η_9 are not adjacent, the distance from η_3 to any vertex in η_9 (w.r.t. $\mathrm{dom}(\eta_3)$) is at least γ. The associated digraph $\overrightarrow{G}_{\mathcal{C}}$ is illustrated in (c).

Due to the truncated exponential distribution, Abraham et al. [6] showed that a small ball $B_G(x, \gamma\Delta)$ is likely to be fully contained in a single supernode. [6] Unfortunately, the supernodes $\{\eta_i\}_{i \geq 1}$ do not have a bounded diameter. Nevertheless, following [38], using the skeleton T_k, one can partition each supernode η_k into clusters of diameter $O(\Delta)$, while cutting each small ball only with a small probability. Combining these two processes together, one obtains a strong $(O(r), \Omega(\frac{1}{r}), O(\Delta))$-padded decomposition. However, it is unclear if it is possible to use the cop decomposition to create a sparse cover. Indeed, the "dependence tree" $\mathcal{T}$ does not have a bounded depth, and the entire process looks very chaotic. Indeed, every small change in the sampling of the radii leads to a completely different outcome. In contrast, the [65] (as well as [3]) clustering process had only a depth of r, and thus [67] enumerated all the possible choices in the process leading to a sparse cover of exponential sparsity.

Buffered Cop Decomposition

In a recent work, Chang et al. [26] obtained a new "separation"-property in the cop-decomposition. Instead of growing a ball with a random radius around the skeleton T_k, Chang et al. constructed the supernode T_K deterministically. The new separation property is the following, consider a supernode η, and a vertex $v \in \mathrm{dom}(\eta)$ such that v belongs to a supernode η', which is descendant of η, but there is no edge from η to η'. Then $d_{G[\mathrm{dom}(\eta)]}(\eta, v) > \frac{\Delta}{r} = \gamma$. In other words, for every descendant η' of η, either they are neighbors, or every path in $\mathrm{dom}(\eta)$ from η to η' is of length at least γ. [7] Chang et al. called the new partition *Buffered Cop Decomposition*, because there is now a buffer between

[6] Specifically, using a sophisticated argument, based on a potential function, Abraham et al. [6] showed that with probability at least $e^{-O(r)\cdot\gamma}$, the ball $B_G(x, \gamma\Delta)$ is fully contained in a single supernode.

[7] Roughly speaking, [26] begin with the supernode η_k being equal to the skeleton T_k. Then, as the algorithm progresses, each time the buffer property is violated we add the violating vertices to a previously created supernode. One can argue that the depth of this process is bounded by r (once for each neighboring ancestor supernode), and thus the cluster vertices are all within Δ distance from the skeleton.

non-neighboring clusters. They used the new buffered cop decomposition to construct a *shortcut-partition* (which is a generalization of scattering partition [41]). Roughly, a shortcut-partition is a partition of the vertices into clusters of diameter at most $\epsilon \cdot D$, such that for every pair of vertices u, v at distance at most D, there is an approximate shortest path going through at most $O_r(\frac{1}{\epsilon})$ clusters. Chang et al. used their shortcut-partitions to construct tree covers [17, 25], distance oracles [85, 66, 1], to solve the Steiner point removal problem [39, 41, 64, 27, 46], and to construct additive embedding of apex minor free graphs into low treewidth graphs [51, 28, 47, 49, 25].

Sparse Covers

The starting point of this paper is the buffered cop decomposition of [26]. We begin by observing some additional properties. Let $\overrightarrow{G}_{\mathcal{C}}$ be a digraph where the supernodes are the vertices, and there is a directed edge from a supernode η to its ancestor η' (w.r.t. $\mathcal{T}$) iff there is an edge between vertices in η and η'. $\overrightarrow{G}_{\mathcal{C}}$ is a DAG (directed acyclic graph) with maximum out-degree $r-2$, and it has additional crucial property: if v has outgoing edges towards u, z than there has to be an edge between u and z (in one way or another). We call a graph with this property a *transitive DAG*. In transitive DAG's, neighboring vertices tend to share many of their neighbors. Denote by $B_{\overrightarrow{G}_{\mathcal{C}}}(\eta, q)$ the set of supernodes towards which there is a directed path from η of length at most q. We use the transitive DAG property to show that the size of $B_{\overrightarrow{G}_{\mathcal{C}}}(\eta, q)$ is bounded by $\binom{r+q}{r}$ [8]. Note that crucially, for $q \geq r$, $\binom{r+q}{r} \approx O(q)^r$ the growth rate is sub-exponential in q. Next, we generalize the buffer property to argue that for every ancestor supernode η' of η such that $\eta' \notin B_{\overrightarrow{G}_{\mathcal{C}}}(\eta, 2q+1)$ it holds that the distance from every vertex $v \in \eta$ to η' in $\mathrm{dom}(\eta')$ is at least $(q+1) \cdot \frac{\Delta}{r}$. Combining these two properties together, it follows that for every vertex v there are at most $\binom{r+q}{r}$ ancestor supernodes at distance $q \cdot \frac{\Delta}{r}$.

Similar to the process of padded decomposition [6, 38], our sparse cover is constructed in two steps. First we cover the vertices using *enlarged* supernodes, and then we separately cover each enlarged supernode. Fix $q \geq 0$, and for every supernode η, let $\hat{\eta} = B_{G[\mathrm{dom}(\eta)]}(\eta, q \cdot \frac{\Delta}{r})$ be all the vertices at distance at most $q \cdot \frac{\Delta}{r}$ from η in $\mathrm{dom}(\eta)$. In particular, a vertex $v \in \eta$ can join only to the enlarged supernodes which are ancestors of η at distance at most $q \cdot \frac{\Delta}{r}$. Consider the ball $B = B_G(v, \frac{q}{2} \cdot \frac{\Delta}{r})$, and let η be the first supernode containing some vertex from B. By the minimality of η, and the triangle inequality, it will follow that the ball $B \subseteq \hat{\eta}$ is contained in the enlarged supernode. From the other hand, due to the properties discussed above, each vertex v will belong to at most $\binom{r+q}{r}$ enlarged supernodes. Thus we get both the sparsity and the padding properties we wanted. The only missing property at this point is the bounded diameter. Next we cover each enlarged supernode $\hat{\eta}$ using the skeleton T_η. T_η consist of at most r shortest path. We go over these shortest paths, and choose a Δ-net N. Specifically, a set such that every two net points are at distance at least Δ, and every point has a net point at distance at most Δ. Fix $R = 2\Delta + q \cdot \frac{\Delta}{r}$. Due to the properties of shortest paths, every point has at most $O(r+q)$ net points at distance $2R$. Now taking all the balls of radius R around net points provides us the desired sparse cover for the enlarged supernode. Taking the union of all the covers for all the enlarged supernodes we obtain the sparse cover for the graph. Fixing $q = 1$ we obtain padding $O(r)$ and sparsity $O(r^2)$, while by taking $q = \Theta(\frac{r}{\epsilon})$ we obtain padding $4+\epsilon$ and sparsity $O(\frac{1}{\epsilon})^r$.

[8] It was brought to our attention that this fact actually follows from Theorem 4.2. in [52].

Metric embedding into ℓ_∞

Our metric embedding into ℓ_∞ is based on our SPCS . The first to construct a sparse cover based metric embedding was Rao [82], who used the [65] padded decomposition to embed K_r minor free graphs into ℓ_2 with distortion $O(r^3 \cdot \sqrt{\log n})$. Given a partition $\mathcal{P}$, for a vertex v belonging to cluster $v \in C_v \in \mathcal{P}$, let $\partial_{\mathcal{P}}(v) = d_X(v, V \setminus C_v)$ be the distance between v to the boundary of the cluster C_v. Note that if v is padded $B_G(v, \frac{\Delta}{\beta}) \subseteq C_v$, then $\partial_{\mathcal{P}}(v) > \frac{\Delta}{\beta}$. For each cluster $C \in \mathcal{P}$, sample $\alpha_C \in \{\pm 1\}$ u.a.r. . For every vertex v, send v to $\alpha_{C_v} \cdot \partial_{\mathcal{P}}(v)$. By the triangle inequality, it follows that the expansion is at most 2. But for which vertex pairs can we guarantee small contraction?

Consider a pair u, v at distance $d_G(v, u) \in (\Delta, 2\Delta]$, and suppose that $\mathcal{P}$ has diameter at most Δ, and v is padded in $\mathcal{P}$. Then u and v must belong to different clusters C_u, C_v. If it so happened that $\alpha_{C_u} \neq \alpha_{C_v}$, then $|\alpha_{C_v} \cdot \partial_{\mathcal{P}}(v) - \alpha_{C_u} \cdot \partial_{\mathcal{P}}(u)| = \partial_{\mathcal{P}}(v) + \partial_{\mathcal{P}}(u) \geq \frac{\Delta}{\beta} \geq \frac{d_G(u,v)}{2\beta}$, and we obtain a bound on the contraction! Rao took $O(\log n)$ independent samples of the coefficients $\{\alpha_C\}_{C \in \mathcal{P}}$, and gets the contraction guarantee in a constant fraction of the samples. Next, Rao also took $O(\log n)$ independent partitions to get that v is padded in a constant fraction of them. Finally, Rao sampled partitions for all possible distance scales, concatenated the resulting embeddings of them all, and obtained the desired $O(r^3 \cdot \sqrt{\log n})$ distortion. Assuming all the distances are in $[1, \text{poly}(n)]$, there are $O(\log n)$ different distances scales, and the resulting dimension is $O(\log^3 n)$: one log for the number of scales, one log to sample many partitions for each scale, and one log to sample the coefficients $\{\alpha_C\}_{C \in \mathcal{P}}$. Nevertheless, in ℓ_2, using dimension reduction [63], one can reduce the dimension to $O(\log n)$ without significantly increasing the distortion.

The focus of our paper is embeddings into ℓ_∞. One can repeat Rao's embedding exactly as is, and get embedding into $\ell_\infty^{O(\log^3 n)}$ with distortion $O(r^3)$ (or $O(r)$ using the improved padding parameter from [6]). Unfortunately, there is no general dimension reduction in ℓ_∞ (ala [63]). Nevertheless, the dimension still can be dramatically improved. First, observe that when embedding into ℓ_∞, we don't need to succeed on a constant fraction of the partitions (or the α coefficients), it is enough to be successful only once! Thus, instead taking $O(\log n)$ independent samples from a padded decomposition, one can use a SPCS . Indeed, Krauthgamer et al. [67] constructed an $(O(r^2), 3^r)$-SPCS for K_r minor free graphs. Using this SPCS immediately leads to an embedding into $\ell_\infty^{\tilde{O}(3^r) \cdot \log^2 n}$ with distortion $O(r^2)$. To remove additional $\log n$ factor, [67] used an additional property of the [65] based SPCS that does not holds in general: it is possible to create 3^r partitions such that for every pair u, v, there will be a single partition where both u and v will be padded **simultaneously**. [67] heavily relied on this property, while our SPCS (and actually all the others as well) lacking it. Hence we cannot apply [67] as is.

Our solution follow similar lines to [67], but avoids using the additional special structure of [65]. Consider a graph G with a (β, τ)-SPCS . First, for every scale $\Delta_i = \rho^i$, for $\rho = O(\frac{\beta}{\epsilon})$, create τ partitions $\mathcal{P}_i^1, \mathcal{P}_i^2, \ldots, \mathcal{P}_i^\tau$, all with diameter Δ_i, and such that every vertex is β-padded in one of them (that is $\forall v,\ B_G(v, \frac{\Delta}{\beta})$ is contained in some cluster). Next, create, laminar partitions that closely resemble the original partitions. Specifically, we create $\{\tilde{\mathcal{P}}_i^1\}_{i \in \mathbb{Z}}, \{\tilde{\mathcal{P}}_i^2\}_{i \in \mathbb{Z}}, \ldots, \{\tilde{\mathcal{P}}_i^\tau\}_{i \in \mathbb{Z}}$, where for every i, j, $\mathcal{P}_i^j$ refines $\mathcal{P}_{i+1}^j$, $\mathcal{P}_i^j$ has radius at most $(1+\epsilon) \cdot \Delta_i$, and for every $v \in V$, and $i \in \mathbb{Z}$, $B_G(v, \frac{\Delta}{(1+\epsilon) \cdot \beta})$ is fully contained in a cluster of one of $\tilde{\mathcal{P}}_i^1, \ldots, \tilde{\mathcal{P}}_i^\tau$. In other words, for every $v \in V$, and $i \in \mathbb{Z}$, $\max_{j \in [\tau]} \partial_{\mathcal{P}_i^j}(v) > \frac{\Delta_i}{(1+\epsilon) \cdot \beta}$. Similar laminar partitions were also created in [67].

Next, our goal is to embed w.r.t. each laminar partition $\{\tilde{\mathcal{P}}_i^j\}_{i\in\mathbb{Z}}$ independently, such that for every pair u,v which is separated in partition $\tilde{\mathcal{P}}_i^j$ it will hold that $\|f(u)-f(v)\|_\infty \geq \partial_{\tilde{\mathcal{P}}_i^j}(v)+\partial_{\tilde{\mathcal{P}}_i^j}(u)$. [9] Note that given such embedding for all the laminar partitions, we can concatenate them all to obtain the desired distortion. Indeed, constant expansion follows by triangle inequality, while for every u,v, $\|f(u)-f(v)\|_\infty \geq \max_{i,j}\left(\partial_{\tilde{\mathcal{P}}_i^j}(v)+\partial_{\tilde{\mathcal{P}}_i^j}(u)\right) = \Omega(\frac{d_G(u,v)}{\beta})$. To create the embedding w.r.t. to the laminar partition $\{\tilde{\mathcal{P}}_i^j\}_{i\in\mathbb{Z}}$, let $i_0\in\mathbb{Z}$ be a the maximum index such that $\tilde{\mathcal{P}}_{i_0}^j$ is partitioned into singletons, and let $k\in\mathbb{N}$ be the maximum such that $\tilde{\mathcal{P}}_{i_0+k}^j$ is not the trivial partition into a single cluster $\{V\}$. Clearly it is enough to embed only w.r.t. the laminar partition $\{\tilde{\mathcal{P}}_i^j\}_{i=i_0}^{i_0+k}$. Let $\tilde{\mathcal{P}}_{i_0+k}^j = \{A_1,\ldots,A_m\}$ be the clusters in the top partition in our hierarchy. We create a prefix free code $\alpha:\tilde{\mathcal{P}}_{i_0+k}^j\to\{\pm1\}^*$. Specifically, each cluster A_q is assigned a string of ±1 of length at most $2\cdot\left\lceil\log\frac{|V|}{|A_q|}\right\rceil$. The strings of different clusters might be of different length. However, for every $A_q, A_{q'}$ there is an index s such that $\alpha_s(A_q),\alpha_s(A_{q'})$ exist and differ. Then the embedding of each vertex $v\in A_q$ defined by concatenating the coordinates $\left(\alpha_1(A_q)\cdot\partial_{\tilde{\mathcal{P}}^j_{i_0+k}}(v),\alpha_2(A_q)\cdot\partial_{\tilde{\mathcal{P}}^j_{i_0+k}}(v),\ldots\right)$ with an embedding created inductively for A_q w.r.t. the induced partition by $\{\tilde{\mathcal{P}}_i^j\}_{i=i_0}^{i_0+k-1}$. To bound the contraction, consider a pair u,v and suppose that they are first separated in level $k'\in[i_0,i_0+k]$. Then the embeddings of u and v are "aligned" in scales $[k'+1,i_0+k]$, while in scale k' they belong to respective clusters $A_v,A_u\in\tilde{\mathcal{P}}_{k'}^j$. The respective codes $\alpha(A_v),\alpha(A_u)$ will differ in some coordinate s and thus $\|f(u)-f(v)\|_\infty \geq \left|\alpha_s(A_u)\cdot\partial_{\tilde{\mathcal{P}}^j_{k'}}(u)-\alpha_s(A_v)\cdot\partial_{\tilde{\mathcal{P}}^j_{k'}}(v)\right| = \partial_{\tilde{\mathcal{P}}^j_{k'}}(u)+\partial_{\tilde{\mathcal{P}}^j_{k'}}(v)$. To conclude a bound on the contraction it remains to observe that for every partition $\tilde{\mathcal{P}}_l^j$ that refines $\tilde{\mathcal{P}}_{k'}^j$ it holds that $\partial_{\tilde{\mathcal{P}}^j_{k'}}(v)+\partial_{\tilde{\mathcal{P}}^j_{k'}}(u)\geq\partial_{\tilde{\mathcal{P}}^j_l}(v)+\partial_{\tilde{\mathcal{P}}^j_l}(u)$.

The overall number of coordinates used for the embedding of the laminar partition $\{\tilde{\mathcal{P}}_i^j\}_{i=i_0}^{i_0+k}$ is $2\cdot\lceil\log n\rceil+2(k+1)$, where k have to be bounded by a logarithm of the aspect ratio $O(\log\Phi)$. If we started from a (β,τ)-SPCS , there are τ laminar partitions and thus the overall dimension is $O(\tau\cdot\log(n\cdot\Phi))$. We remove the dependence on the aspect ratio using fairly standard techniques. Specifically, by observing that for far enough scales, we can use the same coordinate. For this to hold, when treating scale ρ^i, we need to "contract" all vertex pairs at distance at most $\frac{\rho^i}{n^2}$ (as otherwise a pair can accumulate error in unbounded number of scales). Hence we can remove the dependence on the aspect ratio only if the contracted graph still admits a SPCS .

Abstract

A graph is said to contain K_k (a clique of size k) as a *weak immersion* if it has k vertices, pairwise connected by edge-disjoint paths. In 1989, Lescure and Meyniel made the following conjecture related to Hadwiger's conjecture: Every graph of chromatic number k contains K_k as a weak immersion. We prove this conjecture for graphs with at most $1.4(k-1)$ vertices. As an application, we make some progress on Albertson's conjecture on crossing numbers of graphs, according to which every graph G with chromatic number k satisfies $\mathrm{cr}(G) \geq \mathrm{cr}(K_k)$. In particular, we show that the conjecture is true for all graphs of chromatic number k, provided that they have at most $1.4(k-1)$ vertices and k is sufficiently large.

1 Introduction

There are several famous problems in graph theory which state that over all graphs of a given chromatic number, some graph parameter is minimized by a complete graph. Obviously, the chromatic number of a graph is at least its clique number. The converse is false, but partial converses have been of central interest in graph theory. Hadwiger's conjecture states that every graph of chromatic number k contains a K_k-minor. Wagner proved in 1937 that the case $k = 5$ is equivalent to the four color theorem. Hadwiger's conjecture was verified for $k \leq 6$ by Robertson, Seymour, and Thomas [22], and is open for $k \geq 7$. In the 1980's, Kostochka [17] and Thomason [24] proved that every graph of chromatic number k contains a K_t-minor, where $t = \Omega(k/\sqrt{\log k})$, which was improved to $t = \Omega(k/(\log k)^{1/4+\epsilon})$ by Norin, Postle, and Song [20], and very recently, to $t = \Omega(k/\log\log k)$ by Delcourt and Postle [9].

In 1961, Hajós conjectured the following strengthening of Hadwiger's conjecture: Every graph of chromatic number k contains a *subdivision* of the complete graph K_k, i.e., it has k so-called "branch vertices" connected by $\binom{k}{2}$ internally *vertex-disjoint* paths. Hajós' conjecture is true for $k \leq 4$, but for $k \geq 7$ it was disproved by Catlin [8]. In fact, Erdős and Fajtlowicz [13] showed that almost all graphs are counterexamples (see also [14]). The conjecture remains open for $k = 5, 6$.

Lescure and Meyniel [19] suggested a conjecture weaker than Hajós', which may still be true for every k. Instead of requiring that G contains a subdivision of K_k, they wanted to prove the existence of k branch vertices connected by $\binom{k}{2}$ *edge-disjoint* paths. Moreover,

these paths may pass through some branch vertices other than their endpoints. They called such a subgraph of G a *weak immersion* of K_k.

More precisely, a graph G contains H as a weak immersion if there is a mapping ϕ from $V(H) \cup E(H)$, which maps each vertex of H to a vertex in G and each edge of H to a path in G such that

1. $\phi(u) \neq \phi(v)$, for distinct vertices $u, v \in V(H)$;
2. for distinct edges $e, f \in E(H)$, the paths $\phi(e)$ and $\phi(f)$ are edge-disjoint; and
3. for each edge $e = uv \in E(H)$, $\phi(e)$ is a path in G with endpoints $\phi(u)$ and $\phi(v)$.

If the following condition is also satisfied, we say that G contains H as a *strong immersion*.

4. For each edge $e \in E(H)$, the path $\phi(e)$ intersects the set of branch vertices, $\phi(V(H))$, only at its endpoints.

In 1989, Lescure and Meyniel conjectured the following.

▶ **Conjecture 1** ([19]). *Every graph with chromatic number k contains a weak immersion of the complete graph K_k.*

For $k \geq 3$, the Lescure-Meyniel conjecture is an immediate corollary of Hajós' conjecture. DeVos, Kawarabayashi, Mohar, and Okamura [11] verified Conjecture 1 for $4 \leq k \leq 6$. Conjecture 1 remains open for $k \geq 7$. According to a result of Gauthier, Le, and Wollan [16], every graph with chromatic number k contains a weak immersion of K_t, where $t = (k-4)/3.54$ (see also [10, 12] for earlier bounds).

Our first result shows that the Lescure-Meyniel conjecture is true for graphs whose number of vertices is not much larger than its clique number.

▶ **Theorem 2.** *If G is a graph with chromatic number k and at most $1.4(k-1)$ vertices, then G contains K_k as a weak immersion.*

As an application, we use Theorem 2 to obtain new bounds on an old conjecture of Albertson.

The *crossing number* of a graph G, $\mathrm{cr}(G)$, is the smallest number of edge crossings in any drawing of G in the plane. In 2007, Albertson conjectured the following.

▶ **Conjecture 3.** *Every graph G with chromatic number k satisfies $\mathrm{cr}(G) \geq \mathrm{cr}(K_k)$.*

Clearly, Albertson's conjecture is weaker than Hajós' conjecture. Moreover, Conjecture 3 vacuously holds for $k \leq 4$, since $\mathrm{cr}(K_4) = 0$ and, for $k = 5$, Conjecture 3 is equivalent to the four color theorem. After a sequence of results [3, 6, 1], it is now known that Albertson's conjecture holds for $k \leq 18$, but it is open for $k \geq 19$.

A graph G is *k-critical* if $\chi(G) = k$, and every proper subgraph of G has chromatic number less than k. A 1-critical graph is just a graph consisting of a single vertex. As $\mathrm{cr}(G) \geq \mathrm{cr}(H)$ holds for all subgraphs $H \subset G$, it suffices to prove Albertson's conjecture for k-critical graphs. In [6], Barát and Tóth verified Conjecture 3 for all k-critical graphs on at most $k + 4$ vertices, and Ackerman [1] proved the conjecture for all k-critical graphs with at least $3.03k$ vertices. Our next result is the following.

▶ **Theorem 4.** *There is a constant $\delta > 0$ such that the following holds. If k is sufficiently large, then every graph G of chromatic number k on $n \leq (1.4+\delta)k$ vertices satisfies $\mathrm{cr}(G) \geq \mathrm{cr}(K_k)$.*

In the last section, we discuss some concluding remarks on how to improve on the constant factor 1.4 in Theorem 2, which in turn implies a larger range for which Theorem 4 holds.

2 Weak immersion

In this section, we prove Theorem 2. First, let us recall the following lemma. A classic result due to Gallai states that if G is a k-critical graph on n vertices, where $n \leq 2k-2$, then the complement of G is disconnected. This implies the following.

▶ **Lemma 5** ([15]). *Let k, n be positive integers with $n \leq 2k-2$. If G is a k-critical graph on n vertices, then there is a vertex partition*

$$V(G) = V_1 \cup V_2 \cup \cdots \cup V_t,$$

where $t \geq 2$, such that V_i is complete to V_j, for $i \neq j$, $|V_i| = n_i$, and the induced subgraph $G[V_i]$ is k_i-critical with $n_i \geq 2k_i - 1$.

The *chromatic index* $\chi'(H)$ of a multigraph H without loops is the minimum number of colors needed to properly color the edges of H, i.e., to color them in such a way that no two edges that share a vertex receive the same color. A classical theorem of Shannon [23] states that every multigraph H with maximum degree Δ satisfies $\chi'(H) \leq 3\Delta/2$.

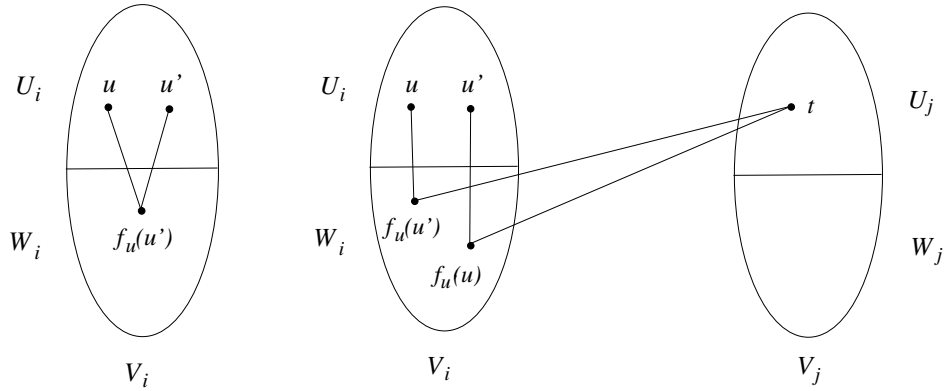
Proof of Theorem 2. We may assume that $k \geq 7$, since otherwise we obtain a weak immersion of K_k by [16]. By possibly deleting vertices and edges, we may assume without loss of generality that G is k-critical. Let $n = |V(G)|$ so $n \leq 1.4(k-1) \leq 2k-2$. By Lemma 5, there is a vertex partition $V(G) = V_1 \cup \cdots \cup V_t$, where $t \geq 2$, such that V_i is complete to V_j for each $i \neq j$, and the induced subgraph $G[V_i]$ is k_i-critical for each i with $n_i \geq 2k_i - 1$ vertices. Hence, $n = \sum_{i=1}^{t} n_i$ and $k = \sum_{i=1}^{t} k_i$. For each i, arbitrarily partition $V_i = U_i \cup W_i$ with $|U_i| = k_i$, so $|W_i| = n_i - k_i$. Let $U = \bigcup_i U_i$.

In what follows, we will construct a weak immersion of K_k with U being the set of branch vertices. Moreover, we will use all edges in U as paths of length one in the weak immersion. By the Gallai decomposition, each nonadjacent pair of vertices in U has both of its vertices in U_i for some i. For each i and vertex $u \in U_i$, let f_u be a one-to-one function from the set of non-neighbors of u in $U_i \setminus \{u\}$ to the set of neighbors of u in W_i. Such a function f_u exists as the degree of u in $G[V_i]$ is at least $k_i - 1$, as $G[V_i]$ is k_i-critical. If a nonadjacent pair (u, u') of vertices in U_i satisfies $f_u(u') = f_{u'}(u)$, then we connect u and u' in the weak immersion by the path of length two with middle vertex $f_u(u')$. Moreover, these paths will be edge-disjoint as f_u is one-to-one. See Figure 1a.

So far we constructed edge-disjoint paths (which are of length one or two) connecting some pairs of branch vertices. We next describe how we connect the remaining pairs of vertices in U by paths, which will each be of length four. For a pair (u, u') of nonadjacent vertices in U_i with $f_u(u') \neq f_{u'}(u)$, we will pick a vertex $t \in U \setminus U_i$ and the path of length four connecting u to u' will have the vertices in order as $u, f_u(u'), t, f_{u'}(u), u'$. We next describe how to pick the vertex $t = t(u, u')$ for each such pair u, u' of nonadjacent vertices in the same U_i with $f_u(u') \neq f_{u'}(u)$. See Figure 1b.

Make an auxiliary multigraph H_i on W_i as follows. For each nonadjacent pair (u, u') with $u, u' \in U_i$ and $f_u(u') \neq f_{u'}(u)$, we add an edge between $f_u(u')$ and $f_{u'}(u)$ in H_i. Clearly, H_i does not contain loops as we require $f_u(u') \neq f_{u'}(u)$. Since f_u is one-to-one, the maximum degree in H_i is at most $|U_i| = k_i$. Being able to pick the desired vertex $t = t(u, u') \in U \setminus U_i$ for each nonadjacent pair $u, u' \in U_i$ with $f_u(u') \neq f_{u'}(u)$, in order to obtain the desired paths of length four for the immersion, is equivalent to being able to properly color the edges of H_i with color set $U \setminus U_i$. As $n_i \geq 2k_i - 1$, we have

$$k_i \leq n_i - k_i + 1 = |W_i| + 1 \leq n - k + 1 \leq 0.4(k-1),$$



(a) $f_u(u') = f_{u'}(u)$ **(b)** $f_u(u') \neq f_{u'}(u)$

Figure 1 Constructing a path from u to u'.

where the last inequality follows from the fact that $n \leq 1.4(k-1)$. This implies that

$$|U \setminus U_i| = k - k_i \geq 3k/5.$$

On the other hand, by Shannon's theorem, we have $\chi'(H_i) \leq 3k_i/2 \leq 3(k-1)/5$. By combining the last two inequalities above, we have $\chi'(H_i) \leq |U \setminus U_i|$, and therefore, we are able to find such a proper edge-coloring, completing the proof. ◀

3 Albertson's conjecture

In this section, we prove Theorem 4.

We recall an old conjecture of Hill, according to which the crossing number of the complete graph on k vertices satisfies $cr(K_k) = H(k)$, where

$$H(k) := \frac{1}{4}\left\lfloor \frac{k}{2} \right\rfloor \left\lfloor \frac{k-1}{2} \right\rfloor \left\lfloor \frac{k-2}{2} \right\rfloor \left\lfloor \frac{k-3}{2} \right\rfloor.$$

It is known that $cr(K_k) \leq H(k)$ by a particular drawing of K_k. In the other direction, Balogh, Lidický, and Salazar [5] proved that $cr(K_k)$ is at least $0.9855H(k)$, for large enough k. In particular, we have the following lemma.

▶ **Lemma 6** ([5]). *If k is sufficiently large, then* $\mathrm{cr}(K_k) > k^4/65$.

A related old conjecture of Zarankiewicz, is that $\mathrm{cr}(K_{a,b}) = \left\lfloor \frac{a}{2} \right\rfloor \left\lfloor \frac{a-1}{2} \right\rfloor \left\lfloor \frac{b}{2} \right\rfloor \left\lfloor \frac{b-1}{2} \right\rfloor$. Towards this conjecture, Balogh et al. [4] recently proved the following result.

▶ **Lemma 7** ([4]). *If a, b are sufficiently large, then* $\mathrm{cr}(K_{a,b}) > .9118a^2b^2/16$.

Before turning to the proof of Theorem 4, as a warm-up, we establish the following useful asymptotic result.

▶ **Lemma 8.** *Let G be a graph on n vertices with $\chi(G) = k$ such that $n \leq 1.4(k-1)$. Then*

$$\mathrm{cr}(G) > \mathrm{cr}(K_k) - k^3/3.$$

In particular, $\mathrm{cr}(G) \geq (1 - o(1))\mathrm{cr}(K_k)$, *as* $k \to \infty$.

Proof. Let G be drawn in the plane with $\mathrm{cr}(G)$ crossings. For a vertex v of G, let $d(v)$ denote the degree of v in G. By Theorem 2, G contains K_k as a weak immersion. Let $v_1, \dots, v_k$ be the branch vertices of the immersion, and let P_{ij} be the path in G used in the weak immersion with endpoints v_i and v_j.

Consider a drawing of K_k in the plane, with vertices $v_1, \dots, v_k$, where the edge between v_i and v_j is drawn along the path P_{ij} such that it goes around every branch vertex that is an internal vertex of P_{ij}. By going either clockwise or counterclockwise around a branch vertex v, we can achieve that in the neighborhood of v, the drawing of the edge between v_i and v_j participates in at most $(d(v)-2)/2$ crossings. Apart from small neighborhoods of the branch vertices along the path P_{ij}, the drawing of the edge connecting v_i to v_j coincides with the drawing of P_{ij}. In particular, the drawing of the edge between v_i and v_j passes through every non-branch vertex that is an internal vertex of P_{ij}.

There are two types of crossings in this drawing of K_k. All crossings that are already crossings in the original drawing of G are of *type 1*, so there are at most $\mathrm{cr}(G)$ of them. The remaining crossings are of *type 2*. They occur in small neighborhoods of vertices of G. The latter crossings fall into two categories depending on whether they occur in a small neighborhood of a non-branch vertex or a branch vertex.

For non-branch vertices v, the number of crossings in the drawing of K_k at v is at most $\binom{f(v)}{2}$, where $f(v)$ denotes the number of paths P_{ij} in the K_k immersion, in which v is an internal vertex of the path P_{ij}. Note that $f(v) \le d(v)/2$, as v is an internal vertex of at most $d(v)/2$ edge-disjoint paths. Obviously, $d(v) \le n-1$ and there are at most $n-k$ non-branch vertices. Therefore, at non-branch vertices, the total number of crossings of type 2 is at most

$$(n-k)\binom{(n-1)/2}{2} \le (n-k)n^2/8.$$

For each of the k branch vertices v_i, there are $k-1$ paths P_{ij} ending at v_i. Thus, v_i is an internal vertex of at most $(d(v_i)-(k-1))/2 \le (n-k)/2$ paths $P_{\ell j}$. In the drawing of K_k, the edge from v_ℓ to v_j participates in at most $(d(v_i)-2)/2 < n/2$ crossings in the neighborhood of v_i, by going either clockwise or counterclockwise around v_i. Thus, in the neighborhoods of branch vertices, altogether there are at most

$$k\frac{n-k}{2}\frac{n}{2}$$

crossings of type 2.

Adding up the above two bounds and using our assumption that $n \le 1.4(k-1)$, we conclude that the total number of crossings in the drawing of K_k, which occur in small neighborhoods of the vertices of G is at most $21k^3/64 < k^3/3$. Thus, we have produced a drawing of K_k with fewer than $\mathrm{cr}(G) + k^3/3$ crossings. Consequently, we have

$$\mathrm{cr}(G) > \mathrm{cr}(K_k) - k^3/3 = (1-o(1))\mathrm{cr}(K_k),$$

as desired. ◀

The well-known crossing lemma discovered by Ajtai, Chvátal, Newborn, Szemerédi [2] and independently, by Leighton [18], states that every graph G with n vertices and $m \ge 4n$ edges satisfies $\mathrm{cr}(G) \ge cm^3/n^2$, where $c > 0$ is an absolute constant. The constant has been improved by several authors. The currently best constant is due to Büngener and Kaufmann.

▶ **Lemma 9** ([7]). *Let G be a graph on n vertices with m edges. If $m \ge 6.95n$, then* $\mathrm{cr}(G) \ge \frac{1}{27.48}\frac{m^3}{n^2}$.

We also need the following two simple lemmas.

▶ **Lemma 10** ([21]). *Let G be a graph with m edges, and let x and y be two nonadjacent vertices. Let $G+xy$ denote the graph obtained by adding the edge (x,y). Then we have*

$$\mathrm{cr}(G+xy) \le \mathrm{cr}(G) + m.$$

▶ **Lemma 11.** *Let G be a graph on n vertices with m edges and $1 \le a \le n$ be an integer. Then G has an induced subgraph on a vertices with at least $m\binom{a}{2}/\binom{n}{2}$ edges.*

Proof. If we take a uniform random subset A of a vertices, the expected number of edges in A is $m\binom{a}{2}/\binom{n}{2}$, and hence, there is an induced subgraph with at least that many edges. ◀

We are now ready to prove Theorem 4. We first prove a variant for k-critical graphs with at most $1.4(k-1)$ vertices.

▶ **Theorem 12.** *There is a constant $c>0$ such that for k sufficiently large, every k-critical graph G on $n \le 1.4(k-1)$ vertices satisfies $\mathrm{cr}(G) \ge \mathrm{cr}(K_k) + c(n-k)k^3$.*

Proof. The proof is by induction on $\ell := n-k$. The base case $\ell = n-k = 0$ is trivial, as in this case $G = K_k$. Let ℓ be a positive integer and suppose we have established the desired result for smaller nonnegative integer values of ℓ. Let k be a large constant that will be specified later, and let G be a k-critical graph on $n \le 1.4(k-1)$ vertices with $n-k=\ell$. By Lemma 5 (Gallai's theorem), G has a vertex partition

$$\mathcal{P} : V(G) = V_1 \cup \ldots \cup V_t$$

into $t \ge 2$ nonempty parts such that each $G[V_i]$ is k_i-critical with n_i vertices with $n_i \ge 2k_i - 1$, and every pair of vertices in different parts are adjacent. In particular, we have $\sum_{i=1}^t k_i = k$ and $\sum_{i=1}^t n_i = n$. Set $\epsilon = 1/8$, $\epsilon' = 2^{-8}$, and $c = 2^{-44}$, say. We distinguish three cases.

Case 1. There is a part V_i with $1 < n_i \le \epsilon k$.

Add missing edges to V_i, one at a time, until V_i is complete. Each time we add an edge, we upper bound the increase of the crossing number by applying Lemma 10. As $G[V_i]$ is k_i-critical, each vertex in $G[V_i]$ has degree at least $k_i - 1$. Hence, the number of nonadjacent pairs in $G[V_i]$ is at most $n_i(n_i-k_i)/2$. In total, by making $G[V_i]$ complete, we increase the crossing number by at most $n^2 n_i(n_i-k_i)/4$. The resulting graph G', obtained by completing part V_i, has n vertices and is k'-critical with $k' = k + n_i - k_i$. Thus,

$$\begin{aligned} \mathrm{cr}(G') &\le \mathrm{cr}(G) + n^2 n_i(n_i-k_i)/4 = \mathrm{cr}(G) + n^2 n_i(k'-k)/4 \\ &\le \mathrm{cr}(G) + \left(\frac{4}{65} - c\right) k^3(k'-k), \end{aligned} \tag{1}$$

where in the last inequality we used that $n \le 1.4(k-1)$, $n_i \le k/8$, and $c = 2^{-44}$.

Applying the induction hypothesis to G', we obtain

$$\mathrm{cr}(G') \ge \mathrm{cr}(K_{k'}) + c(n-k')k'^3. \tag{2}$$

Note that by averaging, we have

$$\begin{aligned} \mathrm{cr}(K_{k'}) &\ge \mathrm{cr}(K_k)\binom{k'}{4}/\binom{k}{4} \ge (k'/k)^4 \mathrm{cr}(K_k) \ge \left(1 + 4\left(\frac{k'}{k} - 1\right)\right)\mathrm{cr}(K_k) \\ &= \mathrm{cr}(K_k) + 4\mathrm{cr}(K_k)(k'-k)/k \ge \mathrm{cr}(K_k) + \frac{4}{65}k^3(k'-k), \end{aligned} \tag{3}$$

where in the last inequality we used Lemma 6.

Putting (1)–(3) together, we obtain

$$\begin{aligned}\mathrm{cr}(G) &\geq \mathrm{cr}(K_{k'}) + c(n-k')k'^3 - \left(\frac{4}{65} - c\right)k^3(k'-k)\\ &\geq \mathrm{cr}(K_k) + ck^3(k'-k) + c(n-k')k'^3\\ &\geq \mathrm{cr}(K_k) + ck^3(n-k).\end{aligned}$$

This completes the proof in this case.

Case 2. There is a part V_i with $k_i \geq \epsilon' k$.

Applying Theorem 2 to G, we obtain K_k as a weak immersion in G. By the proof of Lemma 8, the number of crossings between the edges used in this weak immersion is at least

$$\mathrm{cr}(K_k) - k^3/3. \tag{4}$$

Furthermore, the proof of Theorem 2 shows that no matter how we partition part V_i into $V_i = U_i \cup W_i$ with $|U_i| = k_i$, the edges in $G[W_i]$ are not used in the weak immersion. Note that $G[V_i]$ has minimum degree at least $k_i - 1$, and hence, has at least $n_i(k_i-1)/2$ edges. By Lemma 11, we can pick this partition $V_i = W_i \cup U_i$ so that the number of edges in $G[W_i]$ is at least

$$m_i := \frac{1}{2}n_i(k_i-1)\binom{n_i-k_i}{2}/\binom{n_i}{2} = \frac{1}{2}(k_i-1)(n_i-k_i)(n_i-k_i-1)/(n_i-1).$$

As all three numbers k, $k_i \geq \epsilon' k$, and $n_i - k_i \geq k_i - 1$ are sufficiently large, we have $m_i \geq 6.95(n_i - k_i)$. Thus, we can apply Lemma 9 to obtain that

$$cr(G[W_i]) \geq \frac{1}{27.48}\frac{m_i^3}{(n_i-k_i)^2} \geq 2^{-11}k_i^3(n_i-k_i).$$

We obtain that

$$\begin{aligned}\mathrm{cr}(G) &\geq \mathrm{cr}(K_k) - k^3/3 + \mathrm{cr}(G[W_i])\\ &\geq \mathrm{cr}(K_k) - k^3/3 + 2^{-11}k_i^3(n_i-k_i)\\ &\geq \mathrm{cr}(K_k) + c(n-k)k^3.\end{aligned}$$

In the last inequality, we used that k is sufficiently large, $k_i \geq \epsilon' k$, $n_i - k_i \geq k_i - 1$, $n \leq 1.4(k-1)$, and $c \leq 2^{-44}$. This completes the proof in Case 2.

Case 3. Each part V_i is either a singleton or satisfies $n_i > \epsilon k$ and $k_i < \epsilon' k$.

In this case, as $\ell = n - k > 0$, we must have at least one part that is not a singleton. Recall that $n - k < 0.4k$ and $n - k = \sum_i (n_i - k_i)$. For every i for which V_i is not a singleton, we have $n_i - k_i > \epsilon k - \epsilon' k = (\epsilon - \epsilon')k$. Thus, the number of parts that are not singletons is smaller than $0.4k/(\epsilon - \epsilon')k < 4$, which implies that there are at most *three* non-singleton parts.

Let A be the union of the singleton parts and $B = V(G) \setminus A \neq \emptyset$. Since B is the union of non-singleton parts V_i, each of which is larger than ϵk, we have $|B| > \epsilon k$. The chromatic number of G is k. The chromatic number of $G[B]$, the subgraph of G induced by B, is smaller than $3\epsilon' k$. Using that $A \cup B$ is a vertex partition of G, we obtain that the chromatic number of $G[A]$ is larger than $k - 3\epsilon' k$. As $G[A]$ is a clique, we have $|A| > k - 3\epsilon' k = (1 - 3\epsilon')k$.

It follows by averaging over all cliques of size k in K_{k+1}, just like in (3), that $\mathrm{cr}(K_k)/\binom{k}{4}$ is a monotonically increasing function. Since it is bounded from above, it must converge. As $|A| > (1-3\epsilon')k$, we obtain that

$$\mathrm{cr}(K_{|A|}) \geq (1-12\epsilon')\mathrm{cr}(K_k),$$

provided that k is sufficiently large.

Notice that the clique $G[A]$ and the complete bipartite graph between A and B are disjoint subgraphs of G. Therefore, we get

$$\begin{aligned}\mathrm{cr}(G) &\geq \mathrm{cr}(K_{|A|}) + \mathrm{cr}(K_{|A|,|B|}) \geq (1-12\epsilon')\mathrm{cr}(K_k) + .9118|A|^2|B|^2/16\\ &\geq \mathrm{cr}(K_k) + \left(.9118(1-6\epsilon')\epsilon^2/16 - 12\epsilon'/64\right)k^4\\ &\geq \mathrm{cr}(K_k) + 2^{-7}k^4 > \mathrm{cr}(K_k) + c(n-k)k^3.\end{aligned}$$

Here the second inequality follows by substituting in the bound from Lemma 7 on the crossing number of complete bipartite graphs and using the bound $\mathrm{cr}(K_k) \leq k^4/64$. The last inequality holds with $c = 2^{-44}$, say, because $n - k < .4k$. ◀

Proof of Theorem 4. It suffices to prove the statement for k-critical graphs as every graph of chromatic number k has a k-critical subgraph. So let G be a k-critical graph with chromatic number k with $n \leq (1.4+\delta)k$ vertices. If $n \leq 1.4(k-1)$, then the statement already follows from Theorem 12. So we may assume $1.4(k-1) \leq n \leq (1.4+\delta)k$.

Consider a proper k-coloring of G. Let $k' = (1-3\delta)k$. Let A be the union of the $3\delta k$ largest color classes of this proper k-coloring. Either each of these color classes has size at least two, or the remaining color classes forms a clique on k' vertices.

In the first case, $|A| \geq 6\delta k$, and the remaining induced subgraph after deleting A has chromatic number k'. Let B be the vertex set of a k'-critical subgraph of the induced subgraph on $V(G) \setminus A$. Observe that

$$|B| \leq n - 6\delta k \leq (1.4-5\delta)k = 1.4k' - .8\delta k \leq 1.4(k'-1),$$

provided that $\delta k \geq 7/4$, which holds as k is sufficiently large. By Theorem 12, the induced subgraph on B has crossing number at least $\mathrm{cr}(K_{k'}) + c(|B|-k')k'^3$, where $c > 0$ is an absolute constant (We have seen that $c = 2^{-44}$ will do.) If $|B| \geq 1.2k$, this induced subgraph already has crossing number at least

$$\mathrm{cr}(K_{k'}) + c(|B|-k')k'^3 \geq (1-12\delta)\mathrm{cr}(K_k) + .1ck^4 \geq \mathrm{cr}(K_k) - 12\delta k^4/64 + .1ck^4 \geq \mathrm{cr}(K_k),$$

where we used $\delta = 2^{-45}$. Otherwise, as G is k-critical, each vertex of G has degree at least $k-1$, and there at least $(n-|B|)(k-1)/2 \geq k^2/16$ edges not in $G[B]$. Let G_0 denote the subgraph of G consisting of the edges of G not in $G[B]$. Applying the crossing number bound (Lemma 9) to G_0 and using $n < 2k$, we obtain that

$$\mathrm{cr}(G_0) \geq \frac{1}{27.48}\frac{(k^2/16)^3}{(2k)^2} \geq 2^{-19}k^4.$$

Then

$$\mathrm{cr}(G) \geq \mathrm{cr}(G[B]) + \mathrm{cr}(G_0) \geq \mathrm{cr}(K_{k'}) + 2^{-19}k^4 \geq \mathrm{cr}(K_k) - 12\delta k^4/64 + 2^{-19}k^4 \geq \mathrm{cr}(K_k),$$

where we used $\delta = 2^{-45}$.

In the second case, $|A| = n - k'$ and the edges between A and B form a complete bipartite graph in G with $|A| \geq 2k/5$ and $|B| \geq 4k/5$. This complete bipartite graph has crossing number at least $k^4/200$ by Lemma 7. Together with the $\mathrm{cr}(K_{k'})$ crossings between the edges of the clique of size k', we obtain

$$\mathrm{cr}(G) \geq \mathrm{cr}(K_{k'}) + k^4/200 \geq \mathrm{cr}(K_k) - 12\delta k^4/64 + k^4/200 \geq \mathrm{cr}(K_k).$$ ◀

4 Concluding remarks

One can improve the constant factor 1.4 in Theorem 2, when k is sufficiently large. This can be achieved by being more careful how we pick U and the functions f_u (recall in the proof of Theorem 2, these choices were made arbitrarily). Instead, it is better to make sure that the largest degree vertices in $G[V_i]$ are in U_i, while the remaining vertices in U_i are chosen at random. If there is a pair $u, u' \in U$ for which $f_u(u')$ and $f_{u'}(u)$ haven't already been chosen, then we choose $f_u(u')$, $f_{u'}(u)$ to be equal. Once there is no such pair u, u', we make the remaining choices for the functions f_u uniformly at random. Vizing's theorem [25] states that any multigraph H with maximum degree Δ and maximum edge multiplicity μ satisfies $\chi'(H) \leq \Delta + \mu$. A careful analysis of this procedure produces a considerably smaller bound on the maximum degree of H_i than k_i, and also gives that the maximum edge multiplicity of H_i is $o(k_i)$. This can be proved through optimizing expected values and using standard concentration inequalities.

Abstract

We introduce a quantum algorithm design paradigm called **combine and conquer**, which is a quantum version of the "marriage-before-conquest" technique of Kirkpatrick and Seidel. In a quantum combine-and-conquer algorithm, one performs the essential computation of the combine step of a quantum divide-and-conquer algorithm prior to the conquer step while avoiding recursion. This model is better suited for the quantum setting, due to its non-recursive nature. We show the utility of this approach by providing quantum algorithms for 2D maxima set and convex hull problems for sorted point sets running in $\tilde{O}(\sqrt{nh})$ time, w.h.p., where h is the size of the output.

1 Introduction

In classical computing, **divide and conquer** is an algorithm design pardigm that is usually described in terms of the following three steps:

1. **Divide**: divide a problem into two or more subproblems.
2. **Conquer**: solve the subproblems, typically using recursion.
3. **Combine**: combine subproblem solutions into a solution to the original problem.

Perhaps because of the wide applicability of algorithm design paradigms, like divide and conquer, there is interest in adapting classical paradigms to the quantum setting. For example, Childs, Kothari, Kovacs-Deak, Sundaram, and Wang [9] describe an adaptation of the divide-and-conquer technique to quantum computing that in some cases results in query complexities better than what is possible classically. Likewise, Allcock, Bao, Belovs, Lee, and Santha [3] study the time complexity of a number of quantum divide-and-conquer algorithms, establishing conditions under which search and minimization problems with classical divide-and-conquer algorithms are amenable to quantum speedups. Akmal and Jin [2] adapt classical divide-and-conquer approaches for string problems to the quantum setting. There is also related work by many others; see, e.g., [4, 6, 8, 14, 25, 35, 37].

A well-known problem that can be solved classically using the divide-and-conquer paradigm is the **convex hull** problem; e.g., see Seidel [34]. In the two-dimensional version of this problem, one is given a set, S, of n points in the plane and asked to output a representation of the smallest convex polygon that contains the points in S. (See Figure 1.)

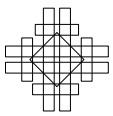

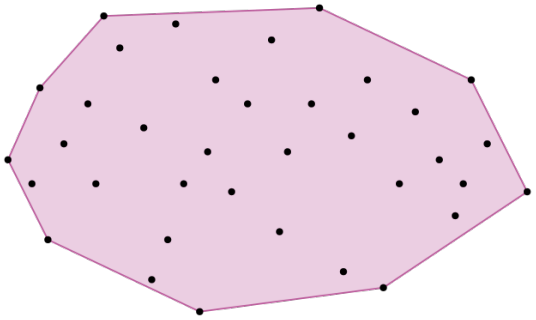

Figure 1 A two-dimensional convex hull.

Asymptotically fast classical convex hull algorithms are **output sensitive**, meaning that their running times depend on both the input size, n, and output size, h, and there are well-known examples that run in $O(n \log h)$ time; e.g., see Kirkpatrick and Seidel [22], Chan [7], and Afshani, Barbay, and Chan [1]. In this paper, we are interested in studying how to efficiently adapt classical output-sensitive divide-and-conquer algorithms, e.g., for convex hull and related problems, to quantum computing models.

Additional Related Work. There is considerable interest in quantum algorithms for solving computational geometry problems. Sadakane, Sugawara, and Tokuyama [32] give a quantum convex hull algorithm that runs in $\tilde{O}(h\sqrt{n})$ time,[1] and this time bound is also achieved by Wang and Zhou [36]. Note that if $h = n$, as can occur, for instance, with points distributed on a circle or parabola, then these algorithms run in $\tilde{O}(n^{3/2})$ time, which is significantly slower than the best classical algorithms. Furthermore, the above quantum algorithms make use of a quantum input data model that assumes that the points are provided in superposition. Many of the procedures require sampling as well, meaning that the algorithms require multiple copies of these input states. We present the algorithm in a standard quantum query model that allows for an even comparison with the existing literature on the subject. In this model, we assume the existence of an oracle that returns the item in the queried index. For completeness, Cortese and Braje [10] showed that there exists a quantum circuit which can take classical data and implement this oracle, with the cost of a logarithmic overhead if the circuit construction time is excluded. Lanzagorta and Uhlmann [23, 24] also describe a quantum convex hull algorithm running in $\tilde{O}(h\sqrt{n})$ time, which, in their case, is a quantum implementation of the well-known Jarvis march convex hull algorithm using Grover search for the inner loop; see, e.g., [11, 16, 29, 30, 33]. They also describe an algorithm that runs in $\tilde{O}(\sqrt{nh})$ time, but this result only applies when h is small and the points are chosen uniformly at random from a bounded convex region. In addition to this quantum prior work, there is a well-developed body of prior work in classical computing models for computing convex hulls where the points are given pre-sorted in lexicographic order; see, e.g., Ghouse and Goodrich [13], Hayashi, Nakano, and Olarlu [18], Berkman, Schieber, and Vishkin [5], Nakano [27], Goodrich [15], and Nakagawa, Man, Ito, and Nakano [26]. The question we seek to answer in this paper is whether it is possible to leverage this assumption in the quantum setting and obtain asymptotically faster output-sensitive algorithms in the model where the input point set is pre-sorted but with no other assumptions about the distribution of points.

[1] We use $\tilde{O}(f(n))$ to denote $O(f(n) \log^c n)$, for some constant $c \geq 0$.

Our Results. In this paper, we introduce **quantum combine and conquer**, which is a novel quantum divide-and-conquer paradigm where we perform the combine step **before** the conquer step and avoid recursion. Our combine-and-conquer paradigm provides a quantum analogue to a classical divide-and-conquer variation that Kirkpatrick and Seidel call "marriage-before-conquest" [20–22]. We show that using this paradigm it is possible to compute the convex hull of a set of points in the plane in $\tilde{O}(\sqrt{nh})$ time given that the input is presorted in lexicographic order. As the sorting problem can be reduced to computing the convex hull, and there is no quantum speed-up for sorting [19], we don't expect quantum algorithms to outperform classical algorithms for this problem in the general case, but this result shows that some reasonable conditions can provide significant speedups. For example, for inputs where h is $O(\log n)$, such as is expected for n points uniformly distributed in a convex polygon with a constant number of sides [17], then our method achieves an $\tilde{O}(n^{1/2})$ running time. Similarly, for inputs where h is $O(n^{1/3})$, such as is expected for n points uniformly distributed in a disk [17, 31], then our method achieves an $\tilde{O}(n^{2/3})$ running time. In general, our algorithms achieve sublinear running times for sorted input sets for h up to almost n. Moreover, our results do not depend on any assumptions about the input points coming from a given distribution, such as uniformly distributed points in a convex region. Indeed, our results hold for adversarial chosen point sets, such as n points on a circle.

To introduce the combine-and-conquer paradigm, we first apply it to constructing the maxima set of a set of lexicographically sorted points in the plane. Our quantum maxima set algorithm runs in $\tilde{O}(\sqrt{nh})$ time, where h is the size of the output. The key idea to our technique is that there is information that can first be computed globally (the combine step), which partitions the computation into the smaller blocks that then use this information to finish the computation locally and (in a conquer step) without recursion.

We then apply our quantum combine-and-conquer paradigm to the convex hull problem. In this case, the combine step is more complex, in that it includes multiple reductions to two-dimensional linear programming. Nonetheless, we show that the combine steps can still be performed before the conquer steps in this case. As a result, we give a quantum convex hull combine-and-conquer algorithm that runs in $\tilde{O}(\sqrt{nh})$ time, where n is the number of (sorted) input points and h is the size of the output. The quantum combine-and-conquer technique provides a novel algorithm design paradigm that may be useful for designing more quantum algorithms that use similar intuition as classical algorithms.

We compare our bounds to previous quantum convex hull algorithms in Table 1. In our algorithm's input model, the data is encoded by a unitary, such that if the input is a list of points, $[p_0, p_1, \ldots, p_{n-1}]$, then we assume access to a unitary U_{in} that maps an index i to the corresponding element in the array p_i: $|i\rangle|0\rangle \xrightarrow{U_{in}} |i\rangle|p_i\rangle$. The existing literature on quantum solutions to this problem assume that the data is given in a uniform superposition state, $(1/\sqrt{n})\sum_i |i\rangle|p_i\rangle$. Access to the unitary U_{in} is a somewhat stronger assumption in that the uniform superposition state can be prepared in unit time given access to U_{in}. On the other hand, the most natural way to prepare such a state is via access to U_{in}, as we do.

2 Preliminaries

We assume basic familiarity with quantum computing; see, e.g., Nielsen and Chuang [28]. A **quantum state** over n qubits is a unit vector of length 2^n with complex entries. The computational basis $\{|j\rangle\}_{j\in[0,\ldots,2^n-1]}$ is a basis over quantum states where $|j\rangle$ represents the unit vector of length n with a 1 in the j-th index and 0 elsewhere. A computational basis state can be used as a classical bit string to simulate any classical algorithm. We can express any quantum state as a weighted sum of these classical basis states,

Table 1 A summary of quantum algorithms to compute the convex hull of a set of n points, where the output has h edges. The algorithms all assume access to a data loading unitary.

	Input point set assumptions	**Runtime**
Sadakane, Sugawara, and Tokuyama [32]	Unsorted, arbitrary point set	$\tilde{O}(h\sqrt{n})$
Wang and Zhou [36]	Unsorted, arbitrary point set	$\tilde{O}(h\sqrt{n})$
Lanzagorta and Uhlmann [23, 24]	Small h, uniformly distributed points	$\tilde{O}(\sqrt{nh})$
This work	Sorted, arbitrary point set	$\tilde{O}(\sqrt{nh})$

$$|\Psi\rangle = \sum_{j=0}^{2^n-1} \alpha_j |j\rangle . \tag{1}$$

If at least two α_j in the above are nonzero, we say the state is in **superposition**. A **measurement** of the state $|\Psi\rangle$ will collapse the state to $|j\rangle$ with probability $|\alpha_j|^2$. The measurement is destructive in the sense that once it is collapsed, there is no way to go back to $|\Psi\rangle$ without running the circuit to prepare that state. The state where all $\alpha_j = \frac{1}{\sqrt{2^n}}$ can be prepared by a circuit of depth 1.

We will assume an input model where the input data $[p_0, p_1, \ldots, p_{n-1}]$ is accessible by a unitary U_{in} that maps an index i to the corresponding element in the array p_i. Since quantum operations must be reversible, it is standard to model the action of this unitary by using an index and data register as $|i\rangle |0\rangle \overset{U_{in}}{\to} |i\rangle |p_i\rangle$. We can use linearity to examine the action of this unitary to a state in superposition

$$U_{in}\left(\sum_{j=0}^{2^n-1} \frac{1}{\sqrt{2^n}} |j\rangle |0\rangle\right) = \sum_{j=0}^{2^n-1} \frac{1}{\sqrt{2^n}} (U_{in} |j\rangle |0\rangle) = \frac{1}{\sqrt{2^n}} \sum_{j=0}^{2^n-1} |j\rangle |p_j\rangle , \tag{2}$$

from which the data point p_j can be retrieved with probability $|\alpha_j|^2$ upon measurement of the index register. Therefore, in this model, we assume that a quantum state representing a distribution of our inputs is preparable in time proportional to the time it takes to prepare the distribution. A transformation from the n-bit zero string $|0^n\rangle$ to a uniform superposition over all n-bit strings can be accomplished by a depth 1 circuit where a Hadamard gate is applied to each qubit in parallel.

Much of the existing literature on this subject assumes access to multiple copies of the state in (2). Our assumption of access to U_{in} is at least as strong of an assumption as having multiple copies of the state. At the same time, it is a standard assumption for states in the form of (2) are generated using access to a unitary like U_{in}. We therefore compare the performance of our algorithm against the existing literature under equal access to U_{in}, and we summarize the performance of each in Table 1 under this model.

Quantum Subroutines. In this section we discuss the two primary quantum subroutines that will be used throughout the paper. The quantum computing components of our algorithms are limited to invocations of these subroutines, and the remainder of the algorithms are done through classical post-processing.

The first subroutine is for preparing superposition states of subsets of points. Our algorithms use the fact that the data $S = [p_0, p_1, \ldots, p_{n-1}]$ is encoded as a sorted list in U_{in}, and we need to prepare h states $|S_0\rangle, |S_1\rangle, \ldots, |S_{h-1}\rangle$ where $|S_j\rangle$ is a uniform superposition of n/h consecutive elements in the array starting at index jn/h and h is a power of 2. Preparation of the $|S_j\rangle$ begins with a register storing an n-bit zero string $|0^n\rangle$, and another register large enough to store a point from the dataset, each of which we will call the index and data register respectively. The first step is to set the first $\log_2 h$ bits of the index register to j. Next, take the remaining $n - \log_2 h$ bits in the index register and prepare a uniform superposition state over the bitstrings of length $n - \log_2 h$. Finally, apply U_{in} on this state and the data register to prepare the superposition of n/h states starting from jn/h,

$$|S_j\rangle = \frac{1}{\sqrt{n/h}} \sum_{k=0}^{n/h-1} |jn/h + k\rangle_{I_j} |p_{jn/h+k}\rangle_{D_j} . \tag{3}$$

We summarize this process in Algorithm 1. Throughout this paper, we use S_j to represent the subset of S storing points in the j-th block, and $|S_j\rangle$ to be the quantum state that encodes this set, as seen in Equation (3).

Algorithm 1 `qPrep`(j, h).

Require: j: The index of the block to prepare; h: the number of blocks to partition into.
Require: Global access to the unitary U_{in} that encodes the sorted data $[d_0, \ldots, d_{n-1}]$
1: Prepare two registers, initialized to $|0^n\rangle_{I_j} |0\rangle_{D_j}$.
2: Set the first $\log_2 h$ bits of I_j to j
3: Apply a Hadamard gate to each remaining qubits in I_j.
4: Apply U_{in} to the pair of registers.
5: **return** $|S_j\rangle$, the state after the previous step as described in equation 3.

The second quantum subroutine we use is a quantum max/min finding algorithm due to Durr and Hoyer [12]. This algorithm takes as input a Boolean function, $f : D \to \{0, 1\}$, a comparator, $\preceq$, to maximize (or minimize) over, the index, j, of the block to perform the search over, and the total number of blocks, h. Our subroutine uses `qPrep`(j) to prepare the superposition state described in Theorem 1. This has the effect of applying the algorithm only to the points in block j, and allows us to search the block in $\tilde{O}(\sqrt{n/h})$ time. Throughout the text, we use the signature, `qMax/qMin(`f`, `$\preceq$`, `j`, `h`)`, when calling this function, and the output is an element of D or null if there are no elements such that $f(d) = 1$. The function f can be passed as, say, a classical circuit which can be converted to a quantum circuit.

▶ **Theorem 1** (Quantum Maximum/Minimum Finding [12]). *Let $D = [d_0, \ldots, d_{n-1}]$ be a list of n elements represented by w bits, and let S be the time required to prepare the state,*

$$|\psi\rangle = \frac{1}{\sqrt{n}} \sum_{i=0}^{n} |i\rangle |d_i\rangle , \tag{4}$$

and Q the time it takes to query a boolean function $f : D \to \{0, 1\}$. Let M be the subset of D such that $f(m) = 1$ for all $m \in M$. Also, let $\preceq$ be some ordering of data values in the data register such that comparisons according to this ordering can be performed in $O(\log w)$ time. Then we can find the maximum (or minimum) value of M under the specified ordering in time $S \cdot Q \cdot \tilde{O}(\sqrt{n})$.

3 Quantum Maxima Sets

In this section, we present a quantum algorithm to solve the maxima set problem using the combine-and-conquer paradigm. In the maxima set problem, we are given a set, S, of n points in the plane and are tasked with finding the subset of points in S that are not dominated by any other points in S. We say that a point p **dominates** a point q if $p.x > q.x$ and $p.y > q.y$. Note that the output size, h, can be as small as 1 or as large as n.

We assume that the input set is sorted in lexicographic order (first by x-coordinates and then by y-coodinates in the case of ties), as discussed in the introduction.

Let us begin by reviewing a simple divide-and-conquer algorithm in the classical computing model, which is provided the set, S, of n points as input in sorted order, and returns the maxima set, M (see Preparata and Shamos [30]). The algorithm splits S into left and right sets, S_1 and S_2, and recursively finds the maxima sets of each. Then it prunes away each point in S_1 with smaller y-coordinate than the point, $p_{\max}$, in S_2 with maximum y-coordinate. The resulting maxima set algorithm, which we give in detail in an appendix, takes $\Theta(n \log n)$ time, even when S is sorted [30]. Kirkpatrick and Seidel [21] show that if the combine step of finding $p_{\max}$ is performed before the divide and conquer steps, and used to prune points in recursive subproblems, then the running time can be improved to $O(n \log h)$.

For our output-sensitive quantum algorithm, we also perform the combine step before the conquer step, but our goal is to design a quantum algorithm that runs in $\tilde{O}(\sqrt{nh})$ time without recursion, which requires a more sophisticated approach. We first describe an algorithm where the output size, h, is known in advance and later show how to use this algorithm to solve the case where the output size is not known.

At a high level, the combine-and-conquer approach performs the combine step first before conquering the subproblems. In the maxima set problem, this is achieved in the following way. We begin by dividing our set S into h different blocks using Algorithm 1. The key observation we use is that we can isolate the problem of finding the maxima set to each of the local blocks once we identify representative information from each block. This representative information is used globally, so we describe the process of finding such information as the **combine step**. The combine-and-conquer paradigm works for problems where, once the global information is identified, the blocks do not need to communicate with each other for the remainder of the algorithm. In the case of computing the maxima set, the combine step consists of searching for the set T of the h highest points in each block. Once the set T is found, we classically compute the maxima set M_T of T. Note that M_T cannot contain more than h points, and if a block does not share a point with M_T no points in that block can be in the final output set. Once the points in M_T are identified, we begin the **conquer step** of the algorithm to find the points in each block that appear in the maxima set. Block number j uses information from two points identified in the combine step to restrict the search region. The first is the y coordinate T_j of the tallest point within the j-th block, which immediately removes all points to the left of it inside block j out of the candidate set. The second is the y coordinate R_j of the highest point that appears in any of the blocks to the right of block j. Note that R_j is left-most point from M_T that is to the right of block j. See Figure 2.

Using T_j and R_j, we can define a Boolean function f that takes as input a point p and returns 1 if p is not dominated by either of T_j and R_j. We then apply Theorem 1 to search for the maximum element in lexicographic order subject to this Boolean function. It turns out that this point is part of the final output set, as R_j tells us it is not dominated by any point in blocks to the right of j and T_j tells us it is not dominated by any point in block j. We then update R_j to equal this maximal point we found, and repeat this process in

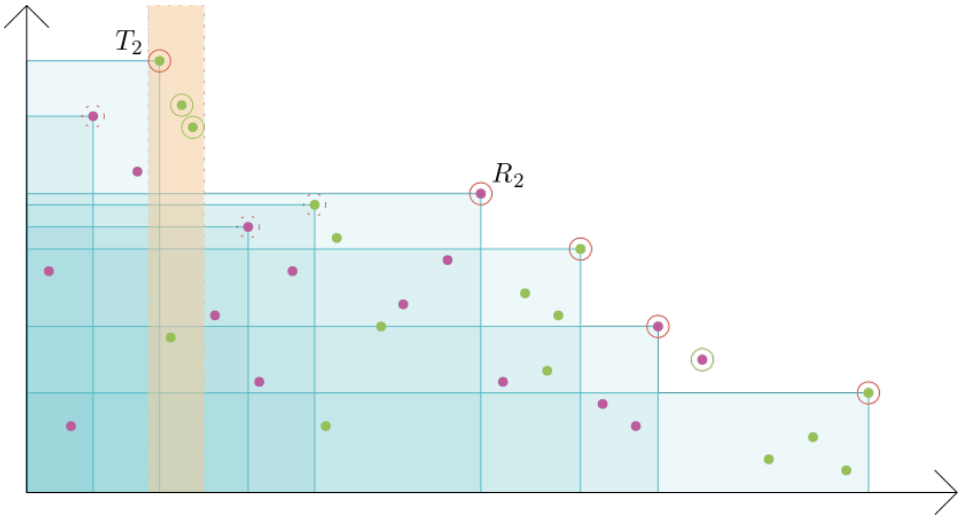

Figure 2 An example instance of maxima set where $n = 32$ and $h = 8$ solved using our quantum combine-and-conquer algorithm. Consecutive blocks of points are colored in alternating purple and green, and the set T of tallest points in each group is circled. The maxima set of T is indicated using solid circles, whereas tallest points that are dominated are circled in dotted lines. To illustrate an example of the conquer step, we focus attention on the group S_2 which is highlighted in orange. In this group, the tallest y coordinate is indicated by T_2, and R_2 is the y coordinate of the tallest point to the right of this group. Thus, the only points that need to be processed are the two points not bound by any blue box. The points that are found in this local check are circled in green.

block j until the Boolean function does not mark any elements in the set. We illustrate the first iteration of this process in Figure 3. Since the output size is h, it suffices to run this process $O(h)$ times in total across all blocks. Finally, we collect the outputs in the blocks that contain a point in M_T, which takes at most $O(h)$ time. See Algorithm 2.

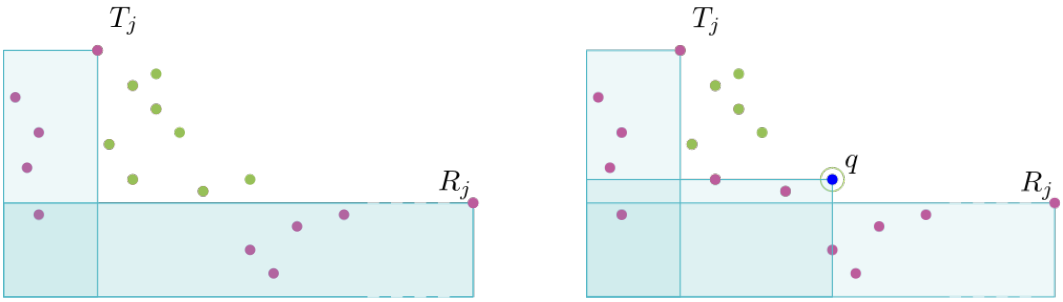

Figure 3 A demonstration of Algorithm 2 where we iteratively search for the maxima point within block j given T_j and R_j. The left shows the state of the first iteration, and all points shown are the contents of block j except for the one labeled R_j. Points are green if they are not dominated by T_j or R_j and thus return 1 to the Boolean function f. Among these points, we search for the lexicographic maximum point q and set this to be the new right boundary for the next iteration. The first q to be discovered in the above instance is marked in blue. This is repeated until there are no remaining green points.

Finally, the case where h is unknown can be handled using an approach where we start with a small estimate of h, then repeat the procedure using $h = 2h$ if we discover more than h points. Thus, the running time forms a geometric sum that is $\tilde{O}(\sqrt{nh})$. See Algorithm 3.

Algorithm 2 `CompleteMaximaSet`$(j,\ h,\ T_j,\ M_j)$.

Require: j, h: The block we are conquering and the total number of blocks.
Require: T_j: The y coordinate of the tallest point in S_j.
Require: R_j: The y coordinate of the first point in M appearing after all points in S_j.
1: Define a Boolean function f that takes as input a point p and returns 1 if p is not dominated by T_j or R_j.
2: **while** `qMax`$(f, \preceq_{Lex}, j, h)$ returns a point q **do**
3: Store q in an output list.
4: Define a new f that takes as input a point p and returns 1 if p is not dominated by T_j or q.

Algorithm 3 `QuantumMaximaSet`(S).

Require: U_{in}: a the unitary that encodes the lexicographically sorted data $[d_0, \ldots, d_{n-1}]$
Require: h: the number of blocks to partition into.
1: $h = 4$.
2: **while** True **do**
3: **for** $j \in [0, 1, \ldots, h-1]$
4: $T_j =$ `qMax`$(f, \preceq_y, j, h)$ where $f(x) = 1$ for all $x \in S$
5: Let $T = [T_0, T_1, \ldots, T_{h-1}]$.
6: $M =$ `ClassicalMaximaSet(`T`)`
7: **for** $j \in [0, 1, \ldots, h-1]$
8: `CompleteMaximaSet(`$j,\ h,\ T_j,\ M_j$`)`
9: **if** The total number of points found exceeds h **then**
10: $h = 2h$
11: **else**
12: Print all the points in the output register of all j blocks and terminate the loop.

▶ **Theorem 2.** *There is a quantum algorithm for finding the maxima set of a presorted set of n points in the plane in $\tilde{O}(\sqrt{nh})$ time, where h is the size of the output.*

Proof. The Grover searches for the tallest points in each block takes $\tilde{O}(h\sqrt{n/h}) = \tilde{O}(\sqrt{nh})$ time. Once this set T is found, the maxima set M of T can be computed classically in $O(h)$ time. The total time incurred by the calls to `CompleteMaximaSet` is dominated by the calls to `qMax`, each of which outputs a point or terminates the call to `CompleteMaximaSet`. Therefore `qMax` is called $O(h)$ times and each call requires $\tilde{O}(\sqrt{n/h})$ time for a total of $\tilde{O}(\sqrt{nh})$ time. Note that the condition that the points we are searching over are between T_j and R_j can be done in constant time. The outer loop repeats at most $O(\log n)$ times, whose contribution is suppressed by $\tilde{O}$. Finally, the time to output the points that were found takes $O(h)$ time and is dominated by the other parts of the algorithm. ◀

4 Quantum Convex Hulls

In this section, we describe a quantum algorithm to construct the convex hull of n points in the plane in $\tilde{O}(\sqrt{nh})$ time, where h is the size of the output. Again, we assume that the input set is sorted in lexicographic order. We follow our combine-and-conquer paradigm, where we use some global properties that can be computed from our subsets to prune off points that do not appear in the output, then use these values to isolate the problem solving within each block. Here, however, the combine step is more complicated that simply finding a point, $p_{\max}$, with maximum y-coordinate.

We begin by reviewing a well-known classical divide-and-conquer algorithm for 2D convex hulls (see, e.g., [11,29,30,33]). The convex hull $CH(S)$ of a set, S, of n points in the plane can be described as a union of the polygonal chains that form the upper hull $UH(S)$ and lower hull $LH(S)$ of the points, where $UH(S)$ (resp., $LH(S)$) is the set of edges of $CH(S)$ with positive (negative) normals. For completeness, we provide a description of a classical divide-and-conquer algorithm for computing $UH(S)$ in appendix D, which divides S into a left set, S_1, and right set, S_2, and recursively finds $UH(S_1)$ and $UH(S_2)$. Then it finds the tanget segment bridge between $UH(S_1)$ and $UH(S_2)$ and prunes away the points under the bridge, resulting in an algorithm running in $O(n \log n)$ time. By a well-known point-line duality, which we also review in an appendix, the bridge edge can be found by a solving a two-dimensional linear program; see, e.g., [11,29,33].

▶ **Lemma 3** (see, e.g., [11, 29, 33]). *Given a vertical line L, and a set S of n points in a plane, one can determine the edge e of $UH(S)$ that intersects L (or that no such edge exists) by finding the highest point of intersection between $O(n)$ halfplanes.*

If we use linear-time 2D linear programming for the bridge-finding step, then the running time for this classical divide-and-conquer algorithm is $O(n \log n)$, even if the points are sorted by x-coordinate. Kirkpatrick and Seidel [22] show that this classical running time can be improved to $O(n \log h)$ by performing the bridge-finding step before the (recursive) conquer steps. Likewise, our quantum convex hull algorithm also performs this combine step before the conquer steps, but avoids recursion.

Before we give our algorithm, let us review another well-known classical algorithm for computing a two-dimensional convex hull – the **Jarvis march** algorithm; see, e.g., [11,30,33]. In this algorithm, we start with a point, p, known to be on the convex hull, such as a point with smallest y-coordinate. Then, we find the next point on the convex hull in a clockwise order, by a simple linear-time maximum-finding step. We iterate this search, winding around the convex hull, until we return to the starting point. Since each iteration takes $O(n)$ time, this algorithm runs in $O(nh)$ time. Lanzagorta and Uhlmann [24] describe a quantum assisted version of the Jarvis march algorithm that runs in $\tilde{O}(h\sqrt{n})$ time, which we review in an appendix.

Let S be a set of n points in the plane sorted lexicographically. For simplicity of expression, let us assume that the points have distinct x-coordinates and we are interested in computing the upper hull, $UH(S)$, of S. As in our maxima set algorithm, let us assume for now that we know the value of h, the number of points on the upper hull of S to simplify the presentation. We divide S into h blocks, $S_0, S_1, \ldots, S_{h-1}$, of size $O(n/h)$ each by vertical lines, $L_1, L_2, \ldots, L_{h-1}$, arranged left-to-right. This is achieved by using Algorithm 1 to partition the input.

At a high level, our quantum combine-and-conquer upper hull algorithm first computes all the bridge edges that are intersected by one of the vertical lines, L_i. This amounts to the combine step of our quantum combine-and-conquer algorithm. Each of these bridge edges belong to the upper hull of S; hence, there are at most h such bridges. Importantly, we show how to compute all these bridges in $\tilde{O}(\sqrt{nh})$ time. Each block of points, S_j, has $O(n/h)$ points, and, of course, there may be remaining upper hull points to compute for each such S_j (between points of tangency for the bridges computed in the combine step). Note that the conquer step for block S_j will return in $O(1)$ time if S_j does not contain any endpoints of a bridge edge or if it contains a single point where two bridge edges meet. See Figure 5 showing the edges that come from the combine step and the edges that come from the conquer step.

To compute the remaining convex hull points, then, we perform a modified quantum Jarvis march for each subset, S_j, which runs in time $\tilde{O}(h_j\sqrt{n/h})$ time, where h_j is the number of additional upper hull points found for S_j. Thus, the total time for this second (conquer) phase of our algorithm is

$$\begin{aligned}\sum_{j=1}^{h} \tilde{O}(h_j\sqrt{n/h}) &\leq \tilde{O}(h\sqrt{n/h}) \\ &= \tilde{O}(\sqrt{nh}).\end{aligned}$$

Given this overview, let us next describe how to perform the different steps of our algorithm, beginning with our quantum algorithm for finding all the bridge edges intersecting the vertical lines, $L_1, L_2, \ldots, L_{h-1}$, which separate the subsets, $S_0, S_1, \ldots, S_{h-1}$, of S. At a high level, our combine-step method can be viewed as a quantum adaptation of a classical algorithm by Goodrich [15] for computing the upper hull of a partially sorted set of points.

As mentioned above, by point-line duality, bridge finding is dual to two-dimensional linear programming. In more detail, let S be a set of n points in the plane, and L be a vertical line in this plane. Let S' be the same set of points after shifting the plane horizontally so that L is the y-axis. We define a dual plane by taking each point $p = (a, b)$ and mapping it to a line $y = ax - b$. A standard result in computational geometry is that the points in the upper hull of S' correspond to the lower envelope of the set of lines in the dual plane; see, e.g., [11, 30, 33]. Furthermore, by the duality transformation, the highest point in the lower envelope is the intersection of two lines in the envelope whose slopes transition from positive to negative. Mapping this point to the primal plane gives us the bridge edge we are looking for. Thus, we can reduce the problem of finding a bridge edge to the problem of finding the largest point in the intersection of n lower-halfplanes. We also use the following lemma due to Sadakane et al. showing that the problem of computing the highest point in the intersection of n halfplanes efficiently using a quantum algorithm.

▶ **Lemma 4** (Sadakane et al. [32]). *The highest point in the intersection of n lower-halfplanes can be computed in $O(\sqrt{n}\log^2 n)$ time, using a quantum computer, with probability $1 - n^{-c}$ for any constant c given the linear constraints in superposition.*

The linear constraints in superposition refers to a state in the following form:

$$|\psi\rangle := \frac{1}{\sqrt{n}} \sum_{i=0}^{n-1} |i\rangle\,|p_i\rangle \tag{5}$$

where p_i are the coordinates of each of the n points. By point-line duality, the coordinates fully describe the halfplanes in the dual plane.

The output element is a point in the dual plane, which maps back to a line in the primal plane. To determine which points this line intersects, we can run two iterations of minimum finding to find the points in S that are on the resulting line by minimizing by the distance to the line. We combine the above two lemmas to a function with the signature,

$$\texttt{qLP}(L,\ i,\ j,\ h), \tag{6}$$

and it returns the endpoints $p_s, p_f \in S$ of the bridge edge as a tuple. This process will also call `qPrep`(i,h) as needed.

We are now ready to describe the full algorithm. The first step will be to divide our input set into h blocks, each containing n/h points. We define a **bridge edge** to be an edge in the upper hull of S whose endpoints are in two different blocks.

Algorithm 4 Bridge(i, j, h).

Require: i, j: The indices of blocks to find the bridge edge over.
Require: h: The total number of blocks that we are partitioning into.
1: Let L be a vertical line drawn between the last point of S_i and the first point of S_j. This can be computed by querying U_{in} at the final and first index of blocks i and j respectively.
2: (p_s, p_f) =qLP(L, i, j, h)
3: Return the two endpoints $p_s \in S_i$ and $p_f \in S_j$ of the bridge edge.

To find the bridge edges, we take inspiration from the classical Graham scan algorithm for computing the convex hull. We will be using the fact that if we traverse the convex hull in the clockwise direction, each edge makes a right turn from its previous edge. Since bridge edges are edges in the upper hull, this is true for them as well. We will compute bridge edges between consecutive pairs, but if at any point a left turn is formed between two bridge edges, we know that these edges will not be a part of the upper hull. Critically, this allows us to ignore an entire block of points, and move on to find the bridge edge between the remaining blocks. The details of the above approach are outlined in Algorithm 5.

Algorithm 5 FindBridgeEdges(h).

1: Initialize an empty stack Σ.
2: Let L_1 :=Bridge$(0, 1, h)$, and push this onto Σ. ▷ L_i will represent the bridge edge that ends in block i.
3: **for** $i \in [2, h-1]$ **do**
4: Let L_i := Bridge$(i-1, i, h)$.
5: **while** L_{i-1} and L_i form a left turn **do**
6: Pop the stack
7: Let t be the index of the item on top of the stack.
8: Let L_i := Bridge(t, i, h).
9: Push L_i on the stack
10: Return Σ as an array.

▶ **Lemma 5.** *Let S be a set of points divided into h blocks such that $p_i \leq p_j$ for all $p_i \in S_i$ and $p_j \in S_j$ where $i \leq j$. Then, the set of bridge edges of this partition can be found in $\tilde{O}(\sqrt{nh})$ time.*

Proof. Each block's pending contribution to the bridge edges can only be popped at most once. Thus, the total time it takes for the loop starting at line 3 of Algorithm 5 will be proportional to $O(h)$. For each edge, we must compute the Bridge between sets S_j and S_i, which will take $\tilde{O}(\sqrt{n/h})$ time by lemma 3 and 4. Thus, the total time it takes to find the bridge edges is $\tilde{O}(\sqrt{nh})$. ◀

Once the bridge edges are identified, what remains is to find the edges of the convex hull whose end points are in the same block. To do this, we use a quantum assisted Jarvis march. Recall that the Jarvis march is another standard convex hull algorithm in which we start with an edge (p, q) on the convex hull, then do a search over the remaining points to find the point r such that the angle formed between (p, q) and (q, r) is maximized.

In each block, S_i, rather than performing a full Jarvis march, however, we start the search from the bridge edge entering S_i from the left, and perform up to h Grover searches for the point maximizing the angle until we find the starting point of the bridge edge leaving S_i. We summarize this step in Algorithm 6 and Lemma 6. See also Figure 4.

Algorithm 6 QuantumBlockJarvisMarch(j, h, B).

Require: B is the set of bridges of S computed in Algorithm 5.

Define f_c to be a function such that $f_c(p) = 1$ iff there is a bridge in B that starts at p.
Define f_f to be a function such that $f_f(p) = 1$ iff there is a bridge in B that ends at p.
$p_c = \texttt{qMax}(f_c, \preceq_{Lex}, j, h)$
$p_f = \texttt{qMax}(f_f, \preceq_{Lex}, j, h)$
If neither are present, Return.
Let p_s, p_c be the two end points of the bridge edge containing p_c.
while $p_c \neq p_f$ **do**
    Define $\preceq_{deg(p_s,p_c)}$ to be the ordering induced by the angle formed between (p_s, p_c) and (p_c, p) for $p \in S$.
    $p_r = \texttt{qMax}(f, \preceq_{deg(p_s,p_c)}, j, h)$ where $f(x) = 1$ for all x.
    Add p_r to the set of output points associated with block j.
    Let $(p_s, p_c) = (p_c, p_r)$.

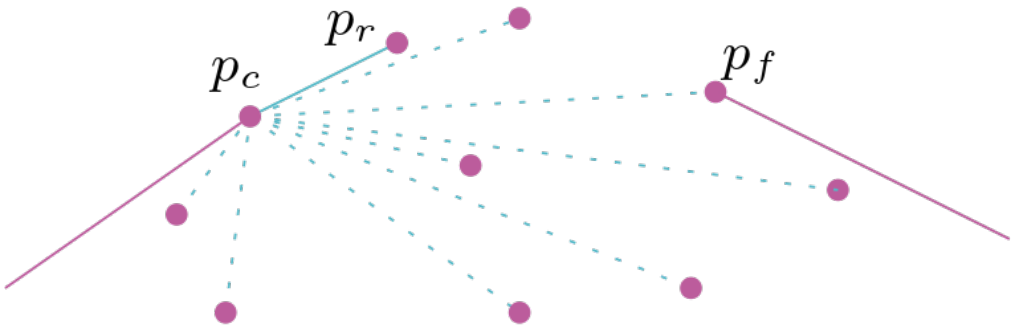

Figure 4 An example of our restricted Jarvis March convex hull algorithm. The purple lines are edges that we know are on the convex hull, and the points are the content of some block S_j. In a Jarvis March algorithm, we start our search from p_c which is known to be on the convex hull, then search for the point that forms the maximum angle with the incoming edge containing p_c. In the above example, the edges we check are in blue, and the solid line denotes the edge that is added to the convex hull. We repeat the search again starting at p_r, until we connect to p_f.

▶ **Lemma 6.** *Let S be a set of m points and p_s, $p_f \in S$ be points on the convex hull of S. The part of the convex hull from p_s to p_f in the clockwise direction can be computed in $\tilde{O}(h\sqrt{m})$ time, where h is the number of points on the convex hull from p_s to p_f.*

We now combine the above pieces to describe our complete quantum convex hull algorithm. See Figure 5. As was the case in the maxima set algorithm, we begin with a guess for the upper bound of h, then during the conquer step detect whether or not we have exceeded this bound. A convex hull requires at least 3 points, so we use 4 as our initial guess, as it is the smallest power of 2 greater than 3. If we exceed our guess, then we double our estimate for h and rerun the algorithm. Thus, the running times across all our guesses form a geometric sum that is $\tilde{O}(\sqrt{nh})$. See Algorithm 7.

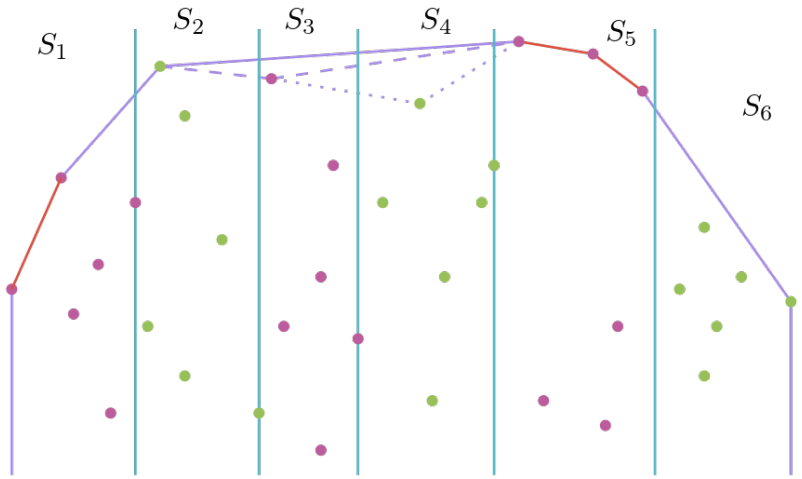

Figure 5 An upper hull with $n = 36$ and $h = 6$. Consecutive blocks of points are colored in alternating purple and green. The bridge edges discovered are shown in purple, and the dotted and dashed lines starting from block S_2 indicate how the algorithm handles left turns. The bridge edge between S_4 and S_5 forms a left turn relative to the previous dotted bridge edge, so both are popped and a new bridge edge is found between S_3 and S_5. This is repeated until no left turns are formed, giving the solid purple line. Finally, the bridge edges do not close the hull in some blocks, which is where we run the quantum Jarvis march to find the edges of the upper hull shown in red.

Algorithm 7 QuantumConvexHull(U_{in}).

Require: U_{in}: A unitary that encodes the lexicographically sorted data $[d_0, \ldots, d_{n-1}]$

Let $h = 4$.
while True **do**
  $B =$ `FindBridgeEdges`(h)
  for $j \in [0, 1, \ldots, h-1]$ **do**
    `QuantumBlockJarvisMarch`(j, h, B)
  if the total number of points found exceeds h **then**
    $h = 2h$
  else
    Print all the points in the output register of each block and terminate the loop.

▶ **Theorem 7.** *There is a quantum algorithm for finding the convex hull of a set of n points in lexicographic order that runs in $\tilde{O}(\sqrt{nh})$ time, where h is the size of the output.*

Proof. As observed, the outer loop will run at most $\log n$ times. By lemma 5, `FindBridgeEdges` takes $\tilde{O}(\sqrt{nh})$ time. By lemma 6, `QuantumJarvisMarch` takes $\tilde{O}(h_j\sqrt{n/h})$ time for block S_j, where h_j is the number of points from S_j that lie on the convex hull of the entire points set S. Since $\sum_j h_j \leq h$, the total running time for all the calls to `QuantumJarvisMarch` is $\tilde{O}(\sqrt{nh})$. Finally, printing the h discovered points takes $O(h)$ time. ◀

In an appendix, we give a lower bound for quantum convex hull that shows our algorithm is optimal up to polylogarithmic factors.

5 Discussion

Afshani, Peyman, and Chan [1] give an instance-optimal classical algorithm for finding 2D convex hulls, which adapts the algorithm by Kirkpatrick and Seidel [22] to run in $O(n(\mathcal{H}(S)+1))$ time, where $\mathcal{H}(S)$ is a classical-computing structural entropy measure that is never more than $O(\log h)$. An interesting direction for future work would be to determine if there is a quantum convex hull algorithm that is instance optimal based on a quantum structural entropy measure.

Abstract

In this work, we explore a non-linear extension of the classical Sylvester-Gallai configuration. Let $\mathbb{K}$ be an algebraically closed field of characteristic zero, and let $\mathcal{F} = \{F_1, \ldots, F_m\} \subset \mathbb{K}[x_1, \ldots, x_N]$ denote a collection of irreducible homogeneous polynomials of degree at most d, where each F_i is not a scalar multiple of any other F_j for $i \neq j$. We define $\mathcal{F}$ to be a product Sylvester-Gallai configuration if, for any two distinct polynomials $F_i, F_j \in \mathcal{F}$, the following condition is satisfied:

$$\prod_{k \neq i,j} F_k \in \mathrm{rad}\,(F_i, F_j)\,.$$

We prove that product Sylvester-Gallai configurations are inherently low dimensional. Specifically, we show that there exists a function $\lambda : \mathbb{N} \to \mathbb{N}$, independent of $\mathbb{K}$, N, and m, such that any product Sylvester-Gallai configuration must satisfy:

$$\dim(\mathrm{span}_{\mathbb{K}}(\mathcal{F})) \leq \lambda(d).$$

This result generalizes the main theorems from (Shpilka 2019, Peleg and Shpilka 2020, Oliveira and Sengupta 2023), and gets us one step closer to a full derandomization of the polynomial identity testing problem for the class of depth 4 circuits with bounded top and bottom fan-in.

1 Introduction

In 1893, Sylvester posed the following basic problem in extremal combinatorial geometry.

▶ **Problem 1** ([49]). *Suppose a finite set of real points are arranged such that any line through two points of the set contains a third point in the set. Prove that the set of points lies on a straight line.*

The first complete affirmative answer to Problem 1 was given by Melchior [35]. The same problem was independently posed in 1943 by Erdős [17], and was answered by Gallai [20]. The above statement is now known as the Sylvester-Gallai theorem.

It is important to note that the answer to Sylvester's problem depends on the base field. For instance, it was known (quite possibly even to Sylvester) that the answer to Problem 1 is negative when the base field is $\mathbb{C}$, as the nine inflection points of any non-singular planar cubic form a 2-dimensional complex configuration satisfying Sylvester's conditions. In 1966, Serre asked in [46] whether any complex configurations satisfying Sylvester's conditions must be 2-dimensional – that is, whether the configurations arising from non-singular planar cubics are extremal. An affirmative answer to Serre's question was given in 1983 by Hirzebruch [29], using highly non-elementary algebro-geometric tools.

Ever since the solution of Sylvester's problem, several generalizations and variations have been studied in combinatorial geometry, theoretical computer science (TCS) and coding theory [15, 27, 42, 16, 7, 13, 39, 40] – see [9, 12] for brief surveys on these generalizations. The usual setup of such generalizations is as follows: given a *finite* collection of geometric objects (points, in the case of Sylvester's problem) satisfying *enough* **local conditions** (collinearity of certain triples of points, in the case of Problem 1), one wants to know if such collection of geometric objects must be "*low dimensional*" (all points must be in one line, in the case of Problem 1). As is usual in the literature, any configuration satisfying the proposed local conditions are called *Sylvester-Gallai configurations*, and the result stating that such configurations are low dimensional is referred to as a *Sylvester-Gallai* type theorem.

One line of generalizations of Problem 1 arises from projective duality, which we now discuss. By projective duality, any point $P = (p_1, \ldots, p_N)$ gives rise to a dual hyperplane, defined by the zero set of the linear form $\ell_P := p_1 x_1 + \cdots + p_N x_N$, which we denote by $V(\ell_P)$. Given three points P, Q, R, the condition that R is in the line defined by P, Q is equivalent to $V(\ell_P, \ell_Q) \subset V(\ell_R)$ in the dual space. Lastly, given points $P_1, \ldots, P_m$, the condition that they are collinear is equivalent to $\dim \operatorname{span}_{\mathbb{R}} \{\ell_{P_1}, \ldots, \ell_{P_m}\} = 2$. Thus, we can recast Sylvester's problem as follows: given a finite set of distinct hyperplanes defined by the set of linear forms $\mathcal{L} := \{\ell_1, \cdots, \ell_m\} \subset \mathbb{R}[x_1, \ldots, x_N]$ such that for any $i \neq j \in [m]$, there is $k \neq i, j$ such that $V(\ell_i, \ell_j) \subset V(\ell_k)$, then it must be the case that $\dim \operatorname{span}_{\mathbb{R}} \{\mathcal{L}\} = 2$. For simplicity, if one applies projective duality in two dimensions, the foregoing statement becomes quite natural: given a finite set of distinct lines (the set $\mathcal{L}$) such that for any two lines $\ell_i, \ell_j \in \mathcal{L}$, there must be a third line in $\mathcal{L}$ which passes through the intersection of ℓ_1, ℓ_2 (i.e., $V(\ell_1, \ell_2)$), then it must be the case that the set of lines forms a pencil (i.e., all lines intersect at a common point). In fact, this dual formulation was precisely the setting treated in [29].

Motivated by questions in algebraic complexity theory, Gupta [24] proposed non-linear, algebro-geometric generalizations to the above (dual) formulation of Sylvester's problem (and their set variants, such as [15]). In this work, we make progress on Gupta's program and fully resolve one such generalization of Sylvester's problem. Before we describe our main result, in the following subsection we describe the connection between the Sylvester-Gallai configurations that we study and the Polynomial Identity Testing (PIT) problem, a fundamental problem in algebraic complexity theory.

1.1 Polynomial Identity Testing (PIT) and Sylvester-Gallai configurations

The Polynomial Identity Testing (PIT) problem is the task of determining whether a given algebraic circuit computes the zero polynomial. While there are simple and efficient randomized algorithms for the PIT problem, developing an efficient deterministic solution remains a significant open problem in theoretical computer science. The PIT problem is

closely tied to fundamental topics such as lower bounds for algebraic circuits [28, 2, 30] and derandomizing key problems in mathematics and computer science [3, 19, 33, 36, 26, 18]. For a deeper exploration of PIT and its applications, see [43, 48, 44].

The recent works [1, 25, 50] have shown that the PIT problem for general circuits can be reduced to solving it for low-depth circuits, such as unrestricted depth-3 or homogeneous depth-4 circuits, which has made these circuit classes a focus of recent study. Notably, progress has been made towards deterministic, polynomial-time PIT for depth-3 circuits of constant top fanin via the connection between this problem and linear Sylvester-Gallai configurations arising from depth-3 identities [14, 32, 45].

Let us now explain how Sylvester-Gallai configurations arise in the context of depth-3 and depth-4 PIT. Let $\mathbf{x} := (x_1, \ldots, x_N)$ be a tuple of N variables and $S := \mathbb{C}[\mathbf{x}]$ be the polynomial ring in N variables. Suppose we are given a depth three circuit with top fan-in three (denoted $\Sigma^3\Pi\Sigma$) that computes a polynomial P. Such a polynomial has the form

$$P = \prod_{i=1}^{m} \ell_i(\mathbf{x}) + \prod_{j=1}^{m} g_j(\mathbf{x}) + \prod_{k=1}^{m} h_k(\mathbf{x}), \tag{1}$$

where ℓ_i, g_j, h_k are linear forms. When $P \equiv 0$, that is, when we have an identity, and moreover this representation of the identity is "efficient,"[1] we may wonder whether the linear forms in the identity must be "low dimensional" (i.e., all such linear forms must "depend on few variables"). To capture the dimensionality of the circuit given by Equation (1), [14] defined the *rank* of the circuit as being the linear span of the forms that appear in the circuit. In case of Equation (1), we have that the rank is $\dim \operatorname{span}_{\mathbb{C}} \{\ell_i, g_j, h_k\}_{i,j,k\in[m]}$.

Consider a linear form ℓ_i from the first gate and a second linear form g_j from the second gate. Since $P \equiv 0$, we have that for any $\mathbf{a} \in \mathbb{C}^N$ such that $\ell_i(\mathbf{a}) = g_j(\mathbf{a}) = 0$, it must be the case that $\prod h_k(\mathbf{a}) = 0$. In other words, we have that $V(\ell_i, g_j) \subset V\left(\prod h_k\right) = \bigcup_k V(h_k)$. Since the algebraic set $V(\ell_i, g_j)$ is irreducible, we must have $V(\ell_i, g_j) \subset V(h_a)$ for some $a \in [m]$. Note that this last condition (combined with the symmetry among the gates) is exactly the local constraint arising from the dual formulation of Sylvester's problem. In [14], the authors asked whether sets $\{\ell_i\}_{i\in[m]}, \{g_j\}_{j\in[m]}, \{h_k\}_{k\in[m]}$ arising from Equation (1) which satisfy the above conditions must be low-dimensional – more precisely, whether $\dim \operatorname{span}_{\mathbb{C}} \{\ell_i, g_j, h_k\}_{i,j,k} = O(1)$.

As it turns out, the Sylvester-Gallai like condition in the previous paragraph can be seen as a set-version of Sylvester's problem, which was studied by [15]. This work showed that such configurations must have constant rank. Thus, we deduce that $\operatorname{span}_{\mathbb{C}} \{\ell_i, g_j, h_k\} = O(1)$. This shows that any $\Sigma^3\Pi\Sigma$ identity essentially depends on constantly many variables. Combined with the results of [31], this gives a black box deterministic PIT algorithm for such circuits. While significantly extra complexity and subtleties arise when one works with $\Sigma^k\Pi\Sigma$ circuits for $k > 3$, the linear forms in "efficient" identities arising from such circuits satisfy enough local relationships to deduce that they have low rank. This approach was carried out by [32, 45], who generalized the above approach and showed an intrinsic and elegant connection between $\Sigma^k\Pi\Sigma$ identities and Sylvester-Gallai configurations (see [45, Theorem 1.4]). As a result of this connection, Sylvester-Gallai theorems imply deterministic, polynomial-time PIT algorithms for $\Sigma^k\Pi\Sigma$ circuits, when $k = O(1)$.

Motivated by these results, Gupta [24] studied depth four circuits with constant top and bottom fan-ins. This circuit family is denoted $\Sigma^k\Pi\Sigma\Pi^d$, and it computes polynomials which can be written as a sum of k products of polynomials of degree at most d.

[1] The formal definition of efficient is simple and minimal, as defined in [32].

Consider a polynomial Q computed by a $\Sigma^3\Pi\Sigma\Pi^d$ circuit. It has the form

$$Q = \prod_{i=1}^{m_1} A_i(\mathbf{x}) + \prod_{j=1}^{m_2} B_j(\mathbf{x}) + \prod_{k=1}^{m_3} C_k(\mathbf{x}),$$

where A_i, B_j, C_k are polynomials of degree at most d. If $Q \equiv 0$ and the representation is efficient, as in the previous case, we have $V(A_i, B_j) \subseteq V\left(\prod C_k\right)$.[2] However, as the forms are not necessarily linear, we have that $V\left(A_i, B_j\right)$ is not necessarily irreducible, and thus we no longer have the same Sylvester-Gallai type configuration, as we cannot guarantee the existence of $k \in [m]$ such that $V\left(A_i, B_j\right) \subset V\left(C_k\right)$. Nevertheless, as there are many constraints of the form $V(A_i, B_j) \subseteq V\left(\prod C_k\right)$, [24] asked whether such Sylvester-Gallai type conditions would be enough to prove that $\dim \operatorname{span}_{\mathbb{C}} \{A_i, B_j, C_k\}_{i,j,k}$ is small enough.

Given any "efficient" $\Sigma^3\Pi\Sigma\Pi^d$ circuit (not necessarily computing the zero polynomial), [24] called it a Sylvester-Gallai circuit if the above constraints on the zerosets (i.e. $V(A_i, B_j) \subseteq V\left(\prod C_k\right)$) hold. The above discussion shows that all such circuits that compute 0 are Sylvester-Gallai circuits, but the converse is not true: for instance, multiplying a single form by a constant can change whether or not the circuit computes 0 without changing the above condition.

Non Sylvester-Gallai circuits are relatively simple compared to Sylvester-Gallai circuits. Non Sylvester-Gallai circuits do not have too many cancellations (the above discussion shows that they can never compute 0), and the circuit structure can be preserved by certain linear variable reduction maps, which is the main tool used in the works [24, 23] to handle these circuits. This allows these works to certify the non-zeroness of non-Sylvester-Gallai circuits.

The cancellations in Sylvester-Gallai circuits on the other hand are a lot more subtle, and it is not clear if they are preserved by the linear maps of [24, 23]. Similar to how linear Sylvester-Gallai configurations have constant rank, Gupta conjectured that sets of higher degree forms satisfying the local condition $V(A_i, B_j) \subset V\left(\prod_k C_k\right)$ must "depend on constantly many variables." If this is true, then we can efficiently test if Sylvester-Gallai circuits are nonzero using the methods of [8]. A simpler form of Gupta's main conjecture is the following generalization of the configurations studied in [15]:

▶ **Conjecture 2** (Gupta's main conjecture - simple form). *Let $\{A_i\}_{i\in[m_1]} \cup \{B_j\}_{j\in[m_2]} \cup \{C_k\}_{k\in[m_3]}$ be a set of irreducible polynomials of degree $\leq d$ such that for any $i \in [m_1], j \in [m_2]$, we have that $V\left(A_i, B_j\right) \subseteq V\left(\prod_k C_k\right)$ (and the same relations hold when exchanging the roles of the polynomials A, B, C). Then there exists a function $\lambda : \mathbb{N} \to \mathbb{N}$ such that*

$$\dim \operatorname{span}_{\mathbb{C}} \{A_i, B_j, C_k\}_{i,j,k} \leq \lambda(d).$$

A first step towards establishing the above conjecture is to establish the Sylvester-Gallai version of the above conjecture. This motivates us to consider the Sylvester-Gallai configurations we study in this article, which we now define. By way of the algebraic-geometric dictionary, we will henceforth replace the geometric condition $V\left(A, B\right) \subset V\left(C\right)$ by the equivalent algebraic condition $\operatorname{rad}\left(C\right) \subset \operatorname{rad}\left(A, B\right)$.

▶ **Definition 3** (Product Sylvester–Gallai configurations). *A finite set $\mathcal{F} \subset \mathbb{C}\left[x_1, \ldots, x_N\right]$ of irreducible forms of degree at most d is a* d-product-SG-configuration *if the following hold.*

- *$F_i \notin (F_j)$ for any $F_i, F_j \in \mathcal{F}$.* *(each form encodes a different hypersurface)*
- *For each $F_i, F_j \in \mathcal{F}$, we have* *(Sylvester-Gallai condition)*

$$\prod_{F\in\mathcal{F}\setminus\{F_i,F_j\}} F \;\in\; \operatorname{rad}\left(F_i, F_j\right).$$

[2] By symmetry among the gates, we also have $V(A_i, C_k) \subseteq V\left(\prod B_j\right)$ and $V(B_j, C_k) \subseteq V\left(\prod A_i\right)$.

As stated above, the reader may find it strange that the product constraint no longer seems local, since the condition for each F_i, F_j involves every other form in the configuration. However, by a standard Bézout type argument it follows that the condition $\prod_{F\in\mathcal{F}\setminus\{F_i,F_j\}} F \in \operatorname{rad}(F_i, F_j)$ is equivalent to the (local) condition that there are indices $k_1, \ldots, k_{d^2}$ different from i, j such that

$$\prod_{a=1}^{d^2} F_{k_a} \in \operatorname{rad}(F_i, F_j).$$

Since d is a constant, each (local) condition now only depends on constantly many forms in the configuration as expected. As this equivalent condition is more cumbersome to state, we prefer to work with the above definition.

In a similar fashion to [24], we can also conjecture that such "product" configurations are "low dimensional." This is the content of the following conjecture:

▶ **Conjecture 4** (Product Sylvester-Gallai Conjecture). *There is a function $\lambda : \mathbb{N} \to \mathbb{N}$ such that if $\mathcal{F}$ is a d-*product-SG-configuration *then* $\dim \operatorname{span}_{\mathbb{C}} \{\mathcal{F}\} = \lambda(d)$.

The above conjecture was first considered by [39], where the authors proved Conjecture 4 for $d = 2$. Our main theorem, which we now state, generalizes their main result to forms of every degree, thus fully settling Conjecture 4.

▶ **Theorem 5** (Product Sylvester-Gallai Theorem). *There is a function $\lambda : \mathbb{N} \to \mathbb{N}$ such that if $\mathcal{F}$ is a d-*product-SG-configuration *then* $\dim \operatorname{span}_{\mathbb{C}} \{\mathcal{F}\} = \lambda(d)$.

Our proof techniques build upon the techniques introduced in [47, 38] to study radical Sylvester-Gallai configurations, which we define in Section 1.3. In Section 1.3 we also discuss related and previous works on non-linear Sylvester-Gallai configurations and the PIT problem for depth-4 circuits. In Section 1.4, we give a high level outline of our proof, highlighting the technical difficulties that need to be overcome, as well as the new conceptual contributions of this work. We will now discuss the main contributions of this work, where we state our main technical result, which is of independent interest. Formal statements and proofs of all claims can be found in the full version of this paper.

1.2 Contributions of this paper

This paper has two main contributions. The first is the proof of Theorem 5, which states that product Sylvester-Gallai configurations of degree bounded by d have dimension uniformly upper bounded by a function which depends only on d. This result simultaneously generalizes [47, 39, 38], putting us one step closer towards a proof of Conjecture 2, and also to the main conjecture of Gupta [24]. To achieve this, we adapt the inductive approach from [38] to work with product configurations. This adaptation, as we discuss in Section 1.4, requires us to deal with several subtleties, one of them being to establish a useful property of the general quotients of [47, 38]: we prove that such general quotients behave well with respect to (a generalized notion of) absolute irreducibility. More precisely, we prove that that these quotients send *absolutely reducible* forms to *reducible* elements, and that forms which are *absolutely irreducible* over the vector space being quotiented out will *remain absolutely irreducible* after a general quotient.

The second contribution is our main technical result which relates absolute irreducibility of a polynomial P with an *effective and uniform bound* on the non-primality of certain ideals containing P. In a simplified form, it can be stated as:

▶ **Theorem 6** (Prime bound - informal). *Let* $S := \mathbb{C}[x_1, \ldots, x_N, y_1, \ldots, y_n]$ *and* $P \in S \setminus (x_1, \ldots, x_N)$ *be a form of degree* d *that is irreducible over* $\overline{\mathbb{C}(x_1, \ldots, x_N)}[y_1, \ldots, y_n]$. *The number of non-associate irreducible forms* $Q \in \mathbb{C}[x_1, \ldots, x_N]$ *such that* (P, Q) *is not prime is bounded above by a function of* d.

We believe that the above theorem, and its more general version (which can be found in the full version), together with its proof, are of independent interest. We now briefly discuss the ingredients needed in the proof of the above theorem. If one only combines results from Gröbner basis theory and elimination theory with techniques from algebraic geometry, one can obtain an effective bound for the above theorem which depends on N, n and d. Since the goal of a Sylvester-Gallai theorem is to obtain bounds *independent of the number of variables*, such a bound will not be good enough for our purposes. By combining the Stillman's uniformity bounds of [5] with results from elimination theory and algebraic geometry, we are able to obtain an effective bound (depending only on n, d) on the number of non-associate irreducible forms Q such that (P, Q) is not prime.

Once the dependence on N has been removed and a finite bound on the number of (non-associate) bad forms Q has been established, we can then use Bertini's theorem and the Ananyan-Hochster principle to further drop the dependency on n, finally obtaining a bound which simply depends on the degree d. To achieve this, we give very effective bounds on the degrees of generators of Gröbner bases for ideals generated by a small number of variables of low degree, and also for certain elimination ideals of such ideals. These bounds could be of independent interest.

An important point to note is that [38] builds on the Ananyan-Hochster principle to show their transfer theorems, which we also use. However, to prove the above theorem, we also need to apply the Ananyan-Hochster principle in a different manner: combined with results from Gröbner basis theory, we use it to find low degree polynomials in elimination ideals of ideals generated by a small number of low degree forms.

1.3 Related Work

1.3.1 Sylvester-Gallai configurations

In [24], as a first step of his plan, Gupta proposed the study of a direct generalization of the linear Sylvester-Gallai configurations, which are captured by the following definition.

▶ **Definition 7** (Radical Sylvester–Gallai configuration). *Let* $\mathcal{F} \subset \mathbb{C}[x_1, \ldots, x_N]$ *be a finite set of irreducible forms of degree at most* d. *We say that* $\mathcal{F}$ *is a* d*-radical Sylvester-Gallai configuration if the following hold.*

- $F_i \notin (F_j)$ *for any* $F_i, F_j \in \mathcal{F}$.
- *For every* $F_i, F_j \in \mathcal{F}$, *we have* $F_k \in \operatorname{rad}(F_i, F_j)$ *for some* $F_k \in \mathcal{F} \setminus \{F_i, F_j\}$.

The following conjecture is a strengthening of [24, Conjecture 2].

▶ **Conjecture 8** (Radical Sylvester-Gallai conjecture). *There is a function* $\lambda : \mathbb{N} \to \mathbb{N}$ *such that if* $\mathcal{F}$ *is a* d*-radical Sylvester-Gallai configuration then* $\dim \operatorname{span}_{\mathbb{C}} \{\mathcal{F}\} = \lambda(d)$.

Conjecture 8 was proved by [47] in the special case when $d = 2$. Subsequently, [37] proved Conjecture 8 for $d = 3$, and [38] fully resolved the above conjecture in the affirmative. Note that the condition $F_k \in \operatorname{rad}(F_i, F_j)$ for forms of degree d is a natural generalization of the condition $\ell_k \in (\ell_i, \ell_j)$: by the Nullstellensatz, these conditions are equivalent to $V(F_k) \supset V(F_i, F_j)$ and $V(\ell_k) \supset V(\ell_i, \ell_j)$ respectively. Therefore Conjecture 8 is a direct generalisation of the usual Sylvester-Gallai theorem for forms of higher degrees.

The first work to consider product Sylvester-Gallai configurations was the work of [39], where the authors settled Conjecture 4 for quadratic forms. In follow up work [40], the same authors settled Conjecture 2 for the case when $d = 2$, therefore proving that Gupta's PIT algorithm runs in deterministic, poly-time for $\Sigma^3\Pi\Sigma\Pi^2$ circuits. Note that the above path in the proofs of Sylvester-Gallai type results is a natural path towards resolving the PIT problem for $\Sigma^3\Pi\Sigma\Pi^d$ circuits, since Conjecture 8 follows from Conjecture 4, and it can be shown that Conjecture 2 would follow from a robust version of Conjecture 4.

Robust and higher dimensional generalizations of the radical Sylvester-Gallai theorems have also been studied by the works [41, 22, 21]. Aside from settling such interesting questions in extremal combinatorial geometry, such variations are also motivated by the PIT problem for depth-4 circuits, in the hope that these more general versions may be useful towards obtaining a (potentially simpler) proof of Gupta's conjectures.

1.3.2 PIT for depth four circuits

Depth-4 circuits with bounded top fan-in are among the "easiest" classes for which we do not have deterministic, poly-time PIT algorithms. There has thus been some work on deterministic PIT for these circuits using methods other than the Sylvester-Gallai based methods discussed above.

In [11], the authors give a quasipolynomial time PIT algorithm for depth 4 circuits of bounded top and bottom fanins, via the Jacobian method of [4]. By using the logarithmic derivative and its power series, they are able to modify the top sum gate in the circuit to a powering gate.

The breakthrough work of [34] on lower bounds for bounded depth circuits gives another approach to PIT for this model. Hardness-randomness tradeoffs have been well studied in algebraic complexity [2, 30], and the work of [10] showed that these tradeoffs also hold in the bounded depth setting. Combining these results gives a subexponential time PIT algorithm for depth four circuits. Based on the lower bounds of [34], a hitting set generator for bounded depth circuits was constructed by [6], which gives another subexponential time PIT algorithm for depth four circuits, with improved parameters.

It is important to note that neither of the above methods seem to be able to give a truly polynomial time algorithm for the PIT problem for $\Sigma^k\Pi\Sigma\Pi^d$ circuits. The only currently known method that might do so is the approach of [24].

1.4 High-level proof overview

In this subsection we provide an overview of the proof of our main result, Theorem 5. We begin by outlining the high-level approach used in previous works to bound the dimension of the span of radical Sylvester-Gallai configurations and discuss the challenges of applying this method in our context. Next, we describe the tools that we employ to address these challenges. Finally, we provide a concise summary of how these components are combined to establish our main theorem.

To illustrate the ideas in this overview, we use a special case of product Sylvester-Gallai configurations with a simplifying assumption as an example. In the final part of this subsection, we explain how this assumption can be eliminated to extend the argument to the general case.

1.4.1 High-level approach

At a high level, our proof uses a similar approach as the previous works on higher degree Sylvester-Gallai configurations [47, 39, 40, 41, 21, 38], which we now summarize.

Let $R := \mathbb{C}[x_1, \ldots, x_N]$, and $S := R[y_1, \ldots, y_n]$ be two polynomial rings and $\mathcal{F} \subset S$ be a radical (or product) Sylvester-Gallai configuration, where the forms in $\mathcal{F}$ have degree at most d. Thus, we can write $\mathcal{F} = \mathcal{F}_1 \cup \cdots \cup \mathcal{F}_d$, where $\mathcal{F}_e$ are the forms in $\mathcal{F}$ of degree e. We start with the assumption that each form only depends on constantly many variables in S. A number of key ideas can already be highlighted in this easier setting.

We want to control the highest degree forms $\mathcal{F}_d$ in our configuration, with the goal of reducing to the case when the highest degree is $d-1$, where we can proceed inductively.

If many ideals of the form (F_i, F_j), where $F_i, F_j \in \mathcal{F}_d$, are radical (or prime), then the set $\mathcal{F}_d$ is essentially a (robust) linear Sylvester-Gallai configuration. In this case, the linear Sylvester-Gallai theorems imply that constantly many forms $F_1, \ldots, F_a$ are a basis for $\operatorname{span}_{\mathbb{C}}\{\mathcal{F}_d\}$, and if $x_1, \ldots, x_r$ is the union of the set of variables of $F_1, \ldots, F_a$, then $\mathcal{F}_d \subset \mathbb{C}[x_1, \ldots, x_r]$. This is sufficient to control the forms of $\mathcal{F}_d$ and apply our inductive step. The interesting case is thus when there are many ideals generated by forms in $\mathcal{F}_d$ that are not radical (or prime). In this case, the goal is to show that the forms in $\mathcal{F}_d$ must share many variables in common. The steps listed below show how previous works have dealt with this case.

1. First, one devises a structure theorem on ideals that are not radical (or prime). In principle, such structure theorems show that if an ideal generated by two polynomials is not radical (or not prime), then the variables appearing in the polynomials must have some special "dependencies".
2. Next, combine the structure theorem with the local conditions to show the existence of constantly many "good variables" $x_1, \ldots, x_b$ such that $\mathcal{F}_d \subset (x_1, \ldots, x_b)$.
   In this step, our approach differs from previous works, as in a product configuration, it may not be possible to directly achieve this high level of control on the forms in $\mathcal{F}_d$. We discuss this in more detail in Step 2 below.
3. Finally, we "randomly project" (i.e., apply a general quotient) the special variables $x_1, \ldots, x_b$ to a new variable z in order to reduce the degree of the forms in $\mathcal{F}_d$.
   Also, in this step our approach will differ from previous works. Instead of reducing degree directly, we will make the forms in $\mathcal{F}$ "*factor more*."

We now elaborate on this approach, pointing out the new difficulties we face in this work, and sketch how we deal with these issues.

1.4.1.1 Step 1 – Structure theorems

Earlier works ([47, 37]) gave fairly strong classification of ideals that are not radical in the first step. In particular, they consider the possible minimal primes that a non-radical ideal of the form (P, Q) can have, and possible multiplicities that these minimal primes can have, giving a structural result for each of these cases. However this strategy is hard to generalise beyond the case of ideals generated by two cubics, since these ideals have very high degree and their primary decomposition becomes much more complex as the degree grows.

Subsequent work by [38] used a significantly weaker (albeit more general) structure theorem, and showed that this suffices to carry out the strategy above. The structure theorem in [38] is the following. If $P \in S$ is an irreducible form of degree d that is not in the ideal $(x_1, \ldots, x_N)$, then there are at most $3d^3$ square-free forms $Q_i \in R$ such that (P, Q_i) is not radical. Informally, this statement says that if a form P depends non-trivially on some

variable(s) y_i, then (P, Q) must be radical for almost every polynomial Q that only depends on $x_1, \ldots, x_N$.

For product Sylvester-Gallai configurations, the ideals of interest are those that are not prime. One could hope to generalize the structural result from [38] to this setting. However, a statement of the above form is no longer true here. Take the form $P = y_1^4 - x_1 x_2 y_2^2$. This form depends on the variables y_1, y_2. However, for every irreducible linear form $Q \in R$, the ideal $\left(P, x_1 x_2 - Q^2\right)$ is not prime, even though P and $x_1 x_2 - Q^2$ are irreducible. This is our first technical difficulty.

We overcome this by showing that the above only happens because P is reducible as a form in $\overline{\mathbb{C}\left(x_1, \ldots, x_N\right)}\left[y_1, y_2\right]$, since it factors as $P = \left(y_1^2 - \sqrt{x_1 x_2} y_2\right)\left(y_1^2 + \sqrt{x_1 x_2} y_2\right)$. This is where our first key conceptual and technical contribution comes in. We show that for any degree d form in $R[y_1, \ldots, y_m]$ that is irreducible in $\overline{\mathbb{C}\left(x_1, \ldots, x_N\right)}\left[y_1, \ldots, y_n\right]$ (such forms are called absolutely irreducible over $R[y_1, \ldots, y_m]$), there are only finitely many $Q_i \in R$ such that (P, Q_i) is not prime.

A fairly subtle issue remains in the above statement. In order to solve the product Sylvester-Gallai problem, we need quantitative bounds on the number of "bad forms" Q_i. Moreover, we need a bound which is solely a function of $\deg(P)$. If we use standard techniques from commutative algebra and algebraic geometry, we obtain bounds which depend on the number of variables (that is: N, n) and on $\deg(P)$. This is not sufficient for us, as we want to show that $\dim \operatorname{span}_{\mathbb{C}} \{\mathcal{F}\}$ does not depend on the number of variables in the polynomial ring. To prove that the number of bad forms is in fact *independent* of N and n, we need to work a bit harder, and we need to make use of two additional tools: Bertini-type theorems (to remove the dependence on n), and the Ananyan-Hochster construction of small strong subalgebras (this will remove the dependence on N). This yields, in its basic form, Theorem 6, which we discussed in Section 1.2.

1.4.1.2 Step 2 – Finding a small set of "good common variables"

Suppose $\mathcal{F}$ is a radical Sylvester-Gallai configuration. By the above, we can assume that $\mathcal{F}_d$ is not a robust linear Sylvester-Gallai configuration. Our assumption implies that for many pairs F_i, F_j, the ideal (F_i, F_j) is not radical. In particular, for a small $0 < \varepsilon < 1$, we can find $3d^3$ forms $F_1, \ldots, F_{3d^3} \in \mathcal{F}_d$ such that $(\mathcal{F}_i, \mathcal{F}_j)$ is not radical for $i \leq 3d^3$ and $j \leq (1-\varepsilon)\left|\mathcal{F}_d\right|$. The radical bound mentioned in Step 1 shows that there is $a \in O(1)$ and an ideal generated by linear forms $(\ell_1, \ldots, \ell_a)$ that contains every such F_j. Repeating this argument, we can find an ideal $(\ell_1, \ldots, \ell_b)$ with b constant such that $\mathcal{F}_d \subset (\ell_1, \ldots, \ell_b)$.

When $\mathcal{F}$ is a product Sylvester-Gallai configuration a number of issues arise: first, our structure theorem deals with prime ideals (instead of radical) and our assumptions are that the forms are absolutely irreducible. Hence, we will only be able to draw the following weaker conclusion: there are constantly many variables $x_1, \ldots, x_b$ such that every $F \in \mathcal{F}_d$ is either in $(x_1, \ldots, x_b)$, or absolutely reducible in the ring $S' := \mathbb{C}\left(x_1, \ldots, x_b\right)\left[x_{b+1}, \ldots, x_N, y_1, \ldots, y_n\right]$. Therefore, when we apply the general quotient (i.e. a random projection), we can no longer guarantee that the degree of our forms reduce. We deal with this issue by changing the way we "decompose" the configuration $\mathcal{F} = \mathcal{F}_1 \cup \cdots \cup \mathcal{F}_d$. This is a key difference between our approach and previous approaches, since this issue does not arise when studying radical Sylvester-Gallai configurations. This new decomposition also allows us to solve an issue that arises when we apply the general quotient. We now state this issue, and discuss the solution.

1.4.1.3 Step 3 – General quotients & degree reduction/lowering degree

The image of an irreducible form under a projection map can be reducible. In order to apply induction, the definition of product Sylvester-Gallai configurations has to be generalised to allow the forms in $\mathcal{F}$ to be reducible. Hence, we update our definition of product Sylvester-Gallai configurations to the following.

▶ **Definition 9** (Product Sylvester–Gallai configurations). *A finite set $\mathcal{F} \subset \mathbb{C}[x_1, \ldots, x_N]$ of forms of degree at most d is a* d-product-SG-configuration *if the following hold.*

- $\gcd(F_i, F_j) = 1$ *for all* $i \neq j$.
- *For every* $F_i, F_j \in \mathcal{F}$, *we have* $\displaystyle\prod_{F \in \mathcal{F} \setminus \{F_i, F_j\}} F \in \operatorname{rad}(F_i, F_j)$.

This generalisation already appears in [38], where reducibility is not an issue when dealing with radical ideals, since the radical bound also applies to reducible forms. The prime bound however can no longer apply, irrespective of any assumption: if P is reducible then (P, Q) can never be prime. In particular, if every form in $\mathcal{F}_d$ is reducible, then we can draw no conclusion about $\mathcal{F}_d$ using the above ideas.

We tackle both these issues by turning this reducibility into an advantage: instead of trying to reduce the degree as in the inductive approaches of [47, 38, 39], we will try and make the forms in our configuration "factor more".

In order to formalise what we mean by "factor more", we introduce the notion of factor sets of a product configuration. Given a (generalized) product Sylvester-Gallai configuration $\mathcal{F}$, we define the factor set $\mathcal{I}$ of $\mathcal{F}$ to be the set of irreducible factors of all forms in $\mathcal{F}$. As before, we write $\mathcal{I} = \mathcal{I}_1 \cup \cdots \cup \mathcal{I}_c$, where $\mathcal{I}_j \subset S_j$.

If every form in $\mathcal{F}$ factors a lot, then all the forms in $\mathcal{I}$ will have low degree. We will induct on the highest integer c such that $\mathcal{I}_c$ is nonzero. Now, the set of "common variables" we look for will not be variables common to $\mathcal{F}_d$, but variables common to $\mathcal{I}_c$. The absolute irreducibility condition remains, and we end up with variables $x_1, \ldots, x_b$ such that every form in $\mathcal{I}_c$ is either in the ideal $(x_1, \ldots, x_b)$ or absolutely reducible. We postpone the discussion of how we do this step to the next subsection. We now show how these common variables are used in the rest of the induction step.

Step 2 lets us find the "common variables" $x_1, \ldots, x_b$. Define a projection map φ that maps each x_i for $1 \leq i \leq b$ to a random multiple of a new variable z, and acts as identity on the other variables. If $F \in (x_1, \ldots, x_b)$ then $\varphi(F) = zF'$, where $\deg(F') < \deg(F)$. We define $\varphi(\mathcal{F})$ to be the image of $\mathcal{F}$ under φ, after factoring out powers of z. Such a projection map preserves radical and product Sylvester-Gallai structure, and also allows bounds on the dimension of $\varphi(\mathcal{F})$ to be lifted back to bounds on the dimension of $\mathcal{F}$.

If we have $\mathcal{F}_d \subset (x_1, \ldots, x_b)$ (as in the case of radical Sylvester-Gallai configurations) then $\varphi(\mathcal{F})$ is a Sylvester-Gallai configuration with forms of degree at most $d - 1$, and induction can be applied. If on the other hand $\mathcal{F}$ is a product Sylvester-Gallai configuration, then we have the weaker condition that every $F \in \mathcal{I}_c$ is either in $(x_1, \ldots, x_b)$ or absolutely reducible in S'. We show that the image of any F that is absolutely reducible in S' under the map φ is reducible. Thus, in either case we conclude that $\mathcal{I}'_c = \emptyset$, where $\mathcal{I}'$ is a factor set of $\varphi(\mathcal{F})$, and we can apply induction.

In the next subsection we show how we find these "common variables" in our setting. Note that we are still under the assumption that every form in $\mathcal{F}$ (and thus in $\mathcal{I}$) depends on only constantly many variables. We will also show how this assumption is removed.

1.4.2 Putting everything together

Let $\mathcal{F}$ be a product Sylvester-Gallai configuration of forms of degree at most d. We now allow forms in $\mathcal{F}$ to be reducible, but still require that they are square-free and are pairwise relatively prime. Let $\mathcal{I} := \mathcal{I}_1 \cup \cdots \cup \mathcal{I}_d$ be the set of irreducible factors of forms in $\mathcal{F}$. We will induct on the largest integer c such that $\mathcal{I}_c \neq \emptyset$. We first go over the base case in our induction.

Our base case is when every form $F_i \in \mathcal{F}$ is a product of linear forms, say $F_i = \prod_a \ell_{ia}$. In this case, $\mathcal{I} = \mathcal{I}_1 = \{\ell_{ia}\}_{i,a}$. Now suppose we pick ℓ_{ia} and ℓ_{jb} with $i \neq j$. The ideal (ℓ_{ia}, ℓ_{jb}) is a minimal prime of (F_i, F_j). Therefore, the product Sylvester-Gallai condition implies that $F_k \in (\ell_{ia}, \ell_{jb})$ for some k, which in turn implies that $\ell_{ke} \in (\ell_{ia}, \ell_{jb})$ for some choice of index e. This is a linear Sylvester-Gallai relationship among the elements of $\mathcal{I}_1$. The choice of ℓ_{ia}, ℓ_{jb} was arbitrary, except the condition that $i \neq j$. Therefore, the set $\mathcal{I}_1$ is a robust linear Sylvester-Gallai configuration, and therefore has bounded rank. This in turn implies that the forms in $\mathcal{F}$ have bounded rank, since they are spanned by monomials of degree at most d in a basis for $\mathcal{I} = \mathcal{I}_1$.

We now sketch the induction step. Suppose c is the largest integer such that $\mathcal{I}_c \neq \emptyset$. Our induction step is further split into two steps, as discussed in the previous subsection.

1. First we show that there are variables $x_1, \ldots, x_b$ such that every form in $\mathcal{I}_c$ is either in the ideal $(x_1, \ldots, x_b)$ or absolutely reducible in $S' := \mathbb{C}(x_1, \ldots, x_b)[x_{b+1}, \ldots, x_N, y_1, \ldots, y_n]$. This is a relaxed version of step 2 in the previous approach, applied to $\mathcal{I}_c$ instead of $\mathcal{F}_d$.
2. We then show that projecting $x_1, \ldots, x_b$ to a new variable z results in a product Sylvester-Gallai configuration with $\mathcal{I}_e = \emptyset$ for any $e \geq c$.

We elaborate on these in the special case when $c = 2$, since this already captures all the main ideas. As before, if $\mathcal{I}_2$ is a robust linear Sylvester-Gallai configuration, then step 2 follows easily by picking a basis for $\mathcal{I}_2$. Consider $A, B \in \mathcal{I}_2$, and suppose $A|F_i$ and $B|F_j$ for some $F_i, F_j \in \mathcal{F}$. Suppose (A, B) is prime. Then (A, B) is a minimal prime of (F_i, F_j). The product Sylvester-Gallai configuration implies $F_k \in (A, B)$ for some k, and therefore $C \in (A, B)$ for some $C|F_k$. Further, by homogeneity, it must be that $C \in \mathcal{I}_2$. This gives us a linear Sylvester-Gallai relationship between the elements $A, B, C \in \mathcal{I}_2$. The assumption that $\mathcal{I}_2$ is not a robust linear Sylvester-Gallai configuration will therefore imply that (A, B) is not prime for many pairs A, B. Since the forms in $\mathcal{I}_2$ are irreducible (even though the forms in $\mathcal{F}$ might not be), by a combinatorial argument and Theorem 6, we deduce the existence of variables $x_1, \ldots, x_b$, completing step 1 above.

We now move on to second step. Suppose φ is a projection map that sends $x_1, \ldots, x_b$ to random multiples of a new variable z. The map φ sends elements in $(x_1, \ldots, x_b)$ to multiples of z. We also prove that φ sends elements of $\mathcal{I}_2 \setminus (x_1, \ldots, x_b)$ that are absolutely reducible in S' to reducible forms. Since $c = 2$, the degree of each of these forms has to be 1. Therefore, if we apply φ to some $F \in \mathcal{F}$, every factor of F will be linear, even though it is possible that $\deg(F) = \deg(\varphi(F))$. This reduces the problem to the base case, and the properties of φ allow us to lift the resulting bound on the dimension of $\varphi(\mathcal{F})$ back to a bound on the dimension of $\mathcal{I}$.

1.4.2.1 Removing the initial assumption

We started with the assumption that every form in $\mathcal{F}$ depended only on constantly many variables. In general, it is of course possible that the forms depend on many or even all the variables. This issue was overcome in [38], building on the seminal work of [5]. They show that forms $H_1, \ldots, H_a$ of high enough strength behave essentially like variables, in

the sense that $\mathbb{C}[H_1, \ldots, H_a]$ is isomorphic to a polynomial ring. Further, the extension $\mathbb{C}[H_1, \ldots, H_a] \subset S$ has many of the properties that the extension $\mathbb{C}[x_1, \ldots, x_a] \subset S$ has, the most useful of them being that this extension preserves arbitrary intersection of ideals.

Motivated by this, [38] define the notion of strong vector spaces and algebras, which are vector spaces of small dimension spanned by forms of high rank, and the algebras they generate. They show that in the general case of the radical Sylvester-Gallai problem (when the forms depend on more than constantly many variables), while there might not be variables $x_1, \ldots, x_b$ such that $\mathcal{F}_d \subset (x_1, \ldots, x_b)$, we can find a strong vector space V such that $\mathcal{F}_d \subset (V)$.

The above change complicates the projection step, since random restriction of higher degree forms is no longer well defined. To fix this, [38] defined generalised projection maps, and again proved that such maps have all the properties that the linear projection maps have. In particular, they preserve the radical Sylvester-Gallai structure, and they allow bounds on the dimension of the image of $\mathcal{F}$ to be lifted back to bounds on $\mathcal{F}$. With these tools, they set up an inductive framework to show radical Sylvester-Gallai configurations have bounded dimension, with linear Sylvester-Gallai configurations acting as the base case.

Extending our results to the setting of strong algebras in order to apply this framework requires two technical results. First we define the notion of absolute reducibility with respect to strong vector spaces. This allows us to extend the prime bound to strong algebras. We then show that general projection maps send forms that are absolutely reducible with respect to strong vector spaces to reducible forms. These two extensions to the above framework allow us to prove our main theorem in the general case.

2 Conclusion

In this work, we prove that product Sylvester-Gallai configurations of forms have bounded dimension, generalising the result of [38], and getting one step closer towards a PIT algorithm for $\Sigma^k\Pi\Sigma\Pi^d$ circuits. To achieve this, we give a novel, and very effective, sufficient condition for the primality of ideals of the form (P, Q), where P "depends on more variables" than Q, via the transfer principle from [38]. This turns out to be far more subtle, and to require more tools from algebraic geometry, than giving a sufficient condition for the ideal to be radical.

Our work leaves two important questions, in order to bridge the gap between our results and a complete analysis for a polynomial-time, deterministic PIT algorithm for $\Sigma^k\Pi\Sigma\Pi^d$ circuits. The first question is to extend this work and prove a higher codimension product Sylvester-Gallai theorem for all degrees, simultaneously generalising the main theorems of [21] and this work. The second question is to provide a tight connection between such Sylvester-Gallai problems and rank bounds for identities in $\Sigma^k\Pi\Sigma\Pi^d$, thereby generalizing the beautiful result in [45, Theorem 1.4] to circuits of depth four.

A PTAS for TSP with Neighbourhoods over Parallel Line Segments

Abstract

We consider the Travelling Salesman Problem with Neighbourhoods (TSPN) on the Euclidean plane ($\mathbb{R}^2$) and present a Polynomial-Time Approximation Scheme (PTAS) when the neighbourhoods are parallel line segments with lengths between $[1, \lambda]$ for any constant value $\lambda \geq 1$. In TSPN (which generalizes classic TSP), each client represents a set (or neighbourhood) of points in a metric and the goal is to find a minimum cost TSP tour that visits at least one point from each client set. In the Euclidean setting, each neighbourhood is a region on the plane. TSPN is significantly more difficult than classic TSP even in the Euclidean setting, as it captures group TSP. A notable case of TSPN is when each neighbourhood is a line segment. Although there are PTASs for when neighbourhoods are fat objects (with limited overlap), TSPN over line segments is **APX**-hard even if all the line segments have unit length. For parallel (unit) line segments, the best approximation factor is $3\sqrt{2}$ from more than two decades ago. The PTAS we present in this paper settles the approximability of this case of the problem. Our algorithm finds a $(1+\varepsilon)$-factor approximation for an instance of the problem for n segments with lengths in $[1, \lambda]$ in time $n^{O(\lambda/\varepsilon^3)}$.

1 Introduction

The Travelling Salesman Problem (TSP) is one of the most fundamental and well-studied problems in combinatorial optimization due to its wide range of applications. In TSP, one is given a set of points in a metric space and the goal is to find a (closed) tour (or walk) of minimum length visiting all the points. For several decades, the classic algorithm by Christofides [10] and independently by Serdyukov [32] which implies a $\frac{3}{2}$-approximation was the best-known approximation for TSP until a recent result in [24] which shows a slight improvement. Several generalizations (or special cases) of TSP have been studied as well, the most notable is when the points are given in fixed dimension Euclidean space. Arora and Mitchell [4, 30] presented different PTASs for (fixed dimension) Euclidean TSP. There have been many papers that have extended these results. Arkin and Hassin [3] introduced the notion of TSP with neighbourhoods (TSPN).

An instance of TSPN is a set of neighbourhoods (or regions) given in a metric space, and the goal is to find a minimum length (or cost) tour that visits all these regions. Each region can be a single point or could be defined by a subset of points. They gave several $O(1)$-approximations for the geometric settings where each region is some well-defined shape on the plane, e.g. disks, and parallel unit length segments. Several papers have studied TSPN for various classes of neighbourhoods and under different metrics.

TSPN is much more difficult than TSP in general and in special cases, just as group Steiner tree is much more difficult than Steiner tree (one can consider each neighbourhood as a group/set from which at least one point needs to be visited). In group Steiner tree or group TSP, one is given a metric along with groups of terminals (each group is a finite set). The goal is to find a minimum cost Steiner tree (or a tour) that contains (or visits) at least one terminal from each group. TSPN generalizes group TSP by allowing infinite size groups. Using the hardness result for group Steiner tree [22], it follows that general TSPN is hard to approximate within a factor better than $\Omega(\log^{2-\varepsilon} n)$ for any $\varepsilon > 0$ even on tree metrics. The algorithms for group Steiner tree on trees in [20], and embedding of metrics onto tree metrics in [18], imply an $O(\log^3 n)$-approximation for TSPN in general metrics. Unlike Euclidean TSP (which has a PTAS), TSPN is **APX**-hard on the Euclidean plane (i.e. $\mathbb{R}^2$) [11]. The special case when each region is an arbitrary finite set of points in the Euclidean plane (group TSP) has no constant approximation [31] and the problem remains **APX**-hard even when each region consists of exactly two points [13].

Focusing on Euclidean metrics, most of the earlier work have studied the cases where the regions (or objects) are *fat*. Roughly speaking, it usually means the ratio of the smallest enclosing circle to the largest circle fitting inside the object is bounded. There are some work on when regions are *not* fat, most notably when the regions are (infinite) lines or line segments or in higher dimensions when they are hyperplanes. For the case of infinite line segments on $\mathbb{R}^2$, the problem for n lines can be solved exactly in $O(n^4 \log n)$ time by a reduction to the Shortest Watchman Route Problem (see [12, 23]). For the same setting, Dumitrescu and Mitchell [14] presented a linear time $\frac{\pi}{2}$-approximation, which was improved to $\sqrt{2}$ by Jonsson [23] (again in linear time). For infinite lines in higher dimensions (i.e. ≥ 3), the problem is proved to be **APX**-hard (see [2] and references there). For neighbourhoods being hyperplanes and dimension being $d \geq 3$, Dumitrescu and Tóth [15] present a constant factor approximation (which grows exponentially with d). For arbitrary d, they present an $O(\log^3 n)$-approximation. For any fixed $d \geq 3$, authors of [1] present a PTAS.

For parallel (unit) line segments on the plane ($\mathbb{R}^2$) Arkin and Hassin [3] presented a $(3\sqrt{2}+1)$-approximation which was improved to $3\sqrt{2}$ by [14], which remains the best-known approximation for this case as far as we know for over two decades. Authors of [17] proved that TSPN for unit line segments (in arbitrary orientation) is **APX**-hard. In this paper, we settle the approximability of TSPN when regions are parallel line segments of similar length (unit length is a special case) and present a PTAS for it. As mentioned above, the best-known approximation for unit length parallel segments has ratio $3\sqrt{2}$ [14]. We first focus on the case of unit line segments and show how our result extends to when line segments have bounded length ratio. This is in contrast with the **APX**-hardness of [17] for unit line segments with arbitrary orientation. Our result also implies a $(2+\varepsilon)$-approximation for the case where the segments can be both vertical and horizontal.

1.1 Related Work

The work on TSPN is extensive, we list a subset of the most notable and relevant work here and refer to the references of them for earlier works. All works listed are for $\mathbb{R}^2$ metric. Arkin and Hassin [3] presented constant factor approximations for several TSPN cases including when the neighbourhoods are parallel unit-length line segments (with ratio $3\sqrt{2}+1$). Very recently, PTASs were proposed for the case of unit disks and unit squares in [5]. Mata and Mitchell [25] presented $O(\log n)$-approximation for general connected polygonal neighbourhoods. Mitchell [28] gave a PTAS the case that regions are *disjoint* fat objects. This built upon his earlier work on PTAS for Euclidean TSP [30]. However, it is still open

whether the problem is **APX**-hard for disjoint (general) shapes. Dumitrescu and Mitchell [14] presented several results, including $O(1)$-approximation for TSPN where objects are connected regions of the same or similar diameter. This implies $O(1)$-approximation for line segments of the same length in arbitrary orientation. They also improved the bounds for cases of parallel segments of equal length, translates of a convex region, and translates of a connected region. For parallel (unit) line segments they obtain a $3\sqrt{2}$-approximation which remained the best ratio for this class until now. Feremans and Grigoriev [19], gave a PTAS for the case that regions are disjoint fat polygons of similar size. A similar result was obtained by [7] which gave a PTAS for TSPN for disjoint fat regions of similar sizes. Mitchell [29] presented an $O(1)$-approximation for planar TSPN with pairwise-disjoint connected neighbourhoods of any size or shape (see also [11]). Subsequently, [16] gave $O(1)$-approximation for discrete setting where regions are overlapping, convex, and fat with similar size.

These results were further generalized by Chan and Elbassioni [8] who presented a QPTAS for fat weakly disjoint objects in doubling dimensions (this allows limited amount of overlapping of the objects). This was further improved to a PTAS for the same setting [9]. The TSPN problem is even harder if the neighbourhoods are disconnected. See the surveys of Mitchell [26, 27]. If the metric is planar and each group (or neighbourhood) is the set of vertices around a face, [6] presents a PTAS for the group Steiner tree and a $(2+\varepsilon)$-approximation for TSPN.

1.2 Our Results and Technique

The main result of this paper is the following theorem.

▶ **Theorem 1.** *Given a set of n parallel (say vertical) line segments with lengths in $[1, \lambda]$ for a fixed λ as an instance of TSPN, there is an algorithm that finds a $(1+\varepsilon)$-approximation solution in time $n^{O(\lambda/\varepsilon^3)}$.*

The algorithm we present is randomized but can be easily derandomized (like the PTAS for classic TSP). To simplify the presentation, we give the proof for the case of unit line segments first.

This problem generalizes the classic (point) TSP (at a loss of $(1+\varepsilon)$ factor). Given a point TSP instance, scale the plane so that the minimum distance between the points is at least $1/\varepsilon$; call this instance $\mathcal{I}$. Obtain instance $\mathcal{I}'$ for line TSP by placing a vertical unit line segment over each point. It is easy to see that the optimum solutions of $\mathcal{I}$ and $\mathcal{I}'$ differ by at most an ϵ factor.

The difficult cases for line TSP are when the line segments are not too far apart (for e.g. they can be packed in a box of size $O(\sqrt{n})$ or smaller). There are two key ingredients to our proof that we explain here. One may try to adapt the hierarchical decomposition by Arora [4] to this setting. Following that hierarchical decomposition, the first issue is that some line segments might be crossing the horizontal dissecting lines, and so we don't have independent sub-instances, and it is not immediately clear in which subproblem these crossing segments must be covered. Note that the number of line segments crossing a dissecting line can be large. Our first insight is the following:

Insight 1: *At a loss of $(1+\varepsilon)$, we can drop the line segments crossing horizontal dissecting lines and instead requiring a subset of portals of each square (of the dissection) to be visited, provided we continue the quad-tree decomposition until each square has size $\Theta(1/\varepsilon)$.*

In other words, assuming all the squares in the decomposition have height at least $\Omega(1/\varepsilon)$, then at a small loss we can show that a solution for the modified instance where line segments on the boundary of the squares are dropped, can be extended to a solution

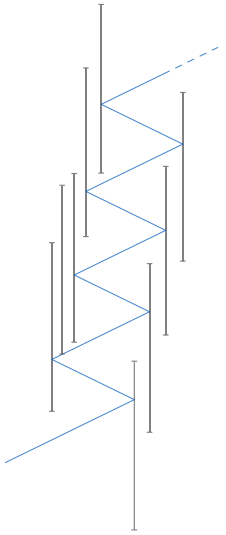

Figure 1 A potential arrangement of line segments where the solution has a large shadow.

for the original instance. So, proving this property allows us to work with the hierarchical (quad-tree) decomposition until squares of size $\Theta(1/\varepsilon)$. This can be proved by a proper packing argument. But then we need to be able to solve instances where the height of the sub-problem instance is bounded by $O(1/\varepsilon)$. Let's define the notion of shadow of a solution (or in general, shadow of a collection of paths on the plane) as the maximum number of times a vertical sweeping line Γ (that moves from left to right) intersects any of these paths. Our second insight is the following:

Insight 2: *If we consider a window that is a horizontal strip of height $O(h)$ and move this window vertically anywhere over an optimum solution, then the shadow of the parts of optimum visible in this strip is at most $O(h)$.*

In other words, one expects that in the base case of the decomposition (where squares have height $\Theta(1/\varepsilon)$), the shadow is bounded by $O(1/\varepsilon)$. Despite our efforts, proving this appears to be more difficult than thought and it seems there are examples where, even in the unit length segments, the shadow may be large (see Figure 1). We were not able to prove this nor come up with an explicit counterexample. However, we are able to prove the following slightly weaker version that still allows us to prove the final result:

(Revised) Insight 2: *There is a $(1+\varepsilon)$-approximate solution such that the shadow of any strip of height h over that solution is bounded by $O(f(\varepsilon)\cdot h)$. for some function $f(\cdot)$.*

The proof of this insight forms the bulk of our work. We characterize specific structures that would be responsible for having a large shadow in a solution and show how we can modify the solution to a $(1+\varepsilon)$-approximate one with shadow $O(1/\varepsilon)$. Consider the unit line segments case, and suppose opt is the cost of an optimum solution.

▶ **Theorem 2.** *Given any $\varepsilon > 0$, there is a solution $\mathcal{O}'$ of cost at most $(1+\varepsilon)\cdot$ opt such that in any strip of height 1, the shadow of $\mathcal{O}'$ is $O(1/\varepsilon)$.*

We will show that this near-optimum solution has in fact further structural properties that allow us to solve the bounded height cases at the base cases of the hierarchical decomposition using a Dynamic Program (DP) which, later on, is referred to as the inner DP. Proof of this theorem is fairly long and involves multiple steps that gradually proves structural properties for specific configurations.

To get a very high level idea of the proof of this theorem, consider some fixed optimum solution OPT. We decompose the problem into horizontal *strips* by drawing horizontal lines, called *cover-lines* that are 1-unit apart. The region of the plane between two consecutive cover-lines is called a *strip*. Note that each line segment crosses one cover-line (or might touch exactly two consecutive cover-lines). Let's consider one strip, say S, and consider the intersection of OPT with this strip. This intersection looks like a collection of paths that enter/exit this strip. We define the shadow of this strip similarly: consider a hypothetical vertical sweep line that moves left to right along the x-axis, the maximum number of intersections of this sweep line with these pieces of OPT restricted to S is the shadow in S. We show that we can modify OPT to a near-optimum solution of cost at most $(1+\varepsilon)$ times that of OPT so that the shadow in each strip is at most $O(1/\varepsilon)$. To prove this, we show that there are certain potential structures that can cause OPT having a large shadow in a strip, one of which we call a zig-zag (see Figure 5). We show that we can modify OPT (at a small increase to the cost) so that the shadow becomes bounded along each zig-zag (or similar structures).

Organization of the paper. We start by some preliminaries in the next section. In Section 3, we present some structural properties of a near-optimum solution and prove Theorem 2. We describe the main algorithm in Section 4, which includes the outer DP and inner DP. All the missing proofs appear in the full version of the paper [21].

2 Preliminaries

Suppose we are given n vertical line segments $s_1, \ldots, s_n$ of lengths in the range $[1, \lambda]$ for some constant $\lambda \geq 1$, and the top and bottom points of each s_i are denoted by s_i^t and s_i^b, respectively. These end-points are also called *tips* of the segment. For any point p, let $x(p)$ and $y(p)$ denote the x and y-coordinates of p, respectively. Similarly, for any segment or vertical line s, let $x(s)$ denote its x-coordinate. For two points p, q, we use $||pq||$ to denote the Euclidean distance between them. A feasible (TSP) tour is specified by a sequence of points where each of these points is on one of the segments of the instance and each line segment has at least one such point, and the tour visits these points consecutively using straight lines. The line that connects two consecutive points in a tour is called a *leg* of the tour. In our problem, the goal is to find a TSP tour of minimum total length. As mentioned earlier, we focus on the case where all the line segments have length 1 and then show how the proof easily extends to the setting where they have lengths in $[1, \lambda]$. Fix an optimum solution, which we refer to by OPT and use opt to refer to its cost. Our goal is to show the existence of a near-optimum (i.e. $(1+\varepsilon)$-approximate) structured solution that allows us to find it using dynamic programming.

First, we show at a small loss we can assume all the line segments have different x-coordinates. We assume that the minimal bounding box of these line segments has length L and height H. For now, assume $H > 3$ (case of $H \leq 3$ is easier, see Theorem 4). Let $B = \max\{L, H-2\}$. So opt $\geq 2B$; we can also assume $B \leq \frac{n}{\varepsilon}$, because otherwise opt $\geq 2n/\varepsilon$ and if we consider an arbitrary point on each line segment (say the lower tip) and use a PTAS for the classic TSP for these points, then it will be a PTAS for our original instance as well (because we pay at most an extra $+2$ for each line for a total of $2n$ which is $O(\varepsilon \cdot \text{opt})$). For a given $\epsilon > 0$, consider a grid on the plane with side length $\frac{\epsilon B}{n^2}$. Now move each line segment (parallel to the y-axis) so that the lower tip of each s_i is moved to the nearest grid point where there is no other line segment s_i with that x-coordinate. By doing this,

all the segments will have different x-coordinates and each segment would move at most $\frac{\sqrt{2}}{2} \cdot \frac{\varepsilon B}{n} < \frac{\epsilon B}{n}$, and in total, all segments would move at most a distance of ϵB. So the optimum value of the new instance has cost at most $(1+\varepsilon) \cdot \text{opt}$. For simplicity of notations, from now on we assume the original instance has this property and let OPT (and opt) refer to an optimum (and its value) of this modified instance.

3 Properties Of A Structured Near-Optimum Solution

One special instance of the problem is when there is a horizontal line that crosses all the input segments. This special case can be detected and solved easily. Otherwise, any optimum solution will visit at least 3 points that are not colinear. In such cases, like in the classic (point) TSP [4], we can assume the optimum does not cross itself, i.e. there are no two legs of the optimum ℓ (between points p, q) and ℓ' (between points p', q') that intersect, as otherwise removing these two and adding the pair of $pq', p'q$ or pp', qq' will be a feasible solution of smaller cost.

▶ **Definition 3.** *Given a collection $\mathcal{P}$ of paths on the plane and a vertical line at point $x_0 \in \mathbb{R}$, the **shadow** at x_0 is the number of legs of the paths in $\mathcal{P}$ that have an intersection with the vertical line at x_0. The shadow of a given range $[a, b]$ is defined to be the maximum shadow of values $x_0 \in [a, b]$.*

Note that if a solution is self-crossing, the operation of uncrossing (which reduces the cost) does not increase the shadow

Suppose the sequence of points of OPT is $p_1, p_2, \ldots, p_\sigma$ and the straight lines connecting these points (i.e. legs of OPT) are $\ell_1, \ell_2, \ldots, \ell_\sigma$ where ℓ_i connects two points p_i, p_{i+1} (with $p_{\sigma+1} = p_1$), and each s_i has at least one point p_j on it. We consider OPT oriented in this order, i.e. going from p_i to p_{i+1}. Since all segments have distinct x-coordinates, we can assume No two consecutive points p_i, p_{i+1} are on the same line segment by short-cutting (so no leg ℓ_i is vertical) and all points p_i on distinct line segments have distinct x-coordinates.

As mentioned before, let the length of the sides of the minimal bounding box of an instance of the problem be $L \times H$. By proving the following special case, we show we can instead focus on the cases that H is large.

▶ **Theorem 4.** *If $H \leq 3$, then the shadow of an optimum solution is at most 2.*

From now on we assume that $H > 3$. Our main goal is to prove Theorem 2.

▶ **Definition 5.** *Given a segment s and a leg ℓ incident to a point on s, we say ℓ is to the **left** of s if ℓ is entirely in the subplane $x \leq x(s)$; and ℓ is to the **right** of s if ℓ is entirely in the subplane $x \geq x(s)$.*

Since there are no vertical legs, there is no leg that is both to the left and to the right of a segment of the instance at the same time. Consider any segment s_i and suppose that ℓ_j, ℓ_{j+1} are the two legs of OPT with common end-point p_j that is on s_i. Let s_i^t and s_i^b denote the top and the bottom tips of s_i. We consider 3 possible cases for the location of p_j and the arrangement of ℓ_j, ℓ_{j+1}. Informally, one possibility is that the two legs ℓ_j, ℓ_{j+1} form a straight line that crosses s_i at p_j; one possibility is that the two legs are touching s_i at one of its tips (i.e. $p_j = s_i^t$ or $p_j = s_i^b$) such that one is to the left and one is to the right of s_i and they don't make a straight line, and the third possibility is that the two legs ℓ_j, ℓ_{j+1} are on the same side (both left or both right) of s_i.

▶ **Observation 6.** *Consider any segment s_i (with top/bottom points s_i^t,s_i^b) and suppose that ℓ_j, ℓ_{j+1} are the two legs of OPT with common end-point p_j that is on s_i. Then either:*

- *The subpath of OPT going through p_{j-1}, p_j, p_{j+1} forms a straight line (i.e. $\angle \ell_j p_j \ell_{j+1} = \pi$), and ℓ_j, ℓ_{j+1} are on two sides (left/right) of s_i; then we call p_j a **straight point**, or*
- *p_j is a tip of s_i (i.e. $p_j = s_i^t$ or $p_j = s_i^b$), $\angle \ell_j p_j \ell_{j+1} \neq \pi$ and ℓ_j and ℓ_{j+1} are on two sides of s_i (one left and one right); in this case p_j is called a **break point**, or*
- *both ℓ_j, ℓ_{j+1} are on the left or on the right of s_i; in this case p_j is called a **reflection point**.*

For the case of a reflection point p_j with two legs ℓ_j, ℓ_{j+1}, if both legs are to the left of the segment it is called a *left reflection* point and otherwise it is a *right reflection* point. Also note that if ℓ_j, ℓ_{j+1} are on the two sides of s_i and $\angle \ell_i p_j \ell_{i+1} \neq \pi$, then p_j must be a tip, or else we could move p_j slightly up or down and reduce the length of OPT (see Figure 2).

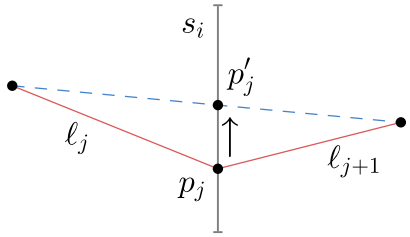

Figure 2 If p_j isn't a tip of s_i, then ℓ_j, ℓ_{j+1} must be collinear.

▶ **Lemma 7.** *If P is a subpath of OPT with end-points p, q where both are to the right of a vertical line Γ, and if P crosses Γ, then the left-most point on P to the left of Γ is a right reflection point (symmetric statement holds for opposite directions).*

▶ **Definition 8.** *Consider an arbitrary reflection point r on a segment s. Let the two legs of OPT incident to r visited before and after r (on the orientation of OPT) be ℓ^- and ℓ^+, respectively. ℓ^- is said to be **on top of** ℓ^+ if all the points of ℓ^- have larger y-coordinate than all of the points of ℓ^+. In this case we also call ℓ^- the* upper leg *and ℓ^+ the* lower leg. *Also, in this case, r is called a **descending** reflection point. If ℓ^+ is on top of ℓ^-, then r is called an **ascending** reflection point.*

If ℓ_j, ℓ_{j+1} are two legs incident to a reflection point p on a segment s, if the angle between ℓ_j and s is the same as the angle between ℓ_{j+1} and s (i.e. ℓ_{j+1} is like the reflection of a ray ℓ_j on mirror s) then p is called a *pure reflection* point.

▶ **Lemma 9.** *Any reflection point that is not a tip of a segment is a pure reflection point.*

We say a subpath contains a reflection point p_j if p_j is not the start or end vertex of the subpath (i.e. both legs of incident to p_j belong to that subpath.)

▶ **Lemma 10.** *If a sweeping vertical line Γ moves left to right on the x-axis, the only values of x for which the shadow at Γ changes will be when Γ hits a reflection point on that x-coordinate. Specifically, this means that any subpath of OPT that doesn't contain a reflection point, must have a shadow of 1 throughout its length.*

▶ **Definition 11.** *Let P_1 and P_2 be any two subpaths of OPT. We say P_1 is **above** P_2 in range $I = [x_0, x_1]$ if for every vertical line Γ with $x(\Gamma) \in I$, the top-most intersection of Γ with these two paths is a point on P_1. We say P_2 is **below** P_1 if the bottom-most intersection of Γ*

*with P_1, P_2 is a point on P_2. Similarly, we say L_1 is to the **left** of L_2 in range $I' = [y_0, y_1]$ if for every horizontal line Λ with $y(\Lambda) \in I'$, the left-most intersection point of Λ with L_1, L_2 (i.e. one with the least x value) always belongs to L_1. We say L_2 is to the **right** of L_1 if the right-most intersection of Λ is with L_2.*

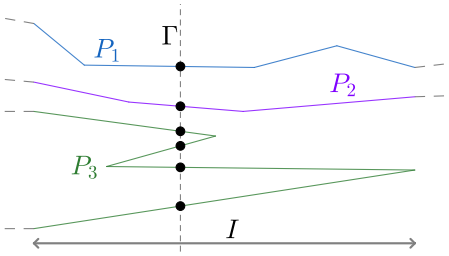

Figure 3 In range I, P_1 is above P_2, P_3, and P_2 is above P_3.

▶ **Lemma 12.** *For any distinct points p_j and $p_{j'}$ on OPT, following OPT according to its orientation, either the path from p_j to $p_{j'}$ or the path from $p_{j'}$ to p_j must contain at least one reflection point.*

▶ **Lemma 13.** *Among the set of points visited by OPT following its orientation, suppose $p_j, p_{j'}$, $j < j'$ (on segments s_i, $s_{i'}$, respectively) are two consecutive reflection points (i.e. no other reflection point exists in between them). Then p_j and $p_{j'}$ cannot be both left or both right reflection points. Furthermore, if s_i is to the left of $s_{i'}$ then p_j is a right reflection and $p_{j'}$ is a left reflection (the opposite holds if $s_{i'}$ is to the left of s_i).*

▶ **Corollary 14.** *Consecutive reflection points in OPT alternate between left and right reflections.*

3.1 Strips, Zig-zag, Sink

We decompose the problem into horizontal *strips* by drawing some parallel horizontal lines, which we call *cover-lines*. Starting from the bottom tip of the top-most segment, draw parallel horizontal lines that are 1-unit apart, these are our *cover-lines*. Each input segment is considered "covered" by the top-most (i.e. the first) cover-line that intersects it. Let's label these cover-lines by $C_1, C_2, \ldots$.

▶ **Definition 15** (strip, top/bottom segments)**.** *The region of the plane between two consecutive cover-lines $C_\tau, C_{\tau+1}$ is called a **strip** and denoted by S_τ. We consider $C_\tau, C_{\tau+1}$ part of S_τ as well. The input line segments that are intersecting the top cover-line of S_τ (C_τ) are called **top segments,** and the segments covered by the bottom cover-line ($C_{\tau+1}$) are called **bottom segments** of the strip.*

We show the near-optimum solution guaranteed by Theorem 2 has more structural properties that will be defined later. Note that once we prove that theorem, it follows that if we restrict a solution to $h > 1$ many strips, then the shadow is bounded by $O(h/\varepsilon)$ as well.

For now, let us focus on an (arbitrary) strip S_τ and imagine we cut the plane along $C_\tau, C_{\tau+1}$ and look at the pieces of line segments of the instance left inside this strip, along with pieces of OPT inside S_τ. Each top segment is now a partial segment in S_τ that has one end on C_τ; and each bottom segment has one end on $C_{\tau+1}$. Let OPT_τ be the restriction of OPT to S_τ. For each leg of OPT that intersects C_τ or $C_{\tau+1}$, we add a dummy point at

the intersection(s) of that leg with C_τ and $C_{\tau+1}$ (so that the components of OPT_τ become consistent with our definition of legs). So OPT_τ can be seen as a collection of subpaths within S_τ (possibly along C_τ or $C_{\tau+1}$). Following the orientation of OPT, each subpath of OPT_τ is formed by it intersecting with S_τ, traveling within S_τ (possibly along one of the cover-lines), and then exiting S_τ. Using the dummy points added, each path in OPT_τ is a subpath of OPT that is between two points on cover-lines (these are called the entry points of the path with the strip. A formal definition is provided below).

▶ **Definition 16** (entry points, loops, ladders). *For each subpath P_j of OPT_τ, let e_j and o_j be the first and last intersections of P_j with the interior of S_τ. Points e_j and o_j are called the **entry points** of P_j.*
*If both e_j and o_j lie on the same cover-line (either C_τ or $C_{\tau+1}$), then P_j is called a **loop**, otherwise it's called a **ladder**. If a subpath of OPT_τ enters S_τ at e_j on a cover-line and follows on that cover-line to point o_j and exits the strip, it is a special case of loop that we refer to as a **cover-line loop**.*

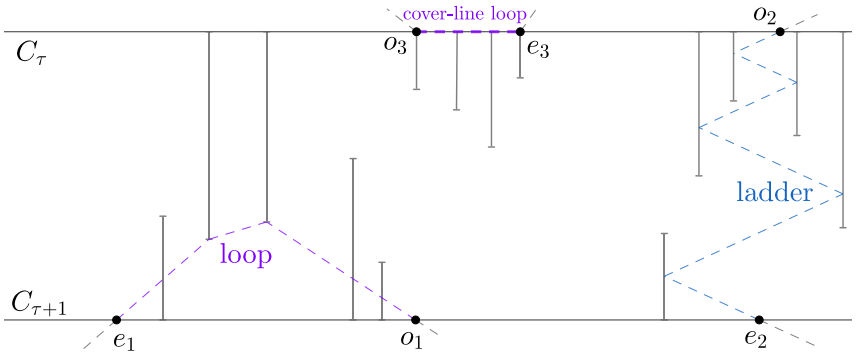

Figure 4 An example of loops and ladders in a strip S_τ (i.e. area between cover-lines $C_\tau, C_{\tau+1}$).

Since we're assuming $H > 3$ (see Theorem 4), we get that OPT is not limited to a single strip, and that it has to indeed enter and exit any given strip that it intersects with (i.e. there is no strip that OPT completely lies inside it). Note that if a path of OPT_τ is a cover-line loop, i.e. a section of the line C_τ or $C_{\tau+1}$, then the entry points of that path must be the two end-points of this section. In other words, if for a cover-line loop of OPT_τ the first point is e_j on (say) C_τ, and the last point is o_j on C_τ, then this subpath must be travelling straight from e_j to o_j without any change of direction. This is true because otherwise, that cover-line loop would have to go back and forth on some portion on a cover-line, which is only possible if it's self-intersecting; but this is against our assumption that OPT is not self-crossing. The two structures defined below (called a zig-zag and a sink) are the two configurations that can cause a large shadow.

▶ **Definition 17** (Zig-zag/Sink). *Consider any loop or ladder of OPT_τ, call it P. Let $\mathcal{R} = r_1, r_2, \ldots, r_t$ be the sequence of points of P that are reflection points (indexed by the order they're visited). Consider any maximal sub-sequence $r_j, r_{j+1}, \ldots, r_q$ of $\mathcal{R}$ (with $q \geq j+1$) such that all are ascending or all are descending reflections, and the segments containing them alternate between top and bottom segments; then the subpath P that starts at r_j and ends at r_q is called a **zig-zag**.*
*If $r_j, r_{j+1}, \ldots, r_q$ is a maximal sub-sequence of $\mathcal{R}$ that are all ascending or all descending, and all belong to top segments or all belong to bottom segments; then the subpath P that starts at r_j and ends at r_q is called a **sink** (see Figure 5).*

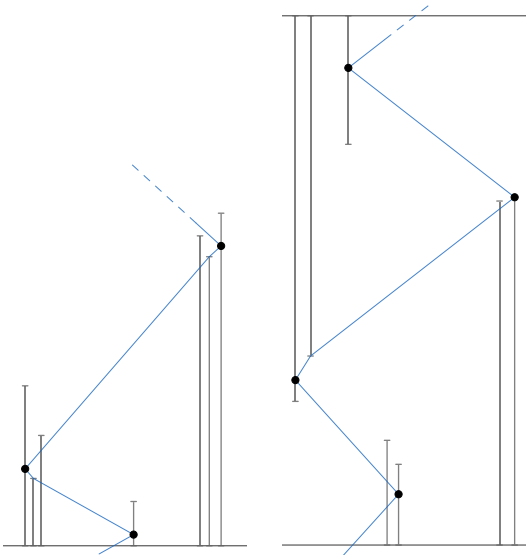

Figure 5 Examples of a sink (left) and a zig-zag (right). Bold dots indicate the reflection points.

Note that each zig-zag has at least two reflection points (or else it will be a sink). Also, using Corollary 14, the reflection points in a zig-zag or sink should alternate between left and right reflection. The next important lemma is used critically to show that very specific structures (namely zig-zags and sinks) are responsible for having large shadow along a ladder or loop in OPT_τ. Additionally, we can partition each ladder/loop into parts (subpaths), such that the shadow of the ladder/loop is equal to the maximum shadow among these parts, and each part is a path that consists of up to three sinks and/or zig-zags. So the shadow of a loop/ladder is within $O(1)$ of the maximum shadow of zig-zag/sinks along it.

▶ **Lemma 18.** *Consider any strip S_τ and any ladder or loop $P \in OPT_\tau$ within S_τ. Suppose the sequence of reflection points of P is $r_1, \ldots, r_q$. Then these reflection points can be partitioned into disjoint parts, say part i consists of reflection points $r_{a_i}, r_{a_i+1}, \ldots, r_{a_j}$, where the subpath of P from r_{a_i} to r_{a_j} is concatenation of up to three sections in the following order:* ***a)*** *A sink , followed by* ***b)*** *A zig-zag , followed by* ***c)*** *A sink, where any of these three sections can possibly be empty, and the last reflection of a section is common with the first reflection of the next section. Furthermore, for any vertical line Γ, there is at most one of these parts (of the partition) that intersects with it, i.e. the shadow of the ladder/loop is the maximum shadow among the parts plus 2.*

The proof of this lemma is rather involved (see [21] for details). To give an idea of the proof, we essentially show that for any loop/ladder in any strip, the vertical line at which the largest shadow for that loop/ladder happens, can intersect with at most two sinks and a zig-zag. So the shadow of a loop or ladder is within $O(1)$ of the maximum shadow of the zig-zags and sinks along itself. The following lemma is one of the main components of proof of Theorem 2.

▶ **Lemma 19.** *Consider OPT_τ for an arbitrary strip S_τ, and let opt_τ be the total cost of OPT_τ. Given any $\varepsilon > 0$, we can change OPT_τ to a solution of cost at most $(1 + O(\varepsilon)) \cdot opt_\tau$ where the shadow of each zig-zag and sink is at most $O(1/\varepsilon)$.*

The following corollary immediately follows from Lemmas 18 and 19:

▶ **Corollary 20.** *There is a $(1+\varepsilon)$-approximate solution in which all loops/ladders have shadow $O(1/\varepsilon)$.*

▶ **Definition 21.** *Let $\mathcal{R} = p_i, p_{i+1}, \ldots, p_q$ be any sequence of consecutive points in OPT such that p_i and p_q are reflection points. If none of p_j's $(i < j < q)$ in $\mathcal{R}$ is a tip of a segment, then $\mathcal{R}$ is called a* ***pure reflection sequence****.*

So each point in $\mathcal{R}$ is either a straight point or a pure reflection according to Lemma 9.

▶ **Lemma 22.** *Consider OPT_τ for an arbitrary strip S_τ and suppose the total length of legs of OPT_τ is opt_τ. Given $\varepsilon > 0$, we can change OPT_τ to a solution of cost at most $(1+\varepsilon)\cdot opt_\tau$ in which the size of any pure reflection sequence is bounded by $O(\frac{1}{\epsilon})$.*

Our next goal is to show that for any vertical line, it can intersect at most $O(1)$ many loops or ladders of OPT_τ in a strip S_τ. This together with the above corollary implies there is a $(1+\varepsilon)$-approximate solution where the shadow in each strip S_τ is $O(1/\varepsilon)$.

▶ **Definition 23.** *A collection of loops and or ladders are said to be* overlapping *with each other if there is a vertical line that intersects all of them.*

▶ **Lemma 24.** *Consider OPT_τ, the restriction of OPT to any strip S_τ. We can modify the solution (without increasing the shadow or the cost) such that there are at most $O(1)$ loops or ladders in OPT_τ that all are overlapping with each other.*

Assuming the correctness of main lemmas defined above (i.e. Lemmas 18, 19, 22, and 24), we can now prove Theorem 2.

Proof of Theorem 2. If the height of the bounding box is at most 3, simply use Theorem 4. Otherwise, consider any strip S_τ (to be more precise, S_τ can be any arbitrary strip of height 1 in the plane). Using Lemma 19, there is a solution $\mathcal{O}''$ of cost at most $(1+\varepsilon)\cdot \mathrm{opt}$ where the shadow of each sink and zig-zag is bounded by $O(1/\varepsilon)$. By Lemma 18, each loop or ladder in S_τ has a shadow that is at most 3 times the maximum shadow of a sink or zig-zag in it, plus two. So each loop or ladder has shadow $O(1/\varepsilon)$. Finally, Lemma 24 shows that there can be at most $O(1)$ overlapping loops or ladders in a strip. Thus, the overall shadow of $\mathcal{O}''$ in S_τ is bounded by $O(1/\varepsilon)$. Furthermore, we apply Lemma 22 on O'' to get a solution $\mathcal{O}'$. This new solution has the property that with an additional cost of factor $(1+O(\varepsilon))$ compared to $\mathcal{O}''$, the size of any pure reflection sequence is bounded by $O(1/\varepsilon)$. The total cost of $\mathcal{O}''$ is at most $(1+O(\varepsilon))\cdot \mathrm{opt}$ and the shadow is bounded by $O(1/\varepsilon)$. ◀

Note. Although having a bound on the length of pure reflection sequences is not in the statement of the theorem, we use this extra property crucially in designing our DP to find a near-optimum solution.

4 Main Algorithm and Reduction to Structured Bounded Height Instances

As mentioned in the introduction, we follow the paradigm of Arora [4] for designing a PTAS for classic Euclidean TSP with some modifications. We focus more on defining the modifications that we need to make to that algorithm. First, we describe the main algorithm and how it reduces the problem into a collection of instances with a constant-height bounding box. We show how those instances can be solved using another DP (referred to as the *inner DP*), and how we can combine the solutions for them using another DP (referred to as the

outer DP) to find a near-optimum solution of the original instance. Recall that in Section 2, we assumed the minimal bounding box of the instance has length L and height H and we defined $B = \max\{L, H-2\}$, and also we can assume that $B \leq \frac{n}{\varepsilon}$. We moved each line segment to be aligned with a grid point with side length $\frac{\epsilon B}{n^2}$ (at a loss of $(1+\varepsilon)$ at approximation). Now, we scale the grid (as well as the line segments of the instance) by a factor of $\rho = \frac{4n^2}{\epsilon B}$ so that each grid cell has size 4. We obtain an instance where each line segment has length ρ, all have even integer coordinates, any two segments are at least 4 units apart, and the bounding box has size $N = O(n^2/\varepsilon)$. Let this new instance be $\mathcal{I}$. Note that if we define cover-lines as before but with a spacing of ρ, all the arguments for the existence of a near-optimum solution with a bounded shadow in any strip (the area between two consecutive cover-lines) still hold. We will present a PTAS for this instance. It can be seen that this implies a PTAS for the original instance of the problem. From now on, we use OPT to refer to an optimum solution of instance $\mathcal{I}$, and opt to refer to its cost. Note that since the bounding box has side length N, then opt $\geq 2N$. Similar to Arora's approach, we do the hierarchical dissectioning of the instance into nested squares using random axis-parallel dissectioning lines, and put portals at these dissecting lines. We continue this dissectioning process until the distances between horizontal (and so vertical) dissecting lines is $h \cdot \rho$ for $h = \lceil 1/\varepsilon \rceil$. So at the leaf nodes of our recursive decomposition quad-tree, each square is $(h \cdot \rho) \times (h \cdot \rho)$, and the height of the decomposition is $\log(N/\rho h) = O(\log n)$ since $B \leq \frac{n}{\varepsilon}$. We choose vertical dissecting lines only at odd x-coordinates so no line segment of the instance will be on a vertical dissecting line.

We define our cover-lines C_τ based on these horizontal dissecting lines carefully. Consider the first (horizontal) dissecting line we choose, this will be a cover-line, and then moving in both up and down directions from this line, we draw horizontal lines that are ρ apart. These will be all the cover-lines. Label the cover-lines from the top to bottom by $C_1, C_2, \ldots, C_\sigma$ in that order. As before, the smallest index τ such that C_τ crosses a line segment is the cover-line that "covers" that line segment. We partition the cover-lines into h groups based on their indices: Group G_j contains all those cover-lines with index τ where $j = \tau \pmod h$. Let G_{j*} be the group of cover-lines that includes the first horizontal dissecting line, and hence all the other horizontal dissecting lines as well. The arguments for the case of unit-length line segments to show there is a near-optimum solution in which the shadow in each strip of height 1 is $O(1/\varepsilon)$ (Theorem 2), also imply the same for the scaled instance $\mathcal{I}$. Furthermore, if we consider h consecutive strips, i.e. the area between two consecutive cover-lines in the same group G_j, then there is a near-optimum solution that has shadow $O(h/\varepsilon) = O(1/\varepsilon^2)$. Our goal is to show that, at a $(1+\varepsilon)$-factor loss, we can simply drop the line segments that are intersecting the horizontal dissecting lines (i.e. all those intersecting cover-lines in G_{j^*}) with appropriate consideration of portals (to be described). Removing the line segments that cross the dissecting lines allows us to decompose the instance into "independent" sub-instances that interact only via portals. The details of how to remove these segments which leads to proof of Lemma 25 below are deferred to the full version [21].

Similar to Arora's scheme for TSP, for $m = O(\frac{1}{\varepsilon}\log(N/\rho h))$, we place portals at all 4 corners of a square in the decomposition, plus an additional $m-1$ equally distanced portals along each side (so a total of $4m$ portals on the perimeter of a square of the dissection). For simplicity, we assume m is a power of 2 and at least $\frac{4}{\varepsilon}\log(N/\rho h)$. We say a tour is *portal respecting* if it crosses between two squares in our decomposition only via portals of the squares. A tour is *r-light* if it crosses the portals on each side of a square of the dissection at most r times. For classic (point) TSP, it can be shown that there is a near-optimum solution that is portal respecting and r-light for $r = O(1/\varepsilon)$. Our goal is to show a similar statement,

except that we want the restriction of the tour to each "base" square of side length $O(h \cdot \rho)$ to have bounded (by $O(h/\varepsilon) = O(1/\varepsilon^2)$) shadow as well. We then show that we can find an optimum solution with a bounded shadow for the base cases using a DP. This will be our *inner DP*. We then show how the solutions of for the 4 sub-squares of a square in our decomposition can be combined into a solution for the bigger subproblem using the outer DP. We show that at a small loss in approximation (i.e. $O(\varepsilon \cdot \text{opt})$), we can drop all the line segments of input that are intersecting the horizontal dissecting lines (i.e. covered by a cover-line in group G_{j^*}), solve appropriate subproblems, and then extend the solutions to cover those dropped segments. This modification requires certain portals of each square in the decomposition to be visited in the solution for that square. We show there is a feasible solution that visits all the remaining segments as well as the "required" portals, of total cost at most $(1+\varepsilon) \cdot \text{opt}$, and that such a solution can be extended to a feasible solution visiting all the segments of the original instance (i.e. including the ones that we dropped) at an extra cost of $O(\varepsilon \cdot \text{opt})$.

▶ **Lemma 25.** *Given instance $\mathcal{I}$, there is another instance $\mathcal{I}'$ that is obtained by removing all the segments that are crossing cover-lines in G_{j^*} (i.e. intersecting horizontal dissecting lines), and instead some of the portals around (more precisely, the top and bottom sides of) each square of quad-tree dissection are required to be covered (visited); such that there is a solution for $\mathcal{I}'$ of cost at most $(1+O(\varepsilon)) \cdot opt$, and such a solution can be extended to a feasible solution of $\mathcal{I}$ of cost at most $(1+O(\varepsilon)) \cdot opt$. Furthermore, the shadow of the solution for $\mathcal{I}'$ between any two consecutive cover-lines in G_{j^*} is at most 4 more than the shadow of OPT between those two lines.*

The outer DP based on the quad-tree dissection is similar to the classic PTAS for Euclidean TSP. One can show that for $r = O(1/\varepsilon)$, there is a r-light portal respecting tour for $\mathcal{I}'$ with cost at most $(1+\varepsilon) \cdot \text{opt}'$ where opt$'$ is the cost of an optimum solution fo $\mathcal{I}'$. The DP will also "guess" in the recursion for each square, which portals are the "required" portals around it. The base case of this DP will be instances with bounding box of size $\rho \cdot h$. For such instances, we solve the problem using an inner DP. Informally, the inner DP is a nontrivial generalization of the DP for the classic (and textbook example) bitonic TSP in which the shadow is 2. In our case, the shadow is $O(1/\varepsilon^2)$. We defer the details of both the inner and outer DP to the full version [21].

Abstract

We show that a variant of the continuous Fréchet distance between polygonal curves can be computed using essentially the same algorithm used to solve the discrete version. The new variant is not necessarily monotone, but this shortcoming can be easily handled via refinement.

Combined with a Dijkstra/Prim type algorithm, this leads to a realization of the Fréchet distance (i.e., a morphing) that is locally optimal (aka locally correct), that is both easy to compute, and in practice, takes near linear time on many inputs. The new morphing has the property that the leash is always as short as possible. These matchings/morphings are more natural, and are better than the ones computed by standard algorithms – in particular, they handle noise more graciously. This should make the Fréchet distance more useful for real world applications.

We implemented the new algorithm, and various strategies to obtain fast practical performance. We performed extensive experiments with our new algorithm, and released publicly available (and easily installable and usable) `Julia` and `Python` packages. In particular, the `Julia` implementation, for computing the regular Fréchet distance, seems to be **significantly faster** than other currently available implementations. See Table 2.2. Our algorithms can be used to compute the almost-exact Fréchet distance between polygonal curves.

Implementations and numerous examples are available here: frechet.xyz.

1 Introduction

1.1 Definitions

Given two polygonal curves, their Fréchet distance is the length of a leash that a person needs, if they walk along one of the curves, while a dog connected by the leash walks along the other curve, assuming they synchronize their walks so as to minimize the length of this leash. (I.e. they walk so as to minimize their maximum distance apart during the walk.) Our approach is slightly different than the standard approach, and we define it carefully first.

1.1.1 Free space diagram and morphings

▶ **Definition 1.** *For a (directed) curve $\pi \subseteq \mathbb{R}^d$, its* **uniform parameterization** *is the bijection $\pi : [0, \|\pi\|] \to \pi$, where $\|\pi\|$ is the length of π, and for any $x \in [0, \|\pi\|]$, the point $\pi(x)$ is at distance x (along π) from the starting point of π.*

▶ **Definition 2.** *The free space diagram of two curves π and σ is the rectangle $R = R(\pi, \sigma) = [0, \|\pi\|] \times [0, \|\sigma\|]$. Specifically, for any point $(x, y) \in R$, we associate the* **elevation function** *$e(x, y) = \|\pi(x) - \sigma(y)\|$.*

The free space diagram R is partitioned into a non-uniform grid, where each cell corresponds to all leash lengths when a point lies on a fixed segment of one curve, and the other lies on a fixed segment of the other curve, see Figure 1.1. For a given value $\delta \geq 0$, the *sublevel set* of a real valued function consists of all inputs whose function value is $\leq \delta$. It is known that for any value $\delta \geq 0$, the sublevel set of the elevation function inside such a grid cell is a clipped ellipse.

▶ **Definition 3.** *A* **morphing**[1] *m between π and σ is a (not self-intersecting) curve $m \subseteq R(\pi, \sigma)$ with endpoints $(0, 0)$ and $(\|\pi\|, \|\sigma\|)$. The set of all morphings between π and σ is $\mathcal{M}_{\pi,\sigma}$. A morphing that is a segment inside each cell of the free space diagram that it visits, is* well behaved[2]*.*

Intuitively, a morphing is a reparameterization of the two curves, encoding a synchronized motion along the two curves. That is, for a morphing $m \in \mathcal{M}_{\pi,\sigma}$, and $t \in [0, \|m\|]$, this encodes the configuration, with a point $\pi\big(x(m(t))\big) \in \pi$ matched with $\sigma\big(y(m(t))\big) \in \sigma$. The ***elevation*** of this configuration is $e(t) = e(m(t)) = \big\|\pi\big(x(m(t)\big) - \sigma\big(y(m(t)\big)\big\|$.

1.1.2 Fréchet distance

▶ **Definition 4.** *The* **width** *of a morphing m between π and σ is $\omega(m) = \max_{t \in [0, \|m\|]} e(t)$. The* **Fréchet distance** *between the two curves π and σ is*

$$\mathsf{d}_{\mathcal{F}}(\pi, \sigma) = \min_{m \in \mathcal{M}^{+}_{\pi,\sigma}} \omega(m),$$

where $\mathcal{M}^{+}_{\pi,\sigma} \subseteq \mathcal{M}_{\pi,\sigma}$ is the set of all x/y-monotone morphings.

[1] A morphing induces a natural homotopy between the two curves.
[2] All the morphings we deal with in this paper are well behaved.

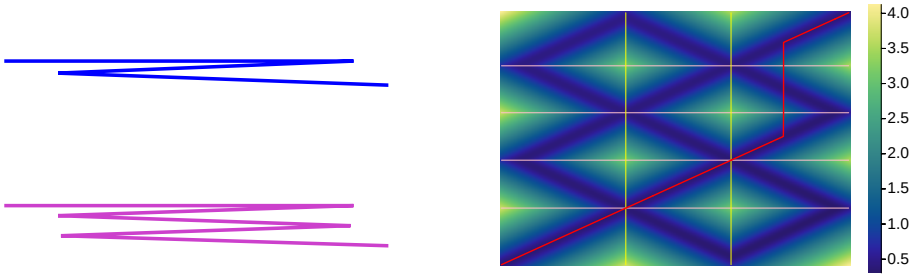

Figure 1.1 Two curves, their free space diagram (and the associated elevation function), and the optimal Fréchet morphing between the two curves encoded as an x/y-monotone curve. More illustrations and animations of this example are available here.

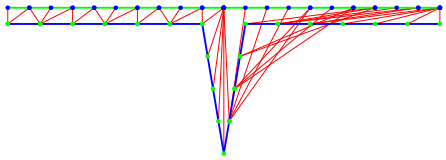
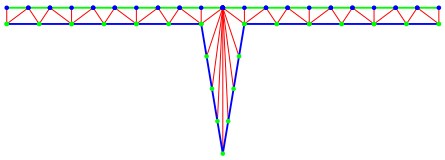


The classical (discrete) Fréchet morphing, caring only about the maximum leash length.



The retractable discrete Fréchet morphing, using the shortest leash possible at each point.

Figure 1.2 A comparison between the classical and retractable Fréchet distances. Observe that the morphing generated by the classical distance can be quite loose in many places. An animation of both morphings is available here.

Conceptually, the Fréchet distance is the problem of computing the minimum bottleneck matching between two curves, respecting the order and continuity of the curves.[3] Alternatively, it is an L_∞-norm type measure of the similarity between two curves. It thus suffers from sensitivity to outliers. Furthermore, even if only a small portion of the morphing requires a long leash, the measure, and the algorithms computing it, may use this long leash in large portions of the walk, generating a matching that is loose in many places, see Figure 1.2.

Observe that the Fréchet distance is the minimum value such that the sublevel set of the elevation function has an x/y-monotone path from $(0,0)$ to $(\|\pi\|, \|\sigma\|)$ in R.

1.2 Background

Alt and Godau [1] presented a rather involved $O(n^2 \log n)$ time algorithm to compute the Fréchet distance using parametric search. The parametric search can be removed by using randomization, giving a simpler algorithm as shown in [12]. Buchin *et al.* [7] presented an alternative algorithm for computing the Fréchet distance that replaces the decision procedure by using a data-structure to maintain appropriate lower envelopes. Despite some simplifications, all these algorithms are somewhat involved.

Unfortunately, it is believed this problem requires quadratic time in the worst case, although a logarithmic speedup is possible; see [5] and references therein. The quadratic time can be improved for realistic inputs by assuming that the input is "nice", and introducing approximation, but the resulting algorithms are still not simple [9].

[3] Formally, since the reparameterization is not one-to-one, this is not quite a matching. One can restrict to using only such bijections, with no adverse effects, but it adds a level of tediousness, which we avoid for the sake of simplicity of exposition.

1.2.1 Variants of the Fréchet distance

Weak Fréchet distance. The ***weak Fréchet distance*** allows morphings where the agents are allowed to go back and traverse portions of the curve visited previously (i.e., the morphing does not have to be x/y-monotone). Since the weak Fréchet distance allows considering more parameterizations, it is potentially smaller, and we have that $\mathsf{d}^w_{\mathcal{F}}(\pi, \sigma) \leq \mathsf{d}_{\mathcal{F}}(\pi, \sigma)$, for any two curves π, σ. Elegantly, Alt and Godau [1] showed the weak Fréchet distance can be reduced to computing the minimum spanning tree of an appropriate graph. Unfortunately, there does not seem to be a natural way to overcome this non-monotonicity (and thus get the "strong" version).

Discrete Fréchet distance. The complexity of these algorithms, together with sensitivity of the Fréchet distance to noise, lead to using "easier" related measures, such as the discrete version of the problem, and dynamic time-warping (discussed below). In the discrete version, you are given two sequences of points $p_1, \ldots, p_n$, and $q_1, \ldots, q_m$, and the purpose is for two "frogs" starting at p_1 and q_1, respectively, to jump through the points in the sequence until reaching p_n, q_m, respectively, while minimizing the maximum distance between the two frogs during this traversal. At each step, only one of the frogs can jump from its current location to the next point in its sequence (no jumping back). Computing the optimal distance under this measure can be done by dynamic-programming, similar to the standard approach to edit-distance. Indeed, the configuration space here is the grid $H = [\![n]\!] \times [\![m]\!]$, where $[\![n]\!] = \{1, \ldots, n\}$.

To use the discrete version in the continuous case, one sprinkles enough points along both input curves, and then solves the discrete version of the problem. Beyond the error this introduces, to get a distance that is close to the standard Fréchet distance, one has to sample the two curves quite densely in some cases.

For the (monotone) discrete Fréchet distance the induced graph on the grid H is a DAG, and the task of computing the Fréchet distance is to find a minimum bottleneck path from $(1, 1)$ to (n, m), where the weights are on the vertices. Here, the weight on the vertex (i, j) is the distance $\|p_i - q_j\|$. In particular, a Fréchet morphing is an x/y-monotone path in H from $(1, 1)$ to (n, m). The standard algorithm to do this traverses the grid, say, by increasing rows i, and in each row by increasing column j, such that the value at (i, j) is the maximum of the length of the leash of this configuration, together with the minimum solution for $(i - 1, j)$ and $(i, j - 1)$. This algorithm leads to a straightforward, $O(nm)$ time algorithm for the discrete Fréchet distance. However, the morphing computed might be inferior, see Figure 1.2 for such a bad example.

Retractable Fréchet. For simplicity, assume that the pairwise distances between all pairs of points in the two sequences are unique. We would like to imagine that we have a retractable leash, that can become shorter at times, and the leash "resists" being longer than necessary. It is thus natural to ask for a morphing where the leash as short as possible at any point in time.

Informally, the optimal *retractable Fréchet morphing* between the two sequences includes the bottleneck configuration, realizing the Fréchet distance, in the middle of its path, and the two subpaths from the endpoints to this configuration have to be also recursively optimal. This is formally defined and described in the Full version of the paper [14]. This concept was introduced by Buchin *et al.* [6]. Interestingly, they show that the discrete version can be computed in $O(nm)$ time, but unfortunately, the algorithm is quite complicated. They also show that the continuous retractable Fréchet can be computed in $O(n^3 \log n)$ time.

Buchin *et al.* [6] refers to this Fréchet distance as *locally correct*, but we prefer the *retractable* labeling. The term "retractable Fréchet" was used by Buchin *et al.* [7], but in a different (and not formally defined) context than ours.

(Continuous) Dynamic Time Warping. One way to get less sensitivity for noise is to compute the total area "swept" by the leash as the walk is being performed. In the discrete case, we simply add up the lengths of the leashes during the configurations in the walk. There is also work on extending this to the continuous setting [15, 2]. For the continuous case this intuitively boils down to computing (or approximating) an integral along the morphing. See full version of the paper [14] for more details.

1.2.2 Critical events

The standard algorithm for computing the Fréchet distance works by performing a "binary" search for the Fréchet distance. Given a candidate distance, it constructs a "parametric" diagram that is a grid, where inside each grid cell the feasible region is a clipped ellipse. The task is then to decide if there is an x/y-monotone path from the bottom left corner to the top right corner, which is easily doable. The critical values the search is done over are:

- **(I)** *Vertex-vertex events*: The distance between two vertices of the two curves,
- **(II)** *Vertex-edge events*: The distance between a vertex of one curve, and an edge of the other.
- **(III)** *Monotonicity events*: This is the minimum distance between a point on one edge e of the curves, and (maximum distance to) two vertices u, v of the other curve. Specifically, it is realized by the point on e with equal distance to u and v.

The first two types of events are easy to handle, but the monotonicity events are the bane of the algorithms for the Fréchet distance.

1.2.3 Algorithm engineering the Fréchet distance

Given the asymptotic complexity and involved implementations of the aforementioned algorithms, there has been substantial work on practical aspects of computing the Fréchet distance. In particular, in 2017, ACM SIGSPATIAL GIS Cup had a programming challenge to implement algorithms for computing the Fréchet distance. See [19] for details.

More recently, Bringmann *et al.* [3] presented an optimized implementation of the decider for the Fréchet distance. Somewhat informally, Bringmann *et al.* [3] builds a decider for the Fréchet distance using a *kd*-tree over the free space diagram, keeping track of the reachable regions on the boundary of each cell, refining cells by continuing down the (virtual) *kd*-tree if needed.

1.3 Our results

1.3.1 Result I: A new algorithm for retractable discrete Fréchet

We observe that a natural approach to compute the retractable Fréchet morphing is to modify Dijkstra's/Prim's algorithm so that it solves the minimum bottleneck path problem. This observation leads to a simpler (but log factor slower) algorithm for computing it. The only modification of Dijkstra necessary is that one always handles the cheapest edge coming out of the current cut induced by the set of vertices already handled. (In the discrete Fréchet case, the weights are on the vertices, but this is a minor issue.) This modified version of

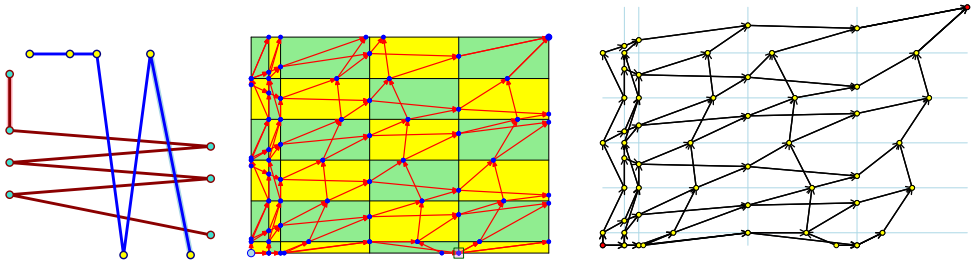


Figure 1.3 Two curves, and their associated VE-Fréchet graph. Note, that every internal edge of the grid contains a portal (i.e., vertex of the graph), but in many cases the portals of two edges are co-located on their common vertex (see the squared marked vertex in the middle figure) For the edges adjacent to the starting and ending corners we set their portals to lie at the corners themselves. See here for more info about a similar example.

Dijkstra is well known, but we include, for the sake of completeness, the proof showing that it indeed computes the recursively optimal path, which is also a retractable Fréchet morphing between the two sequences. This immediately leads to better and more natural morphings, see Figure 1.2.

Maybe more importantly, in practice, one does not need to explore the whole space of nm configurations (since we are in the discrete case, a configuration $(i, j) \in [\![n]\!] \times [\![m]\!]$ encodes the matching of p_i with q_j), as the algorithm can stop as soon as it arrives at the destination configuration (n, m). Informally, if the discrete Fréchet distance is "small" compared to the vast majority of pairwise distances (i.e., the two sequences are similar), then the algorithm only explores a small portion of the configuration space. Thus, this leads to an algorithm that is faster than the standard algorithm in many natural cases, while computing a significantly better output morphing.

1.3.2 Result II: A new distance and algorithm: VE-Fréchet

It is not clear how to extend the above to the continuous case. A natural first step is to consider the continuous Fréchet distance, where one restricts the solution inside each cell of the free space diagram to be a segment (which is already the case for the morphings computed by existing algorithms), but more importantly, insisting that the shape of this segment must be determined only locally, thus facilitating a greedy strategy compatible with the retractable approach. In practical terms, we throw away the (global) monotonicity events.

Traveling only through vertex-edge events. Because of the continuity and strict convexity of the elevation function, the function has a unique minimum on each edge of the free space diagram grid – geometrically, this is the minimum distance between a vertex of one curve, and an edge of the other curve (a *vertex-edge event*). We restrict our solution to enter and leave a cell only through these *portals* (which are easy to compute). The continuous configuration space now collapses to a discrete graph that is somewhat similar to the natural grid graph on $[\![n]\!] \times [\![m]\!]$. Indeed, a grid cell has four portals on its boundary edges. Specifically, there are directed edges from the portal on the bottom edge, to the portal on the top and right edges of the cell. Similarly, there are edges from the portal on the left edge, to the portals

lying on the top and right edges. As before, the values are on the portals, and our purpose is to compute the optimal bottleneck path in this grid-like graph. Examples of this graph are depicted in Figure 1.3, Figure 1.4 and Figure 1.5.

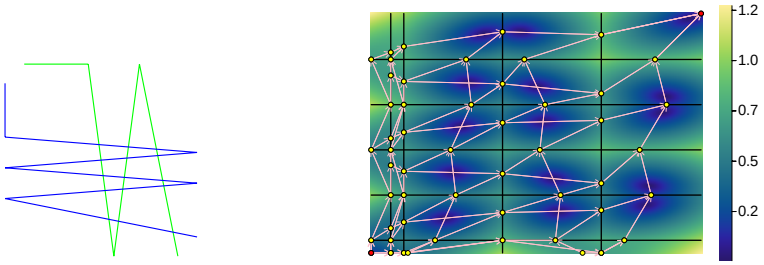

Figure 1.4 Left: Two curves. Right: Their elevation function, and the associated graph. See here for more info.

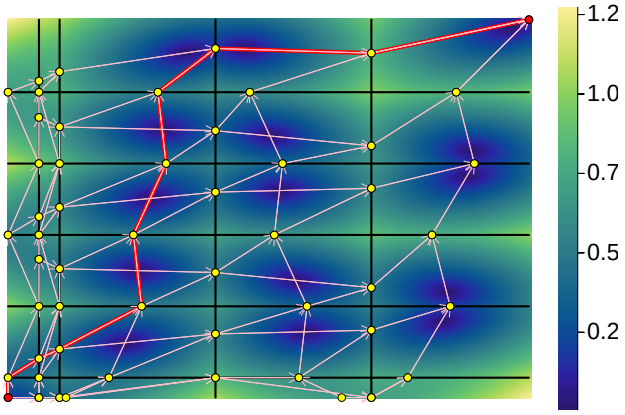

Figure 1.5 The VE-Fréchet morphing for the two curves from Figure 1.3. Note, that the solution is "slightly" not x/y-monotone. For animation of this morphing, follow the link.

▶ Remark 5. A somewhat similar idea was used by Munich and Perona [15], but they used it in the other direction – namely, in defining a better CDTW distance for two discrete sequences. However, this idea was already present (implicitly) in the original work of Alt and Godau [1] – indeed, their algorithm for the Weak Fréchet distance uses only the Vertex-Edge events (i.e., edges in the free space diagram). This boils down to solving the bottleneck shortest path problem in an undirected graph. In this case, this problem can be solved by computing the minimum spanning tree (e.g., by Prim's algorithm, which is a variant of Dijkstra's algorithm), as Alt and Godau do. For the directed case, one needs to use a variant of Dijkstra's algorithm [11] – see full version of the paper [14]. See also Buchin *et al.* [4] who also used a similar idea.

We can now run the retractable bottleneck shortest-path algorithm (i.e., the variant of Dijkstra described above) on this implicitly defined graph computing the vertices and edges of it, as they are being explored. For many natural inputs, this algorithm does not explore a large fraction of the configuration space, as it involves distances that are significantly larger than the maximum leash length needed. The algorithm seems to have near linear running time for many natural inputs. The ***VE-Fréchet*** morphing is the one induced by

the computed path in this graph. Unfortunately, the VE-Fréchet morphing might allow the agents to move backwards on an edge, but importantly, the motion across a vertex is monotone. Namely, the VE-Fréchet is monotone for vertices, but not necessarily monotone on the edges. A vertex is thus a *checkpoint* that once passed, cannot be crossed back.

1.3.3 Result III: New algorithm for the regular Fréchet distance

The natural question is how to use the (easily computable) VE-Fréchet morphing to compute the optimal (regular) continuous Fréchet distance. We next describe how this can be done in practice.

The hunt for a monotone morphing. We denote the VE-Fréchet distance between two curves π and σ by $\mathsf{d}^{ve}_{\mathcal{F}}(\pi,\sigma)$. Clearly, we have that $\mathsf{d}^{w}_{\mathcal{F}}(\pi,\sigma) \leq \mathsf{d}^{ve}_{\mathcal{F}}(\pi,\sigma) \leq \mathsf{d}_{\mathcal{F}}(\pi,\sigma)$.

One can of course turn any morphing into a monotone one by staying put instead of moving back. This is appealing for VE-Fréchet, as the corresponding VE morphing $\boldsymbol{m}$, say between two curves π and σ, never backtracks over vertices (only edges), so we already expect the error this introduces to be relatively small. Let $\boldsymbol{m}^+$ denote the monotone morphing resulting from this simple strategy. Observe that

$$\omega(\boldsymbol{m}) = \mathsf{d}^{ve}_{\mathcal{F}}(\pi,\sigma) \leq \mathsf{d}_{\mathcal{F}}(\pi,\sigma) \leq \omega(\boldsymbol{m}^+).$$

In particular, if $\omega(\boldsymbol{m}) = \omega(\boldsymbol{m}^+)$, then $\mathsf{d}_{\mathcal{F}}(\pi,\sigma)$ is realized by $\boldsymbol{m}^+$, and we have computed the Fréchet distance between π and σ.

A less aggressive approach is to introduce new vertices in the middle of the edges of π and σ as to enforce monotonicity. Indeed, clearly, if we refine both curves by repeatedly introducing vertices into them, the VE-Fréchet distance between the two curves converges to the Fréchet distance between the original curves, as introducing a vertex in the middle of an edge does not change the regular Fréchet distance, while preventing the VE-Fréchet morphing from backtracking over this point.

We refer to this process of adding vertices to the two curves as ***refinement***. (See Figure 1.6.) In practice, in many cases, one or two rounds of (carefully implemented) refinement are enough to isolate the maximum leash in the morphing from the non-monotonicity, and followed by the above brute-force monotonization leads to the (practically) optimal Fréchet distance. Even for pathological examples, after a few more rounds of refinement, this process computes the almost-exact Fréchet distance. That is, the computed lower bound, which is the VE-Fréchet distance, is equal to the width of the computed monotone morphing, which is the Fréchet distance.

▶ Remark 6 (Almost-exact: Floating point issues). As we are implementing our algorithm using floating point arithmetic, and the calculation of the optimal Fréchet distance involves distances, impreciseness is unavoidable. A slight improvement in preciseness can be achieved by using squared distances (and also slightly faster code) – but for simplicity we have not used this idea in our code. In particular, we take the somewhat pragmatic view, that an approximation to the optimal up to a factor of (say) 1.00001 can be considered as computing the "optimal" solution. We refer to such solutions as being ***almost-exact***.

Note that Fréchet morphings are somewhat less sensitive to numerical issues than other geometric problems – indeed, once a morphing is computed, one can compute its width directly.

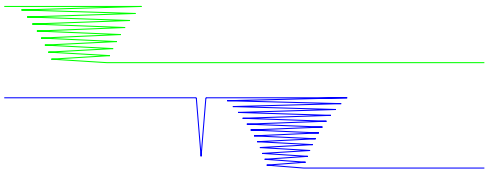

Figure 1.6 For these two curves, the solution involves an agent stopping at one point on one curve while the other agent traverses is zig-zag, and vice versa. The algorithm enforces monotonicity by refining the two curves by introducing new vertices. For the results, see here.

▶ Remark 7 (What if one wants the exact distance?). As pointed above, our algorithm computes the almost-exact Fréchet distance, and in practice there is no difference to the exact Fréchet distance (and in many cases they seem to coincide). Nevertheless, what if one insists on the exact Fréchet distance?

The refinement process can be modified to compute the monotonicity events on the regions on the curves where monotonicity is being violated. This would readily lead to an exact algorithm – from implementation point of view such a modification seems pointless, and we did not pursue it any further.

1.3.4 Result IV: Computing the Fréchet distance quickly for real inputs

The above leaves us with a natural strategy for computing the Fréchet distance between two given curves. Compute quickly, using simplification, a morphing between the two input curves, and maintain (using VE-Fréchet, for example) both upper and lower bounds on the true Fréchet distance. By carefully inspecting the morphing, (re)simplifying the curves in a way that is sensitive to their (local) Fréchet distance, and recomputing the above bounds, one can get an improved morphing. Repeat this process potentially several times till the upper and lower bounds meet, at which point the optimal Fréchet distance has been computed.

This seems somewhat overkill, but it enables us to compute (in practice) the almost-exact Fréchet distance between huge polygonal curves quickly.

1.3.5 Main contribution: Implementation in `Julia` and `Python`

We implemented the above algorithms as official packages in `Python` and `Julia`. The `Python` package is available at `https://github.com/eliotwrobson/FrechetLib`, and the `Julia` package is available at `https://github.com/sarielhp/FrechetDist.jl`. Animations and examples computed by the new algorithm are available at `https://frechet.xyz/`.

1.3.6 Additional results

Sweep distance. We demonstrate how one can convert our algorithm for computing VE-Fréchet to an algorithm that computes a variant of the CDTW distance, which we call the *sweep distance*. One can then use refinement to approximate the CDTW distance. One can also compute a lower bound on this quantity, and the two quantities converge. See the full version of the paper [14] for details.

Fast simplification. We show how to preprocess a curve π with n vertices, in $O(n \log n)$ time, such that given a query w, one can quickly extract a simplification of $\overline{\pi}$ of π, such that $\mathsf{d}_{\mathcal{F}}(\pi, \overline{\pi}) \leq w$. Importantly, the time to extract $\overline{\pi}$ is proportional to its size (i.e., the

extraction is output sensitive). More importantly, in practice, this works quite well – the size of $|V(\overline{\pi})|$ is reasonably close (by a constant factor) to the optimal approximation. Combined with greedy simplification, this yields a very good simplification result. See the full version of the paper [14] for details.

1.4 Significance

We demonstrate in this paper that a minor variant of the **continuous** Fréchet distance can be computed by a strikingly simple Dijkstra type algorithm. Furthermore, for many real world inputs it runs in near linear time (out of the box). Similarly, for many real world inputs, the computed morphing is monotone, thus realizing the (standard) Fréchet distance. More importantly, because of the *retractable* nature of the morphing computed, the matching computed is more natural, and can handle noise/outliers more gracefully than the matchings computed by the current algorithms for the Fréchet distance. Indeed, areas that are noise/outliers are isolated in the morphing to a small interval which can be easily identified and handled, see Figure 1.2. We believe that this makes the morphings computed by our new algorithms significantly better for real world applications than previous algorithms. There is also previous work on other variants of Fréchet distance that are more robust to uncertainty and outliers [10], and shortcutting [8].

We then show how to modify this algorithm to compute the (monotone) Fréchet distance (in cases when the morphing was not already monotone), and how to make it handle large inputs quickly via simplifications (handling all the technical difficulties this gives rise to).

Finally, we implemented our new algorithms in `Julia` and `Python`, and made them publicly available as standard packages, thus making the computation of the Fréchet distance accessible to a wider audience. Using such packages in `Python`/`Julia` is significantly easier than using any not pre-compiled code in `C++`.

Summary. The combination of simplification, new (and not so new) algorithmic ideas (such as retractablity via Dijkstra, and VE-Fréchet, among others), and careful implementation, leads to fast performance in practice beating other implementations. We discuss our implementation next – the algorithmic ideas described above are covered in detail in the appendices.

Full version. Due to space limitations, all the low-level details are omitted from this version. See the full version of the paper [14] (`https://arxiv.org/abs/2407.03101`) for these details.

2 Implementation and experiments

We include here some tables with information about the performance of our implementation. For details about the implementation, see the full version of the paper [14].

2.1 Discussion

Overall, it is clear that our `Julia` implementation is faster than other currently available implementations for computing the Fréchet distance. Beyond that, `Julia` seems like a great programming language to develop geometric algorithms – providing a combination of a safe, multi-threaded, high-level programming language with the performance of `C++`, without the pain involved in working in `C++`.

Table 2.1 The inputs tested and where they are taken from, `birds` referring to the stork migration dataset [18], the GeoLife dataset [20], and `Pigeons` referring to a dataset from [16].

Input	Description
1	`birds: 1787_1 / 1797_1`
2	`birds: 2307_3 / 2859_3`
3	`birds: 2322_2 / 1793_4`
4	`GeoLife 20080928160000 / 20081219114010`
5	`GeoLife 20090708221430 / 20090712044248`
6	`Pigeons RH887_1 / RH887_11`
7	`Pigeons C369_5 / C873_6`
8	`Pigeons C360_10 / C480_9`

Table 2.2 `Julia`/`C++` comparison, demonstrating that the `Julia` implementation is significantly faster. The `C++` implementation is from Bringmann *et al.* [3]. Running times are in seconds. `Julia` MT stands for the multi-threaded implementation – since multi-threading is easy in Julia, and the task at hand is easily parallizable, we tested this, but of course this should not be taken as a direct (or remotely fair) comparison to the `C++` implementation, and is provided for the reader amusement. In particular, the multi-threading done is pretty naive, and better performance should be possible by better fine-grained partition of the tasks. The tests were performed on a Linux system with 64GB memory with Intel `i7-11700` CPU, with a decent 16 threads CPU, but far from the fastest hardware currently available. The "# pairs" column is the number of pairs of curves that had their Fréchet distance compared during this test. The "avg # points" is the average number of vertices per curve in this input set – underlying the benefit of simplification for the GeoLife input set.

			Total RT in seconds			
Dataset	# pairs	avg # points	`C++`	`Julia`	`Julia` MT	`C++` / `Julia`
sigspatial	322,000	247.8	145	102	25	**1.42**
Characters	253,000	120.9	90	72	18	**1.25**
Geolife	322,000	1080.4	646	70	30	**9.22**
All tests combined			881	244	73	**3.61**

One optimization used by the `Julia` code, that should be generally useful, is the following. As a preprocessing step, precompute a hierarchy of simplified curves for each input curve. This improves the query process, but makes the preprocessing more expensive. Thus, storing such precomputed hierarchies might be a good idea if input curves are going to be used repeatedly for performing distance queries. We emphasize that the reported running times include this (light) preprocessing stage (interestingly, the SIGSPTIAL [19] competition allowed such preprocessing to not be included in the overall running time).

Abstract

We present an algorithm for computing the prime factorisation of a knot, which is practical in the following sense: using Regina, we give an implementation that works well for inputs of reasonable size, including prime knots from the 19-crossing census. The main new ingredient in this work is an object that we call an "edge-ideal triangulation", which is what our algorithm uses to represent knots. As other applications, we give an alternative proof that prime knot recognition is in coNP, and present some new complexity results for triangulations. Beyond knots, our work showcases edge-ideal triangulations as a tool for potential applications in 3-manifold topology.

Acknowledgements This work was inspired by discussions at the Dagstuhl workshop "Triangulations in Geometry and Topology" [7]. The authors would like to thank the participants for interesting conversations about knots and normal surfaces. Moreover, the authors thank Nathan Dunfield for suggesting a way to generate hard diagrams of composite knots on which to test our algorithm. We also thank the anonymous reviewers for their helpful comments.

1 Introduction

Computational problems in 3-manifold topology often exhibit a gap between theory and practice. For example, consider the Unknot Recognition problem, which takes a knot K as input, and asks whether K is equivalent to the unknot (see Section 2 for a review of all technical terminology used in this introduction). Although Regina [12] offers an Unknot Recognition algorithm that experimentally exhibits polynomial-time behaviour [15], in theory this algorithm is exponential-time in the worst case. There are other theoretical upper bounds on the complexity of Unknot Recognition, but these often use very different (and

© Alexander He, Eric Sedgwick, and Jonathan Spreer;

in some cases, much more complicated) techniques: it is in both NP [17] and coNP [25, 26], and Lackenby has announced a quasipolynomial-time algorithm [27]. It remains unknown whether there is a (deterministic) polynomial-time algorithm for Unknot Recognition.

We are interested in algorithmically recognising other types of knots as well. Baldwin and Sivek give some complexity results for such other recognition problems in [4]: they show that a range of natural problems are in NP and/or coNP (some unconditionally, others conditional on the Generalised Riemann Hypothesis). Prior to the work in the present paper, none of these problems had algorithms with practical software implementations.

In this paper, we focus on the problem of deciding whether a knot is prime or composite, and in the composite case on computing its prime factorisation. This problem arises from the classical result of Schubert [30] that every knot has a unique prime factorisation. We study variants of this problem, in decreasing order of specificity:

▶ **Problem 1** (Knot Factorisation)**.**
INPUT: *A knot K.*
OUTPUT: *A collection of knots giving the prime factorisation of K.*

▶ **Problem 2** (k-Summands)**.**
INPUT: *A knot K, and a positive integer k.*
QUESTION: *Does the prime factorisation of K have at least k nontrivial summands?*

▶ **Problem 3** (Composite Knot Recognition)**.**
INPUT: *A knot K.*
QUESTION: *Is K a composite knot?*

Most commonly, the input knot K is presented as a knot diagram. However, a diagram is difficult to work with in many settings, and the first step of many algorithms is to convert the diagram into a more useful form. Often, the conversion is to a triangulation of the **knot exterior**: the 3-manifold obtained by deleting a small open neighbourhood of K from the ambient 3-sphere. This is fine for decision problems like Problems 2 and 3; however, for Knot Factorisation, if we require the output to be in the form of knot diagrams – rather than triangulations of knot exteriors – then we have the additional challenge of converting these triangulations to diagrams, which is itself a highly nontrivial problem [16].

Our approach is to encode knots as **edge-ideal triangulations** (**H-triangulations** in [3]). For a knot K, an edge-ideal triangulation is a pair $(\mathcal{T}, \ell)$, where $\mathcal{T}$ is a triangulation of the 3-sphere $\mathbb{S}^3$, and ℓ is an embedded loop (called an **ideal loop**) of edges (called **ideal edges**) in $\mathcal{T}$, such that ℓ is topologically equivalent to K. This idea extends to triangulations $\mathcal{T}$ of arbitrary compact 3-manifolds, and collections of loops in the 1-skeleton of $\mathcal{T}$.

Embedding a knot in the 1-skeleton of a triangulation is, on its own, not a new idea. For knots in 3-manifolds this is a common choice of combinatorial encoding; e.g., see [1, 26]. But even for knots in $\mathbb{S}^3$, this setting has been described and used in many publications with various backgrounds; e.g., see [3, 5, 6, 14, 20, 28] and the references therein.

The novelty of our approach is to view an ideal loop as representing a boundary component of a 3-manifold, loosely analogous to how an ideal triangulation (in the usual sense) has boundary components given by the ideal vertices. More precisely, given an edge-ideal triangulation $(\mathcal{T}, \ell)$ of a knot K, we consider a small open solid torus neighbourhood N of ℓ, and we view $(\mathcal{T}, \ell)$ as a combinatorial presentation of the 3-manifold $\mathcal{M}$ given by deleting N from $\mathcal{T}$. In this article, $\mathcal{T}$ is a 3-sphere and hence $\mathcal{M}$ is just the exterior of K.

To see why this perspective is useful, consider a normal surface S in $\mathcal{T}$. The intersection of S with the solid torus N is a disjoint union of meridian discs, with one such disc for each point in $S \cap \ell$. After deleting N, S becomes a surface that intersects the torus boundary of

$\mathcal{M}$ in curves that all have the same slope (in our case, the slope of the meridian of the knot). Hence, the edge-ideal triangulation carries more information than just the topology of $\mathcal{M}$: it also prescribes a slope along which normal surfaces must intersect the boundary of $\mathcal{M}$.

We use this setting to factorise knots in the 3-sphere. However, we believe other applications for edge-ideal triangulations exist. For instance, consider the problem of recognising Seifert fibred spaces (SFS) with nonempty boundary. This was shown to be in NP by Jackson [22], but the techniques are not well-suited to practical implementation. SFS with boundary fit well into the framework of edge-ideal triangulations: any such SFS $\mathcal{M}$ can be characterised using "vertical" essential annuli, which intersect components of $\partial\mathcal{M}$ in prescribed slopes. Exploring this idea is work in progress.

The utility of edge-ideal triangulations goes beyond the observation about boundary slopes of surfaces. It also allows us to apply the tool of **crushing** a normal surface, discussed in detail below. Crushing plays a central role in a number of practical 3-manifold algorithms provided by Regina [9, 10, 12], such as unknot recognition or 3-sphere recognition.

Our work extends this to give practical algorithms for Problems 1–3. In Section 5.3, we give a straightforward linear-time procedure to convert a diagram of a knot K into an edge-ideal triangulation of K, so our techniques apply equally to either method of encoding the input knot. However, converting an edge-ideal triangulation back into a knot diagram is sufficiently difficult to be beyond the scope of this paper. Thus, we settle for the following:

▶ **Theorem 4.** *There is an algorithm for* Knot Factorisation *that returns the prime factorisation of the input knot K as a collection of edge-ideal triangulations.*

The algorithm (see Algorithm 13) relies heavily on the tool of crushing normal surfaces. For our implementation, we use Regina's [12] longstanding crushing functionality, which is already known to be effective in practice. As it turns out, this practicability extends to our implementation: we are able to run our algorithm on prime knots from the census up to 19 crossings [11], as well as composite knots constructed by summing up to 8 knots sampled from the census (hence, knots with up to 152 crossings), including some "hard" diagrams of composite knots with up 70 crossings. See Section 5.4 for details on these experiments.

In addition to the practical implications, we also adapt our techniques to obtain theoretical upper bounds on computational complexity. Specifically, we prove the following:

▶ **Theorem 5.** *Problem 2 (k-Summands) is in* NP.

Since Problem 3 is a special case of Problem 2, this yields an alternative proof of one of Baldwin and Sivek's results [4, Theorem 7.3]: Composite Knot Recognition is in NP.

The operation of crushing a normal surface is crucial to both the practicality of Algorithm 13 and the proof of Theorem 5, so we now elaborate on its role in our work.

Inspired by unpublished work of Casson, crushing was first studied in detail by Jaco and Rubinstein [23], and later reformulated into a more implementation-friendly framework by Burton [10]. To date, one limitation of crushing is that the theory remains relatively poorly developed for surfaces other than 2-spheres and discs (though see [13, 21]). At first glance, this is an obstacle for the applications we have mentioned. For a knot K, testing whether K is composite entails finding a certain essential annulus (in the exterior of K). The same applies to recognising SFS with boundary.

By working with an edge-ideal triangulation $(\mathcal{T}, \ell)$, we circumvent this issue: the annuli show up in $\mathcal{T}$ as 2-spheres that intersect ℓ in two points. Thus, instead of crushing annuli, we are able to work in the better-understood setting of crushing 2-spheres. In Section 4, we develop the theory required to apply crushing in the presence of ideal loops.

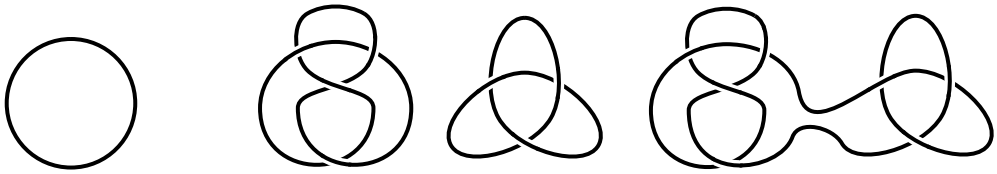
The reason crushing is useful for practical computations is that it never increases the number of tetrahedra in a triangulation. This allows us to factor a knot efficiently: we can repeatedly crush surfaces to progressively "decompose" the knot, whilst simultaneously keeping tight control on the amount of data needed to encode the resulting factorisation.

Another feature of our work is that we work exclusively with **quad vertex** 2-spheres in our edge-ideal triangulations; we show that suitable 2-spheres exist in Section 3. Theoretically, this is necessary to control how crushing affects the ideal loop; see Section 4. But even if this theoretical challenge were not present, working with quad (instead of standard) coordinates is often crucial for improving the practical performance of algorithms involving normal surfaces.

We combine the aforementioned ideas to formulate our main algorithm (Algorithm 13) in Section 5; we prove correctness of the algorithm, discuss some implementation details, and summarise our experimental results. In Section 6, we show how our techniques also give a proof of Theorem 5. Finally, we discuss further applications in relation to triangulation complexity in Section 7.

2 Background

A **knot** is an embedding of a circle $K : S^1 \to \mathbb{R}^3$ into 3-space. We sometimes embed knots into the 3-sphere $\mathbb{S}^3$, instead of $\mathbb{R}^3$; since $\mathbb{S}^3$ is the one-point compactification of $\mathbb{R}^3$, this has the benefit of making our topological space compact, but otherwise makes very little difference to the theory. Two knots are **equivalent**, or of the **same type**, if there is an ambient isotopy $\Phi : \mathbb{R}^3 \times [0,1] \to \mathbb{R}^3$ taking the image of one to the image of the other; intuitively, two knots are equivalent if one can be deformed into the other without passing the knot through itself. If a knot is equivalent to the trivial unknotted circle, we call it the **unknot**, or the **trivial knot**; otherwise, the knot is **nontrivial**.



(a) The unknot. **(b)** Two nontrivial knots (left and middle), and a connected sum of them (right).

Figure 1 Some examples of knot diagrams.

We typically represent a knot by a **diagram**, obtained by generically projecting the knot into a plane, while keeping information about which strand goes over and which goes under at **crossings** of the projection. Given two knots K_1 and K_2, we can construct a **connected sum** $K = K_1 \# K_2$ by cutting both K_1 and K_2 and gluing the ends together to form a new knot. A knot is **composite** if it is the connected sum of two nontrivial knots; otherwise, the knot is **prime**. Every nontrivial knot K has a **factorisation** $K = K_1 \# \ldots \# K_\ell$ into nontrivial prime knots K_i, $1 \leqslant i \leqslant \ell$, and this factorisation is unique up to re-ordering [30].

2.1 Triangulations of manifolds

A **triangulation** $\mathcal{T}$ (of **size** $|\mathcal{T}| := n$) is given by taking a finite set of disjoint tetrahedra $\Delta_1, \ldots, \Delta_n$, and gluing them together along their $4n$ boundary triangles in pairs. Let $\Phi_1, \ldots, \Phi_{2n}$ denote the gluings. The quotient space $\mathcal{T} = \{\Delta_1, \ldots, \Delta_n\}/\{\Phi_1, \ldots, \Phi_{2n}\}$ forms a closed 3-manifold, in which case we call $\mathcal{T}$ a **3-manifold triangulation**, if and only if: *(a)* no edge is identified to itself in reverse; and *(b)* for each vertex v of $\mathcal{T}$, the **link** of v – i.e., the frontier of a small regular neighbourhood of v – forms a 2-sphere.

As a result of the gluings, multiple lower-dimensional faces of $\{\Delta_1, \dots, \Delta_n\}$ become identified and we refer to the equivalence class of such faces as a single face of the triangulation $\mathcal{T}$. In fact, we often consider **1-vertex triangulations**, where all $4n$ vertices of $\{\Delta_1, \dots, \Delta_n\}$ are identified to a single vertex. Two 3-manifold triangulations are said to be **combinatorially isomorphic** if one of them can be turned into the other by a relabelling of its faces.

Let $\mathcal{M}$ be a 3-manifold with non-empty boundary $\partial\mathcal{M}$ a collection of tori. An **ideal triangulation** of $\mathcal{M}$ is a triangulation with one vertex per component of $\partial\mathcal{M}$ such that its vertex link triangulates the boundary component, and $\mathcal{M}$ is homeomorphic to the underlying set of the triangulation with a neighbourhood of the vertices removed.

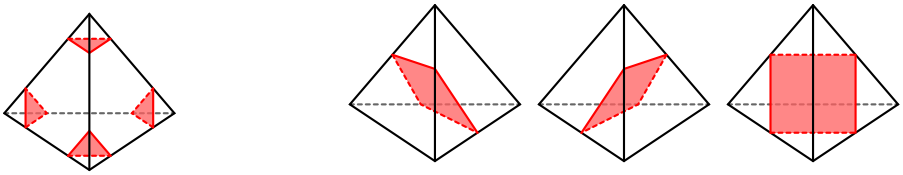
2.2 Normal surface theory and crushing

Consider a disc D properly embedded in a tetrahedron Δ so that its boundary γ is in *general position* – i.e., γ is disjoint from the vertices of Δ, and intersects the edges of Δ transversely. The **weight** of D in Δ is the number of points in which D intersects the edges of Δ.

A **normal surface** S in a triangulation $\mathcal{T}$ is a properly embedded surface such that:

- S is in general position: it is disjoint from the vertices of $\mathcal{T}$, and it intersects the edges and triangular faces of $\mathcal{T}$ transversely.
- For each tetrahedron Δ of $\mathcal{T}$, the intersection $\Delta \cap S$ consists of a (possibly empty) disjoint union of finitely many positive-weight discs, called **elementary discs**, such that the boundary of each elementary disc intersects each edge of Δ at most once.

The combinatorics of a normal surface remains unchanged under a **normal isotopy**: an ambient isotopy that preserves each vertex, edge, face and tetrahedron of the triangulation. Up to normal isotopy, each tetrahedron admits seven types of elementary discs: four **triangle** types and three **quadrilateral** (or **quad**) types (see Figure 2).



(a) The four triangle types. **(b)** The three quad types.

Figure 2 The seven types of elementary disc.

The link of a vertex v is an example of a normal surface. It is built entirely from elementary triangles (see Figure 3); conversely a normal surface consisting only of triangles must be a union of vertex-linking components. With this in mind, we call a normal surface **trivial** if it only has triangles, and **nontrivial** if it has at least one quad.

Normal surfaces can be described purely combinatorially by **coordinates**, counting the number of elementary disc types contained in them. These coordinates are subject to linear **matching equations** forcing the elementary discs to "match up" across triangular faces of $\mathcal{T}$. They must also have at most one quad type per tetrahedron, a condition called the **quad constraint**, to ensure that the surface is embedded. See [18, Section 2.3] for more details.

Using coordinates allows us to form sums of normal surfaces (subject to the quad constraints). More generally, it means that for an n-tetrahedron triangulation $\mathcal{T}$, all normal surface coordinate vectors lie inside a polyhedral cone in $\mathbb{R}^{7n}$, which can be described by providing one normal surface – called a **(standard) vertex** (normal) surface – per extremal ray of this cone. Vertex surfaces can be computed in finite time, and described efficiently [17].

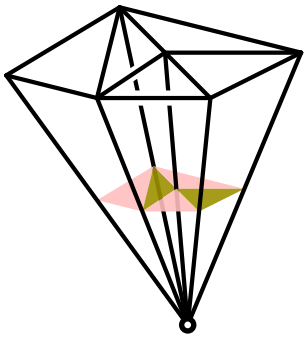


Figure 3 The link of a vertex is a normal surface built entirely from triangles.

Moreover, in all of this, it can be shown that it suffices to keep track of quadrilateral discs, and hence a polyhedral cone in $\mathbb{R}^{3n}$, leading to a (smaller) set of **quad vertex** (normal) surfaces that still describes the space of all normal surfaces in $\mathcal{T}$. See [18, Section 2.4] for more details, as well as some useful characterisations of vertex surfaces.

Given a normal surface S in a triangulation $\mathcal{T}$ of a 3-manifold $\mathcal{M}$, we can cut along S, shrink S to a point, and collapse cells that are not simplices until we recover a (possibly disconnected) triangulation $\mathcal{T}'$. This operation is called **crushing (S in $\mathcal{T}$)** and, in general, destroys much valuable information about $\mathcal{T}$ and $\mathcal{M}$. However, if done carefully, crushing provides an efficient way to "decompose" $\mathcal{T}$ into a new triangulation $\mathcal{T}'$ that represents the manifold $\mathcal{M}'$ obtained from $\mathcal{M}$ by cutting along S and then shrinking S to a point. Moreover, crushing has an extremely important algorithmic advantage: whenever S is nontrivial, we have $|\mathcal{T}'| < |\mathcal{T}|$. See [18, Section 2.5] for more details about crushing.

3 Existence of suitable quad vertex normal spheres

In this section we prove that, in any edge-ideal triangulation $(\mathcal{T}, \ell)$ of a composite knot, we can always find a normal 2-sphere that we can use to either reduce the size of our input, or to witness a (possibly trivial) decomposition of the knot. Crucially, we can ensure that these 2-spheres are quad vertex, which allows us to: *(a)* enumerate candidate 2-spheres efficiently, and *(b)* control the effect of crushing such 2-spheres.

Let $(\mathcal{T}, \ell)$ be an edge-ideal triangulation of a knot K. The ideal loop ℓ consists of a sequence of edges of $\mathcal{T}$, which we denote by $\ell_1, \ldots, \ell_m$. For any edge e of $\mathcal{T}$ and any normal surface S in $\mathcal{T}$, let $w_e(S)$ denote the **edge-weight** of S at e – i.e., the number of times S intersects e. Moreover, we define $w_\ell(S) = \sum_{i=1}^{m} w_{\ell_i}(S)$ – i.e., the number of times S intersects the loop ℓ. We have the following two lemmas (see [18, Section 3] for proofs):

▶ **Lemma 6.** *Let $(\mathcal{T}, \ell)$ be an edge-ideal triangulation of a knot K. If K is a composite knot, then $\mathcal{T}$ contains a nontrivial normal 2-sphere S with $w_\ell(S) = 2$.*

▶ **Lemma 7.** *Let $(\mathcal{T}, \ell)$ be an edge-ideal triangulation of a knot. Moreover, let Ω denote the set of all nontrivial normal 2-spheres S in $\mathcal{T}$ such that either $w_\ell(S) = 0$ or $w_\ell(S) = 2$. If Ω is nonempty, then there must be a quad vertex normal surface in Ω.*

▶ **Corollary 8.** *Let $(\mathcal{T}, \ell)$ be an edge-ideal triangulation of a knot K. If K is composite, then $\mathcal{T}$ contains a quad vertex 2-sphere S such that either $w_\ell(S) = 0$ or $w_\ell(S) = 2$.*

Proof. To apply Lemma 7, we simply note that Ω is nonempty, by Lemma 6. ◀

▶ **Corollary 9.** *Let $(\mathcal{T}, \ell)$ be an edge-ideal triangulation of a knot K. If K is composite, then $\mathcal{T}$ contains a standard vertex 2-sphere S such that either $w_\ell(S) = 0$ or $w_\ell(S) = 2$.*

Proof. This follows from [8, Lemma 4.5]: any quad vertex surface is also *standard* vertex. ◀

4 Tracking ideal edges under crushing

Consider an edge-ideal triangulation $(\mathcal{T}, \ell)$ and a quad vertex 2-sphere S intersecting ℓ twice. It is known that crushing S only mildly changes the topology of $\mathcal{T}$ [10]. In this section, we use a new characterisation of quad vertex 2-spheres to show that crushing S also only mildly changes the ideal loop ℓ. Moreover, using work of Agol, Hass, and Thurston [1, Sections 4 and 6], we can track how ℓ changes in time polynomial in $|\mathcal{T}|$; this is purely theoretical, and in practice a much simpler and more naive tracking method is efficient enough.

4.1 Orbits of segments

Let S be a normal surface in an edge-ideal triangulation $(\mathcal{T}, \ell)$. We say that S splits an (ideal) edge into **(ideal) segments**. After crushing S, each segment either gets destroyed or gets identified with a **surviving** segment that becomes an edge of the new triangulation. To determine how crushing S changes the ideal loop, we track how it causes ideal and surviving segments to be identified. Here, we outline how this can be done using the Agol-Hass-Thurston weighted orbit-counting algorithm from [1]; see [18, Section 4.1] for details.

We begin by defining the **induced orbit** $o(\sigma)$ of a segment σ to be a cell complex comprised of all the parts of $\mathcal{T}$ that get collapsed and identified with σ as a result of crushing S; this is not a subcomplex of $\mathcal{T}$, but rather a subcomplex of the cell decomposition obtained by subdividing $\mathcal{T}$ along S. We say that a segment is **type-k**, $k \in \{0, 1, 2\}$, if S intersects exactly k endpoints of the segment; all the segments in an induced orbit must have the same type, and hence we often say the orbit itself is type-k, for some k.

An induced orbit containing an ideal segment is called an **ideal orbit**, and is of particular interest to us. Indeed, our goal is to algorithmically determine which surviving segments belong to an ideal orbit. The challenge is that an induced orbit can be very large: the number of segments in a type-2 orbit can be of the same order as the size of the normal coordinates of S; this is exponential in $|\mathcal{T}|$ if S is quad vertex [17]. The Agol-Hass-Thurston machinery enables us to avoid the cost of explicitly tracing through such large orbits.

Abstractly, the Agol-Hass-Thurston weighted orbit-counting algorithm [1, Section 6] involves: k **pairings** between sequences of consecutive integers in $[1, N] := \{n \in \mathbb{Z} : 1 \leqslant n \leqslant N\}$ (i.e., bijections that either preserve or reverse the order between sequences); and a **weight function** $w : [1, N] \to \mathbb{Z}^d$. For each orbit in $[1, N]$ under the pairings, the algorithm computes the sum of the weights of the orbit's elements.

To apply this to our setting, we take each triangular face F of $\mathcal{T}$, and use F to define three pairings between sequences of consecutive segments, as illustrated in Figure 4. Two segments then belong to the same orbit under these pairings if and only if they belong to the same induced orbit. For the weights, we assign a coordinate to each surviving or ideal segment, and essentially use the weight vectors as indicator functions. The upshot is that after using the Agol-Hass-Thurston algorithm to compute the total weight of each orbit, we can read off: *(a)* which orbits contain an ideal segment, and *(b)* which surviving segments belong to each ideal orbit. Moreover, if S is a vertex surface, then plugging the bounds from [17] into the running time for the Agol-Hass-Thurston algorithm gives a polynomial in $|\mathcal{T}|$.

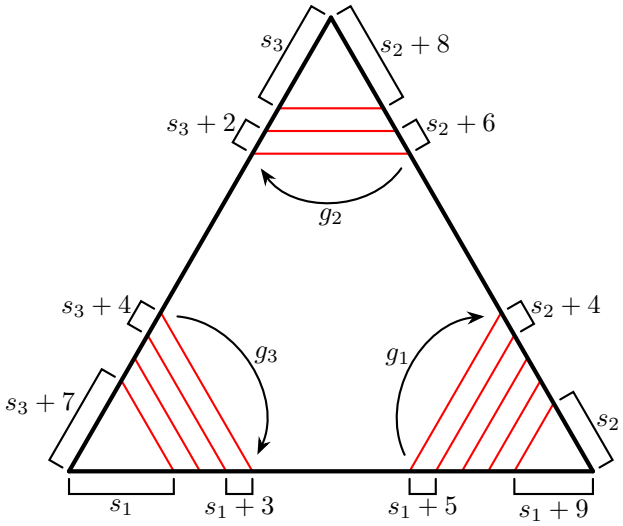

Figure 4 This triangle defines three pairings: $g_1 : [s_1+5, s_1+9] \to [s_2, s_2+4]$, $g_2 : [s_2+6, s_2+8] \to [s_3, s_3+2]$, and $g_3 : [s_3+4, s_3+7] \to [s_1, s_1+3]$. Adapted from Figure 4 of [1].

4.2 Quad vertex 2-spheres and trivial induced orbits

Call a type-1 induced orbit **trivial** if it forms a cone over a homotopically trivial subcomplex of S built from normal arcs and triangles. Call a type-2 induced orbit **trivial** if it forms a homotopically trivial product I-bundle. Our algorithm relies on the fact that quad vertex 2-spheres have trivial induced orbits. In fact, we can prove not just this, but also its converse:

▶ **Lemma 10.** *A normal 2-sphere is quad vertex if and only if every type-1 and every type-2 segment has a trivial induced orbit.*

Proof outline. Jaco and Tollefson gave a characterisation of vertex 2-spheres in terms of an object called an **exchange annulus** [24, Theorem 4.1]. As hinted in Figure 5, exchange annuli are closely related to type-2 orbits; type-1 orbits come into play because we are working with *quad* vertex 2-spheres. We prove the lemma by adapting the techniques from [24] to deal with both types of induced orbit. See [18, Sections 4.2 and 4.3] for details. ◀

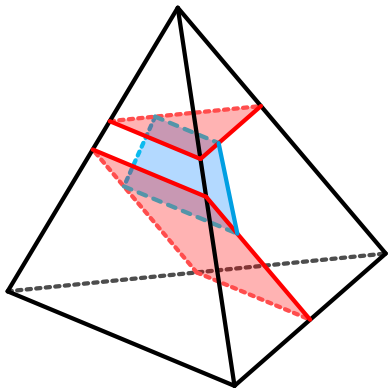

Figure 5 In each tetrahedron, an exchange annulus (blue) is always "close to" a type-2 segment.

4.3 The effect of crushing on ideal loops

Let $(\mathcal{T}, \ell)$ be an edge-ideal triangulation of a (possibly trivial) knot K. We now study the effect of crushing quad vertex 2-spheres that intersect the ideal loop ℓ in at most two points.

▶ **Lemma 11.** *Let $(\mathcal{T}, \ell)$ be an edge-ideal triangulation of a (possibly trivial) knot K, and let S be a quad vertex 2-sphere with $w_\ell(S) = 0$.*

Crushing S yields a new triangulation $\mathcal{T}'$ consisting of either one or two 3-sphere components. Moreover, all the edges in ℓ are left untouched, and together form an embedded loop in a component $\mathcal{T}'_0$ of $\mathcal{T}'$, and $(\mathcal{T}'_0, \ell)$ forms an edge-ideal triangulation of K.

Proof outline. Let $\mathcal{T}'$ denote the triangulation given by crushing S. Because S and ℓ are disjoint, crushing S only changes parts of $\mathcal{T}$ that are sufficiently "far away" from ℓ to ensure that ℓ survives untouched inside a component of $\mathcal{T}'$; in particular, $\mathcal{T}'$ is nonempty. Moreover, since S is quad vertex, it is a consequence of Lemma 10 that $\mathcal{T}'$ has at most two components, each of which must be a 3-sphere. See [18, Lemma 21] for a complete proof. ◀

▶ **Lemma 12.** *Let $(\mathcal{T}, \ell)$ be an edge-ideal triangulation of a (possibly trivial) knot K, and let S be a quad vertex 2-sphere with $w_\ell(S) = 2$, so that S cuts ℓ into two ideal arcs α_1 and α_2, corresponding respectively to two (possibly trivial) knots K_1 and K_2 such that $K = K_1 \# K_2$.*

Crushing S yields a new triangulation $\mathcal{T}'$ consisting of either one or two 3-sphere components. Moreover, for each new knot K_i, $i = 1, 2$, we have either:

1. *all the segments in α_i survive the crushing to become an embedded loop ℓ'_i in a component $\mathcal{T}'_i$ of $\mathcal{T}'$, so that $(\mathcal{T}'_i, \ell'_i)$ forms an edge-ideal triangulation of K_i;*
2. *α_i consists of two type-1 segments, and these two segments merge to form a single non-loop edge ℓ'_i in a component $\mathcal{T}'_i$ of $\mathcal{T}'$; or*
3. *α_i is deleted.*

Cases 2 and 3 can only happen if K_i is trivial. If K_1 and K_2 both fall under Case 1, then the corresponding components $\mathcal{T}'_1$ and $\mathcal{T}'_2$ are distinct.

Proof outline. We give some intuition for the three cases. See [18, Lemma 22] for details.

Since S is a quad vertex 2-sphere, it is a consequence of Lemma 10 that crushing S gives a triangulation $\mathcal{T}'$ with at most two components, each of which is a 3-sphere. Moreover, since S is a separating 2-sphere, the two ideal arcs α_1 and α_2 must end up in different components of $\mathcal{T}'$. In the case where $\mathcal{T}'$ has fewer than two components, this simply means that the corresponding ideal arc α_i was deleted entirely (this is Case 3); it can be shown that this only occurs if the corresponding knot K_i is trivial.

It remains to consider what happens for an ideal arc α_i that survives. Since crushing involves collapsing S to a point, we know that the endpoints of α_i become identified in $\mathcal{T}'$. If these are the only points of α_i that get identified, then the result is an ideal loop corresponding to the knot K_i (this is Case 1). Otherwise, if crushing causes further identifications in α_i, then it can be shown that α_i falls under Case 2, and that K_i is trivial. ◀

To summarise, Lemmas 11 and 12 show that if we crush suitable quad vertex 2-spheres, then this changes the ideal loop in a topologically meaningful way. Moreover, as a consequence of the Agol-Hass-Thurston machinery described in Section 4.1, we can also efficiently keep track of how the ideal loop changes. These two pieces of machinery are, together, what allow us to give the algorithmic applications that follow in Sections 5 and 6.

5 Algorithm and implementation

The algorithm below takes a knot K as input, and produces the prime factorisation of K as a collection of edge-ideal triangulations. As stated, the input is a diagram of K, but by skipping Step 1 the algorithm can also be seen as taking an edge-ideal triangulation as input.

▶ **Algorithm 13.** *Given a diagram of a knot K, compute the prime factorisation of K (represented as edge-ideal triangulations) as follows:*

1. *Build an edge-ideal triangulation $(\mathcal{T}_K, \ell_K)$ of K; i.e., build a triangulation $\mathcal{T}_K$ of $\mathbb{S}^3$ such that K is embedded in $\mathcal{T}_K$ as an ideal loop ℓ_K. Section 5.3 describes how this can be done.*
2. *Create an empty list $\mathcal{P}$ (which will eventually contain all the prime summands). Also, create a list $\mathcal{L}$ of edge-ideal triangulations to process, initially containing just $(\mathcal{T}_K, \ell_K)$.*
3. *If $\mathcal{L}$ is nonempty, then pick and remove one edge-ideal triangulation $(\mathcal{T}, \ell)$ from $\mathcal{L}$ and **continue to Step 4**. Otherwise, **terminate with output** $\mathcal{P}$.*
4. *Search for a quad vertex normal 2-sphere S in $\mathcal{T}$ with either $w_\ell(S) = 0$ or $w_\ell(S) = 2$.*
   - *If S exists, crush it and keep track of the resulting ideal loops, as discussed in Section 4. Append all components of the resulting triangulation to $\mathcal{L}$ that contain an ideal loop. Discard the others.*
   - *If S does not exist, test whether ℓ forms a nontrivial knot. If so, add $(\mathcal{T}, \ell)$ to $\mathcal{P}$.*

   *In either case, **return to Step 3**.*

5.1 Correctness of the algorithm

▶ **Theorem 14.** *Algorithm 13 terminates and correctly factorises K into prime knots.*

Proof outline. To see that the algorithm terminates, note that only Steps 3 and 4 repeat. Together they replace (in $\mathcal{L}$) a triangulation $(\mathcal{T}, \ell)$ with (any of the nontrivial) triangulations obtained by crushing $(\mathcal{T}, \ell)$ along a normal sphere. As crushing strictly reduces the number of tetrahedra, the total number of tetrahedra contained in $\mathcal{L}$ decreases, and the number of iterations is at most the number of tetrahedra in the initial triangulation.

Each time before we execute Step 3 we verify that: *(a)* items in $\mathcal{L}$ are edge-ideal triangulations of (possibly trivial or composite) knots; *(b)* items in $\mathcal{P}$ are edge-ideal triangulations of nontrivial prime knots; and *(c)* K is given by composing all knots in $\mathcal{P} \cup \mathcal{L}$. This is true the first time we execute Step 3. For every other non-final iteration, we remove a summand from $\mathcal{L}$ that is processed by Step 4. If a suitable sphere is found, it is crushed and any nontrivial subsummands (by Lemmas 11 and 12) are returned to $\mathcal{L}$. If no sphere is found, then by Corollary 8 the summand is prime and moved to $\mathcal{P}$. In either case, *(a)–(c)* continue to hold.

In the final execution of Step 3, $\mathcal{L}$ is empty and thus the output list $\mathcal{P}$ contains the prime summands of K. See [18, Theorem 24] for details omitted from this proof outline. ◀

5.2 Optimisations and other implementation details

The most obvious optimisation is to simplify triangulations before attempting any other computations. For ideal triangulations of the knot complement, we can use the simplification tools available in Regina [12]. But for *edge-ideal* triangulations, we must instead use custom simplification tools to ensure that the ideal loop is preserved; see [18, Section 5.4] for details.

Furthermore, the algorithm has some potential bottlenecks that provide opportunity for optimisation. We found it effective to run multiple techniques in parallel to determine the best performing technique for any particular input.

1. We use different techniques for turning a knot into an edge-ideal triangulation. The most reliable one directly constructs an edge-ideal triangulation with $9n$ tetrahedra from an n-crossing input diagram, before simplifying it; it is illustrated in Figure 6. Other heuristics may be faster, or produce smaller triangulations. See Section 5.3 for details.

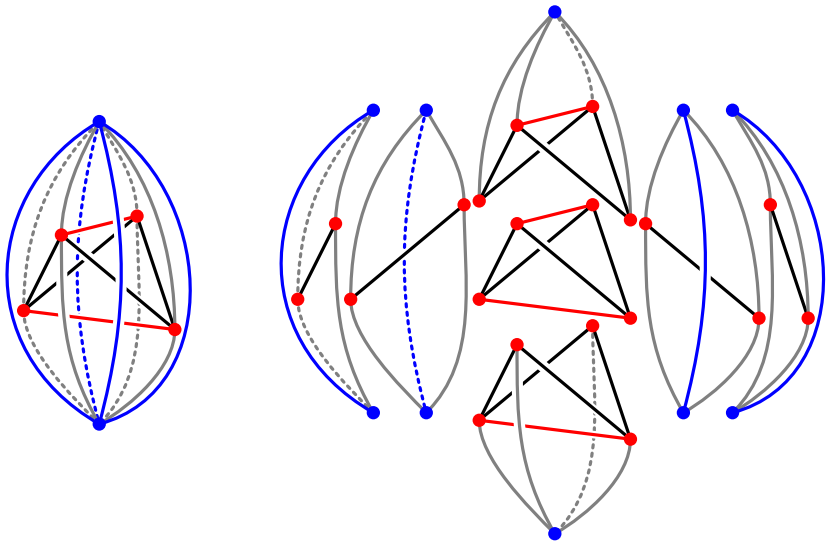

Figure 6 The 9 tetrahedron crossing gadget. Left: fully assembled gadget; red edges correspond to over- and under-crossing strands. Right: exploded view showing the individual tetrahedra.

2. In practice, the quad vertex surface enumeration in Step 4 usually terminates quickly. In the rare cases where the enumeration is not so quick, our remedy is to run the following in parallel with the enumeration: repeatedly randomise the triangulation, and attempt a (hopefully quick) enumeration on the new triangulation. See [18, Section 5.5] for details.
3. We can conclusively determine whether a knot is nontrivial using solid torus recognition, but this can be slow because it requires normal surface enumeration. In practice, running the algorithm on a nontrivial knot never seems to produce unknotted ideal loops. Thus, the main opportunity for optimisation here is to use fast heuristics that are usually good at certifying that a knot is nontrivial. See [18, Section 5.6] for details.

5.3 Building an edge-ideal triangulation from a knot

When the input knot K is presented as a knot diagram, our first task is to convert this into an edge-ideal triangulation of K. We use two techniques in parallel to achieve this task.

The first technique takes a knot diagram with n crossings, and guarantees to produce an edge-ideal triangulation of size $9n$ with an ideal loop of length $2n$. This is excellent in theory since the cost of the conversion is only linear, but as we discuss shortly 9 is a large enough constant to be a challenge in practice.

To describe the construction, view the input knot diagram as a 4-regular graph embedded in a 2-sphere S, with over- and under-crossing information recorded at each vertex of the graph. The dual graph decomposes S into 4-sided faces, with one crossing per face. Viewing the ambient 3-sphere as a suspension of S (i.e., two cones over S, glued together along S), we obtain a decomposition of the 3-sphere into 4-sided footballs: each football is a suspension of one of the 4-sided faces of S. We build an edge-ideal triangulation of the knot by triangulating each football with 9 tetrahedra, with two edges corresponding respectively to the over- and under-crossing strands inside that football; see Figure 6.

This construction is fast to perform, but the resulting triangulation is too large to give practical running times. Using combinatorial moves, our implementation reduces the length of the ideal loop to 1, and usually produces a significantly smaller triangulation. However, this simplification step is sufficiently slow to be a bottleneck for our implementation.

Our second technique is a heuristic construction that, though not guaranteed to terminate, typically produces small edge-ideal triangulations. Starting with a knot diagram, *(1)* triangulate the knot exterior, *(2)* modify this triangulation so that the meridian and longitude appear as boundary edges, and *(3)* attach a snapped 3-ball (a 1-tetrahedron gadget) to ensure that the meridian bounds a disc. Topologically, this realises a $\frac{1}{0}$ Dehn filling, and the longitude becomes the ideal loop. Regina [12] provides functionality for each of these steps, but the overall procedure is not guaranteed to terminate because we only have a *heuristic* method for *(2)*. See [18, Section 5.3] for more details on this second technique.

In practice, the second technique is often very fast, but sometimes prohibitively slow. Thus, running both techniques in parallel is an essential feature of our implementation.

5.4 Experimental results

In this section we demonstrate that Algorithm 13 is practical – and in some cases even quite efficient – for typical inputs. The code and the experimental data can be accessed from `https://github.com/AlexHe98/idealedge`.

On a laptop with an Intel Core i5-7200U processor, we ran Algorithm 13 over: *(a)* all 122 torus knots with 15 to 100 crossings; *(b)* all 376 satellite knots from the census [11] of prime knots with 15 to 19 crossings; *(c)* 100 hyperbolic knots with 15 or 16 crossings; and *(d)* a sample of composite knots with up to 8 prime summands and 152 crossings.

Algorithm 13 certified primeness of: all 122 torus knots in 310.02 seconds (2.54 seconds per knot); all 376 satellite knots in 404.66 seconds (1.08 seconds per knot); and all 100 hyperbolic knots in 138.48 seconds (1.38 seconds per knot). Note that for hyperbolic knots, the crushing part of our algorithm rarely has to run because heuristics for verifying hyperbolicity are often very efficient.

To obtain composite knots, we randomly sample census knots and form their connected sum. Thirty of these composite knots were sums of two prime knots, with diagrams deliberately constructed to "look prime"; Algorithm 13 factorised all of these in 124.82 seconds (4.16 seconds per knot). We also generated 430 composite knots with diagrams constructed in the standard way; timings for these are summarised in the table below.

# prime summands	# of samples	avg. running time per knot
2	100	4.71
3	100	10.95
4	100	24.06
5	100	33.06
6	10	47.75
7	10	70.21
8	10	88.68

Finally, we used the algorithm from [2] to randomly sample 1-vertex triangulations of 3-spheres, and look at the knot types of their edges. To maximise the variety of knots encountered, we started at a triangulation with no unknotted edges from [14]. We sampled 285 knots in triangulations of size 25–30, with running times of ≈ 0.23 seconds per knot.

6 NP certificate for composite knots

We now adapt our techniques to prove Theorem 5: Problem 2 is in NP, and hence Composite Knot Recognition is in NP. Recall that Problem 2 asks whether a given knot K has at least k summands in its prime factorisation.

Our certificate consists of a sequence of edge-ideal triangulations $(\mathcal{T}_0, L_0), \dots, (\mathcal{T}_m, L_m)$ and quad vertex normal surfaces S_i of $\mathcal{T}_i$, $i \in \{0, \dots, m-1\}$, such that: *(a)* $(\mathcal{T}_0, L_0)$ is obtained from K via the procedure outlined in Section 5.3; *(b)* every $(\mathcal{T}_{i+1}, L_{i+1})$ is obtained from $(\mathcal{T}_i, L_i)$ by crushing a suitable quad vertex normal sphere S_i of $\mathcal{T}_i$; and *(c)* for all $i \in \{0, \dots, m\}$, $(\mathcal{T}_i, L_i)$ is a union of edge-ideal triangulations of knots in $\mathbb{S}^3$, such that the input knot K is equal to the connected sum of the knots represented by the components of L_i. The certificate is completed by a set of k components of L_m together with a certificate that they form nontrivial knots in their respective components.

Since crushing reduces the size of a triangulation, the S_i are quad vertex normal surfaces, and knottedness lies in NP, the certificate is of polynomial size due to [17, 26].

The procedure from Section 5.3 to build an edge-ideal triangulation $(\mathcal{T}_0', L_0')$ of K, and the verification that $(\mathcal{T}_0', L_0')$ is combinatorially isomorphic to $(\mathcal{T}_0, L_0)$ are both polynomial time procedures (see, e.g., [29, Lemma 3.1 and Remark 3.2]). The same applies to checking for each $i \in \{0, \dots, m-1\}$, that either $w_{\ell_i}(S_i) = 0$ or $w_{\ell_i}(S_i) = 2$, and certifying that S_i is a quad vertex 2-sphere. For this latter task, we must show that type-1 and type-2 induced orbits are trivial, and that S_i is connected; see [18, Section 6.1] for details.

Crushing $\mathcal{T}_i$ along S_i to obtain triangulation $\mathcal{T}'$ can be done in polynomial time; see [18, Section 2.5]. The same is true for identifying the new collection of ideal loops L_{i+1}', following Section 4; and for verifying that $(\mathcal{T}_{i+1}', L_{i+1}')$ and $(\mathcal{T}_{i+1}, L_{i+1})$ are combinatorially isomorphic. Verifying knottedness of components of L_m is polynomial time due to [26].

To prove correctness of the above algorithm, it suffices to check that condition *(c)* above is valid for all $i \in \{0, \dots, m\}$. It then follows from the uniqueness of prime factorisation [30], that this is enough to verify that the input knot K has at least k summands.

First note that *(c)* is clearly satisfied for $(\mathcal{T}_0, L_0)$. To proceed by induction, assume that *(c)* is satisfied for some $(\mathcal{T}_i, L_i)$, $0 \leqslant i < m$. Let C_i denote the component of $\mathcal{T}_i$ containing S_i and with ideal loop ℓ_i. Lemmas 11 and 12 imply that crushing S_i replaces (C_i, ℓ_i) with either a new edge-ideal triangulation of the same knot, or a pair of edge-ideal triangulations giving a pair of knots obtained by a (possibly trivial) connected sum decomposition of ℓ_i. Either way, *(c)* is also satisfied for $(\mathcal{T}_{i+1}, L_{i+1})$. See [18, Section 6.3] for more details.

For the converse, suppose the verification algorithm succeeds. It follows that $(\mathcal{T}_0, L_0)$ must be an edge-ideal triangulation of K. Moreover, it follows that the S_i are quad vertex normal surfaces, and hence Lemmas 11 and 12 imply that *(c)* holds for all $i \in \{0, \dots, m\}$. Hence, it follows that $(\mathcal{T}_m, L_m)$ contains k nontrivial knot summands. By uniqueness of the prime factorisation of K, this verifies that K has at least k summands.

7 Triangulation complexity

In this section we leverage the fact that crushing a nontrivial normal surface reduces the size of its ambient triangulation to study **triangulation complexity** – i.e., the minimum number of tetrahedra necessary to triangulate a given manifold within a fixed class of triangulations.

Let $\mathcal{M}$ be the exterior of a composite knot K in $\mathbb{S}^3$, and let $\tilde{c}(\mathcal{M})$ be the triangulation complexity of $\mathcal{M}$ over the class of edge-ideal triangulations. Write $K = K_1 \# \cdots \# K_m$ for the unique prime factorisation of K. Starting with an edge-ideal triangulation $(\mathcal{T}, \ell)$ for K, our results from Section 4.3 ensure that we can iteratively find quad vertex 2-spheres to

crush at least $m-1$ times to obtain edge-ideal triangulations for each of the prime knots $K_1, \ldots, K_m$. If we only crush $m-1$ times, then every crush performs a nontrivial connected sum decomposition; thus, by Lemma 12, each crush increases the number of ideal edges by exactly 2. Due to the excess ideal edges, it can be shown (see [18, Lemma 25]) that we can crush an additional 2-sphere. So in fact, we can always crush at least m times, and each crush strictly decreases the overall number of tetrahedra, which establishes the bound

$$\tilde{c}(\mathbb{S}^3 \setminus K) \geqslant m + \sum_{i=1}^{m} \tilde{c}(\mathbb{S}^3 \setminus K_i). \tag{1}$$

▶ **Example 15.** There are two knot complements of ideal edge complexity 1: the unknot and the trefoil 3_1 (both are represented by edges in the unique 1-tetrahedron 1-vertex 3-sphere triangulation). The only knot complement of ideal-edge complexity 2 is 5_1. The knot complements of ideal-edge complexity 3 are 4_1, 7_1, 8_{19} and 10_{124}.

It follows from Equation (1) that the ideal-edge complexity of the complements of $3_1\#3_1$ and $3_1\#5_1$ are at least 4 and 5, respectively. However, such triangulations of $\mathbb{S}^3$ do not exist in the census. Instead, the smallest triangulations of $\mathbb{S}^3$ containing an ideal edge of type $3_1\#3_1$ and $3_1\#5_1$ have sizes 5 and 6, respectively.

Example 15 motivates the following question.

▶ **Question 16.** *Is there a composite knot that realises tightness in Equation* (1)*?*

We can also adapt our methods to obtain complexity results about ideal triangulations of knot complements; see [18, Section 7.2] for details.

Abstract

Geometric data structures have been extensively studied in the regime where the dimension is much smaller than the number of input points. But in many scenarios in Machine Learning, the dimension can be much higher than the number of points and can be so high that the data structure might be unable to read and store all coordinates of the input and query points.

Inspired by these scenarios and related studies in feature selection and explainable clustering, we initiate the study of geometric data structures in this ultra-high dimensional regime. Our focus is the *approximate nearest neighbor* problem.

In this problem, we are given a set of n points $C \subseteq \mathbb{R}^d$ and have to produce a *small* data structure that can *quickly* answer the following query: given $q \in \mathbb{R}^d$, return a point $c \in C$ that is approximately nearest to q, where the distance is under ℓ_1, ℓ_2, or other norms. Many groundbreaking $(1+\epsilon)$-approximation algorithms have recently been discovered for ℓ_1- and ℓ_2-norm distances in the regime where $d \ll n$.

The main question in this paper is: *Is there a data structure with sublinear ($o(nd)$) space and sublinear ($o(d)$) query time when $d \gg n$?* This question can be partially answered from the machine-learning literature: [1]

- For ℓ_1-norm distances, an $\tilde{O}(\log(n))$-approximation data structure with $\tilde{O}(n \log d)$ space and $O(n)$ query time can be obtained from explainable clustering techniques [Dasgupta et al. ICML'20; Makarychev and Shan ICML'21; Esfandiari, Mirrokni, and Narayanan SODA'22; Gamlath et al. NeurIPS'21; Charikar and Hu SODA'22].
- For ℓ_2-norm distances, a $(\sqrt{3}+\epsilon)$-approximation data structure with $\tilde{O}(n \log(d)/\mathrm{poly}(\epsilon))$ space and $\tilde{O}(n/\mathrm{poly}(\epsilon))$ query time can be obtained from feature selection techniques [Boutsidis, Drineas, and Mahoney NeurIPS'09; Boutsidis et al. IEEE Trans. Inf. Theory'15; Cohen et al. STOC'15].
- For ℓ_p-norm distances, a $O(n^{p-1}\log^2(n))$-approximation data structure with $O(n\log(n)+n\log(d))$ space and $O(n)$ query time can be obtained from the explainable clustering algorithms of [Gamlath et al. NeurIPS'21].

An important open problem is whether a $(1+\epsilon)$-approximation data structure exists. This is not known for any norm, even with higher (e.g. $\mathrm{poly}(n)\cdot o(d)$) space and query time.

In this paper, we answer this question affirmatively. We present $(1+\epsilon)$-approximation data structures with the following guarantees.

[1] All data structures discussed here are randomized and answer each query correctly with $\Omega(1)$ probability. The space complexity refers to the number of words and the time is in the word-RAM model. $\tilde{O}(f(n))$ hides $\mathrm{polylog}(f(n))$ factors

- For ℓ_1- and ℓ_2-norm distances: $\tilde{O}(n \log(d)/\text{poly}(\epsilon))$ space and $\tilde{O}(n/\text{poly}(\epsilon))$ query time. We show that these space and time bounds are tight up to $\text{poly}(\log n/\epsilon)$ factors.
- For ℓ_p-norm distances: $\tilde{O}(n^2 \log(d)(\log\log(n)/\epsilon)^p)$ space and $\tilde{O}\left(n(\log\log(n)/\epsilon)^p\right)$ query time.

Via simple reductions, our data structures imply sublinear-in-d data structures for some other geometric problems; e.g. approximate orthogonal range search (in the style of [Arya and Mount SoCG'95]), furthest neighbor, and give rise to a sublinear $O(1)$-approximate representation of k-median and k-means clustering. We hope that this paper inspires future work on sublinear geometric data structures.

1 Introduction

Nearest Neighbor. The *nearest neighbor* problem in geometric spaces is defined as follows: We are given a set of n points $C \subseteq \mathbb{R}^d$ to preprocess and then have to produce a data structure that can answer the following queries: given $q \in \mathbb{R}^d$, return the point c^* in C whose distance to q is smallest, where the distance can be induced by ℓ_1-, ℓ_2-, and other norms.

In the so-called *low-dimensional regime* [4] – when $d = o(\log n)$ and thus the data structure's space and time complexities can be *exponential* in d – classical data structures can solve this problem efficiently (e.g. [15, 25, 26, 8]). Recently, novel techniques such as locality-sensitive hashing and sketching (e.g. [22, 2, 3, 5, 23]) have led to a new wave of data structures in the *high-dimensional regime* that solve the problem approximately: for any $\alpha \geq 1$, a α-approximation data structure is the one that returns a point $c \in C$ whose distance to q is at most α times the distance between c^* and q. These recent data structures typically require space and time complexities that are linear or super linear in d, which is acceptable in most applications. In fact, many papers start with an assumption that $d = O(\log n)$ which can be assumed due to Johnson-Lindenstrauss lemma [24] at the cost of additional $\tilde{O}(d)$ space and query time.

Ultra-High Dimensions. But what if we cannot read all coordinates of the query q and cannot store all coordinates of all n points in C? There can be various reasons for such a situation to arise. For example, we may be unable to access the whole q due to the high-cost concern of obtaining the data (e.g. high-cost medical tests or genome sequencing) and privacy concerns (e.g. providing only the necessary medical or genetic information while protecting

unrelated sensitive data). More crucially, the size of the data, i.e., d might be prohibitively large to query all of its attributes (as is usually the case for genetic data) and, yet, n can be much smaller than d. For example, each point in C may be a center of a cluster among some small number of clusters obtained from prior training and we aim to classify a new data point $q \in \mathbb{R}^d$ by assigning it to the nearest representative. In this case, to accurately classify q without accessing all attributes of q, we need to exploit the fact that there are typically a small number of clusters. Additionally, classifying q based on a few attributes is crucial for *explainability* – when it is important for human users to know which factors play a role in the classifying decision.

Related Work and Existing Results. Scenarios like the above are a motivation behind at least two lines of research in machine learning. **(i)** In *Feature Selection*, the goal is to select a subset of relevant features of the input dataset. For example, Boutsidis, Drineas, and Mahoney in NeurIPS'09 [9] (also see [10]) show that given a set $S \subseteq \mathbb{R}^d$ and a parameter $k \ll d$, we can select roughly k coordinates such that we are required to only access these coordinates when computing k-means clustering, at the expense of a $(3+\epsilon)$ multiplicative approximation factor. The approximation factor was subsequently improved to $(1+\epsilon)$ in the STOC'15 paper by Cohen et al. [16]. **(ii)** In *Explainable Clustering*, given data that are already classified into k clusters via cluster centers, the goal is to construct a decision tree with some desired properties that can classify the input data points into clusters without too much loss in the clustering cost compared to the original clustering. For example, Makarychev and Shan [27] show that given a k-median clustering on ℓ_1 distance, one can construct such a decision tree that returns a clustering whose cost is $\tilde{O}(\log k)$ times the original cost. Since the number of accessed coordinates intuitively plays an important role in explainability, it is not surprising that one of the desired properties of the decision tree is that it never accesses more than $O(k)$ coordinates.

The feature selection and explainable clustering problems are *static problems*; i.e., the algorithms for these problems receive all of their inputs before returning the output. This is in contrast to the nearest neighbor problem which is a *data structure problem*. Nevertheless, given the connections between clustering and nearest neighbor problems, techniques from some of the previous works on these static problems can be extended to the nearest neighbor problem. (All data structures discussed here are randomized and answer each query correctly with $\Omega(1)$ probability. The space complexity refers to the number of words and the time is in the word-RAM model. $\tilde{O}(f(n))$ hides polylog$(f(n))$ factors.)

- For ℓ_1-norm distances, an $O(\log(n))$-approximation data structure with $O(n\log(n) + n\log d)$ space and $O(n)$ query time can be obtained by adapting the explainable clustering algorithms of [20, 29]. This is because these algorithms only require the center of each cluster, and not the remaining input data points. Weaker results can also be obtained from [18, 27, 31, 19].
- For ℓ_2-norm distances, a $(\sqrt{3}+\epsilon)$-approximation data structure with $\tilde{O}(n\log(d)/\epsilon^2)$ space and $O(n\log(n)/\epsilon^2)$ query time can be obtained by reducing to feature selection algorithms [9, 10, 16] (see Appendix F).[2] Weaker results for the case of ℓ_2-norm distances can also be obtained from explainable clustering algorithms of [28, 27, 18, 19, 11, 31].

[2] In Appendix F we also argue why a natural reduction to feature selection [16] fails to give a $(1+\epsilon)$-approximate nearest neighbor data structure.

- For ℓ_p-norm distances, an $O(n^{p-1}\log^2(n))$-approximation data structure with $O(n\log(n)+n\log(d))$ space and $O(n)$ query time can be obtained from the explainable clustering algorithms of [19].

In contrast to other regimes, where many efficient $(1+\epsilon)$-approximation data structures are known, no $(1+\epsilon)$-approximation data structure is known for the ultra-high dimensional regime for any norm, and even when we allow higher space and query time (e.g. $\text{poly}(n)\cdot o(d)$ space and query time).

Our Results. We first observe that every $(1+\epsilon)$-approximate nearest neighbor data structure requires $\Omega(n)$ space and must make $\Omega(n)$ queries (see Theorem G.1). Our main contributions are data structures with nearly matching space and query bounds in the ultra-high dimensional regime. Our data structures require polynomial preprocessing time, answer each query correctly with $1-\delta$ probability, and guarantee the following bounds.

- For ℓ_1-norm distances: $O(n\log^2(n/\delta)\log(d)/(\epsilon^5\delta^4))$ space and $O(n\log(n/\delta)/(\epsilon^3\delta^2))$ query time. See Theorem 4.2.
- For ℓ_2-norm distances: $O(n\log^2(n/\delta)\log(d)/(\epsilon^6\delta^4))$ space and $O(n\log(n/\delta)/(\epsilon^3\delta^2))$ query time. See Theorem B.3.
- For ℓ_p-norm distances: $O(n^2\log(n/\delta)\log(d)(\log\log n)^p/\epsilon^{p+2})$ space and $O(n\log(n/\delta)(\log\log n)^p/\epsilon^{p+2})$ query time. See Theorem D.1.

Our data structure for ℓ_1- and ℓ_2-norm distances uses essentially the same space and query time as the previously best result and provides a stronger approximation guarantee. For other norms, our data structure needs higher (but sublinear) space and gives strong approximation guarantees.

Connection to Explainable Clustering. A recent line of research investigates explainable clustering [18, 27, 31, 19, 20, 29]. The input is a set C of k cluster centers. The output is a (random) decision tree assigning any query point to a cluster represented by a label in $[k]$. The current best result [20] for explainable k-median clustering under ℓ_1-distances guarantees that for *any* set P of data points the clustering generated by the decision tree is in expectation within a factor $O(\log k)$ of the optimal assignment of P to the centers in C, that is, of the nearest-center assignment. The decision tree has k leaves. Therefore, it can be interpreted as $O(\log k)$-approximate representation of the clustering C with sublinear $\tilde{O}(k)$ space and query complexity. There are two aspects why this representation is considered explainable: (i) the decision tree is easy to interpret for humans (ii) it is compact as it has only sublinear $\tilde{O}(k)$ space and query complexity. When applied to a single query point these data structures constitute a $O(\log k)$-approximate nearest neighbor data structure in expectation.

Our techniques have implications in the converse direction. We argue (see Section C) that our techniques give a sublinear $\tilde{O}(k)$ space and query complexity data structure for an $O(1)$-approximate nearest neighbor in *expectation*. This implies a sublinear $O(1)$-approximate representation for k-median clustering improving upon the $O(\log k)$-approximation obtained via decision trees. Notice that while our data structure does not produce decision trees it does constitute a compact representation of the clustering. Our techniques also imply a sublinear $O(1)$-approximate representation of k-means clustering in Euclidean space improving upon the $O(\log^2 k)$-bound implied by explainable k-means clustering [28].

Perspective: Sublinear Data Structures. Geometric data structures are fundamental computational objects that have been extensively studied and used for decades. To the best of our knowledge, there was no prior result on geometric data structure problems in the ultra-high dimensional regime. Showing that it is possible to design sublinear geometric data structures is the main conceptual contribution of our paper.

As another example of where our techniques are applicable, consider the orthogonal range search problem. Here, we are given a set $C \subseteq \mathbb{R}^d$ to preprocess and need to answer the following query: Given q_1 and q_2 in $\mathbb{R}^d$, return all points $p \in C$ such that the i^{th} attribute of p has value between the i^{th} attributes of q_1 and q_2, for every i. This problem can be solved using range trees and k-d trees [7, 30, 12, 13] in the low-dimensional regime. For higher dimensions, some approximation algorithms have been proposed where some other points can be returned as long as they are not "far" from the query [6, 14, 17], i.e., the distance between the point returned and the range is within an ϵ fraction of the distance between q_1 and q_2 – we call such a range search as $(1+\epsilon)$-approximate range search. We approach this problem, as before, from a data-structure point of view. Using similar techniques, we can design a data structure of size $\tilde{O}(n)$ that processes n centers such that given any "valid" orthogonal range (q_1, q_2) (i.e., a range which contains at least one center point), queries only $\tilde{O}(n/\epsilon^2)$ coordinates of q_1 and q_2 to report all centers that are within the $(1+\epsilon)$-approximate range. The details of this can be found in Appendix E.

Besides orthogonal range search, simple reductions also lead to data structures for other proximity problems such as the furthest neighbor problem, where we can guarantee the same bounds as the nearest neighbor problem.

We hope that this paper inspires future work on sublinear geometric data structures.

Organization. Section 2 gives an overview of the main technical contributions of the paper. Section 4 describes our $(1+\epsilon)$-approximate nearest neighbor data structures with $\tilde{O}(n)$ space and query complexity for the ℓ_1- and ℓ_2-norm.

Appendix A contains the outline of a simple data structure with space $\tilde{O}(n^2)$ and query time $\tilde{O}(n)$ for ℓ_1-norm, with some simplifying assumptions as warmup. Appendix B contains missing proofs of Section 4 and extension to ℓ_2 case. Appendix C describes our expected constant-approximate nearest neighbor data structure, and shows the connection to explainable clustering. Appendix D describes our $(1+\epsilon)$-approximate nearest neighbor data structure with space $\tilde{O}(n^2)$ and query time $\tilde{O}(n)$ that works for general ℓ_p-norms. Appendix E shows the implications of our results for Range Search problem. Appendix F shows the connection between approximate nearest neighbor and feature selection for clustering. Appendix G shows $\Omega(n)$ space and query tight lower bound.

2 Technical Overview

Warmup: Quadratic Space via Pairwise Sampling. Let c be an input point, let q be an unknown query point, and let $\|c-q\|_1 = \sum_b |c^{(b)} - q^{(b)}|$ denote their ℓ_1 distance. First, observe that approximating this distance requires memorizing *all* coordinates of c because c and q may differ in only a single coordinate. Our strategy is to *compare* distances to multiple input points without knowing the (approximate) distances. For intuition, consider when we have two input points c_1 and c_2. Consider an extreme case when c_1 and c_2 differ only in one coordinate b. In this case, keeping only this coordinate suffices to tell for any query q if it is

closer to c_1 or c_2. To extend this intuition to when c_1 and c_2 differ in many coordinates, a natural idea is to sample each coordinate b independently with probability proportional to the difference $|c_1^{(b)} - c_2^{(b)}|$; more precisely, the probability that we sample coordinate b is[3]

$$p^{(b)} = \frac{|c_1^{(b)} - c_2^{(b)}|}{\|c_1 - c_2\|_1}.$$

We further scale the sample entry by a factor of $1/p^{(b)}$. The expected number of sampled coordinates is then $\sum_b p^{(b)} = \sum_b |c_1^{(b)} - c_2^{(b)}|/\|c_1 - c_2\|_1 = 1$. Let $\epsilon \in (0,1)$ be the approximation parameter, and let $\delta \in (0,1)$ be a bound on the error probability. We repeat this process to store a set I of $O(\log(1/\delta)/\epsilon^2)$ coordinates in total. For $x \in \mathbb{R}^d$, we denote by $x^{(I)}$ the restriction of x to coordinates in I. We denote by $S = \mathsf{diag}((1/p^{(b)})_{b\in I})$ denote the diagonal matrix representing the scaling factors. Then $Sx^{(I)}$ is the vector obtained from applying the above sampling process to x.

Under what we call *bounding box assumption* (which we will remove later), where $\min(c_1^{(b)}, c_2^{(b)}) \le q^{(b)} \le \max(c_1^{(b)}, c_2^{(b)})$ for each coordinate b, we can find a $(1+\epsilon)$-approximate nearest neighbor between c_1 and c_2. This is due to the following property. (Details in Section A.)

> *Comparator Property:* Let $\epsilon, \delta \in (0,1)$ and assume we sample a set I of $O(\log(1/\delta)/\epsilon^2)$ coordinates as described above. If $\|c_2 - q\|_1 > (1+\epsilon)\|c_1 - q\|_1$ then $\|Sc_2^{(I)} - Sq^{(I)}\|_1 > (1+\epsilon/2)\|Sc_2^{(I)} - Sq^{(I)}\|_1$ with probability $1-\delta$.

With this idea, we can construct an $\tilde{O}(n^2)$-space data structure by repeating the above for every pair (c_i, c_j) of input points. It is not hard to find the approximately nearest neighbor to q with $n-1$ comparisons: this is very simple if the comparator is exact, and the same idea can be extended for our approximate comparator as well; see Section A for details (also see [1] for previous work on imprecise comparisons).

Towards Linear Space via Global Sampling. The drawback of the previous algorithm is its $\tilde{O}(n^2)$ space complexity. To avoid this, a natural idea is to reduce the number of pairs for which we perform the above sampling process. However, it is unclear to us if this is possible at all. Another idea is to do the above process *more globally* instead of pairwise. Here is a simple way to do this: Let $C = \{c_1, \ldots, c_n\}$ be the set of input points. We (independently) sample each coordinate b with probability $p^{(b)} = \max_{ij} p_{ij}^{(b)}$ where $p_{ij}^{(b)} = |c_i^{(b)} - c_j^{(b)}|/\|c_i - c_j\|_1$ denotes the probability of sampling b under the pairwise sampling process for $c_i, c_j \in C$.

At least two questions arise from the idea above: (i) For any pair c_i and c_j and query q in the bounding box can we still tell (approximately) if c_i or c_j is nearer to q as in the pairwise process (in particular, are we creating noise by sampling some coordinates with higher probility than $p_{ij}^{(b)}$)? This is not so hard to address: Despite sampling each coordinate with probability higher than $p_{ij}^{(b)}$, the expectation does not change due to rescaling by $1/p^{(b)}$, and the concentration behavior is only better. More precisely, the comparator property can still be proven.

A more unclear point is: (ii) How many coordinates do we sample in total? For example, why is it not possible that in the worst case every pair c_i and c_j needs different coordinates and thus we are forced to select $\Omega(n^2)$ coordinates in total. We show that this bad situation

[3] This can be viewed as an application of so-called importance sampling – a technique for variance reduction. The independent sampling process described here differs slightly from the one in Section A.

will not happen. To give an idea, we consider the special case $C \subseteq \{0,1\}^d$. The overall expected number of coordinates sampled is $S(C) = \sum_b p^{(b)} = \sum_b \max_{ij} p_{ij}^{(b)}$. (We ignore sampling repetition, which increases our bound only by $O(\log n)$.) Assume w.l.o.g. that (c_1, c_2) is the closest pair in C. Notice that $p^{(b)} = p_{12}^{(b)}$ for every coordinate b in the set D of coordinates where c_1 and c_2 differ; they minimize $\|c_i - c_j\|_1$ and hence maximize $p_{ij}^{(b)}$. Therefore $S(C)$ drops by at most $\sum_b p_{12}^{(b)} = \sum_b |c_1^{(b)} - c_2^{(b)}|/\|c_1 - c_2\|_1 = 1$ if we remove the coordinates in D from all input points. On the other hand, we can identify c_1 and c_2 after removing D obtaining a set C' with at most $n-1$ points. Thus $S(C) \leq S(C') + 1$. Using induction we can upper bound $S(C)$ by n. This inductive proof strategy can be extended to the general ℓ_1 metric although the proof is notably more technical. Even though ℓ_1 and ℓ_2 metrics are equivalent on the Boolean cube, we do not know how to extend the above proof strategy to the general ℓ_2 metric. To obtain a linear bound for ℓ_2 we rely on an entirely different, linear-algebraic approach leveraging a latent connection between our sampling probabilities and the singular-value decomposition. Our proof is based on a connection to the feature selection approach by Boustidis et al. [10] for k-Means clustering. In fact, our sampling probabilities can be upper bounded by theirs, which are based on SVD. Notice, however, that we achieve a $(1+\epsilon)$-approximation for nearest neighbor as compared to their $(3+\epsilon)$-approximation for k-Means.[4]

Let I denote the set of coordinates sampled by our global scheme. Memorizing these coordinates for all input points would still require $n|I| = \tilde{O}(n^2)$ space. To obtain $\tilde{O}(n)$ space we apply standard dimension reduction tools such as the Johnson-Lindenstrauss transform for ℓ_2 or the technique by Indyk [21] for ℓ_1. Specifically, we sample a suitable random $m \times |I|$ matrix M, where $m = O(\log n)$, and store the set $C' = \{\, MSc_i^{(I)} \mid c_i \in C \,\}$ requiring $mn = \tilde{O}(n)$ space. Storing M itself requires $m|I| = \tilde{O}(n)$ space, too, as does storing I itself. Upon receiving a query q, we compute $MSq^{(I)}$ and output the nearest neighbor in C', which takes $\tilde{O}(n)$ coordinate queries. Here we use that the comparator property guarantees $\|Sq^{(I)} - Sc_j^{(I)}\|_1 > (1+\epsilon/2)\|Sq^{(I)} - Sc_i^{(I)}\|_1$ if $\|q - c_j\|_1 > (1+\epsilon)\|q - c_i\|_1$. Therefore, if we bound the distance distortion of the dimension reduction by, say, $1 + \epsilon/10$ then $F(MSq^{(I)}, MSc_j^{(I)}) > (1+\epsilon/5)F(MSq^{(I)}, MSc_i^{(I)})$ for the function F from the ℓ_1 dimension reduction by Indyk [21]. This is sufficient for approximately comparing the distances.

Removing the Bounding Box Assumption. If a query point q does not satisfy the bounding box property for two points $c_i, c_j \in C$ the comparator property may fail with too high probability. Specifically, it may happen that $\|q - c_j\|_1 > (1+\epsilon)\|q - c_i\|_1$ and yet $\|Sq^{(I)} - Sc_j^{(I)}\|_1 = (1+\xi)\|Sq^{(I)} - Sc_i^{(I)}\|_1$ for some positive $\xi \ll \epsilon$. In such a scenario, applying dimension reduction via matrix M may result in $F(MSq^{(I)}, MSc_j^{(I)}) < F(MSq^{(I)}, MSc_i^{(I)})$ because it distorts distances by factor $1 + \Theta(\epsilon)$.

A natural attempt to resolve this issue is to "truncate" the query point so it comes sufficiently close to the bounding box. This approach is described in Section D and can in fact be applied to general ℓ_p metrics. However, it requires explicitly storing the projected points and therefore $\tilde{O}(n^2)$ space.

To retain our near-linear space bound, we do not actually change the sampling or the query procedure. Rather, we relax in our analysis on the requirement that the comparator property needs to hold for all point pairs. Specifically, we argue (using Markov) that with

[4] In Section F, we provide a formal reduction to feature selection by Boustidis et al. [10]. There is follow-up work achieving even guarantee $1+\epsilon$ for feature selection in clustering [16]. However, we do not know how to apply their approach to our setting. In particular, the above reduction is not applicable.

sufficiently high probability our distance estimate to the (unknown) nearest neighbor o is within a bounded factor (*). We argue that under this condition all comparisons with o do satisfy the comparator property, which is enough to satisfy correctness. Towards this, we distinguish for each $c \in C$ between *good* coordinates b where $q^{(b)}$ is relatively close to the interval $[c^{(b)}, o^{(b)}]$. For the set of good coordinates, strong concentration properties hold – similar to those under the bounding box assumption. For the remaining (bad) coordinates, we use two properties: First, the query point is indifferent between c and o on the set of bad coordinates as it is sufficiently distant and thus indifferent between o and c on these coordinates. This and property (*) automatically implies that the total contribution of the bad coordinates cannot be too high. Together, these properties imply that (a relaxation of) the comparator property holds for all comparisons with o thereby implying the $(1+\epsilon)$-approximation guarantee also after removing the bounding box assumption. For details, we refer to the full technical sections below.

3 Preliminaries

In this section, we list some basic terminology, definitions and notation that we use throughout.

▶ **Definition 3.1** (Approximate Notation). *Given real numbers $a, b > 0$ and $0 < \epsilon < 1$, we say that $a \approx_\epsilon b$ if $(1-\epsilon)b \le a \le (1+\epsilon)b$.*

▶ **Definition 3.2** (Coordinate Index Notation). *For a point $a \in \mathbb{R}^d$, we use $a^{(i)}$ to represent the i-th coordinate of a. For a set or multiset $I = \{i_1, i_2, \ldots, i_m\} \subseteq [d]$, we denote $a^{(I)}$ to be $\left(a^{(i_1)}, a^{(i_2)}, \ldots, a^{(i_m)}\right) \in \mathbb{R}^m$.*

In this paper, we look into the approximate nearest neighbor problem, defined as follows.

▶ **Definition 3.3** (α-Approximate Nearest Neighbor Problem). *Given a set $C = \{c_1, c_2, \ldots, c_n\}$ of n points in a metric space (X, dist), build a data structure that given any query point $q \in X$, returns index $i \in [n]$, such that $\mathsf{dist}(q, c_i) \le \alpha \cdot \min_{j \in [n]} \mathsf{dist}(q, c_j)$.*

When C only has 2 points, we use the shorthand *2-point comparator* to denote such an approximate nearest neighbor data structure.

▶ **Definition 3.4** (2-point Comparator). *Given a set $C = \{c_1, c_2\}$ of 2 points in a metric space (X, dist) and parameters $0 \le \epsilon, \delta < 1$, we call a data structure as a 2-point comparator, if for any query point $q \in X$, with probabilty $1-\delta$, it returns index $i \in \{1, 2\}$, such that $\mathsf{dist}(q, c_i) \le (1+\epsilon) \cdot \min_{j \in \{1,2\}} \mathsf{dist}(q, c_j)$.*

We use the following Chernoff bounds in this paper.

▶ **Theorem 3.5** (Chernoff Bound). *Let $X_1, X_2, \ldots, X_n$ be independent random variables, and $X_i \in [0, c]$. Define $X = \sum_{i=1}^n X_i$ and $\mu = \mathbb{E}[X]$. Then*

$$\mathbb{P}\left[X \ge (1+\delta)\mu\right] \le \exp(-\delta^2\mu/(3c)), \text{ for } 0 < \delta \le 1$$

$$\mathbb{P}\left[X \ge (1+\delta)\mu\right] \le \exp(-\delta\mu/(3c)), \text{ for } \delta \ge 1$$

$$\mathbb{P}\left[X \le (1-\delta)\mu\right] \le \exp(-\delta^2\mu/(2c)), \text{ for } \delta \ge 0.$$

4 Near-linear Space Data Structures for ℓ_1 and ℓ_2 Metrics

In this section, we design a data structure with near-linear space and query complexity for approximate nearest neighbor under ℓ_1 and ℓ_2 metrics. We prove the following theorem.

▶ **Theorem 4.1.** *Consider a set C of n points $c_1, \ldots, c_n \in \mathbb{R}^d$ equipped with ℓ_1 or ℓ_2 metric. Given $0 < \epsilon < 1/4$ and $0 < \delta < 1$, we can efficiently construct a randomized data structure such that for any query point $q \in \mathbb{R}^d$ the following conditions hold with probability $1 - \delta$. (i) The data structure reads $O(n \log(n)/(\text{poly}(\epsilon, \delta)))$ coordinates of q. (ii) It returns $i \in [n]$ where c_i is a $(1+\epsilon)$-approximate nearest neighbor of q in C. (iii) The data structure has a size of $O(n \log^2(n) \log(d)/(\text{poly}(\epsilon, \delta)))$ words.*

The proof of Theorem 4.1 for the case of ℓ_1-metric is presented in Section 4.1 with missing proofs deferred to Appendix B.1, where as the proof for the case of ℓ_2-metric is in Appendix B.2. Both proofs follow the same structure although they differ in details.

4.1 Data Structure for ℓ_1-metric with Near-linear Space and Query Time

The preprocessing and querying procedures of our data structure are described in Section 4.1. The algorithm receives a set C of n points and parameters $\epsilon, \delta \in (0, 1)$ as inputs for its preprocessing phase. During preprocessing, it iteratively samples coordinates from $[d]$ to form a multiset I.[5] Let R denote the set C of n points restricted to I. An ℓ_1 dimension reduction is then applied to R to further reduce the space. In the query phase, the algorithm receives a query $q \in \mathbb{R}^d$. It probes q on all coordinates in I and applies the same ℓ_1 dimension reduction to the coordinate-selected query. The output, identifying which point in C is the nearest neighbor of q, is determined by which point, after coordinate selection and dimension reduction, is closest to the query.

Algorithm 1 An approximate nearest neighbor data structure for n points in $\mathbb{R}^d$ for ℓ_1 metric.

Preprocessing (C, ϵ, δ) `// Inputs:` $C = \{c_1, \ldots, c_n\} \subseteq \mathbb{R}^d, \epsilon \in (0, \frac{1}{4}), \delta \in (0, 1)$
  Let $I \leftarrow \emptyset$ be a multiset and $T \leftarrow O(\log(n/\delta)/(\epsilon^3\delta^2))$;
  for $t \in [T]$ **do**
    for $b \in [d]$ **do**
      Add b to I with probability $p^{(b)} \triangleq \max_{(i,j)\in\binom{n}{2}} \frac{\left|c_i^{(b)} - c_j^{(b)}\right|}{\|c_i - c_j\|_1}$;
  Let $R = \{r_1, r_2, \ldots, r_n\} \subseteq \mathbb{R}^I$, where for $i \in [n], b \in I$, we have $r_i^{(b)} = c_i^{(b)}/p^{(b)}$;
  Let $m \leftarrow O(\log(n/\delta)/(\epsilon^2\delta^2))$;
  Sample $M \in \mathbb{R}^{[m]\times I}$, where each entry of M follows the Cauchy distribution, whose density function is $c(x) = \frac{1}{\pi(1+x^2)}$. Notice that $M(\cdot)\colon \mathbb{R}^I \to \mathbb{R}^m$ is an oblivious linear mapping [21];
  store I, $M(R) = \{Mr_i | i \in [n]\}$, $\{p^{(b)} | b \in I\}$, M
Query (q) `// Inputs:` $q \in \mathbb{R}^d$
  Query $q^{(b)}, \forall b \in I$;
  Let $u \in \mathbb{R}^I$, where $\forall b \in I, u^{(b)} = q^{(b)}/p^{(b)}$;
  Let $F((x_1, \ldots, x_m), (y_1, \ldots, y_m)) \coloneqq \mathsf{median}(|x_1 - y_1|, \ldots, |x_m - y_m|)$;
  Let $\hat{i} = \arg\min_{i\in[n]} F(Mr_i, Mu)$;
  return $\hat{i}$

[5] Multiple coordinates may be added to I in the same iteration, and I may contain repeated coordinates.

▶ **Theorem 4.2.** *Consider a set C of n points $c_1, \ldots, c_n \in \mathbb{R}^d$ equipped with ℓ_1 metric. Given $0 < \epsilon < 1/4$ and $0 < \delta < 1$, with probability $(1-\delta)$, we can efficiently construct a randomized data structure (See Section 4.1) such that for any query point $q \in \mathbb{R}^d$ the following conditions hold with probability $1-\delta$. (i) The data structure reads $O(n \log(n/\delta)/(\epsilon^3\delta^2))$ coordinates q. (ii) It returns $i \in [d]$ where c_i is a $(1+\epsilon)$-approximate nearest neighbor of q in C. (iii) The data structure has a size of $O(n \log^2(n/\delta) \log(d)/(\epsilon^5\delta^4))$ words.*

To prove Theorem 4.2, we consider the following four events and prove that each of them holds with probability $1-\delta'$, where $\delta' = \delta/4$. We establish the correctness of the data structure by conditioning on the first three events. By conditioning on the last event, we demonstrate the space and query complexity.

1. The first event is that the distance between a query and its nearest neighbor is overestimated at most by the factor $4/\delta$.
2. The second event is that for a query point the estimated distance to its nearest neighbor is significantly smaller than the estimated distance to any center that is not an approximate nearest neighbor.
3. The third event is that the dimension reduction preserves the distances between the coordinate-selected points and the query.
4. The fourth event is that at most near-linear many coordinates are sampled in the preprocessing and accessed in the query phase.

Finally, by applying a union bound, we show that all four events hold with probability $1-\delta$, which implies that the requirements of Theorem 4.1 are met. We show the proof in the following subsections in line with the structure described above.

4.1.1 Upper Bound for Estimate of Distance between Query and its Nearest Neighbor

We first show that the distance between a query point and its nearest neighbor is overestimated at most by a factor $1/\delta'$ with probability $1-\delta'$.

▷ Claim 4.3. Let $q \in \mathbb{R}^n$ be a query and let $i^* \in [n]$ be the index of its nearest neighbor. It holds that $\frac{1}{T}\|r_{i^*} - u\|_1 \leq \frac{1}{\delta'}\|c_{i^*} - q\|_1$, with probability $1-\delta'$.

4.1.2 Coordinate Selection Preserves Distance Ratio

In this section, we show that, the following holds: for any query point $q \in \mathbb{R}^n$, whose nearest neighbor is c_{i^*}, with probability $1-2\delta'$, for all $c_i \in C$ such that $\frac{\|c_i - q\|_1}{\|c_{i^*} - q\|_1} \geq 1+\epsilon$, the estimated ratio is significantly larger than one, that is $\frac{\|r_i - u\|_1}{\|r_{i^*} - u\|_1} \geq 1 + \epsilon\delta'/4$. This statement is formalized in Lemma 4.8.

To prove the statement, we first partition the coordinates in $[d]$ into good and bad regions for each pair of points. In the good region are the coordinates on which the query is not too far away from one of the points. The remaining coordinates are in the bad region. The intuition is that, restricted to the coordinates in the good region, the distance between one of the points and the query is bounded. This implies that we can estimate these distances using a Chernoff bound. For the bad coordinates the intuition is that the distances from the query to the 2 points are so large that the ratio between these distances is close to one. Additionally these distances are not overestimated because of the previous event in Section 4.1.1.

▶ **Definition 4.4** (Good region and bad region). *Consider two points $c_1, c_2 \in \mathbb{R}^d$, and a query point $q \in \mathbb{R}^d$. We define the good region* $\mathsf{Good}(c_1, c_2, q)$ *w.r.t.* (c_1, c_2, q) *as*

$$\{z \in [d] \mid \min\{c_1^{(z)}, c_2^{(z)}\} - \frac{8}{\epsilon\delta'}|c_1^{(z)} - c_2^{(z)}| \leq q^{(z)} \leq \max\{c_1^{(z)}, c_2^{(z)}\} + \frac{8}{\epsilon\delta'}|c_1^{(z)} - c_2^{(z)}|\}.$$

We define the bad region w.r.t. (c_1, c_2, q) *as* $\mathsf{Bad}(c_1, c_2, q) = [d] \setminus \mathsf{Good}(c_1, c_2, q)$. *When there is no ambiguity, we use* Good *for* $\mathsf{Good}(c_1, c_2, q)$, *and* Bad *for* $\mathsf{Bad}(c_1, c_2, q)$.

Additionally, we define the distance between points restricted to subsets of coordinates.

▶ **Definition 4.5** (Restricted distance). *Given $x, y \in \mathbb{R}^d$, we define the distance between x and y restricted to region $J \subseteq [d]$ as* $\mathsf{dist}_J(x, y) = \sum_{z \in J} \left|x^{(z)} - y^{(z)}\right|$. *Furthermore, for $u, v \in \mathbb{R}^I$, where I is a multiset, whose elements are from $[d]$, we define* $\mathsf{dist}_J(u, v) = \sum_{z \in I} \mathbb{1}_{z \in J} \cdot \left|x^{(z)} - y^{(z)}\right|$.

The following lemma shows that for two points, whose distances to the query differ significantly, then the majority of the distance between the two points is present in the good region. The intuition of the lemma is that if the bad region contributes a lot to the distance $\|b - a\|_1$, it implies that the bad region contributes much to $\|b - q\|_1$ and $\|a - q\|_1$, then the ratio between the two distances should be very close to 1.

▶ **Lemma 4.6.** *Consider three points $a, b, q \in \mathbb{R}^d$. If $\frac{\|b-q\|_1}{\|a-q\|_1} \geq 1+\epsilon$, then $\frac{\mathsf{dist}_{\mathsf{Good}(a,b,q)}(b,a)}{\|b-a\|_1} \geq \frac{13}{16}$.*

The following lemma shows that for two points c_i, c_j and a query q such that q is significantly closer to c_j, we can estimate the distances, restricted to the good region, between one of the points and the query.

▶ **Lemma 4.7.** *Let c_i, c_j where $i, j \in [n]$ be such that for the query point $q \in \mathbb{R}^d$ it holds that $\|c_i - q\|_1 \geq (1 + \epsilon)\|c_j - q\|_1$. Let* Good *be shorthand for* $\mathsf{Good}(c_i, c_j, q)$ *and* Bad *for* $\mathsf{Bad}(c_i, c_j, q)$. *The following statements are true:*

1. $\mathsf{dist}_{\mathsf{Good}}(c_i, q) \geq (1 + \epsilon)\mathsf{dist}_{\mathsf{Good}}(c_j, q)$.
2. *If* $\mathsf{dist}_{\mathsf{Good}}(c_j, q) \geq \frac{1}{8}\mathsf{dist}_{\mathsf{Good}}(c_i, c_j)$, *then with probability* $1 - \delta'/n$,

$$\mathsf{dist}_{\mathsf{Good}}(r_i, u) \approx_{\frac{\epsilon}{16}} T \cdot \mathsf{dist}_{\mathsf{Good}}(c_i, q),$$
$$\mathsf{dist}_{\mathsf{Good}}(r_j, u) \approx_{\frac{\epsilon}{16}} T \cdot \mathsf{dist}_{\mathsf{Good}}(c_j, q).$$

3. *If* $\mathsf{dist}_{\mathsf{Good}}(c_j, q) < \frac{1}{8}\mathsf{dist}_{\mathsf{Good}}(c_i, c_j)$, *then* $\frac{\mathsf{dist}_{\mathsf{Good}}(c_i,q)}{\mathsf{dist}_{\mathsf{Good}}(c_j,q)} > 7$. *With probability* $1 - \delta'/n$,

$$\mathsf{dist}_{\mathsf{Good}}(r_i, u) \approx_{\frac{\epsilon}{16}} T \cdot \mathsf{dist}_{\mathsf{Good}}(c_i, q),$$
$$\frac{\mathsf{dist}_{\mathsf{Good}}(r_i, u)}{\mathsf{dist}_{\mathsf{Good}}(r_j, u)} \geq 3.$$

In the following lemma we state that our bounds on the distance estimates are good enough. Concretely, for a point that is not an approximate nearest neighbor, the estimated distance between this point and the query is significantly larger than the estimated distance between the nearest neighbor and the query.

▶ **Lemma 4.8.** *For any query point $q \in \mathbb{R}^d$, with probability $1 - 2\delta'$, it holds for all $i \in [n]$, if $\frac{\|c_i-q\|_1}{\|c_{i^*}-q\|_1} \geq 1 + \epsilon$, then $\frac{\|r_i-u\|_1}{\|r_{i^*}-u\|_1} \geq 1 + \epsilon\delta'/4$.*

4.1.3 ℓ_1 Dimension Reduction Preserves the Distance Ratio

▶ **Theorem 4.9** (Theorem 1 in [21]). *Consider 2 points $a, b \in \mathbb{R}^d$ and parameters $0 < \epsilon, \delta < 1$. We sample a random matrix $M \in \mathbb{R}^{m \times d}$, where $m = O(\log(1/\delta)/(\epsilon^2))$ and each entry of M is sampled from Cauchy distribution, whose density function is $c(x) = \frac{1}{\pi(1+x^2)}$. Then with probability $1 - \delta$, $F(Ma, Mb) \approx_\epsilon \|a - b\|_1$, where $F((x_1, \ldots, x_m), (y_1, \ldots, y_m)) \coloneqq \mathsf{median}(|x_1 - y_1|, \ldots, |x_m - y_m|)$.*

▷ Claim 4.10. Let $q \in \mathbb{R}^n$ be a query. Furthermore, let $i^* \in [n]$ be the index of its nearest neighbor. Section 4.1 outputs an index i such that

$$\frac{\|c_i - q\|_1}{\|c_{i^*} - q\|_1} \leq 1 + \epsilon$$

with probability $1 - 3\delta'$.

Proof. Applying Theorem 4.9 with $m = O(\log(n/\delta')/(\epsilon^2\delta'^2))$, given any $v \in R$, it holds with probability $1 - \delta'/(n+1)$, that $F(Mv, Mu) \in [1 - \epsilon\delta'/100, 1 + \epsilon\delta'/100]\|v - u\|_1$. By union bound, with probability $1 - \delta'$, it holds for all $v \in R$. By Lemma 4.8 it holds with probability $1 - 2\delta'$ that for all $i \in [n]$, if $\frac{\|c_i - q\|_1}{\|c_{i^*} - q\|_1} \geq 1 + \epsilon$, then $\frac{\|r_i - u\|_1}{\|r_{i^*} - u\|_1} \geq 1 + \epsilon\delta'/4$, thus $\frac{F(Mr_i, Mu)}{F(Mr_{i^*}, Mu)} > 1$ with probability $1 - 3\delta'$, i.e. the algorithm will not output i as the index of the approximate nearest neighbor. ◁

4.1.4 Space and Query Complexity

Next, we argue the space and query complexity. The main result in this section is that for any set C of centers the sum of probabilities $\sum_{b \in [d]} p^{(b)}$ is upper bounded by the number of centers.

▶ **Lemma 4.11.** $1 \leq \sum_{b \in [d]} p^{(b)} \leq n$.

Proof. The lower bound for $\sum_{b \in [d]} p^{(b)}$ can be seen as follows: Fix arbitrary $i_1, j_1 \in [n]$ s.t. $\|c_{i_1} - c_{j_1}\|_1 \neq 0$. We have, $\sum_{b \in [d]} p^{(b)} \geq \sum_{b \in [d]} \frac{\left|c_{i_1}^{(b)} - c_{j_1}^{(b)}\right|}{\|c_{i_1} - c_{j_1}\|_1} = 1$.

Next we prove the upper bound for $\sum_{b \in [d]} p^{(b)}$. We first introduce an operation that we call "collapse". For real numbers $\tau_1 \leq \tau_2$,

$$\mathsf{collapse}_{\tau_1, \tau_2}(x) \coloneqq \begin{cases} x, & x \leq \tau_1, \\ \tau_1, & \tau_1 < x \leq \tau_2, \\ x - (\tau_2 - \tau_1), & x > \tau_2. \end{cases}$$

For $\tau_1 > \tau_2$, $\mathsf{collapse}_{\tau_1, \tau_2}(x) \coloneqq \mathsf{collapse}_{\tau_2, \tau_1}(x)$.

We also slightly abuse the notation, and define for $a, b, c \in \mathbb{R}^d$,

$$\mathsf{collapse}_{a,b}(c) \triangleq (\mathsf{collapse}_{a_1, b_1}(c_1), \mathsf{collapse}_{a_2, b_2}(c_2), \ldots, \mathsf{collapse}_{a_d, b_d}(c_d)) \in \mathbb{R}^d.$$

▷ Claim 4.12. Let $x, y, \tau_1, \tau_2 \in \mathbb{R}$, where $x \geq y$. We have (i) $x - |\tau_1 - \tau_2| \leq \mathsf{collapse}_{\tau_1, \tau_2}(x) \leq x$ and (ii) $x - y - |\tau_1 - \tau_2| \leq \mathsf{collapse}_{\tau_1, \tau_2}(x) - \mathsf{collapse}_{\tau_1, \tau_2}(y) \leq x - y$.

Proof. Denote $x' = \mathsf{collapse}_{\tau_1, \tau_2}(x)$ and $y' = \mathsf{collapse}_{\tau_1, \tau_2}(y)$. Assume w.l.o.g. that $\tau_1 \leq \tau_2$, otherwise we switch them.

For the first argument, $\forall x \in \mathbb{R}, x - |\tau_1 - \tau_2| \leq \mathsf{collapse}_{\tau_1, \tau_2}(x) \leq x$, this is true because of the definition of collapse.

For the second argument, $\forall x \geq y \in \mathbb{R}$, $x-y-|\tau_1-\tau_2| \leq \mathsf{collapse}_{\tau_1,\tau_2}(x)-\mathsf{collapse}_{\tau_1,\tau_2}(y) \leq x-y$, consider

$$f(x) = x - \mathsf{collapse}_{\tau_1,\tau_2}(x) = \begin{cases} 0, & x \leq \tau_1, \\ x-\tau_1, & \tau_1 \leq x \leq \tau_2, \\ \tau_2-\tau_1, & x > \tau_2. \end{cases}$$

Notice that $f(x)$ is a non-decreasing function, thus $f(x) \geq f(y)$, which proves $x-y \geq x'-y'$. Notice that $0 \leq f(x) \leq \tau_2-\tau_1$, thus $f(x) \leq f(y)+(\tau_2-\tau_1)$, which proves $x'-y' \geq x-y-(\tau_2-\tau_1)$. ◁

▷ Claim 4.13. Let c_{i_0}, c_{j_0} be the closest pair of points in a set $C = \{c_1, c_2, \ldots, c_n\}$ of points, i.e., $(i_0, j_0) = \arg\min_{(i,j):\, i \neq j} \|c_i - c_j\|_1$. Define $P_n(C)$ to be $\sum_{b\in[d]} \max_{i\neq j} \frac{|c_i^{(b)} - c_j^{(b)}|}{\|c_i - c_j\|_1}$. The set $C' = \{c'_i = \mathsf{collapse}_{c_{i_0},c_{j_0}}(c_i) | i \in [n]\}$ is such that (i) it contains $n-1$ points and (ii) $P_n(C) \leq P_{n-1}(C') + 1$.

Proof. Note, by the definition of the collapse operation, that $c'_{i_0} = c'_{j_0}$. Hence, C' has at most $n-1$ points, proving part (i) of the claim.

To prove (ii), define $p_b = \max_{c_i,c_j\in C, i\neq j} \frac{|c_i^{(b)} - c_j^{(b)}|}{\|c_i - c_j\|_1}$ and $p'_b = \max_{c'_i,c'_j\in C', i\neq j} \frac{|c_i'^{(b)} - c_j'^{(b)}|}{\|c'_i - c'_j\|_1}$. We prove that $p_b - p'_b \leq \frac{|c_{i_0}^b - c_{j_0}^b|}{\|c_{i_0} - c_{j_0}\|_1}, \forall b \in [d]$. The claim follows, since $P_k(C) - P_{k-1}(C') = \sum_b (p_b - p'_b) \leq \sum_b \frac{|c_{i_0}^{(b)} - c_{j_0}^{(b)}|}{\|c_{i_0} - c_{j_0}\|_1} = 1$.

Fix some b, choose $(u, v) = \arg\max_{(i,j):\, c_i^{(b)} \neq c_j^{(b)}} \frac{|c_i^{(b)} - c_j^{(b)}|}{\|c_i - c_j\|_1}$, i.e. $p_b = \frac{|c_u^{(b)} - c_v^{(b)}|}{\|c_u - c_v\|_1}$.

If $c_u'^{(b)} \neq c_v'^{(b)}$, $p_b' \geq \frac{|c_u'^{(b)} - c_v'^{(b)}|}{\|c'_u - c'_v\|_1} \geq \frac{|c_u^{(b)} - c_v^{(b)}| - |c_{i_0}^{(b)} - c_{j_0}^{(b)}|}{\|c_u - c_v\|_1}$. The second inequality follows from Claim 4.12. Thus $p_b - p'_b \leq \frac{|c_{i_0}^{(b)} - c_{j_0}^{(b)}|}{\|c_u - c_v\|_1} \leq \frac{|c_{i_0}^{(b)} - c_{j_0}^{(b)}|}{\|c_{i_0} - c_{j_0}\|_1}$. If $c_u'^{(b)} = c_v'^{(b)}$, it means $|c_u^{(b)} - c_v^{(b)}| \leq |c_{i_0}^{(b)} - c_{j_0}^{(b)}|$, thus $p_b - p'_b \leq p_b = \frac{|c_u^{(b)} - c_v^{(b)}|}{\|c_u - c_v\|_1} \leq \frac{|c_{i_0}^{(b)} - c_{j_0}^{(b)}|}{\|c_{i_0} - c_{j_0}\|_1}$. ◁

Solving the recurrence given by Claim 4.13 with the boundary condition that for a set C'' of two points, $P_2(C'') = 1$, we get that $P_n(C) \leq n$. Since $P_n(C)$, for the set of n points, is by definition, equal to $\sum_{b\in[d]} p^{(b)}$, the statement of the lemma follows. ◀

▷ Claim 4.14. With probability $1-\delta'$, we have $|I| \leq 2Tn$.

Proof. We define $X_{t,z}$ for $t \in [T], z \in [d]$ to be the indicator random variable for the event that we add z to I at iteration t. Note that $\Pr[X_{t,z} = 1] = p^{(z)}$. We can see that $|I| = \sum_{t\in[T], z\in[d]} X_{t,z}$. Hence, $\mathbb{E}[|I|] = \sum_{t\in[T],z\in[d]} p^{(z)} \leq T \cdot \sum_{b\in[d]} p^{(b)} \leq T \cdot n$, where the last inequality follows from Lemma 4.11. Similarly, we can see that $\mathbb{E}[|I|] \geq T$. Using Chernoff bound, we have $\Pr[|I| - \mathbb{E}[|I|] \geq \mathbb{E}[|I|]] \leq \exp(-\mathbb{E}[|I|]/3) \leq \exp(-T/3) \leq \delta/4$. Thus, with probability $1-\delta/4$, we have $|I| \leq 2E[|I|] \leq 2Tn$. ◁

▶ **Lemma 4.15.** *With prob. $1-\delta'$, the space complexity of Section 4.1 is $O(\frac{n\log^2(n/\delta)\log(d)}{\epsilon^5\delta^4})$ wordsize, and the number of coordinates that we query is $O(\frac{n\log(n/\delta)}{\epsilon^3\delta^2})$.*

Proof. By Claim 4.14, we have that the number of coordinates of q that we query is $|I| = O(Tn) = O(\frac{n\log(n/\delta)}{\epsilon^3\delta^2})$. Next we analyze the space complexity of the data structure. Matrix M is of wordsize $O(m|I|)$, $M(R)$ is of wordsize $O(mn)$, I is of wordsize $O(|I|\log(d))$. Thus the space complexity of the our data strcuture is $O(m|I| + mn + |I|\log(d)) = O(\frac{n\log^2(n/\delta)\log(d)}{\epsilon^5\delta^4})$ wordsize. ◀

Using union bound, the success probability of the data structure is at least $1-4\delta' = 1-\delta$.

Snap Rounding: A Cautionary Tale

John Hershberger
Siemens EDA, Wilsonville, OR, USA

Abstract

This paper describes the author's experience using and modifying the technique of snap rounding to meet the needs of a circuit verification system. The interplay of theory and practice illuminates the subtle challenges of both.

1 Introduction

As a discipline, computational geometry is based on real-world problems. Where is the nearest post office? What is the shortest path to grandma's house? What route should a delivery truck follow? To solve these problems, we abstract them, focusing on the key features and ignoring ones that seem irrelevant. We can (we assume) ignore the specifics of post offices, grandparents, and the kinds of goods delivered.

If computational geometry is to remain relevant, the abstract solutions it develops have to be brought to bear on the specific problems that inspired them. The problem features that were ignored may turn out to matter after all. The difference between ice cream and oriental rugs may matter a lot when planning a delivery route! This paper describes one example of applying the computational geometry technique of snap rounding [7, 8, 12] to a problem in the design of integrated circuits.

The specific problem to be solved is computing Boolean operations on polygonal regions. This is a key subroutine in representing the layers of metal, polysilicon, diffusion, etc., used to design a modern IC (integrated circuit) [3, 13, 15]. For example, given a collection of possibly overlapping polygons drawn by a circuit designer, a design system may need to compute the boundary of the union of the polygons. Or alternatively, given two collections of polygons, the system may need to find the points inside the first collection and not the second. (These operations are called single-layer OR and two-layer NOT, respectively.)

Computing the overlay of two subdivisions of the plane is a classic computational geometry problem, with a classic plane sweep algorithm to solve it. From the overlay one can compute any of the Boolean operations simply by noting which input polygons overlap each region of the overlay [5].

Like many computational geometry problems, the overlay problem is stated and solved in the Real RAM model, in which point coordinates are specified and computed with arbitrary precision. On a computer in the real world, the Real RAM is not realistic. Coordinates and computations can use only a limited number of bits. In this problem of polygon Boolean operations, the vertices of the input polygons are specified with k-bit integer coordinates ($k = 64$), and the result polygons must use the same format. This immediately presents a problem of accuracy. If the endpoints of two intersecting line segments are specified with k-bit integers, then rough calculation shows that the intersection point may need up to $5k$ bits to represent each of its coordinates precisely as a rational number. The vertices of the Boolean result must be rounded to the integer grid to satisfy the requirements of the IC design system.

Rounding the result of a geometric computation raises problems of accuracy and topological correctness. How much inaccuracy is introduced by rounding? Is it possible to guarantee that the rounded result faithfully represents the unrounded one? *Snap rounding* was invented to round geometric arrangements as accurately and correctly as possible. Section 2 describes this technique in more detail.

This paper tells the story of my experience using snap rounding in an IC design system. Features of snap rounding that seemed natural and unobjectionable in theory turned out to be ugly stumbling blocks in practice. Resolving these issues led to new theory, further practical challenges, and (eventually) a deeper understanding of the interplay between theory and practice.

2 Definitions

Snap rounding solves the problem of rounding the vertices of an arrangement of line segments to the integer grid. The algorithm is simple to define and relatively simple to implement; it comes with guarantees on the quality of its results [2, 6, 7, 8, 9, 10, 12, 14].

The input to snap rounding is a collection of *ursegments* ("ur" is short for "UnRounded" and is also a German prefix meaning "original"). In the IC design application, ursegment endpoints are 64-bit integer grid points, but snap rounding itself does not restrict its inputs. The vertices of the arrangements of ursegments, both endpoints and intersections, determine the rounding. The Cartesian plane is divided into *pixels*, unit squares centered on the integer grid points. Pixels are closed on their left and bottom sides and open on their right and top sides – thus for integer x and y, the corner $(x - \frac{1}{2}, y - \frac{1}{2})$ belongs to the pixel centered at (x, y), and the other three corners do not. Snap rounding is defined by the interaction of ursegments and pixels:

> Every pixel that contains a vertex of the ursegment arrangement becomes a *hot pixel*. Every ursegment s is replaced by a polygonal path joining the centers of the hot pixels that s intersects.

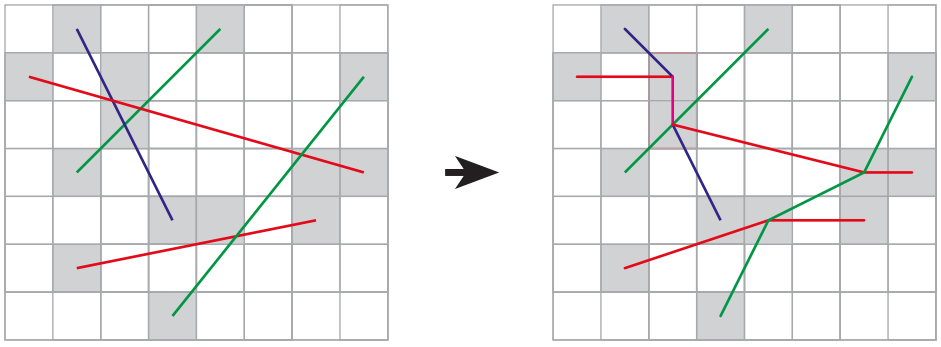

Figure 1 Hot pixels are created by vertices of the ursegment arrangement. Each ursegment is replaced by a polygonal path connecting hot pixel centers.

This simple rounding scheme, illustrated in Figure 1, has two desirable features, as proven by Guibas and Marimont [8]: no segment moves by more than half a pixel, and the topology of the input arrangement is preserved up to collapsing of features. (Here the word "topology" is used to refer to adjacency and ordering relationships.) The order of intersections between ursegments is preserved in the rounded segments, the order of intersection of ursegments with a vertical or horizontal line is preserved, and triangle orientations are preserved, all up

to collapsing of features. This reflects the fact that the rounded arrangement is a homotopic deformation of the arrangement of ursegments. The proofs are sketched below because they will be needed later.

▶ **Lemma 1.** *No segment moves by more than half a pixel. That is, the L_∞ Hausdorff distance between any ursegment and its rounded representation is at most $\frac{1}{2}$.*

Proof. For every ursegment $s = \overline{ab}$, we pick a point $p_i \in s$ belonging to each hot pixel that s intersects, with the first and last points equal to the segment endpoints: $a = p_1, \ldots, p_k = b$. Thus s is trivially represented by the polygonal path $(p_1, \ldots, p_k)$. Let q_i denote the center of the hot pixel containing each p_i, and define $\Delta_i = p_i - q_i$. Since p_i belongs to the hot pixel centered at q_i, $||\Delta_i||_\infty \leq \frac{1}{2}$. The rounded version of s is the polygonal path $(q_1, \ldots, q_k)$. Any point $p \in \overline{p_i p_{i+1}}$ is a convex combination of the endpoints, $p(t) = (1-t) \cdot p_i + t \cdot p_{i+1}$, for $t \in [0, 1]$. The corresponding point of $\overline{q_i q_{i+1}}$ is $q(t) = (1-t) \cdot q_i + t \cdot q_{i+1}$. By linearity, $p(t) = q(t) + ((1-t) \cdot \Delta_i + t \cdot \Delta_{i+1})$, so $||p(t) - q(t)||_\infty \leq \frac{1}{2}$. This one-to-one mapping between points of s and points of the rounded segment shows that the Hausdorff distance between s and the rounded segment is at most $\frac{1}{2}$. See Figure 2. ◀

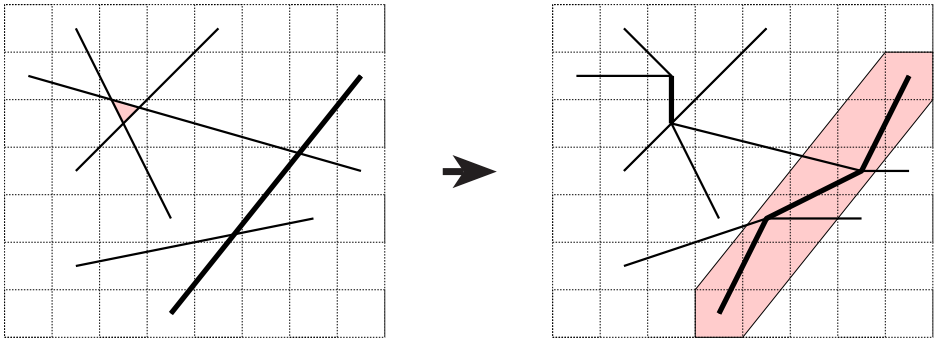

Figure 2 The rounded version of the lower right ursegment is contained in the region within L_∞ distance $\frac{1}{2}$ of the ursegment.

▶ **Lemma 2.** *The topology of the arrangement of ursegments is preserved in the rounded arrangement, up to collapsing of features.*

Proof. (Summary) Guibas and Marimont's proof uses a continuous deformation of the arrangement that maps the input arrangement to the rounded one. Topology is preserved at every instant of the deformation, and hence it is preserved over the whole deformation.

The first step of the argument introduces internal vertices on each ursegment at its first and last contacts with hot pixel boundaries. The deformation shrinks each hot pixel to its center, first by a uniform horizontal contraction to a line segment and then by a vertical contraction to a point. All the hot pixels shrink simultaneously, at the same rate. The arrangement inside each hot pixel shrinks uniformly (affinely) with the hot pixel, so all spatial and topological relationships inside the pixel are preserved (up to collapsing of features). As the hot pixels shrink, the segments outside the hot pixels move, dragged along by their endpoints on the hot pixel boundaries. Guibas and Marimont's key observation is that no external segment can pass over another segment or vertex without crossing into a hot pixel (because all endpoints and ursegment crossings are inside hot pixels), but the deformation is defined such that the hot pixel corners move away from the segments at least as fast as the segments approach – the segments never catch up with the corners.

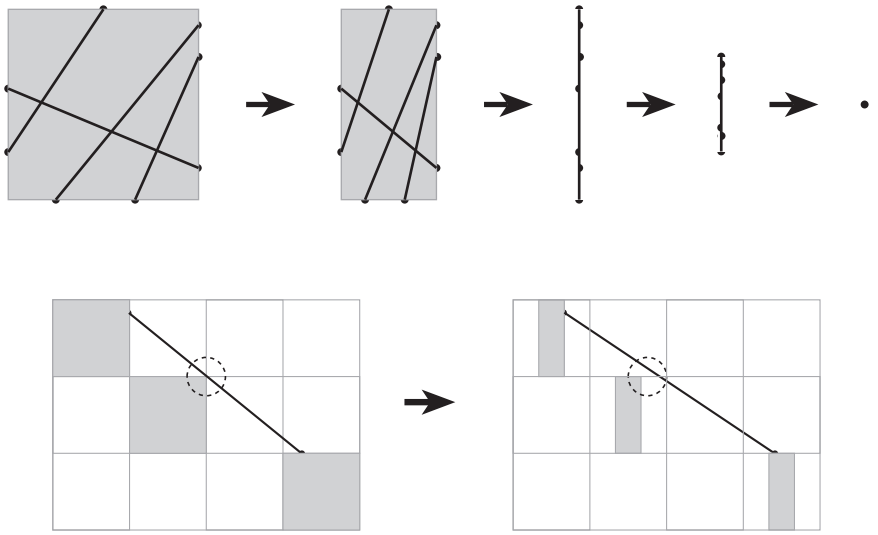

Figure 3 Contraction of a hot pixel does not affect topological relationships inside it. A deforming edge that starts outside all hot pixels never crosses into any hot pixel.

Specifically, let p_0 and p_1 be two consecutive breakpoints along some ursegment, and let $p(\tau)$ be a point on the segment between them, with $p(\tau) = (1-\tau) \cdot p_0 + \tau \cdot p_1$ for $\tau \in [0,1]$. During the horizontal contraction phase, let $p_0(t)$, $p_1(t)$, and $p(\tau,t)$ be the corresponding points at time t of the contraction, where t is the hot pixel half-width, decreasing uniformly from $\frac{1}{2}$ to 0. As t decreases, the corners of all the hot pixels move inward (left or right) at speed 1. Endpoints $p_0(t)$ and $p_1(t)$ move left or right at speed at most 1 (exactly 1 if the endpoint is on the left or right side of a hot pixel; less if it is on the bottom or top). It follows by linearity that $p(\tau,t)$ also moves left or right at speed at most 1, and therefore, because $p(\tau)$ starts outside all hot pixels, $p(\tau,t)$ never crosses into the interior of one. The same argument also works for the vertical contraction phase. See Figure 3. ◀

3 Theory meets practice

I implemented snap rounding as part of a C++ application for physical verification of integrated circuits. Because I wanted to apply snap rounding to solve a variety of problems, I used C++ templates to separate the rounding algorithm from the applications that use it in a scanline sweep.

The scanline package is partitioned into six policies, each with its own role and interface. The *input policy* extracts polygon edge data from a compressed in-memory format and presents them in left-to-right, bottom-to-top order; the *scanline representation* holds the edges intersected by the scanline at its current x-position; the *rounding policy* receives edge events in sorted order and maintains the scanline representation while generating events that describe the rounded subsegments; the *region characteristic* maintains an application-specific characterization of the region above each edge in the scanline (e.g., the depth of coverage); the *output policy* receives rounded segments and consults the scanline representation and region characteristics to produce application-specific output (e.g., polygon Boolean results); and the *event manager* coordinates the interactions between all the other subsystems, including maintaining event queues for the rounding policy and updating the region characteristics

exactly where they need to be recalculated. This decomposition of scanline functionality into distinct roles allows each subsystem to be upgraded independently of the others and allows for substantial reuse between applications. Most applications can use off-the-shelf versions of the input policy, scanline representation, rounding policy, and event manager. The region characteristic can often be reused. Only the output policy always needs a custom implementation.

This structure is both a strength and a weakness of the scanline package. It allows snap rounding to be deployed in a variety of applications with very good reliability, but the strict adherence to interface communication protocols means that out-of-band communication between subsystems is difficult or impossible, say if one subsystem needs to compensate for a problem in another.

Note that application design has already influenced the choice of algorithm. I wanted to use snap rounding to find incidences between polygons and/or edges, as one of the output policies, so the rounding policy needs to identify all the ursegments that contribute to each rounded segment. (Multiple ursegments may be rounded to the same segment in the rounded arrangement.) That means the rounding policy must provide more information than is present in the rounded arrangement of ursegments. That is, the number of notifications is asymptotically larger than the size of the rounded arrangement in the worst case. See Figure 4. Hershberger proposed an output-sensitive snap rounding algorithm that deals with these configurations efficiently [10], but the algorithm is more complicated than necessary for the inputs that arise in practice.

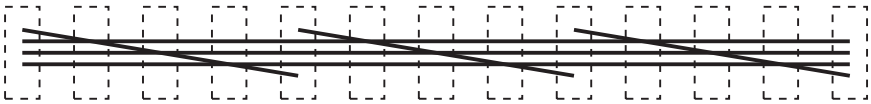

Figure 4 A pathological example with $O(n^2)$ segments in the rounded arrangement, each with $O(n)$ ursegments contributing (rounding) to it. Pixels are stretched vertically for clarity.

The implementation of the rounding policy uses a simple Bentley-Ottmann scanline [1]. The algorithm sweeps a vertical line over the arrangement of ursegments from left to right, maintaining the intersection of the line with the arrangement at each position. Whenever an ursegment intersection or endpoint is detected, it makes the containing pixel *hot*. A local search in the scanline finds all the ursegments that intersect each hot pixel.

This high-level picture becomes a bit more complicated when we look at the details. The implementation gains efficiency by exploiting the knowledge that the result of the Bentley-Ottmann scan is a rounded arrangement. Unlike a classic Bentley-Ottmann scanline, this one does not need to know the precise relative x-order of the ursegment intersections. It is enough to identify the hot pixel containing each intersection and determine whether the intersection lies in the left or right half of the pixel. The crossings inside each half-pixel can then be processed in arbitrary order. Ignoring the precise x-ordering of crossing events reduces the polynomial degree of the required arithmetic computations from quintic to cubic.

Note that the Bentley-Ottmann scanline is a suboptimal algorithmic choice, at least in theory. The scanline processes every vertex of the input arrangement $\mathcal{A}_{in}$, giving complexity $O(|\mathcal{A}_{in}| \log n)$. But $|\mathcal{A}_{in}|$ may be $\Omega(n^2)$ while the output complexity $|\mathcal{A}_{out}|$ is $O(n)$, as shown in Figure 5. It is possible to round such an arrangement in $O(n \log n)$ time, using an algorithm that spends $O(\log n)$ time for each incidence between an ursegment and a hot pixel [6]. However, this is unimportant in the IC design application: arrangements like the one in Figure 5 do not occur in practice. Simplicity of implementation beats theoretical worst-case efficiency.

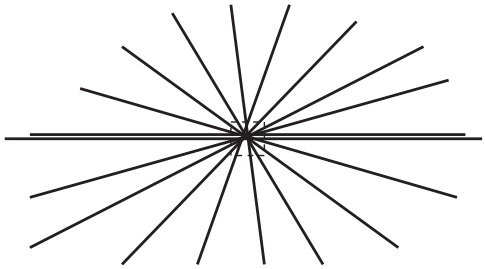

Figure 5 $O(n^2)$ ursegment intersections occur inside a single hot pixel.

The output policy for Boolean operations on polygons maintains a "depth of coverage" (winding number) above each segment in the scanline. Every edge is assigned a value of $+1$ or -1, depending on whether the polygon interior it bounds lies above or below it. The sum of the edge values along the scanline from $-\infty$ to each point on the scanline determines how many polygons cover that point. In the OR operation, for example, a region of the rounded arrangement of segments belongs to the result if its depth of coverage is positive. When the rounding policy notifies the event manager of the left/right end of a rounded segment, it also provides a pointer into the scanline. The event manager uses these pointers to update the depth of coverage counts exactly where they have been changed by scanline updates. When the right end of a rounded segment is processed, the segment gets written to the result by the output policy if and only if the segment forms the boundary between a region inside and a region outside the desired Boolean result. Because of rounding, two segments that are classified as being on the result boundary by depth of coverage may snap to be collinear. When that happens, the two segments annihilate – both are removed from the result. Correspondingly, two regions of the result interior are separated or joined, depending on whether the result interior lies between the two annihilating edges or not.

The design system requires each connected polygon to have a unique polygon number. Here "connected" refers to the polygon interior – polygons may be nonsimple (have holes), but are not connected by contact at vertices. Polygon numbers are assigned on the fly using a disjoint set (Union-Find) data structure [4].[1] Each edge in the output gets its own number; the sets for two edge numbers are joined if the edges are adjacent on the boundary of the result, or if they are vertically visible through the result interior. (Both of these conditions can be checked in constant time per edge.) At the end of the scan, the disjoint set structure is condensed to map the edge numbers to a dense set of polygon numbers. One pass through the output then suffices to replace every edge number with its corresponding polygon number.

The implementation of Boolean operations based on snap rounding replaced an earlier implementation that used a heuristic rounding scheme. That algorithm also detected intersections with a scanline, breaking each segment at rounded intersections. However, the right-hand side of each broken segment was subject to future rounding, so it was possible, though unlikely, for rounded segments to drift arbitrarily far. A second weakness became apparent in the use of Boolean operations to partition and reconstruct polygonal regions in

[1] The disjoint set structure is a simple array, with all joins linking an element to a predecessor. That means that height-balancing (linking the shorter tree to the taller) is not possible, and hence the theoretical performance bound of $O(n\alpha(n))$ is not achievable. However, path compression gives an $O(n \log n)$ worst-case performance bound, and performance in practice is excellent.

IC design. When a polygon is fractured into pieces, geometric rounding may leave tiny gaps (less than a pixel wide) between them. It is desirable for the OR of the pieces to fill in those gaps, but the previous algorithm was inconsistent in achieving that goal.

The new implementation of Boolean operations based on snap rounding has proven to be very successful. Performance is generally good, and snap rounding gives much more predictable, dependable results than the previous heuristic algorithm. Lemma 1 guarantees that rounded results are within half a pixel of the input ursegments – no segment drift is possible. Lemma 2 guarantees topological correctness. Furthermore, the fact that snap rounding moves all ursegments that hit a hot pixel is also beneficial: when snap rounding computes the OR of polygons with tiny gaps between them, the result heals up the gaps better than the earlier implementation.

4 Practice meets theory

The trouble with abstracting a practical problem to get something clean and simple is that some goals may get lost in the translation from practice to theory. This isn't an issue for basic problems like sorting, but becomes relevant for more complex problems. For example, in the problem of rounding an arrangement, symmetry is a practical goal that is difficult to achieve.[2]

In snap rounding, every ursegment that passes through a hot pixel is deformed to pass through the center of the hot pixel. But what if an ursegment merely grazes a hot pixel? What counts as "passing through"? A hot pixel is defined to be closed on its left and bottom sides, and open on its top and right sides. Thus out of the four corners of a hot pixel, only the lower left belongs to it. This means that for the configuration of segments on the left side of Figure 6, the rounded result is asymmetric, as shown on the right.

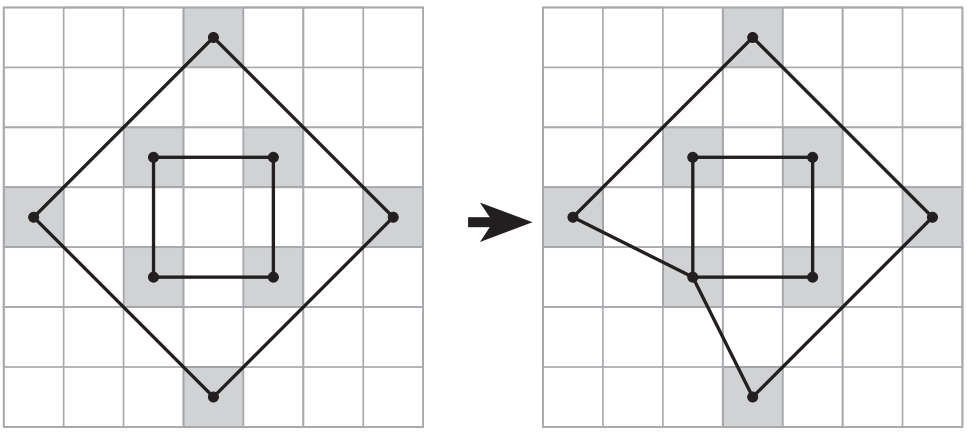

Figure 6 Snap rounding deforms one of the four segments of the outer diamond to pass through a vertex of the inner square.

[2] For efficiency's sake, modern ICs are designed hierarchically. Smaller "cells" (design components) are placed within larger cells. The result of instantiating all the placements, all the way down, is the *flat* design, which should be equivalent to the hierarchical design. However, in a hierarchical design, geometric rounding is performed in the frame of reference of individual cells. If those cells are rotated by a multiple of 90° before placement, as often occurs, any asymmetry in rounding creates a difference between the hierarchical design and the ideal flat design, in which rounding occurs after expansion of placements. Thus asymmetry is to be avoided if possible.

The previous rounding algorithm, the one that snap rounding replaced, did not perturb any of the segments in the left-hand configuration. Thus for this configuration and others like it, the results of snap rounding are perceived as worse by the users of the polygon Boolean application. Unfortunately, predictability and solid definitions are virtues that appeal to theoreticians more than to practitioners. The practitioner is likely to say, "The new algorithm gives worse results on this example. I want an algorithm that does *the right thing* on all of my test cases." The theoretician can say, loftily, "This undisciplined wish for a simultaneous solution to incompatible requirements is how we ended up with the original mess of an algorithm," but it's a tough argument to make.

5 Relaxed snap rounding (Theory gives in to practice)

Eventually, the complaints of the practitioners wore me down. Yes, by the rules of snap rounding, the rounded version of the configuration in Figure 6 has to be asymmetric, but perhaps there's *another* rounding scheme that would give better results.

For example, Hershberger's *stable snap rounding* algorithm might fit the bill [11]. Stable snap rounding has two kinds of hot pixels, magnets and pins, with magnets created by crossings or vertices not at the pixel center. An ursegment that hits a magnet is forced to pass through its center, but one that hits a pin is not – if the segment moves because of magnet vertices, the only restriction is that it may not pass over a pin, as illustrated in Figure 7. In the example of Figure 6, stable snap rounding would not move any of the segments, leaving a symmetric result.

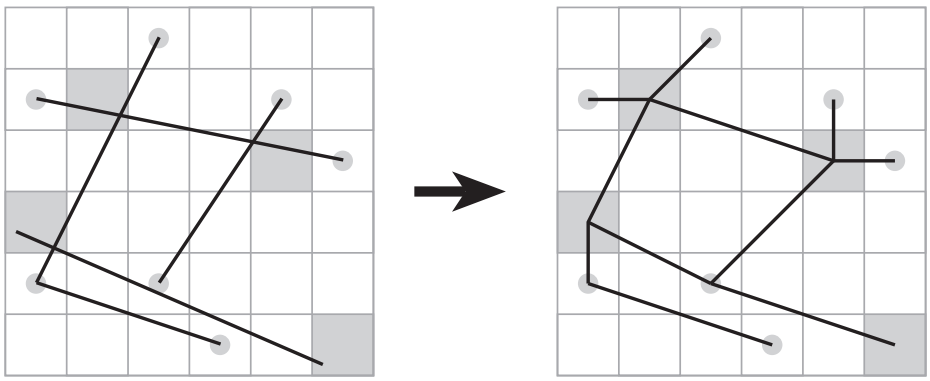

Figure 7 Shaded squares are magnets (pixels containing ursegment crossings or off-grid endpoints); shaded disks are pins (all other hot pixels). Stable snap rounding does not force ursegments to deform to pins, but maintains ursegment homotopy relative to pins.

I didn't want to implement stable snap rounding to solve the asymmetry problem. The behavior of stable snap rounding is much different from ordinary snap rounding. It was hard enough for our software testers to adapt to the differences between snap rounding and the previous algorithm – I didn't want to start the whole qualification process over again. Instead, I wanted a quick, small change that would fix this little asymmetry problem without breaking anything else. [Reader, if you are feeling uneasy about this goal – you have cause!]

I came up with the idea of *relaxed snap rounding*. This borrows an idea from stable snap rounding and applies it in one special circumstance. The rules of relaxed snap rounding are the same as those of ordinary snap rounding *except*

> If a hot pixel contains no ursegment intersections and has ursegment endpoints only at its center, then an ursegment that crosses the pixel's lower left corner *is not considered to contact the hot pixel*.

That is, if a segment crosses the lower left corner of a pixel that is hot only because of ursegment endpoints at its center, the segment is not required to deform to the pixel's center. All other rules remain the same – if an ursegment touches a hot pixel's interior, it *does* deform to the pixel center.

I was quite pleased when I came up with the idea of relaxed snap rounding. In fact, I even considered writing a short paper about it. Relaxed snap rounding solved the asymmetry problem, and I could prove that it had the same good properties as ordinary snap rounding.

- No ursegment moves by more than half a pixel. The original argument applies unchanged. An ursegment is deformed to pass through a subset of the hot pixels that it touches under ordinary snap rounding, so *a fortiori* its deformation is no greater than that produced by ordinary snap rounding.
- Topology of the input arrangement is preserved up to collapsing of features. This, too, can be proved by an adaptation of the original argument of Guibas and Marimont. Once again, we break each ursegment at its intersections with hot pixel boundaries, except that for each pixel made hot only by ursegment endpoints at its center, any segment passing only through its lower left corner is not broken there. Each hot pixel is collapsed to a point, first by uniform horizontal contraction of all hot pixels simultaneously, then by uniform vertical contraction of all the hot pixels (which are now just vertical segments). Each ursegment is split into subsegments at its breakpoints on the hot pixel boundaries, and as the hot pixels contract, the subsegments move with their breakpoint vertices. Every internal point of a subsegment is a convex combination of the subsegment endpoints. Since each endpoint moves left or right (during the first contraction) or up or down (during the second) with speed at most 1, the same is true of every internal point of a segment. Because the corners of each hot pixel move inward at speed 1, no subsegment that starts strictly outside all hot pixels can ever enter any hot pixel. Since all ursegment intersections and endpoints are inside hot pixels, the original arrangement's topology is preserved. In the worst case, a segment that passes through a hot pixel's lower left corner may stay in contact with that corner as it deforms, so the segment ends up passing through the hot pixel center. However, this still preserves topology up to collapsing of features.

Relaxed snap rounding was a big success! The asymmetry problem was resolved, with very few changes to behavior overall. It was rare for an ursegment to pass through the lower left corner of an endpoint-only hot pixel, and when the situation did occur, leaving the segment unbroken at that corner gave more desirable results than the alternative.

6 The fly in the ointment

It was not until a year later that the other shoe dropped. People began to notice that the polygon Boolean operations sometimes produced results that were not well-formed polygons. Some polygons were only weakly simple, like the one shown in Figure 8.

What was the cause of these errors? After several days of debugging, eventually I traced the problem back to a previously overlooked weakness in relaxed snap rounding: no snapping means no noticing. The output policy gets notified of a snapped segment at the segment's right end, when the segment is snapped to pass through a hot pixel's center. The polygon

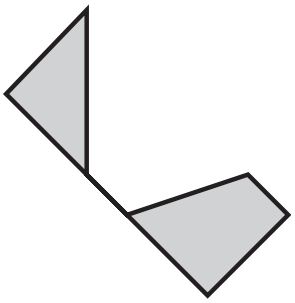

Figure 8 Relaxed snap rounding created polygons with disconnected interiors!

Boolean operation uses that notification to identify oppositely-oriented segments that cancel each other out, and to identify vertices where a polygon pinches off into two. With relaxed snap rounding, a snapped segment may pass through a hot pixel center, but the incidence is not noticed when the hot pixel is processed. The incidence is caused by snapping in another, later hot pixel. See Figure 9.

Note that this problem does not occur for ordinary snap rounding:

▶ **Lemma 3.** *Under ordinary snap rounding, an ursegment s is snapped to pass through the center of a hot pixel h if and only if s contacts h.*

Proof. Contact implies snapping, so the only thing to prove is that if s does not contact h, its snapped version cannot pass through the center of h.

Any point on s moves by at most $\frac{1}{2}$ in x and/or y during the snap rounding deformation, which means that any point of s strictly outside the closure of h (denoted $\overline{h}$) cannot deform to the center of h. The points of $\overline{h} \setminus h$ are the top and right edges and the three corners incident to those edges. If a point $p \in s$ is on the top edge of h and internal to that edge, then s is horizontal – otherwise it would intersect the interior of h. In this case all the hot pixels that s contacts are above h, so s will snap upward, away from h. A similar argument applies for s collinear with the right edge of h. If s passes through a non-contact corner of h (denoted by p) and deforms to pass through the center of h, let h_1 and h_2 be the hot pixels that s contacts immediately before and after p. For p to move to the center of h, the intersections of s with $\overline{h_1}$ and $\overline{h_2}$ must both move by $\frac{1}{2}$ in both x- and y-coordinates, in the same direction as from p toward the center of h. This implies that the contact between s and h_1 (resp. h_2) is at the same corner of h_1 (h_2) that p occupies relative to h. But contact is defined the same for all hot pixels, so since s does not contact h at p, it cannot contact h_1 or h_2, either, a contradiction. ◀

That is to say, in a scanline implementation of ordinary snap rounding, every incidence between a snapped ursegment and a hot pixel center is detected when the hot pixel is processed, but this is not true for relaxed snap rounding. As in Figure 9, it is possible for polygon Boolean operations using relaxed snap rounding to produce a pinch-off, e.g., to separate a single result polygon into two components, without detecting it.

7 The way forward

In hindsight, relaxed snap rounding seemed like a big mistake. It sacrificed the algorithmic guarantee of ordinary snap rounding for a small improvement in result quality. Unfortunately, once user expectations had been set for relaxed snap rounding's behavioral improvements, it was impossible to go backward.

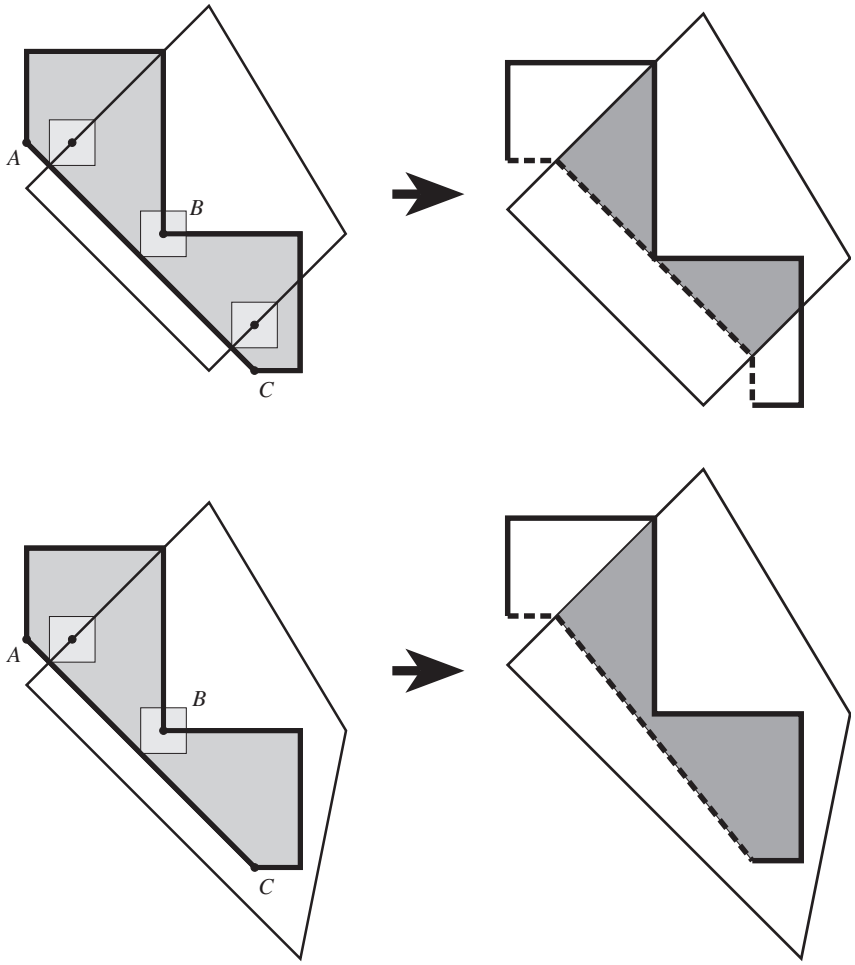

Figure 9 The shaded polygon is ANDed with the unshaded polygon. Depending on what occurs to the right of B, the segment $\overline{AC}$ may or may not snap to pass through B, creating either two or one polygons in the AND result. The relevant hot pixels are highlighted. The incidence between $\overline{AC}$ and the hot pixel at B in the upper figure is not detected by relaxed snap rounding. The snapping that creates the incidence does not occur until the scanline is past B. When the scanline is at position B, the configurations in the upper and lower figures are indistinguishable, even though the results of the AND near B are very different.

I had to find a way to reconstruct the incidences that relaxed snap rounding fails to detect. In this case, the separation of the rounding policy from the polygon Boolean output policy is a liability. The rounding policy knows when a contact between an endpoint-only hot pixel and an ursegment is being ignored, but "ignoring" means that the rounding policy does not generate an end-of-segment event for the non-incidence. The output policy is left to compensate for the rounding policy's omissions.

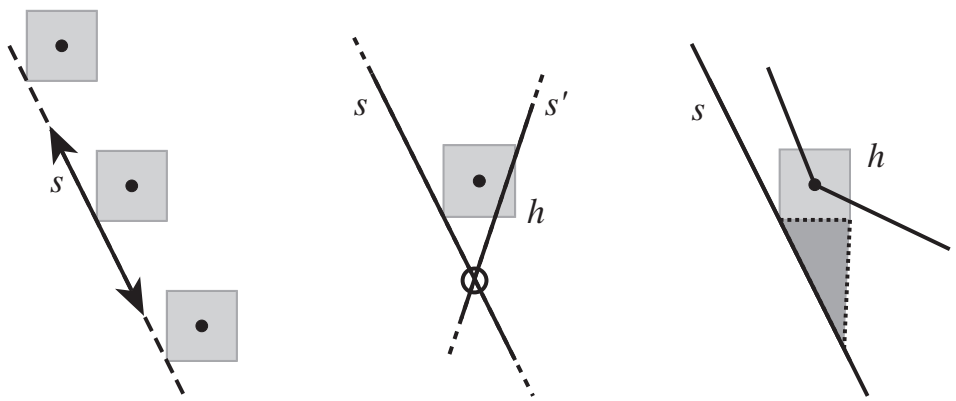
As a first step, I defined a *vulnerable vertex* as a hot pixel that contains no crossings and has an ursegment passing through its lower left corner. Vulnerable vertices can lead to undetected incidences, and every undetected incidence occurs at a vulnerable vertex. The following lemma characterizes these vulnerable vertices.

▶ **Lemma 4.** *Let s be an ursegment that passes through the lower left corner of a hot pixel h without touching the interior of h. If the contact between s and h is ignored under relaxed snap rounding, but s is snapped to pass through the center of h, then*

1. *The x-span of s contains the x-span of h in its interior.*
2. *If $s' \neq s$ is an ursegment that extends to the left of the x-span of h and rounds to pass through its center, then its leftmost intersection with h is on the top or left boundary.*
3. *If any ursegment $s' \neq s$ extends to the left of h and rounds to pass through its center, then s is immediately below the lowest such segment. Otherwise, s is immediately below the lowest segment with its left endpoint in h.*

Proof. Note that because s's contact with h is ignored, h has at least one ursegment vertex at its center, but contains no ursegment intersections.

(1) Let h_l and h_r be the hot pixels that s contacts before and after h. Since s snaps to pass through the center of h, s needs to move by $(\Delta x, \Delta y) = (\frac{1}{2}, \frac{1}{2})$ at both h_l and h_r, i.e., it must pass through their lower left corners. That means h_l must be strictly left of h, and h_r must be strictly to the right. See Figure 10(1).



(1) (2) (3)

Figure 10 (1) The hot pixels that s contacts before and after h are strictly left and right of h. (2) Ursegments s and s' intersect in the column of pixels below h. (3) The shaded triangle below h must be empty of ursegments (except possibly for ones that contact h).

(2) Let x_h be the x-coordinate of h's center. If s' first intersects the bottom of h, then it has positive slope. Segment s has negative slope. Consequently s and s' must intersect in the x-interval $(x_h - \frac{1}{2}, x_h + \frac{1}{2})$, somewhere below h. This means that h_r, the first hot pixel on s right of $x_h - \frac{1}{2}$, has its center on $x = x_h$. By (1), this means that s cannot snap to pass through the center of h. See Figure 10(2).

(3) If any ursegment that does not contact h intersects the interior of the triangle formed by s, the vertical line $x = x_h + \frac{1}{2}$, and the bottom of h, then either s has an intersection in the x-interval $(x_h - \frac{1}{2}, x_h + \frac{1}{2})$ or it crosses a hot pixel created by an ursegment endpoint in the column below h. In either case, h_r is not to the right of h, contradicting (1). Hence this triangle is free of all ursegments except possibly for ones that intersect h, implying that s is immediately below the lowest left or right segment in h, as claimed. See Figure 10(3). ◀

It is possible to detect vulnerable vertices in constant time apiece using the events that *are* passed to the output policy. Whenever the scanline passes the left or right end of an ursegment, it generates an event that is reported to the output policy with a pointer to the scanline location where the vertex occurs. Any segment with an undetected incidence lies just below one of the segments with a vertex at h's center, by Lemma 4(3). By looking at the neighboring edges in the scanline for each endpoint event, it is possible to identify all vulnerable vertices.

I used vulnerable vertices as the basis of a two-part scheme to restore correct behavior for Boolean operations. The first step uses vulnerable vertices to identify undetected incidences. The vulnerable vertices are identified in left-to-right order and stored in a table in that order. The detection scheme keeps a sliding window of vulnerable vertices. The width of the window is defined by the edges intersecting the current scanline. When the scanline reaches the right end of a snapped segment s that forms part of the result polygon, if s snaps up and to the right by $(\frac{1}{2}, \frac{1}{2})$, the scheme searches the active vulnerable vertices to see whether the snapping creates an incidence in the segment interior. If so, the identity of the output polygon containing s is recorded for later processing.

The second part of the scheme processes any incidences that have been discovered. Fortunately, incidences occur rarely enough in practice that fairly expensive cleanup is affordable. After the polygon Boolean operation completes, if any internal incidences were detected, the cleanup code extracts the edges of all polygons containing an incidence and performs an OR operation again on the extracted edges, without further snapping. Then these updated polygons are renumbered and integrated back into the rest of the output. This, finally, restores correct output.

This is quite ugly and potentially inefficient, as the reader will have observed. With the addition of more data structures, it could be made more efficient, but for now, it seems to be efficient enough for the application. I declared victory and slunk from the field.

8 Lessons learned

The most obvious take-away from this experience is no surprise at all: implementation is hard, and we theoreticians ignore that fact, or sweep it under the rug, at our peril. The requirements of an application often do not precisely match the assumptions of a theoretical algorithm. My mistake in "proving" the correctness of relaxed snap rounding was that I forgot the dependencies of the polygon Boolean operation on the scanline implementation of snap rounding. Although relaxed snap rounding meets its approximation guarantees, it fails to detect all incidences between snapped segments and hot pixel centers, and the polygon Boolean operation depends on incidence detection for correctness. Even if incidence detection is restored with a post-processing step, incidences are not detected in left-to-right order, so the simplicity of the scanline Boolean algorithm is compromised.

As someone who has worked in both the theoretical and applied communities for many years, I think that in some ways, the life of a theoretician is easy – if the problem as posed is too hard, we can solve a related problem and wave our hands to argue that the new problem is just as interesting as the original. The life of an implementor of applications is easy, too – there's no need for an optimal implementation, just one that is correct (enough) and fast enough on the data that occur in practice. However, the life of someone who wears both hats can be very challenging: finding (or inventing) an algorithm that solves the given problem efficiently and is simple enough to implement is hard to do repeatedly. Nevertheless, success, even only occasional success, is quite satisfying when it comes, and makes the struggle worthwhile.

That brings me to the key question of this section, "Have *I* learned *my* lesson?" For good or ill, the answer is *no*. I continue to struggle (actually, to play) at the boundary between theory and practice, trying to find or make theory that is practical enough to use, trying to find practical problems that are elegant enough to appeal to theoreticians, and doing my best to implement elegant, efficient solutions to real-world problems.

Tracking the Persistence of Harmonic Chains: Barcode and Stability

Abstract

The persistence barcode is a topological descriptor of data that plays a fundamental role in topological data analysis. Given a filtration of data, the persistence barcode tracks the evolution of its homology groups. In this paper, we introduce a new type of barcode, called the harmonic chain barcode, which tracks the evolution of harmonic chains. In addition, we show that the harmonic chain barcode is stable. Given a filtration of a simplicial complex of size m, we present an algorithm to compute its harmonic chain barcode in $O(m^3)$ time. Consequently, the harmonic chain barcode can enrich the family of topological descriptors in applications where a persistence barcode is applicable, such as feature vectorization and machine learning.

1 Introduction

There are two primary tasks in topological data analysis (TDA) [27, 30, 53]: reconstruction and inference. In a typical TDA pipeline, the data is given as a point cloud in $\mathbb{R}^N$. A "geometric shape" K in $\mathbb{R}^N$ is reconstructed from the point cloud, usually as a simplicial complex, and K is taken to represent the (unknown) space X from which the data is sampled. X is then studied using K as a surrogate for properties that are invariant under invertible mappings (technically, homeomorphisms). The deduced "topological shape" is not specific to the complex K or the space X, but is a feature of the homeomorphism type of K or X. For example, a standard round circle has the same topological shape as any closed loop such as a knot in the Euclidean space. Although topological properties of X alone are not sufficient to reconstruct X exactly, they are among a few global features of X that can be inferred from the data sampled from X.

An (ordinary) persistence barcode [10, 31] (or equivalently, a persistence diagram [14, 19, 29]) captures the evolution of homological features in a filtration constructed from a simplicial complex K. It consists of a multi-set of intervals in the extended real line, where the start and end points of an interval (i.e., a bar) are the birth and death times of a homological feature in the filtration. Equivalently, a persistence diagram is a multi-set of points in the extended plane, where a point in the persistence diagram encodes the birth and death time of a homological feature.

A main drawback of ordinary persistent homology is that it does not provide canonical choices of geometric representatives for each bar in the barcode. Specifically, there are two levels of choices in assigning representatives for bars in a persistence barcode: first, we choose a basis for persistent homology in a consistent way across the filtration; second, we choose a cycle representative inside each homology class in the basis. Both levels of choices involve choosing among significantly distinct geometric features of data to represent the same bar in the barcode. Since such choices are not canonical, it can be challenging to interpret their underlying geometric meaning. In addition, while existing works [7, 25, 51] compute optimal representatives for ordinary persistence, the optimality would rely on a choice of weights for the simplices and on the optimality criterion, leading to different shapes. Moreover, computing the optimal representatives is NP-hard in many interesting situations [17, 11, 12, 5, 32, 25].

As our first contribution, we introduce a new type of barcode called *harmonic chain barcode*. This barcode is obtained by tracking the birth and death of harmonic chains in an increasing filtration. Since there is always a *unique* harmonic chain in a homology class, the *harmonic representatives* in our harmonic chain barcode immediately remove the second level of choices in a natural way. The main idea is to take the harmonic chain groups along an increasing filtration, and to observe that the groups grow or shrink due to the birth and death of harmonic chains, resulting in a zigzag module with inclusion maps. Like any zigzag module [8], the module of harmonic chain groups decomposes into interval modules, which then form the harmonic chain barcode. Moreover, since the maps in this zigzag module are essentially inclusions, each representative for a bar in our harmonic chain barcode consists of a single harmonic chain which is alive over the entire bar. We emphasize that our harmonic chain barcode is distinct from the ordinary persistence barcode; see for example Figs. 1 and 2.

The ordinary persistence barcode is shown to be stable [19], which is crucial for applications. The stability means that small changes in the data imply only small changes in the barcode. For our second contribution, we show that our harmonic chain barcode is also stable in the same sense as the stability of persistence barcode [19].

Finally, we present an algorithm for computing the harmonic chain barcode in $O(m^3)$ time for a filtration of size m, matching the complexity of practical algorithms for ordinary persistence.

The interpretation of homological features is crucial for applications such as extracting hierarchical structures of amorphous solids [36] and quantifying the growing branching architectures of plants [42]. Such an interpretation is closely related to the existence of canonical chain representatives for a barcode. In our harmonic chain barcode, using orthogonality, each bar enjoys a canonical choice of representative (within a homology class) which *lives exactly at the time-interval of the bar*. This arguably promises a more interpretable data feature. Therefore, we expect our harmonic chain barcodes to enrich the family of topological descriptors in applications where ordinary persistence barcodes are used, such as feature vectorization and machine learning. Note that just from the fact that our barcode is different from the ordinary persistence one cannot argue in favor or against our suggested barcode. Such a comparison is only meaningful in a specific domain of application and when performed using experimental evaluations. We refer to [35] for an interesting pipeline of data analysis using extra properties of harmonic chains. [35] also contains a method of propagating the information from harmonic chains back to the original data points, which we find also relevant to our harmonic representatives.

2 Related work

Harmonic chains were first studied in the context of functions on graphs, where they were identified as the kernel of the Laplacian operator on graphs [40]. The graph Laplacian and its kernel are important tools in studying graph properties, see [48, 50] for surveys. Eckmann [28] introduced the higher-order Laplacian for simplicial complexes, and proved the isomorphism of harmonic chains and homology. The work [33] studied the stability of higher-order Laplacians. Horak and Jost [37] defined a weighted Laplacian for simplicial complexes. Already their theoretical results on Laplacian [37] anticipated the possibility of applications, as the harmonic chains are thought to contain important geometric information. They are eigenvectors of the 0 eigenvalue of the Laplace operator on simplicial complexes and the spectrum of the Laplace operator has significant geometric information, see e.g. [38]. This has been validated by recent results that use curves of eigenvalues of Laplacians in a filtration in data analysis [18, 52]. The Laplacian was applied to improve the mapper algorithm [49], and for coarsening triangular meshes [39]. The persistent Laplacian [47] and its stability [44] is an active research area. Due to the close relation of harmonic chains and Laplacians, harmonic chains could find applications in areas that Laplacians have been used. Computing reasonable representative cycles for persistent homology is also an active area of research. Here, usually an optimality criterion is imposed on cycles in a homology class to obtain a unique representative. For a single homology class, a number of works [16, 23, 25, 51, 7, 13, 17, 23, 41] consider different criteria for optimality of cycles. Hardness of computing optimal representatives has been studied by [17, 11, 12, 13, 5, 32, 25]. For persistent homology, the authors of [25] studied the hardness of choosing optimal cycles for persistence bars. Furthermore, the study in [20] uses harmonic cycles in a persistent homology setting to compute the persistence barcode. Lieutier [43] studied the harmonic chains in persistent homology classes, called persistent harmonic forms.

Relation to the work of Basu and Cox. The most relevant work to ours is the inspiring work of Basu and Cox [2]. Basu and Cox had a similar goal as ours, namely, to associate geometric information to each bar in order to obtain a more interpretable data feature. To that end, they introduced the notion of *harmonic persistent barcode*, by associating a subspace of harmonic chains to each bar in the *ordinary* persistence barcode. When the multiplicity of the bar is 1, the subspace is 1-dimensional. This is the space of harmonic chains that are born at s and die entering t. In general, this is a quotient subspace of harmonic chains at time s. Using orthogonality, they can represent this subquotient as a subspace of the harmonic cycles at time s. As a result, they successfully assign a canonical harmonic cycle to a bar in the ordinary persistence diagram. We note that, in general, a bar in the persistence barcode cannot be represented using a single harmonic chain that *remains harmonic during the lifetime of the bar*. The harmonic cycle associated to a bar using the Basu-Cox approach is the initial harmonic representative of the bar, that is, the harmonic cycle that represents the bar at its birth. Basu and Cox also used the *terminal harmonic cycle* in some of their arguments, thus showing that the choice is not entirely canonical. However, Basu and Cox proved significant properties of the initial cycles in terms of what they call *relative essential content*. The novelty of our result is that, in contrast to [2], we define a new barcode distinct from the ordinary persistence barcode, in which each bar has a harmonic cycle associated with it that is harmonic during the lifetime of the bar. Basu and Cox also proved stability for their harmonic persistent barcode, by considering subspaces as points of a Grassmannian manifold and measuring distances in the Grassmannian. Such a distance quantifies the angles

between subspaces, whereas our notions of stability are stronger in the sense that they use the classical bottleneck distance analogous to the ordinary persistence homology. The authors of [34] studied a method that permits the construction of stable persistence diagrams that are equipped with a canonical choice of representative cycles for filtrations over arbitrary finite posets. If the underlying poset is a finite subset of the real line, using persistent Laplacians, they obtained harmonic cycles connected (through a certain isomorphism) to those identified by Basu and Cox.

3 Background

In this section, we review the notion of harmonic chains and persistent homology. Homology and cohomology are defined with real coefficients $\mathbb{R}$ (instead of $\mathbb{Z}_2$). Let K be a simplicial complex and p the homology dimension (or equivalently, homology degree). $C_p(K)$, $Z_p(K)$, and $H_p(K)$ denote the p-th chain group, cycle group, and homology group of K, whereas $C^p(K)$, $Z^p(K)$, and $H^p(K)$ denote the p-th cochain group, cocycle group, and cohomology group of K, respectively. Groups across all dimensions are denoted as $C_*(K)$, $C^*(K)$, etc. We use ∂ and δ to denote boundary and coboundary operators, respectively.

3.1 Harmonic cycles

Based on the standard notions of homology and cohomology with $\mathbb{R}$ coefficients, we identify chains and cochains via duality, i.e., $C_p(K) = C^p(K) = \mathbb{R}^{n_p}$, where n_p is the number of p-simplices. Therefore, we can talk about coboundaries of cycles in $Z_p(K)$. We first introduce the notion of harmonic chains.

▶ **Definition 1.** *The* p-th harmonic chain group *of* K*, denoted* $\mathbb{H}_p(K)$*, is the group of* p*-cycles that are also* p*-cocylces. Equivalently,* $\mathbb{H}_p(K) := Z_p(K) \cap Z^p(K)$*. Each element in* $\mathbb{H}_p(K)$ *is called a* harmonic p-chain*. The harmonic chain group in all dimensions is the group* $\mathbb{H}(K) := \bigoplus_p \mathbb{H}_p(K)$*.*

We sometimes use *harmonic cycles* in place of *harmonic chains* to emphasize the fact that harmonic chains are cycles.

▶ **Lemma 2** ([28])**.** $\mathbb{H}_p(K)$ *is isomorphic to* $H_p(K)$ *and* $H^p(K)$*. Specifically, each homology and cohomology class has a unique harmonic cycle in it.*

Harmonic cycles enjoy certain geometric properties. As an example, we mention the following Proposition 3; see [21, Proposition 3] for a proof. In other words, a harmonic cycle is the chain with the least squared-norm in a cohomology class.

▶ **Proposition 3** ([21])**.** *Let* $\alpha \in C^p(K)$ *be a cochain. There is a unique solution* $\overline{\alpha}$ *to the least-squares minimization problem* $\arg\min_{\overline{\alpha}}\{||\overline{\alpha}||^2 \mid \exists \gamma \in C^{p-1}(K); \alpha = \overline{\alpha} + \delta\gamma\}$*. Moreover,* $\overline{\alpha}$ *is characterized by the relation* $\partial\overline{\alpha} = 0$*.*

There is an alternative definition of harmonic cycles. Consider the natural inner product on $C_p(K)$ given by $\langle \sigma_i, \sigma_j \rangle = \delta_{i,j}$. The harmonic chain group can be defined as $\mathbb{H}_p(K) = Z_p(K) \cap B_p(K)^\perp$. With this definition, the isomorphism of Lemma 2 is realized by a map that sends $z + B_p(K)$ to its projection to $B_p(K)^\perp$. In addition, the harmonic cycles satisfy $\mathbb{H}_p(K) = \ker(\partial_p) \cap \ker(\partial_{p+1}^\perp)$. For a short proof of the equivalence among the definitions of harmonic cycles above, see [2]. Importantly, our algorithm relies on the fact that harmonic cycles are cocycles whose boundaries are zero.

3.2 Ordinary persistence

Ordinary persistent homology takes a *filtration* of a simplicial complex K as input. A *continuous* filtration F assigns to each $r \in \mathbb{R}$ a subcomplex $K_r \subseteq K$ such that $K_r \subseteq K_s$ for $r \leq s$. Since K is finite, there are finitely many $t_0, t_1, \ldots, t_m \in \mathbb{R}$ where K_{t_i} changes. We then abuse the notations slightly by letting $K_i := K_{t_i}$ and have a *discrete* form of F,

$$F : \emptyset = K_0 \hookrightarrow K_1 \hookrightarrow \cdots \hookrightarrow K_{m-1} \hookrightarrow K_m = K, \tag{1}$$

where each $K_i \hookrightarrow K_{i+1}$ is an inclusion. Unless stated otherwise, we assume that F is *simplex-wise*, i.e., each two K_i and K_{i+1} differ by at most a single simplex. For simplicity of the exposition, complexes in F sometimes are subscripted by real-valued "timestamps" of the form K_{t_i} (e.g., in Sec. 6) or subscripted by integers of the form K_i (e.g., in Sec. 5), which should not cause any confusions. Applying homology functor to Eq. (1), we obtain a sequence of homology groups and connecting linear maps (homomorphisms), forming a *persistence module*:

$$\mathcal{M} : H_p(K_0) \to H_p(K_1) \to \cdots \to H_p(K_{m-1}) \to H_p(K_m). \tag{2}$$

For $s \leq t$, let $f_p^{s,t} : H_p(K_s) \to H_p(K_t)$ denote the map induced on the p-th homology by inclusion. The image of the map, $f_p^{s,t}(H_p(K_s)) \subseteq H_p(K_t)$, is called the p-th (s,t)-*persistent homology group*, denoted $H_p^{s,t}$. The group $H_p^{s,t}$ consists of homology classes which exist in K_s and survive until K_t. The dimensions of these vector spaces are the *persistent Betti numbers*, denoted $\beta_p^{s,t}$. An *interval module*, denoted $I = I[b,d)$, is a persistence module of the form

$$0 \to \cdots \to 0 \to \mathbb{R} \to \cdots \to \mathbb{R} \to 0 \to \cdots \to 0.$$

In the above, $\mathbb{R}$ is generated by a homology class and the connecting homomorphisms map generator to generator. We have $I_r = \mathbb{R}$ for $b \leq r < d$ and $I_r = 0$ for other r. Any persistence module can be decomposed into a collection of interval modules in a unique way [45]. The collection of $[b,d)$ for all interval modules is called the *persistence barcode*. When plotted as points in an extended plane, the result is the equivalent *persistence diagram*.

Stability of persistence diagram/barcode. The stability of persistence diagrams (or barcodes) is a crucial property for applications. It says that small changes in data lead to small changes in the persistence diagrams. We only review the stability for sublevel-set filtrations here. Let D and D' denote two persistence diagrams. Recall that a persistence diagram is a multi-set of points in the extended plane (each of which is a birth-death pair) which also contains all points on the diagonal. The *bottleneck distance* of D, D' is defined as

$$d_B(D, D') = \inf_\gamma \sup_{p \in D} ||p - \gamma(p)||_\infty,$$

where γ ranges over all bijections between D and D' and $||\cdot||_\infty$ is the largest absolute value of differences of the points' coordinates.

A function $\tilde{f} : |K| \to \mathbb{R}$ is called *simplex-wise linear* if it is linear on each simplex. Let $K_r = \{\sigma \in K \mid \forall x \in |\sigma|, \tilde{f}(x) \leq r\}$ be the *sublevel set complex* at value $r \in \mathbb{R}$. The complexes K_r and the inclusions between them form a *sublevel set filtration* $\tilde{F}$ (which is not necessarily simplex-wise). We denote the persistence diagram of $\tilde{F}$ as $\mathrm{Dgm}(\tilde{f})$. We refer to [19, 14] for proof of the following Theorem 4. See [19, 14] for the stability of ordinary persistence.

▶ **Theorem 4.** *Let $\tilde{f}, \tilde{g} : |K| \to \mathbb{R}$ be simplex-wise linear functions. Then*

$$d_B(\mathrm{Dgm}(\tilde{f}), \mathrm{Dgm}(\tilde{g})) \leq ||\tilde{f} - \tilde{g}||_\infty.$$

3.3 Zigzag persistence

We provide a brief overview of zigzag persistence; see [8, 9] for details. A zigzag module

$$\mathcal{M} : V_0 \xleftrightarrow{g_0} V_1 \xleftrightarrow{g_1} \cdots \xleftrightarrow{g_{k-1}} V_k$$

is a sequence of vector spaces connected by linear maps that could be forward or backward, i.e., each g_i could be $g_i : V_i \to V_{i+1}$ or $g_i : V_i \leftarrow V_{i+1}$. The module $\mathcal{M}$ decomposes into a direct sum of interval modules $I[b, d]$ of the form

$$0 \longleftrightarrow \cdots \longleftrightarrow 0 \longleftrightarrow \mathbb{R} \longleftrightarrow \cdots \longleftrightarrow \mathbb{R} \longleftrightarrow 0 \cdots \longleftrightarrow 0$$

with 1-dimensional vector spaces in the range $[b, d]$. The multi-set of intervals in the decomposition defines the *barcode* of $\mathcal{M}$, denoted as $\mathsf{B}(\mathcal{M})$.

Conventions. In this paper, we may omit the subscript/dimension of a homology group if there is no danger of ambiguity. Moreover, we use the terms persistence barcode and persistence diagram interchangeably.

4 Harmonic chain barcodes and representatives

As reviewed in Sec. 3.2, by directly taking the homology functor, an increasing filtration of simplicial complexes leads to an *ordinary persistence module* consisting of homology groups [15, 27]. These homology groups are connected by forward maps of the form $H(K_i) \to H(K_{i+1})$. The ordinary persistence module then decomposes into interval modules, which define the *ordinary persistence barcode*. In this section, we show that the harmonic chain groups of all the complexes in a filtration constitute an abstract *zigzag persistence module* (see Sec. 3.3). The main idea is that we take the harmonic chain groups along the filtration, where the groups could grow or shrink, resulting in a zigzag module. Moreover, the maps in this zigzag module are inclusions. Like any zigzag module [8], the module of harmonic chain groups decomposes into interval modules. These intervals form the harmonic chain barcode, the main object of interest in this paper.

Throughout the section, consider a simplex-wise filtration

$$F : \emptyset = K_0 \xhookrightarrow{\sigma_0} K_1 \xhookrightarrow{\sigma_1} \cdots \xhookrightarrow{\sigma_{m-1}} K_m = K,$$

where each K_{i+1} differs from K_i by the addition of a simplex σ_i. Recall that $K_i := K_{t_i}$ for $t_i \in \mathbb{R}$ where K_{t_i} is a complex from a *continuous* filtration indexed over $\mathbb{R}$; see Sec. 3.2.

▶ **Proposition 5.** *For each inclusion* $K_i \xhookrightarrow{\sigma_i} K_{i+1}$ *in* F*:*

$$\dim(\mathbb{H}(K_{i+1})) = \dim(\mathbb{H}(K_i)) \pm 1.$$

Proof. This follows from Lemma 2 and some well-known facts in persistence (see [27, 29]). ◀

▶ **Definition 6.** *A simplex* σ_i *inserted in* F *is called* positive *if* $\dim(\mathbb{H}(K_{i+1})) = \dim(\mathbb{H}(K_i)) + 1$, *and* negative *if* $\dim(\mathbb{H}(K_{i+1})) = \dim(\mathbb{H}(K_i)) - 1$.

We describe how we connect the harmonic chain groups of complexes in F by inclusions. For each K_i and each chain $c = \sum_{j=0}^{i-1} \alpha_j \sigma_j$ in $C_p(K_i)$, we identify c as a chain $c = \sum_{j=0}^{m-1} \alpha_j \sigma_j$ in $C_p(K)$, where $\alpha_j = 0$ for $j \geq i$. This makes both $C_p(K_i)$ and $C_p(K_{i+1})$ a subspace of $C_p(K)$. We then have the following inclusion:

$$Z_p(K_i) \hookrightarrow Z_p(K_{i+1}). \tag{3}$$

Recall that $\mathbb{H}_p(K_i) := Z_p(K_i) \cap Z^p(K_i)$, which means that $\mathbb{H}_p(K_i) \subseteq Z_p(K_i) \subseteq C_p(K)$. Hence, we also identify each harmonic cycle in $\mathbb{H}_p(K_i)$ as a chain in $C_p(K)$. We then observe in Theorem 7 a similar inclusion as in Eq. (3) between any harmonic chain groups $\mathbb{H}_p(K_i)$ and $\mathbb{H}_p(K_{i+1})$, with a possible flip on the direction.

▶ **Theorem 7.** *For each arrow $K_i \xhookrightarrow{\sigma_i} K_{i+1}$ in F, where σ_i is a p-simplex:*
- *There is an inclusion $\mathbb{H}_p(K_i) \hookrightarrow \mathbb{H}_p(K_{i+1})$ if σ_i is positive;*
- *And there is an inclusion $\mathbb{H}_{p-1}(K_i) \hookleftarrow \mathbb{H}_{p-1}(K_{i+1})$ if σ_i is negative.*

In addition, in each case the harmonic chain groups in other dimensions remain unchanged, i.e., $\mathbb{H}_q(K_i) = \mathbb{H}_q(K_{i+1})$ for any other $q \notin \{p, p-1\}$.

Proof. The only harmonic chain groups that might change from K_i to K_{i+1} are those in dimension p because cycle and cocycle groups in other dimensions do not change.

First consider Case I that σ_i is positive. Let $\iota : K_i \hookrightarrow K_{i+1}$ be the inclusion map. As noted above, we identify any $c \in C_*(K_i) = C^*(K_i)$ with $\iota_\sharp(c) \in C_*(K_{i+1}) = C^*(K_{i+1})$.

Case I.1: $\mathbb{H}_p(K_i) \subseteq \mathbb{H}_p(K_{i+1})$. Take $z \in \mathbb{H}_p(K_i)$. Obviously, $\iota_\sharp(z)$ is a cycle in K_{i+1}. For any $c \in C_{p+1}(K_{i+1})$, $\delta(\iota_\sharp(z))(c) = \iota_\sharp(z)(\partial c)$. Since $C_{p+1}(K_i) = C_{p+1}(K_{i+1})$, c and hence ∂c exist in K_i, meaning that $\iota_\sharp(z)(\partial c) = z(\partial c) = (\delta z)(c) = 0$. It follows that $\iota_\sharp(z)$ is a cocycle in K_{i+1}. Therefore, $\mathbb{H}_p(K_i) \subseteq \mathbb{H}_p(K_{i+1})$.

Case I.2: $\mathbb{H}_{p-1}(K_i) = \mathbb{H}_{p-1}(K_{i+1})$. Take $z \in \mathbb{H}_{p-1}(K_{i+1})$. Since σ_i is a positive p-simplex, we have $Z_{p-1}(K_{i+1}) = Z_{p-1}(K_i)$ and $B_{p-1}(K_i) = B_{p-1}(K_{i+1})$. So $z \in Z_{p-1}(K_i)$ and we consider z as a cochain in K_i. Then, for any $c \in C_p(K_i)$, $\delta(z)(c) = z(\partial c) = 0$, with the last equality due to $\partial c \in B_{p-1}(K_i) = B_{p-1}(K_{i+1})$. Therefore, $\mathbb{H}_p(K_{i+1}) \subseteq \mathbb{H}_p(K_i)$. Take $z \in \mathbb{H}_{p-1}(K_i)$. For any $c \in C_p(K_{i+1})$, $\delta(\iota_\sharp z)(c) = (\iota_\sharp z)(\partial c) = 0$, with the last equality due to $\partial c \in B_{p-1}(K_{i+1}) = B_{p-1}(K_i)$. Therefore, $\mathbb{H}_{p-1}(K_i) = \mathbb{H}_{p-1}(K_{i+1})$.

Now consider Case II that σ_i is negative.

Case II.1: $\mathbb{H}_p(K_{i+1}) = \mathbb{H}_p(K_i)$. Since σ_i is negative, $Z_p(K_{i+1}) = Z_p(K_i)$ and $B_p(K_{i+1}) = B_p(K_i)$. The verification for this case is then the same as the verification for Case I.2 with a shift on the homology degree.

Case II.2: $\mathbb{H}_{p-1}(K_{i+1}) \subseteq \mathbb{H}_{p-1}(K_i)$. Take $z \in \mathbb{H}_{p-1}(K_{i+1})$. We have $Z_{p-1}(K_{i+1}) = Z_{p-1}(K_i)$. Therefore, $z \in Z_{p-1}(K_i)$ and we consider z as a cochain in K_i. For any $c \in C_p(K_i)$, $\delta(z)(c) = z(\partial c) = 0$, with the last equality due to $\partial c \in B_{p-1}(K_i) \subseteq B_{p-1}(K_{i+1})$. Therefore, $\mathbb{H}_{p-1}(K_{i+1}) \subseteq \mathbb{H}_{p-1}(K_i)$. ◀

▶ **Definition 8** (Harmonic chain barcode). *Consider the following* harmonic zigzag module

$$\mathbb{H}(F) : \mathbb{H}(K_0) \leftrightarrow \mathbb{H}(K_1) \leftrightarrow \cdots \leftrightarrow \mathbb{H}(K_m), \tag{4}$$

where the harmonic chain groups are connected by either forward inclusions (e.g., $\mathbb{H}(K_i) \to \mathbb{H}(K_{i+1})$) or backward inclusions (e.g., $\mathbb{H}(K_i) \leftarrow \mathbb{H}(K_{i+1})$); see Theorem 7. Define the harmonic chain barcode $\mathsf{B}^{\mathbb{H}}(F)$ *of F as the barcode of the zigzag module $\mathbb{H}(F)$, that is,*

$$\mathsf{B}^{\mathbb{H}}(F) := \mathsf{B}(\mathbb{H}(F)).$$

In general, the harmonic chain barcode is different from the ordinary persistence barcode for a filtration; see Fig. 2. In this paper, we also consider the zigzag module $\mathbb{H}_p(F)$ derived by taking $\mathbb{H}_p(K_i)$ on each K_i in F. While the p-th harmonic chain groups in $\mathbb{H}_p(F)$ are still connected by forward or backward inclusions, we may have $\mathbb{H}_p(K_i) = \mathbb{H}_p(K_{i+1})$ for two consecutive groups in $\mathbb{H}_p(F)$. We therefore define the *p-th harmonic chain barcode* $\mathsf{B}^{\mathbb{H}}_p(F)$ of F as the barcode of $\mathbb{H}_p(F)$, i.e., $\mathsf{B}^{\mathbb{H}}_p(F) := \mathsf{B}(\mathbb{H}_p(F))$. Since $\mathbb{H}(F) = \bigoplus_p \mathbb{H}_p(F)$ (following from Theorem 7), we have $\mathsf{B}^{\mathbb{H}}(F) = \bigsqcup_p \mathsf{B}^{\mathbb{H}}_p(F)$.

Harmonic representatives. In the rest of the section, we define harmonic representatives.

▶ **Proposition 9.** *Let $[b,d]$ be an interval in $\mathsf{B}^{\mathbb{H}}(F)$. The inclusion $\mathbb{H}(K_{b-1}) \hookrightarrow \mathbb{H}(K_b)$ in $\mathbb{H}(F)$ is forward. Moreover, if $d < m$, then the inclusion $\mathbb{H}(K_d) \hookleftarrow \mathbb{H}(K_{d+1})$ is backward.*

Proof. This follows from Theorem 7 and the fact that $\dim(\mathbb{H}(K_b)) = \dim(\mathbb{H}(K_{b-1})) + 1$ and $\dim(\mathbb{H}(K_{d+1})) = \dim(\mathbb{H}(K_d)) - 1$. ◀

Representatives for general zigzag modules were introduced in [4, 46] (see also [26]), which consist of a sequence of cycles for each interval. However, since the harmonic chain groups are connected by inclusion maps in $\mathbb{H}(F)$, we have:

▶ **Proposition 10.** *Each representative for an interval in $\mathsf{B}^{\mathbb{H}}(F)$ contains a single harmonic cycle.*

We then adapt the definition of representatives for general zigzag modules [26, 46] and define harmonic representatives as follows:

▶ **Definition 11** (Harmonic representative)**.** *A* harmonic p-representative (*or simply* p-representative) *for an interval $[b,d] \in \mathsf{B}_p^{\mathbb{H}}(F)$ is a p-cycle $z \in \mathbb{H}_p(K_i)$ for $i \in [b,d]$ satisfying:*
Birth condition: *z is born in $\mathbb{H}_p(K_b)$, i.e., $z \in \mathbb{H}_p(K_b) \setminus \mathbb{H}_p(K_{b-1})$ (notice that $b > 0$);*
Death condition: *z dies leaving $\mathbb{H}_p(K_d)$, i.e., $z \in \mathbb{H}_p(K_d) \setminus \mathbb{H}_p(K_{d+1})$ if $d < m$.*

Sometimes we relax the restriction of $[b,d] \in \mathsf{B}_p^{\mathbb{H}}(F)$ and have a harmonic representative for an arbitrary integer interval $[b,d] \subseteq [0,m]$. For details of the original definition of zigzag representatives and justification of Proposition 10 and Definition 11, see the full version of the paper.

5 A cubic-time algorithm for computing harmonic chain barcode

In this section, we propose an $O(m^3)$ algorithm for computing the harmonic chain barcode and its harmonic representatives given a filtration containing m insertions. We first overview the algorithm and then describe the implementation. Although there have been algorithms [9, 22, 26, 46] for computing zigzag barcodes in the general case, these algorithms target zigzag modules induced from directly taking the homology functor on zigzag filtrations. Our algorithm targets the special type of zigzag module $\mathbb{H}(F)$, where harmonic chain groups are derived from an ordinary non-zigzag filtration and are connected by inclusions (on the chain level).

For simplicity, when describing the algorithm, complexes in a filtration are always indexed by integers instead of the real-valued timestamps (see Sec. 3.2). Again, we assume that the input is a simplex-wise filtration $F : \emptyset = K_0 \xhookrightarrow{\sigma_0} K_1 \xhookrightarrow{\sigma_1} \cdots \xhookrightarrow{\sigma_{m-1}} K_m = K$, where each K_{i+1} differs from K_i by the addition of a simplex σ_i.

Algorithm 1 provides an overview: our algorithm computes the harmonic chain barcode by iteratively maintaining the harmonic representatives. It processes the insertions in F one by one and finds *pairings* of the *birth indices* (starting points of the intervals) and *death indices* (ending points of the intervals) to form intervals in $\mathsf{B}^{\mathbb{H}}(F)$. When we encounter a new birth index, it is initially *unpaired*; when we encounter a new death index, an unpaired birth index is chosen to pair with the death index.

The following definition helps present the algorithm.

▶ **Definition 12.** *For an interval $[b,i] \subseteq [0,m]$, a* partial p-representative *for $[b,i]$ is a p-representative as in Definition 11 by ignoring the death condition.*

Algorithm 1 Computing the harmonic chain barcode.

Let U^p be the set of unpaired birth indices for each homology degree p, where $U^p = \emptyset$ initially. Before each iteration that processes the insertion $K_i \xhookrightarrow{\sigma_i} K_{i+1}$, we maintain a p-cycle z for each $b \in U^p$ that is a partial representative for the interval $[b, i]$. We use partial representatives to determine a finalized representative when a birth index is paired with a death index (by making sure the death condition is satisfied).

When processing the insertion of a p-simplex σ_i via $K_i \xhookrightarrow{\sigma_i} K_{i+1}$, we proceed as follows:

If σ_i is positive:

- Since $\dim(\mathbb{H}_p(K_{i+1})) = \dim(\mathbb{H}_p(K_i)) + 1$ (by Theorem 7), we add a new birth index $i+1$ to U^p.
- Find a harmonic p-cycle $z \in \mathbb{H}_p(K_{i+1}) \setminus \mathbb{H}_p(K_i)$, and let z be the partial representative for $i+1 \in U^p$.

If σ_i is negative:

- Since $\dim(\mathbb{H}_{p-1}(K_{i+1})) = \dim(\mathbb{H}_{p-1}(K_i)) - 1$, we have a new death index i.
- Let $U^{p-1} = \{b_j \mid j = 1, \dots, k\}$, where each b_j has a partial $(p-1)$-representative z_j.
- Let $U' = \{b_j \in U^{p-1} \mid z_j \notin \mathbb{H}_{p-1}(K_{i+1})\}$, i.e., U' contains all birth indices in U^{p-1} whose partial representatives do not persist to K_{i+1}.
- Pair the *smallest* (i.e., the "oldest") index $b_{j^*} \in U'$ with i which forms a new interval $[b_{j^*}, i] \in \mathsf{B}^{\mathbb{H}}_{p-1}(F)$. Assign z_{j^*} as the representative for $[b_{j^*}, i] \in \mathsf{B}^{\mathbb{H}}_{p-1}(F)$ and remove i from U^{p-1}.
- Consider each $b_j \in U' \setminus \{b_{j^*}\}$. We have that $z_j \notin \mathbb{H}_{p-1}(K_{i+1})$ because $\delta(z_j)$ becomes non-zero in K_{i+1} (∂z_j is always zero after being born). Also, the only reason that $\delta(z_j) \neq 0$ in K_{i+1} is because $\alpha_j := \delta(z_j)(\sigma_i) = z_j(\partial\sigma_i) \neq 0$. Let $\alpha_* = z_{j^*}(\partial\sigma_i)$. Update the partial representative for b_j as $z_j := z_j - (\alpha_j/\alpha_*) \cdot z_{j^*}$ so that z_j now persists to $\mathbb{H}_{p-1}(K_{i+1})$.

After processing all the insertions, for each b in each U^p with a partial representative z, let $[b, m]$ form an interval in $\mathbb{H}_p(F)$ with a representative z.

▶ **Example.** Fig. 1 provides an example of how Algorithm 1 computes harmonic chain barcode $\mathbb{H}_1(F)$ and representatives for a filtration F, with the resulting barcode in Fig. 2. For simplicity, K_0, K_1, K_2 are omitted and vertex insertions are ignored. In K_4, K_5, and K_7, new 1-cycles are born that are also harmonic cycles due to a lack of triangles. The partial representatives z_4, z_5, z_7 for the indices $U^1 = \{4, 5, 7\}$ all persist till K_7. When the triangle abe is inserted in K_8 (producing a death index 7), $\delta(z_4)(abe) = 1$, $\delta(z_5)(abe) = 1$, and $\delta(z_7)(abe) = 3$. We pair $4 \in U^1$ with 7 and have $[4, 7] \in \mathbb{H}_1(F)$ with a representative z_4. We also let $z_5 := z_5 - z_4$ and $z_7 := z_7 - 3z_4$, which now both persist to $\mathbb{H}_1(K_8)$. The remaining steps are similar. Notice that when abe is inserted, the "alive" bar represented by the boundary of abe (i.e., $ab + be - ae$) is not killed. This is a significant difference from ordinary persistence (which will kill the alive bar represented by $\partial(abe)$ when abe is inserted).

▶ Remark 13. Algorithm 1 chooses the "oldest" birth, among the options, to pair with a death while the ordinary persistence chooses the "youngest" one [29]. A brief explanation is that a summation of representatives *persists* to the next harmonic chain group in $\mathbb{H}(F)$, whereas a summation of representatives in the ordinary persistence *becomes trivial* in the next homology group (and cannot persist). We refer to [26, 46] for a formal definition of the different types of birth/death ends and how they impact the computation of persistence.

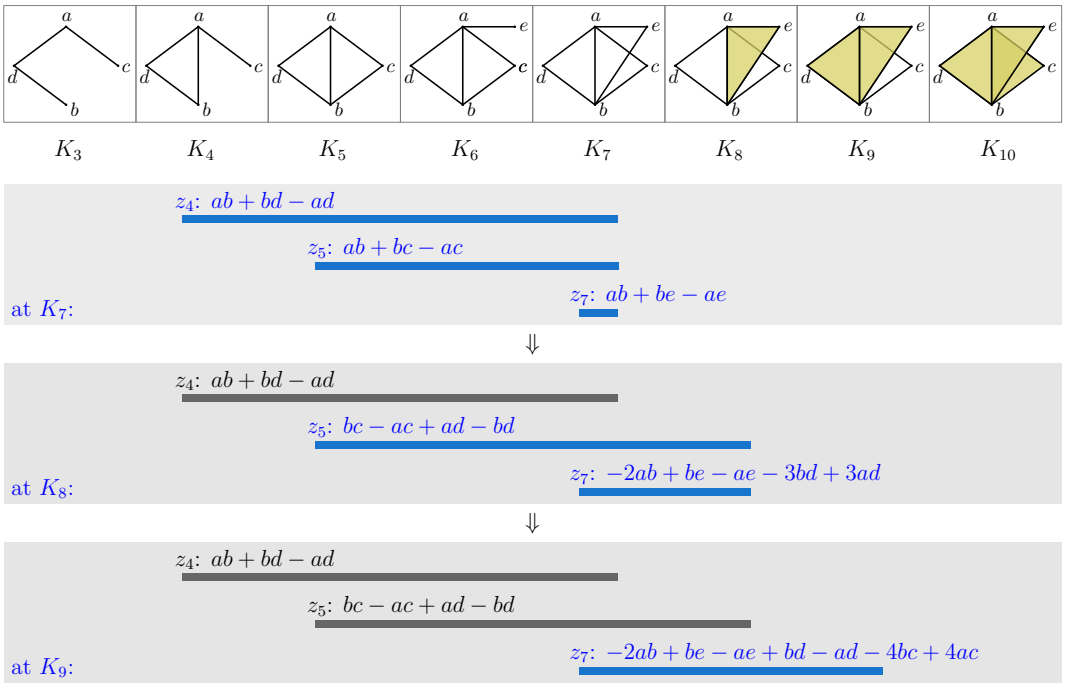

Figure 1 An example of the computation of harmonic chain barcode $\mathbb{H}_1(F)$ and representatives.

(a) Harmonic chain barcode (b) Ordinary persistence barcode

Figure 2 Harmonic chain barcode and ordinary persistence barcode for the filtration in Fig. 1. Deviating from conventions in ordinary persistence, bars are drawn as closed integer intervals, e.g., $[7, 7]$ in the ordinary barcode is killed by the addition of abe in K_8.

The following (rephrased) proposition from [24] helps prove the correctness of Algorithm 1:

▶ **Proposition 14** (Proposition 9, [24]). *If a pairing π of the birth and death indices in $\mathbb{H}(F)$ satisfies that each interval from π has a harmonic representative, then π induces the harmonic chain barcode $\mathsf{B}^{\mathbb{H}}(F)$.*

▶ **Theorem 15.** *Algorithm 1 correctly computes the harmonic chain barcode for filtration F.*

Proof. We first show by induction that before Algorithm 1 processes each σ_i, the p-cycle z maintained for any $b \in U^p$ is a partial p-representative for $[b, i]$. Suppose that the claim is true before processing σ_i. If σ_i is positive, index $i + 1$ is added to U^p and we assign $z \in \mathbb{H}_p(K_{i+1}) \setminus \mathbb{H}_p(K_i)$ to $i + 1$, which is clearly a partial representative for $[i + 1, i + 1]$. For an index b previously in U^p having a partial representative z, since $\mathbb{H}_p(K_i) \subseteq \mathbb{H}_p(K_{i+1})$ (Theorem 7), we have that z is still a partial representative for the interval $[b, i + 1]$.

In the case that σ_i is negative, whenever we update a representative z_j as $z_j - (\alpha_j/\alpha_*) \cdot z_{j^*}$, we have that $b_{j^*} < b_j$ and hence the updated z_j remains born in $\mathbb{H}_{p-1}(K_{b_j})$. Therefore, the new z_j is still a partial representative for $[b, i]$, which is also a partial representative for $[b, i + 1]$ because now $z_j \in \mathbb{H}_{p-1}(K_{i+1})$.

By Proposition 14, we only need to show that each interval output by the algorithm admits a harmonic representative. This follows from the algorithm. For example, whenever we output an interval $[b_{j^*}, i] \in \mathsf{B}^{\mathbb{H}}_{p-1}(F)$ when σ_i is negative, we have $z_{j^*} \notin \mathsf{B}^{\mathbb{H}}_{p-1}(K_{i+1})$, which ensures the death condition. ◀

Implementation. Due to space limitations, we only briefly describe the gist of the implementation; refer to the full version of the paper for details and missing proofs. The only step in Algorithm 1 that cannot be easily implemented is finding a new harmonic cycle born in $\mathbb{H}_p(K_{i+1})$ when σ_i is positive. In this case, the dimension of the harmonic chain group increases and we need to find a single harmonic cycle independent of the previous harmonic group. We can do this naively by computing a basis for the kernel of δ in K_{i+1}, and check all cocycles in the basis to see if they are independent of the existing set of harmonic representatives maintained for K_i. This, however, requires at least $\Theta(m^3)$ per simplex insertion.

For a more efficient implementation, before iteration i that processes the insertion $K_i \xhookrightarrow{\sigma_i} K_{i+1}$, we maintain the following matrices for each homology degree p:

1. $\mathtt{H}^p$: Columns in $\mathtt{H}^p$ are partial p-representatives for all indices in U^p.
2. $\mathtt{R}^p$: Columns in $\mathtt{R}^p$ form a boundary basis with distinct pivots for $B_p(K_i)$.
3. $\mathtt{Cob}^p$: Columns in $\mathtt{Cob}^p$ form a coboundary basis for $B^p(K_i)$.
4. $\mathtt{SC}^p$: Columns in $\mathtt{SC}^p$ encode "p-pseudo-cochains" (see full version for definition) in K_i based on the basis provided in $\mathtt{R}^p$, whose coboundaries are columns in $\mathtt{Cob}^{p+1}$.
5. $\mathtt{BoC}^p$: Columns in $\mathtt{BoC}^p$ are boundaries of the coboundaries in $\mathtt{Cob}^{p+1}$, with distinct pivots.

In summary, columns in $\mathtt{SC}^{p-1}$, $\mathtt{Cob}^p$, and $\mathtt{BoC}^{p-1}$ have one-to-one correspondence as follows:

$$\mathtt{SC}^{p-1}[j] \overset{\delta}{\longmapsto} \mathtt{Cob}^p[j] \overset{\partial}{\longmapsto} \mathtt{BoC}^{p-1}[j].$$

Assuming σ_i is a p-simplex, the rationale for maintaining the matrices is as follows:

- We use $\mathtt{BoC}^{p-1}$ to find a linear combination ϕ of $\hat{\sigma}_i$ and cocycles in $\mathtt{Cob}^p$ such that $\partial\phi = 0$ (see Algorithm 2). The cocycle ϕ is then a new harmonic p-cycle when σ_i is positive (see Proposition 16).
- $\mathtt{SC}^{p-1}$ helps maintain the coboundary basis in $\mathtt{Cob}^p$.
- $\mathtt{R}^{p-1}$ provides the boundary basis on which pseudo-cochains in $\mathtt{SC}^{p-1}$ can be defined (again, refer to the full version for details of pseudo-cochains).

Algorithm 2 Reduction based on $\mathtt{BoC}^{p-1}, \mathtt{Cob}^p$ for finding a new-born harmonic cycle.

```
φ ← σ̂_i
ζ ← ∂(σ̂_i)
while ζ ≠ 0 and ∃j s.t. pivot(BoC^{p-1}[j]) = pivot(ζ) do
    k ← pivot(ζ)
    α1 ← ζ[k]
    α2 ← BoC^{p-1}[j][k]
    ζ ← ζ − (α1/α2) · BoC^{p-1}[j]
    φ ← φ − (α1/α2) · Cob^p[j]
```

▶ **Proposition 16.** *If Algorithm 2 ends with $\zeta = 0$, then σ_i is positive and ϕ is a new harmonic p-cycle born in $\mathbb{H}_p(K_{i+1})$; otherwise, σ_i is negative.*

Besides finding a new harmonic cycle when σ_i is positive, our algorithm also needs to do the following: (1) update $\texttt{Cob}^p$ (and also $\texttt{BoC}^{p-1}$) because columns of $\texttt{Cob}^p$ may not be coboundaries anymore as we proceed; (2) update $\texttt{BoC}^{p-1}$ (and also $\texttt{SC}^{p-1}$, $\texttt{Cob}^p$) to make pivots in $\texttt{BoC}^{p-1}$ distinct again; (3) add a new coboundary to $\texttt{Cob}^p$ (and new columns to $\texttt{SC}^{p-1}$, $\texttt{BoC}^{p-1}$) to form a coboundary basis for $B_p(K_{i+1})$ when σ_i is negative. See the full version for details. We conclude the following:

▶ **Theorem 17.** *The harmonic chain barcode of F can be computed in $O(m^3)$ time.*

6 Sublevel set harmonic chain barcode and its stability

In this section, we briefly introduce the notion of *sublevel set harmonic chain barcodes* and present our stability results based on this notion; for details and proofs, refer to the full version of the paper. Our stability proof makes use of the work on the algebraic stability of block decomposable $\mathbb{R}^2$-modules [1, 6]. In brief, we "lift" the 1-parameter harmonic zigzag module to an $\mathbb{R}^2$-indexed 2-parameter persistence module which is block decomposable. We then show that in the typical setting of sublevel set filtrations, there exists an interleaving between the lifted modules. Our main work here is to construct a concrete extension to $\mathbb{R}^2$-modules and an interleaving between the extensions realizing the category-theoretic concepts employed in [1, 6]. From the Isometry Theorem [3, 6], we then deduce the stability of the sublevel set harmonic chain barcode. We also address the disparity between the natural harmonic chain barcode of a sublevel set filtration (which consists of closed-open intervals[1]) and common conventions of zigzag persistence (which work with closed-closed intervals in our setting).

We assume, up until now, that a filtration is simplex-wise. This assumption is not true for a sublevel set filtration, but we shall construct a simplex-wise filtration from a general filtration.

Let $\tilde{F}$ be an increasing filtration of K that is not necessarily simplex-wise, i.e., two consecutive complexes in $\tilde{F}$ can differ by more than one simplex. We fix an ordering, once and for all, for vertices of K, which also fixes an ordering for all simplices in K (using, say, the lexicographic ordering of the ordered sequence of vertices in a simplex). Given $\delta > 0$ small enough, we expand $\tilde{F}$ into a simplex-wise filtration $\tilde{F}(\delta)$ by expanding each inclusion $K_{t_{i-1}} \hookrightarrow K_{t_i}$ in $\tilde{F}$ starting with $i = 1$. To differentiate, denote each complex in $\tilde{F}(\delta)$ as K'_t where $t \in \mathbb{R}$ is a timestamp. In each iteration, we expand the inclusion $K_{t_{i-1}} \hookrightarrow K_{t_i}$ in $\tilde{F}$ into several simplex-wise inclusions in $\tilde{F}(\delta)$:

$$K_{t_{i-1}} = K'_s \hookrightarrow K'_{t_i-\delta} \hookrightarrow K'_{t_i} \hookrightarrow K'_{t_i+\delta} \hookrightarrow \cdots \hookrightarrow K'_{t_i+(k-1)\delta} = K_{t_i}.$$

In the above, $K'_{t_i-\delta}$ is a "dummy" complex equal to K'_s (so $K'_s \hookrightarrow K'_{t_i-\delta}$ is an identity map) and k is the number of simplices added from $K_{t_{i-1}}$ to K_{t_i} in $\tilde{F}$. We also have that the k number of simplices are added based on their simplex ordering described above.

To see the rationale of introducing $\tilde{F}(\delta)$, we first define the following:

▶ **Definition 18.** *Let $\tilde{F}$ be an increasing filtration of complex K that is not necessarily simplex-wise and let $z \in Z_p(K)$ be a p-cycle. Let $t_{b(z)}$ be the time when z is born, i.e., $z \in Z_p(K_{t_{b(z)}}) \setminus Z_p(K_{t_{b(z)-1}})$, and $t_{d(z)}$ be the time when z dies as a harmonic chain, i.e.,*

[1] The closed-open intervals over the real values we have here are different from the closed-open intervals of [1, 6] over the integers. Indeed, when considering only integer indices, we only have closed-closed intervals in our setting. The extension of our closed-open interval would be similar to a closed block of [6] but with the right vertical side open.

$\delta(z) \neq 0$ in $K_{t_{d(z)}}$, but $\delta(z) = 0$ in K_t for $t_{b(z)} \leq t < t_{d(z)}$. Define the span *of z as $span(z) := [t_{b(z)}, t_{d(z)})$. If z is not harmonic at birth, its span is the empty set (notice that a cycle continues to be non-harmonic once it becomes so). Moreover, define the* bar *of z as $bar(z) := [t_{b(z)}, t_{d(z)-1}]$.*

Based on the construction, we observe a relation between the bar of z in $\tilde{F}(\delta)$ and the span of z in $\tilde{F}$ for a cycle z. Moreover, adding the dummy complexes makes sure that the closed bars of the simplex-wise filtration $\tilde{F}(\delta)$ "induce" the closed-open time intervals in $\tilde{F}$ in which a cycle is harmonic (see full version for details). In particular, for any small δ, we obtain an obvious mapping $\Gamma : \tilde{F}(\delta) \to \tilde{F}$. We then have the following Definition 19.

▶ **Definition 19.** *Let F be a simplex-wise filtration (as in Sec. 3.2) and let $\breve{\mathsf{B}}^{\mathbb{H}}(F)$ be the* closed-open barcode of $\mathbb{H}(F)$*, i.e., $[t_b, t_d) \in \breve{\mathsf{B}}^{\mathbb{H}}(F)$ iff $[t_b, t_{d-1}] \in \mathsf{B}^{\mathbb{H}}(F)$. Moreover, let $\tilde{F}$ and $\tilde{F}(\delta)$ be as defined in this section. We define the* harmonic chain barcode of $\tilde{F}$ *as the set $\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F}) := \Gamma(\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F}(\delta)))$ for δ small enough.*

▶ Remark 20. Note that $\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F})$ is the limit of $\mathsf{B}^{\mathbb{H}}(\tilde{F}(\delta))$ as δ approaches 0.

We now state our stability result for sublevel set filtrations. See the full version for the proof of this theorem (and additional observations).

▶ **Theorem 21.** *Let $\hat{f}, \hat{g} : |K| \to \mathbb{R}$ be simplex-wise linear functions, and let $\tilde{F}$ and $\tilde{G}$ be the sublevel set filtrations of $\hat{f}$ and $\hat{g}$ respectively. Then,*

$$d_B(\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F}), \breve{\mathsf{B}}^{\mathbb{H}}(\tilde{G})) \leq ||\hat{f} - \hat{g}||_\infty.$$

Inducing the barcode $\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F})$ from $\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F}(\delta))$ allows us to use the off-the-shelf results of [6] for proving stability and does not affect the computation of $\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F})$. In particular, we have the following.

▶ **Theorem 22.** *Given a sublevel-set filtration $\tilde{F}$ of the complex K with m simplices, the harmonic chain barcode $\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F})$ can be computed in $O(m^3)$ time.*

Proof. The computation of $\breve{\mathsf{B}}^{\mathbb{H}}(\tilde{F})$ is equivalent to the computation of $\mathsf{B}^{\mathbb{H}}(\tilde{F}(\delta))$ for a single δ small enough, using the algorithm in Sec. 5 and mapping the resulting bars using Γ to the filtration $\tilde{F}$. This simply amounts to changing timestamps of the form $t_i \pm \ell\delta$ into t_i. ◀

Incremental Planar Nearest Neighbor Queries with Optimal Query Time

John Iacono
Université libre de Bruxelles, Belgium

Yakov Nekrich
Michigan Technological University, Houghton, MI, USA

Abstract

In this paper we show that two-dimensional nearest neighbor queries can be answered in optimal $O(\log n)$ time while supporting insertions in $O(\log^{1+\varepsilon} n)$ time. No previous data structure was known that supports $O(\log n)$-time queries and polylog-time insertions. In order to achieve logarithmic queries our data structure uses a new technique related to fractional cascading that leverages the inherent geometry of this problem. Our method can be also used in other semi-dynamic scenarios.

1 Introduction

In the nearest neighbor problem a set of points S is stored in a data structure so that for a query point q the point $p \in S$ that is closest to q can be found efficiently. The nearest neighbor problem and its variants are among the most fundamental and extensively studied problems in computational geometry; we refer to [19] for a survey. In this paper we study dynamic data structures for the Euclidean nearest neighbor problem in two dimensions. We show that the optimal $O(\log n)$ query time for this problem can be achieved while allowing insertions in time $O(\log^{1+\epsilon} n)$.

Previous Work

See Table 1. In the static scenario the planar nearest neighbor problem can be solved in $O(\log n)$ time by point location in Voronoi diagrams. However the dynamic variant of this problem is significantly harder because Voronoi diagrams cannot be dynamized efficiently: it was shown by Allen et al. [2] that a sequence of insertions can lead to $\Omega(\sqrt{n})$ amortized combinatorial changes per insertion in the Voronoi diagram. A static nearest-neighbor data structure can be easily transformed into an insertion-only data structure using the logarithmic method of Bentley and Saxe [3] at the cost of increasing the query time to $O(\log^2 n)$. Several researchers [9, 11, 20] studied the dynamic nearest neighbor problem in the situation when the sequence of updates is random in some sense (e.g. the deletion of any element in the data structure is equally likely). However their results cannot be extended to the case when the complexity of a specific sequence of updates must be analyzed.

Using a lifting transformation [10], 2-d nearest neighbor queries can be reduced to extreme point queries on a 3-d convex hulls. Hence data structures for the dynamic convex hull in 3-d can be used to answer 2-d nearest neighbor queries. The first such data structure (without

assumptions about the update sequence) was presented by Agarwal and Matoušek [1]. Their data structure supports queries in $O(\log n)$ time and updates in $O(n^\varepsilon)$ time; another variant of their data structure supports queries in $O(n^\varepsilon)$ time and updates in $O(\log n)$ time. A major improvement was achieved in a seminal paper by Chan [4] where he presented a structure that supports queries in $O(\log^2 n)$ time, insertions in $O(\log^3 n)$ expected time and deletions in $O(\log^6 n)$ expected time. The update procedure can be made deterministic using the result of Chan and Tsakalidis [6]. The deletion time was further reduced to $O(\log^5 n)$ [16] and to $O(\log^4 n)$ [5]. This sequence of papers makes use of shallow cuttings, a general powerful technique, but, alas, all uses of it for the point location problem in 2-d have resulted in $O(\log^2 n)$ query times.

Even in the case of insertion-only scenario, the direct application of the 45-year-old classic technique of Bentley and Saxe [3] remains the best insertion-only method with polylogarithmic update before this work; no data structure with $o(\log^2 n)$ query time and polylogarithmic update time was described previously.

Our Results

We demonstrate that optimal $O(\log n)$ query time and poly-logarithmic update time can be achieved in some dynamic settings. The following scenarios are considered in this paper:

1. We describe a *semi-dynamic insertion-only* data structure that uses $O(n)$ space, supports insertions in $O(\log^{1+\varepsilon} n)$ amortized time and answers queries in $O(\log n)$ time.
2. In the *semi-online* scenario, introduced by Dobkin and Suri [12], we know the deletion time of a point p when a point p is inserted, i.e., we know how long a point will remain in a data structure at its insertion time. We describe a semi-online fully-dynamic data structure that answers queries in $O(\log n)$ time and supports updates in $O(\log^{1+\varepsilon} n)$ amortized time. The same result is also valid in the *offline* scenario when the entire sequence of updates is known in advance.
3. In the *offline partially persistent scenario*, the sequence of updates is known and every update creates a new version of the data structure. Queries can be asked to any version of the data structure. We describe an offline partially persistent data structure that uses $O(n \log^{1+\varepsilon} n)$ space, can be constructed in $O(n \log^{1+\varepsilon} n)$ time and answers queries in $O(\log n)$ time.

All three problems considered in this paper can be reduced to answering point location queries in (static) Voronoi diagrams of $O(\log n)$ different point sets. For example, we can obtain an insertion-only data structure by using the logarithmic method of Bentley and Saxe [3], which we now briefly describe. The input set S is partitioned into a logarithmic number of subsets $S_1, \ldots, S_f$ of exponentially increasing sizes. In order to find the nearest neighbor of some query point q we locate q in the Voronoi diagram of each set S_i and report the point closest to q among these nearest neighbors. Since each point location query takes $O(\log n)$ time, answering a logarithmic number of queries takes $O(\log^2 n)$ time.

The fractional cascading technique [7] applied to this problem in one dimension decreases the query cost to logarithmic by sampling elements of each S_i and storing copies of the sampled elements in other sets S_j, $j < i$. Unfortunately, it was shown by Chazelle and Liu [8] that fractional cascading does not work well for two-dimensional non-orthogonal problems, such as point location: in order to answer $O(\log n)$ point location queries in $O(\log n)$ time, we would need $\tilde{\Omega}(n^2)$ space, even in the static scenario.

To summarize, the two obvious approaches to the insertion-only problem are to maintain a single search structure and update it with each insertion, the second is to maintain a collection of static Voronoi diagrams of exponentially-increasing size and to execute nearest neighbor queries by finding the closest point in all structures, perhaps aided by some kind of fractional cascading. The first approach cannot obtain polylogarithmic insertion time due to the lower bound on the complexity change in Voronoi diagrams caused by insertions [2], and the second approach cannot obtain $O(\log n)$ search time due to Chazelle and Liu's lower bound [8]. Our main intellectual contribution is showing that the lower bound of Chazelle and Liu [8] can be circumvented for the case of point location in Voronoi diagrams. Specifically, a strict fractional cascading approach requires finding the closest point to a query point in each of the subsets S_i; we loosen this requirement: in each S_i, we either find the closest point or provide a certificate that the closest point in S_i is not the closest point in S. This new, powerful and more flexible form of fractional cascading is done by using a number of novel observations about the geometry of the problem. We imagine our general technique may be applicable to speeding up search in other dynamic search problems. Our method employs planar separators to sample point sets and uses properties of Voronoi diagrams to speed up queries. We explain our method and show how it can be applied to the insertion-only nearest neighbor problem in Section 2.

A further modification of our method, that is described in the full version of this paper [15], improves the insertion time and the insertion time to $O(\log^{1+\varepsilon} n)$ and space usage to $O(n)$. The description of partially persistent and semi-online variants is also in the full version.

2 Basic Insertion-Only Structure

We present our basic insertion only structure in several parts. In the first part, the overview (§2.1), we present the structure where one needed function, jump, is presented as a black box. With the jump function abstracted, our structure is a combination of known techniques, notably the logarithmic method of Bentley and Saxe [3] and sampling. In §2.2 we present the implementation of the jump function and the needed geometric preliminaries. In contrast to combination of standard techniques presented in the overview which require little use of geometry, our implementation of the jump function is novel and requires thorough geometric arguments. We then fully describe the underlying data structures needed in §2.3. Note that all arguments presented here are done with the goal of obtaining $O(\log n)$ queries and polylogarithmic insertion. We opt here for clarity of presentation versus reducing the number of logarithmic factors in the insertion, as the arguments are already complex.

2.1 Overview

We let S denote the set of points currently stored in the structure, and use n to denote $|S|$. In this section we set a constant d to 2. Even though for this section d is fixed, we will express everything as a function of d.

Let $\mathcal{S} = \{S_1, S_2, \dots S_f\}$ denote a partition of S into sets of exponentially-increasing size where $f \coloneqq |\mathcal{S}| = \Theta(\log_d n)$ and $|S_i| = \Theta(d^i)$. Note that the partition of $\mathcal{S}$ into S_i is not unique. Let $NN(P, q)$ be the nearest neighbor of q in a point set P, which we assume to be unique. Given a point q, the computation of $NN(S, q)$ is the query that our data structure will support.

We now define a sequence of point sets $T_1, \dots T_f$. The intuition is that, as in classical fractional cascading [7], the set T_i contains all elements of S_i and a sample of elements from the sets T_j where $j > i$; this implies the last sets are equal: $T_f = S_f$. This sampling will be provided by the function $Sample_j(k)$ which returns a subset of T_j of size $O(|T_j|/d^{2k})$; while it will have other important properties, for now only the size matters.

We now can formally define T_i: $T_i \coloneqq S_i \cup \bigcup_{j=i+1}^{f} Sample_j(j-i)$. From this definition we have several observations which we group into a lemma, the proof can be found in the full version of this paper:

▶ **Lemma 1. Facts about T_i**

1. $T_f = S_f$
2. *T_i is a function of the S_j, for $j \geq i$.*
3. $S = \cup_{i=1}^{f} T_i$
4. $NN(S, q) \in \bigcup_{i=1}^{f} \{NN(T_i, q)\}$
5. $|T_i| = \Theta(d^i)$
6. *For any i* $\sum_{j=i+1}^{f} |Sample_j(j-i)| = \Theta(|T_i|)$

A note on notation

We assume the partition of S into the sets $\mathcal{S} = \{S_1, S_2, \dots, S_f\}$. Any further notation that includes a subscript, such as T_i, is a function of the S_j, for $j \geq i$. This compact notation makes explicit the dependence of $anything_i$ only on S_j, for $j \geq i$. This dependence in one direction only (i.e., on non-smaller indexes only) is crucial to the straightforward application of the standard Bentley and Saxe [3] rebuilding technique in the implementation of the data structure and the insertion operation described in section §2.3-2.4.

Voronoi and Delaunay

Let $Vor(P)$ be the Voronoi diagram of point set P, let $Cell(P, p)$ be the cell of a point p in $Vor(P)$, that is the locus of points in the plane whose closest element in P is p. Thus $q \in Cell(P, p)$ is equivalent to $NN(P, q) = p$. Let $|Cell(P, p)|$ be the complexity of the cell, that is, the number of edges on its boundary. Let $G(P)$ refer to the Delaunay graph of P, the dual graph of the Voronoi diagram of P; the degree of p in $G(P)$ is thus $|Cell(P, p)|$ and each point in P corresponds to a unique vertex in $G(P)$. Delaunay graphs are planar. To simplify the description, we will not distinguish between points in a planar set P and vertices of $G(P)$. For example, we will sometimes say that a point p has degree x or say that a point p' is a neighbor of p. We will find it useful to have a compact notation for expressing the union of Voronoi cells; thus for a set of points $P' \subseteq P$, let $Cells(P, P')$ denote $\bigcup_{p \in P'} Cell(P, p)$.

Pieces and Fringes

Given a graph, $G = (V, E)$, and a set of vertices $V' \subseteq V$, the *fringe* of V' (with respect to G) is the subset of V' incident to edges whose other endpoint is in $V \setminus V'$. Let $G = (V, E)$ be a planar graph. For any ρ, Frederickson [13] showed the vertices of G can be decomposed[1] into $\Theta(|V|/\rho)$ *pieces*, so that: (i) Each vertex is in at least one piece. (ii) Each piece has at most ρ vertices in total and only $O(\sqrt{\rho})$ vertices on its fringe. (iii) If a vertex is a non-fringe vertex of a piece (with respect to G), then it is not in any other pieces. (iv) The total size of all pieces is in $\Theta(|V|)$. Intuitively, the pieces are almost a partition of V where those vertices on the fringe of each piece may appear in multiple pieces. Such a decomposition of G can be computed in time $O(|V|)$ [14, 18]. We will apply this decomposition to T_i, which is both a point set and the vertex set of $G(T_i)$, for exponentially increasing sizes of ρ.

Given integers $1 \leq k < j < f$, let

$$Pieces_j(k) \coloneqq \{Piece_j^1(k), Piece_j^2(k), \ldots Piece_j^r(k)\}$$

be a decomposition of T_j into $r = \Theta(|T_j|/d^{4k})$ subsets such that each subset $Piece_j^l(k)$ has size $O(d^{4k})$ and a fringe of size $O(d^{2k})$ with respect to $G(T_i)$. We let

$$Seps_j(k) \coloneqq \{Sep_j^1(k), Sep_j^2(k), \ldots Sep_j^r(k)\}$$

be defined such that $Sep_j^\ell(k)$ denotes the fringe of $Piece_j^\ell(k)$, and let $\overline{Sep}_j^\ell(k)$ be $Piece_j^\ell(k) \setminus Sep_j^\ell(k)$. Thus each $Piece_j^\ell(k)$ is partitioned into its fringe vertices, $Sep_j^\ell(k)$, and its interior non-fringe vertices $\overline{Sep}_j^\ell(k)$; note that $\overline{Sep}_j^\ell(k)$ may be empty if all elements of $Piece_j^\ell(k)$ are on its fringe.

Finally, we define $Sample_j(k)$ to be the union of all the fringe vertices:

$$Sample_j(k) \coloneqq \bigcup_{Sep \in Seps_j(k)} Sep$$

thus $Seps_j(k)$ is a decomposition of $Sample_j(k)$.

For any $k \in [1..j-1]$, the decomposition of T_j into $Pieces_j(k)$, the partition of each $Piece_j^\ell(k)$ into $Sep_j^\ell(k)$ and $\overline{Sep}_j^\ell(k)$, and the set $Seps_j(k)$ can all be computed in time $O(|T_j|)$ using [18] if the Delaunay triangulation is available; if not it can be computed in time $O(|T_j| \log |T_j|)$. Thus computing these for all valid i takes time and space $O(|T_j| \log |T_j| \log_d |T_j|)$ as $k < j = O(\log_d |T_j|)$.

One property of this sampling technique is that points in T_j with Voronoi cells in $Vor(T_j)$ of complexity at least k are included in T_i if $j > i$ and $j - i = O(\log_d k)$. By complexity of a region, we mean the number of edges that bound this region.

▶ **Lemma 2.** *Given $i < j$, if $p \notin T_i$ and $p \in T_j$ then the complexity of $Cell(T_j, p)$ is $O(d^{4(j-i)})$.*

Proof. Suppose that $|Cell(T_j, p)| > cd^{4(j-i)}$, for a constant c chosen later, we will show this implies $p \in T_i$. Thus the degree of p in $G(T_j)$ is greater than $cd^{4(j-i)}$. Consider the piece $Piece_j^\ell(j-i)$ in $Pieces_j(j-i)$ that contains p. This piece has size at most $O(d^{4(j-i)})$, which is at most $cd^{4(j-i)}$ for some c (here we choose c). Thus in $G(T_j)$, p must have neighbors which are not in $Piece_j^\ell(j-i)$. By definition, p is thus in the fringe $Sep_j^\ell(j-i)$, which implies $p \in Sep_j^\ell(j-i)$. From the definition of T_i, $T_i \subset Sep_j^\ell(j-i)$ and which gives $p \in T_i$. ◀

[1] We use the word *decomposed* to mean a division of a set into into a collection of sets, the *decomposition*, whose union is the original set, but, unlike with a partition, elements may belong to multiple sets.

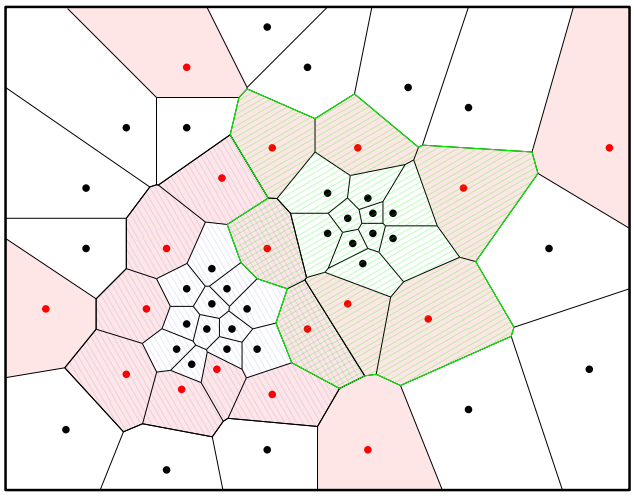

Figure 1 Part of a Voronoi diagram for a point set T_j. Two elements of $Pieces_j(k)$ have been highlighted, one in striped blue, call it $Piece_j^1(k)$, and one in striped green, call it $Piece_j^2(k)$. For each piece, the cells of fringe vertices are shaded red. Thus, the set $Sample_j(k)$ are the red verticies, and the region $Cells(T_j, Sample_j(k))$ is shaded red. The green-and-red shaded region is $Cells(T_j, Sep_j^2(k))$ and the green-but-not-red shaded region is $Cells(T_j, \overline{Sep}_j^2(k))$.

While we cannot bound the complexity of any Voronoi cell in a fringe, we can bound the complexity of $\overline{Sep}_j^\ell(j-i)$, the cells inside a fringe. Intuitively, each piece has the fringe cells on its exterior and non-fringe cells on its interior; imagining the fringe cells of a piece as an annulus gives two boundaries, the exterior boundary of the fringes, which is the boundary between the cells of this and other pieces, and the interior boundary of the fringes, which is the boundary between the fringe cells and the interior cells in this piece. Crucially, while the exterior boundary could have high complexity, the interior boundary does not, which we now formalize:

▶ **Lemma 3.** *The complexity of* $Cells(T_j, \overline{Sep}_j^\ell(j-i))$ *is* $O(d^{4(j-i)})$.

Proof. See Figure 2. Each cell in $Cells(T_j, \overline{Sep}_j^\ell(j-i))$ is adjacent to either other cells in $Cells(T_j, \overline{Sep}_j^\ell(j-i))$ or cells in $Cells(T_j, Sep_j^\ell(j-i))$. The adjacency graph of these Voronoi regions is planar, and as $\overline{Sep}_j^\ell(j-i) \cup Sep_j^\ell(j-i) = Piece_j^\ell(j-i)$, and recalling that $|Piece_j^\ell(j-i)| = O(d^{4(j-i)})$ gives the lemma. ◀

The Jump function: definition

At the core of our nearest neighbor algorithm is the function $Jump$, defined as follows. We will find it helpful to use $NN_R(q)$ for a range $R = [l, r]$ to denote $NN(\cup_{i\in[l,r]} T_i, q)$; for example $NN_{[1,k]}(q)$ is the nearest neighbor of q in $T_1, T_2, \ldots T_k$.

Intuitively, a call to $Jump(i, j, q, p_i, e_i)$ is used when trying to find the nearest neighbor of q, and assuming we know the nearest neighbor of q in $T_1, T_2 \ldots T_{(i+j)/2}$ determines whether there are any points that could be the nearest neighbor of q in $T_{(i+j)/2+1} \ldots T_j$. This

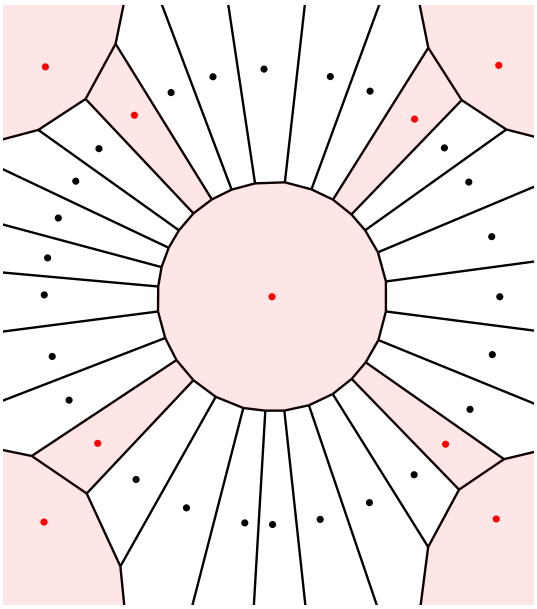

Figure 2 High complexity cells can occur in Voronoi diagrams. Such cells must be included in fringe verticies $Sample_j(k)$, illustrated in red for some point set T_j. This results in the complexity of the boundary of the interior sets $Cells(T_j, \overline{Sep}_j^{\ell}(k))$, the connected components of white Voronoi cells, are of complexity $O(d^{4(j-i)})$ by Lemma 3.

information could be either a simple *no*, or it could provide the nearest neighbor of q for some prefix of these sets. Additionally, the edge of an the Voronoi cell of the currently known nearest neighbor in the direction of the query point is always passed and returned to aide the search using the combinatorial bounds from Lemma 8, point 4.

- **Input to $Jump(i, j, q, p_i, e_i)$**:
  - Integers i and j, where $j - i$ is required to be a power of 2. We use m to refer to $(j + i)/2$, the midpoint.
  - Query point q.
  - Point p_i where $p_i = NN(T_i, q)$.
  - The edge e_i on the boundary of $Cell(T_i, p_i)$ that the ray $\overrightarrow{p_i q}$ intersects.
- **Output**: Either one of two results, *Failure* or a triple $(j', p_{j'}, e_{j'})$
  - If *Failure*, this is a certificate that $NN_{(m,\min(j,f)]}(q) \neq NN_{[1,\min(j,f)]}(q)$
  - If a triple $(j', p_{j'}, e_{j'})$ is returned, it has the following properties:
    - The integer j' is in the range $(m, j]$ and $NN_{(m,j')}(q) \neq NN_{[1,j')}(q)$.
    - The point $p_{j'}$ is $NN(T_{j'}, q)$.
    - The edge $e_{j'}$ is on the boundary of $Cell(T_{j'}, p_j)$ that the ray $\overrightarrow{p_{j'} q}$ intersects.

We will show later that $Jump$ runs in $O(j - i)$ time. Implementation details are deferred to Section 2.2.

The nearest neighbor procedure

A nearest neighbor query can be answered through a series of calls to the $Jump$ function:

- Initialize $i = 1, j = 2$, p_1 to be $NN(T_1, q)$, and e_1 to be the edge of $Cell(T_1, p_1)$ crossed by the ray $\overrightarrow{p_1 q}$; all of these can be found in constant time as $|T_1| = \Theta(1)$. Initialize $p_{nearest}$ to p_1.

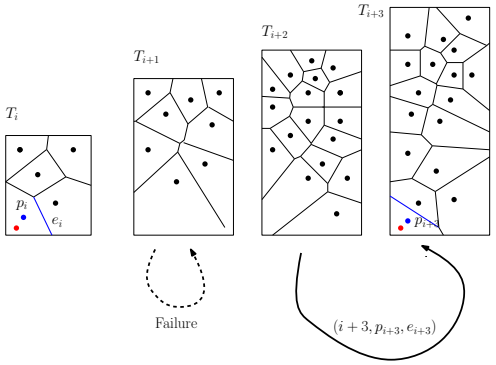

Figure 3 Two iterations of the Jump procedure. The query point q is shown in red. Points $p_i = NN(T_i, q)$, $p_{i+3} = NN(T_{i+3}, q)$, and edges e_i and e_{i+3} are shown in blue.

- Repeat the following while $\frac{i+j}{2} \leq f$:
  - Run $Jump(i, j, q, p_i, e_i)$. If the result is failure:
    - Set $j = j + (j - i)$
  - Else a triple $(j', p_{j'}, e_{j'})$ is returned:
    - If $d(p_{j'}, q) < d(p_{nearest}, q)$ set $p_{nearest} = p_{j'}$
    - Set $i = j'$ and set $j = j' + 1$
- Return $p_{nearest}$

We will show in the rest of this section that, given this jump function as a black box, we can correctly answer a nearest neighbor query in $O(\log n)$ time.

Correctness

The loop in the jump procedure will maintain the invariants that $p_{nearest}$ is $NN_{[1,\min(f,\frac{i+j}{2})]}(q)$, $i < j$ and $j - i$ is a power of two. The latter is because $j - i$ is set to either 1 or is doubled with each iteration of the loop. As to the first invariant, before the loop runs, the invariant requires $p_{nearest} = NN(T_1, q)$, which p_1 and $p_{nearest}$ are initialized to. During the loop we subscript i and j by new and old to indicate the value of variables at the beginning and at the end of the loop. Thus $p_{nearest} = NN_{[1,\min(f,\frac{i_{old}+j_{old}}{2})]}(q)$. Also if the loop runs, we know $\min(j_{old}, f) = j_{old}$. We distinguish between two cases depending on whether the jump function returns failure or a triple.

If the jump function returns failure, we know that

$$NN_{(\frac{i_{old}+j_{old}}{2},\min(j_{old},f)]}(q) \neq NN_{[1,\min(j_{old},f)]}(q).$$

Using this fact we can go from the invariant in terms of the old variables to the new ones:

$$\begin{aligned}
p_{nearest} &= NN_{[1,\min(f,\frac{i_{old}+j_{old}}{2})]}(q) && \text{Invariant}\\
&= NN_{[1,\frac{i_{old}+j_{old}}{2}]}(q) && \frac{i_{old}+j_{old}}{2} \leq f\\
&= NN_{[1,\min(j_{old},f)]}(q) && NN_{(\frac{i_{old}+j_{old}}{2},\min(j_{old},f)]}(q) \neq NN_{[1,\min(j_{old},f)]}(q)\\
&= NN_{[1,\min(f,\frac{i_{old}+j_{old}+(j_{old}-i_{old})}{2})]}(q) && \text{math}\\
&= NN_{[1,\min(f,\frac{i_{new}+j_{new}}{2})]}(q) && i_{new} = i_{old}; j_{new} = j_{old} + (j_{old} - i_{old})
\end{aligned}$$

Now we consider the case when a triple $(j', p_{j'}, e_{j'})$ is returned by the *Jump* function. We know that $NN_{(m,j']}(q) \neq NN_{[1,j']}(q)$, and using the same logic as from the failure case we can conclude that the old $p_{nearest}$ is $NN_{[1,j')}(q)$. The code sets $p_{nearest}$ to the point that is closer to q among the old $p_{nearest}$, equal to $NN_{[1,j')}(q)$, and $p_{j'}$, which is $NN(T_{j'}, q)$. Thus the new $p_{nearest}$ is equal to $NN_{[1,j']}(q)$ (note the closed interval) which we can rewrite to get the invariant as follows, using the fact that the subscript of NN is only dependent on the integers in the given range:

$$NN_{[1,j']}(q) = NN_{[1,i_{new}]}(q) = NN_{[1,\frac{i_{new}+i_{new}+1}{2}]}(q) = NN_{[1,\frac{i_{new}+j_{new}}{2}]}(q)$$

When the loop finishes, we have $j > f$ and thus

$$p_{nearest} = NN_{[1,\min(f,\frac{i+j}{2})]}(q) = NN_{[1,f]}(q) = \underset{p\in\{T_k | k\in[1,f] \text{ and } k\in\mathbb{Z}\}}{\arg\min} d(p,q) = NN(S,q)$$

Running time

▶ **Lemma 4.** *Given the Jump function, the running time of the nearest neighbor search function in $O(\log n)$.*

Proof. We use a potential argument. Let i_t and j_t denote the values of i and j after the loop has run t times, let a_t denote the runtime of the tth iteration of the loop, and let T denote the number of times the loop runs. The total runtime is thus $O(1) + \sum_{t=1}^{T} a_t$. Define $\Phi_t := c(2i_t + j_t)$, for some constant c chosen so that $a_t \leq \frac{c}{2}(j_j - i_t)$; as $i_0 = 1$ and $j_0 = 2$, $\Phi_0 = 4c$. (recall that the runtime of Jump is $O(j - i)$ for constant d).

We will argue that for all t, $a_t \leq \Phi_t - \Phi_{t-1} + O(1)$. Summing, this gives $\sum_{t=1}^{T} a_t \leq \Phi_T - \Phi_0 + O(T)$. Since i, j and T are in the range $[1, f]$, this bounds $\sum_{t=1}^{T} a_t$ by $3cf + O(f) = \Theta(\log n)$. Thus all that remains is to argue that $a_t \leq \Phi_t - \Phi_{t-1}$ for the two cases where the tth run of Jump ends in failure or returns a triple.

Case 1, Jump returns failure. In the case of failure, i remains the same, thus $i_t = i_{t-1}$ but j increases by $j - i$, thus $j_t = 2j_{t-1} - i_{t-1}$. Thus the potential increases by $c(j - i)$.

$$\begin{aligned}
\Phi_t - \Phi_{t-1} &= c(2i_t + j_t) - c(2i_{t-1} + j_{t-1}) \\
&= c(2i_{t-1} + 2j_{t-1} - i_{t-1}) - c(2i_{t-1} + j_{t-1}) \\
&= c(j_{t-1} - i_{t-1}) \\
&\geq a_t
\end{aligned}$$

Case 2, Jump returns a triple. i_t is set to j' and j_t changes to $j' + 1$. The key observation is that, due to the invariant in our correctness argument, $j_t \geq \frac{i_{t-1}+j_{t-1}}{2}$. Thus $i_t = j' \geq j_{t-1} \geq \frac{i_{t-1}+j_{t-1}}{2}$ and $j_t = j' + 1 \geq j_{t-1} + 1 \geq \frac{i_{t-1}+j_{t-1}}{2} + 1$; the potential change is

$$\begin{aligned}
\Phi_t - \Phi_{t-1} &= c(2i_t + j_t) - c(2i_{t-1} + j_{t-1}) \\
&\geq c(2 \cdot \frac{i_{t-1} + j_{t-1}}{2} + \frac{i_{t-1} + j_{t-1}}{2} + 1) - c(2i_{t-1} + j_{t-1}) \\
&= \frac{c}{2}(j_{t-1} - i_{t-i}) + c \\
&\geq a_t
\end{aligned}$$

◀

2.2 The jump function

2.2.1 Basic geometric facts

We begin with our most crucial geometric lemma, the one that we build upon to make our algorithm work. Informally, given point sets A and B which possibly have elements in common, and a query point q, if the closest point to q in B is also in A, then the closest point to q in $A \cup B$ is in A, and not in $B \setminus A$.

▶ **Lemma 5.** *Given i, j, $i < j$, suppose that there is a point q such that $q \in Cell(T_i, p_i) \cap Cell(T_j, p_j)$ for some $p_j \in Sample_j(j - i)$. Then $q \in Cell(T_i \cup T_j, p_i)$, or equivalently $NN(T_i \cup T_j, q) = p_i$.*

Proof. Since $p_j \in Sample_j(j - i)$, $p_j \in T_i$ by the definition of T_i. Since $q \in Cell(T_i, p_i)$, $dist(q, p_i) \leq dist(q, p_j)$. However, $q \in Cell(T_j, p_j)$ and p_j is the closest point to q in T_j: $dist(q, p_j) \leq dist(q, p'_j)$ for all p'_j in T_j. Combining $dist(q, p_i) \leq dist(q, p_j)$ with $dist(q, p_j) \leq dist(q, p'_j)$ for all p'_j in T_j gives the lemma. ◀

▶ **Lemma 6.** *If all elements of a point set P are in $Cell(S, p)$ for some point set S and $p \in S$, then all elements of the convex hull of P are in $Cell(S, p)$ as well.*

Proof. Immediate as $Cell(S, p)$ is convex. ◀

Lemmata 5 and 6 give us a tool to determine which parts of the Voronoi cell of some p_i in $\mathrm{Vor}(T_i)$ must also be part of the Voronoi cell of p_i in $\mathrm{Vor}(T_i \cup T_j)$. We define this region as $Hull_i(j, p_i)$, and then prove its properties.

Let $Hull_i(j, p_i)$, for some $p_i \in T_i$, denote the convex hull of

$$\{p_i\} \cup (Cell(T_i, p_i) \cap Cells(T_j, Sample_j(j - i))).$$

See Figure 4 for an example.

▶ **Lemma 7.** *$Hull_i(j, p_i) \subseteq Cell(T_i \cup T_j, p_i)$ and thus if $q \in Hull_i(j, p_i)$, $NN(q, S) \notin T_j \setminus T_i$*

Proof. The point p_i is in its own cell, $Cell(T_i \cup T_j, p_i)$, and by Lemma 5, all elements of $Cell(T_i, p_i) \cap Cells(T_j, Sample_j(j - i))$ are also in $Cell(T_i \cup T_j, p_i)$. Thus the convex hull of these points is a subset of $Cell(T_i \cup T_j, p_i)$ by Lemma 6. ◀

Thus, if a query point q is in $Hull_i(j, p_i)$, then, by Lemma 7, the set T_j can be ignored because $dist(q, p_i) \leq dist(q, p')$ for any $p' \in T_j \setminus T_i$.

Geometrically, determining whether a point in $Cell(T_i, p_i)$ is in a $Hull_i(j, p_i)$ and thus a full search in $\mathrm{Vor}(T_j)$ can be skipped is what our jump function does. We now need to turn to examining the combinatorial issues surrounding $Hull_i(j, p_i)$ and its interaction with $Cell(T_i, p_i)$ as we need the complexity of the regions examined to be bounded in such a way to allow efficient searching to see if a point is in $Cell(T_i, p_i)$. We begin by defining the part of $Cell(T_i, p_i)$ that is not in $Hull_i(j, p_i)$ as $\overline{Hull}_i(j, p_i)$ and proving a number of properties of this possibly disconnected region.

▶ **Lemma 8.** *Consider the region*

$$\overline{Hull}_i(j, p_i) \coloneqq Cell(T_i, p_i) \setminus Hull_i(j, p_i)$$

1. *Each connected component of $\overline{Hull}_i(j, p_i)$ is a subset of the union of Voronoi cells in one element of $Pieces_j(j - i)$; that is, each connected component of $\overline{Hull}_i(j, p_i)$ is a subset of $Cells(T_j, Piece^{\ell}_j(j - i))$ for some $Piece^{\ell}_j(j - i) \in Pieces_j(j - i)$.*

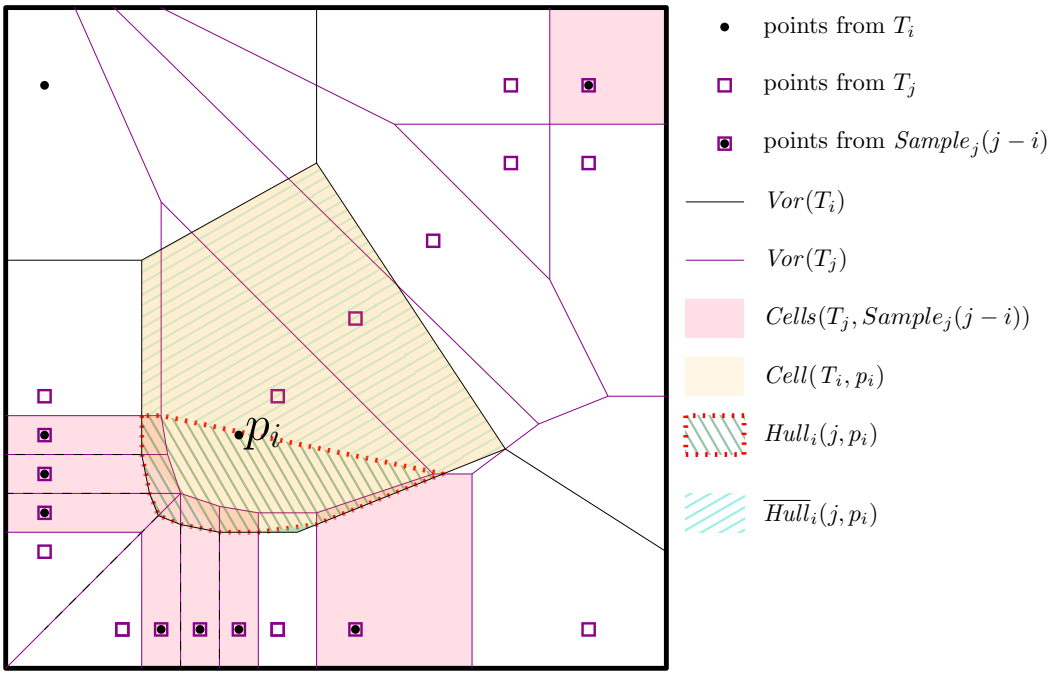

Figure 4 Illustration of the computation of $Hull_i(j, p_i)$ and $\overline{Hull}_i(j, p_i)$. Observe that $Hull_i(j, p_i)$ is the convex hull of those parts of $Cells(T_j, Sample_j(j-i))$ (shaded pink) that are inside $Cell(T_i, p_i)$ (shaded tan). $\overline{Hull}_i(j, p_i)$ is simply the remainder of $Cell(T_i, p_i)$, and has two connected components, including a small one at the bottom. By Lemma 7, the closest point in $T_i \cup T_j$ to all points in $Hull_i(j, p_i)$ is p_i.

2. *$\overline{Hull}_i(j, p_i)$ intersects each bounding edge of $Cell(T_i, p_i)$ in at most two connected components, each of which includes a vertex of $Cell(T_i, p_i)$.*
3. *Any line segment $\overline{p_i q}$, where q is on the boundary of $Cell(S_i, p_i)$ intersects $\overline{Hull}_i(j, p_i)$ in at most one connected component that, if it exists, includes q.*
4. *Let $\overline{qr}$ be a boundary edge of $Cell(T_i, p_i)$. The solid triangle $\triangle p_i qr$ intersects at most $d^{O(j-i)}$ edges on the boundary separating $Hull_i(j, p_i)$ from $\overline{Hull}_i(j, p_i)$.*

Proof.

1. Suppose one connected component $\overline{Hull}_i(j, p_i)$ contains points p, p' in both $Cells(T_j, Piece_j^{\ell}(j-i))$ and $Cells(T_j, Piece_j^{\ell'}(j-i))$ where $Piece_j^{\ell}(j-i)$ and $Piece_j^{\ell'}(j-i)$ are different elements of $Pieces(S_j, j-i)$. Consider a polyline that connects p and p' while remaining in the same connected component of $\overline{Hull}_i(j, p_i)$. Such a polyline must cross, at some point, some cell $Cell(T_j, p_j)$ of some $p_j \in T_j$ where $p_j \in Piece_j^{\ell}(j-i)$ but where the cell $Cell(T_j, p_j)$ is adjacent to at least one other cell in $Vor(T_j)$ that is not in $Piece_j^{\ell}(j-i)$. Thus p_j is by definition in $Sep_j^{\ell}(j-i)$; thus p_j is in $Hull_i(j, p_i)$ by its definition in Lemma 7. But this contradicts p_j is in $\overline{Hull}_i(j, p_i)$.
2. If this does not hold, there are points q_2 and q_3 on $\overline{Hull}_i(j, p_i)$, with q_2 closer to j than q_3, such that $q_2 \notin \overline{Hull}_i(j, p_i)$ and $q_3 \in \overline{Hull}_i(j, p_i)$. But this cannot happen: We know $p \in Hull_i(j, p_i)$ by construction and if p and q_2 are in $Hull_i(j, p_i)$, q_2 must be as well because the hull is a convex set.
3. By a similar argument as the last point, if this did not hold, there would be points p_1, q_1, q_2, q_3 in order on $\overline{p_i q}$, where there are some points q_1, q_2, q_3, q_4, q_5, in order, such that $q_1, q_3, q_5 \in \overline{Hull}_i(j, p_i)$ and $q_2, q_4 \in Hull_i(j, p_i)$. But this cannot happen: if q_2 and q_4 are in $Hull_i(j, p_i)$, q_3 must be as well because the hull is a convex set.

4. The complexity of $Hull_i(j, p_i) \cap \triangle p_i q r$ is at most the complexity of $Cells(T_j, \overline{Seps}_j^{\ell}(j-i))$ and $Cells(T, \overline{Seps}_j^{\ell'}(j-i))$, where $q \in Cells(T_j, \overline{Seps}_j^{\ell}(j-i))$ and $r \in Cells(T_j, \overline{Seps}_j^{\ell'}(j-i))$. By Lemma 3, the complexity of these regions (within the triangle $\triangle p_i q r$) is at most $d^{O(j-i)}$. Taking the convex hull only decreases the complexity of the objects on which a hull is defined. ◀

We can use these geometric facts to present the following corollary, which shows how we can use inclusion in $Hull_i(j, p_i)$ to determine where to find the nearest neighbor of q in T_j or to determine that $NN(S, q)$, q's nearest neighbor in S, is not in T_j *without needing to find the nearest neighbor of* q *in* T_j. This is our main novel idea, since, as discussed in the introduction, finding the nearest neighbors in every T_j in logarithmic time is not possible.

▶ **Corollary 9.** *Given:*

- i *and* j, $i < j$
- *a query point* q
- *a point* p_i *where* $p_i = NN(T_i, q)$
- *the edge* $\overline{v_1 v_2}$ *on the boundary of* $Cell(T_i, p_i)$ *that the ray* $\overrightarrow{p_i q}$ *intersects.*

then, by testing q *against the part of* $Hull_i(j, p_i)$ *that is inside* $\triangle p_i v_1 v_2$ *and has complexity* $d^{O(j-i)}$ *one of the following is true:*

- *If* q *is inside* $Hull_i(j, p_i)$*, then* q *is in* $Cell(T_i \cup T_j, p_i)$ *and* $NN(S, q)$ *is not in* T_j*.*
- *If* q *is outside* $Hull_i(j, p_i)$ *(and thus inside* $\overline{Hull}_i(j, p_i)$*): then* $NN(T_j, q)$ *is in the same element of* $\overline{Seps}_j(j-i)$ *as either* v_1 *or* v_2*.*

2.2.2 Implementing the jump function

We now use one additional idea to speed up the jump function: While testing if q is inside or outside of the part of $Hull_i(j, p_i)$ that intersects $\triangle p_i v_1 v_2$ can be done in time $O((j-i)\log d)$ (since the complexity of this part of the hull is $d^{O(j-i)}$ by Lemma 8, point 4), we can in fact do something stronger. We can test if q is inside or outside of the part of $Hull_i(j', p_i)$ that intersects $\triangle p_i v_1 v_2$, **for all** $\frac{i+j}{2} < j' < j$, in the same time $O((j-i)\log d)$. This is because the complexity of the subdivision of the plane induced by $\frac{j-i}{2}$ hulls of size $d^{O(j-i)}$ has complexity $d^{O(j-i)} \cdot O((j-i)^2)$ and thus we can determine in time $O((j-i)\log d)$ which is the smallest j' in the range $i < j' \leq j$ where q is not inside $Hull_i(j', p_i)$, or determine that for all j' in the range $i < j' \leq j$.

Thus we obtain the final jump procedure:

Method to compute $Jump(i, j, q, p_i, e_i)$:

1. Test to see what is the smallest j', $\frac{i+j}{2} < j' \leq j$ such that q is outside of the part of $Hull_i(j', p_i)$ that intersects $\triangle p_i v_1 v_2$. This will be done in time $O(\log d(j-i))$ with the convex hull search structure described in Section 2.3. If it is inside all such hulls, then $NN(S, q) \notin T_{j'}$ for all j' such that $\frac{i+j}{2} < j' \leq j$ and failure is returned. Otherwise:
2. Let $Piece_{v_1}$ and $Piece_{v_2}$ denote the elements of $Pieces_j(j'-i)$ that contain v_1 and v_2. These will be precomputed and accessible in constant time with the piece lookup structure described in Section 2.3.
3. Search in $Vor(T_{j'}, Piece_{v_1})$ and $Vor(T_{j'}, Piece_{v_2})$ to find $NN(Piece_{v_1} \cup Piece_{v_2}, q)$, call it $p_{j'}$. Note that, $p_{j'}$ is $NN(T_j, q)$. As both $Vor(T_{j'}, Piece_{v_1})$ and $Vor(T_{j'}, Piece_{v_2})$ have complexity $O(d^{j'-i})$, this can be done in time $O((j-i)\log d)$ with the piece interior search structure described in Section 2.3.
4. Find the edge $e_{j'}$ bounding $Cell(T_{j'}, p_{j'})$ that the ray $\overrightarrow{p_{j'} q}$ intersects. As $Cell(T_{j'}, p_{j'})$ has complexity $d^{O(j'-i)}$, this can be done in time $O((j-i)\log d)$ with binary search.

2.3 Data structures needed

The data structure is split into levels, where level i consists of:

I. S_i,
II. T_i,
III. The Voronoi diagram of T_i, $Vor(T_i)$, and a point location search structure for the cells of $Vor(T_i)$,
IV. The Delaunay triangulation of T_i, $G(T)$.
V. Additionally, we keep for each j, $1 \leq j < i$:
   i. The partition of T_i into $Pieces_j(k) \coloneqq \{Piece_j^1(k), Piece_j^2(k), \ldots Piece_j^{|Pieces_j(k)|}(k)\}$
   ii. The partition of each $Piece_j^\ell(k)$ into $Sep_j^\ell(k)$ and $\overline{Sep}_j^\ell(k)$
   iii. The set $Sample_j(k) \coloneqq \bigcup_{Sep \in Seps_j(k)} Sep$

For any level i, this information can be computed from T_i in time $O(|T_i| \log |T_i|)$ using [18][Theorem 3] to compute the partition into pieces, and standard results on Delaunay/Voronoi construction.

Additionally, less elementary data structures are needed for each level, which we describe separately: the convex hull search structure, the piece lookup structure, and the piece interior search structure.

Convex hull search structure

For level i, a convex hull structure is built for every combination of:

- A point p_i in T_i
- An edge e_i of $Cell(T_i, p_i)$
- An index j where $i < j$, $\frac{i+j}{2} \leq f$ and $j - i$ is a power of 2.

A convex hull structure answers queries of the form: given a point q in $Cell(T_i, p_i)$, return the smallest j', $\frac{i+j}{2} < j' \leq j$ such that q is outside of the part of $Hull_i(j', p_i)$ that intersects $\triangle p_i v_1 v_2$, where v_1 and v_2 are endpoints of e_i. There are $O(|T_i| \log \log_d |T_i|)$ such structures as j is at most $f = \Theta(\log_d n)$, and the complexity of a Voronoi diagram $Vor(T_i)$ is linear in the number of points it is defined on.

The method used is to simply store a point location structure which contains subdivision within $\triangle p_i v_1 v_2$ formed by the overlay of all boundaries of $Hull_i(j', p_i)$, for $\frac{i+j}{2} < j' \leq j$. As previously mentioned the complexity of this overlay is $O(d^{j-i} \cdot (j-i)^2)$ and thus point location can be done in the logarithm of this, which is $O((j-i) \log d)$.

As noted earlier there are $O(|T_i| \log \log_d n)$ structures, each of which takes space at most $O(j - i) = O(\log_d n)$ plus the number of intersections in the point location structure within the triangle. The $O(j-i)$ comes from the at most 2 edges from each hull that can pass through the triangle without intersection. For a given j, the sum of the complexities of $Hull_i(j, p_i)$ over all $p_i \in T_i$ is $O(T_i)$. As each hull edge can intersect at most $O(j - i) = O(\log_d n)$ other hull edges, that bounds the total space needed over one j to be $O(n \log_d n)$. The overall space usage is $O(n \log_d^2 n)$.

Piece lookup structure

Level i of the piece lookup structure contains for j, $i < j \leq \min(2i, f)$ and for each vertex v_i of $Vor(T_i)$ the index of which piece $Piece_j^\ell(j - i) \in Pieces_j^\ell(j - i)$ has q in $Cells(T_j, Piece_j^\ell(j - i))$. This can be precomputed using the point location search structure for $Vor(T_j)$ in time $O(\log d^j) = O(j \log d) = O(i) = O(\log n)$ for fixed d for each of the $O(|T_i|)$ vertices of $Vor(T_i)$. Summing over the choices for j gives a total runtime of $O(|T_i| \log^2 n)$ to pre-compute all answers. The space usage is $O(|T_i| \log n)$.

Piece interior search structure

For each $1 \leq i < j \leq f$ we store a point location structure that supports point location in time $O(j-i)$ in the Voronoi diagram for each set of points in $Pieces_j(j-i)$. Any standard linear-sized point location structure, such as that of Kirkpatrick [17], suffices since each element of $Pieces_j(j-i)$ has $O(4^{j-i})$ elements. For any fixed j, there are $j-1$ choices for i, and the sets in $Pieces_j(j-i)$ partition T_i. Thus the total size of all these structures is $O(|T_j| \log n)$. The construction cost, given the $Pieces_j(j-i)$, incurs another logarithmic factor due to the need to construct the Voronoi diagram and the point location structure (we do not assume each piece is connected). Thus the piece interior search structure for level j is constructed in $O(|T_j| \log^2 n)$ time.

2.4 Insertion time

Our description of the data structures needed can be summarized as follows:

▶ **Lemma 10.** *Level i of the data structure can be built in time and space $O(|T_i| \log^2 n)$ given all levels $j > i$.*

Insertion is thus handled by the classic logarithmic method of Bentley and Saxe [3] which transforms a static construction into a dynamic structure, and which we briefly summarize. To insert, we put the new point into S_1 and rebuild level 1. Every time a set S_i exceeds the upper limit of $\Theta(d^i)$, half of the items are moved from S_i to S_{i+1} and all levels from $i+1$ down to S_1 are rebuilt. So long as the upper and lower constants in the big Theta are at least a constant factor apart, the amortized insertion cost is $O(\log n)$ times the cost per item to rebuild a level, thus obtaining:

▶ **Lemma 11.** *Insertion can be performed with an amortized running time of $O(\log^3 n)$.*

The performance of our data structure can be summarized as follows:

▶ **Theorem 12.** *There exists a semi-dynamic insertion-only data structure that answers two-dimensional nearest neighbor queries in $O(\log n)$ time and supports insertions in $O(\log^3 n)$ amortized time. The data structure uses $O(n \log^2 n)$ space.*

Abstract

We study the three-dimensional Knapsack (3DK) problem, in which we are given a set of axis-aligned cuboids with associated profits and an axis-aligned cube knapsack. The objective is to find a non-overlapping axis-aligned packing (by translation) of the maximum profit subset of cuboids into the cube. The previous best approximation algorithm is due to Diedrich, Harren, Jansen, Thöle, and Thomas (2008), who gave a $(7+\varepsilon)$-approximation algorithm for 3DK and a $(5+\varepsilon)$-approximation algorithm for the variant when the items can be rotated by 90 degrees around any axis, for any constant $\varepsilon > 0$. Chlebík and Chlebíková (2009) showed that the problem does not admit an asymptotic polynomial-time approximation scheme.

We provide an improved polynomial-time $(139/29+\varepsilon) \approx 4.794$-approximation algorithm for 3DK and $(30/7+\varepsilon) \approx 4.286$-approximation when rotations by 90 degrees are allowed. We also provide improved approximation algorithms for several variants such as the cardinality case (when all items have the same profit) and uniform profit-density case (when the profit of an item is equal to its volume). Our key technical contribution is *container packing* – a structured packing in 3D such that all items are assigned into a constant number of containers, and each container is packed using a specific strategy based on its type. We first show the existence of highly profitable container packings. Thereafter, we show that one can find near-optimal container packing efficiently using a variant of the Generalized Assignment Problem (GAP).

1 Introduction

Three-dimensional Knapsack (3DK) is a fundamental problem in computational geometry, operations research, and approximation algorithms. In 3DK, we are given a set of items which are axis-aligned cuboids (defined by their width, depth, and height) with associated profits, and a three-dimensional (3D) knapsack which is an axis-aligned unit cube. The goal is to find a nonoverlapping axis-aligned packing (by translation) of a subset of items into the knapsack such that the profit of the packed items is maximized.

In 1965, Gilmore and Gomory [13] introduced the 3D Knapsack problem – motivated by cutting stock problems (e.g., cutting up of graphite blocks for anodes). They provided heuristics for the special case when the items need to be cut along axis-aligned planes. Since then, the problem and its several variants (under practical constraints) have been well-studied in operations research – typically from the viewpoints of meta-heuristics, MILP, tree search, machine learning methods, and greedy algorithms [5, 25]. In the last decade, 3DK has become a central problem in logistics to increase operational efficiency by efficiently utilizing the space in various domains, such as airline cargo management, warehouse management, and robotic container loading [1]. The prominence of this problem in the industry is evidenced by the comprehensive survey on 3D packing by Ali, Ramos, Carravilla, and Oliveira [1], who have mentioned hundreds of papers in recent years.

Packing problems are fundamental and popular among mathematicians (e.g., see Kepler's sphere packing conjecture [23] and *Soma cube* puzzle [14]). Surprisingly, 3DK is relatively less studied in computational geometry and approximation algorithms. Only in 2008, Diedrich, Harren, Jansen, Thöle, and Thomas [10] provided the first provable approximation guarantees for the problem. They first gave a simple polynomial-time $(9+\varepsilon)$-approximation algorithms for any constant $\varepsilon > 0$. Thereafter, they gave a more sophisticated $(7+\varepsilon)$-approximation algorithm for 3DK. For the case when the items can be rotated by 90 degrees around any axis, they provided a $(5+\varepsilon)$-approximation algorithm. Afterward, Chlebík and Chlebíková [7] showed that the problem admits no asymptotic polynomial-time approximation schemes (APTAS) even for the cardinality case (when each item has the same profit). Lu, Chen, and Cha [24] showed that even packing cubes into a cube is strongly NP-hard.

There has been progress in some special cases. When all items are d-dimensional hypercubes, Harren [15] gave a $(1+2^{-d}+\varepsilon)$-approximation algorithm. Recently, Jansen, Khan, Lira, and Sreenivas [17] gave a PTAS for this special case. Afterwards, Buchem, Deuker, and Wiese [4] obtained an EPTAS. Furthermore, they gave dynamic algorithms with polylogarithmic query and update times, matching the same approximation guarantees.

For the 2D variant when all items are rectangles (2DK), Jansen and Zhang [20] gave a $(2+\varepsilon)$-approximation algorithm. Gálvez, Grandoni, Ingala, Heydrich, Khan, and Wiese [11] gave an improved 1.89-approximation algorithm. Later, Gálvez, Grandoni, Khan, Ramírez-Romero, and Wiese [12] gave a pseudopolynomial-time 4/3-approximation algorithm. For the variant of *guillotine packing* (where items need to be packed such that they can be separated by a series of end-to-end cuts), Khan, Maiti, Sharma, and Wiese [21] gave a pseudopolynomial-time approximation scheme (PPTAS) for the problem.

Compared to the classical (1D) Knapsack, multidimensional Knapsack is much harder as there are different types of items and they can interact in a complicated way. For example, 2D items can be big (large in both dimensions), small (tiny in both dimensions), vertical (large in

height, small in width), or horizontal (large in width, small in height). Most approximation algorithms for 2DK show the existence of a highly profitable structured packing where the knapsack is partitioned into a constant number of boxes such that each box contains only items of one type and can be packed easily by simple greedy algorithms. Large boxes contain a single large item, vertical (resp. horizontal) boxes contain only vertical (resp. horizontal) items (thus, one can essentially ignore the long dimension of the item, and the box becomes a 1D knapsack), and small boxes contain small items (one can consider the area of an item as a proxy and use 1D knapsack solution). However, this is difficult for 3D packing. As pointed out by Bansal, Correa, Kenyon, and Sviridenko [3], one of the obstacles to generalize methods from rectangle packing to cuboid packing is that "*the interaction of say 3-dimensional rectangles which are long in one direction but short in the other two seems much more complicated than in the two-dimensional case.*"

In 2008, the authors in [10] mentioned that "*it is of interest whether here (for 3DK) an algorithm with ratio* $(6+\varepsilon)$ *or less exists.*" However, despite significant progress in the 2D case, there has been no improved approximation algorithm for 3DK in almost two decades.

1.1 Our results

In this paper, we introduce *container packing* for 3D Knapsack. We show that we can divide the 3D knapsack into $O(1)$ number of regions (called *containers*) such that the dimensions of these containers come from a polynomial-sized set. For each container C we define its capacity $\texttt{cap}(C) \in \mathbb{Q}_{\geq 0}$ and for each item i we define its size in C to be $f_C(i) \in \mathbb{Q}_{\geq 0}$. We also associate an algorithm $\mathcal{A}_C$ for the container. We require $\mathcal{A}_C, f_C$ such that for any C and any set of items T satisfying the packing constraint $\sum_{i \in T} f_C(i) \leq \texttt{cap}(C)$, almost all items in T (barring a small profit subset) can be packed into C by algorithm $\mathcal{A}_C$. The assignment of items into containers thus becomes a variant of the Multiple Knapsack problem (however, the knapsacks can have different capacities and items can have sizes specific to the knapsacks) – also a special case of Generalized Assignment Problem (GAP). For $O(1)$ knapsacks, there exists a PTAS for GAP [11]. After the assignment of items to the container C, the corresponding algorithm $\mathcal{A}_C$ ensures that the items admit a feasible profitable packing.

Container packing is a powerful and general technique. For example, by choosing appropriate functions f_C, our containers can handle complicated packings, beyond simple greedy algorithms. For example, we use six different types of containers in this work (see Figures 4 and 8). Apart from the Stack containers and Volume containers (similar to 2D packing), we introduce Area containers (packed using a variant of Next-Fit-Decreasing-Height (`NFDH`) algorithm [9]), Steinberg containers (where different types of items are packed together using our new volume-based packing algorithm `3D-Vol-Pack` – it packs items in layers where each layer is packed using either a greedy algorithm or a 2D packing algorithm called Steinberg's algorithm [26]), and L-Containers (where two different types of stacks are packed together when rotations are allowed). Note that Steinberg container or L-Container goes beyond simple stack or shelf-based algorithms and equips us to handle more complicated packings of different types of items. Finally, we show that given an optimal packing, we can modify it to some *container packing* having significant profit. The functions f_C can be considered analogous to the *weighting functions* in bin packing [9], and we expect that more complicated packing algorithms can be incorporated into this framework by suitably defining f_C.

Using this, we obtain improved approximation guarantees for 3DK (see Table 1). In particular, we obtain $(139/29+\varepsilon)$-approximation for 3DK and $(30/7+\varepsilon)$-approximation for 3DKR (when rotations by 90 degrees are allowed around all axes). For the cardinality case

Table 1 Summary of our results.

	General case	**Cardinality case**	**Profit = Volume**
Without rotations	$\frac{139}{29} + \varepsilon < 4.794$	$\frac{17}{4} + \varepsilon = 4.25 + \varepsilon$	$4 + \varepsilon$
With rotations	$\frac{30}{7} + \varepsilon < 4.286$	$\frac{24}{7} + \varepsilon < 3.429$	$3 + \varepsilon$

(when all items have the same profit), we obtain $17/4 + \varepsilon$ and $24/7 + \varepsilon$, respectively, for the cases without and with rotations. Finally, in the case when the profit of an item is equal to its volume (also called uniform profit-density), we obtain approximation guarantees of $4 + \varepsilon$ and $3 + \varepsilon$, without and with rotations, respectively.

Due to space limitations, some parts of the proofs are omitted in this extended abstract. For missing details, we refer the reader to the full version [16].

1.2 Related work

Two other related problems are 3D Bin Packing (BP) and Strip Packing (SP). In 3D BP, given a set of cuboids and unit cubes as bins, the goal is to find a nonoverlapping axis-aligned packing of all items into the minimum number of bins. In 3D SP, given a set of cuboids, the goal is to pack them into a single 3D rectangular box of unlimited height such that the height of the packing is minimized. For 3D BP and 3D SP, the best-known (asymptotic) approximation ratios are $T_\infty^2 \approx 2.86$ [6] and $3/2 + \varepsilon$ [19], respectively. For more details on related problems, we refer the readers to surveys [2, 8] on approximation and online algorithms for multidimensional packing.

2 Notation and Preliminaries

We are given a set of n items $I = \{1, 2, \ldots, n\}$. Each item $i \in I$ is a cuboid with width $w_i \in (0, 1]$, depth $d_i \in (0, 1]$, height $h_i \in (0, 1]$, and an associated profit $p_i \in \mathbb{Q}$. The volume of an item i is $v(i) = w_i \times d_i \times h_i$, and its base area is defined as $w_i d_i$. We are also given a 3D unit cube knapsack $K := [0, 1] \times [0, 1] \times [0, 1]$. If an item i is placed (by translation) in an axis-aligned way at (i_x, i_y, i_z) then it occupies the region: $[i_x, i_x + w_i] \times [i_y, i_y + d_i] \times [i_z, i_z + h_i]$. For a feasible packing we need $i_x \in [0, 1 - w_i], i_y \in [0, 1 - d_i], i_z \in [0, 1 - h_i]$. In a packing, two items are nonoverlapping if their interiors are disjoint. Our goal is to find a nonoverlapping packing of a subset of these items that maximizes the total profit. In 3DK, we allow only translation, whereas 3DKR allows translation and rotation by 90 degrees around all axes. For any set of items T, we shall let $p(T), h(T)$ and $v(T)$ denote the total profit, sum of heights, and volume of T, respectively. Let OPT denote an optimal packing and $\texttt{opt} := p(\text{OPT})$.

2.1 Packing subroutines

We now describe a few procedures that we repeatedly use throughout the paper to pack items. For a cuboidal box B, let w_B, d_B, h_B denote the width, depth, and height of B, respectively. The volume of the box is then $v(B) = w_B \times d_B \times h_B$.

Next-Fit-Decreasing-Height (`NFDH`) Algorithm [9]. `NFDH` is a shelf-based packing algorithm for packing rectangles. `3D-NFDH` is its generalization in three dimensions (see Figure 1). The following lemmas summarize the guarantees of these algorithms.

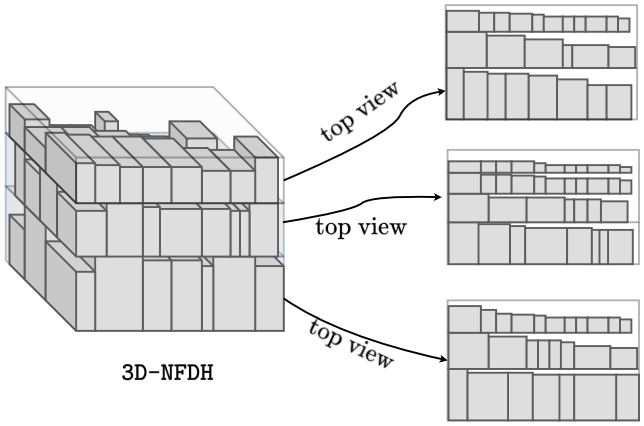

Figure 1 `3D-NFDH` with three layers. Each layer is packed using (two-dimensional) `NFDH`.

▶ **Lemma 1** ([11]). *We are given a rectangular box of length ℓ (horizontal dimension) and breadth b (vertical dimension), and a set S of n (2D) rectangles, where each $i \in S$ has length $\ell_i \leq \varepsilon\ell$ and breadth $b_i \leq \varepsilon b$. If $\sum_{i\in S} \ell_i b_i \leq (1-2\varepsilon)\ell b$, then the whole set S can be packed into the box using NFDH in $O(n \log n)$ time.*

▶ **Lemma 2.** *We are given a cuboidal box B, and a set T of n items where each $i \in T$ satisfies $w_i \leq \varepsilon w_B$, $d_i \leq \varepsilon d_B$ and $h_i \leq \varepsilon h_B$. If $v(T) \leq (1-3\varepsilon)v(B)$, then the whole set T can be packed into B using 3D-NFDH in $O(n \log^2 n)$ time.*

Steinberg's Algorithm [26]. Steinberg's Algorithm is a commonly used 2D packing algorithm with the following performance guarantee.

▶ **Lemma 3** ([26]). *We are given a set S of n rectangles and a rectangular box of size $\ell \times b$. Let $\ell_{\max} \leq \ell$ and $b_{\max} \leq b$ be the maximum length and maximum breadth among the rectangles in S, respectively, and let $a(S)$ be the total area of the rectangles in S. Also, we denote $x_+ := \max(x, 0)$. If $2a(S) \leq \ell b - (2\ell_{\max} - \ell)_+(2b_{\max} - b)_+$, then there is an algorithm that can pack the whole set S into the rectangular box in $O\left(\frac{n \log^2 n}{\log \log n}\right)$ time.*

We utilize the above algorithm to pack items in layers inside a box. Below, we present two algorithms `3D-Vol-Pack` and `3DR-Vol-Pack` for packing 3D items for the cases without and with rotations, respectively. As Steinberg's algorithm is used as a black box in many 2D packing problems, we believe our volume-based bounds and algorithms should find usage in other 3D packing problems. In both cases, we are given a box B with height h_B, width w_B, and depth d_B, and a set of items T.

`3D-Vol-Pack`. We assume that each $i \in T$ satisfies either $w_i \leq w_B/2$ or $d_i \leq d_B/2$. Let T_w be the items of T having width at most $w_B/2$, and let $T_d = T \setminus T_w$. Then, similar to [10], we further classify T_w as follows: let $T_{w\ell} \subseteq T_w$ be the items whose base area (area of the bottom face) exceeds $\frac{1}{6}w_B d_B$, and let $T_{ws} = T_w \setminus T_{w\ell}$. Next, we sort the sets $T_{w\ell}$ and T_{ws} in non-increasing order of heights. We group the items of $T_{w\ell}$ in pairs (except possibly the last item), and pack each pair in a single layer. See Figure 2. For packing items in T_{ws}, we group them into maximal collections of total base area not exceeding $\frac{1}{2}w_B d_B$, and pack each collection in a single layer using Steinberg's algorithm (Lemma 3). Analogously, we obtain a

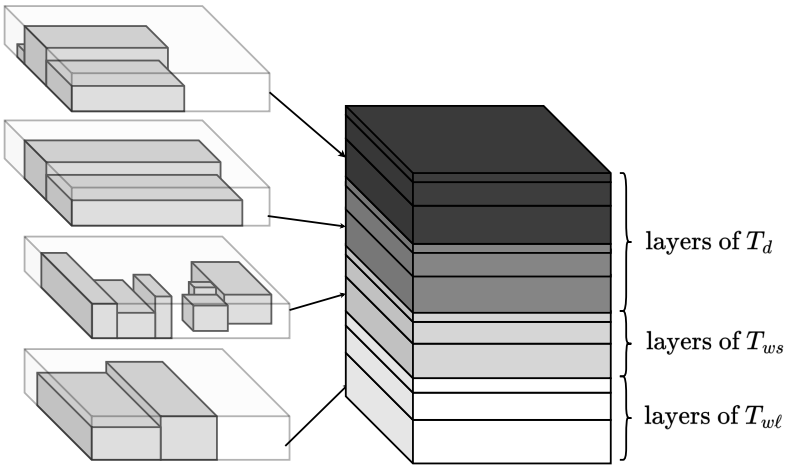

Figure 2 An example packing by Algorithm `3D-Vol-Pack`.

packing of the items in T_d in layers. Finally, we stack the layers one above the other inside the box B as long as the height of the box is not exceeded. The following lemma provides a guarantee when the item heights are small compared to the box height.

▶ **Lemma 4.** *Given a box B, and a set T of n items where each $i \in T$ satisfies $w_i \leq w_B$, $d_i \leq d_B$ and $h_i \leq \varepsilon h_B$. Further, either $w_i \leq w_B/2$ or $d_i \leq d_B/2$ holds for every $i \in T$. If $v(T) \leq \left(\frac{1}{3} - 2\varepsilon\right) v(B)$, then `3D-Vol-Pack` packs the whole set T into B in $O\left(\frac{n \log^2 n}{\log \log n}\right)$ time.*

Next, we give an algorithm when the items can be rotated by 90 degrees about any axis.

`3DR-Vol-Pack`. Let $T_\ell = \{i \in T \mid w_i > w_B/2 \text{ and } d_i > d_B/2\}$, and let $T_s = T \setminus T_\ell$. First, we pack T_s in layers using `3D-Vol-Pack`. Next, we sort the items of T_ℓ in non-increasing order of their widths and pack them in layers, one in each layer, touching the left face of the box, as long as the height of the box is not exceeded. Following this, we rotate the remaining items of T_ℓ about the depth dimension so that their widths and heights are interchanged, and as long as possible, pack them next to each other starting from the right face of the box, such that each item touches the top face of the box (see Figure 3).

The next lemma states that when B is a cube and when the height of each item is very small compared to box B, we can pack a significant volume.

▶ **Lemma 5.** *Given a cubical box B of side length w, and a set T of n items where for each $i \in T$, there exists an orientation so that $w_i \leq w$, $d_i \leq w$ and $h_i \leq \varepsilon^2 w$ holds. If $v(T) \leq \left(\frac{7}{24} - 5\varepsilon\right) v(B)$, then T can be packed into B by `3DR-Vol-Pack` in $O\left(\frac{n \log^2 n}{\log \log n}\right)$ time.*

3 Container Packing

In this section, we first define container packing and describe the containers used in our work. Then, we state our main structural result which shows that there exist container packings with high profit that can be found in polynomial time.

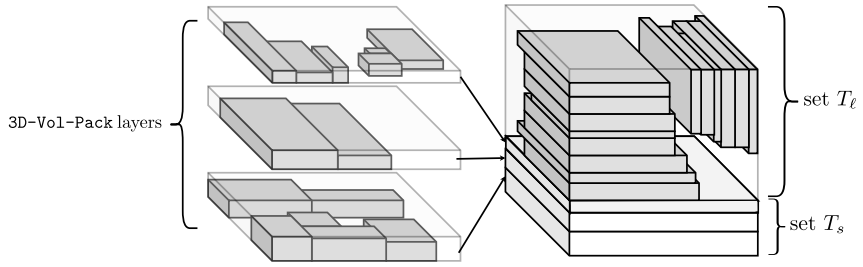

Figure 3 An example packing by Algorithm `3DR-Vol-Pack`.

▶ **Definition 6** (Container Packing). *A packing of a set of items $I' \subseteq I$ is said to be a Container Packing if*

- *the knapsack can be partitioned into a collection $\mathcal{C}$ of non-overlapping regions called containers and some empty spaces. Each container $C \in \mathcal{C}$ has an associated capacity $\mathtt{cap}(C)$, a function $f_C \colon I \to \mathbb{Q}_{\geq 0}$, and a polynomial-time algorithm $\mathcal{A}_C$,*
- *there is a function $g \colon I' \to \mathcal{C}$, such that for each $C \in \mathcal{C}$, items in $g^{-1}(C)$ are packed into C using algorithm $\mathcal{A}_C$,*
- *for any $C \in \mathcal{C}$ and $T \subseteq I$ such that $\sum_{i \in T} f_C(i) \leq \mathtt{cap}(C)$, for any constant $\varepsilon > 0$, there exists a polynomial-time computable set $T' \subseteq T$ with $p(T') \geq (1 - O(\varepsilon))p(T)$ such that T' can be packed into C by the algorithm $\mathcal{A}_C$.*

A Container Packing is said to be *guessable* if

- the number of containers inside the knapsack is bounded by a constant $O_\varepsilon(1)$,[1]
- the number of distinct possible types of containers (defined by their sizes along each dimension) is bounded by $n^{O_\varepsilon(1)}$, a polynomial in n,
- whether a given collection of $O_\varepsilon(1)$ containers can be placed non-overlappingly inside the knapsack, can be checked in $n^{O_\varepsilon(1)}$ (polynomial) time.

We shall call a container *guessable* if it comes from some polynomially-sized set of distinct container types. Though, in this paper we only use cuboids as containers, the idea of container packing can be generalized to other shapes in 3D or higher dimensions.

▶ **Theorem 7.** *There is a PTAS for maximum profit guessable container packing.*

Proof. We consider all feasible choices of containers that fit into the 3D knapsack, and for each such choice, we create an instance of GAP with one (1D) knapsack per container, where the (1D) knapsack corresponding to a container C has capacity $\mathtt{cap}(C)$ and the size of an item i for the (1D) knapsack is given by $f_C(i)$. The profit of an item for any (1D) knapsack is set to be the same as the actual profit of the item. Using the PTAS for GAP with $O(1)$ knapsacks [11], we obtain a feasible assignment of items into the containers, and finally for each container C, we use the algorithm $\mathcal{A}_C$ to pack a subset of the items assigned to it, by losing only an $O(\varepsilon)$-fraction of profit. ◀

3.1 Classification of containers

We now describe the various types of containers that we use to pack items. For a container C, its width, depth, and height are denoted by w_C, d_C, and h_C, respectively, and its volume

[1] The notation $O_\varepsilon(f(n))$ means that the implicit constant hidden in big-O notation can depend on ε.

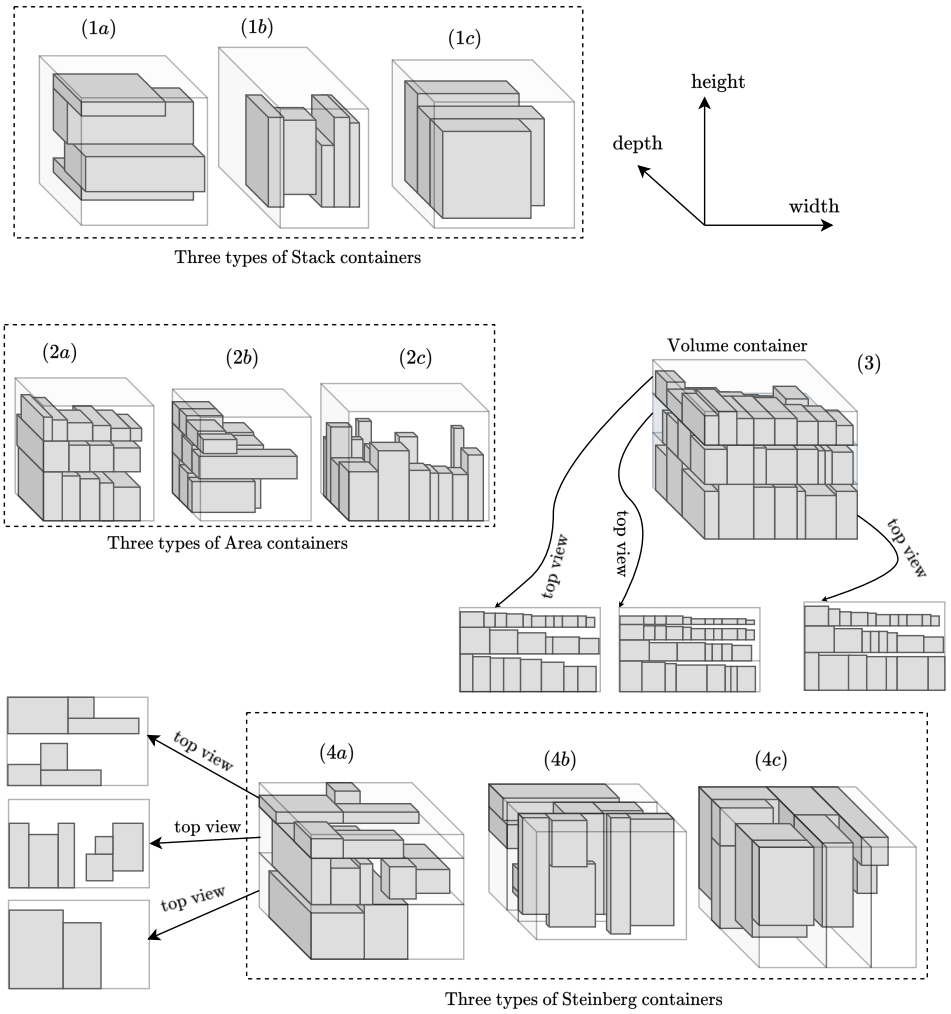

Figure 4 Different kinds of containers that we use. We have one type of Volume container and three types of Stack, Area, and Steinberg containers (one for each dimension).

$v(C) := w_C \times d_C \times h_C$. For each container C, we specify its capacity $\texttt{cap}(C)$, the function f_C, and the packing algorithm $\mathcal{A}_C$. Let T denote the set of items assigned to C such that $\sum_{i \in T} f_C(i) \leq \texttt{cap}(C)$. We suggest the reader to follow the descriptions alongside Figure 4.

- **Stack containers:** These containers pack items in layers, with one item in each layer. We consider a container C that stacks items along the height. See container $(1a)$ in Figure 4. The capacity $\texttt{cap}(C)$ of such a container is set to its height h_C, and for any item i, $f_C(i) := h_i$ if $w_i \leq w_C$ and $d_i \leq d_C$, and $f_C(i) := \infty$ otherwise.

  $\mathcal{A}_C$ just stacks the items of set T in the container C one above the other. Analogously containers $(1b)$ and $(1c)$ show containers that stack along width and depth, respectively.
- **Area containers:** Inside these containers, the items are packed using the `NFDH` algorithm, by ignoring one of the dimensions. We describe Area containers that use `NFDH` along the front face of the container (see container $(2a)$). For such a container C, we set $\texttt{cap}(C) := w_C h_C$, and for any item i, we set $f_C(i) := w_i h_i$ if $w_i \leq \varepsilon w_C$, $h_i \leq \varepsilon h_C$ and $d_i \leq d_C$, and $f_C(i) := \infty$ otherwise.

$\mathcal{A}_C$ first sorts the items of set T in non-increasing order of profit/front area ratio. Then, we select the largest prefix whose total front area does not exceed $(1-2\varepsilon)w_C h_C$. We pack this prefix using `NFDH` on the front face. Analogously, container $(2b)$ and $(2c)$ show packing when `NFDH` is used on the left and bottom face of C, respectively.

- **Volume containers:** The items are packed using `3D-NFDH` inside these containers (see container (3)). The capacity of such a container C is set to be its volume $v(C)$, and $f_C(i) := v(i)$ if $w_i \leq \varepsilon w_C$, $d_i \leq \varepsilon d_C$ and $h_i \leq \varepsilon h_C$, and $f_C(i) := \infty$ otherwise.
  $\mathcal{A}_C$ sorts the items of T in non-decreasing order of profit/volume and selects the largest prefix with volume not exceeding $(1-3\varepsilon)w_C h_C d_C$. We pack this prefix using `3D-NFDH`.
- **Steinberg containers:** These containers pack items in layers using `3D-Vol-Pack`. We describe Steinberg containers that pack items in layers along the height (analogous for other cases). We set $\texttt{cap}(C) := v(C)/3$. For any item i, we set $f_C(i) := v(i)$ if $h_i \leq \varepsilon h_C$, and either $w_i \leq w_C/2$ or $d_i \leq d_C/2$ holds. For all other items, we set $f_C(i) := \infty$.
  $\mathcal{A}_C$ first sorts the items in T in non-increasing order of profit/volume ratio. Then, we select the largest prefix whose volume does not exceed $\left(\frac{1}{3} - 2\varepsilon\right) v(C)$, and pack this prefix using `3D-Vol-Pack`. Analogously, container $(4b)$ and $(4c)$ show packing when layers are stacked along the depth and width, respectively.

3.2 Our Structural Lemma

Let $\texttt{opt}_{\text{gs}}$ be the maximum profit of a guessable container packing. The main structural result of our paper is the following.

▶ **Lemma 8.** *For any $\varepsilon > 0$, the optimal profit* `opt` *and the optimal profit of a guessable container packing* $\texttt{opt}_{\text{gs}}$ *satisfies* $\texttt{opt} \leq \left(\frac{139}{29} + \varepsilon\right) \texttt{opt}_{\text{gs}}$.

Together with Theorem 7, this gives us the following theorem.

▶ **Theorem 9.** *For any constant $\varepsilon > 0$, there is a polynomial-time $\left(\frac{139}{29} + \varepsilon\right)$-approximation algorithm for 3DK.*

We prove Lemma 8 in Section 4 by establishing several lower bounds on $\texttt{opt}_{\text{gs}}$. Specifically, we present five different ways to restructure OPT into a guessable container packing. Our first lower bound is based on a structural result of the 3D Strip Packing problem due to [19]. The second lower bound is obtained by restructuring the packing of items in $\text{OPT} \cap (I_{1\ell} \cup L)$ (or similarly $\text{OPT} \cap (I_{2\ell} \cup L)$ or $\text{OPT} \cap (I_{3\ell} \cup L)$). The third and fourth lower bounds are based on volume-based arguments, using our simple packing algorithm `3D-Vol-Pack`. Our final lower bound is based on a structural result from the 2D Knapsack problem [11].

4 Proof of Structural Lemma

Now we prove the structural lemma. First, we classify the items.

Classification of items. Let $\varepsilon > 0$ be an accuracy parameter. Let μ be a sufficiently small constant depending on ε (setting $\mu := \varepsilon^{2^{1/\varepsilon^2}}$ suffices). We now classify the input items based on their dimensions. Let $L \subseteq I$ be the set of items whose width, depth and height all exceed μ. Let $I_1 \subseteq I$ be the set of items having height at most μ. Similarly, let $I_2 \subseteq I \setminus I_1$ be those items whose widths are at most μ, and $I_3 := I \setminus (L \cup I_1 \cup I_2)$ be the remaining items. Thus each item in I_3 has depth at most μ. Let $I_{1\ell}$ consist of the items in I_1 whose width and depth are both more than $1/2$, and let $I_{1s} = I_1 \setminus I_{1\ell}$. See Figure 5. The sets $I_{2\ell}, I_{2s}, I_{3\ell}, I_{3s}$ are defined analogously.

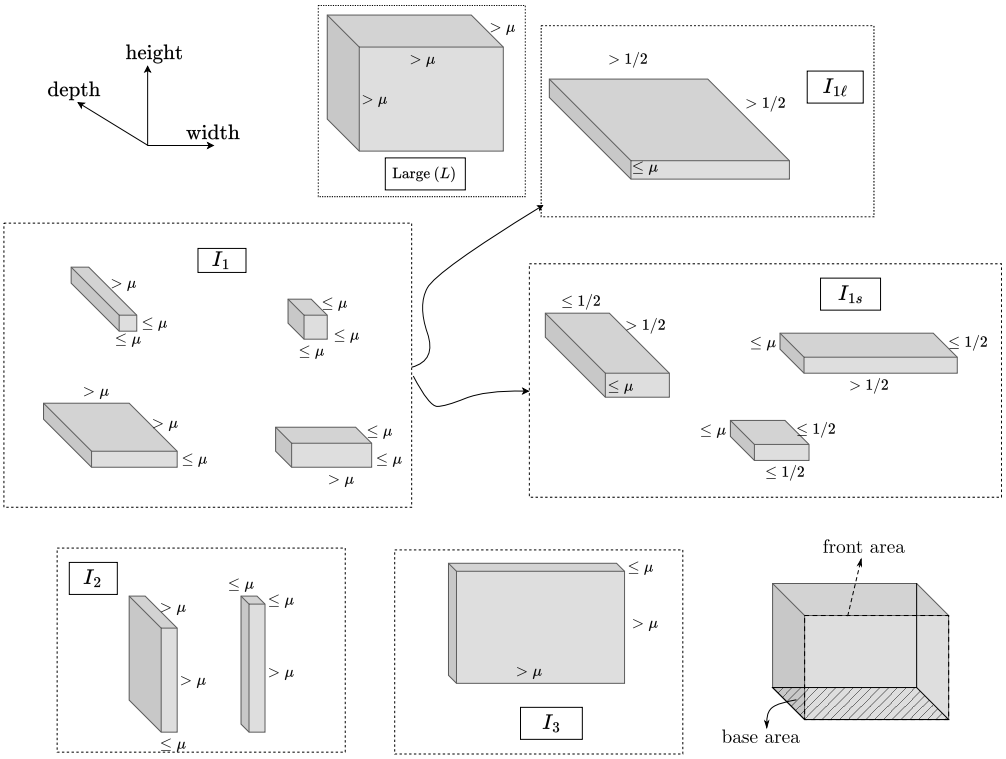

Figure 5 Classification of input items. Front area and base area are shown at the bottom right.

Let $\mathtt{opt}_i := p(\mathrm{OPT} \cap I_i)$ for $i \in [3]$, and $\mathtt{opt}_L := p(\mathrm{OPT} \cap L)$, so that $\mathtt{opt} = \mathtt{opt}_1 + \mathtt{opt}_2 + \mathtt{opt}_3 + \mathtt{opt}_L$. Let $\mathtt{opt}_{1\ell} := p(\mathrm{OPT} \cap I_{1\ell})$ and $\mathtt{opt}_{1s} := p(\mathrm{OPT} \cap I_{1s})$, so that $\mathtt{opt}_{1\ell} + \mathtt{opt}_{1s} = \mathtt{opt}_1$. The quantities $\mathtt{opt}_{2\ell}, \mathtt{opt}_{2s}$ and $\mathtt{opt}_{3\ell}, \mathtt{opt}_{3s}$ are defined analogously for the sets I_2 and I_3, respectively.

Finally, let $v_1 := v(\mathrm{OPT} \cap I_1)$, and define v_2, v_3 analogously. Clearly, v_1, v_2, v_3 sum up to at most the volume of the knapsack which is 1. We define $h_{1\ell} := h(\mathrm{OPT} \cap I_{1\ell})$ and $v_{1s} := v(\mathrm{OPT} \cap I_{1s})$. The quantities v_{2s}, v_{3s} are defined analogously.

4.1 First lower bound on $\mathtt{opt}_{\mathbf{gs}}$

We consider the packing of the items in $\mathrm{OPT} \cap I_1$ (i.e., items with height at most μ) whose total profit is $\mathtt{opt}_1$. We build on the structure derived from the 3D Strip Packing algorithm of Jansen and Prädel [19]. However, we need several refinements to transform the packing of [19] into a guessable container packing.

First, using standard arguments, we discard a set of (medium) items (items whose widths or depths lie in the range $[\delta^{10}, \delta)$ for a suitably chosen δ) at a $(1+\varepsilon)$-factor loss in the approximation ratio. Then the items are divided into four classes depending on their dimensions. An item i is big if both $w_i \geq \delta$ and $d_i \geq \delta$, wide if $w_i \geq \delta$ and $d_i < \delta^{10}$, long if $w_i < \delta^{10}$ and $d_i \geq \delta$, and small if both $w_i < \delta^{10}$ and $d_i < \delta^{10}$. The following lemma is obtained by an adaptation of the result of [19] (see Figure 6).

▶ **Lemma 10.** *There exist disjoint sets $T_1, T_2 \subseteq OPT \cap I_1$ having a profit of at least $\left(\frac{2}{3} - O(\varepsilon)\right) \mathtt{opt}_1$, such that*

- *Items of T_1 are packed into a collection of $O(1/\delta^6)$ configurations, where each configuration is a box having a 1×1 base, that is partitioned into $O(1/\delta^2)$ (cuboidal) slots for packing big items, $O(1/\delta^6)$ slots for packing wide and long items (using NFDH), and $O(1/\delta^5)$ slots for packing small items (using 3D-NFDH). The height of a slot is the same as the height of the corresponding configuration,*
- *The configurations are stacked one on top of the other inside the knapsack and their heights sum up to at most $1 - 2\varepsilon$,*
- *The set T_2 contains only wide, long and small items and has a total volume of $O(\delta^4)$.*

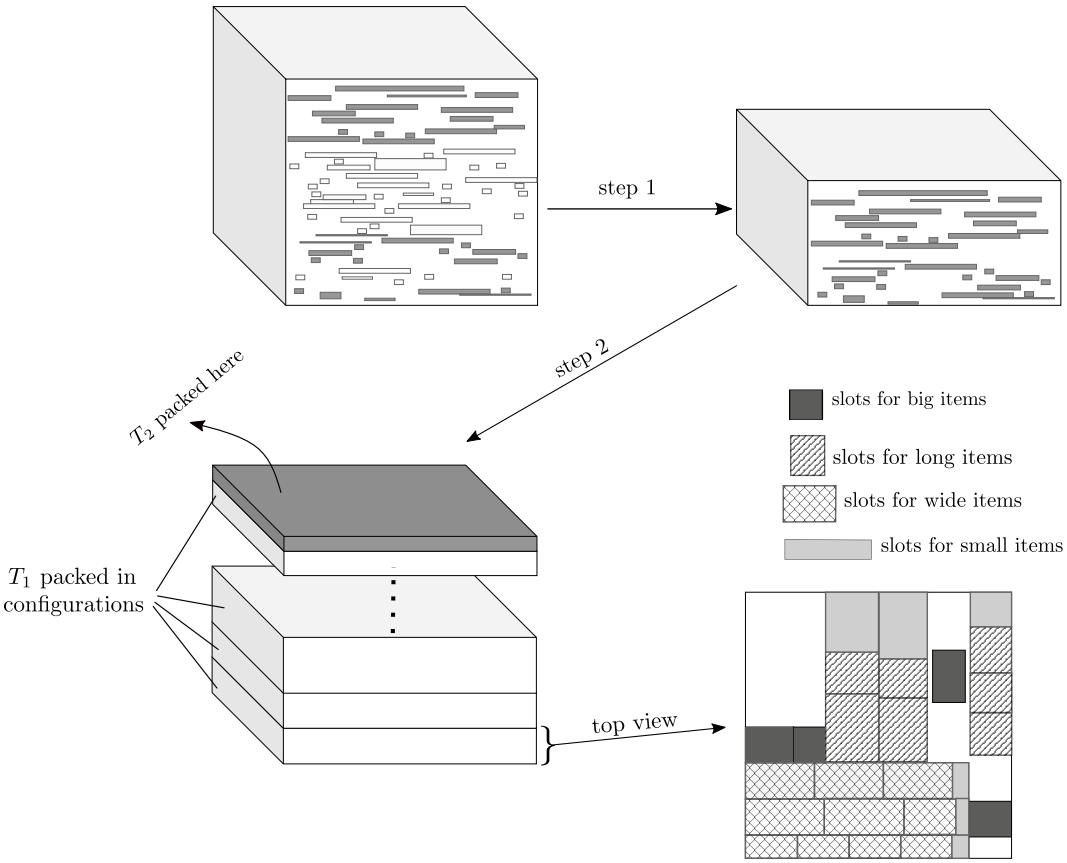

Figure 6 In Step 1, we remove at most $(1/3 + O(\varepsilon))$ fraction of the profit. In Step 2, we obtain a structured packing by [19].

Our objective is to build Area and Volume containers out of the slots for packing the wide/long and small items, respectively. The trouble is that the slot dimensions might not be large enough compared to the dimensions of the packed items, which is a necessary condition for the construction of such containers (see Section 3.1). We obtain a guessable container packing by the following lemma.

▶ **Lemma 11.** *By losing a profit of at most $\delta \mathtt{opt}_1$, and rounding the height of each configuration to the next integer multiple of μ/ε, each configuration for T_1 can be further partitioned into $O(1/\delta^6)$ guessable containers. Moreover, the items of T_2 can be packed inside a Steinberg container of height ε.*

After applying the above lemma, the rounded heights of all the configurations for T_1 sum up to at most $(1-2\varepsilon) + \frac{\mu}{\varepsilon} \cdot O(\frac{1}{\delta^6}) \leq 1-\varepsilon$, for sufficiently small μ. Since items of T_2 are packed inside a Steinberg container of height ε, all the containers fit inside the knapsack and we obtain the following theorem overall.

▶ **Theorem 12.** *We can repack a subset of $OPT \cap I_1$ with profit at least $\left(\frac{2}{3} - O(\varepsilon)\right) \mathtt{opt}_1$ into $O(1/\delta^{12})$ guessable Stack, Area, and Volume containers.*

An equivalent restructuring of $\mathrm{OPT} \cap I_2$ and $\mathrm{OPT} \cap I_3$ gives the following corollary.

▶ **Corollary 13.** $\mathtt{opt}_{\mathrm{gs}} \geq \left(\frac{2}{3} - O(\varepsilon)\right) \max\{\mathtt{opt}_1, \mathtt{opt}_2, \mathtt{opt}_3\}$.

4.2 A simple $(5+\varepsilon)$-approximation

We now present a simple $(5+\varepsilon)$-approximation for 3DK, which already improves upon the $(7+\varepsilon)$-approximation [10]. For this, first, we provide the following packing guarantee.

▶ **Lemma 14.** *Let T be a set of items such that each $i \in T$ satisfies $h_i \leq \varepsilon^4$. If $v(T) \leq 1/4$, then there exists $T' \subseteq T$ with $p(T') \geq (1-\varepsilon)p(T)$ such that there is a guessable container packing of T' into a Stack and a Steinberg container.*

Then the following lemma, together with Theorem 7, gives a $(5+\varepsilon)$-approximation.

▶ **Lemma 15.** $\mathtt{opt} \leq (5+\varepsilon)\mathtt{opt}_{\mathrm{gs}}$.

Proof. Trivially we have $\mathtt{opt}_{\mathrm{gs}} \geq \mathtt{opt}_L$, since we can create a Stack container for every item in $\mathrm{OPT} \cap L$ (at most $1/\mu^3$ such items). Hence if $\mathtt{opt}_L > \mathtt{opt}/5$, we are already done. Otherwise we have $\mathtt{opt}_1 + \mathtt{opt}_2 + \mathtt{opt}_3 \geq \frac{4}{5}\mathtt{opt}$. Now since $v_1 + v_2 + v_3 \leq 1$, there must exist an $i \in [3]$ such that $\frac{\mathtt{opt}_i}{v_i} \geq \frac{4}{5}\mathtt{opt}$ – w.l.o.g. assume $i = 1$. We have two cases.

Case 1: $v_1 \leq \frac{1}{4}$**.** In this case, Lemma 14 implies that $\mathtt{opt}_{\mathrm{gs}} \geq (1-\varepsilon)\mathtt{opt}_1$ (since each item in I_1 has height at most $\mu < \varepsilon^4$). Hence if $\mathtt{opt}_1 > \mathtt{opt}/5$, we are done. Otherwise we have $\mathtt{opt}_2 + \mathtt{opt}_3 \geq \frac{3}{5}\mathtt{opt}$. W.l.o.g. assume that $\mathtt{opt}_2 \geq \frac{3}{10}\mathtt{opt}$, Corollary 13 gives us $\mathtt{opt}_{\mathrm{gs}} \geq \left(\frac{2}{3} - O(\varepsilon)\right) \cdot \frac{3}{10}\mathtt{opt} = \left(\frac{1}{5} - O(\varepsilon)\right)\mathtt{opt}$.

Case 2: $v_1 > \frac{1}{4}$**.** In this case, we sort the items of $\mathrm{OPT} \cap I_1$ in non-increasing order of their profit to volume ratio, and pick the maximal prefix T whose volume does not exceed $\frac{1}{4}$. Then we have $v(T) \geq \frac{1}{4} - \mu$. Applying Lemma 14 to T, we obtain $\mathtt{opt}_{\mathrm{gs}} \geq (1-\varepsilon)\left(\frac{1/4-\mu}{v_1}\right)\mathtt{opt}_1 \geq \left(\frac{1}{5} - O(\varepsilon)\right)\mathtt{opt}$, thus completing the proof. ◀

The ratio of $(5+\varepsilon)$ is tight. One such instance is given when $v_1 = \frac{1}{8}, v_2 = v_3 = \frac{3}{8}$ and $\mathtt{opt}_1 = \mathtt{opt}_L = \frac{1}{5}\mathtt{opt}$ and $\mathtt{opt}_2 = \mathtt{opt}_3 = \frac{3}{10}\mathtt{opt}$.

We will obtain further improvements by using the lower bounds in the following sections.

4.3 Second lower bound on $\mathtt{opt}_{\mathrm{gs}}$

In this subsection, we consider the packing of $\mathrm{OPT} \cap (I_{1\ell} \cup L)$, and restructure it to obtain a guessable container packing, by losing only an $O(\varepsilon)$-fraction of the profit. Let $\mathrm{OPT}_{1\ell} := \mathrm{OPT} \cap I_{1\ell}$ and $\mathrm{OPT}_L := \mathrm{OPT} \cap L$. Since each item in L has all side lengths at least μ, the number of such items in the packing is $|\mathrm{OPT}_L| \leq 1/\mu^3$. Also, since the width and depth of each item in $I_{1\ell}$ is at least $1/2$, the items of $\mathrm{OPT}_{1\ell}$ must be packed in layers, i.e., the top and bottom faces of any item in $\mathrm{OPT}_{1\ell}$ when extended parallel to the bottom face of the knapsack will not intersect another item from $\mathrm{OPT}_{1\ell}$. We now discretize the positions of the items in the packing.

▶ **Lemma 16.** *The distance of the left (resp. front) face of any item from the left (resp. front) face of the knapsack can be assumed to lie in a polynomial-sized set.*

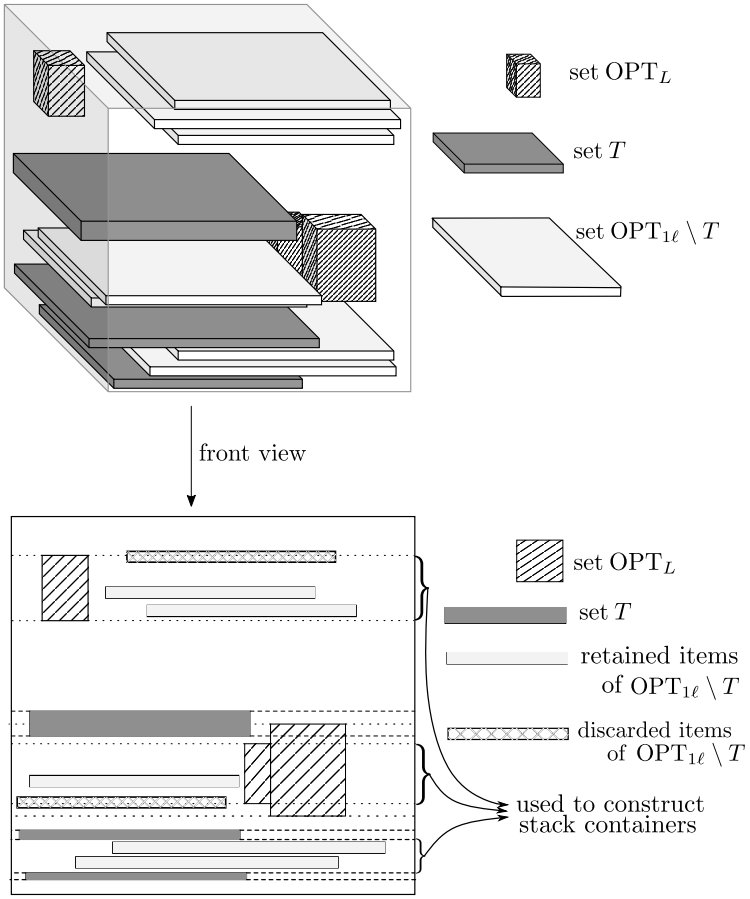

Figure 7 Packing of items in $OPT \cap (L \cup I_{1\ell})$: The dotted (resp. dashed) lines show (front view of) horizontal planes passing through the top and bottom faces of items in OPT_L (resp. T). We discard the items in $\mathrm{OPT}_{1\ell} \setminus T$ that are cut by these planes.

Let $T \subseteq \mathrm{OPT}_{1\ell}$ be the k items of largest profit in $\mathrm{OPT}_{1\ell}$, for some k to be chosen later. Our goal is to obtain a container packing of all items in OPT_L, together with a subset of $\mathrm{OPT}_{1\ell}$ having a profit of at least $(1-\varepsilon)\mathtt{opt}_{1\ell}$. To this end, we shall pack all items in T and ensure that the number of discarded items of $\mathrm{OPT}_{1\ell}$ is bounded by ck, for some constant c. By a result of [18], the profit of the discarded items can be bounded by $\varepsilon\mathtt{opt}_{1\ell}$, for appropriately chosen k. We now outline the details of our restructuring procedure. See Figure 7.

We draw horizontal planes passing through the top and bottom faces of the items in $T \cup \mathrm{OPT}_L$, and discard the items of $\mathrm{OPT}_{1\ell} \setminus T$ intersecting these planes (see Figure 7). The number of discarded items is bounded by $2|\mathrm{OPT}_L| = O(1/\mu^3)$. The remaining items of $\mathrm{OPT}_{1\ell} \setminus T$ are now completely packed inside at most $k + 2|\mathrm{OPT}_L| + 1$ horizontal strips demarcated by the planes. Each such strip is a cuboidal box that is pierced from top to bottom by at most $1/\mu^2$ Large items. Further, there are only polynomially-many positions of these Large items inside the strip owing to Lemma 16. We focus on one such strip $\mathcal{S}$.

▶ **Lemma 17.** *The items of $OPT_{1\ell} \setminus T$ present inside the strip $\mathcal{S}$ can be repacked into at most $O(1/\mu^8)$ Stack containers, whose widths and depths lie in a polynomial-sized set.*

For each item in $T \cup \mathrm{OPT}_L$, we create a Stack container containing the single item itself. Together with Lemma 17, we get $O_\mu(1)$ number of Stack containers inside the knapsack. We now discretize the heights of the Stack containers, so that they lie in a polynomial-sized set.

▶ **Lemma 18.** *By discarding $O(1/\mu^{11})k$ items from $OPT_{1\ell} \setminus T$, the height of each Stack container can be made of the form $j\bar{h}$, where $j \in [n]$ and $\bar{h}$ is the height of some item in $I_{1\ell} \cup L$.*

Together with the $O(1/\mu^3)$ items that were discarded previously, Lemma 18 gives us that the total number of discarded items so far is at most $O(1/\mu^{11})k$. We now use the following lemma from [18].

▶ **Lemma 19** ([18])**.** *Let $p_1 \geq p_2 \geq \ldots \geq p_n > 0$ be a sequence of real numbers and $P = \sum_{i=1}^{n} p_i$. Let c be a nonnegative integer and $\varepsilon > 0$. If $n = c^{\Omega(1/\varepsilon)}$, then there is an integer $k \leq c^{O(1/\varepsilon)}$ such that $p_{k+1} + \ldots p_{k+ck} \leq \varepsilon P$.*

The above lemma invoked with $c = O(1/\mu^{11})$ and with the correct guess of k gives us that the total profit of the discarded items is at most $\varepsilon \mathtt{opt}_{1\ell}$, assuming that $|\mathrm{OPT}_{1\ell}|$ was sufficiently large (at least $n_0 := (1/\mu)^{\Omega(1/\varepsilon)}$) to begin with (otherwise, it is trivial). The following theorem summarizes the arguments of this section.

▶ **Theorem 20.** *Consider the packing of $\mathrm{OPT} \cap (I_{1\ell} \cup L)$. Then by discarding items of $\mathrm{OPT} \cap I_{1\ell}$ having a total profit of at most $\varepsilon \mathtt{opt}_{1\ell}$, the remaining items can be repacked into a guessable container packing, wherein items of L are placed inside at most $1/\mu^3$ Stack containers, and items of $I_{1\ell}$ are packed into at most $(1/\mu)^{O(1/\varepsilon)}$ Stack containers.*

4.4 Third lower bound on $\mathtt{opt}_{\mathbf{gs}}$

In this subsection, we restructure the packing of items in $\mathrm{OPT} \cap I_1$. Recall that $\mathtt{opt}_{1\ell} = p(\mathrm{OPT} \cap I_{1\ell})$ and $\mathtt{opt}_{1s} = p(\mathrm{OPT} \cap I_{1s})$, so that $\mathtt{opt}_{1\ell} + \mathtt{opt}_{1s} = \mathtt{opt}_1$. Also, $v_1 := v(\mathrm{OPT} \cap I_1)$ and $v_{1s} = v(\mathrm{OPT} \cap I_{1s})$.

▶ **Theorem 21.** *Consider the packing of $OPT \cap I_1$. It is possible to repack subsets of $OPT \cap I_{1\ell}$ and $OPT \cap I_{1s}$ into a guessable Stack and Steinberg container, respectively, whose profit, say P, satisfies the following properties:*

- $P \geq (1 - O(\varepsilon)) \dfrac{\mathtt{opt}_{1s}}{\max\{3v_{1s}, 1\}}$,
- *If $v_1 \leq 1/3$, then* $P \geq (1 - O(\varepsilon)) \left(\dfrac{3}{4} \mathtt{opt}_{1\ell} + \mathtt{opt}_{1s} \right)$,
- *If $v_1 \leq 1/4$, then* $P \geq (1 - O(\varepsilon)) \mathtt{opt}_1$.

4.5 Fourth lower bound on $\mathtt{opt}_{\mathbf{gs}}$

In the previous sections, we repacked items from exactly one set out of I_1, I_2, I_3. In this subsection, we restructure the packing of a subset of items from I_1, together with items from $I_2 \cup I_3 \cup L$. To this end, we introduce a classification of the items in $I_2 \cup I_3 \cup L$. Let S_2 (resp. S_3, S) be the set of items in I_2 (resp. I_3, L) with height at most $1/2$. Define $\mathtt{opt}_{2t} := p(\mathrm{OPT} \cap S_2)$ and $\mathtt{opt}_{2h} := p(\mathrm{OPT} \cap (I_2 \setminus S_2))$, so that $\mathtt{opt}_{2t} + \mathtt{opt}_{2h} = \mathtt{opt}_2$. The quantities $\mathtt{opt}_{3t}$ and $\mathtt{opt}_{3h}$ are defined analogously. Let $\mathtt{opt}_{Lt} := p(\mathrm{OPT} \cap S)$ and $\mathtt{opt}_{Lh} := p(\mathrm{OPT} \cap (L \setminus S))$ so that $\mathtt{opt}_{Lt} + \mathtt{opt}_{Lh} = \mathtt{opt}_L$. The following theorem repacks items from $I_1 \cup S_2 \cup S_3 \cup S$.

▶ **Theorem 22.** *Consider the packing of* $OPT \cap (I_1 \cup S_2 \cup S_3 \cup S)$ *and assume that* $v_1 \leq 1/6$ *and* $v_2, v_3 > 1/4$*. Then there is a guessable container packing of a subset* T *of these items into* $O(1/\mu^3)$ *Stack and Steinberg containers having a profit of at least*

$$(1 - O(\varepsilon)) \left(\frac{3}{4}\mathtt{opt}_{1\ell} + \mathtt{opt}_{1s} + \max\left\{ \frac{3}{20}(\mathtt{opt}_{2t} + \mathtt{opt}_{3t}), \frac{1}{3}\mathtt{opt}_{Lt} \right\} \right).$$

4.6 Fifth lower bound on $\mathtt{opt}_{\mathtt{gs}}$

In the previous subsection, we repacked items from S_2, S_3 or S together with items in I_1. Now we consider items in $(I_2 \setminus S_2) \cup (I_3 \setminus S_3) \cup (L \setminus S)$ in OPT. As all these items have heights of more than 1/2, they can not be stacked on top of each other. So, we can ignore their heights, and effectively obtain a 2D Knapsack instance. Now we use a container-based algorithm for 2DK from [22] to obtain a container packing of these items.

▶ **Theorem 23.** *Consider the packing of* $OPT \cap ((I_2 \cup I_3 \cup L) \setminus (S_2 \cup S_3 \cup S))$*. Then there is a guessable container packing into* $O_\mu(1)$ *Stack and Area containers each of height 1, having profit at least* $\left(\frac{1}{2} - O(\varepsilon)\right)(\mathtt{opt}_{2h} + \mathtt{opt}_{3h} + \mathtt{opt}_{Lh})$*.*

4.7 Bounding $\mathtt{opt}_{\mathtt{gs}}$

Equipped with all the lower bounds of the preceding subsections, we establish Lemma 8 by an intricate case analysis depending on the volumes of various sets of items in the optimal packing. Since v_1, v_2, v_3 sum up to at most the volume of the knapsack which is 1, at least one among them must not exceed 1/3. If at most one of them exceeds 1/3, we show a stronger bound of $\left(\frac{9}{2} + \varepsilon\right)$ on the approximation ratio. Otherwise, we assume w.l.o.g. that $v_1 \leq 1/3$ and $v_2, v_3 > 1/3$. We further divide into subcases depending on the values of v_{2s} and v_{3s}. It turns out that the worst bound on $\mathtt{opt}_{\mathrm{gs}}$ occurs when v_{2s}, v_{3s} both exceed 1/3 and $v_1 \leq 1/6$. However for this case, Theorem 22 and Theorem 23 give us highly profitable packings, and we achieve an approximation ratio of $\left(\frac{139}{29} + \varepsilon\right)$. The details of the analysis are deferred to the full version [16].

5 Other variants

Using our techniques, we obtain further improvements for other variants: (1) cardinality case (when all items have the same profit), and (2) uniform profit-density case (when the profit of an item is equal to its volume).

▶ **Theorem 24.** *For any constant* $\varepsilon > 0$*, there is a polynomial-time* $(17/4 + \varepsilon)$*-approximation algorithm for 3DK when all items have the same profit.*

▶ **Theorem 25.** *For any constant* $\varepsilon > 0$*, there is a polynomial-time* $(4 + \varepsilon)$*-approximation algorithm for 3DK when the profit of an item is equal to its volume.*

5.1 Rotational case

When the items can be rotated by 90 degrees around any axis, we show the existence of improved container packing. Specifically, we introduce a new type of container called L-Container and obtain improved guarantees based on the packed volume.

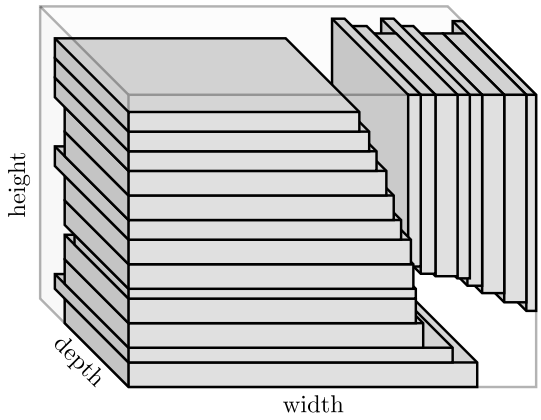

Figure 8 An example packing of items inside an L-Container.

L-Container. We describe L-Containers which ignore depth while packing the items (see Figure 8; two other types of L-Containers exist which ignore width, height, respectively). We first require that C must satisfy the condition $w_C \geq h_C$. The capacity of C, $\texttt{cap}(C)$, is given by $w_C h_C - w_C^2/4$. For each item i packed inside C, there must be some orientation with width at least $w_C/2$, depth at least $d_C/2$, and height at most εh_C. If these conditions are satisfied, then we set $f_C(i) \coloneqq w_i h_i$ and ∞ otherwise. Algorithm $\mathcal{A}_C$ is as follows. Given a set of items T satisfying $f_C(T) \leq \texttt{cap}(C)$, we arrange them in non-increasing order of profit/(front area) ratio. Then, we select the largest prefix T' whose total front area does not exceed $w_C h_C - w_C^2/4 - 3\varepsilon h_C^2$. We now sort the items in T' in non-increasing order of widths, start from the bottom left corner, and keep stacking them one upon each other to the maximum extent possible. Then, we rotate the remaining items by 90 degrees around the depth axis, start from the top right corner and keep packing them side by side.

The main ingredient to obtain improved approximation ratios in the rotational case is our algorithm `3DR-Vol-Pack` (see Section 2.1). Although, as stated the algorithm does not pack into (guessable) containers, it can be modified to return a guessable container packing into Stack, Steinberg, and L-Containers. Using this, we obtain the following theorems for the general case, cardinality case, and uniform profit-density case, respectively.

▶ **Theorem 26.** *For any constant $\varepsilon > 0$, there is a polynomial-time $(30/7 + \varepsilon)$-approximation algorithm for 3DKR.*

▶ **Theorem 27.** *For any constant $\varepsilon > 0$, there is a polynomial-time $(24/7 + \varepsilon)$-approximation algorithm for 3DKR when all items have the same profit.*

▶ **Theorem 28.** *For any constant $\varepsilon > 0$, there is a polynomial-time $(3 + \varepsilon)$-approximation algorithm for 3DKR when the profit of an item is equal to its volume.*

6 Conclusion

In this work, our primary focus has been to obtain improved polynomial-time approximation guarantees. Our current runtime of $n^{f(1/\varepsilon)}$ is mainly because of the step where we guess the containers and assign the items. Once this is done, every $\mathcal{A}_C$ runs in time $O(n \log^2 n)$. Hence, one interesting direction is whether the time to guess the containers and assign the items can be brought down to $(n \cdot (\log n)^{f(1/\varepsilon)})$ using the recent techniques of [4]. Another interesting open problem is to provide a tight approximation for algorithms based on container packing.

Abstract

We prove a fractional Helly theorem for k-flats intersecting fat convex sets. A family $\mathcal{F}$ of sets is said to be ρ-fat if every set in the family contains a ball and is contained in a ball such that the ratio of the radii of these balls is bounded by ρ. We prove that for every dimension d and positive reals ρ and α there exists a positive $\beta = \beta(d, \rho, \alpha)$ such that if $\mathcal{F}$ is a finite family of ρ-fat convex sets in $\mathbb{R}^d$ and an α-fraction of the $(k+2)$-size subfamilies from $\mathcal{F}$ can be hit by a k-flat, then there is a k-flat that intersects at least a β-fraction of the sets of $\mathcal{F}$. We prove spherical and colorful variants of the above results and prove a $(p, k+2)$-theorem for k-flats intersecting balls.

1 Introduction

We say that a family $\mathcal{T}$ of geometric objects *hits* or *pierces* another family $\mathcal{F}$ if for every $F \in \mathcal{F}$ there is a $T \in \mathcal{T}$ such that $T \cap F \neq \emptyset$. If $\mathcal{T}$ consists of a single k-flat (k-dimensional affine subspace), then we say that $\mathcal{F}$ has a k-transversal. In this language, Helly's theorem [10] states, that for a finite family $\mathcal{F}$ of convex sets in $\mathbb{R}^d$, if every subfamily of size $d+1$ has a 0-transversal, i.e., a point contained in all $d+1$ sets, then the whole family has a 0-transversal, i.e., a point contained in all the sets. Vicensini [21] asked whether one can generalize Helly's theorem to k-transversals for $0 < k < d$, but this was shown to be false by Santaló [19], who constructed arbitrarily large families of convex sets in the plane without a 1-transversal whose every proper subfamily has a 1-transversal.

A natural next question in this direction is whether the following fractional Helly theorem of Katchalski and Liu has any analog for k-transversals.

▶ **Theorem 1** (Katchalski and Liu [14]). *For every dimension d there exists a function $\beta\colon (0,1] \to (0,1]$ with the following property. Let $\mathcal{F}$ be a finite family of convex sets in $\mathbb{R}^d$ and $\alpha \in (0,1]$. If at least $\alpha\binom{|\mathcal{F}|}{d+1}$ of the $(d+1)$-size subfamilies of $\mathcal{F}$ have a 0-transversal, then there exists a subfamily of $\mathcal{F}$ of size at least $\beta(\alpha)|\mathcal{F}|$ which has a 0-transversal.*

Alon and Kalai showed that it can indeed be generalized to $(d-1)$-transversals (hyperplanes) intersecting convex sets.

▶ **Theorem 2** (Alon and Kalai [1]). *For every dimension d there exists a function $\beta\colon (0,1] \to (0,1]$ with the following property. Let $\mathcal{F}$ be a finite family of convex sets from $\mathbb{R}^d$ with $|\mathcal{F}| = n$. If for some positive α at least $\alpha\binom{n}{d+1}$ of the $(d+1)$-size subfamilies of $\mathcal{F}$ have a $(d-1)$-transversal, then there exists a subfamily of $\mathcal{F}$ of size at least $\beta(\alpha)n$ which has a $(d-1)$-transversal.*

Later, Alon, Kalai, Matoušek and Meshulam showed that the above statement does not generalize to 1-flats (lines) intersecting convex sets in $\mathbb{R}^3$.

▶ **Theorem 3** (Alon, Kalai, Matoušek and Meshulam [2]). *For every integers n and m there exists a family of at least n convex sets in $\mathbb{R}^3$ such that any m of them have a 1-transversal, but no $m+4$ of them have a 1-transversal.*

By a suitable lifting argument this implies that there are no fractional Helly theorems for k-flats intersecting convex sets if $0 < k < d-1$. Following this example it is natural to look for fractional Helly-type theorems for special kinds of sets and k-flats with $0 < k < d-1$. For example, Matoušek proved, that k-flats intersecting a family of sets with bounded description complexity admit a fractional Helly theorem [16]. A family of sets is said to have bounded description complexity, if each of the sets can be described using a bounded number of bounded degree polynomial inequalities.

▶ **Theorem 4** (Matoušek [16]). *For every dimension d there exists a function $\beta\colon (0,1] \to (0,1)$ with the following property. Let $\mathcal{F}$ be a finite family of sets of bounded description complexity in $\mathbb{R}^d$ and $\alpha \in (0,1]$. If at least $\alpha\binom{|\mathcal{F}|}{(k+1)(d-k)+1}$ of the $((k+1)(d-k)+1)$-size subfamilies of $\mathcal{F}$ have a k-transversal, then there exists a subfamily of $\mathcal{F}$ of size at least $\beta(\alpha)|\mathcal{F}|$ which has a k-transversal.*

We prove a fractional Helly theorem for ρ-fat convex sets. A family $\mathcal{F}$ of sets is ρ-fat, if for every $K \in \mathcal{F}$ there exist $x_K \in \mathbb{R}^d$ and $r_K, R_K \in \mathbb{R}$ such that $R_K \leq \rho r_K$ and K contains a ball of radius r_K centered at x_k and is contained in a ball of radius R_K centered at x_k.[1]

▶ **Theorem 5.** *For every d and ρ there exists a function $\beta\colon (0,1] \to (0,1)$ with the following property. Let $\mathcal{F}$ be a finite family of ρ-fat convex sets in $\mathbb{R}^d$, $0 \leq k \leq d$ an integer, and $\alpha \in (0,1]$. If at least $\alpha\binom{|\mathcal{F}|}{k+2}$ of the $(k+2)$-tuples of $\mathcal{F}$ have a k-transversal, then $\mathcal{F}$ has a subfamily of size at least $\beta(\alpha)|\mathcal{F}|$ which has a k-transversal.*

As discussed above, the $k = d-1$ case is known to hold even without the fatness assumption [1], but the $0 < k < d-1$ case is known to be false without fatness, even if we replace the $(k+2)$-tuples in the assumption with m-tuples for any finite m [2].

Note that as any convex body in $\mathbb{R}^d$ can be made d-fat with an affine transformation by John's theorem [12], our result also holds for the family of homothets of any fixed convex body. For these, Matoušek's result would only work if the convex body has bounded union complexity, like a ball or a polyhedron, and even in this case would only give $((k+1)(d-k)+1)$-size subfamilies, which is improved by our $(k+2)$-size subfamilies for all $k < d-1$. (This is an improvement because by averaging if some α fraction of the $((k+1)(d-k)+1)$-tuples intersect, then also some α fraction of the $(k+2)$-tuples intersect.)

[1] Note that requiring these balls to be concentric is not a significant restriction; if K is contained in some ball of radius R, then it is contained in a ball of radius $2R$ centered at any point of K.

The proof of our main Theorem 5 can be found in Section 2. Along the way we prove spherical and colorful variants of the result as well.

Now we turn to the history of our other main result. A celebrated generalization of Helly's theorem is the following (p, q)-theorem of Alon and Kleitman.

▶ **Theorem 6** (Alon and Kleitman [3]). *For every $p \geq d+1$ there exists $C(p, d)$ such that the following holds. If $\mathcal{F}$ is a family of compact convex sets in $\mathbb{R}^d$ such that among any p members of $\mathcal{F}$ there are $d+1$ with a 0-transversal, then there exist at most C points hitting all of $\mathcal{F}$.*

The fractional Helly theorem of Katchalski and Liu plays a crucial role in the proof of Theorem 6. It would be very interesting to know whether our fractional Helly theorem for k-flats intersecting ρ-fat convex sets has such a corollary.

▶ **Conjecture 7.** *For every p, d, k and ρ there exists a C such that the following holds. If $\mathcal{F}$ is a family of ρ-fat compact convex sets in $\mathbb{R}^d$ such that among any p members of $\mathcal{F}$ there are $k+2$ with a k-transversal, then there exist at most C k-flats hitting all of $\mathcal{F}$.*

We do not even know whether the statement holds if we replace $k+2$ by any $m > k+2$ which does not depend on $\mathcal{F}$. The missing ingredient is a weak ε-net theorem for k-flats intersecting ρ-fat convex bodies. In Section 4, we discuss how two of the main approaches used to prove the existence of (weak) ε-nets fails in our case. As one of the standard approaches can be used if we replace ρ-fat convex sets with balls (1-fat convex sets), we obtain the following corollary.

▶ **Theorem 8.** *For every three positive integers d, $k < d$ and $p \geq k+2$ there exists a $C = C(d, k, p)$ such that the following holds. If $\mathcal{F}$ is a (possibly infinite) family of closed balls in $\mathbb{R}^d$ such that among any p members of $\mathcal{F}$ there are $k+2$ that can be hit by a single k-flat, then there exist at most C k-flats hitting all of $\mathcal{F}$.*

Theorem 8 follows from results in Section 4. We show spherical and colorful variants of this result as well. Note that a weaker version of Theorem 8, where we replace $k+2$ by $(k+1)(d-k)+1$ follows from the more general results of Matoušek [16].

Keller and Perles showed that if $\mathcal{F}$ is an infinite family of d-dimensional balls, and among any $\aleph_0$ balls some $k+2$ balls have a k-transversal, then the whole family can be pierced with finitely many k-dimensional affine subspaces [15]. In a forthcoming paper [13] it is shown that this infinite variant follows from our Theorems 5 and 8 with a purely combinatorial proof.

Our Theorem 8 generalizes to certain uniformly fat families as follows. A family $\mathcal{F}$ of sets in $\mathbb{R}^d$ is called (r, R)-fat if for every $K \in \mathcal{F}$ there is an $x_K \in \mathbb{R}^d$ such that $B(x_K, r) \subseteq K \subseteq B(x_K, R)$. Note that an (r, R)-fat family is ρ-fat with $\rho = \frac{R}{r}$ but a ρ-fat family might not be (r, R)-fat for any fixed r, R as it can contain arbitrarily small and large sets. Because of this, the argument described in the next paragraph, does not apply directly to ρ-fat sets in $\mathbb{R}^d$.

Fractional Helly and (p, q)-type results about k-transversals of (congruent) balls generalize easily to (not necessarily convex) (r, R)-fat sets as were described in [6, 15].

▶ **Corollary 9.** *For every three positive integers d, $k < d$ and $p \geq k+2$, and positive reals $r \leq R$ there exists a $C = C(d, k, p, R/r)$ such that the following holds. If $\mathcal{F}$ is a (possibly infinite) family of (r, R)-fat sets in $\mathbb{R}^d$ such that among any p members of $\mathcal{F}$ there are $k+2$ that can be hit by a single k-flat, then there exist at most C k-flats hitting all of $\mathcal{F}$.*

We give a short summary of the argument here. If among every p members of an (r, R)-fat family $\mathcal{F}$, there are $k+2$ which have a k-transversal, then so do the $(k+2)$-tuples of balls of radius R containing them. We can apply Theorem 8 to the family of R-balls to obtain a bounded size family $\mathcal{T}$ of k-flats hitting all the balls. By considering parallel k-flats close to members of $\mathcal{T}$, we can conclude that a bounded number of them stab the r-balls contained in the members of $\mathcal{F}$. Therefore, there is a bounded size family of k-flats hitting every member of $\mathcal{F}$. This argument works even in the case when the members of $\mathcal{F}$ are not convex. Not even connectedness is required, only (r, R)-fatness.

Holmsen and Matoušek asked whether a fractional Helly theorem exists for disjoint translates of a convex set in $\mathbb{R}^3$ with respect to lines [11]. As any convex body in $\mathbb{R}^3$ can be made 3-fat with an affine transformation, our Theorem 5 answers their question. But we cannot really take credit for this, as a positive answer already follows from a result of Matoušek [16] combined with the trick of making the set $(1, 3)$-fat with an affine transformation, and then using the reduction to balls that we sketched earlier. This method would only give a fractional Helly theorem where the assumption is about lines intersecting 5-tuples of sets (without using our Theorem 5); it was observed by Dobbins and Holmsen a few years ago (personal communication), independently of us, that this can be improved to the optimal 3, and they have also obtained fractional Helly theorems for (r, R)-fat sets with respect to k-flats (unpublished).

As another direction generalizing Helly-type theorems to k-transversals, we mention a result of Hadwiger which shows that although Helly's theorem does not generalize directly to 1-transversals, a finite family of pairwise disjoint convex sets in the plane has a 1-transversal if and only if the family has a linear ordering such that any 3-tuple of convex sets has a 1-transversal which is consistent with the ordering [8] (see the definition there). Hadwiger's result has been generalized to $(d-1)$-transversals by Goodman, Pollack and Wenger [7], and very recently to k-transversals for any $0 \leq k < d$ by McGinnis and Sadovek [17].

2 Fractional Helly Theorems

In this section we prove Theorem 5 in the below more general, colorful form, an analog of a colorful version of the fractional Helly theorem due to Bárány, Fodor, Montejano, Oliveros, and Pór [5]. Note that our Theorem 5 is a special case of Theorem 10 with $\mathcal{F}_i = \mathcal{F}$ for all i.

▶ **Theorem 10.** *For every $\rho \geq 1$ and every dimension d there exists a function $\beta : (0, 1] \to (0, 1)$ with the following property. Let $\mathcal{F}_1, \ldots, \mathcal{F}_{k+2}$ be families of ρ-fat convex sets in $\mathbb{R}^d$. If at least $\alpha|\mathcal{F}_1| \cdots |\mathcal{F}_{k+2}|$ of the colorful selections have a k-transversal, then there exists an i with $\mathcal{F}_i$ having a subfamily of size at least $\beta(\alpha)|\mathcal{F}_i|$ which has a k-transversal.*

Our inductive proof of Theorem 10 also requires a spherical analog, for which we need the following definitions. A cap of the sphere $\mathbb{S}^d$ is the intersection of $\mathbb{S}^d$ with a ball in $\mathbb{R}^{d+1}$ (we can assume that the center of the ball is on $\mathbb{S}^d$), a great k-sphere is the intersection of $\mathbb{S}^d$ with a $(k+1)$-dimensional linear subspace of $\mathbb{R}^{d+1}$ (assuming that the origin is the center of $\mathbb{S}^d$), and a spherical k-transversal for a spherical family is a great k-sphere intersecting all members of the family. We can describe caps as subsets of $\mathbb{S}^d$ of the form $B(x, \varepsilon) = \{y \in \mathbb{S}^d : \angle(x, y) = \cos^{-1}(xy) \leq \varepsilon\}$ where $x \in \mathbb{S}^d$. Beware that the definition of $B(x, r)$ implicitly depends on the space we are working in! We intentionally do not use a different notation so that our argument can be described more generally, but it will be always clear from the context in which space we are in. A ρ-fat family of spherical sets can be defined analogously to the Euclidean case, with the existence of caps $B(x_K, r_K)$ and $B(x_K, R_K)$ for

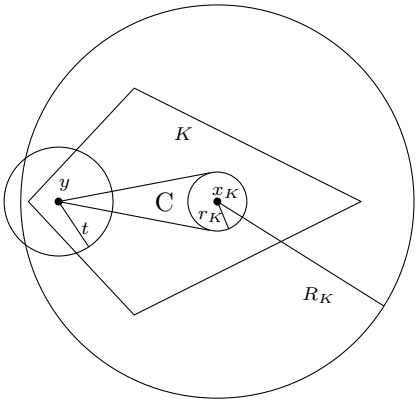

Figure 1 A property of fat convex sets.

every $K \in \mathcal{F}$ with the property that $B(x_K, r_K) \subset K \subset B(x_K, R_K)$ and $R_K \leq \rho r_K$. A set $K \subset \mathbb{S}^d$ is (spherically) convex, if either $K = \mathbb{S}^d$, or for no $v \in \mathbb{S}^d$ we have both $v, -v \in K$, and K contains the shorter great circle arc connecting any two points from K.

▶ **Theorem 11.** *For every $\rho \geq 1$ and every dimension d there exists a function $\beta : (0, 1] \to (0, 1)$ with the following property. Let $\mathcal{F}_1, \ldots, \mathcal{F}_{k+2}$ be families of ρ-fat convex sets in $\mathbb{S}^d$. If at least $\alpha|\mathcal{F}_1| \cdots |\mathcal{F}_{k+2}|$ of the colorful selections have a spherical k-transversal, then there exists an i with $\mathcal{F}_i$ having a subfamily of size at least $\beta(\alpha)|\mathcal{F}_i|$ which has a spherical k-transversal.*

Notice that in fact Theorem 11 implies Theorem 10 as any counterexample in $\mathbb{R}^d$ would also give a counterexample on the surface of a large enough sphere $\mathbb{S}^d$ with small (compared to the radius of the sphere) ρ-fat sets on it. However, we prove both Theorems 10 and 11 as we believe that our argument is easier to understand in the more natural setting of $\mathbb{R}^d$, and then think it through that it also works in $\mathbb{S}^d$ without much change. We mark the differences in our simultaneous proof for both theorems with brackets [ ].

The following is a key property of ρ-fat convex sets.

▷ Claim 12. For all d and ρ we have a $\gamma > 0$ such that the following holds. If K is a ρ-fat convex set in $\mathbb{R}^d$ [or in $\mathbb{S}^d$], $y \in K$ and $t \leq R_K$, then $\mathrm{vol}(K \cap B(y, t)) \geq \gamma \,\mathrm{vol}(B(y, t))$, where $B(y, t)$ denotes the ball [or spherical cap] of radius t centered at y. (See Figure 1.)

Proof. Let $B(x_K, r_K) \subset K \subset B(x_K, R_K)$ with $R_K \leq \rho r_K$, and define $r'_K = \min(r_K, t) \geq t/\rho$ and $C = \mathrm{conv}(\{y\} \cup B(x_K, r_K)) \subset K$. C contains all the points u of $B(y, r'_K)$ such that $\angle(u - y, x_K - y)$ is at most some number depending only on ρ, so C contains a constant fraction of $B(y, t)$. ◁

Proof of Theorems 10 and 11. The proof is by induction on k and d. Let $n_i = |\mathcal{F}_i|$. Let $\mathcal{H}$ be the $(k + 2)$-uniform hypergraph with vertex set $\mathcal{F} = \cup \mathcal{F}_i$, where the edges are those colorful $(k + 2)$-tuples which have a [spherical] k-transversal. Charge every hyperedge to its member K with the smallest bounding radius R_K. In case of ties, charge arbitrarily to one of the members K with smallest R_K.

Since in total there are $\alpha n_1 \cdots n_{k+2}$ many charges, there is a color class $\mathcal{F}_i$ whose members are charged $\frac{\alpha}{k+2} n_1 \cdots n_{k+2}$ times. Without loss of generality, we may assume that this color class is $\mathcal{F}_{k+2}$. Pick the set K_0 from $\mathcal{F}_{k+2}$ with the most charge. By averaging, K_0 was charged at least $\frac{\alpha}{k+2} n_1 \cdots n_{k+1}$ times.

If $k = 0$, then we have $\frac{\alpha}{2}n_1$ sets from $\mathcal{F}_1$ intersecting $K_0 \in \mathcal{F}_2$. We have a point $y_K \in B(x_{K_0}, R_{K_0}) \cap K$ for all such $K \in \mathcal{F}_1$. Since $R_{K_0} \leq R_K$, the set K contains a positive fraction of the ball $B(y_K, R_{K_0})$ by Claim 12. Moreover, $B(y_K, R_{K_0})$ occupies a positive fraction of $B(x_{K_0}, 2R_{K_0})$, so it follows that every K contains a positive fraction of $B(x_{K_0}, 2R_{K_0})$. In this case, a constant fraction of the $\frac{\alpha}{2}n_1$ sets can be hit by a single point by the volumetric pigeonhole principle (where the constant depends only on the dimension and ρ).

If $k > 0$, we can reduce finding a [spherical] k-transversal in $\mathbb{R}^d$ [in $\mathbb{S}^d$] to finding a spherical $(k-1)$-transversal in $\mathbb{S}^{d-1}$ as follows.

Euclidean case. If we are in the Euclidean space $\mathbb{R}^d$, we may assume that $B_0 = B(x_{K_0}, R_{K_0})$ is the unit ball centered at the origin. Let $K' = K + B_0$ (where $+$ denotes the Minkowski sum) if $K \in \cup\mathcal{F}_i \setminus \{K_0\}$, and let K'_0 be the degenerate ball containing only the origin. Denote the new families by $\mathcal{F}' = \cup\mathcal{F}'_i$.

▷ Claim 13. At least $\frac{\alpha}{k+2}n_1 \cdots n_{k+1}$ of the colorful selections of $\mathcal{F}'_1, \ldots, \mathcal{F}'_{k+1}$ have a k-dimensional *linear* subspace hitting them.

Proof. The set K_0 was charged $\frac{\alpha}{k+2}n_1 \cdots n_{k+1}$ times. Take $K_1 \in \mathcal{F}_1, \ldots, K_{k+1} \in \mathcal{F}_{k+1}$ such that $\{K_0, K_1, \ldots, K_{k+1}\}$ was charged to K_0 and translate their hitting k-flat to the origin. As the translation is by at most R_{K_0}, if any K_i was hit by the original k-flat, then K'_i is hit by the translated (linear) k-flat. ◁

Now, centrally project every set in $\mathcal{F}' \setminus \{K'_0\}$ to the surface of the unit sphere from the origin. (If a set contains the origin, its projection is the entire sphere.)

▷ Claim 14. A projection of a ρ-fat convex set is $\frac{\pi}{2}\rho$-fat.

Proof. The projection of a ball $B(x, r)$ to the unit sphere centered at the origin is a cap of the unit sphere with radius $\sin^{-1}(r/t)$ if x is at distance $t \geq r$ of the origin. Thus, the projection of a ρ-convex set K is $\frac{\sin^{-1}(R_K/t)}{\sin^{-1}(r_K/t)}$-fat if x_K is at distance $t > R_K$ from the origin. But $t \leq \sin^{-1}(t) \leq \frac{\pi}{2}t$, thus $\frac{\sin^{-1}(R_K/t)}{\sin^{-1}(r_K/t)} \leq \frac{\pi}{2}\frac{R_k}{r_k} = \frac{\pi}{2}\rho$ and the image of K is $\frac{\pi}{2}\rho$-fat.

If $t \leq R_K$, then the projection of $B(x_K, r_K)$ is a cap with radius $\sin^{-1}(r_K/t) \geq \frac{r_K}{t} \geq \frac{1}{\rho}$. Either the projection of K is contained in a cap of radius $\pi/2$ and contains a cap of radius $\frac{1}{\rho}$, or the image of K is the complete unit sphere. In both cases the projection is $\frac{\pi}{2}\rho$-fat. ◁

Denote the obtained family of $\rho' = \frac{\pi}{2}\rho$-fat spherically convex sets by $\mathcal{F}^*$. As $\frac{\alpha}{k+2}n_1 \cdots n_{k+1}$ of the colorful selections of $\mathcal{F}'_1, \ldots, \mathcal{F}'_{k+1}$ have a k-dimensional *linear* subspace hitting them by Claim 13, we have that $\frac{\alpha}{k+2}n_1 \cdots n_{k+1}$ of the colorful selections of $\mathcal{F}^*_1, \ldots, \mathcal{F}^*_{k+1}$ have a great $(k-1)$-sphere intersecting them. The assumptions of the spherical colorful fractional Helly Theorem 11 on $\mathbb{S}^{d-1}$ with great $(k-1)$-spheres are satisfied, thus we have an $i \in [k+1]$ and a subfamily $\mathcal{G}^* \subset \mathcal{F}^*_i$ of size at least $\beta^*|\mathcal{F}^*_i|$ which can be hit by a great $(k-1)$-sphere, where β^* is the value we obtain from Theorem 11 with parameters $d-1, k-1$ and $\frac{\alpha}{k+2}$. This means that the corresponding family of preimages $\mathcal{G}' = \{K' \in \mathcal{F}' : \mathrm{proj}_{\mathbb{S}^{d-1}} K' \in \mathcal{G}^*\}$ can be hit by a k-dimensional linear subspace F. Let $\mathcal{G} = \{K \in \mathcal{F} : K' \in \mathcal{G}'\}$. If we project K_0 and every set $K \in \mathcal{G}$ to the orthogonal complement $F^\perp$ of F, every projected set $\mathrm{proj}_{F^\perp} K$ will intersect the set $\mathrm{proj}_{F^\perp} K_0$.

Since for all K there exists a $y_K \in B(0,1) \cap \mathrm{proj}_{F^\perp} K$, and $\mathrm{proj}_{F^\perp} K$ contains a ball of $F^\perp$ of radius ρ, we know that K occupies a constant fraction of $B(y_K, 1) \cap F^\perp \subset B(0,2) \cap F^\perp$ by Claim 12 and thus a positive fraction of $B(0,2) \cap F^\perp$. By the pigeonhole principle

we can find a point $x \in F^\perp$ in the intersection of a constant fraction of the projections $\{\text{proj}_{F^\perp} K : K \in \mathcal{G}'\}$. $F + x$ (the translation of F by x) is a k-flat intersecting a constant fraction of the fat convex sets in $\mathcal{G}'$.

Spherical case. For this case, we need some claims about the geometry of spherical caps and great k-spheres which are described in Section 3, but otherwise the main argument is the same as in the Euclidean case. First, we deal with the case where there are many large sets in $\cup_i \mathcal{F}_i$. Note that we may assume that all the n_is are large enough, otherwise a β-fraction of a color class will consists of a single set K (if β is chosen to be small enough). Let $c < \alpha/(k+2)$ be a small constant. If there is an $\mathcal{F}_i$ such that for at least cn_i of the sets $K \in \mathcal{F}_i$ we have $R_K > \pi/8$, then a constant fraction of them can be hit with a single point by the volumetric pigeonhole principle, as all of them contain caps with radius at least $\rho\pi/8$. This constant fraction depends only on d and ρ. If we do not have this many large sets in any of the $\mathcal{F}_i$, we can simply delete the large ones, as this way we loose at most $c(k+2)n_1 \dots n_{k+2}$ out of the original $\alpha n_1 \dots n_{k+2}$ colorful $(k+2)$-tuples with a spherical k-transversal. Thus, we can have families of size at least $(1-c)n_i$ with at least an $(\alpha - c(k+2))n_1 \dots n_{k+2}$ colorful $(k+2)$-tuples having a spherical k-transversal and no set K in the families with $R_K > \pi/8$.

Let K_0 be the most charged set as defined above, let $\varepsilon = R_{K_0}$ and $B_0 = B(x_{K_0}, \varepsilon)$. For a set $K \subset \mathbb{S}^d$, its ε-neighborhood is $K^\varepsilon = \{u \in \mathbb{S}^d : \exists v \in K \text{ with } \angle(u,v) \le \varepsilon\}$, and $\text{conv}(K)$ is the intersection of all the spherically convex sets containing K. If K is a ρ-fat convex set, then $\text{conv}(K^\varepsilon)$ is a ρ-fat convex set by Claim 15. For every $K \in \cup\mathcal{F}_i \setminus \{K_0\}$, let $K' = \text{conv}(K^\varepsilon)$ and let $K_0' = \{x_{K_0}\}$. Denote the new families of spherically convex ρ-fat sets by $\mathcal{F}' = \cup\mathcal{F}_i'$. By Claim 16, if some sets in $\mathcal{F}$ can be hit by a great k-sphere, then the corresponding sets in $\mathcal{F}'$ can be hit by a great k-sphere as well. Now let $\mathcal{F}^* = \text{proj}_{B_0} \mathcal{F}'$, where proj_{B_0} denotes the projection into the boundary ∂B_0. By Claim 19, $\mathcal{F}^*$ is a family of spherically convex $\rho' = \frac{\pi^3}{4}\rho^2$-fat sets of the $(d-1)$-dimensional sphere ∂B_0. Without loss of generality, assume that $K_0 \in \mathcal{F}_{k+2}$. As K_0 is the most charged set, at least $\frac{\alpha}{k+2}$-fraction of the colorful selections of $\mathcal{F}_1', \dots, \mathcal{F}_{k+1}'$ have a spherical k-transversal containing x_0. These great k-spheres of $\mathbb{S}^d$ become great $(k-1)$-spheres of ∂B_0 after the projection. Thus, at least $\frac{\alpha}{k+2}$-fraction of the colorful selections of $\mathcal{F}_1^*, \dots, \mathcal{F}_{k+1}^*$ have a $(k-1)$-transversal. The assumptions of the spherical colorful fractional Helly Theorem 11 on ∂B_0 with spherical $(k-1)$-transversals are satisfied, thus we have an i and a subfamily $\mathcal{G}^* \subset \mathcal{F}_i^*$ of size at least $\beta^*|\mathcal{F}_i^*|$ which has a spherical $(k-1)$-transversal. This means that the corresponding family of preimage sets $\mathcal{G}'$ has a spherical k-transversal. By Claim 20, a large subfamily of $\mathcal{G}$ has a spherical k-transversal as well. ◀

3 Caps and projections on the sphere

In this section, we prove the claims about spherical sets that were used in the proof of Theorem 11. All the arguments are fairly straight-forward modifications of the simple proofs used in the Euclidean case, but more tedious calculations are required.

Recall that $B(v,\varepsilon)$ is the spherical cap centered at v with angle ε, and a great k-sphere of $\mathbb{S}^d$ is the intersection of $\mathbb{S}^d$ with a $(k+1)$-dimensional linear subspace of $\mathbb{R}^{d+1}$ [4]. A great 1-sphere is called a great circle.

For $u \in \mathbb{S}^d \setminus \{v, -v\}$, let $\text{rot}(u,v)$ be the rotation r with $r(u) = v$ which is constant on $\text{span}(\{u,v\})^\perp$, so we rotate with the uov angle $\angle(u,v)$ around the center o, keeping $\text{span}(\{u,v\})^\perp$ fixed. If $u \notin \{v,-v\}$, the projection of $u \in \mathbb{S}^d$ onto the boundary $\partial B(v,\varepsilon)$ of the cap $B(v,\varepsilon)$ is the intersection of $\partial B(v,\varepsilon)$ with the halfplane embedded in $\mathbb{R}^{d+1}$ containing

o and v on its boundary, and u in its interior. In other words, if $u \notin B(v,\varepsilon)$, then the projection is the point of $\partial B(v,\varepsilon)$ that is hit when we rotate u to v. It is denoted by $\mathrm{proj}_B(u)$, or simply $\mathrm{proj}(u)$ if B is clear from the context. For any set X and cap $B = B(v,\varepsilon)$, let $\mathrm{proj}_B X = \{\mathrm{proj}_B(u) : u \in X\}$ if $X \cap \{v,-v\} = \emptyset$, and let $\mathrm{proj}_B X = B$ if $X \cap \{v,-v\} \neq \emptyset$.

▷ Claim 15. If $K \subseteq \mathbb{S}^d$ is ρ-fat, then $\mathrm{conv}(K^\varepsilon)$ is ρ-fat as well.

Proof. If $\mathrm{conv}(K^\varepsilon) = \mathbb{S}^d$, then it is ρ-fat with $\rho = 1$. Otherwise, as $B(x_K, r_K+\varepsilon) \subseteq \mathrm{conv}(K^\varepsilon) \subseteq B(x_K, R_K+\varepsilon)$, the ρ-fatness of K^ε follows from $\frac{R_K+\varepsilon}{r_K+\varepsilon} \leq \frac{R_K}{r_K} \leq \rho$. ◁

▷ Claim 16. If the spherical sets $K_1,\dots,K_n \subset \mathbb{S}^d$ can be pierced with a great k-sphere, and $K_1 \subset B(v,\varepsilon)$, then $B(v,0), K_2^\varepsilon, \dots, K_n^\varepsilon$ can also be pierced with a great k-sphere.

Proof. Take a great k-sphere F intersecting all of $K_1,\dots,K_n \subset \mathbb{S}^d$, let $v' = \mathrm{proj}_F(v)$ and $\mathrm{rot} = \mathrm{rot}(v',v)$. For any point $u \in \mathbb{S}^d$, the spherical distance between u and $\mathrm{rot}(u)$ is at most ε. Hence, if $u \in K_i \cap F$, then $\mathrm{rot}(u) \in K_i^\varepsilon \cap \mathrm{rot}(F)$, thus the great k-sphere $\mathrm{rot}(F)$ intersects all of $B(v,0), K_2^\varepsilon, \dots, K_n^\varepsilon$. ◁

We want to show that during a gnomonic projection the distance of two points close to the center of the projected image cannot be distorted too much. This is probably a well-known statement, but we could not find it anywhere, so we include the simple calculation below. If we embed $\mathbb{S}^d$ into $\mathbb{R}^{d+1}$ as the unit sphere, the spherical distance of x and y becomes $\angle(x,y)$, while their Euclidean distance is $|x-y|$.

▷ Claim 17. Embed $\mathbb{S}^d$ into $\mathbb{R}^{d+1}$ as the unit sphere. If $u,v \in B(w,\pi/4) \subset \mathbb{S}^d$ and p is the central projection from the origin to the supporting hyperplane of $\mathbb{S}^d$ at w, then we have $\angle(u,v) \leq |p(u)-p(v)| \leq 2\angle(u,v)$.

Proof. As u,v,w are contained in a 2-dimensional subsphere, it is enough to show the claim for $d=2$. First we calculate the distortion of length if u and w have the same latitude of longitude.

Case 1: u,v,w are on the same great circle. As we have $|p(u)-w| = \tan(\angle(u,w))$ and $1 \leq \tan'(\varphi) \leq 2$ if $\varphi \in (0,\pi/4)$, we have $\angle(u,v) \leq |u-v| \leq 2\angle(u,v)$.

Case 2: $\angle(u,w) = \angle(v,w) = \varphi$. In this case p acts on them as a homothety with ratio $1/\cos(\varphi)$, which is between 1 and $\sqrt{2}$ if $\varphi \in (0,\pi/4)$.

We can argue that these are the extreme cases and the distortion of length is always between 1 and 2. We show that for close enough points the distortion of distance is between 1 and 2. But then the global distortion has to be in the same interval.

For every $u \in B(w,\pi/4)$ the points of $\mathbb{S}^d$ with a small enough given distance from u form a circle inside $B(w,\pi/4)$. Its image under p is an ellipse. Due to symmetry the axes of the ellipse correspond to point pairs with the same latitude or longitude. We have seen in Cases 1 and 2 that the ratios of the lengths of the axes and the radius of the circle are between 1 and 2. But then for every point v in the circle we have $\angle(u,v) \leq |p(u)-p(v)| \leq 2\angle(u,v)$. ◁

▷ Claim 18. If $K \subseteq B(w,\pi/8) \subset \mathbb{S}^d$ is convex and $\varepsilon \leq \pi/8$, then $\mathrm{conv}(K^\varepsilon) \subset K^{2\varepsilon}$.

Proof. If $u \in \mathrm{conv}(K^\varepsilon)$, then there are $u',u'' \in K^\varepsilon$ such that $u \in \mathrm{conv}(\{u',u''\})$. Let $v',v'' \in K$ be such that $\angle(u',v'), \angle(u'',v'') \leq \varepsilon$. Let p be the central projection of $B(w,\pi/4)$ from the origin to the supporting hyperplane of $\mathbb{S}^d$ at w. As $u',u'',v',v'' \in B(w,\pi/4)$, we have $|p(u')-p(v')|, |p(u'')-p(v'')| \leq 2\varepsilon$ by Claim 18. As the projections of $\mathrm{conv}(\{u',u''\})$ and $\mathrm{conv}(\{v',v''\})$ are segments of a Euclidean space whose endpoints have distance at most 2ε, there is a point $v \in \mathrm{conv}(\{v',v''\})$ such that $|p(v)-p(u)| \leq 2\varepsilon$. We have $\angle(u,v) \leq 2\varepsilon$ by Claim 18. As $v \in K$, this proves $u \in K^{2\varepsilon}$. ◁

▷ Claim 19. Let $B = B(v, \varepsilon)$ be a cap, and K be a ρ-fat convex set of $\mathbb{S}^d$. The projection $\mathrm{proj}_B K$ is a $\frac{\pi^3}{4}\rho^2$-fat convex set of the $(d-1)$-dimensional sphere ∂B.

Proof. If $\mathrm{proj}_B K = B$, then it is convex by definition. Otherwise, as proj_B maps (shorter) great circle arcs to (shorter) great circle arcs or points, the projection is convex. Let $\rho' = \frac{\pi^3}{4}\rho^2$. To show ρ'-fatness, we need to examine how the radius of $B(x_K, r_K) \subset K$ and $B(x_K, R_K) \supset K$ change after the projection.

Assume that $B(x, r)$ is any cap of $\mathbb{S}^d$ and $v \notin B(x, r)$. Embed $\mathbb{S}^d$ in $\mathbb{R}^{d+1}$ as the unit sphere and look at the simplex spanned by $\underline{0}, x, v$ and b where $b \in \partial B(x, r)$. The radius φ of $\mathrm{proj}_{B(v,\varepsilon)} B(x, r)$ will be $\max_b \angle(b - v, x - v)$.

As $\frac{\sin\angle(b-v,x-v)}{|x-b|} = \frac{\sin\angle(x-b,v-b)}{|x-v|}$ by the law of sines, $\angle(b - v, x - v)$ is maximal if $\angle(x - b, v - b) = \pi/2$. Fix such a b. We have $\sin\varphi = \frac{|x-b|}{|x-v|}$.

Let $\angle(v, x) = t$. As $|x| = |v| = |b| = 1$, we have $|x-v| = 2-2\cos t$ and $|x-b| = 2-2\cos r$ by the law of cosines. As $1 - \cos t = \sin^2(t/2)$ and $\sin t \le t$, we have $\varphi \ge \sin\varphi = \frac{|x-b|}{|x-v|} = \frac{\sin^2(r/2)}{\sin^2(t/2)}$. If $\varphi \le \pi/2$, then we also have $\varphi \le \frac{\pi}{2}\sin\varphi = \frac{\pi}{2}\frac{\sin^2(r/2)}{\sin^2(t/2)}$.

Now returning to the proof, for simplicity we will write proj for proj_B. Let φ_r and φ_R be such that $\mathrm{proj}\, B(x_K, r_K) = B(\mathrm{proj}\, x_K, \varphi_r)$ and $\mathrm{proj}\, B(x_K, R_K) = B(\mathrm{proj}\, x_K, \varphi_R)$.

If $\varphi_R \ge \pi/2$, then $R \ge t$. In this case we have either $\varphi_r \ge \pi/2$ or $\varphi_r \ge \sin\varphi_r = \frac{\sin^2(r/2)}{\sin^2(t/2)} \ge \frac{4}{\pi^2}\frac{r^2}{t^2} \ge \frac{4}{\pi^2}\frac{r^2}{t^2} \ge \frac{4}{\pi^2\rho^2}$ and so $\varphi_R \le \pi \le \frac{\pi^3}{4}\rho^2\varphi_r$.

Otherwise $\varphi_R < \varphi/2$ and we have $\frac{\varphi_R}{\varphi_r} \le \frac{\pi}{2}\frac{\sin\varphi_R}{\sin\varphi_r} = \frac{\pi}{2}\frac{\sin^2(R/2)}{\sin^2(r/2)} \le \frac{\pi^3}{8}\frac{R^2}{r^2} \le \frac{\pi^3}{8}\rho^2$. As $\mathrm{proj}\, B(x_K, r_K) \subset \mathrm{proj}\, K \subset \mathrm{proj}\, B(x_K, R_K)$, in this case K is $\frac{\pi^3}{8}\rho^2$-fat. ◁

▷ Claim 20. For every d, ρ and k there exists a constant $c > 0$ such that the following holds for every $\varepsilon > 0$. Let $K_2, \dots, K_n$ be ρ-fat convex sets of $\mathbb{S}^d$ with $\varepsilon \le R_{K_i}$ for all $i \in \{2, \dots, n\}$. If $\mathrm{conv}(K_2^\varepsilon), \dots, \mathrm{conv}(K_n^\varepsilon)$ can be hit with a great k-sphere, then cn sets from $K_2, \dots, K_n$ can be hit with a great k-sphere as well.

Proof. If $R_{K_i} \ge \pi/8$ for at least half of the sets, then, as those sets all contain caps of radius at least $\pi/(8\rho)$, a constant fraction of them can be hit even with a single point by the volumetric pigeonhole principle. Otherwise delete all the sets K_i with $R_{K_i} \ge \pi/8$ and at least half of the sets remain. Let the family of the remaining at least $n/2$ sets be $\mathcal{H}$.

Let F be the great k-sphere hitting all the sets of $\{\mathrm{conv}(K^\varepsilon) : K \in \mathcal{H}\}$. In this case, all $K \in \mathcal{H}$ are at distance at most 2ε from F by Claim 18.

If $k = 0$, let $F = \{\pm v\}$. For all $K \in \mathcal{H}$ there exists a $y_K \in K$ which is at distance at most 2ε from one of the two antipodal points of F. As K occupies a constant fraction of $B(y_K, \varepsilon)$ by Claim 12 and $B(y_K, \varepsilon)$ contains a constant fraction of $B(v, 2\varepsilon) \cup B(-v, 2\varepsilon)$, the volumetric pigeonhole principle yields a point intersecting cn of the sets of $\mathcal{H}$.

We can reduce the $k > 0$ case to the $k = 0$ case with a suitable projection. For a $K \in \mathcal{H}$, let $f(K)$ be a closest point of F to K. Let $\delta = \delta(d, k) > 0$ be a small enough number, and let N be a metric δ-net of F (its size depends only on k and d). By the pigeonhole principle, there exists a point $u \in N$ and a subfamily $\mathcal{H}' \subset \mathcal{H}$ with $|\mathcal{H}'| \ge c'|\mathcal{H}|$ such that for all $K \in \mathcal{H}'$, the point $f(K)$ has distance at most δ from u.

Embed $\mathbb{S}^d$ into $\mathbb{R}^{d+1}$ as the unit sphere and let V be the $(k+1)$-dimensional linear subspace of $\mathbb{R}^{d+1}$ with $V \cap \mathbb{S}^d = F$. Let $u, u_1, \dots, u_k$ be an orthonormal basis of V. Let $B_i = B(u_i, \pi/2)$ be the halfsphere centered at u_i, let $\mathrm{proj}_i = \mathrm{proj}_{B_i}$ be the projection from $\mathbb{S}^d$ to ∂B_i as defined above, and let $\mathrm{proj}_{F,u} = \mathrm{proj}_1 \circ \mathrm{proj}_2 \circ \dots \circ \mathrm{proj}_k$. The repeated application of Claim 19 gives us that if $K \subset \mathbb{S}^d$ is a ρ-fat convex set, then $\mathrm{proj}_{F_u} K$ is a $\rho' = c^k\rho^{2k}$-fat convex set where $c \ge 1$ is a universal constant.

Apply $\mathrm{proj}_{F,u}$ to F and the sets of $\mathcal{H}'$ to get projections in the great $(d-k)$-sphere $\partial B_2 \cap \ldots \cap \partial B_k$. This way F becomes a pair of antipodal points $\{\pm u\}$, the projections of members of $\mathcal{H}'$ are ρ'-fat, and if $\delta(d,k)$ is sufficiently small, they are at distance at most 3ε from u. By the $k=0$ case we can find a point intersecting a constant fraction of the sets in $\{\mathrm{proj}_{F,u} K : K \in \mathcal{H}'\}$. The preimage of this point under $\mathrm{proj}_{F,u}$ is part of a great k-sphere of $\mathbb{S}^d$, and hits a constant fraction of $\mathcal{H}'$, thus a constant fraction of $\mathcal{H}$ and of $\{K_2, \ldots, K_n\}$. ◁

4 $(p, k+2)$-theorems

The specific $\rho = 1$ case of the fractional Helly results of Section 2 implies (p,q)-type results for k-flats intersecting balls. In this section we summarize arguments showing that Theorem 10 implies Theorem 8. The following colorful generalization can also be proved with a variant of this method. To keep the presentation simple, we only describe the arguments in a non-colorful setting. The interested reader can find a version of the colorful arguments in [5].

▶ **Theorem 21.** *For every three positive integers d, $k < d$ and $p \geq k+2$ there exists a C such that the following holds. If $\mathcal{F}_1, \ldots, \mathcal{F}_p$ are families of closed balls in $\mathbb{R}^d$ such that for every $B_1 \in \mathcal{F}_1, \ldots, B_p \in \mathcal{F}_p$ there are $k+2$ balls that can be hit by a single k-flat, then there exist an $i \in [p]$ and at most C k-flats hitting all balls of $\mathcal{F}_i$.*

By the same method, the following is a corollary of Theorem 11.

▶ **Theorem 22.** *For every three positive integers d, $k < d$ and $p \geq k+2$ there exists a C such that the following holds. If $\mathcal{F}_1, \ldots, \mathcal{F}_p$ are finite families of closed caps in $\mathbb{S}^d$ such that for every $B_1 \in \mathcal{F}_1, \ldots, B_p \in \mathcal{F}_p$ there are $k+2$ caps that can be hit by a great k-sphere, then there exist an $i \in [p]$ and at most C great k-spheres hitting all caps of $\mathcal{F}_i$.*

Note that the case where the families of balls (caps) can be infinite follows from the finite case by a standard compactness argument. The proofs of the finite versions are simple applications of the Alon-Kleitman method established in [3], later described in a more general setting in [2], and adapted to colorful variants in [5]. The abstract (purely combinatorial) proof described in [2] has two main steps. To state them, we phrase the fractional Helly and (p,q)-theorems in an abstract, purely combinatorial language as follows.

Let $\mathcal{H}$ be a set system over the base set V. For an integer q and a function $\beta\colon (0,1] \to (0,1]$, the set system $\mathcal{H}$ satisfies the fractional Helly property $\mathrm{FH}(q,\beta)$ if the following holds. For every $\alpha > 0$ and every finite family $\mathcal{G} \subset \mathcal{H}$, if $\alpha\binom{|\mathcal{G}|}{q}$ of the q-tuples of $\mathcal{G}$ has a nonempty intersection, then there exists a subfamily $\mathcal{G}' \subset \mathcal{G}$ of size $\beta(\alpha)|\mathcal{G}|$ such that all the members of $\mathcal{G}'$ have an element of V in common. The fractional Helly theorem of Katchalski and Liu (Theorem 1) states that if $V = \mathbb{R}^d$, and $\mathcal{H}$ consists of all the convex sets, then there exists β such that $\mathcal{H}$ satisfies $\mathrm{FH}(d+1,\beta)$. Our Theorem 5 states that if $V = \{k\text{-flats of } \mathbb{R}^d\}$ and $\mathcal{H}$ consists of families of k-flats intersecting a common ρ-fat convex set, then $\mathcal{H}$ satisfies $\mathrm{FH}(k+2,\beta)$ with some β.

A set system $\mathcal{H}$ satisfies the (p,q)-condition if among any p members of $\mathcal{H}$, some q intersect. Note that for $p \geq q \geq r$, the (p,q)-condition implies the (p,r)-condition. The transversal number $\tau(\mathcal{H})$ denotes the minimum size of a set $T \subset V$ with $T \cap H \neq \emptyset$ for all $H \in \mathcal{H}$. The fractional transversal number $\tau^*(\mathcal{H})$ is the minimum $\sum_{v \in V} t(v)$ over functions $t\colon V \to [0,1]$ with $\sum_{v \in H} t(v) \geq 1$ for all $H \in \mathcal{H}$. Alon, Kalai, Matoušek and Meshulam proved the following two theorems.

▶ **Theorem 23** (Theorem 8 in Alon, Kalai, Matoušek and Meshulam [2])**.** *If $\mathcal{H}$ satisfies $FH(q,\beta)$ and the (p,q)-condition with some $p \geq q$, then $\tau^*(\mathcal{H}) \leq O_{p,q,\beta}(1)$.*

Let $\mathcal{H}^\cap$ be the family of all sets that are the intersections of some members of $\mathcal{H}$.

▶ **Theorem 24** (Theorem 9 in Alon, Kalai, Matoušek and Meshulam [2]). *For every q and β there exists a function $f_{q,\beta}$ such that if $\mathcal{H}^\cap$ satisfies $FH(q,\beta)$, then $\tau(\mathcal{H}) \leq f_{q,\beta}(\tau^*(\mathcal{H}))$.*

Note that if $\mathcal{H}^\cap$ satisfies $F(q,\beta)$ and $\mathcal{H}$ satisfies the (p,q) condition, then its transversal number is bounded by a function of p, q and β as a consequence of the above two theorems. As the family of convex sets of $\mathbb{R}^d$ is closed under intersection, and satisfies $FH(d+1,\beta)$, this provides an alternative proof of Theorem 6 of Alon and Kleitman. But the same reasoning is usually not applicable to questions about k-transversals with $k > 0$, as the corresponding $\mathcal{H}^\cap \neq \mathcal{H}$ is hard to analyze, for example, for balls the intersections are no longer fat. However, in this special case, another proof method works.

If we restrict the question to k-transversals of balls [caps], as in Theorem 21 [Theorem 22], then we can bound τ as a function of τ^* and thus prove our $(p, k+2)$-theorems. The bound on τ follows from a classical result of Haussler and Welzl [9] . The VC-dimension of $\mathcal{H}$ is the supremum of the sizes of subsets $S \subseteq V$ such that for every $X \subseteq S$ there is an $H \in \mathcal{H}$ satisfying $H \cap S = X$.

▶ **Theorem 25** (Haussler and Welzl [9]). *For every d there exists a function f_d such that if $\mathcal{H}$ has VC-dimension at most d, then $\tau(\mathcal{H}) \leq f_d(\tau^*(\mathcal{H}))$.*

The VC-dimension of k-flats intersecting balls [caps] is bounded by the Milnor-Thom theorem on sign patterns of polynomials [18, 20], because a family of k-flats intersecting a given ball [cap] can be described by a bounded number of polynomial inequalities of bounded degree.

As for k-flats intersecting ρ-fat convex sets neither Theorem 24, nor Theorem 25 is applicable, the missing ingredient is proving a (p,q)-theorem for k-flats intersecting ρ-fat convex sets.

▶ **Conjecture 26.** *There is a function f such that if $\mathcal{H}$ consists of families of k-flats intersecting members of a family of ρ-fat convex sets in $\mathbb{R}^d$, then $\tau(\mathcal{H}) \leq f(\tau^*(\mathcal{H}))$.*

Abstract

The ℓ_2^2 min-sum k-clustering problem is to partition an input set into clusters $C_1, \ldots, C_k$ to minimize $\sum_{i=1}^{k} \sum_{p,q \in C_i} \|p-q\|_2^2$. Although ℓ_2^2 min-sum k-clustering is NP-hard, it is not known whether it is NP-hard to approximate ℓ_2^2 min-sum k-clustering beyond a certain factor.

In this paper, we give the first hardness-of-approximation result for the ℓ_2^2 min-sum k-clustering problem. We show that it is NP-hard to approximate the objective to a factor better than 1.056 and moreover, assuming a balanced variant of the Johnson Coverage Hypothesis, it is NP-hard to approximate the objective to a factor better than 1.327.

We then complement our hardness result by giving a fast PTAS for ℓ_2^2 min-sum k-clustering. Specifically, our algorithm runs in time $O(n^{1+o(1)}d \cdot 2^{(k/\varepsilon)^{O(1)}})$, which is the first nearly linear time algorithm for this problem. We also consider a learning-augmented setting, where the algorithm has access to an oracle that outputs a label $i \in [k]$ for input point, thereby implicitly partitioning the input dataset into k clusters that induce an approximately optimal solution, up to some amount of adversarial error $\alpha \in \left[0, \frac{1}{2}\right)$. We give a polynomial-time algorithm that outputs a $\frac{1+\gamma\alpha}{(1-\alpha)^2}$-approximation to ℓ_2^2 min-sum k-clustering, for a fixed constant $\gamma > 0$.

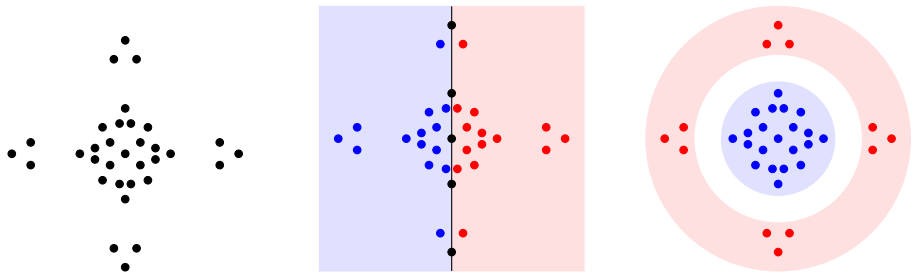
1 Introduction

Clustering is a fundamental technique that partitions an input dataset into distinct groups called clusters, which facilitate the identification and subsequent utilization of latent structural properties underlying the dataset. Consequently, various formulations of clustering are used across a wide range of applications, such as computational biology, computer vision, data mining, and machine learning [39, 70]. Ideally, the elements of each cluster are more similar to each other than to elements in other clusters. To formally capture this notion, a dissimilarity metric is often defined on the set of input elements, so that more closer objects in the metric correspond to more similar objects. Perhaps the most natural goal would be to minimize the intra-cluster dissimilarity in a partitioning of the input dataset. This objective is called the *min-sum k-clustering* problem and has received significant attention due to its intuitive clustering objective [33, 37, 58, 63, 11, 24, 22, 2, 12, 10, 18].

In this paper, we largely focus on the ℓ_2^2 min-sum k-clustering formulation. Formally, the input is a set X of n points in $\mathbb{R}^d$ and the goal is to partition $X = C_1 \dot\cup \cdots \dot\cup C_k$ into k clusters to minimize the quantity $\min_{C_1,\ldots,C_k} \sum_{i=1}^{k} \sum_{p,q\in C_i} \|p-q\|_2^2$, where $\|\cdot\|_2$ denotes the standard Euclidean ℓ_2 norm.

Whereas classical centroid-based clustering problems such as k-means and k-median leverage distances between data points and cluster centroids to identify convex shapes that partition the dataset, min-sum k-clustering is a density-based clustering that can handle complex structures in data that may not be linearly separable. In particular, min-sum k-clustering can be more effective than traditional centroid-based clustering in scenarios where clusters have irregular, non-convex shapes or overlapping clusters. A simple example of the ability of min-sum clustering to capture more natural structure is an input that consists of two concentric dense rings of points in the plane. Whereas min-sum clustering can partition the points into the separate rings, centroid-based clustering will instead create a separating hyperplane between these points, thereby "incorrectly" grouping together points of different rings. See Figure 1 for an example of the ability of min-sum clustering to capture natural structure in cases where centroid-based clustering fails.

Moreover, min-sum clustering satisfies Kleinberg's consistency axiom [47], which informally demands that the optimal clustering for a particular objective should be preserved when distances between points inside a cluster are shrunk and distances between points in different clusters are expanded. By contrast, many centroid-based clustering objectives, including k-means and k-median, do not satisfy Kleinberg's consistency axiom [57].



(a) Input dataset. **(b)** Centroid-based clustering. **(c)** Density-based clustering.

Figure 1 Clustering of input dataset in Figure 1a with $k = 2$. Figure 1b is an optimal centroid-based clustering, e.g., k-median or k-means, while the more natural clustering in Figure 1c is an optimal density-based clustering, e.g., ℓ_2 min-sum k-clustering.

On the other hand, theoretical understanding of density-based clustering objectives such as min-sum k-clustering is far less developed than that of their centroid-based counterparts. It can be shown that min-sum k-clustering with the ℓ_2^2 cost function is NP-hard, using arguments from [2]. The problem is NP-hard even for $k = 2$ [25] in the metric case, where the only available information about the points is their pairwise dissimilarity. In fact, for general k in the metric case, it is NP-hard to approximate the problem within a 1.415-multiplicative factor [32, 18]. However, no such hardness of approximation is known for the Euclidean case, i.e., ℓ_2^2 min-sum, where the selected cost function is based on the geometry of the underlying space; the only known lower bound is the NP-hardness of the problem [2, 10, 3]. Thus a fundamental open question is:

▶ **Question 1.** *Is ℓ_2^2 min-sum k-clustering APX-hard? That is, does there exist a natural hardness-of-approximation barrier for polynomial time algorithms?*

Due to existing APX-hardness results for centroid-based clustering such as k-means and k-median [50, 17, 19], it is widely believed that ℓ_2^2 min-sum clustering is indeed APX-hard. Thus, there has been a line of work preemptively seeking to overcome such limitations. Indeed, on the positive side, [36] first showed that min-sum k-clustering in the d-dimensional ℓ_2^2 case can be solved in polynomial time if both d and k are constants. For general graphs and fixed constant k, [33] gave a 2-approximation algorithm using runtime $n^{\mathcal{O}(k)}$. The approximation guarantees were improved by a line of work [37, 58, 63], culminating in polynomial-time approximation schemes by [24] for both the ℓ_2^2 case and the metric case. Without any assumptions on d and k, [11] introduced a polynomial algorithm that achieves an $\mathcal{O}\left(\frac{1}{\varepsilon}\log^{1+\varepsilon} n\right)$-multiplicative approximation. Therefore, a long-standing direction in the study of ℓ_2^2 min-sum clustering is:

▶ **Question 2.** *How can we algorithmically bridge the gap between the NP-hardness of solving the ℓ_2^2 min-sum clustering and the large multiplicative guarantees of existing approximation algorithms?*

A standard approach to circumvent poor dependencies on the size of the input dataset is to sparsify the problem. Informally, we would like to reduce the search space by considering fewer candidate solutions and reduce the dependency on the number of input points by aggregating them. For min-sum clustering this is a particular challenge, as a candidate solution is a partition and the cost of that partition depends on all pairwise distances between all the points. While sparsification algorithms exist for graph clustering [40, 51] and k-means clustering [21, 20], where the output is typically called a coreset, similar constructions are not known to exist for min-sum clustering.

Another standard approach to overcome limitations inherent in worst-case impossibility barriers is to consider beyond worst case analysis. To that end, recent works have observed that in many applications, auxiliary information is often available and can potentially form the foundation upon which machine learning models are built. For example, previous datasets with potentially similar behavior can be used as training data for models to label future datasets. However, these heuristics lack provable guarantees and can produce embarrassingly inaccurate predictions when generalizing to unfamiliar inputs [65]. Nevertheless, *learning-augmented algorithms* [60] have been shown to achieved both good algorithmic performance when the oracle is accurate, i.e., consistency, and standard algorithmic performance when the oracle is inaccurate, i.e., robustness for a wide range of settings, such as data structure design [48, 59, 55], algorithms with faster runtime [26, 15, 23], online algorithms with better

competitive ratio [62, 30, 49, 68, 69, 9, 35, 56, 1, 4, 8, 31, 45, 41, 5, 64], and streaming algorithms that are more space-efficient [34, 38, 43, 14, 13, 54]. In particular, [28, 61] introduce algorithms for k-means and k-median clustering that can achieve approximation guarantees beyond the known APX-hardness limits.

1.1 Our Contributions

In this paper, we perform a comprehensive study on the approximability of the ℓ_2^2 min-sum k-clustering by answering Question 1 and Question 2.

Hardness-of-approximation of min-sum k-clustering. We first answer Question 1 in the affirmative, by not only showing that the ℓ_2^2 min-sum k-clustering is APX-hard but further giving an explicit constant NP-hardness of approximation result for the problem.

▶ **Theorem 3** (Hardness of approximation of ℓ_2^2 min-sum k-clustering)**.** *It is NP-hard to approximate ℓ_2^2 min-sum k-clustering to a factor better than* 1.056*. Moreover, assuming the Dense and Balanced Johnson Coverage Hypothesis (*$\mathsf{Balanced} - \mathsf{JCH}^*$*), we have that the ℓ_2^2 min-sum k-clustering is NP-hard to approximate to a factor better than* 1.327*.*

We remark that $\mathsf{Balanced} - \mathsf{JCH}^*$ in the theorem statement above is simply a balanced formulation of the recently introduced Johnson Coverage Hypothesis [19].

Fast polynomial-time approximation scheme. In light of Theorem 3, a natural question would be to closely examine alternative conditions in which we can achieve a $(1+\varepsilon)$-approximation to min-sum k-clustering, i.e., Question 2. To that end, there are a number of existing polynomial-time approximation schemes (PTAS) [37, 58, 63, 24], the best of which uses runtime $n^{\mathcal{O}\left(k/\varepsilon^2\right)}$ for the ℓ_2^2 case. However, as noted by [22], even algorithms with runtime quadratic in the size n of the input dataset are generally not sufficiently scalable to handle large datasets. In this paper, we present an algorithm with a running time that is nearly nearly linear. Specifically, we show

▶ **Theorem 4.** *There exists an algorithm running in time $O\left(n^{1+o(1)}d \cdot 2^{\eta \cdot k^2 \cdot \varepsilon^{-12}\log^2(k/(\varepsilon\delta))}\right)$, for some absolute constant η, that computes a $(1+\varepsilon)$-approximate solution to ℓ_2^2 k-MinSum Clustering with probability $1-\delta$.*

We again emphasize that the runtime of 4 is linear in the size n of the input dataset, though it has exponential dependencies in both the number k of clusters and the approximation parameter $\varepsilon > 0$. By contrast, the best previous PTAS uses runtime $n^{\mathcal{O}\left(k/\varepsilon^2\right)}$, which has substantially worse dependency on the size n of the input dataset.

Learning-augmented algorithms. Unfortunately, exponential dependencies on the number k of clusters can still be prohibitive for moderate values of k. To that end, we turn our attention to learning-augmented papers. We consider the standard *label oracle* model for clustering, where the algorithm has access to an oracle that provides a label for each input point. Formally, for each point x of the n input points, the oracle outputs a label $i \in [k]$ for x, so that the labels implicitly partition the input dataset into k clusters that induce an approximately optimal solution. However, the oracle also has some amount of adversarial error that respects the precision and recall of each cluster; we defer the formal definition to Definition 25. One of the reasons label oracles have been used for learning-augmented algorithms for clustering is their relative ease of acquisition via machine learning models

that are trained on a similar distribution of data. For example, a smaller separate dataset can be observed and used as a "training" data, an input to some heuristic to cluster the initial data, which we can then use to form a predictor for the actual input dataset. Indeed, implementations of label oracles have been shown to perform well in practice [28, 61].

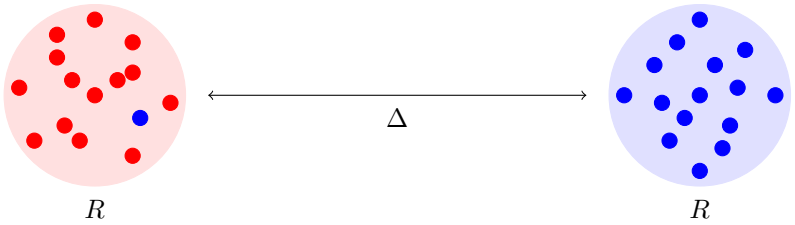


Figure 2 Note that with arbitrarily small error rate, i.e., $\frac{1}{n}$, a single mislabeled point among the n input points causes the resulting clustering to be arbitrarily bad for $\Delta \gg n^2 \cdot R$.

We also remark that perhaps counter-intuitively, a label oracle with arbitrarily high accuracy does not trivialize the problem. In particular, the naïve algorithm of outputting the clustering induced by the labels does not work. As a simple example, consider an input dataset where half of the n points are at $x = 0$ and the other half of the points are at $x = 1$. Then for $k = 2$, the clear optimal clustering is to cluster the points at the origin together, and cluster the points at $x = 1$ together, which induces the optimal cost of zero. However, if even one of the n points is incorrect, then the clustering output by the labels has cost at least 1. Therefore, even with error rate as small as $\frac{1}{n}$, the multiplicative approximation of the naïve algorithm can be arbitrarily bad. See Figure 2 for an illustration of this example. Of course, this example does not rule out more complex algorithms that combines the labels with structural properties of optimal clustering and indeed, our algorithm utilizes such properties.

We give a polynomial-time algorithm for the ℓ_2^2 min-sum k-clustering that can provide guarantees beyond the computational limits of Theorem 3, given a sufficiently accurate oracle.

▶ **Theorem 5.** *There exists a polynomial-time algorithm that uses a label predictor with error rate* $\alpha \in \left[0, \frac{1}{2}\right)$ *and outputs a* $\frac{1+\gamma\alpha}{(1-\alpha)^2}$*-approximation to the* ℓ_2^2 *min-sum* k*-clustering problem, where* $\gamma = 7.7$ *for* $\alpha \in \left[0, \frac{1}{7}\right)$ *or* $\gamma = \frac{5\alpha - 2\alpha^2}{(1-2\alpha)(1-\alpha)}$ *for* $\alpha \in \left[0, \frac{1}{2}\right)$.

We remark that Theorem 5 does not require the true error rate α as an input parameter. Because we are in an offline setting, where can run Theorem 5 multiple times with guesses for the true error rate α, in decreasing powers of $\frac{1}{\lambda}$ for any constant $\lambda > 1$. We can then compare the resulting clustering output by each guess for α and take the output the best clustering.

1.2 Technical Overview

Hardness of approximation. Recently, the authors of [19] put forth the Johnson Coverage Hypothesis (JCH) and introduced a framework to obtain (optimal) hardness of approximation results for k-median and k-means in ℓ_p-metrics. The proof of Theorem 3 builds on this framework. JCH roughly asserts that for large enough constant z, given as input an integer k and a collection of z-sets (i.e., sets each of size z) over some universe, it is NP-hard to distinguish the completeness case where there is a collection C of k many $(z-1)$-sets such

that every input set is covered[1] by some set in C, from the soundness case where every collection C of k many $(z-1)$-sets does not cover much more than $1-\frac{1}{e}$ fraction of the input sets (see Hypothesis 7 for a formal statement).

In this paper, we consider a natural generalization of JCH, called Balanced − JCH*, where we assume that the number of input sets is "dense", i.e., $\omega(k)$, and more importantly that in the completeness case, the collection C covers the input z-sets in a balanced manner, i.e., we can partition the input to k equal parts such that each part is completely covered by a single set in C (see Hypothesis 9 for a formal statement).

We now sketch the proof of Theorem 3 assuming Balanced − JCH*. Given a collection of m many z-sets over a universe $[n]$ as input, we create a point for each input set, which is simply the characteristic vector of the set as a subset of $[n]$, i.e., the points are all n-dimensional Boolean vectors of Hamming weight z. In the completeness case, from the guarantees of Balanced − JCH*, it is easy to see that the points created can be divided into k equal clusters of size m/k such that all the z-sets of a cluster are completely covered by a single $(z-1)$-set. This implies that the squared Euclidean distance between a pair of points within a cluster is exactly 2 and thus the ℓ_2^2 min-sum k-clustering cost is $k \cdot 2 \cdot (m/k)(m/k-1) \approx 2m^2/k$.

On the other hand, in the soundness case, we first use the density guarantees of Balanced − JCH* to argue that most clusters are not small. Then suppose that we had a low cost ℓ_2^2 min-sum k-clustering, we look at a typical cluster and observe that the squared distance of any two points in the cluster must be a positive even integer, and it is exactly 2 only when the two input sets corresponding to the points intersect on a $(z-1)$-set. Thus, if the cost of the clustering is close to $\alpha \cdot 2m^2/k$ (for some $\alpha \geq 1$), then we argue (using convexity) that for a typical cluster that there must be a $(z-1)$-set that covers $(1-\alpha')m/k$ many z-sets in that cluster, where α' depends on α. Thus, from this we decode k-many $(z-1)$-sets which cover a large fraction of the input z-sets. In order to obtain the unconditional NP-hardness result, much like in [19], we need to extend the above reduction to a more general problem. This is indeed established in Theorem 12, and after this we prove a special case of a generalization of Balanced − JCH* (when $z=3$) which is done in Theorem 11 and this involved proving additional properties of the reduction of [19] from the multilayered PCPs of [27, 46] to 3-Hypergraph Vertex Coverage.

Nearly Linear Time PTAS. An important feature of ℓ_2^2 Min-Sum Clustering is that we can use assignments of clusters to their mean to obtain the cost of the points in the cluster, an idea previously used in [37, 58, 63, 24]. We show how to reduce the number of candidate means to a constant (depending only on k and ε. The idea here is to use D^2 sampling methods akin to k-means++ [6]. Unfortunately, by itself, it is not sufficient as there may exist clusters that have significant Min-Sum clustering cost, but are not detectable by D^2 sampling. To this end, we augment D^2 sampling via a careful pruning strategy that removes high costing points, increasing the relative cost of clusters of high density. Thereafter, we show that given sufficiently many samples, we can find a small set of suitable candidate means that are induced by a nearly optimal clustering.

What remains to be shown is how to find an assignment of points to these centers with similar cost. For this, we could use a flow-based approach, but this results in a n^3 running time. Instead, we employ a discretization and bucketing strategy that allows us to sparsify the point set while preserving the Min-Sum clustering cost, akin to coresets.

[1] A $(z-1)$-set covers a z-set if the former is a subset of the latter.

Learning-augmented algorithm. Our starting point for our learning-augmented algorithm for min-sum k-clustering is the learning-augmented algorithms for k-means clustering by [28, 61]. We can rewrite the Min-Sum clustering cost in terms of weighted squared distances to the means or centroids. Our goal is therefore to quickly identify suitable centroids c_i. The algorithms note that the clustering objective can be decomposed across the points that are given each label $i \in [k]$. Thus we consider the subset P_i of points of the input dataset X that are given label i by the oracle.

The cluster P_i can have an α fraction of incorrect points. The main observation is that there can be two cases. Either P_i includes a number of "bad" points that are far from the true mean and thus easy to identify, or P_i includes a number of "bad" points that are difficult to identify but also are close to the true mean and thus do not largely affect the overall clustering cost. Thus the algorithm simply needs to prune away the points that are far away, which can be achieved by selecting the interval of $(1 - \mathcal{O}(\alpha))$ points that has the best clustering cost. Therefore, we have a set of centers for which there exists an assignment that obtains a good approximation of the cost of the optimal min-sum k-clustering; it remains to identify the actual clusters.

To find an assignment of points to candidate means, we use min-cost flow approach, similar to [24]. The constrained min-cost flow problem can be written as a linear program. Therefore to identify the overall clusters, we run any standard polynomial-time algorithm for solving linear programs [44, 66, 67, 52, 53, 16, 42]. It then follows by that well-known integrality theorems for min-cost flow, the resulting solution is integral and thus provides a valid clustering with approximately optimal ℓ_2^2 min-sum k-clustering objective.

2 Hardness of Approximation of ℓ_2^2 Min-Sum k-Clustering

In this section, we show the hardness of approximation of ℓ_2^2 min-sum k-clustering, i.e., Theorem 3. We first define the relevant formulations of Johnson Coverage Hypothesis in Section 2.1. Next, in Section 2.2 we provide the main reduction from the Johnson coverage problem to the ℓ_2^2 min-sum k-clustering problem. Finally, we prove a special case of a generalization of $\mathsf{Balanced} - \mathsf{JCH}^*$ which yields the unconditional NP-hardness factor claimed in Theorem 3.

2.1 Johnson Coverage Hypothesis

In this section, we recall the Johnson Coverage problem, followed by the Johnson Coverage hypothesis [19]. Let $n, z, y \in \mathbb{N}$ such that $n \geq z > y$. Let $E \subseteq \binom{[n]}{z}$ and $S \in \binom{[n]}{y}$. We define the coverage of S w.r.t. E, denoted by $\mathsf{cov}(S, E)$ as follows: $\mathsf{cov}(S, E) = \{T \in E \mid S \subset T\}$.

▶ **Definition 6** (Johnson Coverage Problem). *In the (α, z, y)-Johnson Coverage problem with $z > y \geq 1$, we are given a universe $U := [n]$, a collection of subsets of U, denoted by $E \subseteq \binom{[n]}{z}$, and a parameter k as input. We would like to distinguish between the following two cases:*

- **Completeness**: *There exists $\mathcal{C} := \{S_1, \ldots, S_k\} \subseteq \binom{[n]}{y}$ such that*

$$\mathsf{cov}(\mathcal{C}) := \bigcup_{i \in [k]} \mathsf{cov}(S_i, E) = E.$$

- **Soundness**: *For every $\mathcal{C} := \{S_1, \ldots, S_k\} \subseteq \binom{[n]}{y}$ we have $|\mathsf{cov}(\mathcal{C})| \leq \alpha \cdot |E|$.*

We call $(\alpha, z, z-1)$-Johnson Coverage as (α, z)-Johnson Coverage.

Notice that $(\alpha, 2)$-Johnson Coverage Problem is simply the well-studied vertex coverage problem (with gap α). Also, notice that if instead of picking the collection $\mathcal{C}$ from $\binom{[n]}{y}$, we replace it with picking the collection $\mathcal{C}$ from $\binom{[n]}{1}$ with a similar notion of coverage, then we simply obtain the Hypergraph Vertex Coverage problem (which is equivalent to the Max k-Coverage problem for unbounded z). In Figure 3 we provide a few examples of instances of the Johnson coverage problem.

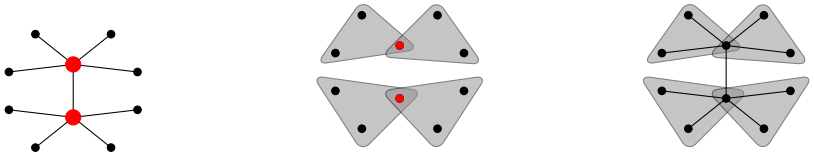

Figure 3 Examples of input instances of the Johnson Coverage Hypothesis for $k = 2$. Figure 3a shows an example of a completeness instance of $(0.7, 2, 1)$, since all subsets of size 2, i.e., all edges, can be covered by $k = 2$ choices of subset of size 1, i.e., two vertices. Figure 3b shows an example of a completeness instance of $(0.7, 3, 1)$, since all subsets of size 3 can be covered by $k = 2$ vertices. Figure 3c shows an example of a soundness instance of $(0.7, 3, 2)$, since at most $2 \leq 0.7 \cdot 4$ subsets of size 3 can be covered by any choice of $k = 2$ edges.

▶ **Hypothesis 7** (Johnson Coverage Hypothesis (JCH) [19])**.** *For every constant $\varepsilon > 0$, there exists a constant $z := z(\varepsilon) \in \mathbb{N}$ such that deciding the $\left(1 - \frac{1}{e} + \varepsilon, z\right)$-Johnson Coverage Problem is* NP*-Hard.*

Note that since Vertex Coverage problem is a special case of the Johnson Coverage problem, we have that the NP-Hardness of (α, z)-Johnson Coverage problem is already known for $\alpha = 0.944$ [7] (under unique games conjecture).

On the other hand, if we replace picking the collection $\mathcal{C}$ from $\binom{[n]}{z-1}$ by picking from $\binom{[n]}{1}$, then for the Hypergraph Vertex Coverage problem, we do know that for every $\varepsilon > 0$ there is some constant z such that the Hypergraph Vertex Coverage problem is NP-Hard to decide for a factor of $\left(1 - \frac{1}{e} + \varepsilon\right)$ [29]. For continuous clustering objectives, a dense version of JCH is sometimes needed to prove inapproximability results (see [19] for a discussion on this). Thus, we state:

▶ **Hypothesis 8** (Dense Johnson Coverage Hypothesis (JCH*) [19])**.** JCH *holds for instances (U, E, k) of Johnson Coverage problem where $|E| = \omega(k)$.*

More generally, let (α, z, y)-Johnson Coverage* problem be the special case of the (α, z, y)-Johnson Coverage problem where the instances satisfy $|E| = \omega(k \cdot |U|^{z-y-1})$. Then JCH* states that for any $\varepsilon > 0$, there exists $z = z(\varepsilon)$ such that $(1 - 1/e + \varepsilon, z, z - 1)$-Johnson Coverage* is NP-Hard. This additional property has always been obtained in literature by looking at the hard instances that were constructed. In [17], where the authors proved the previous best inapproximability results for continuous case k-means and k-median, it was observed that hard instances of $(0.94, 2, 1)$-Johnson Coverage constructed in [7] can be made to satisfy the above property. Now we are ready to define the variant of JCH needed for proving inapproximability of ℓ_2^2 min-sum k-clustering. For any two non-empty finite sets A, B, and a constant $\delta \in [0, 1]$, we say a function $f : A \to B$ is δ-balanced if for all $b \in B$ we have $|\{a \in A : f(a) = b\}| \leq (1 + \delta) \cdot \frac{|A|}{|B|}$. We then put forth the following hypothesis.

▶ **Hypothesis 9** (Dense and Balanced Johnson Coverage Hypothesis (Balanced − JCH*))**.** JCH *holds for instances* (U, E, k) *of Johnson Coverage problem where* $|E| = \omega(k)$ *and in the completeness case there exists* $\mathcal{C} := \{S_1, \ldots, S_k\} \subseteq \binom{[n]}{z-1}$ *and a* **0-balanced** *function* $\psi : E \to [k]$ *such that for all* $T \in E$ *we have* $S_{\psi(T)} \subset T$*.*

More generally, let (α, z, y, δ)-Balanced Johnson Coverage* problem be the special case of the (α, z, y)-Johnson Coverage* problem where the instances admit a δ-balanced function $\psi : E \to [k]$ in the completeness case which partitions E to k parts, say $E_1 \dot\cup \cdots \dot\cup E_k$ such that for all $i \in [k]$ we have $\mathsf{cov}(S_i, E_i) = E_i$ and $|E_i| \leq \frac{|E|}{k} \cdot (1 + \delta)$. Then Balanced − JCH* states that for any $\varepsilon > 0$, there exists $z = z(\varepsilon)$ such that $(1 - 1/e + \varepsilon, z, z - 1, 0)$-Balanced Johnson Coverage* is NP-Hard. As with the case of JCH*, the balanced addition to JCH* is also quite natural and candidate constructions typically give this property for free. To support this point, we will prove some special case of this. In [19] the authors had proved the following special case of JCH*.

▶ **Theorem 10** ([19])**.** *For any* $\varepsilon > 0$*, given a simple 3-hypergraph* $\mathcal{H} = (V, H)$ *with* $n = |V|$*, it is NP-hard to distinguish between the following two cases:*

- **Completeness:** *There exists* $S \subseteq V$ *with* $|S| = n/2$ *that intersects every hyperedge.*
- **Soundness:** *Any subset* $S \subseteq V$ *with* $|S| \leq n/2$ *intersects at most a* $(7/8 + \varepsilon)$ *fraction of hyperedges.*

Furthermore, under randomized reductions, the above hardness holds when $|H| = \omega(n^2)$*.*

▶ **Theorem 11.** *Theorem 10 holds even with the following additional completeness guarantee for all* $\delta > 0$*: there exists* $S := \{v_1, \ldots, v_k\} \subseteq V$ *and a* δ*-balanced function* $\psi : H \to [k]$ *such that for all* $e \in H$ *we have* $v_{\psi(e)} \in e$*.*

This result will be used to prove the unconditional NP-hardness of approximating ℓ_2^2 min-sum k-clustering problem.

2.2 Inapproximability of ℓ_2^2 min-sum k-clustering

▶ **Theorem 12.** *Assume* (α, z, y, δ)*-Balanced Johnson Coverage** *is* NP*-Hard. For every constant* $\varepsilon > 0$*, given a point-set* $P \subset \mathbb{R}^d$ *of size* n *(and* $d = \mathcal{O}(\log n)$*) and a parameter* k *as input, it is* NP*-Hard to distinguish between the following two cases:*

- **Completeness***: There exists partition* $P_1^* \dot\cup \cdots \dot\cup P_k^* := P$ *such that*

$$\sum_{i \in [k]} \sum_{p,q \in P_i^*} \|p - q\|_2^2 \leq (1 + 3\delta) \cdot (z - y) \cdot \rho n^2 / k,$$

- **Soundness***: For every partition* $P_1 \dot\cup \cdots \dot\cup P_k := P$ *we have*

$$\sum_{i \in [k]} \sum_{p,q \in P_i} \|p - q\|_2^2 \geq (1 - o(1)) \cdot \left(\alpha \cdot \sqrt{z - y} + (1 - \alpha) \cdot \sqrt{z - y + 1}\right)^2 \cdot \rho n^2 / k,$$

for some constant $\rho > 0$*.*

Putting together the above theorem with Theorem 11 (i.e., NP-hardness of $(7/8+\varepsilon, 3, 1, \delta)$-Balanced Johnson Coverage* problem for all $\varepsilon, \delta > 0$), we obtain the NP-hardness of approximating ℓ_2^2 min-sum k-clustering. The above theorem also immediately yields the hardness of approximating ℓ_2^2 min-sum k-clustering under Balanced − JCH* (i.e., conditional NP-hardness of $(1 - 1/e + \varepsilon, z, z - 1, 0)$-Balanced Johnson Coverage* problem for all $\varepsilon > 0$ and some $z = z(\varepsilon) \in \mathbb{N}$). This completes the proof of Theorem 3.

3 PTAS based on D^2 Sampling

For a set $A \subset \mathbb{R}^d$, let $\mu(A) := \frac{1}{|A|}\sum_{p\in A} p$ denote its mean. Let $\mathcal{C} = \{C_1, \dots C_k\}$ be an optimal k-MinSum clustering of a point set A. We use $\mu_i = \mu(C_i)$ to denote the mean of C_i and we use $\Delta_i = \frac{\sum_{p\in C_i}\|p-\mu_i\|^2}{|C_i|}$ to denote the average mean squared distance of C_i to μ_i. We further use C_i^β to denote the subset of C_i with $\|p-\mu_i\|^2 \le \beta\cdot\Delta_i$. Finally, let OPT denote the cost of an optimal solution. So, $\mathsf{OPT} = \sum_{i=1}^k |C_i|^2\cdot\Delta_i$.

▶ **Definition 13.** *We say that m is an ε-approximate mean of C_i if $\|m-\mu_i\|^2 \le \varepsilon\cdot\Delta_i$. We say that a set $S\subset A$ is an (ε,β)-mean seeding set for $C_i\in\mathcal{C}$, if there exists a subset $S'\cup\{s\}\subset S$ with $\|s-\mu_i\|^2\le\beta\cdot\Delta_i$ and a weight assignment $w: S'\to\mathbb{R}_{\ge 0}$ such that $\left\|\frac{1}{\sum_{p\in S'}w(p)}\sum_{p\in S'}w(p)\cdot p-\mu_i\right\|^2 \le \varepsilon\cdot\Delta_i$.*

We will use the following well-known identities for Euclidean means.

▶ **Lemma 14** ([36])**.** *Let $A\subset\mathbb{R}^d$ be a set of points. Then for any $c\in\mathbb{R}^d$:*

- $\sum_{p\in A}\|p-c\|^2 = \sum_{p\in A}\|p-\mu(A)\|^2 + |A|\cdot\|\mu(A)-c\|^2$.
- $\sum_{p,q\in A}\|p-q\|^2 = 2\cdot|A|\cdot\sum_{p\in A}\|p-\mu(A)\|^2$.

We also show that we only have to consider seeding sets with $\beta\in\Theta(\varepsilon^{-2})$.

▶ **Lemma 15.** *For any cluster C_i, $\varepsilon\in(0,1)$ and $\beta\ge 12\varepsilon^{-2}$, we have that $\mu_i(C_i^\beta) = \frac{1}{|C_i^\beta|}\sum_{p\in C_i^\beta} p$ is a ε-approximate mean of C_i.*

Finally, we also show how to efficiently extract a mean from a mean seeding set, while being oblivious to Δ_i.

▶ **Lemma 16.** *Let S be an $(\varepsilon/4,\beta)$-mean seeding set of a cluster C_j with mean μ_j. Then we can compute $\left(\frac{10\beta\cdot|S|}{\varepsilon}+1\right)^{|S|}$ choices of weights in time linear in the size of choices such that at least one of the computed choices satisfies $\left\|\frac{1}{\sum_{p\in S}w(p)}\sum_{p\in S}w(p)\cdot p-\mu_j\right\|^2\le\varepsilon\cdot\Delta_j$.*

Computing a Mean-Seeding Set via Uniform Sampling

▶ **Lemma 17.** *Let $\varepsilon\in(0,1)$ and $\beta > 48\varepsilon^2$. With probability at least $1-\delta$, a set of $32k\varepsilon^{-1}\log\delta^{-1}$ points S sampled uniformly at random with replacement from A contains is a (ε,β)-mean seeding set of any C_i with $|C_i|\ge\frac{n}{k}$.*

D^2 Subsampling

We now define an algorithm for sampling points that induce means from the target clusters. The high level idea is as follows. We construct a rooted tree in which every node is labeled by a set of candidate cluster means. For a parent and child pair of nodes, the parent's set is a subset of the child's set. The construction is iterative. Given an interior node, we construct its children by adding a candidate mean to the parent's set. The candidantes are generated using points sampled at random from a distribution that will be defined later. The goal is to have, eventually, an ε-approximate mean for every optimal cluster. This will be achieved with high probability at one of the leaves of the tree. The root of the tree is labeled with the empty set, and its children are constructed via uniform sampling. Subsequently, we refine the sampling distribution to account for various costs and densities of the clusters.

We now go into more detail for the various sampling stages of the algorithm.

Preprocessing: We ensure that all points are not too far from each other.

Initialization: We initialize the set of means via uniform sampling. Due to Lemma 17, we can enumerate over potential sets of ε-approximate means for all clusters of size $\frac{n}{k}$. Each candidate mean defines a child of the root.

Sampling Stage: Consider a node of the tree labeled with a non-empty set of candidate means M. We put $\Gamma_i = 2^{-i} \cdot \sum_{q \in A} \min_{m \in M} \|q-m\|^2$ for $i \in \{0, 1, \ldots, 13 \log(nk/\varepsilon)\}$, where η is an absolute constant to be defined later. Let $A_{i,M} = \{q \in A \colon \min_{m \in M} \|q-m\|^2 \leq \Gamma_i\}$. (Note that $A_{0,M}$ includes all the points.) Let $\mathbb{P}_i$ denote the probability distribution on $A_{i,M}$ induced by setting, for each $p \in A_{i,M}$, $\mathbb{P}_i[p] = \frac{\min_{m \in M} \|p-m\|^2}{\sum_{p \in A_{i,M}} \min_{m \in M} \|p-m\|^2}$ We'll use $\mathbb{P}$ to denote $\mathbb{P}_0$. For each i, we sample a sufficient (polynomial in k and ε, but independent of n) number of points independently from the distribution $\mathbb{P}_i$. Let S denote the set of sampled points.

Mean Extraction Stage: We enumerate over combinations of points in $M \cup S$, using some non-uniform weighing to fix a mean to add to M, see Lemma 16. Each choice of mean is added to M to create a child of the node labeled M.

Throughout this section we will use the following definition. Given a set of centers M, we say that a cluster C_i is ε-covered by M if $|C_i|^2 \cdot \min_{m \in M} \|\mu_i - m\|^2 \leq \frac{\varepsilon}{2} \cdot \left(\frac{1}{k} \cdot OPT + |C_i|^2 \Delta_i\right)$. Our goal will be to prove the following lemma.

▶ **Lemma 18.** *Let $\mathcal{C} = \{C_1, \ldots C_k\}$ be the clusters of an optimal Min-Sum k-clustering and let η be an absolute constant. For every $\delta, \epsilon > 0$, there is a randomized algorithm that outputs a collection of at most $n^{o(1)} \cdot 2^{\eta \cdot k^2 \cdot \varepsilon^{-12} \log^2(k/(\varepsilon\delta))}$ sets of at most k centers M, such that with probability $1-\delta$ at least one of them that ε-covers every $C_i \in \mathcal{C}$. The algorithm runs in time $n^{1+o(1)} \cdot d \cdot 2^{\eta \cdot k^2 \cdot \varepsilon^{-12} \log^2(k/(\varepsilon\delta))}$.*

Note that if all clusters of $\mathcal{C}$ are ε-covered, then there exists an assignment of points to centers, such that Min-Sum clustering cost of the resulting clustering is at most $(1+\varepsilon) \cdot \mathsf{OPT}$.

Preprocessing

The first lemma allows us to assume that all points are in some sense close to each other.

▶ **Lemma 19.** *Suppose $n > 20$. Given an set of n points $A \subset \mathbb{R}^d$, we can partition a point set into subsets $A_1, \ldots A_k$, such that $\|p-q\|^2 \leq n^{10} \cdot \mathsf{OPT}$ for any two points $p, q \in A_i$ and such that any cluster C_j is fully contained in one of the A_i. The partitioning takes time $\tilde{O}(nd + k^2)$.*

Computing a Mean-Seeding Set via D^2 Sampling

We now consider a slight modification of Lemma 17 to account for sampling points from a cluster non-uniformly. We introduce the notion of a distorted core as follows. Given a cluster C_j, a set of centers M, and parameters α, β, we say that a subset of $C_j^\beta \cup M$ is a (C_j, β, α, M)-distorted core (denoted $core(C_j, \beta, \alpha, M)$) iff it is the image of a mapping $\pi_{\alpha,M} : C_j^\beta \to C_j^\beta \cup M$ such that for any point $p \in C_j^\beta$, we have

$$\pi_{\alpha,M}(p) = \begin{cases} p & \text{if } \min_{m \in M} \|p-m\|^2 \geq \alpha \cdot \Delta_j \\ \operatorname{argmin}_{m \in M} \|p-m\|^2 & \text{if } \min_{m \in M} \|p-m\|^2 < \alpha \cdot \Delta_j \end{cases}.$$

We use $D(C_j, \beta, \alpha, M)$ to denote the set of points in C_j^β such that $\min_{m \in M} \|p-m\|^2 < \alpha \cdot \Delta_j$.

The following lemmas relate the goodness of a mean computed on an α-distorted core to the mean on the entire set of points when sampling points proportionate to squared distances. We start by proving an analogue of Lemma 15.

▶ **Lemma 20.** *Let $\alpha \leq \frac{\varepsilon}{4}$ and let $\beta \geq \frac{144}{\varepsilon^2}$. Given a set of centers M and a cluster C_j, let $\hat{\mu_j} = \frac{1}{|C_j^\beta|} \sum_{p \in C_j^\beta} \pi_{\alpha,M}(p)$. Then, $\|\hat{\mu_j} - \mu_j\|^2 \leq \varepsilon \cdot \Delta_j$.*

We now characterize when M either covers a cluster C_j, or when M is a suitable seeding set for C_j. The following lemma says that if M is not a seeding set of C_j, then there exist many points in the core C_j^β of C_j that are far from M.

▶ **Lemma 21.** *Given $\alpha \leq \frac{\varepsilon}{16}$, $\beta \geq \frac{2400}{\varepsilon^2}$, and $\gamma \leq \sqrt{\frac{\varepsilon}{16(\beta+\alpha)}}$, and a set of centers M, let C_j be a cluster for which $|D(C_j, \beta, \alpha, M)| \geq (1-\gamma) \cdot |C_j^\beta|$. Then M is an (ε, β)-mean seeding set of C_j.*

Next, we show that the marginal probability of picking a point from an uncovered cluster C_j cannot be significantly smaller than the marginal probability of picking a point from the union of covered clusters with larger cardinality than C_j.

▶ **Lemma 22.** *Let M be a set of centers, and let $\mathcal{C}$ denote a set of clusters that are ε-covered by M. Let $\mathcal{H}$ denote the set of points in all the clusters in $\mathcal{C}$. Let $\beta > \frac{2400}{\varepsilon^2}$. Consider a cluster $C_j \notin \mathcal{C}$. Let i be the largest index such that $C_i \in \mathcal{C}$. Suppose that M is not an (ε, β)-mean seeding set of C_j, and that $i < j$. Then $\mathbb{P}[p \in C_j^\beta \mid p \in \mathcal{H} \cup C_j] \geq \frac{\varepsilon^4 \cdot \beta^{-3/2}}{1088k}$.*

We now consider a cluster C_j that is small compared to the union of the clusters C_j' with $j' > j$. In this case, we show that one of the distance-proportional distributions that we use guarantees that the probability of sampling points from the core of C_j is large.

▶ **Lemma 23.** *Let M be a set of centers. Let $\beta > \frac{2400}{\varepsilon^2}$. Let j be the smallest index such that C_j is not ε-covered by M. If M is not an (ε, β)-mean seeding set for C_j, then there exists $i \in \{0, 1, \ldots, \eta \log(nk/\varepsilon)\}$ such that $C_j^\beta \in A_{i,M}$ and $\mathbb{P}_i[p \in C_j^\beta] \geq \frac{1}{4352 \cdot k} \cdot \left(\frac{\varepsilon}{\beta^{5/8}}\right)^4$*

Finally, we show how to account for the sampling bias when estimating the means.

▶ **Lemma 24.** *Let M be a set of centers. Let j be the smallest index such that C_j is not ε-covered by M. Suppose that M is not an $(\varepsilon/4, \beta)$-mean seeding set for C_j. Consider a set of points S' sampled iid from $\mathbb{P}_i$, and let $S = S' \cap C_j^\beta$. If $\beta \geq 2400\varepsilon^{-2}$ and $S > 17825792 \cdot k \left(\frac{\beta^{7/12}}{\varepsilon}\right)^6 \log(2/\delta)$, then with probability at least $1-\delta$, we have that $S' \cup M$ is an $(\varepsilon/4, \beta)$-mean seeding set of C_j.*

The proof of Lemma 18 now argues that, given a set of points M, that we can find a seeding set for the largest uncovered cluster via D^2 sampling with respect to a suitable distribution $\mathbb{P}_i$. The existence of such a distribution, as well as the number of samples is given via Lemma 24 and extracting a suitable mean can be done via Lemma 16. The overall number of candidate solutions is now exponential in the number of points sampled over the course of the procedure, which is bounded by $\text{poly}(k, \varepsilon^{-1}, \log \delta^{-1})$.

Obtaining the Parameterized PTAS

We complete this section by explaining how to funnel the mean-seeding procedure into a PTAS. This yields Theorem 4. For every candidate solution given by Lemma 18, we bucket points by squared distance to the respective centers. This number of buckets depends on a

guess of the optimum, which is inexpensive to obtain, as well as a discretization over possible different distances to centers, of which we show there cannot exist too many. Since the number of buckets are very small, we can efficiently find an assignment. Then we show that we can extract a clustering from the bucketed assignment in linear time.

4 Learning-Augmented ℓ_2^2 Min-Sum k-Clustering

In this section, we describe and analyze our learning-augmented algorithm, corresponding to Theorem 5. We first formally define the precision and recall guarantees of a label predictor.

▶ **Definition 25** (Label predictor). *Suppose that there is an oracle that produces a label $i \in [k]$ for each $x \in X$, so that the labeling partitions $X = P_1 \dot\cup \ldots \dot\cup P_k$ into k clusters $P_1, \ldots, P_k$, where all points in P_i have the same label $i \in [k]$. We say the oracle is a* label predictor *with error rate α if there exists some fixed optimal min-sum clustering $P_1^*, \ldots, P_k^*$ such that for all $i \in [k]$, $|P_i \cap P_i^*| \geq (1-\alpha)\max(|P_i|, |P_i^*|)$. We say that $P^* = \{P_1^*, \ldots, P_k^*\}$ is the clustering consistent with the label oracle.*

We also recall the following guarantees of previous work on learning-augmented k-means clustering for a label predictor with error rate $\alpha \in \left[0, \frac{1}{2}\right)$.

▶ **Theorem 26** ([61]). *Given a label predictor with error rate $\alpha < \frac{1}{2}$ consistent with some clustering $P^* = \{P_1^*, \ldots, P_k^*\}$ with centers $\{c_1^*, \ldots, c_k^*\}$, there exists a polynomial-time algorithm* LearnedCenters *that outputs a set of centers $\{c_1, \ldots, c_k\}$, so that for each $i \in [k]$, $\sum_{x \in P_i^*} \|x - c_i\|_2^2 \leq (1 + \gamma_\alpha \alpha) \sum_{x \in P_i^*} \|x - c_i^*\|_2^2$, where $\gamma_\alpha = 7.7$ for $\alpha \in \left[0, \frac{1}{7}\right)$ or $\gamma_\alpha = \frac{5\alpha - 2\alpha^2}{(1-2\alpha)(1-\alpha)}$ for $\alpha \in \left[0, \frac{1}{2}\right)$.*

Unfortunately, although the centers $\{c_1, \ldots, c_k\}$ returned by LearnedCenters are good centers for the clustering induced by a near-optimal ℓ_2^2 min-cost k-clustering, it is not clear what the resulting assignment should be. In fact, we emphasize that unlike k-means clustering, the optimal ℓ_2^2 min-cost k-clustering may not assign each point to its closest center.

Constrained min-cost flow. To that end, we now create a constrained min-cost flow problem as follows. We first create a source node s and a sink node t and require that $n = |X|$ flow must be pushed from s to t. We create a node u_x for each point $x \in X$ and create a directed edge from s to each node u_x with capacity 1 and cost 0. There are no more outgoing edges from s or incoming edges to each u_x. This ensures that to achieve n flow from s to t, a unit of flow must be pushed across each node u_x.

Algorithm 1 Learning-augmented min-sum k-clustering.

Input: Dataset X with partition $P_1, \ldots, P_k$ induced by label predictor with error rate α
Output: Labels for all points consistent with a $(1 + \mathcal{O}(\alpha))$-optimal min-sum k-clustering

1: Let $c_1, \ldots, c_k$ be the output centers of LearnedCenters on $P_1, \ldots, P_k$
2: Create a min-cost flow problem $\mathcal{F}$ with required flow n
3: Solve the flow problem $\mathcal{F}$
4: For each $x \in X$, let the flow from u_x be sent to the node v_{ℓ_x}, so that $\ell_x \in [k]$
5: Label x with ℓ_x

We then adjust an integrality theorem to handle capacitated edges, thereby showing that the resulting solution for the min-cost flow problem is integral, and show that since the constraint matrix is totally unimodular, i.e., all submatrices have determinant -1, 0, or 1, then a valid clustering can be recovered by using the output of a linear program solver. Thus, we have the following guarantees for our learning-augmented algorithm.

▶ **Theorem 27.** *There exists a polynomial-time algorithm that uses a label predictor with error rate α and outputs a $\frac{1+\gamma_\alpha \alpha}{(1-\alpha)^2}$-approximation to min-sum k-clustering, where γ_α is the fixed constant from Theorem 26.*

The Maximum Clique Problem in a Disk Graph Made Easy

Abstract

A disk graph is an intersection graph of disks in $\mathbb{R}^2$. Determining the computational complexity of finding a maximum clique in a disk graph is a long-standing open problem. In 1990, Clark, Colbourn, and Johnson gave a polynomial-time algorithm for computing a maximum clique in a unit disk graph. However, finding a maximum clique when disks are of arbitrary size is widely believed to be a challenging open problem. In this paper, we provide a new perspective to examine adjacencies in a disk graph that helps obtain the following results.

- We design an $\mathcal{O}^*(n^{2k})$-time algorithm, where $\mathcal{O}^*$ hides a polynomial factor, to find a maximum clique in a n-vertex disk graph with k different sizes of radii. This is polynomial for every fixed k, and thus settles the open question for the case when $k = 2$.
- Given a set of n unit disks, we show how to compute a maximum clique inside each possible axis-aligned rectangle determined by the disk centers in $O(n^5 \log n)$-time. This is at least a factor of $n^{4/3}$ faster than applying the fastest known algorithm for finding a maximum clique in a unit disk graph for each rectangle independently.
- We give an $\mathcal{O}^*(n^{2rk})$-time algorithm to find a maximum clique in a n-vertex ball graph with k different sizes of radii where the ball centers lie on r parallel planes. This is polynomial for every fixed k and r, and thus contrasts the previously known NP-hardness result for finding a maximum clique in an arbitrary ball graph.
- We design an $\mathcal{O}^*(n^{2k})$-time algorithm to find a maximum clique in the intersection graph of a set S of n L-visible convex polygons, where k is the number of distinct shapes in S. This contrasts the known hardness result on finding a maximum clique in the intersection graph of unit disks and axis-aligned rectangles.

1 Introduction

A *geometric intersection graph* consists of a set of geometric objects as vertices and a set of edges that are determined by the intersection of these objects, i.e., two vertices are considered adjacent if and only if the corresponding objects intersect. Geometric objects of different shapes and their intersection graphs are often used to model applied contexts,

e.g., unit disks for problems in wireless networks [24, 28], line segments (time intervals) for task scheduling [34], trapezoids for channel routing in VLSI design [23], etc. Many NP-hard graph problems are known to admit polynomial-time solutions on various types of geometric intersection graphs (see e.g., [8, 16]). There also exist cases where a graph problem is known to be NP-hard, but its time complexity status is open for some intersection graph class (see e.g. the open problems posed in [2, 1, 5, 33]). In this paper, we restrict our attention to one such scenario, where the problem of interest is finding a *maximum clique*, i.e., a maximum subset of pairwise adjacent vertices, and the intersection graph we examine is a *disk graph*. Here, a *disk graph* G is an intersection graph of disks in $\mathbb{R}^2$, where each vertex of G corresponds to a disk and two vertices are adjacent in G if and only if their disks intersect.

The maximum clique problem is NP-hard for many well-known intersection graph classes such as intersection graph of rays [13], grounded strings [33], triangles [3], ellipses [3], and a combination of axis-aligned rectangles and unit disks [7, 21], whereas polynomial-time solvable for circle graphs [36], trapezoid graphs [23], circle trapezoid graphs [23], unit disk graphs [16], axis-aligned rectangle intersection graphs [29], and so on. However, determining the time complexity of computing a maximum clique in a disk graph is a long-standing open question [3, 4, 24]. In a seminal paper published in 1990, Clark, Colbourn, and Johnson [16] gave a polynomial-time algorithm for the case of unit disk graphs. However, the time-complexity question for general disk graphs has remained open since then. Although this was not posed as an open problem in [16], it has long been known to be a challenging problem [4], even before it was explicitly posed as an open problem (e.g., by Fishkin [24], Ambühl and Wagner [3] and Cabello [11, 12]). In fact, the problem has been emphasized in various ways in the literature, e.g., as "an intriguing open question", as "a notorious open question in computational geometry" [5], as being "elusive with no new positive or negative results" [4], and several times as a "long-standing open problem" [21, 25, 27].

Although no polynomial-time exact solution is known for finding a maximum clique in general disk graphs, a 2-approximate solution [3] can be obtained by guessing all stabbing sets of four points. There always exists a stabbing set of at most four points for every set of disks that forms a clique [17, 39, 14]. Therefore, one can take the largest solution obtained from all guesses. However, obtaining a better approximation ratio appears to be a challenge. Cabello [11, 12] even asked whether a 1.99 approximation can be achieved if we restrict the input to disks that have at most two different sizes of radii.

Several recent research has shown interesting progress on various fronts of the problem. The $O(n^{4.5})$-time algorithm for finding a maximum clique in a unit disk graph [16], which was improved first to $O(n^{3.5}\log n)$-time [9] and then to $O(n^3\log n)$-time [19], has been improved further in SoCG'23 to $O(n^{2.5}\log n)$ [21]. Chan [15] observed that the running time of [21] can be expressed as $O(n \cdot h(m)^{1+o(1)})$, where $h(m)$ is the time to compute a maximum matching in a bipartite graph that has a biclique cover[2] of size m, and m in this context is known to be $O(n^{4/3}\text{polylog}(n))$ [31]. One can leverage such a biclique cover to compute a maximum matching in $O(m^{1+o(1)})$ time [22]. Therefore, the overall running time becomes $O(n^{7/3+o(1)})$. In FOCS'18, the authors in [6] gave a QPTAS, a randomized EPTAS (and thus a fixed-parameter-tractable algorithm [7]), and a subexponential algorithm for computing a maximum clique in a disk graph. They also showed how to extend these results for *unit ball graphs*, which are intersection graphs of 3-dimensional balls of unit radius. In SODA'22, the authors in [35] designed further subexponential-time fixed-parameter-tractable algorithms

[2] A *biclique cover* of a bipartite graph G is a set of complete bipartite subgraphs of G that cover the edges of G. The size of the cover is the number of elements in the set.

for many other fundamental graph problems on disk graphs. While the maximum clique problem is open for disk graphs with arbitrary radii, it is NP-hard for ball graphs [6]. The hardness result holds in a very restricted setting with all radii falling within the interval $[1, 1+\epsilon]$, $\epsilon > 0$, where even a subexponential-time approximation scheme is unlikely unless the exponential-time-hypothesis [30] fails.

A rich body of research examined the maximum clique problem in the intersection graph of various types of convex shapes. A t-directional convex polygon is a polygon with sides parallel to one of the prespecified t directions. A t-directional convex graph is an intersection graph of t-directional polygons. The paper in [10] showed that a maximum clique in k-directional convex graphs can be solved in time $O(n^{k+3})$ time, and given a geometric representation, this can be improved to $O(n^{k+1})$. The maximum-clique problem can be solved in polynomial time for the intersection graph of unit disks and 2-pancakes [26], where a 2-pancake is defined using a segment on the x-axis. Specifically, a 2-pancake is the Minkowski sum of the unit disk centered at $(0, 0)$ and the line segment with endpoints $(x_1, 0)$ and $(x_2, 0)$, i.e., the union of all unit disks with center on the line segment x_1x_2. Bonnet, Grelier, and Miltzow [7] extends the polynomial-time algorithm for unit disks [16] to translates of any fixed convex set. This algorithm does not generalize any further, i.e., no polynomial-time algorithm is known for the translates of two fixed convex sets.

Our Contribution

We show that a maximum clique in a unit disk graph can be obtained by examining *slabs* (i.e., regions that are bounded by two parallel lines), whereas all prior algorithms depend on a more constrained lens-shaped region. We show how our new slab-based idea can be extended to compute a maximum clique in polynomial time when the number of different radii sizes is fixed, and even to address the case of ball graphs in some restricted settings. Specifically, we obtain the following results, where in all cases, we assume that an arrangement of disks, i.e., a disk representation of the disk graph, is given as an input.

Disk graph with k Different Sizes of Radii. We give an $\mathcal{O}^*(n^{2k})$-time algorithm, where $\mathcal{O}^*$ hides a polynomial factor, to find a maximum clique in a disk graph where k is the number of different types of radii. For every fixed k, the running time becomes polynomial. This settles the open question posed by Cabello [11, 12] on whether a polynomial-time algorithm exists when $k = 2$.

Range Query in a Unit disk graph. We show that our slab-based idea can help the range query version of the maximum clique problem, where the input unit disks should be preprocessed such that several queries that may appear at a later time can be answered efficiently. We examine the case of *axis-aligned rectangular query*, where a maximum clique needs to be reported over disks with centers in the query rectangle. A natural approach for handling rectangular range queries is to precompute the maximum cliques for all possible axis-aligned rectangles (determined by the given disk centers) such that given a query R, a solution can be obtained first by identifying the smallest enclosing rectangle R' for the disk centers in R, and then by a table look-up using R'. Applying an existing lens-based algorithm on all $O(n^4)$ possible axis-aligned rectangles determined by the input disk centers takes $O(n^{19/3+o(1)})$ time. In contrast, we can use our slab-based idea to precompute all such solutions in $O(n^5 \log n)$, achieving a speed up by at least a factor of $n^{4/3}$.

Ball graphs with k Different Sizes of Radii. Given a set of n balls in the Euclidean plane with k different sizes of radii where the ball centers lie on r parallel planes, we show how to compute a maximum clique in the corresponding ball graph in $\mathcal{O}^*(n^{2rk})$ time. For fixed k and r, the running time becomes polynomial in n. We then show that the restriction of the planes being parallel can be removed as long as the input planes are all perpendicular to a different plane. This result contrasts the known NP-hardness result [5] for finding a maximum clique in a ball graph where the radii of the balls are very close to each other, i.e., in the interval $[1, 1+\varepsilon]$, where $\varepsilon > 0$.

Intersection graphs of L-visible convex polygons. Given a set S of n convex polygons that are L-visible, we show how to find a maximum clique in their intersection graph in $\mathcal{O}^*(n^{2k})$-time, where k is the number of distinct shapes in S. This strengthens a result in [7]. Here two points p, q in a polygon are called *L-visible* if the axis parallel rectangle with diagonal pq is contained in the polygon. We refer to a polygon P as a *L-visible polygon* if it contains a point from which every point of the polygon is L-visible. For example, a disk and a regular hexagon with one side parallel to x-axis are L-visible, whereas a triangle is not necessarily an L-visible polygon. Our result implies that the maximum clique can be computed in polynomial time in the intersection graph of the translates of a unit disk and a set of fixed axis-aligned rectangles. In contrast, if the number of rectangle shapes is not bounded then the problem is known to be NP-hard, e.g., consider the case of unit disks and axis-aligned rectangles [7, 21].

2 Preliminaries

In this section we discuss some notation and preliminary results.

By $D_{a,r}$, we denote a disk with a center at point a and radius r. Given a pair of disks $D_{a,r}$ and $D_{b,r'}$, we refer to their common intersection region as a *lens* (Figure 1(a)). Let G be a disk graph. For simplicity, sometimes we say a pair of disks are adjacent in G, which means that the disks intersect and their corresponding vertices are adjacent in G. By $B_{a,r}$, we denote a ball with a center at point a and radius r.

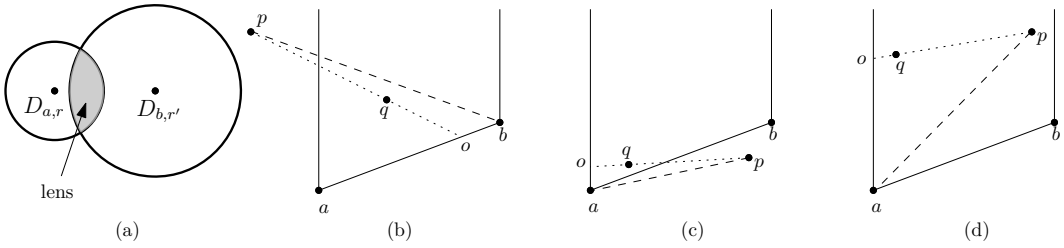

Figure 1 Illustration for (a) a lens, (b)–(d) Illustration for Lemma 1.

For a pair of points a and b, we denote the line passing through them as ℓ_{ab}. By ab and $|ab|$ we denote the line segment with endpoints a, b and the Euclidean distance between a and b, respectively. By ℓ_p^h and ℓ_p^v we denote the horizontal and vertical lines through a point p, respectively. By an *upper slab* U_{ab} of ab, we denote the region above ab, which is bounded by the lines ℓ_a^v and ℓ_b^v. Similarly, by a *lower slab* $\overline{U}_{ab}$ we denote the region below ab, which is bounded by ℓ_a^v and ℓ_b^v.

▶ **Lemma 1.** *Let ab be a line segment and let U_{ab} be the upper slab of ab. Let q be a point in U_{ab} and let p be a point (not necessarily in U_{ab}) with a y-coordinate equal to or larger than the y-coordinate of q. Then $|pq| \leq \max\{|pa|, |pb|\}$.*

Proof. We distinguish two scenarios depending on whether ab is vertical or not.

Scenario 1 (The x-coordinates of a and b are different): Without loss of generality assume that a has a strictly smaller x-coordinate than that of b. Since the y coordinate of p is equal to or larger than the y-coordinate of q, the ray that starts at p and passes through q must hit the boundary of U_{ab}. Let o be the point of intersection when the ray exits U_{ab} (e.g., Figure 1(b)–(d)). It suffices to show that $|po| \leq \max\{|pa|, |pb|\}$.

Consider first the case when o lies on ab (e.g., Figure 1(b)). Let m be the point on line ℓ_{ab} that minimizes the distance $|pm|$, i.e., ℓ_{pm} is perpendicular to ℓ_{ab}. We now move o away from m along line ℓ_{ab} until it hits either a or b. Since we are moving o away from m, the length $|po|$ increases monotonically, and the largest length it can attain is $\max\{|pa|, |pb|\}$.

Consider now the case when o lies on the vertical sides of U_{ab} (e.g., Figure 1(c)–(d)). We move o downward along the side of U_{ab} until it hits either a or b. Since p has a higher y-coordinate than q, moving o downward increases the length $|po|$ monotonically, and the largest length it can attain is $\max\{|pa|, |pb|\}$.

Scenario 2 (The x-coordinates of a and b are the same): In this case, ab is a vertical segment. If a has a smaller y-coordinate than that of b, then $|pq| \leq |pa|$. Otherwise, $|pq| \leq |pb|$. ◀

3 Maximum Clique in Disk Graphs with k Different Radii

In this section we give an $\mathcal{O}^*(n^{2k})$-time algorithm to find a maximum clique in a disk graph where k is the number of different types of radii.

We first introduce some notation. Let $\mathcal{D}_k$ be a disk graph where the number of different types of radii is at most k. For convenience, we denote these different types of radii as $r_1, r_2, \ldots, r_k$, where for every $1 \leq i < j \leq k$, we have $r_i < r_j$. By a *type-i disk* we denote a disk of radius r_i. Let $\mathcal{C}$ be a maximum clique of $\mathcal{D}_k$. By $\mathcal{C}_i$ we denote a maximal clique in $\mathcal{C}$ where all disks are of type i.

The idea of the algorithm is as follows. We guess the number of different types of radii that may appear in a maximum clique and we take the maximum over all the solutions computed from these 2^k guesses. We now describe how a solution is computed for a particular guess for a set of radii that may appear in the maximum clique $\mathcal{C}$. For each disk type i, we guess two disk centers a_i, b_i from $\mathcal{C}_i$, where a_i is the leftmost (i.e., with the smallest x-coordinate) and b_i is the rightmost (i.e., with the largest x-coordinate) over all the disk centers in $\mathcal{C}_i$. Note that a_i may coincide with b_i if $\mathcal{C}_i$ contains only one disk, or if the centers of all disks in $\mathcal{C}_i$ are on a vertical line. Let Ψ be the set of these $2k$ disks. For every upper slab $U_{a_ib_i}$, we construct a set X_i by taking every disk that has its center in $U_{a_ib_i}$ and intersects all the disks of Ψ. We show that the union of these disks, i.e., $X = (X_1 \cup X_2 \cup \ldots \cup X_k)$, is a clique in $\mathcal{D}_k$. Similarly, for each lower slab $\overline{U}_{a_ib_i}$, we construct a set Y_i by taking every disk that has its center in $\overline{U}_{a_ib_i}$ and intersects all the disks of Ψ. We show that their union $Y = (Y_1 \cup Y_2 \cup \ldots \cup Y_k)$ is a clique in $\mathcal{D}_k$. Since the disks of Ψ are assumed to be in $\mathcal{C}$, it is straightforward to observe that $\mathcal{C}$ is a subset of the disks in $(\Psi \cup X \cup Y)$. Since the complement of the disk graph determined by the disks $(X \cup Y)$ is a bipartite graph H, we can compute the maximum clique $\mathcal{C}$ from a maximum bipartite matching in H. It now suffices to show that the disks in X (similarly, the disks in Y) are mutually adjacent.

▶ **Lemma 2.** *For every i, j, where $1 \leq i, j \leq k$, the disks in $X_i \cup X_j$ are mutually adjacent.*

Proof. Let D_{p,r_i} and D_{q,r_j} be two disks, where p belongs to X_i and q belongs to X_j. We now show that D_{p,r_i} and D_{q,r_j} must mutually intersect.

Consider first the case when $i = j$. Without loss of generality assume that the y-coordinate of p is larger than or equal to that of q. Then by Lemma 1, $|pq| \leq \max\{|pa_i|, |pb_i|\}$. By the construction of X, the disk D_{p,r_i} intersects D_{a_i,r_i} and D_{b_i,r_i}. We thus have $|pq| \leq \max\{|pa_i|, |pb_i|\} \leq 2r_i$, and since p and q correspond to type-i disks, they must intersect.

Consider now the case when $i \neq j$.

If the y-coordinate of p is larger than or equal to that of q, then we apply Lemma 1 to obtain $|pq| \leq \max\{|pa_j|, |pb_j|\}$. By the construction of X, the disk D_{p,r_i} intersects D_{a_j,r_j} and D_{b_j,r_j}. We thus have $|pq| \leq \max\{|pa_j|, |pb_j|\} \leq r_i + r_j$. Consequently, D_{p,r_i} and D_{q,r_j} mutually intersect.

If the y-coordinate of p is smaller than that of q, then we apply Lemma 1 by swapping the role of p and q, i.e., by using the condition that $p \in U_{a_i,b_i}$ whereas q has a larger y-coordinate than that of p. We thus have $|pq| \leq \max\{|qa_i|, |qb_i|\}$. By the construction of X, we have $\max\{|qa_i|, |qb_i|\} \leq r_i + r_j$. Consequently, D_{p,r_i} and D_{q,r_j} mutually intersect. ◀

We now consider the running time. There are at most $\binom{n}{0} + \binom{n}{1} + \binom{n}{2} = O(n^2)$ ways to guess the pair of disks for a particular disk type, irrespective of whether these two disks are distinct or not. Therefore, the number of ways we can guess k pairs is $O(n^{2k})$. For each guess of k pairs, it is straightforward to construct the sets X and Y in $O(kn)$ time. Since the corresponding bipartite graph and its maximum matching can be computed in polynomial time, the overall running time becomes $\mathcal{O}^*(n^{2k})$.

The following theorem summarizes the result of this section.

▶ **Theorem 3.** *Given a set of n disks in the Euclidean plane with k different types of radii, a maximum clique in the corresponding disk graph can be computed in $\mathcal{O}^*(n^{2k})$ time.*

4 Rectangular Range Query over Unit Disks

In this section, we consider the problem of reporting a maximum clique given a rectangular range query over an arrangement of unit disks. To this end, we show how to compute a maximum clique for every axis-aligned rectangle (determined by the input disk centers) in $O(n^5 \log n)$ time, which is at least a factor of $n^{4/3}$ faster than applying the algorithm of [21] separately for each axis-aligned rectangle.

To better explain such advantages of our technique, we first give an overview of the existing algorithms to compute a maximum clique in a unit disk graph. The idea of Clark, Colbourn, and Johnson's $O(n^{4.5})$-time algorithm [16] is to guess the farthest pair of vertices (v, w) in the clique, and then to find a maximum clique C that contains both v and w. Since v and w are the farthest pair, the set S of vertices that are adjacent to both v, w must lie in a lens-shaped region, i.e., the common intersection region of the two disks centered at v and w with radius $|vw|$. They showed that the lens can be partitioned by the line segment vw into two halves where the disks with centers in the same half are pairwise intersecting. Consequently, the complement of the disk graph corresponding to S is a bipartite graph H, and the maximum clique C can be computed by finding a maximum independent set in H. The running time for the unit disk case has subsequently been improved to $O(n^{3.5} \log n)$ by using non-trivial data structures [9], then to $O(n^3 \log n)$ by examining the lenses in a particular order so that the solution for each lens does not need to be computed from scratch [19, 20], and finally, to $O(n \cdot h(m)^{1+o(1)})$ by a combination of divide-and-conquer and plane sweep approach using a circular arc [21, 15]. Here $h(m)$ is

the time to compute a maximum matching in H, i.e., the complement of the disk graph inside a lens, and m is the size of the biclique cover of H. Since $m \in O(n^{4/3}\text{polylog}(n))$ [31] and a maximum matching can be computed using a maximum-flow algorithm in $O(m^{1+o(1)})$ time [22], the running time becomes $O(n^{7/3+o(1)})$. Consider now the scenario of computing a maximum clique for every possible rectangle determined by the input disk centers. Since lenses examined by these algorithms are not necessarily axis-aligned, finding an order of the lenses to compute solutions for the rectangles by dynamic point insertion and deletion appears to be challenging. A straightforward approach that solves each rectangular region independently takes $O(n^{6.33+o(1)})$ time.

The idea of our algorithm is to maintain solutions for all possible slabs where one can insert and delete points as necessary to find the solutions for all possible rectangles within the slab. For convenience, we assume that the centers of the disks are in general position, i.e., no two centers have the same y-coordinates. We now describe the details.

Consider first an alternative (slower) approach that uses slabs to compute a maximum clique that guesses the leftmost and rightmost points a, b of a maximum clique. For every such guess, one can find a maximum clique by considering the set S of disks that are adjacent to both a, b and have their centers in the slab bounded by ℓ_a^v and ℓ_b^v. By Lemma 1, the disks of S that have their centers in U_{ab} (similarly, in $\overline{U}_{a,b}$) are mutually adjacent. Consequently, the complement of the disk graph underlying S is a bipartite graph H, and a maximum clique can be computed by finding a maximum independent set in H.

We now consider maintaining the solutions for all possible slabs under point insertion and deletion. Initially, the solution for each slab is set to null. We now sweep the plane upward with two horizontal lines ℓ^b and ℓ^u in two phases.

In the first phase, ℓ^b is placed so that it passes through the disk center with the lowest y-coordinate, and ℓ^u is used to sweep the plane upward starting at ℓ_b. Each time ℓ^u moves to a new point, a point is inserted into the corresponding slabs and their solutions are updated. Every time the horizontal slab between ℓ^b and ℓ^u contains the guessed points of a slab (i.e., the two points determining a slab), we obtain a solution for a new rectangular region, and the corresponding solution is stored in a table. It is straightforward to observe that each insertion changes $O(n^2)$ slabs, and hence we have $O(n^3)$ insertion operations in total.

In the next phase, we sweep the plane upward using ℓ^b. Each time ℓ^b moves to a new point, a point is deleted from the corresponding rectangular regions we considered in the first phase. A deletion changes $O(n^3)$ previous solutions, i.e., the solutions corresponding to $O(n^2)$ slabs and $O(n)$ regions in each slab determined by the positions of ℓ_b. Therefore, we have $O(n^4)$ deletion operations in total.

Each insertion and deletion operation updates existing lenses, each of which is determined by a pair of guessed points. It is known that such updates can be done in $O(n \log n)$ time by performing an alternating path search to update the maximum independent set in the bipartite graph determined by the complement of the disk graph inside the lens [20, 19]. For $O(n^4)$ update operations, the running time becomes $O(n^5 \log n)$. By $S[p_\ell, p_r, p_t, p_b]$ we denote the size of a maximum clique inside a rectangle R with its left, right, top and bottom sides being determined by the lines through the disk centers p_ℓ, p_r, p_t, p_b, respectively, where $|p_\ell, p_r|$ is at most two units and p_ℓ, p_r appear on the left and right sides of R. If $|p_\ell, p_r|$ is larger than two units, then $S[p_\ell, p_r, p_t, p_b]$ is 0.

We now compute a maximum clique for each axis-aligned rectangle determined by the input disk centers. We first compute two sorted orders of the disk centers, one based on increasing x-coordinates and the other based on increasing y-coordinates. We now use a dynamic programming approach, where the base cases are the entries of S, and the $O(n^4)$

rectangles that do not contain any disk center in their proper interior. The latter can be computed and stored in a table in $O(n^4)$ time. Let $M[p_\ell, p_r, p_t, p_b]$ be the maximum clique of a rectangle R with its left, right, top and bottom sides being determined by the lines through p_ℓ, p_r, p_t, p_b, respectively. Note that the disk centers of the maximum clique may not appear on the sides of R. Let p'_ℓ and p'_r be the disk centers immediately after and before p_ℓ and p_r, respectively, which can be determined from the precomputed sorted order. Similarly, p'_t and p'_b are the disk centers immediately before and after p_t and p_b, respectively. We now can find a solution using $O(1)$ table look-ups as follows.

$$M[p_\ell, p_r, p_t, p_b] = \begin{cases} \max\{S[p_\ell, p_r, p_t, p_b], M[p'_\ell, p_r, p_t, p_b], \\ \qquad M[p_\ell, p'_r, p_t, p_b], M[p_\ell, p_r, p'_t, p_b], \\ \qquad M[p_\ell, p_r, p_t, p'_b]\}, & \text{if } p_\ell \text{ and } p_r \text{ appear on } R \\ \max\{M[p'_\ell, p_r, p_t, p_b], M[p_\ell, p'_r, p_t, p_b], \\ \qquad M[p_\ell, p_r, p'_t, p_b], M[p_\ell, p_r, p_t, p'_b]\}, \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{otherwise.} \end{cases}$$

Since there are $O(n^4)$ cells in the table and each entry is computed by $O(1)$ table look-ups which are determined in $O(\log n)$ time, the overall running time remains $O(n^5 \log n)$.

▶ **Theorem 4.** *Given a set of n unit disks in the Euclidean plane, a maximum clique for every possible axis-aligned rectangle determined by the given disk centers can be computed in $O(n^5 \log n)$ time.*

5 Maximum Clique in Ball Graphs with k Different Radii

We now give an $\mathcal{O}^*(n^{2rk})$-time algorithm for computing a maximum clique in a ball graph, where the centers of the balls are contained in r planes which are all perpendicular to a different plane (Section 5.2). For simplicity, we first consider a scenario when the input planes are parallel to each other (Section 5.1).

5.1 Ball Centers are on r Parallel Planes

Without loss of generality, we assume that the r input planes are parallel to the xy-plane. We first show that a version of Lemma 1 holds in three dimensions, as follows.

▶ **Lemma 5.** *Let ab be a line segment on a plane L, where L is parallel to the xy-plane, and let U_{ab} be the upper slab of ab on L. Let q be a point in U_{ab}. Let p be a point (not necessarily on L) with a y-coordinate equal to or larger than the y-coordinate of q. Then $|pq| \leq \max\{|pa|, |pb|\}$.*

Proof. Let p' be the projection of p on L (Figure 2(a)). Then the y-coordinate of p' is equal to or larger than the y-coordinate of q. By Lemma 1, $|p'q| \leq \max\{|p'a|, |p'b|\}$ and thus

$$\begin{aligned} & \sqrt{|pq|^2 - |pp'|^2} \leq \max\{\sqrt{|pa|^2 - |pp'|^2}, \sqrt{|pb|^2 - |pp'|^2}\} \\ \implies & |pq|^2 - |pp'|^2 \leq \max\{|pa|^2 - |pp'|^2, |pb|^2 - |pp'|^2\} \\ \implies & |pq| \leq \max\{|pa|, |pb|\}. \end{aligned}$$

◀

Let B_k be a ball graph with k different types of radii. Similar to Section 3, we guess the number of different types of radii that may appear in a maximum clique and we take the maximum over all the solutions computed from these 2^k guesses. For each ball type i,

we guess at most $2r$ ball centers $\{a_i^1, b_i^1\}, \ldots, \{a_i^r, b_i^r\}$ from $\mathcal{C}_i$. Here a_i^j is the leftmost and b_i^j is the rightmost over all the ball centers in $\mathcal{C}_i$ on the jth plane, where $1 \leq j \leq r$. Note that a_i^j may sometimes coincide with b_i^j. Let Ψ be the set of these $2rk$ balls. For every upper slab $U_{a_i^j b_i^j}$ on the jth plane, we construct a set X_i^j by taking every ball that has its center in $U_{a_i^j b_i^j}$ and intersects all the balls of Ψ. We show that the union of these balls, i.e., $X = \bigcup_{1 \leq i \leq k} (X_i^1 \cup X_i^2 \cup \ldots \cup X_i^r)$, is a clique in $\mathcal{D}_k$. Similarly, for each lower slab $\overline{U}_{a_i b_i}$, we construct a set Y_i^j by taking every ball that has its center in $\overline{U}_{a_i^j b_i^j}$ and intersects all the balls of Ψ. We show that their union $Y = \bigcup_{1 \leq i \leq k} (Y_i^1 \cup Y_i^2 \cup \ldots \cup Y_i^r)$ is a clique in $\mathcal{D}_k$. It now suffices to show that the balls in X (similarly, the balls in Y) are mutually adjacent.

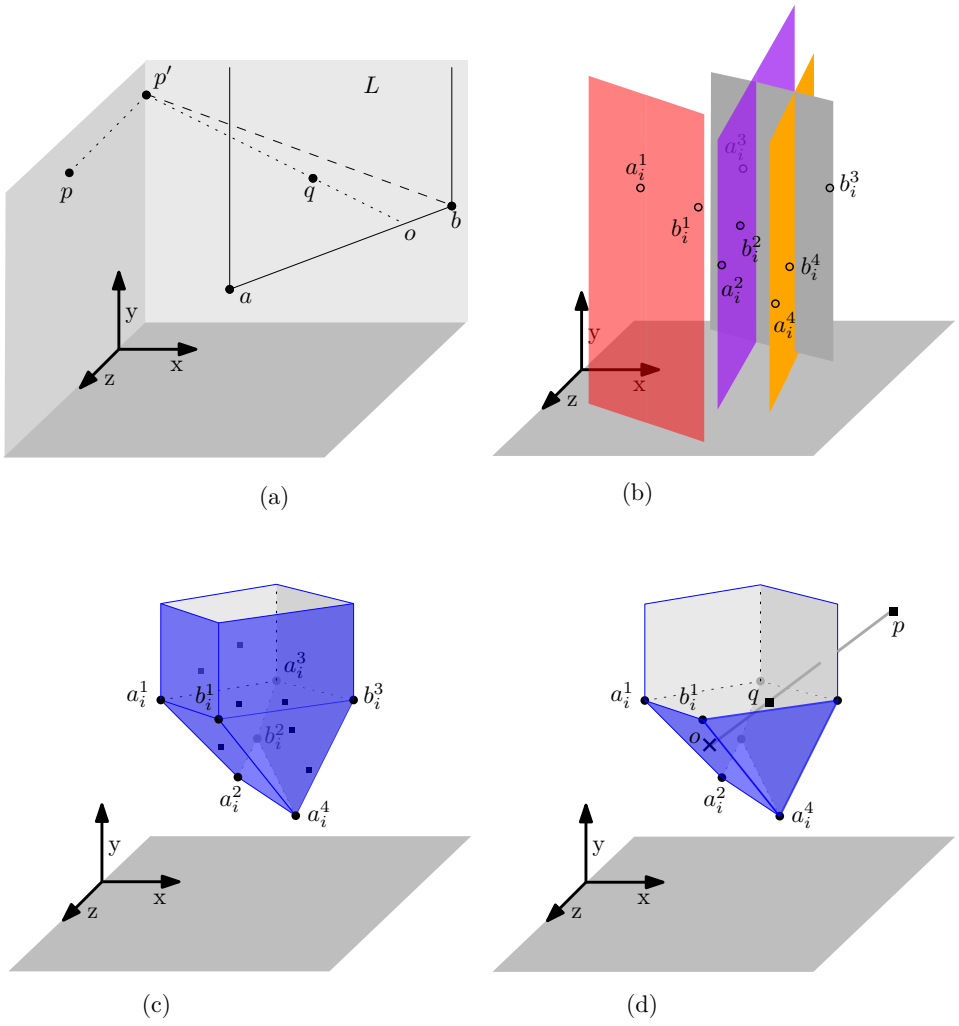

Figure 2 Illustration for (a) Lemma 5, and (b)–(d) Lemma 9.

▶ **Lemma 6.** *For every i, j, where $1 \leq i, j \leq k$, the balls in $X_i^g \cup X_j^h$, where $1 \leq g \leq h \leq r$, are mutually adjacent.*

Proof. Let B_{p,r_i} and B_{q,r_j} be two balls, where p belongs to X_i^g and q belongs to X_j^h. We now show that B_{p,r_i} and B_{q,r_j} must mutually intersect. If $g = h$, then the proof follows from Lemma 2. Therefore, we may assume that $g \neq h$. However, the proof in this case is the same as that of Lemma 2 except that we use Lemma 5 instead of Lemma 1 for the arguments, as follows.

Consider first the case when $i = j$. Without loss of generality assume that the y-coordinate of p is larger than or equal to that of q. Then by Lemma 5, $|pq| \leq \max\{|pa_j^h|, |pb_j^h|\}$. By the construction of X, the ball B_{p,r_i} intersects $B_{a_j^h,r_i}$ and $B_{b_j^h,r_i}$. We thus have $|pq| \leq \max\{|pa_j^h|, |pb_j^h|\} \leq 2r_j$, and since p and q correspond to type-j balls, they must intersect.

Consider now the case when $i \neq j$. If the y-coordinate of p is larger than or equal to that of q, then we apply Lemma 5 to obtain $|pq| \leq \max\{|pa_j^h|, |pb_j^h|\}$. By the construction of X, the ball B_{p,r_i} intersects $B_{a_j^h,r_j}$ and $B_{b_j^h,r_j}$. We thus have $|pq| \leq \max\{|pa_j^h|, |pb_j^h|\} \leq r_i + r_j$. Consequently, B_{p,r_i} and B_{q,r_j} mutually intersect. If the y-coordinate of p is smaller than that of q, then we apply Lemma 5 by swapping the role of p and q, i.e., by using the condition that $p \in U_{a_i^g,b_i^g}$ whereas q has a larger y-coordinate than that of p. We thus have $|pq| \leq \max\{|qa_i^g|, |qb_i^g|\}$. By the construction of X, we have $\max\{|qa_i^g|, |qb_i^g|\} \leq r_i + r_j$. Consequently, B_{p,r_i} and B_{q,r_j} mutually intersect. ◀

We now consider the running time. For a single plane, there are at most $O(n^2)$ ways to guess the pair of balls for a particular ball type, and thus $O(n^{2k})$ ways for k pairs considering all types. Since we have r planes, the total number of guesses is $O(n^{2rk})$. For each guess of rk pairs, it is straightforward to construct the sets X and Y in $O(rkn)$ time. Since the the ball graph determined by the balls $(X \cup Y)$ and the corresponding maximum matching can be computed in polynomial time. the running time becomes $\mathcal{O}^*(n^{2rk})$.

The following theorem summarizes the result of this section.

▶ **Theorem 7.** *Given a set of n balls in the Euclidean plane with k different types of radii where the ball centers are contained on r parallel planes, a maximum clique in the corresponding ball graph can be computed in $\mathcal{O}^*(n^{2rk})$ time.*

5.2 Ball Centers are on r Planes that are Perpendicular to Another Plane

We now show that the condition for the input planes being parallel to each other can be relaxed as long as the input planes are all perpendicular to a different plane. Without loss of generality assume that the r input planes are perpendicular to the xz-plane (e.g., Figure 2(b)). We first observe the following property of a maximum clique.

▶ **Lemma 8.** *Let B_k be a ball graph with k different radii with centers on r planes that are perpendicular to the xz-plane. Let $\mathcal{C}_i$ be all the balls of type i in a maximum clique of B_k. Let P be the projection of the ball centers in $\mathcal{C}_i$ on the xz-plane. Then the convex-hull boundary of P contains at most $2r$ vertices (i.e., they correspond to strictly convex corners).*

Proof. If three points of P come from the same original plane, then they are collinear in the xz-plane, thus only two of them can appear as strictly convex corners on the convex-hull boundary of P. Therefore, the r planes can contribute to at most $2r$ vertices in total. ◀

Let Q be a set of points in three dimensions. By a *convex hull* of Q we denote the smallest convex polyhedra that contains all points in Q. A *lower (upper) envelope* of Q consists of all points that lie at the boundary of the convex hull of Q such that the rays that start at these points and move along the negative y-axis (positive y-axis) do not contain any interior

point of the convex hull. An *extended lower envelope* of Q is a three-dimensional region that consists of the points on the lower envelope and all points that are hit by the rays that start at the lower envelope and move along the positive y-axis. Figure 2(c) illustrates an extended lower envelope. We also define an *extended upper envelope* of Q symmetrically.

Similar to Section 3, we guess the set of different types of radii that may appear in a maximum clique. For each ball type i, we guess at most $2r$ ball centers $\{a_i^1, b_i^1\}, \ldots, \{a_i^r, b_i^r\}$ from $\mathcal{C}_i$, where a_i^j is the leftmost and b_i^j is the rightmost over all the ball centers in $\mathcal{C}_i$ (e.g., Figure 2(b)) on the jth plane. It is straightforward to observe that the convex hull of the projection of the guessed ball centers on the xz-plane contains the projection of all ball centers of $\mathcal{C}_i$. Let Ψ be the set of at most $2rk$ balls that we guess over all radii types.

For every extended lower envelope U_i for the ball centers guessed for type i, we construct a set $\mathcal{X}_i$ by taking every ball that has its center in U_i and intersects all the balls of Ψ. We show that the union of these balls, i.e., $\mathcal{X} = (\mathcal{X}_1 \cup \mathcal{X}_2 \cup \ldots \cup \mathcal{X}_k)$, determines a clique. Similarly, for each extended upper envelope $\overline{U}_i$, we construct a set $\mathcal{Y}_i$ by taking every ball that has its center in $\overline{U}_i$ and intersects all the balls of Ψ. We show that their union $\mathcal{Y} = (\mathcal{Y}_1 \cup \mathcal{Y}_2 \cup \ldots \cup \mathcal{Y}_k)$, determines a clique. It now suffices to show that the balls in $\mathcal{X}$ (similarly, the balls in $\mathcal{Y}$) are mutually adjacent.

▶ **Lemma 9.** *For every i, j, where $1 \leq i, j \leq k$, the balls in $\mathcal{X}_i \cup \mathcal{X}_j$ are mutually adjacent.*

Proof. Let B_{p,r_i} and B_{q,r_j} be two balls, where p belongs to $\mathcal{X}_i$ and q belongs to $\mathcal{X}_j$. We now show that B_{p,r_i} and B_{q,r_j} must mutually intersect.

The argument in the rest of the proof works irrespective of whether $i = j$ or not. Without loss of generality assume that the y-coordinate of p is larger than or equal to that of q. Let R be the ray that starts at p and passes through q, and let o be the intersection point of R when R exits the extended lower envelope U_i. Figure 2(d) illustrates this when $i \neq j$.

Assume first that o hits a face F of the lower envelope, and let L be the plane determined by F. Let m be the point of L that minimizes the distance $|pm|$. Since F is convex, moving o away from m on F would increase the length $|po|$ monotonically and hit a vertex w of F. Since B_{p,r_i} intersects B_{w,r_j}, and since $|pq| \leq |po| \leq |pw| \leq r_i + r_j$, the balls B_{p,r_i} and B_{q,r_j} must intersect.

Assume now that o does not belong to the lower envelope but hits a side F of the extended lower envelope, and let L be the plane determined by F. Let m be the point of L that minimizes the distance $|pm|$. Since F is convex, moving o towards negative y-axis and away from m on F would increase the length $|po|$ monotonically and hit a vertex w of F. Since B_{p,r_i} intersects B_{w,r_j}, and since $|pq| \leq |po| \leq |pw| \leq r_i + r_j$, the balls B_{p,r_i} and B_{q,r_j} must intersect. ◀

The following theorem summarizes the result of this section.

▶ **Theorem 10.** *Given a set of n balls in the Euclidean plane with k different types of radii where the ball centers are contained on r planes that are perpendicular to a single different plane, a maximum clique in the corresponding ball graph can be computed in $\mathcal{O}^*(n^{2rk})$ time.*

6 Maximum Clique in Disk-Like Graphs

In this section we give an $\mathcal{O}^*(n^{2k})$-time algorithm to compute a maximum clique in the intersection graph of n L-visible convex polygons with k distinct shapes. Figure 3(a) illustrates an L-visible polygon, where every point of the polygon is L-visible from a center point c.

We first introduce some notation. Let $\mathcal{S}_k$ be an intersection graph of L-visible polygons, where the number of different types of shapes is at most k. For convenience, we denote these shapes as $S_1, S_2, \ldots, S_k$ and for each shape S_i, designate a center c_i, i.e., all points

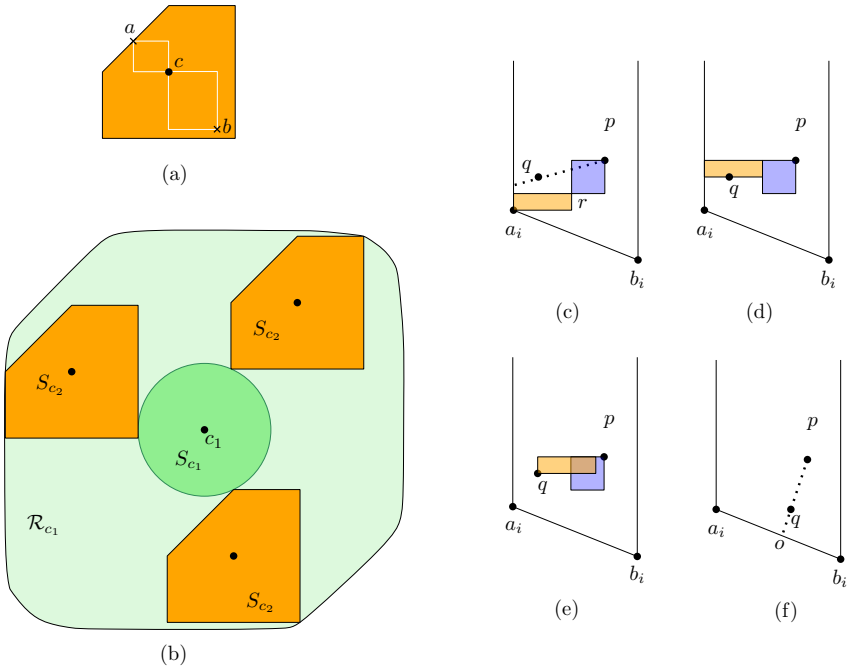

Figure 3 (a) Illustration for L-visibility. (b) $\mathcal{R}_{c_1}$. (c)–(f) Illustration for the proof of Lemma 12.

of S_i are L-visible from c_i. Let $\mathcal{C}$ be a maximum clique of $\mathcal{S}_k$. By $\mathcal{C}_i$ we denote a maximal clique in $\mathcal{C}$ where all shapes are of type i. We also use the following properties of L-visible shapes which are straightforward to verify using the concept of Minkowski sum of two convex polygons [18].

▶ Remark 11. Let S_1 and S_2 be two L-visible convex shapes with centers c_1 and c_2, respectively. Let $\mathcal{R}_{c_1}$ be the region that consists of points where S_2 can be placed to intersect S_1. Then $\mathcal{R}_{c_1}$ is convex (Figure 3(b)).

The idea of the algorithm is similar to that of Section 3. We guess the set of different types of shapes that may appear in a maximum clique and we take the maximum over all the solutions computed from these 2^k guesses. For each type i, we guess the leftmost and rightmost shape centers a_i and b_i, respectively, over the shapes in $\mathcal{C}_i$. Let Ψ be the set of these $2k$ shapes. For every upper slab $U_{a_ib_i}$, we construct a set X_i by taking every shape that has its center in $U_{a_ib_i}$ and intersects all the shapes of Ψ. We show that the union of these shapes, i.e., $X = (X_1 \cup X_2 \cup \ldots \cup X_k)$, is a clique in $\mathcal{S}_k$. Similarly, for each lower slab $\overline{U}_{a_ib_i}$, we construct a set Y_i by taking every shape that has its center in $\overline{U}_{a_ib_i}$ and intersects all the shapes of Ψ. We show that their union $Y = (Y_1 \cup Y_2 \cup \ldots \cup Y_k)$ is a clique in $\mathcal{S}_k$. A maximum clique can then be found from a maximum bipartite matching in the complement of the intersection graph of $(X \cup Y)$. The time to compute the graph and the matching is polynomial in n and m, where m is the *shape complexity*, i.e., upper bound on the number of smooth curves on the boundary of a shape.

▶ **Lemma 12.** *For every i, j, where $1 \leq i, j \leq k$, the shapes in $X_i \cup X_j$ are mutually adjacent.*

Proof. Let $S_q \in X_i$ and $S_p \in X_j$ be two shapes with centers q and p, respectively. We now show that S_p and S_q must mutually intersect.

Consider first the case when $i = j$, i.e., p and q both belong to the upper slab $U_{a_ib_i}$. Without loss of generality assume that the y-coordinate of p is larger than or equal to that of q. We now consider two scenarios.

If the ray starting at p passing through q does not intersect a_ib_i, then assume without loss of generality that it intersects the left side of $U_{a_ib_i}$ after passing through q (Figure 3(c)). Let r be a point that is common to both S_{a_i} and S_p. Let R be the axis-aligned rectangle with diagonal rp. We can then consider moving the center a_i along the left side of $U_{a_ib_i}$ until we reach the y-coordinate of q, and then move a_i horizontally until it coincides with q (Figure 3(d)–(e)). Throughout the process the axis-aligned rectangle with diagonal a_ir maintains an intersection region with R. Hence S_q must intersect S_p.

If the ray starting at p passing through q intersects a_ib_i at a point o (Figure 3(f)), then we prove the adjacency of S_p and S_q as follows. By Remark 11, $\mathcal{R}_p$ is convex. Since S_p intersects a_i and b_i, $\mathcal{R}_p$ also contains a_i and b_i. By the convexity of $\mathcal{R}_p$, the segment a_ib_i belongs to $\mathcal{R}_p$. We now move the center a_i to o along the line a_ib_i. Since $a_io \in \mathcal{R}_p$, throughout the process S_{a_i} intersects S_p. We now move a_i from o to q along the line op. Since L-visible shapes are convex, moving a pair of intersecting L-visible shapes closer along the the line determined by their centers keeps them intersected. Therefore, throughout the process S_{a_i} maintains an intersection with S_p. Hence S_q must intersect S_p.

Consider now the case when $i \neq j$. If the y-coordinate of p is larger than or equal to that of q, then the proof above still applies. The only difference is that p can now be outside of $U_{a_ib_i}$, but this leaves the above argument the same as we only used the property that the y-coordinate of p is larger than or equal to that of q. If the y-coordinate of p is smaller than that of q, then we can swap the role of p and q, i.e., by using the condition that $p \in U_{a_i,b_i}$ whereas q has a larger y-coordinate than that of p. ◀

The running time can now be computed in the same way as in Section 3.

▶ **Theorem 13.** *Given a set of n L-visible convex shapes in the Euclidean plane where the number of distinct shapes is k, a maximum clique in the corresponding intersection graph can be computed in $\mathcal{O}^*(n^{2k})$ time.*

7 Direction for Future Research

We gave an $\mathcal{O}^*(n^{2k})$-time algorithm to find a maximum clique in a n-vertex disk graph with k different radii. Designing faster algorithms is a natural direction to explore. Existing techniques [38] that computes maximum clique on unit disk graphs even when a geometric representation is not given do not generalize to our context. Therefore, finding efficient algorithms when a geometric representation of the disk graph is not given would be interesting.

We showed that given a set of n unit disks, one can compute a maximum clique for each possible axis-aligned rectangle determined by the input disk centers in $O(n^5 \log n)$ time. Consequently, given a rectangular range query R, the maximum clique C inside R can be reported in $O(\log \log n + |C|)$ time, where the $O(\log \log n)$ term is to locate the rectangle R' (using range searching data structures [37]) for which a solution is precomputed. Improving the $O(n^5 \log n)$ running time or establishing tight time-space trade-offs can be interesting.

For ball graphs, we gave an $\mathcal{O}^*(n^{2rk})$-time algorithm to find a maximum clique, where k is the number of different radii and the ball centers are contained in r planes that are perpendicular to a single different plane. One may attempt to relax our perpendicularity constraint. The NP-hardness reduction for computing a maximum clique in a ball graph [6] allows for arbitrary radii whereas our result provides polynomial-time algorithms when $r, k \in O(1)$. The case when $k \in o(n)$ can be explored. Finally, can we find a polynomial-time algorithm for computing maximum clique in the intersection graph of convex shapes that are not necessarily L-visible, where the number of distinct shapes is fixed?

Abstract

The Generalized Persistence Diagram (GPD) for multi-parameter persistence naturally extends the classical notion of persistence diagram for one-parameter persistence. However, unlike its classical counterpart, computing the GPD remains a significant challenge. The main hurdle is that, while the GPD is defined as the Möbius inversion of the Generalized Rank Invariant (GRI), computing the GRI is intractable due to the formidable size of its domain, i.e., the set of all connected and convex subsets in a finite grid in $\mathbb{R}^d$ with $d \geq 2$. This computational intractability suggests seeking alternative approaches to computing the GPD.

In order to study the complexity associated to computing the GPD, it is useful to consider its classical one-parameter counterpart, where for a filtration of a simplicial complex with n simplices, its persistence diagram contains at most n points. This observation leads to the question: *Given a d-parameter simplicial filtration, could the cardinality of its GPD (specifically, the support of the GPD) also be bounded by a polynomial in the number of simplices in the filtration?* This is the case for $d = 1$, where we compute the persistence diagram directly at the simplicial filtration level. If this were also the case for $d \geq 2$, it might be possible to compute the GPD directly and much more efficiently without relying on the GRI.

We show that the answer to the question above is negative, demonstrating the inherent difficulty of computing the GPD. More specifically, we construct a sequence of d-parameter simplicial filtrations where the cardinalities of their GPDs are not bounded by any polynomial in the number of simplices. Furthermore, we show that several commonly used methods for constructing multi-parameter filtrations can give rise to such "wild" filtrations.

1 Introduction

(Multi-parameter) Persistent Homology. Persistent homology is a central concept in Topological Data Analysis (TDA), which is useful for studying the multi-scale topological features of datasets [16, 17, 27]. In the classical one-parameter setting, topological features in datasets are summarized in the form of persistence diagrams or barcodes [23, 65], which serve as complete, discrete invariants of the associated persistence modules.

Multi-parameter persistent homology generalizes persistent homology. In the d-parameter setting, topological features of datasets are indexed by the poset $\mathbb{R}^d$ or a subposet of $\mathbb{R}^d$ [11, 18]. This generalization allows for a finer extraction of topological features, enabling a more detailed analysis of complex datasets [19, 24, 46, 47, 59, 63, 64]. However, the algebraic structure of multi-parameter persistence modules, i.e. functors from the poset $\mathbb{R}^d$ ($d \geq 2$) to the category $\mathbf{vec}_{\mathbb{F}}$ of finite dimensional vector spaces over a field $\mathbb{F}$, is significantly more complex, and in fact no complete discrete invariant exists for multi-parameter persistence modules [18].

Generalized Persistence Diagram (GPD). Many incomplete, but potentially useful invariants for multi-parameter persistence modules have been studied; e.g. [3, 4, 8, 12, 21, 34, 35, 44, 45, 51, 54, 58]. The Generalized Persistence Diagram (GPD) is one such invariant and is a natural extension of the persistence diagram for one-parameter persistence [39, 55]. The GPD is defined as the Möbius inversion of the Generalized Rank Invariant (GRI)[1], which captures "persistence" in multi-parameter persistence modules or, more generally, any linear representations of posets [40]. Many aspects of the GPD and GRI–such as stability, discriminating power, computation, connections to other invariants, and generalizations–have been studied; e.g. [5, 12, 22, 25, 26, 31, 41, 42]. Also, a vectorization method for the (restricted) GRI has recently been proposed and utilized in a machine learning context [53, 64]. There are also other works on invariants of multi-parameter persistence modules that are closely related to the GPD and GRI; e.g. [3, 4, 5, 8, 15, 34, 36].

Challenges in Computing the GPD. While many properties of the GPD have been clarified in the aforementioned works, computing the GPD, unlike its classical counterpart, remains a significant challenge. The main hurdle is that, while the GPD is defined as the Möbius inversion of the GRI, computing the GRI is intractable mainly due to the formidable size of its domain. For instance, the domain of the GRI of a persistence module over a finite grid $G \subset \mathbb{R}^d$ is the set of all *intervals* in G (cf. Definitions 2 and 5). The cardinality of the domain is huge relative to the cardinality $|G|$ of G even when $d = 2$; cf. [2, Theorem 31]. This computational intractability suggests seeking alternative approaches to computing the GPD.

In order to study the complexity associated to computing the GPD, it is useful to consider its classical one-parameter counterpart, where for a filtration of a simplicial complex with N simplices, its persistence diagram contains at most N points. This observation leads to the question: *Given a d-parameter simplicial filtration, could the cardinality of its GPD (more precisely, the support of the GPD) also be bounded by a polynomial in the number of simplices in the filtration?* In what follows, we make this question more precise.

Size of the GPD. Let K be an abstract simplicial complex, and let ΔK be the set of subcomplexes of K ordered by inclusion. A monotone map $\mathcal{F} : \mathbb{R}^d \to \Delta K$ such that there exists a $p \in \mathbb{R}^d$ with $\mathcal{F}_p := \mathcal{F}(p) = K$ is called a **(d-parameter simplicial) filtration (of K)**. The number of simplices in the filtration $\mathcal{F}$ is defined as the number of simplices in K.

[1] The term "generalized persistence diagram" sometimes refers to different concepts; e.g. [14, 52, 56]. Also, we note that the notion of the GRI stems from the concept of the rank invariant [18].

▶ **Definition 1** ([45]). *We call the filtration $\mathcal{F}$ **finite**, if K is finite, and in $\mathcal{F}$, every simplex $\sigma \in K$* is born at finitely many points of $\mathbb{R}^d$, *i.e. there exist finitely many points $q_1, \ldots, q_{t(\sigma)} \in \mathbb{R}^d$ s.t. $\sigma \in \mathcal{F}_p$ for $p \in \mathbb{R}^d$ if and only if $q_i \leq p$ in $\mathbb{R}^d$ for some $i = 1, \ldots, t(\sigma)$. We call those points $q_1, \ldots, q_{t(\sigma)}$ the **birth indices** of σ. We also say that σ is **born** at $q_1, \ldots, q_{t(\sigma)} \in \mathbb{R}^d$.*

If $\mathcal{F}$ is finite, then for each homology degree $m \in \mathbb{Z}_{\geq 0}$, the persistence module $\mathrm{H}_m(\mathcal{F}; \mathbb{F}) : \mathbb{R}^d \to \mathbf{vec}_{\mathbb{F}}$ is finitely presentable (cf. Definition 3 and Remark 4). This guarantees that the ***m*-th GPD** of any finite d-parameter filtration is well-defined as an integer-valued function on a *finite* subset of intervals of $\mathbb{R}^d$ (cf. Definition 5 and Remark 7), denoted by $\mathrm{dgm}_m(\mathcal{F})$. By the **size** of $\mathrm{dgm}_m(\mathcal{F})$ we mean the cardinality of the *support* of $\mathrm{dgm}_m(\mathcal{F})$, i.e. $|\{I \in \mathrm{Int}(\mathbb{R}^d) : \mathrm{dgm}_m(\mathcal{F})(I) \neq 0\}|$ (cf. Definition 2). Since the notion of the GPD reduces to that of the persistence diagram when $d = 1$ [22, Section 3], in this case, the size of the GPD becomes the number of points in the persistence diagram. Our question is as follows.

▶ **Question.** Does there exist $k \in \mathbb{Z}_{\geq 0}$ such that for *any* homology degree $m \geq 0$, the size of the m-th GPD of *any* finite simplicial filtration $\mathcal{F}$ over $\mathbb{R}^d$ is $O(N^k)$ where N stands for the number of simplicies in $\mathcal{F}$?

Note that when $d = 1$, the answer to the question is *yes*, and k can be taken to be 1, in which case we compute the persistence diagram directly at the simplicial filtration level [28]. If the answer is also *yes* when $d \geq 2$, it might be possible to compute the GPD of multi-parameter filtrations directly and much more efficiently without relying on the GRI of the persistence module $\mathrm{H}_m(\mathcal{F}; \mathbb{F}) : \mathbb{R}^d \to \mathbf{vec}_{\mathbb{F}}$.

Our contributions

1. We show that the answer to **Question** above is negative, demonstrating the inherent difficulty of computing the GPD (Theorem 13). More specifically, we construct a sequence $(\mathcal{F}_n)$ of finite d-parameter simplicial filtrations where the sizes of their GPDs are not bounded by any polynomial in the number of simplices in $\mathcal{F}_n$.
2. We also show that several well-known methods for constructing multi-parameter filtrations – Sublevel-Rips, Sublevel-Čech, Degree-Rips, and Degree-Čech – can give rise to such "wild" filtrations (Theorems 24 and 25).
3. We find that computing the value of the GPD for a 2-parameter filtration containing $O(n^s)$ simplices, for some $s \in \mathbb{N}$, via the Möbius inversion of the GRI can result in the problem of summing $\Theta(2^n)$ integers, which is an EXPTIME problem (Corollary 26). This implies that, even with the fully computed GRI, computing the GPD through Möbius inversion of the GRI remains computationally challenging.

It is noteworthy that in the proofs of some of our results, we employ techniques inspired by some recent works on the GRI [12, 22] as well as Rota's Galois connections [33]; see the proof of Theorem 13 for the case of $d > 2$ and that of Lemma 21.

Other related works. Botnan, Oppermann, Oudot investigated the computational complexity of the minimal rank decomposition of the standard rank invariant as part of their results [12, Remark 5.3]. Also, Botnan, Oppermann, Oudot, Scoccola found an upper bound on the size of the rank *exact* decomposition of a persistence module, which is a polynomial in the size of the (usual) multigraded Betti numbers of the module [13].

Clause, Kim, Mémoli identified a *tame* persistence module M over $\mathbb{Z}^2$ (a concept introduced by Miller [51]) whose GRI does not admit a Möbius inversion [22, Theorem B]. Our construction of persistence modules in Section 3 is reminiscent of that of M, making it natural to interpret M as a limit object of the types of persistence modules we construct.

Morozov and Patel elucidated a connection between 1- and 2-parameter persistence settings in order to find an output-sensitive algorithm for computing the Möbius inversion of the birth-death function [52]. We also note that there are many recent examples of utilizing Möbius inversion to extract information from (multi-parameter) persistent (co)homology: see e.g. [7, 33, 34, 49, 50, 52, 54, 56, 62].

Alonso, Kerber, Skraba showed that many multi-parameter filtration constructions, such as density- or degree-Rips bifiltrations, and across a general category of point samples in Euclidean space, the probability of the homology-induced persistence module decomposing into interval modules approaches zero as the sample size tends to infinity [1].

Organization. In Section 2, we review basic terminology and well-known theorems related to persistence modules, as well as the GPD and GRI. In Sections 3 and 4, we establish our main results, as mentioned above. Finally, in Section 5, we discuss future research directions.

2 Preliminaries

Persistence modules and barcodes. Throughout this paper, $P = (P, \leq)$ is a poset, regarded as the category whose objects are the elements of P, and for any pair $p, q \in P$, there exists a unique morphism $p \to q$ if and only if $p \leq q$. All vector spaces in this paper are over a fixed field $\mathbb{F}$. Let $\mathbf{vec}_{\mathbb{F}}$ denote the category of finite-dimensional vector spaces and linear maps over $\mathbb{F}$. A functor $P \to \mathbf{vec}_{\mathbb{F}}$ will be referred to as a **persistence module over P** or simply a **P-module**. A morphism between P-modules is a natural transformation between the P-modules. For any P-modules M and N, their direct sum $M \oplus N$ is defined pointwisely. A P-module M is **trivial** if $M(p) = 0$ for all $p \in P$, and we write $M = 0$. A nontrivial P-module M is **indecomposable** if the assumption $M \cong M' \oplus M''$ for some P-modules M' and M'' implies that either $M' = 0$ or $M'' = 0$. By Krull-Remak-Schmidt-Azumaya's theorem [6, 9], any P-module is isomorphic to a direct sum of indecomposable P-modules, and this decomposition is unique up to isomorphism and permutation of summands.

▶ **Definition 2.** *An **interval** I of P is a subset $I \subseteq P$ such that:*

- **(i)** *I is nonempty.*
- **(ii)** *If $p, q \in I$ and $p \leq r \leq q$, then $r \in I$.*
- **(iii)** *I is **connected**, i.e. for any $p, q \in I$, there is a sequence $p = p_0, p_1, \cdots, p_\ell = q$ of elements of I with p_i and p_{i+1} comparable for $0 \leq i \leq \ell - 1$.*

By $\mathrm{Int}(P)$ we denote the set of all intervals of P.

For any $p \leq q$ in P, the set $[p, q] := \{r \in P : p \leq r \leq q\}$ is called a **segment**. The collection of all segments (resp. intervals) in P will be denoted by $\mathrm{Seg}(P)$ (rep. $\mathrm{Int}(P)$). It is not difficult to see that $\mathrm{Seg}(P) \subset \mathrm{Int}(P)$.

Given any $I \in \mathrm{Int}(P)$, the **interval module** $\mathbb{F}_I$ is the P-module, with

$$\mathbb{F}_I(p) := \begin{cases} \mathbb{F} & \text{if } p \in I \\ 0 & \text{otherwise.} \end{cases}, \qquad \mathbb{F}_I(p \leq q) := \begin{cases} \mathrm{id}_{\mathbb{F}} & \text{if } p \leq q \in I \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

Every interval module is indecomposable [10, Proposition 2.2]. A P-module M is called **interval-decomposable** if it is isomorphic to a direct sum of interval modules. The **barcode** of an interval decomposable P-module $M \cong \bigoplus_{j\in J} \mathbb{F}_{I_j}$ is defined as the multiset $\mathrm{barc}(M) := \{I_j : j \in J\}$.

For $p \in P$, let $p^{\uparrow}$ (resp. $p^{\downarrow}$) denote the set of points $q \in P$ such that $p \le q$ (resp. $q \le p$). Clearly, both $p^{\uparrow}$ and $p^{\downarrow}$ belong to $\mathrm{Int}(P)$.

▶ **Definition 3.** *A P-module is called **finitely presentable** if it is isomorphic to the cokernel of a morphism $\bigoplus_{b\in B} \mathbb{F}_{p_b^{\uparrow}} \to \bigoplus_{a\in A} \mathbb{F}_{p_a^{\uparrow}}$, where $\{p_a : a \in A\}$ and $\{p_b : b \in B\}$ are finite multisets of elements of P.*

▶ Remark 4. It is well known that, for any finite d-parameter simplicial filtration $\mathcal{F}$ (Definition 1), the induced $\mathbb{R}^d$-module $\mathrm{H}_m(\mathcal{F};\mathbb{F})$, for each $m \in \mathbb{Z}_{\ge 0}$, is finitely presentable. Namely, $\mathrm{H}_m(\mathcal{F};\mathbb{F})$ is isomorphic to the cokernel of a morphism $\bigoplus_{j\in J} \mathbb{F}_{p_j^{\uparrow}} \to \bigoplus_{i\in I} \mathbb{F}_{p_i^{\uparrow}}$, where $\{p_j : J \in J\} \cup \{p_i : i \in I\}$ is a subset of the smallest finite d-d grid in $\mathbb{R}^d$ that contains all the birth indices of m- and $(m+1)$-simplices in $\mathcal{F}$. See, e.g. [45].

Generalized Rank invariant and Generalized Persistence Diagram. Any P-module M admits both a **limit** and a **colimit** [48, Chapter V]: A limit of M, denoted by $\varprojlim M$, consists of a vector space L together with a collection of linear maps $\{\pi_p : L \to M(p)\}_{p\in P}$ such that

$$M(p \le q) \circ \pi_p = \pi_q \text{ for every } p \le q \text{ in } P. \tag{2}$$

A colimit of M, denoted by $\varinjlim M$, consists of a vector space C together with a collection of linear maps $\{i_p : M(p) \to C\}_{p\in P}$ such that

$$i_q \circ M(p \le q) = i_p \text{ for every } p \le q \text{ in } P. \tag{3}$$

Both $\varprojlim M$ and $\varinjlim M$ satisfy certain universal properties, making them unique up to isomorphism.

Let us assume that P is connected. The connectedness of P alongside the equalities given in Equations (2) and (3) imply that $i_p \circ \pi_p = i_q \circ \pi_q : L \to C$ for any $p, q \in P$. This fact ensures that the **canonical limit-to-colimit map** $\psi_M : \varprojlim M \longrightarrow \varinjlim M$ given by $i_p \circ \pi_p$ for any $p \in P$ is well-defined. The **(generalized) rank** of M is defined to be[2] $\mathrm{rank}(M) := \mathrm{rank}(\psi_M)$, which is finite as $\mathrm{rank}(M) = \mathrm{rank}(i_p \circ \pi_p) \le \dim(M(p)) < \infty$ for *any* $p \in P$. The rank of M is a count of the "persistent features" in M that span the entire indexing poset P [40].

Now, we refine the rank of a P-module, which is a single integer, into an integer-valued function. Options for the domain of the function include $\mathrm{Seg}(P)$ or the larger set $\mathrm{Int}(P)$.

▶ **Definition 5** ([22, 39])**.** *Let M be a P-module.*

(i) *The **generalized rank invariant (GRI)** is the map $\mathrm{rk}_M : \mathrm{Int}(P) \to \mathbb{Z}_{\ge 0}$ given by $I \mapsto \mathrm{rank}(M|_I)$ where $M|_I$ is the restriction of M to I.*

(ii) *The **generalized persistence diagram (GPD) of M** is defined as the function $\mathrm{dgm}_M : \mathrm{Int}(P) \to \mathbb{Z}$ that satisfies the equality*[3]

$$\forall I \in \mathrm{Int}(P), \quad \mathrm{rk}_M(I) = \sum_{\substack{J\in\mathrm{Int}(P)\\ J\supseteq I}} \mathrm{dgm}_M(J), \tag{4}$$

where the right-hand side of the equation includes only finitely many nonzero summands.

[2] This construction was considered in the study of quiver representations [43].
[3] This equality generalizes *the fundamental lemma of persistent homology* [29].

We also remark that, in Definition 5, by replacing all instances of $\mathrm{Int}(P)$ by $\mathrm{Seg}(P)$, we obtain the notions of the *rank invariant* and its *signed barcode* [12, 13, 18].

▶ **Theorem 6** (Existence and Uniqueness of the GPD). *Let M be a P-module.*

(i) *If P is finite, then the GPD of M exists.*

(ii) *If $P = \mathbb{R}^d$ $(d = 1, 2, \ldots)$, and M is finitely presentable, then the GPD of M exists. Furthermore, dgm_M is finitely supported, i.e. there exist only finite many $I \in \mathrm{Int}(\mathbb{R}^d)$ such that $\mathrm{dgm}_M(I) \neq 0$.*

(iii) *In each of the previous two cases, the GPD is unique.*

Proof. (i): If P is finite, then $\mathrm{Int}(P)$ is finite. Thus, the claim directly follows from the Möbius inversion formula [57]. (ii): This statement is precisely that of [22, Theorem C(iii)]. (iii): In the setting of (i), the uniqueness is also a direct consequence of the Möbius inversion formula. In the setting of (ii), the uniqueness is proved in [22, Proposition 3.2]. ◀

▶ Remark 7 ([22, Theorem C (iii)]). For any finitely presentable $\mathbb{R}^d$-module M, assume that M is the cokernel of a morphism $\bigoplus_{b\in B} \mathbb{F}_{p_b^{\uparrow}} \to \bigoplus_{a\in A} \mathbb{F}_{p_a^{\uparrow}}$, where A and B are finite index sets. Let $\mathcal{C} := \{p_a : a \in A\} \cup \{p_b : b \in B\} \subset \mathbb{R}^d$. Consider the finite full subposet $P := \prod_{i=1}^d \pi_i(\mathcal{C}) \subset \mathbb{R}^d$, where $\pi_i : \mathbb{R}^d \to \mathbb{R}$ is the canonical projection to the i-th coordinate. Then, the GPD of M is directly obtained from the GPD of the restriction $M|_P$, as follows.

We extend $\mathbb{R}^d$ to $\mathbb{R}^d \cup \{-\infty\}$ by declaring that $-\infty \leq x$ for all $x \in \mathbb{R}^d$. Let $\lfloor - \rfloor_P : \mathbb{R}^d \to P \cup \{-\infty\}$ be the map sending each $x \in \mathbb{R}^d$ to the maximal point $p =: \lfloor x \rfloor_P$ in $P \cup \{-\infty\}$ such that $p \leq x$ in $\mathbb{R}^d \cup \{-\infty\}$. For any $I \subseteq \mathbb{R}^d$, let $\lfloor I \rfloor_P$ denote the set of the points $\lfloor x \rfloor_P$ for $x \in I$. Then, the GPD of M, i.e. $\mathrm{dgm}_M : \mathrm{Int}(\mathbb{R}^d) \to \mathbb{Z}$, is equal to

$$I \mapsto \begin{cases} \mathrm{dgm}_{M|_P}(\lfloor I \rfloor_P), & \text{if } I = \lfloor - \rfloor_P^{-1}(J) \text{ for some } J \in \mathrm{Int}(P) \\ 0, & \text{otherwise.} \end{cases}$$

This implies that **there exists a bijection between the supports of $\mathbf{dgm}_M$ and $\mathbf{dgm}_{M|_P}$.**

We also remark that if P is a finite poset, the condition given in Equation (4) holds if and only if

$$\forall I \in \mathrm{Int}(P), \quad \mathrm{dgm}_M(I) = \sum_{\substack{J \in \mathrm{Int}(P) \\ J \supseteq I}} \mu(J, I) \cdot \mathrm{rk}_M(J), \tag{5}$$

where μ is the *Möbius function* of the poset $(\mathrm{Int}(P), \supseteq)$; see [61, Section 3.7] for a general reference on Möbius inversion, and [40] for a discussion of Möbius inversion in this specific context.

We define the **size** of rk_M, denoted by $\|\mathrm{rk}_M\|$, as the cardinality of its support. Likewise, the size of dgm_M is defined as the cardinality of its support and is denoted by $\|\mathrm{dgm}_M\|$.

▶ Remark 8. For any P-module M, the following holds.

(i) (Monotonicity) $\mathrm{rk}_M(I) \leq \mathrm{rk}_M(J)$ for any pair $I \supseteq J$ in $\mathrm{Int}(P)$ [39, Proposition 3.8].

(ii) For any $I \in \mathrm{Int}(P)$, if $\mathrm{rk}_M(I) = 0$, then $\mathrm{dgm}_M(I) = 0$. Hence, we have $\|\mathrm{dgm}_M\| \leq \|\mathrm{rk}_M\|$ [40, Remark 8].

(iii) If M is interval decomposable and $I \in \mathrm{Int}(P)$, then $\mathrm{dgm}_M(I)$ equals the multiplicity of I in $\mathrm{barc}(M)$ [25, Theorem 2.10].

In establishing results in later sections, we will utilize the following well-known concrete formulation for the limit of a P-module M (see, for instance, [39, Appendix E]):

▶ **Convention 9.** The limit of a P-module M is the pair $(L, (\pi_p)_{p\in P})$ described as:

$$L := \left\{ (\ell_p)_{p\in P} \in \prod_{p\in P} M(p) : \ \forall p \le q \in P, M(p \le q)(\ell_p) = \ell_q \right\}$$

where for each $p \in P$, the map $\pi_p : L \to M(p)$ is the canonical projection. Elements of L are called **sections** of M.

On 2-d grid lattices. A **join** (a.k.a. least upper bound) of $S \subseteq P$ is an element $q_0 \in P$ such that (i) $s \le q_0$, for all $s \in S$, and (ii) for any $q \in P$, if $s \le q$ for all $s \in S$, then $q_0 \le q$. A **meet** (a.k.a. greatest lower bound) of $S \subseteq P$ is an element $r_0 \in P$ such that (i) $r_0 \le s$ for all $s \in S$, and (ii) for any $r \in P$, if $r \le s$ for all $s \in S$, then $r \le r_0$. If a join and a meet of S exist, then they are unique. Hence, whenever they exist, we refer to them as *the* join (denoted by $\bigvee S$) and *the* meet (denoted by $\bigwedge S$), respectively. When S consists of exactly two points s_1 and s_2, we also use $s_1 \vee s_2$ and $s_1 \wedge s_2$ instead of $\bigvee S$ and $\bigwedge S$, respectively. A **lattice** is a poset such that for any pair of elements, their meet and join exist. For any $n \in \mathbb{Z}_{\ge 0}$, let $[n] := \{0 < 1 < \cdots < n\}$. By a **finite *d*-d grid lattice**, we mean a poset isomorphic to the lattice $[n_1] \times [n_2] \times \cdots \times [n_d]$ for some $n_1, n_2, \cdots, n_d \in \mathbb{Z}_{\ge 0}$.

Let p and q be any two points in a poset P. We say that q **covers** p if $p < q$ and there is no $r \in P$ such that $p < r < q$. By $\mathrm{Cov}(p)$, we denote the set of all points $q \in P$ that cover p.

▶ **Lemma 10** ([4, Theorem 5.3]). *Let μ be the Möbius function of the poset $(\mathrm{Int}([n]^2), \supseteq)$. Then, for all $J, I \in \mathrm{Int}([n]^2)$ with $J \supseteq I$,*

$$\mu(J, I) = \begin{cases} 1, & \text{if } I = J, \\ \displaystyle\sum_{\substack{J = \bigwedge S \\ \emptyset \neq S \subseteq \mathrm{Cov}(I)}} (-1)^{|S|}, & \text{otherwise,} \end{cases}$$

where $|S|$ denotes the cardinality of S. Note that when $I \neq J$ and there is no nonempty $S \subseteq \mathrm{Cov}(I)$ such that $J = \bigwedge S$, the sum above is empty, and thus $\mu(J, I) = 0$. We also remark that $\bigwedge S$ represents the smallest interval in $[n]^2$ that contains all the intervals in S.

A subposet $L \subset P$ (resp. $U \subset P$) is called a **lower (resp. upper) fence** of P if L is connected, and for any $q \in P$, the intersection $L \cap q^{\downarrow}$ (resp. $U \cap q^{\uparrow}$) is nonempty and connected [25, Definition 3.1].

▶ **Lemma 11** ([25, Proposition 3.2]). *Let L and U be a lower and an upper fence of a connected poset P, respectively. Given any P-module M, we have*

$$\varprojlim M \cong \varprojlim M|_L \quad \text{and} \quad \varinjlim M \cong \varinjlim M|_U.$$

Let I be any subset of P. By $\min(I)$ and $\max(I)$, we denote the collections of minimal and maximal elements of I, respectively. A **zigzag poset** of n points is $\bullet_1 \leftrightarrow \bullet_2 \leftrightarrow \ldots \bullet_{n-1} \leftrightarrow \bullet_n$ where $\leftrightarrow$ stands for either $\le$ or $\ge$.

▶ **Definition 12** ([25, Definition 3.5]). *For $I \in \mathrm{Int}([n]^2)$ with $\min(I) = \{p_0, p_1, \ldots, p_k\}$, and $\max(I) = \{q_0, q_1, \ldots, q_l\}$, we define the following two zigzag posets*

$$\begin{aligned} \min_{\mathrm{ZZ}}(I) &:= \{p_0 < (p_0 \vee p_1) > p_1 < (p_1 \vee p_2) > \cdots < (p_{k-1} \vee p_k) > p_k\} \\ &= \min(I) \cup \{p_i \vee p_{i+1} : i = 0, \ldots, k-1\}, \\ \max_{\mathrm{ZZ}}(I) &:= \{q_0 > (q_0 \wedge q_1) < q_1 > (q_1 \wedge q_2) < \cdots > (q_{l-1} \wedge q_l) > q_l\} \\ &= \max(I) \cup \{q_i \wedge q_{i+1} : i = 0, \ldots, l-1\}, \end{aligned}$$

which are lower and upper fences of I, respectively [25, Section 3.2].

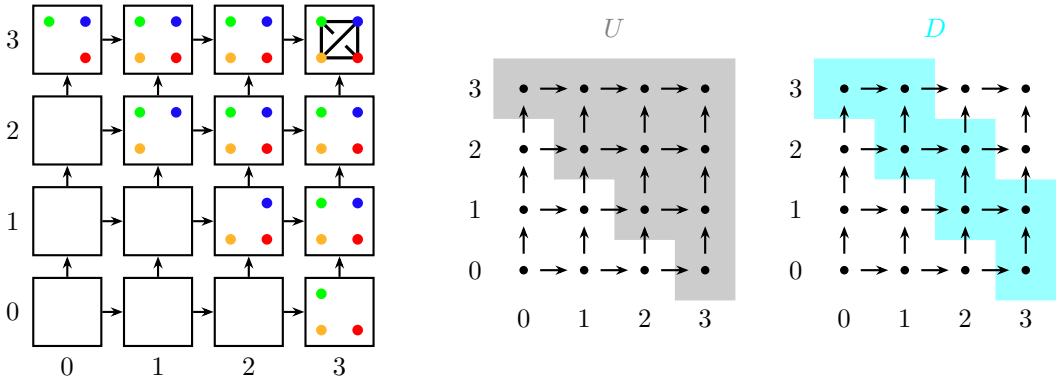

Figure 1 For $n = 3$, the filtration over $[n]^2$ defined in Equation (6), along with the intervals U and D of $[n]^2$, as described in Equation (9).

3 Super-Polynomial Growth of the GPD

The goal of this section is to establish the following theorem.

▶ **Theorem 13** (Super-polynomial Growth of the GPD). *Let $d, m \in \mathbb{Z}_{\geq 0}$ with $d \geq 2$. There does* not *exist $k \in \mathbb{Z}_{\geq 0}$ such that, for* all *finite filtrations $\mathcal{F}$ over $\mathbb{R}^d$ containing N simplices, $\|\mathrm{dgm}_m(\mathcal{F})\|$ belongs to $O(N^k)$.*

Let K be an abstract simplicial complex and let $m \in \mathbb{Z}_{\geq 0}$. Let $C_m(K;\mathbb{F})$ and $Z_m(K;\mathbb{F})$ be the group of m-chains and that of m-cycles of K, respectively. Let K^m be the m-skeleton of K.

To prove the statement, we construct a sequence $(\mathcal{F}_n)$ of filtrations where $\mathcal{F}_n$ contains $O(n^t)$ simplices for some $t \in \mathbb{Z}_{\geq 0}$, but $\|\mathrm{dgm}_m(\mathcal{F}_n)\| \notin O(n^k)$ for *any* $k \in \mathbb{Z}_{\geq 0}$. By Remarks 4 and 7, it suffices to construct filtrations $\mathcal{F}_n$ over the discrete posets $[n]^d$.

▶ Remark 14. In [45], the *size* of a finite d-parameter filtration of a simplicial complex K is defined as the total number of birth indices across all $\sigma \in K$. Even if we adopt this quantity as N in the above theorem, the statement remains true.

We also remark that some techniques used in the following proof are similar to those employed in the proof of [22, Theorem B]. We first prove the statement for the case of $d = 2$.

Proof of Theorem 13 when $d = 2$. We consider the cases of $m = 0$ and $m \geq 1$ separately.

Case 1 ($m = 0$). Fix $n \in \mathbb{Z}_{\geq 0}$. Let $K := K_n$ be the simplicial complex on the vertex set $K^0 = \{z_0, z_1, \ldots, z_n\}$ that consists of the 1-simplices $\{z_i, z_j\}$ $(0 \leq i < j \leq n)$ and their faces. We define a filtration $\mathcal{F} := \mathcal{F}_n$ of K over $[n]^2$ as follows. For $(i,j) \in [n]^2$, let (see Figure 1):

$$\mathcal{F}_{(i,j)} := \begin{cases} \emptyset, & \text{if } i+j < n \\ K^0 - \{\{z_i\}\}, & \text{if } i+j = n \\ K^0, & \text{if } i+j > n \text{ and } (i,j) \neq (n,n) \\ K, & \text{if } (i,j) = (n,n). \end{cases} \tag{6}$$

Let $M := \mathrm{H}_0(\mathcal{F};\mathbb{F}) : [n]^2 \to \mathbf{vec}_{\mathbb{F}}$. Then, we have:

$$M(i,j) \cong \begin{cases} 0, & \text{if } i+j < n \\ \mathbb{F}^n, & \text{if } i+j = n \\ \mathbb{F}^{n+1}, & \text{if } i+j > n \text{ and } (i,j) \neq (n,n) \\ \mathbb{F}, & \text{if } (i,j) = (n,n). \end{cases} \tag{7}$$

Let $i \in [n]$. Then, for every $(x,y) \in [n]^2$ that covers $(i, n-i)$, we have that

$$M((i,n-i) \leq (x,y)) \quad = \quad \iota_i^n : \quad \mathbb{F}^n \to \mathbb{F}^{n+1}$$
$$(v_1, \dots, v_n) \mapsto (v_1, \dots, v_i, 0, v_{i+1}, \dots, v_n). \tag{8}$$

In what follows, we use ι_i in place of ι_i^n. Now, we consider the following two intervals of $[n]^2$ (see Figure 1):

$$U := \{(i,j) \in [n]^2 : \ n \leq i+j\} \ \text{ and } \ D := \{(i,j) \in [n]^2 : n \leq i+j \leq n+1\}. \tag{9}$$

By proving the following claims, we complete the proof for the case of $m = 0$.

▷ Claim 15. If $J \in \mathrm{Int}([n]^2)$ is not a proper subset of U, then $\mathrm{rk}_M(J) = 0$.

Proof. First, assume that there exists a point $p \in J - U$. Then, by the construction of M, $\dim(M(p)) = 0$ and thus $\mathrm{rk}_M(J) = 0$ by monotonicity of rk_M (Remark 8 (i)). Next, assume that $J = U$. Since $\mathrm{rk}_M(U) = \mathrm{rank}(\varprojlim M|_U \to \varinjlim M|_U)$, it suffices to show $\varprojlim M|_U = 0$. Again, since $D = \min_{\mathrm{ZZ}}(U)$, by Lemma 11, it suffices to show that $\varprojlim M|_D = 0$. By Equation (8), the diagram $M|_D$ is given by

$$\mathbb{F}^n \xrightarrow{\iota_0} \mathbb{F}^{n+1} \xleftarrow{\iota_1} \mathbb{F}^n \xrightarrow{\iota_1} \mathbb{F}^{n+1} \xleftarrow{\iota_2} \mathbb{F}^n \xrightarrow{\iota_2} \mathbb{F}^{n+1} \xleftarrow{\iota_3} \mathbb{F}^n \xrightarrow{\iota_3} \cdots \xleftarrow{\iota_n} \mathbb{F}^n.$$

From this, it is not difficult to see that $\varprojlim M|_D = 0$: For $p \in D$, let $\pi_p : \varprojlim M|_D \to M(p)$ be the canonical projection. For any $i = 0, \dots, n$ and for any $v \in \varprojlim M|_D$, let $\pi_{(i,n-i)}(v) =: (v_1^i, v_2^i, \dots, v_n^i) \in \mathbb{F}^n = M(i, n-i)$. Then, Equations (2) and (8) imply the following pair of equalities for each $i = 1, \dots, n$:

$$\begin{aligned} \pi_{(i,n-i+1)}(v) &= \iota_{i-1} \circ \pi_{(i-1,n-i+1)}(v) &&= (v_1^{i-1}, \dots, v_{i-1}^{i-1}, 0, v_i^{i-1}, v_{i+1}^{i-1}, \dots, v_n^{i-1}), \\ \pi_{(i,n-i+1)}(v) &= \iota_i \circ \pi_{(i,n-i)}(v) &&= (v_1^i, \dots, v_{i-1}^i, v_i^i, 0, v_{i+1}^{i-1}, \dots, v_n^i), \end{aligned}$$

and thus $v_i^i = v_i^{i-1} = 0$ for $i = 1, \dots n$. From this, we deduce that $v_j^i = 0$ for all $i = 0, 1, \dots, n$ and $j = 1, 2, \dots, n$. Therefore, $\pi_{(i,n-i)}(v) = 0$ for all $i = 0, 1, \dots, n$ and in turn $v = 0$. Since $v \in \varprojlim M|_D$ was arbitrary, we have $\varprojlim M|_D = 0$. ◁

Consider the following intervals of $[n]^2$ (see Figure 2):

$$U_i := U - \{(i, n-i)\} \ \text{ for each } i \in [n]. \tag{10}$$

▷ Claim 16. Let $J \in \mathrm{Int}([n]^2)$ such that $\bigcap_{i=0}^n U_i \subseteq J \subsetneq U$. Then, $\mathrm{rk}_M(J) = 1$.

Proof. Since $J \subsetneq U$, there exists $i \in [n]$ such that $J \subseteq U_i$. Fix such i. Since $\max(J) = \{(n,n)\}$, by Lemma 11, we have the isomorphism $\varinjlim M|_J \overset{(*)}{\cong} M(n,n)$. Observe that for every $p \in J \subseteq U_i$, $\{z_i\} \in \mathcal{F}_p$. Hence, by Convention 9 and the definition of M, we have that

$$([z_i])_{p \in J} \in \varprojlim M|_J \subset \bigoplus_{p \in J} \mathrm{H}_0(\mathcal{F}_p; \mathbb{F}).$$

Clearly, this tuple $([z_i])_{p \in J}$ maps to $[z_i] \in \mathrm{H}_0(\mathcal{F}_{(n,n)}; \mathbb{F}) = M(n,n)$ via the limit-to-colimit map of M over J, followed by the isomorphism $(*)$. Since $[z_i] \in M(n,n)$ is nonzero and $\dim M(n,n) = 1$ (cf. Equation (7)), we have that $\mathrm{rk}_M(J) = 1$, as desired. ◁

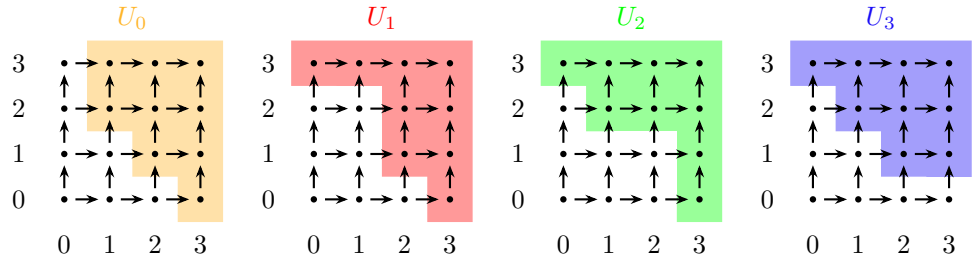

Figure 2 For $n = 3$, the intervals U_0, U_1, U_2, U_3 of $[n]^2$ that are defined in Equation (10).

▷ Claim 17. $\mathrm{dgm}_M(U_i) = 1$ for every $i \in [n]$.

Proof. We have:

$$\begin{aligned} 1 &= \mathrm{rk}_M(U_i) && \text{by Claim 16} \\ &= \sum_{\substack{I \in \mathrm{Int}([n]^2) \\ I \supseteq U_i}} \mathrm{dgm}_M(I) && \text{by Equation (4)} \\ &= \mathrm{dgm}_M(U_i) && \text{by Claim 15 and Remark 8 (ii).} \end{aligned}$$ ◁

For each nonempty $S \subset [n]$, we define $U_S := \bigcap_{i \in S} U_i$, which is an interval of $[n]^2$.

▷ Claim 18. For each nonempty $S \subset [n]$, we have that $\mathrm{dgm}_M(U_S) = (-1)^{|S|+1}$.

Proof. Let $I := U_S$. When $|S| = 1$, there exists $i \in [n]$ such that $I = U_i$. We already proved that $\mathrm{dgm}_M(U_i) = (-1)^{1+1} = 1$. If $|S| > 1$, then

$$\begin{aligned} \mathrm{dgm}_M(I) &= \sum_{\substack{J \in \mathrm{Int}(P) \\ J \supseteq I}} \mu(J, I) \cdot \mathrm{rk}_M(J) && \text{by Equation (5)} \\ &= \sum_{\substack{J \in \mathrm{Int}(P) \\ U \supsetneq J \supseteq I}} \mu(J, I) \cdot \mathrm{rk}_M(J) && \text{by Claim 15} \\ &= \sum_{\substack{J \in \mathrm{Int}(P) \\ U \supsetneq J \supseteq I}} (-1)^{|J-I|} \cdot \mathrm{rk}_M(J) && \text{by Lemma 10} \\ &= \sum_{S' \subsetneq S} (-1)^{|S'|} && \text{by Claim 16, letting } S' = J - I \\ &= (1-1)^{|S|} - (-1)^{|S|} = (-1)^{|S|+1} && \text{by the binomial theorem} \end{aligned}$$

as desired. The number of nonempty subsets $S \subset [n]$ is $2^{n+1} - 1$ and each S corresponds to the interval U_S such that $\mathrm{dgm}_M(U_S) \neq 0$. Hence, $\|\mathrm{dgm}_0(\mathcal{F})\| = \|\mathrm{dgm}_M\| \geq 2^{n+1} - 1$. In particular, there is no $k \in \mathbb{Z}_{\geq 0}$ such that $2^{n+1} - 1 \in O(N^k)$ for $N := (n^2 + n)/2$, the number of simplices in the filtration $\mathcal{F}$, completing the proof. ◁

Case 2 ($m \geq 1$). Let $K' := K_{n,m}$ be the smallest simplicial complex on the vertex set $\{x_0, \cdots, x_n, y_0, \cdots, y_m\}$, containing all m-simplices τ, τ_{ij}, and $(m+1)$-simplices σ_{ij} that are the underlying sets of the following oriented simplices (see Figure 3a):

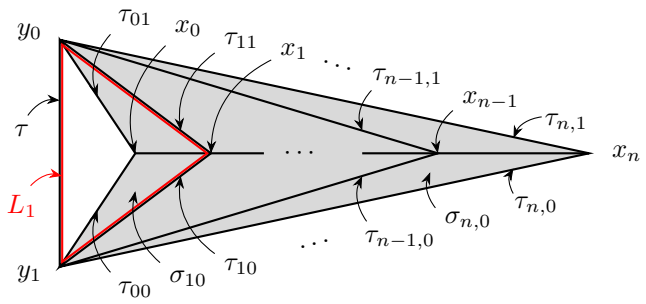
$$\begin{aligned} \tau^+ &:= [y_0, \cdots, y_m] \\ \tau_{ij}^+ &:= [x_i, y_0, \cdots, y_{j-1}, y_{j+1}, \cdots, y_m], && \text{for } 0 \leq i \leq n,\ 0 \leq j \leq m, \\ \sigma_{ij}^+ &:= [x_{i-1}, x_i, y_0, \cdots, y_{j-1}, y_{j+1}, \cdots, y_m], && \text{for } 1 \leq i \leq n,\ 0 \leq j \leq m. \end{aligned}$$

For $0 \le k \le n$, let L_k be the m-dimensional subcomplex of K', whose m-simplices are exactly τ and $\{\tau_{kj} : 0 \le j \le m\}$ (see Figure 3a).

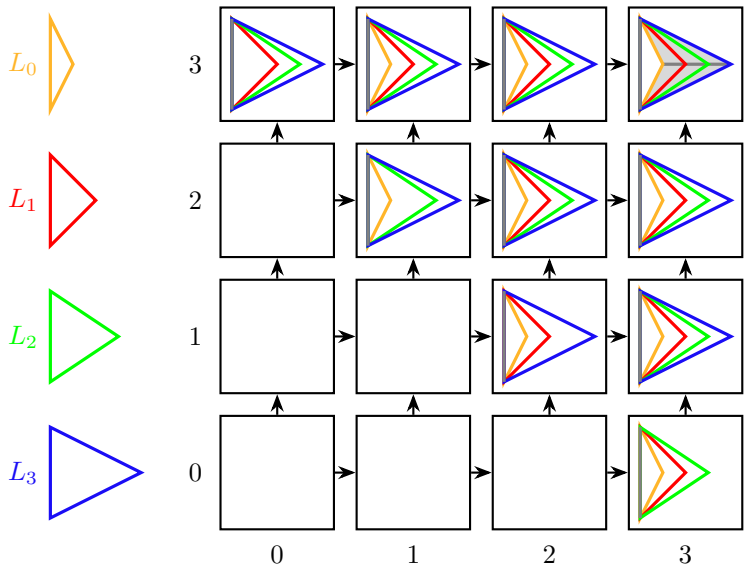
We define the filtration $\mathcal{F}' := \mathcal{F}'_{n,m} : [n]^2 \to \Delta K'$ $(= \Delta K_{n,m})$ as (see Figure 3b):

$$\mathcal{F}'_{(i,j)} := \begin{cases} \emptyset, & \text{if } i+j < n \\ \bigcup_{k \in [n]-\{i\}} L_k, & \text{if } i+j = n \\ \bigcup_{k \in [n]} L_k, & \text{if } i+j > n \text{ and } (i,j) \neq (n,n) \\ K', & \text{if } (i,j) = (n,n). \end{cases} \tag{11}$$

Note that, for each $0 \le i \le n$, the m-chain $c_i = \tau^+ - \sum_{j=0}^{m} (-1)^j \tau_{ij}^+$ in $C_m(K'; \mathbb{F})$ satisfies $\partial c_i = 0$, i.e. c_i is an m-cycle. Moreover, $\mathrm{H}_m(L_i; \mathbb{F})$, which is isomorphic to $Z_m(L_i; \mathbb{F})$, is the 1-dimensional vector space generated by the homology class $[c_i]$.



(a) For $m = 1$, the simplicial complex $K' = K_{n,m}$ given in **Case 2**.



(b) For $m = 1$ and $n = 3$, the filtration $\mathcal{F}' = \mathcal{F}'_{n,m}$ given in **Case 2**.

Figure 3 Illustration of the constructions described in **Case 2**.

Let $N := \mathrm{H}_m(\mathcal{F}'; \mathbb{F}) : [n]^2 \to \mathbf{vec}_{\mathbb{F}}$. We claim that N is isomorphic to M, given in Equation (7). Indeed,

$$N(i,j) \cong \begin{cases} 0, & \text{if } i+j < n \\ \langle [c_0], \cdots, [c_{i-1}], [c_{i+1}], \cdots, [c_n] \rangle \cong \mathbb{F}^n, & \text{if } i+j = n \\ \langle [c_0], \cdots, [c_n] \rangle \cong \mathbb{F}^{n+1}, & \text{if } i+j > n \text{ and } (i,j) \neq (n,n) \\ \mathbb{F}, & \text{if } (i,j) = (n,n) \end{cases}$$

and for each pair $p \leq q$ in $[n]^2$, $N(p \leq q) \cong M(p \leq q)$. Therefore, there is no $k \in \mathbb{Z}_{\geq 0}$ such that $\|\mathrm{dgm}_m(\mathcal{F}')\| = \|\mathrm{dgm}_N\| = \|\mathrm{dgm}_M\| = 2^{n+1} - 1 \notin O(N^k)$ for N, the number of simplices in the filtration $\mathcal{F}'$, which belongs to $O(n^{m+2})$. ◀

In order to prove Theorem 13 for the case where $d > 2$, we utilize a result from [12, Section 3.2] and techniques present in [22, Section 3]. See the full version [38] for details.

▶ Remark 19. Notably, the supports of the GPDs we have considered contain many overlapping intervals with opposite-signed values. This makes it difficult to interpret the information the GPDs convey, unlike persistence diagrams for one-parameter persistence modules.

4 Super-Polynomial Growth of the GPDs Induced by Finite Metric Spaces

In this section, we show that the sizes of the 1-st GPDs of the sublevel-Rips, sublevel-Čech, degree-Rips, and degree-Čech bifiltrations are *not* bounded by *any* polynomial in the number of points in the input metric space (Theorems 24 and 25). We prove these results by constructing specific point sets in $\mathbb{R}^3$ that induce persistence modules isomorphic, or structurally similar to, those appearing in the proof of Theorem 13. Also, we make use of Rota's Galois connection.

A **Galois connection** between two posets P and Q is a pair of monotone maps $g_1 : P \rightleftarrows Q : g_2$ satisfying $g_1(p) \leq q$ iff $p \leq g_2(q)$ for any $p \in P$ and $q \in Q$. Let $f : P \to Q$ be any function. For any $h : P \to \mathbb{Z}$, the **pushforward** of h along f is the function $f_\sharp h : Q \to \mathbb{Z}$ given by $f_\sharp h(q) = \sum_{p \in f^{-1}(q)} h(p)$. For any $\ell : Q \to \mathbb{Z}$, the **pullback** of ℓ along f is the function $f^\sharp \ell : P \to \mathbb{Z}$ defined by $f^\sharp \ell(p) = (\ell \circ f)(p)$. For any poset P, let ∂_P denote the Möbius inversion operator over P. To say that the GPD of a P-module M exists is equivalent to stating that $\partial_{\mathrm{Int}(P)} \mathrm{rk}_M$ is well-defined and equals dgm_M.

▶ **Lemma 20** ([33, Theorem 3.1]). *Let P be a finite poset, Q be any poset, and $g_1 : P \rightleftarrows Q : g_2$ be a Galois connection. Then, $\partial_Q \circ g_2^\sharp = {g_1}_\sharp \circ \partial_P$.*

Lemma 20 is crucial for establishing the following lemma, whose second item is essential for the proofs of both Theorem 24 and Theorem 25. See the full version [38] for the proof.

▶ **Lemma 21.** *Let P be a finite poset, M be a P-module, and $I \subset P$ be an interval of P. Then,*

(i) *for every $J \in \mathrm{Int}(I)$, we have $\mathrm{dgm}_{M|_I}(J) = \sum_{\substack{J' \in \mathrm{Int}(P) \\ J \in \Pi(J' \cap I)}} \mathrm{dgm}_M(J')$, where $\Pi(J' \cap I)$ denotes the coarsest partition of $J \cap I$ into disjoint intervals of I.*

(ii) *Furthermore, if P and I are finite 2-d grid, then $\|\mathrm{dgm}_M\| \geq \|\mathrm{dgm}_{M|_I}\|$.*

▶ Remark 22. Lemma 21 (ii) does not generally hold in higher dimensions, i.e. for $d \geq 3$, there exist d-d grids P and I with $I \subseteq P$ and a P-module M such that $\|\mathrm{dgm}_M\| < \|\mathrm{dgm}_{M|_I}\|$.

4.1 Sublevel-Rips and Sublevel-Čech Bifiltrations

For $r \in \mathbb{R}_{\geq 0}$, the **Vietoris-Rips complex** of a metric space (X, d_X) at scale r is defined as

$$\mathrm{Rips}((X,\mathsf{d}_X))_r = \left\{ \text{finite } \sigma \subset X : \max_{x,y\in\sigma} \mathsf{d}_X(x,y) \leq r \right\}.$$

Now assume that $X \subset \mathbb{R}^d$, where $\mathbb{R}^d$ is equipped with a metric d, and $\mathsf{d}_X = \mathsf{d}|_{X\times X}$. The **Čech complex of (X, d_X) in $(\mathbb{R}^d, \mathsf{d})$ at scale r** is

$$\check{\mathrm{C}}\mathrm{ech}((X,\mathsf{d}_X))_r = \left\{ \text{finite } \sigma \subset X : \bigcap_{x\in\sigma} B_r(x) \neq \emptyset \right\},$$

where $B_r(x) = \{y \in \mathbb{R}^d : \mathsf{d}(x,y) \leq r\}$.

▶ **Lemma 23** ([32, Lemma VII]). *Let $(\mathbb{R}^d, \rho)$ be the Euclidean space with the supremum metric ρ. For any finite $X \subset \mathbb{R}^d$ and any $r \in \mathbb{R}_{\geq 0}$, we have* $\check{\mathrm{C}}\mathrm{ech}((X,\rho|_{X\times X}))_r = \mathrm{Rips}((X,\rho|_{X\times X}))_{2r}$.

Let $\gamma : X \to \mathbb{R}$ be a function. For any $a \in \mathbb{R}$ and any $r \in \mathbb{R}_{\geq 0}$ (see e.g. [18]),

(i) the **sublevel-Rips complex at scale r and threshold a** is $\mathrm{Rips}^{\downarrow}((X,\mathsf{d},\gamma))_{a,r} := \mathrm{Rips}(\gamma^{-1}((-\infty,a]))_r$. The **sublevel-Rips bifiltration** of (X,d,γ) is the simplicial filtration $\mathrm{Rips}^{\downarrow}((X,\mathsf{d},\gamma)) := \{\mathrm{Rips}^{\downarrow}((X,\mathsf{d},\gamma))_{a,r}\}_{a\in\mathbb{R},r\in\mathbb{R}_{\geq 0}}$ over $\mathbb{R}\times\mathbb{R}_{\geq 0}$.

(ii) the **sublevel-Čech complex at scale r and threshold a** is $\check{\mathrm{C}}\mathrm{ech}^{\downarrow}((X,\mathsf{d},\gamma))_{a,r} := \check{\mathrm{C}}\mathrm{ech}(\gamma^{-1}((-\infty,a]))_r$. The **sublevel-Čech bifiltration** of (X,d,γ) is the simplicial filtration $\check{\mathrm{C}}\mathrm{ech}^{\downarrow}((X,\mathsf{d},\gamma)) := \{\check{\mathrm{C}}\mathrm{ech}^{\downarrow}((X,\mathsf{d},\gamma))_{a,r}\}_{a\in\mathbb{R},r\in\mathbb{R}_{\geq 0}}$ over $\mathbb{R}\times\mathbb{R}_{\geq 0}$.

Let

$$\Gamma_X := \mathrm{im}(\gamma) \subset \mathbb{R} \quad \text{and} \quad T_X := \mathrm{im}(\mathsf{d}) \subset \mathbb{R}_{\geq 0}. \tag{12}$$

By Remarks 4 and 7, for each $m \in \mathbb{Z}_{\geq 0}$, the size of the GPD of $M := \mathrm{H}_m(\mathrm{Rips}^{\downarrow}((X,\mathsf{d},\gamma)),\mathbb{F}) : \mathbb{R}\times\mathbb{R}_{\geq 0} \to \mathbf{vec}_{\mathbb{F}}$ equals $\|\mathrm{dgm}_{M|_{\Gamma_X\times T_X}}\|$.

▶ **Theorem 24** (Super-polynomial GPD of Sublevel-Rips and Sublevel-Čech filtrations). *There does* not *exist $k \in \mathbb{Z}_{\geq 0}$ such that for* every *metric space (X,d) and* every *function $\gamma : X \to \mathbb{R}$, $\|\mathrm{dgm}_1(\mathcal{F}_{(X,\mathsf{d},\gamma)})\|$ belongs to $O(|X|^k)$, where $\mathcal{F}_{(X,\mathsf{d},\gamma)} \in \{\mathrm{Rips}^{\downarrow}((X,\mathsf{d},\gamma)), \check{\mathrm{C}}\mathrm{ech}^{\downarrow}((X,\mathsf{d},\gamma))\}$.*

Given any set $A \subset \mathbb{R}^d$ and $r \in \mathbb{R}$, let $rA := \{ra \in \mathbb{R}^d : a \in A\}$. When $d \geq 2$, let $\pi : \mathbb{R}^d \to \mathbb{R}^2$ be the projection $(x_1,\ldots,x_d) \mapsto (x_1,x_2)$.

Proof Sketch. By Lemma 23, it suffices to show the statement when $\mathcal{F}_{(X,\mathsf{d},\gamma)} = \mathrm{Rips}^{\downarrow}((X,\mathsf{d},\gamma))$. Let $n \geq 1$. We construct an $X_n \subset \mathbb{R}^3$, which consists of $4n(n+2)$ points and inherits the metric d_n from the supremum metric on $\mathbb{R}^3$. Our goal is to show that $\|\mathrm{dgm}_1(\mathrm{Rips}^{\downarrow}((X_n,\mathsf{d}_n,\gamma_n)))\|$ does not belong to $O(n^k)$ for any k, which then does not belong to $O(|X_n|^k)$ for any k. Let $\epsilon_n := 1/n^2$. Let $X_n = \left(\bigcup_{i=0}^{n} Y_i\right) \cup \left(\bigcup_{i=0}^{n-1} Z_i\right)$ (see Figure 4), where, for $i \in [n]$, Y_i is the subset of the plane $z = 2in$ in $\mathbb{R}^3$ whose projected image πY_i onto $\mathbb{R}^2$ is described below, and Z_i is the subset of the plane $z = (2i+1)n$ in $\mathbb{R}^3$ whose projected image πZ_i onto $\mathbb{R}^2$ is described below. Let $A := \{(1,0),(0,1),(-1,0),(0,-1)\}$, $b_j := n - j\epsilon_n$ for $j \in [n]$, $\pi Y_i := \bigcup_{\substack{0\leq j\leq n \\ j\neq i}} b_j A$, and $\pi Z_i := b_0 A$. Note that $|X_n| = \left|\bigcup_{i=0}^{n} Y_i\right| + \left|\bigcup_{i=0}^{n-1} Z_i\right| =$

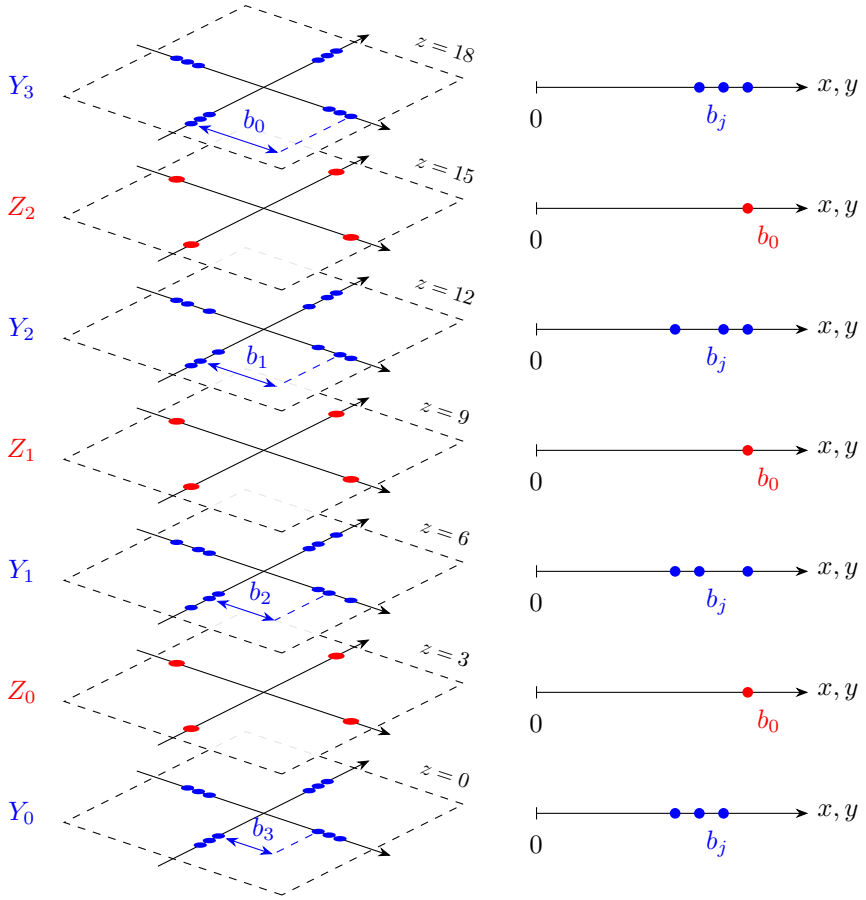


Figure 4 For $n = 3$, the set X_n that is defined in the proof of Theorem 24.

$4n(n+1) + 4n = 4n(n+2)$. Let $\gamma_n : X_n \to \mathbb{R}$ be

$$\gamma_n(w) = \begin{cases} j, & \text{if } w \in \bigcup_{i=0}^{n} Y_i \text{ and } \pi(w) \in b_j A \text{ for some } 0 \le j \le n, \\ n, & \text{if } w \in \bigcup_{i=0}^{n-1} Z_i \end{cases}$$

so that $\Gamma_{X_n} = \mathrm{im}(\gamma_n) = \{0 < 1 < \ldots < n\} \subset \mathbb{R}$. In the full version [38], we show that for $\mathcal{F}_n := \mathrm{Rips}^{\downarrow}((X_n, \mathsf{d}_n, \gamma_n))$ on $\Gamma_{X_n} \times T_{X_n}$ (Figure 5), $\|\mathrm{dgm}_1(\mathcal{F}_n)\|$ does not belong to $O(|X_n|^k)$ for any k. In particular, we identify an interval of $\Gamma_{X_n} \times T_{X_n}$ on which the restriction of $M_n := \mathrm{H}_1(\mathcal{F}_n; \mathbb{F})$ is isomorphic to M from Equation (7), and then apply Lemma 21 (ii). ◀

4.2 Degree-Rips and Degree-Čech Bifiltrations

Let (X, d) be a metric space. For $d \in \mathbb{Z}$ and $r \in \mathbb{R}_{\ge 0}$,

(i) the **Degree-Rips complex at scale r and degree d** [45], denoted $\mathrm{DRips}((X, \mathsf{d}))_{d,r}$, is the maximal subcomplex of $\mathrm{Rips}((X, \mathsf{d}))_r$ whose vertices have degree at least $d-1$ in the 1-skeleton of $\mathrm{Rips}((X, \mathsf{d}))_r$. The **Degree-Rips bifiltration** of (X, d) is the simplicial filtration $\mathrm{DRips}((X, \mathsf{d})) := \{\mathrm{DRips}((X, \mathsf{d}))_{d,r}\}_{d \in \mathbb{Z}^{\mathrm{op}}, r \in \mathbb{R}_{\ge 0}}$ over $\mathbb{Z}^{\mathrm{op}} \times \mathbb{R}_{\ge 0}$.

(ii) The **Degree-Čech complex at scale r and degree d** [30], denoted $\mathrm{DČech}((X, \mathsf{d}))_{d,r}$, is the maximal subcomplex of $\check{\mathrm{C}}\mathrm{ech}((X, \mathsf{d}))_r$ whose vertices have degree at least $d-1$ in the 1-skeleton of $\check{\mathrm{C}}\mathrm{ech}((X, \mathsf{d}))_r$. The **Degree-Čech bifiltration** of (X, d) is the simplicial filtration $\mathrm{DČech}((X, \mathsf{d})) := \{\mathrm{DČech}((X, \mathsf{d}))_{d,r}\}_{d \in \mathbb{Z}^{\mathrm{op}}, r \in \mathbb{R}_{\ge 0}}$ over $\mathbb{Z}^{\mathrm{op}} \times \mathbb{R}_{\ge 0}$.

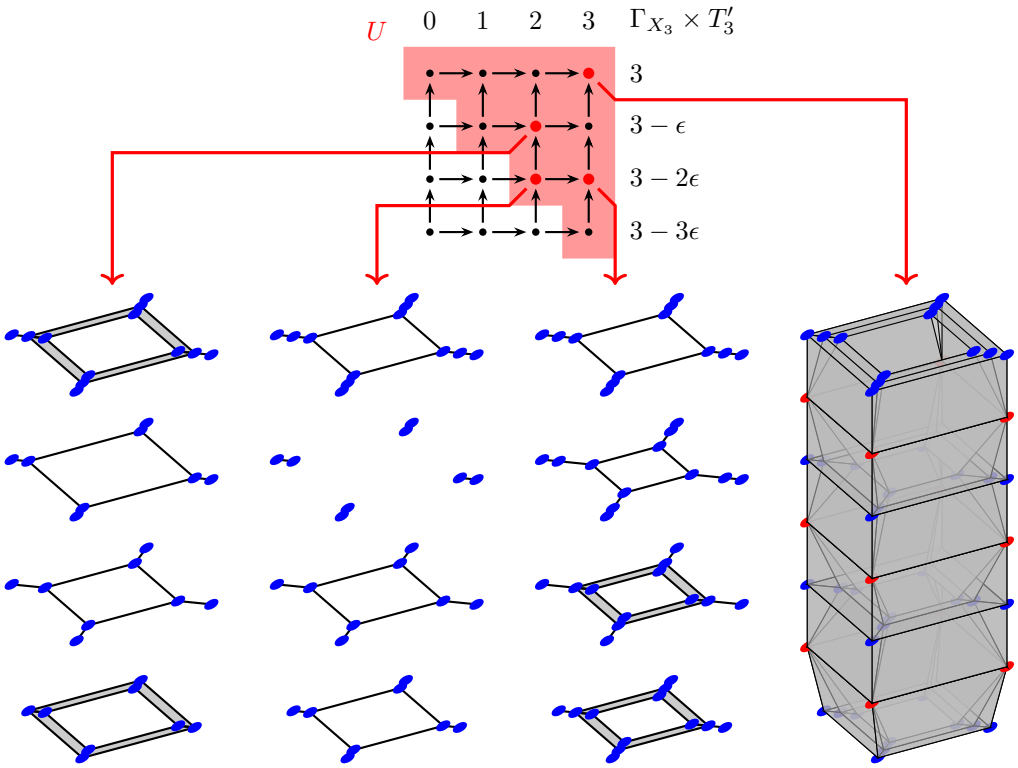

Figure 5 Partial illustration of the filtration $\mathcal{F}_3$ on $\Gamma_{X_3} \times T'_3$. The body of $\mathcal{F}_3(3,3)$ is homotopy equivalent to the cylinder $S^1 \times [0,1]$. The 1-cycles in $\mathcal{F}_3(2, 3-\epsilon_3)$, $\mathcal{F}_3(2, 3-2\epsilon_3)$, and $\mathcal{F}_3(3, 3-2\epsilon_3)$ become homologous in $\mathcal{F}_3(3,3)$.

We consider the finite subposets

$$J_X := \{|X| - 1 < |X| - 2 < \ldots < 1\} \subset \mathbb{Z}^{\mathrm{op}} \quad \text{and} \quad T_X := \mathrm{im}(\mathsf{d}) \subset \mathbb{R}_{\geq 0}.$$

By Remarks 4 and 7, for each $m \in \mathbb{Z}_{\geq 0}$, the size of the GPD of $M := \mathrm{H}_m(\mathrm{DRips}((X,\mathsf{d})), \mathbb{F}) : \mathbb{Z}^{\mathrm{op}} \times \mathbb{R}_{\geq 0} \to \mathbf{vec}_{\mathbb{F}}$ equals $\|\mathrm{dgm}_{M|_{J_X \times T_X}}\|$.

▶ **Theorem 25** (Super-polynomial GPD of Degree-Rips and Degree-Čech filtrations). *There does* not *exist $k \in \mathbb{Z}_{\geq 0}$ such that for* every *finite metric space (X,d), $\|\mathrm{dgm}_1(\mathcal{F}_{(X,\mathsf{d})})\|$ belongs to $O(|X|^k)$, where $\mathcal{F}_{(X,\mathsf{d})} \in \{\mathrm{DRips}((X,\mathsf{d})), \mathrm{D\check{C}ech}((X,\mathsf{d}))\}$.*

Proof Sketch. By Lemma 23, it suffices to show the statement when $\mathcal{F}_{(X,\mathsf{d})} = \mathrm{DRips}((X,\mathsf{d}))$.

Let $n \geq 1$. We construct an $X_n \subset \mathbb{R}^3$, which consists of $4(n+1)^2$ points and inherits the metric d_n from the supremum metric on $\mathbb{R}^3$. Our goal is to show that $\|\mathrm{dgm}_1(\mathrm{DRips}((X_n,\mathsf{d}_n)))\|$ does not belong to $O(n^k)$ for any k, which then does not belong to $O(|X_n|^k)$ for any k. Let $\epsilon_n := 1/n^2$. Let $X_n := \bigcup_{i=0}^{n} Y_i$ (see Figure 6), where, for $i \in [n]$, Y_i is the subset of the plane $z = (n+\epsilon_n)i$ in $\mathbb{R}^3$ whose projected image πY_i onto $\mathbb{R}^2$ is described below. Let $A := \{(1,0),(0,1),(-1,0),(0,-1)\}$, $B := \{(1,\epsilon_n),(-\epsilon_n,1),(-1,-\epsilon_n),(\epsilon_n,-1)\}$, and $a := n - n\epsilon_n$. For $j \in [n+1]$, let $b_j := a + j\epsilon_n = n + (j-n)\epsilon_n$. Let

$$\pi Y_i := aA \cup \Big(\bigcup_{\substack{0 \leq j \leq n \\ j \neq i}} (a+b_i)A \Big) \cup (a+b_{i+1})B.$$

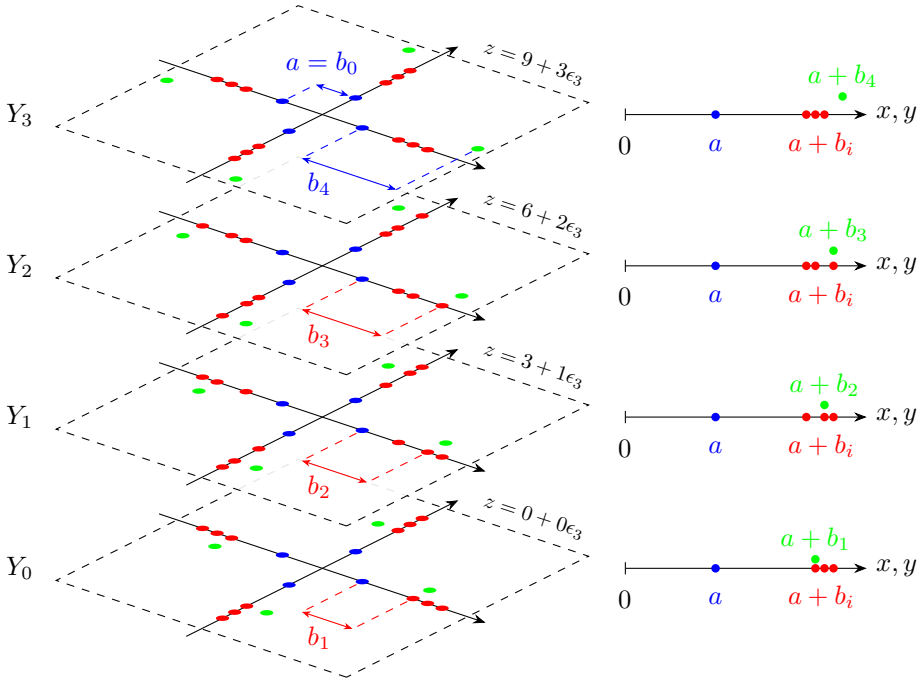

Figure 6 For $n = 3$, the set X_n that is defined in the proof of Theorem 25.

In the full version [38], we show that for the filtration $\mathcal{F}_n := \mathrm{DRips}((X_n, \mathsf{d}_n))$, $\|\mathrm{dgm}_1(\mathcal{F}_n)\|$ does not belong to $O(|X_n|^k)$ for any k. For this, we identify an interval of $\Gamma_{X_n} \times T_{X_n}$ on which the restriction of $M_n := \mathrm{H}_1(\mathcal{F}_n; \mathbb{F})$ is similar to M from Equation (7). Then, we prove claims analogous to Claim 15 through 18, and apply Lemma 21 (ii). ◀

It is known that, for $m \in \mathbb{Z}_{\geq 0}$, adding m integers has time complexity $O(m)$ [37]. Hence, as a direct corollary of Theorems 13, 24, and 25, we obtain:

▶ **Corollary 26.** *Let $n, d \in \mathbb{Z}_{\geq 0}$, $d \geq 2$, and $I \in \mathrm{Int}([n]^d)$. For an arbitrary $[n]^d$-module M, computing $\mathrm{dgm}_M(I)$ via the Möbius inversion of the GRI of M requires at least $\Theta(2^n)$ in time. In particular, M can arise as the homology of a simplicial filtration over $[n]^d$, with the number of simplices being polynomial in n.*

Proof. Let M be the persistence module defined in the proof of Theorem 13 for $d = 2$ and $m = 0$. Let $I := U_{[n]}$, as described immediately above Claim 18 in that proof. By Lemma 10, we have $\mathrm{dgm}_M(I) = \sum_{S' \subsetneq [n]} (-1)^{|S'|} = (-1)^{n+2}$. This sum contains $2^{n+1} - 1$ nonzero summands, requiring $\Theta(2^n)$ time for computation. ◀

5 Conclusion

We showed that the size of the GPD can be super-polynomial in the number of simplices in a given multi-parameter filtration, and such sizes can arise even from well-known constructions. Furthermore, we noted that the GRI can be "locally densely supported" (see Claim 18), which suggests that using the Möbius inversion of the GRI to compute the GPD can be intractable. These findings highlight the need to compute the GPD (or any invariant approximating it) directly, without relying on the GRI.

From a different perspective, developing an output-sensitive algorithm for computing the GPD might be a more practical approach, potentially extending or adapting ideas from [52]. Moreover, combining optimization techniques to address challenges in computing the GPD appears to be a promising research direction. In line with this, [20] proposes a method for "sparsifying" the GPD via gradient descent.

It also remains an interesting question whether special types of multi-parameter filtrations not explored in this work can also give rise to GPDs of super-polynomial size. Examples include multicover and barycentric (subdivision) bifiltrations [60].

Abstract

The *crossing number* of a graph is the least number of crossings over all drawings of the graph in the plane. Computing the crossing number of a given graph is NP-hard, but fixed-parameter tractable (FPT) with respect to the natural parameter. Two well-known variants of the problem are *2-layer crossing minimization* and *circular crossing minimization*, where every vertex must lie on one of two *layers*, namely two parallel lines, or a circle, respectively. In both cases, edges are drawn as straight-line segments. Both variants are NP-hard, but admit FPT-algorithms with respect to the natural parameter.

In recent years, in the context of beyond-planar graphs, a local version of the crossing number has also received considerable attention. A graph is *k-planar* if it admits a drawing with at most k crossings per edge. In contrast to the crossing number, recognizing k-planar graphs is NP-hard even if $k = 1$ and hence not likely to be FPT with respect to the natural parameter k.

In this paper, we consider the two above variants in the local setting. The k-planar graphs that admit a straight-line drawing with vertices on two layers or on a circle are called *2-layer k-planar* and *outer k-planar* graphs, respectively. We study the parameterized complexity of the two recognition problems with respect to the natural parameter k. For $k = 0$, the two classes of graphs are exactly the caterpillars and outerplanar graphs, respectively, which can be recognized in linear time. Two groups of researchers independently showed that outer 1-planar graphs can also be recognized in linear time [Hong et al., Algorithmica 2015; Auer et al., Algorithmica 2016]. One group asked explicitly whether outer 2-planar graphs can be recognized in polynomial time.

Our main contribution consists of XP-algorithms for recognizing 2-layer k-planar graphs and outer k-planar graphs, which implies that both recognition problems can be solved in polynomial time for every fixed k. We complement these results by showing that recognizing 2-layer k-planar graphs is XNLP-complete and that recognizing outer k-planar graphs is XNLP-hard. This implies that both problems are W[t]-hard for every t and that it is unlikely that they admit FPT-algorithms. On the other hand, we present an FPT-algorithm for recognizing 2-layer k-planar graphs where the order of the vertices on one layer is specified.

1 Introduction

When evaluating the quality of a graph drawing, one of the established metrics is the number of crossings, whose importance is supported by user experiments [42]. Unfortunately, computing the crossing number of a given graph, that is, the minimum number of crossings over all drawings of the graph, is NP-hard [27], even for graphs that become planar after removal of a single edge [14]. On the other hand, the problem is fixed-parameter tractable (FPT) with respect to the natural parameter, that is, the number of crossings [29, 33]. Many variants of the crossing number have been studied; see Schaefer's survey [44]. Two variants with geometric restrictions have attracted considerable attention: *2-layer crossing minimization* and *circular* (or *convex*, or *1-page*) *crossing minimization*, where the placement of the vertices is restricted to two parallel lines (called *layers*) and to a circle, respectively. In both cases, edges are drawn as straight-line segments. Circular crossing minimization is NP-hard, but admits FPT-algorithms with respect to the natural parameter [6, 34]. In practice, often the so-called *sifting heuristic* is used [7]. Circular crossing minimization can be seen as a special case of a *book embedding problem*, where vertices must lie on a straight line, the *spine* of the book, and each edge must be drawn on one of a given number of halfplanes called *pages* whose intersection is the spine. In this setting, crossing minimization is interesting even if the order of the vertices along the spine is given [8, 38].

The 2-layer variant comes in two settings: *one-sided crossing minimization* (*OSCM*) and *two-sided crossing minimization* (*TSCM*). In OSCM, the input consists of a (bipartite) graph and a linear order for the vertices on one side of the bipartition; the task is to find a linear order for the vertices on the other side that minimizes the total number of crossings. In TSCM, the linear orders on both layers can be chosen freely. OSCM is an important step in the so-called Sugiyama framework for drawing hierarchical graphs [46], that is, graphs where each vertex is assigned to a specific layer. OSCM was the topic of the Parameterized Algorithms and Computational Experiments Challenge (PACE[1]) 2024. Both OSCM and TSCM are NP-hard; OSCM even for the disjoint union of 4-stars [39] and for trees [19]. On the positive side, OSCM admits a subexponential FPT-algorithm; it runs in $O(k2^{\sqrt{2k}} + n)$ time [35]. TSCM also admits an FPT-algorithm; it runs in $2^{O(k)} + n^{O(1)}$ time [36].

In the context of beyond-planar graphs, a local version of the crossing number has also received considerable attention [18, 22]. A graph is *k-planar* if it admits a drawing with at most k crossings per edge. The *local crossing number* of a graph is the smallest k such that the graph is k-planar. The recognition of 1-planar graphs has long been known to be NP-hard [28]. Later, it turned out that the recognition of k-planar graphs is NP-hard for every k [47]. Hence, it is unlikely that FPT- or XP-algorithms exist with respect to the natural parameter k. On the other hand, recognizing 1-planar graphs is fixed-parameter tractable with respect to tree-depth and cyclomatic number [5]. The problem remains NP-hard, however, for graphs of bounded bandwidth (and hence, pathwidth and treewidth). The local crossing number has also been studied in the context of book embeddings [1, 37].

In this paper, we study the above-mentioned geometric restrictions, but with respect to the *local* crossing number. The resulting graph classes are called *2-layer k-planar* graphs and *outer k-planar* graphs; see Figure 1. The former were studied by Angelini, Da Lozzo, Förster, and Schneck [3]. Among others, they gave bounds on the edge density of these graphs and characterized 2-layer k-planar graphs with the maximum edge density for $k \in \{2, 4\}$. They concluded that "the general recognition and characterization of 2-layer k-planar graphs

[1] https://pacechallenge.org/2024/

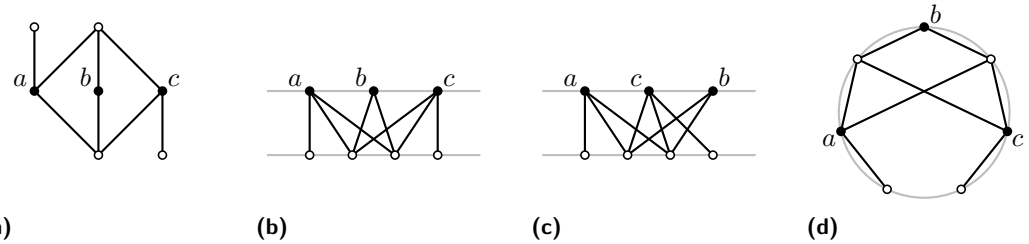

Figure 1 Drawings of the same bipartite graph with optimal local crossing number in different settings: (a) planar drawing, (b) 2-layer 2-planar drawing without restriction, (c) 2-layer 3-planar drawing where the vertex order on the upper layer is fixed, (d) outer 1-planar drawing.

remain important open problems". According to Schaefer's survey [44] on crossing numbers, Kainen [32] introduced the "local outerplanar crossing number", which minimizes, over all circular drawings, the largest number of crossings along any edge. Outer k-planar graphs have been studied by Pach and Tóth [40], who showed that any outer k-planar graph with n vertices has at most $4.1\sqrt{k}n$ edges. For $k \leq 3$, they established a better bound $(k+3)(n-2)$, which is tight for $k \in \{1,2\}$. For $k \geq 5$, the constant factor was later improved to $\sqrt{243/40} \approx 2.46$ [2].

We study the parameterized complexity of the two recognition problems with respect to the natural parameter k. For $k = 0$, the two classes of graphs are exactly the caterpillars and outerplanar graphs, respectively, which can be recognized in linear time. There are also linear-time algorithms for recognizing outer 1-planar graphs [4,30]. The authors of [30] posed the existence of polynomial-time algorithms for recognizing outer 2-planar graphs as an open problem. A partial answer has been given by Hong and Nagamochi [31], showing that *full* outer 2-planar graphs can be recognized in linear time. Outer k-planar drawings are *full* if no crossing appears on the boundary of the outer face. The authors of [16] generalized this result and showed that, for every integer k, full outer k-planarity is testable in $O(f(k) \cdot n)$ time, for a computable function f. They also showed that outer k-planar graphs can be recognized in quasi-polynomial time, which implies that, for every integer k, testing outer k-planarity is not NP-hard unless the Exponential-Time Hypothesis fails.

Parameterized complexity. We assume that the reader is familiar with basic concepts in parameterized complexity theory (see [17,20,25] for definitions of these concepts). Zehavi [48] gives a survey specifically on the parameterized analysis of crossing minimization problems. The class XNLP consists of all parameterized problems that can be solved non-deterministically in time $f(k)n^{O(1)}$ and space $f(k)\log n$, where f is some computable function, n is the input size, and k is the parameter. A parameterized problem $L_2 \subseteq \Sigma^* \times \mathbb{N}$ is said to be XNLP-*hard* if for any $L_1 \in$ XNLP, there is a *parameterized logspace reduction* from L_1 to L_2, that is, there is an algorithm $\mathcal{A}$ and computable functions f and g that satisfy the following: Given $(x_1, k_1) \in \Sigma^* \times \mathbb{N}$, the algorithm $\mathcal{A}$ computes $(x_2, k_2) \in \Sigma^* \times \mathbb{N}$ such that $(x_1, k_1) \in L_1$ if and only if $(x_2, k_2) \in L_2$, $k_2 \leq g(k_1)$, and $\mathcal{A}$ runs in space $O(f(k_1) + \log |x_1|)$. A parameterized problem is said to be XNLP-*complete* if it is XNLP-hard and belongs to XNLP. The class XNLP contains the class W[t] for every $t \geq 1$ [13]. Moreover, Pilipczuk and Wrochna [41] conjectured that an XNLP-hard problem does not admit an algorithm that runs in $n^{f(k)}$ time and $f(k) \cdot n^{O(1)}$ space for a computable function f, where n is the size of the instance and k is the parameter. We refer to [13,23] for more information.

Recently, the authors of [10] showed the first graph-drawing problem to be XNLP-complete, namely *ordered level planarity*, parameterized by the number of levels. Ordered level planarity is a restricted version of level planarity, where for each level, the vertices on that level are given in order (and the problem is to route the edges in a y-monotone and crossing-free way).

Our contribution. We present XP-algorithms for recognizing 2-layer k-planar graphs and outer k-planar graphs, which implies that both recognition problems can be solved in polynomial time for every fixed k; see Sections 4.1 and 5.1, respectively. This solves the open problem regarding the recognition of outer 2-planar graphs posed by the authors of [30]. We complement these results by showing that recognizing 2-layer k-planar graphs is XNLP-complete even for trees (Section 4.2) and that recognizing outer k-planar graphs is XNLP-hard (Section 5.3). This implies that both problems are W[t]-hard for every t [13] and that it is unlikely that they admit FPT-algorithms. On the other hand, we present an FPT-algorithm for recognizing 2-layer k-planar graphs where the order of the vertices on one layer is specified; see Figure 1c and Section 3.1. We prove that two *edge-weighted* versions of this problem are NP-hard; see Section 3.2. Finally, we show that the local circular crossing number cannot be approximated even for graphs that are almost trees (that is, graphs with feedback vertex number 1); see Section 5.2. We conclude with open problems; see Section 6.

The proofs of statements marked with a (clickable) $\star$ are in the full version.

2 Preliminaries

Let G be a graph. We let $V(G)$ and $E(G)$ denote the sets of vertices and edges of G, respectively. For a vertex v of G, let $N_G(v)$ be the set of neighbors of v in G, and let $\delta_G(v)$ be the set of edges incident to v. For $U \subseteq V(G)$, we define $N_G(U) = (\bigcup_{v\in U} N_G(v)) \setminus U$, $N_G[U] = N_G(U) \cup U$, and $\delta_G(U) = \bigcup_{v\in U} \delta_G(v)$. We may omit the subscript G when it is clear from the context. The subgraph of G induced by $U \subseteq V(G)$ is denoted by $G[U]$. A vertex is called a *leaf* if it has exactly one neighbor.

We use $[\ell]$ as shorthand for $\{1, 2, \dots, \ell\}$. Let $n = |V(G)|$, and let $\sigma\colon V(G) \to [n]$ be a linear order of the vertices of G (i.e., a bijection between $V(G)$ and $[n]$). For $\{u, v\} \in E$, the *stretch* of edge $\{u, v\}$ in σ is defined as $|\sigma(u) - \sigma(v)|$. The *bandwidth* of σ (with respect to G) is the maximum stretch of an edge of G in σ. The *bandwidth* of G, denoted by $\mathrm{bw}(G)$, is the minimum integer k such that G has a linear order σ of V with bandwidth at most k.

We define a *circular drawing* of a graph G to be a cyclic order $D = (v_1, \dots, v_n)$ of $V(G)$. We say that an edge $\{v_i, v_j\}$ with $i < j$ *pierces* a pair of (not necessarily adjacent) vertices $\{v_{i'}, v_{j'}\}$ with $i' < j'$ if either $1 \le i < i' < j < j' \le n$ or $1 \le i' < i < j' < j \le n$ holds. In particular, if $\{v_{i'}, v_{j'}\}$ is an edge of G, we say that $\{v_i, v_j\}$ *crosses* $\{v_{i'}, v_{j'}\}$. For an edge e, let $\mathrm{cr}_D(e)$ denote the number of edges that cross e in D. A circular drawing D is *k-planar* (or an *outer k-planar drawing*) if every edge crosses at most k edges in D. Since whether two edges cross is determined only by the cyclic vertex order, in this paper, we allow the edges to be drawn arbitrarily.

Let G be a bipartite graph with $V(G) = X \cup Y$, $X \cap Y = \emptyset$, and $E(G) \subseteq X \times Y$. A *2-layer drawing* of G is a pair $D = (<_X, <_Y)$ of (strict) linear orders $<_X$ and $<_Y$ defined on X and on Y, respectively. A *crossing* in D is defined by a pair of edges $\{x, y\}$ and $\{x', y'\}$ with distinct endpoints $x, x' \in X$ and distinct endpoints $y, y' \in Y$ such that $x <_X x'$ and $y' <_Y y$. The notation $\mathrm{cr}_D(e)$ is defined as above. Moreover, for two distinct edges e and e', let $\mathrm{cr}_D(e, e')= 1$ if e crosses e'; $\mathrm{cr}_D(e, e') = 0$ otherwise. For distinct $x, x' \in X$, we say that x is *to the left of* x' in D if $x <_X x'$. Equivalently, we say that x' is *to the right of* x. The *leftmost* (resp. *rightmost*) of X in D is the smallest (resp. largest) vertex in X under the linear order $<_X$. We also use these notions for vertices in Y. For an integer $k \ge 0$, a 2-layer drawing D of G is said to be *k-planar* if, for each edge e of G, $\mathrm{cr}_D(e) \le k$. For (not necessarily disjoint) vertex sets $A, B \subseteq X \cup Y$ and 2-layer drawings D_A of $G[A]$ and D_B of $G[B]$, we say that D_A is *compatible* with D_B (or equivalently D_B is compatible with D_A) if, for every pair $\{z, z'\} \subseteq A \cap B$ of vertices that both are in the same set of the bipartition $Z \in \{X, Y\}$, we have that $z <_Z z'$ in D_A if and only if $z <_Z z'$ in D_B.

3 Recognizing 2-Layer k-Planar Graphs – The One-Sided Case

In this section, we design an FPT-algorithm for recognizing 2-layer k-planar graphs when the order of the vertices on one layer is given as input. The problem is defined as follows.

Problem: One-Sided k-Planarity
Input: A bipartite graph $(X \cup Y, E)$, an integer $k \geq 0$, and a linear order $<_X$ of X.
Question: Does Y admit a linear order $<_Y$ such that $(<_X, <_Y)$ is a 2-layer k-planar drawing of $(X \cup Y, E)$?

Degree reduction. Let $G = (X \cup Y, E)$ be a bipartite graph, and let k be a non-negative integer. We describe two simple reduction rules that yield an equivalent instance of One-Sided k-Planarity where every vertex in X has degree at most $2k + 2$.

▶ **Observation 1** (⋆). *Let $G = (X \cup Y, E)$ be a bipartite graph that contains a vertex with more than $2k + 2$ non-leaf neighbors. Then G is not 2-layer k-planar.*

▶ **Lemma 2** (⋆). *Let $(G, <_X, k)$ be an instance of One-Sided k-Planarity. If G contains a vertex $v \in X$ with $\deg(v) > 2k + 2$ and with a leaf neighbor $y \in Y$, then $(G, <_X, k)$ is a* YES-instance if and only if $(G - y, <_X, k)$ is a YES-instance.

Hence, in the following, we assume that every vertex in X has degree at most $2k + 2$.

3.1 An FPT-Algorithm

Let n be the number of vertices in G. In this section, we prove the following result.

▶ **Theorem 3.** *One-Sided k-Planarity can be solved in time $2^{O(k \log k)} n^{O(1)}$, that is, One-Sided k-Planarity is fixed-parameter tractable when parameterized by k.*

We assume that G has no isolated vertices; otherwise, we simply remove them. For a 2-layer drawing D of a subgraph G' of G, we say that D *respects* $<_X$ if, for every $x, x' \in V(G')$, it holds that x is to the left of x' in D if and only if $x <_X x'$.

We first give a simpler algorithm with running time $2^{O(k^2 \log k)} n^{O(1)}$. Let $x_1, \ldots, x_{|X|}$ be the vertices of X appearing in this order in $<_X$. If $|X| < 2k + 1$, then $|Y| \leq 2k(2k + 2)$, and we can simply enumerate all the possible 2-layer drawings in time $2^{O(k^2 \log k)} n^{O(1)}$. Thus, we assume $|X| \geq 2k + 1$. Let $\ell = 2k$. For $i \in [|X| - \ell]$, let $X_{\leq i} = \{x_1, \ldots, x_{i+\ell}\}$ and $X_i = \{x_i, \ldots, x_{i+\ell}\}$. Correspondingly, let $G_{\leq i} = G[N[X_{\leq i}]]$ and $G_i = G[N[X_i]]$. Our algorithm recursively decides whether $G_{\leq i}$ admits a 2-layer k-planar drawing that extends a prescribed partial drawing D of G_i. To be more precise, let D be a 2-layer k-planar drawing of G_i that respects $<_X$. Given $i \in [|X| - \ell]$, a partial drawing D of G_i respecting $<_X$, and a function $\chi \colon \delta(X_i) \to \{0, \ldots, k\}$, we define a Boolean value $\texttt{draw}(i, D, \chi)$ to be `true` if and only if $G_{\leq i}$ admits a 2-layer k-planar drawing $D_{\leq i}$ such that

- $D_{\leq i}$ is compatible with D and
- for every edge $e \in \delta(X_i)$, it holds that $\chi(e) = \mathrm{cr}_{D_{\leq i}}(e)$.

Our goal is to compute $\texttt{draw}(|X| - \ell, D, \chi)$ for some partial drawing D of $G_{|X|-\ell}$ and χ, which is done by the following dynamic programming algorithm.

For the base case $i = 1$, we compute the table entries by brute force: For each possible 2-layer k-planar drawing D of G_1 respecting $<_X$ and for every function $\chi \colon \delta(X_1) \to \{0, \ldots, k\}$, we set $\texttt{draw}(1, D, \chi) = \texttt{true}$ if $\chi(e) = \mathrm{cr}_D(e)$ for every $e \in \delta(X_1)$; otherwise, we set $\texttt{draw}(1, D, \chi) = \texttt{false}$. Now we show that, in any 2-layer k-planar drawing, if two edges have endpoints in X that are far apart, then the edges do not cross.

▶ **Lemma 4 (⋆).** *If $e = (x_p, y)$ and $f = (x_q, y')$ are distinct edges such that $p + \ell < q$, then, in every 2-layer k-planar drawing $D = (<_X, <_Y)$ of G, it holds that $y <_Y y'$ or that $y = y'$.*

This suggests the following recurrence for the dynamic program.

▶ **Lemma 5.** *Let $2 \leq i \leq |X| - \ell$, let D be a 2-layer k-planar drawing of G_i respecting $<_X$, and let $\chi\colon \delta(X_i) \to \{0, \dots, k\}$ such that $\chi(e) = \mathrm{cr}_D(e)$ for every $e \in \delta(x_{i+\ell})$. Then,*

$$\texttt{draw}(i, D, \chi) = \bigvee_{D_{i-1}, \chi_{i-1}} \texttt{draw}(i-1, D_{i-1}, \chi_{i-1}),$$

where the D_{i-1} are taken over all 2-layer k-planar drawings of G_{i-1} that are compatible with D, and the χ_{i-1} are taken over all functions $\delta(X_{i-1}) \to \{0, \dots, k\}$ that satisfy

$$\chi_{i-1}(e) = \chi(e) - \sum_{f \in \delta(x_{i+\ell})} \mathrm{cr}_D(e, f)$$

for every edge $e \in \delta(X_i) \cap \delta(X_{i-1})$.

Proof. Suppose that $\texttt{draw}(i, D, \chi) = \texttt{true}$. Then, there is a 2-layer k-planar drawing $D_{\leq i}$ of $G_{\leq i}$ that is compatible with D and, for every edge $e \in \delta(X_i)$, it holds that $\chi(e) = \mathrm{cr}_{D_{\leq i}}(e)$. We need to show that there exists a triplet $t = (i-1, D_{i-1}, \chi_{i-1})$ such that $\texttt{draw}(t) = \texttt{true}$. Let $D_{\leq i-1}$ and D_{i-1} be subdrawings of $D_{\leq i}$ induced by $G_{\leq i-1}$ and G_{i-1}, respectively. Then $D_{\leq i-1}$ is compatible with D_{i-1}. By Lemma 4, edges incident to $x_{i+\ell}$ do not cross edges incident to x_{i-1}. Thus, for every edge $e \in \delta(x_{i-1})$, we have $\mathrm{cr}_{D_{\leq i}}(e) = \mathrm{cr}_{D_{\leq i-1}}(e)$. Moreover, every edge $e \in \delta(X_i) \cap \delta(X_{i-1})$ has exactly $\chi(e) - \sum_{f \in \delta(x_{i+\ell})} \mathrm{cr}_D(e, f)$ crossings in $D_{\leq i-1}$. Define χ_{i-1} by setting $\chi_{i-1}(e) = \mathrm{cr}_{D_{\leq i-1}}(e)$ for every edge $e \in \delta(X_{i-1})$. Then, by definition, $\texttt{draw}(i-1, D_{i-1}, \chi_{i-1}) = \texttt{true}$ since $D_{\leq i-1}$ is a 2-layer k-planar drawing of $G_{\leq i-1}$ compatible with D_{i-1} and, for every $e \in \delta(X_{i-1})$, it trivially holds that $\chi_{i-1}(e) = \mathrm{cr}_{D_{\leq i-1}}(e)$.

We omit the converse direction, which readily follows by reversing the above argument. ◀

Our algorithm evaluates the recurrence of Lemma 5 in a dynamic programming manner. To see the runtime bound, observe that, for each $i \in [|X| - \ell]$, the number of possible 2-layer k-planar drawings of G_i is upper bounded by $|N(X_i)|! \leq ((\ell+1) \cdot (2k+2))! = 2^{O(k^2 \log k)}$ and the number of possible functions from $\delta(X_i)$ to $\{0, \dots, k\}$ is upper bounded by $(k+1)^{|\delta(X_i)|} = 2^{O(k^2 \log k)}$. Hence, we can evaluate the recurrence in time $2^{O(k^2 \log k)} n^{O(1)}$.

We can improve the exponential dependency of our running time as follows. Instead of fixing the "window size" to $2k+1$, for every i, we dynamically take the smallest ℓ_i such that $\delta(\{x_i, \dots, x_{i+\ell_i}\})$ consists of at least $2k+1$ edges. It is easy to verify that Lemma 4 (and hence Lemma 5) still holds for this dynamic window size. Since the degree of every vertex in X is at most $2k+2$, we have that $|\delta(\{x_i, \dots, x_{i+\ell_i}\})| \leq 4k+2$. This improves the running time to $2^{O(k \log k)} n^{O(1)}$, completing the proof of Theorem 3.

3.2 NP-Hardness of the Weighted Version

We can generalize One-Sided k-Planarity to weighted settings. Let $G = (X \cup Y, E)$ be a bipartite graph, and let $w\colon E \to \mathbb{N}_{>0}$ be an edge-weight function. A 2-layer drawing D of (G, w) is said to be k-planar if, for each edge e of G, it holds that

$$\sum_{f \text{ crosses } e \text{ in } D} w(f) \leq k. \tag{1}$$

It is straightforward to extend our algorithm to this weighted setting. Although we believe that One-Sided k-Planarity is NP-hard, we can only show the following weaker result.

▶ **Theorem 6** (⋆). *The weighted* One-Sided k-Planarity *is (weakly)* NP*-hard under (1).*

Proof (sketch). The claim is shown by performing a reduction from Partition, which is known to be (weakly) NP-hard [26]. The problem asks, given a set of n integers $A = \{a_1, \ldots, a_n\}$, whether the set can be partitioned into two subsets of equal sum. We construct a bipartite graph G consisting of a path of length 2 with two edges e_0 and e_{n+1} of weight 1, and n isolated edges with weight proportional to the integers in A. By appropriately defining the order $<_X$ on X, we can ensure that each isolated edge crosses either e_0 or e_{n+1}; see Figure 2. Setting k properly induces two balanced subsets of A. ◀

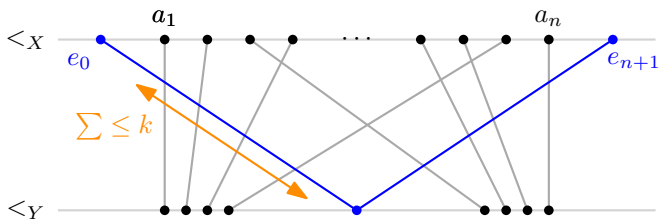

Figure 2 The graph G and $<_X$ we construct. $\sum$ is the sum of weights of edges that cross e_0.

We remark that there is another reasonable definition of crossings in a weighted graph: A 2-layer drawing is defined to be k-planar if, for each edge $e \in E$, it holds that

$$\sum_{f \text{ crosses } e \text{ in } D} w(e) \cdot w(f) \leq k. \tag{2}$$

By making $w(e_0)$ and $w(e_{n+1})$ sufficiently large, a similar reduction will work.

▶ Remark 7. The weighted One-Sided k-Planarity is (weakly) NP-hard under (2).

4 Recognizing 2-Layer k-Planar Graphs – The Two-Sided Case

The algorithm in Theorem 3 exploits the prescribed order $<_X$ on X, which is not specified in the two-sided case. This difference is reflected by the parameterized complexity of the two problems. The two-sided case turns out to be XNLP-hard, meaning that it is unlikely to be fixed-parameter tractable. On the other hand, we design a polynomial-time algorithm for the two-sided case, provided that k is fixed. We use this algorithm also to show that the problem is contained in XNLP. Formally, the problem is defined as follows.

Problem: Two-Sided k-Planarity
Input: A bipartite graph $G = (X \cup Y, E)$ and an integer $k \geq 0$.
Question: Does G admit a 2-layer k-planar drawing?

4.1 An XP-Algorithm

To solve Two-Sided k-Planarity, we extend the algorithm for One-Sided k-Planarity presented in Section 3. Let $G = (X \cup Y, E)$ be a bipartite graph, let n be the number of vertices of G, and let $k \in \mathbb{N}$. We assume that G is connected; otherwise, the problem can be solved independently for each connected component. Moreover, by applying Observation 1 and applying Lemma 2 first to X and then to Y, we assume that every vertex has degree at most $2k + 2$. Our algorithm employs a dynamic programming approach analogous to that

presented in Section 3. Instead of a "window", we specify a subset $X_i \subseteq X$ of $\ell + 1 = 2k + 1$ vertices, which plays the same role as the window $\{x_i, \dots, x_{i+\ell}\}$. However, this subset does not specify the graph $G_{\le i}$ on the left of the window, preventing us from defining the same type of subproblems as there. We overcome this obstacle by applying an idea similar to that of Saxe [43] for recognizing bandwidth-k graphs. To properly define the subproblems, we observe that $N[X_i]$ separates the subdrawings of the components of $G[V(G) \setminus N[X_i]]$ into left and right parts.

▶ **Lemma 8.** *Let $D = (<_X, <_Y)$ be a 2-layer k-planar drawing of G, and let $S \subseteq X$ be a set of $\ell + 1$ vertices that appears consecutively in D. Let x and x' be the leftmost vertex and the rightmost vertex of S in D, respectively. Then, for each component C of $G[V(G) \setminus N[S]]$, the vertices in $C \cap X$ are either entirely to the left of x or entirely to the right of x'.*

Proof. Suppose that C has two vertices $u, v \in X \setminus S$ such that u is to the left of x and v is to the right of x' in D. Let P be a path between u and v in $G[C]$. We can assume that P has exactly two edges, e and f. Observe that each edge incident to a vertex in S crosses either e or f. Since each vertex in S has at least one incident edge, at least one of e and f involves more than k crossings. ◀

Suppose that G has a 2-layer k-planar drawing $D = (<_X, <_Y)$. For a family $\mathcal{D} \subseteq 2^{V(G)}$, we use $\mathcal{D}^X$ as shorthand for $\bigcup_{C \in \mathcal{D}} C \cap X$. Let $x_1, \dots, x_{|X|}$ be the vertices of X appearing in this order in $<_X$. For $1 \le i \le |X| - \ell$, let $\mathcal{C}_i$ be the set of connected components in $G[V(G) \setminus N[\{x_i, \dots, x_{i+\ell}\}]]$. By Lemma 8, we have $\mathcal{C}^X = \{x_1, \dots, x_{i-1}\}$ for some $\mathcal{C} \subseteq \mathcal{C}_i$.

Now, we can formally define our subproblems. Let $S \subseteq X$ with $|S| = \ell + 1$, let D be a 2-layer k-planar drawing of $G[N[S]]$, let $\chi\colon \delta(S) \to \{0, \dots, k\}$, and let $\mathcal{C} \subseteq \mathcal{C}_S$, where $\mathcal{C}_S$ is the set of components in $G[V(G) \setminus N[S]]$. We define a Boolean value $\texttt{draw}(S, D, \chi, \mathcal{C})$ to be `true` if and only if there is a 2-layer k-planar drawing D^* of $G[N[S \cup \mathcal{C}^X]]$ such that

- D^* is compatible with D and
- for every edge $e \in \delta(S)$, it holds that $\chi(e) = \mathrm{cr}_{D^*}(e)$.

Hence, G has a 2-layer k-planar drawing if and only if $\texttt{draw}(S, D, \chi, \mathcal{C}_S) = \texttt{true}$ for some $S \subseteq X$, D, χ, and $\mathcal{C}_S$.

To compute the values $\texttt{draw}(S, D, \chi, \mathcal{C})$ for $S \subseteq X$ with $|S| = \ell + 1$, D, χ, and $\mathcal{C} \subseteq \mathcal{C}_S$, we first compute the base cases where $\mathcal{C} = \emptyset$ and then the other cases in ascending order of $|S \cup \mathcal{C}^X|$. This can be done by using a recurrence similar to the one in Lemma 5.

To see the running time bound of the above algorithm, observe that the number of possible choices for S, D, χ, and $\mathcal{C}$ is at most

$$\sum_{S \subseteq X} |S|! \cdot |N(S)|! \cdot (k+1)^{|\delta(S)|} \cdot 2^{|\mathcal{C}_S|} = n^{\ell+1} \cdot 2^{O(k^2 \log k)} \cdot 2^{|\mathcal{C}_S|}.$$

The third factor can be bounded by $2^{O(k^3)}$ as follows: Since G is connected, each connected component of $G[V(G) \setminus N[S]]$ contains at least one vertex in $N(N(S)) \setminus S$. This implies that the number of components in $G[V(G) \setminus N[S]]$ is at most $|N(N(S)) \setminus S| \le (2k+2)(2k+1)^2$.

▶ **Theorem 9.** *Two-Sided k-Planarity can be solved in time $2^{O(k^3)} n^{2k+O(1)}$, that is, Two-Sided k-Planarity is polynomial-time solvable when k is fixed.*

The above algorithm easily turns into a non-deterministic algorithm that runs in polynomial time and space $k^{O(1)} \log n$, which implies the following.

▶ **Corollary 10** ($\star$). *Two-Sided k-Planarity is in* XNLP.

4.2 XNLP-Completeness

To complement the positive result in the previous subsection, we show that Two-Sided k-Planarity is XNLP-hard even on trees. In contrast to our result, TSCM can be solved in polynomial time on trees [45].

▶ **Theorem 11** (⋆). *Two-Sided k-Planarity is* XNLP*-complete w.r.t. k even on trees.*

Proof (sketch). Membership in XNLP follows from Corollary 10. We prove the claim by showing a parameterized logspace reduction from Bandwidth, which is known to be XNLP-hard even on trees [11,13]. Let T be a tree. We subdivide each edge e of T once by introducing a vertex w_e, and we add ℓ leaves adjacent to each original vertex of T for some $\ell = \Theta(b^2)$. Let G be the graph obtained in this way. Next, we show that $\mathrm{bw}(T) \leq b$ if and only if G has a 2-layer k-planar drawing for some $k = \Theta(b^3)$.

Let $X = V(T)$, let $Y = V(G) \setminus X$, and let σ be a vertex order of T with bandwidth b. Define a vertex order $<_X$ on X by setting $<_X = \sigma$. Since the stretch of each edge in σ is at most b, there are at most $b-1$ vertices between its endpoints. This implies that we can place the vertices in Y so that there will be only $O(b^3)$ crossings per edge; see Figure 3. Conversely, in any 2-layer k-planar drawing of G, the endpoints of every edge $e = \{u, v\}$ of T are close to each other, as each vertex between u and v causes at least ℓ crossings on the path (u, w_e, v). Hence, the order on X turns into a vertex order of T with bandwidth at most b. ◀

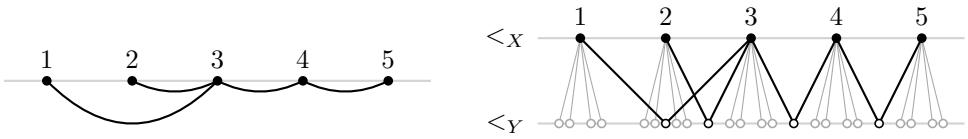

Figure 3 A minimum-bandwidth order of T and the 2-layer drawing of G that we construct.

5 Recognizing Outer k-Planar Graphs

In this section, we discuss the parameterized complexity of recognizing outer k-planar graphs.

Problem: Outer k-Planarity
Input: A graph G with n vertices and an integer k.
Question: Does G admit an outer k-planar drawing?

5.1 An XP-Algorithm

In this subsection, we show our main result, an XP-algorithm for Outer k-Planarity with respect to k. Note that a graph is outer k-planar if and only if its biconnected components are outer k-planar; this can be shown in a similar manner as [31, Theorem 4] for $k = 2$. Hence, we assume the input graph to be biconnected.

▶ **Theorem 12.** *Outer k-Planarity can be solved in time $2^{O(k \log k)} n^{3k+O(1)}$, that is, Outer k-Planarity is polynomial-time solvable when k is fixed.*

Let G be the input graph, let $\vec{e} = (u, v)$ be an ordered pair of two distinct vertices of G, and let R be a subset of $V(G) \setminus \{u, v\}$ such that there are at most k edges between R and L, where $L = V(G) \setminus (\{u, v\} \cup R)$. Let C be the set of these edges. Let τ be a linear order of

C, let $c_1, \dots, c_\ell$ denote the vertices of C in the order given by τ, and let $\chi\colon C \to \{0, \dots, k\}$. Let $G_{\tau,\vec{e},R}$ be the graph obtained by adding ℓ vertices $t_1^\tau, t_2^\tau, \dots, t_\ell^\tau$ to the induced subgraph $G[\{u,v\} \cup R]$ and by connecting t_i^τ and the endpoint of c_i in R for every $i \in [\ell]$. Then we define a Boolean value $\texttt{draw}(\vec{e}, R, \tau, \chi)$ to be `true` if and only if $G_{\tau,\vec{e},R}$ admits an outer k-planar drawing D with the following properties:

(P1) the cyclic order of D contains $(u, t_1^\tau, t_2^\tau, \dots, t_\ell^\tau, v)$ as a consecutive subsequence, and

(P2) for every edge $c_i \in C$, it holds that $\chi(c_i) = \mathrm{cr}_D(c_i)$.

Clearly, the graph G admits an outer k-planar drawing if and only if there exists a vertex pair $\vec{e}$ such that $\texttt{draw}(\vec{e}, V(G) \setminus \{u,v\}, f_\emptyset, f_\emptyset) = \texttt{true}$, where $f_\emptyset$ is the empty function.

We evaluate the recurrence as follows. For every base case, namely where $R = \emptyset$, $\texttt{draw}(\vec{e}, R, \tau, \chi)$ is `true` since C is also empty.

When $R \neq \emptyset$, we compute $\texttt{draw}(\vec{e}, R, \tau, \chi)$ for smaller sets of type R. In this case, with the same technique as that used in [24, Lemma 6], we can show the following.

▶ **Lemma 13** (⋆). *If $G_{\tau,\vec{e},R}$ admits an outer k-planar drawing D with properties P1 and P2, there is $w \in R$ such that vertex pairs $\{u,w\}$ and $\{v,w\}$ are pierced by at most k edges in D.*

Hence, we can compute $\texttt{draw}(\vec{e}, R, \tau, \chi)$ by checking all the ways to split the instance at the vertex w. Let $\{R_1, R_2\}$ be a partition of $R \setminus \{w\}$, let $L_1 = V(G_{\tau,\vec{e},R}) \setminus (\{u,w\} \cup R_1)$ and let $L_2 = V(G_{\tau,\vec{e},R}) \setminus (\{v,w\} \cup R_2)$. For $i \in [2]$, let C_i be the set of edges between R_i and L_i, let $\ell_i = |C_i|$, let τ_i be a linear order of C_i, and let $\chi_i\colon C_i \to \{0, \dots, k\}$ be a function. We say that $w, R_1, \tau_1, \chi_1, R_2, \tau_2, \chi_2$ are *consistent* if the following holds ($\mathrm{cr}_{\tau,\tau_1,\tau_2}$ is defined below):

- there are at most k edges between L_1 and R_1 and at most k edges between L_2 and R_2,
- for every edge c between L and R_i, $\chi_i(c) = \chi(c) - \mathrm{cr}_{\tau,\tau_1,\tau_2}(c)$ holds for $i \in [2]$,
- for every edge c between L and $\{w\}$, $\chi(c) = \mathrm{cr}_{\tau,\tau_1,\tau_2}(c)$,
- for every edge c between $\{v\}$ and R_1, $\chi_1(c) + \mathrm{cr}_{\tau,\tau_1,\tau_2}(c) \leq k$,
- for every edge c between $\{u\}$ and R_2, $\chi_2(c) + \mathrm{cr}_{\tau,\tau_1,\tau_2}(c) \leq k$, and
- for every edge c between R_1 and R_2, $\chi_1(c) + \chi_2(c) + \mathrm{cr}_{\tau,\tau_1,\tau_2}(c) \leq k$.

Informally, the value $\mathrm{cr}_{\tau,\tau_1,\tau_2}(c)$ is the number of crossings on c inside the "triangle" consisting of $\{u,v,w\}$. To define it formally, let us consider a circular drawing $D_H = (u, t_1^\tau, \dots, t_\ell^\tau, v, t_{\ell_2}^{\tau_2}, \dots t_1^{\tau_2}, w, t_{\ell_1}^{\tau_1}, \dots, t_1^{\tau_1})$ of a graph H. For each edge $c \in (E \cap \{u,v\}) \cup C \cup C_1 \cup C_2$, the graph H contains an edge $f(c)$ defined as follows. If $c = \{u,v\}$, $f(c)$ simply connects u and v. Suppose that c is incident to exactly one vertex $x \in \{u,v,w\}$. This implies that c is contained in exactly one of C, C_1, and C_2, which also means that c is contained in the domain of exactly one $\tau' \in \{\tau, \tau_1, \tau_2\}$. Then $f(c)$ connects x and $t_{\tau'(c)}^{\tau'}$. Otherwise, c is contained in exactly two of C, C_1, and C_2, since c is not contained in $C \cap C_1 \cap C_2$. Similarly to the previous case, c is contained in the domains of distinct $\tau', \tau'' \in \{\tau, \tau_1, \tau_2\}$. Then $f(c)$ connects $t_{\tau'(c)}^{\tau'}$ and $t_{\tau''(c)}^{\tau''}$. Now we define $\mathrm{cr}_{\tau,\tau_1,\tau_2}(c) = \mathrm{cr}_{D_H}(f(c))$.

We are ready to state Lemma 14, which formalizes the above idea of splitting an instance $((u,v), R, \tau, \chi)$ at a vertex w in R into two subinstances $((u,w), R_1, \tau_1, \chi_1)$ and $((w,v), R_2, \tau_2, \chi_2)$; see Figure 4, where some edges are curved for better visualization.

▶ **Lemma 14.** *For $\vec{e} = (u,v)$, it holds that*

$$\texttt{draw}(\vec{e}, R, \tau, \chi) = \bigvee_{\substack{w, R_1, \tau_1, \chi_1, R_2, \tau_2, \chi_2 \\ \textit{consistent}}} \texttt{draw}((u,w), R_1, \tau_1, \chi_1) \wedge \texttt{draw}((w,v), R_2, \tau_2, \chi_2).$$

Proof. Suppose that $\texttt{draw}(\vec{e}, R, \tau, \chi) = \texttt{true}$, that is, there is an outer k-planar drawing $D = (u, t_1^\tau, \dots, t_\ell^\tau, v, v_1, \dots, v_r)$ of $G_{\tau,e,R}$ that satisfies properties P1 and P2. We assume that edges are drawn as straight-line segments in D. By Lemma 13 there is a vertex $w \in R$ for

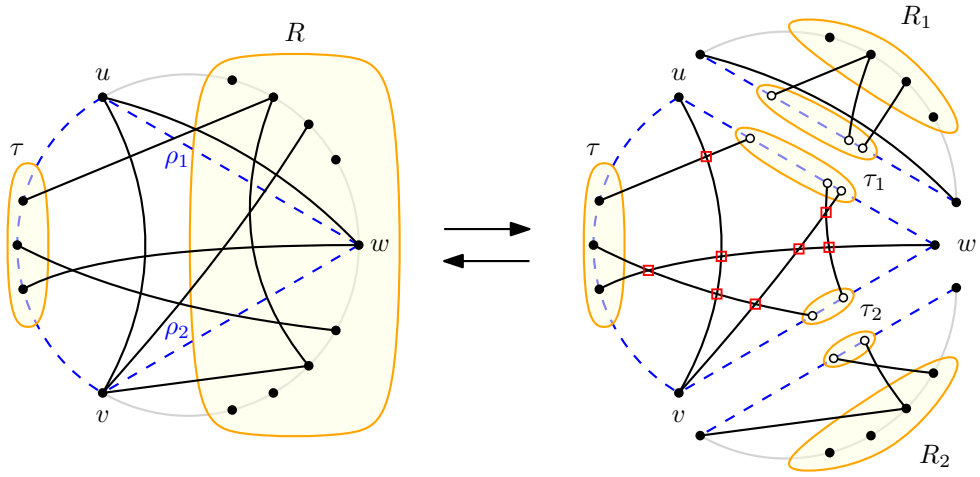

Figure 4 An image of Lemma 14. The red boxes are the crossings considered in $\mathrm{cr}_{\tau,\tau_1,\tau_2}$.

some $w = v_i$ such that both $\{u, w\}$ and $\{v, w\}$ have at most k piercing edges. The vertices u, v, w divide the circumference into the three arcs $\rho_{\bar{u}}, \rho_{\bar{v}}, \rho_{\bar{w}}$, where $\rho_{\bar{x}}$ is the arc between vertices other than x that does not pass through x for each $x \in \{u, v, w\}$. Then, following the line through u and w, we can take a curve ρ_1 between u and w, inside the circle, such that it crosses exactly the piercing edges, does not pass through any crossing between piercing edges, and separates v and the segment representing the edge $\{u, w\}$ (if it exists). We can take a curve ρ_2 between v and w similarly. Let $R_1 = \{v_{i+1}, \ldots, v_r\}$ and $R_2 = \{v_1, \ldots, v_{i-1}\}$. We then define a linear order τ_1 on the edges between R_1 and $L_1 \coloneqq V(G_{\tau,\vec{e},R}) \setminus (\{u, w\} \cup R_1)$ in such a way that τ_1 orders those edges in ascending order of the distance between u and the crossing with the curve ρ_1. Similarly, τ_2 is defined in such a way that τ_2 orders the edges R_2 and $L_2 \coloneqq V(G_{\tau,\vec{e},R}) \setminus (\{v, w\} \cup R_2)$ in ascending order of the distance between w to the crossing with the curve ρ_2. If we cut the drawing D along the curves as Figure 4, the drawing D can be decomposed into three subdrawings D_H, D_1, and D_2: D_H is the drawing inside the region surrounded by arcs $\rho_{\bar{w}}$, ρ_2, and ρ_1; D_1 is the drawing inside the region surrounded by arcs $\rho_{\bar{v}}$ and ρ_1; D_2 is the drawing inside the region surrounded by arcs $\rho_{\bar{u}}$ and ρ_2. Since each crossing on the edges between R_1 and L_1 is contained in exactly one of D_H, D_1, D_2, we have $\chi_1(c) = \chi(c) - \mathrm{cr}_{\tau,\tau_1,\tau_2}(c)$ for each edge c between L and R_1, and we have $\chi_1(c) + \mathrm{cr}_{\tau,\tau_1,\tau_2}(c) \leq k$ for each edge c between $\{v\}$ and R_1. As D_1 is a circular drawing of $G_{\tau_1,(u,w),R_1}$ that satisfies P1 and P2, we have $\texttt{draw}((u, w), R_1, \tau_1, \chi_1) = \texttt{true}$, and similarly, we have $\texttt{draw}((w, v), R_2, \tau_2, \chi_2) = \texttt{true}$. Since each edge c between R_1 and R_2 satisfies $\chi_1(c) + \chi_2(c) + \mathrm{cr}_{\tau,\tau_1,\tau_2}(c) \leq k$, we conclude that $w, R_1, \tau_1, \chi_1, R_2, \tau_2, \chi_2$ are consistent.

Suppose that there are consistent w, R_1, τ_1, χ_1, R_2, τ_2, χ_2 such that $\texttt{draw}((u, w), R_1, \tau_1, \chi_1) = \texttt{draw}((w, v), R_2, \tau_2, \chi_2) = \texttt{true}$. Let D_1 and D_2 be circular drawings of $G_{\tau_1,(u,w),R_1}$ and $G_{\tau_2,(w,v),R_2}$, respectively, that satisfy P1 and P2. Let $\sigma_1 = (w, \ldots, u)$ and $\sigma_2 = (v, \ldots, w)$ be the linear orders of $\{w, u\} \cup R_1$ and $\{v, w\} \cup R_2$ obtained from D_1 and D_2 by removing the vertices $t_i^{\tau_1}$ and $t_j^{\tau_2}$ for $i \in [\ell_1]$ and $j \in [\ell_2]$, respectively. Then we obtain a cyclic order σ of $G_{\tau,e,R}$ by concatenating $\sigma_2, \sigma_1, (u, t_1^{\tau}, \ldots, t_\ell^{\tau}, v)$ in this order, identifying the two occurrences of each of w, u, v with each other. It is not difficult to see that, by combining D_H, D_1, and D_2 as in Figure 4, we obtain a drawing D with linear order σ that satisfies P1 and P2. In other words, $\texttt{draw}(\vec{e}, R, \tau, \chi) = \texttt{true}$. ◀

Naïvely, the number of R's to consider is $\Theta(2^n)$, which does not give an XP-algorithm. However, the following lemma assures that it is not so large.

▶ **Lemma 15** (⋆). *Let G be a biconnected graph that admits an outer k-planar drawing D. Let $\{u, v\}$ be a pair of distinct vertices of G that has at most k piercing edges in D. Then the number of R's such that $\texttt{draw}((u, v), R, \tau, \chi) = \texttt{true}$ for some τ and χ is at most $2^{O(k)}m^{k+O(1)}$, where $m = |E(G)|$. Moreover, such R's can be enumerated in $2^{O(k)}m^{k+O(1)}$ time.*

Proof (sketch). We show that, given the set of edges piercing $\{u, v\}$, there are $2^{O(k)}$ possibilities for R that are separated by these piercing edges. Since R is a union of components in the graph obtained from $G[V(G) \setminus \{u, v\}]$ by deleting the piercing edges, it suffices to show that there are only $O(k)$ components in this graph. The proof shares the same underlying idea with Lemma 8, but it is more involved as the maximum degree is no longer bounded. The upper bound can be obtained by considering that there are at most k piercing edges of $\{u, v\}$ and the number of components in $G[V(G) \setminus \{u, v\}]$ is at most $2k + 3$. ◀

With Lemma 15 and the fact that $m = O(\sqrt{k}n)$ [40], the number of combinations of arguments $\{e, R, \sigma, \chi\}$ to consider is at most

$$n^2 \cdot 2^{O(k)}m^{k+O(1)} \cdot k! \cdot (k + 1)^k = 2^{O(k \log k)}n^{k+O(1)}.$$

To compute the value $\texttt{draw}(\vec{e}, R, \sigma, \chi)$ as in Lemma 14, we guess at most

$$n \cdot (2^{O(k \log k)}n^{k+O(1)})^2 = 2^{O(k \log k)}n^{2k+O(1)}$$

possible combinations of $w, R_1, \tau_1, \chi_1, R_2, \tau_2, \chi_2$. For each guess, checking the consistency takes $n^{O(1)}$ time. Hence, the total running time to fill the table is $2^{O(k \log k)}n^{3k+O(1)}$. This completes the proof of Theorem 12.

5.2 NP-Hardness of Approximation

In this subsection, we show an inapproximability result for Outer k-Planarity even for graphs that are almost trees, whereas trees can be drawn without any crossings.

▶ **Theorem 16.** *For any fixed $c \geq 1$, there is no polynomial-time c-approximation algorithm for Outer k-Planarity unless $\mathsf{P} = \mathsf{NP}$, even for graphs with feedback vertex number 1.*

Our proof is by reduction from Bandwidth on trees, which is NP-hard to approximate within any constant factor [21]. In other words, given a tree T, there is no polynomial-time algorithm to distinguish between the cases $\mathrm{bw}(T) \leq b$ and $\mathrm{bw}(T) > cb$ for any constant $c \geq 1$, unless $\mathsf{P} = \mathsf{NP}$.

Let T be a tree, and let n denote $|V(T)|$. We construct a graph G from T by adding a vertex w and making it adjacent to all vertices of T. Clearly, G has feedback vertex number 1 since $G[V(G) \setminus \{w\}]$ is a tree.

▶ **Lemma 17** (⋆). *If G is outer k-planar, then $\mathrm{bw}(T) \leq k - 1$.*

▶ **Lemma 18** (⋆). *Let $b \geq 1$. If $\mathrm{bw}(T) \leq b$, then G is outer $(5b - 5)$-planar.*

Proof (sketch). From a vertex order $(v_1, \ldots, v_n)$ of T with bandwidth at most b, we construct a circular drawing D of G as $D = (w, v_1, \ldots, v_n)$. Each edge $\{w, v_i\}$ incident to w has at most $2b - 2$ crossings in D since these crossing edges lie between vertices that are "close" to v_i. For other edge $\{v_i, v_j\} \in E(T)$ with $i < j$, it only crosses (1) edges incident to w and (2)

edges in T. There are at most $b-1$ edges of (1) since the stretch of $\{v_i, v_j\}$ is at most b, and at most $4b-4$ edges of (2) since these edges lie between vertices that are "close" to v_i or v_j. Hence, each edge has at most $5b-5$ crossings in total. ◀

Suppose that there is a polynomial-time c-approximation algorithm $\mathcal{A}$ for Outer k-Planarity. Let T be a tree, and let $b = \mathrm{bw}(T)$. By Lemma 18, $\mathcal{A}$ would output an outer $5bc$-planar drawing D of G. By Lemma 17, D can be transformed into a linear order of $V(T)$ with bandwidth at most $5bc$. Thus, we can find a $5c$-approximate solution for Bandwidth in polynomial time, which is impossible under $\mathsf{P} \neq \mathsf{NP}$. This completes the proof of Theorem 16.

5.3 XNLP-Hardness

In the proof of Theorem 16, we reduced the gap-version of Bandwidth to Outer k-Planarity. We exploited the gap to accommodate the crossings between edges in the original instance, which may increase the crossing number of each edge by $O(b)$. However, if we allow parallel edges, we can reduce from (the exact version of) Bandwidth by making the edges incident to w so thick that we can ignore the $O(b)$ increase in the crossing numbers. The following theorem is shown by emulating those parallel edges with rigid structures.

▶ **Theorem 19** ($\star$). *Outer k-Planarity is* XNLP*-hard when parameterized by k.*

Proof (sketch). As in Theorem 11, we give a parameterized logspace reduction from Bandwidth on trees. The idea of the reduction is similar to that used in Theorem 16. Instead of connecting w with each v_i, we replace each vertex v_i with a clique path gadget that appears consecutively in any outer k-planar drawing for some $k = \Theta(b^4)$ and connect w with sufficiently many vertices in the gadget. Since there are many edges between w and each gadget, two adjacent gadgets are placed closely in any outer k-planar drawing. ◀

6 Open Problems

We conclude with a number of problems that we have left open in this paper.

- Is One-Sided k-Planarity NP-hard?
- We conjecture that Outer k-Planarity is XALP-complete (see [12] for the definition).
- Can we extend the algorithm for Two-Sided k-Planarity to obtain an XP-algorithm for ℓ-layer k-planarity parameterized by $\ell + k$?
- Another way to extend k-planarity is to consider *min-k-planarity*, which is also called *weak k-planarity* [9, 15]. In a min-k-planar drawing, in every crossing, at least one of the two edges must have at most k crossings. Can 2-layer min-k-planar graphs and outer min-k-planar graphs be recognized by XP-algorithms with respect to k?
- Two-Sided k-Planarity can be seen as a restricted version of Outer k-Planarity for bipartite graphs where the vertices of the two sets of the bipartition must not interleave in the cyclic vertex order. This can be generalized as follows: For $k \geq 3$, can we efficiently recognize k-partite graphs that admit a k-planar straight-line drawing on the regular k-gon? A related question has been investigated for fixed-order book embedding [1].

Lipschitz Decompositions of Finite ℓ_p Metrics

Robert Krauthgamer
Weizmann Institute of Science, Rehovot, Israel

Nir Petruschka
Weizmann Institute of Science, Rehovot, Israel

Abstract

Lipschitz decomposition is a useful tool in the design of efficient algorithms involving metric spaces. While many bounds are known for different families of finite metrics, the optimal parameters for n-point subsets of ℓ_p, for $p > 2$, remained open, see e.g. [Naor, SODA 2017]. We make significant progress on this question and establish the bound $\beta = O(\log^{1-1/p} n)$. Building on prior work, we demonstrate applications of this result to two problems, high-dimensional geometric spanners and distance labeling schemes. In addition, we sharpen a related decomposition bound for $1 < p < 2$, due to Filtser and Neiman [Algorithmica 2022].

1 Introduction

The pursuit of approximating metric spaces by simpler structures has inspired the development of fundamental concepts, such as graph spanners [47, 46] and low-distortion embeddings into various spaces [37, 7], both of which have a wide range of algorithmic applications. Many of these results, including for instance [7, 48, 17, 30, 6, 19], rely on various notions of decomposition of a metric space into low-diameter clusters, and these decompositions are most often randomized. One extensively studied notion, see e.g. [13, 24, 17, 25], is *Lipschitz decomposition* (also called *separating decomposition*), which informally is a random partition of a metric space into low-diameter clusters, with a guarantee that nearby points are likely to belong to the same cluster.

▶ **Definition 1.1** (Lipschitz decomposition [7]). *Let (X, ρ) be a metric space. A distribution $\mathcal{D}$ over partitions of X is called* (β, Δ)-Lipschitz *if*

1. *for every partition $P \in \mathrm{supp}(\mathcal{D})$, all clusters $C \in P$ satisfy* $\mathrm{diam}(C) \le \Delta$*; and*
2. *for all $x, y \in X$,*

$$\Pr_{P \in \mathcal{D}}[P(x) \neq P(y)] \le \beta \cdot \frac{\rho(x,y)}{\Delta},$$

where $P(z)$ denotes the cluster of P containing $z \in X$ and $\mathrm{diam}(C) := \sup_{x,y \in C} \rho(x, y)$.

Typical applications require such decompositions where Δ is not known in advance, or even multiple values of Δ (say for every power of 2). We naturally seek small β and thus define the (optimal) *decomposition parameter of* (X, ρ) as

$$\beta^*(X) := \inf_{\beta \geq 1} \Big\{ \beta : \forall \Delta > 0, \text{ every finite } X' \subseteq X \text{ admits a } (\beta, \Delta)\text{-Lipschitz decomposition} \Big\},$$

and we extend this to a family of metric spaces $\mathcal{X}$, by defining $\beta^*(\mathcal{X}) := \sup_{X \in \mathcal{X}} \beta^*(X)$.

Obtaining bounds on the decomposition parameter of various metrics (and families of metrics) is of significant algorithmic importance, and we list in Table 1 several known bounds. One fundamental example where we know of (nearly) tight bounds is the metric space ℓ_p^d, for $p \geq 1$, which stands for $\mathbb{R}^d$ equipped with the ℓ_p norm. For $p \in [1, 2]$, we have $\beta^*(\ell_p^d) = \Theta(d^{1/p})$ due to [13], and for $p \in [2, \infty]$ we have $\beta^*(\ell_p^d) = \tilde{\Theta}(d^{1/2})$ due to [40] (see discussion therein about an incorrect claim made in [13]).[1] Observe that an upper bound for $X = \ell_p^d$ immediately extends to all subsets of it, implying in particular a bound for the family $\mathcal{X}$ of all finite subsets of ℓ_p^d. These bounds depend on d, and are thus most suitable for low-dimensional settings.

We focus on finite metrics X, aiming to bound $\beta^*(X)$ in terms of $n = |X|$, which is often useful in high-dimensional settings. For instance, it is well-known that $\beta^* = \Theta(\log n)$ the family of all n-point metric spaces [7]. To write this assertion more formally, define $\beta_n^*(X) := \beta^*(\{X' \subseteq X : \ |X| = n\})$ and then the above asserts that $\beta_n^*(\ell_\infty) = \Theta(\log n)$, where we used that every finite metric embeds isometrically in ℓ_∞. For the family of n-point ℓ_2 metrics, combining $\beta^*(\ell_2^d) = \tilde{\Theta}(\sqrt{d})$ with the famous JL Lemma [27] immediately yields $\beta_n^*(\ell_2) = O(\sqrt{\log n})$, which is tight by [13]. For n-point ℓ_p metrics, $1 < p < 2$, we have $\beta_n^*(\ell_p) = \frac{O(\log^{1/p} n)}{p-1}$ due to [35, 40], nearly matching the lower bound of $\beta_n^*(\ell_p) = \Omega(\log^{1/p} n)$ from [13]. However, for n-point ℓ_p metrics, $p > 2$, to the best of our knowledge, the only known upper bound is $\beta_n^*(\ell_p) = O(\log n)$, obtained by trivially applying the results for general n-point metric spaces. The following question was raised by Naor [40, Question 1], see also [41, Question 83].

▶ **Question 1.2** ([40]). *Is it true that for every $p \in (2, \infty)$, $\beta_n^*(\ell_p) = o(\log n)$? More ambitiously, is it true that $\beta_n^*(\ell_p) = O_p(\sqrt{\log n})$?*

Our main result, in Theorem 1.3, answers the first part of this question in the affirmative. Additionally, we show in Section 2 an analogous result for another notion of decomposability that was introduced in [22] (and we call capped decomposition) and is particularly suited for high-dimensional geometric spanners.

Geometric Spanners. A *spanner with stretch* $t \geq 1$ (in short a *t-spanner*) for a finite metric $M = (X, \rho)$ is a graph $G = (X, E)$, that satisfies $\rho(x, y) \leq \rho_G(x, y) \leq t \cdot \rho(x, y)$ for all $x, y \in X$, meaning that the shortest-path distance ρ_G in the graph G approximates the original distance $\rho(x, y)$ within factor t, where by definition every edge $\{u, v\} \in E$ has weight $\rho(u, v)$. Of particular interest are spanners that are *sparse*, meaning they contain a small number of edges, ideally linear in $n = |X|$. Another important parameter is the *lightness* of a spanner, defined as the total weight of its edges divided by the weight of a minimum spanning tree of X. Clearly, the lightness is at least 1. These spanners are called geometric because the input is a metric space (rather than a graph). They are natural and useful

[1] Throughout, the notation $\tilde{O}(f)$ hides $\text{poly}(\log f)$ factors, and $O_\alpha(\cdot)$ hides a factor that depends only on α.

Table 1 Known bounds on the decomposition parameter of some important families of metrics.

Family of Metrics	β^* or β_n^*	Reference	Comments
ℓ_p^d spaces $1 \le p \le 2$	$\Theta(d^{1/p})$	[13]	
ℓ_p^d spaces $p \ge 2$	$\tilde{\Theta}(\sqrt{d})$	[40]	
finite metrics	$\Theta(\log n)$	[7]	
ℓ_2 space (Euclidean)	$\Theta(\sqrt{\log n})$	[13]	
ℓ_p spaces $1 \le p \le 2$	$\Theta_p(\log^{1/p} n)$	[35, 40]	
ℓ_p spaces $p \ge 2$	$O(\log^{1-1/p} n)$	Theorem 1.3	conjectured $\beta_n^* = \Theta(\sqrt{\log n})$
doubling constant λ	$\Theta(\log \lambda)$	[24]	
K_r-minor-free graphs	$O(r)$	[1, 18]	conjectured $\beta^* = \Theta(\log r)$
graphs with genus g	$\Theta(\log g)$	[36, 1]	
graphs with treewidth w	$\Theta(\log w)$	[20]	

representations of a metric, and as such, have been studied extensively, see the surveys [16, 49, 2]. Spanners for n-point metrics in low-dimensional spaces (e.g., in fixed-dimensional Euclidean space or doubling metrics) are well-studied and well-understood. For instance, metrics with doubling dimension ddim admit $(1+\varepsilon)$-spanners with near-optimal sparsity $n(1/\varepsilon)^{O(\text{ddim})}$ and lightness $(1/\varepsilon)^{O(\text{ddim})}$ [12, 34].

However, in high-dimensional spaces, our understanding of spanners is rather limited. Har-Peled, Indyk, and Sidiropoulos [25] showed that every n-point Euclidean metric admits, an $O(t)$-spanner with $\tilde{O}(n^{1+1/t^2})$ edges for every $t \ge 1$. Filtser and Neiman [22] extended this result to all metric spaces that admit a certain decomposition that we call capped decomposition (Definition 2.4), showing that in those spaces, it is possible to construct spanners that are both sparse and light. In particular, they showed that every n-point subset of ℓ_p, $1 < p \le 2$, has an $O(t)$-spanner with $n^{1+\tilde{O}(1/t^p)}$ edges and lightness $n^{\tilde{O}(1/t^p)}$ for every $t \ge 1$. It remained open whether the spaces ℓ_p for $p \in (2, \infty)$ admit the aforementioned capped decomposition. To the best of our knowledge, all known spanners for these spaces have a tradeoff of stretch $O(t)$ with sparsity $O(n^{1+1/t})$.

1.1 Our Results

Our main contribution is the construction of a Lipschitz decomposition for finite ℓ_p metrics, $p \ge 2$, as follows.

▶ **Theorem 1.3.** *Let $p \in [2, \infty]$. Then $\beta_n^*(\ell_p) = O(\log^{1-1/p} n)$. That is, for every n-point metric $X \subset \ell_p$ and $\Delta > 0$, there exists an $(O(\log^{1-1/p} n), \Delta)$-Lipschitz decomposition of X.*

Previously, this bound was known only for the extreme values $p = 2, \infty$, and in these cases it is actually tight. More precisely, for $p = 2$ our bound coincides with the well-known result $\beta_n^*(\ell_2) = \Theta(\sqrt{\log n})$ [13], and for $p = \Omega(\log n)$ it is known that $\beta_n^*(\ell_p) = \Theta(\log n)$, because all n-point metrics embed into ℓ_p with $O(1)$-distortion [38]. For intermediate values, say fixed $p \in (2, \infty)$, our bound is the first one to improve over $O(\log n)$, which applies to all n-point metrics, and leaves a gap from the $\Omega(\sqrt{\log n})$ lower bound that follows from Dvoretzky's Theorem [15].

We compare our bound with those for other metric spaces in Table 1.

The proof of Theorem 1.3 appears in Section 2.1, and has interesting technical features. It relies on *two* known decompositions of finite metrics, one for general metrics and one for Euclidean metrics, that are composed via a metric-embedding tool called the Mazur map. Our decomposition method is data-dependent, i.e., not oblivious to the data, and we discuss this intriguing aspect in Sections 2.1 and 5.

Note added in proof. Shortly after this work was posted online, two groups working in parallel to each other [31, 42] improved our result in Theorem 1.3 to $\beta_n^*(\ell_p) = O_p(\sqrt{\log n})$ for every $2 < p < \infty$, thereby resolving in the affirmative also the second part of Question 1.2. These two papers design a recursive process that relies on the technique developed here for proving Theorem 1.3, see each paper for its dependence on p.

Geometric Spanners for $p \geq 2$. We then use similar ideas to obtain a new bound for another notion of decomposability, that was introduced in [22] and we call capped decomposition; and this immediately yields geometric spanners in ℓ_p, for $p \geq 2$. While for $p = 2$ these spanners coincide with the known bounds from [25, 22], for fixed $2 < p < \infty$, our spanners are the first improvement over the trivial bounds that hold for all metric spaces.

▶ **Theorem 1.4.** *Let $p \in [2, \infty)$ and $t \geq 1$. Then every n-point metric $X \subset \ell_p$ admits an $O(t)$-spanner of size $\tilde{O}\left(n^{1+1/t^q}\right)$ and lightness $\tilde{O}\left(n^{1/t^q}\right)$, where $q \in (1, 2)$ is such that $\frac{1}{p} + \frac{1}{q} = 1$.*

The proof of this theorem appears in Section 2.2, and includes both the spanner construction, which follows [22], and our new bound for capped decomposition, which is the main technical result.

Geometric Spanners for $p \leq 2$. We also sharpen the known spanner results for ℓ_p spaces with $1 < p < 2$, which say that every n-point subset admits an $O(t)$-spanner with $n^{1+O(\log^2 t/t^p)}$ edges and lightness $n^{O(\log^2 t/t^p)}$ for every $t \geq 1$ [22]. We improve upon this result by eliminating the $\log^2 t$ factor in the exponent.

▶ **Theorem 1.5.** *Let $p \in (1, 2]$ and $t \geq 1$. Then every n-point metric $X \subset \ell_p$ admits an $O(t)$-spanner of size $\tilde{O}(n^{1+1/t^p})$ and lightness $\tilde{O}(n^{1/t^p})$.*

The proof of this theorem, presented in Section 3, follows the construction of [22], but replacing a key step, in which they rely on results from [43], with results from [4]. Interestingly, our improved spanner bound "matches" the bounds of Theorem 1.4, up to duality between p and q.

Distance Labeling Schemes. Distance labeling for a metric space (X, ρ) assigns to each point $x \in X$ a label $l(x)$, so that one can later recover (perhaps approximately) the distance between any two points in X based only on their labels (without knowledge of the metric space). It was formulated in [45], motivated by applications in distributed computing, and has been studied intensively, see e.g. [23, 21]. An immediate corollary of our main result in Theorem 1.3 is a distance labeling scheme for finite metrics in ℓ_p for $p > 2$, as follows.

▶ **Theorem 1.6.** *Let $p \in (2, \infty)$. Then the family of n-point metrics in ℓ_p with pairwise distances in the range $[1, \Delta_{max}]$ admits a distance labeling scheme with approximation $O(\log^{1/q} n)$ and label size $O(\log n \log \Delta_{max})$ bits, where $q \in (1, 2)$ is such that $\frac{1}{p} + \frac{1}{q} = 1$.*

A formal definition of the distance labeling model and a proof of Theorem 1.6 appear in Section 4.

1.2 Related Work

We focus on Lipschitz decomposition and on capped decomposition, that was introduced in [22], but the literature studies several different decompositions of metric spaces into low-diameter clusters, see e.g. [39, 19]. In particular, the notion of padded decomposition [48, 29]

is closely related and was used extensively, see for example [48, 8, 35, 39, 30]. While a Lipschitz decomposition guarantees that nearby points are likely to be clustered together, a padded decomposition guarantees that each point is, with good probability, together with all its nearby points in the same cluster. Remarkably, if a metric space admits a padded decomposition then it admits also a Lipschitz decomposition with almost the same parameters [35], however the other direction is not true, as demonstrated by ℓ_2^d.

The problem of computing efficiently the optimal decomposition parameters for an input metric space (X, ρ) was studied in [32]. Specifically for Lipschitz decomposition, they show that $\beta^*(X)$ can be $O(1)$-approximated in polynomial time (in n).

2 Decompositions and Spanners in ℓ_p for $p > 2$

In this section we consider finite subsets of ℓ_p for $p \in (2, \infty)$. We first present (in Section 2.1) a new Lipschitz decomposition, which proves Theorem 1.3. Next, we show (in Section 2.2) a new construction of capped decomposition, which is a related notion of decomposability that was introduced in [22] without a concrete name. Finally we obtain (in Section 2.3) new spanners, which prove Theorem 1.4. This is actually an immediate corollary of our capped decomposition, by following the spanner construction of [22].

2.1 Lipschitz Decomposition in ℓ_p for $p \in (2, \infty)$

Before presenting the proof of Theorem 1.3, we first provide the intuition behind the proof. A common approach in many algorithms for metric spaces is to embed the given metric into a simpler one (e.g., a tree metric), solve the problem in the target metric, and then pull back this solution to the original metric. For our purpose, of constructing a Lipschitz decomposition of $X \subset \ell_p$, $p > 2$, a natural idea is to seek a low-distortion embedding of X into ℓ_2, because we already have decompositions for that space, namely, $\beta_n^*(\ell_2) = O(\sqrt{\log n})$. Ideally, the embedding into ℓ_2 would be *oblivious*, meaning that it embeds the entire ℓ_p (not only X) into ℓ_2, but unfortunately such an embedding does not exist (it would imply oblivious dimension reduction in ℓ_p for $p > 2$, which is provably impossible [14]). We get around this limitation by employing a *data-dependent* approach, where the decomposition depends on the input set X. More precisely, we use Mazur maps, which provide a low-distortion embedding from ℓ_p to ℓ_2, but only for sets of bounded diameter (see Corollary 2.3). We thus first decompose X into bounded-diameter subsets by applying a standard Lipschitz decomposition (that is applicable for every n-point metric). The final decomposition is obtained by pulling back the solution (clusters) we found in ℓ_2.

We proceed to introduce some technical results needed for our proof of Theorem 1.3. The first one is a well-known bound for Lipschitz decomposition of a finite metric.

▶ **Theorem 2.1** ([7]). *Every n-point metric (X, ρ) admits an $(O(\log n), \Delta)$-Lipschitz decomposition for every $\Delta > 0$.*

Next, we define the *Mazur map*, which is an explicit embedding $M_{p,q} : \ell_p^m \to l_q^m$ for $1 < q < p < \infty$. The image of an input vector v is computed in each coordinate separately, by raising the absolute value to power p/q while keeping the original sign. The next theorem appears in [10], where it is stated as an adaptation of [11], and we will actually need the immediate corollary that follows it.

▶ **Theorem 2.2** ([11, 10]). *Let $1 \le q < p < \infty$ and $C_0 > 0$, and let M be the Mazur map $M_{p,q}$ scaled down by factor $\frac{p}{q}C_0^{p/q-1}$. Then for all $x, y \in \ell_p$ such that $||x||_p, ||y||_p \le C_0$,*

$$\tfrac{q}{p}(2C_0)^{1-p/q}||x-y||_p^{p/q} \le ||M(x)-M(y)||_q \le ||x-y||_p.$$

▶ **Corollary 2.3.** *Let $2 < p < \infty$. Every n-point set $X \subset \ell_p$ with diameter at most $C_0 > 0$ admits an embedding $f : X \to \ell_2$ such that*

$$\forall x, y \in X, \qquad \tfrac{2}{p}(2C_0)^{1-p/2}\|x-y\|_p^{p/2} \le \|f(x)-f(y)\|_2 \le \|x-y\|_p.$$

Proof of Theorem 1.3. Let $\Delta > 0$, and let $X \subset \ell_p$ be an n-point metric space for $p \in (2, \infty)$. Construct a partition of X in the following steps:

1. Construct for X an $(O(\log n), \log^{1/p} n \cdot \Delta/4)$-Lipschitz decomposition $P_{\text{init}} = \{K_1, \ldots, K_t\}$ using Theorem 2.1.
2. Embed each cluster $K_i \subset \ell_p$ into ℓ_2 using the embedding f^{K_i} provided by Corollary 2.3 for $C_0 := \log^{1/p} n \cdot \Delta/4$.
3. For each embedded cluster $f^{K_i}(K_i)$, construct an $(O(\sqrt{\log n}), \frac{1}{2}\Delta/\log^{1/2-1/p} n)$-Lipschitz decomposition $P_i = \{K_i^1, \ldots, K_i^{k_i}\}$ using [13] and the JL Lemma [27].
4. The final decomposition P_{out} is obtained by taking the preimage of every cluster of every P_i.

It is easy to see that P_{out} is indeed a partition of X, consisting of $\sum_{i=1}^{t} k_i$ clusters. Next, consider $x, y \in X$ and let us bound $\Pr[P_{\text{out}}(x) \ne P_{\text{out}}(y)]$. Observe that a pair of points can be separated only in steps 1 or 3. Therefore,

$$\begin{aligned}
&\Pr\Big[P_{\text{out}}(x) \ne P_{\text{out}}(y)\Big] \\
&\quad \le \Pr\Big[P_{\text{init}}(x) \ne P_{\text{init}}(y)\Big] + \Pr\Big[P_i(f^{K_i}(x)) \ne P_i(f^{K_i}(y)) \mid P_{\text{init}}(x) = P_{\text{init}}(y) = K_i\Big] \\
&\quad \le O(\log n)\frac{\|x-y\|_p}{\log^{1/p} n \cdot \Delta/4} + O(\sqrt{\log n})\frac{\|f^{K_i}(x) - f^{K_i}(y)\|_2}{\frac{1}{2}\Delta/\log^{1/2-1/p} n} \\
&\quad \le O(\log^{1-1/p} n)\frac{\|x-y\|_p}{\Delta},
\end{aligned}$$

where the last inequality follows because each f^{K_i} is non-expanding on its cluster $K_i \subset \ell_p$.

It remains to show that the final clusters all have diameter at most Δ. Let $x, y \in X$ be in the same cluster, i.e., $P_{\text{out}}(x) = P_{\text{out}}(y)$. Then $P_{\text{init}}(x) = P_{\text{init}}(y) = K_i$ and $P_i(f^{K_i}(x)) = P_i(f^{K_i}(y))$. Combining the maximum possible diameter of $P_{\text{init}}(x)$ and $P_i(f^{K_i}(x))$ with the contraction guarantees of $f = f^{K_i}$, we get

$$\frac{2}{p}\Big(2(\log^{1/p} n)\frac{\Delta}{4}\Big)^{1-p/2}\|x-y\|_p^{p/2} \le \|f(x)-f(y)\|_2 \le \frac{\Delta}{2}\log^{1/p-1/2} n.$$

Rearranging this, we obtain $\|x-y\|_p \le \frac{\sqrt[p/2]{p/2}}{2}\Delta \le \Delta$, which completes the proof. ◀

2.2 Capped Decomposition in ℓ_p for $p \in (2, \infty)$

We now present our construction of capped decomposition, which is a notion of decomposability that was introduced in [22] without a concrete name. We start with its definition, and then present our construction.

▶ **Definition 2.4.** *Let (X, ρ) be a metric space. A distribution $\mathcal{D}$ over partitions of X is called* (t, Δ, η)-capped *if*

1. *for every partition $P \in \mathrm{supp}(\mathcal{D})$, all clusters $C \in P$ have $\mathrm{diam}(C) \leq \Delta$; and*
2. *for every $x, y \in X$ such that $\rho(x, y) \leq \frac{\Delta}{t}$,*

$$\Pr_{P \in \mathcal{D}}[P(x) = P(y)] \geq \eta.$$

Observe that here, unlike in Lipschitz decomposition, we have a guarantee on the probability that points $x, y \in X$ are clustered together only if they are within distance $\frac{\Delta}{t}$ of each other, hence the name "capped decomposition". Moreover, the probability bound does not depend on the exact value of $\rho(x, y)$. We say that (X, ρ) admits a (t, η)-capped decomposition, where $\eta = \eta(|X|, t)$, if it admits a (t, Δ, η)-capped decomposition for every $\Delta > 0$. A family of metrics admits a (t, η)-capped decomposition if every metric in the family admits a (t, η)-capped decomposition.

▶ **Theorem 2.5.** *Let $p \in (2, \infty)$. Then every n-point metric in ℓ_p admits a $(t, n^{-O(1/t^q)})$-capped decomposition for all $t \geq 1$, where $q \in (1, 2)$ is such that $\frac{1}{p} + \frac{1}{q} = 1$.*

Previously, such a decomposition was known only for the extreme case $p = 2$ by [22], see Proposition 2.6, and our bound above in fact converges to their bound when $p \to 2$. Our proof of Theorem 2.5 is similar to Theorem 1.3, and relies on two known capped decompositions, that we introduce next, together with the Mazur map Corollary 2.3.

▶ **Proposition 2.6** ([22])**.** *Every n-point subset of ℓ_2 admits a $(t, n^{-O(1/t^2)})$-capped decomposition for all $t \geq 1$.*

▶ **Proposition 2.7** (Implicit in [39])**.** *Every n-point metric space admits a $(t, n^{-O(1/t)})$-capped decomposition for all $t \geq 1$.*

Proof of Theorem 2.5. Let $\Delta > 0$ and $t \geq 1$. Let $X \subset \ell_p$ be an n-point subset of $p \in (2, \infty)$, where q is such that $\frac{1}{p} + \frac{1}{q} = 1$. Construct a partition of X in the following steps:

1. Construct for X a $(t_1 := t^q/4, \Delta_1 := \Delta/4t^{1-q}, n^{-O(1/t^q)})$-capped decomposition $P_{\mathrm{init}} = \{K_1, \ldots, K_t\}$ using Proposition 2.7.
2. Embed each cluster $K_i \subset \ell_p$ into ℓ_2 using the embedding f^{K_i} provided by Corollary 2.3 for $C_0 := \Delta_1$.
3. For each embedded cluster $f^{K_i}(K_i)$ construct a $(t_2 := t^{q/2}/2, \Delta_2 := \Delta/2t^{1-q/2}, n^{-O(1/t^q)})$-capped decomposition $P_i = \{K_i^1, \ldots, K_i^{k_i}\}$ using Proposition 2.6.
4. The final decomposition P_{out} is obtained by taking the preimage of every cluster of every P_i.

It is easy to see that that P_{out} is indeed a partition of X, consisting of $\sum_{i=1}^{t} k_i$ clusters. Next, consider $x, y \in X$ with $\|x - y\|_p \leq \Delta/t$ and let us bound $\Pr[P_{\mathrm{out}}(x) = P_{\mathrm{out}}(y)]$. Observe that $\Delta_1/t_1 = \Delta_2/t_2 = \Delta/t$, and therefore

$$\begin{aligned}
&\Pr\Big[P_{\mathrm{out}}(x) = P_{\mathrm{out}}(y)\Big] \\
&\quad = \Pr\Big[P_{\mathrm{init}}(x) = P_{\mathrm{init}}(y)\Big] \cdot \Pr\Big[P_i(f^{K_i}(x)) = P_i(f^{K_i}(y)) \mid P_{\mathrm{init}}(x) = P_{\mathrm{init}}(y) = K_i\Big] \\
&\quad \geq n^{-O(1/t^q)} \cdot n^{-O(1/t^q)} = n^{-O(1/t^q)},
\end{aligned}$$

where the inequality follows because each f^{K_i} is non-expanding on its cluster $K_i \subset \ell_p$.

It remains to show that each cluster has diameter at most Δ. Let $x, y \in X$ be in the same cluster, i.e., $P_{\text{out}}(x) = P_{\text{out}}(y)$. Then $P_{\text{init}}(x) = P_{\text{init}}(y) = K_i$ and $P_i(f^{K_i}(x)) = P_i(f^{K_i}(y))$. Combining the maximum possible diameter of $P_{\text{init}}(x)$ and $P_i(f^{K_i}(x))$ with the contraction guarantees of $f = f^{K_i}$, we get

$$\frac{2}{p}\Big(2\frac{\Delta}{4t^{1-q}}\Big)^{1-p/2}\|x-y\|_p^{p/2} \le \|f(x)-f(y)\|_2 \le \frac{\Delta}{2t^{1-q/2}}.$$

Rearranging this, we obtain $\|x-y\|_p \le \frac{\sqrt[p/2]{p/2}}{2}\Delta \le \Delta$, which completes the proof. ◀

2.3 Spanners in ℓ_p for $p \in (2, \infty)$

We can now prove Theorem 1.4, by applying the following spanner construction of [22].

▶ **Theorem 2.8** ([22]). *Let (X, ρ) be an n-point metric space admitting a (t, η)-capped decomposition for some $t \ge 1$. Then, for every $\epsilon \in (0, 1/8)$, there exists a $(2+\epsilon)t$-spanner for X with $O_\epsilon(\frac{n}{\eta} \cdot \log n \cdot \log t)$ edges and lightness $O_\epsilon(\frac{t}{\eta} \cdot \log^2 n)$.*

Proof of Theorem 1.4. The proof follows directly by combining Theorem 2.5 and Theorem 2.8, as we can assume $t = O(\log n)$ without loss of generality. ◀

3 Spanners in ℓ_p for $p \in (1, 2)$

This section presents an improved construction of geometric spanners in ℓ_p for $p \in (1, 2)$. Previously, $O(t)$-spanners of size $O(n^{1+\log^2 t/t^p})$ for all $t \ge 1$ were constructed in [22]; in particular, setting $t = (\log n \log\log n)^{1/p}$ yields an $O(t)$-spanner of near-linear size $\tilde{O}(n)$. We first present in Section 3.1 two different constructions of near-linear-size spanners with a slightly better stretch. Then in Section 3.2 we use yet another technique, namely Locality Sensitive Hashing (LSH), to slightly improve the construction of [22] of spanners with general stretch $O(t)$.

3.1 Spanners of Near-Linear Size

We slightly improve the near-linear size spanner construction of [22] by shaving the $(\log\log n)^{1/p}$ factor from the stretch, as follows.

▶ **Theorem 3.1.** *For every fixed $p \in (1, 2)$, every n-point metric $X \subset \ell_p$ admits an $O(\log^{1/p} n)$-spanner of size $\tilde{O}(n)$.*

We present two related but different proofs for this theorem. Both are based on modifying the spanner algorithm for ℓ_2 from [25], and therefore we start with an overview of that algorithm. Given an input set $X \subseteq \ell_2$, the algorithm begins by constructing a hierarchical set of 2^i-nets $X = N_0 \supseteq N_1 \supseteq \cdots \supseteq N_{\log \Delta_X}$, where we assume that the minimum and maximum distances in X are 1 and Δ_X, respectively. Then, for each level i, it constructs an $(O(\sqrt{\log n}), O(\sqrt{\log n}) \cdot 2^{i+1})$-Lipschitz decomposition of N_i by combining the JL Lemma [27] with the Lipschitz decomposition of [13]. For each cluster in it, the algorithm add to the spanner edges in a star-like fashion, meaning that all cluster points are connected to one arbitrary point within the cluster. The last two steps are repeated $O(\log n)$ times to ensure that with high probability, for each level i, every $x, y \in N_i$ with $\|x-y\|_2 \le 2^{i+1}$ are clustered together in at least one of the $O(\log n)$ repetitions. It is shown in [25] that this algorithm constructs an $(O(\sqrt{\log n}))$-spanner of size $\tilde{O}(n)$.

Proof of Theorem 3.1 via Lipschitz Decomposition. Observe that the above algorithm of [25] uses the fact that the points lie in ℓ_2 only for the construction of Lipschitz Decompositions, and relies on an optimal decomposition for finite ℓ_2 metrics to conclude that the spanner's stretch is $O(\beta_n^*(\ell_2))$. For finite ℓ_p metrics, $p \in (1,2)$, we can use instead a Lipschitz decomposition from [35, 40], which has $\beta = \frac{O(\log^{1/p} n)}{p-1}$, to conclude the claimed stretch. ◀

We next present a proof that modifies the algorithm of [25] differently, and relies on a decomposition that is similar to a Lipschitz decomposition but has slightly weaker guarantees. Interestingly, this technique yields a slightly stronger result than Theorem 3.1, where p need not to be fixed and can depend on n (e.g., $p \to 1$). We proceed to introduce some technical results from [9] regarding a weak form of dimensionality reduction in ℓ_p, for $p \in [1,2]$, which are needed for our proof.

▶ **Definition 3.2** ([44]). *Let (X,ρ), (Y,τ) be metric spaces and $[a,b]$ be a real interval. An embedding $f : X \to Y$ is called* $[a,b]$-range preserving with distortion $D \geq 1$ *if there exists $c > 0$ such that for all $x, x' \in X$:*

1. *If $a \leq \rho(x,x') \leq b$, then $\rho(x,x') \leq c \cdot \tau(f(x), f(x')) \leq D \cdot \rho(x,x')$.*
2. *If $\rho(x,x') > b$, then $c \cdot \tau(f(x), f(x')) \geq b$.*
3. *If $\rho(x,x') < a$, then $c \cdot \tau(f(x), f(x')) \leq D \cdot a$.*

We say that (X,ρ) admits *an R-range preserving embedding* into (Y,τ) with distortion D, if for all $u > 0$, there exists a $[u, uR]$-range preserving embedding into Y with distortion D.

▶ **Theorem 3.3** ([9]). *Let $1 \leq p \leq 2$. For every n-point set $S \subset \ell_p$, and for every range parameter $R > 1$, there exists an R-range preserving embedding $f : S \to \ell_p^k$ with distortion $1+\epsilon$, such that $k = O\left(\frac{R^{O(1/\epsilon)} \cdot \log n}{\epsilon}\right)$.*

Proof of Theorem 3.1 via Weak Dimension Reduction. Observe that the above algorithm of [25] only requires the decomposition of each net N_i to ensure that points $x, y \in N_i$ with $\|x-y\|_2 \leq 2^{i+1}$ are clustered together with constant probability, and that the diameter of all clusters is at most $O(\sqrt{\log n}) \cdot 2^i$; of course, for $X \subset \ell_p$, $p \in (1,2)$, we replace the $O(\sqrt{\log n})$ factor with $O(\log^{1/p} n)$. A careful examination shows that these properties are preserved by first reducing the dimension using the range-preserving embedding provided by Theorem 3.3 with $\varepsilon = \frac{1}{2}$ and $R = 2$, and then constructing a Lipschitz decomposition for the image points in $\ell_p^{O(\log n)}$ using [13]. ◀

3.2 Spanners with Stretch-Size Tradeoff

We now present, in Theorem 1.5, a construction of $O(t)$-spanners in ℓ_p, where $p \in (1,2)$, of size $\tilde{O}(n^{1+1/t^p})$ for all $t \geq 1$, which slightly improves over the $O(t)$-spanners of size $\tilde{O}(n^{1+\log^2 t/t^p})$ from [22]. It is worth noting that Theorem 1.5 generalizes the results of Theorem 3.1, and thus provides an alternative proof for it.

▶ **Definition 3.4** (LSH [26]). *Let $\mathcal{H}$ be a family of hash functions mapping a metric (X,ρ) to some universe U. We say that $\mathcal{H}$ is* (r, tr, p_1, p_2)-sensitive *if for every $x, y \in X$, the following is satisfied:*

1. *If $\rho(x,y) \leq r$, then $\Pr_{h\in\mathcal{H}}[h(x) = h(y)] \geq p_1$.*
2. *If $\rho(x,y) > tr$, then $\Pr_{h\in\mathcal{H}}[h(x) = h(y)] \leq p_2$.*

Such $\mathcal{H}$ is called an LSH family *with parameter $\gamma := \frac{\log(1/p_1)}{\log(1/p_2)}$.*

▶ **Lemma 3.5** ([22]). *Let (X,ρ) be a metric space such that for every $r > 0$, there exists a (r, tr, p_1, p_2)-sensitive LSH family with parameter γ. Then (X,ρ) admits a $(t, n^{-\mathcal{O}(\gamma)})$-capped decomposition.*

For $p = 2$, the LSH family constructed in [3] can be used in Lemma 3.5 to conclude that ℓ_2 admits a $(t, n^{-O(1/t^2)})$-capped decomposition for every $t \geq 1$ [22], thereby proving Theorem 1.5 for this case of $p = 2$. In a similar fashion, an LSH family constructed in [43] for $p \in (1, 2)$ was used in [22] to show that these spaces admit a $(t, n^{-O(\log^2 t/t^p)})$-capped decomposition. We observe that this result can be improved by replacing the LSH family from [43], with an alternative one that is briefly mentioned in [4], and consequently prove Theorem 1.5. For completeness, we reproduce this LSH family for ℓ_p, where $p \in (1, 2)$.

▶ **Lemma 3.6** ([4]). *Let $p \in (1, 2)$, $r > 0$, and large enough $t > 1$. Then there exists a (r, tr, p_1, p_2)-sensitive LSH family for ℓ_p with parameter $\gamma = \frac{1}{t^p} + o(1)$.*

Proof. Let $p \in (1, 2)$, $r > 0$, and sufficiently large $t > 1$. Let $f : \ell_p \to \ell_2$ be the isometric embedding of the $(p/2)$-snowflake of ℓ_p into ℓ_2 from [28, Theorem 4.1]. Take $r' = r^{p/2}$ and $t' = t^{p/2}$, and let $\mathcal{H}$ be the $(r', t'r', p_1, p_2)$-sensitive LSH family for ℓ_2 with parameter $\gamma = \frac{1}{t'^2} + o(1)$ from [3]. Observe that, for every $x, y \in \ell_p$, if $\|x - y\|_p \leq r$, then $\|f(x) - f(y)\|_2 = \|x - y\|_p^{p/2} \leq r^{p/2} = r'$, and thus

$$\Pr_{h \in \mathcal{H}}[h(f(x)) = h(f(y))] \geq p_1.$$

Similarly, if $\|x - y\|_p > tr$, then $\|f(x) - f(y)\|_2 = \|x - y\|_p^{p/2} > (tr)^{p/2} = t'r'$, and hence

$$\Pr_{h \in \mathcal{H}}[h(f(x)) = h(f(y))] \leq p_2.$$

We therefore conclude that $\mathcal{H} \circ f$ is an (r, tr, p_1, p_2)-sensitive LSH family for ℓ_p with parameter $\gamma = \frac{1}{t^p} + o(1)$. ◀

Proof of Theorem 1.5. The proof follows immediately by constructing a capped decomposition based on Lemma 3.5 and Lemma 3.6, and using it in the spanner construction from Theorem 2.8. ◀

▶ Remark 3.7. While [28, Theorem 4.1] does not provide an efficiently computable embedding, one can compute such an embedding for a finite set of points in polynomial time by [37].

4 Distance Labeling

In the distance labeling model, a scheme is designed for an entire a family $\mathcal{X}$ of n-point metrics (and in some scenarios, all these metrics have the same point set X, e.g., different graphs on the same vertex set). A *scheme* is an algorithm that preprocesses each metric X in $\mathcal{X}$ and assigns to each point $x \in X$ a label $l(x)$.

▶ **Definition 4.1.** *A scheme is* a distance labeling *with approximation $D \geq 1$ and label size of k if*

1. *every label (for every point in every metric in $\mathcal{X}$) consists of at most k bits; and*
2. *there is an algorithm $\mathcal{A}$ that, given the labels $l(x), l(y)$ of two points x, y in a metric $(X, \rho) \in \mathcal{X}$ (but not given (X, ρ) or the points x, y), outputs an estimate $\mathcal{A}(l(x), l(y))$ that satisfies*

$$\rho(x, y) \leq \mathcal{A}(l(x), l(y)) \leq D \cdot \rho(x, y).$$

The following theorem was presented in [24] with limited details, and we include a proof of it below for completeness.

▶ **Theorem 4.2** ([24]). *Let $\mathcal{X}$ be a family of n-point metrics, and assume that all the pairwise distances in all metrics (X, ρ) in $\mathcal{X}$ are in the range $[1, \Delta_{max}]$. Then $\mathcal{X}$ admits a distance-labeling scheme with approximation $O(\beta^*(\mathcal{X}))$ and label size $O(\log n \log \Delta_{\max})$ bits.*

It is straightforward to see that Theorem 1.6 follows by combining Theorem 4.2 and Theorem 1.3.

Proof of Theorem 4.2. We first describe the preprocessing algorithm, denoting $\beta := \beta^*(\mathcal{X})$. Perform the following steps for all levels $i = 0, \ldots, \log \Delta_{\max}$. Begin by constructing a $(\beta, \Delta_i := 4\beta 2^i)$-Lipschitz decomposition, and observe that every two points $x, y \in X$ with $\rho(x, y) \leq 2^i$ are separated with probability at most $\frac{1}{4}$. Then, assign a random bit to each cluster, and observe that if two points are at distance greater than Δ_i, they always fall in different clusters, hence, the probability that they are assigned the same bit is exactly $\frac{1}{2}$, and if they are at distance at most $2^i = \Delta_i/(4\beta)$ they are assigned the same bit with probability at least $\frac{3}{4}$. Repeat the last two steps $k = O(\log n)$ times, and then with high probability, every two points x, y are assigned the same bit at least $\frac{5}{8}k$ times if $\rho(x, y) \leq \Delta_i/(4\beta)$ and fewer than $\frac{5}{8}k$ times if $\rho(x, y) > \Delta_i$. Finally, label each point by concatenating the bit assigned to its cluster in all the repetitions at all levels.

The label-size analysis is straightforward. It remains to show that, given two labels $l(x), l(y)$, it is possible to approximate the distance $\rho(x, y)$ within factor $O(\beta)$. This can be achieved by identifying the smallest level i such that x and y are assigned the same bit at least $\frac{5}{8}k$ times, and then the above analysis (used in contrapositive form) implies that $\Delta_{i-1}/(4\beta) < \rho(x, y) \leq \Delta_i$, where by convention $\Delta_{-1} := 1$. ◀

5 Future Directions

Lipschitz Decompositions. We stress that our decomposition in Theorem 1.3 employs a data-dependent approach, and is not oblivious to the input set X (as, say, the decomposition for ℓ_2 in [13], even when applied together with the JL Lemma). In retrospect, this feature is perhaps not very surprising, because data-dependent approaches have been already shown to be effective for central problems, such as nearest neighbor search [5, 33]. We thus mention that a major open problem in the field is whether dimension reduction is possible in ℓ_p for $p \neq 1, 2, \infty$; we know that for $p > 2$ this is not possible via an oblivious mapping [14], raising the question whether data-dependent mappings can overcome this limitation.

Geometric Spanners. The geometric spanners in [25, 22] for ℓ_p, $1 < p \leq 2$, are not known to be optimal, i.e., we do not know of matching lower bounds, except for the more restricted case of 2-hop spanners [25]. We conjecture that tight instances exist in these spaces, i.e., the spanner bounds obtained in [25, 22] are optimal for every stretch t. We similarly do not know of matching lower bounds for the geometric spanners in ℓ_p, for fixed $2 \leq p < \infty$, that we obtain in Theorem 1.4, and it is quite plausible that our upper bounds are not tight. We do know however, based on known results, that for every n, there exist tight instances in ℓ_p for $p = \Omega(\log n)$.

Abstract

Deformations of knots and links in ambient space can be studied combinatorially on their diagrams via local modifications called Reidemeister moves. While it is well-known that, in order to move between equivalent diagrams with Reidemeister moves, one sometimes needs to insert excess crossings, there are significant gaps between the best known lower and upper bounds on the required number of these added crossings. In this article, we study the problem of turning a diagram of a split link into a split diagram, and we show that there exist split links with diagrams requiring an arbitrarily large number of such additional crossings. More precisely, we provide a family of diagrams of split links, so that any sequence of Reidemeister moves transforming a diagram with c crossings into a split diagram requires going through a diagram with $\Omega(\sqrt{c})$ extra crossings. Our proof relies on the framework of bubble tangles, as introduced by the first two authors, and a technique of Chambers and Liokumovitch to turn homotopies into isotopies in the context of Riemannian geometry.

1 Introduction

The Reidemeister theorem [32] is a fundamental and powerful result in low-dimensional topology. It states that any two link diagrams represent equivalent links[1] if and only if they can be related by a sequence of planar isotopies and local moves, called **Reidemeister moves**, pictured in Figure 1. This theorem is at the heart of many theoretical results as well as computational applications. Indeed, many knot invariants, from the most basic ones such as tri-colourability [1, Section 1.5] to more advanced ones such as the Jones polynomial [20]

[1] A link is an embedding of a collection of circles into $\mathbb{R}^3$ and two links are considered equivalent if they are ambient isotopic. Link diagrams are projections of links into a plane as shown, for instance, in Figure 2. We refer to Section 2 for standard definitions in knot theory.

or Khovanov homology [3], can be shown to be invariants by demonstrating that they are not modified by Reidemeister moves. From a computational point of view, the Reidemeister theorem allows for a discretisation of the space of possible transformations to consider when testing for knot equivalence. This fact is at the root of a straightforward algorithm to study algorithmic problems in knot theory: at the level of diagrams, apply Reidemeister moves in a random or brute-force manner until a desired property is verified.

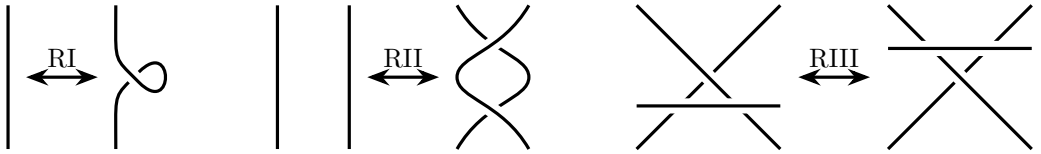

Figure 1 The three Reidemeister moves RI, RII, and RIII.

A primary example of such a knot theory problem is recognising the **unknot**, that is, the unique knot admitting a diagram with no crossings. This is a first instance of the fundamental problem of knot theory of deciding whether two knots are equivalent. It turns out that some unknot diagrams, called **hard unknot diagrams** or **culprits** [6, 21], exhibit an unwanted behaviour for the above algorithm. Namely, given an initial diagram $\mathcal{D}$ of the unknot, the largest number of crossings of a diagram in any sequence of Reidemeister moves from $\mathcal{D}$ to the 0-crossing diagram must be larger than in $\mathcal{D}$. This means one first needs to *add* crossings before being able to reach the 0-crossing diagram. The existence of such diagrams implies that it is not possible to untangle an unknot diagram by only applying Reidemeister moves that do not increase the number of crossings. An example of such a hard unknot diagram, called the **Goeritz culprit**, is shown in Figure 2. In [6], it is shown that, when diagrams in $\mathbb{S}^2$ are considered, at least one extra crossing is required to untangle this unknot. We do not know of systematic techniques or methods to prove easily that a given diagram of the unknot is hard. Instead, all proofs known to the authors resort to an exhaustive search in the graph of Reidemeister moves, which quickly becomes infeasible. Recently, new techniques based on reinforcement learning have been applied to find large numbers of hard unknot diagrams [2], but the proofs of hardness still involved exhaustive enumerations.

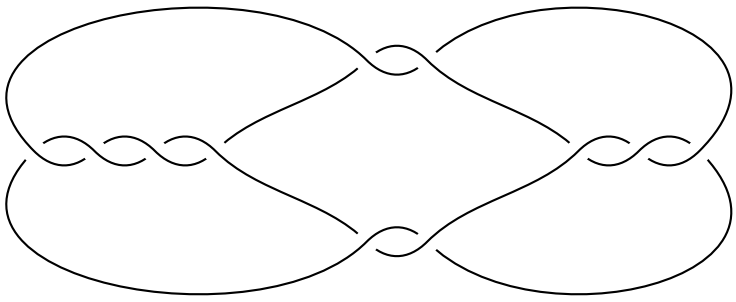

Figure 2 The Goeritz culprit: using Reidemeister moves in $\mathbb{S}^2$, one must add at least one extra crossing to untangle this unknot diagram.

Following the notations of [6, 21] we denote the number of crossings in a diagram $\mathcal{D}$ by $\mathrm{cr}(\mathcal{D})$. For diagrams $\mathcal{D}_1$ and $\mathcal{D}_2$ of equivalent links, and a sequence R of r Reidemeister moves transforming $\mathcal{D}_1$ into $\mathcal{D}_2$, we define $\mathbf{Top}(\boldsymbol{\mathcal{D}_1}, \boldsymbol{R}) = \max_{i\in\{0,1,\dots,r\}}\{\mathrm{cr}(\mathcal{D}^i) - \mathrm{cr}(\mathcal{D}_1)\}$ where $\mathcal{D}^i$, $0 \leq i \leq r$, is the diagram after performing the first i moves of the sequence. The minimal number of extra crossings to pass from $\mathcal{D}_1$ to $\mathcal{D}_2$ is denoted by $\mathbf{Add}(\boldsymbol{\mathcal{D}_1}, \boldsymbol{\mathcal{D}_2})$,

which, formally, is the minimum of $\mathrm{Top}(\mathcal{D}_1, R)$ taken over all sequences of Reidemeister moves R transforming $\mathcal{D}_1$ into $\mathcal{D}_2$. Hence, $\mathrm{Add}(\mathcal{D}_1, \mathcal{D}_2)$ is a lower bound on the number of crossings we must add in any sequence of Reidemeister moves performed on $\mathcal{D}_1$ to reach $\mathcal{D}_2$.

Let $\mathcal{D}$ be a diagram of the unknot and $\hat{\mathcal{D}}$ be its 0-crossing diagram. Naturally, $\mathcal{D}$ is a hard unknot diagram if and only if $\mathrm{Add}(\mathcal{D}, \hat{\mathcal{D}})$ is positive. This measure of complexity is called m in [6] (see also the *recalcitrance* in [21]). Studying these complexity measures and hard unknot diagrams is trickier than one might think. In fact, one of the purposes of [6] is to confirm or invalidate claims about previously known hard unknot diagrams using an exhaustive computer search over all possible sequences of Reidemeister moves. Still, the "hardest" known diagrams of the unknot have only been verified to require at least three extra crossings before they can be untangled. In contrast, the following conjecture is folklore.

▶ **Conjecture 1.** *Let m be an integer and let $\hat{\mathcal{D}}$ be the 0-crossing diagram of the unknot. Then there exists a diagram of the unknot $\mathcal{D}$ with n crossings such that any sequence of Reidemeister moves from $\mathcal{D}$ to $\hat{\mathcal{D}}$ passes through a diagram with at least $n + m$ crossings.*

Note that a proof of Conjecture 1, formulated in terms of recalcitrance, is claimed in [21], but concerns about the correctness of this proof are raised in [6].

In this article, as a possible step towards a proof of Conjecture 1, we shift our focus to **split links**. A link L is said to be split if there exists a sphere disjoint from L separating at least two link components of L. If such a sphere exists, there exists a link diagram in which two sublinks of L are disjoint: they are separated by a circle in the plane. Such a diagram is called a **split diagram**. By capping off the aforementioned circle with one disc above and one disc below the plane of projection, we can verify that conversely a split diagram witnesses a split link. Determining if a link is split is known as the **splitting problem**.

Given a split link L with a diagram $\mathcal{D}_1$, we study $\mathrm{Add}(\mathcal{D}_1, \mathcal{D}_2)$ where $\mathcal{D}_2$ is a split diagram of L. If the minimum of $\mathrm{Add}(\mathcal{D}_1, \mathcal{D}_2)$ over all split diagrams $\mathcal{D}_2$ of L, called the **crossing-complexity** and denoted by $\mathbf{CC}(D_1)$, is positive, we call $\mathcal{D}_1$ a **hard split link**.

Our results. We exhibit a family of link diagrams $\mathcal{D}(p, q)$ of split links $L(p, q)$ with two unlinked sublinks. The first sublink $M = M(p, q)$ is made of two linked torus knots $T_{p,q}$, and the second is an unknot U surrounding one of the torus knots (see Figure 3 for an illustration). For any split diagram $\mathcal{D}'(p, q)$ of $L(p, q)$, we prove Theorem 2, implying that $\mathrm{Add}(\mathcal{D}(p, q), \mathcal{D}'(p, q)) = \Omega(\min(p, q))$. More precisely, we have the following main theorem.

▶ **Theorem 2.** *For all $n \geq 2$, any sequence of Reidemeister moves transforming diagram $\mathcal{D}(n, n + 1)$ of the link $L(n, n + 1)$ with $2n^2 + 2$ crossings into a split diagram passes through a diagram with at least $2n^2 + \frac{2}{3}n$ crossings. In particular, there exist hard split links of arbitrarily large crossing-complexity.*

This is to our knowledge the first construction of split links with super-constant crossing-complexity, and we cannot rely on exhaustive search methods to prove Theorem 2. Instead, we develop new techniques to lower-bound the crossing-complexity. It was proved by Dynnikov [12, Theorem 2] that $\mathrm{CC}(D) = O(|D|^2)$, where $|D|$ denotes the number of crossings in a diagram D, so there is still a significant gap between this upper bound and the $\Omega(\sqrt{|D|})$ lower bound provided by our theorem.

▶ Remark 3. Theorem 2 is one of the many knot-theoretical statements that seems intuitively clear but is surprisingly delicate to prove: inspecting Figure 3, "clearly" the only way to split U from the two components of M is through an overlay of U on top of one of these

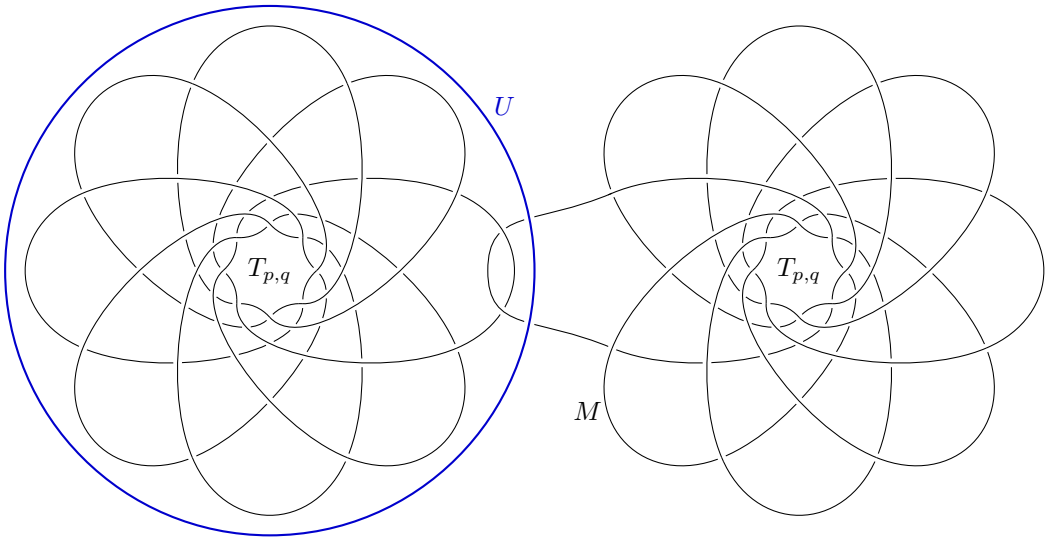

Figure 3 The link diagram $\mathcal{D}(p,q)$, $(p,q) = (7,8)$: two linked torus knots $T_{7,8}$ and an unknot U.

components, yielding the claimed increase in the number of crossings. In fact, the following idea to prove Theorem 2 may seem straightforward: if there is a sequence of Reidemeister moves splitting U from M without adding too many crossings, then we can find a continuous family of planes $(P_t)_{t\in\{0,1\}}$ in $\mathbb{R}^3$ sweeping one of the torus knots in M such that none of the planes P_t intersects M in too many points. Known results on *bridge position* [30, 31] and *thin position* [14, 29] of torus knots then imply that such a family cannot exist[2].

However, this proof idea has two issues. First, during a sequence of Reidemeister moves, the unknot U might come to intersect itself, making it difficult to define a continuous family of planes that mimics its intersections with M. Second, the Reidemeister moves might lead U to move back and forth, leading to a non-monotone behaviour of the planes P_t, which is not allowed in the aforementioned positions commonly used in knot theory. This leads us to rely on more advanced tools to prove Theorem 2.

Overview of the proof. The proof of Theorem 2 works by contradiction. That is, we start by assuming that there exists a sequence of Reidemeister moves R transforming $\mathcal{D}(n,n+1)$ into a split diagram and such that $\mathrm{Top}(\mathcal{D}(n,n+1),R)$ remains small. This implies that, throughout performing R, the number of crossings involving U and M always remains small.

The main tool that we rely on is the framework of bubble tangles introduced by the first and second authors in [26]. More precisely, we use the evolution of U throughout R to define a collection of 2-dimensional spheres that continuously sweep $\mathbb{S}^3$ (a *sweep-out*) and that – according to our assumptions – all have a small number of intersections with M. This sweep-out resembles the sphere decompositions of [26], but presents two notable differences. On the one hand it is simpler: it is linear and features no double bubbles. On the other hand, it is not monotone: a sphere involved in this sweep-out may go back-and-forth, while this behaviour is not allowed in the sphere decompositions from [26]. Despite this last difference, the bubble tangles, which are obstructions to thin sphere decompositions developed in [26], are versatile enough to show that the existence of this sweep-out leads to a contradiction.

[2] This argument is the basis of the proof in [8] showing that torus knot diagrams have high tree-width.

As mentioned in Remark 3, building the sweep-out is not straightforward. Intuitively, one would like to lift each unknot U to a sphere by capping it off above and below the diagram. However, the projection of the unknot U may intersect itself during the sequence of Reidemeister moves, which complicates the process. We alleviate this problem using results and methods from Chambers and Liokumovich [7] to transform homotopies of curves on a Riemannian surface into isotopies of similar length. The connection is the following: we think of the projection of the link M as a discrete metric for curves in the projection plane. In this discrete model, the **length** of a curve is given by its number of intersections with M, similarly to the cross-metric model commonly used in computational topology of surfaces (see for example [11]). Our assumptions imply that there exists a homotopy of the projection of U where intermediate curves all have small length. The techniques of [7] show that this implies that there also exists an isotopy of the projection of U with the same bounds on lengths. Since such an isotopy must consist of simple curves, we can then lift it into a sweep-out of $\mathbb{S}^3$ with 2-spheres, which all have a controlled number of intersections with M. However, a subtlety is that we cannot use the results of [7] out of the box. Indeed, the discrete metric defined by the link M is not fixed but evolves with the Reidemeister moves in R. In Section 3 we explain why the proof techniques in [7] can be adapted to deal with this issue.

The tools of the first and second authors [26] are then used to find a contradiction between the existence of the sweep-out and the topological properties of our link M. Namely, $L(n, n+1)$ consists of two torus knots $T_{n,n+1}$, which are embedded on tori in a specific way (they both have high *compression-representativity*). Hence, they can be used to define two **bubble tangles** using [26, Theorem 1.2] (In a nutshell, a bubble tangle is a way of choosing a "small side" for each sphere of the sweep-out, where the intuition is that the small side should be easy to sweep, see Section 2 for a formal definition). We then prove that, since in the initial diagram U lies in-between the two tori, different small sides are chosen for the corresponding sphere by each of the two bubble tangles. But the existence of the sweep-out with a small number of intersections with M forces the small sides of both bubble tangles to agree, leading to a contradiction.

Related work. The splitting problem has been studied several times as a useful and easier problem for understanding the unknot recognition problem [12, 23]. In 1961, Haken used normal surface theory to show that it is decidable [15]. Later, it was determined to be in **NP** [16] and also in co-**NP** [24, Theorem 1.6].

Several decision problems related to the splitting problem have been studied as well. For instance, the problem of deciding whether changing at most k crossings can transform a link diagram into the diagram of a split link is known to be **NP**-hard [22], and Lackenby provided an algorithm to detect links which can be split using exactly one crossing change [25].

Another natural question is to ask for the minimal number of Reidemeister moves needed to split a diagram. An exponential bound for this number was first provided by [19], and this bound was later greatly improved by Lackenby in [23], where he provided a polynomial bound using a combination of normal surface theory [16] and Dynnikov's work on grid diagrams [12]. There is a quadratic lower bound on the number of moves needed to untangle a specific unknot diagram in [17], and it was shown in [9, 10] that finding the shortest sequence of Reidemeister moves to untangle an unknot is **NP**-hard.

Organisation of this paper. After going through our setup in Section 2, we explain how to use the results of [7] in Section 3. This step is crucial for our definition of sweep-outs. Then, we exploit obstructions from [26] to prove Theorem 2 in Section 4.

2 Setup and definitions

Knots and links. Many concepts from this paper come from knot theory: while we strive to be as self-contained as possible, we refer to standard textbooks [5, 28] for an introduction to this topic and to Hatcher [18] for background on algebraic topology. Throughout this article, we work in the piecewise-linear (PL) category, which means that all the objects and functions that we consider are piecewise-linear with respect to a fixed polyhedral decomposition of the ambient space (generally $\mathbb{S}^3$). Two embeddings i_1 and i_2 in a topological space S are **(ambient) isotopic** if there exists a continuous family of homeomorphisms $h : S \times [0,1] \to S$ such that $h(i_1, 0) = i_2$ and $h(\cdot, 1)$ is the identity. A **knot**, resp. a **link**, is an embedding of the circle $\mathbb{S}^1$, resp. of a disjoint union of circles, into $\mathbb{S}^3$. In the following, we introduce the main definitions for knots for simplicity, but they apply identically to links. Two knots K_1 and K_2 are considered to be equivalent if they are isotopic. Since every knot misses at least one point of $\mathbb{S}^3$, via stereographic projection we can equivalently consider knots to be embedded in $\mathbb{R}^3$, and we freely switch between these two perspectives. The **unknot** is, up to equivalence, the unique embedding of S^1 in $\mathbb{R}^3$ with image a triangle. A **torus knot** $T_{p,q}$ is a knot embedded on a surface of an unknotted torus $\mathbb{T}$ in $\mathbb{S}^3$, for example a standard torus of revolution. It winds p times around the revolution axis, and q times around the core of the torus. We refer to Figure 3 for an illustration of two torus knots and an unknot.

A **knot diagram** $\mathcal{D}$ is a planar four-regular graph, where each crossing is decorated to indicate which strands are above and below. From such a diagram, one can easily obtain the data of a knot $K \hookrightarrow \mathbb{R}^3$ and a linear **projection** map $p : \mathbb{R}^3 \to P \simeq \mathbb{R}^2$ so that $p(K) = \mathcal{D}$ (respecting the decorations), where P is a plane of $\mathbb{R}^3$ called the **projection plane**. The **crossing number** of a knot is the minimal number of crossings among all of its diagrams. The Reidemeister theorem [32] shows that two diagrams represent equivalent knots if and only if they can be connected by a sequence of planar isotopies and local moves called **Reidemeister moves** and pictured in Figure 1.

Finally, recall that a **homotopy** between two simple closed curves of a surface Σ, $\gamma_0 : \mathbb{S}^1 \hookrightarrow \Sigma$ and $\gamma_1 : \mathbb{S}^1 \hookrightarrow \Sigma$ is a continuous map $\gamma : \mathbb{S}^1 \times [0,1] \to \Sigma$ such that $\gamma(\mathbb{S}^1, 0) = \gamma_0$ and $\gamma(\mathbb{S}^1, 1) = \gamma_1$. In particular, closed curves are allowed to self-intersect in a homotopy, while this is disallowed in an isotopy. Throughout this paper, to distinguish between links and their projections, we use calligraphic letters to designate diagrams, and capital letters to designate links so that a diagram of the link M is denoted by $\mathcal{M}$.

▶ Remark 4. We work with the standard setting of knot diagrams in $\mathbb{R}^2$, but it is also possible to work with diagrams in $\mathbb{S}^2$, which therefore allow for more Reidemeister moves (this is the perspective taken in [6]). Our results also hold in that setting, since a knot diagram in $\mathbb{S}^2$ lifts to a knot $K \hookrightarrow \mathbb{S}^2 \times [-\varepsilon, \varepsilon] \subseteq \mathbb{R}^3$, with the natural projection map $p : \mathbb{S}^2 \times [-\varepsilon, \varepsilon], (s,t) \mapsto (s, 0)$. The definitions of the spheres obtained from the diagrams in Section 4 can be directly adapted to this setting, and the rest of the proof is identical.

Our link diagrams. Throughout this article, we write $L(p,q)$ for the split link consisting of two linked torus knots $T_{p,q}$, denoted by $M(p,q)$ and shown in Figure 3, and an unlinked unknot component U. We consider two diagrams of $L(p,q)$. The first, denoted by $\mathcal{D}(p,q)$, is shown in Figure 3, and the second diagram $\mathcal{D}'(p,q)$ is any split link diagram of $L(p,q)$.

Let R be a sequence of Reidemeister moves turning $\mathcal{D}(p,q)$ into $\mathcal{D}'(p,q)$, such that $\mathrm{Top}(\mathcal{D}(p,q), R) \leq k$, $k \geq 0$. Our goal is to prove that k cannot be smaller than a function depending only on p and q. Since the values of p and q are mostly fixed and have little influence on our arguments, we mostly omit the parameters (p,q) from L, M, $\mathcal{D}$, and $\mathcal{D}'$.

The following lemma directly follows from known results on torus knots.

▶ **Lemma 5.** *Let $n \geq 2$, and let $\mathcal{D}'$ be a link diagram equivalent to $\mathcal{D}(n, n+1)$ by Reidemeister moves. Then $\mathrm{cr}(\mathcal{D}') \geq 2n^2$, that is, $\mathcal{D}'$ has at least $2n^2$ crossings.*

Proof. Let $\mathcal{D}'$ be a diagram of $L = L(n, n+1)$. First note that, since $n \geq 2$, it follows from a theorem of Murasugi [27, Proposition 7.5] that each of the torus knot components $T_{n,n+1}$ of L has at least $(n+1) \times (n-1) = n^2 - 1$ crossings. Since the two torus knots are linked, they share at least 2 crossings in each diagram of L, and it follows that $\mathrm{cr}(\mathcal{D}) \geq 2n^2$. ◀

From a sequence of Reidemeister moves to continuous operations. As detailed above, we work with a sequence of Reidemeister moves R turning the link diagram $\mathcal{D}$ of L into the split diagram $\mathcal{D}'$. From this sequence of Reidemeister moves, we can obtain an ambient isotopy $\Phi_R : \mathbb{R}^3 \times [0,1] \to \mathbb{R}^3$ and a projection $p : \mathbb{R}^3 \to \mathbb{R}^2$ so that the diagrams $p(\Phi_R(L,t))$ follow the evolution of $\mathcal{D}$ under the moves R, and in particular the combinatorial types of the diagrams $p(\Phi_R(L,t))$ only change for a finite number of values of t, one for each Reidemeister move. The projection p is regular except at the **critical times** of R, which are times where the projection $p \circ \Phi_R(L,t)$ displays a tangency or a triple point, see Figure 4 for an illustration. For any non-critical time t, we write $L_t = \Phi_R(L,t)$ and we denote the diagram defined by $p(L_t) = p(\Phi_R(L,t))$ by $\mathcal{D}_t$. Naturally, we have $\mathcal{D}_0 = \mathcal{D}$ and $\mathcal{D}_1 = \mathcal{D}'$.

Figure 4 Critical times corresponding to Reidemeister moves RII (left) and RIII (right).

Note that the definition of $\mathrm{Top}(\mathcal{D}, R)$ naturally coincides with $\sup_{t\in[0,1]}\{\mathrm{cr}(\mathcal{D}_t) - \mathrm{cr}(\mathcal{D}_0)\}$. Indeed, the diagram $\mathcal{D}_t$ at critical times has fewer intersections than one of $\mathcal{D}_{t+\epsilon}$ or $\mathcal{D}_{t-\epsilon}$ for ϵ small enough. Furthermore, $\mathrm{cr}(\mathcal{D}_t)$ is constant for all t between two critical times.

In Section 3 we consider the movements of U and of M under the Reidemeister moves separately. We use $\mathcal{M}_t = p(\Phi_R(M,t))$ as a shorthand for the diagram of the sublink $M \subset L$ at time t. For $\mathcal{U}$ we consider the homotopy $\phi_U : \mathbb{S}^1 \times [0,1] \to \mathbb{R}^2$ in the plane induced by the projection $p(\Phi_R(U,t))$. We denote the corresponding curves by $\mathcal{U}_t = \phi_U(\mathbb{S}^1, t)$ and emphasise that we consider these as immersions of closed curves in the plane. That is, we forget which strand is over which at each self-crossing of $\mathcal{U}_t$. See Figure 5 for a summary of this setup.

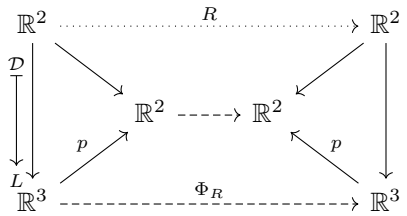

Figure 5 Definition of our homotopies from the sequence of Reidemeister moves R.

3 From homotopies to isotopies

We work with the definitions of Section 2. We start with a sequence of Reidemeister moves R turning $\mathcal{D}$ into $\mathcal{D}'$, and consider the induced homotopy ϕ_U of the link component $\mathcal{U}$ in the plane of projection. The goal of this section is to use results from [7] in order to locally alter the images $\mathcal{U}_t = \phi_U(\mathbb{S}^1, t)$ into simple closed curves, and hence to obtain an isotopy taking $\mathcal{U}_0$ to $\mathcal{U}_1$. After these modifications, the altered simple closed curves representing U still sweep over the remainder $\mathcal{M}_t$ of the diagrams $\mathcal{D}_t$, but this sweep no longer necessarily corresponds to a sequence of Reidemeister moves on the original link L.

Nevertheless, in the next section we use the isotopy from $\mathcal{U}_0$ to $\mathcal{U}_1$ to define a family of 2-spheres in $\mathbb{S}^3$ sweeping through M. This setup then allows us to use bubble tangles to obstruct small values of $\mathrm{Top}(\mathcal{D}, R)$ in the initial sequence of Reidemeister moves R.

The key points of this process are given by the following statement.

▶ **Proposition 6.** *Let R be a sequence of Reidemeister moves turning $\mathcal{D}$ into the split diagram $\mathcal{D}'$ such that for all $t \in [0,1]$, $\mathrm{cr}(\mathcal{D}_t) \leq m$ for some integer $m \geq 0$. Then there exists an ambient isotopy $\Phi' : \mathbb{S}^3 \times [0,1] \to \mathbb{S}^3$ and an isotopy $h : \mathbb{S}^1 \times [0,1] \to \mathbb{R}^2$ such that*

1. *$h(\mathbb{S}^1, 0) = \mathcal{U}_0$ and $h(\mathbb{S}^1, 1) = \mathcal{U}_1$; and*
2. *for all $t \in [0,1]$, the total number of crossings in the overlay of $p(\Phi'(M,t))$ and $h(\mathbb{S}^1, t)$ in $\mathbb{R}^2$ is at most m.*

We emphasise that in the second item of Proposition 6, we only consider the sublink M in $\Phi'(M,t)$, and not the entire link. That is, the proposition provides an ambient isotopy for M in $\mathbb{R}^3$ and an isotopy for $p(U)$ in $\mathbb{R}^2$, while preserving a bound on the total number of intersections of $p(\Phi'(M,t))$ and $h(\mathbb{S}^1, t)$ in the plane of projection. This proposition follows from the techniques of Chambers and Liokumovich developed in Chapter 2 of [7], the proof is detailed in the full version of the article for completeness. We first state one of their main results.

▶ **Definition 7** (Chambers, Liokumovich [7, Definition 1.3])**.** *Two curves α and β on a Riemannian 2-manifold M are **ϵ-image equivalent**, $\alpha \sim_\epsilon \beta$, if (i) there exists a finite collection of disjoint intervals $\bigsqcup_{i=1}^n I_i \subset \mathbb{S}^1$ such that $\|\alpha(\mathbb{S}^1 \setminus \bigsqcup I_i)\| + \|\beta(\mathbb{S}^1 \setminus \bigsqcup I_i)\| < \epsilon$, and (ii) there exists a permutation σ of $\{1, \ldots, n\}$ and a map $f : \{1, \ldots, n\} \to \{0, 1\}$, such that $\alpha|_{I_i} = (-1)^{f(i)} \beta|_{I_{\sigma(i)}}$ for all i. Here, $\|\alpha\|$ denotes the length of the curve α.*

The main result we use for the proof of Proposition 6 is given by the following statement.

▶ **Theorem 8** (Chambers, Liokumovich [7, Theorem 1.1'])**.** *Suppose that γ is a smooth homotopy of closed curves on a Riemannian 2-manifold M and that γ_0 is a simple closed curve. Then, for every $\epsilon > 0$, there exists an isotopy $\overline{\gamma}$ such that $\overline{\gamma_0} = \gamma_0$ and $\overline{\gamma_1}$ is ϵ-image equivalent to a small perturbation of γ_1. Additionally, for every t, there exists a t' such that $\overline{\gamma_t}$ is ϵ-image equivalent to a small perturbation of $\gamma_{t'}$. If γ_1 is simple, or is a point, then this homotopy also ends at γ_1, up to a change in orientation.*

Informally, we think of Definition 7 and Theorem 8 as follows. When a curve α self-intersects in the plane, each crossing point can be **resolved** in one of two ways by reconnecting the endpoints in a small ball around the crossing point, see Figure 6 on the right. When all the crossings have been resolved in some way and we obtain a simple closed curve α', we say that α' is a **resolution** of α. The theorem states that if we have a homotopy γ on a surface

between two simple curves γ_0 and γ_1, one can obtain an *isotopy* $\overline{\gamma}$ between γ_0 and γ_1[3] where each intermediate curve $\overline{\gamma_t}$ is a resolution of some intermediate curve $\gamma_{t'}$. Note that, here, the times t and t' may not coincide.

If M is endowed with a metric (for example, a Riemannian one), the lengths of γ_t and of $\overline{\gamma_{t'}}$ differ by an arbitrarily small quantity. Hence, Theorem 8 immediately implies that, for all $\varepsilon > 0$, if there exists a homotopy between two simple curves γ_0 and γ_1 where each intermediate curve has length at most ℓ, then there also exists an isotopy between γ_0 and γ_1 where each intermediate curve has length at most $\ell + \varepsilon$.

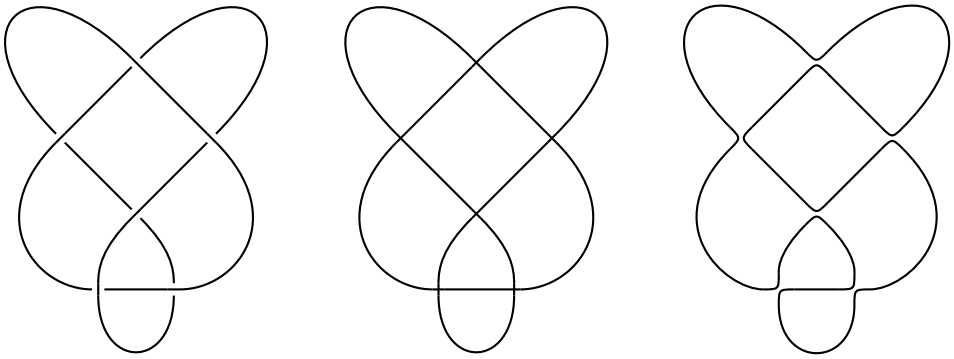

Figure 6 Left: A diagram of the unknot U. Middle: A projection $\mathcal{U}_t$ of this unknot, where the crossing information has been forgotten. Right: A resolution of $\mathcal{U}_t$.

Theorem 8 can be applied as a black-box to prove Proposition 6 in the particular case where the sublink M stays invariant throughout the sequence of Reidemeister moves R, i.e., $\Phi_R(M,t) = \Phi_R(M,0)$ for all $t \in [0,1]$. Indeed, in this case, we can think of $\mathcal{M}_t$ as a discrete metric measuring the length of a curve $\mathcal{U}_t$ by its number of intersections with $\mathcal{M}_t$. More formally, we can take γ to be the homotopy ϕ_U between $\mathcal{U}_0$ and $\mathcal{U}_1$, which are both simple closed curves by the definition of the link diagram $\mathcal{D}$. Applying Theorem 8 provides us with an isotopy h between $\mathcal{U}_0$ and $\mathcal{U}_1$ where all intermediate curves $\mathcal{U}'_t$ are obtained from resolving intersections of some $\mathcal{U}_{t'}$. In particular, for all $t \in [0,1]$, the number of intersections between $\mathcal{U}'_t$ and $\mathcal{M}_t$ is at most the number of intersections between $\mathcal{U}_{t'}$ and $\mathcal{M}_t$, which is at most k since $\mathcal{M}_t = \mathcal{M}_0$ does not depend on t.

A careful reading of [7] shows that the general case of Proposition 6, where the diagram $\mathcal{M}_t$ of the sublink M evolves during the sequence of Reidemeister moves, can also be obtained using the same proof techniques: The basic idea of the proof of Theorem 8 is to first decompose the homotopy of γ into a sequence of local moves, and then replace each curve γ_t by one of its resolutions.

For the first step, they track discrete times where the self-intersection pattern (i.e., the homeomorphism type) of γ_t changes. By an argument similar to the proof of the Reidemeister theorem, one can assume that this only happens at **critical events**, when a curve γ_t undergoes a homotopy move, which is a transformation analogue to a Reidemeister move but without any crossing information. This step is formalised by their Proposition 2.1 and Lemma 2.2. Note that this step is unnecessary for us, since by construction the local transformations undergone by ϕ_U are projections of Reidemeister moves.

[3] Or γ_1 with its orientation reversed. Since it is safe to disregard orientations for our purpose, we always consider curves up to orientation reversal.

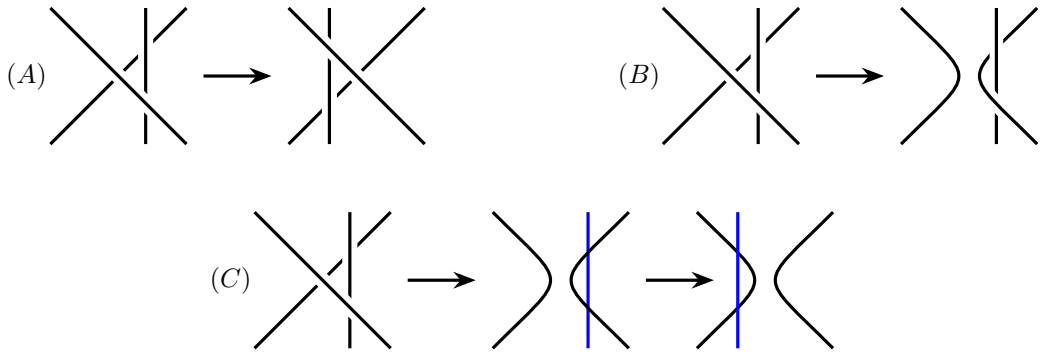

Figure 7 (A) Reidemeister III move. (B) a problematic resolution of $\mathcal{U}_t$. (C) The unknot $\mathcal{U}_t$ (black) seen as a curve sweeping through $\mathcal{M}$ (blue).

Between these critical events, any homotopy of a curve γ_t can be applied similarly to any of its resolutions, yielding an isotopy. Hence, the idea is to replace each of these Reidemeister moves by a resolution of the move, as explained by their Figure 2. However, doing so in a naive way runs into discontinuity issues, a basic example of which is detailed in [7, Example 2], which is associated to their Figures 3 and 4. Therefore, the authors provide a more intricate workaround: the key to the proof of Theorem 8 is to show how to choose the correct resolutions and connect their isotopies together. This is achieved by defining an auxiliary graph of resolutions (see their Figure 7), synthesising how they are connected by local isotopies. The precise definition for this graph follows their Figure 8. The proof is then finalised by finding a path through this graph by using the handshaking lemma [13].

In our case, the critical events are exactly the times t when $\mathcal{U}_t$ undergoes a Reidemeister move. In-between these critical events, there are other Reidemeister moves involving either (i) both $\mathcal{U}_t$ and $\mathcal{M}_t$, or (ii) only $\mathcal{M}_t$. Note that in case (i), the Reidemeister move only changes the relative position of $\mathcal{U}_t$ and $\mathcal{M}_t$, and hence such a move can be treated as leaving the isotopy type of $\mathcal{M}_t$ unchanged. Therefore the homotopy of $\mathcal{U}_t$ can be used as an isotopy of any of its resolutions in this case. In case (ii), $\mathcal{M}_t$ changes, but $\mathcal{U}_t$, considered up to isotopy, does not. Therefore, by applying the same Reidemeister moves to $\mathcal{M}_t$, any motion of $\mathcal{U}_t$ between critical events can be applied to any of its resolutions while preserving the number of intersections with $\mathcal{M}_t$. These motions can then be connected using the same handshaking argument as in the proof of Theorem 8. Summarising, the proof technique directly adapts to the case of an evolving metric, as long as these evolutions are applied appropriately throughout the new sequence of isotopies.

▶ Remark 9. We emphasise that in this section, we apply the framework of Theorem 8 to the *projection* of U without crossing information, which is thus considered as a closed, non-embedded, curve in the projection plane $\mathbb{R}^2$. Instead, it might be tempting to apply these techniques *directly at the level of Reidemeister moves*. This way one may hope to prove that in any sequence of Reidemeister moves splitting $\mathcal{U}$ from $\mathcal{M}$, one can assume that $\mathcal{U}$ remains simple while preserving a bound on the number of added crossings. However, this proof strategy fails because some resolutions applied to $\mathcal{U}$ can block the application of RIII moves involving $\mathcal{U}$ and $\mathcal{M}$. Such a case is pictured in Figure 7(B).

4 Sweep-outs, bubble tangles and proof of the lower bound

For the remainder of this article, we use Proposition 6 to assume that the homotopy $\phi_U : \mathbb{S}^1 \times [0,1] \to \mathbb{R}^2$ sweeping U across M is an isotopy. In other words, let h be the isotopy of $\mathcal{U}$ in $\mathbb{R}^2$ and Φ' be the ambient isotopy of M in $\mathbb{S}^3$ from Proposition 6, and for all $t \in [0,1]$, we replace $\phi_U(\mathbb{S}^1, t)$ by $h(\mathbb{S}^1, t) = \mathcal{U}_t$ which is a simple closed curve.

4.1 A sweep-out of 2-spheres

For each t, we associate a 2-sphere S_t to the simple curve $\mathcal{U}_t$, by extending $\mathcal{U}_t$ infinitely towards the direction of the projection p. Seen in $\mathbb{S}^3$ this produces a torus pinched at ∞, and cutting the surface at ∞ yields S_t (see Figure 8). By construction, S_t intersects $M_t = \Phi'(M, t)$ only in the pre-images of $\mathcal{U}_t \cap \mathcal{M}_t$ by the projection p. Altogether, this produces a continuous family of spheres S_t sweeping a continuous family of links M_t. By applying the ambient isotopy Φ'^{-1} to S_t and M_t, we can assume that M_t is fixed. We slightly abuse notation and make this assumption, while still denoting the family of spheres by S_t.

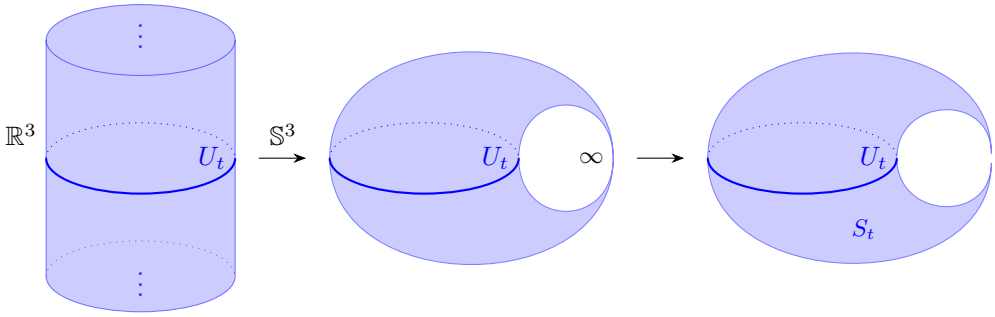

Figure 8 Gluing two infinite annuli on U and cutting the resulting pinched torus at ∞ in $\mathbb{S}^3$.

We now relate $\mathrm{Top}(\mathcal{D}(n, n+1), R)$ to our continuous family of spheres $\{S_t\}_{t\in[0,1]}$.

▶ **Lemma 10.** *We have* $\sup_{t\in[0,1]} |S_t \cap M_t| - 2 \leq \mathrm{Top}(\mathcal{D}(n, n+1), R)$.

Proof. For $\mathcal{M}$ and $\mathcal{M}'$ two components of a link diagram, we denote by $\mathrm{cr}(\mathcal{M}, \mathcal{M}')$ the number of crossings involving strands of $\mathcal{M}$ and $\mathcal{M}'$. If $\mathcal{M} = \mathcal{M}'$, then $\mathrm{cr}(\mathcal{M}, \mathcal{M}')$ is the number of self-crossings of $\mathcal{M}$.

Since $\mathcal{U}_t$ is simple for all times t, we have $\mathrm{cr}(\mathcal{D}_t) = \mathrm{cr}(\mathcal{M}_t, \mathcal{U}_t) + \mathrm{cr}(\mathcal{M}_t, \mathcal{M}_t)$. By definition, $\mathcal{D}_t$ is the diagram obtained from $\mathcal{D}(n, n+1)$ at time t of the sequence of Reidemeister moves R, and is hence equivalent to $\mathcal{D}(n, n+1)$. It follows from Lemma 5, that $\mathrm{cr}(\mathcal{M}_t, \mathcal{M}_t) \geq 2n^2$ at all times t. Furthermore, $\mathrm{cr}(\mathcal{M}_t, \mathcal{U}_t) = |S_t \cap M_t|$ by construction of S_t. By definition of $\mathcal{D}(n, n+1) = \mathcal{D}_0$, we have $\mathrm{cr}(\mathcal{D}_0) = 2n^2 + 2$. Hence, $\mathrm{cr}(\mathcal{D}_t) - \mathrm{cr}(\mathcal{D}_0) \geq 2n^2 + |M_t \cap S_t| - 2n^2 - 2$.

Thus, $\sup_{t\in[0,1]} |S_t \cap M_t| - 2 \leq \sup_{t\in[0,1]} \{\mathrm{cr}(\mathcal{D}_t) - \mathrm{cr}(\mathcal{D}_0)\} = \mathrm{Top}(\mathcal{D}(n, n+1), R)$. ◀

4.2 Bubble tangles

The aim for the remainder of this section is to use results from [26] to exhibit an obstruction to $|S_t \cap M_t|$ remaining small throughout the sweep-out defined in Section 4.1.

The key objects that we rely on are bubble tangles. Before introducing those, we need the following definitions. A **double bubble** consists of two spheres intersecting on a disc (see the left of Figure 9 for an illustration). The complement of a double bubble consists of

three balls, and we say that they are **induced** by the double bubble. A 3-ball in $\mathbb{S}^3$ is said to be ***L*-trivial**, if it intersects $L \subset \mathbb{S}^3$ in a single unknotted segment or in the empty set, see Figure 9 on the middle for an example and on the right for a non-example.

▶ **Definition 11** ([26], Definition 2.3). *Let $L \in \mathbb{S}^3$ be a link and let $k \in \mathbb{N}$. A **bubble tangle $\mathcal{T}$ of order $k \geq 2$**, is a collection of closed balls in $\mathbb{S}^3$ such that:*

1. *For all balls $B \in \mathcal{T}$, we have $|\partial B \cap L| < k$.*
2. *For all 2-spheres $S \in \mathbb{S}^3$ transverse to L, if $|S \cap L| < k$, then exactly one of the two[4] balls B_i, $i \in \{1, 2\}$ with boundary S is in $\mathcal{T}$.*
3. *For all triples of balls $\{B_1, B_2, B_3\}$, if $\{B_1, B_2, B_3\}$ induces a double bubble transverse to L, then $\{B_1, B_2, B_3\} \not\subset \mathcal{T}$.*
4. *For every closed ball B in $\mathbb{S}^3$, if B is L-trivial and $|\partial B \cap L| < k$, then $B \in \mathcal{T}$.*

Informally, we think of a bubble tangle as a way to choose, for each sphere S having less than k intersections with L, one of the two balls that it bounds. We refer to this ball as the **small side** of S, with the intuition that this small side intersects L in a simpler pattern than the other side. The essential property of a bubble tangle is the requirement that we cannot cover all of $\mathbb{S}^3$ using three small sides of a triple of spheres arranged in a double bubble. One of the main results of [26] states that if a bubble tangle of L of order k exists, any sweep-outs of $\mathbb{S}^3$ by 2-spheres contains at least one sphere with at least k intersections with L. As discussed in the introduction, our sweep-outs differ from those in [26]. However, we show that despite their differences, a bubble tangle can also be used to preclude the existence of a sweep-out S_t having few intersections with M.

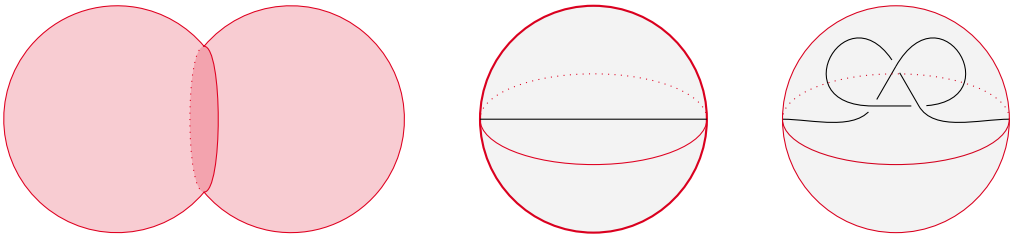

Figure 9 Left: a double bubble. Middle: an L-trivial ball. Right: a ball that is not L-trivial.

We denote by M^1 and M^2 the two torus links composing M. By definition, each of them can be embedded on a standard torus $\mathbb{T}$ as pictured in Figure 11. A simple curve on $\Sigma \subseteq \mathbb{S}^3$ is **compressible** if it is non-contractible on Σ and bounds a disk in $\mathbb{S}^3 \setminus \Sigma$. The **compression-representativity** of a knot K embedded on a surface Σ is the minimum number of intersections between K and a compressible curve in Σ. The compression-representativity of M_1 and M_2 is n, see [26, Section 5]. Note that, since M^1 and M^2 are linked, their underlying tori intersect, but this is of no consequence for us. By [26, Theorem 1.2], there exist two bubble tangles $\mathcal{T}^1, \mathcal{T}^2$ of order $\frac{2}{3}n$, where each $\mathcal{T}^i$ is the bubble tangle defined by M^i while completely forgetting about the other torus knot. Thus, $\mathcal{T}^i$ is a bubble tangle *induced* by the torus on which M^i is embedded. Such bubble tangles induced by a surface are called **compression bubble tangles**: given a link embedded on a surface Σ, the small sides of the bubble tangle are the balls B which are either disjoint from Σ or intersect Σ trivially, i.e., the inclusion $i : B \cap \Sigma \to \Sigma$ is π_1-trivial, which means that it

[4] By the PL Schoenflies theorem [4, Theorem XIV.1], a PL 2-sphere in $\mathbb{S}^3$ bounds exactly two balls.

induces a trivial map on fundamental groups. For example, the annulus and disc obtained by intersecting the torus and green ball of Figure 10 have a π_1-trivial inclusion in the torus, but the annulus stemming from the intersection between the red ball and the torus does not.

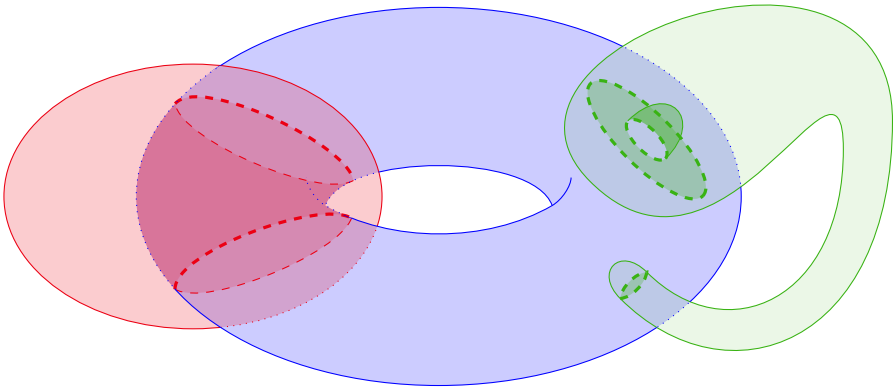

Figure 10 The green ball intersects the torus trivially while the red ball does not.

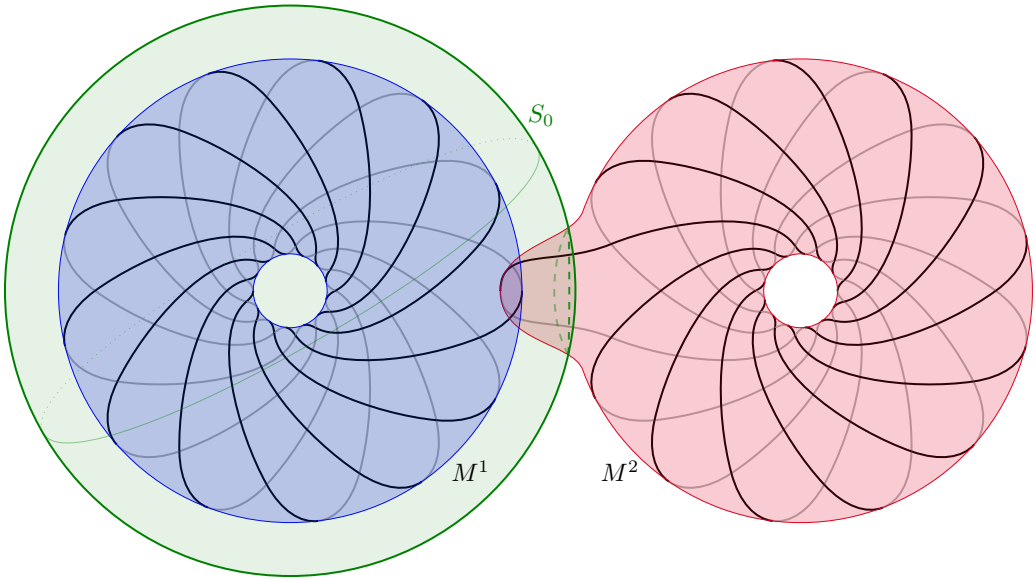

Figure 11 Link components M^1 and M^2 embedded on tori, and sphere S_0.

4.3 Proof of Theorem 2

In order to prove Theorem 2, we assume that $\mathrm{Top}(\mathcal{D}(n, n+1), R) < k = \frac{2}{3}n - 2$. By virtue of Lemma 10, it follows that $|M_t^i \cap S_t| \leq |M_t \cap S_t| < \frac{2}{3}n$ for $i \in \{1, 2\}$. Now, changes to $|M_t \cap S_t|$ can only happen at critical times where the number of crossings involving $\mathcal{U}_t$ in $\mathcal{D}_t$ increases or decreases. In particular, we can ignore RIII moves between $\mathcal{U}_t$ and $\mathcal{M}_t$. Since we only consider moves involving both $\mathcal{U}_t$ and $\mathcal{M}_t$, only RII moves are relevant for our study. We denote the critical times of RII moves involving both $\mathcal{U}_t$ and $\mathcal{M}_t$ by $(t_j)_{1 \leq j \leq s} \subset [0, 1]$. These times are the only times where S_t is not transverse to M_t, but **finitely tangent**, meaning that M_t is tangent to S_t, but their number of intersections is still finite.

Recall that, up to applying ϕ'^{-1}, we assume that for all $t \in [0,1]$ M_t is fixed; we denote it by M. By 2, for all times $t \in [0,1] \setminus \{t_j\}_{1\leq j\leq s}$, S_t has a small side corresponding to a 3-ball $B_t^i \in \mathcal{T}^i$. We study how these small sides evolve throughout the sweep-out. Special attention must be paid to tangencies at times $\{t_j\}_{1\leq j\leq s}$, where small sides are not defined. For convenience, we denote by $\Theta : \mathbb{S}^3 \times [0,1] \to \mathbb{S}^3$ an isotopy describing the evolution of S_t, i.e., such that $\Theta(S_0, t) = S_t$.

We start by defining the **agreement** between bubble tangles $\mathcal{T}^1$ and $\mathcal{T}^2$ as a map $a : [0,1] \setminus \{t_j\}_{1\leq j\leq s} \to \{0,1\}$, such that $a(t) = 1$ if $B_t^1 = B_t^2$ and 0 otherwise. With this definition, and under the assumption that $\mathrm{Top}(\mathcal{D}(n, n+1), R) < k$, we can infer that $a(0) = 0$ and $a(1) = 1$: First, note that $a(1) = 1$. Indeed, $\mathcal{U}_1$ is disjoint from $\mathcal{M}$ so that S_1 is disjoint from M. It follows that one side of S_1 is an empty ball with respect to both M^1 and M^2 and thus $a(1) = 1$ by 4. Second, the small side of S_0 in $\mathcal{T}^1$ is, by 4, the ball not containing M^1. For $\mathcal{T}^2$, as it is illustrated by Figure 11, S_0 contains an M^2-trivial ball and M^1 on its small side, and the remaining of M^2 on the other side. It follows that the small sides disagree at time 0, and hence $a(0) = 0$.

We want to show that a stays constant on its domain of definition. For this, we introduce the following definition: Two disjoint spheres $S, S' \subset \mathbb{S}^3$ are **braid-equivalent** with respect to some link $L \subset \mathbb{S}^3$, if L forms a braid in the product region between S and S', or, equivalently, if the product region between S and S' is homeomorphic to $S_\ell \times [0,1]$ where S_ℓ is the 2-sphere with ℓ holes, $\ell \geq 0$, see Figure 12 for an illustration.

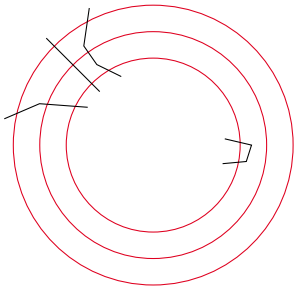

Figure 12 A cross-section view of three spheres and a link. The two outermost spheres are braid-equivalent, but the innermost one is not braid-equivalent to the others.

We have the following statement for two disjoint braid-equivalent spheres.

▶ **Lemma 12** ([26], Lemma 3.2)**.** *Let $\mathcal{T}$ be a bubble tangle and $S, S' \subset \mathbb{S}^3$ be two braid-equivalent spheres. Define $\mathbb{S}^3 \setminus S = \{B_1, B_2\}$ and $\mathbb{S}^3 \setminus S' = \{B_1', B_2'\}$ such that $B_1 \subset B_1'$. If $B_1 \in \mathcal{T}$ then $B_1' \in \mathcal{T}$.*

The compression bubble tangles furthermore have the following property.

▶ **Lemma 13.** *Let $\mathcal{T}$ be a compression bubble tangle of L, induced by an embedding of L into some surface $\Sigma \subset \mathbb{S}^3$, and let k be the order of $\mathcal{T}$. Then, for two closed 3-balls $A, B \subset \mathbb{S}^3$, if $A \in \mathcal{T}$, $B \subset A$, and $|\partial B \cap L| < k$, then $B \in \mathcal{T}$. That is, $\mathcal{T}$ is* stable by inclusion *up to 1.*

Proof. Let A and B be two closed balls of $\mathbb{S}^3$ such that $|\partial A \cap L|, |\partial B \cap L| < k$, and $A \in \mathcal{T}$. By definition, $A \cap \Sigma$ is π_1-trivial. Since $B \subset A$, we have $B \cap \Sigma \subset A \cap \Sigma$ so that the inclusion morphisms i_* satisfy $\pi_1(B \cap \Sigma) \to \pi_1(A \cap \Sigma) \to 0$. Hence, $B \cap \Sigma$ is π_1-trivial and $B \in \mathcal{T}$. ◀

To handle the back-and-forths of our sweep-out, we introduce a new equivalence relation on spheres. Two intersecting spheres $S, S' \subset \mathbb{S}^3$ are **intersection-equivalent** if there exists an isotopy between them which stays constant on their intersection $S \cap S'$, see Figure 13. Note that, by this definition, a sphere S is intersection-equivalent with itself.

The structure of the remainder of the proof is to show that the agreement a is constant on $[0,1]$ by showing that it is locally constant via Lemmas 15 and 16.

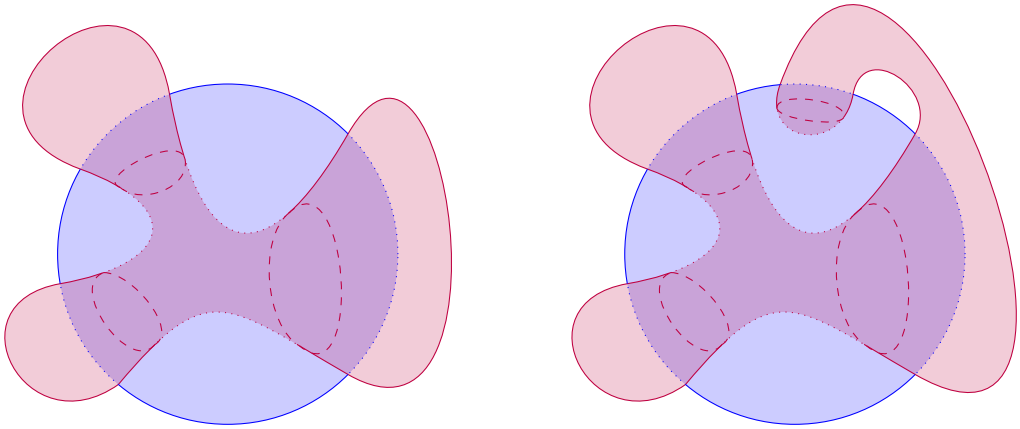

Figure 13 Left: two intersection-equivalent spheres. Right: two spheres that are not intersection-equivalent: the red sphere has an annulus component that cannot be mapped to a component of the blue one. Indeed, the components of the blue sphere are discs and a sphere with 4 punctures.

Since we work in the piecewise-linear setting, we have the following observation:

▶ **Lemma 14.** *Let $t \in [0,1]$. There exists a neighbourhood $V \subset [0,1]$ of t such that for all spheres S_v, $v \in V$, S_v and S_t are either disjoint or intersection-equivalent.*

The proofs of the two following lemmas, given in the full version of the article, are similar.

▶ **Lemma 15.** *Let $t \in [0,1] \setminus \{t_j\}_{1 \leq j \leq s}$ be a non-critical time. There exists a neighbourhood $V \subset [0,1] \setminus \{t_j\}_{1 \leq j \leq s}$ of t such that a is constant on V.*

Sketch of proof. The idea is to keep track of the small sides of two close spheres for each $\mathcal{T}^i$. Either the two spheres are disjoint and the result follows from Lemma 12 and Lemma 13, or they are intersection-equivalent and the proof proceeds similarly by applying these two lemmas in succession on the parts inside and outside of a small side.

▶ **Lemma 16.** *Let $t \in [0,1]$. Then there exists a neighbourhood $V \subset [0,1]$ of t such that a is constant on $V \setminus \{t\}$.*

▶ **Proposition 17.** *The agreement a is constant on $[0,1] \setminus \{t_j\}_{1 \leq j \leq s}$ and hence $a(0) = a(1)$.*

Proof. We can cover $[0,1]$ by open discs from Lemma 16 on which a is constant. Since $[0,1]$ is compact, only finitely many of them are enough to cover it. On each connected component of $[0,1] \setminus \{t_j\}_{1 \leq j \leq s}$ the agreement function is constant by the continuity of a (a is locally constant). Moreover, we know from Lemma 16 that for $u < t_j < v$ close enough we have $a(u) = a(v)$. Hence, a is constant on $[0,1] \setminus \{t_j\}_{1 \leq j \leq s}$, and $a(0) = a(1)$. ◀

Proof of Theorem 2. The initial discussion of this subsection states that $a(0) = 0$ and $a(1) = 1$. This contradicts Proposition 17. Thus, our assumption that $\mathrm{Top}(\mathcal{D}(n, n+1), R) < \frac{2}{3}n - 2$ does not hold. Therefore, during the sequence, at least one diagram has at least $2n^2 + \frac{2}{3}n$ crossings. ◀

In the full version of the article, we discuss variants of our construction for which our arguments also provide lower bounds on the crossing-complexity.

Persistent (Co)Homology in Matrix Multiplication Time

Dmitriy Morozov

Queen Mary University of London, UK

Abstract

Most algorithms for computing persistent homology do so by tracking cycles that represent homology classes. There are many choices of such cycles, and specific choices have found different uses in applications. Although it is known that persistence diagrams can be computed in matrix multiplication time for the more general case of zigzag persistent homology [21], it is not clear how to extract cycle representatives, especially if specific representatives are desired. In this paper, we provide the same matrix multiplication bound for computing representatives for the two choices common in applications in the case of ordinary persistent (co)homology. We first provide a fast version of the reduction algorithm, which is simpler than the algorithm in [21], but returns a different set of representatives than the standard algorithm [15]. We then give a fast version of a variant called the row algorithm [10], which returns the same representatives as the standard algorithm.

1 Introduction

Persistent homology [15] is one of the core techniques in topological data analysis. Because of its theoretical importance as well as its wide use in applications, a lot of work has been dedicated to its efficient computation both in theory [21, 10, 7, 4, 20] and in practice [2, 3, 1, 18, 17, 26]. On the theoretical side, the connection between persistent homology and Gaussian elimination was established early on [27], and as a result it has been long accepted that persistence can be computed in matrix multiplication time. Milosavljevic et al. [21] gave an explicit algorithm for the more general case of zigzag persistence [5, 6]. The main difficulty in applying standard linear algebra techniques is the strict constraint on the row and column ordering of the boundary matrix.

As persistent homology has evolved as a field, the significance of its formulation as an $\mathbf{R} = \mathbf{DV}$ decomposition [8] of the input boundary matrix $\mathbf{D}$ has become clear. The cycles and chains recovered from this decomposition found many uses in attributing topological features to the input data [11, 9, 24]. However, it is not immediately clear from the algorithm in [21] how to recover the matrices $\mathbf{R}$ and $\mathbf{V}$ necessary in applications. Rather than deconstructing the algorithm of Milosavljevic et al. [21], we simplify it for the case of ordinary persistence.

We describe how to compute two different forms of the $\mathbf{R} = \mathbf{DV}$ decomposition that come up in applications – lazy and exhaustive reductions. This allows us to recover specific cycle representatives in matrix multiplication time. As a benefit, due to its simpler setting, the algorithms in this paper are greatly simplified compared to [21]. Finally, using Dey and Hou's fast zigzag construction [13], which reduces computation of zigzag persistence to ordinary persistence; the algorithms in this paper give another way to compute zigzag persistence in matrix multiplication time.

2 Preliminaries

We are concerned with the persistent homology of a filtration, an increasing sequence of simplicial complexes indexed by the natural numbers $\mathbb{N}$:

$$\emptyset = K_0 \subset K_1 \subset \ldots \subset K_N = K$$

While persistent homology can be defined more generally, from an algorithmic perspective this is sufficiently general as nearly all considered cases may be reduced to this setting. We further assume that $|K_i - K_{i-1}| = 1$, or equivalently that the filtration is a total order, i.e., each step in the filtration adds a single cell. If the initial filtration does not satisfy this requirement, and defines only a partial order, we may always extend it to an arbitrary compatible total order, e.g., breaking ties by lexicographical ordering and dimension.

Notation. Throughout, we use the following notation:

- Matrices are denoted by bold capital letters, e.g., $\mathbf{M}$, with sub-matrices indexed by square brackets, e.g., the j-th column is $\mathbf{M}[\cdot, j]$, the i-th row is $\mathbf{M}[i, \cdot]$.
- Indexing starts at 1 and indices may be indexed by sets, e.g., $A = \{1, \ldots, k\}$, $\mathbf{M}[\cdot, A]$ refers to the first k columns. Note that the set may not refer to contiguous columns/rows.
- We consider permutations implicitly, so $(\mathbf{P} \cdot \mathbf{M})[A, \cdot]$ refers to the rows indexed **after** the permutation $\mathbf{P}$ is applied to matrix $\mathbf{M}$. For all the algorithms, performing an explicit permutation, then undoing it, does not affect the asymptotic running time.

2.1 Persistence Algorithm

For completeness, we recount the standard persistence algorithm, see [15], [27], and [16] for a more complete description. Let $\mathbf{D}$ denote the boundary operator, which we represent as an $n \times n$-matrix over some fixed (finite) field $\mathbb{F}$. The rows (top-down) and columns (left-right) are ordered by appearance in the filtration. Hence, the i-th row and column represents the simplex $\sigma = K_i - K_{i-1}$ and $\mathbf{D}[\cdot, i]$ represents the boundary of σ respectively. The goal is to compute the $\mathbf{RV}$-decomposition [8]. That is, find matrices $\mathbf{R}$ and $\mathbf{V}$ such that

$$\mathbf{R} = \mathbf{D} \cdot \mathbf{V},$$

where $\mathbf{R}$ is a matrix in reduced column echelon form and $\mathbf{V}$ is a full-rank upper-triangular matrix; we let $\mathbf{U} = \mathbf{V}^{-1}$. We introduce the helper function

$$\mathbf{low}(j) = \arg\max_i \mathbf{R}[i, j] \neq 0,$$

which is defined whenever $\mathbf{R}[\cdot, j] \neq \mathbf{0}$. When defined, it returns the largest row index i where the column is non-zero; we refer to these lowest non-zero elements as **pivots**. Throughout this paper, **low** always applies to $\mathbf{R}$. The persistence diagram is then given by:

$$\text{dgm} = \{(i, j) \mid i = \mathbf{low}(j)\} \cup \{(i, \infty) \mid \mathbf{R}[\cdot, i] = \mathbf{0} \text{ and } i \neq \mathbf{low}(j)\ \forall j\}. \tag{1}$$

Algorithm 1 Standard Persistence Algorithm (Lazy reduction).

```
R = D
V = I_n, U = I_n
for j = 1 to n do
    while R[·, j] ≠ 0 and ∃j′ < j such that low(j) = low(j′) do
        i ← low(j)
        α ← R[i, j]/R[i, j′]
        R[·, j] ← R[·, j] − α · R[·, j′]
        V[·, j] ← V[·, j] − α · V[·, j′]
        U[j′, ·] ← U[j′, ·] + α · U[j, ·]        (equivalently, U[j′, j] ← α)
```

The standard algorithm is a variant of Gaussian elimination. Algorithm 1, which we call the **lazy reduction**, reduces each column by considering pivots in the columns to the left. In each step of the loop, it removes the lowest non-zero entry until a new pivot is found or the entire column is zeroed out. A straightforward analysis gives a running time bound of $O(n^3)$. In [22], a filtration where this algorithm takes cubic time was given, showing that the bound is tight. The updates of matrix $\mathbf{V}$ follow those of matrix $\mathbf{R}$. The updates in matrix $\mathbf{U}$ undo the updates in $\mathbf{V}$ to maintain $\mathbf{U} \cdot \mathbf{V} = \mathbf{I}$. Because the columns of $\mathbf{R}$ are processed from left to right, during the update of matrix $\mathbf{U}$, the row $\mathbf{U}[j, \cdot]$ has a single (diagonal) element. Therefore, the update in $\mathbf{U}$ is equivalent to just setting the entry $\mathbf{U}[j', j]$ to α.

Algorithm 2 "Look-ahead" Variant of Standard Persistence (Exhaustive reduction).

```
R = D
V = I_n, U = I_n
for j = 1 to n do
    if low(j) is defined then
        i ← low(j)
        for j′ > j and R[low(j), j′] ≠ 0 do
            α ← R[i, j′]/R[i, j]
            R[·, j′] ← R[·, j′] − α · R[·, j]
            V[·, j′] ← V[·, j′] − α · V[·, j]
            U[j, ·] ← U[j, ·] + α · U[j′, ·]        (not the same as U[j, j′] ← α!)
```

We introduce another variant of persistence computation used in applications. This one "looks ahead" and eliminates as many elements from the matrix as it can; so we call it the **exhaustive reduction**. In Algorithm 2, by the time a column is considered, it is already reduced. It is then applied to all columns to the right, zeroing out the entire row. In this way, when a column is processed, all previous pivots have already been applied. Because column $\mathbf{R}[\cdot, j']$ may have already been used to reduce another column $\mathbf{R}[\cdot, j'']$, when an update is applied to it, the row $\mathbf{U}[j', \cdot]$ need not consist of a single diagonal element. Hence, the row update in matrix $\mathbf{U}$ is not equivalent to just setting $\mathbf{U}[j, j']$ to α, like in the lazy version of the algorithm.

Lazy vs. Exhaustive. The algorithms based on the two reductions are in a sense the extreme cases: lazy reduction reduces columns only when necessary; and the exhaustive reduction reduces them as much as possible. To illustrate the difference, in the exhaustive reduction, the entire row to the right of a pivot will be zeroed out, whereas in the case of the lazy

reduction, only those columns will be zeroed out which have a conflicting pivot in the same row. There are, of course, any number of possible other reductions between these – but we do not know of any applications that rely on them.

▶ Remark 1. As noted in [10, Section 3.4], persistent cohomology can be computed by performing the same algorithm on the anti-transpose of $\mathbf{D}$. As such all the algorithms in this paper can compute persistent cohomology.

2.2 Cycle Representatives

Given an $\mathbf{R} = \mathbf{DV}$ decomposition, we distinguish between two types of simplices in the filtration: *positive* simplices create new homology classes; *negative* simplices destroy them. From the matrix decomposition, one can recover a set of cycle representatives of persistent homology. There are two sources of this information, although with different content.

1. $\mathbf{V}$ matrix: The columns of positive simplices in $\mathbf{V}$ correspond to zero columns in the reduced matrix $\mathbf{R}$. These columns in $\mathbf{V}$ are cycles, by definition.
2. $\mathbf{R}$ matrix: The columns of negative simplices in $\mathbf{R}$ are non-zero. They store linear combinations of boundaries, which are cycles (at the time of their birth) that eventually die in the filtration.

The cycles one recovers from matrix $\mathbf{R}$ differ between the lazy and exhaustive reductions. Exhaustive reduction was called total reduction by Cohen-Steiner et al. [9]. They show that these cycles form a lexicographically optimal basis, which can be used to triangulate point cloud data. Nigmetov and Morozov [24] use the lazy reduction – specifically, the columns and rows from matrices $\mathbf{V}$ and $\mathbf{U}$ – to recover "critical sets," subsets of simplicial complexes affected by optimization with the loss formulated in terms of a persistence diagram.

Minimum Spanning Acycle Basis. The negative simplices in the filtration represent a minimal spanning acycle (MSA) [19, 25]. The columns in $\mathbf{V}$ obtained from either lazy or exhaustive reduction – or any reduction that never adds columns of positive simplices to other columns – have the form $\sum_{\tau \in MSA} \lambda_\tau \tau + \lambda_\sigma \sigma$. The support of the chain is one (positive) simplex σ plus a linear combination of simplices in the minimum spanning acycle.

▶ **Lemma 2.** *The representatives from* $\mathbf{V}$ *are the same for lazy and exhaustive reduction.*

Proof. Which columns of $\mathbf{R}$ are non-zero does not depend on the algorithm used; the set of negative simplices only depends on the order of the filtration. We observe that the boundaries of the negative simplices form a basis (since their pivots are in distinct rows). By definition, the boundary of a positive simplex may be expressed as a linear combination of boundaries of negative simplices. Since the boundaries of the negative simplices form a basis, this linear combination is unique. ◀

Death Basis. An alternative is to get cycle representatives directly from the $\mathbf{R}$ matrix. Its non-zero columns represent cycles because multiplying $\mathbf{D} \cdot \mathbf{R} = 0$. This follows directly since $\mathbf{R} = \mathbf{D} \cdot \mathbf{V}$, so $\mathbf{D} \cdot \mathbf{R} = \mathbf{D} \cdot \mathbf{D} \cdot \mathbf{V} = 0$, since $\mathbf{D} \cdot \mathbf{D} = 0$. These columns give cycle representatives for all finite classes, i.e., those homology classes that eventually die.

▶ Remark 3. Following [10], this may be used for cohomology – applying the algorithms to $\mathbf{D}^\perp$, the anti-transpose of $\mathbf{D}$ to obtain the decomposition $\mathbf{R}^\perp = \mathbf{D}^\perp \cdot \mathbf{V}^\perp$. The cocycle representatives are then given by columns in $\mathbf{V}^\perp$. To see that these are cocycles, observe that by construction, they map to zero via the coboundary operator $\mathbf{D}^\perp$ before the corresponding

death time, i.e., below the pivot in the corresponding column of $\mathbf{R}^\perp$, as we have reversed the indexing with the anti-transpose. Likewise, the cocycle representatives of essential cocycles are given by the columns of $\mathbf{V}^\perp$ whose: corresponding columns in $\mathbf{R}^\perp$ are zero *and* they must not be coboundaries, i.e., the corresponding rows in $\mathbf{R}^\perp$ must not contain pivots.

3 Matrix Preliminaries

We recount a few classical results on matrix multiplication. We assume the matrices are over some field $\mathbb{F}$.

▶ **Lemma 4.** *Let $\mathbf{B}$ be an $n \times k$ matrix and $\mathbf{C}$ be a $k \times k$ matrix. The product $\mathbf{B} \cdot \mathbf{C}$ can be computed in $O(nk^{\omega-1})$-time.*

Proof. Divide $\mathbf{B}$ into $\lceil \frac{n}{k} \rceil$ sub-matrices $\mathbf{B}_i$ of size $k \times k$:

$$\mathbf{B} \cdot \mathbf{C} = \begin{bmatrix} \mathbf{B}_1 \\ \vdots \\ \mathbf{B}_{\lceil n/k \rceil} \end{bmatrix} \cdot \mathbf{C} = \begin{bmatrix} \mathbf{B}_1 \cdot \mathbf{C} \\ \mathbf{B}_2 \cdot \mathbf{C} \\ \vdots \\ \mathbf{B}_{\lceil n/k \rceil} \cdot \mathbf{C} \end{bmatrix}$$

Each $\mathbf{B}_i \cdot \mathbf{C}$ is a product of two $k \times k$ matrices, which by definition takes $O(k^\omega)$ time. There are $\lceil \frac{n}{k} \rceil$ products to compute yielding a running time of $O\left(\frac{n+1}{k} k^\omega\right) = O(nk^{\omega-1})$. ◀

Column Operations via Matrix Multiplication. Here we relate matrix multiplication with the reduction steps used in the persistence algorithms, i.e., representing column operations via matrix multiplication. Assume that we have the following block matrix,

$$\left[\begin{array}{c|c} \mathbf{B} & \mathbf{C} \end{array}\right] = \left[\begin{array}{ccc|ccc} b(1) & \dots & b(n) & c(1) & \dots & c(m) \end{array}\right]$$

where $b(i)$ and $c(j)$ are (column) vectors. Reducing $c(j)$ which we denote $c'(j)$, using the vectors $b(i)$, is expressed as a linear combination

$$c'(j) = c(j) + \sum_i \lambda_i(j) b(i),$$

where $\lambda_i(j)$ are the coefficients. Reducing only the j-th column of $\mathbf{C}$ may be written as

$$\begin{bmatrix} \mathbf{B} & c'(j) \end{bmatrix} = \begin{bmatrix} \mathbf{B} & c(j) \end{bmatrix} \cdot \begin{bmatrix} \mathbf{I} & \lambda(j) \\ 0 & \mathbf{1}_j \end{bmatrix},$$

where $\mathbf{1}_j$ is a column vector where the j-th entry is 1 and zero everywhere else. If we consider $\mathbf{\Lambda}[i,j] := \lambda_i(j)$, we can rewrite the reduction of $\mathbf{C}$ by

$$\begin{bmatrix} \mathbf{B} & \mathbf{C}' \end{bmatrix} = \begin{bmatrix} \mathbf{B} & \mathbf{C} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{I} & \mathbf{\Lambda} \\ 0 & \mathbf{I} \end{bmatrix},$$

or equivalently, the reduced matrix is $\mathbf{C}' = \mathbf{C} - \mathbf{B} \cdot \mathbf{\Lambda}$.

▶ **Lemma 5.** *Multiplying a permutation matrix with an $n \times m$ matrix, takes $O(nm)$ time.*

Proof. As a permutation matrix rewrites each element once, the total number of elements gives the bound. ◀

4 Column Algorithms

Here we describe the algorithm in [21] for the special case of classical persistent homology. To aid in exposition, we first recall the **Schur complement**. Given a block matrix

$$\begin{bmatrix} \mathbf{B}_1 & \mathbf{C}_1 \\ \mathbf{B}_2 & \mathbf{C}_2 \end{bmatrix},$$

assuming $\mathbf{B}_2$ is non-singular, we can compute an updated matrix where the rows corresponding to $\mathbf{B}_2$ are zeroed out by the following transformation:

$$\begin{bmatrix} \mathbf{B}_1 & \mathbf{C}_1 \\ \mathbf{B}_2 & \mathbf{C}_2 \end{bmatrix} \begin{bmatrix} \mathbf{I} & -\mathbf{B}_2^{-1}\mathbf{C}_2 \\ 0 & \mathbf{I} \end{bmatrix} = \begin{bmatrix} \mathbf{B}_1 & \mathbf{C}_1 - \mathbf{B}_1\mathbf{B}_2^{-1}\mathbf{C}_2 \\ \mathbf{B}_2 & 0 \end{bmatrix} \tag{2}$$

where $\mathbf{C}_1 - \mathbf{B}_1\mathbf{B}_2^{-1}\mathbf{C}_2$ is referred to as the Schur complement.

▶ **Observation 6.** *The matrix $\mathbf{B}_2^{-1}\mathbf{C}_2$ encodes the column operations required to zero out $\mathbf{C_2}$, that is, $\mathbf{B}_2^{-1}\mathbf{C}_2 = \mathbf{\Lambda}$.*

A key fact we will use in the algorithm is that matrix inversion has the same algorithmic complexity as matrix multiplication.

▶ **Theorem 7.** *Inverting a (square) non-singular (upper or lower) triangular matrix can be done in matrix multiplication time.*

Proof. See [23, Appendix] for a simplified proof for the special case of triangular matrices. ◀

4.1 Fast Exhaustive Algorithm

Algorithm 3 Column Algorithm($A = [i, j]$).

```
1:  if i = j then                                                    ▷ leaf
2:      if R[·, i] = 0 then                                          ▷ If no pivot exists
3:          ℓ ← arg min_{ℓ>n} R[·, ℓ] ≠ 0                            ▷ find the next pivot in I_{m+n}
4:          Permute columns i and ℓ
5:          Z ← Z ∪ i
6:  else
7:      B ← [i, (i + j)/2)                                           ▷ left child
8:      C ← [(i + j)/2, j]                                           ▷ right child
9:      Recurse on B
10:     Apply updates from columns B to C:
11:         L ← ⟨low(ℓ) : ℓ ∈ B⟩          ▷ Implicit permutation; L preserves order
12:         Λ ← R[L, B]^{-1} · R[L, C]                               ▷ A_2^{-1} B_2
13:         R[L̄, C] ← R[L̄, C] − R[L̄, B] · Λ   ▷ Apply B to C; Schur update (k × k) · (k × n)
14:         R[L, C] = 0
15:         V[·, C] ← V[·, C] − V[·, B] · Λ                          ▷ Matching update in V
16:     Recurse on C
```

We present a fast version of exhaustive reduction in Algorithm 3. The general structure follows Algorithm 2. However, rather than apply the pivots when we find them, we apply them in batches via the Schur complement through a standard recursion. We first augment

the boundary matrix with an identity matrix, which is of size at least n, for reasons we shall describe below. To simplify notation, we assume n is a power of 2. If it is not, we can set the size of the identity matrix to $m+n$ with $m < n$ such that $m + 2n = 2^x$. Therefore, our initial matrices are:

$$\mathbf{R} = \begin{bmatrix} \mathbf{D} & 0 \\ 0 & \mathbf{I}_{m+n} \end{bmatrix}, \qquad \mathbf{V} = \mathbf{I}_{m+2n}.$$

Throughout the algorithm, we implicitly perform two types of permutations by taking appropriate subsets of rows and columns. The first are column permutations. To ensure that the appropriate submatrices are invertible, we require that after processing k columns of $\mathbf{R}$, there are k pivots, or, equivalently, that the matrix corresponding to the processed columns is full (column) rank. Because cycles reduce to zero columns, the if-statement in Algorithm 3 permutes a zero column from $\mathbf{R}$ with a non-zero column from the identity matrix $\mathbf{I}_{m+n}$, and records the indices of such columns in list Z, to eventually undo the permutation.

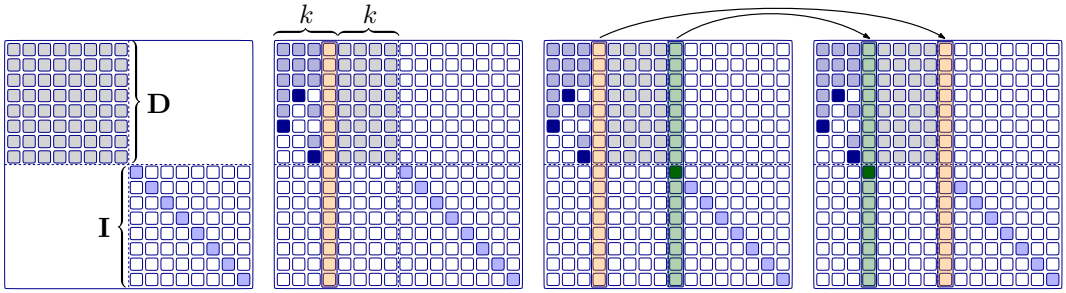

Figure 1 An example of the column permutation in the exhaustive algorithm. (a) Initially, we append an identity matrix to the boundary matrix. (b) Assume we have processed the first k columns. The blue entries represent non-zero entries, and the dark blue boxes represent the pivots. To apply these pivots to next k columns (shown in gray), the first k columns must contain k pivots. (c-d) If there is a a zero column (shown in orange), we transpose it with the first non-zero entry in the appended identity matrix, ensuring the processed k columns all have pivots.

We must also consider row permutations. To apply Theorem 7, we must find the inverse $\mathbf{R}^{-1}[L, B]$ in Algorithm 3, which is used in the Schur complement. We construct a sequence $L = \langle \mathbf{low}(\ell) : \ell \in B \rangle$ of the pivot rows in columns B. Denoting by $\bar{L}$ the sequence of rows outside of L, we denote a permutation that places rows L below $\bar{L}$ as $\mathbf{P}_L$:

$$(\mathbf{P}_L \cdot \mathbf{R}) = \begin{bmatrix} \mathbf{R}[\bar{L}, \cdot] \\ \mathbf{R}[L, \cdot] \end{bmatrix}. \tag{3}$$

See Figure 2(b-c). The permutation is explicitly given by,

$$P_L : \mathbf{low}(B(i)) \mapsto m + n - |B| + i \qquad \text{for } i = 1, \ldots, |B|$$

where $B(i)$ is the i-th entry of the indices in B.

▶ **Lemma 8.** *After permuting the rows by $\mathbf{P}_L$, the bottom-left $k \times k$ matrix is lower triangular, where $k = |L|$.*

We delay the proof until after the description of the algorithm. We now follow a recursion: we split matrix $\mathbf{R}$ into the first half of the columns denoted by B and the second half denoted by C. We proceed to call the algorithm on the first half of the matrix. Once we reach a

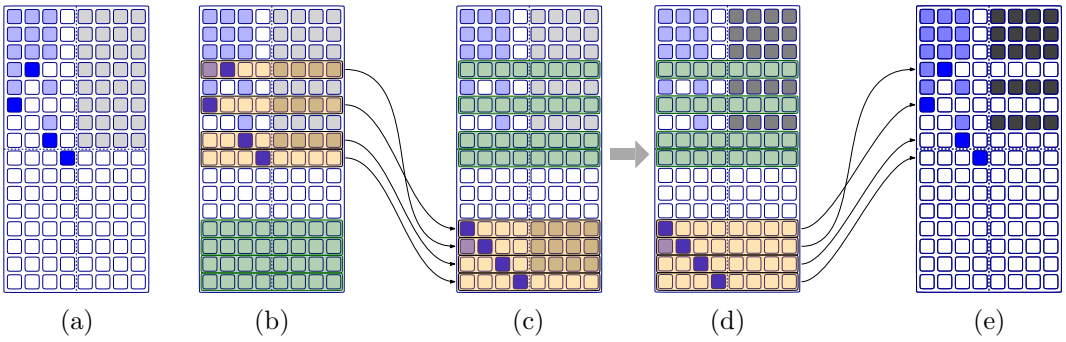

Figure 2 An example of the row permutations. (a) A submatrix consisting of 8 columns where the 4 columns on the left have been reduced, and we need to apply the pivots to the following 4 columns (in gray). (b-c) Each row which has a pivot gets permuted to the bottom of the matrix in the same order as the columns – resulting in a lower triangular matrix. (d) Applying the Schur complement zeros out the gray entries on the bottom right and we update the entries in the upper right (dark gray). (e) With the pivot rows zeroed out on the right, we reverse the permutation.

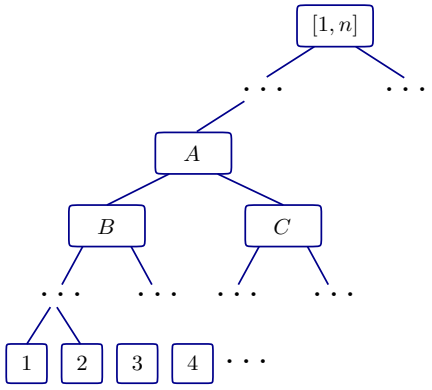

Figure 3 The standard binary recursion tree in how we split the matrix by column. Observe that $|B| = |C| = |L|$ in Algorithm 3 and that $\mathbf{R}[L, B] = (\mathbf{P}_L \cdot \mathbf{R})[\{n - |B| + 1, \ldots, n\}, B]$, the bottom $|B|$ rows in the permuted matrix.

leaf in the recursion tree (shown in Figure 3), the matrix consists of a single column. The key invariant is that whenever we reach a leaf, the corresponding column is reduced with respect to all the columns which come prior to it in the filtration. For the first column, this is tautologically true and we delay the proof for the general case until later.

If we are not in the base case (a single column), we must apply the pivots in the columns indexed by B (left half of the submatrix) to the the columns indexed by C (right half of the submatrix). As described in Equation (3), we construct the permutation $\mathbf{P}_L$ such that

$$(\mathbf{P}_L \cdot \mathbf{R})[\cdot, B \cup C]) = \begin{bmatrix} \mathbf{R}[\bar{L}, B] & \mathbf{R}[\bar{L}, C] \\ \mathbf{R}[L, B] & \mathbf{R}[L, C] \end{bmatrix}$$

By construction of $\mathbf{P}_L$, $\mathbf{R}[L, B]$ is lower-triangular with non-zero diagonal entries and so is full-rank. We can then apply the Schur complement to zero out all the corresponding rows in the columns C, $\mathbf{R}[L, C] \leftarrow 0$ and update the rest of the rows:

$$\underbrace{\mathbf{R}[\bar{L}, C]}_{\mathbf{C}_1} \leftarrow \underbrace{\mathbf{R}[\bar{L}, C]}_{\mathbf{C}_1} - \underbrace{\mathbf{R}[\bar{L}, B]}_{\mathbf{B}_1} \cdot \underbrace{\mathbf{R}[L, B]^{-1}}_{\mathbf{B}_2^{-1}} \cdot \underbrace{\mathbf{R}[L, C]}_{\mathbf{C}_2} = \mathbf{R}[\bar{L}, C] - \mathbf{R}[\bar{L}, B] \cdot \mathbf{\Lambda}$$

To update matrix $\mathbf{V}$, we perform the same operations $\mathbf{\Lambda} = \mathbf{R}[L, B]^{-1} \cdot \mathbf{R}[L, C]$ on $\mathbf{V}$:

$$\mathbf{V}[\bar{L}, C] \leftarrow \mathbf{V}[\bar{L}, C] - \mathbf{V}[\bar{L}, C] \cdot \mathbf{\Lambda}$$

Once the left half of the matrix has been applied to the right half, we recurse on the second half, i.e., C. Here again, because $\mathbf{R}[L, B]$ is lower-triangular full-rank and $\mathbf{R}[L, C] = 0$, the first column of $\mathbf{R}[\cdot, C]$ is reduced. We now prove correctness.

▶ **Lemma 9.** *When the recursion base case is reached for column k, $\mathbf{R}[\mathbf{low}(j), k] = 0$ for all $j < k$.*

Proof. For $k = 1$, this is tautological since $\mathbf{low}(j)$ is empty. For $k > 1$, we observe that entry $\mathbf{R}[\mathbf{low}(i), k]$ was made zero when $i \in B$ and $k \in C$. As the recursion always splits the column range in half, this condition must be satisfied somewhere in the recursion before the base case of k is reached. ◀

Proof of Lemma 8. We observe that when $\mathbf{P}_L$ is applied, the columns corresponding to L have a pivot. By construction, $\mathbf{P}_L$ places the pivots onto the diagonal in the bottom $|L|$ rows. For any of these rows above the diagonal, the entries are 0 by Lemma 9, implying the bottom $k \times k$ matrix is lower triangular. ◀

▶ **Theorem 10.** *Algorithm 3 computes the persistence diagram correctly.*

Proof. By Equation (1), it suffices to show that for all i, $\mathbf{low}(i)$ is computed correctly. For $i = 1$, this is trivially true. For $i > 1$, observe that at any step of the algorithm, we maintain

$$\mathbf{R} = \mathbf{D} \cdot \mathbf{V},$$

as any operations on $\mathbf{R}$ are applied to $\mathbf{V}$. Assuming the pivots are correct for $j < i$, by the above and Lemma 9, $\mathbf{V}$ gives a transformation depending only on columns $j < i$, such that all elements in $\mathbf{R}[\mathbf{low}(j), i] = 0$. If $\mathbf{low}(i)$ does not exist, $D[\cdot, i]$ was in the span of the previous columns and hence a cycle. If $\mathbf{low}(i)$ exists, it is distinct from $\{\mathbf{low}(j)\}_{j<i}$ and so we have a new pairing. The correctness of this pairing follows from the Pairing Uniqueness Lemma [8]. ◀

Running Time Analysis. The base case takes $O(1)$ time. For a general step where $|B| = |C| = k$, applying the update requires a row permutation of a $2n \times 2k$ matrix which takes $O(nk)$ time. We must compute $\mathbf{R}[L, B]^{-1}$ which is inverting a $k \times k$ matrix. Multiplying it with $\mathbf{R}[L, C]$ takes $O(k^\omega)$ time as both are $k \times k$ matrices. Finally, we multiply this product with the $n \times k$ matrix $\mathbf{R}[\bar{L}, C]$, which by Lemma 4, takes $O(nk^{\omega-1})$ time. Solving the recursion, we find that the total running time is $O(n^\omega)$ for $\omega > 2$ or $O(n^2 \log n)$ if $\omega = 2$. For completeness, we include the derivation in the full version [23].

5 Row Algorithm

While Algorithm 3 produces the exhaustive reduction in matrix multiplication time, a natural question is whether the same can be done for computing the lazy reduction (and its representatives). In this section, we present an algorithm which achieves this. We first give the iterative version before describing how it can be computed in $O(n^\omega)$. The idea behind this reduction is to consider rows from the bottom up. Observe that a pivot in the bottom row can be directly identified in $\mathbf{D}$ as the earliest (leftmost) non-zero entry, similarly as the

Algorithm 4 Incremental Row Algorithm.

```
1: R = D
2: V = I_n, U = I_n
3: for i = n to 1 do
4:     if lft(i) is defined then
5:         j ← lft(i)
6:         for j' > j and low(j') = i do
7:             α ← R[i, j']/R[i, j]
8:             R[·, j'] ← R[·, j'] − α · R[·, j]
9:             V[·, j'] ← V[·, j'] − α · V[·, j]
10:            U[j, ·] ← U[j, ·] + α · U[j', ·]        (equivalently, U[j, j'] ← α)
```

pivot in the first column can be directly identified. To formalize the notion of the earliest eligible pivot in a given row, we define

$$\mathbf{lft}(i) = \arg\min_j \{\mathbf{R}[i,j] \neq 0 : \mathbf{low}(j) = i\}$$

As in the case of **low**, we only apply this function to $\mathbf{R}$. The function **lft** returns the earliest column j which is non-zero and is the lowest such non-zero entry in its column. This condition is important as the earliest (left-most) non-zero entry may have pivots below it. This column is used to zero out the i-th row in columns to the right provided they do not already contain a pivot, i.e., if $\mathbf{low}(j) = i$, then the column is applied. This condition is why we obtain equivalence with the lazy reduction – we do not apply the pivot column to later columns which already contain a pivot.

▶ **Lemma 11.** *Algorithm 4 produces the same decomposition as the lazy reduction.*

Proof. This is equivalent to [10, Theorem 3.1]. ◀

5.1 Fast Row Algorithm

The fast version of Algorithm 4 is given in Algorithm 5. As above, it reduces the matrix row by row from the bottom up. This variant does not require matrix inversion and requires less padding. The trade-off is that it requires a more complex sequence of updates. Assuming $\mathbf{D}$ is an $n \times n$ matrix, we set $m < n$ such that $m + n = 2^x$. We initialize our matrices as:

$$\mathbf{R} = \left[\begin{array}{c|c} \mathbf{D} & \\ \mathbf{0}_m & \mathbf{I}_{m+n} \end{array}\right], \qquad \mathbf{\Lambda} = \mathbf{I}_{m+n}.$$

To simplify notation, from this point on, we assume n is a power of 2 (as $m + n < 2n$), so the resulting matrix is $\begin{bmatrix}\mathbf{D} & \mathbf{I}_n\end{bmatrix}$. This ensures that $\mathbf{lft}(i)$ is defined for all i in $\mathbf{R}$, i.e., the identity matrix ensures there are no zero rows.

It will be convenient to again consider permutations, but here they will be column permutations. We build up the permutation incrementally. In the i-th step, we update the permutation with the column transposition

$$\pi(i) : \mathbf{lft}(n - i + 1) \leftrightarrow i.$$

Algorithm 5 Row Algorithm($A = [i, j]$).

if $i = j$ **then** ▷ *leaf*
  $k \leftarrow \mathbf{lft}(n - i + 1)$ ▷ *Identify the pivot in row* $(n - i + 1)$
  Update permutation matrix $\mathbf{P}$ with transposition $i \leftrightarrow k$.
  $(\mathbf{P}\cdot\mathbf{\Lambda}\cdot\mathbf{P})[i, j] \leftarrow -\frac{(\mathbf{R}\cdot\mathbf{P})[n-i+1,j]}{(\mathbf{R}\cdot\mathbf{P})[n-i+1,i]}$ for $j > i$.
  $(\mathbf{R}\cdot\mathbf{P})[n - i + 1, \{i + 1, \ldots, n\}] \leftarrow 0$ ▷ *Zero out* $(n - i + 1)$*-st row; see Remark 12*
else
  $B \leftarrow [i, (i + j)/2)$ ▷ *left child*
  $C \leftarrow [(i + j)/2, j]$ ▷ *right child*
  $C_r \leftarrow n - C + 1$ ▷ *Rows are indexed top-down but the algorithm goes bottom up*
  Recurse on B
  Apply updates from rows B to C: ▷ *full row update;* $(k \times k) \cdot (k \times n)$
    $(\mathbf{R}\cdot\mathbf{P})[C_r, \cdot] \leftarrow (\mathbf{R}\cdot\mathbf{P})[C_r, \cdot] + (\mathbf{R}\cdot\mathbf{P})[C_r, B])(\mathbf{P}\cdot\mathbf{\Lambda}\cdot\mathbf{P})[B, \cdot]$
  Recurse on C
  $\bar{A}_r = [1, i]$ ▷ *everything above A*
  Full column update:
    $(\mathbf{R}\cdot\mathbf{P})[\bar{A}_r, C] \leftarrow (\mathbf{R}\cdot\mathbf{P})[\bar{A}_r, C] + (\mathbf{R}\cdot\mathbf{P})[\bar{A}_r, B] \cdot (\mathbf{P}\cdot\mathbf{\Lambda}\cdot\mathbf{P})[B, C]$ ▷ $(n \times k) \cdot (k \times k)$

which we use a shorthand for the two mappings $\mathbf{lft}(n - i + 1) \mapsto i$ and $i \mapsto \mathbf{lft}(n - i + 1)$. As **lft** is always defined, two columns are permuted in each step. The permutation after i steps is then given by

$$\mathbf{P}_i = \prod_{j \le i} \pi(j).$$

Note that we apply the permutations in order, i.e., for $i = 1, 2, \ldots$ While the columns corresponding to $\mathbf{lft}(n - i + 1)$ are fixed at i for all permutations, the original column at i may be permuted several times. In the algorithm, we omit the subscript; $\mathbf{P}$ refers to the accumulated permutation. As in the case of the column algorithm, we perform the permutations implicitly. We observe that in the permuted order, we arrange pivots on the left along the anti-diagonal, see Figure 4.

We keep track of the operations directly in the matrix $\mathbf{\Lambda}$ which is initialized as the identity matrix. Before delving into the details of the algorithm, assume that the all rows below the i-th row have been reduced. The updates in the i-th row are given by

$$(\mathbf{P} \cdot \mathbf{\Lambda} \cdot \mathbf{P})[i, j] = \begin{cases} -\frac{(\mathbf{R}\cdot\mathbf{P})[n-i+1,j]}{(\mathbf{R}\cdot\mathbf{P})[n-i+1,i]} & j > i \\ 1 & n - i + 1 = j \\ 0 & \text{else} \end{cases}$$

We digress here to explain why this works. As mentioned above, if we consider the column-permuted matrix $\mathbf{R} \cdot \mathbf{P}$, it has the pivots in the bottom-left along the anti-diagonal (Figure 4). The i-th column corresponds to the column given by $\mathbf{lft}(n - i + 1)$ (in the original filtration order). Hence, it is the earliest column with a non-zero entry in the i-th row from the bottom such that there is no pivot below. For any non-zero entry to the right of i, it must occur to the right of i in the original filtration order (before permuting), or it would have been returned by $\mathbf{lft}(n - i + 1)$ rather than the current i-th column in the permuted order.

▶ Remark 12. Hence in Algorithm 5, all non-zeros in the row to the right of i are pivots (lowest entries), because every column with a pivot below $n - i + 1$ has been moved to the left of i in the permuted order and so no reduction will be applied, i.e., coefficient will be 0.

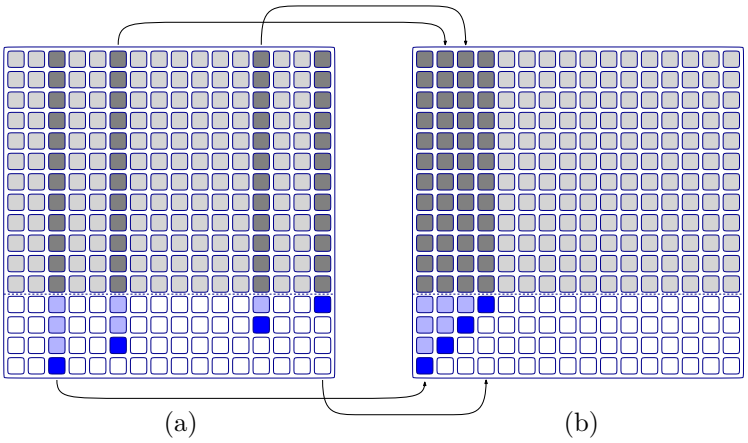

Figure 4 The permutation of the columns so that the pivots in the bottom k rows are on the right. An important observation is that despite this reshuffling of columns, because of the definition of $\mathbf{lft}(\cdot)$, we never "accidentally" reduce columns which occur earlier in the filtration order.

Finally, as we permute the columns we must also permute the rows of the $\mathbf{\Lambda}$ matrix so that the recorded column operations match. This represents the base case of the recursion. As $\mathbf{\Lambda}$ is initialized as the identity matrix, the case $n - i + 1 = j$ is taken care of implicitly.

Returning to the algorithm, we proceed by recursing as in the column algorithm, but on the rows rather than on the columns. We divide the rows of the sub-matrix into the top and bottom halves. We recurse first on the bottom half. Because the pivots are determined by rows below the current one, we can directly identify the pivot with $\mathbf{lft}$.

The base case is a single row. By assumption, rows below the current row have been updated. At row $n - i + 1$, we first find the left-most non-zero entry and perform a column permutation setting the column $\mathbf{lft}(n - i + 1)$ to the i-th column, making $\mathbf{R}[n - i, i]$ a pivot as required. By the reasoning above, we may zero out the row, recording the operations in $\mathbf{\Lambda}$ and we can update $(\mathbf{R} \cdot \mathbf{P})[n - i, \{i + 1, \ldots, n\}] \leftarrow 0$.

Though the recursion proceeds as in Algorithm 3, splitting the matrix into the indices in the "first half" and "second half," a complication is that the columns are processed left to right (same as the indexing), while the rows are processed bottom-up while being indexed top-down. Hence, we introduce:

$$C_r = n - C + 1,$$

by which we mean for any $i \in C$, $i \mapsto n - i + 1$. This indexes the rows from the bottom of the matrix as required by the algorithm. Returning to the recursion, once we processed the columns for B, we first apply the updates to the rows C_r,

$$(\mathbf{R} \cdot \mathbf{P})[C_r, \cdot] \leftarrow (\mathbf{R} \cdot \mathbf{P})[C_r, \cdot] + (\mathbf{R} \cdot \mathbf{P})[C_r, B] \cdot (\mathbf{P} \cdot \mathbf{\Lambda} \cdot \mathbf{P})[B, \cdot],$$

shown in orange in Figure 5. Note that though B_r is shown in Figure 5, it is not used explicitly in the algorithm as all the operations in those rows have already been performed. On the other hand, B in $(\mathbf{P} \cdot \mathbf{\Lambda} \cdot \mathbf{P})[B, \cdot]$ and in $(\mathbf{R} \cdot \mathbf{P})[C_r, B]$ do not need to be reversed, as they both represent column operations which are in the standard order. After this, the first row in C_r is now up-to-date with all operations from rows below it. This allows us to correctly identify $\mathbf{lft}$ for this row and perform the column transposition accordingly. Hence, when we recurse on C, the base case can be carried out.

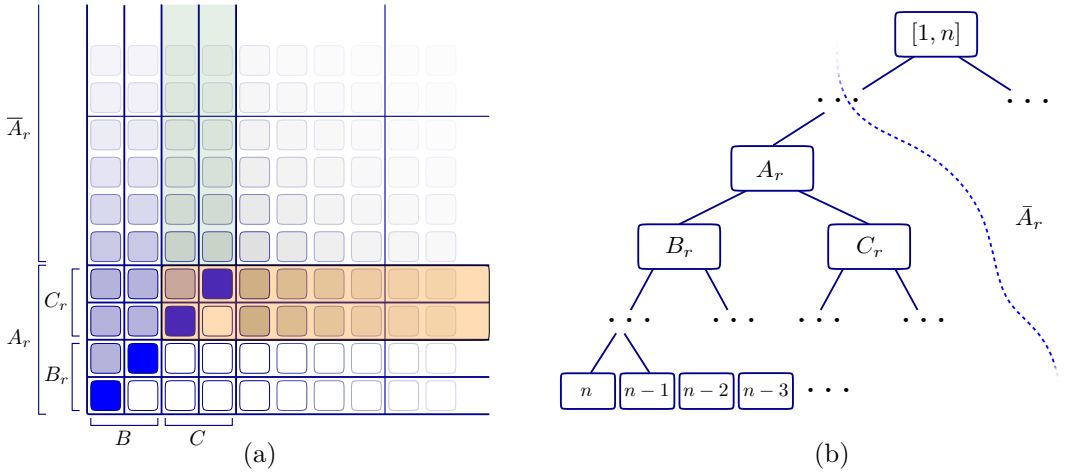

Figure 5 The updating steps in Algorithm 5. On the right we have the recursion tree for the rows, as opposed to the columns which is the same as in Figure 3 – as rows proceed bottom-up and columns proceed left to right. When we return from the recursion on B (or B_r), we have zeroed out all the entries to the right of columns B in rows B_r. We then first need to apply these to the rows in C_r (line 11 in Algorithm 5), shown in orange. We can then identify the correct pivot columns for rows C_r (after recursing), and complete the step by applying the operations from columns B to C above. This is shown in green – and corresponding to the right of $A_r = B_r \cup C_r$ in the recursion tree (the rows above A_r – denoted $\bar{A}_r$) to the right of the dashed line. This makes columns $B \cup C$ and rows A_r completely processed/reduced.

Returning from C, we complete the recursion by performing the update operations on the remaining parts of the columns in C, shown in green in Figure 5. Note, the columns are indexed by C not C_r. Let $\bar{A}_r = \{1, \dots, \min(C_r) - 1\}$. The column update is given as

$$(\mathbf{R} \cdot \mathbf{P})[\bar{A}_r, C] \leftarrow (\mathbf{R} \cdot \mathbf{P})[\bar{A}_r, C] + (\mathbf{R} \cdot \mathbf{P})[\bar{A}_r, B] \cdot (\mathbf{P} \cdot \mathbf{\Lambda} \cdot \mathbf{P})[B, C]$$

Now all columns prior to and including C and all rows below and including C_r are up to date. We show the update sequence in Figure 5 (omitting the permutations). Note that in the column update, the rows in $\bar{A}_r$ are correctly indexed, so no reversal is necessary.

▶ **Theorem 13.** *Algorithm 5 computes the lazy reduction.*

Proof. The algorithm is equivalent to Algorithm 4, but it performs the operations by batches. Observe that in the base case for row $n - i + 1$, the column operations recorded in $\mathbf{\Lambda}$ are equal to α in the i-th step of Algorithm 4. If we performed the operations on the entire column, we would, in fact, obtain exactly Algorithm 4 (since there would be no need for any further updates in the recursion).

Hence, to show correctness, we need to ensure that we can correctly compute $\mathbf{lft}(i)$ in each base case. This is trivially true in the first step. In further steps, we need to ensure that all the column operations have been applied to $(\mathbf{R} \cdot \mathbf{P})[C, \cdot]$. We can directly verify that any column operations coming from row $j < i$, fall in exactly one B (with i in C) in the recursion and hence are applied before the base case for i. It only remains to show that the columns $(\mathbf{R} \cdot \mathbf{P})[\cdot, C]$ are up to date before the columns operations from rows in C_r are applied in the appropriate rows of $(\mathbf{R} \cdot \mathbf{P})[\bar{A}_r, \cdot]$, which is done in line 14. ◀

▶ **Theorem 14.** *Matrix* $\mathbf{U} = 2 \cdot \mathbf{I} - \mathbf{\Lambda}$ *satisfies* $\mathbf{D} = \mathbf{R} \cdot \mathbf{U}$*, or equivalently,* $\mathbf{V} = \mathbf{U}^{-1}$*.*

Proof. During a regular reduction, Algorithm 4, updates in matrix $\mathbf{U}$ use row operations to "undo" the column operations in matrices $\mathbf{R}$ and $\mathbf{V}$. When a column j in $\mathbf{R}$ is subtracted from column j', which itself has not been used to reduce any other column, its corresponding row $\mathbf{U}[j', \cdot]$ contains a single diagonal element – compare the situations in Algorithms 1 and 2. In this case, the update in matrix $\mathbf{U}$ is equivalent to setting entry $\mathbf{U}[j', j]$ to the coefficient that is the negation of the coefficient used for the column update. When a column j in $\mathbf{R}$ is subtracted from column j', which itself has not been used to reduce any other column, its corresponding row $\mathbf{U}[j', \cdot]$ contains a single diagonal element.

Algorithm 5 satisfies this property (which is why it produces a lazy reduction): when an update is recorded in matrix $\mathbf{\Lambda}$, the column that is being updated has not yet been used to reduce any other column. Therefore, off the diagonal, the corresponding matrix $\mathbf{U}$ is the negation of matrix $\mathbf{\Lambda}$ – compare the coefficients in Algorithm 5 with α in Algorithm 4. On the diagonal, both $\mathbf{\Lambda}$ and $\mathbf{U}$ are all ones. So adding $2 \cdot \mathbf{I}$ to $-\mathbf{\Lambda}$ recovers $\mathbf{U}$. ◀

▶ Remark 15. As $\mathbf{U}$ is an upper triangular matrix, by Theorem 7, it can be inverted in $O(n^\omega)$-time as required.

Running Time Analysis. The base case takes $O(n)$ time as recording the permutation and zeroing out operations each take linear time. Hence the base case takes $O(n)$ time. For the general case, we need to first apply the column permutations. Since we are permuting at most an $n \times k$ (or $k \times n$) matrix, applying the permutation (and undoing it) takes $O(nk)$ time by Lemma 5. Next, applying the row updates from B_r to C_r, assuming $|B| = |C| = k$, requires multiplying $(\mathbf{P} \cdot \mathbf{\Lambda} \cdot \mathbf{P})[B, \cdot]$, a $k \times n$ matrix, with $(\mathbf{R} \cdot \mathbf{P})[C_r, B]$, a $k \times k$ matrix – taking $O(nk^{\omega-1})$ time by Lemma 4. To complete the update, the subtractions take $O(nk)$ time. To compute the column updates, we must multiply $(\mathbf{R} \cdot \mathbf{P})[\bar{A}_r, B]$, an $n \times k$ matrix with $(\mathbf{P} \cdot \mathbf{\Lambda} \cdot \mathbf{P})[B, C]$, a $k \times k$ matrix, which again takes $O(nk^{\omega-1})$ time. Putting these together, we find that the full step can be completed in $O(nk^{\omega-1})$ time and as in the column algorithm case, solving the recursion gives an $O(n^\omega)$ running time for $\omega > 2$ and a $O(n^2 \log n)$ running time for $\omega = 2$.

6 Discussion

In this paper, we have shown that in the case of persistent (co)homology, the standard bases returned by the exhaustive and lazy reductions can be computed in matrix multiplication time. It is worth noting that while both the columns and row algorithms utilize batch updates, they are qualitatively different: (1) Only the column algorithm critically relies on fast matrix inversion; (2) The row algorithm update sequence is substantially more complex but requires only column permutations. While one can use the column algorithm to compute the lazy basis and the row algorithm for the exhaustive basis in the same asymptotic running time, the resulting algorithms are both complex and not particularly illuminating. There are also numerous technical complications to deal with, so we omit them from this paper. Another outstanding issue is whether it is possible to transform the exhaustive representatives to lazy representatives and vice versa without redoing the reduction. Again, we believe this possible, but omit the details due to space and because the resulting asymptotic running time is the same. Finally, we conclude with an open question: what is the optimal running time for computing representatives in zigzag persistence. Recently, this has been partially addressed in [12, 14] but optimality in full generality remains open.

Abstract

The Betti tables of a multigraded module encode the grades at which there is an algebraic change in the module. Multigraded modules show up in many areas of pure and applied mathematics, and in particular in topological data analysis, where they are known as persistence modules, and where their Betti tables describe the places at which the homology of filtered simplicial complexes changes. Although Betti tables of singly and bigraded modules are already being used in applications of topological data analysis, their computation in the bigraded case (which relies on an algorithm that is cubic in the size of the filtered simplicial complex) is a bottleneck when working with large datasets. We show that, in the special case of 0-dimensional homology (relevant for clustering and graph classification) Betti tables of bigraded modules can be computed in log-linear time. We also consider the problem of computing minimal presentations, and show that minimal presentations of 0-dimensional persistent homology can be computed in quadratic time, regardless of the grading poset.

1 Introduction

Betti tables and persistence. Betti tables are a classical descriptor of a multigraded modules [18, 29, 34], which encode the grades of the generators in a minimal projective resolution of the module (see, e.g., Figure 1 and Example 15). Informally, one can interpret the Betti tables of a graded module as recording the grades at which there is an algebraic change in the module. Graded modules have applications in a wide variety of areas of pure and applied mathematics, including topological data analysis, and more specifically, persistence theory [33, 6], where they are known as *persistence modules*, and where they are used to describe the varying topology of simplicial complexes and other spaces as they are filtered by one or more real parameters.

Informally, *one-parameter persistence modules* correspond to $\mathbb{Z}$-graded $\Bbbk[x]$-modules, and can thus be classified up to isomorphism effectively. *Multiparameter persistence modules* [11, 6] correspond to $\mathbb{Z}^n$-graded $\Bbbk[x_1, \ldots, x_n]$-modules, and thus do not admit any reasonable classification up to isomorphism (formally, one is dealing with categories of wild representation type [31]; see [11, 2, 4] for manifestations of this phenomenon in persistence theory). For this reason, much of the research in multiparameter persistence is devoted to the study of incomplete descriptors of multiparameter persistence modules. Betti tables (also known as multigraded Betti numbers) provide one of the simplest such descriptors, and various properties of this descriptor from the point of view of persistence theory are well understood, including their effective computation [27, 25, 19, 3], their relationship to discrete Morse theory [22, 1, 21], their optimal transport Lipschitz-continuity with respect to perturbations [32], and their usage in supervised learning [28, 39].

Two-parameter persistent homology. The simplest case beyond the one-parameter case (i.e., the singly graded case) is the two-parameter case (i.e., the bigraded case). Here, one is usually given a finite simplicial complex K together with a function $f : K \longrightarrow \mathbb{R}^2$ mapping the simplices of K to $\mathbb{R}^2$, which is monotonic, i.e., such that $f(\sigma) \leq f(\tau)$ whenever $\sigma \subseteq \tau \in K$ (see Figure 1 for an example). By filtering K using f and taking homology in dimension $i \in \mathbb{N}$ with coefficients in a field $\Bbbk$, one obtains an $\mathbb{R}^2$-graded module, or equivalently, a functor $H_i(K, f; \Bbbk) : \mathbb{R}^2 \longrightarrow \mathbf{Vec}_{\Bbbk}$. Examples include geometric complexes of point clouds filtered by a function on data points, such as a density estimate [8, 12], and graphs representing, say, molecules or networks, filtered by two application-dependent quantities [15]. Applying homology to a bifiltered simplicial complex is justified by the fact that the output is automatically invariant under relabeling, meaning that any operation based on this module, such as computing its Betti tables, will result in a relabeling-invariant descriptor. In this setup, one of the main stability results of [32] implies that, for $f, g : K \longrightarrow \mathbb{R}^2$ any two monotonic functions, we have $\|\mu_f - \mu_g\|_1^{\mathsf{K}} \leq 2 \cdot \|f - g\|_1$, where $\| - \|_1^{\mathsf{K}}$ denotes the Kantorovich–Rubinstein norm between signed measures (also known as the 1-Wasserstein distance), and μ_f and μ_g are the signed measures on $\mathbb{R}^2$ obtained as the alternating sum of Betti tables of $H_i(K, f; \Bbbk)$ and $H_i(K, g; \Bbbk)$, respectively; see [28, Theorem 1] for details. The upshot is that the Betti tables of the homology of bifiltered simplicial complexes form a perturbation-stable, relabeling-invariant descriptor of bifiltered simplicial complexes.

The current standard algorithm for computing the Betti tables of $H_i(K, f; \Bbbk)$ in the two-parameter case is the Lesnick–Wright algorithm [27], which runs in time $O(|K|^3)$. Because of results such as those of [17], one does not expect to find algorithms with better worst-case time complexity than matrix-multiplication time, at least when $i \in \mathbb{N}$ is arbitrary. Current options to speed up practical computations include sparsifying the filtered complex before computing homology [42], as well as computational shortcuts that are known to significantly reduce computational time in practice [25, 3]. Nevertheless, computational cost is still a main bottleneck in real-world applications of persistence, limiting the size of the datasets on which it can be applied.

Zero-dimensional persistent homology. In many applications, persistent homology in dimension zero is all that is required, as it encodes information about the changes in connectivity of filtered simplicial complexes, making it useful for clustering [10, 9, 14, 8, 35, 38] and graph classification [41, 13, 24, 28, 23].

But, if one is only interested in 0-dimensional homology $H_0(K, f; \Bbbk)$, algorithms relying on linear algebra are usually far from the most efficient ones: For example, in the one-parameter case, the Betti tables of the 0-dimensional homology of an $\mathbb{R}$-filtered graph (G, f) can be

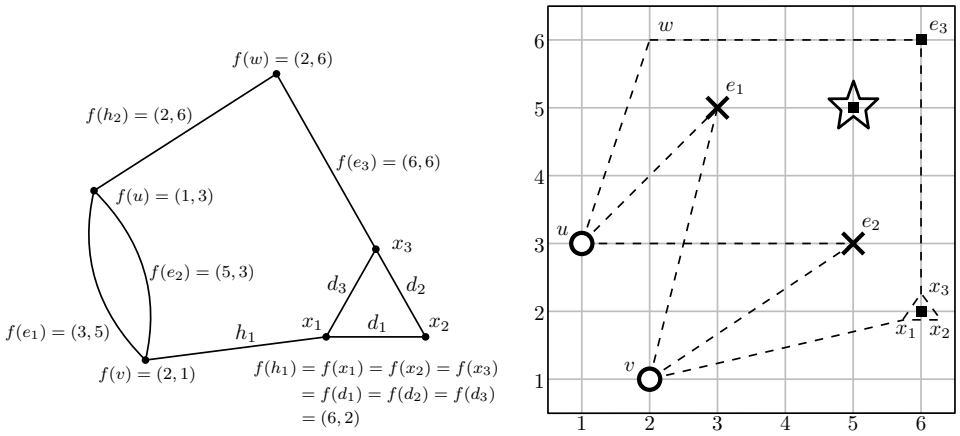

Figure 1 *Left.* A bifiltered graph (G, f) with vertex set $\{u, v, w, x_1, x_2, x_3\}$ and edge set $\{e_1, e_2, e_3, h_1, h_2, d_1, d_2, d_3\}$. *Right.* The bifiltered graph schematically mapped to $\mathbb{R}^2$, together with the Betti tables $\beta_0(H_0(G, f))$ (circles), $\beta_1(H_0(G, f))$ (crosses), $\beta_2(H_0(G, f))$ (stars), and $\beta_0(H_1(G, f))$ (squares).

computed in $O(|G| \log |G|)$ time by first sorting the simplices of G by their f-value, and then doing an ordered pass using a union-find data structure; in the language of barcodes, the Betti tables simply record the endpoints of the barcode, and the barcode can be computed using the elder rule (see [16, pp. 188] or [35, Algorithm 1]).

Contributions. The paper is concerned with the following question: What is the complexity of computing the Betti tables of graphs filtered by posets other than $\mathbb{R}$?

We introduce algorithms for the computation of a minimal set of generators and of a minimal presentation of 0-dimensional persistent homology indexed by an arbitrary poset.

▶ **Theorem A.** *Let $\mathcal{P}$ be any poset, and let (G, f) be a finite $\mathcal{P}$-filtered graph. Algorithm 2 computes the 0th Betti table of $H_0(G, f; \Bbbk)$ in $O(|G|)$ time. Algorithm 3 computes a minimal presentation (and hence the 0th and 1st Betti tables) of $H_0(G, f; \Bbbk)$ in $O(|G|^2)$ time.*

We also introduce a more efficient algorithm specialized to the two-parameter case, which computes all Betti tables, that is, 0th, 1st, and 2nd, by Hilbert's syzygy theorem.

▶ **Theorem B.** *Let (G, f) be a finite $\mathbb{R}^2$-filtered graph. Algorithm 4 computes minimal presentations and the Betti tables of $H_0(G, f; \Bbbk)$ and $H_1(G, f; \Bbbk)$ in $O(|G| \log |G|)$ time.*

Of note is the fact that Betti tables of 0-dimensional two-parameter persistent homology can be computed in log-linear time, as in the one-parameter case.

As another main contribution, we establish a connection between minimal presentations and connectivity properties of filtered graphs (Theorems 23 and 25), which allows us to abstract away the algebraic problem, and focus on a simpler combinatorial problem. The correctness of our algorithms is based on this. Another interesting consequence of these results is that, for arbitrary posets, the 0th and 1st Betti tables of 0-dimensional persistent homology are independent of the field of coefficients, while for the poset $\mathbb{R}^2$, all Betti tables of a filtered graph are independent of the field of coefficients.

Summary of approach and structure of the paper. The main body of the paper has three sections: one on background (Section 2), one on theoretical results (Section 3), and one on algorithms (Section 4). [30, Appendix A] contains proofs.

In order to describe and prove the correctness of our algorithms, we introduce, in the theory section, the notion of a *minimal filtered graph* (Definition 17). Informally, a minimal filtered graph is one whose vertices and edges induce a minimal presentation of its 0-dimensional persistent homology (see Theorem 23). A graph is not minimal if it has some edge that can be either contracted or deleted without changing its 0-dimensional persistent homology (for example, the graph of Figure 1 has both contractible and deletable edges, and is thus not minimal; see Examples 15 and 18). The idea is that, by contracting and deleting edges that do not change 0-dimensional persistent homology, one inevitably ends up with a minimal filtered graph, from which a minimal presentation can be easily extracted. Our main theoretical contributions (Theorems 23 and 25) make this idea precise by giving an explicit minimal presentation of H_0 of any minimal filtered graph, and an explicit minimal resolution of H_0 of any minimal $\mathbb{R}^2$-filtered graph. Our main algorithmic contributions are efficient algorithms for contracting and deleting edges as necessary. Algorithm 4 makes use of a dynamic tree data structure [40], which is the main ingredient that allows us to compute the Betti tables of bifilitered graphs in log-linear time; we give more details in Section 4.

Remark about multi-critical filtrations. The filtrations considered in this paper are 1-*critical*, meaning that each simplex (vertex or edge, in the case of graphs) appears at exactly one grade. In [30, Appendix B], we describe a simple preprocessing step to turn a finite multi-critical filtration by a lattice into a 1-critical filtration with the same 0-dimensional homology. In the two-parameter case, this construction does not change the input complexity, but for other lattices it may increase the input size. Note that the construction does not (necessarily) preserve 1-dimensional homology.

Related work. To the best of our knowledge, the only subcubic algorithm related to Algorithm 4 is that of [8], which, in particular, can be used to compute the Betti tables of H_0 of a function-Rips complex of a finite metric space X in time $O(|X|^2 \log |X|)$. When applied to a function-Rips complex, our Algorithm 4 has the same time complexity; however, our Algorithm 4 applies to arbitrary bifiltered graphs, while function-Rips complexes are very special (and do not include arbitrary filtered graphs). The inner workings of Algorithm 4 are also different from those of [8]: While we rely on dynamic trees, their algorithm relies on a dynamic minimum spanning tree, and, notably, on the fact that, in a function-Rips bifiltration, vertices are filtered exclusively by one of the two filtering functions (so that vertices are linearly ordered in the bifiltration).

The computation of minimal presentations of $\mathbb{R}^n$-filtered complexes is studied in [5]. Since they consider homology in all dimensions, their complexity is significantly worse than the quadratic complexity of Algorithm 3, which only applies to 0-dimensional homology.

Part of the contributions in this paper could be rephrased using the language of discrete Morse theory for multiparameter filtrations [1, 37, 7], specifically, Algorithms 1 and 2 are essentially computing acyclic matchings which respect the filtration. However, this point of view requires extra background, and, to the best of our understanding, cannot be used to describe the more interesting Algorithm 4.

2 Background

As is common in persistence theory, we assume familiarity with very basic notions of category theory, specifically, that of a category and of a functor. We let $\Bbbk$ denote a field, $\mathbf{Vec}_\Bbbk$ denote the category of $\Bbbk$-vector spaces, and $\mathbf{Set}$ denote the category of sets. When the field $\Bbbk$ plays no role, we may denote $\mathbf{Vec}_\Bbbk$ simply by $\mathbf{Vec}$. Proofs can be found in [30, Appendix A.1].

Graphs and filtered graphs. A *graph* $G = (V, E, \partial)$ consists of finite sets V and E, and a function $\partial : E \longrightarrow V \times V$. We refer to the elements of V as *vertices*, typically denoted $v, w, x, y \in V$, and to the elements of E as *edges*, typically denoted $e, d, h \in E$. If $\partial e = (v, w)$, we write $e_0 = v$ and $e_1 = w$. The *size* of a graph G is $|G| = |V| + |E|$.

A *subgraph* of a graph $G = (V, E, \partial)$ is a graph $G' = (V', E', \partial')$, where $V' \subseteq V$, $E' \subseteq E$, and such that $\partial' = \partial|_{E'}$ takes values in $V' \times V' \subseteq V \times V$. If G' is a subgraph of G, we write $G' \subseteq G$.

If $E' \subseteq E$ is a set of edges of G, we let $G \setminus E'$ be the subgraph of G with the same vertices and $E \setminus E'$ as set of edges.

Let $\mathcal{P}$ be a poset. A $\mathcal{P}$-*filtered graph* (G, f^V, f^E) consists of a graph G and functions $f^V : V \longrightarrow \mathcal{P}$ and $f^E : E \longrightarrow \mathcal{P}$ such that $f^V(e_0) \leq f^E(e)$ and $f^V(e_1) \leq f^E(e)$ for all $e \in E$. When there is no risk of confusion, we refer to $\mathcal{P}$-filtered graphs simply as filtered graph, and denote both f^V and f^E by f and the filtered graph (G, f^V, f^E) by (G, f).

If (G, f) is a $\mathcal{P}$-filtered graph and $r \in \mathcal{P}$, we let $(G, f)_r$ be the subgraph of G with vertices $\{v \in V : f(v) \leq r\}$ and edges $\{e \in E : f(e) \leq r\}$.

Persistence modules and persistent sets. Let $\mathcal{P}$ be a poset. A $\mathcal{P}$-*persistence module* is a functor $\mathcal{P} \longrightarrow \mathbf{Vec}$, where $\mathcal{P}$ is the category associated with $\mathcal{P}$. Explicitly, a $\mathcal{P}$-persistence module $M : \mathcal{P} \longrightarrow \mathbf{Vec}$ consists of the following:

- for each $r \in \mathcal{P}$, a vector space $M(r)$;
- for each pair $r \leq s \in \mathcal{P}$, a linear morphism $\varphi^M_{r,s} : M(r) \longrightarrow M(s)$; such that
- for all $r \in \mathcal{P}$, the linear morphism $\varphi^M_{r,r} : M(r) \longrightarrow M(r)$ is the identity;
- for all $r \leq s \leq t \in \mathcal{P}$, we have $\varphi^M_{s,t} \circ \varphi^M_{r,s} = \varphi^M_{r,t} : M(r) \longrightarrow M(t)$.

When there is no risk of confusion, we may refer to a $\mathcal{P}$-persistence module as a persistence module. An *n-parameter persistence module* ($n \geq 1 \in \mathbb{N}$) is an $\mathbb{R}^n$-persistence module.

A *morphism* $g : M \longrightarrow N$ between persistence modules is a natural transformation between functors, that is, a family of linear maps $\{g_r : M(r) \longrightarrow N(r)\}_{r \in \mathcal{P}}$ with the property that $\varphi^N_{r,s} \circ g_r = g_s \circ \varphi^M_{r,s} : M(r) \longrightarrow N(s)$, for all $r \leq s \in \mathcal{P}$. Such a morphism is an *isomorphism* if $g_r : M(r) \longrightarrow N(r)$ is an isomorphism of vector spaces for all $r \in \mathcal{P}$.

If $M, N : \mathcal{P} \longrightarrow \mathbf{Vec}$ are persistence modules, their *direct sum*, denoted $M \oplus N : \mathcal{P} \longrightarrow \mathbf{Vec}$, is the persistence module with $(M \oplus N)(r) \coloneqq M(r) \oplus N(r)$ and with $\varphi^{M \oplus N}_{r,s} \coloneqq \varphi^M_{r,s} \oplus \varphi^N_{r,s} : M(r) \oplus N(r) \longrightarrow M(s) \oplus N(s)$, for all $r \leq s \in \mathcal{P}$.

Similarly, a $\mathcal{P}$-*persistent set* is a functor $\mathcal{P} \longrightarrow \mathbf{Set}$. The concepts of *n-parameter persistent set*, and of *morphism* and *isomorphism* between persistent sets are defined analogously.

Persistent homology and connected components of filtered graphs. If $S \in \mathbf{Set}$, we let $\langle S \rangle_{\Bbbk} \in \mathbf{Vec}$ denote the free vector space generated by S; this defines a functor $\langle - \rangle_{\Bbbk} : \mathbf{Set} \longrightarrow \mathbf{Vec}_{\Bbbk}$. Let $G = (V, E, \partial)$ be a graph. Consider the $\Bbbk$-linear map

$$\begin{aligned} \langle E \rangle_{\Bbbk} &\xrightarrow{d} \langle V \rangle_{\Bbbk} \\ e &\longmapsto e_1 - e_0 \end{aligned} \tag{1}$$

The 0-*dimensional homology* of G, denoted $H_0(G; \Bbbk)$, is the $\Bbbk$-vector space $\operatorname{coker}(d)$, and the 1-*dimensional homology* of G, denoted $H_1(G; \Bbbk)$, is the $\Bbbk$-vector space $\ker(d)$. In particular, every vertex $v \in V$ gives an element $[v] \in H_0(G; \Bbbk)$. When there is no risk of confusion, we omit the field $\Bbbk$ and write $H_i(G)$ instead of $H_i(G; \Bbbk)$.

Homology is functorial, in the following sense. If $G' = (V', E', \partial')$ is a subgraph of G, we have a commutative square

$$\begin{array}{ccc} \langle E' \rangle_{\Bbbk} & \xrightarrow{d'} & \langle V' \rangle_{\Bbbk} \\ \downarrow & & \downarrow \\ \langle E \rangle_{\Bbbk} & \xrightarrow{d} & \langle V \rangle_{\Bbbk} \end{array}$$

induced by the inclusions $V' \subseteq V$ and $E' \subseteq E$. This induces linear maps $H_0(G') \longrightarrow H_0(G)$ and $H_1(G') \longrightarrow H_1(G)$. Moreover, the morphism $H_\bullet(G'') \longrightarrow H_\bullet(G)$ induced by a subgraph $G'' \subseteq G' \subseteq G$ is equal to the composite $H_\bullet(G'') \longrightarrow H_\bullet(G') \longrightarrow H_\bullet(G)$.

If (G, f) is a $\mathcal{P}$-filtered graph, and $i \in \{0, 1\}$, we get a $\mathcal{P}$-persistence module $H_i(G, f) : \mathcal{P} \longrightarrow \mathbf{Vec}$, with $H_i(G, f)(r) = H_i((G, f)_r)$, and with structure morphism $H_i(G, f)(r) \longrightarrow H_i(G, f)(s)$ for $r \leq s \in \mathcal{P}$ induced by the inclusion of graphs $(G, f)_r \subseteq (G, f)_s$.

The set of *connected components* of G, denoted $\pi_0(G)$, is the quotient of V by the equivalence relation $\sim$ where $v \sim w \in V$ if and only if there exists a path in G between v and w. If $v \in V$, we let $[v] \in \pi_0(G)$ denote its connected component, so that $[v] = [w] \in \pi_0(G)$ if and only if v and w belong to the same connected component.

The set of connected components is also functorial with respect to inclusions $G' \subseteq G$, since $[v] = [w] \in \pi_0(G')$ implies $[v] = [w] \in \pi_0(G)$. In particular, if (G, f) is a $\mathcal{P}$-filtered graph, we get a $\mathcal{P}$-persistent set $\pi_0(G, f) : \mathcal{P} \longrightarrow \mathbf{Set}$, with $\pi_0(G, f)(r) = \pi_0((G, f)_r)$, and with the structure morphism $\pi_0(G, f)(r) \longrightarrow \pi_0(G, f)(s)$ for $r \leq s \in \mathcal{P}$ induced by the inclusion of graphs $(G, f)_r \subseteq (G, f)_s$.

The following is straightforward to check.

▶ **Lemma 1.** *If G is a graph, then the map $\langle \pi_0(G) \rangle_{\Bbbk} \longrightarrow H_0(G)$ sending a basis element $[v] \in \pi_0(G)$ to $[v] \in H_0(G)$ is well-defined and an isomorphism of vector spaces. In particular, if (G, f) is a $\mathcal{P}$-filtered graph, composing the persistent set $\pi_0(G, f) : \mathcal{P} \longrightarrow \mathbf{Set}$ with the free vector space functor $\langle - \rangle_{\Bbbk} : \mathbf{Set} \longrightarrow \mathbf{Vec}$ yields a persistence module isomorphic to $H_0(G, f) : \mathcal{P} \longrightarrow \mathbf{Vec}$.* ⌟

Projective persistence modules. Given $r \in \mathcal{P}$, let $\mathsf{P}_r : \mathcal{P} \longrightarrow \mathbf{Vec}$ be the persistence module with $\mathsf{P}_r(s) = \Bbbk$ if $r \leq s$ and $\mathsf{P}_r(s) = 0$ if $r \not\leq s$, with all structure morphisms $\Bbbk \longrightarrow \Bbbk$ being the identity. Equivalently, one can define P_r to be $H_0(\{x\}, \emptyset, \partial, f)$, with $f(x) = r$.

▶ **Notation 2.** *If I is a finite set and $f : I \longrightarrow \mathcal{P}$ is any function, we can consider the direct sum $M = \bigoplus_{i \in I} \mathsf{P}_{f(i)} : \mathcal{P} \longrightarrow \mathbf{Vec}$. When we need to work with elements of such a direct sum, we distinguish summands by writing $M = \bigoplus_{i \in I} \left(\mathsf{P}_{f(i)} \cdot \{i\}\right)$, so that $\left(\mathsf{P}_{f(i)} \cdot \{i\}\right)(r) = 0$ if $r \not\geq f(i)$ and $\left(\mathsf{P}_{f(i)} \cdot \{i\}\right)(r)$ is equal to the free vector space generated by $\{i\}$, for $r \geq f(i)$.*

▶ **Definition 3.** *A persistence module $M : \mathcal{P} \longrightarrow \mathbf{Vec}$ is* projective of finite rank *if there exists a function $\beta^M : \mathcal{P} \longrightarrow \mathbb{N}$ of finite support such that $M \cong \bigoplus_{r \in \mathcal{P}^n} \mathsf{P}_r^{\beta^M(r)}$.*

Note that, drawing inspiration from commutative algebra, projective persistence modules are sometimes also called *free*. The following result justifies the term projective used in Definition 3; see, e.g., [36, Section 3.1] for the usual notion of projective module.

▶ **Lemma 4.** *Let $g : M \longrightarrow N$ be a surjection between $\mathcal{P}$-persistence modules, and let $h : P \longrightarrow N$ with P projective of finite rank. There exists a morphism $h' : P \longrightarrow M$ such that $g \circ h' = h$.*

Resolutions, presentations, and Betti tables. The next result is standard; see, e.g., [26, Proposition 6.24].

▶ **Lemma 5.** *If M is projective of finite rank, then there exists exactly one function (necessarily of finite support) $\beta^M : \mathcal{P} \longrightarrow \mathbb{N}$ such that $M \cong \bigoplus_{r\in\mathcal{P}} \mathsf{P}_r^{\beta^M(r)}$.* ⌟

▶ **Definition 6.** *The* Betti table *of a persistence module $M : \mathcal{P} \longrightarrow \mathbf{Vec}$ that is projective of finite rank is the function $\beta^M : \mathcal{P} \longrightarrow \mathbb{N}$ of Lemma 5.*

The following notation is sometimes convenient.

▶ **Notation 7.** *If $r \in \mathcal{P}$, we let $\delta_r : \mathcal{P} \longrightarrow \mathbb{N}$ be the function defined by $\delta_r(r) = 1$ and $\delta_r(s) = 0$ if $s \neq r$. In particular, $\delta_r = \beta^{\mathsf{P}_r} : \mathcal{P} \longrightarrow \mathbb{N}$.*

▶ **Definition 8.** *Let $M : \mathcal{P} \longrightarrow \mathbf{Vec}$ be a $\mathcal{P}$-persistence module. A* finite projective cover *of M is a surjective morphism $P \longrightarrow M$ where P is projective of finite rank, and $\sum_{r\in\mathcal{P}} \beta^P(r) \in \mathbb{N}$ is minimal.*

▶ **Definition 9.** *Let $M : \mathcal{P} \longrightarrow \mathbf{Vec}$ be a $\mathcal{P}$-persistence module, and let $k \in \mathbb{N}$. A* finite projective k-resolution *(resp.* minimal finite projective k-resolution*) of M, denoted $C_\bullet \longrightarrow M$, is a sequence of morphisms $C_k \xrightarrow{\partial_k} C_{k-1} \xrightarrow{\partial_{k-1}} \cdots \xrightarrow{\partial_2} C_1 \xrightarrow{\partial_1} C_0 \xrightarrow{\partial_0} M$ satisfying*

- *$C_0 \longrightarrow M$ is surjective (resp. a projective cover);*
- *$\partial_i \circ \partial_{i+1} = 0$, for every $0 \leq i \leq k-1$ (so that ∂_{i+1} factors through $\ker \partial_i$);*
- *$C_{i+1} \xrightarrow{\partial_{i+1}} \ker(\partial_i)$ is surjective (resp. a projective cover), for every $0 \leq i \leq k-1$;*
- *C_i is projective of finite rank, for every $0 \leq i \leq k$.*

In particular, a minimal finite projective 0-resolution is simply a projective cover.

▶ **Notation 10.** *Since we only consider finite resolutions, we omit the word "finite" and simply say projective k-resolution. A* (minimal) projective presentation *is a* (minimal) projective 1-resolution*.*

▶ **Definition 11.** *Let $k \in \mathbb{N}$. A persistence module $M : \mathcal{P} \longrightarrow \mathbf{Vec}$ is* finitely k-resolvable *if it admits a finite projective k-resolution.*

▶ **Definition 12.** *Let $M : \mathcal{P} \longrightarrow \mathbf{Vec}$ be finitely k-resolvable and let $0 \leq i \leq k$. The* ith Betti table *of M is the function $\beta_i^M : \mathcal{P} \longrightarrow \mathbb{N}$ (necessarily of finite support) defined as $\beta_i^M := \beta^{C_i}$, where $C_\bullet \longrightarrow M$ is a minimal k-resolution of M.*

▶ **Notation 13.** *When convenient, we write $\beta_i(M)$ instead of β_i^M for the Betti tables of a persistence module M.*

The Betti tables of M are also sometimes called the *(multigraded) Betti numbers* of M. The Betti tables of M, as defined in Definition 12, are independent of the choice of minimal presentation or resolution, thanks to the following standard result.

▶ **Lemma 14.** *Let $k \in \mathbb{N}$. If $M : \mathcal{P} \longrightarrow \mathbf{Vec}$ is finitely k-resolvable, then it admits a minimal projective k-resolution $C_\bullet \longrightarrow M$. Moreover, any other projective k-resolution $C'_\bullet \longrightarrow M$ has the property that $\beta^{C_i} \leq \beta^{C'_i}$ for all $0 \leq i \leq k$.*

▶ **Example 15.** Consider the graph $G = (V, E, \partial)$ with $V = \{x, y\}$, $E = \{a, b\}$, and $\partial(a) = \partial(b) = (x, y)$. Consider the filtration $f : G \longrightarrow \mathbb{R}^2$ with $f(x) = f(y) = (0, 0)$, $f(a) = (0, 1)$, and $f(b) = (1, 0)$. Then, a minimal resolution of $H_0(G, f)$ is given by

$$0 \longrightarrow \mathsf{P}_{(1,1)} \cdot \{\alpha\} \xrightarrow{\partial_2} \mathsf{P}_{(1,0)} \cdot \{a\} \oplus \mathsf{P}_{(0,1)} \cdot \{b\} \xrightarrow{\partial_1} \mathsf{P}_{(0,0)} \cdot \{x\} \oplus \mathsf{P}_{(0,0)} \cdot \{y\} \xrightarrow{\partial_0} H_0(G, f),$$

where $\partial_0(\{x\}) = [x]$, $\partial_0(\{y\}) = [y]$, $\partial_1(\{a\}) = \partial_1(\{b\}) = \{y\} - \{x\}$, and $\partial_2(\{\alpha\}) = \{a\} - \{b\}$. In particular, $\beta_0(H_0(G,f)) = \delta_{(0,0)} + \delta_{(0,0)}$, $\beta_1(H_0(G,f)) = \delta_{(1,0)} + \delta_{(0,1)}$, and $\beta_2(H_0(G,f)) = \delta_{(1,1)}$. This can be easily checked by hand, but it also follows from Theorems 23 and 25, since (G,f) is a minimal filtered graph, in the sense of Definition 17, which we give in the next section.

3 Theory

We start with a simple, standard result which says that a projective presentation of 0-dimensional homology is given by using the grades of vertices as generators, and the grades of edges as relations. Proofs can be found in [30, Appendix A.2].

▶ **Lemma 16.** *Let $\mathcal{P}$ be a poset, let (G,f) be a $\mathcal{P}$-filtered graph, and consider the following morphism of projective modules*

$$\begin{array}{ccc} \bigoplus_{e\in E} \mathsf{P}_{f(e)} \cdot \{e\} & \xrightarrow{\partial_1^{(G,f)}} & \bigoplus_{v\in V} \mathsf{P}_{f(v)} \cdot \{v\} \\ \{e\} & \longmapsto & \{e_1\} - \{e_0\} \end{array}$$

Then $H_0(G,f) \cong \operatorname{coker}\left(\partial_1^{(G,f)}\right)$ and $H_1(G,f) \cong \ker\left(\partial_1^{(G,f)}\right)$. In particular, $H_0(G,f)$ is a finitely presentable persistence module.

The point of minimal filtered graphs, which we now introduce, is that they make the presentation in Lemma 16 minimal (see Theorem 23).

▶ **Definition 17.** *Let (V,E,∂,f) be a filtered graph and let $e \in E$.*
- *The edge e is* collapsible *if $e_0 \neq e_1$ and $f(e) = f(e_i)$ for some $i \in \{0,1\}$.*
- *The edge e is* deletable *if $[e_0] = [e_1] \in \pi_0(V, E\setminus\{e\}, \partial, f)(f(e))$.*

A filtered graph (G,f) is
- vertex-minimal *if it does not contain any collapsible edges.*
- edge-minimal *if it does not contain any deletable edges.*
- minimal *if it is vertex-minimal and edge-minimal.*

▶ **Example 18.** The graph of Example 15 is minimal, as neither of the two edges is collapsible or deletable. On the other hand, the graph of Figure 1 is not minimal since h_1, h_2, d_1, d_2, and d_3 are collapsible, and e_3 is deletable.

As their name suggests, collapsible and deletable edges can be collapsed or deleted:

▶ **Construction 19.** *Let $(G,f) = (V,E,\partial,f)$ be a filtered graph.*
- *If $e \in E$ is collapsible, let $i \in \{0,1\}$ be such that $f(e) = f(e_i)$. Define the* simple collapse *$G \downarrow e \coloneqq (V\setminus\{e_i\}, E\setminus\{e\}, \partial')$, where $\partial' = (\varphi\times\varphi)\circ\partial$ and $\varphi : V \longrightarrow V$ is given by $\varphi(v) = v$ if $v \neq e_i$ and $\varphi(v) = e_{1-i}$ if $v = e_i$.*
- *If $e \in E$ is any edge, define the* simple deletion *$G \setminus e \coloneqq (V, E\setminus\{e\}, \partial)$.*

We now study the effect of collapsing collapsible edges, and of deleting deletable edges. We start with a useful observation, whose proof is straightforward.

▶ **Lemma 20.** *Let (G,f) be a filtered graph and let e and d be two different edges of G.*
1. *Assume that e is collapsible. If d is not collapsible (resp. deletable) in (G,f), then d is not collapsible (resp. deletable) in $(G\downarrow e, f)$.*
2. *If d is not collapsible (resp. deletable) in (G,f), then d is not collapsible (resp. deletable) in $(G\setminus e, f)$.* ⌟

▶ **Lemma 21.** *If $(G, f) = (V, E, \partial, f)$ is a filtered graph and $e \in E$ is collapsible, then $H_i(G, f) \cong H_i(G \downarrow e, f)$ for $i \in \{0, 1\}$.*

▶ **Lemma 22.** *If $(G, f) = (V, E, \partial, f)$ is a filtered graph and $e \in E$ is deletable, then $H_0(G, f) \cong H_0(G \setminus e, f)$ and $H_1(G, f) \cong H_1(G \setminus e, f) \oplus \mathsf{P}_{f(e)}$.*

Next is a construction of a minimal presentation of H_0 of a minimal filtered graph.

▶ **Theorem 23.** *Let $\mathcal{P}$ be a poset, let (G, f) is a $\mathcal{P}$-filtered graph, and let $\partial_1^{(G,f)} : C_1 \longrightarrow C_0$ be the morphism of Lemma 16.*

1. *If (G, f) is vertex-minimal, then the map $C_0 \longrightarrow \operatorname{coker}(\partial_1^{(G,f)})$ is a projective cover. In this case, $\beta_0\big(H_0(G, f)\big) = \sum_{v \in V} \delta_{f(v)}$.*
2. *If (G, f) is a minimal filtered graph, then $C_1 \xrightarrow{\partial_1^{(G,f)}} C_0 \longrightarrow \operatorname{coker}(\partial_1^{(G,f)})$ is a minimal presentation. In this case, we also have $\beta_1\big(H_0(G, f)\big) = \sum_{e \in E} \delta_{f(e)}$.*

We now focus on the case of $\mathbb{R}^2$-filtered graphs. If (G, f) is an $\mathbb{R}^2$-filtered graph, let $f_{\mathbf{x}}, f_{\mathbf{y}} : G \longrightarrow \mathbb{R}$ denote the first and second coordinates of f, respectively.

▶ **Definition 24.** *Let (V, E, ∂, f) be a minimal $\mathbb{R}^2$-filtered graph, and let $\prec$ be a total order on the set of edges E that refines the lexicographic order induced by f (i.e., $e \prec e'$ implies that $f_{\mathbf{x}}(e) < f_{\mathbf{x}}(e')$ or $f_{\mathbf{x}}(e) = f_{\mathbf{x}}(e')$ and $f_{\mathbf{y}}(e) \leq f_{\mathbf{y}}(e')$). An edge $d \in E$ is* cycle-creating *with respect to $\prec$ if $[d_0] = [d_1] \in \pi_0(V, \{e \in E : e \prec d\}, \partial)$.*

Thus, $d \in E$ is cycle-creating if there exists a list of edges $e^1, \ldots, e^k \in E$ with $e^i \prec d$ for $1 \leq i \leq k$, and a list of signs $s^1, \ldots, s^k \in \{+, -\}$, such that $s^1 e^1, \ldots, s^k e^k$ is a directed path from d_0 to d_1. Such a path $w = (s^\bullet, e^\bullet)$ is called a *witness* for d, and we denote $f(w) \coloneqq \big(f_{\mathbf{x}}(d), \max_{1 \leq i \leq k} f_{\mathbf{y}}(e^i)\big)$. A *minimal witness* w of a cycle-creating edge d is one for which $f_{\mathbf{y}}(w) \in \mathbb{R}$ is as small as possible.

Since $\prec$ refines the lexicographic order, we have $f_{\mathbf{x}}(e^i) \leq f_{\mathbf{x}}(d)$ for all i; thus, if $\max_{1 \leq i \leq k} f_{\mathbf{y}}(e^i) \leq f_{\mathbf{y}}(d)$, we would have that $[d_0] = [d_1] \in \pi_0(V, E \setminus \{d\}, \partial, f)(f(d))$, which contradicts the fact that the filtered graph is minimal. This means that if w is a witness for d, then $\max_{1 \leq i \leq k} f_{\mathbf{y}}(e^i) > f_{\mathbf{y}}(d)$, and thus $f(d) < f(w)$.

▶ **Theorem 25.** *Let $(G, f) = (V, E, \partial, f)$ be a minimal $\mathbb{R}^2$-filtered graph, and $\prec$ a total order on E refining the lexicographic order. For each $d \in E$ cycle-creating, let $w_d = (s_d^\bullet, e_d^\bullet)$ be a minimal witness wrt to $\prec$. The kernel of the morphism $\partial_1^{(G,f)}$ of Lemma 16 is given by:*

$$\begin{array}{ccc} \bigoplus_{\substack{d \in E \\ \text{cycle-creating}}} \mathsf{P}_{f(w_d)} \cdot \{d\} & \xrightarrow{\kappa^{(G,f)}} & \bigoplus_{e \in E} \mathsf{P}_{f(e)} \cdot \{e\} \\ \{d\} & \longmapsto & \{d\} - \big(s_d^1 \{e_d^1\} + \cdots + s_d^k \{e_d^k\}\big). \end{array}$$

It follows that

- $\beta_0(H_0(G, f)) = \sum_{v \in V} \delta_{f(v)}$;
- $\beta_1(H_0(G, f)) = \sum_{e \in E} \delta_{f(e)}$;
- $\beta_0(H_1(G, f)) = \beta_2(H_0(G, f)) = \sum_{d \in E, \text{cycle-creating}} \delta_{f(w_d)}$;
- $\beta_i(H_0(G, f)) = 0$ *for* $i \geq 3$, *and* $\beta_i(H_1(G, f)) = 0$ *for* $i \geq 1$.

4 Algorithms

Outline. We first introduce some technical notions and overview the algorithms.

Two $\mathcal{P}$-filtered graph (G, f) and (G', f') are *homology-equivalent* (over $\Bbbk$) if $H_0(G, f; \Bbbk) \cong H_0(G', f'; \Bbbk)$ and $H_1(G, f; \Bbbk) \cong H_1(G', f'; \Bbbk)$.

Algorithm 2 reduces the input filtered graph to a vertex-minimal filtered graph by collapsing edges; it relies on Algorithm 1, which collapses local collapsible edges. A *local collapsible edge* of (G, f) is an edge e such that $e_0 \neq e_1$ and $f(e) = f(e_0) = f(e_1)$. Algorithm 2 then identifies *minimal vertices*, that is, vertices with no adjacent collapsible edge decreasing the grade, and runs a depth-first search from each of these to build and collapse a tree of collapsible edges.

Algorithm 3 first calls Algorithm 2 to perform all collapses and then deletes deletable edges until there are no more deletable edges. It then builds the presentation of Lemma 16.

Algorithm 4 first calls Algorithm 2 to perform all collapses, and then goes through all edges, with respect to the lex order on their grades, and identifies deletable edges, non-deletable edges, and cycle-creating edges.

Dynamic dendrograms. Since this is used in Algorithm 4, we now introduce the dynamic dendrogram data structure, which, informally, represents a dendrogram where elements merge as time goes from $-\infty$ to ∞, and is dynamic in that one is allowed to change the dendrogram by making two elements merge earlier.

▶ **Definition 26.** *Let $(G, f) = (V, E, \partial, f)$ be a $[-\infty, \infty)$-filtered graph. A* dynamic dendrogram *D for (G, f) is a data structure supporting the following operations:*

- *If $v, w \in V$, the operation $D.\mathsf{time_of_merge}(v, w)$ returns the smallest $r \in [-\infty, \infty)$ such that $[v] = [w] \in \pi_0(G, f)(r)$, or ∞ if $[v] \neq [w] \in \pi_0(G, f)(r)$ for all $r \in [-\infty, \infty)$.*
- *If $v, w \in V$ and $t \in [-\infty, \infty)$, the operation $D.\mathsf{merge_at_time}(v, w, t)$ modifies the dendrogram so that it is a dynamic dendrogram for $(V, E \sqcup \{e\}, \partial', f')$, with $f'|_E = f$, $\partial'|_E = \partial$, $f'(e) = t$, and $\partial'(e) = (v, w)$.*

A dynamic dendrogram D can easily and efficiently be implemented using a *mergeable tree* T in the sense of [20]. These trees store heap-ordered forests, i.e., a collection of rooted labeled trees, where the labels decrease (or in our case increase) along paths to the root. The data structures support a wealth of operations for dynamic updates. We need only three of them: $\mathsf{insert}(v, t)$ inserts node v with label t into the forest; $\mathsf{nca}(v, w)$ finds the nearest common ancestor of two nodes v and w; $\mathsf{merge}(v, w)$ merges the paths of v and w to their root(s) while preserving the heap order. We use these operations to implement dynamic dendrograms as follows:

- To implement $D.\mathsf{time_of_merge}(v, w)$, return the label of $T.\mathsf{nca}(v, w)$.
- To implement $D.\mathsf{merge_at_time}(v, w, t)$, let h be a new vertex not already in the mergeable tree T, do $T.\mathsf{insert}(h, t)$, then $T.\mathsf{merge}(v, h)$, and $T.\mathsf{merge}(w, h)$.

Presentation matrices. In the algorithms, to represent a Betti table $\beta_i(M)$ we use a list of elements of the indexing poset. If we have represented the 0th and 1st Betti tables of M with lists β_0 and β_1, we represent a minimal presentation for M with a sparse matrix using coordinate format, that is, with a list of triples (i, j, v) representing the fact that v is the entry at row i and column j, and where i represents the ith element of β_0 and j represents the jth element of β_1.

Algorithm 1 Collapse local collapsible edges.

Input: Filtered graph $(G, f) = (V, E, \partial, f)$
Output: Filtered graph (G', f) homology-equivalent to (G, f) and without local collapsible edges

Initialize dictionary φ with identity map, $\varphi[v] = v$ for $v \in V$
Initialize empty set visited
Initialize $E' \leftarrow E$
for $v \in V$ **do** ▷ Run depth-first search from v on local edges
  Initialize stack with $(v, \emptyset, v)$
  while stack *is not empty* **do**
    $(v, e, u) \leftarrow$ stack.**pop**()
    if $u \notin$ visited **then**
      add u to visited
      if $e \neq \emptyset$ **then**
        $\varphi[u] \leftarrow v$
        remove e from E'
      for $e \in E$ *with* $\{e_0, e_1\} = \{u, x\}$ *and* $f(e) = f(x) = f(u)$ **do** ▷ local collapsible
        push (v, e, x) onto stack
$V' \leftarrow \{v \in V : \varphi[v] = v\}$
return $(G', f) = (V', E', (\varphi \times \varphi) \circ \partial, f)$

Algorithm 2 Collapse to vertex-minimal filtered graph.

Input: Filtered graph $(G, f) = (V, E, \partial, f)$
Output: Vertex-minimal filtered graph (G', f) homology-equivalent to (G, f), and $\beta_0(H_0(G, f))$

$(G_i, f) = (V_i, E_i, \partial_i, f) \leftarrow$ Algorithm 1(G, f)
Initialize dictionary φ with identity map, $\varphi[v] = v$ for $v \in V_i$
Initialize empty set visited
Initialize $E' \leftarrow E_i$
for v *in* V_i **do** ▷ Run depth-first search from minimal vertices
  if $\exists$ *edge* $e \in E_i$ *with* $\{e_0, e_1\} = \{u, v\}$ *and* $f(e) = f(v) > f(u)$ **then** ▷ v is not minimal
    continue
  Initialize stack with $(v, \emptyset, v)$
  while stack *is not empty* **do**
    $v, e, u \leftarrow$ stack.**pop**()
    if $u \notin$ visited **then**
      add u to visited
      if $e \neq \emptyset$ **then**
        $\varphi[u] \leftarrow v$
        remove e from E'
      for *every edge* $e \in E_i$ *with* $\{e_0, e_1\} = \{u, x\}$ *with* $f(e) = f(x) > f(u)$ **do**
        push (v, e, x) onto stack
$V' \leftarrow \{v \in V_i : \varphi[v] = v\}$
return $(G', f) = (V', E', (\varphi \times \varphi) \circ \partial_i, f)$ and $\beta_0 = [f(v) : v \in V']$

Algorithm 3 Minimal presentation of $\mathcal{P}$-filtered graph.

Input: Filtered graph $(G, f) = (V, E, \partial, f)$
Output: Minimal presentation of $H_0(G, f; \Bbbk)$

Initialize β_0, β_1 with empty lists
Initialize empty sparse matrix $\mathcal{M}$ and empty dictionary row_idx
$(V', E', \partial', f) \leftarrow$ Algorithm 2(G, f)
for $e \in E'$ **do** ▷ Check each edge, and delete it if it is deletable
  Define set of vertices $V_e \leftarrow \{v \in V' : f(v) \leq f(e)\}$
  Define set of edges $E_e \leftarrow \{d \in E' : f(d) \leq f(e)\} \setminus e$
  Run breadth-first search on (V_e, E_e, ∂') starting from e_0
  if e_1 *is reachable from* e_0 **then** ▷ $[e_0] = [e_1] \in \pi_0(V_e, E_e, \partial')$ so e is deletable
    $E' \leftarrow E' \setminus \{e\}$
for $v \in V'$ **do**
  β_0.append$(f(v))$
  row_idx$[v] \leftarrow |\beta_0|$

      $\mathcal{M}$.append(row_idx$[e_1]$, $|\beta_1|$, 1)
      if $s < \infty$ **then** ▷ The edge is cycle-creating
        β_2.append$(\,(x, s)\,)$
        β_0^1.append$(\,(x, s)\,)$
return $\beta_0, \beta_1, \beta_2, \beta_0^1, \mathcal{M}$

Complexity and correctness. We conclude the paper by using the theoretical results of Section 3 to prove the main results in the introduction. Proofs for the results in this section are in [30, Appendix A.3].

We start by with a convenient lemma, which gives conditions under which one can collapse an entire subgraph and produce a homology-equivalent filtered graph. The following definition describes the type of subgraph that can be collapsed.

▶ **Definition 27.** *Let $(G, f) = (V, E, \partial, f)$ be a filtered graph. A subset $E' \subseteq E$ is a* monotonic forest *of (G, f) if:*

1. *The subgraph of G spanned by the edges in E' is a forest.*
2. *For every vertex v in the forest, there exists at most one edge $e \in E'$ such that $\{e_0, e_1\} = \{v, w\}$ and $f(w) < f(v)$.*

▶ **Lemma 28.** *Let $(G, f) = (V, E, \partial, f)$ be a filtered graph, and let $E' \subseteq E$ be a set of collapsible edges, which forms a monotonic forest. If $e \in E'$, then all the edges in $E' \setminus \{e\}$ are collapsible in $(G \downarrow e, f)$. In particular, the whole forest E' can be collapsed (in any order) to obtain a filtered graph that is homology-equivalent to (G, f).*

▶ **Lemma 29.** *Let (G, f) be a $\mathcal{P}$-filtered graph. Algorithm 1 outputs a filtered graph homology-equivalent to (G, f) and without local collapsible edges in time $O(|G|)$.*

▶ **Proposition 30.** *Let (G, f) be a $\mathcal{P}$-filtered graph. Algorithm 2 outputs a vertex-minimal filtered graph homology-equivalent to (G, f) and $\beta_0(H_0(G, f))$ in $O(|G|)$ time.*

▶ **Proposition 31.** *Let (G, f) be a finite $\mathcal{P}$-filtered graph. Algorithm 3 outputs a minimal presentation of $H_0(G, f)$ in $O(|G|^2)$ time.*

With these results, we prove Theorem A and Theorem B in [30, Appendix A.4].

Abstract

Rivers, estuaries, intertidal zones, and other hydrological systems often give rise to complex networks of interconnected channels. Even today, such networks are typically drawn manually by domain experts. Traditional watershed methods for automating this process, where water flows are assumed to follow steepest descent, fail to capture behavior particular to low-relief terrains. At SoCG 2017, Kleinhans et al. proposed a method to construct a network of source-to-sink paths separated by sufficient sediment volume. However, this method is unstable with respect to minor changes of the input terrain, and constructs only channels that flow from one side of the terrain to the other, thereby failing to detect the dead-end channels ("fingers") that characterize intertidal zones.

We show how to compute geomorphologically salient networks that avoid these issues. After extending elevation data to a discrete Morse function on the terrain, we identify channels that flow through saddles and have sufficient volume of sediment on both sides. We then detect fingers, which follow the boundary of "spurs" that have sufficient volume of sediment above a particular height. The main challenge here lies in meaningfully modeling salient spurs and determining suitable heights to measure volume. We implemented our method and applied it to real-world data. Our expert users have validated the mathematical modeling by confirming that the resulting (finger) channels indeed constitute a geomorphologically salient network.

1 Introduction

Rivers and estuaries are important natural landscapes. Their channels can effectively be represented by networks. The analysis of such networks is a powerful tool to answer fundamental questions about dynamics of nodes, emergent network properties [18, 17, 24, 25], and the propagation of disturbances. However, geoscientists and engineers struggle with

the creation and analysis of networks from spatial data such as satellite imagery and echo-sounding bathymetries. In general, the number of datasets and models is growing explosively, but the tools to analyze them lag behind considerably. Present practice relies on manual creation and somewhat arbitrary rules: a laborious process with unreliable results.

In this paper we describe an algorithm that constructs geomorphologically salient networks based on the topological properties of the river bed as represented by a digital elevation model (DEM). In computational geometry, algorithms for computing networks from high-relief DEMs are well-studied, for example, in the context of *drainage networks* or *flows* [2, 1, 5, 3, 26]. But most models for water flow in terrains, including drainage networks, generally assume that water follows the direction of steepest descent. On steep terrains this is a reasonable assumption, but channels within a braided river or estuary do not follow steepest descent. Firstly, the inertia of flowing water can result in deviations from the true steepest descent direction. Secondly, water can fill up local minima in the riverbed. Furthermore, if a river always follows steepest descent, it can never split. Yet in practice such splits, called *bifurcations*, form frequently in most braided rivers and multi-channel estuaries; they are key elements for network properties [15].

Kleinhans, van Kreveld, Ophelders, Sonke, Speckmann, and Verbeek [16] were the first to propose a method that computes networks for braided rivers and estuaries based on bathymetry. Their algorithm constructs the network from a set of (partially overlapping) low paths through the DEM (a *striation*), which ensures that bifurcations and confluences can be represented. There are many possible low paths and corresponding channels. The authors choose significant channels based on a morphological concept: sediment volume. Two channels can be considered similar if the volume of terrain between the channels is small,

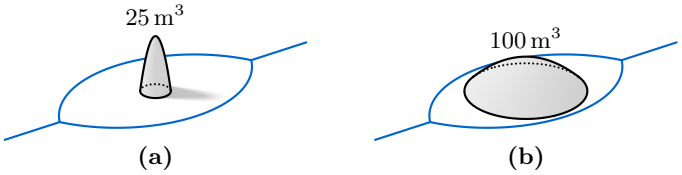

Figure 2 In (a) the channels are separated by a lower volume of sediment than in (b). We hence consider the channels in (a) more similar, even though the maximum in (a) is higher than in (b).

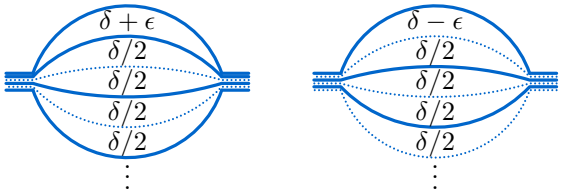

Figure 3 With striation-based methods, if a sediment volume changes by just ε, the set of paths selected from the striation (solid blue lines) may change dramatically even far away from the change.

modeling the fact that a small volume of sediment can easily be eroded in a short time by water flow, merging the two channels into one [14]. The algorithm hence selects a subset of the striation paths which are separated by sufficient volume of sediment (see Figure 2). This method has two drawbacks. First and foremost, it is unstable with respect to minor changes of the terrain (see Figure 3). Secondly, in low-relief terrains, such as intertidal zones and estuaries, there are many geomorphologically significant dead-end channels (*fingers*), caused by tidal in- and outflow (see Figure 1 and its "tree of fingers"). Striation paths by design flow from one side of the terrain to the other and hence the method fails to detect fingers.

In this paper we retain the notion of volume-separated channels, but turn to persistence and discrete Morse theory to avoid instability. Specifically, we use the concept of *volume persistence*, which considers only those topological features of the DEM that correspond to "sand bars" of sufficient volume. That is, we use a *volume-simplified* DEM, which we obtain by *pruning* topological features of the terrain that can be eliminated by removing only a small amount of volume. Topological persistence was introduced by Edelsbrunner, Letscher, and Zomorodian [7], and is a record of homological changes throughout a *filtration* of an underlying space. Such filtrations are often defined with respect to the distance between points, however, other measures can be used. Carr, Snoeyink, and van der Panne [4] describe a method to simplify contour trees using so-called *local geometric measures*, such as (in 2D terrains) the line length of the contour, the area enclosed by the contour, or the volume of the enclosed region. This last type of filtration is exactly the one we use. The remaining channels in our volume-persistent network separate regions of the terrain with high significance.

A couple of years ago, a geomorphologcial paper [23] sketched how to use volume persistence to compute networks from bathymetry; however, the exposition lacks mathematical detail. Height persistence has previously been employed to fill local minima in terrains [5]. De Floriani, Iuricich, Magillo, and Simari [6] compared watershed methods and discrete Morse theory for the construction of watersheds, but only on terrains with high relief and water flow that follows steepest descent.

Contribution and organization. In this paper we give a mathematically sound formalization of volume persistence and its use for network computation. In Section 2 we provide background on discrete Morse theory. Section 3 describes our method to construct a network based on volume persistence. By design these networks are stable under perturbations of small volume, however, like the channels that stem from striations, they connect one side of the terrain to the other. In Section 4 we develop the additional theory necessary to detect salient fingers. The major challenge here is to characterize the area and corresponding terrain volume that defines a finger. It is clear which area lies between two channels that first bifurcate and then merge again. Correspondingly, it is straightforward to compute the volume of terrain between two channels. But what area determines a finger? When are two fingers similar? Which fingers should be retained in a network given a volume threshold

for persistence? To address these challenges, we introduce the notion of "spurs" on the terrain and define salient fingers as those that bound spurs of sufficient volume. Finally, in Section 5 we showcase the results of our method as implemented in our tool TopoTide (`https://github.com/tue-alga/topotide`).

2 Preliminaries

Our network extraction methods are grounded in discrete Morse theory and concepts from topology are useful to describe them. Additionally, various notions of volume play a central role in our methods. Therefore, in this section, we provide definitions related to these topics.

Discrete Morse theory. Traditional Morse theory enables us to study a manifold by defining a Morse function, a differentiable function on the manifold, and studying its features such as critical points and stable and unstable manifolds. As the data describing our terrain is not continuous, but consists of discrete points, we assume the terrain is a two-dimensional *cell complex* T: a surface defined by a set of zero-, one-, and two-cells so that the intersection of any two cells in T is in T itself. We then turn to *discrete Morse theory* [11, 20].

For cells τ and σ, we say that τ is a *face* of σ (or σ is a *coface* of τ) if $\tau \subseteq \sigma$, and we say that τ is a *facet* of σ (or σ is a *cofacet* of τ) if τ is a face of σ and $\dim(\tau) = \dim(\sigma) - 1$. A *discrete Morse function* (DMF) is a map $f\colon T \to \mathbb{R}$ such that every cell has a lower (higher) value than its cofacets (facets) with at most one exception. It may be helpful to visualize f as pairing facets to cofacets where these exceptions occur, in an analog to gradient flow from the smooth setting. These pairings are called *gradient pairs* and we may illustrate them using arrows pointing from facets to cofacets, as in Figure 4. A cell σ is *critical* if σ is not paired with any of its facets or cofacets. A critical zero-cell is called a *minimum*, a critical one-cell is called a *saddle*, and a critical two-cell is called a *maximum*.

Given a DMF f, an *ascending path* is a sequence that alternates between zero- and one-cells, "swimming upstream" along the pairings induced by f. Similarly, a *descending path* is a sequence that alternates between two- and one-cells, following the pairings induced by f. The union of all ascending paths forms a spanning forest, and so does the union of all descending paths; these spanning forests are dual, with the exception of saddles. For each facet of a saddle, there exists a unique ascending path ending at that zero-cell and originating at a minimum; we define the *ascending Morse–Smale complex* (or *MS-complex* for brevity) as a graph $G = (V, E)$ with nodes V corresponding to the minima of f, and arcs E corresponding to the pairs of ascending paths connected via saddles between them. See Figure 4. Similarly, for each cofacet of a saddle, there is a unique descending path ending

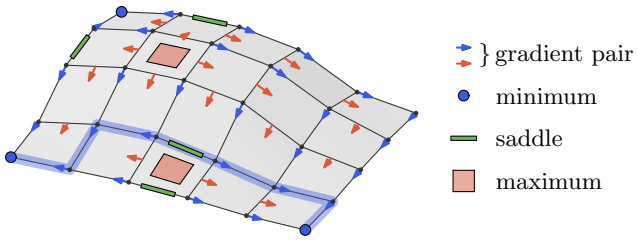

Figure 4 Gradient pairing induced by a DMF on a terrain. Arcs of G are paths of zero- and one-cells that begin and end at minima and pass through a saddle, following gradient pairings. One such arc is highlighted above in blue. We emphasize that gradient pairing arrows do not indicate network flow; because of tides, wind, etc., flow direction is not appropriate for our applications.

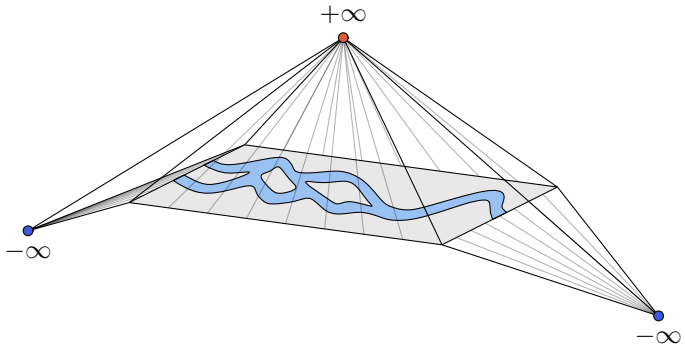

Figure 5 To make T a sphere, we connect three zero-cells at $-\infty$, $-\infty$, and $+\infty$ to the boundary.

at that two-cell and originating at a maximum. Note that, while a node $v \in V$ corresponds to a zero-cell, an arc $e \in E$ represents the union of potentially many zero- and one-cells. Furthermore, the highest zero-cell along e is the highest facet of its saddle. Each face of G contains a single maximum. For a subset $E' \subseteq E$, we write $G - E'$ to denote the arc-induced subgraph on $E \setminus E'$, i.e., the graph containing only the arcs $E \setminus E'$ and their endpoints.

Terrain data. The input to our methods is a *digital elevation model* (DEM), a set of points and associated elevations. These points and elevations correspond to the elevations of geographic locations in a real-world or simulated terrain. DEMs come in many varieties, for instance triangular irregular networks (TINs) or other point configurations. In this paper, we suppose our DEM data consists of a regular rectilinear grid of measurement points. However, we emphasize that discrete Morse theory along with many of the methods we describe, generalizes to a wide variety of DEM types and structures.

We assume that our input DEM corresponds to a region homeomorphic to a disk, i.e., there are no arches or more complex structures. If any two zero-cells have identical elevation, we perform a slight perturbation so that general position is satisfied [8]. We add three additional zero-cells to an input DEM. First, we add two zero-cells at elevation $-\infty$ to represent a global source and sink, and connect to the appropriate regions of the DEM (conceptually, the source and sink along this boundary). We then add a zero-cell at elevation $+\infty$ to represent the land that is not part of the terrain of interest (e.g., the bank of a river), which we assign elevation $+\infty$, and connect to the entire (new) boundary, including the minimum points. Thus, T is topologically a sphere (see Figure 5). Note that T contains non-square two-cells adjacent to the infinite points, so T does not have an entirely grid-like structure; however, the region of interest, namely, points that correspond to data measurements, is endowed with a grid structure, and it suffices to conceptualize T as cubulated. We call a DEM adapted in this way a *terrain*, which is the starting point for our work.

Choosing a discrete Morse function. A discrete Morse function (DMF) $f : T \to \mathbb{R}$ assigns a real value to every cell of T: not only the zero-cells, but also the one- and two-cells. On the other hand, our terrain data consists of elevation values for the zero-cells of T, but not the one- and two-cells. Thus, we have to extend these measurements on the zero-cells to every cell of T in such a way that we obtain a discrete Morse function, whose critical points and gradient pairs reflect the input measurements. Several choices have been proposed in the literature, see for example [21, 12, 13, 9, 22, 19, 10]. In this paper we use the method proposed in [22]; we sketch the relevant gradient pairings in the following construction.

▶ **Construction 1** (From Elevations to Pairings). *The real values associated to every zero-cell in a terrain induce a high-to-low lexicographical order on all cells. First, pair every zero-cell with its lowest lower cofacet, if it exists. Next, for every remaining one-cell w, consider the cofacets of w for which w is the highest facet. Among these, pair w with the two-cell for which the one-cell opposite w is lowest. Finally, repeat the previous step for every remaining one-cell w', considering the unpaired cofacets of w' for which w' is the second-highest facet.*

A main contribution of [22] shows the gradient pairings described above are valid, and do not contradict given elevation data.

▶ **Lemma 2** (Adapted from [22]). *Let T be a terrain. Then the pairings of Construction 1 correspond to a valid DMF f on T, where, for all zero-cells $z \in T$, $f(z)$ is the elevation of z.*

Since a set of valid gradient pairings is equivalent to a DMF inducing those pairings, we generally proceed by discussing gradient pairings rather than an explicit function.

Volume and Paths. Our filtrations depend on a volume-based parameter. Thus, we first need to define the *volume* of a region in T. Conceptually, we think of the elevation of each zero-cell as volume being divided among its four adjacent two-faces, so that each zero-cell contained in a region contributes zero, one, two, three, or four quarters of its volume (height value) to the total, depending on how many of its adjacent two-faces are in the region.

▶ **Definition 3** (Quarter-Pillar Volume). *Consider some height h and two-cell $t \subseteq T$. Denote the zero-cells adjacent to t by z_1, z_2, z_3, and z_4, and for $i \in \{1, 2, 3, 4\}$, let $f(z_i)$ denote the elevation of z_i. Then we define the volume of t above h as*

$$\sum_{i=1}^{4} \frac{\max\{f(z_i) - h, 0\}}{4}.$$

That is, each zero-cell contributes a quarter of its elevation above h to the volume of t. Next, let $H \subseteq T$. We define the volume of H *as the sum of volumes of all two-cells contained in H.*

Note that Definition 3 could easily be adapted for more general settings, e.g., if faces do not necessarily have exactly four nodes, or if the size or shape of the faces is salient. We want to know the volume of regions of the terrain that are above a particular elevation, but as elevation is only defined on zero-cells, we introduce the following concept.

▶ **Definition 4** (Zero-Cell Superlevel Set). *Given a zero-cell z of some terrain T, the* zero-cell superlevel set of z *is the collection of zero-cells of T with equal or higher elevation than z.*

We are generally interested in measuring volumes that correspond to continuous regions of the terrain. This is formalized in the following definition.

▶ **Definition 5** (Zero-Cell Connected). *Let $H_0 \subseteq T$ be a set of zero-cells. Two zero-cells $z_1, z_n \in H_0$ are* (zero-cell) connected *if and only if there is a sequence $z_1, z_2, \ldots, z_n$ such that, for $1 < i < n$, every z_i is contained in H_0 and every adjacent pair, z_i and z_{i+1}, are faces of a common two-cell of T. We say that H_0 is* (zero-cell) connected *if every pair of zero-cells in H_0 is zero-cell connected. A* connected component of H_0 *is a connected set that is not a proper subset of any other connected set in H_0.*

Next, we introduce an idea that allows us to consider lexicographically lowest paths.

▶ **Definition 6** (Lexicographic Order of Paths). *In a terrain T, let P_1 and P_2 be paths of alternating zero- and one-cells. Then we say P_1 is* lexicographically lower than *P_2 if the list of zero-cells in P_1 sorted by elevation from high to low is lexicographically lower than the sorted list of zero-cells in P_2.*

Roughly speaking, Construction 1 defines ascending paths of an MS-complex by introducing zero-/one-cell pairings that are lexicographically low. This has the following consequence.

▶ **Corollary 7** (Lowest Paths are Arcs of G). *Suppose that T is a terrain with a DMF defined as in Construction 1, and consider two minima, z_1 and z_2. Then the lexicographically lowest path through zero- and one-cells of T connecting z_1 and z_2 corresponds to arcs of the corresponding MS-complex, G.*

3 Volume Persistence for Braided Rivers and Estuaries

In this section, we detail our network extraction method when the terrain in question is a braided river or estuary in which no channels truncate (i.e., there are no degree one nodes in the network).

In practice, terrains corresponding to actual data are quite noisy, so a network G that is simply the MS-complex for some corresponding DMF is much more complex than what we might want. Thus, we filter G based on a *volume parameter*. Conceptually, we want to keep channels that run between two "hills" that contain enough volume. Note that if an arc e ends at a minimum in a shallow basin, an endpoint of e may have degree one, i.e., e does not separate two hills. We specify arcs that separate hills more formally below.

▶ **Definition 8** (Splitting Arcs). *Let G be the MS-complex for a DMF on a terrain T. For an arc $e \in E(G)$, let z denote the highest zero-cell of T contained in e. Let H_0 denote the connected component of the zero-cell superlevel set at the height of z that contains z. We say that e is a* splitting arc *if $H_0 \setminus z$ is two connected components.*

Next, we assign a volume to each splitting arc, corresponding to the volume of sediment that would need to be removed in order for the channel to no longer be defined.

▶ **Definition 9** (Volume Persistence of Splitting Arcs). *Let G be the MS-complex for a DMF on a terrain T. For a splitting arc $e \in E(G)$, let z denote the highest zero-cell of T in e. Let H_0 be the connected component of the zero-cell superlevel set at the height of z that contains z. Let H_0^a and H_0^b be the two connected components of $H_0 \setminus z$. Finally, let H^a (and H^b) be the set of two-cells that have at least one incident zero-cell in H_0^a (and H_0^b, respectively). We define the* volume persistence of e *as the minimum volume of H^a or H^b.*

See Figure 6. If the volume persistence of an arc is low, a small change to the terrain would remove the arc. Thus we use the volume persistence of arcs to filter G, as follows.

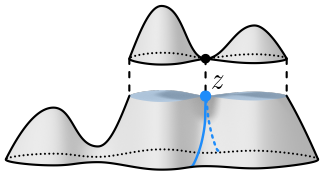

Figure 6 Zero-cell z is the highest zero-cell along a splitting arc of G (shown in blue). The volume persistence of the arc is the smaller volume of the two "hills above z".

▶ **Definition 10** (Volume-Filtered Subnetwork)**.** *For the MS-complex G of a terrain T, and for $\delta \in \mathbb{R}_{\geq 0}$, let G_δ be the graph induced by the set of splitting arcs with volume persistence at least δ, along with all (remaining) lowest paths between nodes in G_δ.*

Note that by Corollary 7, the lowest path between a pair of minima is made up of arcs of G, which may be splitting or non-splitting. The following lemma asserts that using δ as a parameter defines a *filtration* of G, where inclusion occurs as δ decreases.

▶ **Lemma 11.** *Let G be an MS-complex for a terrain T, and let $\delta, \delta' \in \mathbb{R}_{\geq 0}$ such that $\delta \leq \delta'$. Then $G_{\delta'} \subseteq G_\delta$.*

Proof. Consider a splitting arc $e \in E(G_{\delta'})$. Then the volume persistence of e is greater than or equal to $\delta' \geq \delta$, meaning $e \in E(G_\delta)$. Since our choice of e was arbitrary, every splitting arc of G'_δ is a splitting arc of G_δ, and $V(G_{\delta'}) \subseteq V(G_\delta)$. Then the lowest paths between two nodes of $G_{\delta'}$ are also in $G_{\delta'}$. Thus, $G_{\delta'} \subseteq G_\delta$. ◀

We also take the following general position assumptions. Let f be a DMF of a terrain T. We assume f is injective on the zero-cells of T with a finite height, i.e., they each have a unique height. Furthermore, given G, the MS-complex associated to T, each arc of G has a unique volume persistence in the sense of Definition 9.

3.1 Properties of Merging Faces

Given a DMF over a terrain T and the associated MS-complex G, our goal is now to produce the volume-filtered subnetwork G_δ for any $\delta > 0$. The computational challenge is to efficiently compute the volume persistence of each splitting arc $e \in E(G)$. Recall that, for z the highest zero-cell of T along e, the volume persistence of e is the minimum volume of a connected component of the superlevel set above and on either side of z, so we first need to identify such components. A naïve approach might be to begin at a saddle one-cell and use a depth-first search method to explore neighboring two-cells, adding them to the connected components for e until we identify a boundary made up of cells with lower height, i.e., the boundary of the relevant connected components of the superlevel set. However, in doing so, we would potentially revisit the cells in the highest face of G s times (where s is the number of saddles), cells in the second highest face $s-1$ times, and so on. Instead, we propose a faster method to find relevant superlevel sets that makes use of containment properties. By processing arcs "from high to low," we can use information about previously explored regions and avoid the need to analyze the same two-cells more than once. More formally, the following lemma establishes a helpful property that is a result of this strategy.

▶ **Lemma 12.** *Let G be the MS-complex of a DMF on a terrain T with gradient pairings as in Construction 1. Let $e_1, e_2, \ldots, e_m$ be the total ordering of the arcs from high to low via their highest zero-cell. For $1 \leq i \leq m$, let z_i denote the highest zero-cell of e_i. Then the connected component of all zero-cells in the superlevel set above and containing z_i is strictly contained in the faces of the graph $G^i = G - \{e_1, e_2, \ldots, e_{i-1}\}$ that are adjacent to e_i.*

Proof. For some $1 \leq i \leq m$, let z_i denote the highest zero-cell of T along arc e_i, and let H_0 denote the zero-cell connected component of the superlevel set above and containing z_i (i.e., the zero-cells in the *hills above* z_i). Let F denote the union of the faces of G^i adjacent to e_i, considered as a collection of zero-, one-, and two-cells.

First, suppose the boundary of F does not contain e_i. Then arcs in the boundary of F all have a highest zero-cell lower than the height of z_i. In particular, all zero-cells contained in the boundary of F have lower elevation than z_i, and are therefore not contained in H_0.

Then any connected collection of zero-cells of H_0 may not cross the boundary of F. By construction, H_0 intersects e_i at the single point z_i, an interior point of F, so clearly H_0 is not disjoint from F. Thus, $H_0 \cap F = H_0$, as desired.

In the case that the boundary of F contains e_i (for instance, if e_i has a node with degree one), the boundary of F is comprised of a set of arcs whose collective highest zero-cell is z_i. Then the only way for a connected collection of zero-cells in H_0 to leave F is through z_i. However, z_i is not an endpoint of e_i (endpoints of e_i are local minima), so all zero-cells neighboring z_i with higher elevation must be in the interior of F, and the claim follows by similar logic to the preceding case. ◀

Finally, we aim to show that the behavior of zero-cell connectivity of superlevel sets mimics behavior in a continuous terrain; namely, all points in the superlevel set above an arc contained in a face of G^i are part of the same zero-cell connected component.

We first establish a helpful lemma for G, before any arcs have been removed.

▶ **Lemma 13.** *Let G be the MS-complex of a DMF on a terrain T, with gradient pairings as in Construction 1. Let z denote the highest zero-cell along the boundary of some face of G. Then the connected component of the superlevel set of z contains both z and the highest zero-cell of the maximum in that face.*

Proof. Recall that each maximum is contained in a distinct face of G. Let z denote the highest zero-cell along the boundary of some face of G. The saddle containing z is the face of some two-cell, which we denote β. Since the union of descending paths in a face of G forms a spanning tree, there is a unique path P from β to the maximum, following gradient pairs up (i.e., a path of alternating paired one- and two-cells).

For any gradient pair from a one-cell α to a two-cell β, we claim that the highest zero-cell of β is also a zero-cell of α. Recall from Construction 1 that α can be paired with β only if α is lexicographically either the highest or second-highest one-cell of β. In both cases, the highest zero-cell is necessarily a face of α. Thus, by following P, we obtain a non-decreasing path of zero-cells from z to the highest zero-cell of the maximum. ◀

Using Lemma 13, we now show that particular superlevel sets contained in faces of G^i (i.e., G without the first $i-1$ highest arcs) are connected. Importantly, this means intuition about superlevel sets from a continuous terrain also applies in our discretized setting.

▶ **Lemma 14.** *Let G be the MS-complex of a DMF a terrain T, with gradient pairings as in Construction 1. Let $e_1, e_2, \ldots, e_m$ be the total ordering of the arcs from high to low via their highest zero-cell. For $1 \leq i \leq m$, let z_i denote the highest zero-cell of e_i. Then the zero-cells of the superlevel set at z_i contained in a face of the graph $G^i = G - \{e_1, e_2, \ldots, e_{i-1}\}$ adjacent to e_i form a single zero-cell connected component.*

Proof. For some $1 \leq i \leq m$, consider the graph G^i. Let F denote a face of G^i adjacent to e_i, let z_i denote the highest zero-cell along e_i, and let H_0 denote the superlevel set at the height of z_i that is contained in F. First, we observe that any connected component of H_0 has some zero-cell with maximum height, and so is adjacent to at least one maximum. We therefore aim to show all maxima in F that are adjacent to zero-cells of H_0 (i.e., the maxima of F that are "in" the superlevel set) are connected in H_0. By Lemma 13, we know that any two such maxima are in the same connected component of the superlevel set of z_j, where z_j is the highest zero-cell of the arc e_j that separates these maxima in G. However, such a zero-cell z_j is interior to F, which means z_j must be higher than z_i, otherwise, the arc e_j would not have been removed in G^i, and the arc e_j would be a boundary of F. This means maxima in F adjacent to a zero-cell of H_0 are connected in H_0, and we have shown the claim. ◀

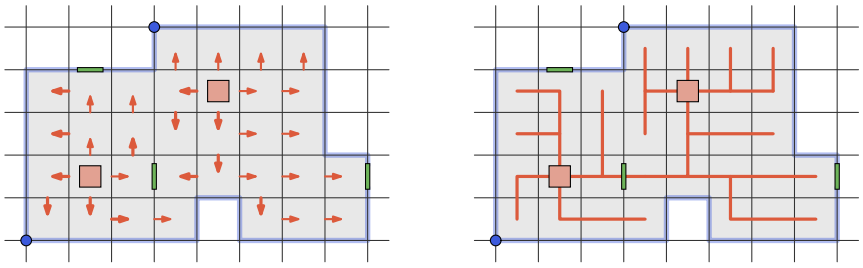

Figure 7 In this single face of G_δ, there are two maxima, so the gradient pairs form a spanning forest consisting of two trees rooted at the maxima (left). By including the saddle, we obtain the red tree for this face, here drawn as the dual (right).

For a single two-cell t, consider the function for volume in t above a particular height; as the height increases/decreases, the volume changes according to a piecewise linear function, with discontinuities every time the height passes over one of the zero-cells of t. Thus, we have a piecewise linear function associated to each two-cell in the terrain.

The function for volume under a face of G above some height is then simply the sum of functions for each two-cell of the face. If the parameters at which the volume function for the face of G changes are sorted (i.e., if the heights of zero-cells in the face are sorted), we can query the function at a specific height by using binary search on the parameters in $O(\log n)$ time. By Lemma 12, by processing arcs from high to low, we know exactly which faces are in the relevant components of the superlevel set above some arc; it is the adjacent merges of faces after we remove all higher arcs from G. The function for volume after the merge of two faces is the sum of functions for volume in each face individually.

4 Volume Persistence for Intertidal Zones

We shift our attention to the detection of fingers, which is primarily relevant when analyzing intertidal zones. As before, we assume our input is a terrain T and use Construction 1 to identify gradient pairings corresponding to a compatible DMF. One major difference between detecting bars separating channels (Section 3) and detecting fingers is that fingers are not necessarily arcs of the MS-complex. Therefore, we have to search for fingers inside each face of the MS-complex. We thus first apply the method from Section 3 for some fixed $\delta > 0$ to identify channels from the MS-complex that separate "sufficient volume." These remaining channels divide the terrain into faces; our goal is to extract fingers within each such face.

First, we define an adaptation of descending paths. Recall that descending paths are alternating sequences of two- and one-cell gradient pairs that collectively form a spanning forest over the terrain, and each maximum corresponds to a tree in this forest. When we filter the MS-complex in Section 3, we remove entire arcs, so that multiple maxima are contained within the same region. Thus, just as we included saddles to connect ascending paths in Section 3, we include saddles to connect descending paths within a particular region. This is illustrated in Figure 7 and defined formally below.

▶ **Definition 15** (Red Tree). *For a terrain, T, and $\delta > 0$, let G_δ denote the associated volume-filtered subnetwork. Within a face of G_δ, add saddles from high to low to the union of descending paths contained within a face of G_δ, stopping once the set of initial trees is joined to form a single (spanning) tree, and omitting any saddles whose inclusion would form a cycle. We call this merged collection of descending paths and saddles a* red tree.

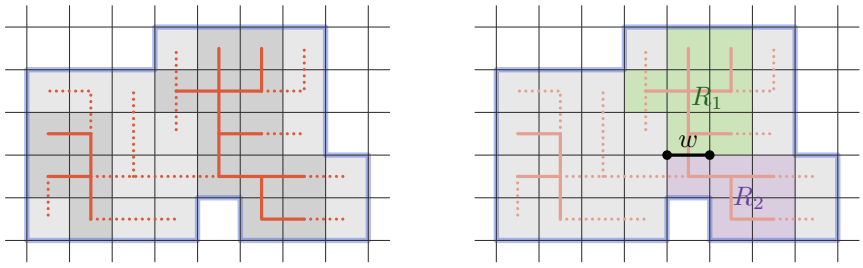

Figure 8 Left: the forest R' for some height h. Right: the volume of a one-cell w is the minimum of the volumes within R_1 and R_2.

Volume and Height Filtration of Descending Paths. In Section 3, we associate volumes to splitting arcs of G, based on the minimum volume of either of the two hills that the arc separates. Here, we take a finer-grained approach and, instead, associate volume to *individual* one-cells in a red tree. While a one-cell generally does not separate hills like a splitting arc of G does, we take inspiration from this sort of behavior and instead, consider the volumes of the two subtrees formed by the one-cell's removal, above a given height. Note that it makes sense to discuss "volume of a subtree" in this setting, as the subtrees are collections of two- and one-cells, and thus, the quarter pillar volume (Definition 3) may be nonzero. More formally, we have the following.

▶ **Definition 16** (Volume of a One-Cell for Height h). *Let R be a red tree with one-cells W. We define the* volume function at any fixed height $h \in \mathbb{R}$, $vol_h \colon W \to \mathbb{R}_{\geq 0}$ *as follows. For a one-cell $w \in W$, let R' be the subforest of R whose one-cells are each incident to some zero-cell with height at least h. Let R_1 and R_2 denote the two subtrees of $R' - \{w\}$ adjacent to w. Let vol_{R_1} and vol_{R_2} be the volumes of the part of the superlevel set of h that corresponds to R_1 and R_2, respectively. Then we define $vol_h(w) = \min\{vol_{R_1}, vol_{R_2}\}$.*

See Figure 8. If the volume of a one-cell at a particular height is low, it does not represent a location in the terrain with significant "separation." Since we eventually use the structure of one-cells that *do* have significant separation in order to identify the locations of our finger channels, we filter the red tree in the following way.

▶ **Definition 17.** *For $\delta \geq 0$, consider G_δ, a volume-filtered subnetwork for some terrain. Suppose that R is a red tree corresponding to G_δ. Let W denote the set of one-cells of R. Then, for $h \geq 0$, we define*

$$R_{\delta,h} = R - \{w \in W \mid vol_h(w) < \delta\}.$$

Note that we now have both a volume and height parameter. If δ varies within a range that does not change the volume filtered subnetwork, G_δ, then decreasing δ or h means more one-cells become part of $R_{\delta,h}$, i.e., we have a bifiltration. However, if δ varies within a range such that G_δ changes, we are no longer guaranteed this property. In particular, if δ increases and an arc of G_δ is removed, two previously disconnected red trees merge, potentially causing the involved one-cells to have a jump in their volumes. In other words, one-cells are monotonically included only within intervals of δ for which G_δ does not change.

Identifying Significant Spurs. First, we define a spur, which is a structure defined for a fixed volume parameter and, conceptually, is determined by noting the order in which various red one-cells have sufficient volume as height varies. It may be helpful to recall that R is a tree made up of one- and two-cells.

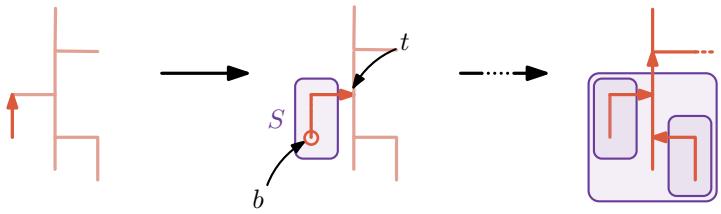

Figure 9 The spur S is defined by beginning at b and stopping once we find two neighbors with higher significance than the previous one-cell. This then defines t and b as the top and bottom of S, respectively. Repeating this process for other leaves, we eventually find all spurs (right).

▶ **Definition 18** (Spurs). *Let R be a red tree. For a fixed $\delta > 0$, each one-cell w of R has a height above which it has volume at least δ; call this the significance of w. Let b be a leaf of R; we check if its adjacent one-cell itself has exactly one adjacent one-cell with higher significance; if so, we move to this new one-cell and repeat this process. Once we encounter a one-cell that does not have exactly one adjacent one-cell with higher significance, we note its last two-cell, t, and define a* spur S with top t and bottom b, *which is the entire subtree of R rooted at t containing the path from b to t. We identify all other spurs by repeating this process for every leaf one-cell of R.*

See Figure 9. The following lemma gives us insight into the structure of spurs of R.

▶ **Lemma 19.** *Let R be a red tree with ℓ leaves, and, for a fixed volume $\delta > 0$, let $(t_i, b_i)_{i=1}^{\ell}$ denote the set of spur top and bottom pairs. Then, for $1 \leq i, j \leq \ell$ if the paths from b_i to t_i and b_j to t_j intersect, the intersection contains either t_i or t_j.*

Proof. When $i = j$, the claim holds trivially. Then consider some $i \neq j$ and suppose that the path from b_i to t_i intersects the path from b_j to t_j, i.e., there is some last two-cell, p, contained in both paths. Towards a contradiction, suppose p is not either t_i or t_j. Then we can denote w_i^1 and w_i^2 as the one-cells on the path from b_i to t_i just before and just after p respectively: define w_j^1 and w_j^2 similarly. Since p is the last two-cell in the intersection, $w_i^2 \neq w_j^2$.

Without loss of generality, suppose the significance of w_i^1 is no higher than that of w_j^1. Note that w_i^2 and w_j^2 are both adjacent to w_i^1, and only w_i^2 can have a higher significance than w_i^2, otherwise, w_i^1 would be adjacent to t_i, contradicting $p \neq t_i$. But then both w_j^2 and w_i^2 would have higher significance than w_j^2, contradicting that w_j^2 is not adjacent to t_j. ◀

Since a spur is a connected collection of one- and two-cells, we measure the volume of a spur using quarter-pillar volume, just as we did previously for other types of superlevel sets.

▶ **Definition 20** (Volume Persistence of Spurs). *Let S be a spur and suppose that the highest zero-cell adjacent to a cell of S has height h_*. We say that the* volume persistence of S *is the volume of the superlevel set at height h_* contained in S.*

A spur with volume persistence of at least δ corresponds to a region of the terrain with enough volume to separate a channel on either side of it, at least up to its flanking height. Specifically, we place fingers along the boundaries of spurs, defined below.

▶ **Definition 21** (Spur Boundaries). *Consider a spur, S. We refer to the collection of zero- and one-cells of S that are adjacent to some two-cell not in S the* boundary of S.

We choose fingers that lie on spur boundaries; our final lemma helps justify this choice.

▶ **Lemma 22.** *Let S be a spur with top t. Then all zero- and one-cells on the boundary of S that are not adjacent to t lie on some collection of ascending paths and saddles.*

Proof. Suppose, towards a contradiction, that w is a one-cell in the boundary of S, not adjacent to t, that does not lie on an ascending path or saddle of the terrain. Recall that every one-cell is either part of an ascending path, is a saddle, or is part of a descending path. I.e., it must be that w is part of a descending path, and thus has a gradient pair to some adjacent two-cell, q. But, since S is the entire subtree below its top, we have $q \in S$, which contradicts our assumption that w is on the boundary of S. ◀

Intertidal Network Computation. We are now ready to compute fingers. We summarize our entire procedure as follows:

1. Extend given elevation data to a DMF on all cells (Construction 1).
2. Compute G_δ, i.e., channels that separate hills of volume no less than δ (Section 3), for an appropriate choice of $\delta > 0$ (in practice, this value is determined by domain experts).
3. In each face of G_δ, create a red tree (Definition 15).
4. For such a red tree, determine its set of spurs (Definition 18).
5. Consider the subset, $\mathcal{S}_\delta$, of spurs with volume persistence no less than δ (Definition 20).
6. For each spur $S \in \mathcal{S}_\delta$, consider the two walks (clockwise and counterclockwise) around the boundary of S starting at the top of S. In each direction, note the first zero-cell we encounter with height no more than the flanking height of S. Such zero-cells define the degree-one end of a finger, and we complete the finger by flowing down via the lowest lexicographical path (along the boundary of S, and then possibly through additional ascending paths and saddles) until we reach a minimum of G_δ.
7. Output G_δ along with all fingers as the resulting network.

We end with a remark that highlights connections between this section and Section 3.

▶ Remark 23. We present intertidal network computation within a face of G_δ and the methods for computing G_δ (Section 3) as two separate operations, but the outputs for each actually share many fundamental behaviors in relation to the terrain. Namely, suppose we consider faces of G_δ as a variant of a spur. The maximum height at which such a face has volume no less than δ is at the highest zero-cell along its boundary, which is necessarily the zero-cell of some saddle. That is, this highest zero-cell height behaves like the flanking height for a spur. Then, just as in Step 6 of the intertidal network computation procedure, by flowing down from this zero-cell (this time in two directions) via the lowest lexicographical path to a minimum of some other face, we recover G_δ as a network. Thus, we could think of network computation in a more streamlined way, and not differentiate between types of ascending paths. However, we chose to present the computation of G_δ as a filtration of channels for clarity, as well as to connect better with related work.

5 Implementation and Validation

To validate our modeling, we implemented our methods and tested the implementation using two real-world datasets: a DEM of the Western Scheldt estuary, and a DEM of a part of the Wadden Sea. The first dataset serves to demonstrate the network extraction from Section 3, while the second dataset demonstrates the finger extraction from Section 4.

Western Scheldt. Figure 10 shows the input and output for the Western Scheldt dataset. In the resulting network (Figure 10f) the color of each arc encodes its volume persistence: from dark purple (high volume) to bright pink (low volume). Arcs with volume persistence less than δ are not shown.

In practice, we found that the method is quite stable under small changes in the DEM. To demonstrate this stability, in Figure 11 we show the networks extracted from historical DEMs from 1999, 2004, 2009, and 2014. Though some areas of the estuary underwent rapid changes during this period, the other parts of the extracted network stay similar.

Figure 11 Networks generated for a time series of four historical DEMs of the Western Scheldt.

Wadden Sea. Figure 12 shows the input and output for the Wadden Sea dataset. This dataset spans the same area as depicted in Figure 1. Figure 12b shows the result of our network extraction method. The method detects one significant bar between two channels, but as expected, does not detect the other features, as they are all fingers. Figure 12d then shows the result of our finger extraction method. The spurs (Figure 12c) represent areas of sufficient volume between fingers, and the extracted fingers capture the tree-like structure of the tidal basin well. In most cases, the flanking height of each spur is a good choice for determining how high the starting point of each finger lies. However, some of the extracted fingers are very short because the flanking height is quite low. This may be alleviated by filtering out fingers in their entirety if their length is below a given threshold.

(b) Network as computed by the method from Section 3.

(c) Spurs shaded with distinct colors.

(d) Network extended with fingers (drawn in orange).

Figure 12 Our finger extraction method (Section 4) applied to a DEM of the Wadden Sea.

Conclusion. The networks found by the implementation show that our algorithm is indeed able to identify geomorphologically salient networks, including fingers, in low-relief terrains. Domain experts have confirmed the high quality of the networks and thereby validated our mathematical modeling.

Abstract

In numerous fields, dynamic time series data require continuous updates, necessitating efficient data processing techniques for accurate analysis. This paper examines the banana tree data structure, specifically designed to efficiently maintain the multi-scale topological descriptor commonly known as *persistent homology* for dynamically changing time series data. We implement this data structure and conduct an experimental study to assess its properties and runtime for update operations. Our findings indicate that banana trees are highly effective with unbiased random data, outperforming state-of-the-art static algorithms in these scenarios. Additionally, our results show that real-world time series share structural properties with unbiased random walks, suggesting potential practical utility for our implementation.

1 Introduction

Time series are pervasive across numerous disciplines, ranging from economics and finance to environmental science and healthcare. Often, time series data is dynamic, not static; for example, wearable devices continuously monitor health metrics such as heart rate or blood sugar levels, requiring robust techniques for instant analysis and decision-making. Effective synthesis of the underlying trends in such dynamic data is crucial for predictive modeling and strategic interventions.

Within the field of topological data analysis, persistent homology [4, 11] is recognized as a powerful framework for capturing multi-scale features in complex datasets. Researchers have long considered the challenge of dynamic persistence, and the vineyard algorithm [7]

was the first developed to address updates in persistence diagrams (defined in Section 2.1) as the input data evolves; see [15] for an implementation. This algorithm, while capable of handling data more general than just time series, requires time linear in the size of the input complex per update, which is restricted to swapping the order of two values. This prompts us to question whether faster processing could be achieved for one-dimensional data. To address this challenge, we implement the banana tree data structure [8], recently introduced and tailored specifically for the persistent homology of dynamic time series. Their theoretical analysis promises the processing of each update in time logarithmic in the number of items plus linear in the number of changes in the persistent diagram; compare this with the linear time require to recompute the diagram [12]. This paper investigates what these results mean in practice. We highlight some of the specific contributions:

- *Efficiency at scale:* we demonstrate that for large datasets, such as those containing over 10^6 items, performing a local or topological update on an unbiased random walk using banana trees is at least 100 times faster than recomputing persistence with `Gudhi` [16], the state of the art static algorithm (see Figure 4).
- *Structure and performance:* we explore how the structure of banana trees, characterized by parameters such as the number of critical items, the nesting depth of bananas, and the lengths of trails, directly impacts the running time of our algorithms. This analysis identifies the types of data best suited for efficient processing (see Figure 2).
- *Worst-case scenarios:* we construct specific examples that challenge our algorithms, and show empirically that these scenarios are rare and highly unstable, reinforcing the robustness of our approach (see Table 2).
- *Real-world data:* through analysis of three specific datasets, we illustrate that real-world data sometimes exhibits structural properties similar to those of unbiased random walks. Preliminary evidence suggests potential for the broad applicability of banana trees in practical scenarios (see Table 3).

In software for topological data analysis, tools like the `Gudhi` library [16], Dionysus [17, 18], and Ripser [2] are established for static datasets but require complete recomputation for updates, making them less suited in dynamic settings. We aim for our implementation to set a new standard in the topological processing of dynamic time series.

Outline. Section 2 introduces persistent homology tailored to time series data and gives an overview of the banana trees data structure. Section 3 evaluates the performance of banana trees through experiments involving time series generated from random walks, with and without a bias. Section 4 explores three distinct types of input time series to assess the performance of banana trees: worst-case scenarios, quasi-periodic signals, and real-world data. Section 5 concludes the paper with a summary of our findings.

2 Banana Trees for Time Series

We start by introducing persistent homology, a method to discern features of data across multiple scales [10]. Forfeiting the generality of this theory, we focus on time series data. We also explain what banana trees are and how they relate to persistent homology; see [8] for details on this data structure and its algorithms.

2.1 Persistent Homology of Time Series

By a *time series* we mean a linear list of real numbers, $c_0, c_2, \ldots, c_{n-1}$, which we view as a piecewise linear map, $f\colon [0, n-1] \to \mathbb{R}$, with $f(i) = c_i$ for $0 \leq i \leq n-1$. We refer to i as an *item* and c_i its *value*. A *critical item* is a local minimum or a local maximum of this map,

and all other items are *non-critical*, e.g. item i if $f(i-1) < f(i) < f(i+1)$. To simplify the discussion, we assume that the map is *generic*, by which we mean that its items have distinct values. In this case, the endpoints (items 0 and $n-1$) are necessarily critical.

The *sublevel set* of f at $t \in \mathbb{R}$, denoted $f_t = f^{-1}(-\infty, t]$, are the points $x \in [0, n-1]$ that satisfy $f(x) \leq t$. When t passes the value of a minimum from below, then the number of connected components of f_t increases by 1, and if t passes the value of a maximum from below, the number of connected components decreases by 1, unless the maximum is an endpoint, in which case the number does not change. Symmetrically, we call $f^t = f^{-1}[t, \infty)$ the *superlevel set* of f at t. Observe that f^t is the sublevel set of $-f$ at $-t$, and that the minima and maxima of $-f$ are the maxima and minima of f. Persistent homology tracks the evolution of the connected components while the sublevel set of f grows, and formally defines when a component is born and when it dies. Complementing this with the same information for the superlevel sets of f, we get what is formally referred to as *extended persistent homology*; see [6] for details. It is best constructed in two phases:

- In *Phase One*, we track the connected components of the sublevel set, f_t, as t increases from $-\infty$ to ∞. A component is *born* at the smallest value of t at which a point of the component belongs to f_t, which is necessarily a minimum. The component *dies* when it merges with another component that was born earlier, which is necessarily at a maximum in the interior of $[0, n-1]$. The *ordinary subdiagram* of f records the birth and death of every component with a point in the plane whose abscissa and ordinate are those values of t at which the component is born and dies, respectively; see Figure 1.
- In *Phase Two*, we track the connected components of the superlevel set, f^t, as t decreases from ∞ to $-\infty$. Birth and death are defined accordingly, and the components are recorded in the *relative subdiagram*.

By construction, the points in the ordinary subdiagram lie above and those of the relative subdiagram lie below the diagonal. The component born at the global minimum of f is special because it does not die during Phase One. Instead, it dies at the global minimum of $-f$, which is the global maximum of f. In topological terms, this happens because the one connected component still alive at the beginning of Phase Two dies in relative homology when its first point enters the superlevel set. This class is represented by the sole point in the *essential subdiagram*. The *extended persistence diagram* is the disjoint union of the three subdiagrams. Hence, the diagram is a multi-set of points in $\mathbb{R}^2$, and so are the three subdiagrams, unless the map is generic, in which case the diagram is a set. See the left panel in Figure 1 for an example but note that it only shows a small number of points in the ordinary subdiagram. An important property of persistence diagrams is their stability with respect to small perturbation of the input data, which was first proved in [5].

The points in the persistence diagram can be characterized using the concept of a *window* introduced in [3]: start with a rectangular frame spanned by a minimum and a maximum in the graph of f such that the minimum lies on the lower edge, and extend the frame horizontally as long as the graph does not intersect the upper edge in its interior. Call the initial frame the *mid-panel*, its extension the *in-panel*, and the symmetric extension for $-f$ the *out-panel*. As proved in [3], the min-max pair defines a point in the persistence diagram iff the graph of f reaches the lower edge in the out-panel. In this case, we call the twice extended frame a *triple-panel window*. The corresponding *double-panel window* consists of the mid-panel and the in-panel but not the out-panel. Any two double-panel windows of f are either disjoint or nested, a property not shared by the triple-panel windows. We use this property to *augment* the persistence diagram by drawing an arrow from a point to another, if the double-panel windows of the first point is nested inside the double-panel window of

the other point, without any other window being nested between them. See Figure 1, which shows four double-panel windows and the corresponding points and arrows in the augmented persistence diagram. The displayed frames are indeed windows because each has an out-panel – next to the mid-panel and thus opposite to the in-panel – which extends as far as the horizontal projection of the minimum (a maximum of $-f$) to the graph of the function.

2.2 Banana Trees

We sketch the banana trees while referring to [8] for the details. Suffice to say that they are based on the Cartesian tree introduced by Vuillemin [21], which stores a list of items in order such that each path from a leaf to the root is ordered by value. This tree has a unique decomposition into paths that correspond to double-panel windows, and the banana tree splits each path into two trails representing the windows nested inside the in-panel and the mid-panel of the corresponding window.

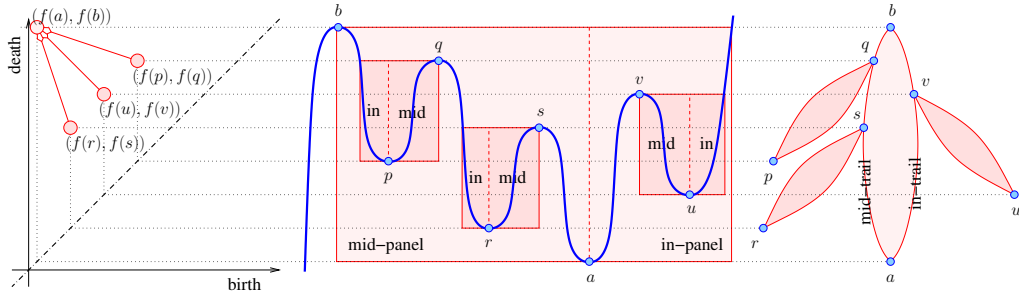

Figure 1 *Middle:* a piece of the graph of f with four double-panel windows of which three are nested inside the fourth. *Left:* the corresponding points in the persistence diagram and the arrows that reflect the nesting relation among the windows. *Right:* the four corresponding bananas in the up-tree of f.

A time series represented by a piecewise linear function, f, is stored in two banana trees together with a linked list and two standard dictionaries. We call the first banana tree the *up-tree* of f because it corresponds to Phase One of the persistence diagram construction. The second banana tree is the *down-tree* of f, which is the up-tree of $-f$. Because of this symmetry, it suffices to describe the up-tree of f. Its *leaves* are the minima of f, and its *internal nodes* are the maxima of f, with the exception of endpoint maxima, if they exist, since they are not critical in Phase One. Each point in the ordinary persistence diagram is a min-max pair, (a, b), and it is represented by a *banana* that connects the leaf a to the internal node b with two parallel trails. The *mid-trail* is a doubly-linked list connecting a to b with the maxima that span windows nested in the mid-panel of the window of a, b, and the *in-trail* is symmetrically defined; see the right panel in Figure 1. The tree structure arises because the maxima belong to the similarly defined bananas of the nested windows. Each trail is sorted in the order of value but also in the order of location along the time series. For example, the mid-trail of the big banana in Figure 1 stores a, s, q, b, which monotonically increases in value and monotonically decreases in location. Compare this with the in-trail storing a, v, b, which monotonically increases in value and in location after we discard b. Indeed, we think of b as part of the mid-trail while only connecting the in-trail to the rest of the tree without properly belonging to it. The global minimum of f (not shown in Figure 1) is special because it is not paired in Phase One. Indeed, it is the extra leaf whose path upward does not end at an internal node. We therefore add a *special root* as the parent of

the root, connected to the global minimum by the *root banana*. While there is only one root banana, there are possibly many *leaf bananas*, which are the bananas with two empty trails (beside the minimum and maximum they connect). Indeed, we call the number of nodes strictly between the minimum and maximum the *length* of the trail, which for trails of leaf bananas is necessarily zero. Another important concept is the *nesting depth* of a banana, which is the number of windows that contain the corresponding window. The root banana has nesting depth zero, and all other bananas have positive nesting depth.

Each update to a time series stored in a banana tree reduces to a sequence of elementary operations, which we name by their impact on the function, f. An *interchange* happens when two maxima or two minima swap the order of their values. Unless their locations are near each other, there is a good chance that an interchange does not have any effect on the banana tree. Otherwise, it is akin a rotation in a binary search tree, if the interchange is between two maxima, and akin a local rearrangement of the path decomposition, if the interchange is between two minima. A *cancellation* removes a min-max pair or, equivalently, the corresponding leaf banana, an *anti-cancellation* is the inverse of a cancellation, and a *slide* swaps the type of a critical item with that of a neighboring non-critical item. The latter three operations appear only a constant number of times whenever we adjust a value. Nevertheless, anti-cancellations present challenges to fast implementation as we have to find out where the new banana is to be inserted, and this search is not supported by any special purpose data structure. On the other hand, multiple interchanges may happen in sequence, so it is important to charge the time for processing each to a change in the persistence diagram. We refer to [8] for details.

3 Experimental Results for Random Walks

This section studies the structural properties of banana trees for random walks, both biased and unbiased. In addition, it compares the running times of local and topological operations with the static algorithm in `Gudhi` [16]. We do not compare it with vineyards [7], which lack optimized software for the one-dimensional case.

We implemented the banana trees data structure in C++20, using the AVL trees and splay trees provided by `boost.intrusive` [14]. The former offer good performance in general, the latter allow for simple splitting and joining. Hence, we use splay trees when performing topological operations and AVL trees everywhere else. The experiments were run on a machine with two AMD EPYC 9534 64 core CPUs and 1.5 terabyte of main memory.

3.1 The Experimental Set-up

We write $\gamma \sim \mathcal{N}(\mu, \sigma)$ for a normally distributed random variable with mean μ and standard deviation σ. Given μ, σ, a *random walk* of length n is a function, $r = r_{\mu,\sigma}$, from the first n non-negative integers to the reals, defined by

$$r(0) = 0 \quad \text{and} \quad r(i) = r(i-1) + \gamma_i \quad \text{for } 1 \leq i < n, \tag{1}$$

in which the $\gamma_i \sim \mathcal{N}(\mu, \sigma)$ are independent. The random walk is *unbiased* if $\mu = 0$ and *biased* if $\mu \neq 0$. We assume $\sigma = 1$ unless stated otherwise.

To evaluate the performance of local updates, we change the value of a single item, and since it depends on the amount, we fix parameters $\Delta \in \mathbb{R}$ and $k \in \mathbb{N}$ and do $2k+1$ parallel updates by changing the value of the i-th item from $r(i)$ to $r(i) + \delta_j$, with $\delta_j = \frac{j}{k}\Delta$ for all integers j with $-k \leq j \leq k$. For the experiments, we pick $\Delta = 5.0$ or 50.0 and $k = 10$, while doing the update on a random walk of length between 10^2 and 10^6 generated for $\mu \in [-1, 1]$

and $\sigma = 1$. Each experiment is repeated one hundred times and averages as well as deviations from the average are reported. For each experiment, we also measure the time to run `Gudhi` on the walk after the value change. This provides the appropriate reference time, since `Gudhi` needs to recompute the persistence diagram from scratch after each update.

To evaluate the performance of topological updates, we pick a fraction, $c \in (0, 1)$, generate a random walk of length n, and then cut it into a *left walk* containing the first $\lfloor cn \rfloor$ items and a *right walk* containing the remaining $\lceil (1-c)n \rceil$ items. There are two such updates, which we now define. To *split*, we first construct the banana tree of the entire random walk, which we then cut into two banana trees, one for the left and the other for the right walk. To *glue*, we first construct the banana trees of the left and right walks, which we then combine to a single banana tree for the walk of length n. Doing this for fractions $c \in \{0.1, 0.3, 0.5, 0.7, 0.9\}$, we compare the time to split with the time used by `Gudhi` to construct the persistence diagrams of the left and right walks, and the time to glue with the time used by `Gudhi` to construct the persistence diagram of the entire random walk.

3.2 Structural Properties

We focus on three structural properties of banana trees, which have direct implications for the running time of our algorithms: the *number of critical items*, the *nesting depth of bananas*, and the *lengths of trails*. Since a banana tree does not store non-critical items, its number of nodes is the number of critical items. In an unbiased random walk, the expected number of critical items is 50% of all items. This fraction decreases when the bias increases, with about 27% for $\mu = \pm 1$; see the left panel in Figure 2 for more detailed information.

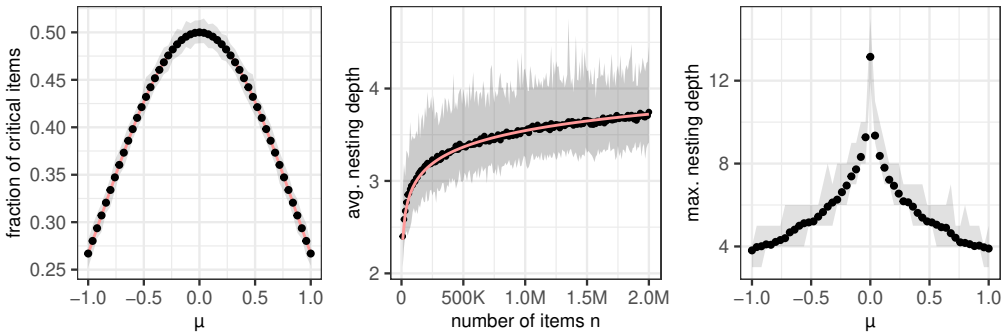

Figure 2 *Left:* the average fraction of items that are critical as a function of the bias μ. *Middle:* the average nesting depth of leaf bananas in banana trees of unbiased random walks with n items. The *ribbon* extends from the minimum to the maximum observed value for each n; the dots mark the mean. The *red line* is the graph of a constant times $\log n$ obtained by linear regression. *Right:* the maximum nesting depth at $n = 10^6$ items as a function of the bias μ.

The middle panel of Figure 2 shows the average nesting depth of a leaf banana for an unbiased random walk, which appears to scale like the logarithm of the number of items. In the unbiased case, even the maximum nesting depth seems to be small (about 13 on average for a random walk of length $2 \cdot 10^6$), and scale logarithmically in the number of items. With increasing bias, the maximum nesting depth decreases, to about 4 at $\mu = \pm 1$; see the right panel of Figure 2. This is because in the biased case, there are fewer critical items but also the bananas tend to arrange in parallel rather than inside each other. We observe that the nesting depth is about the same on average in up-trees and down-trees, both for biased and unbiased random walks, so our results hold for both trees.

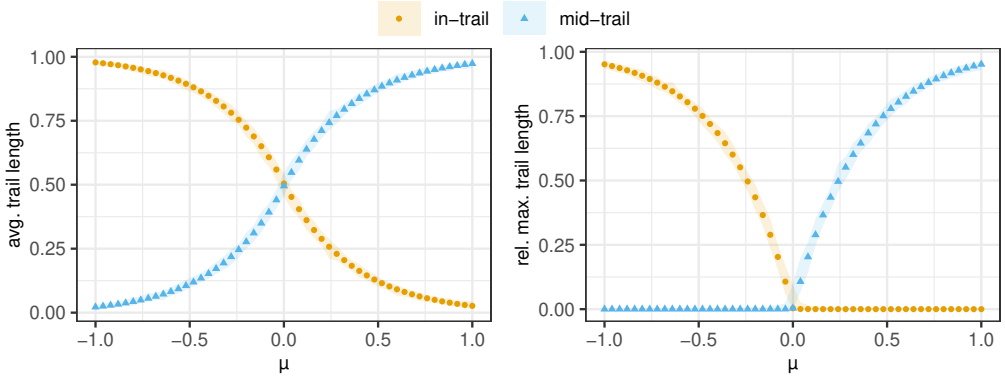

Figure 3 *Left:* the average length of in-trails (*orange dots*) and mid-trails (*blue triangles*) in banana trees of random walks with bias μ, averaged over all input sizes. *Right:* the fraction of nodes on the longest in-trail (*orange dots*) and longest mid-trails (*blue triangles*) in banana trees of random walks with bias μ, averaged over all input sized.

For topological reasons, the mid-trails of the up-tree are the mid-trails of the down-tree, except that they are upside down. In contrast, the in-trails of the two trees are not directly related because the in-panels in one direction become the out-panels in the other. Notwithstanding, we observe that the length of the in-trails in the up-tree and the mid-trails in the down tree are very similar on the average, and by symmetry the same holds for the mid-trails in the up-tree and the in-trails in the down-tree. These two facts do not contradict each other, because for biased data most of the critical items belong to the root banana, which does not adhere to the topological constraints just mentioned. Let us therefore focus on the up-tree. The left panel in Figure 3 shows how the average length of in- and mid-trails depends on the bias. In the unbiased case, both types of trails have the same length on average. For positive μ, the mid-trails tend to be longer than the in-trails, while the reverse happens for negative μ. The main cause for this trend is the longest trail, which starts to dominate the others in length as the bias increases; see the right panel in Figure 3. Assuming $\mu > 0$, the global minimum and maximum tend to lie to the left and right of the middle, respectively, with the majority of the items between them. By convention, the connecting in-trail and mid-trail contain the items to the left and right of the global minimum, respectively. This explains why the mid-trail dominates in this case, and why the in-trail dominates when $\mu < 0$. Indeed, for $\mu = \pm 1$, we observe about 95% of the internal nodes (the local maxima) on the longest trail.

3.3 Local Maintenance

We evaluate the performance of banana trees when the value of a single item changes by δ. Note that the corresponding update is a combination of some number of interchanges and at most one cancellation, at most one anti-cancellation, and at most two slides [8]. Not surprisingly, the time increases with the amount of change. For example, there is no effect at all on the persistence diagram for about 70% of the updates with $\delta = \pm 0.26$, for about 36% of the updates with $\delta = \pm 0.79$, but only about 1% for updates with $\delta = \pm 3.4$. Taking this into account, it is not surprising that banana trees are faster than `Gudhi` when $\delta = \pm 0.26$ for all lengths of random walks we tried.

The left panel in Figure 4 focuses on the case $\delta = \pm 5.0$. As indicated by the vertical dashed and dotted lines, banana trees are faster than `Gudhi` for all random walks of length $n \geq 1059$, and faster in the median for all $n \geq 144$. Not shown in the panel is that the

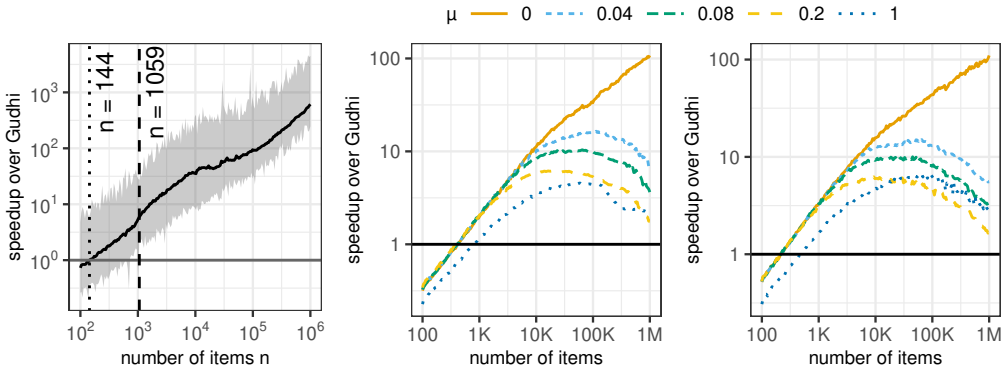

Figure 4 Comparing the maintenance of banana trees with reconstructing the persistence diagram with `Gudhi`, in which the baseline of no speedup ($10^0 = 1$) is marked with a *horizontal gray* line. *Left:* the speedup for updating a value with $\delta = \pm 5.0$ depending on the length of the random walk, n. The ribbon spans the minimum and maximum observed speedup, with the *black curve* tracing the median speedup. *Middle:* the speedup for using banana trees to cut a random walk with bias μ in half. The type and color of the curve encodes the amount of bias, and each curve shows the median speedup over a hundred repeats for each n. *Right:* the speedup for using banana trees to concatenate two equally long random walks with bias μ.

speedup decreases with increasing bias. In particular, for $n = 10^6$, the speedup of 612 at $\mu = 0$ decreases to 258 at $\mu = 1$, and for $n = 1059$, the speedup of 6.0 at $\mu = 0$ decreases to 2.9 at $\mu = 1$. This can be explained by recalling that for large bias the majority of the internal nodes belong to the longest trail, which connects the global minimum to the global maximum. Hence, items with similar values are likely to be near each other and thus require interchanges when an update is performed. However, even for a large change, such as for $\delta = \pm 50.0$, maintaining the banana tree is still faster than reconstructing the persistence diagram with `Gudhi`. For example, the median speedup for $n = 10^4$ exceeds 10 and for $n = 10^6$ it exceeds 100.

3.4 Topological Maintenance

We call the operations of *cutting* a list into two, and *concatenating* two lists to one topological because they change the number of lists in the overall organization of the data. We begin with evaluating the performance of cutting a random walk. The middle panel in Figure 4 shows the speedup over `Gudhi` when we cut a biased or unbiased random walk in half. In the unbiased case, the speedup increases with the length of the walk. Recalling the discussion of structural properties, this can be rationalized by noticing that the maximum nesting depth bounds the number of bananas that need to be split, and the trail length bounds the time to reorganize bananas. The maximum nesting depth scales like $\log n$ and the average trail length is only 0.5, so we anticipate logarithmic time for splitting, which we indeed observe in our experiments. Altering the position of the cut increases the speedup, namely by about 2% for $c = 0.5 \pm 0.2$ and by about 7% for $c = 0.5 \pm 0.4$.

The advantage of the banana tree over `Gudhi` diminishes when the random walks get progressively more biased. The reason is again that the larger the bias, the larger the fraction of internal nodes in the longest trail of the banana tree. Splitting the corresponding banana requires the resetting of many pointers stored in nodes along this trail, which in some cases costs time proportional to the number of critical items, which we indeed observe in our

experiments. Unfortunately, this more than compensates for the low nesting depth, which guarantees that only a small number of bananas need to be split. The upper half of Table 1 shows the running time and the speedup over `Gudhi` for cutting a random walk in half.

Table 1 *Upper half*: the average time for cutting a random walk of length $n = 10^6$ in half, and the speedup over `Gudhi`. *Lower half*; the average time for concatenating two random walks of length $n = 10^6/2$ each, and the speedup over `Gudhi`.

		$\mu = 0$	$\mu = 0.04$	$\mu = 0.08$	$\mu = 0.2$	$\mu = 1$
Cut	time in μs	93	1417	2807	5350	1683
	speedup	105.00	7.24	3.54	1.68	2.15
Concatenate	time in μs	90	1809	3041	5138	1228
	speedup	105.00	5.31	3.12	1.74	3.22

We finally address the reverse operation, that of concatenating two random walks or, correspondingly, of gluing two banana trees. The curves in the right panel of Figure 4 are similar to those in the middle panel, which suggests that the performance is similar to that of cutting, which is confirmed by the numbers in Table 1. For $n \leq 10^4$, gluing appears to be slightly faster than splitting, but the difference is less clear already for $n = 10^6$.

4 Special Time Series

This section considers three types of time series: *worst-case examples* to expose when banana trees under-perform, *quasi-periodic data* to illustrate how banana trees reflect periodicity, and *real-world data* to demonstrate that banana trees are not just theory. While banana trees struggle for data of the first type, they mirror the performance observed in unbiased random walks for the latter two types.

4.1 Worst-Case Examples

The size of the augmented persistence diagram (number of points and arrows) is proportional to the number of critical items. There are configurations in which a single update changes almost the entire diagram and thus takes time at least linear in the number of such items. We construct such *worst-case inputs* and study the performance of banana trees when confronted with such data.

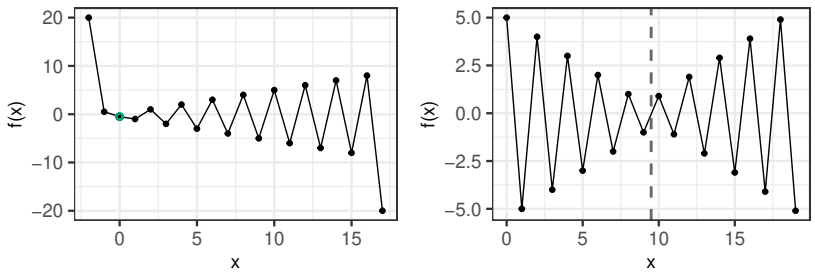

Figure 5 Worst-case examples for local and topological maintenance. *Left:* to increase the value of the marked item triggers a linear number of interchanges. *Right:* to cut the list at the *dashed line* affects every persistent pair. Both operations take time linear in the number of critical items, which for the two time series are all or almost all items.

Consider first the operation that increases the value of the marked item in the left panel of Figure 5. Initially, we have a linear sequence of double-panel windows, each nested inside the next. When the value of the marked item passes that of its left neighbor, an anti-cancellation adds the banana they span to the banana tree, and its window is nested inside the others. As we increase the value further, the marked item interchanges with the maxima to its right, each time moving up one level within the sequence of windows. When the marked item finally becomes the global maximum, it will have interchanged with all other maxima, which takes $\Theta(n)$ time. For $n = 10^2$ and $n = 10^6$, we measured 3.4μs and 4.7ms on average, respectively. This corresponds to a median speedup by a factor of 0.05 and 0.02 if compared with `Gudhi`, which is really a slowdown by a factor of 20 and 50, respectively.

Table 2 Performance of splitting and gluing banana trees for the example time series in the right panel of Figure 5, showing the median slowdown/speedup if compared to `Gudhi`. The parameter interpolates between these time series at $\lambda = 0$ and unbiased random walks at $\lambda = 1$.

	split				glue			
	$\lambda = 0.0$	0.0001	0.01	1.0	$\lambda = 0.0$	0.0001	0.01	1.0
$n = 10^2$	0.06	0.06	0.04	0.35	0.40	0.44	0.68	2.38
$n = 10^4$	0.04	0.03	5.81	11.20	0.46	0.83	33.6	41.40
$n = 10^6$	0.09	4.71	54.70	111.00	0.46	81.0	255	397.00

Consider second the operation that cuts the time series in the right panel of Figure 5 in the middle, which is marked by the vertical dashed line. We observe an average running time between 10μs at $n = 10^2$ and 72ms at $n = 10^6$. Compare this with an average running time of 7μs at $n = 10^2$ and 48ms at $n = 10^6$ for concatenating the two lists back to the original length. This comparison agrees with the earlier observation that gluing banana trees is slightly faster than splitting them. Table 2 lists the speedup if compared to `Gudhi`, which for a factor less than 1 is really a slowdown. To create a more informative experiment, we interpolate between these time series and unbiased walks, with drastic improvements even for small $\lambda > 0$; see Table 2. Indeed, the noise quickly flattens the banana tree by decreasing the length of trails, which explains the improvement.

4.2 Quasi-Periodic Data

Random walks are not periodic, but real-world time series often exhibit some amount of periodicity, at least approximately. To study banana trees under these conditions, we construct what we call *quasi-periodic* inputs. This term does not have a mathematical definition, and for our experiments just means a periodic signal that is randomly perturbed. Specifically, we generate such input by modifying the iterative construction in (1):

$$r(0) = 0 \quad \text{and} \quad r(i) = r(i-1) + \eta_i \quad \text{for } 1 \leq i < n, \tag{2}$$

in which the $\eta_i \sim \mathcal{N}(\mu_i, \sigma)$ are independent and normally distributed, with the mean changing periodically, $\eta_i = \sin(2\pi\omega i)$, as governed by the *frequency parameter* $0 \leq \omega < 1$, which we fix to $\omega = 5/n$. It will be useful to compare the influence of the standard deviation, so we no longer assume $\sigma = 1$.

For large σ, the banana trees of the time series show the features we have seen for unbiased random walks, while for small σ, they locally behave like biased random walks. For example, for $\sigma = 1$, we observe about 37% of the items to be critical, while for $\sigma = 0.5$ and $\sigma = 0.02$ only about 21% and 1% of the items are critical, on average. Like the number of critical

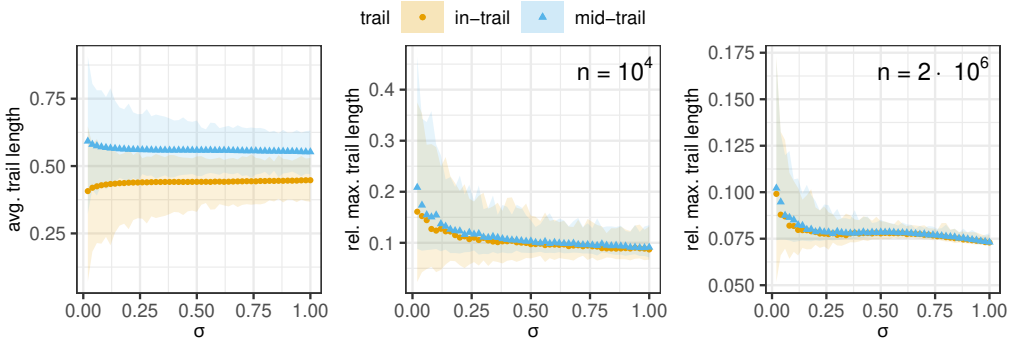

Figure 6 Measuring trail lengths. The in-trails and mid-trails are marked with *orange dots* and *blue triangles*, respectively, and the ribbons extend from the minimum to the maximum observed values. *Left:* the average length of in-trails and mid-trails depending on the standard deviation and averaged over all input sizes. *Middle and right:* the fraction of nodes on the longest in-trail and mid-trail, again depending on the standard deviation but now averaged over inputs of size 10^4 and $2 \cdot 10^6$, respectively.

items, also the maximum nesting depth for quasi-periodic signals is similar to that of random walks: it scales like $\log n$ for large σ and decreases as σ goes to 0. In contrast, the average nesting depth is independent of n, ranging from 2 to 4.7 with mean 2.4. The behavior of the trail length is illustrated in Figure 6. As shown in the left panel, the average trail length is about 0.5, with consistently shorter in-trails than mid-trails, on average. This difference is more pronounced for small σ, when the quasi-periodic signal behaves more like a biased rather than unbiased random walk. The middle and right panels show how the fraction of internal nodes on the longest trail increases as σ goes to 0.

We conclude that banana trees on quasi-periodic signals with large standard deviation resemble unbiased random walks in terms of their structural parameters, and drift toward biased random walks as the standard deviation goes to 0.

4.3 Real World Examples

We analyze structural properties of banana trees constructed on three types of real-world time series:

- electrocardiography (ECG) data from PhysioNet [13, 1, 20]; limiting ourselves to recordings of length at least 10^5, each separated into up to 12 leads, gives 32443 time series in total;
- audio data from EasyCom [9], of which we use 1336 audio files;
- physical activity data from PAMAP2 [19] (temperature, heart rate along with recordings from accelerometers, gyroscopes, and magnetometers), of which we use 560 time series.

We preprocess the data by adding uniformly distributed noise to ensure all values are distinct, making sure the noise is small enough so it breaks ties but does not otherwise alter the ordering.

We observe that the average max nesting depth for the three data sets is only a small factor larger than for unbiased random walks; see the middle three columns in Table 3. The largest maximum nesting depth for PhysioNet data is a bit higher, by a factor 6.3, but 99% of the time series from this data have maximum nesting depth at most 1.68 times that for unbiased random walks. The average trail lengths are again similar to those of

Table 3 Structural properties of the banana trees constructed for time series from three databases. The average, minimum, and maximum of the maximum nesting depth is measured relative to the depth we observe for unbiased random walks with the same fraction of critical items.

	fraction of critical items	max nesting depth			average length	
		avg	min	max	in-trail	mid-trail
PhysioNet	0.24	1.2	0.8	6.3	0.48	0.52
EasyCom	0.22	2.7	1.6	4.9	0.48	0.52
PAMAP2	0.48	1.9	1.2	3.2	0.49	0.51

unbiased random walks – see the last two columns, with standard deviation about 0.05 throughout – and so are the fractions of items in the longest trails, whose geometric means are $0.8\%, 0.008\%, 0.1\%$ of all critical items for the in-trails and $0.8\%, 0.008\%, 0.2\%$ of all critical items for the mid-trails in the three data sets, compared with about 0.3% and 0.4% in unbiased random walks.

5 Discussion

We provide an implementation of the banana tree data structure and supply experimental evidence demonstrating its efficiency. The work reported in this paper confirms the theoretical advantages of banana trees over static alternatives and opens up avenues for further theoretical inquiries and practical applications. One intriguing question that arises in the context of quasi-periodic data is whether we can determine the (possibly varying) period of the data without prior knowledge, or provide meaningful quantification of the extent to which a signal deviates from being periodic.

The potential applications of banana trees extend beyond academic research into practical, real-world scenarios. Comparisons with other methods and identifying impactful use cases represents a promising next step to provide valuable insights in fields such as healthcare, where real-time analysis of patient data is crucial, or finance, where the swift analysis of market data is essential.

Geometric Bipartite Matching Based Exact Algorithms for Server Problems

Rachita Sowle
Virginia Commonwealth University, Richmond, VA, USA

Abstract

For any given metric space, obtaining an offline optimal solution to the classical k-server problem can be reduced to solving a minimum-cost partial bipartite matching between two point sets A and B within that metric space.

For d-dimensional ℓ_p metric space, we present an $\tilde{O}(\min\{nk, n^{2-\frac{1}{2d+1}} \log \Delta\} \cdot \Phi(n))$ time algorithm for solving this instance of minimum-cost partial bipartite matching; here, Δ represents the spread of the point set, and $\Phi(n)$ is the query/update time of a d-dimensional dynamic weighted nearest neighbor data structure. Our algorithm improves upon prior algorithms that require at least $\Omega(nk\Phi(n))$ time. The design of minimum-cost (partial) bipartite matching algorithms that make sub-quadratic queries to a weighted nearest-neighbor data structure, even for bounded spread instances, is a major open problem in computational geometry. We resolve this problem at least for the instances that are generated by the offline version of the k-server problem.

Our algorithm employs a hierarchical partitioning approach, dividing the points of $A \cup B$ into rectangles. It maintains a partial minimum-cost matching where any point $b \in B$ is either matched to another point $a \in A$ or to the boundary of the rectangle it is located in. The algorithm involves iteratively merging pairs of rectangles by erasing the shared boundary between them and recomputing the minimum-cost partial matching. This continues until all boundaries are erased and we obtain the desired minimum-cost partial matching of A and B. We exploit geometry in our analysis to show that each point participates in only $\tilde{O}(n^{1-\frac{1}{2d+1}} \log \Delta)$ number of augmenting paths, leading to a total execution time of $\tilde{O}(n^{2-\frac{1}{2d+1}} \Phi(n) \log \Delta)$.

We also show that, for the ℓ_1 norm and d dimensions, any algorithm that can solve instances of the offline n-server problem with an exponential spread in $T(n)$ time can be used to compute minimum-cost bipartite matching in a complete graph defined on two $(d-1)$-dimensional point sets under the ℓ_1 norm within $T(n)$ time. This suggests that removing spread from the execution time of our algorithm may be difficult as it immediately results in a sub-quadratic algorithm for bipartite matching under the ℓ_1 norm.

1 Introduction

This paper considers two classical optimization problems: the *offline k-server* problem and the *minimum-cost bipartite matching* problem in geometric settings.

Offline k-server problem and its variant. Consider a sequence of requests $\varsigma = \langle r_1, \ldots, r_m \rangle$ in a metric space equipped with the cost function $\mathrm{d}(\cdot, \cdot)$. The cost of a single server *servicing* the requests in ς is the sum of the distances between every consecutive pair of points in the sequence, i.e., $\mathfrak{c}(\varsigma) = \sum_{i=1}^{m-1} \mathrm{d}(r_i, r_{i+1})$. Given a sequence $\sigma = \langle r_1, \ldots r_n \rangle$ of n requests and an integer $1 \leq k \leq n$, the *k-sequence partitioning problem* (or simply the k-SP problem) requires partitioning the requests in σ into k subsequences $\varsigma_1, \ldots, \varsigma_k$ so that $\sum_{i=1}^{k} \mathfrak{c}(\varsigma_i)$ is minimized. The optimal solution for the k-sequence partitioning problem is the cheapest way for k servers to service all of the requests in σ. We also consider a variant: the *k-sequence partitioning with initial locations problem* (or the k-SPI problem). Here, in addition to the requests σ, we are also given the initial locations $\eta = \langle s_1, \ldots, s_k \rangle$ for the k servers. The objective of this problem is to partition $\sigma' = \eta\sigma$ into k subsequences $\varsigma_1, \ldots, \varsigma_k$ so that the initial location s_j of server j appears in the first element of the subsequence ς_j and the cost $\sum_{i=1}^{k} \mathfrak{c}(\varsigma_k)$ is minimized. The optimal solution to the k-SPI problem is the offline optimal solution to the well-known k-server problem.

We assume that the requests in σ and the initial locations in η are scaled and translated so that they are contained inside the unit hypercube $[0, 1]^d$. Such scaling and translation do not impact the optimal solutions for the k-SP and k-SPI problems. We define the diameter $\mathrm{Diam}(\sigma)$ to be the largest distance between any two request locations in σ and the *closest pair distance*, denoted by $\mathrm{CP}(\sigma)$, to be the smallest non-zero distance between any two requests in σ. The *spread*, denoted by Δ, is the ratio of the diameter to the closest-pair distance, i.e., $\Delta = \mathrm{Diam}(\sigma)/\mathrm{CP}(\sigma)$.

Minimum-cost bipartite matching. Consider a weighted bipartite graph $G(A \cup B, E \subseteq A \times B)$, where each edge between u and v is assigned a real-valued cost. Let $n := \min\{|A|, |B|\}$. A *matching* of size $t \leq n$, or simply a *t-matching*, is a set of t edges in G that are vertex-disjoint. The *cost* of any matching M is the sum of the costs of its edges. Given a parameter $t \leq n$, the *minimum-cost bipartite t-matching* problem seeks to find a t-matching with a minimum cost. When $|A| = |B| = n$, a matching of size n is called a *perfect matching*. When A and B are d-dimensional point sets and the cost of any edge between $a \in A$ and $b \in B$ is the ℓ_p distance $\|a - b\|_p$, the problem of finding the minimum-cost bipartite t-matching is also called the (partial) *geometric bipartite matching problem*.

Relating the two problems. Chrobak *et al.* [4] established a reduction from the minimum-cost bipartite t-matching problem to the k-SPI problem.

▶ **Lemma 1** ([4, Theorem 11]). *Any algorithm that computes an optimal solution to the n-SPI in an arbitrary metric space in $T(n)$ time can also find, in $T(n) + O(n^2)$ time, a minimum-cost perfect matching in any complete bipartite graph with real-valued costs.*

We strengthen the connection between the two problems by showing a reduction in the reverse direction, i.e., we reduce the k-SP (resp. k-SPI) problem to the minimum-cost bipartite t-matching problem. Given an input sequence σ of requests to the k-SP problem, we construct a bipartite graph $\mathcal{G}_\sigma$ with a vertex set $A \cup B$ and a set of edges $\mathcal{E}$ as follows. *Vertex Set:* For each request r_i, we create a vertex b_i (resp. a_i) in B (resp. A) and designate it as the *entry* (resp. *exit*) gate for request r_i. *Edge Set:* The exit gate a_i of request r_i is connected to the entry gate b_j of every subsequent request r_j with $j > i$ with an edge. The cost of this edge is $\mathrm{d}(a_i, b_j) = \|r_i - r_j\|_p$. Any minimum-cost $(n - k)$-matching M in $\mathcal{G}_\sigma$ can be used to find an optimal solution to the k-SP problem. See Figure 1.

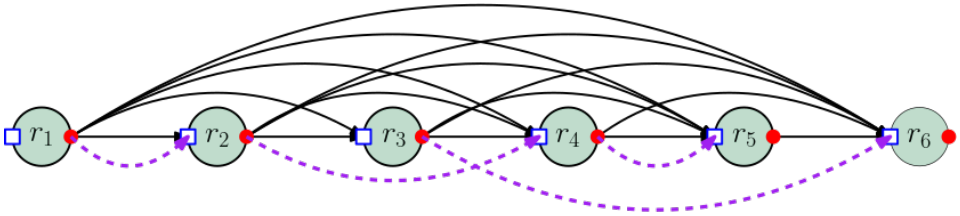

Figure 1 The graph $\mathcal{G}_\sigma$ constructed for $\sigma = \langle r_1, r_2, \ldots, r_6 \rangle$. The vertex set A (red disks) and B (blue squares) represent the exit and entry gates of each request, and the purple dashed lines show an $(n-2)$-partial matching on $\mathcal{G}_\sigma$ representing a 2-partitioning $\langle r_1, r_2, r_4, r_5 \rangle$ and $\langle r_3, r_6 \rangle$.

For the k-SPI problem, for each server j, we add a vertex a^j at the initial location s_j to A and connect a^j to the entry gate b_i of every request r_i in σ. The cost of this edge is $\mathrm{d}(a^j, b_i) = \|s_j - b_i\|_p$. A minimum-cost n-matching in this graph can be converted to an optimal solution for the k-SPI problem.

A different reduction from k-SP and k-SPI problems to the minimum-cost flow problem has been presented in previous works [4, 22, 24], leading to the development of $O(n^2k)$ time algorithm. However, unlike our reduction, their approach generates instances that include edges whose costs are $-\infty$ and fails to maintain the metric properties of costs.

▶ **Lemma 2.** *An optimal solution for an instance σ (resp. σ') of k-SP (resp. k-SPI) problem can be found by computing a minimum-cost matching of size $n-k$ (resp. n) in $\mathcal{G}_\sigma$ (resp. $\mathcal{G}_{\sigma'}$).*

Finally, we extend the reduction Chrobak *et al.* [4] to geometric settings and provide a reduction from the geometric minimum-cost matching problem under the ℓ_1-norm to the geometric version of the n-SPI problem. This reduction, however, creates an instance of the n-SPI problem with a spread of 3^n. Lemma 3 follows directly from this reduction.

▶ **Lemma 3.** *Any algorithm that can solve the d-dimensional n-SPI problem under the ℓ_1 costs in $T(n)$ time can also be used to solve an instance of minimum-cost bipartite matching under the ℓ_1 costs on a complete graph in $T(n)$ time.*

Related work. For a graph with m edges and n vertices, the classical Hungarian algorithm computes a minimum-cost t-matching for all values of $0 \le t \le n$ [11, 16]. Starting with an empty matching, the Hungarian algorithm iteratively builds a minimum-cost i-matching from the maintained minimum-cost $(i-1)$-matching in $O(m + n \log n)$ time by finding a *minimum net-cost augmenting path*, i.e., an augmenting path that increases the matching cost by the smallest value. The overall execution time of the Hungarian algorithm is $O(nm + n^2 \log n)$, or $O(n^3)$ when $m = \Theta(n^2)$. Despite substantial efforts, this remains the most efficient algorithm for the problem. Notable exceptions include specialized cases, such as graphs with small vertex separators [13] or integer edge weights [2, 5, 6].

In geometric settings, Vaidya showed that each iteration of the Hungarian algorithm can be implemented in $\tilde{O}(n\Phi(n))$ time, where $\Phi(n)$ represents the query/update time of a dynamic weighted nearest neighbor (DWNN) data structure. Thus, the minimum-cost t-matching can be computed in $O(n^2\Phi(n))$ time, which is sub-cubic in n provided $\Phi(n)$ is sub-linear. For instance, for the ℓ_1 norm and d dimensions, $\Phi(n) = O(\log^d n)$ [27] and for the ℓ_2 norm and 2 dimensions, $\Phi(n) = \log^{O(1)} n$ [8]. In these cases, the Hungarian algorithm can be implemented in near-quadratic time.

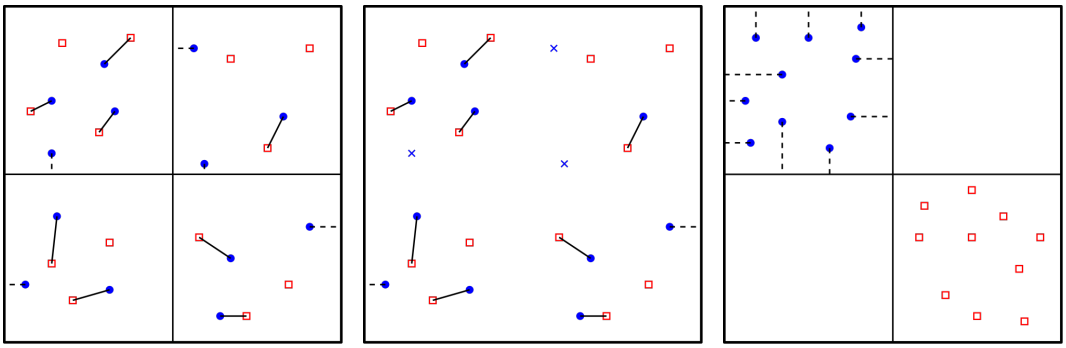

Figure 2 Illustration of the GRS algorithm.

Designing algorithms that compute a minimum-cost matching using sub-quadratic DWNN queries remains a central open problem in computational geometry. There are three notable exceptions. First, for points with integer coordinates and the ℓ_1 and ℓ_∞ norms, Sharathkumar and Agarwal [26] adapted a cost-scaling algorithm [5] and presented an algorithm that executes in $\tilde{O}(n^{3/2}\Phi(n))$ time. Second, Sharathkumar [25] extended this result to 2-dimensional point sets with integer coordinates and the ℓ_2 costs. Their result, however, relies on planarity as well as the edge costs being the square root of integers and does not extend to d-dimensional points with real-valued coordinates. Third, Gattani *et al.* [7] presented a divide-and-conquer algorithm (GRS algorithm) with a worst-case runtime of $\tilde{O}(n^2\Phi(n)\log\Delta)$, where Δ is the spread of the points. For 2-dimensional *stochastic* points drawn from an unknown distribution, however, the expected runtime of the GRS algorithm improves to $\tilde{O}(n^{7/4}\Phi(n)\log\Delta)$.

The GRS algorithm uses a randomly-shifted quadtree to divide the problem into smaller subproblems. Within each square $\square$ of the quadtree, it recursively computes a *minimum-cost extended matching*, allowing each point of B in $\square$ to match either to a point of A in $\square$ or to the boundaries of $\square$ (Figure 2(left)). The algorithm then combines the matchings of the child squares by *erasing* their common boundaries, freeing points of B that were matched to those boundaries (Figure 2(middle)), and then it iteratively matches the freed points.

Gattani *et al.* [7] showed that for stochastic point sets A and B, most points in B will match to a close-by point in A and only $\tilde{O}(n^{3/4})$ points will match to boundaries. Thus, erasing these boundaries creates $\tilde{O}(n^{3/4})$ free points, each again matched in $O(n\Phi(n))$ time, resulting in an overall runtime of $\tilde{O}(n^{7/4}\Phi(n))$. However, this efficiency does not extend to arbitrary point sets. For instance, if all points in A lie in one child $\square_1$ and all points in B lie in another child $\square_2$, then all edges of a minimum-cost matching cross the boundaries. In this case, the minimum-cost extended matching in $\square_2$ matches all points in B to its boundary (Figure 2(right)), and erasing the boundary creates n free points. Hence, the merge step takes $\Omega(n^2\Phi(n))$ time. Furthermore, unlike the Hungarian algorithm, the GRS algorithm does not guarantee optimal intermediate matchings and cannot compute minimum-cost t-matchings.

Our results. The optimal solutions to the k-SP (resp. k-SPI) problems can be computed in $\tilde{O}(nk\Phi(n))$ time by non-trivially adapting the Hungarian algorithm to find a minimum-cost $(n-k)$-matching (resp. n-matching) in $\mathcal{G}_\sigma$ (resp. $\mathcal{G}_{\sigma'}$). This algorithm, however, makes quadratic queries to a DWNN data structure when $k = \Theta(n)$. The main contribution of this paper is the design of a novel algorithm that, for any k, computes the optimal solution to the k-SP and k-SPI problems using only a sub-quadratic number of DWNN queries.

▶ **Theorem 4.** *Given any sequence σ (resp. $\sigma' = \eta\sigma$) of n requests (resp. n requests and k initial server locations) in 2 dimensions with a spread of Δ, and a value $1 \leq k \leq n$, there exists a deterministic algorithm that computes the optimal solution for the instance of k-SP (resp. k-SPI) problem under the ℓ_p norm in $\tilde{O}(\min\{nk, n^{1.8}\log\Delta\}\cdot\Phi(n))$ time.*

Our algorithm also extends to higher dimensions, and for any dimension $d \geq 2$, it computes optimal solutions to the k-SP and k-SPI problems in $\tilde{O}(\min\{nk, n^{2-\frac{1}{2d+1}}\log\Delta\}\cdot\Phi(n))$ time.

Designing geometric bipartite matching algorithms that perform a sub-quadratic number of queries to a DWNN data structure is challenging. Nevertheless, Theorem 4 shows that the bipartite matching instances generated by k-SP and k-SPI problems with bounded spread can be solved using sub-quadratic DWNN queries. For unbounded spread cases, the challenge remains elusive, at least for the k-SPI problem since, by Lemma 3, such an algorithm yields a sub-quadratic solution for the d-dimensional minimum-cost bipartite matching problem under ℓ_1 costs.

Our algorithm uses a hierarchical partitioning tree, whose nodes (referred to as cells) are axis-parallel rectangles with an aspect ratio of at most 3, and each cell splits into two smaller rectangles, forming its children. Our algorithm maintains a set of *current* cells $\mathcal{C}$ that partition the input points and computes a minimum-cost extended $(n-k)$-matching, where the points in B are allowed to match to the cell boundaries. It then replaces a pair of sibling rectangles in $\mathcal{C}$ with their parent, effectively erasing their shared boundary and creating additional free points. These free points are then matched again by finding minimum net-cost augmenting paths. When all the boundaries are erased, the algorithm terminates with the desired minimum-cost $(n-k)$-matching.

Our efficiency analysis faces three main hurdles. First, while finding a minimum net-cost augmenting path typically requires a search on the entire graph, we show that for extended matchings, such paths lie entirely within a current cell, allowing efficient local searches inside each current cell and selecting the global minimum across cells. Second, bounding the time to merge two cells is challenging, especially since some current cells may hold $\Theta(n)$ points, where each point is matched to a far away point in the optimal solution (Figure 3(left)). We address this challenge by showing that any minimum-cost extended matching has only $O(n^{0.8})$ points matched to the shared boundary. To establish this, we critically use the fact that every sub-problem has a hidden low-cost high-cardinality matching with sub-linearly many free points (see Figure 3 (right)). Finally, the k free points in our extended matching M may differ from those in the minimum-cost $(n-k)$-matching M^*. For instance, a point $b \in B$ may be free in M^* but matched to the boundary in M, leaving another point b' unmatched. While correcting such mismatches via alternating and augmenting paths can take $\Theta(n)$ time each (leading to a naïve bound of $O(nk)$), we use geometry to show that only $O(n^{0.8})$ such corrections occur for each cell, yielding an overall runtime to $\tilde{O}(n^{1.8}\Phi(n)\log\Delta)$.

Our proof techniques also refine the analysis of the GRS algorithm when the cost between points $a \in A$ and $b \in B$ is $\|a-b\|_2^q$ for any $q \geq 2$. Prior work showed that the GRS algorithm computes the minimum-cost perfect matching between two 2-dimensional stochastic point sets in $\tilde{O}(n^{2-\frac{1}{2(q+1)}}\Phi(n))$ time [7], which implies a quadratic number of queries to the DWNN data structure as $q \to \infty$. Raghvendra *et al.* [20] observed that, for any $q \geq 1$, there exists a low-cost, high-cardinality matching with sublinear free points. Building on a similar observation and our novel analysis techniques, we show that the GRS algorithm makes only a sub-quadratic number of DWNN queries, regardless of the value of q.

▶ **Theorem 5.** *Suppose U is a set of $2n$ points inside the unit square and A is a subset chosen uniformly at random from all subsets of size n. Let $B = U \setminus A$. Then, there exists an algorithm that computes the minimum-cost perfect matching on the complete bipartite graph on A and B under ℓ_2^q costs in $\tilde{O}(n^{7/4}\Phi(n)\log\Delta)$ expected time.*

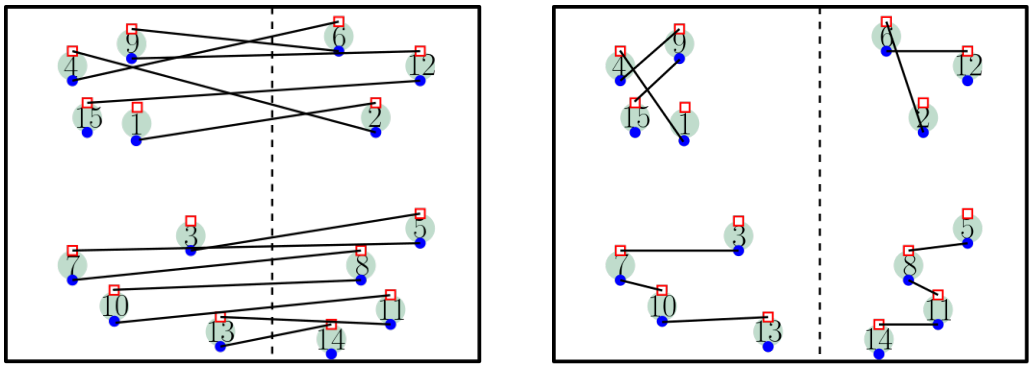

Figure 3 (left) A sub-problem of the k-SP problem, where the optimal solution has a high cost, and (right) there exists a low-cost high-cardinality matching inside the sub-problems.

The setting originally considered in the analysis of the GRS algorithm [7], where A and B are samples from the same distribution, is a special case of randomly partitioning a set of $2n$ points into two sets A and B of n points, considered in Theorem 5.

Due to space limitations, we restrict the description of our algorithm and its analysis to the k-SP problem in 2 dimensions. All other results, including extensions to higher dimensions, are presented in the full version of our paper.

2 Geometric Primal-Dual Framework

Let σ be an input to the k-SP problem, where the distance between two locations a and b is given by $\mathrm{d}(a,b) = \|a-b\|_p$. In this section, we introduce a primal-dual framework based on hierarchical partitioning to compute a minimum-cost $(n-k)$-matching in $\mathcal{G}_\sigma = (A \cup B, E \subset A \times B)$. We begin by describing the hierarchical partitioning scheme.

2.1 Hierarchical Partitioning

Using $\lambda := 9n^{-1/5}$, we construct a hierarchical partitioning $\mathcal{H}$ recursively. Each node of $\mathcal{H}$ is an axis-parallel rectangle, referred to as a *cell*. The root node, $\square^* := [-3n, 3n]^2$, contains all points in $A \cup B$. For each node $\square$, let $A_\square$ and $B_\square$ be the points of A and B inside $\square$ and let $n_\square = |A_\square \cup B_\square|$. If $n_\square \le 2$ (i.e., $\square$ is empty or contains the entry and exit gates of a single request), then $\square$ is marked as a leaf node. Otherwise, we partition $\square$ into two smaller rectangles as follows. Let $\ell_\square$ be the larger of the length and width of rectangle $\square$. Without loss of generality, assume that $\ell_\square$ is the width of $\square$ and let $x_{\min}$ be the x-coordinate of the bottom-left corner of $\square$. For any value $\hat{x} \in [x_{\min} + \frac{\ell_\square}{3}, x_{\min} + \frac{2\ell_\square}{3}]$, define $\Lambda(\hat{x}) := \{u \in A_\square \cup B_\square : |u_x - \hat{x}| \le \ell_\square \lambda\}$; here, u_x denotes the x coordinate of the point u. Let $x^* := \arg\min_{\hat{x} \in [x_{\min} + \frac{\ell_\square}{3}, x_{\min} + \frac{2\ell_\square}{3}]} |\Lambda(\hat{x})|$. We partition $\square$ into two smaller rectangles by using a vertical line defined by $x = x^*$ and add them as the children of $\square$ to $\mathcal{H}$. We refer to the segment partitioning $\square$ into its two children as its *divider* and denote it by $\Gamma_\square$. See Figure 4(left). For any cell $\square$, the four sides of its rectangle are defined by the dividers of its ancestor or the boundaries of the root square. This completes the construction of $\mathcal{H}$. Note that the height of the tree is $O(\log n\Delta)$. A simple sweep-line algorithm can compute x^* in $O(n_\square \log n_\square)$ time. Using this procedure, we construct $\mathcal{H}$ in $\tilde{O}(n \log(n\Delta))$ time.

▶ **Lemma 6.** *For each cell $\square$ of $\mathcal{H}$, the ratio of the largest to the smallest side of $\square$ is at most 3. Furthermore, the number of points of $A_\square \cup B_\square$ with a distance smaller than $\ell_\square\lambda$ to the divider $\Gamma_\square$ is $O(n_\square\lambda)$.*

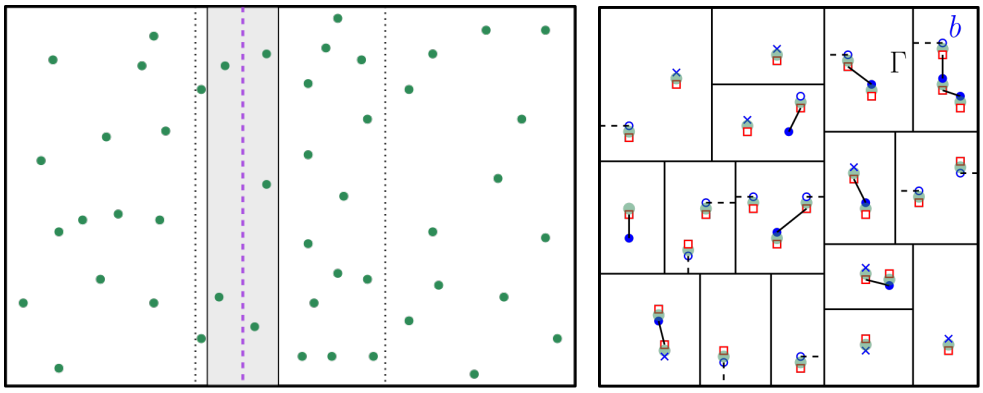

Figure 4 (left) Partitioning a rectangle into two children (the purple dashed vertical line is the divider), and (right) a $\mathcal{C}$-extended 20-matching with 9 matched points (blue discs), 11 boundary-matched points (blue circles), and 8 free points (blue crosses). The matching cost is the total length of the solid and dashed lines. The boundary-matched point b is matched to the divider Γ.

Recollect that a matching M in $\mathcal{G}_\sigma$ is a subset of vertex-disjoint edges. We refer to a point $b \in B$ as *unmatched* in M if it does not have an edge of M incident on it and *matched* otherwise. The following structural property of the k-SP problem will be critical in bounding the efficiency of our algorithm.

▶ **Lemma 7.** *For any cell $\square$ of $\mathcal{H}$, there exists a matching M' between $A_\square \cup B_\square$ that matches all except $O(n_\square^{4/5})$ points of $B_\square$ and has a cost $O(\ell_\square n_\square^{3/5})$.*

2.2 Extended Bipartite Matching

Suppose we are given a subset $\mathcal{C}$ of cells from $\mathcal{H}$ that partitions $\square^*$, i.e., the cells of $\mathcal{C}$ are interior disjoint and these cells cover the root square $\square^*$. Let $\mathrm{d}(u, \square)$ denote the shortest distance from u to the boundaries of the cell $\square$. For any point u inside $\square^*$, let $\square_u$ be the cell of $\mathcal{C}$ that contains u. We define $\mathrm{d}(b, \mathcal{C}) = \mathrm{d}(b, \square_b)$. We extend the definition of matching to allow points in B to match to the boundaries of cells in $\mathcal{C}$. A *$\mathcal{C}$-extended matching* consists of a matching M as well as a subset $B^{\mathcal{C}}$ of points of B that are unmatched in M but instead matched to the boundaries of the cells of $\mathcal{C}$ that contain them. See Figure 4(right). The cost of a $\mathcal{C}$-extended matching $M^{\mathcal{C}}$ is

$$w_{\mathcal{C}}(M^{\mathcal{C}}) := \sum_{(a,b)\in M} \mathrm{d}(a, b) + \sum_{b \in B^{\mathcal{C}}} \mathrm{d}(b, \mathcal{C}). \tag{1}$$

We refer to all points of $B^{\mathcal{C}}$ as *boundary-matched*. All points of B that are neither matched in M nor boundary-matched are considered *free*. All points of A that are not matched in M are also considered free. The size of $M^{\mathcal{C}}$ is equal to $|M| + |B^{\mathcal{C}}|$. When $\mathcal{C}$ is clear from the context, we refer to $M^{\mathcal{C}}$ as an extended matching. An extended matching $M^{\mathcal{C}}$ of size t with the minimum cost is called a *minimum-cost $\mathcal{C}$-extended t-matching*.

Consider the partitioning $\mathcal{C}^* = \{\square^*\}$, where $\square^*$ is the root cell of $\mathcal{H}$. Using the fact that the input points are far from the boundaries of $\square^*$, we show in Lemma 8 below that any minimum-cost $\mathcal{C}^*$-extended matching $M^{\mathcal{C}^*}$ of size t is also a minimum-cost t-matching, i.e., no point of B is boundary-matched in $M^{\mathcal{C}^*}$.

▶ **Lemma 8.** *Suppose $\mathcal{C}^* = \{\square^*\}$, where $\square^*$ is the root cell of $\mathcal{H}$. Let $M^{\mathcal{C}^*} = (M, B^{\mathcal{C}^*})$ be a minimum-cost extended t-matching on $\mathcal{G}_\sigma$, for $t < n$. Then, the matching M is a minimum-cost t-matching.*

Let $M^{\mathcal{C}} = (M, B^{\mathcal{C}})$ denote a $\mathcal{C}$-extended matching. Any path P on the graph $\mathcal{G}_\sigma$ whose edges alternate between matching and non-matching edges in M is called an *alternating path*. An alternating path P is called an *augmenting path* if P starts from a free point $b \in B$ and ends with either (i) a free point $a \in A$, or (ii) a point $b' \in B$. We *augment* the extended matching $M^{\mathcal{C}}$ along an augmenting path P by updating its matching $M \leftarrow M \oplus P$ and for case (ii), we match b' to the boundary and update $B^{\mathcal{C}}$ to include b'. The *net-cost* of P in case (i) is $\phi(P) := \sum_{(a,b)\in P\setminus M} \mathrm{d}(a,b) - \sum_{(a,b)\in P\cap M} \mathrm{d}(a,b)$, and in case (ii) is

$$\phi(P) := \mathrm{d}(b', \mathcal{C}) + \sum_{(a,b)\in P\setminus M} \mathrm{d}(a,b) - \sum_{(a,b)\in P\cap M} \mathrm{d}(a,b).$$

From Lemma 8, given a sequence σ of n requests in the unit square, one can compute an optimal solution to the k-SP problem on σ by computing a minimum-cost $\mathcal{C}^*$-extended $(n-k)$-matching on $\mathcal{G}_\sigma$. Given a partitioning $\mathcal{C}$, to compute a minimum-cost $\mathcal{C}$-extended $(n-k)$-matching, similar to the Hungarian algorithm, one can start from an empty extended matching $M^{\mathcal{C}}$ and iteratively augment $M^{\mathcal{C}}$ along a minimum net-cost augmenting path. In the next section, we present a primal-dual framework that our algorithm uses to efficiently compute minimum net-cost augmenting paths.

2.3 A Constrained Dual Formulation for Extended Matchings

Suppose $\mathcal{C}$ is a set of cells of $\mathcal{H}$ partitioning the root cell $\square^*$. Consider a $\mathcal{C}$-extended matching $M^{\mathcal{C}} = (M, B^{\mathcal{C}})$ on $\mathcal{G}_\sigma$ along with a set of non-negative dual weights $y : A \cup B \to \mathbb{R}_{\geq 0}$. Let A_F be the set of free points of A with respect to $M^{\mathcal{C}}$. We say that $M^{\mathcal{C}}, y(\cdot)$ is *feasible* if,

$$y(b) - y(a) \leq \mathrm{d}(a,b), \qquad \forall (a,b) \in E, \tag{2}$$
$$y(b) - y(a) = \mathrm{d}(a,b), \qquad \forall (a,b) \in M, \tag{3}$$
$$y(b) \leq \mathrm{d}(b, \mathcal{C}), \qquad \forall b \in B, \tag{4}$$
$$y(b) = \mathrm{d}(b, \mathcal{C}), \qquad \forall b \in B^{\mathcal{C}}, \tag{5}$$
$$y(a) = 0, \qquad \forall a \in A_F. \tag{6}$$

For any edge $(a,b) \in E$, the *slack* of (a,b) is defined as $s(a,b) := \mathrm{d}(a,b) - y(b) + y(a)$. The edge (a,b) is *admissible* if $s(a,b) = 0$. For any point $b \in B$, the slack of b is defined as $s(b) := \mathrm{d}(b, \mathcal{C}) - y(b)$. For any feasible extended matching $M^{\mathcal{C}}, y(\cdot)$, the slack of every edge as well as every point $b \in B$ is non-negative. Recall that an augmenting path P starts at a free point $b \in B$ and ends at (i) a free point $a \in A$ or (ii) a point $b' \in B$. The path P is *admissible* if all edges of P are admissible and in case (ii), the slack of the end-point b' is $s(b') = 0$. The following properties of extended feasible matchings are critical in the design of an efficient and correct algorithm.

▶ **Lemma 9.** *Given a feasible $\mathcal{C}$-extended t-matching $M^{\mathcal{C}} = (M, B^{\mathcal{C}})$ and a set of non-negative dual weights $y(\cdot)$ on $A \cup B$, let P be a minimum net-cost augmenting path with respect to $M^{\mathcal{C}}$. Let, for any $\square \in \mathcal{C}$, $y_\square = \max_{b' \in B_\square} y(b')$. Then,*

(a) *all points of P lie inside a single cell of $\mathcal{C}$, and*

(b) *if, for every cell $\square \in \mathcal{C}$, $y_\square \leq \phi(P)$ and for all free points $b \in B_\square$, $y(b) = y_\square$, then $M^{\mathcal{C}}$ is a minimum-cost extended t-matching.*

The property described in Lemma 9(a) is important for the design of an efficient algorithm. Unlike the Hungarian algorithm, which searches the entire graph for the minimum net-cost augmenting path, our algorithm can find the minimum net-cost augmenting path by searching

for the cheapest augmenting path inside each cell $\square \in \mathcal{C}$ and then taking the smallest among them. Thus, we can replace a global search with a search inside each cell of $\mathcal{C}$. The property in Lemma 9(b) is important for the design of a correct algorithm since it provides conditions under which an extended matching is a minimum-cost extended matching. Our algorithm is designed to maintain these conditions as invariants during its execution. Lemma 10 provides a method to update the dual weights, which is essential during the process of merging cells.

▶ **Lemma 10.** *Suppose $M^{\mathcal{C}}, y(\cdot)$ is a feasible $\mathcal{C}$-extended matching and P is a minimum net-cost augmenting path. For any cell $\square \in \mathcal{C}$, define $y_{\square} = \max_{b' \in B_{\square}} y(b')$, and suppose $y_{\square} \leq \phi(P)$ and $y(b_f) = y_{\square}$ for all free points $b_f \in B_{\square}$. Then, one can update the dual weights in $\tilde{O}(n_{\square}\Phi(n_{\square}))$ time such that $M^{\mathcal{C}}, y(\cdot)$ remains feasible, $y(b) \leq \phi(P)$ for all $b \in B_{\square}$, and $y(b_f) = \phi(P)$ for all free points $b_f \in B_{\square}$.*

The next lemma provides critical properties that allow for correctly and efficiently merging cells in $\mathcal{C}$.

▶ **Lemma 11.** *For a cell $\square$ of $\mathcal{H}$, suppose $\square'$ and $\square''$ denote its two children, and let $\mathcal{C}$ denote a partitioning containing $\square'$ and $\square''$. Let $\mathcal{C}' = \mathcal{C} \cup \{\square\} \setminus \{\square', \square''\}$. Given a feasible $\mathcal{C}$-extended matching $(M, B^{\mathcal{C}}), y(\cdot)$, let $B^{\mathcal{C}}_{\square} \subseteq B^{\mathcal{C}}$ denote the subset of boundary-matched points that are matched to the divider $\Gamma_{\square}$ of $\square$. Then,*
(a) *the $\mathcal{C}'$-extended matching $(M, B^{\mathcal{C}} \setminus B^{\mathcal{C}}_{\square}), y(\cdot)$ is also feasible, and,*
(b) $|B^{\mathcal{C}}_{\square}| = O(n^{4/5})$.

From Lemma 11(a), erasing a divider does not cause the feasibility conditions to be violated. The proof of Lemma 11(a) relies on the fact that when we erase the divider of a cell in $\mathcal{C}$, the RHS of (4) will only increase and so it is not violated. Despite preserving the feasibility conditions, erasing the boundary may result in the violation of Lemma 9(b), i.e., the matching may no longer be a minimum-cost extended matching. In our algorithm in Section 3, we describe a process to adjust the matching $M^{\mathcal{C}}$ and dual weights $y(\cdot)$ and obtain a minimum-cost extended matching.

Residual Graph. Similar to the Hungarian algorithm, we define a residual graph that assists in finding the minimum net-cost augmenting path. Consider a feasible $\mathcal{C}$-extended matching $M^{\mathcal{C}} = (M, B^{\mathcal{C}})$ along with a set of dual weights $y(\cdot)$ on points of $A \cup B$. For each cell $\square \in \mathcal{C}$, we define a residual graph $\mathcal{G}_{\square}$. The vertex set of $\mathcal{G}_{\square}$ is a source vertex s and the points in $A_{\square} \cup B_{\square}$. For any edge $(a, b) \in E$ inside $\square$, if $(a, b) \in M$ (resp. $(a, b) \notin M$), there is an edge directed from a to b (resp. from b to a) with a weight $s(a, b)$ in $\mathcal{G}_{\square}$. Furthermore, there is an edge directed from s to every free point $b \in B$ with a weight $y(b)$.

3 A Sub-Quadratic Algorithm for the k-SP Problem

In this section, we describe an algorithm that, given a sequence σ of n requests in 2-dimensions, computes the optimal solution to the k-SP problem in $\tilde{O}(n^{1.8}\Phi(n)\log(n\Delta))$ time.

3.1 Algorithm

Initialize $\mathcal{C}$ to the leaf cells of $\mathcal{H}$. Let $M^{\mathcal{C}} = (M, B^{\mathcal{C}})$ be the extended matching maintained by the algorithm and initialized to $M = \emptyset$ and $B^{\mathcal{C}} = \emptyset$. For each point $v \in A \cup B$, let $y(v)$ denote its dual weight initialized to $y(v) = 0$. Let B_F, initialized to B, be the free points of B with respect to $M^{\mathcal{C}}$. For each cell $\square$ that contains at least one free point $b \in B_F$, let

$P_\square$ denote the minimum net-cost augmenting path inside $\square$. Initially, since $\square$ is a leaf of $\mathcal{H}$, it contains only one point $b \in B_F$, and therefore, $P_\square$ is this point with a net-cost equal to $\mathrm{d}(b, \mathcal{C})$. Our algorithm maintains a priority queue PQ storing every leaf cell $\square \in \mathcal{C}$ with at least one free vertex with a key of $\phi(P_\square)$. At any time during the execution of our algorithm, let $\square_{\min}$ be the cell with the smallest key in PQ and let φ be the key of $\square_{\min}$. Execute the following steps until PQ becomes empty:

- While $|B_F| > k$,
  - *Extended Hungarian search step:* Extract the cell $\square$ with the minimum key of φ from PQ. Augment the matching $M^{\mathcal{C}}$ along $P_\square$ and update the key of $\square$ in PQ (See Section 3.1.1 for details).
- *Merge step:* If $\mathcal{C} = \{\square^*\}$, remove $\square^*$ from PQ and return the matching M of $M^{\mathcal{C}}$. Otherwise, pick a cell $\square' \in \mathcal{C}$ with the smallest perimeter and let $\square$ and $\square''$ be the parent and sibling of $\square'$ in $\mathcal{H}$, respectively. Erase the divider of $\square$, i.e., set $\mathcal{C} = \mathcal{C} \setminus \{\square', \square''\} \cup \{\square\}$. We execute a Merge procedure that updates the matching $M^{\mathcal{C}}$ inside the cell $\square$ so that $\phi(P_\square)$ is at least φ (See Section 3.1.2 for details). At this point, the size of the updated extended matching $M^{\mathcal{C}}$ may not be $(n-k)$, i.e., there may be more than k free points.

Invariants. For each cell $\square \in \mathcal{C}$, let $y_\square = \max_{b \in B_\square} y(b)$. During the execution of our algorithm,

(I1) the extended matching $M^{\mathcal{C}}, y(\cdot)$ is feasible,

(I2) For each cell $\square \in \mathcal{C}$, $y_\square \le \varphi$ and for all free point $b \in B_\square$, $y(b) = y_\square$, and,

(I3) The φ-value is non-decreasing. Furthermore, after each step of the algorithm, φ denotes the smallest net-cost of all augmenting paths with respect to $M^{\mathcal{C}}$.

3.1.1 Details of the Extended Hungarian Search Step

Given a feasible extended matching $M^{\mathcal{C}}, y(\cdot)$ and a cell $\square \in \mathcal{C}$, the extended Hungarian search procedure computes the minimum net-cost augmenting path $P_\square$ and augments $M^{\mathcal{C}}$ along $P_\square$. It then computes the new minimum net-cost augmenting path and updates the key of $\square$ in PQ to be its net-cost. This procedure is similar to the classical Hungarian search procedure executed on $\mathcal{G}_\square$ and is mildly modified to include the augmenting paths that end at the boundary of $\square$. Details of the procedure are as follows.

1. *Update duals:* With s as the source vertex, execute Dijkstra's shortest path algorithm on the residual graph $\mathcal{G}_\square$. Let P_v be the shortest path from s to each $v \in A_\square \cup B_\square$ and let κ_v be the cost of P_v. Let

$$\kappa = \min\{ \min_{a \in A_\square^F} \kappa_a, \min_{b \in B_\square} \kappa_b + s(b)\}. \tag{7}$$

   For any $v \in A_\square \cup B_\square$, if $\kappa_v < \kappa$, set $y(v) \leftarrow y(v) + \kappa - \kappa_v$.
2. *Augment:* Let $u \in A_\square^F \cup B_\square$ be the point realizing the minimum distance in Equation (7). Let P be the augmenting path obtained by removing s. Augment $M^{\mathcal{C}}$ along P.
3. *Update key:* If $B_\square$ has no free points, then remove $\square$ from PQ. Otherwise,
   a. Recompute the residual graph $\mathcal{G}_\square$ with respect to the updated matching,
   b. With s as the source, execute the Dijkstra's shortest path algorithm on $\mathcal{G}_\square$. For each $v \in A_\square \cup B_\square$, let κ_v be the distance from s to v.
   c. Update the key of $\square$ in PQ to $\kappa_\square = \min\{\min_{a \in A_\square^F} \kappa_a, \min_{b \in B_\square} \kappa_b + s(b)\}$.

   Lemma 12 establishes the properties of the extended Hungarian search procedure.

▶ **Lemma 12.** *After the execution of the extended Hungarian search procedure for a cell $\square$, the extended matching $M^{\mathcal{C}}, y(\cdot)$ remains feasible, $y(v) \leq \varphi$ for all points $v \in A_{\square} \cup B_{\square}$, and $y(b_f) = \varphi$ for all free points $b_f \in B_{\square}$. Furthermore, the path P computed by the procedure is a minimum net-cost augmenting path inside $\square$. After augmenting along P, the updated key for $\square$ is the smallest net-cost of all augmenting paths inside $\square$ and is at least φ.*

3.1.2 Details of the Merge Step

Given a feasible extended matching $M^{\mathcal{C}} = (M, B^{\mathcal{C}}), y(\cdot)$, any cell $\square$ of $\mathcal{H}$ where both of its children $\square'$ and $\square''$ are in $\mathcal{C}$, and a value φ, the merge procedure uses the algorithm in Lemma 10 to update the dual weights $y(\cdot)$ inside $\square'$ (resp. $\square''$) so that $M^{\mathcal{C}}, y(\cdot)$ remains feasible, the dual weights of all points in $\square'$ (resp. $\square''$) are at most φ, and the dual weight of all free points $b'_f \in B_{\square'}$ (resp. $b''_f \in B_{\square''}$) is $y(b'_f) = \varphi$ (resp. $y(b''_f) = \varphi$). The procedure then updates $\mathcal{C} \leftarrow \mathcal{C} \cup \{\square\} \setminus \{\square', \square''\}$ and makes the points matched to the divider $\Gamma_{\square}$ free. While there exists a free point $b \in B_{\square}$ with $y(b) < \varphi$,

1. With s as the source, execute Dijkstra's shortest path algorithm on the residual graph $\mathcal{G}_{\square}$. For each $v \in A_{\square} \cup B_{\square}$, let P_v be the shortest path from s to v in $\mathcal{G}_{\square}$ and let κ_v be its cost. Define

$$\kappa = \min\{\min_{a \in A^F_{\square}} \kappa_a, \min_{b \in B_{\square}} \kappa_b + s(b), \min_{b \in B_{\square}} \kappa_b + \varphi - y(b)\}. \tag{8}$$

2. Let $u \in A^F_{\square} \cup B_{\square}$ be the point realizing the minimum value in Equation (8). Let P be the path obtained by removing s from the path P_u.
   a. If $u \in B_{\square}$ and $\kappa = \kappa_u + \varphi - y(u)$ (i.e., κ is determined by the third element in the RHS of Equation (8)), then P is a path from a free point $b \in B_{\square}$ to the matched point u. For each $v \in A_{\square} \cup B_{\square}$, if $\kappa_v < \kappa$, update its dual weight to $y(v) \leftarrow y(v) + \kappa - \kappa_v$. The path P is an admissible alternating path with respect to the updated dual weights. Set $M \leftarrow M \oplus P$. Note that u is now a free point with $y(u) = \varphi$.
   b. Otherwise, P is an augmenting path. For each $v \in A_{\square} \cup B_{\square}$, if $\kappa_v < \kappa$, update its dual weight to $y(v) \leftarrow y(v) + \kappa - \kappa_v$. The path P is an admissible augmenting path with respect to the updated dual weights. Augment M along P.

At the end of this execution, all free points of B in $\square$ have a dual weight of φ. Finally, we update the key for $\square$ by executing steps 3(a)–(c) from the extended Hungarian search step.

The following lemma states the useful properties of the merge step.

▶ **Lemma 13.** *After the execution of the merge procedure on a cell $\square$, the updated extended matching $M^{\mathcal{C}}, y(\cdot)$ is feasible, the dual weights $y(v)$ for every $v \in A_{\square} \cup B_{\square}$ is at most φ, and $y(b_f) = \varphi$ for all free points $b_f \in B_{\square}$. Furthermore, the updated key for $\square$ is the smallest net-cost of all augmenting paths within $\square$ and is at least φ.*

3.2 Analysis

We begin by showing in Section 3.2.1 that the three invariants (I1)–(I3) hold during the execution of our algorithm and use them to show the correctness of our algorithm. We then show in Section 3.2.2 that the running time of our algorithm is $\tilde{O}(n^{9/5}\Phi(n)\log n\Delta)$.

3.2.1 Correctness

Our algorithm initializes $M^{\mathcal{C}}$ with a feasible $\mathcal{C}$-extended matching and sets all dual weights and φ to 0. Therefore, (I1) and (I2) hold at the start of the algorithm. The extended Hungarian search (Lemma 12) as well as the merge step (Lemma 13) do not violate the feasibility of

the extended matching and therefore (I1) holds during the execution of the algorithm. The extended Hungarian search (Lemma 12) and the merge (Lemma 13) procedures keep the dual weight of every point inside $\square$ at or below φ, while ensuring that the dual weight of free points inside $\square$ is φ; hence, (I2) holds. Finally, both the extended Hungarian search (Lemma 12) and the merge (Lemma 13) procedures update the key of $\square$ to the smallest net-cost of all augmenting paths inside $\square$ and do not decrease the key of any cell. From this observation, (I3) follows in a straightforward way.

From (I1) and (I2), our algorithm maintains a feasible $\mathcal{C}$-extended matching where, for each cell $\square \in \mathcal{C}$, $y_{\square} \leq \varphi$. From (I3), φ is equal to the minimum net-cost of all augmenting paths with respect to $M^{\mathcal{C}}$; combining this with Lemma 9(b), we conclude that $M^{\mathcal{C}}$ is a minimum-cost $\mathcal{C}$-extended matching. Upon termination, the algorithm returns a minimum-cost $\mathcal{C}^*$-extended $(n-k)$-matching for $\mathcal{C}^* = \{\square^*\}$, which from Lemma 8 has no boundary-matched points. Therefore, this matching is also a minimum-cost $(n-k)$-matching, as desired.

3.2.2 Efficiency

Both the merge step and the extended Hungarian search step require an execution of Dijkstra's shortest path algorithm on $\mathcal{G}_{\square}$. In the full version of our paper, we show that this execution takes $\tilde{O}(n_{\square}\Phi(n_{\square}))$ time. Using this, we analyze the execution time.

We begin by establishing a bound on the execution time of the merge step, which combines $\square'$ and $\square''$ into a single cell $\square$. At the start of this step, the dual weight of all free points in $\square'$ and $\square''$ are raised to φ (from Lemma 10). As a result, once the divider is removed, the only free points with dual weights below φ are those that are matched to the divider $\Gamma_{\square}$. From Lemma 11(b), the number of points matched to $\Gamma_{\square}$ is $O(n^{4/5})$. Therefore, the while-loop in the merge procedure executes only $O(n^{4/5})$ times. Since each iteration takes $\tilde{O}(n_{\square}\Phi(n_{\square}))$ time, the total execution time of a single execution of the merge step is $\tilde{O}(n^{4/5}n_{\square}\Phi(n_{\square}))$. Given that each point is in only $O(\log n\Delta)$ many cells of $\mathcal{H}$, the total time taken by the merge step across all cells of $\mathcal{H}$ is $\tilde{O}(n^{9/5}\Phi(n)\log n\Delta)$.

Similarly, if the execution time for the extended Hungarian search within a single cell $\square$ is bounded by $O(n^{4/5}n_{\square}\Phi(n_{\square}))$, then the cumulative execution time of the extended Hungarian search across all cells – and consequently, the total runtime of the entire algorithm – can be bounded by $\tilde{O}(n^{9/5}\Phi(n)\log n\Delta)$. In the remainder of our analysis, we establish a bound of $O(n^{4/5}n_{\square}\Phi(n_{\square}))$ for the time taken by the extended Hungarian search within a single cell $\square$. Recall that the algorithm selects a cell $\square$ containing the minimum net-cost augmenting path from the priority queue PQ and performs an extended Hungarian search procedure within $\square$, requiring $\tilde{O}(n_{\square}\Phi(n_{\square}))$ time. To analyze the total execution time of the extended Hungarian search procedure, we show that any cell $\square$ can be selected by the algorithm at most $O(n^{4/5})$ times. In particular, we categorize the selection of $\square$ as a *low-net-cost* case if $\varphi \leq \ell_{\square}n^{-1/5}$ and a *high-net-cost* case otherwise. First, we show that in the high-net-cost case ($\varphi > \ell_{\square}n^{-1/5}$), the number of free points remaining in $\square$ is $O(n^{4/5})$, and as a result, the total number of high-net-cost selections of $\square$ is $O(n^{4/5})$.

▶ **Lemma 14.** *Given a feasible extended matching $M^{\mathcal{C}}, y(\cdot)$ and any cell $\square \in \mathcal{C}$, if the net-cost of the minimum net-cost augmenting path inside $\square$ is greater than $\ell_{\square}n^{-1/5}$, then the number of free points of $M^{\mathcal{C}}$ is $O(n^{4/5})$.*

Next, we bound the number of low-net-cost selections of $\square$. Define $\mathcal{C}_{\square}$ as the set of all cells $\square' \in \mathcal{H}$ that are processed by the merge procedure while $\square \in \mathcal{C}$ and $\varphi \leq \ell_{\square}n^{-1/5}$ (Figure 5). Our algorithm always picks the smallest perimeter cells to merge, and as a result, we obtain the following lemma.

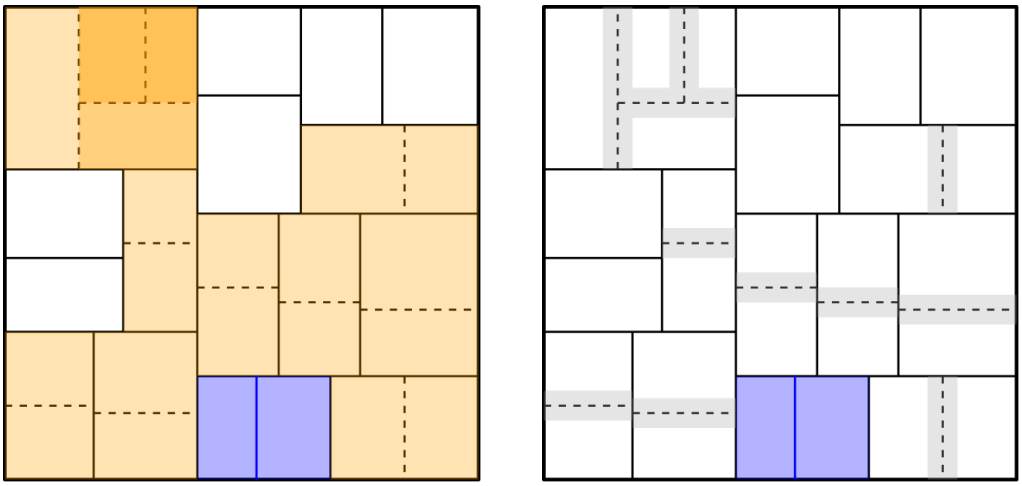

Figure 5 (left) The set $\mathcal{C}_\square$ (the cells shaded in orange with dashed lines as their divider) for a cell $\square$ (shaded in blue), and (right) any boundary-matched point in the gray area might cause a low-net-cost execution of the extended Hungarian search procedure on $\square$.

▶ **Lemma 15.** *For any non-leaf cell $\square$ in $\mathcal{H}$ and any cell $\square' \in \mathcal{C}_\square$, $\frac{1}{3}\ell_{\square'} \leq \ell_\square \leq \frac{9}{4}\ell_{\square'}$.*

For any cell $\square' \in \mathcal{C}_\square$, the merge step erases the divider $\Gamma_{\square'}$ and makes the points that are matched to $\Gamma_{\square'}$ free. Each of these new free points might cause $\square$ to be selected by the algorithm. Therefore, to bound the number of low-net-cost selections of $\square$, we show that the total number of points that are matched to the dividers of the cells in $\mathcal{C}_\square$ is at most $O(n^{4/5})$. For any cell $\square' \in \mathcal{C}_\square$, let $\mathcal{B}_{\square'}$ denote the set of points of $B^{\mathcal{C}}$ that are matched to the divider $\Gamma_{\square'}$ when our algorithm starts the merge step on $\square'$. Thus, we have to bound $\sum_{\square' \in \mathcal{C}_\square} |\mathcal{B}_{\square'}|$ by $O(n^{4/5})$. By invariant (I2), for each point $b \in \mathcal{B}_{\square'}$, $y(b) \leq \varphi \leq \ell_\square n^{-1/5}$. Furthermore, by Condition (5), $y(b) = \mathrm{d}(b, \square') = \mathrm{d}(b, \Gamma_{\square'})$. Therefore, the point b is within a distance $\ell_\square n^{-1/5}$ from the divider $\Gamma_{\square'}$. From Lemma 15, for each cell $\square' \in \mathcal{C}_\square$ and each point $b \in \mathcal{B}_{\square'}$, the point b is within a distance $\ell_\square n^{-1/5} < \ell_{\square'}\lambda$ from the divider $\Gamma_{\square'}$, and from the construction of $\mathcal{H}$ (Lemma 6), $|\mathcal{B}_{\square'}| = O(n_{\square'} n^{-1/5})$. Furthermore, from Lemma 15 and the construction of $\mathcal{H}$, each point $b \in B$ can lie inside a constant number of cells in $\mathcal{C}_\square$; hence, $\sum_{\square' \in \mathcal{C}_\square} |\mathcal{B}_{\square'}| = O(\sum_{\square' \in \mathcal{C}_\square} n_{\square'} n^{-1/5}) = O(n^{4/5})$. Therefore, the total number of low-net-cost selections of $\square$ by the extended Hungarian search procedure is $O(n^{4/5})$.

4 Conclusion and Open Questions

We presented an exact algorithm for the k-SP and k-SPI problems on d-dimensional point sets with bounded spread Δ, achieving sub-quadratic queries to a DWNN data structure and only logarithmic dependence on Δ. We highlight two open directions: First, can the $O(\log \Delta)$ dependence be removed? This would yield sub-quadratic algorithms for geometric bipartite matching, addressing a central open problem in computational geometry. Second, our reductions frame the k-server problem as a mild variant of online metric matching. This connects with extensive work on the online k-server problem [1, 3, 9, 10, 12, 14, 21, 23]. The reduction suggests simplifications and improvements to work function-based implementations, including the scalable algorithm by Raghvendra and Sowle [21]. Moreover, can we adapt the RM algorithm [15, 17, 18], which is the best-known online metric algorithm, to establish tighter bounds on its competitive ratio for k-server?

Embedding Graphs as Euclidean kNN-Graphs

Abstract

Let $G = (V, E)$ be a directed graph on n vertices where each vertex has out-degree k. We say that G is kNN-realizable in d-dimensional Euclidean space if there exists a point set $P = \{p_1, p_2, \ldots, p_n\}$ in $\mathbb{R}^d$ along with a one-to-one mapping $\phi : V \to P$ such that for any $u, v \in V$, u is an out-neighbor of v in G if and only if $\phi(u)$ is one of the k nearest neighbors of $\phi(v)$; we call the map ϕ a *kNN-realization* of G in $\mathbb{R}^d$. The kNN-realization problem, which aims to compute a kNN-realization of an input graph in $\mathbb{R}^d$, is known to be NP-hard already for $d = 2$ and $k = 1$ [Eades and Whitesides, Theoretical Computer Science, 1996], and to the best of our knowledge has not been studied in dimension $d = 1$. The main results of this paper are the following:

- For any fixed dimension $d \geq 2$, we can efficiently compute an embedding realizing at least a $1 - \varepsilon$ fraction of G's edges, or conclude that G is not kNN-realizable in $\mathbb{R}^d$.
- For $d = 1$, we can decide in $O(kn)$ time whether G is kNN-realizable and, if so, compute a realization in $O(n^{2.5}\mathsf{poly}(\log n))$ time.

1 Introduction

The *kNN-graph* of a set P of points in $\mathbb{R}^d$ is a directed graph with vertex set P and edges defined as follows: there is a directed edge from $a \in P$ to $b \in P$ if and only if b is one of the k-nearest neighbors of a in P (under the Euclidean distance). A directed graph $G = (V, E)$ is *kNN-realizable* in $\mathbb{R}^d$ if it is isomorphic to the kNN-graph of a set of points in $\mathbb{R}^d$. In this paper, we consider the following natural problems regarding kNN-graphs: Can we efficiently check whether a given directed graph is kNN-realizable in $\mathbb{R}^d$? If so, can we efficiently find a kNN-realization of G? More formally, a kNN-*realization* (or kNN-*embedding*) of G in $\mathbb{R}^d$ is a one-to-one mapping $\phi : V \to P$ from the vertex set V of G to a set P of points in $\mathbb{R}^d$ that induces an isomorphism between G and the kNN-graph of P. Throughout the paper, we use the terms embedding and realization interchangeably.

The kNN-graph is a member of the well-known family of *proximity* graphs in computational geometry that includes minimum spanning trees, relative neighborhood graphs, Gabriel graphs, and Delaunay triangulations [11]. Over the past several decades, a substantial research effort has been directed to design efficient algorithms to compute these structures for an input set of points. The *inverse* problem – the focus of our paper – where we want to recover the points that produce a given proximity graph, however, remains less well understood.

An early example of a positive result in this direction is on Euclidean minimum spanning trees. Monma and Suri [22] show that any tree with maximum node degree 5 can be realized as a minimum spanning tree of points in the plane and, additionally, every planar point set admits a minimum spanning tree with degree at most 5. This settles the above problem for *non-degenerate* planar point sets but if we allow co-circularities, then a planar minimum spanning tree can have maximum node degree 6; in that case, the problem of computing a 1NN-realization was proved to be NP-complete by Eades and Whitesides [13]. Dillencourt [12] considers the problem of recognizing triangulations that can be realized as Delaunay triangulations in the plane, and it is also known that all outerplanar triangulations are realizable [24]. (These proofs are non-constructive, however, and only exponential time algorithms are known for computing the coordinates of the points in the realization [1].) Among other related results, Bose et al. [5] give a characterization of *trees* that can be realized in the plane as relative neighborhood or Gabriel graphs, and Eppstein et al. [15] establish some structural properties of kNN graphs of random points in the plane.

The kNN-realization is not directly related to the *metric embedding* problem but there are some obvious similarities. The input to metric embedding is a weighted graph satisfying triangle inequalities and the goal is to find an embedding realizing all pairwise distances. This is not always possible [20] – there are simple metrics that cannot be embedded in any finite dimensional Euclidean space. However, if we allow some *distortion* (i.e. approximation) of distances, then any n-node metric graph can be embedded in $O(\log n)$ dimensional space with polylog distortion [6], or using the celebrated Johnson-Lindenstrauss theorem [18] in dimension $O(\log n/\varepsilon^2)$ with distortion $1+\varepsilon$ for any fixed constant $\varepsilon > 0$.

In metric embedding the goal is to realize all pairwise distances (approximately), while in kNN-realization the goal is only to preserve all *ordinal* neighbor relations in a *directed* graph: a neighbor of each vertex must be closer than any of its non-neighbors but the choice of specific distances does not matter. Although there is some work in embedding ordinal relations as well, the main focus is specialized metric spaces and *bounds* on *ordinal distortion*. In particular, Alon et al. [2] consider embeddings with ordinal relaxations into ultrametric spaces, and Bădoiu et al. [7] improve their bounds for tree and line embeddings. A different line of research concerns *triplets* embedding, where the input is a set of triples (a, b, c) specifying constraints of the form $d(a, b) < d(a, c)$. Even for embedding in one dimension $\mathbb{R}^1$, the general triplet problem as well as the related "betweenness" problem is MAXSNP-hard [9], and a FPTAS is known for maximizing the number of satisfied triplet constraints [17]. (If all $\binom{n}{3}$ triplet constraints are given, then the problem is trivial to solve – indeed, once the leftmost point is determined, the rest of the ordering can be easily decided.) In contrast with the general triplet constraints, the pairwise relations in a kNN-realization problem in $\mathbb{R}^1$ have a richer structure that allows us to solve the problem efficiently.

The kNN-realization is also related to the *sphericity* of graphs [19], where the goal is to embed a (undirected) graph $G = (V, E)$ into an Euclidean space $\mathbb{R}^k$ such that there is a point $p(u)$ for each vertex $u \in V$, and $d(p(u), p(v)) \leq 1$ iff $(u, v) \in E$. The smallest dimension k that admits such an embedding is called the *sphericity* of G [19]. (Another related problem is the *dimension* of a graph, introduced by Erdős, Harary and Tutte [16]: it is the smallest number k such that G can be embedded into Euclidean k-space with every edge of G having length 1.) Along these lines, Chatziafratis and Indyk [8] also show that if we want to preserve the relative distances among the k nearest neighbors of each point, then the embedding dimension must grow linearly with k. Unlike these results, our work is algorithmic – we design efficient algorithms to realize a given graph G in a specified dimension d.

Euclidean embedding of neighbor relations is also studied in social sciences for geometric realization of preference orderings. Given a set V of n voters, a set C of m candidates, and a rank ordering of the candidates by each voter, we say that the preference graph can be realized in Euclidean d-space if each voter's preferences are consistent with its Euclidean distances to all the candidates. In this case, the smallest dimension must satisfy $d \geq \min\{n, m-1\}$ [4].

1.1 Main results

We study the *kNN-realization* problem, which takes a directed graph G as an input and aims to compute a kNN-realization of G in $\mathbb{R}^d$ (or decide the nonexistence of such a realization). Throughout we focus on the *unranked* kNN-realization problem where nearest neighbors are realized as an *unordered set* but our results also hold (with minor caveat) for the ranked version where edges of G specify each of the k neighbors in order (see Concluding Remarks). Our two main results are the following.

1. Assuming that G is kNN-realizable in $\mathbb{R}^d$, we can find a d-dimensional realization in polynomial time that preserves at least a $1-\varepsilon$ fraction of the edges of G, for any fixed $\varepsilon > 0$. If our algorithm fails, we can also conclude that G is *not* kNN-realizable in $\mathbb{R}^d$. In particular, our algorithm is an EPTAS (*efficient polynomial-time approximation scheme*) for the kNN-realization problem for fixed k and d.
2. We give a *linear-time* algorithm to decide wether G is kNN-realizable in $\mathbb{R}^1$. Specifically, the algorithm runs in $O(kn)$ time, which is linear in the size of the input graph. If G is realizable, our algorithm can compute a realization in $O(n^{2.5}\mathsf{poly}(\log n))$ time.

1.2 Basic definitions

For a (directed or undirected) graph G, we use $V(G)$ and $E(G)$ to denote the set of its vertices and edges, respectively. If G is a directed graph, we say G is *k-regular* if the out-degree of every vertex of G is exactly equal to k. We use $\mathsf{in}[v]$ (resp., $\mathsf{out}[v]$) to denote the set consisting of v itself and all in-neighbors (resp., out-neighbors) of v. A *kNN-realization* of $G = (V, E)$ in a metric space $\mathcal{M} = (M, \mathsf{dist})$ is an injective map $\phi : V \to M$ such that $\mathsf{dist}(\phi(v), \phi(u)) < \mathsf{dist}(\phi(v), \phi(u'))$, for any distinct triple $v, u, u' \in V$ where $(v, u) \in E$ and $(v, u') \notin E$. We say G is *kNN-realizable* in $\mathcal{M}$ if there exists a kNN-realization of G in $\mathcal{M}$.

2 Approximate kNN-realization in $\mathbb{R}^d$

We first observe that it is easy to decide in polynomial time whether a given graph G is kNN-realizable in a finite-dimensional Euclidean space. We just have to check the acyclicity of an auxiliary graph defined as follows. Let Λ_G be a directed graph whose vertices correspond to pairs of vertices in $V(G)$ with a directed edge $(\{v, u\}, \{v, u'\})$ for every distinct triple $v, u, u' \in V(G)$ where $(v, u) \in E(G)$ and $(v, u') \notin E(G)$. Intuitively, Λ_G encodes the $\leq$-relation among the pairwise distances of points in any (potential) kNN-realization of G. If Λ_G has a directed cycle, then clearly G is not kNN-realizable. Otherwise, a topological sort of Λ_G gives a total ordering of the vertex pairs in G. With this ordering, we can find a kNN-realization of G in $\mathbb{R}^n$ using the result of Bilu and Linial [3].

On the other hand, deciding whether G is kNN-realizable in $\mathbb{R}^d$, for a specific dimension d, is NP-hard. This is shown by Eades and Whitesides [14] who proved the hardness for $d = 2$ and $k = 1$. Therefore, in this section, we explore an *approximation* algorithm for the realization problem in any fixed dimension d. We first need to define an approximate

solution to our problem. There is a natural way to measure how well a map $\phi : V(G) \to \mathbb{R}^d$ approximates a kNN-realization: randomly sample an edge $(u, v) \in E(G)$ and consider the probability that $\phi(v)$ is among the k nearest neighbors of $\phi(u)$. Formally, we introduce the following definition.

▶ **Definition 1** (approximate kNN-realization)**.** *Let G be a k-regular directed graph. For $c \in [0, 1]$, a map $\phi : V(G) \to \mathbb{R}^d$ is a **c-approximate kNN-realization** of G in $\mathbb{R}^d$ if*

$$\sum_{(u,v)\in E(G)} \sigma_\phi(u, v) \geq c \cdot |E(G)|,$$

where $\sigma_\phi : V(G) \times V(G) \to \{0, 1\}$ is the indicator function defined as $\sigma_\phi(u, v) = 1$ if we have $|\{v' \in V(G)\backslash\{u\} : \|\phi(u) - \phi(v')\|_2 \leq \|\phi(u) - \phi(v)\|_2\}| \leq k$ and $\sigma_\phi(u, v) = 0$ otherwise.

Our main result is an algorithm for computing a $(1 - \varepsilon)$-approximate kNN-realization of G in $\mathbb{R}^d$ with time complexity $f(k, d, \varepsilon) \cdot n^{O(1)}$, for any given $\varepsilon > 0$ (provided that G is kNN-realizable in $\mathbb{R}^d$), where f is some computable function. In other words, for fixed k and d, we obtain an *efficient polynomial-time approximation scheme* (EPTAS) for the kNN-realization problem in $\mathbb{R}^d$.

At a high level, our algorithm consists of two main steps. In the first step, it computes a set $E \subseteq E(G)$ of edges such that $|E| \leq \varepsilon|E(G)|$ and each weakly-connected component of $G - E$ contains $O_\varepsilon(1)$ vertices. The existence of E follows from the result of Miller et al. [21] on graph separators, and the computation of E relies on the approximate minimum cut algorithm of Chuzhoy et al. [10]. The edges in E are the ones we sacrifice in our approximation and so, in the second step, our algorithm computes a map $\phi : V(G) \to \mathbb{R}^d$ satisfying $\sigma_\phi(u, v) = 1$ for all edges $(u, v) \in E(G)\backslash E$. This turns out to be easy, since the weakly-connected components of $G - E$ are of size $O_\varepsilon(1)$ and we can work on these components individually. These two steps will be presented in Sections 2.1 and 2.2, respectively.

2.1 Splitting the graph by removing few edges

A *balanced cut* of an *undirected* graph H is a subset $E \subseteq E(H)$ such that every connected component of $H - E$ contains at most $|V(H)|/2$ vertices. Every directed graph G naturally corresponds to an undirected graph G_0 defined as $V(G_0) = V(G)$ and $E(G_0) = \{\{u, v\} : (u, v) \in E(G)$ or $(v, u) \in E(G)\}$. We need the following important result.

▶ **Lemma 2.** *Let G be a directed graph that is kNN-realizable in $\mathbb{R}^d$, and G_0 be the undirected graph corresponding to G. Then any subgraph H of G_0 with $|V(H)| \geq 2$ admits a balanced cut of size $O(|V(H)|^{1-\frac{1}{d}})$, where the constant hidden in $O(\cdot)$ only depends on k and d.*

Proof sketch. Let $k, d \in \mathbb{N}$ be fixed numbers. The lemma follows from two results in [21]. Specifically, it was shown in [21] that if a graph G is kNN-realizable in $\mathbb{R}^d$, then its corresponding undirected graph G_0 satisfies the following conditions.

1. The degree of every vertex in G_0 is $O(1)$.
2. For every subgraph H of G_0, there exists $S \subseteq V(H)$ such that $|S| = O(|V(H)|^{1-\frac{1}{d}})$ and every connected component of $H - S$ contains at most $\frac{d+1}{d+2} \cdot |V(H)|$ vertices.

We remark that [21] only claimed condition 2 above for the case $H = G_0$, but the argument extends to any subgraph H of G_0. Using the two conditions above, it is fairly easy to construct the desired balanced cut for any subgraph of G_0. ◀

A *minimum* balanced cut refers to a balanced cut consisting of the minimum number of edges. A *c-approximate* minimum balanced cut refers to a balanced cut whose size is at most $c \cdot \mathsf{opt}$, where opt is the size of a minimum balanced cut. The above lemma implies that

if G is kNN-realizable in $\mathbb{R}^d$, then the size of a minimum balanced cut of any subgraph H of G_0 is $O(|V(H)|^{1-\frac{1}{d}})$. We need the following algorithm by Chuzhoy et al. for computing approximate minimum balanced cuts.

▶ **Theorem 3** ([10]). *For any fixed number $\alpha > 0$, there exists an algorithm that, given an undirected graph H of n vertices and m edges, computes a $\log^{O(1/\alpha)} n$-approximate minimum balanced cut of H in $O(m^{1+\alpha})$ time.*

The following lemma is the main result of this section, which states that one can remove a small fraction of edges from G to split G into small components.

▶ **Lemma 4.** *Let $k, d \in \mathbb{N}$ be fixed numbers. Given a k-regular directed graph G and a number $\varepsilon \in (0, 1]$, one can either compute a subset $E \subseteq E(G)$ such that $|E| \leq \varepsilon|E(G)|$ and each weakly-connected component of $G - E$ contains at most $(\frac{1}{\varepsilon})^{O(1)}$ vertices, or conclude that G is not kNN-realizable in $\mathbb{R}^d$, in $O(|V(G)|^{1+\alpha})$ time for any constant $\alpha > 0$. Here the constants hidden in $O(\cdot)$ depend on k, d, and α.*

Proof. Let G_0 be the corresponding undirected graph of G, and $\alpha > 0$ be a constant. It suffices to compute $E \subseteq E(G_0)$ such that $|E| \leq \varepsilon|E(G_0)|$ and each connected component of $G_0 - E$ contains at most $(\frac{1}{\varepsilon})^{O(1)}$ vertices. Indeed, the edges in G corresponding to E form a subset of $E(G)$ of size $O(\varepsilon|E(G)|)$ which satisfies the desired property. This is fine since our algorithm works for an arbitrary $\varepsilon > 0$.

Pick a constant $\alpha' \in (0, \alpha)$ and let ApprxMinCut(H) denote the algorithm in Theorem 3, which returns an approximate minimum balanced cut of H in $O(|V(H)|^{1+\alpha'})$ time. Our algorithm, presented in Algorithm 1, computes $E \subseteq E(G_0)$ by recursively applying ApprxMinCut as a sub-routine. We fix some threshold $\delta = (\frac{1}{\varepsilon})^c$ for a sufficiently large c (depending on k, d, and α). If $|V(G_0)| \leq \delta$, then we simply return $E = \emptyset$. Otherwise, we apply ApprxMinCut(G_0) to obtain an approximate minimum balanced cut of G_0, and add the edges in the cut to E. Then for every connected component C of $G_0 - E$, we recursively apply our algorithm on C, which returns a subset of $E_C \subseteq E(C)$, and we add the edges in E_C to E. Finally, we return E as the output of our algorithm.

Algorithm 1 CutEdge(G_0).

```
1: if |V(G_0)| ≤ δ then return ∅
2: E ← ApprxMinCut(G_0)
3: 𝒞 ← set of connected components of G_0 − E
4: for every C ∈ 𝒞 do
5:     E ← E ∪ CutEdge(C)
6: return E
```

Clearly, every connected component of $G_0 - E$ contains at most $\delta = (\frac{1}{\varepsilon})^{O(1)}$ vertices. So it suffices to show $|E| \leq \varepsilon|E(G_0)|$ and analyze the running time of the algorithm. To bound $|E|$, we observe that when applying ApprxMinCut on any subgraph H of G_0, the size of the edge set obtained is of size $|V(H)|^{1-\frac{1}{d}} \log^{O(1/\alpha')} |V(H)|$. Indeed, a minimum balanced cut of H has size $O(|V(H)|^{1-\frac{1}{d}})$ by Lemma 2, and ApprxMinCut(H) returns a $\log^{O(1/\alpha')} |V(H)|$-approximate minimum balanced cut of H. Since we defined $\delta = (\frac{1}{\varepsilon})^c$ for a sufficiently large c, we may assume that the size of ApprxMinCut(H) is at most $|V(H)|^{1-\frac{1}{2d}}$ for any subgraph H of G_0 such that $|V(H)| > \delta$. Also, we may assume that $\varepsilon(2^{\frac{1}{3d}} - 1)n^{1-\frac{1}{3d}} > n^{1-\frac{1}{2d}}$ for all $n > \delta$. We shall prove that when applying our algorithm on a subgraph H of G_0 with $|V(H)| = n$, the size of $E \subseteq E(H)$ returned is at most $\varepsilon(n - n^{1-\frac{1}{3d}})$.

We apply induction on n. If $V(H) \leq \delta$, then our algorithm returns an empty set and thus the statement trivially holds. Assume the statement holds for $|V(H)| \in [n-1]$, and we consider the case $|V(H)| = n$ (where $n > \delta$). Our algorithm applies ApprxMinCut(H) to obtain an approximate minimum balanced cut $E_0 \subseteq E(H)$ of H. As aforementioned, $|E_0| \leq n^{1-\frac{1}{2d}}$. Let $C_1, \ldots, C_r$ be the connected components of $H - E_0$. Set $n_i = |V(C_i)|$ for $i \in [r]$. We have $n_i \leq n/2$ for all $i \in [r]$, by the definition of a balanced cut. We recursively call our algorithm on each C_i to obtain a subset $E_i \subseteq E(C_i)$. By our induction hypothesis, $|E_i| \leq \varepsilon(n_i - n_i^{1-\frac{1}{3d}})$. Finally, the algorithm returns $E = \bigcup_{i=0}^{r} E_i$. Thus, we have $|E| = |E_0| + \sum_{i=1}^{r} |E_i|$. As $\sum_{i=1}^{r} n_i = n$, $\sum_{i=1}^{r} |E_i| \leq \varepsilon n - \varepsilon \sum_{i=1}^{r} n_i^{1-\frac{1}{3d}}$. Furthermore, since $n_i \leq n/2$ for all $i \in [r]$ and $\sum_{i=1}^{r} n_i = n$, it holds $\sum_{i=1}^{r} n_i^{1-\frac{1}{3d}} \geq 2(\frac{n}{2})^{1-\frac{1}{3d}} = 2^{\frac{1}{3d}} n^{1-\frac{1}{3d}}$. Combining the bounds for $|E_0|$ and $\sum_{i=1}^{r} |E_i|$, we have

$$|E| \leq n^{1-\frac{1}{2d}} + \varepsilon n - \varepsilon \cdot 2^{\frac{1}{3d}} n^{1-\frac{1}{3d}}.$$

Recall our assumption $\varepsilon(2^{\frac{1}{3d}} - 1)n^{1-\frac{1}{3d}} \geq n^{1-\frac{1}{2d}}$. Together with the inequality above, this gives us $|E| \leq \varepsilon(n - n^{1-\frac{1}{3d}})$, so our induction works. In particular, when we apply Algorithm 1 on G_0, the output $E \subseteq E(G_0)$ satisfies $|E| \leq \varepsilon(|V(G_0)| - |V(G_0)|^{1-\frac{1}{3d}}) \leq \varepsilon|V(G_0)|$.

To analyze the time complexity of Algorithm 1, we consider the recursion tree T of our algorithm when applying on G_0. Each node $t \in T$ corresponds to a recursive call, and denote by $G_0(t)$ the corresponding graph handled in that call (which is a subgraph of G_0). The time cost at a node $t \in T$ is $O(|E(G_0(t))|^{1+\alpha'})$, which is just $O(|V(G_0(t))|^{1+\alpha'})$ because $|E(G_0(t))| \leq k|V(G_0(t))|$. Since ApprxMinCut always returns a balanced cut, we know that $|V(G_0(t))| \leq |V(G_0(t'))|/2$ if t' is the parent of t in T. This implies that the depth of T is $O(\log |V(G_0)|)$. Also, the sum of $|V(G_0(t))|$ for all nodes $t \in T$ at one level of T is at most $|V(G_0)|$. Thus $\sum_{t \in T} |V(G_0(t))| \leq |V(G_0)| \log |V(G_0)|$ and $\sum_{t \in T} |V(G_0(t))|^{1+\alpha'} \leq |V(G_0)|^{1+\alpha'} \log |V(G_0)|$. The latter implies that the time complexity of Algorithm 1 is $O(|V(G_0)|^{1+\alpha'} \log |V(G_0)|)$, which is $O(|V(G_0)|^{1+\alpha})$ since $\alpha > \alpha'$. We remark that a more careful analysis can be applied to show that the running time of our algorithm is actually $O(|V(G_0)|^{1+\alpha'})$ instead of $O(|V(G_0)|^{1+\alpha'} \log |V(G_0)|)$. But for simplicity, we chose this looser analysis, which is already sufficient for our purpose. ◀

2.2 Computing the approximate realization

After computing the set $E \subseteq E(G)$ of edges using Lemma 4, we consider the graph $G - E$. Let $C_1, \ldots, C_r$ be the weakly-connected components of $G - E$. We have $|V(C_i)| = (\frac{1}{\varepsilon})^{O(1)}$ by Lemma 4. For each $i \in [r]$, we want to compute a "kNN-realization" of C_i in $\mathbb{R}^d$. Of course, here each C_i is not necessarily k-regular, and thus a kNN-realization of C_i is not defined. But we can slightly generalize the definition of kNN-realization as follows. For a directed graph C, we say a map $\phi : V(C) \to \mathbb{R}^d$ is a *quasi-kNN-realization* of C in $\mathbb{R}^d$ if for every edge $(u, v) \in E(C)$, $|\{v' \in V(C) \backslash \{u\} : \|\phi(u) - \phi(v')\|_2 \leq \|\phi(u) - \phi(v)\|_2\}| \leq k$. By this definition, a kNN-realization is also a quasi-kNN-realization. Also, it is clear that if $\phi : V(H) \to \mathbb{R}^d$ is a quasi-kNN-realization of a directed graph H in $\mathbb{R}^d$, then for any subgraph C of H, the map $\phi_{|V(C)}$ is a quasi-kNN-realization of C in $\mathbb{R}^d$. Therefore, if G is kNN-realizable in $\mathbb{R}^d$, then each of $C_1, \ldots, C_r$ admits a quasi-kNN-realization in $\mathbb{R}^d$.

Next, we discuss how to compute a quasi-kNN-realization of each C_i in $\mathbb{R}^d$ (or conclude it does not exist). To this end, we need the following lemma.

▶ **Lemma 5.** *Let C be a directed graph where $|V(C)| \geq k + 1$. If C admits a quasi-kNN-realization in $\mathbb{R}^d$, then there exists a k-regular supergraph C' of C with $V(C') = V(C)$ such that C' is kNN-realizable in $\mathbb{R}^d$.*

Proof. Assume $\phi : V(C) \to \mathbb{R}^d$ is a quasi-kNN-realization of C in $\mathbb{R}^d$. We can slightly perturb ϕ so that for any distinct $u, v, v' \in V(C)$, $\|\phi(u) - \phi(v')\|_2 \neq \|\phi(u) - \phi(v)\|_2\}$. Now define C' as a directed graph with $V(C') = V(C)$ and $E(C') = \{(u, v) \in V(C') \times V(C') : u \neq v$ and $\mathsf{rank}_\phi(u, v) \leq k\}$, where

$$\mathsf{rank}_\phi(u, v) = |\{v' \in V(C')\backslash\{u\} : \|\phi(u) - \phi(v')\|_2 \leq \|\phi(u) - \phi(v)\|_2\}|.$$

The construction guarantees that C' is k-regular and ϕ is a kNN-realization of C' in $\mathbb{R}^d$. Since ϕ is a quasi-kNN-realization of C, $E(C) \subseteq E(C')$ and thus C' is a supergraph of C. ◀

If $|V(C_i)| \leq k$, then any map from $V(C_i)$ to $\mathbb{R}^d$ is a quasi-kNN-realization of C_i. Otherwise, by the above lemma, to compute a quasi-kNN-realization of C_i in $\mathbb{R}^d$, it suffices to consider every supergraph C_i' of C_i with $V(C_i') = V(C_i)$ and try to compute a kNN-realization of C_i' (or conclude that C_i' is not kNN-realizable). Note that the number of such supergraphs is at most $\exp((\frac{1}{\varepsilon})^{O(1)})$ because $|V(C_i)| = (\frac{1}{\varepsilon})^{O(1)}$. If we obtain a kNN-realization of some C_i', then it is a quasi-kNN-realization of C_i. To compute a kNN-realization $\phi : V(C_i') \to \mathbb{R}^d$ of C_i', we formulate the problem as finding a solution to a system of $(\frac{1}{\varepsilon})^{O(1)}$ degree-2 polynomial inequalities on $(\frac{1}{\varepsilon})^{O(1)}$ variables. For each $v \in V(C_i')$, we represent the coordinates of $\phi(v)$ by d variables $x_1(v), \ldots, x_d(v)$. Then for all distinct $u, v, v' \in V(C_i')$ such that $(u, v) \in E(C_i')$ and $(u, v') \notin E(C_i')$, we introduce a degree-2 polynomial inequality $\sum_{j=1}^d (x_j(u) - x_j(v))^2 \leq \sum_{j=1}^d (x_j(u) - x_j(v'))^2$, which expresses $\|\phi(u) - \phi(v)\|_2 < \|\phi(u) - \phi(v')\|_2$. Clearly, the solutions to this system of inequalities one-to-one correspond to the kNN-realizations of C_i' in $\mathbb{R}^d$. Renegar [23] showed that a system of p degree-2 polynomial inequalities on q variables can be solved in $p^{O(q)}$ time. Therefore, we can compute in $(\frac{1}{\varepsilon})^{(\frac{1}{\varepsilon})^{O(1)}}$ time a kNN-realization of C_i' in $\mathbb{R}^d$ (or decide its non-existence). This further implies that we can compute in $(\frac{1}{\varepsilon})^{(\frac{1}{\varepsilon})^{O(1)}}$ time a quasi-kNN-realization of C_i in $\mathbb{R}^d$ (or decide its non-existence). The total time cost for all C_i is then $(\frac{1}{\varepsilon})^{(\frac{1}{\varepsilon})^{O(1)}} \cdot n$, since $r \leq n$.

If C_i does not admit a quasi-kNN-realization in $\mathbb{R}^d$ for some $i \in [r]$, then we can directly conclude that G is not kNN-realizable in $\mathbb{R}^d$. Otherwise we construct a $(1 - \varepsilon)$-approximate kNN-realization of G in $\mathbb{R}^d$ as follows. Let $\phi_i : V(C_i) \to \mathbb{R}^d$ be the quasi-kNN-realization of C_i in $\mathbb{R}^d$ we compute, for $i \in [r]$. Define a map $\phi : V(G) \to \mathbb{R}^d$ as follows. Pick a vector $\vec{x} \in \mathbb{R}^d$ such that $\|\vec{x}\|_2 >> \max_{i\in[r]} \max_{u,v\in V(C_i)} \|\phi_i(u) - \phi_i(v)\|_2$. Then for each $i \in [r]$ and each $v \in V(C_i)$, set $\phi(v) = i\vec{x} + \phi_i(v)$. The choice of $\vec{x}$ guarantees that for a vertex $v \in V(C_i)$, the ϕ-images of the vertices in C_i are closer to $\phi(v)$ than the ϕ-images of the vertices outside C_i. Also, for any $u, v \in V(C_i)$, $\|\phi(u) - \phi(v)\|_2 = \|\phi_i(u) - \phi_i(v)\|_2$. Therefore, for any $u, v \in V(C_i)$, we have

$$\begin{aligned}
&\{v' \in V(G)\backslash\{u\} : \|\phi(u) - \phi(v')\|_2 \leq \|\phi(u) - \phi(v)\|_2\} \\
&= \{v' \in V(C_i)\backslash\{u\} : \|\phi(u) - \phi(v')\|_2 \leq \|\phi(u) - \phi(v)\|_2\} \\
&= \{v' \in V(C_i)\backslash\{u\} : \|\phi_i(u) - \phi_i(v')\|_2 \leq \|\phi_i(u) - \phi_i(v)\|_2\}.
\end{aligned}$$

Recall the function $\sigma_\phi : V(G) \times V(G) \to \{0, 1\}$ in Definition 1. The above equality shows that for $u, v \in V(C_i)$, if $|\{v' \in V(C_i)\backslash\{u\} : \|\phi_i(u) - \phi_i(v')\|_2 \leq \|\phi_i(u) - \phi_i(v)\|_2\}| \leq k$, then $\sigma_\phi(u, v) = 1$. It follows that $\sigma_\phi(u, v) = 1$ for any $(u, v) \in E(C_i)$ because ϕ_i is a quasi-kNN-realization of C_i, so we have

$$\sum_{(u,v)\in E(G)} \sigma_\phi(u, v) \geq \sum_{i=1}^{r} |E(C_i)| = |E(G)| - |E| \geq (1 - \varepsilon) \cdot |E(G)|.$$

Therefore, ϕ is a $(1-\varepsilon)$-approximate kNN-realization of G in $\mathbb{R}^d$. Combining the time costs for computing E and the maps $\phi_1, \ldots, \phi_r$, the overall time complexity of our algorithm is $O(n^{1+\alpha})$, where $O(\cdot)$ hides a constant depending on k, d, α, and ε.

▶ **Theorem 6.** *Let $\alpha > 0$ be any fixed number. Given a k-regular directed graph G of n vertices and a number $\varepsilon > 0$, one can compute in $f(k, d, \varepsilon) \cdot n^{1+\alpha}$ time a $(1-\varepsilon)$-approximate kNN-realization of G in $\mathbb{R}^d$, or conclude that G is not kNN-realizable in $\mathbb{R}^d$, where f is some computable function depending on α.*

3 kNN-Realization in $\mathbb{R}^1$

To the best of our knowledge, the kNN-realization problem on the line does not seem to have been studied, and it is the focus of this section. A number of line embedding problems are NP-hard as mentioned earlier, including triplet constraints and betweenness problems [9]. In the former, we are given a set of triplet constraints of the form $d(a, b) < d(a, c)$, while in the latter each constraint (a, b, c) requires the ordering to satisfy $a < b < c$. Given the hardness result, the focus in these problems is on approximating the maximum number of satisfied constraints in the linear ordering [17].

Unlike these intractable embedding problems on the line, we show that the partial order constraints implied by a kNN-realization problem have sufficiently rich structure to admit a polynomial time solution. Most of the difficulty is in *deciding* whether a k-regular directed graph G is kNN-realizable on the line; if the answer is yes, then one can easily compute the embedding in polynomial time using linear programming. (It is also worth pointing out that the decision problem for kNN-realization on the line is significantly more complicated than the special case of triplet constraints in [17] when *all* $\binom{n}{3}$ *triples are specified.* Indeed, in that case, one can guess the leftmost point, and then all the remaining points are immediately determined by the triplet constraints. This is not the case in kNN-realization: fixing the leftmost point does not fix its neighbors' order.)

The *decision* version of the kNN-realization problem, of course, is easy *if* we are given a permutation of G's vertices $(v_1, \ldots, v_n)$. In this case, we can easily compute a kNN-realization $\phi : V(G) \to \mathbb{R}^1$ satisfying $\phi(v_1) < \cdots < \phi(v_n)$, or decide that a feasible realization does not exist, by formulating the problem as a linear program (LP) with n variables $x_1, \ldots, x_n$ and the following set of constraints

- $x_i \le x_j$ for all $i, j \in [n]$ with $i \le j$,
- $\Delta_{i,j} < \Delta_{i,k}$ for all distinct $i, j, k \in [n]$ such that $(v_i, v_j) \in E(G)$ and $(v_i, v_k) \notin E(G)$, where $\Delta_{i,j} = x_{\max\{i,j\}} - x_{\min\{i,j\}}$ and $\Delta_{i,k} = x_{\max\{i,k\}} - x_{\min\{i,k\}}$.

Clearly, if $x_1, \ldots, x_n$ satisfy these constraints, then setting $\phi(v_i) = x_i$ gives us the desired realization. On the other hand, if ϕ is the realization we want, then the numbers $x_1, \ldots, x_n$ where $x_i = \phi(v_i)$ must satisfy the constraints. Therefore, we begin with this key problem: efficiently computing an ordering of the images of the vertices on $\mathbb{R}^1$.

3.1 Finding the vertex ordering

We say an ordering $(v_1, \ldots, v_n)$ of $V(G)$ is a *feasible vertex ordering* of G if there exists a kNN-realization $\phi : V(G) \to \mathbb{R}^1$ of G in $\mathbb{R}^1$ satisfying $\phi(v_1) < \cdots < \phi(v_n)$. The goal of this section is to give an $O(kn)$-time algorithm for computing a feasible vertex ordering of G (assuming it exists). We may assume, without loss of generality, that G is weakly-connected; otherwise we can consider each weakly-connected component of G individually.

Our first observation states two key properties of a feasible vertex ordering: (1) for each v_i its k out-neighbors form a contiguous block, and for different v_i's their blocks have the same linear ordering as the vertex ordering, and (2) for each v_i its in-neighbors also form a continuous block, which extends at most k vertices to the left and at most k to the right of v_i. (Recall that both $\mathsf{out}[v]$ and $\mathsf{in}[v]$ include v, for all vertices $v \in V(G)$.) See figure 1.

▶ **Observation 7.** *A feasible vertex ordering $(v_1, \dots, v_n)$ of G satisfies the following.*

1. *There exist $p_1, \dots, p_n \in [n-k]$ such that* **(i)** $\mathsf{out}[v_i] = \{v_{p_i}, \dots, v_{p_i+k}\}$ *for all $i \in [n]$,* **(ii)** $p_1 \leq \cdots \leq p_n$*, and* **(iii)** $p_i \leq i \leq p_i + k$ *for all $i \in n$.*
2. *There exist $q_1, \dots, q_n, q'_1, \dots, q'_n \in [n]$ such that* **(i)** $\mathsf{in}[v_i] = \{v_{q_i}, \dots, v_{q'_i}\}$ *for all $i \in [n]$,* **(ii)** $q_1 \leq \cdots \leq q_n$*,* **(iii)** $q'_1 \leq \cdots \leq q'_n$*, and* **(iv)** $q_i \leq q'_i \leq q_i + 2k$ *for all $i \in [n]$.*

Proof. Let $\phi : V(G) \to \mathbb{R}^1$ be a kNN-realization of G in $\mathbb{R}^1$ satisfying $\phi(v_1) < \cdots < \phi(v_n)$. Clearly, for each $i \in [n]$, the $k+1$ points in $\{\phi(v_1), \dots, \phi(v_n)\}$ closest to $\phi(v_i)$ are $\{\phi(v_{p_i}), \dots, \phi(v_{p_i+k})\}$ for some $p_i \in [n-k]$ such that $p_i \leq i \leq p_i + k$. Furthermore, one can easily verify that $p_1 \leq \cdots \leq p_n$. Assume $p_i > p_j$ for some $i, j \in [n]$ with $i < j$. Then we have $\phi(v_{p_j}) < \phi(v_{p_i}) \leq \phi(v_i) < \phi(v_j) \leq \phi(v_{p_j+k}) < \phi(v_{p_i+k})$. On the other hand, since $v_{p_i+k} \notin \{\phi(v_{p_j}), \dots, \phi(v_{p_j+k})\}$ and $v_{p_j} \notin \{\phi(v_{p_i}), \dots, \phi(v_{p_i+k})\}$,

$$\phi(v_j) - \phi(v_{p_j}) \leq \phi(v_{p_i+k}) - \phi(v_j) \leq \phi(v_{p_i+k}) - \phi(v_i) \leq \phi(v_i) - \phi(v_{p_j}),$$

which contradicts the fact $\phi(v_{p_j}) < \phi(v_{p_i}) \leq \phi(v_i) < \phi(v_j)$. By the definition of kNN-realization, we see $\mathsf{out}[v_i] = \{v_{p_i}, \dots, v_{p_i+k}\}$ for all $i \in [n]$. This proves condition 1.

Condition 2 follows from condition 1. Observe that for each $i \in [n]$, it holds that $\mathsf{in}[v_i] = \{v_j : p_j \leq i \leq p_j + k\} = \{v_j : i - k \leq p_j \leq i\}$. Since $p_1 \leq \cdots \leq p_n$, this implies $\mathsf{in}[v_i] = \{v_{q_i}, \dots, v_{q'_i}\}$ where $q_i = \min\{j : i - k \leq p_j \leq i\}$ and $q'_i = \max\{j : i - k \leq p_j \leq i\}$. The monotoncities $q_1 \leq \cdots \leq q_n$ and $q'_1 \leq \cdots \leq q'_n$ follow directly from the monotoncity $p_1 \leq \cdots \leq p_n$. It suffices to show that $q_i \leq q'_i \leq q_i + 2k$ for all $i \in [n]$. The inequality $q_i \leq q'_i$ is trivial. To see $q'_i \leq q_i + 2k$, assume that $q'_i > q_i + 2k$. Then there exists $j, j' \in [n]$ with $j' > j + 2k$ such that $i - k \leq p_j \leq i$ and $i - k \leq p_{j'} \leq i$. By condition 1, we have $j \geq p_j$ and $p_{j'} \geq j' - k > j + k$. Therefore, $p_{j'} > j + k \geq p_j + k \geq (i - k) + k = i$, which contradicts the fact $i - k \leq p_{j'} \leq i$. This proves condition 2. ◀

Consider the equivalence relation $\sim$ defined on $V(G)$ as $u \sim v$ iff $\mathsf{out}[u] = \mathsf{out}[v]$. Let $\mathcal{C}_G$ be the set of equivalence classes of this relation, which is a partition of $V(G)$ into groups of vertices with the same set of out neighbors. One can easily compute $\mathcal{C}_G$ in $O(k^2 n)$ time as follows. Given a vertex $v \in V(G)$, we check whether $\mathsf{out}[u] = \mathsf{out}[v]$, for all $u \in \mathsf{out}[v]$, which takes $O(k^2)$ time since $|\mathsf{out}[v]| = k + 1$ and each equality test takes $O(k)$ time. Thus, the time for computing all classes is $O(k^2 n)$. Interestingly, we use Observation 7 to compute $\mathcal{C}_G$ in $O(kn)$ time, if G is kNN-realizable in $\mathbb{R}^1$, as shown in the following Lemma. Due to space constraints the proof is included in the full version.

▶ **Lemma 8.** *Let G be a k-regular directed graph of n vertices. One can compute in $O(kn)$ time a partition $\mathcal{C}$ of $V(G)$ such that $\mathcal{C} = \mathcal{C}_G$ if G is kNN-realizable in $\mathbb{R}^1$.*

Write $r = |\mathcal{C}_G|$. Let $(v_1, \dots, v_n)$ be a feasible vertex ordering of G. Observation 7 implies that each class $C \in \mathcal{C}_G$ is a set of consecutive vertices in the sequence $(v_1, \dots, v_n)$, i.e., $C = \{v_\alpha, \dots, v_\beta\}$ for some $\alpha, \beta \in [n]$. Define $\mathsf{out}[C] = \mathsf{out}[v]$ for an arbitrary vertex $v \in C$. Therefore, there is a natural ordering $(C_1, \dots, C_r)$ of the classes in $\mathcal{C}_G$, in which the indices of the vertices in C_i are smaller than the indices of the vertices in C_j for all $i, j \in [r]$ with $i < j$. We call $(C_1, \dots, C_r)$ a *feasible class ordering* of G.

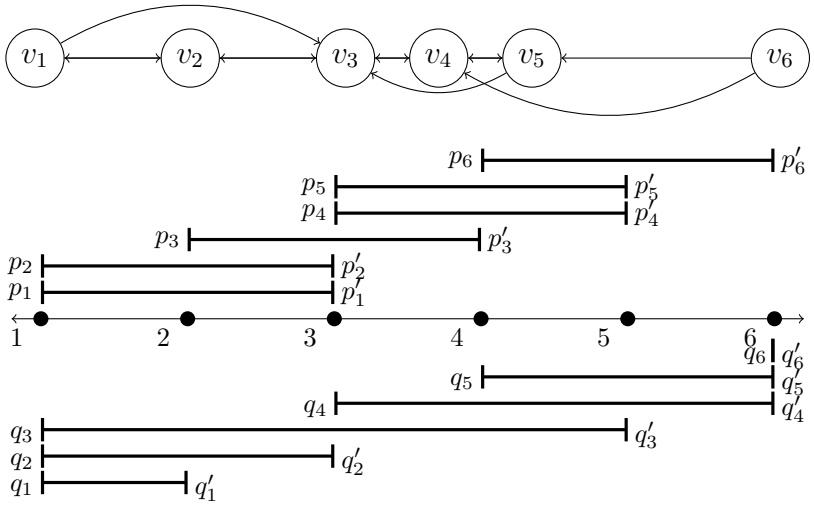

Figure 1 A 2-regular graph on 6 vertices and its realization (top). The values of p, p', q, q' for each vertex illustrate a natural ordering of the in and out-neighborhoods corresponding to the feasible vertex ordering $v_1, \cdots, v_6$ (bottom).

▶ **Observation 9.** *If $(C_1, \ldots, C_r)$ is the feasible class ordering of G corresponding to a feasible vertex ordering $(v_1, \ldots, v_n)$ of G, then there exist $c_1, \ldots, c_r \in [n-k]$ satisfying*

- $\mathsf{out}[C_i] = \{v_{c_i}, \ldots, v_{c_i+k}\}$ *for all* $i \in [r]$,
- $c_1 < \cdots < c_r$,
- *if G is weakly-connected, then $c_{i+1} \leq c_i + k$ for all $i \in [r-1]$.*

Proof. Let $p_1, \ldots, p_n \in [n-k]$ be the indices in condition 1 of Observation 7, for the feasible vertex ordering $(v_1, \ldots, v_n)$. For each $i \in [r]$, set $c_i = p_s$ where $s = 1 + \sum_{j=1}^{i-1} |C_j|$, and we then have $\mathsf{out}[C_i] = \mathsf{out}[v_s] = \{v_{c_i}, \ldots, v_{c_i+k}\}$. Since $p_1 \leq \cdots \leq p_n$, we have $c_1 \leq \cdots \leq c_r$. Furthermore, for all $i \in [r-1]$, we have $c_i \neq c_{i+1}$, simply because $\mathsf{out}[C_i] \neq \mathsf{out}[C_{i+1}]$. Thus, $c_1 < \cdots < c_r$. To see the last property, assume $c_{i+1} > c_i + k$ for some $i \in [r-1]$. Then $(\bigcup_{j=1}^{i} \mathsf{out}[C_j]) \cap (\bigcup_{j=i+1}^{r} \mathsf{out}[C_j]) = \emptyset$. Note that $\bigcup_{j=1}^{i} C_j \subseteq \bigcup_{j=1}^{i} \mathsf{out}[C_j]$ and $\bigcup_{j=i+1}^{r} C_j \subseteq \bigcup_{j=i+1}^{r} \mathsf{out}[C_j]$. So there is no edge between $\bigcup_{j=1}^{i} C_j$ and $\bigcup_{j=i+1}^{r} C_j$, which implies that G is not weakly connected. ◀

To compute a feasible vertex ordering of G, we first compute a feasible class ordering, using the previous observation. Due to space constraints the proof of the following lemma is included in the full version.

▶ **Lemma 10.** *Let G be a weakly-connected k-regular directed graph of n vertices. Given $\mathcal{C}_G$, one can compute in $O(kn)$ time an ordering of $\mathcal{C}_G$, which is a feasible class ordering of G if G is kNN-realizable in $\mathbb{R}^1$.*

Next, we show how to compute a corresponding feasible vertex ordering of G given a feasible class ordering $(C_1, \ldots, C_r)$. By definition, we know that in the feasible vertex ordering, the vertices in C_i must appear before the vertices in C_j for all $i, j \in [r]$ with $i < j$. So it suffices to figure out the "local" ordering of the vertices in each class C_i. We do this by considering the in-neighbors of each vertex. As observed before, for each $v \in V(G)$, $\mathsf{in}[v]$ is the union of several classes in $\mathcal{C}_G$, and in addition, $\mathsf{in}[v] = \bigcup_{i=p}^{q} C_i$ for some $p, q \in [r]$, by condition 2 of Observation 7. It turns out that we can sort the vertices in each class according to the values of p and q. Formally, we prove the following lemma.

▶ **Lemma 11.** *Let G be a weakly-connected k-regular directed graph of n vertices, and $r = |\mathcal{C}_G|$. Given an ordering $(C_1, \ldots, C_r)$ of $\mathcal{C}_G$, one can compute in $O(kn)$ time an ordering $(v_1, \ldots, v_n)$ of $V(G)$ such that if $(C_1, \ldots, C_r)$ is a feasible class ordering of G, then $(v_1, \ldots, v_n)$ is a feasible vertex ordering of G.*

Proof. Our algorithm for computing a feasible vertex ordering of G is presented in Algorithm 2. First, for each $v \in V(G)$, we compute a pair $R(v) = (p, q)$ where $p \in [r]$ (resp., $q \in [r]$) is the minimum (resp., maximum) index such that $C_p \subseteq \mathsf{in}[v]$ (resp., $C_q \subseteq \mathsf{in}[v]$). We define a partial order $\preceq$ on index-pairs by setting $(p, q) \preceq (p', q')$ if $p + q \leq p' + q'$. Then we order the vertices in each class C_i as $(u_1, \ldots, u_{|C_i|})$ such that $R(u_1) \preceq \cdots \preceq R(u_{|C_i|})$. If there exist $u, v \in C_i$ such that $R(u)$ and $R(v)$ are incomparable under the order $\preceq$, then we just arbitrarily order the vertices in C_i. We will see later that in this case, $(C_1, \ldots, C_r)$ is not a feasible class ordering of G. By concatenating the orderings of $C_1, \ldots, C_r$, we obtain an ordering $(v_1, \ldots, v_n)$ of $V(G)$.

We first show that Algorithm 2 can be implemented in $O(kn)$ time. Computing $R(v)$ for all $v \in V(G)$ can be done in $O(kn)$ time, because $|\mathsf{in}[v]| = O(k)$ by (ii) of Observation 7. To see the time cost for ordering the vertices in each C_i, observe that $|C_i| \leq k$. Indeed, $v \in \mathsf{out}[v] = \mathsf{out}[C_i]$ for all $v \in C_i$, which implies $C_i \subseteq \mathsf{out}[C_i]$ and thus $|C_i| \leq |\mathsf{out}[C_i]| = k$. If we sort the vertices in C_i directly, it takes $O(k \log k)$ time. One can improve the time cost to $O(k)$ by observing that for any $v \in C_i$, the pair $R(v) = (p, q)$ satisfies $p \geq i - k$ and $q \leq i + k$, by condition 2 of Observation 7, which implies $2i - 2k \leq p + q \leq 2i + 2k$. In other words, in the sorting task, the keys are all in the range $\{2i - 2k, \ldots, 2i + 2k\}$, whose size is $O(k)$. Thus, the task can be done in $O(k)$ time using bucket sorting. It follows that Algorithm 2 can be implemented in $O(kn)$ time.

To see the correctness of our algorithm, suppose $(C_1, \ldots, C_r)$ is a feasible class ordering of G, and let $(v_1^*, \ldots, v_n^*)$ be a corresponding feasible vertex ordering of G. We do not necessarily have $(v_1, \ldots, v_n) = (v_1^*, \ldots, v_n^*)$. However, as we will see, it holds that $(R(v_1), \ldots, R(v_n)) = (R(v_1^*), \ldots, R(v_n^*))$, which turns out to be sufficient. By (ii) of Observation 7, for each $v \in V(G)$ with $R(v) = (p, q)$, we have $\mathsf{in}[v] = \bigcup_{i=p}^{q} C_i$, and furthermore, $R(v_1^*) \preceq \cdots \preceq R(v_n^*)$. Now consider a class C_i. Note that $C_i = \{v_\alpha, \ldots, v_\beta\} = \{v_\alpha^*, \ldots, v_\beta^*\}$, where $\alpha = 1 + \sum_{j=1}^{i-1} |C_j|$ and $\beta = \sum_{j=1}^{i} |C_j|$. We have $R(v_\alpha^*) \preceq \cdots \preceq R(v_\beta^*)$, and our algorithm guarantees that $R(v_\alpha) \preceq \cdots \preceq R(v_\beta)$. Therefore, $(R(v_\alpha), \ldots, R(v_\beta)) = (R(v_\alpha^*), \ldots, R(v_\beta^*))$. It then follows that $(R(v_1), \ldots, R(v_n)) = (R(v_1^*), \ldots, R(v_n^*))$.

To see $(v_1, \ldots, v_n)$ is a feasible vertex ordering of G, we further observe that the function $\pi : V(G) \to V(G)$ defined as $\pi(v_i) = v_i^*$ for $i \in [n]$ is an automorphism of G. Consider indices $i, j \in [n]$. We have $\mathsf{out}[v_i] = \mathsf{out}[v_i^*]$, since v_i and v_i^* belong to the same class in $\mathcal{C}_G$. Thus, $(v_i, v_j) \in E(G)$ iff $(v_i^*, v_j) \in E(G)$. On the other hand, because $R(v_j) = R(v_j^*)$, we have $\mathsf{in}[v_j] = \mathsf{in}[v_j^*]$ and hence $(v_i^*, v_j) \in E(G)$ iff $(v_i^*, v_j^*) \in E(G)$. As such, $(v_i, v_j) \in E(G)$ iff $(v_i^*, v_j^*) \in E(G)$, which implies that π is an automorphism of G. Now consider a kNN-realization $\phi : V(G) \to \mathbb{R}^1$ of G in $\mathbb{R}^1$ satisfying $\phi(v_1^*) < \cdots < \phi(v_n^*)$. Set $\phi' = \phi \circ \pi$, which is a map from $V(G)$ to $\mathbb{R}^1$. As π is an automorphism of G, ϕ' is also a kNN-realization of G. Furthermore, $\phi'(v_i) = \phi(\pi(v_i)) = \phi(v_i^*)$ for all $i \in [n]$, which implies $\phi'(v_1) < \cdots < \phi'(v_n)$. The existence of ϕ' shows that $(v_1, \ldots, v_n)$ is a feasible vertex ordering of G. ◀

▶ **Theorem 12.** *Given a k-regular directed graph G of n vertices, one can compute in $O(kn)$ time an ordering $(v_1, \ldots, v_n)$ of $V(G)$, which is a feasible vertex ordering of G if G is kNN-realizable in $\mathbb{R}^1$.*

Proof. For the case where G is weakly-connected, the theorem follows directly from Lemmas 8, 10 and 11. Otherwise, we compute the orderings for the weakly-connected components of G individually and concatenate them; this gives us the desired ordering of $V(G)$. ◀

Algorithm 2 VertexOrder$(G, (C_1, \ldots, C_r))$.

for $v \in V(G)$ **do**
  $p \leftarrow \min\{i \in [r] : C_i \subseteq \mathsf{in}[v]\}$
  $q \leftarrow \max\{i \in [r] : C_i \subseteq \mathsf{in}[v]\}$
  $R(v) \leftarrow (p, q)$
for $i = 1, \ldots, r$ **do**
  $L_i \leftarrow$ an ordering $(u_1, \ldots, u_{|C_i|})$ of C_i satisfying $R(u_1) \preceq \cdots \preceq R(u_{|C_i|})$
return $L_1 + \cdots + L_r$

3.2 Deciding the realizability and computing the realization

To decide the kNN-realizability of G, we first run the algorithm of Theorem 12, which returns the vertex ordering $(v_1, \ldots, v_n)$ of $V(G)$, and then run the linear program given at the beginning of Section 3 for this ordering. Either the LP is feasible, in which case the solution gives a kNN-realization of G in $\mathbb{R}^1$, or LP is infeasible, in which case we can conclude that $(v_1, \ldots, v_n)$ is not a feasible vertex ordering and thus G is not kNN-realizable in $\mathbb{R}^1$. Thus, the kNN-realization problem in $\mathbb{R}^1$ can be solved in polynomial time.

Interestingly, we can show that if we are only interested in the *decision* problem (and not actual embedding), then solving the LP is not necessary. Specifically, we can decide whether $(v_1, \ldots, v_n)$ is a feasible vertex by simply checking condition 1 of Observation 7. If the ordering satisfies that condition, then the LP is *always feasible*. The proof of the following lemma is somewhat technical and is presented in the full version.

▶ **Lemma 13.** *Let G be a k-regular directed graph of n vertices. An ordering $(v_1, \ldots, v_n)$ of $V(G)$ is a feasible vertex ordering of G iff it satisfies condition 1 of Observation 7. In particular, one can decide whether a given ordering of $V(G)$ is a feasible vertex ordering of G or not in $O(kn)$ time.*

We can now state the main result of this section.

▶ **Theorem 14.** *Given a k-regular directed graph G of n vertices, one can decide in $O(kn)$ time whether G is kNN-realizable in $\mathbb{R}^1$, and if so, a kNN-realization of G in $\mathbb{R}^1$ can be computed in $O(n^{2.5}\mathsf{poly}(\log n))$ time.*

4 Concluding remarks and extensions

We considered the problem of realizing a directed graph G as an Euclidean kNN graph. Our key results are: (1) for any fixed d, we can efficiently embed at least a $1 - \varepsilon$ fraction of G's edges in $\mathbb{R}^d$ or conclude that G is not realizable, and (2) a linear time algorithm to decide if G is realizable in $\mathbb{R}^1$. Our theorems extend to the case where the neighbors of each vertex in G are given as a *ranked* list, meaning that the embedding must satisfy $||\phi(v) - \phi(u_i)|| < ||\phi(v) - \phi(u_{i+1})||$, for $i = 1, \ldots, k-1$, where u_i is the ith nearest neighbor of v (except in $\mathbb{R}^1$ where we need to solve the LP to decide if it is feasible). Our approximation scheme also applies to other proximity graphs that meet the following conditions: (1) the graph can be partitioned into constant-sized components using a sublinear size separator, and (2) each component's edges can be embedded independently. For example, we can approximately embed Delaunay triangulations in the plane with maximum degree $k = O(n^{\frac{1}{3}})$.

The Point-Boundary Art Gallery Problem Is $\exists\mathbb{R}$-Hard

Jack Stade
University of Copenhagen, Denmark

Abstract

We resolve the complexity of the point-boundary variant of the art gallery problem, showing that it is $\exists\mathbb{R}$-complete, meaning that it is equivalent under polynomial time reductions to deciding whether a system of polynomial equations has a real solution.

The art gallery problem asks whether there is a configuration of *guards* that together can see every point inside of an *art gallery* modeled by a simple polygon. The original version of this problem (which we call the point-point variant) was shown to be $\exists\mathbb{R}$-hard [Abrahamsen, Adamaszek, and Miltzow, JACM 2021], but the complexity of the variant where guards only need to guard the walls of the art gallery was left as an open problem. We show that this variant is also $\exists\mathbb{R}$-hard.

Our techniques can also be used to greatly simplify the proof of $\exists\mathbb{R}$-hardness of the point-point art gallery problem. The gadgets in previous work could only be constructed by using a computer to find complicated rational coordinates with specific algebraic properties. All of our gadgets can be constructed by hand and can be verified with simple geometric arguments.

1 Introduction

1.1 Art gallery problem

The original form of the art gallery problem (AGP) presented by Victor Klee (see O'Rourke [11]) asks whether a simple polygonal region P can be *guarded* by n guards. That is, whether there is a set of n points (called the *guards*) in P such that every point in P is *visible* to some guard, meaning that the the line segment between that point and that guard is contained in P. The polygon P is referred to as the *art gallery*.

The vertices of P are usually restricted to rational or integer coordinates, but even so an optimal configuration might require guards with irrational coordinates. Abrahamsen, Adamaszek and Miltzow give explicit examples that require irrational coordinates in [1]. For this reason, we don't expect algorithms to actually output the guarding configurations, only to determine how many guards are necessary.

It is non-trivial to see that the problem is even decidable. The first exact algorithm for the most general variants of the AGP is attributed to Sharir (see Efrat and Har-Peled [7]).

1.2 The complexity class $\exists\mathbb{R}$

The decision problem ETR (Existential Theory of the Reals) asks whether a sentence of form:

$$\exists X_1 \dots \exists X_n \Phi(X_1, \dots, X_n)$$

is true, where the X_i are real variables and Φ is a formula in the X_i involving 0, 1, $+$, $-$, $\cdot$, $=$, $<$, $\leq$, $\neg$, $\wedge$, and $\vee$. The complexity class $\exists\mathbb{R}$ consists of problems that can be reduced to ETR in polynomial time. A number of interesting problems have been shown to be complete for $\exists\mathbb{R}$, including for example packing polygons in a square [3] and the problem of deciding whether there exists a point configuration with a given order type [10, 14].

By a result of Schaefer and Stefankovic [12], the exact inequalities used don't matter; for example we obtain an equivalent definition of $\exists\mathbb{R}$ if we don't allow $=$, $\leq$, or $\neg$ in Φ. The same authors have more recently shown that similar results hold at every level of a *real hierarchy*, of which $\exists\mathbb{R}$ is the first level [13].

It is straightforward to show that NP $\subseteq \exists\mathbb{R}$. It is also known, though considerably more difficult to prove, that $\exists\mathbb{R} \subseteq$ PSPACE (Canny [6]). It is unknown whether either inclusion is strict.

1.3 Art gallery variants

A natural class of variants of the art-gallery problem is given by restricting both the positions that can be occupied by the guards and the points that need to be guarded. We will adopt the notation used in [4]:

▶ **Definition 1.** *(Agrawal, Knudsen, Lokshtanov, Saurabh, and Zehavi [4]) The* X-Y Art Gallery problem*, where $X, Y \in \{Vertex, Point, Boundary\}$, asks whether the polygon P can be guarded with n guards, where if $X = Vertex$ the guards are restricted to lie on the vertices of the polygons, if $X = Boundary$ the guards are restricted to lie on the boundary of the polygon, and if $X = Point$ then the guards can be anywhere inside the polygon. The region that must be guarded is determined by Y analogously.*

Table 1 lists these variants and the known bounds on complexity.

Table 1 Variants of the art gallery problem.

Variant	Complexity Lower Bound	Complexity Upper Bound
Vertex-Y	NP[9]	NP
X-Vertex	NP[9]	NP
Point-Point	∃ℝ[2]	∃ℝ[2]
Boundary-Point	∃ℝ[2]	∃ℝ[2]
Point-Boundary	∃ℝ**[this paper]**	∃ℝ[2]
Boundary-Boundary	NP[9]	∃ℝ[2]

If X or Y is *Vertex*, then the problem is easily seen to be in NP. Lee and Lin [9] showed that all of these variants are NP-hard (the result is stated for all the X-Point variants, but their constructions also work for the other variants. See also [8]). More recently, Abrahamsen, Adamaszek, and Miltzow [2] showed that the point-point and boundary-point variants are $\exists\mathbb{R}$ complete. It is straightforward to extend their proof of membership in $\exists\mathbb{R}$ to any of these variants, but they list $\exists\mathbb{R}$ hardness of the point-boundary variant an open problem.

1.4 Our results

Our main result is that the point-boundary variant of the art gallery problem is, up to polynomial time reductions, as hard as deciding whether a system of polynomial equations has a real solution.

▶ **Theorem 2.** *The point-boundary variant of the art gallery problem is $\exists\mathbb{R}$-complete.*

While the complexity of the boundary-boundary variant is still unsolved, this is is enough to show that the the X-Y art gallery problem is equivalent to the Y-X art gallery problem for $X, Y \in \{\text{Vertex}, \text{Point}, \text{Boundary}\}$.

Our ideas can also be used to considerably simplify the construction in [2]. Both the construction and verification of each of our gadgets is simpler than that of the corresponding gadget in [2]. Indeed, our gadgets can be drawn by hand with little more than compass-and-straightedge-style constructions. Each gadget is specified by a simple set of geometric properties rather than by exact coordinates. Our gadgets are quite flexible and the geometry could probably be adapted to other settings.

Our reduction is from a problem called ETR-INV-REV, which is a slight modification of a problem ETR-INV from [2]. In Section 2, we define this problem and show that it is $\exists\mathbb{R}$-hard.

Given an instance Φ of ETR-INV-REV, we show how to construct a polygon whose boundary can be guarded by some number n guards if and only if Φ has a satisfying assignment. In Section 3, we describe the overall structure of the polygon that we construct and explain how to constrain the positions of guards. In Section 4, we describe copy gadgets that are required in order to use a single variable in multiple constraints. Finally, in Section 5 we describe the gadgets that create constraints and prove Theorem 2.

Throughout, statements marked with ($\star$) have proofs omitted. The proofs can be found in the full version.

2 ETR-INV-REV

The proof of Theorem 2 is by reduction of the problem we call ETR-INV-REV to the point-boundary variant of the art gallery problem.

▶ **Definition 3.** *(ETR-INV-REV) In the problem ETR-INV-REV, we are given a set of real variables $\{x_1, \dots, x_n\}$ and a set of inequalities of the form:*

$$x = 1, \quad xy \geq 1, \quad x\left(\frac{5}{2} - y\right) \leq 1, \quad x + y \leq z, \quad x + y \geq z,$$

for $x, y, z \in \{x_1, \dots, x_n\}$. The problem asks whether there is an assignment of the x_i satisfying these inequalities with each $x_i \in [\frac{1}{2}, 2]$.

Abrahamsen, Adamaszek and Miltzow [2] proved the $\exists\mathbb{R}$-hardness of the point-point and boundary-point variants using a similar problem called ETR-INV.

▶ **Definition 4.** *(Abrahamsen, Adamaszek and Miltzow [2]) (ETR-INV) In the problem ETR-INV, we are given a set of real variables $\{x_1, \dots, x_n\}$ and a set of equations of the form:*

$$x = 1, \quad xy = 1, \quad x + y = z,$$

for $x, y, z \in \{x_1, \dots, x_n\}$. The problem asks whether there is a solution to the system of equations with each $x_i \in [\frac{1}{2}, 2]$.

▶ **Theorem 5.** *(Abrahamsen, Adamaszek, Miltzow [2]) The problem ETR-INV is $\exists\mathbb{R}$-complete.*

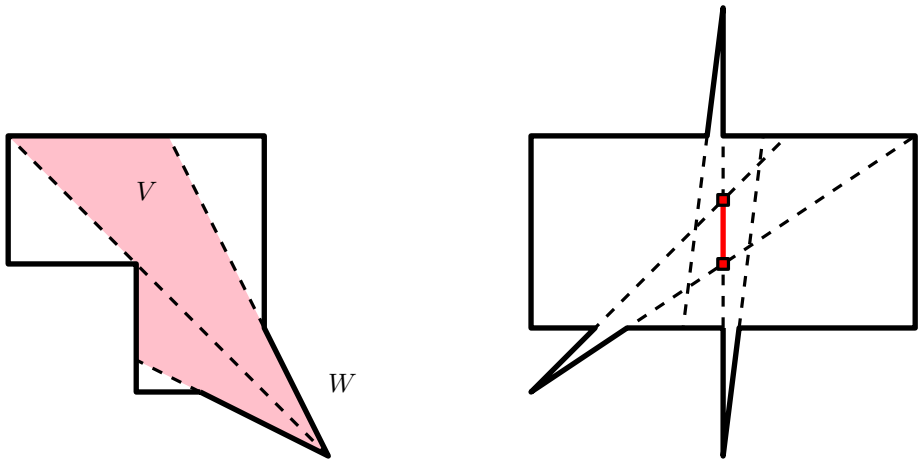

Figure 1 Left: A wedge (W) and its visibility region (V). Right: The intersection of the visibility regions of the three wedges shown forms a guard segment. This method of using 3 wedges to form a guard segment is due to Bertschinger, El Maalouly, Miltzow, Schnider and Weber [5] and is a slight simplification of the method for forming guard segments from [2].

Regardless of the specific art gallery variant, it seems to be difficult to make a construction that admits both $xy \leq 1$ and $xy \geq 1$ constraints. The $xy \leq 1$ inversion gadget in [2] is actually closer to a $x\left(\frac{5}{2} - y\right) \leq 1$ gadget, and another gadget is used to compute a constraint like $y' = \left(\frac{5}{2} - y\right)$. By reducing from ETR-INV-REV instead, our construction avoids the need for a reversing gadget.

▶ **Theorem 6.** ($\star$) *The problem ETR-INV-REV is ∃ℝ-hard.*

3 Arranging the art gallery

Throughout this section, and the rest of the paper, AB refers to a line segment with endpoints A and B, $\overleftrightarrow{AB}$ is the line containing that segment, and $|AB|$ is the length of that segment.

3.1 Creating guard regions

We will designate some number n of disjoint *guard regions* inside the art gallery such that any guarding configuration with n guards must have exactly one guard in each region. Each guard region is determined by *wedges* on the polygon boundary. Each wedge is formed by two edges of the art gallery meeting at a convex corner. The *visibility region* of a wedge is the set of points that can see the tip of the wedge. A wedge and its visibility region is shown in Figure 1 (left).

In a guarding configuration, the visibility region of each wedge must contain a guard. We designate a guard region by specifying some (non-zero) number of wedges, and the guard region is the intersection of the visibility regions of those wedges. These must be chosen that visibility regions of any two wedges *corresponding to different guard regions* do not intersect. A guard region shaped like a line segment is called a *guard segment*, as in Figure 1 (right).

▶ **Lemma 7.** *If we designate n guard regions, then any guarding configuration has at least n guards, and a guarding configuration with exactly n guards has 1 guard in each guard region.*

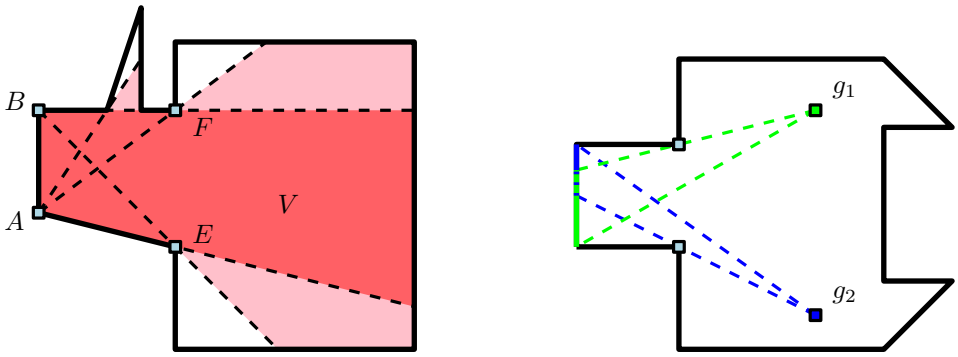

Figure 2 Left: A nook with nook segment AB, opening points E restricting A and F restricting B, and partial visibility region V. The outer parts of V (lighter) can only see part of the nook segment. Right: This art gallery can be guarded by two guards, but there is no such configuration where the nook segment on the left is guarded entirely by a single guard. This creates a continuous constraint between the positions of the two guards.

Proof. Choose wedges $w_1, \ldots, w_n$, one from each of the guard regions. The guard regions are chosen so that the visibility regions of these wedges do not intersect. In a guarding configuration, each of these regions contains at least 1 guard. Since these region do not intersect, this requires at least n guards.

If a guarding configuration contains exactly n guards, then there will be exactly 1 guard in the visibility region of w_i for each i. Consider the guard region containing w_j and suppose v is another wedge forming that guard region. There is a guard in the visibility region of v, and this region doesn't intersect the visibility region of w_i for $i \neq j$, so this guard must be the one in w_j. Repeating this argument for the other wedges forming this guard region, we see that the guard in w_j must be in each of them. So the guard is in the guard region.

So a guarding configuration with exactly n guards has 1 guard in each guard region. ◀

The guard segments in our construction will all be vertical, and the position of a guard on a guard segment will encode a variable in the interval $[\frac{1}{2}, 2]$, with the bottom endpoint of the interval corresponding to $\frac{1}{2}$ and the top endpoint corresponding to 2.

3.2 Constraint nooks

We use constraint *nooks* to enforce constraints involving multiple variables. Each nook consists of a line segment on the boundary of the art gallery, called the *nook segment*, and two polygon vertices called *opening points*. The *region of partial visibility* of a nook is the set of points which can see some part of the nook segment.

If the nook segment has endpoints A and B and the opening points are E and F where E, A, B, F occur in that order on the polygon boundary, then we say that E *restricts* A and F *restricts* B (see Figure 2).

These are slightly more general than the nooks from [2], in that it will sometimes be necessary to intersect a wedge with a nook, as in Figure 2 (left).

A guarding configuration will have some non-zero number of guards in the partial visibility region of a nook, that together must guard the nook segment, as in Figure 2 (right). Multiple guards can collaborate to guard a single nook segment, creating a continuous dependence between the positions of those guards.

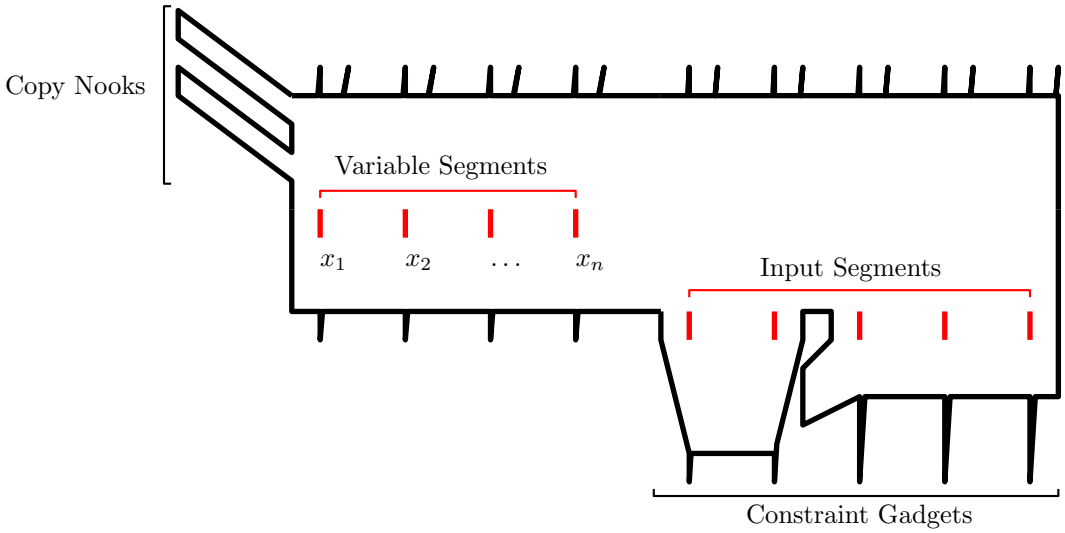

Figure 3 A schematic of the art gallery that we construct (not to scale). The variables are encoded by positions of guards on the variable segments (red, middle). The constraint gadgets on the bottom right enforce constraints like $xy \geq 1$ or $x + y \leq z$ on the variables encoded by the input segments (red, bottom right). The copy nooks copy the values of the appropriate variables onto the input segments. The wedges creating the segment-shaped guard regions can be seen along the top and bottom walls of the art gallery.

3.3 Schematic of the art gallery

Figure 3 shows a schematic of the entire art gallery construction. We start with an instance Φ of ETR-INV-REV with variables $x_1, \ldots, x_n$ and constraints of form:

$$x = 1, \quad xy \geq 1, \quad x\left(\frac{5}{2} - y\right) \leq 1, \quad x + y \leq z, \quad x + y \geq z,$$

Each variable is represented by a guard region called a *variable segment*. The variable segments are arranged in a row near the middle of the art gallery. The height of a guard on a variable segment corresponds linearly to the value of the variable encoded, with the bottom of the variable segment mapping to $\frac{1}{2}$ and the top mapping to 2.

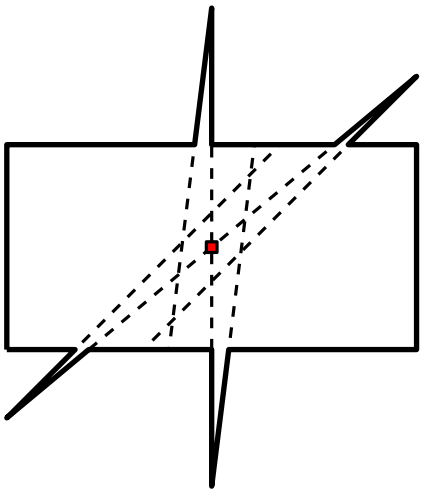

Figure 4 Four wedges create a point-shaped guard region.

The constraints of form $x = 1$ in Φ are created by adding wedges to create a guard region consisting of only a single point, as shown in Figure 4. Each constraint involving more than one variable is created by a *constraint gadget*, which we place in a row on the bottom right of the art gallery. The constraint gadgets are modular in the sense that they (almost) do not depend on Φ. Each constraint gadget operates on either 2 or 3 guard segments called *input segments*. Nooks in the constraint gadget create constraints on the variables represented by the guards on the input segments.

Each input segment can only appear in one constraint gadget, so we need *copy nooks* to relate each input segment to the variable segment for the variable that it represents.

4 Construction of the copy nooks

If a guard on a variable segment encodes a value x and a guard on an input segment encodes a value y, then a copy nook creates a constraint like $x \leq y$ or $x \geq y$. Figure 5 shows an example of a copy nook enforcing a constraint like $x \geq y$. This type of copy nook is due to Stade and Tucker-Foltz [15].

4.1 Verifying a single copy nook

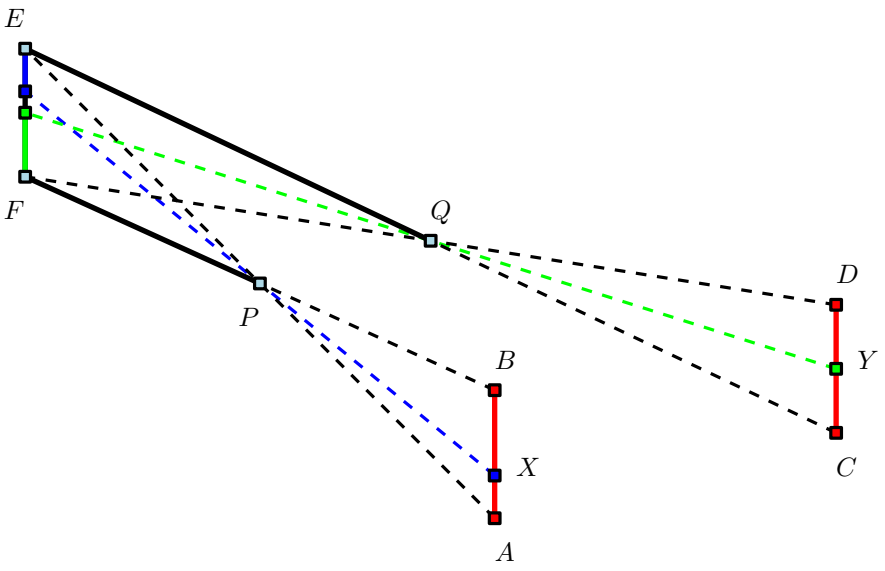

Figure 5 A copy nook, shown in the situation where the guard positions don't fully guard the nook.

▶ **Lemma 8.** *Suppose segments AB and CD are such that $\overleftrightarrow{AB}$ and $\overleftrightarrow{CD}$ are parallel, and suppose $\overleftrightarrow{AC}$ and $\overleftrightarrow{BD}$ intersect at a point P, as in Figure 6. If a line through P intersects AB at a point X and intersects CD at a point Y, then $\frac{|AX|}{|AB|} = \frac{|CY|}{|CD|}$.*

Proof. Triangles APB and CPD are similar, so $\frac{|AP|}{|AB|} = \frac{|CP|}{|CD|}$. Also, the triangles AXP and CYP are similar, so $\frac{|AX|}{|AP|} = \frac{|CY|}{|CP|}$. Multiplying, we obtain $\frac{|AX|}{|AB|} = \frac{|CY|}{|CD|}$. ◀

▶ **Lemma 9.** *Suppose that AB and CD are parallel guard segments and there is a nook with nook segment EF that is parallel to AB and CD. Suppose the nook has openings points P on the intersection point of $\overleftrightarrow{AE}$ and $\overleftrightarrow{BF}$ and Q on the intersection of $\overleftrightarrow{BE}$ and $\overleftrightarrow{CF}$ so that P restricts F and Q restricts G.*

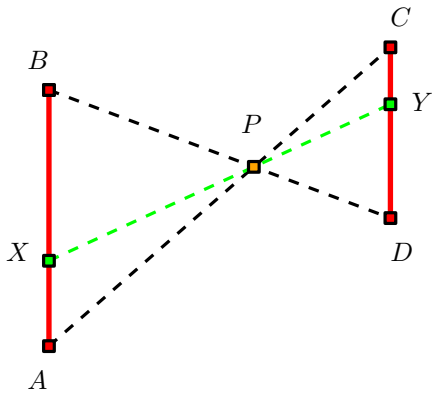

Figure 6 Setup for Lemma 8.

Suppose also that the nook is unobstructed, that is that every segment through P from a point on AB to a point on EF is contained in the art gallery and segments through Q are similarly unobstructed.

Then guards at positions X and Y on AB and CD respectively guard the nook if and only if:

$$\frac{|AX|}{|AB|} \geq \frac{|CY|}{|CD|}$$

The setup for Lemma 9 is shown in Figure 5. The proof is a straightforward application of Lemma 8.

By changing which intersection point restricts which endpoint of the nook segment, we can create a constraint either $x \leq y$ or $x \geq y$. Figure 7 shows a pair of guard segments with both types of copy nook between them.

Enforcing a constraint $x = y$ requires 2 nooks, but all of the constraints allowed by ETR-INV-REV are monotone with respect to any single variable, so we only need a single copy nook for each input segment. For example, $xy \geq 1$ is equivalent to $x'y' \geq 1$, $x \geq x'$ and $y \geq y'$ (when there are no other constraints on x' and y').

In the full version, we show that it is possible to arrange all the copy nooks in such a way that none of them interfere with each other. This construction ensures that the partial visibility region of each copy nook is bounded by lines with slope between $-\frac{1}{2}$ and -1, a fact that will be useful in order to make sure that the constraint gadgets don't interfere with the copy nooks.

5 The constraint gadgets

We start with some specifications that a constraint gadget should adhere to in order to be compatible with the copy nooks. There are several bad cases that we need to prevent:

- The constraint gadget obstructs the visibility between an input segment and a copy nook.
- A guard on a variable segment can see part of a nook segment in the constraint gadget.
- An guard used by the gadget (called an *auxiliary guard*) can see part of the nook segment of a copy nook.

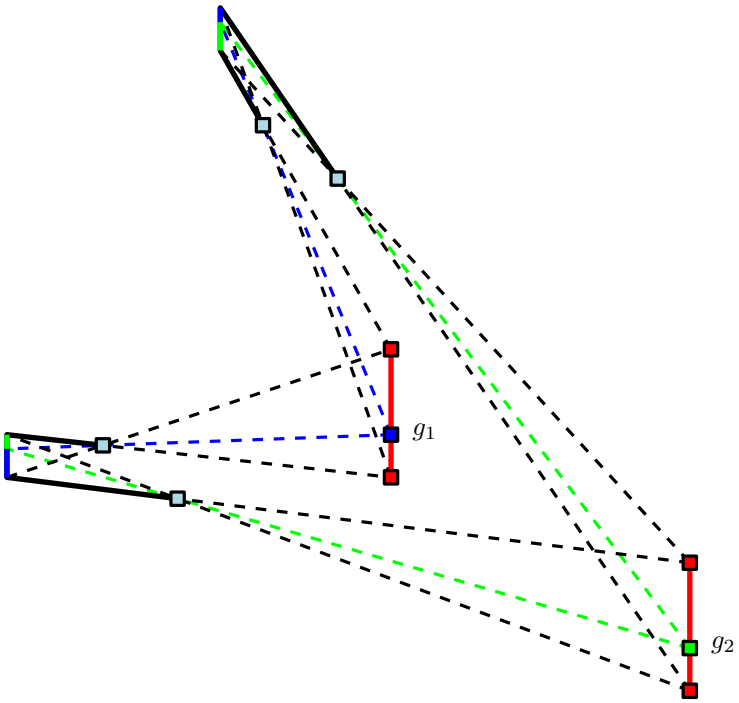

Figure 7 A guard (g_1) on a variable segment and a guard (g_2) on an input segment are related by two copy nooks. The upper nook is guarded when the value encoded by g_1 is at least the value encoded by g_2, and the lower nook is guarded when the value encoded by g_1 is at most the value encoded by g_2.

For each constraint gadget, we designate R_1 and R_2, shown in Figure 8. The region R_1 is bounded by the convex hull of the input segments to that gadget and lines of slope $-\frac{1}{2}$ and -1 through the bottom of the leftmost input segment and the top of the rightmost input segment respectively. R_2 is the set of points that can be connected to a point outside of the constraint gadget by a line segment that is contained in the polygon and has slope between -1 and 0.

▶ **Lemma 10.** *The region R_1 contains all possible sight lines between an input segment and the nook segment of one of the copy nooks, so if the constraint gadget does not have any walls that intersect this region then it will not obstruct the copy gadgets.*

Proof. The construction in Section 4 ensures that all sight lines between an input segment and a nook segment have slope between -1 and $-\frac{1}{2}$, and so are contained in the region R_1. ◀

▶ **Lemma 11.** *The only points in a constraint gadget that can be seen by a variable segment are in R_2. So any nook with a nook segment that doesn't intersect R_2 must be guarded by guards on input segments or auxiliary guards in that gadget.*

Points in a constraint gadget outside of R_2 cannot see any part of the nook segment of any copy nook. So if any auxiliary guard regions don't overlap R_2, then a guard in that region can't help guard any of the copy nooks.

Proof. The construction of the copy nooks ensures that any line between a variable segment and a point at the top of a constraint gadget has slope between -1 and 0. Any sight line between a point on a variable segment and a point in the constraint gadget must pass through the top, so any such line has slope between -1 and 0. So R_2 contains all points in the constraint gadget that can be seen by a point on a variable segment.

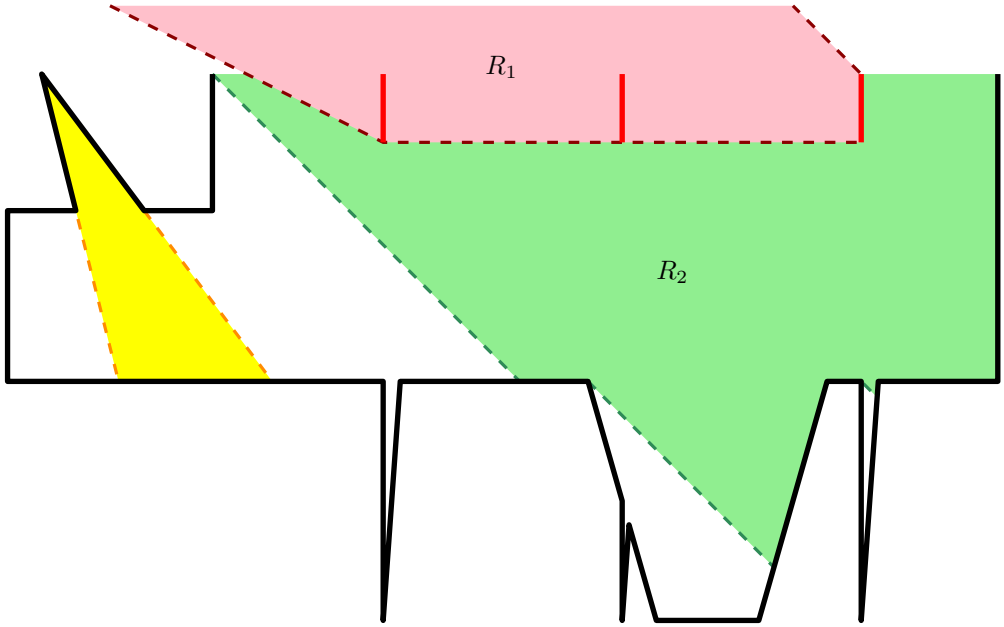

Figure 8 Diagram of a constraint gadget. The region R_1 is bounded by lines with slope -1 and $-\frac{1}{2}$. The region R_2 is bounded by lines with slope -1 and the polygon wall. The yellow region is a an auxiliary guard region, which must not intersect R_2.

The construction of the copy nooks also ensures that the partial visibility region of each copy nook is bounded by lines with slope between -1 and $-\frac{1}{2}$. So the only points in a constraint gadget that can see part of a nook segment of a copy nook are in R_2. ◀

5.1 Inversion gadgets

Each inversion gadget consists of a single constraint nook interacting with the two input variables. Figures 9 and 10 show the $xy \geq 1$ and $x\left(\frac{5}{2} - y\right) \leq 1$ inversion gadgets respectively. Figures 11 and 12 show the geometry of these gadgets in more detail.

In either gadget, we suppose that there is a guard at X on the input segment GH. The nook has opening points P and Q, so the guard at X can see all the points to the left of point Y on the nook segment IJ. For the $xy \geq 1$ gadget, this means that a guard on AB see the rest of IJ if and only if it is above the point W. For the $x\left(\frac{5}{2} - y\right) \leq 1$ gadget, a guard on AB should be below W instead.

In both cases, the guard on AB represents the input x and the guard on GH represents the input y. The segments represent the intervals $[\frac{1}{2}, 2]$, with lower points on the segments corresponding to lower values. So we should show that:

$$\left(\frac{3}{2} \cdot \frac{|AW|}{|AB|} + \frac{1}{2}\right)\left(\frac{3}{2} \cdot \frac{|GX|}{|GH|} + \frac{1}{2}\right) = 1$$

for any X on GH and W on AB as shown.

▶ **Lemma 12.** *If line segments AB and CD are not parallel, as in Figure 13, let P be the intersection of $\overleftrightarrow{AD}$ and $\overleftrightarrow{BC}$. Let E be the point on $\overleftrightarrow{AB}$ such that $\overleftrightarrow{PE}$ and $\overleftrightarrow{CD}$ are parallel, and let F be the point on $\overleftrightarrow{CD}$ such that $\overleftrightarrow{PF}$ and $\overleftrightarrow{AB}$ are parallel. Suppose that a point Y on CD and a point Z on AB are such that P, Y and Z are collinear. Then $\frac{|EA|}{|EB|} = \frac{|FC|}{|FD|}$, and letting $\alpha^2 = |EA||EB|$ and $\beta^2 = |FC||FD|$ we have $\frac{|EZ|}{\alpha} \cdot \frac{|FY|}{\beta} = 1$.*

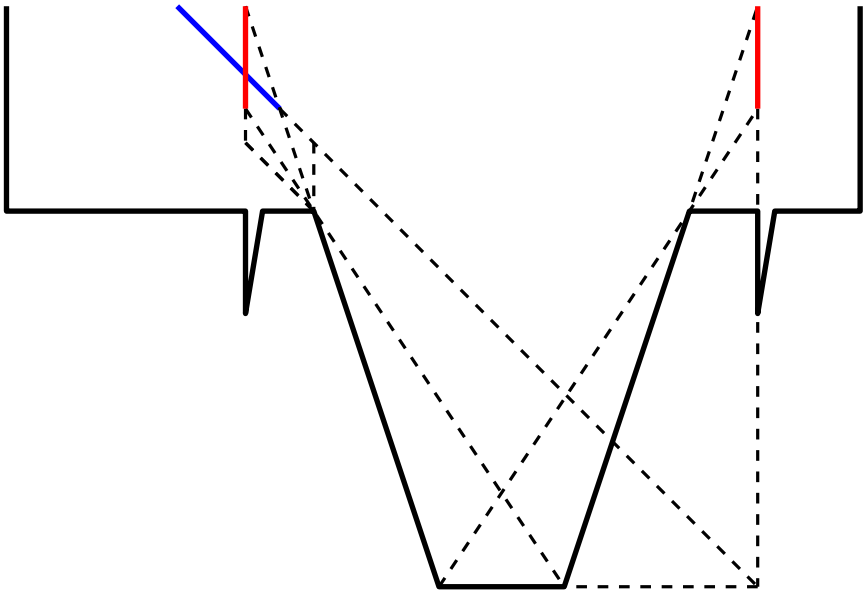

Figure 9 The $xy \geq 1$ inversion gadget. The two red segments are the input segments, with the left segment representing the variable x and the right segment representing y. Both guards see more of the nook segment the higher they are. The blue segment is a "phantom" segment that is used to help verify the gadget.

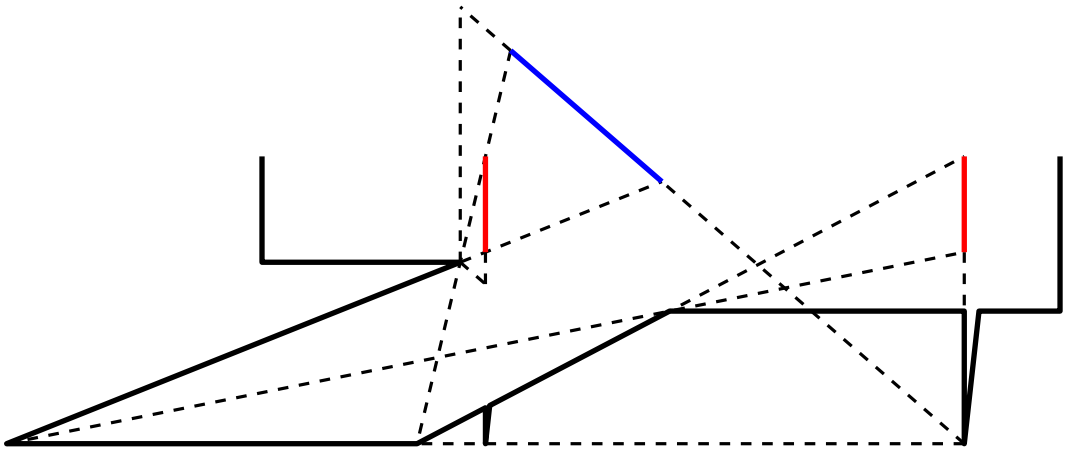

Figure 10 The $x\left(\frac{5}{2} - y\right) \leq 1$ inversion gadget. Compared to the $xy \geq 1$ gadget, the guard on the left segment (representing x) now sees more of the nook segment when it is lower.

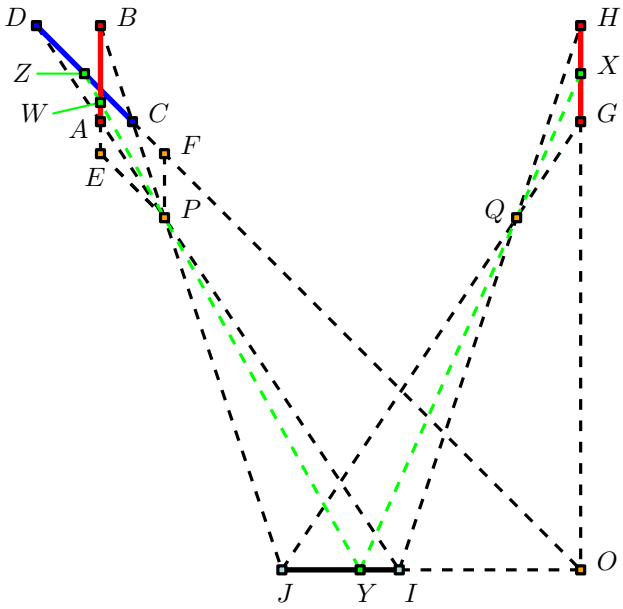

Figure 11 Labeled diagram of the $xy \geq 1$ inversion gadget shown in Figure 10.

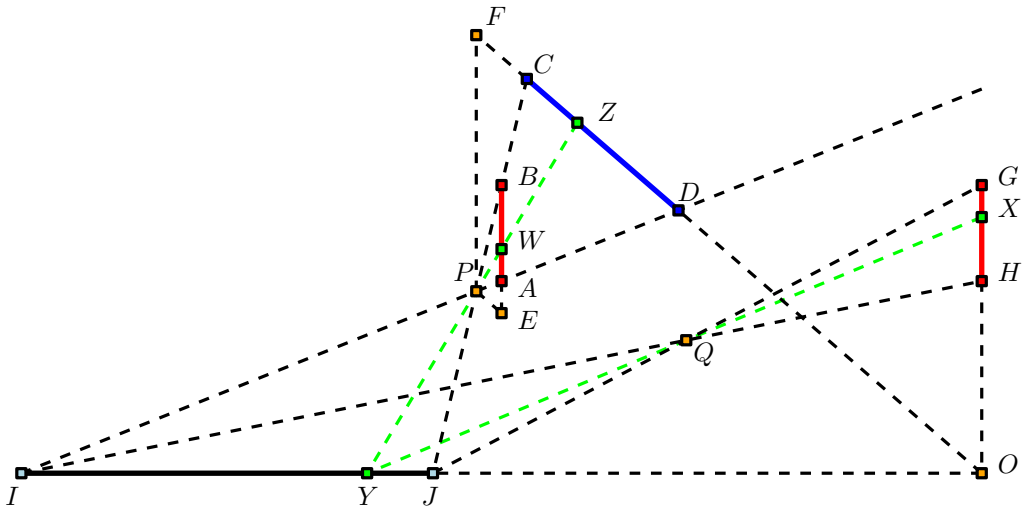

Figure 12 Labeled diagram of the $x\left(\frac{5}{2} - y\right) \leq 1$ inversion gadget shown in Figure 9.

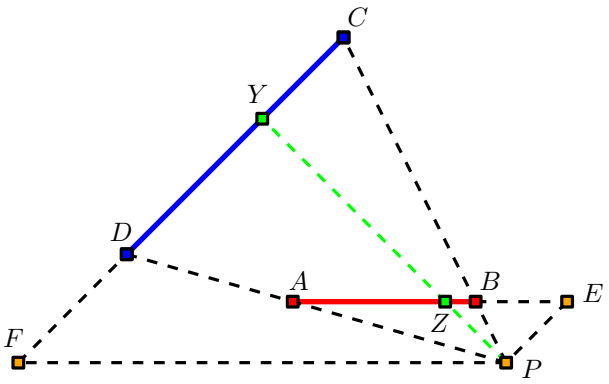

Figure 13 As long as the points P, Y, and Z are colinear, then the value of $|EZ||FY|$ does not depend on the positions of Y and Z, so the positions of Z and Y are related by inversion. The curved relationship occurs because AB and CD are not parallel.

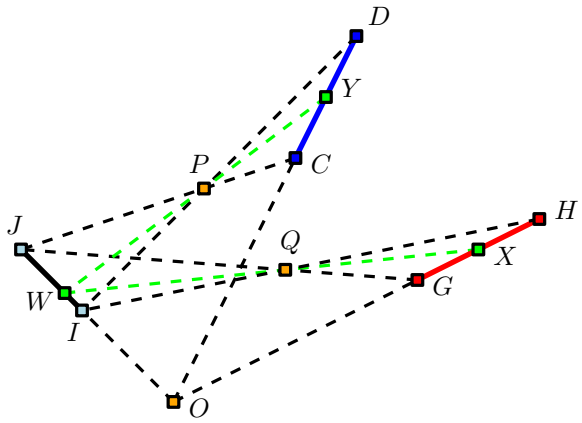

Figure 14 If X is on GH, then define Y by projecting X onto IJ through Q and then projecting that point onto CD through P. The relative position of X on GH is the same as the relative position of Y on CD.

Proof. The triangles EPX and FYP are similar, so $\frac{|EZ|}{|EP|} = \frac{|FP|}{|FY|}$, so $|EZ||FY| = |FP||EP|$. In particular, when $Z = A$, we have $|EA||FD| = |FP||EP|$, and when $Z = B$, we have $|EB||FC| = |FP||EP|$, so $|EA||FD| = |EB||FC|$ and $\frac{|EA|}{|EB|} = \frac{|FC|}{|FD|}$.

Now $|EZ||FY| = |FP||EP| = |EA||FD| = |EB||FC|$, so:

$$|EZ||FY| = \sqrt{|EA||FD||EB||FC|} = \sqrt{\alpha^2\beta^2} = \alpha\beta$$ ◀

The formulas $\frac{|EZ|}{\alpha}$ and $\frac{|EY|}{\beta}$ give mappings from points on the input segments to $\mathbb{R}$. We want the input segment to correspond to the intervals $[\frac{1}{2}, 2]$, so we choose $|EB| = 4|EA|$ (and therefore $|FD| = 4|FC|$), so $\alpha = 2|EA| = \frac{1}{2}|EB|$ and $\beta = 2|FC| = \frac{1}{2}|FD|$. This means that $\frac{|EZ|}{\alpha}$ and $\frac{|FY|}{\beta}$ will map the segments AB and CD respectively onto $[\frac{1}{2}, 2]$.

On its own, Lemma 12 could be used to construct a nook which enforces an inversion constraint on two input segments which aren't parallel. The input segments to a constraint gadget should be parallel, so we will need the result of Lemma 13 to correct the orientation.

▶ **Lemma 13.** *Suppose line segments GH, CD, and IJ are such that $\overleftrightarrow{GH}$, $\overleftrightarrow{CD}$, and $\overleftrightarrow{IJ}$ all intersect at a point O, as in Figure 14. Also suppose that the ratios $\frac{|OG|}{|OH|}$ and $\frac{|OC|}{|OD|}$ are the same. Let P be the point where ID and JC intersect, and Q be the point where IH and JG intersect. Suppose that points X on GH, Y on CD and W on IJ are such that W, P, and Y are collinear and W, Q and X are collinear. Then $\frac{|GX|}{|GH|} = \frac{|CY|}{|CD|}$.*

Proof. Place the figure in the vector space $\mathbb{R}^2$ with the point O at $(0, 0)$. We will show that there is a linear map which sends points G, X and H to C, Y and D respectively.

The pairs of vectors $\{I, G\}$ and $\{I, C\}$ are each bases for $\mathbb{R}^2$. Let θ be the linear isomorphism $\mathbb{R}^2 \to \mathbb{R}^2$ which sends a vector V to the coefficients (t, s) such $V = tI + sG$, and let ψ be a similar map which writes V as $tI + sC$. Now the linear map $\psi^{-1} \circ \theta$ fixes points on the line containing I and J, and sends G to C. Since $\frac{|OA|}{|OB|} = \frac{|OC|}{|OD|}$, this map sends H to D, and so sends Q to P. The point W is fixed, so the line $\overleftrightarrow{WQ}$ is sent to $\overleftrightarrow{WP}$, meaning that X is sent to Y. So points G, X and H are sent to C, Y and D respectively. Since linear maps preserve ratios of distances along a line, we see that:

$$\frac{|GX|}{|GH|} = \frac{|CY|}{|CD|}$$

◀

Note that the mappings from GH to IJ and from IJ to CD are in general *not* linear, only the composition is.

▶ **Lemma 14.** *In either the $xy \geq 1$ or $x\left(\frac{5}{2} - y\right) \leq 1$ gadget, suppose there are points C on $\overleftrightarrow{JP}$ and D on $\overleftrightarrow{IP}$ such that $\overleftrightarrow{GH}$, $\overleftrightarrow{CD}$ and $\overleftrightarrow{IJ}$ all intersect at a point O, with C and D satisfying:*

$$\frac{|OG|}{|OH|} = \frac{|OC|}{|OD|}$$

Suppose also that there are points E on $\overleftrightarrow{AB}$ and F on $\overleftrightarrow{CD}$ so that A is between E and B, C is between F and D, $\overleftrightarrow{PF}$ and $\overleftrightarrow{AB}$ are parallel and $\overleftrightarrow{PE}$ and $\overleftrightarrow{CD}$ are parallel, with $|FD| = 4|FC|$ and $|EB| = 4|EA|$. Then:

$$\left(\frac{3}{2} \cdot \frac{|AW|}{|AB|} + \frac{1}{2}\right)\left(\frac{3}{2} \cdot \frac{|GX|}{|GH|} + \frac{1}{2}\right) = 1$$

so the two inversion gadgets enforce the appropriate constraints.

Proof. Examples of points C, D, E and F with these properties are shown in Figures 11 and 12. Let Z be the intersection of $\overleftrightarrow{YP}$ with CD. By Lemma 13:

$$\frac{|GX|}{|GH|} = \frac{|CZ|}{CD}$$

By Lemma 12, we have that:

$$\frac{|EW|}{2|EA|} \cdot \frac{|FZ|}{2|FC|} = 1$$

Since $4|EA| = |EB| = \frac{4}{3}|AB|$, we have that:

$$\left(\frac{3}{2} \cdot \frac{|AW|}{|AB|} + \frac{1}{2}\right) = \left(\frac{|AW|}{2|EA|} + \frac{|EA|}{2|EA|}\right) = \frac{|EW|}{2|EA|}$$

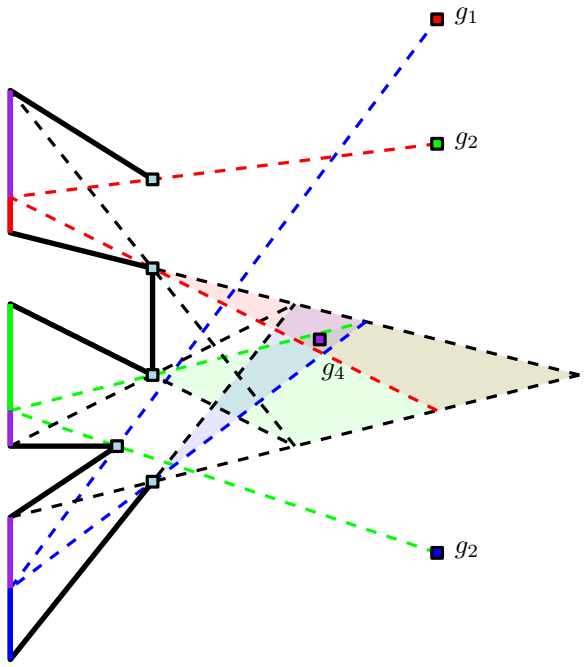

Figure 15 Creating a constraint between 3 variables. The guard g_1, g_2 and g_3 each see part of one of the nook segments. If the three shaded regions intersect, then a guard g_4 can be placed in the intersection so that g_4 guards the parts of the nook segments that aren't guarded by g_1, g_2 and g_3. If the three shaded regions do not intersect, then this isn't possible.

Similarly:

$$\left(\frac{3}{2}\cdot\frac{|GX|}{|GH|}+\frac{1}{2}\right)=\left(\frac{3}{2}\cdot\frac{|CZ|}{|CD|}+\frac{1}{2}\right)=\frac{|FZ|}{2|FC|}$$

So:

$$\left(\frac{3}{2}\cdot\frac{|AW|}{|AB|}+\frac{1}{2}\right)\left(\frac{3}{2}\cdot\frac{|GX|}{|GH|}+\frac{1}{2}\right)=1$$ ◀

It remains to show that gadgets satisfying the conditions of Lemma 14 can actually be created. The most direct approach would require solving a quadratic equation, potentially introducing irrational coordinates. The authors of [2] solved a similar issue with their inversion gadgets by carefully choosing coordinates that yield quadratic equations with rational solutions. However, our gadgets can be constructed more geometrically.

▶ **Lemma 15.** ($\star$) *Geometry for the $xy \geq 1$ and $x\left(\frac{5}{2}-y\right)\leq 1$ gadgets can be constructed in a way that satisfies the conditions of Lemmas 10, 11, and 14. This does not require irrational coordinates.*

5.2 Addition gadgets

Each nook creates a constraint between the positions of only 2 guards, but the addition gadgets should create a constraint involving 3 variables. This can be accomplished by allowing both coordinates of one guard to vary, as illustrated in Figure 15.

The addition gadgets are shown in Figures 16 and 17. Each gadget has 3 input segments, an auxiliary guard region, and three constraint nooks. Each constraint nook creates a constraint between the auxiliary guard and one input segment.

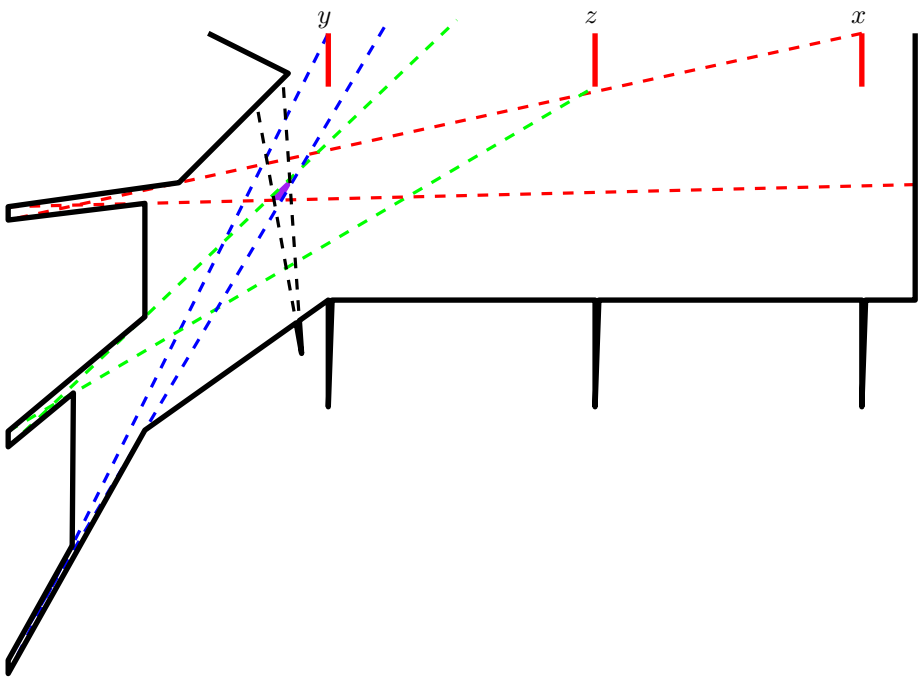

Figure 16 The $x + y \leq z$ addition gadget. The partial visibility regions of the 3 nooks are marked, as is the visibility region of the wedge forming the auxiliary guard region. The auxiliary guard will need to be somewhere in the purple shaded region.

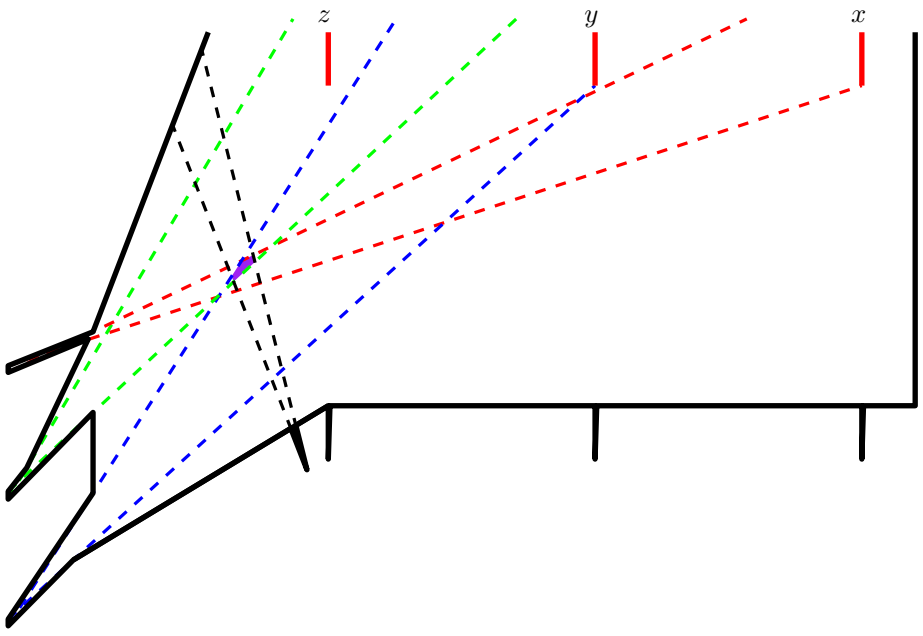

Figure 17 The $x + y \geq z$ addition gadget.

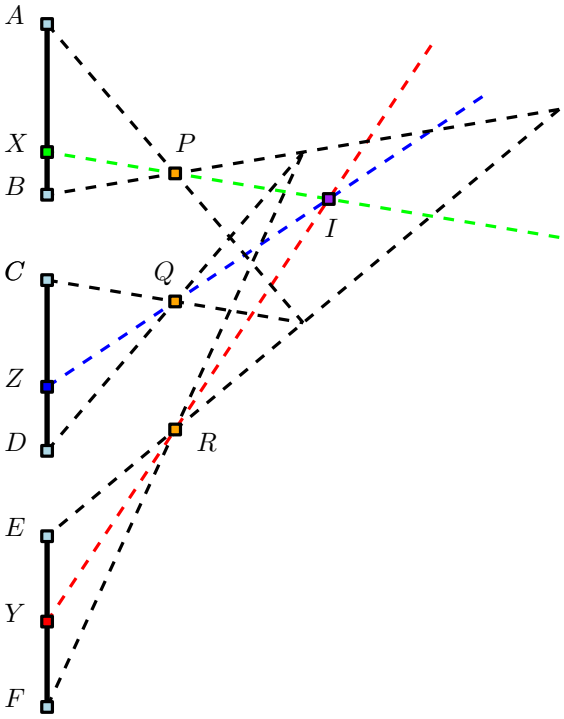

Figure 18 By Lemma 16, $\frac{1}{2}(|AX| + |EY|) = |CZ|$.

The gadget can be guarded when it is possible to place a guard in the auxiliary guard region so that it can see the parts of the nook segments that aren't visible to the input guards. We can use Lemma 8 to control the relationship between the positions of the guards on the input segments and their "shadows" on the nook segments. Lemma 16 allows us to determine what parts of these nook segments can be seen by an auxiliary guard.

▶ **Lemma 16.** *Suppose the line segments AB, CD, and EF have the same length and lie on the same vertical line, as in Figure 18, and suppose $|CB| = |DE|$. Let points P, Q, and R lie on a vertical line, with $|QP| = |QR|$. Note that $\overleftrightarrow{AP}$, $\overleftrightarrow{CQ}$, and $\overleftrightarrow{ER}$ intersect in a single point, and the same is true of $\overleftrightarrow{BP}$, $\overleftrightarrow{DQ}$, and $\overleftrightarrow{FR}$.*

Suppose points X and Y lie on AB and EF respectively. Now $\overleftrightarrow{XP}$ and $\overleftrightarrow{YQ}$ intersect at a point I. Let Z be the point on the intersection of CD and $\overleftrightarrow{IQ}$.

If all is as above, then $\frac{1}{2}(|AX| + |EY|) = |CZ|$.

Proof. The idea is to transform the geometry from Figure 18 to obtain something like Figure 19.

This transformation should send straight lines to straight lines and should fix the line containing points A, B, C, D, E, F, X, Y and Z. Additionally, the points P, Q and R should be sent to "infinity", lines through P should be sent to lines with slope -1, lines through Q should be sent to lines with slope 0, and lines through R should be sent to lines with slope $+1$. If such a transformation exists, then it is clear by straightforward linear algebra that $\frac{1}{2}(|AX| + |EY|) = |CZ|$.

Isomorphisms of the projective space $\mathbb{R}P^2$ send straight lines to straight lines. A degrees-of-freedom argument would be sufficient to find a transformation of projective space with the required properties. Instead we just give it explicitly. Assume that the line containing

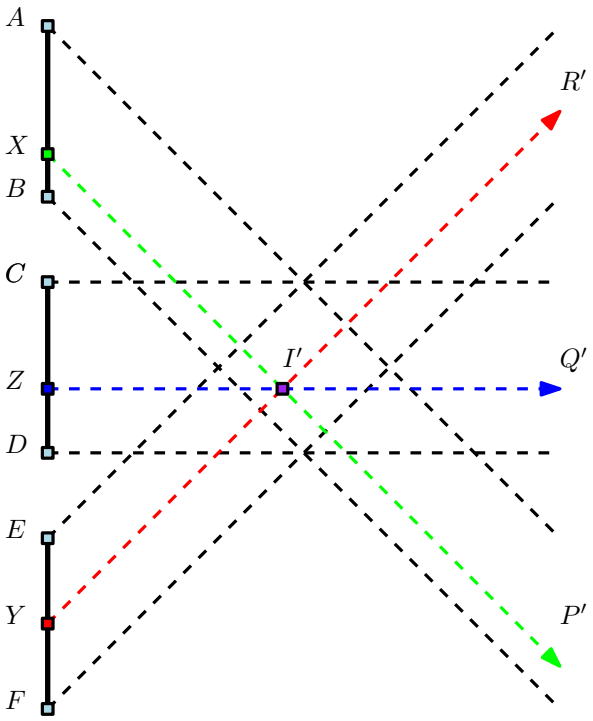

Figure 19 A projective transformation sends points P, Q, and R to points P', Q' and R' at infinity, so the family of lines through any one of these points is sent to a family of parallel lines.

A and B is vertical, and let x_0 be the x-coordinate of this line. Let x_1 be the x-coordinate of P, Q and R, y_0 the y-coordinate of Q, and let $a = |QP| = |QR|$, so P has y-coordinate $y_0 + a$ and R has y-coordinate $y_0 - a$. Then the transformation $(x, y) \to (x', y')$ with the desired properties is defined by:

$$\begin{bmatrix} x_0 + a & 0 & -(x_1 + a)x_0 \\ y_0 & x_0 - x_1 & -y_0 x_0 \\ 1 & 0 & -x_1 \end{bmatrix} \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} = \lambda \begin{bmatrix} x' \\ y' \\ 1 \end{bmatrix}$$

Writing the map in this form makes it easy to check what happens to lines through P, Q, and R. In particular, for a 3×3 matrix A, if:

$$A \begin{bmatrix} p_x \\ p_y \\ 1 \end{bmatrix} = \begin{bmatrix} a \\ b \\ 0 \end{bmatrix}$$

then the map $(x, y) \to (x', y')$ given by:

$$\lambda \begin{bmatrix} x' \\ y' \\ 1 \end{bmatrix} = A \begin{bmatrix} x \\ y \\ 1 \end{bmatrix}$$

sends lines through (p_x, p_y) to lines parallel to $\begin{bmatrix} a \\ b \end{bmatrix}$.

Note that the setup used here is very similar the addition gadgets in [2], although our verification is different. ◀

We want to create gadgets enforcing $x + y = z$, not $\frac{1}{2}(x + y) = z$, so we need to use Lemma 8 to change the scale and offset of z. A schematic of the nooks used by the addition gadgets are shown in Figures 20 and 21.

▶ **Lemma 17.** ($\star$) *It is possible to construct addition gadgets enforcing constraints $x + y \geq z$ or $x + y \leq z$.*

5.3 Final verification

▶ **Lemma 18.** *Given an instance Φ of ETR-INV-REV, it is possible to construct in polynomial time an art gallery P and a number n so that P can be guarded by n guards if and only if Φ is satisfiable.*

Proof. First, create corresponding constraint gadgets for every constraint of form $xy \leq 1$, $x\left(\frac{5}{2} - y\right) \leq 1$, $x + y \leq z$, or $x + y \geq z$ that occurs in Φ. Arrange these in a horizontal row along the bottom of the art gallery so that all the input segments occur in a horizontal row and the distance between any pair of input segments is a multiple of $d = 5$ times the length of a single input segment.

The construction in Section 4 can be used to place the copy nooks and variable segments. Now connect all the pieces of the art gallery and add the wedges forming all the guard segments. These wedges should be chosen to be sufficiently narrow so that visibility regions of wedges from different guard regions do not intersect.

It is straightforward to check that this construction can be done in polynomial time and that the coordinates needed are rational numbers with at most polynomially many bits.

There are n guard regions, consisting of the variable segments, input segments, and auxiliary guards. By Lemma 7, any guarding configuration with n guards must have one guard in each guard region. Conversely, any guarding configuration with one guard in each guard can clearly guard all of these wedges.

There are some walls of the art gallery that aren't part of the wedges, copy nooks, or constraint gadgets. The top, bottom, and right walls of the art gallery can be guarded by any guard on a variable segment. For any two copy nooks, a segment connecting can always be guarded by either of the guards on the variable segments in the visibility regions of those nooks. So any guarding configuration with one guard in each guard region will guard everything expect for possibly the copy nook and constraint gadgets.

By Lemmas 14 and 17, each constraint gadget can be guarded if and only if the guards on its input segments represent variables satisfying the corresponding constraint. Whenever a variable in Φ appears in a constraint, there are copy nooks between that variable segment and an input segment to the gadget representing that constraint. By Lemma 9, these copy nooks are guarded if and only if the guard on the input segment and the guard on the variable segment represent the value in $[\frac{1}{2}, 2]$.

So P can be guarded by n guards if and only if Φ has a satisfying assignment. ◀

The $\exists\mathbb{R}$-hardness of the point-boundary art-gallery problem follows from the $\exists\mathbb{R}$-hardness of ETR-INV-REV, proving Theorem 2.

6 Conclusions

Our result shows that the X-Y and Y-X variants of the art gallery problem are equivalent under polynomial time reductions when $X, Y \in \{\text{Vertex}, \text{Point}, \text{Boundary}\}$. Visibility is reflexive, so this result seems unsurprising. Maybe it could be proven more directly.

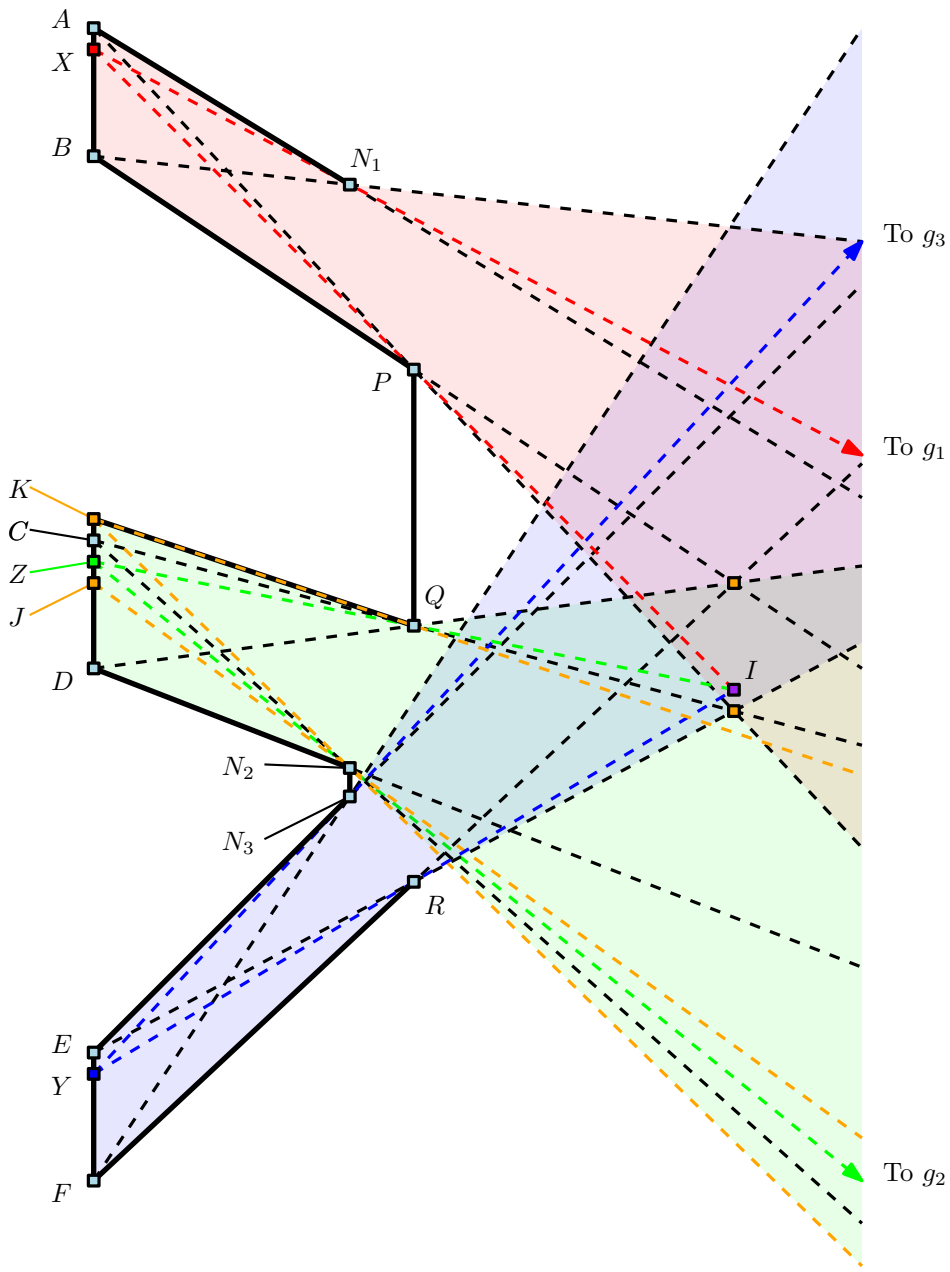

Figure 20 Schematic of the $x + y \leq z$ addition gadget. In the actual gadgets, the lines bounding all the visibility regions have positive slopes as shown in Figures 16 and 17, but it is not possible to draw this faithfully at a readable scale.

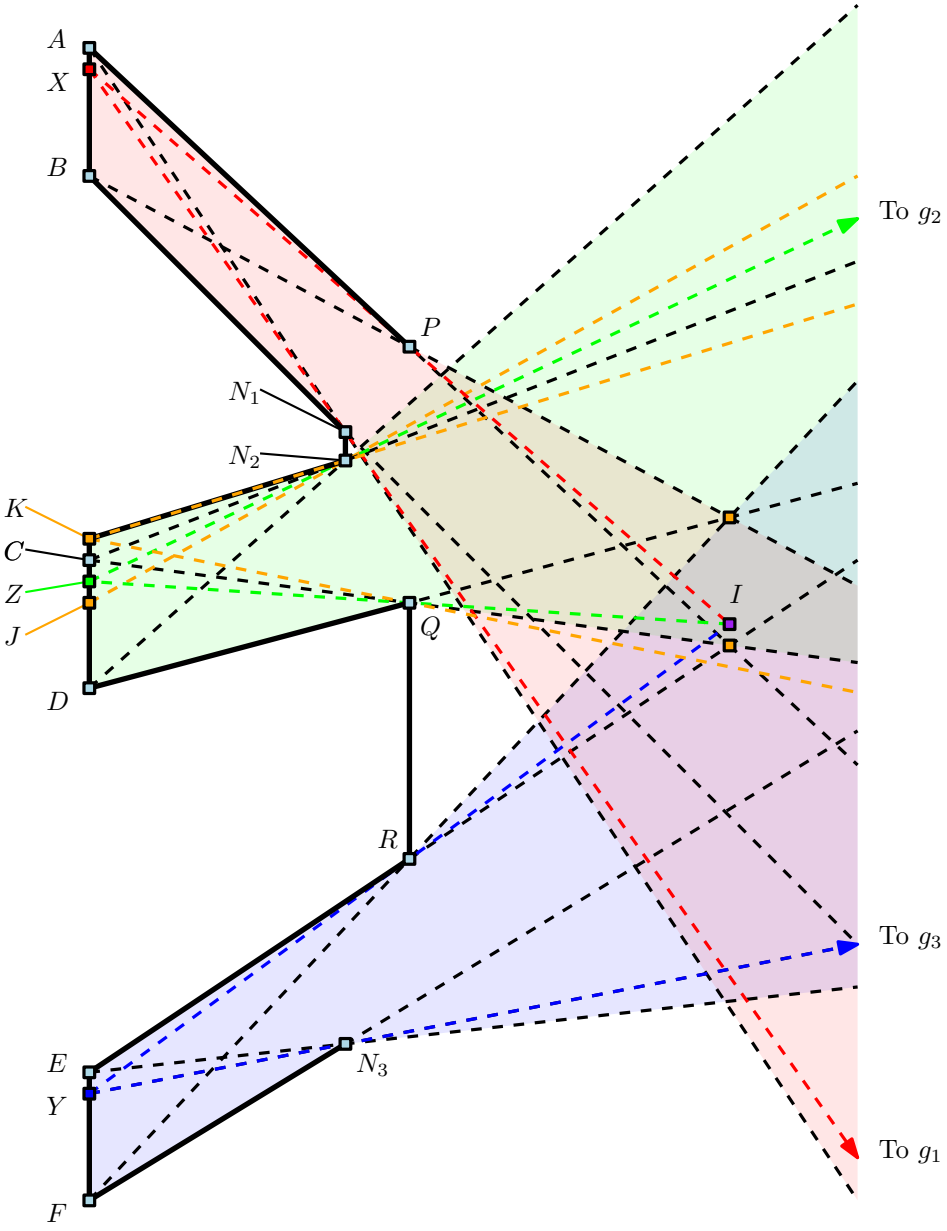

Figure 21 The nooks for the $x + y \geq 1$ gadget.

It is interesting to note that our construction, while intended for the point-boundary variant of the art gallery problem, is also sufficient to show the ∃ℝ-hardness of the standard point-point variant. When it is possible to guard an art gallery produced by our construction in the point-boundary setting, the same guarding configuration is also a point-point guarding configuration. Something similar happens in [2], where the construction for the boundary-point variant is also a construction for the point-point variant. It doesn't seem to be possible to adapt either construction to the boundary-boundary variant.

Unlike the construction from [2], the nook segments in our construction can be chosen to all be axis-parallel. Each other segment is always entirely guarded by a single guard. It may be possible to adapt our construction to show that guarding orthogonal polygons is ∃ℝ-hard.

Levels in Arrangements: Linear Relations, the g-Matrix, and Applications to Crossing Numbers

Abstract

A long-standing conjecture of Eckhoff, Linhart, and Welzl, which would generalize McMullen's Upper Bound Theorem for polytopes and refine asymptotic bounds due to Clarkson, asserts that for $k \leqslant \lfloor \frac{n-d-2}{2} \rfloor$, the complexity of the $(\leqslant k)$-level in a simple arrangement of n hemispheres in S^d is maximized for arrangements that are polar duals of neighborly d-polytopes. We prove this conjecture in the case $n = d + 4$. By Gale duality, this implies the following result about crossing numbers: In every *spherical arc drawing* of K_n in S^2 (given by a set $V \subset S^2$ of n unit vectors connected by spherical arcs), the number of crossings is at least $\frac{1}{4}\lfloor \frac{n}{2} \rfloor \lfloor \frac{n-1}{2} \rfloor \lfloor \frac{n-2}{2} \rfloor \lfloor \frac{n-3}{2} \rfloor$. This lower bound is attained if every open linear halfspace contains at least $\lfloor (n-2)/2 \rfloor$ of the vectors in V.

Moreover, we determine the space of all linear and affine relations that hold between the face numbers of levels in simple arrangements of n hemispheres in S^d. This completes a long line of research on such relations, answers a question posed by Andrzejak and Welzl in 2003, and generalizes the classical fact that the Dehn–Sommerville relations generate all linear relations between the face numbers of simple polytopes (which correspond to the 0-level).

To prove these results, we introduce the notion of the *g-matrix*, which encodes the face numbers of levels in an arrangement and generalizes the classical *g-vector* of a polytope.

1 Introduction

Levels in arrangements (and the dual notions of k-sets and k-facets) play a fundamental role in discrete and computational geometry and are a natural generalization of convex polytopes (which correspond to the 0-level); we refer to [21, 30, 45] for more background.

It is a classical result in polytope theory that the *Euler–Poincaré relation* is the only linear relation between the face numbers of arbitrary d-dimensional convex polytopes, and that the *Dehn–Sommerville relations* (which we will review below) generate all linear relations between the face numbers of *simple* (or, dually, *simplicial*) polytopes [23, Chs. 8–9]. Another central result in polytope theory is McMullen's *Upper Bound Theorem* [31], which asserts that *cyclic polytopes* have the largest possible number of faces among all d-dimensional convex polytopes with a given number of vertices.

Here, we are interested in generalizations of these results to levels and sublevels in arrangements. To state our results formally, it will be convenient to work with *spherical arrangements* in S^d (which can be seen as a "compactification" of arrangements of affine hyperplanes or halfspaces in $\mathbf{R}^d$ that avoids technical issues related to *unbounded* faces).

1.1 Levels in Arrangements, Dissection Patterns, and Polytopes

Throughout this paper, let $r = d + 1 \geqslant 1$, and let S^d be the unit sphere in $\mathbf{R}^r$. We denote the standard inner product in $\mathbf{R}^r$ by $\langle \cdot, \cdot \rangle$, and write $\operatorname{sgn}(x) \in \{-1, 0, +1\}$ for the *sign* of a real number $x \in \mathbf{R}$. For a sign vector $F \in \{-1, 0, +1\}^n$, let F_+, F_0, and F_- denote the subsets of coordinates $i \in [n]$ such that $F_i = +1$, $F_i = 0$, and $F_i = -1$, respectively.

Let $V = \{v_1, \ldots, v_n\} \subset \mathbf{R}^r$ be a set of $n \geqslant r$ vectors; fixing the labeling of the vectors, we will also view V as a matrix $V = [v_1 | \ldots | v_n] \in \mathbf{R}^{r \times n}$ with columns v_i. Unless stated otherwise, we assume that V is in general position, i.e., that any r of the vectors are linearly independent. We refer to V as a *vector configuration* of *rank* r.

Every vector $v_i \in V$ defines a great $(d-1)$-sphere $H_i = \{x \in S^d \mid \langle v_i, x \rangle = 0\}$ in S^d and two open hemispheres

$$H_i^+ = \{x \in S^d \mid \langle v_i, x \rangle > 0\}, \qquad H_i^- = \{x \in S^d \mid \langle v_i, x \rangle < 0\}.$$

The resulting *arrangement* $\mathcal{A}(V) = \{H_1^+, \ldots, H_n^+\}$ of hemispheres in S^d determines a decomposition of S^d into *faces* of dimensions 0 through d, where two points $u, u' \in S^d$ lie in the relative interior of the same face of $\mathcal{A}(V)$ iff $\operatorname{sgn}(\langle v_i, u \rangle) = \operatorname{sgn}(\langle v_i, u' \rangle)$ for $1 \leqslant i \leqslant n$. Let $\mathcal{F}(V)$ be the set of all sign vectors $(\operatorname{sgn}(\langle v_1, u \rangle), \ldots, \operatorname{sgn}(\langle v_n, u \rangle)) \in \{-1, 0, +1\}^n$, where u ranges over all non-zero vectors (equivalently, unit vectors) in $\mathbf{R}^r$; we can identify each face of $\mathcal{A}(V)$ with its *signature* $F \in \mathcal{F}(V)$. By general position, the face with signature F has dimension $d - |F_0|$ (the arrangement is *simple*, i.e., there are no faces with $|F_0| > d$). Moreover, we call $|F_-|$ the *level* of the face. Equivalently, the elements of $\mathcal{F}(V)$ correspond bijectively to the partitions of V by oriented linear hyperplanes, and we will also call them the *dissection patterns* of V. In what follows, we will pass freely back and forth between a vector configuration V and the corresponding arrangement $\mathcal{A}(V)$ and refer to this correspondence as *polar duality* (to distinguish it from *Gale duality*, see below).

▶ **Definition 1** (f-matrix and f-polynomial)**.** *For integers s and t, let*[1]

$$f_{s,t} := f_{s,t}(V) := |\{F \in \mathcal{F}(V) \mid |F_0| = s, |F_-| = t\}|.$$

Thus, $f_{s,t}(V)$ counts the $(d-s)$-dimensional faces of level t in $\mathcal{A}(V)$.

Together, these numbers form the f-matrix $f(V) = [f_{s,t}(V)]$*. Equivalently, we can encode this data into the bivariate* f-polynomial $f_V(x, y) \in \mathbf{Z}[x, y]$ *defined by*

$$f_V(x, y) := \sum_{s,t} f_{s,t}(V)\, x^s y^t = \sum_{F \in \mathcal{F}(V)} x^{|F_0|} y^{|F_-|}.$$

We call a vector configuration V *pointed* if it is contained in an open linear halfspace $\{x \in \mathbf{R}^r : \langle u, x \rangle > 0\}$, for some $u \in S^d$, or equivalently, if $\bigcap_{i=1}^n H_i^+ \neq \emptyset$. The closure of this intersection is then a simple (spherical) polytope P, the 0-level of $\mathcal{A}(V)$. By radial projection onto the tangent hyperplane $\{x \in \mathbf{R}^r : \langle u, x \rangle = 1\}$, every pointed configuration $V \subset \mathbf{R}^r$ corresponds to a point set $S \subset \mathbf{R}^d$, see [30, Sec. 5.6]. The convex hull $P^\circ = \operatorname{conv}(S)$ is a simplicial polytope (the polar dual of P), and the elements of $\mathcal{F}(V)$ correspond to the partitions of S by affine hyperplanes; in particular, $f_{s,0}(V)$ counts the $(s-1)$-dimensional faces of P°, and $f_{0,k}(V)$ counts the *k-sets* of S.

[1] By general position, $f_{s,t}(V) = 0$ unless $0 \leqslant s \leqslant d$ and $0 \leqslant t \leqslant n - s$.

1.2 Exact Upper Bounds for Sublevels

The following two special vector configurations will play an important role in this paper.

▶ **Example 2** (Cyclic and Cocyclic Configurations). Let $t_1 < t_2 < \cdots < t_n$ be real numbers and define $v_i := (1, t_i, t_i^2, \ldots, t_i^{r-1}) \in \mathbf{R}^r$. We call $V_{\text{cyclic}}(n,r) := \{v_1, \ldots v_n\}$ and $V_{\text{cocyclic}}(n,r) := \{(-1)^i v_i \colon 1 \leqslant i \leqslant n\}$ the *cyclic* and *cocyclic* configurations of n vectors in $\mathbf{R}^r$, respectively.[2]

Cyclic and cocyclic configurations are examples of neighborly and coneighborly configurations, which we define next. Let $V = \{v_1, \ldots, v_n\} \subseteq \mathbf{R}^r$ be a vector configuration in general position. A subset $W \subseteq V$ is *extremal* if there exists a linear hyperplane H bounding an open halfspace H^+ such that $W \subset H$ and $V \setminus W \subset H^+$. In particular, V is pointed iff $\emptyset \subset V$ is extremal.

▶ **Definition 3** (Neighborly and Coneighborly Configurations). *A vector configuration $V = \{v_1, \ldots, v_n\} \subseteq \mathbf{R}^r$ is* coneighborly *if every open linear halfspace contains at least $\lfloor \frac{n-r+1}{2} \rfloor$ vectors of V. It is* neighborly *if every subset $W \subseteq V$ of size $|W| \leqslant \lfloor \frac{r-1}{2} \rfloor$ is* extremal.

Cyclic configurations are neighborly, cocyclic configurations are coneighborly [48, Cor. 0.8], and these notions are Gale dual to each other (see Section 2). Every neighborly vector configuration $V \subset \mathbf{R}^r$ is pointed, hence corresponds to a point set $S \subset \mathbf{R}^d$, $d = r-1$, and V being neighborly means the simplicial d-polytope $\text{conv}(S)$ is a *neighborly polytope*, i.e., every subset of S of size at most $\lfloor \frac{d}{2} \rfloor$ forms a face. We note that for $r = 1, 2$ ($d = 0, 1$) neighborliness is the same as being pointed, and for $r = 3, 4$ ($d = 2, 3$) V is neighborly iff the point set S is in convex position. By a celebrated result of McMullen [31] neighborly polytopes maximize the number of faces of any dimension:

▶ **Theorem 4** (Upper Bound Theorem for Convex Polytopes). *Let $V \subset \mathbf{R}^r$ be a configuration of n vectors in general position. Then*

$$f_{s,0}(V) \leqslant f_{s,0}(V_{\text{cyclic}}(n,r)) \qquad (0 \leqslant s \leqslant d = r-1)$$

with equality if V is neighborly.

Eckhoff [20, Conj. 9.8], Linhart [26], and Welzl [46], independently of one another (and in slightly different forms) conjectured a far-reaching generalization of Theorem 4 for sublevels of arrangements. To state this conjecture, let $f_{s,\leqslant k}(V) := \sum_{t \leqslant k} f_{s,t}(V)$.

▶ **Conjecture 5** (Generalized Upper Bound Conjecture for Sublevels). *Let $V \subset \mathbf{R}^r$ be a configuration of n vectors in general position, and $0 \leqslant k \leqslant \lfloor \frac{n-r-1}{2} \rfloor$. Then*

$$f_{s,\leqslant k}(V) \leqslant f_{s,\leqslant k}(V_{\text{cyclic}}(n,r)) \qquad (0 \leqslant s \leqslant d = r-1)$$

Equality holds if V is neighborly.

A random sampling argument due to Clarkson (see [18]) shows that Conjecture 5 is true *asymptotically*, for fixed r and $n, k \to \infty$, up to a constant factor depending on r. For the case $s = d$ of vertices at sublevel ($\leqslant k$), Conjecture 5 was proved by Peck [36] and by Alon and Győri [10] for $r \leqslant 3$ and by Welzl [46] for *pointed* vector configurations in rank $r = 4$. The second author [44] proved that it is true up to a factor of 4 for arbitrary rank r. Here, we prove the conjecture for *corank* $n - r = 3$.

[2] The combinatorial types of these configurations are independent of the choice of the parameters t_i.

▶ **Theorem 6.** *Let $V \subset \mathbf{R}^{n-3}$ be a configuration of n vectors in general position. Then*

$$f_{s,\leqslant k}(V) \leqslant f_{s,\leqslant k}(V_{\text{cyclic}}(n,r)) \qquad (0 \leqslant k \leqslant 1, 0 \leqslant s \leqslant d = r-1)$$

Equality holds if V is neighborly.

▶ Remark 7. Bounding the maximum number of faces at level *exactly* k is of a rather different flavor. For coneighborly configurations, all $2\binom{n}{r-1}$ vertices of the dual arrangement are concentrated at one or two consecutive levels $k = \lfloor \frac{n-r+1}{2} \rfloor$ and $k = \lceil \frac{n-r+1}{2} \rceil$. By contrast, determining the maximum number $f_{d,k}$ of vertices at level k for *pointed* vector configurations in $\mathbf{R}^r$ is a difficult open problem, first studied by Lovász [28] and Erdős, Lovász, Simmons, and Straus [22] in the 1970s (see [45] or [30, Ch. 11] for more details and background); even for $r = 3$ (i.e., $d = 2$) there remains a big gap between the best upper and lower bounds to date, which are $O(nk^{1/3})$ and $ne^{\Omega(\sqrt{\log k})}$, respectively (due to Dey [19] and Tóth [43]).

1.3 The Spherical Arc Crossing Number of K_n

By Gale duality (see Section 2), Theorem 6 yields the following result about crossing numbers.

Determining the crossing number $\operatorname{cr}(K_n)$ of the complete graph K_n (the minimum number of crossings in any drawing of K_n in the plane, or equivalently in the sphere S^2, with edges represented by arbitrary Jordan arcs) is one of the foundational unsolved problems in geometric graph theory, first studied by Hill in the 1950's. Hill conjectured the following:

▶ **Conjecture 8** (Hill)**.**

$$\operatorname{cr}(K_n) = X(n) := \frac{1}{4}\left\lfloor \frac{n}{2} \right\rfloor \left\lfloor \frac{n-1}{2} \right\rfloor \left\lfloor \frac{n-2}{2} \right\rfloor \left\lfloor \frac{n-3}{2} \right\rfloor = \frac{3}{8}\binom{n}{4} + O(n^3) \tag{1}$$

This is known to hold for $n \leqslant 12$, but remains open in general (see [37, Sec. 1.3] or [42] for further background and references). There are several families of drawings showing that $\operatorname{cr}(K_n) \leqslant X(n)$ for all n, but the best lower bound to date [14] is $\operatorname{cr}(K_n) \geqslant 0.985 \cdot X(n)$.

We prove Hill's conjecture for the following class of drawings. Let $V = \{v_1, \ldots, v_n\} \subset S^2$ be a configuration of n *unit* vectors in general position. If we connect every pair of vectors in V by the shortest geodesic arc between them in S^2 (which is unique, since no two vectors are antipodal, by general position) we obtain a drawing of the complete graph K_n in S^2, which we call a *spherical arc drawing*. Let $\operatorname{cr}(V)$ denote the number of crossings in this drawing.

▶ **Theorem 9.** *For every configuration $V \subset S^2$ of n unit vectors in general position,*

$$\operatorname{cr}(V) \geqslant \frac{1}{4}\left\lfloor \frac{n}{2} \right\rfloor \left\lfloor \frac{n-1}{2} \right\rfloor \left\lfloor \frac{n-2}{2} \right\rfloor \left\lfloor \frac{n-3}{2} \right\rfloor$$

Moreover, the lower bound is attained with equality if V is coneighborly.

The fact that coneighborly configurations yield spherical arc drawings of K_n achieving the number $X(n)$ of crossings in Hill's conjecture, and the connection to the Eckhoff–Linhart–Welzl conjecture were first observed by Wagner [44, 45]. It is known [35] that there are at least $n^{\frac{3}{2}(1-o(1))n}$ combinatorially different coneighborly configurations of n vectors in S^2.

Spherical arc drawings generalize the well-studied class of *rectilinear drawings* of K_n (given by n points in general position in $\mathbf{R}^2$ connected by straight-line segments), which correspond to spherical arc drawings given by pointed vector configurations $V \subset S^2$.

Theorem 9 complements earlier results of Lovász, Vesztergombi, Wagner, and Welzl [29] and Ábrego and Fernández-Merchant [6], who showed that the *rectilinear crossing number* $\overline{\operatorname{cr}}(K_n)$ (the minimum number of crossings in any rectilinear drawing of K_n) is at least

$X(n)$; in fact, $\overline{\mathrm{cr}}(K_n) \geqslant (\frac{3}{8} + \varepsilon + o(1))\binom{n}{4}$ for some constant $\varepsilon > 0$ [29]. Thus, unlike the spherical arc crossing number, the rectilinear crossing number $\overline{\mathrm{cr}}(K_n)$ is strictly larger than $X(n) \geqslant \mathrm{cr}(K_n)$ in the asymptotically leading term. We refer to [8] for a detailed survey, including a series of subsequent improvements [15, 9, 7, 4] leading to the currently best bound [5] $\overline{\mathrm{cr}}(K_n) > 277/729\binom{n}{4} + O(n^3) > 0.37997\binom{n}{4} + O(n^3)$. We remark that the arguments in [29, 6] have been generalized to verify Hill's conjecture for other classes of drawings, including 2-page drawings [2], monotone drawings [13], cylindrical, x-bounded, and shellable drawings [3], bishellable drawings [1], and seq-shellable drawings [34]. Currently we do not know how spherical arc drawings relate to these other classes of drawings.

1.4 The g-Matrix

The central notion of this paper is the *g-matrix* $g(V \to W)$ of a pair $V, W \in \mathbf{R}^{r\times n}$ of vector configurations, which encodes the difference $f(W) - f(V)$ between the f-matrices. The geometric definition of the g-matrix is given in Sec. 3, based on how the f-matrix changes by *mutations* in the course of generic *continuous motion* (an idea with a long history, see, e.g., [11]). The g-matrix is characterized by the following properties:

▶ **Theorem 10.** *Let $V, W \in \mathbf{R}^{r\times n}$ be a pair of vector configurations in general position.*

The g-matrix *$g(V \to W)$ of the pair is an $(r+1)\times(n-r+1)$-matrix with integer entries $g_{j,k} := g_{j,k}(V \to W)$, $0 \leqslant j \leqslant r$, $0 \leqslant k \leqslant n-r$, which has the following properties:*

1. *For $0 \leqslant j \leqslant r$ and $0 \leqslant k \leqslant n-r$, the g-matrix satisfies the skew-symmetries*

$$g_{j,k} = -g_{r-j,k} = -g_{j,n-r-k} = g_{r-j,n-r-k} \tag{2}$$

Thus, the g-matrix is determined by the submatrix $[g_{j,k} : 0 \leqslant j \leqslant \lfloor\frac{r-1}{2}\rfloor, 0 \leqslant k \leqslant \lfloor\frac{n-r-1}{2}\rfloor]$, which we call the small g-matrix. *Equivalently, the* g-polynomial *$g(x,y) := g_{V\to W}(x,y) := \sum_{j,k} g_{j,k}x^j y^k \in \mathbf{Z}[x,y]$ satisfies*

$$g(x,y) = -x^r g(\tfrac{1}{x}, y) = -y^{n-r} g(x, \tfrac{1}{y}) = x^r y^{n-r} g(\tfrac{1}{x}, \tfrac{1}{y}) \tag{3}$$

2. *The g-polynomial determines the difference $f_W(x,y) - f_V(x,y)$ of f-polynomials by*

$$f_W(x,y) - f_V(x,y) = (1+x)^r g(\tfrac{x+y}{1+x}, y) = \textstyle\sum_{j=0}^{r}\sum_{k=0}^{n-r} g_{j,k}\cdot(x+y)^j(1+x)^{r-j}y^k \tag{4}$$

Equivalently (by comparing coefficients), for $0 \leqslant s \leqslant d$ and $0 \leqslant t \leqslant n$,

$$f_{s,t}(W) - f_{s,t}(V) = \sum_{j,k}\binom{j}{t-k}\binom{r-j}{s-j+t-k} g_{j,k}(V \to W), \tag{5}$$

3. *$g(W \to V) = -g(V \to W)$, and $g(U \to W) = g(U \to V) + g(V \to W)$*

▶ Remark 11. The system of equations (5) yields a linear transformation $T = T_{n,r}$ through which the g-matrix $g = g(V \to W)$ of the pair determines the difference $\Delta f = f(W) - f(V)$ of f-matrices by $\Delta f = T(g)$. In the presence of the skew-symmetries (2), the transformation T is injective (Lemma 25), i.e., $g(V \to W)$ is uniquely determined by $\Delta f = f(W) - f(V)$. Thus, Theorem 10 could be taken as a formal definition of the g-matrix.

1.5 Linear Relations

Linear relations between face numbers of levels in simple arrangements have been studied extensively [33, 24, 27, 12, 16].

The first set of linear relations is given by the antipodal symmetry $F \leftrightarrow -F$ of $\mathcal{F}(V)$:

▶ **Observation 12.** *Let $V = \{v_1, \dots, v_n\} \subset \mathbf{R}^r$. Then $f_V(x,y) = y^n f_V(\frac{x}{y}, \frac{1}{y})$; equivalently,*

$$f_{s,t}(V) = f_{s,n-s-t}(V) \quad \text{for all } s \text{ and } t \tag{6}$$

Moreover, it is well-known [23, Sec. 18.1] that the total number of faces of a given dimension $d-s$ (of any level) in a simple arrangement in S^d depends only on n, d, and s:

▶ **Lemma 13.** *Let $\mathcal{A}(V)$ be a simple arrangement of n hemispheres in S^d. Then, for $0 \leqslant s \leqslant d$, the total number of $(d-s)$-dimensional faces (of any level) in $\mathcal{A}(V)$ equals*

$$\sum_t f_{s,t}(V) = 2\binom{n}{s}\sum_{i=0}^{d-s}\binom{n-s-1}{i} = \sum_{i=0}^{d}(1+(-1)^i)\binom{n}{d-i}\binom{d-i}{s} \tag{7}$$

In terms of the f-polynomial, this can be expressed very compactly as

$$f_V(x,1) = \textstyle\sum_{i=0}^{d}\binom{n}{i}\left(1+(-1)^{d-i}\right)(1+x)^i = 2\left(\binom{n}{d}(x+1)^d + \binom{n}{d-2}(x+1)^{d-2} + \dots\right) \tag{8}$$

Linhart, Yang, and Philipp [27] proved the following result, which generalizes the classical *Dehn–Sommerville relations* for simple polytopes:

▶ **Theorem 14** (Dehn–Sommerville Relations for Levels in Simple Arrangements)**.** *Let $V \in \mathbf{R}^{r\times n}$ be a vector configuration in general position. Then*

$$f_V(x,y) = (-1)^d f_V(-(x+y+1), y) \tag{9}$$

Equivalently (by comparing coefficients), for $0 \leqslant s \leqslant d$ and $0 \leqslant t \leqslant n$,

$$f_{s,t}(V) = \sum_j \sum_\ell (-1)^{d-j}\binom{j}{s}\binom{j-s}{t-\ell} f_{j,\ell}(V) \tag{10}$$

▶ Remark 15. The Dehn–Sommerville relations for polytopes correspond to the identity $f_V(x,0) = (-1)^d f_V(-(x+1),0)$. The coefficients on the right-hand side of (10) are zero unless $\ell \leqslant t$ (and $j \geqslant s$). This yields, for every k, a linear system of equations among the numbers $f_{s,t}$, $0 \leqslant s \leqslant d$ and $t \leqslant k$, of face numbers of the $(\leqslant k)$-*sublevel* of the arrangement $\mathcal{A}(V)$. An equivalent system of equations (expressed in terms of an *h-matrix* that generalizes the h-vector of a simple polytope) was proved earlier by Mulmuley [33], under the additional assumption that the $(\leqslant k)$-sublevel is contained in an open hemisphere. Related relations have been rediscovered several times (e.g., in the recent work of Biswas et al. [16]).

▶ Remark 16. The skew-symmetry $g(x,y) = -x^r g(\frac{1}{x}, y)$ of the g-matrix reflects the Dehn–Sommerville relation (9), and the symmetry $g(x,y) = x^r y^{n-r} g(\frac{1}{x}, \frac{1}{y})$ reflects the antipodal symmetry (6).

Let $\mathcal{V}_{n,r}$ denote the set of vector configurations $V \in \mathbf{R}^{r\times n}$ in general position. Let

$$\mathfrak{F}_{n,r} := \operatorname{aff}\{f(V) \colon V \in \mathcal{V}_{n,r}\}, \qquad \mathfrak{G}_{n,r} := \operatorname{lin}\{g(V \to W) \colon V, W \in \mathcal{V}_{n,r}\}$$

be the affine space spanned by all f-matrices, and the linear space spanned by all g-matrices of pairs, respectively. Let $\mathcal{V}^0_{n,r} \subset \mathcal{V}_{n,r}$ be the subset of pointed configurations, and let

$$\mathfrak{F}^0_{n,r} := \operatorname{aff}\{f(V) \colon V \in \mathcal{V}^0_{n,r}\}, \qquad \mathfrak{G}^0_{n,r} := \operatorname{lin}\{g(V \to W) \colon V, W \in \mathcal{V}^0_{n,r}\}$$

be the corresponding subspaces of $\mathfrak{F}_{n,r}$ and $\mathfrak{G}_{r,n}$. Answering a question posed by Andrzejak and Welzl [12], we determine these spaces:

▶ **Theorem 17.** $\dim \mathfrak{F}_{n,r} = \dim \mathfrak{G}_{n,r} = \lfloor \frac{r+1}{2} \rfloor \lfloor \frac{n-r+1}{2} \rfloor$. *More precisely,*

$$\mathfrak{G}_{n,r} = \left\{ g \in \mathbf{R}^{(r+1)\times(n-r+1)} : \begin{array}{c} g_{j,k} = -g_{r-j,k} = -g_{j,n-r-k} = g_{r-j,n-r-k} \\ \text{for } 0 \leqslant j \leqslant r, 0 \leqslant k \leqslant n-r \end{array} \right\} \tag{11}$$

is the space of all real $(r+1) \times (n-r+1)$*-matrices satisfying the skew-symmetries* (2)*, and*

$$\mathfrak{F}_{n,r} = f(V_0) + T(\mathfrak{G}_{n,r})$$

for any fixed $V_0 \in \mathcal{V}_{n,r}$*, where* $T = T_{n,r}$ *is the injective linear transformation given by* (5)*.*

▶ **Theorem 18.** $\dim \mathfrak{F}^0_{n,r} = \dim \mathfrak{G}^0_{n,r} = \lfloor \frac{r-1}{2} \rfloor \lfloor \frac{n-r+1}{2} \rfloor$. *More precisely,*

$$\mathfrak{G}^0_{n,r} = \{ g \in \mathfrak{G}_{n,r} : g_{0,k} = 0, 0 \leqslant k \leqslant n-r \}, \quad \text{and} \quad \mathfrak{F}^0_{n,r} = f(V_0) + T(\mathfrak{G}^0_{n,r})$$

for any $V_0 \in \mathcal{V}^0_{n,r}$*.*

As a specific base configuration V_0 in both theorems, one can take the *cyclic* vector configuration $V_{\text{cyclic}}(n,r)$ (see Example 2), whose f-matrix is known explicitly [12].

2 Gale Duality and Dependency Patterns

Let $V = \{v_1, \dots, v_n\} \subset \mathbf{R}^r$ be a vector configuration in general position, and let $\mathcal{F}^*(V)$ be the set of all sign vectors $(\operatorname{sgn}(\lambda_1), \dots, \operatorname{sgn}(\lambda_n)) \in \{-1, 0, +1\}^n$ given by non-trivial linear dependencies $\sum_{i=1}^n \lambda_i v_i = 0$ (with coefficients $\lambda_i \in \mathbf{R}$, not all of them are zero). We call $\mathcal{F}^*(V)$ the *dependency patterns* of V. Both $\mathcal{F}^*(V)$ and $\mathcal{F}(V)$ are invariant under invertible linear transformations of $\mathbf{R}^r$ and under positive rescaling (multiplying each vector v_i by some positive scalar $\alpha_i > 0$).

If V is a pointed configuration corresponding to a point set $S \subset \mathbf{R}^d$, $d = r-1$, then the elements of $\mathcal{F}^*(V)$ encode the sign patterns of affine dependencies of S, hence they correspond bijectively to (ordered) *Radon partitions* $S = S_- \sqcup S_0 \sqcup S_+$, $\operatorname{conv}(S_+) \cap \operatorname{conv}(S_-) \neq \emptyset$.

▶ **Definition 19** (f^*-matrix and f^*-polynomial)**.** *For integers* s *and* t*, define*[3]

$$f^*_{s,t}(V) := |\{F \in \mathcal{F}^*(V) \mid |F_-| = t, |F_+| = s-t\}|$$

Together, these numbers form the f^*-matrix $f^*(V) = [f^*_{s,t}(V)]$*. Equivalently, we can encode this data into the bivariate* f^*-polynomial $f^*_V(x,y) \in \mathbf{Z}[x,y]$ *defined by*

$$f^*_V(x,y) := \sum_{F \in \mathcal{F}^*(V)} x^{|F_0|} y^{|F_-|} = \sum_{s,t} f^*_{s,t}(V)\, x^{n-s} y^t$$

Dependency patterns and dissection patterns are, in a precise sense, dual to each other:

▶ **Definition 20** (Gale Duality)**.** *Two vector configurations* $V \in \mathbf{R}^{r\times n}$ *and* $W \in \mathbf{R}^{(n-r)\times n}$ *are called* Gale duals *of one another if the rows of* V *and the rows of* W *span subspaces of* $\mathbf{R}^n$ *that are orthogonal complements of one another.*

Since we always assume that V and W are in general position and of full rank, V and W are Gale dual to each other iff $VW^\top = 0$.

[3] Note that $f^*_{s,t}(V) = 0$ unless $r+1 \leqslant s \leqslant n$ and $0 \leqslant t \leqslant s$.

It is well-known that Gale dual configurations determine each other up to linear isomorphisms of their ambient spaces $\mathbf{R}^r$ and $\mathbf{R}^{n-r}$, respectively [30, Sec. 5.6]. Thus, we will speak of *the Gale dual* of V, which we denote by V^*. It follows from the definition that $(V^*)^* = V$.

As another consequence of the definition, $\mathcal{F}^*(V) = \mathcal{F}(V^*)$, hence $f^*_{s,t}(V) = f_{n-s,t}(V^*)$ for all s, t; equivalently, $f^*_V(x, y) = f_{V^*}(x, y)$.

By the well-known separation theorem for convex sets [30, Sec. 1.2], a vector configuration V in general position is either pointed (equivalently, $f_{0,0}(V) = 1$), or there is a linear dependence of the vectors all of whose coefficients are positive (i.e., $f^*_{n,0}(V) = 1$); the same holds for all subsets $W \subseteq V$. It follows from this that $\mathcal{F}(V)$ and $\mathcal{F}^*(V)$ determine each other (see, e.g., [40, Sec. 2] for more details). In particular, a vector configuration $V \subset \mathbf{R}^r$ is neighborly iff $f^*_{s,t}(V) = 0$ for $t \leqslant \lfloor \frac{r-1}{2} \rfloor$, i.e., V is neighborly iff V^* is coneighborly.

Moreover, one can show that the f-matrix and the f^*-matrix of a vector configuration, or equivalently the polynomials $f_V(x, y)$ and $f^*_V(x, y)$ determine each other as well [40, Sec. 2]:

▶ **Theorem 21.** *Let $V \in \mathbf{R}^{r\times n}$ be a vector configuration in general position. Then*

$$f^*_V(x, y) = (x + y + 1)^n - (-1)^r x^n - (x + 1)^n f_V(-\tfrac{x}{x+1}, \tfrac{x+y}{x+1}) \tag{12}$$

and

$$f_V(x, y) = (x + y + 1)^n - (-1)^{n-r} x^n - (x + 1)^n f^*_V(-\tfrac{x}{x+1}, \tfrac{x+y}{x+1}) \tag{13}$$

By Gale duality, Theorem 17 immediately gives a complete description of the affine space $\mathfrak{F}^*_{n,r}$ spanned by the f^*-matrices of vector configurations $V \in \mathbf{R}^{r\times n}$, and there is an analogous characterization for the subspace $(\mathfrak{F}^*_{n,r})^0$ spanned by the f^*-matrices of pointed vector configurations in $\mathbf{R}^r$ (which count the number of Radon partitions of given types for the corresponding point sets in $\mathbf{R}^d$), see [40, Sec. 1.2]

We say that two vector configurations $V, W \in \mathbf{R}^{r\times n}$ have the same *combinatorial type* if (up to a permutation of the vectors) $\mathcal{F}(V) = \mathcal{F}(W)$ (equivalently, $\mathcal{F}^*(V) = \mathcal{F}^*(W)$). Furthermore, we call V and W *weakly equivalent* if they have identical f-matrices (equivalently, identical f^*-matrices).

▶ Remark 22. For readers familiar with *oriented matroids* (see [48, Ch. 6] or [17]), $\mathcal{F}^*(V)$ and $\mathcal{F}(V)$ are precisely the sets of *vectors* and *covectors*, respectively, of the oriented matroid realized by V. However, speaking of "(co)vectors of a vector configuration" seems potentially confusing, and we hope that the terminology of dissection and dependency patterns is more descriptive. The Dehn–Sommerville relations hold for (uniform, not necessarily realizable) oriented matroids. The definition of the g-matrix via continuous motion does not carry over to the oriented matroid setting, but one can still define the g-matrix formally, by the properties described in Theorem 10. We plan to treat this in detail in a future paper.

3 Continuous Motion and the g-Matrix

3.1 The g-Matrix of a Pair

Any two configurations $V = \{v_1, \dots, v_n\}$ and $W = \{w_1, \dots, w_n\}$ of n vectors in general position in $\mathbf{R}^r$ can be deformed into one another through a continuous family $V(t) = \{v_1(t), \dots, v_n(t)\}$ of vector configurations, where $v_i(t)$ describes a continuous path from $v_i(0) = v_i$ to $v_i(1) = w_i$ in $\mathbf{R}^r$. If we choose this continuous motion sufficiently generically, then there is only a finite set of events $0 < t_1 < \cdots < t_N < 1$, called *mutations*, during which the combinatorial type of $V(t)$ (which is encoded by $\mathcal{F}(V(t))$), changes, in a controlled way (see Figures 1 and 2 for an illustration in the case $d = 2$). Specifically, during a mutation,

a unique r-tuple of vectors in $V(t)$, indexed by some $R = \{i_1, \dots, i_r\} \subset [n]$, momentarily becomes linearly dependent and the orientation of this r-tuple (i.e., the sign of $\det[v_{i_1}| \dots |v_{i_r}]$) changes, while the orientations of all other r-tuples of vectors remain unchanged. Thus, any two vector configurations are connected by a finite sequence $V = V_0, V_1, \dots, V_N = W$ such that V_{s-1} and V_s differ by a mutation, $1 \leqslant s \leqslant N$.

We describe the change from $\mathcal{F}(V)$ to $\mathcal{F}(W)$ when V and W differ by a mutation. Let $R \in \binom{[n]}{r}$ index the unique r-tuple of vectors that become linearly dependent. In terms of the polar dual arrangements, this means that the r-tuple of great $(d-1)$-spheres H_i, $i \in R$, momentarily intersect in an antipodal pair $u, -u$ of points in S^d. Immediately before and immediately after the mutation, these r great $(d-1)$-spheres bound an antipodal pair of simplicial d-faces $\sigma, -\sigma$ in $\mathcal{A}(V)$ and a corresponding pair of simplicial d-faces $\tau, -\tau$ in $\mathcal{A}(W)$, respectively. We have $F \in \mathcal{F}(V) \setminus \mathcal{F}(W)$ iff the face of $\mathcal{A}(V)$ with signature F is contained in σ or $-\sigma$, and $F \in \mathcal{F}(W) \setminus \mathcal{F}(V)$ iff the face of $\mathcal{A}(W)$ with signature F is contained in τ or $-\tau$. All other faces are preserved, i.e., they belong to $\mathcal{F}(V) \cap \mathcal{F}(W)$.

Let $Y \in \mathcal{F}(W)$ be the signature of τ. We define a partition $[n] = I \sqcup J \sqcup A \sqcup B$ by

$$I := R \cap Y_+, \quad J := R \cap Y_-, \quad A := ([n] \setminus R) \cap Y_+, \qquad B := ([n] \setminus R) \cap Y_-$$

Define $j := |J|$ and $k := |B|$. We call the pair (j, k) the *type* of the simplicial face τ. The signature $X \in \mathcal{F}(V)$ of the corresponding simplicial face σ of $\mathcal{A}(V)$ satisfies $X_i = -Y_i$ for $i \in R$ and $X_i = Y_i$ for $i \in [n] \setminus R$. Thus, σ is of type $(r-j, k)$. Analogously, $-\tau$ and $-\sigma$ are of type $(r-j, n-r-k)$ and $(j, n-r-k)$, respectively, see Figures 1 and 2.

Let us define $f_\sigma(x, y) := \sum_{F \subseteq \sigma} x^{|F_0|} y^{|F_-|}$, where we use the notation $F \subseteq \sigma$ to indicate that the sum ranges over all $F \in \mathcal{F}(V)$ corresponding to faces of $\mathcal{A}(V)$ contained in σ. The polynomials $f_{-\sigma}(x, y)$, $f_\tau(x, y)$, and $f_{-\tau}(x, y)$ are defined analogously. These four polynomials have a simple form:

$$f_\sigma(x,y) = y^k \left[(x+1)^j (x+y)^{r-j} - x^r\right], \quad f_{-\sigma}(x,y) = y^{n-r-k} \left[(x+1)^{r-j}(x+y)^j - x^r\right]$$
$$f_\tau(x,y) = y^k \left[(x+1)^{r-j} (x+y)^j - x^r\right], \quad f_{-\tau}(x,y) = y^{n-r-k} \left[(x+1)^j (x+y)^{r-j} - x^r\right]$$

We say that the mutation $V \to W$ is of *Type* $(j, k) \equiv (r-j, n-r-k)$. The reverse mutation $W \to V$ is of Type $(r-j, k) \equiv (j, n-r-k)$. We can summarize the discussion as follows:

▶ **Lemma 23.** *Let $V \to W$ be a mutation of Type $(j, k) \equiv (r-j, n-r-k)$ between configurations of n vectors in $\mathbf{R}^r$. Then*

$$f_W(x,y) - f_V(x,y) = \left(y^k - y^{n-r-k}\right) \left[(x+1)^{r-j}(x+y)^j - (x+1)^j (x+y)^{r-j}\right] \tag{14}$$

Note that the right-hand side of (14) is zero if $2j = r$ or $2k = n - r$.

We are now ready to define the g-matrix $g(V \to W)$ of a pair of vector configurations.

▶ **Definition 24** (g-Matrix of a pair)**.** *Let V, W be configurations of n vectors in $\mathbf{R}^r$.*

If $V \to W$ is a single mutation of Type $(i, \ell) \equiv (r-i, n-r-\ell)$ then we define the g-matrix $g(V \to W) = [g_{j,k}(V \to W)]$, $0 \leqslant j \leqslant r$ and $0 \leqslant k \leqslant n-r$, as follows:

If $2i = r$ or $2\ell = n - r$, then $g_{j,k}(V \to W) = 0$ for all j, k. If $2i \neq r$ and $2\ell \neq n-r$, then

$$g_{j,k}(V \to W) := \begin{cases} +1 & \text{if } (j,k) = (i,\ell) \text{ or } (j,k) = (r-i, n-r-\ell) \\ -1 & \text{if } (j,k) = (r-i,\ell) \text{ or } (j,k) = (i, n-r-\ell) \\ 0 & \text{else.} \end{cases}$$

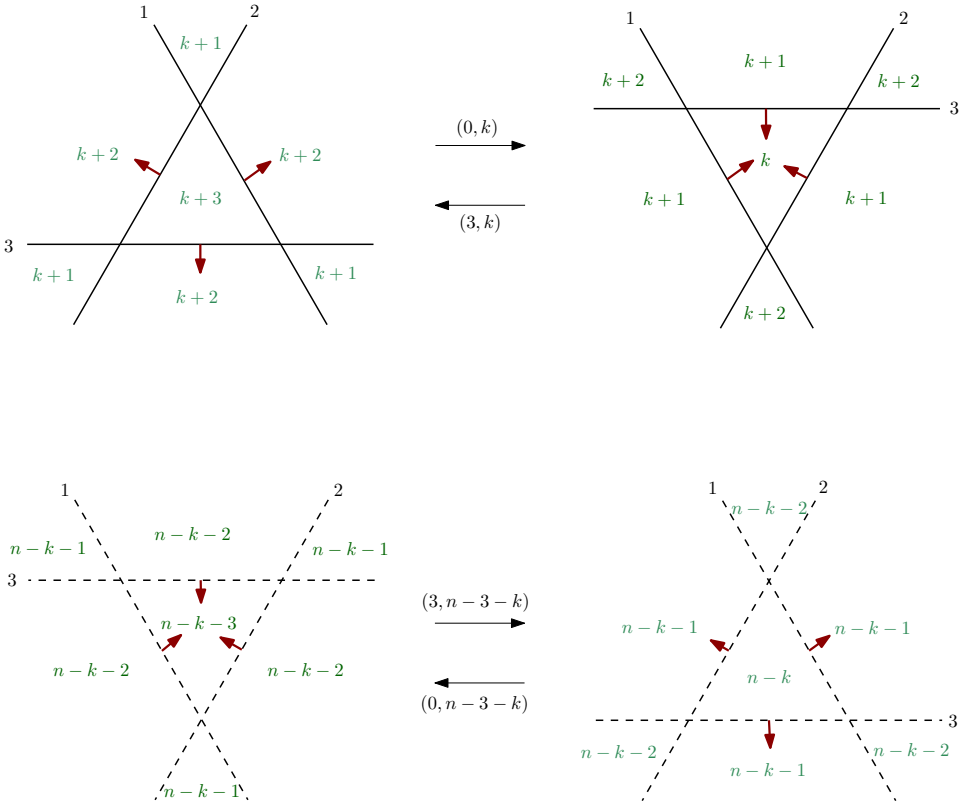

Figure 1 A mutation of Type $(0,k) \equiv (3,n-3-k)$ (from left to right), respectively $(3,k) \equiv (0,n-3-k)$ (from right to left) in S^2. The upper row shows the triangular faces σ and τ before and after the mutation, and the lower row shows the corresponding antipodal faces $-\sigma$ and $-\tau$. The little arrows indicate positive halfspaces, and the labels in full-dimensional faces indicate levels.

More generally, if V and W are connected by a sequence $V = V_0, V_1, \ldots, V_N = W$, where V_{s-1} and V_s differ by a single mutation, then we define

$$g_{j,k}(V \to W) := \sum_{s=1}^{N} g_{j,k}(V_{s-1} \to V_s)$$

Proof of Thm 10. All three properties follow directly from Definition 24 and Lemma 23. ◀

A priori, it may seem that the definition of the g-matrix depends on the choice of a particular sequence of mutations transforming V to W. However, this is not the case:

▶ **Lemma 25.** *Let $f(x,y) = \sum_{s,t} f_{s,t} x^s y^t$ and $g(x,y) = \sum_{j,k} g_{j,k} x^j y^k$ be polynomials (with real coefficients $f_{s,t}$ and $g_{j,k}$ that are zero unless $0 \leqslant s \leqslant d$ and $0 \leqslant t \leqslant n$, respectively $0 \leqslant j \leqslant r$ and $0 \leqslant k \leqslant n-r$). Suppose that $f(x,y)$ and $g(x,y)$ satisfy the identity*

$$f(x,y) = (1+x)^r g(\tfrac{x+y}{1+x}, y) = \textstyle\sum_{j=0}^{r} \sum_{k=0}^{n-r} g_{j,k} \cdot (x+y)^j (1+x)^{r-j} y^k \tag{15}$$

Then, for every fixed t, the numbers $g_{j,t}$, $0 \leqslant j \leqslant r$, are linear combinations of the numbers $f_{s,\ell}$, $0 \leqslant s \leqslant d$ and $0 \leqslant \ell \leqslant t$, with coefficients given inductively by the polynomial equations

$$\sum_j g_{j,t} x^{r-j} = \sum_s f_{s,t} (x-1)^s - \sum_j \sum_{k<t} g_{j,k} \binom{j}{t-k} x^{r-j}$$

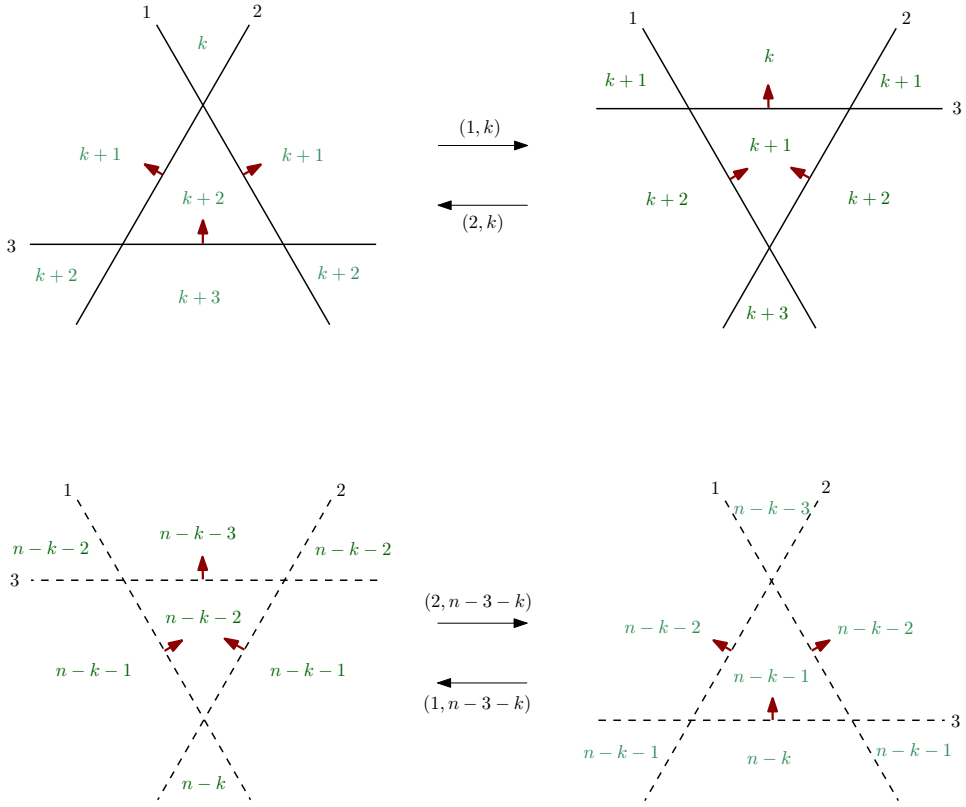

Figure 2 A mutation of Type $(1,k) \equiv (2, n-3-k)$ (from left to right), respectively $(2,k) \equiv (1, n-3-k)$ (from right to left) in S^2.

Proof. The coefficient of y^t in $(x+y)^j(x+1)^{r-j}y^k$ equals $\binom{j}{t-k}(x+1)^{r-j}$ (which is zero unless $0 \leqslant k \leqslant t$). Thus, fixing t and collecting terms in (15) according to y^t, we get

$$\sum_s f_{s,t}x^s = \sum_j \sum_{k \leqslant t} g_{j,k}\binom{j}{t-k}(1+x)^{r-j}$$

Moving the terms with $k < t$ to the other side yields

$$\sum_j g_{j,t}(1+x)^{r-j} = \sum_s f_{s,t}x^s - \sum_j \sum_{k<t} g_{j,k}\binom{j}{t-k}(1+x)^{r-j}$$

The result follows by a change of variable from x to $x-1$ (inductively, the numbers $g_{j,k}$, $k < t$, are determined by the numbers $f_{s,\ell}$, $\ell < t$.) ◀

By Theorem 21, the f-polynomial and the f^*-polynomial of a vector configuration determine each other. This yields the following analogue of Theorem 10 (which can also proved directly, by studying how $\mathcal{F}^*$ changes during mutations):

▶ **Theorem 26.** *Let V, W be configurations of n vectors in $\mathbf{R}^r$. Then*

$$f^*_W(x,y) - f^*_V(x,y) = \sum_{j,k} \underbrace{g_{j,k}(W \to V)}_{=-g_{j,k}(V \to W)}(x+y)^k(x+1)^{n-r-k}y^j \tag{16}$$

Theorems 10 and 26 imply the following:

▶ **Corollary 27.** *Let $V, W \in \mathbf{R}^{r\times n}$ be vector configurations, and let $V^*, W^* \in \mathbf{R}^{(n-r)\times n}$ be their Gale duals. Then $g_{j,k}(V \to W) = -g_{k,j}(V^* \to W^*)$.*

Using the above results, one can show [40, Sec. 3.1] that any pair of neighborly configurations of n vectors in $\mathbf{R}^r$ have the same f-matrix and the same f^*-matrix (equivalently, the g-matrix of the pair is identically zero); analogously for coneighborly configurations.

Moreover, an inductive argument based on *deletions* and *contractions* [40, Sec. 3.2] yields the following result. We say that a vector configuration $V \subset \mathbf{R}^r$ is *j-neighborly* if every subset of V of size j is extremal, and we call V is *k-coneighborly* if $f_{s,t} = 0$ for $t \leqslant k$, i.e., if every open linear halfspace contains at least $k+1$ vectors from V.

▶ **Lemma 28.** *Let $0 \leqslant j \leqslant \frac{r-1}{2}$, $0 \leqslant k \leqslant \frac{n-r-1}{2}$, and let $V, W \in \mathbf{R}^{r\times n}$ be vector configurations such that V is k-coneighborly and W is j-neighborly. Then*

$$g_{j,k}(V \to W) = \tbinom{n-k-r+j}{j}\tbinom{k+r-1-j}{k} - \tbinom{n-k-r+j-1}{j-1}\tbinom{k+r-j}{k} > 0 \tag{17}$$

3.2 The g-Matrix and the g^*-Matrix

We are now ready to define the g-matrix and the g^*-matrix of a vector configuration.

▶ **Definition 29** (g-matrix and g^*-matrix)**.** *Let V be a configuration of n vectors in $\mathbb{R}^r$. Set*

$$g_{j,k}(V) := g_{j,k}(V_{\text{cocyclic}}(n,r) \to V), \qquad \text{and} \qquad g^*_{j,k}(V) := g_{j,k}(V \to V_{\text{cyclic}}(n,r))$$

for $0 \leqslant j \leqslant r$ and $0 \leqslant k \leqslant n-r$. We call $g(V) = [g_{j,k}(V)]$ and $g^*(V) = [g^*_{j,k}(V)]$ the g-matrix *and the* g^*-matrix *of V, respectively. By the skew-symmetries* (2)*, both matrices are determined by their "upper left" quadrants indexed by $0 \leqslant j \leqslant \lfloor\frac{r-1}{2}\rfloor$ and $0 \leqslant k \leqslant \lfloor\frac{n-r-1}{2}\rfloor$, which we call the* small g-matrix *and the* small g^*-matrix, respectively.

By Gale duality, we get $g^*_{j,k}(V) = g_{k,j}(V^*)$, i.e., the g^*-matrix of V is the transpose of the g-matrix of the Gale dual V^*. Moreover, by Lemma 28,

$$g_{j,k}(V) + g^*_{j,k}(V) = \tbinom{n-k-r+j}{j}\tbinom{k+r-1-j}{k} - \tbinom{n-k-r+j-1}{j-1}\tbinom{k+r-j}{k} > 0 \tag{18}$$

for $0 \leqslant j \leqslant \frac{r-1}{2}$ and $0 \leqslant k \leqslant \frac{n-r-1}{2}$.

The 0-th column $[g_{j,0}(V) \mid 0 \leqslant j \leqslant r]$ of the g-matrix corresponds to the classical g-vector of a simple polytope. The *Generalized Lower Bound Theorem* (first proved by Stanley [39], as part of a full characterization of g-vectors, and hence f-vectors of simple polytopes, see [48, Sec. 8.6]), asserts that $g_{j,0}(V) \geqslant 0$ for $0 \leqslant j \leqslant \frac{r-1}{2}$.

The 0-th row $[g^*_{0,k} \mid 0 \leqslant k \leqslant n-r]$ corresponds to a Gale dual version of the g-vector of convex polytopes studied by Lee [25] and Welzl [46]. The following is implicit in [46, Sec. 4] (and implies McMullen's Upper Bound Theorem):

▶ **Theorem 30.** *Let $V \subset \mathbf{R}^r$ be a configuration of n vectors in general position. Then*

$$g^*_{0,k}(V) \leqslant \binom{k+r-1}{r-1} \qquad (0 \leqslant k \leqslant \lfloor\frac{n-r-1}{2}\rfloor)$$

Equivalently, by (18)*, $g_{0,k} \geqslant 0$ for $0 \leqslant k \leqslant \lfloor\frac{n-r-1}{2}\rfloor$. Equality holds if V is coneighborly.*

As a common generalization of the Upper Bound Theorem, the Generalized Lower Bound Theorem, and the Eckhoff–Linhart–Welzl Conjecture (Conj. 5), we propose the following:

▶ **Conjecture 31** (Nonnegativity of the Small g-Matrix)**.** *Let $V \subset \mathbf{R}^r$ be a configuration of n vectors in general position. Then $g_{j,k}(V) \geqslant 0$ for $0 \leqslant j \leqslant \frac{r-1}{2}$ and $0 \leqslant k \leqslant \frac{n-r-1}{2}$.*

Our main result (which implies Theorems 9 and 6) is the following:

▶ **Theorem 32.** *Let $V \subset \mathbf{R}^3$ be a configuration of n vectors in general position. Then*

$$g^*_{1,k}(V) \leqslant (k+1)n - 3\binom{k+2}{2} \qquad (0 \leqslant k \leqslant \lfloor \frac{n-4}{2} \rfloor)$$

Equivalently, $g_{1,k}(V) \geqslant 0$ for $0 \leqslant k \leqslant \lfloor \frac{n-4}{2} \rfloor$. Equality holds if V is coneighborly.

4 The Space $\mathfrak{G}_{n,r}$ Spanned by g-Matrices

Here, we prove Theorem 17. (The proof of the corresponding result for pointed configurations – Theorem 18 – uses similar ideas but is more involved, see [40]). By Theorem 10, the description of the space $\mathfrak{F}_{n,r}$ follows from the description of the space $\mathfrak{G}_{n,r}$, so it remains to prove the latter. Recall that $\mathcal{V}_{n,r}$ is the set of all vector configurations $V \in \mathbf{R}^{r\times n}$ in general position.

By Theorem 10, the g-matrix $g = g(V \to W)$ of any pair $V, W \in \mathcal{V}_{n,r}$ satisfies the skew-symmetries $g_{j,k} = -g_{r-j,k} = -g_{j,n-r-k} = g_{r-j,n-r-k}$ in (2). Thus, in order to prove Theorem 17, it remains to show that $\mathfrak{G}_{n,r} = \operatorname{lin}\{g(V \to W) \colon V, W \in \mathcal{V}_{n,r}\}$ has dimension $\lfloor \frac{r+1}{2} \rfloor \lfloor \frac{n-r+1}{2} \rfloor$. To see this, consider a generic continuous deformation from a coneighborly configuration V_0 to a neighborly configuration V_N, and let V_t, $0 \leqslant i \leqslant N$, be the intermediate vector configurations, i.e., V_t and V_{t-1} differ by a mutation. Thus, the g-matrices $g(V_0 \to V_t)$ and $g(V_0 \to V_{t-1})$ differ by the g-matrix of a mutation, i.e., their first quadrants (small g-matrices) differ in at most one coordinate, by $+1$ or -1. Moreover, $g(V_0 \to V_0)$ is identically zero, and every entry of the first quadrant of $g(V_0 \to V_N)$ is strictly positive by Lemma 28. Thus, the proof of Theorem 17 is completed by the following lemma:

▶ **Lemma 33.** *Let $X_0, X_1, \ldots, X_N$ be vectors in $\mathbf{R}^m$ such that*

1. *$X_0 = 0$;*
2. *X_t and X_{t-1} differ in one coordinate, by $+1$ or -1;*
3. *All coordinates of X_N are non-zero.*

Then there is a subset $X_{t_1}, \ldots, X_{t_m}$ of vectors that form a basis of $\mathbf{R}^m$.

Proof. For $1 \leqslant i \leqslant m$, let t_i be the smallest $t \in \{1, \ldots, N\}$ such that the i-th coordinate of X_{t_i} is non-zero; the index t_i exists by Properties 1 and 3. Moreover, by Property 2, no two coordinates can become non-zero at the same time, i.e., the indices t_i are pairwise distinct. Up to re-labeling the coordinates, we may assume $t_1 < t_2 < \ldots < t_m$. Then, for $1 \leqslant i \leqslant m$, the vector X_{t_i} is linearly independent from the vectors $X_{t_1}, \ldots X_{t_{i-1}}$, since all of the latter vectors have i-th coordinate zero. Thus, the X_{t_i} form a basis. ◀

5 Bounding the Spherical Arc Crossing Number

In this section, we outline the proof of Theorem 32 and explain how it implies Theorems 6 and 9. By Gale duality, Theorem 6 is equivalent to the following:

▶ **Theorem 34.** *Let $V = \{v_1, \ldots, v_n\} \subset \mathbf{R}^3$ be a vector configuration in general position. Then, for all $s \leqslant n$, the numbers $f^*_{s,0}(V)$ and $f^*_{s,\leqslant 1}(V) := f^*_{s,0}(V) + f^*_{s,1}(V)$ are maximized if V is coneighborly.*

Theorem 26 and the skew-symmetries of the g^*-matrix imply the following (see [41]):

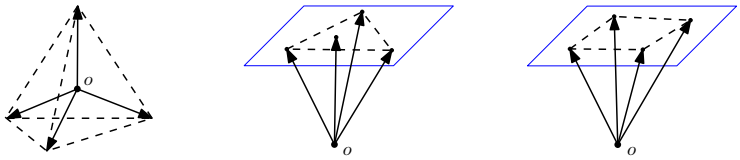

Figure 3 The three combinatorial types of four vectors in general position in $\mathbf{R}^3$.

▶ **Lemma 35.** *Let $V \in \mathbf{R}^{3\times n}$ be a vector configuration in general position and let $s \geqslant 4$. Then there are non-negative integers $\alpha(n,s,k)$ and $\beta(n,s,k)$, $0 \leqslant k \leqslant \lfloor \frac{n-4}{2} \rfloor$, such that*

$$f^*_{s,0}(V) = \sum_{k=0}^{\lfloor \frac{n-4}{2} \rfloor} \alpha(n,k,s) \cdot g^*_{0,k}(V)$$

and

$$f^*_{s,\leqslant 1}(V) = \sum_{k=0}^{\lfloor \frac{n-4}{2} \rfloor} \alpha(n,k,s) \cdot g^*_{1,k}(V) + \sum_{k=0}^{\lfloor \frac{n-4}{2} \rfloor} \beta(n,s,k) \cdot g^*_{0,k}(V)$$

Specifically, $\alpha(n,k,s) = \binom{n-3-k}{s-3} - \binom{k}{s-3}$ and $\beta(n,s,k) = \binom{n-3-k}{s-4}k - \binom{k}{s-4}(n-3-k)$.

Proof of Theorem 34. By Lemma 35, for $s \geqslant 4$, $f^*_{s,0}(V)$ and $f^*_{s,\leqslant 1}(V)$ are non-negative linear combinations of the numbers $g^*_{0,k}(V)$ and $g^*_{1,k}(V)$, $0 \leqslant k \leqslant \lfloor \frac{n-4}{2} \rfloor$. Hence, Theorem 34 follows from Theorems 30 and 32. ◀

Proof of Theorem 9. Let $V \subset \mathbf{R}^3$ be a configuration of n vectors in general position. There are three combinatorial types of quadruples $W \subset V$, which we call Type 0, Type 1, and Type 2, respectively, see Fig. 3. Each quadruple of Type i supports exactly two dependency patterns $F, -F \in \mathcal{F}^*(V)$ with four non-zero signs, one with $|F_-| = i$ negative signs, and the other one with $|F_+| = 4 - i$ negative signs. It follows that

$$f^*_{4,0}(V) + f^*_{4,1}(V) + \frac{1}{2} f^*_{4,2}(V) = \binom{n}{4}$$

Moreover, if all the vectors in V have unit length, then the number of crossings in the induced spherical arc drawing of K_n equals $\mathrm{cr}(V) = \frac{1}{2} f^*_{4,2}(V)$. Thus Theorem 9 is equivalent to the statement that $f^*_{4,2}(V) \geqslant 2X(n)$, equivalently, $f^*_{4,0}(V) + f^*_{4,1}(V) \leqslant \binom{n}{4} - X(n)$, where equality holds in both bounds if V is coneighborly. By the special case $s = 4$ of Theorem 34,

$$f^*_{4,\leqslant 1}(V) \leqslant \sum_{k=0}^{\lfloor \frac{n-4}{2} \rfloor} (n-3-2k)\left((k+1)n - 3\binom{k+2}{2}\right) =: Y(n), \tag{19}$$

with equality if V is coneighborly. By a direct calculation (see [41]), $Y(n) = \binom{n}{4} - X(n)$. ◀

▶ Remark 36. We mention a connection to geometric probability. Let μ be a probability distribution on $\mathbf{R}^3$; we assume that μ is non-degenerate in the sense that every plane through the origin has μ-measure zero. A beautiful argument due to Wendel [47] shows that if μ is *centrally symmetric* and $W = \{w_1, w_2, w_3, w_4\} \subset \mathbf{R}^3$ is a set of four independent μ-random vectors then the probability that W is of Type $i \in \{0,1,2\}$ (Fig. 3) equals q_i, where $q_0 = \frac{\binom{4}{0}+\binom{4}{4}}{2^4} = \frac{1}{8}$, $q_1 = \frac{\binom{4}{1}+\binom{4}{3}}{2^4} = \frac{1}{2}$, and $q_2 = \frac{\binom{4}{2}}{2^4} = \frac{3}{8}$; it follows that for any set $V \subset \mathbf{R}^3$ of

n independent μ-random vectors, the expected number of quadruples of type i equals $q_i\binom{n}{4}$. In particular, if the vectors in V are chosen independently and uniformly at random from S^2 then the expected number of crossings in the spherical arc drawing given by V is $\frac{3}{8}\binom{n}{4}$, which was also independently shown by Moon [32]. Theorem 9, together with a well-known limiting argument [38] implies that for an arbitrary (not necessarily centrally symmetric) non-degenerate probability distribution μ on S^2, the expected number of crossings in the spherical arc drawing given by n independent μ-random points is *at least* $\frac{3}{8}\binom{n}{4}$.

To conclude, we outline some of the main ideas for the proof of Theorem 32 (see [41] for the details). Let $V = \{v_1, \dots, v_n\} \subset \mathbf{R}^3$ be a configuration of n vectors in general position. We will view V as the set $S - o$ of differences $v_i = p_i - o$ between a point set $S = \{p_1, \dots, p_n\} \subset \mathbf{R}^3$ (the *tips* of the vectors) and another point $o \in \mathbf{R}^3$ (the *origin*).

Choose a line ℓ in $\mathbf{R}^3$ through o in general position. By positively rescaling the vectors v_i, we may assume that S is a subset of the cylinder Z consisting of the points in $\mathbf{R}^3$ at Euclidean distance 1 from ℓ; in particular, S is a point set in convex position.

The point set $S \subset \mathbf{R}^3$ corresponds to a neighborly configuration $U = \{u_1, \dots, u_n\}$ of vectors in $\mathbf{R}^4$, and the origin $o \in \mathbf{R}^3$ corresponds to an additional vector $u_0 \in \mathbf{R}^4$. Let $\mathcal{A}(\{u_0\} \sqcup U) = \{H_0^+, H_1^+, \dots, H_n^+\}$ be the polar dual arrangement of hemispheres in S^3. The intersection $\mathcal{A}(U) \cap H_0$ is a spherical arrangment in the equatorial 2-sphere $H_0 \cong S^2$, which is combinatorially isomorphic to the arrangement $\mathcal{A}(V)$.

Let $C = H_i \cap H_j$ be the great circle in S^3 formed by the intersection of two great 2-spheres of the arrangement $\mathcal{A}(U)$, $1 \leqslant i < j \leqslant n$. For $k \leqslant \lfloor \frac{n-4}{2} \rfloor$, consider the subgraph of $\mathcal{A}(U)$ consisting of the vertices and edges of $\mathcal{A}(U)$ contained in C and at sublevel $(\leqslant k)$. This subgraph cannot cover the entire circle C, since C contains at least one pair of antipodal vertices at levels $\lfloor \frac{n-2}{2} \rfloor, \lceil \frac{n-2}{2} \rceil$. Thus, the connected components of this subgraph form closed intervals, which we call *k-arcs* of $\mathcal{A}(U)$. We define $\lambda_k(U, u_0)$ as the number of k-arcs of $\mathcal{A}(U)$ that are completely contained in the negative open hemisphere H_0^-.

Suppose we move the origin o continuously along the line ℓ, while keeping the set S fixed. Consider the corresponding continuous motions of the vector configurations $V = S - o$ in $\mathbf{R}^3$ and $\{u_0\} \sqcup U$ in $\mathbf{R}^4$. A careful analysis of how $\lambda_k(U, u_0)$ and $g_{1,k}(V)$ change during this continuous motion yields

$$g_{1,k}(V) = \lambda_k(U, u_0) \geqslant 0$$

for $0 \leqslant k \leqslant \lfloor \frac{n-4}{2} \rfloor$, which proves Theorem 32.

Abstract

For fixed $d \geq 3$, we construct subsets of the d-dimensional lattice cube $[n]^d$ of size $n^{\frac{3}{d+1}-o(1)}$ with no $d+2$ points on a sphere or a hyperplane. This improves the previously best known bound of $\Omega(n^{\frac{1}{d-1}})$ due to Thiele from 1995.

1 Introduction

The famous *no-three-in-line problem*, raised by Dudeney [5] in 1917 in the special case $n = 8$, asks if it is possible to select $2n$ points from the lattice square $[n]^2$ such that no three are collinear. Clearly, one cannot do better than $2n$ as $[n]^2$ can be covered by n lines. For $n \leq 52$, many authors have published solutions to this problem obtaining the bound of $2n$ (e.g. see [6]). However, for large values of n, the best known lower bound is due to Hall et al. [9] which contains at least $\left(\frac{3}{2} - \varepsilon\right) n$ points, for any $\varepsilon > 0$ and n sufficiently large.

The similar *no-four-on-a-circle* problem, raised by Erdős and Purdy in 1981 (see [8]), asks to determine the maximum number of points that can be selected from $[n]^2$ such that no four are on a circle. Here, a line is also considered to be a *degenerate* circle. Again, we have the trivial upper bound of $3n$ as any vertical line must contain at most three points. This upper bound was improved by Thiele [19], who showed that at most $\frac{5}{2}n - \frac{3}{2}$ points can be selected, and moreover, he gave a construction of $\frac{n}{4}$ points from $[n]^2$ with no four on a circle (or a line).

In this paper, we study the no-four-on-a-circle problem in higher dimensions (Problem 4 in Chapter 10 of [3]). A *k-sphere* is a k-dimensional sphere. Thus, a 0-sphere is a pair of points, a 1-sphere is a circle, and etc. For simplicity, we will simply use the term *sphere* when referring to a $(d-1)$-dimensional sphere in $\mathbb{R}^d$. Again, the maximum number of points that can be selected from the d-dimensional lattice cube $[n]^d$ with no $d+2$ points on a sphere or a hyperplane is at most $(d+1)n$ since we can cover $[n]^d$ with n hyperplanes. In the other direction, Thiele [18] showed that one can select $\Omega(n^{\frac{1}{d-1}})$ points from $[n]^d$ with no $d+2$ points on a sphere or a hyperplane, providing the first non-trivial construction for this problem. In this note, we prove the following.

▶ **Theorem 1.** *Let $d \geq 3$ be a positive integer. Then there is a subset of the d-dimensional lattice cube $[n]^d$ with $n^{\frac{3}{d+1}-o(1)}$ points with no $d+2$ members on a sphere or a hyperplane.*

While it is possible that one can improve this bound to $\Omega(n)$, we make the following more modest conjecture.

▶ **Conjecture 2.** *Let $d \geq 3$ be a positive integer. Then there is a subset of the d-dimensional lattice cube $[n]^d$ with $\Omega(n^{\frac{d}{d+1}})$ points with no $d+2$ members on a sphere or a hyperplane.*

Our paper is organized as follows. In Section 2, we recall several results from VC-dimension theory that will be used in the proof of Theorem 1. In Section 3, we prove Theorem 1. We conclude our paper with several remarks and related problems. For sake of clarity, we systemically remove floor and ceilings whenever they are not crucial. All logarithms are in based 2 unless stated otherwise.

2 VC-dimension theory

In this section, we recall several results from VC-dimension theory that will be used in the proof of Theorem 1. First we introduce some terminology.

Let $G = (P, Q, E)$ be a bipartite graph with independent sets P, Q and edges $E \subset P \times Q$. For $q \in Q$ we define the neighbourhood $N_Q(q) = \{p \in P \colon (p, q) \in E\}$. Define the set-system $\mathcal{F} = \{N_G(q) \colon q \in Q\}$ with ground set P. We say a set $S \subset P$ is *shattered* by $\mathcal{F}$ if for every subset $B \subset S$, there is a set $A \in \mathcal{F}$ such that $A \cap S = B$. The *Vapnik-Chervonenkis dimension* (VC-dimension) of $(P, \mathcal{F})$ is the largest integer d for which there exists a subset $S \subset P$, with $|S| = d$, that is shattered by $\mathcal{F}$.

The *primal shatter function* of $(P, \mathcal{F})$ is defined as

$$\pi_{\mathcal{F}}(z) = \max_{P' \subset P, |P'|=z} |\{A \cap P' \colon A \in \mathcal{F}\}|.$$

The well-known Sauer-Shelah lemma [14, 16] states that if d_0 is the VC-dimension of $\mathcal{F}$, then

$$\pi_{\mathcal{F}}(z) \leq \sum_{i=0}^{d_0} \binom{z}{i}. \tag{1}$$

We will need the following result due to Fox, Pach, Sheffer, Suk, and Zahl.

▶ **Theorem 3** ([7])**.** *Let $G = (P, Q, E)$ be a bipartite graph with $|P| = m$ and $|Q| = n$, such that the set system $\mathcal{F}_1 = \{N(q) \colon q \in Q\}$, with ground set P, satisfies $\pi_{\mathcal{F}_1}(z) \leq cz^{d_0}$ for all z. Then if G is $K_{t,t}$-free, we have*

$$|E(G)| \leq c_1(mn^{1-1/d_0} + n),$$

where $c_1 = c_1(c, d_0, t)$. In particular, $c_1 \leq 10 \cdot ct^{2d_0+1}(d_0 \log d_0)^{d_0}$.

A subset $A \subset [n]^d$ is a *maximal spherical set of* $[n]^d$ if all points in A lie on a single sphere S in $\mathbb{R}^d$, and no point of $[n]^d$ can be added to A while keeping all points on the sphere S. Let $\mathcal{S}_{n,d}$ denote the set-system of all maximal spherical sets of $[n]^d$, with ground set $[n]^d$.

▶ **Lemma 4.** *For $d \geq 2$, the VC-dimension of the set-system $([n]^d, \mathcal{S}_{n,d})$ is at most $d+1$.*

Proof. We proceed by induction on d. The base case $d = 1$ is trivial since a 0-sphere consists of 2 points. For the inductive step, assume the statement holds for $d' < d$. For sake of contradiction, suppose that a set Q of $d+2$ points in $[n]^d$ is shattered by $\mathcal{S}_{n,d}$.

Case 1. Suppose Q is in general position, that is, no $d+1$ members in Q lie on a hyperplane. By linear algebra, any $d+1$ points in Q determines a unique sphere in $\mathbb{R}^d$. However, since Q is shattered by $\mathcal{S}_{n,d}$, there is a sphere that contains Q. Hence, there is no sphere that contains exactly $d+1$ points from Q. Contradiction.

Case 2. Suppose Q contains a $(d+1)$-tuple Q' that lies on a hyperplane h in $\mathbb{R}^d$. Since the intersection of a sphere with h is a $(d-2)$-sphere in h, by induction on d, Q' cannot be shattered by $\mathcal{S}_{n,d}$. Hence, Q cannot be shattered by $\mathcal{S}_{n,d}$, which is a contradiction. ◀

3 Proof of Theorem 1

In this section, we prove Theorem 1. First, let us recall several results. The first is the well-known Chernoff inequality (see [11, Theorem 2.8]).

▶ **Lemma 5** (Chernoff's inequality). *Let $X_1, \dots, X_n$ be independent random variables such that $\mathbb{P}(X_i = 1) = q$ and $\mathbb{P}(X_i = 0) = 1-q$, and let $X = \sum_i X_i$. Then for $0 < \delta < 1$, we have*

$$\mathbb{P}(X \geq (1+\delta)qn) \leq e^{-\frac{\delta^2 qn}{3}},$$

and

$$\mathbb{P}(X \leq (1-\delta)qn) \leq e^{-\frac{\delta^2 qn}{3}}.$$

Next, we estimate the number of points from $[n]^d$ that can lie on a sphere or a hyperplane. For the latter, we will use the following result due to Balogh and White.

▶ **Lemma 6** ([2]). *Let $d \geq 2$ be a positive integer, and $a_1, \dots, a_d \in \mathbb{Z}$ not be all zero with greatest common denominator 1. Let $s = \max_i\{|a_i|\}$, $n \geq s$ be a positive integer, and set*

$$\mathcal{L} = \{(x_1, \dots, x_d) \in \mathbb{Z}^d \colon \sum_{i=1}^{d} a_i x_i = 0\}.$$

If $\mathcal{L} \cap [n]^d$ spans a $(d-1)$-dimensional subspace, then $|\mathcal{L} \cap [n]^d| \leq 3^d n^{d-1}/s$.

▶ **Lemma 7.** *The number of $(d+2)$-tuples in $[n]^d$ that lie on a common hyperplane is at most $O(n^{d^2+d-1})$.*

Proof. By the lemma above, the number of $(d+1)$-tuples in $[n]^d$ that lie on a hyperplane which passes through the origin is at most

$$\sum_s \left(\frac{n^{d-1}}{s}\right)^{d+1} s^{d-1} = O(n^{d^2-1}).$$

By symmetry, for any fixed point $p \in [n]^d$, the number of $(d+1)$-tuples in $[n]^d$ that lies on a hyperplane which passes through p is at most $O(n^{d^2-1})$. After summing over all points in $[n]^d$, the statement follows. Note that Lemma 7 applies to hyperplanes whose intersection with $[n]^d$ spans a $(d-1)$-dimensional subspace. We can assume that any $(d+2)$-tuple in $[n]^d$ lying on a common hyperplane meets this requirement by adding other points from $[n]^d$ if needed. ◀

Finally, we will use the following result due to Sheffer that bounds the number of points from $[n]^d$ that lies on a k-sphere in $\mathbb{R}^d$, for $k \leq d-1$. See also [10, Sec. 11.2, Equation 11.9], [17, Theorem 2].

▶ **Lemma 8** ([15], Lemma 3.2). *Let $d \geq 2$ and $k \leq d-1$. Then there is a positive constant $c = c(d)$ such that every k-sphere in $\mathbb{R}^d$ contains at most $n^{k-1+c/\log\log n}$ points from $[n]^d$.*

Before we prove Theorem 1, let us give a brief outline of the argument. First, we use the probabilistic method and Lemmas 7 and 8 to obtain a large subset $A \subset [n]^d$ such that very few members of A lie on a $(d-2)$-sphere or a hyperplane in $\mathbb{R}^d$. We then apply Theorem 3 and ideas from incidence geometry to estimate the number of r-tuples in A that lie on a common sphere. Finally, we apply the deletion method to find a large subset $A'' \subset A$ such that no $d+2$ members of A'' lie on a sphere or a hyperplane. We now flesh out all of the details of the proof.

Proof of Theorem 1. Without loss of generality, we can assume that n is a power of 2. Indeed, otherwise we can find an integer $n' < n$ that is a power of 2 such that $n' > n/2$, and apply the arguments below to the subcube $[n']^d$. This would only change the hidden constant in the $o(1)$ term in the exponent. Moreover, we will assume that n is sufficiently large.

Fix a positive integer $D < n$ that will be determined later, such that D divides n. We partition the d-dimensional cube $[n]^d$ into D^d smaller cubes $Q_1, \ldots, Q_{D^d}$, where each Q_i is of the form

$$\left\{i_1\frac{n}{D}+1, \ldots, (i_1+1)\frac{n}{D}\right\} \times \cdots \times \left\{i_d\frac{n}{D}+1, \ldots, (i_d+1)\frac{n}{D}\right\}.$$

where $i_1, \ldots, i_d \in \{0, \ldots, D-1\}$. Hence, $|Q_i| = (n/D)^d$.

Consider a random subset $A \subset [n]^d$ obtained by selecting each point in $[n]^d$ independently with probability n^{3-d}. Set $P_i = Q_i \cap A$, for $i = 1, \ldots, D^d$. Let $\mathcal{W}$ be the event that the subset $A \subset [n]^d$ satisfies the following properties.

1. $n^3/2 \leq |A| \leq 2n^3$.
2. $n^3 D^{-d}/2 \leq |P_j| \leq 2n^3 D^{-d}$ for all $1 \leq j \leq D^d$.
3. Every $(d-2)$-sphere contains less than $n^{c_1/\log\log n}$ points of A, where $c_1 = c_1(d)$.
4. The number $(d+2)$-tuples in A that lie on a common hyperplane is at most $c_2 n^{2d+5}$, where $c_2 = c_2(d)$.

By Lemma 5 and Markov's inequality, event $\mathcal{W}$ holds with probability at least $1/2$. Indeed, by Lemma 5, the probability that $|A| > 2n^3$ or $|A| < n^3/2$ is at most $e^{-\frac{n^3}{3}} + e^{-\frac{n^3}{12}}$. Thus, the first property holds with high probability, that is, with probability tending to 1 as n approaches infinity. A similar argument follows for the second property. For the third property, let us fix a $(d-2)$-sphere S in $\mathbb{R}^d$. By Lemma 8, there is a constant $c = c(d)$ such that S contains at most $n^{d-3+c/\log\log n}$ points from $[n]^d$. By Lemma 5,

$$\mathbb{P}[|S \cap A| \geq 2n^{c/\log\log n}] \leq e^{-\frac{n^{c/\log\log n}}{3}}.$$

Since there are at most n^{d^2} $(d-2)$-spheres in $\mathbb{R}^d$ with at least d points from $[n]^d$, the union bound implies that the third property holds with high probability. For the fourth property, let X denote the number $(d+2)$-tuples in A that lie on a common hyperplane. By Lemma 7, we have $\mathbb{E}[X] \leq c' n^{2d+5}$, where $c' = c'(d)$. By Markov's inequality (see [1]), we have

$$\mathbb{P}[X > 10c'n^{2d+5}] < \frac{\mathbb{E}[X]}{10c'n^{2d+5}} < \frac{1}{10}.$$

Putting everything together, and setting c_1, c_2 sufficiently large, event $\mathcal{W}$ holds with probability at least $1/2$.

Thus, let us fix $A \subset [n]^d$ with the four properties described above, and set $t = 2n^{c_3/\log\log n}$, where $c_3 = \max\{c_1, c_2\}$. Let $\mathcal{S}$ be the collection of spheres in $\mathbb{R}^d$, such that each sphere in $\mathcal{S}$ contains at least $d+1$ points from A in general position. Hence, $|\mathcal{S}| = O(|A|^{d+1})$. Let $\mathcal{S}_j \subset \mathcal{S}$ be the set of spheres in $\mathcal{S}$ that contains at least one point of $P_j = Q_j \cap A$. Let $G_j = (P_j, \mathcal{S}_j, E_j)$ be the bipartite incidence graph between P_j and $\mathcal{S}_j$. Since the intersection of two distinct spheres in $\mathbb{R}^d$ is a $(d-2)$-sphere, and every $(d-2)$-sphere contains less than t points from A, each graph G_j is $K_{t,2}$-free.

Let $\mathcal{F}_j$ be the set system whose ground set is P_j, and whose sets are $S \cap P_j$, where $S \in \mathcal{S}_j$ and $|S \cap P_j| \geq t$. That is,

$$\mathcal{F}_j = \{S \cap P_j : S \in \mathcal{S}_j, |S \cap P_j| \geq t\}.$$

By Lemma 4, the VC-dimension of $\mathcal{F}_j$ is at most $d+1$. By inequality (1), we have

$$\pi_{\mathcal{F}_j}(z) = O(z^{d+1}).$$

Hence, we apply Theorem 3 with $t = n^{c_3/\log\log n}$ to conclude that

$$|E_j| \leq n^{c_4/\log\log n}\left(|P_j||\mathcal{S}_j|^{\frac{d}{d+1}} + |\mathcal{S}_j|\right),$$

where $c_4 = c_4(d)$.

Given the partition $[n]^d = Q_1 \cup \cdots \cup Q_{D^d}$ described above, we say that a sphere S *crosses* the subcube Q_i if $S \cap Q_i \neq \emptyset$.

▶ **Observation 9.** *For fixed $d \geq 2$, every sphere S in $\mathbb{R}^d$ crosses at most $c_5 D^{d-1}$ subcubes Q_i, where $c_5 = c_5(d)$.*

Proof. Let $c_5 = c_5(d)$ be a large constant that depends only on d. We will determine c_5 later. For sake of contradiction, suppose there is a sphere S in $\mathbb{R}^d$ the crosses more than $c_5 D^{d-1}$ subcubes Q_i. Note that we will not make any serious attempts to optimize the constant c_5.[1]

Let $T \subset [n]^d \cap S$ be a subset of points $[n]^d \cap S$ obtained by selecting 1 point from each subcube Q_i that S crosses. Hence, $|T| \geq c_5 D^{d-1}$. Let $\mathcal{G} = (T, E)$ be an auxiliary graph on T, where two points in T are adjacent if their distance is less than n/D. Since two points in T have distance less than n/D only if they lie in adjacent subcubes Q_i and Q_j, this implies that $\mathcal{G}$ has maximum degree $3^d - 1$. By Turan's theorem, we can find a subset $T' \subset T$, such that the minimum distance between any two points in T' is at least n/D. Moreover, $|T'| \geq (c_5/3^d)D^{d-1}$.

For each point $p \in T'$, consider the spherical cap C_p obtained by intersecting S with the ball B_p centered at p with radius $n/(2D)$. Since the minimum distance among the points in T' is at least n/D, the collection of spherical caps corresponding to the points in T' will have pairwise disjoint interiors. Moreover, since each spherical cap arises from a ball whose center is on S with radius $n/(2D)$, each spherical cap will have area at least $c_6(n/D)^{d-1}$ where $c_6 = c_6(d)$. Hence, the total area of all of the spherical caps corresponding to the points in T' is at least

$$|T'|c_6(n/D)^{d-1} \geq \frac{c_5 c_6}{3^d} n^{d-1}.$$

[1] A careful calculation shows that one can take $c_5 = 2^{O(d)}$. Another proof follows from a simple inductive argument with $c_5 = d^{O(d)}$.

On the other hand, all of the spherical caps on S will lie inside of a "large" ball B with radius dn. Hence, the area of all of the spherical caps is at most the surface area of the ball B with radius dn. Since the surface area of B is at most $c_7 n^{d-1}$, where $c_7 = c_7(d)$, we have

$$c_7 n^{d-1} \geq \frac{c_5 c_6}{3^d} n^{d-1}.$$

By setting c_5 sufficiently large, we have a contradiction. ◀

By the observation above, $\sum_{j=1}^{D^d} |\mathcal{S}_j| = O(D^{d-1}|\mathcal{S}|)$. Putting all of these bounds together and applying Jensen's inequality, the number of incidences between A and $\mathcal{S}$ is at most

$$\begin{aligned}
\sum_{j=1}^{D^d} |E_j| &\leq n^{c_4/\log\log n} \sum_{j=1}^{D^d} \left(|P_j||\mathcal{S}_j|^{\frac{d}{d+1}} + |\mathcal{S}_j| \right) \\
&\leq 2n^{3+c_4/\log\log n} D^{-d} \sum_{j=1}^{D^d} |\mathcal{S}_j|^{\frac{d}{d+1}} + n^{c_4/\log\log n} \sum_{j=1}^{D^d} |\mathcal{S}_j| \\
&\leq 2n^{3+c_4/\log\log n} D^{-d} D^{\frac{d}{d+1}} \left(\sum_{j=1}^{D^d} |\mathcal{S}_j| \right)^{\frac{d}{d+1}} + c_5 D^{d-1} n^{c_4/\log\log n} |\mathcal{S}| \\
&\leq 2c_5^{\frac{d}{d+1}} n^{3+c_4/\log\log n} D^{-\frac{d}{d+1}} |\mathcal{S}|^{\frac{d}{d+1}} + c_5 D^{d-1} n^{c_4/\log\log n} |\mathcal{S}|.
\end{aligned}$$

Set D to be a power of 2 such that

$$n^{\frac{3(d+1)}{d^2+d-1}} |\mathcal{S}|^{-\frac{1}{d^2+d-1}} \leq D \leq 2n^{\frac{3(d+1)}{d^2+d-1}} |\mathcal{S}|^{-\frac{1}{d^2+d-1}}.$$

Note that $|\mathcal{S}| \leq |A|^{d+1}$. From above, the number of incidences between $\mathcal{S}$ and A is at most

$$n^{\frac{3(d^2-1)}{d^2+d-1} + c_8/\log\log n} |\mathcal{S}|^{\frac{d^2}{d^2+d-1}},$$

where $c_8 = c_8(d)$. Let $\mathcal{S}_r \subset \mathcal{S}$ denote the set of r-rich spheres in $\mathcal{S}$, that is, the set of spheres in $\mathcal{S}$ with at least r points from A. Then we have

$$r|\mathcal{S}_r| \leq n^{\frac{3(d^2-1)}{d^2+d-1} + c_8/\log\log n} |\mathcal{S}_r|^{\frac{d^2}{d^2+d-1}},$$

which implies

$$|\mathcal{S}_r| \leq n^{3(d+1)+c_8/\log\log n} r^{-\frac{d^2+d-1}{d-1}}.$$

Let $\mathcal{T}_i \subset \mathcal{S}$ be the set of spheres in $\mathcal{S}$ with at least 2^i points from A, and at most 2^{i+1} from A. Hence

$$|\mathcal{T}_i| \leq |\mathcal{S}_{2^i}| = n^{3(d+1)+c_8/\log\log n} 2^{-i\frac{d^2+d-1}{d-1}}.$$

Therefore, the number of $(d+2)$-tuples of A that lie on a common sphere $S \in \mathcal{S}$ is at most

$$\sum_{i=1}^{\log|A|} |\mathcal{T}_i| \binom{2^{i+1}}{d+2} \leq n^{3(d+1)+c_8/\log\log n} \sum_{i=1}^{\log|A|} 2^{-i\frac{1}{d-1}} \leq n^{3(d+1)+c_8/\log\log n}.$$

We now consider a random subset $A' \subset A$ obtained by selecting each point in A independently with probability p, where p will be determined later. Let X be the number of $(d+2)$-tuples of A' that lie on a common sphere or a hyperplane. Then, by linearity of expectation, we have

$$\mathbb{E}[X] \leq n^{3(d+1)+c_8/\log\log n}p^{d+2} + O(n^{2d+5})p^{d+2} \leq n^{3(d+1)+c_9/\log\log n}p^{d+2},$$

and

$$\mathbb{E}[|A'|] = p|A| \geq n^3 p/2,$$

where $c_9 = c_9(d)$. Hence, there is a $c_{10} = c_{10}(d)$ such that for $p = n^{-3d/(d+1)-c_{10}/\log\log n}$, we have $\mathbb{E}[X] < \mathbb{E}[|A'|]/4$. By Lemma 5, there is a subset $A' \subset A$ of size at least $p|A|/2$, such that A' contains at most $p|A|/4$ $(d+2)$-tuples on a sphere or a hyperplane. By deleting one point from each $(d+2)$-tuple on a sphere or a hyperplane, we obtain a subset $A'' \subset A'$ of size at least

$$|A|p/4 \geq n^{\frac{3}{d+1}-2c_{10}/\log\log n} = n^{\frac{3}{d+1}-o(1)},$$

such that no $d+2$ members in A'' lie on a sphere or a hyperplane. ◀

4 Concluding remarks

Several authors [13, 12, 4] observed that if n is prime, then by selecting n points from $[n]^d$ on the "modular moment curve" $(x, x^2, \ldots, x^d) \mod n$, for $x = 1, \ldots, n$, no $d+1$ points will lie on a hyperplane, and moreover, no $2d+1$ points lie on a sphere. Unfortunately, this construction may contain $(d+2)$-tuples on a sphere. Nevertheless, one can make the following simple observation.

▶ **Theorem 10.** *Let $d \geq 2$ be a fixed positive integer. Then there is a subset of the d-dimensional lattice cube $[n]^d$ of size $\Omega(n)$ with no $d+1$ points on a hyperplane, and no $2d$ points on a sphere.*

Proof. Let n be prime, and let $A \subset [n]^d$ be points from the d-dimensional cube on the moment curve $(x, x^2, \ldots, x^d) \mod n$, for $1 \leq x \leq \lfloor n/(4d) \rfloor$. Hence, $|A| = \lfloor n/(4d) \rfloor$. For sake of contradiction, suppose there is a sphere S in $\mathbb{R}^d$, such that S contains $2d$ points from A. Note that this means S contains $2d$ of $[n]^d$ when viewed as a sphere in $\mathbb{F}_n^d$. Let the center of $S \subset \mathbb{F}_n^d$ be $(c_1, \ldots, c_d)$ and radius r, such that S contains $2d$ points from A. Then we have $2d$ solutions $s_1, s_2, \ldots, s_{2d}$ to the equation

$$(x-c_1)^2 + (x^2-c_2)^2 + \cdots (x^d - c_d)^2 - r^2 = 0 \mod n.$$

On the other hand, by the division algorithm, we have

$$(x-c_1)^2 + (x^2-c_2)^2 + \cdots (x^d - c_d)^2 - r^2 = (x-s_1)(x-s_2)\cdots(x-s_{2d}) \mod n,$$

which implies that $s_1 + \cdots + s_{2d} = 0 \mod n$ as the coefficient of x^{2d-1} is $0 \mod n$. However, $s_i \leq n/(4d)$, which implies $s_1 + \cdots + s_{2d} \neq 0 \mod n$, contradiction. Hence, no $2d$ points in A lie on a sphere and no $d+1$ points lie on a hyperplane. If n is not prime, we apply Bertrand's postulate to obtain a prime $n' < n$ such that $n' > n/2$, and apply the argument above to $[n']^d$. ◀

Another natural question is to determine the maximum number of points that can be selected from $[n]^d$ with no $d+2$ points on a sphere, but allowing many points on a hyperplane. Since each point from $[n]^d$ lies on a sphere centered at the origin with radius $\sqrt{t}$, where $t = 1, 2, \ldots, dn^2$, we have an upper bound of $d(d+1)n^2$ for this problem. Using Lemma 8 and the probabilistic method, one can show the existence of $n^{2-4/(d+1)-o(1)}$ points from $[n]^2 \subset [n]^d$ with no $d+2$ on a sphere.

Abstract

Given a set of geometric objects in the plane (rectangles, squares, disks etc.), its maximum *depth* (or *geometric clique*) is the largest number of objects with a common intersection. In this paper, we present data structures for dynamically maintaining the maximum depth under insertions and deletions of geometric objects, with sublinear update time. We achieve the following results:

- a $\frac{1}{k}$-approximate dynamic maximum-depth data structure for (axis-parallel) rectangles with $O(n^{1/(k+1)} \log n)$ amortized update time, for any fixed $k \in \mathbb{Z}^+$. In particular, when $k = 1$, this gives an exact data structure for rectangles with $O(\sqrt{n} \log n)$ amortized update time, almost matching the best known bound for the offline version of the problem.
- a $(\frac{1}{2} - \varepsilon)$-approximate dynamic maximum-depth data structure for disks with $n^{2/3} \log^{O(1)} n$ amortized update time, for any constant $\varepsilon > 0$. Having exact data structures for disks with sublinear update time is unlikely, since the static maximum-depth problem for disks is 3SUM-hard and thus does not admit subquadratic-time algorithms.

1 Introduction

We consider the problem of *dynamically* maintaining a set $\mathcal{O}$ of geometric objects (rectangles, squares, disks etc.) under insertions and deletions so that at any instant we can find its maximum depth. The *maximum depth* of $\mathcal{O}$ is the largest depth of any point in the plane, where the depth of a point p, denoted $\mathsf{dep}(p, \mathcal{O})$, is defined as the number of objects in $\mathcal{O}$ containing p. The maximum depth of the set $\mathcal{O}$, written as $\mathsf{dep}(\mathcal{O}) = \max_{p \in \mathbb{R}^d} \mathsf{dep}(p, \mathcal{O})$, is equivalent to its *maximum geometric clique*, namely, the largest subset of objects in $\mathcal{O}$ with a nonempty common intersection. It is easy to see that for axis-parallel rectangles and squares in the plane the geometric cliques correspond to graph-theoretic cliques in the *intersection graph* of $\mathcal{O}$ because the Helly number of rectangles is two. This equivalence, however, does not hold for general geometric objects (even if the objects are convex), where the size of the maximum geometric clique can be smaller than the size of the maximum clique in the intersection graph. Nevertheless, in some cases, the maximum depth is closely related to the maximum clique size in the intersection graph. For example, it is well-known that for disks, the maximum depth is at least $\frac{1}{4}$ of the size of the maximum clique [8].

The problem of computing a maximum geometric clique for simple planar shapes such as rectangles, squares, or disks (and their counterparts in d-dimensions) is well-studied in computational geometry, and several efficient algorithms are known [14, 2, 9, 12]. The

primary focus of our work is to *dynamically* maintain the maximum depth as well as a point p^* that realizes this depth, i.e., $\mathsf{dep}(p^*, \mathcal{O}) = \mathsf{dep}(\mathcal{O})$. To the best of our knowledge, the fully dynamic version of the maximum-depth problem has not been studied before, except for the case of 1-dimensional intervals on the line, where it can be easily solved optimally with $O(\log n)$ update time [14].

The maximum-depth problem in two dimensions provides an interesting setting for dynamic data structures: unlike the NP-complete problems such as set cover, hitting set or independent set for rectangles, which have been the focus of recent work in dynamic data structures [13, 10, 1, 7, 11, 6], the *static* maximum depth problem for rectangles is polynomial-time solvable [14]. Yet, in attempting to design a dynamic data structure for the maximum depth, we face challenges similar to those in set cover etc, and sometimes have to settle for *approximation* to achieve fast update time. For example, for the maximum depth of (axis-parallel) rectangles, it is very difficult to achieve an $O(n^c)$ update time for $c < 1/2$, since the best known static algorithm requires $n^{1.5}/\log^{O(1)} n$ time [9]. Similarly, for the maximum depth of disks, a sublinear update time is unlikely even in the insertion-only setting (if we want exact depth), because the static problem is known to be 3SUM-hard [3] and thus does not admit a (truly) subquadratic-time algorithm by conjecture.

Another challenge for dynamic maximum depth is the non-decomposability of the problem. Specifically, even if we can partition the set $\mathcal{O}$ of geometric objects as $\mathcal{O} = \mathcal{O}_1 \cup \mathcal{O}_2$, the value of $\mathsf{dep}(\mathcal{O})$ cannot be computed from $\mathsf{dep}(\mathcal{O}_1)$ and $\mathsf{dep}(\mathcal{O}_2)$. This non-decomposability makes many techniques in data structure designing inapplicable to the maximum-depth problem.

1.1 Our results

In this paper, we study the dynamic maximum-depth problem for (axis-parallel) rectangles and disks, designing exact and approximate dynamic maximum-depth data structures with sublinear update time. Formally, a dynamic maximum-depth data structure maintains a set $\mathcal{O}$ of geometric objects in $\mathbb{R}^2$ (or more generally $\mathbb{R}^d$) under insertions and deletions, and can report a point $p^* \in \mathbb{R}^2$ satisfying $\mathsf{dep}(p^*, \mathcal{O}) = \mathsf{dep}(\mathcal{O})$ together with the value of $\mathsf{dep}(\mathcal{O})$.

Our main result for rectangles is the following theorem.

▶ **Theorem 1.** *For every $k \in \mathbb{Z}^+$, there exists a $\frac{1}{k}$-approximate dynamic maximum-depth data structure for axis-parallel rectangles with $O(n^{1/(k+1)} \log n)$ amortized update time.*

When $k = 1$, the above theorem gives us an exact data structure for dynamic maximum depth of rectangles, with $O(\sqrt{n} \log n)$ update time. Up to logarithmic factors, this bound matches the update time of the best known *offline* dynamic data structure for the problem [9], which is $O((\sqrt{n}/\sqrt{\log n}) \cdot \log^{3/2} \log n)$. Indeed, $\widetilde{O}(\sqrt{n})$ update time may be best one can expect, even in the insertion-only version, because it is a longstanding open problem whether the static maximum-depth problem for rectangles can be solved in $O(n^{1.5-\varepsilon})$ time. The data structure in Theorem 1 can also be used to dynamically maintain the maximum clique of a rectangle graph with the same update time, because the maximum clique size of a rectangle intersection graph equals the maximum depth of the rectangles.

Our main result for disks is the following theorem.

▶ **Theorem 2.** *For any constant $\varepsilon > 0$, there exists a $(\frac{1}{2} - \varepsilon)$-approximate dynamic maximum-depth data structure for disks with $n^{2/3} \log^{O(1)} n$ amortized update time.*

The static maximum-depth problem for disks is known to be 3SUM-hard [3] with a conjectured lower bound of $\widetilde{\Omega}(n^2)$. It is, therefore, unlikely that an exact dynamic maximum-depth data structure for disks with (truly) sublinear update time exists, even in the insertion-only setting.

Theorem 2 also gives a data structure for dynamically maintaining a $(\frac{1}{8}-\varepsilon)$-approximation of the maximum clique size of a disk graph, with the same update time, because the maximum clique size of a disk graph is at most 4 times the maximum depth of the disks [8]. For convenience, we call such a data structure a *dynamic maximum-clique data structure* for disk graphs.

▶ **Corollary 3.** *For any constant $\varepsilon > 0$, there exists a $(\frac{1}{8}-\varepsilon)$-approximate dynamic maximum-clique data structure for disk graphs with $n^{2/3}\log^{O(1)} n$ amortized update time.*

The key idea underlying the data structure of Theorem 2 is to reduce the original problem to dynamic *discrete* maximum depth (for disks), by introducing a $\frac{1}{2}-\alpha$ multiplicative error. In the discrete version of the problem, besides a dynamic set $\mathcal{D}$ of disks, we also have a dynamic set S of points in $\mathbb{R}^2$, and what we want to maintain is $\max_{p\in S}\mathsf{dep}(p,\mathcal{D})$. This kind of reduction works for not only disks, but also general fat objects (where the multiplicative error depends on the fatness of the objects). We believe that this idea is of independent interest and may find applications in other problems as well.

1.2 Related Work

Dynamic data structures have been a focus of research in computational geometry from its very beginning, and there exists a vast literature. Since our work pertains to the dynamic geometric *optimization* problem, we limit our review to the narrow set of papers that have considered related problems. In recent years, a number of papers have addressed the problem of dynamically maintaining such functions as the minimum geometric set cover, minimum geometric hitting set, maximum geometric independent sets, etc., for simple geometric shapes such as rectangles, squares, disks, or their d-dimensional counterpart. In particular, Agarwal et al. [1] were the first to present sub-linear time data structures for maintaining approximate minimum geometric set covers (and hitting sets) of intervals in one dimension and unit squares in two dimensions. The update time bounds were improved and the results generalized to rectangles as well as weighted objects by Chan et al.[10, 11]. Henzinger et al. [13] consider the problem of approximately maintaining the maximum independent set of d-dimensional rectangles. Bhore and Chan [6] present dynamic data structures for a number of other geometric optimization problems such as minimum piercing sets, minimum vertex cover, maximum independent set of rectangles. Yildiz et al. [16] give a data structure to maintain Klee's measure dynamically in a discrete setting.

2 Preliminaries

In this section, we introduce the basic notions used throughout the paper.

Depth. Given a set $\mathcal{O}$ of geometric shapes in $\mathbb{R}^d$, the depth of a point p with respect to $\mathcal{O}$ is the number of objects in $\mathcal{O}$ that contain p. Formally, $\mathsf{dep}(p,\mathcal{O}) = |\{O\in\mathcal{O} : p\in O\}|$. The maximum depth of the set $\mathcal{O}$ is denoted by $\mathsf{dep}(\mathcal{O}) = \max_{p\in\mathbb{R}^d}\mathsf{dep}(p,\mathcal{O})$. We often use p^* to denote a point that maximizes the depth with respect to the set $\mathcal{O}$, i.e., $\mathsf{dep}(p^*,\mathcal{O}) = \mathsf{dep}(\mathcal{O})$, and $\mathcal{O}^*$ to denote a maximum geometric clique for $\mathcal{O}$, i.e., $\mathcal{O}^* = \{O\in\mathcal{O} : p^*\in O\}$.

Disk and fat object. For a disk D, $\mathsf{ctr}(D)$ and $\mathsf{rad}(D)$ denote its center and radius, respectively. This notation also holds for balls. In this paper, the fat object, which generalizes both rectangle and disk, is defined as follows: Let O be a *convex* object in $\mathbb{R}^d$. Let O_{in} be

the largest ball that is contained in O. We say O is α-*fat*, for some parameter $\alpha \geq 1$, if O_{out}, the ball that is concentric with O_{in} and has radius $\mathsf{rad}(O_{\text{out}}) = \alpha \cdot \mathsf{rad}(O_{\text{in}})$, contains O. We call the center of O_{in} the *center* of O and $\mathsf{rad}(O_{\text{in}})$ the *in-radius* of O.[1]

3 Dynamic maximum-depth for rectangles

In this section, we consider the dynamic maximum-depth problem for rectangles. We first describe a data structure for maintaining the exact maximum depth with $O(\sqrt{n}\log n)$ amortized update time and $O(n^{1.5}\log n)$ preprocessing time. This proves the base case of Theorem 1, namely, $k = 1$. We then inductively prove the theorem for all $k \in \mathbb{Z}^+$.

Let $\mathcal{Q}$ be a dynamic set of rectangles in $\mathbb{R}^d$, and denote by n the initial size of $\mathcal{Q}$. Our data structure applies the standard reconstruction technique. Specifically, we will reconstruct the data structure periodically: the $(i+1)$-th reconstruction will be done after handling $n_i/2$ operations following the i-th reconstruction, where n_i is the size of $\mathcal{Q}$ at the time of the i-th reconstruction. Thus, during the i-th period, i.e., the period between the i-th reconstruction and the $(i+1)$-th reconstruction, the size of $\mathcal{Q}$ is always $\Theta(n_i)$. Since our data structure will have an $O(n^{1.5}\log n)$ preprocessing time, the time cost for the $(i+1)$-th reconstruction is $O(n_i^{1.5}\log n_i)$, which can be amortized to the $n_i/2$ operations in the i-th period, which is $O(\sqrt{n_i}\log n_i)$ per operation. Because of the reconstruction, we only need to consider the first period, i.e., the first $n/2$ operations.

Let r be a parameter to be determined later. To construct our data structure, we first partition the plane into r horizontal slabs $L_1, \ldots, L_r$ using $r-1$ horizontal lines such that each slab contains (in its interior) at most $4n/r$ corners of rectangles in $\mathcal{Q}$. For each slab L_i, we construct a dynamic data structure $\mathcal{D}(L_i)$ that can maintain a point $p_i \in L_i$ that maximizes $\mathsf{dep}(p_i, \mathcal{Q})$, as well as the value of $\mathsf{dep}(p_i, \mathcal{Q})$, under insertions and deletions on $\mathcal{Q}$. We call $\mathcal{D}(L_1), \ldots, \mathcal{D}(L_r)$ *slab data structures* for convenience. The design of the slab data structures will be presented shortly. During the update, for each $i \in [r]$ whenever the number of rectangle corners contained in (the interior of) L_i reaches $8n/r$, we split L_i into two horizontal slabs L_i' and L_i'' each of which contains $4n/r$ corners, and replace $\mathcal{D}(L_i)$ with two new slab data structures $\mathcal{D}(L_i')$ and $\mathcal{D}(L_i'')$. In this way, we guarantee that the number of rectangle corners contained in each slab is always $O(n/r)$. We observe that slab splitting can happen at most $O(r)$ times (in the first period).

▶ **Fact 4.** *During the first t operations, the number of slab splittings is at most $2tr/n$.*

Proof. Let $\mathcal{L}$ be the set of all slabs occurred when processing the first t operations. Consider the insertions in the t operations. For each inserted rectangle Q, we charge it to the (at most) two slabs containing the corners of R when Q is inserted. Observe that a slab $L \in \mathcal{L}$ eventually splits only if it gets charged at least n/r times. Indeed, L contains $4n/r$ rectangle corners when it is created and contains $8n/r$ rectangle corners when it splits. Thus, from the time point that L is created to the time point that L splits, there are at least n/r inserted rectangles which have corners in L, which implies that L gets charged at least n/r times. Since there can be at most t inserted rectangles, the total number of charges is bounded by $2t$, which implies that the number of slab splitting is bounded by $2tr/n$. ◀

[1] There are different definitions of fat objects in different papers. One can easily show that our definition is equivalent to the others.

Clearly, using the information stored in the slab data structures, we can compute in $O(r)$ time a point p^* satisfying $\mathsf{dep}(p^*, \mathcal{Q}) = \mathsf{dep}(\mathcal{Q})$, as well as the value of $\mathsf{dep}(\mathcal{Q})$. More precisely, we just consider the points $p_1, \ldots, p_r$ stored in the slab data structures (and their depths with respect to $\mathcal{Q}$) and define p^* as the one that maximizes its depth with respect to $\mathcal{Q}$. Therefore, the remaining task now is to design efficient slab data structures.

The slab data structures. Consider a slab L. We want to maintain a point $p \in L$ that maximizes $\mathsf{dep}(p, \mathcal{Q})$, as well as the value of $\mathsf{dep}(p, \mathcal{Q})$. Clearly, we can ignore the rectangles in $\mathcal{Q}$ that are disjoint from L. Thus, in the following we assume that every rectangle in $\mathcal{Q}$ intersects L. We classify the rectangles in $\mathcal{Q}$ into two types: *long* rectangles and *short* rectangles. A rectangle is *long* if its four corners are all outside L and is *short* if at least one corner is inside (the interior of) L. Let $\mathcal{Q}_{\mathsf{long}} \subseteq \mathcal{Q}$ and $\mathcal{Q}_{\mathsf{short}} \subseteq \mathcal{Q}$ be the sets of long and short rectangles in $\mathcal{Q}$, respectively.

To maintain the maximum depth of $\mathcal{Q}$ inside L, our main idea is to reduce the problem to maintaining the maximum depth of *weighted* intervals. Specifically, we shall construct a set $\mathcal{I}$ of weighted intervals from $\mathcal{Q}$ such that the maximum depth of $\mathcal{Q}$ inside L is equal to the maximum (weighted) depth of $\mathcal{I}$. The construction is done as follows. For each long rectangle $Q = [x^-, x^+] \times [y^-, y^+] \in \mathcal{Q}_{\mathsf{long}}$, we include in $\mathcal{I}$ the interval $[x^-, x^+]$ with weight 1. For the set $\mathcal{Q}_{\mathsf{short}}$ of short rectangles, we first define a *depth function* $f : \mathbb{R} \to \mathbb{N}$ as $f(r) = \max_{p \in \ell_r \cap L} \mathsf{dep}(p, \mathcal{Q}_{\mathsf{short}})$ where ℓ_r is the vertical line with equation $x = r$. One can easily observe that f is a piecewise-constant function with $O(|\mathcal{Q}_{\mathsf{short}}|)$ pieces, since the value of f only changes at the x-coordinates of the corners of the short rectangles. Therefore, we can partition the real line $\mathbb{R}$ into $s = O(|\mathcal{Q}_{\mathsf{short}}|)$ intervals $I_1, \ldots, I_s$ such that f is a constant function when restricted to each I_i. Also, for each I_i, there is a y-coordinate $y_i \in \mathbb{R}$ such that $I_i \times \{y_i\} \subseteq L$ and $f(x) = \mathsf{dep}(p, \mathcal{Q}_{\mathsf{short}})$ for any $x \in I_i$ and $p \in I_i \times \{y_i\}$. Define a function $g : \mathbb{R} \to \mathbb{R}$ as $g(x) = y_i$ if $x \in I_i$. We include $I_1, \ldots, I_s$ in $\mathcal{I}$ and set the weight of each I_i to be $f(x)$ for an arbitrary $x \in I_i$. (See Figure 1 for an illustration.)

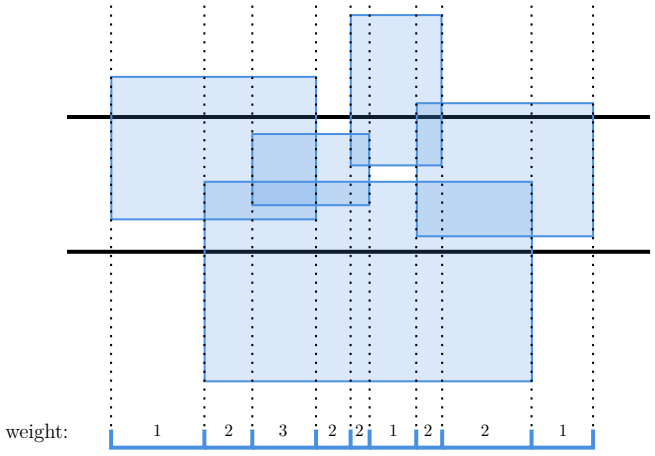

Figure 1 Construct of weighted intervals corresponding to $\mathcal{Q}_{\mathsf{short}}$.

We observe the following simple fact.

▶ **Fact 5.** *If $x^* \in \mathbb{R}$ satisfies that $\mathsf{dep}(x^*, \mathcal{I}) = \mathsf{dep}(\mathcal{I})$, the point $p^* = (x^*, g(x^*)) \in L$ satisfies $\mathsf{dep}(p^*, \mathcal{Q}) = \mathsf{dep}(x^*, \mathcal{I}) = \max_{p \in L} \mathsf{dep}(p, \mathcal{Q})$.*

Proof. We first prove that $\mathsf{dep}(p^*, \mathcal{Q}) = \mathsf{dep}(x^*, \mathcal{I})$. By definition, $\mathsf{dep}(p^*, \mathcal{Q}) = \mathsf{dep}(p^*, \mathcal{Q}_{\mathsf{long}}) + \mathsf{dep}(p^*, \mathcal{Q}_{\mathsf{short}})$. Note that a rectangle in $\mathcal{Q}_{\mathsf{long}}$ contains p^* iff its corresponding weight-1 interval in $\mathcal{I}$ contains x^*. So x^* is contained in exactly $\mathsf{dep}(p^*, \mathcal{Q}_{\mathsf{long}})$ weight-1 intervals corresponding to the rectangles in $\mathcal{Q}_{\mathsf{long}}$. Meanwhile, the total weight of the intervals containing x^* which correspond to the rectangles in $\mathcal{Q}_{\mathsf{short}}$ is equal to $f(x^*)$. It follows that $\mathsf{dep}(x^*, \mathcal{I}) = \mathsf{dep}(p^*, \mathcal{Q}_{\mathsf{long}}) + f(x^*)$. As $p^* = (x^*, g(x^*))$, we have $\mathsf{dep}(p^*, \mathcal{Q}_{\mathsf{short}}) = f(x^*)$ by the definition of g. Thus, $\mathsf{dep}(x^*, \mathcal{I}) = \mathsf{dep}(p^*, \mathcal{Q}_{\mathsf{long}}) + \mathsf{dep}(p^*, \mathcal{Q}_{\mathsf{short}}) = \mathsf{dep}(p^*, \mathcal{Q})$.

Since $\mathsf{dep}(p^*, \mathcal{Q}) \leq \max_{p \in L} \mathsf{dep}(p, \mathcal{Q})$, it suffices to show that $\mathsf{dep}(x^*, \mathcal{I}) \geq \max_{p \in L} \mathsf{dep}(p, \mathcal{Q})$. Consider a point $p \in L$. Again, a rectangle in $\mathcal{Q}_{\mathsf{long}}$ contains p iff its corresponding weight-1 interval in $\mathcal{I}$ contains $x(p)$. Also, $f(x(p)) \geq \mathsf{dep}(p, \mathcal{Q}_{\mathsf{short}})$ by the definition of f. Therefore,

$$\mathsf{dep}(x(p), \mathcal{I}) = \mathsf{dep}(p, \mathcal{Q}_{\mathsf{long}}) + f(x(p)) \geq \mathsf{dep}(p, \mathcal{Q}_{\mathsf{long}}) + \mathsf{dep}(p, \mathcal{Q}_{\mathsf{short}}) = \mathsf{dep}(p, \mathcal{Q}).$$

Since $\mathsf{dep}(x^*, \mathcal{I}) = \mathsf{dep}(\mathcal{I})$, we have $\mathsf{dep}(x^*, \mathcal{I}) \geq \mathsf{dep}(x(p), \mathcal{I}) \geq \mathsf{dep}(p, \mathcal{Q})$. ◀

For our slab data structure $\mathcal{D}(L)$, we can simply use the following result of Imai and Asano [14], which is a byproduct of their (static) algorithm for the maximum-depth problem for weighted rectangles.

▶ **Lemma 6** ([14]). *There exists a dynamic maximum-depth data structure $\mathcal{A}$ for weighted intervals with $O(\log n)$ update time and $O(n \log n)$ preprocessing time.*

Given $\mathcal{Q}$, we first compute the set $\mathcal{I}$ as stated above (as well as the functions f and g), and then build $\mathcal{A}(\mathcal{I})$, i.e., the interval data structure of the above lemma on $\mathcal{I}$). $\mathcal{A}(\mathcal{I})$ maintains $x^* \in \mathbb{R}$ satisfying $\mathsf{dep}(x^*, \mathcal{I}) = \mathsf{dep}(\mathcal{I})$, as well as the value of $\mathsf{dep}(x^*, \mathcal{I})$. The point we maintain is $p^* = (x^*, g(x^*))$, which satisfies $\mathsf{dep}(p^*, \mathcal{Q}) = \max_{p \in L} \mathsf{dep}(p, \mathcal{Q})$ by Fact 5. Also, the value of $\mathsf{dep}(p^*, \mathcal{Q})$ is equal to $\mathsf{dep}(x^*, \mathcal{I})$ by Fact 5, and we can maintain the latter from $\mathcal{A}(\mathcal{I})$.

Consider an insertion/deletion on $\mathcal{Q}$, and let Q be the inserted/deleted rectangle. If Q is a long rectangle, we just need to insert/delete its corresponding weight-1 interval on $\mathcal{I}$ and update $\mathcal{A}(\mathcal{I})$. If Q is a short rectangle, the situation is more complicated and what we do is the following. First, we delete from $\mathcal{I}$ all intervals corresponding to the rectangles in the old $\mathcal{Q}_{\mathsf{short}}$. Then we construct the intervals corresponding to the rectangles in the new $\mathcal{Q}_{\mathsf{short}}$ (we shall show how to do this efficiently) and insert them to $\mathcal{I}$. Also, we re-compute the functions f and g corresponding to the new $\mathcal{Q}_{\mathsf{short}}$. For both deletions and insertions on $\mathcal{I}$, we need to update $\mathcal{A}(\mathcal{I})$ accordingly.

Next, we analyze the preprocessing time and update time for our slab data structure. To this end, we first show that one can compute the weighted intervals in $\mathcal{I}$ corresponding to the short rectangles, as well as the functions f and g, in $O(|\mathcal{Q}_{\mathsf{short}}| \log |\mathcal{Q}_{\mathsf{short}}|)$ time. Indeed, we can directly apply the classical (static) rectangle maximum-depth algorithm [14] on $\mathcal{Q}_{\mathsf{short}}$. The algorithm sweeps a vertical line ℓ from left to right, and maintains the maximum depth of $\mathcal{Q}_{\mathsf{short}}$ on ℓ. Therefore, it exactly computes the function f and g, together with their piece intervals $I_1, \ldots, I_s$. The running time of the algorithm is $O(|\mathcal{Q}_{\mathsf{short}}| \log |\mathcal{Q}_{\mathsf{short}}|)$. The intervals in $\mathcal{I}$ corresponding to the long rectangles can be constructed directly. Overall, the time for constructing $\mathcal{I}$ is $O(|\mathcal{Q}| \log |\mathcal{Q}|)$, i.e., $O(n \log n)$. By Lemma 6, $\mathcal{A}(\mathcal{I})$ can also be built in $O(n \log n)$ time as $|\mathcal{I}| = O(|\mathcal{Q}|)$. So the preprocessing time of our slab data structure is $O(n \log n)$. For the update time, we need to distinguish long rectangles and short rectangles. Inserting/deleting a long rectangle corresponds to an insertion/deletion on $\mathcal{A}(\mathcal{I})$ and thus can be done in $O(\log n)$ time. For the insertion/deletion of a short rectangle, we need to

delete $O(|\mathcal{Q}_{\mathsf{short}}|)$ intervals from $\mathcal{I}$, re-compute the intervals corresponding to $\mathcal{Q}_{\mathsf{short}}$ and the functions f and g, and insert $O(|\mathcal{Q}_{\mathsf{short}}|)$ intervals to $\mathcal{I}$. The $O(|\mathcal{Q}_{\mathsf{short}}|)$ insertions/deletions on $\mathcal{A}(\mathcal{I})$ can be done in $O(|\mathcal{Q}_{\mathsf{short}}| \log n)$ time by Lemma 6, and the re-computation can be done in $O(|\mathcal{Q}_{\mathsf{short}}| \log |\mathcal{Q}_{\mathsf{short}}|)$ time as discussed above. As the number of rectangle corners in a slab is always $O(n/r)$, we have $|\mathcal{Q}_{\mathsf{short}}| = O(n/r)$. Thus, the update time for a short rectangle is $O((n/r) \log n)$.

▶ **Lemma 7.** *One can construct each slab data structure in $O(n \log n)$ time such that for insertions/deletions of long (resp., short) rectangles, the data structure can be updated in $O(\log n)$ time (resp., $O((n/r) \log n)$ time).*

Overall time complexity. Using Lemma 7, we can now analyze the overall preprocessing time and update time of our data structure. Partitioning the plane into slabs can be done in $O(n \log n)$ time by sorting the corners of the rectangles in $\mathcal{Q}$. Since there are r slabs and each slab data structure can be constructed in $O(n \log n)$ time, the preprocessing time is $O(rn \log n)$. To analyze the update time, let Q be the inserted/deleted rectangle. Note that there are at most two slabs in which Q is a short rectangle. So among the updates of the slab data structures, there can be at most two updates for short rectangles and $O(r)$ updates for long rectangles. By Lemma 7, these updates take $O((n/r) \log n + r \log n)$ time. Also, rectangle insertions might cause slab splittings and for each slab splitting we need $O(n \log n)$ time to build the new slab data structures. By Fact 4, the time cost for slab splitting during the first t operations is $O(tr \log n)$, and the amortized time cost is then $O(r \log n)$. Therefore, the overall (amortized) update time of our data structure is $O((n/r) \log n + r \log n)$. To balance the two terms, we set $r = \sqrt{n}$, yielding $O(\sqrt{n} \log n)$ update time. The preprocessing time is then $O(n^{1.5} \log n)$. Based on the above discussion, we have the following conclusion, which is the base case $k = 1$ of Theorem 1.

▶ **Lemma 8.** *There exists a dynamic maximum-depth data structure for axis-parallel rectangles with $O(\sqrt{n} \log n)$ amortized update time, which can be built in $O(n^{1.5} \log n)$ time.*

Approximate data structures. Now we are able to prove Theorem 1 for a general $k \in \mathbb{N}$. As aforementioned, we apply induction on k. Lemma 8 gives us the base case $k = 1$. Suppose there exists a $\frac{1}{k}$-approximate dynamic maximum-depth data structure for rectangles with $O(n^{1/(k+1)} \log n)$ (amortized) update time and $O(n^{1+1/(k+1)} \log n)$ preprocessing time. We want to show the existence of a $\frac{1}{k+1}$-approximate data structure with $O(n^{1/(k+2)} \log n)$ update time and $O(n^{1+1/(k+2)} \log n)$ preprocessing time.

As before, our data structure partitions the plane into r slabs. The only difference occurs in the design of the slab data structures. Consider a slab L. We want our slab data structure for L to maintain a point $p^* \in L$ satisfying that $\mathsf{dep}(p^*, \mathcal{Q}) \geq \frac{1}{k+1} \cdot \max_{p \in L} \mathsf{dep}(p, \mathcal{Q})$; this guarantees that our overall data structure achieves the approximation ratio $\frac{1}{k+1}$. Again, let $\mathcal{Q}_{\mathsf{long}}$ and $\mathcal{Q}_{\mathsf{short}}$ denote the set of long and short rectangles in $\mathcal{Q}$ with respect to L, respectively. Unlike in our exact data structure, we now handle $\mathcal{Q}_{\mathsf{long}}$ and $\mathcal{Q}_{\mathsf{short}}$ separately. For long rectangles, we maintain a point $p_1^* \in L$ that maximizes $\mathsf{dep}(p_1^*, \mathcal{Q}_{\mathsf{long}})$. This can be done using exactly the same idea as before: map each long rectangle $Q = [x^-, x^+] \times [y^-, y^+] \in \mathcal{Q}_{\mathsf{long}}$ to the interval $[x^-, x^+]$, and build $\mathcal{A}$ on these intervals. For short rectangles, we maintain a point $p_2^* \in L$ satisfying the condition that $\mathsf{dep}(p_2^*, \mathcal{Q}_{\mathsf{short}}) \geq \frac{1}{k} \cdot \max_{p \in L} \mathsf{dep}(p, \mathcal{Q}_{\mathsf{short}})$. To this end, we build a $\frac{1}{k}$-approximate dynamic maximum-depth data structure on $\mathcal{Q}_{\mathsf{short}}$, which can give us the desired point p_2^*. By our induction hypothesis, there exists such a data structure with $O(n^{1/(k+1)} \log n)$ update time and $O(n^{1+1/(k+1)} \log n)$ preprocessing time. Define $p^* = p_1^*$ if $\mathsf{dep}(p_1^*, \mathcal{Q}_{\mathsf{long}}) \geq \mathsf{dep}(p_2^*, \mathcal{Q}_{\mathsf{short}})$ and $p^* = p_2^*$ if $\mathsf{dep}(p_1^*, \mathcal{Q}_{\mathsf{long}}) < \mathsf{dep}(p_2^*, \mathcal{Q}_{\mathsf{short}})$. We observe the following.

▶ **Lemma 9.** $\mathsf{dep}(p^*, \mathcal{Q}) \geq \frac{1}{k+1} \cdot \max_{p \in L} \mathsf{dep}(p, \mathcal{Q})$.

Proof. Let $p \in L$ be a point that maximizes $\mathsf{dep}(p, \mathcal{Q})$. By definition, we have $\mathsf{dep}(p, \mathcal{Q}) = \mathsf{dep}(p, \mathcal{Q}_{\mathsf{long}}) + \mathsf{dep}(p, \mathcal{Q}_{\mathsf{short}})$. We consider two cases: $\mathsf{dep}(p, \mathcal{Q}_{\mathsf{long}}) \geq \frac{1}{k+1}\mathsf{dep}(p, \mathcal{Q})$ and $\mathsf{dep}(p, \mathcal{Q}_{\mathsf{long}}) < \frac{1}{k+1}\mathsf{dep}(p, \mathcal{Q})$. If $\mathsf{dep}(p, \mathcal{Q}_{\mathsf{long}}) \geq \frac{1}{k+1}\mathsf{dep}(p, \mathcal{Q})$, we have

$$\mathsf{dep}(p^*, \mathcal{Q}) \geq \mathsf{dep}(p_1^*, \mathcal{Q}) \geq \mathsf{dep}(p_1^*, \mathcal{Q}_{\mathsf{long}}) \geq \mathsf{dep}(p, \mathcal{Q}_{\mathsf{long}}) \geq \frac{1}{k+1}\mathsf{dep}(p, \mathcal{Q}).$$

On the other hand, if $\mathsf{dep}(p, \mathcal{Q}_{\mathsf{long}}) < \frac{1}{k+1}\mathsf{dep}(p, \mathcal{Q})$, we must have $\mathsf{dep}(p, \mathcal{Q}_{\mathsf{short}}) > \frac{k}{k+1}\mathsf{dep}(p, \mathcal{Q})$. In this case, we have

$$\mathsf{dep}(p^*, \mathcal{Q}) \geq \mathsf{dep}(p_2^*, \mathcal{Q}) \geq \mathsf{dep}(p_2^*, \mathcal{Q}_{\mathsf{short}}) \geq \frac{1}{k} \cdot \mathsf{dep}(p, \mathcal{Q}_{\mathsf{short}}) > \frac{1}{k+1} \cdot \mathsf{dep}(p, \mathcal{Q}).$$

Therefore, we always have $\mathsf{dep}(p^*, \mathcal{Q}) \geq \frac{1}{k+1} \cdot \mathsf{dep}(p, \mathcal{Q})$. ◀

The data structure for maintaining p_1^* can be constructed in $O(|\mathcal{Q}_{\mathsf{long}}| \log |\mathcal{Q}_{\mathsf{long}}|)$ time and updated in $O(\log |\mathcal{Q}_{\mathsf{long}}|)$ time, by Lemma 6. Furthermore, the data structure for maintaining p_2^* can be constructed in $O(|\mathcal{Q}_{\mathsf{short}}|^{1+1/(k+1)} \log |\mathcal{Q}_{\mathsf{short}}|)$ time and updated in $O(|\mathcal{Q}_{\mathsf{short}}|^{1/(k+1)} \log |\mathcal{Q}_{\mathsf{short}}|)$ time. Since $|\mathcal{Q}_{\mathsf{long}}| = O(n)$ and $|\mathcal{Q}_{\mathsf{short}}| = O(n/r)$, for each slab data structure, the preprocessing time is $O(n \log n + (n/r)^{1+1/(k+1)} \log(n/r))$ and the update time is $O(\log n)$ for long rectangles and $O((n/r)^{1/(k+1)} \log(n/r))$ for short rectangles. This implies that our overall data structure has preprocessing time $O(rn \log n + r(n/r)^{1+1/(k+1)} \log(n/r))$ and update time $O(r \log n + (n/r)^{1/(k+1)} \log(n/r))$. By setting $r = n^{1/(k+2)}$, we have the desired $\frac{1}{k+1}$-approximation data structure with $O(n^{1/(k+2)} \log n)$ amortized update time and $O(n^{1+1/(k+2)} \log n)$ preprocessing time.

▶ **Theorem 1.** *For every $k \in \mathbb{Z}^+$, there exists a $\frac{1}{k}$-approximate dynamic maximum-depth data structure for axis-parallel rectangles with $O(n^{1/(k+1)} \log n)$ amortized update time.*

4 Dynamic maximum-depth for disks

We now describe our dynamic maximum-depth data structure for disks. The main idea underlying our result is to reduce the maximum-depth problem to *discrete* maximum depth.

Suppose we want to design a $(\frac{1}{2} - \varepsilon)$-approximate maximum-depth data structure for disks, where $\varepsilon > 0$ is a constant. Without loss of generality, we assume that ε is sufficiently small, say, $\varepsilon < 0.1$. Let δ be a sufficiently large integer such that $\frac{1}{\delta} \leq 1 - \cos \varepsilon\pi$. For a disk D in $\mathbb{R}^2$ with center (x, y) and radius r, we define

$$\Gamma_\delta(D) = \{(x - 3r + ir/\delta, y - 3r + jr/\delta) \in \mathbb{R}^2 : i, j \in [6\delta]\},$$

and call the points in $\Gamma_\delta(D)$ the *companion points* of D. For a set $\mathcal{D}$ of disks, write $\Gamma_\delta(\mathcal{D}) = \bigcup_{D \in \mathcal{D}} \Gamma_\delta(D)$. The set of companion points is the discrete point set for which our data structure dynamically maintains depth. The following fact is straightforward.

▶ **Fact 10.** *Let D be a disk and S be a set of points in D. There exists a circular sector X of D with angle $(1 - 2\varepsilon)\pi$ such that $|S \cap X| \geq (\frac{1}{2} - \varepsilon) \cdot |S|$.*

Proof. Suppose we randomly sample a circular sector X of D with angle $(1 - 2\varepsilon)\pi$, from the uniform distribution over the space of all such sectors. The probability that a specific point $p \in S$ is contained in X is 1 if p is the center of D and is $\frac{1}{2} - \varepsilon$ otherwise. Therefore, $\mathbb{E}[|S \cap X|] \geq (\frac{1}{2} - \varepsilon) \cdot |S|$, which in turn implies that there exists a sector X of D with angle $(1 - 2\varepsilon)\pi$ for which $|S \cap X| \geq (\frac{1}{2} - \varepsilon) \cdot |S|$. ◀

▶ **Lemma 11.** *Let $\mathcal{D}$ be a set of congruent disks such that $\bigcap_{D\in\mathcal{D}} D \neq \emptyset$. Then for every $D \in \mathcal{D}$, there exists $p \in \Gamma_\delta(D)$ such that $\mathsf{dep}(p, \mathcal{D}) \geq \left(\frac{1}{2} - \varepsilon\right) \cdot |\mathcal{D}|$.*

Proof. Without loss of generality, we assume that the disks in $\mathcal{D}$ are unit disks. Let $p^* \in \bigcap_{D\in\mathcal{D}} D$ and P^* be the unit disk centered at p^*. Define $\mathsf{ctr}(\mathcal{D})$ as the set of the centers of the disks in $\mathcal{D}$. Since $p^* \in \bigcap_{D\in\mathcal{D}} D$, we have $\mathsf{ctr}(\mathcal{D}) \subseteq P^*$. By Fact 10, there is a circular sector X of P^* with angle $(1-2\varepsilon)\pi$ such that $|\mathsf{ctr}(\mathcal{D}) \cap X| \geq (\frac{1}{2} - \varepsilon) \cdot |\mathsf{ctr}(\mathcal{D})| = (\frac{1}{2} - \varepsilon) \cdot |\mathcal{D}|$. Suppose u and v are the two vertices of X on the boundary of P^*. Define o as the middle point of the segment connecting u and v, and D_o as the disk centered at o with radius $1 - \cos \varepsilon\pi$. We claim that $\mathsf{dep}(p, \mathcal{D}) \geq \left(\frac{1}{2} - \varepsilon\right) \cdot |\mathcal{D}|$ for any point $p \in D_o$. Consider an arbitrary point $p \in D_o$. Since the angle of X is $(1-2\varepsilon)\pi$, the distance between o and p^* is $\sin \varepsilon\pi$. Also, the distance between o and u (resp., v) is $\cos \varepsilon\pi$. Recall that $\varepsilon < 0.1$ by our assumption, which implies that $\sin \varepsilon\pi < \cos \varepsilon\pi$. Therefore, the distance between p and p^* is at most $\sin \varepsilon\pi + (1 - \cos \varepsilon\pi) < 1$, and the distance between p and u (resp., v) is at most $\cos \varepsilon\pi + (1 - \cos \varepsilon\pi) = 1$. Therefore, the unit disk centered at p contains points p^*, u, v, which further implies that it contains X. Consequently, the unit disks in $\mathcal{D}$ whose centers lie in X contains p. We have $|\mathsf{ctr}(\mathcal{D}) \cap X| \geq (\frac{1}{2} - \varepsilon) \cdot |\mathcal{D}|$, which then implies that $\mathsf{dep}(p, \mathcal{D}) \geq \left(\frac{1}{2} - \varepsilon\right) \cdot |\mathcal{D}|$. See Figure 2 for an illustration.

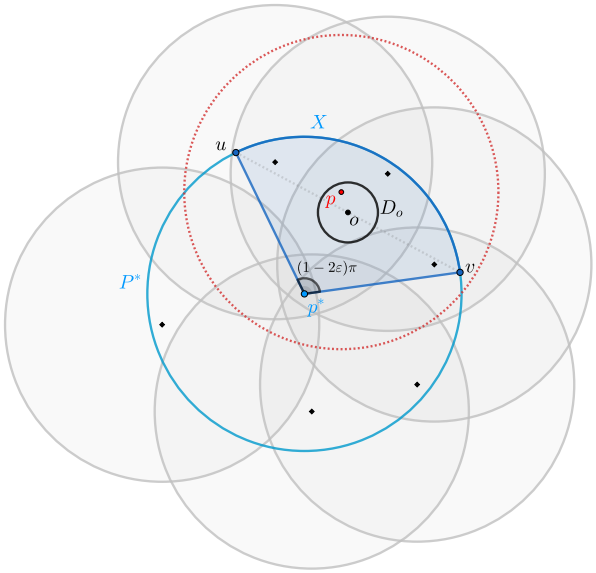

Figure 2 Illustrating the proof of Lemma 11.

Now it suffices to show $\Gamma_\delta(D) \cap D_o \neq \emptyset$ for every $D \in \mathcal{D}$. Note that the distance between o and the center of D is at most 2, since $p^* \in D$ and $o \in P^*$. Furthermore, D_o contains an axis-parallel square centered at o with side-length $1 - \cos \varepsilon\pi$, as its radius is $1 - \cos \varepsilon\pi$. Since $1 - \cos \varepsilon\pi \geq \frac{1}{\delta}$, this square then contains a point in $\Gamma_\delta(D)$, by our construction of $\Gamma_\delta(D)$. Therefore, $\Gamma_\delta(D) \cap D_o \neq \emptyset$. ◀

▶ **Corollary 12.** *For any set $\mathcal{D}$ of disks in $\mathbb{R}^2$, the following holds:*

$$\max_{p\in\Gamma_\delta(\mathcal{D})} \mathsf{dep}(p, \mathcal{D}) \geq \left(\frac{1}{2} - \varepsilon\right) \cdot \mathsf{dep}(\mathcal{D}).$$

Proof. Let $p^* \in \mathbb{R}^2$ such that $\mathsf{dep}(p^*, \mathcal{D}) = \mathsf{dep}(\mathcal{D})$, and $\mathcal{D}^* = \{D \in \mathcal{D} : p^* \in D\}$. Suppose $D_0 \in \mathcal{D}^*$ is the smallest disk in $\mathcal{D}^*$. For each disk $D \in \mathcal{D}^*$, we can find a smaller disk $D' \subseteq D$ with the same radius as D_0 such that $p^* \in D'$. Let $\mathcal{D}'$ be the set of all these disks. Then $\mathcal{D}'$

is a set of congruent disks containing p^*, and $\mathsf{dep}(p, \mathcal{D}') \leq \mathsf{dep}(p, \mathcal{D}^*)$ for any $p \in \mathbb{R}^2$. The former implies that $\bigcap_{D \in \mathcal{D}'} D \neq \emptyset$. Furthermore, we have $D_0 \in \mathcal{D}'$. By Lemma 11, there exists $p \in \Gamma_\delta(D_0)$ such that $\mathsf{dep}(p, \mathcal{D}') \geq (\frac{1}{2} - \varepsilon) \cdot |\mathcal{D}'| = (\frac{1}{2} - \varepsilon) \cdot |\mathcal{D}^*| = (\frac{1}{2} - \varepsilon) \cdot \mathsf{dep}(\mathcal{D})$. This proves the corollary. ◀

Using this corollary, we can reduce the task of maintaining a $(\frac{1}{2} - \varepsilon)$-approximation of the maximum depth of disks to the dynamic *discrete* maximum-depth problem for disks. Let $\mathcal{D}$ be a dynamic set of disks. Corollary 12 implies that $\max_{p \in S} \mathsf{dep}(p, \mathcal{D}) \geq (\frac{1}{2} - \varepsilon) \cdot \mathsf{dep}(\mathcal{D})$, where $S = \Gamma_\delta(\mathcal{D})$. Therefore, it suffices to consider the dynamic discrete maximum-depth instance with point set S and disk set $\mathcal{D}$.

4.1 Dynamic discrete maximum depth for disks

In this section, we design a dynamic discrete maximum-depth data structure for disks with $n^{2/3} \log^{O(1)} n$ amortized update time. Via the standard lifting argument, the dynamic discrete maximum-depth problem for disks can be reduced to the same problem for 3D halfspaces. To construct the discrete maximum-depth data structure, we first need a dynamic *depth-query* data structure for halfspaces. Specifically, such a data structure maintains a dynamic set $\mathcal{H}$ of hyperplanes and can return, for a query point $q \in \mathbb{R}^3$, the value of $\mathsf{dep}(q, \mathcal{H})$.

▶ **Lemma 13.** *There exists an dynamic depth-query data structure for 3D halfspaces with $n^{2/3} \log^{O(1)} n$ query time and $\log^{O(1)} n$ amortized update time. The data structure can be built in $n \log^{O(1)} n$ time.*

Proof. By duality between points and halfspaces, the depth-query problem is equivalent to the range-counting problem: store a dynamic set S of points in $\mathbb{R}^3$ such that for a query halfspace H, one can return the value $|S \cap H|$. A dynamic 3D halfspace range-counting data structure with $n^{2/3} \log^{O(1)} n$ query time and $\log^{O(1)} n$ amortized update time can be directly obtained using the dynamic partition tree given by Matoušek [15]. ◀

Let S be the dynamic set of points and $\mathcal{H}$ be the dynamic set of halfspaces, and we want to maintain $\max_{p \in S} \mathsf{dep}(p, \mathcal{H})$. We build the dynamic depth-query data structure in Lemma 13 for $\mathcal{H}$. We store the points in S in a standard partition tree $\mathcal{T}$ [15]. The tree $\mathcal{T}$ has $|S| \log^{O(1)} |S|$ nodes and can be built in $|S| \log^{O(1)} |S|$ time. The depth of $\mathcal{T}$ is $\log^{O(1)} |S|$ and the leaves of $\mathcal{T}$ one-to-one correspond to the points in S. Each node v of $\mathcal{T}$ corresponds to a subset $S(v) \subseteq S$, which consists of the points on the leaves of the subtree rooted at v. Furthermore, given any halfspace H in $\mathbb{R}^3$, one can find $k = |S|^{2/3} \log^{O(1)} |S|$ nodes $v_1, \ldots, v_k$ of $\mathcal{T}$ in $|S|^{2/3} \log^{O(1)} |S|$ time such that $S \cap H = \bigcup_{i=1}^{k} S(v_i)$ and the sets $S(v_1), \ldots, S(v_k)$ are pairwise disjoint; these nodes are called the *canonical nodes* for H. For each node v, we maintain two fields, $\sigma(v)$ and $\mu(v)$. The fields $\sigma(v)$ satisfies the following invariant: for any point $p \in S$, the sum of $\sigma(v)$ over all nodes v satisfying $p \in S(v)$ is equal to $\mathsf{dep}(p, \mathcal{H})$. The field $\mu(v)$ is defined as

$$\mu(v) = \begin{cases} \sigma(v) & \text{if } v \text{ is a leaf,} \\ \sigma(v) + \max_{u \in \mathsf{ch}(v)} \mu(u) & \text{otherwise,} \end{cases}$$

where $\mathsf{ch}(v)$ is the set of children of v. By the invariant for the σ-fields, we see that the μ-field of the root of $\mathcal{T}$ is just equal to $\max_{p \in S} \mathsf{dep}(p, \mathcal{H})$.

Halfspace insertion/deletion. For a halfspace insertion/deletion, we do not need to change the partition tree $\mathcal{T}$ itself; instead, we need to update the σ-fields and μ-fields. Let H be a halfspace to be inserted. We find the canonical nodes $v_1, \ldots, v_k$ for H. Then we increase the fields $\sigma(v_1), \ldots, \sigma(v_k)$ by 1. We also update the μ-fields of all ancestors of $v_1, \ldots, v_k$. Note that if a node is not an ancestor of any of $v_1, \ldots, v_k$, then its μ-field is not changed. The deletion of a halfspace can be handled in the same way, with the only difference that we decrease the fields $\sigma(v_1), \ldots, \sigma(v_k)$ by 1. The update time is $|S|^{2/3} \log^{O(1)} |S| = n^{2/3} \log^{O(1)} n$. Besides, we also need to update the depth-query data structure for $\mathcal{H}$, which takes $|\mathcal{H}|^{2/3} \log^{O(1)} |\mathcal{H}| = n^{2/3} \log^{O(1)} n$ time as well.

Point insertion/deletion. To delete a point p from S, we can directly remove the leaf v of $\mathcal{T}$ corresponding to p, and update the μ-fields of all ancestors of v. This takes $\log^{O(1)} n$ time. To handle point insertions, we apply the classical logarithmic method [4]. This method, instead of using one partition tree, stores S in $O(\log |S|)$ partition trees each of which corresponds to a subset of S whose size is a power of 2. The only problem we need to solve here is how to efficiently merge two partition trees storing subsets of S with size 2^i into a larger partition tree $\mathcal{T}$, with the σ-fields and μ-fields. The tree $\mathcal{T}$ itself can be built in $2^i \cdot i^{O(1)}$ time. To compute the σ-fields and μ-fields for the nodes of $\mathcal{T}$, what we do is the following. Let $S' \subseteq S$ be the subset $\mathcal{T}$ stores. We use the depth-query data structure to obtain $\mathsf{dep}(p, \mathcal{H})$ for all $p \in S'$. For each leaf v of $\mathcal{T}$, we set $\sigma(v) = \mathsf{dep}(p, \mathcal{H})$, where $p \in S'$ is the point corresponding to v. We set $\sigma(v) = 0$ for all internal nodes v of $\mathcal{T}$. Clearly, the invariant for the σ-fields holds. Using the σ-fields, we then compute the μ-field for every node of $\mathcal{T}$ in a bottom-up order. The most time-consuming part in this procedure is the depth queries, which takes $|S'| \cdot |\mathcal{H}|^{2/3} \log^{O(1)} |\mathcal{H}| = 2^i n^{2/3} \log^{O(1)} n$ time. As such, the amortized update time for a point insertion is $n^{2/3} \log^{O(1)} n$.

▶ **Lemma 14.** *There exists a dynamic discrete maximum-depth data structure for disks with $n^{2/3} \log^{O(1)} n$ amortized update time for insertions/deletions of points and disks; here n is the total number of points and disks in the instance.*

▶ **Theorem 2.** *For any constant $\varepsilon > 0$, there exists a $(\frac{1}{2} - \varepsilon)$-approximate dynamic maximum-depth data structure for disks with $n^{2/3} \log^{O(1)} n$ amortized update time.*

Proof. We just build the data structure of Lemma 14 on the point set $S = \Gamma_\delta(\mathcal{D})$ and the disk set $\mathcal{D}$. The data structure maintains a point $p^* \in S$ such that $\mathsf{dep}(p^*, \mathcal{D}) = \max_{p \in S} \mathsf{dep}(p, \mathcal{D})$ and thus $\mathsf{dep}(p^*, \mathcal{D}) \geq (\frac{1}{2} - \varepsilon) \cdot \mathsf{dep}(\mathcal{D})$ by Corollary 12. Each insertion (resp., deletion) on $\mathcal{D}$ corresponds to $O(1)$ insertions (resp., deletions) on S and one insertion (resp., deletion) on $\mathcal{D}$. Therefore, the update time is $O(n^{2/3} \log^{O(1)} n)$ in total. ◀

We remark that our data structure for disks can be generalized to balls in higher dimensions. Indeed, the proof of Fact 10 holds for balls in any fixed dimension. To solve dynamic discrete maximum depth for balls in $\mathbb{R}^d$, one can reduce to the problem for halfspaces in $\mathbb{R}^{d+1}$ and use partition trees in $\mathbb{R}^{d+1}$. The update time becomes $n^{d/(d+1)} \log^{O(1)} n$.

4.2 Generalization to fat objects

In this section, we discuss how our reduction from the dynamic maximum-depth problem to its discrete counterpart works for general fat objects (where the approximation ratio depends on the fatness of the objects).

For a α-fat object O in $\mathbb{R}^d$ with whose center $(x_1 \cdots, x_d)$ and in-radius r, we define its *companion points* as

$$\Gamma_\alpha(O) = \left\{(x_1 \pm \sqrt{2} i_1 r, \cdots, x_d \pm \sqrt{2} i_d r) : i_1, \cdots, i_d \in \left[\lceil \sqrt{2}\alpha \rceil\right]\right\}.$$

The key observation of the reduction for general fat objects is the following fact.

▶ **Fact 15.** *A d-dimensional ball with center $(x_1 \cdots, x_d)$ and radius $2\alpha r$ can be covered by balls with centers in $\Gamma_\alpha(O)$ and radii r.*

▶ **Corollary 16.** *For any set $\mathcal{O}$ of α-fat objects in $\mathbb{R}^d$, the following holds:*

$$\max_{p \in \Gamma_\alpha(\mathcal{O})} \mathsf{dep}(p, \mathcal{O}) \geq \frac{1}{\left(2\lceil \sqrt{2}\alpha \rceil\right)^d} \cdot \mathsf{dep}(\mathcal{O}).$$

Proof. Let $p^* \in \mathbb{R}^d$ such that $\mathsf{dep}(p^*, \mathcal{O}) = \mathsf{dep}(\mathcal{O})$, and $\mathcal{O}^* = \{O \in \mathcal{O} : p^* \in O\}$. Suppose $O_0 \in \mathcal{O}^*$ is the smallest object in $\mathcal{O}^*$, i.e., O_0 has the smallest in-radius, which is assumed to be 1 without loss of generality. For each object $O \in \mathcal{O}^*$, we can find a unit ball $O' \subseteq O$ as following: the unit ball centered on the line segment between p^* and $\mathsf{ctr}(O)$, which is tangent to all tangent hyperplanes of O at p^*. (See Figure 3 for an illustration.)

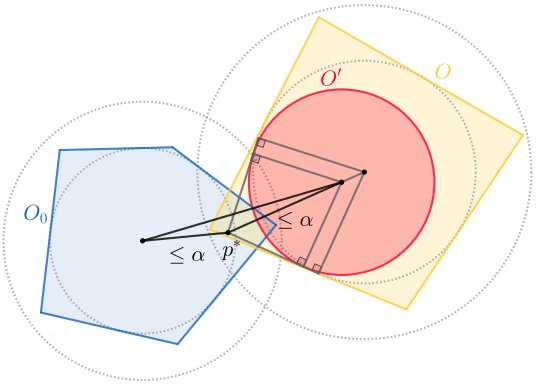

Figure 3 Illustrating the proof of Corollary 16 in $\mathbb{R}^2$.

Since O_0 contains p^*, we have the distance between p^* and $\mathsf{ctr}(O_0)$ is at most α. Moreover, it is clear that the distance between p^* and $\mathsf{ctr}(O')$ is at most α. Therefore, the distance between $\mathsf{ctr}(O')$ and $\mathsf{ctr}(O_0)$ is at most 2α, which means that the centers of these unit balls lie within a ball with center $\mathsf{ctr}(O_0)$ and radius 2α. By Fact 15, we can cover this ball by unit balls with centers in $\Gamma_\alpha(O_0)$. Therefore, by the pigeonhole principle, we have

$$\max_{p \in \Gamma_\alpha(\mathcal{O})} \mathsf{dep}(p, \mathcal{O}) \geq \max_{p \in \Gamma_\alpha(\mathcal{O}_0)} \mathsf{dep}(p, \mathcal{O}) \geq \frac{1}{|\Gamma_\alpha(\mathcal{O}_0)|} \cdot \mathsf{dep}(\mathcal{O}) = \frac{1}{\left(2\lceil \sqrt{2}\alpha \rceil\right)^d} \cdot \mathsf{dep}(\mathcal{O}),$$

which completes the proof. ◀

As a concluding remark, we note that our reduction for general fat objects relies on the following question: Given a ball of radius 2α in $\mathbb{R}^d$, how many unit balls are needed to cover it? We employ a rather general method in the construction of $\Gamma_\alpha(O)$, to illustrate the main idea, and the constant $\left(2\lceil \sqrt{2}\alpha \rceil\right)^d$ in Corollary 16 can be improved for specific values of α and d. For example, in the case of disk ($d = 2$ and $\alpha = 1$), as proved in [5], only 7 unit disks are needed, instead of 16 in Corollary 16. This optimization problem for particular values of α and d may have independent interest.

Abstract

We cluster a set of trajectories $\mathcal{T}$ using subtrajectories of $\mathcal{T}$. We require for a clustering C that any two subtrajectories $(\mathcal{T}[a,b], \mathcal{T}[c,d])$ in a cluster have disjoint intervals $[a,b]$ and $[c,d]$. Clustering quality may be measured by the number of clusters, the number of vertices of $\mathcal{T}$ that are absent from the clustering, and by the Fréchet distance between subtrajectories in a cluster.

A Δ-cluster of $\mathcal{T}$ is a cluster $\mathcal{P}$ of subtrajectories of $\mathcal{T}$ with a centre $P \in \mathcal{P}$, where all subtrajectories in $\mathcal{P}$ have Fréchet distance at most Δ to P. Buchin, Buchin, Gudmundsson, Löffler and Luo present two $O(n^2 + nm\ell)$-time algorithms: $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ computes a *single* Δ-cluster where P has at least ℓ vertices and maximises the cardinality m of $\mathcal{P}$. $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ computes a *single* Δ-cluster where $\mathcal{P}$ has cardinality m and maximises the complexity ℓ of P.

In this paper, which is a mixture of algorithms engineering and theoretical insights, we use such maximum-cardinality clusters in a greedy clustering algorithm. We first provide an efficient implementation of $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ and $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ that significantly outperforms previous implementations. Next, we use these functions as a subroutine in a greedy clustering algorithm, which performs well when compared to existing subtrajectory clustering algorithms on real-world data. Finally, we observe that, for fixed Δ and $\mathcal{T}$, these two functions always output a point on the Pareto front of some bivariate function $\theta(\ell, m)$. We design a new algorithm $\mathbf{PSC}(\Delta, \mathcal{T})$ that in $O(n^2 \log^4 n)$ time computes a 2-approximation of this Pareto front. This yields a broader set of candidate clusters, with comparable quality to the output of the previous functions. We show that using $\mathbf{PSC}(\Delta, \mathcal{T})$ as a subroutine improves the clustering quality and performance even further.

1 Introduction

Trajectories describe the movement of objects. The moving objects are modeled as a sequence of locations. Trajectory data often comes from GPS samples, which are being generated on an incredible scale through cars, cellphones, and other trackers. We focus on *subtrajectory clustering* where clusters are sets of subtrajectories. The goal is to create few clusters and to ensure that subtrajectories within a cluster have low pairwise discrete Fréchet distance. This algorithmic problem has been studied extensively [1, 8, 10, 12, 13, 15, 16, 19, 21, 22, 20, 24, 27, 30] in both theoretical and applied settings. For surveys, see [7] and [28].

Subtrajectory clustering. Comparing whole trajectories gives little information about shared structures. Consider two trajectories T_1 and T_2 that represent individuals who drive the same route to work, but live in different locations. For almost all distance metrics, the distance between T_1 and T_2 is large because their endpoints are (relatively) far apart. However, T_1 and T_2 share similar subtrajectories. Subtrajectory clustering allows us to model a wide range of behaviours: from detecting commuting patterns, to flocking behaviour, to congestion areas [12]. In the special case where trajectories correspond to traffic on a known road network, trajectories can be mapped to the road network. In many cases, the underlying road network might not be known (or it may be too dense to represent). In such cases, it is interesting to construct a sparse representation of the underlying road network based on the trajectories. The latter algorithmic problem is called *map construction*, and it has also been studied extensively [2, 6, 3, 14, 17, 25, 26]. We note that subtrajectory clustering algorithms may be used for map construction: if each cluster is assigned one centre, then the collection of centres can be used to construct an underlying road network [9, 10].

Related work. BBGLL [12] introduce the following problem. Rather than clustering $\mathcal{T}$, their goal is to compute a *single* cluster. Given $\mathcal{T}$, a Δ-*cluster* is any pair $(P, \mathcal{P})$ where:

- P is a subtrajectory of a trajectory in $\mathcal{T}$,
- $\mathcal{P}$ is a set of subtrajectories, where for all $\mathcal{T}[a,b], \mathcal{T}[c,d] \in \mathcal{P}$, $[a,b] \cap [c,d] = \emptyset$,
- and, for all $P' \in \mathcal{P}$, the Fréchet distance between P and P' is at most Δ.

See Figure 1. They define two functions that each output a single Δ-cluster $(P, \mathcal{P})$:

- $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ requires that $|P| = \ell$ and maximises $|\mathcal{P}|$.
- $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ requires that $|\mathcal{P}| = m$ and maximises $|P|$.

If $|P| = \ell$ and $|\mathcal{P}| = m$, their algorithms use $O(n^2 + nm\ell)$ time and $O(n\ell)$ space.

AFMNPT [1] propose a clustering framework. They define a clustering C as any set of clusters. They propose a scoring function with constants (c_1, c_2, c_3) that respectively weigh: the number of clusters, the radius of each cluster, and the number of uncovered vertices. Their implement a heuristic algorithm that uses this scoring function.

BBDFJSSSW [9] do map construction. They compute a set of Δ-clusters C for various Δ. For each $(P, \mathcal{P}) \in C$, they use P as a road on the map they are constructing. Thus, it may be argued that [9] does subtrajectory clustering. As a preprocessing step, they implement $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$. Choosing various ℓ and Δ, they compute a collection S of "candidate" clusters. They greedily select a cluster $(P, \mathcal{P}) \in S$, add it to the clustering, and remove all subtrajectories in $\mathcal{P}$ from all remaining clusters in S. For a cluster $(Q, \mathcal{Q}) \in S$, this may split a $Q' \in \mathcal{Q}$ into two subtrajectories. BBGHSSSSSW [10] give improved implementations.

ABCD [4] do not require that for all $\mathcal{T}[a,b], \mathcal{T}[c,d] \in \mathcal{P}$, $[a,b] \cap [c,d] = \emptyset$. They do require that the final clustering C has no uncovered vertices, and that for each cluster $(P, \mathcal{P})$, $|P| \leq \ell$ for some given ℓ. For any Δ, denote by k_Δ the minimum-sized clustering that meets

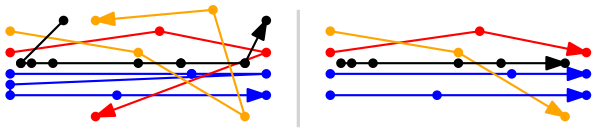

Figure 1 (left) Four trajectories. (right) Five subtrajectories $\mathcal{P}$. Depending on the choice of $P \in \mathcal{P}$, we may get five different clusters $(P, \mathcal{P})$.

their requirements. Their randomised polynomial-time algorithm computes a clustering of $O(\Delta)$-clusters of size $\tilde{O}(k_\Delta \ell)$. BCD [8] give polynomial-time clustering algorithm of $O(\Delta)$-clusters of size $\tilde{O}(k_\Delta)$. Conradi and Driemel [16] implement an $\tilde{O}(\ell^2 n^4 + k_\Delta \ell n^4)$-time algorithm that computes a set of $O(\Delta)$-clusters of size $O(k_\Delta \log n)$.

Contribution. Our contribution is threefold. First, in Section 5, we describe an efficient implementation of $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ and $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$. We compare our implementation to all existing single-core implementations.

In Section 5 we propose that $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ produces high-quality clusters across all clustering metrics. We create a greedy clustering algorithm that fixes (ℓ, Δ) and iteratively adds the solution $(P, \mathcal{P}) = \mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ to the clustering (removing all vertices in $\mathcal{P}$ from $\mathcal{T}$). An analogous approach for $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ gives two clustering algorithms.

In Section 6 we note that the functions $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ and $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ search a highly restricted solution space, having fixed either the minimum length of the centre of a cluster or the minimum cardinality. We observe that these functions always output a cluster on the Pareto front of some bivariate function $\theta(m, \ell)$. Since points on this Pareto front give high-quality clusters, we argue that it may be beneficial to approximate all vertices of this Pareto front directly – sacrificing some cluster quality for cluster flexibility. We create a new algorithm $\mathbf{PSC}(\Delta, \mathcal{T})$ that computes in $O(n^2 \log^4 n)$ time and $O(n)$ space a set of clusters that is a 2-approximation of the Pareto font of $\theta(m, \ell)$. We show that using $\mathbf{PSC}(\Delta, \mathcal{T})$ as a subroutine for greedy clustering gives even better results.

In Section 7 we do experimental analysis. We compare our clustering algorithms to AFMNPT [1] and BBGHSSSSSW [10]. We adapt the algorithm in [10] so that it terminates immediately after computing the subtrajectory clustering. We do not compare to Conradi and Driemel [16] as their setting is so different that it produces incomparable clusters. We compare the algorithms based on their overall run time and space usage. We evaluate the clustering quality along various metrics such as the number of clusters, the average cardinality of each cluster, and the Fréchet distance between subtrajectories in a cluster. Finally, we consider the scoring function by AFMNPT [1].

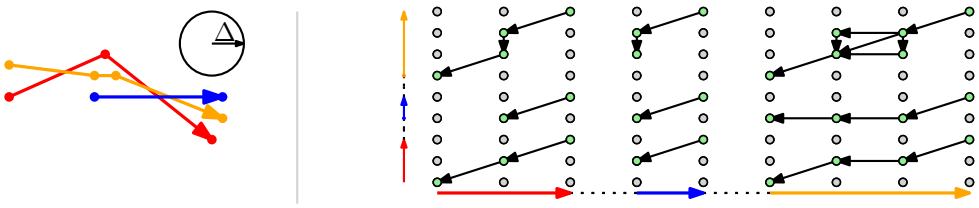

Figure 2 A set of trajectories $\mathcal{T}$ and the matrix $M_\Delta(\mathcal{T}, \mathcal{T})$ as a graph.

2 Preliminaries

The input is a set $\mathcal{T}$ of trajectories where $n = \sum_{T \in \mathcal{T}} |T|$. We denote by $\mathcal{X}$ all vertices of $T \in \mathcal{T}$. We view any trajectory T with n_T vertices as a map from $[n_T]$ to $\mathbb{R}^2$ where $T(i)$ is the i'th vertex on T. For brevity, we refer to $\mathcal{T}$ as a single trajectory obtained by concatenating all trajectories in $\mathcal{T}$ arbitrarily. A *boundary edge* in $\mathcal{T}$ is any edge in $\mathcal{T}$ between the endpoints of two consecutive trajectories. A *subtrajectory* $\mathcal{T}[a, b]$ of $\mathcal{T}$ is defined by $a, b \in [n]$ with $a \leq b$, where we require that the subcurve from $\mathcal{T}(a)$ to $\mathcal{T}(b)$ contains no boundary edge.

Fréchet distance. We first define discrete walks for pair of trajectories $P = (p_1, \ldots, p_x)$ and $T = (t_1, \ldots, t_y)$ in $\mathbb{R}^2$. We say that an ordered sequence F of points in $[x] \times [y]$ is a *discrete walk* if consecutive pair $(i, j), (s, l) \in F$ have $s \in \{i, i-1\}$ and $l \in \{j, j-1\}$. The *cost* of a discrete walk F is the maximum distance $d(P(i), Q(j))$ over $(i, j) \in F$. The discrete Fréchet distance is the minimum-cost discrete walk from (x, y) to $(1, 1)$:

$$\mathcal{D}_F(P, Q) := \min_F \text{cost}(F) = \min_F \max_{(i,j) \in F} d(P(i), Q(j)).$$

Free-space matrix. Given $\mathcal{T}$ and a value Δ, the *Free-space matrix* $M_\Delta(\mathcal{T}, \mathcal{T})$ is an $n \times n$ 01-matrix where for all $(i, j) \in [n] \times [n]$ the matrix has a zero at position i, j if $d(\mathcal{T}(i), \mathcal{T}(j)) \leq \Delta$. We use matrix notation where (i, j) denotes row i and column j. In the plane, $(0, 0)$ denotes the top left corner. We also use $M_\Delta(\mathcal{T}, \mathcal{T})$ to denote the digraph where the vertices are all $(i, j) \in [n] \times [n]$ and there exists an edge from (i, j) to (s, k) whenever (see Figure 2):

- $s \in \{i, i-1\}$ and $k \in \{j, j-1\}$, and
- $M_\Delta(\mathcal{T}, \mathcal{T})[i, j] = M_\Delta(\mathcal{T}, \mathcal{T})[s, k] = 0$.

Alt and Godeau [5] show that for any two subtrajectories $\mathcal{T}[a, b]$ and $\mathcal{T}[c, d]$: $\mathcal{D}_F(T[a, b], T[c, d]) \leq \Delta$ if and only if there is a directed path from (b, d) to (a, c).

▶ **Definition 1.** *Given Δ and $\mathcal{T}$, we say that a vertex (b, x) in $M_\Delta(\mathcal{T}, \mathcal{T})$ can* reach *row a if there exists an integer $x' \leq x$ such that there is a directed path from (b, x) to (a, x'). We denote by $\texttt{row}(b, x)$ the minimum integer a' such that (b, x) can reach row a'.*

▶ **Definition 2** (Figure 1)**.** *A cluster is any pair $(P, \mathcal{P})$ where P is a subtrajectory and $\mathcal{P}$ is a set subtrajectories with $P \in \mathcal{P}$. We require that for all $\mathcal{T}[a, b], \mathcal{T}[c, d] \in \mathcal{T}$, $[a, b] \cap [c, d] = \emptyset$. We define its* length $|P|$*,* cardinality $|\mathcal{P}|$*, and* coverage $\texttt{cov}(P, \mathcal{P}) = \bigcup_{S \in \mathcal{P}} S$.

Note that we follow [1, 9, 10, 12] and consider only *disjoint* clusterings, meaning $\forall (P, \mathcal{P}') \in C$, $\forall \mathcal{T}[a, b], \mathcal{T}[c, d] \in \mathcal{P}$, the intervals $[a, b]$ and $[c, d]$ are disjoint. For brevity, we say that a Δ-cluster is any cluster $(P, \mathcal{P})$ where $\forall P' \in \mathcal{P} : \mathcal{D}_F(P, P') \leq \Delta$.

▶ **Definition 3.** *A* clustering C *is a set of clusters. Its* coverage *is* $\texttt{cov}(C) := \bigcup_{(P,\mathcal{P}) \in C} \texttt{cov}(P, \mathcal{P})$.

AFMNPT [1] propose a cost function to determine the quality of a clustering C. We distinguish between *k-centre* and *k-means* clustering:

▶ **Definition 4.** *Given constants* (c_1, c_2, c_3) *,* $\texttt{Score}(C)$ *is a sum that weights three terms:*

1. *The number of clusters in* C*:* $c_1|C|$.
2. *The chosen cost function for the clustering. I.e.,*
   $c_2 \max_{(P,\mathcal{P})\in C} \text{cen}(P,\mathcal{P}) = c_2 \max_{(P,\mathcal{P})\in C} \max_{P'\in\mathcal{P}} \mathcal{D}_F(P,P')$ *when doing* k*-centre clustering, or*
   $c_2 \sum_{(P,\mathcal{P})\in C} \text{mean}(P,\mathcal{P}) = c_2 \sum_{(P,\mathcal{P})\in C} \sum_{P'\in\mathcal{P}} \mathcal{D}_F(P,P')$ *when doing* k*-means clustering.*
3. *The fraction of uncovered points:* $c_3 \frac{|\mathcal{X}\setminus \texttt{cov}(C)|}{|\mathcal{X}|}$.

We also consider unweighted metrics: the maximal and average Fréchet distance between subtrajectories in a cluster, and the maximal and average cardinality of the clusters.

3 Data

We use five real-world data sets (see Table 1). For some of these data sets we include a subsampled version that only retains a $\frac{1}{c}$ fraction of the trajectories.

- The first three data sets are Athens-small, Chicago and Berlin, consisting of GPS samples from car traffic across these cities. These data sets are widely used benchmark tests for road map construction [2, 9, 31, 23].
- The fourth data set is the *Drifter* data set that was used for subtrajectory clustering by Driemel and Conradi [16]. It consists of GPS data from ocean drifters.
- The fifth data set is the UnID data set, which is the smallest data set used in [29].

Unfortunately, we cannot use any of the data sets in [1]. Most of these are no longer available. Those that are available are far too large. It is unknown how [1] preprocessed these.

Synthetic data. All competitor algorithms do not terminate on the larger real-world data sets, even when the time limit is 24 hours. Thus, we primarily use these sets to compare algorithmic efficiency. Our qualitative analysis uses the subsampled data sets and synthetic data. We generate data by creating a random domain X. Then, for some parameter c, we randomly select $c\%$ of the domain and invoke an approximate TSP solver. We add the result as a trajectory. This results in a collection of trajectories with many similar subtrajectories. Synthetic-A has a random domain of 200 vertices. Synthetic-B has a random domain of 100 vertices. For both of these, we consider $c \in \{50, 90, 95\}$.

Table 1 Our data sets, their sizes, and whether we subsampled a fraction of their trajectories.

Name	Real world	# of trajectories	# of vertices	Subsampled
Athens-small	yes	128	2840	no
Chicago-4	yes	222	29344	$\frac{1}{4}$'th
Chicago	yes	888	118360	no

Synthetic-B	no	100	5000 - 9500	no

4 Introducing and solving SC(m, ℓ, Δ, $\mathcal{T}$)

BBGLL [12] introduce the problem **SC**(m, ℓ, Δ, $\mathcal{T}$). The input are integers m, ℓ, Δ and a set of trajectories $\mathcal{T}$. The goal is to find a Δ-cluster $(P, \mathcal{P})$ where $|\mathcal{P}| \geq m$ and $|P| = \ell$. The problem statement may be altered by maximising m or ℓ instead. This yields the problems **SC**(max, ℓ, Δ, $\mathcal{T}$) and **SC**(m, max, Δ, $\mathcal{T}$). There exist three single-core implementations of these algorithms (the *MOVETK library* [18], *map-construct* [9] and *map-construct-rtrees* [10], a version of *map-construct* that uses r-trees). [18] uses $O(n^2)$ space and $O(n^2 + nm\ell)$ time. Both [9, 10] use $O(n\ell)$ space and $O(n^2 + nm\ell)$ time, and [10] offers running time improvements over [10]. The latter uses the semi-continuous instead of discrete Fréchet distance. On the experimental input, switching between these metrics does not change the output. We do not compare to the existing GPU-based implementation [21].

Contribution. We sketch how we optimise the BBGLL algorithm in the full version Considers two integers a, b with $\ell = b - a$ (Figure 3). It alternates between `StepFirst` which increments a, `StepSecond` which increments b, and `Query` that given $(\Delta, \ell = b - a, m)$ aims to find a Δ-cluster $(P, \mathcal{P})$ with $P = \mathcal{T}[a, b]$ and $|\mathcal{P}| = m$. We apply two ideas:

1. **Windowing.** By [12], it suffices to keep only $M_\Delta(\mathcal{T}[a, b], \mathcal{T})$ in memory. Furthermore, one may store only the $z' \in O(n\ell)$ zeroes in this sub-matrix. This is implemented in [9, 10]. By cleverly abandoning memory, our `StepFirst` deletes a row in constant time. The `StepSecond` function is then the bottleneck, as it adds a new row.
2. **Row generation.** In [12], the `StepSecond` and `Query` functions iterate over all n cells in the bottommost row of $M_\Delta(\mathcal{T}, \mathcal{T})$. By applying a range searching data structure, we instead only iterate over all zeroes in this row.

We note that map-construct-rtree [10] uses r-trees for row generation (we refer to the journal version [11]). However, we believe that the size of their r-tree implementation dominates the time and space used by their algorithm in our experiments. In the full version, we describe how to use a light-weight range tree to implement this principle.

Experiments. We compare the implementations across our data sets for a variety of choices of Δ and m. We use the implementations of **SC**(m, max, Δ, $\mathcal{T}$) so that our experiments have to fix fewer parameters. Figures 4 and 5 shows the time and space usage across a subset of our experiments. The data clearly shows that our implementation is significantly more efficient than the previous single-core implementations. It is often more than a factor 1000 more efficient in terms of runtime and memory usage. We do not provide a more extensive analysis of these results since this is not our main contribution.

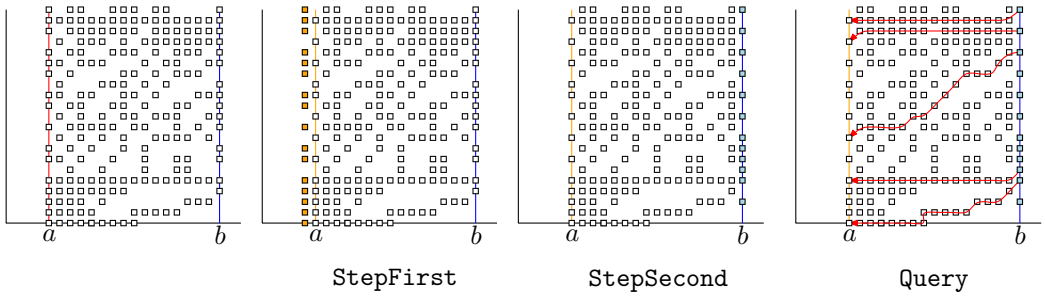

Figure 3 An overview of the algorithm in [12]. We illustrate zeroes in $M_\Delta(\mathcal{T}, \mathcal{T})$ with a square.

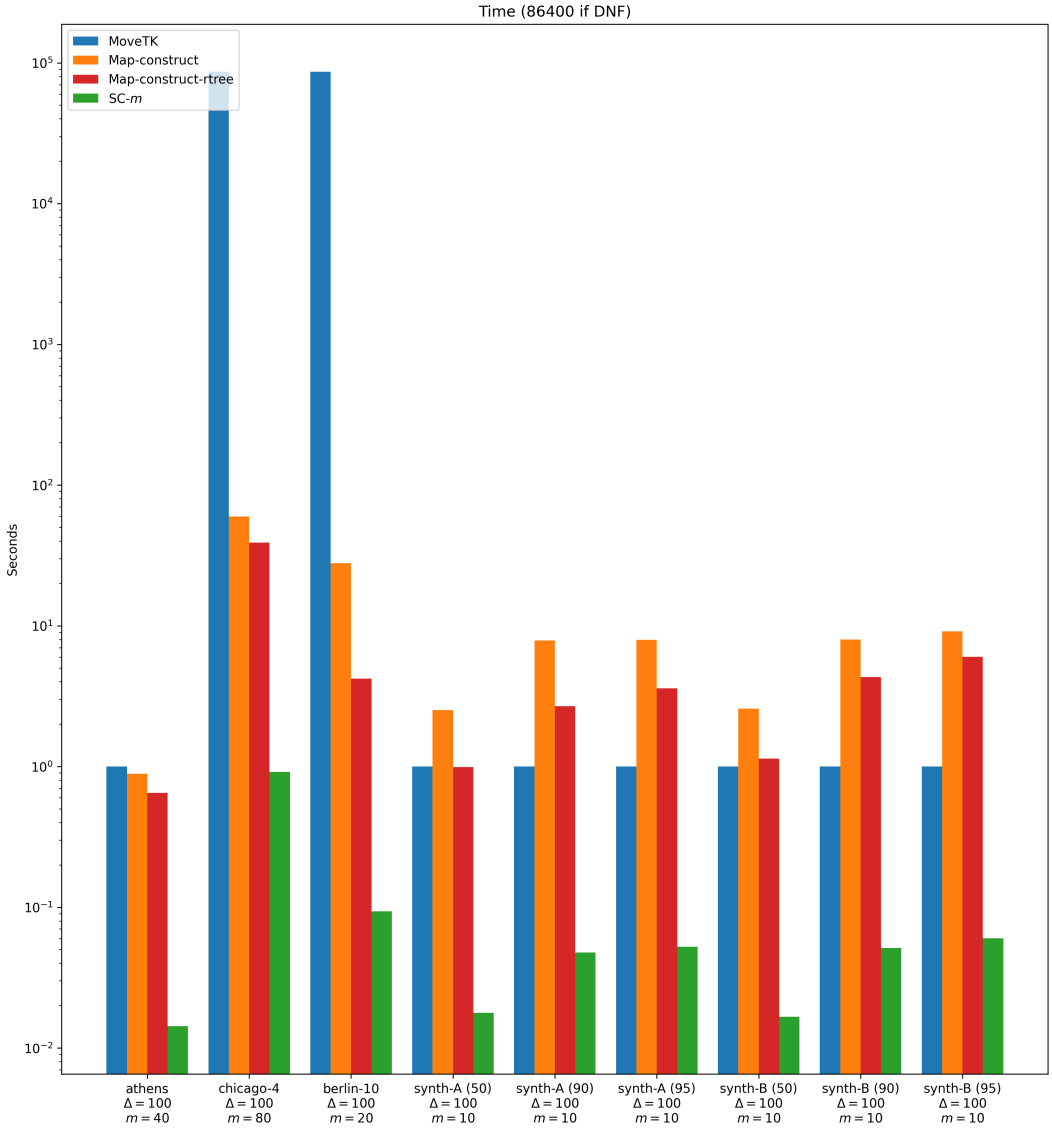

Figure 4 ■ BBGLL implementation comparison ■ Running time ■ Logarithmic scaling.

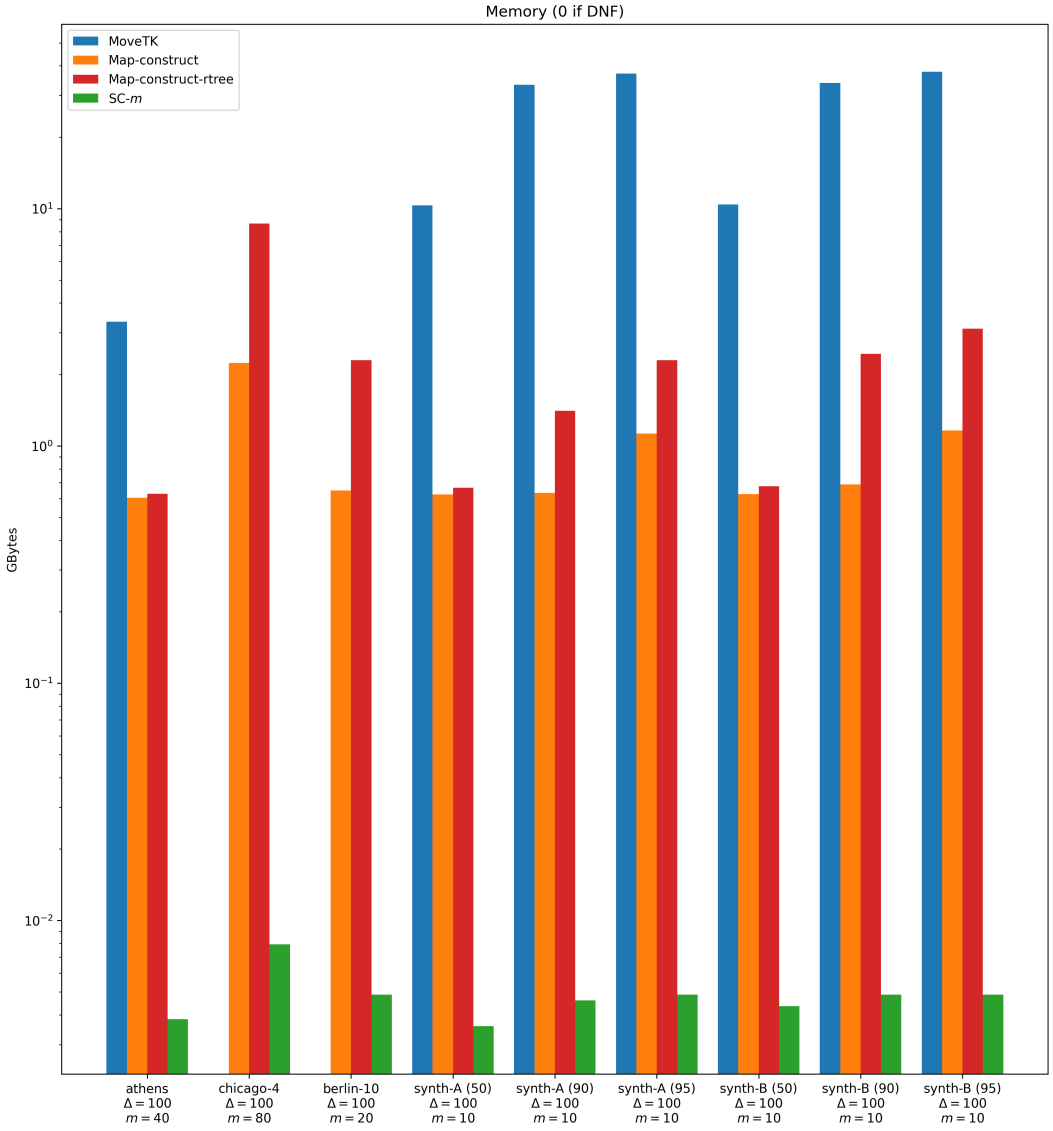

Figure 5 ■ BBGLL implementation comparison ■ Memory usage ■ Logarithmic scaling.

5 Greedy clustering using SC(max, ℓ, Δ, $\mathcal{T}$)

Our primary contribution is that we propose to use **SC**(max, ℓ, Δ, $\mathcal{T}$) in a greedy clustering algorithm. On a high level, our clustering algorithm does the following:

- We first choose the scoring function and constants (see Definition 4).
- Our input is the set of trajectories $\mathcal{T}$, some Δ, some ℓ, and an empty clustering C.
- We obtain a cluster $(P, \mathcal{P}) = \mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$, and add it to C.
- We then remove all subtrajectories in $\mathcal{P}$ from $\mathcal{T}$, and recurse.
- We continue this process until the addition of $(P, \mathcal{P})$ to C no longer increases $\texttt{Score}(C)$.

The implementation details depend on whether we are doing k-centre or k-median clustering.

5.1 k-centre clustering.

Given are (c_1, c_2, c_3) and a set of trajectories $\mathcal{T}$. We choose some integer ℓ. The k-centre clustering scoring function weighs the value: $\max_{(P,\mathcal{P})\in C} \text{cen}(P, \mathcal{P}) = \max_{(P,\mathcal{P})\in C} \max_{P'\in\mathcal{P}} \mathcal{D}_F(P, P')$.
If C is a set of Δ-clusters (we assume there exists a cluster in C whose radius is Δ) then:

$$\texttt{Score}(C) = c_1 \cdot |C| + c_2 \cdot \Delta + c_3 \cdot \frac{|\mathcal{X} \setminus \texttt{cov}(C)|}{|\mathcal{X}|}.$$

Let C be a set of Δ-clusters and $(P, \mathcal{P}) = \mathbf{SC}(\max, \ell, \Delta, \mathcal{T} - \texttt{cov}(C))$. Per construction of our algorithm, $\texttt{cov}(P, \mathcal{P}) \cap \texttt{cov}(C) = \emptyset$ and so the contribution of $(P, \mathcal{P})$ to $\texttt{Score}(C \cup \{(P, \mathcal{P})\})$ equals $c_1 - c_3 \cdot \frac{|\texttt{cov}(P,\mathcal{P})|}{|\mathcal{X}|}$. We obtain $|\texttt{cov}(P, \mathcal{P})|$ using constant additional time throughout our algorithm. This leads to the following algorithm:

▶ **Clustering 1** (SC-$\ell((c_1, c_2, c_3), \mathcal{T})$ under k-centre clustering). *We run Algorithm 1 (c_1, c_2, c_3) for exponentially increasing $\Delta \in (2, 4, \ldots)$ where the subroutine f is **SC**(max, ℓ, Δ, $\mathcal{T}$). We then output the maximum-score clustering C over all runs.*

Algorithm 1 `k_centre`(`vector` (c_1, c_2, c_3), `value` Δ, `trajectory` $\mathcal{T}$, `subroutine` f).

```
C ← ∅, T ← 𝒯.
while |T| > 0 do
    (P, 𝒫) ← the result of applying f to (Δ, T)
    if Score(C ∪ {(P, 𝒫)}) > Score(C) then
        C.add((P, 𝒫)).
        T ← T − 𝒫.
    else
        Break.
    end if
end while
return C
```

We may also fix m instead of ℓ. Or, formally:

▶ **Clustering 2** (SC-$m((c_1, c_2, c_3), \mathcal{T})$ under k-centre clustering). *We run Algorithm 1 (c_1, c_2, c_3) for exponentially increasing $\Delta \in (2, 4, \ldots)$ where the subroutine f is **SC**(m, max, Δ, $\mathcal{T}$). We then output the maximum-score clustering C over all runs.*

5.2 k-means clustering.

Our algorithm for k-means clustering is less straightforward. To get good performance we must iterate over different choices of Δ across the algorithm. Consider a clustering C and $(P, \mathcal{P}) = \mathbf{SC}(\max, \ell, \Delta, \mathcal{T} - \texttt{cov}(C))$ for some Δ. Under k-centre clustering, the more points a Δ-cluster covers, the better its scoring contribution. For k-means clustering this is no longer true as the contribution of $(P, \mathcal{P})$ to $\texttt{Score}(C \cup \{(P, \mathcal{P})\})$ equals:

$$\text{Contribution of } (P, \mathcal{P}) \text{ to } \texttt{Score}(C) = c_1 - c_3 \cdot \frac{|\texttt{cov}(P, \mathcal{P})|}{|\mathcal{X}|} + \sum_{P' \in \mathcal{P}} c_2 \cdot \mathcal{D}_F(P, P').$$

We abuse the fact that subtrajectories share no vertices to simplify the above expression to:

$$\text{Contribution of } (P, \mathcal{P}) \text{ to } \texttt{Score}(C) = c_1 + \sum_{P' \in \mathcal{P}} \left(c_2 \cdot \mathcal{D}_F(P, P') - c_3 \frac{|P'|}{|\mathcal{X}|} \right).$$

Consider a set of "candidate" clusters S. To select the best cluster from S, we use the same greedy set cover technique as [1]. We assign to every cluster a evaluation value. This is the ratio between how much it reduces the score, and how much it increases the score. I.e.,

$$\texttt{evaluation}(P, \mathcal{P}) = \frac{\sum_{P' \in \mathcal{P}} c_3 \frac{|P'|}{|\mathcal{X}|}}{c_1 + \sum_{P' \in \mathcal{P}} c_2 \cdot \mathcal{D}_F(P, P')}$$

We then select the cluster with the best evaluation among all $(P, \mathcal{P}) \in S$.

▶ **Clustering 3** (SC-$\ell((c_1, c_2, c_3), \mathcal{T})$ under k-means clustering). *We run Algorithm 2 where the subroutine f is $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$.*

▶ **Clustering 4** (SC-$m((c_1, c_2, c_3), \mathcal{T})$ under k-means clustering). *We run Algorithm 2 where the subroutine f is $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$.*

Algorithm 2 `k_means`(`vector` (c_1, c_2, c_3), `trajectory` $\mathcal{T}$, `subroutine` f).

```
C ← ∅, T ← 𝒯.
while |T| > 0 do
    (P, 𝒫) ← null
    for Δ ∈ (2, 4, ...) do
        (Q, 𝒬) ← the result of applying f to (Δ, 𝒯)
        if evaluation(Q, 𝒬) > evaluation(P, 𝒫) then
            (P, 𝒫) ← (Q, 𝒬).
        end if
    end for
    if Score(C ∪ {(P, 𝒫)}) > Score(C)) then
        C.Add((P, 𝒫)).
        T ← T − 𝒫.
    else
        Break.
    end if
end while
return C
```

6 A new algorithm as a subroutine

Our previous clusterings 1-4 fix a parameter ℓ (or m) and subsequently *only* produce clusters $(P, \mathcal{P})$ of maximal cardinality with $|P| = \ell$ (or of maximum length with $|\mathcal{P}| = m$).

This approach has three clear downsides:

1. To find a suitable ℓ (or m) you have to train the algorithm on a smaller data set.
2. Using multiple values of ℓ (or m) to broaden the search space is computationally expensive.
3. Even if we fix constantly many choices for ℓ and m, the corresponding algorithm has a heavily restricted solution space which affects the quality of the output.

To alleviate these downsides, we design a new algorithm based on the following observation:

▶ **Definition 5.** *For fixed $(\Delta, \mathcal{T})$, we define a bivariate Boolean function $\theta(m, \ell)$ where $\theta(m, \ell)$ is 1 if and only if there exists a Δ-cluster $(P, \mathcal{P})$ of $\mathcal{T}$ with $m = |\mathcal{P}|$ and $\ell = |P|$.*

The functions $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ and $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ always output a Δ-cluster $(P, \mathcal{P})$ where $\theta(|P|, |\mathcal{P}|)$ lies on the Pareto Front of $\theta(\cdot, \cdot)$. If clusters on the Pareto front of $\theta(\cdot, \cdot)$ are good candidates to include in a clustering, then it may be worthwhile to directly compute an approximation of this Pareto front as a candidate set:

▶ **Definition 6.** *Given $(\Delta, \mathcal{T})$, a set of Δ-clusters S is a 2-approximate Pareto front if for every Δ-cluster $(P, \mathcal{P})$ there exists a $(Q, \mathcal{Q}) \in S$ with: $|\mathcal{P}| \leq |\mathcal{Q}|$ and $|P| \leq 2|Q|$.*

Our new algorithm, $\mathbf{PSC}(\Delta, \mathcal{T})$, *iterates* over a 2-approximate Pareto front. Storing this front explicitly uses $O(n^2 \log n)$ space. Instead, we generate these clusters on the fly.

High-level description. Let $B(\mathcal{T})$ be a balanced binary tree over $\mathcal{T}$. Let $S(\Delta, \mathcal{T})$ start out as empty. Our algorithm $\mathbf{PSC}(\Delta, \mathcal{T})$ (defined by Algorithm 3) does the following:

- For each inner node in B, denote by $\mathcal{T}[a, b]$ the corresponding subtrajectory of $\mathcal{T}$.
- For every prefix or suffix P of $\mathcal{T}[a, b]$, let $(P, \mathcal{P})$ be a Δ-cluster maximising $|\mathcal{P}|$.
- We add $(P, \mathcal{P})$ to $S(\Delta, \mathcal{T})$.

Computing all prefix clusters for $\mathcal{T}[a, b]$. Given a trajectory $\mathcal{T}[a, b]$ and our current set $S(\Delta, \mathcal{T})$, we simultaneously compute for all prefixes P of $\mathcal{T}[a, b]$ a maximum-cardinality cluster $(P, \mathcal{P})$ and add this cluster to $S(\Delta, \mathcal{T})$. We define an analogue of Definition 1:

▶ **Definition 7.** *Consider row a in $M_\Delta(\mathcal{T}, \mathcal{T})$. For $(x, y) \in M_\Delta(\mathcal{T}, \mathcal{T})$ let $\texttt{col}_a(x, y)$ be the maximum column $d \leq y$ such that there exists a directed path from (x, y) to (a, d).*

Given $\mathcal{T}[a, b]$ we initialize our algorithm by storing integers a and $c \leftarrow a$. We increment c and maintain for all $y \in [n]$ the value $\texttt{col}_a(c, y)$. This uses $O(n)$ space, as does storing row c. Given this data structure, we alternate between a `StepSecond` and `Query` subroutine:

`StepSecond`: We increment c by 1. For each $y \in [n]$, we check if $d(\mathcal{T}(c), \mathcal{T}(y)) > \Delta$. If it is then (c, y) is an isolated vertex in the graph $M_\Delta(\mathcal{T}, \mathcal{T})$. Thus, there exists no directed path from (c, y) to any vertex in row a and we set $\texttt{col}_a(c, y) = -\infty$. Otherwise, $\texttt{col}_a(c, y) = \max\{\texttt{col}_a(\alpha, \beta) \mid \alpha \in \{c, c-1\}, \beta \in \{y, y-1\}\}$ which we compute in $O(1)$ time.

`Query`: For a prefix $P = \mathcal{T}[a, c]$ of $\mathcal{T}[a, b]$ we compute a maximum-cardinality Δ-cluster $(P, \mathcal{P})$ using the values $\texttt{col}_a(c, y)$ (see Algorithm 4).

Note that Algorithm 4 is essentially the same as the algorithm in [12] that we described in Section 5. Thus, it computes a maximum-cardinality cluster. The key difference is that we, through $\texttt{col}_a(b, j_2)$, avoid walking through the free-space matrix in $O(\ell)$ time to compute j_1. We denote by `Query`'$(T[c, b], \Delta, \mathcal{T}, S(\Delta, \mathcal{T}))$ the function which computes for a suffix $P = \mathcal{T}[c, b]$ of $\mathcal{T}[a, b]$ a maximum-cardinality cluster $(P, \mathcal{P})$ in an analogous manner.

▶ **Lemma 8.** *The set $S(\Delta, \mathcal{T})$ is a 2-approximate Pareto front.*

Proof. Consider any Δ-cluster $(P, \mathcal{P})$. Let $P = \mathcal{T}[a, b]$. Let $\mathcal{T}[i, k]$ be the minimal subtrajectory in our tree that has $\mathcal{T}[a, b]$ as a subtrajectory. Let the children of $\mathcal{T}[i, k]$ in our tree be $\mathcal{T}[i, j]$ and $\mathcal{T}[j + 1, k]$. Then, $a \leq j < b$ by minimality of $\mathcal{T}[i, k]$. Hence, $\mathcal{T}[a, j]$ is a suffix of $\mathcal{T}[i, j]$, and $\mathcal{T}[j + 1, b]$ is a prefix of $\mathcal{T}[j + 1, k]$. There must exist a trajectory $P' \in \{\mathcal{T}[a, j], \mathcal{T}[j + 1, b])\}$ which contains at least half as many vertices as $T[a, b]$. Since P' is either a prefix or suffix of a subtrajectory in our tree, we must have added some maximum-cardinality cluster $(P', \mathcal{P}')$ to $S(\Delta, \mathcal{T})$. Moreover, since P' is a subtrajectory of P, $|\mathcal{P}'| \geq |\mathcal{P}|$ (since any discrete walk from row b to row a is also a discrete walk in the Free-space matrix from row d to row c for $[c, d] \subseteq [a, b]$). ◀

▶ **Theorem 9.** *The algorithm PSC(Δ, $\mathcal{T}$) iterates over a 2-approximate Pareto front of $\mathcal{T}$ in $O(z \log^4 n)$ time using $O(n \log n$ space. Here, z denotes the number of zeroes in $M_\Delta(\mathcal{T}, \mathcal{T})$.*

Proof. Consider the balanced binary tree $B(\mathcal{T})$. Each level of depth of $B(\mathcal{T})$ corresponds to a set of subtrajectories that together cover $\mathcal{T}$. For every such subtrajectory $\mathcal{T}[a, b]$, both `StepSecond` and `Query` get invoked for each row $c \in [a, b]$. Since the tree has depth $\log n$, it follows that we invoke these functions $O(\log n)$ times per row c of $M_\Delta(\mathcal{T}, \mathcal{T})$ (i.e. $O(n \log n)$ times in total). Naively, both the `StepSecond` and `Query` functions iterate over all columns in their given row c. However, just as in Section 5, we note that our functions skip over all (j_2, c) for which $d(\mathcal{T}(j_2), \mathcal{T}(c)) > \Delta$. It follows that we may use our row generation trick to spend $O(Z_c \log^3 n)$ time instead (Z_c denotes the number of zeroes in row c). Since each row c gets processed $O(\log n)$ times, this upper bounds our running time by $O(z \log^4 n)$.

For space, we note that invoking `StepSecond` and `Query` for a row c need only rows c and $c - 1$ in memory. So the total memory usage is $O(n)$. Explicitly storing $S(\Delta, \mathcal{T})$ takes $O(n^2 \log n)$ space. However, since we only iterate over $S(\Delta, \mathcal{T})$, the total space usage remains $O(n)$. The range tree therefore dominates the space with its $O(n \log n)$ space usage. ◀

6.1 Greedy clustering using PSC(Δ, $\mathcal{T}$)

We reconsider Algorithms 1 and 2 in Section 5 for k-centre and k-means clustering. As written, these algorithms invoke a subroutine f that returns a single cluster $(P, \mathcal{P})$. Then, the algorithm computes whether it wants to add $(P, \mathcal{P})$ to the current clustering. We can

Algorithm 3 **PSC**(Δ, $\mathcal{T}$).

```
S(Δ, T) ← ∅.
B(T) ← balanced binary tree over T.
for all T[a, b] ∈ B(T) do
    for all c ∈ [a, b] do
        StepSecond(Δ, T, c).
        Query(T[a, c], Δ, T, S(Δ, T)).
    end for
    for all c ∈ [a, b] in decreasing order do
        StepSecond(Δ, T, c).
        Query'(T[c, b], Δ, T, S(Δ, T)).
    end for
end for
return S(Δ, T)
```

Algorithm 4 Query($P = \mathcal{T}[a, c]$, Δ, $\mathcal{T}$, $S(\Delta, \mathcal{T})$).

$(c, j_2) \leftarrow M_\Delta(\mathcal{T}, \mathcal{T})[c, n]$, $\mathcal{P} \leftarrow \emptyset$
while $j_2 > 0$ **do**
  if $\texttt{col}_a(c, j_2) \neq -\infty$ **then**
    $j_1 \leftarrow \texttt{col}_a(b, j_2)$.
    Add $\mathcal{T}[j_1, j_2]$ to $\mathcal{P}$.
    $(c, j_2) \leftarrow (c, j_1 - 1)$.
  else
    $(c, j_2) \leftarrow (c, j_2 - 1)$.
  end if
end while
Add $(P, \mathcal{P})$ to $S(\Delta, \mathcal{T})$.

adapt these algorithms to this new function. For f, we invoke $\mathbf{PSC}(\Delta, \mathcal{T})$. This function iterates over a set of clusters $(P, \mathcal{P})$. For each cluster $(P, \mathcal{P})$ that we encounter, we let either Algorithm 1 or 2 compute whether it wants to add $(P, \mathcal{P})$ to the current clustering.

7 Experiments

We propose three new greedy clustering algorithms for k-centre clustering:

1. `SC-`ℓ runs Algorithm 1, for exponentially scaling Δ, with $f \leftarrow \mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$,
2. `SC-`m runs Algorithm 1, for exponentially scaling Δ, with $f \leftarrow \mathbf{SC}(m, \max, \Delta, \mathcal{T})$, and
3. `PSC` runs Algorithm 1, for exponentially scaling Δ, with $f \leftarrow \mathbf{PSC}(\Delta, \mathcal{T})$.

Our algorithms `SC-`ℓ and `SC-`m need to fix a parameter ℓ and m respectively. We choose $\ell \in \{4, 8, 16, 32, 64\}$ and $m \in \{2, 4, 8, 16\}$ and do a separate run for each choice. Thus, together with `PSC`, we run ten different algorithm configurations. We additionally compare to the subtrajectory clustering algorithm from [10], which is oblivious to the scoring function.

- `Map-construction` runs the algorithm in [10]. We terminate this map construction algorithm as soon as it has constructed a clustering of $\mathcal{T}$.

***k*-means clustering.** For k-means clustering, we obtain three algorithms by running Algorithm 2 instead. Note that our clustering algorithms invoked Algorithm 1 across several runs for exponentially scaling Δ. Our clustering algorithms do not invoke Algorithm 2 in this manner. Instead, Algorithm 2 considers exponentially scaling Δ's internally. Our experiments show that this heavily impacts the clustering's performance on large input.

We again obtain ten algorithm configurations. In addition, we run the map construction algorithm from [10] and the k-means subtrajectory clustering algorithms from [1]:

- `Envelope` runs the algorithm from [1] with the scoring parameters (c_1, c_2, c_3).

Experimental setup. We design different experiments to measure performance and the scoring function. For performance, we run fourteen experiments across the five real-world data sets. Seven experiments for k-centre clustering, and seven for k-means clustering. Each experiment ran three times, using a different vector (c_1, c_2, c_3). Each experiment runs 11 programs for k-centre clustering, or 12 for k-means clustering. If a program fails to terminate after 24 hours, we do not extract any output or memory usage.

We restrict scoring measurements to the three smaller or subsampled real-world data sets. This is necessary to make `Map-construct` and `Envelope` terminate. We add six synthetic data sets. We only compare under k-means clustering since only our algorithms can optimise for k-centre clustering. The experiments were conducted on a machine with a 4.2GHz AMD Ryzen 9 7950X3D and 128GB memory. Over 90 runs hit the timeout. Running the total set of experiments sequentially takes over 100 days on this machine.

The full results per experiment are organised in tables in the full version. Here, we restrict our attention to only three plots.

Choosing (c_1, c_2, c_3). Recall that c_1 weighs the number of clusters in the clustering and that c_3 weighs the fraction of uncovered points. We follow the precedent set in [1] and choose $c_1 = 1$, and c_3 equal to the number of trajectories in $\mathcal{T}$. Finally, c_2 weighs the Fréchet distance across clusters. For each data set, we first find a choice for c_2 such the algorithms lead to a non-trivial clustering. We then also run the algorithms using the scoring vectors $(c_1, 10 \cdot c_2, c_3)$ and $(c_1, 0.1 \cdot c_2, c_3)$, for a total of three scoring vectors per data set.

Comparing quality. To compare solution quality, we measure the scoring function and other qualities such as: the total number of clusters in the clustering, the maximum Fréchet distance from a subtrajectory to its centre, and the average Fréchet distance across clusters. Our competitor algorithms frequently time out on the real-world data sets. Hence, the qualitative comparison also makes use of our synthetic data set. We use three different configurations of our synthetic set to create input of different size. We choose to compare only under k-means clustering for a more fair comparison to other algorithms. Indeed, the algorithm by [1] was designed for the k-means metric ([10] is scoring function oblivious). Consequently, comparing under k-centre would only give us an unfair advantage.

7.1 Results for k-means clustering

The bar plot in Figure 6 visualizes how the algorithms score. Figures 7 and 8 show, respectively, a logarithmic-scale plot of the time and space usage. These plots use the "medium" choice for c_2 for each data set. Note that our choice of c_2 is very similar across the data sets in the figure. This is because *Athens*, *Berlin* and *Chicago* come from the same source, and thereby have the same scaling. We subsequently designed our synthetic data to match this scaling. Plots for the other scoring vector choices are contained in the full version.

Clustering quality. Figure 6 shows that `Map-construct` (which is oblivious to the scoring function) scores poorly on all inputs. One reasons for this is that it always outputs a large number of clusters. The `Envelope` algorithm, which was specifically designed for this scoring function, almost always obtains the best score.

For any data set, for any scoring vector, we always find a choice for ℓ (or m) where `SC-`ℓ and `SC-`m obtain a comparable score to `Envelope`. The algorithm `PSC` scores best out of all newly proposed clustering algorithms. Across all data sets and scoring functions it frequently competes with, and sometimes even improves upon, the score of `Envelope`.

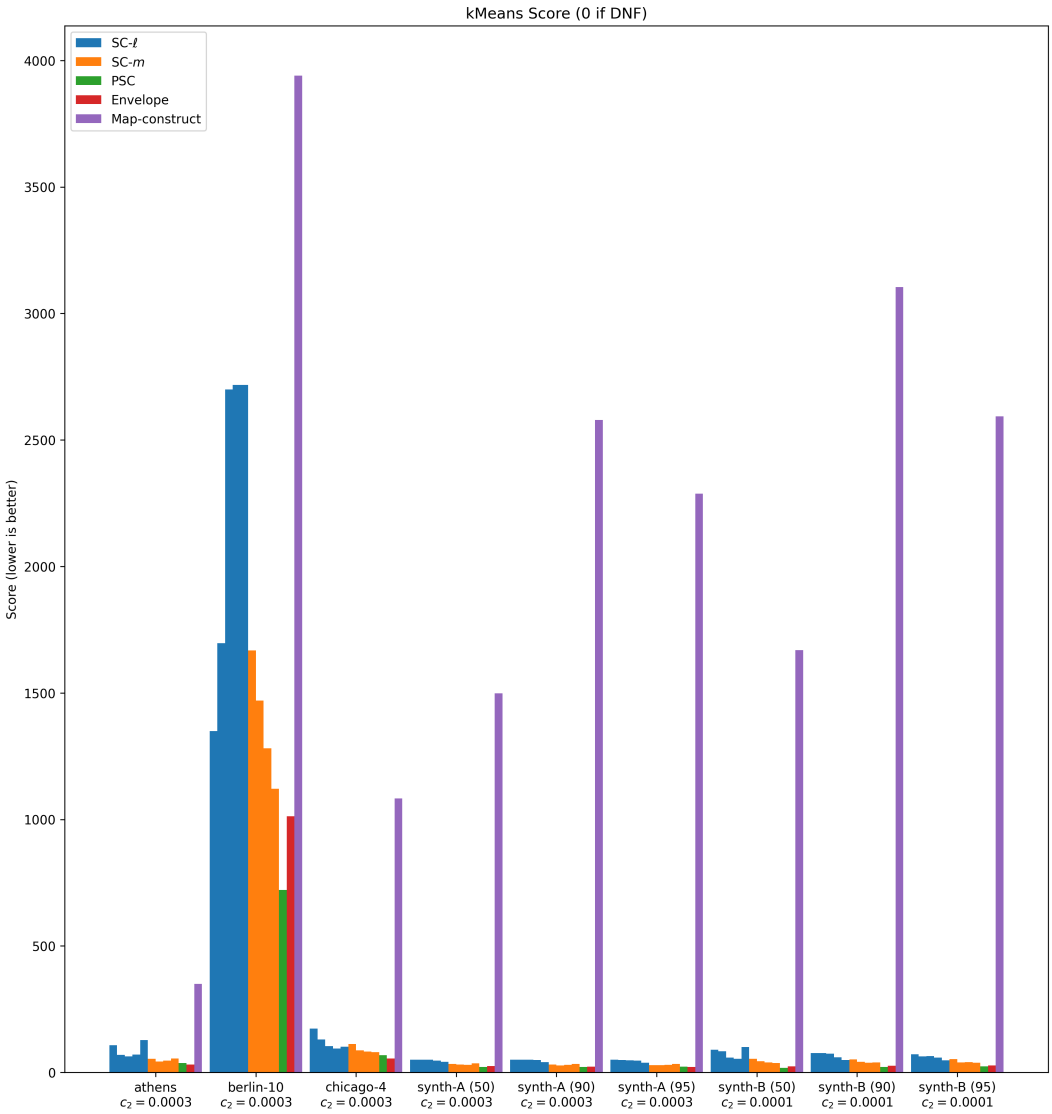

Figure 6 ■ k-means clustering ■ k-means score ■.

Other quality metrics. We briefly note that the full data in the appendix also considers other quality metrics: the number of clusters and the maximum and average Fréchet distance within a cluster. Perhaps surprisingly, `Map-construct` does not perform better on the latter two metrics even though it outputs many clusters. `Envelope` scores worse on these metrics across nearly all data sets and scoring vectors. However, it stays within a competitive range.

Runtime comparison. Figure 7 shows the runtime performance in logarithmic scale. On the *Berlin* data set, no algorithm terminates in time. On *Drifter* and *UniD*, only `PSC` terminates within the time limit. In the figure, we consider the synthetic data sets their place.

`Envelope` may produce high-quality clusterings, but takes significant time to do so. Despite using considerably less memory than `Map-construct`, it is consistently more than a factor two slower. Our algorithms `SC-`ℓ and `SC-`m can always find a choice of ℓ or m such that previous algorithms are orders of magnitude slower. Our `PSC` algorithm is always orders of magnitude faster than the existing clustering algorithms. This is especially true on larger data sets, which illustrates that our algorithms have better scaling.

When we compare our own algorithms, we note that we can frequently find a choice for ℓ such that SC-ℓ is significantly faster than SC-m and PSC. However, when considering the runtime to quality ratio, PSC appears to be a clear winner.

Memory consumption. Figure 8 shows memory performance on a logarithmic scale. The figure excludes *Drifter*, *UniD* and *Berlin* for the same reason as when comparing running times. We record zero memory usage whenever an algorithm times out.

We observe that `Map-construct` uses an order of magnitude more memory than its competitors. This is because it stores up to $O(n^2)$ candidate clusters in memory, together with the entire free-space matrix $M_\Delta(\mathcal{T}, \mathcal{T})$ for various choices of Δ. `Envelope` also has a large memory footprint and uses at least a factor 100 more memory on all of the inputs.

When comparing our own implementations, we observe that SC-ℓ and PSC have a very small memory footprint. These algorithms use $O(n\ell)$ and $O(n)$ space. Since we fix ℓ to be a small constant, both algorithms use near linear space. The space usage of SC-m is $O(n\ell)$ where ℓ is the length of the longest subtrajectory P such that there exists a Δ-cluster $(P, \mathcal{P})$ with $|\mathcal{P}| \geq m$. The data shows that for many choices of (m, Δ), this $O(n\ell)$ space is considerable. Yet, it is still considerably lower than pre-existing algorithms.

7.2 Results for k-centre clustering

When comparing score, runtime, or memory usage under k-centre clustering, we reach the same conclusions. The only difference is that the performance of SC-m becomes more competitive to SC-ℓ and PSC on large data sets. This is because $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ uses much time and space whenever both the data set and Δ are large. Our k-means clustering meta-algorithm considers a large Δ each round, and invokes $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ every round.

Our k-centre clustering meta-algorithm has a separate run for each Δ. If Δ is large, it terminates quickly because it adds very high-cardinality clusters to the clustering. This speeds up all our implementations, but SC-m the most.

8 Conclusion

We proposed new subtrajectory clustering algorithms. Our first two approaches use the algorithms $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ and $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$ by BBGLL [12]. We use these algorithms as a subroutine in a greedy clustering algorithm to cluster a set of trajectories $\mathcal{T}$.

Consider the Boolean function $\theta(\ell, m)$ that outputs `true` if there exists a Δ-cluster $(P, \mathcal{P})$ of $\mathcal{T}$ with $|P| = \ell$ and $|\mathcal{P}| = m$. We observe that these functions always output a point on the Pareto front of this function. We show a new algorithm $\mathbf{PSC}(\Delta, \mathcal{T})$ that, instead of returning a single cluster on this Pareto front, iterates over a 2-approximation of this Pareto front instead. Intuitively, this function iterates over a broader set of candidate clusters that have comparable quality to any output of $\mathbf{SC}(\max, \ell, \Delta, \mathcal{T})$ and $\mathbf{SC}(m, \max, \Delta, \mathcal{T})$. We create a greedy clustering algorithm PSC using this algorithm as a subroutine.

Our analysis shows that our new clustering algorithms significantly outperform previous algorithms in running time and space usage. We primarily use the scoring function from [1] to measure clustering quality and observe that our algorithms give competitive scores. For other quality metrics, our algorithms often perform better than their competitors. We observe that PSC is the best algorithm when comparing the ratio between score and performance.

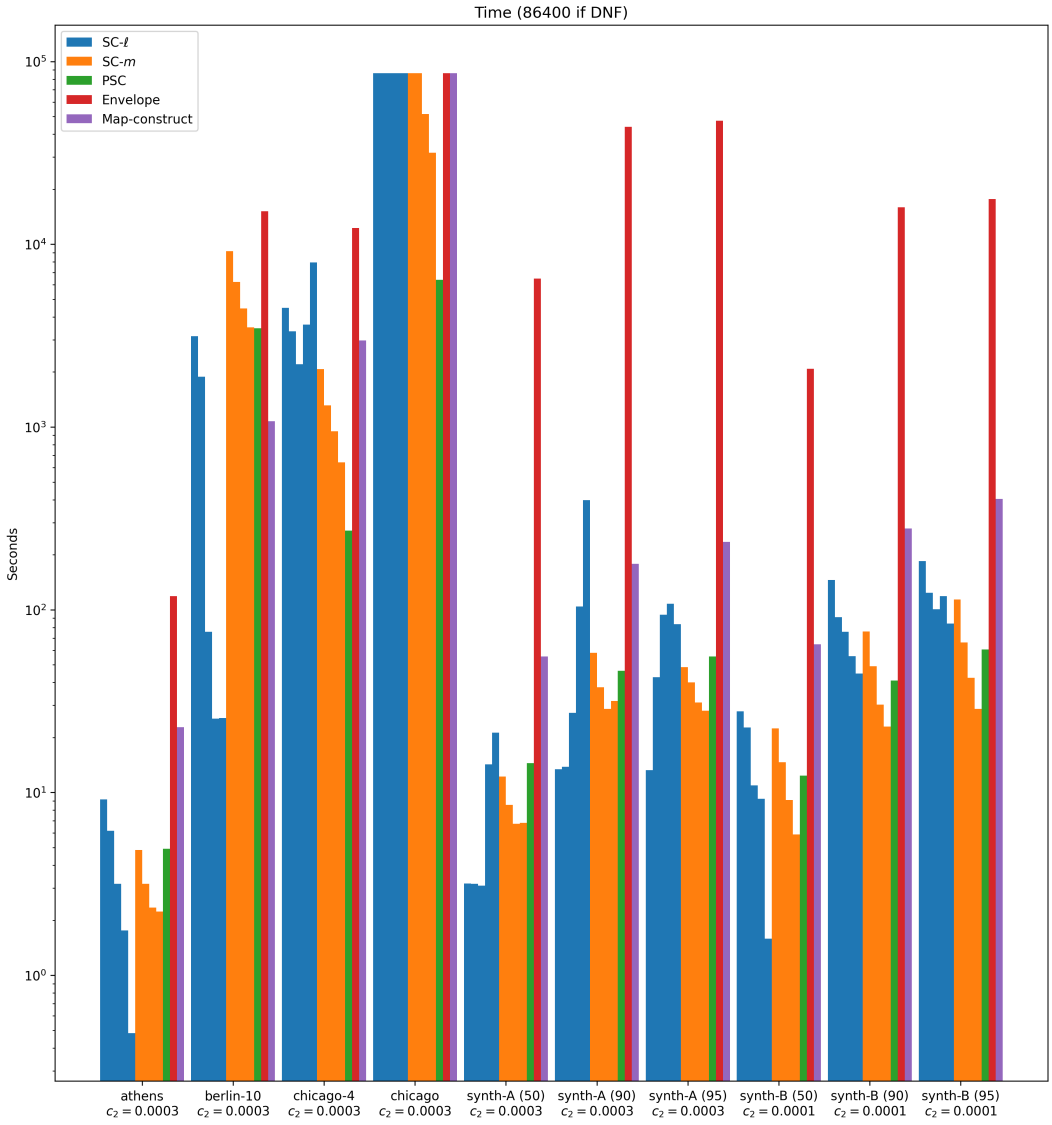

Figure 7 ■ k-means clustering ■ Running time ■ Logarithmic scaling.

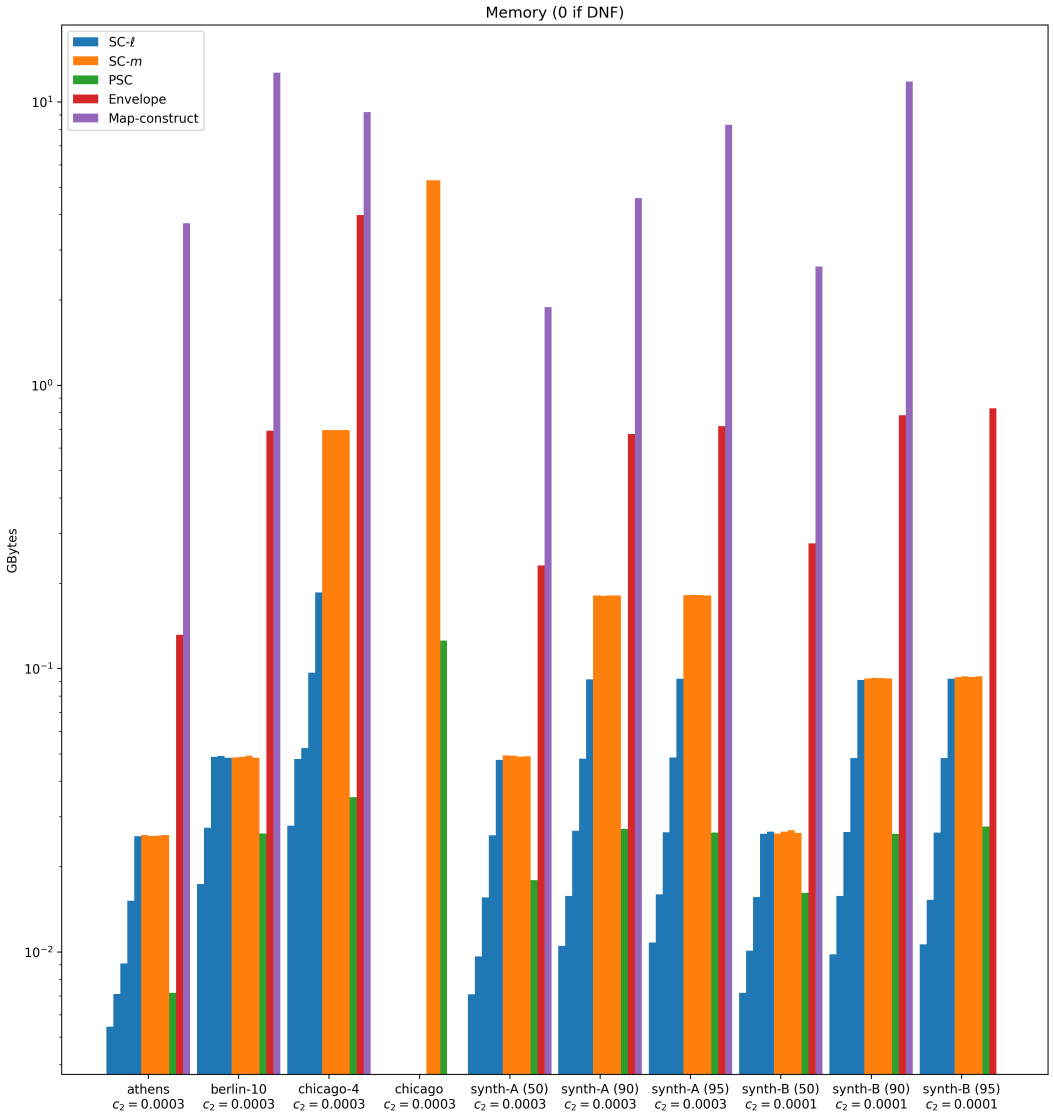

Figure 8 ■ k-means clustering ■ Memory usage ■ Logarithmic scaling
Whenever a run did not terminate, we display a memory usage of zero.

Abstract

We present the winning implementation of the Seventh Computational Geometry Challenge (CG:SHOP 2025). The task in this challenge was to find non-obtuse triangulations for given planar regions, respecting a given set of constraints consisting of extra vertices and edges that must be part of the triangulation. The goal was to minimize the number of introduced Steiner points. Our approach is to maintain a constrained Delaunay triangulation, for which we repeatedly remove, relocate, or add Steiner points. We use local search to choose the action that improves the triangulation the most, until the resulting triangulation is non-obtuse.

1 Introduction

The Computational Geometry Challenge (CG:SHOP) is an annual competition on geometric optimization. The 2025 edition involved finding non-obtuse triangulations of a given planar straight-line graph (PSLG), a planar embedding of a graph where edges are represented as line segments; see Figure 1. The input consists of a PSLG $G = (V, E)$ and a simple polygon P with vertices in V. The goal is to output a non-obtuse triangulation $\mathcal{T}$ of P with vertices V' so that $V \subseteq V'$ and the edges of $\mathcal{T}$ cover E. The vertices $V' \setminus V$ are called *Steiner points* and the objective is to minimize them. We refer to the survey [10] for further details.

The problem of finding non-obtuse triangulations has a long history, dating back to the 1960s [6, 4, 3, 11, 13, 5]. In the 2-dimensional setting, the latest development is Bishop's algorithm – the only one to provably output a non-obtuse triangulation of any PSLG with a number of Steiner points polynomial in the vertices of the input. In general, the computational complexity of minimizing the number of Steiner points or triangles remains unknown, and the problem may be intractable already for simple polygons.

In this paper, we present our winning implementation. The instance set of the callenge consisted of 150 instances with $|V|$ and $|E|$ as large as 250. Our computed solutions were the best for 116 instances, while the runner-up team, "Gwamegi" [2], was best in 4. For the remaining 30 instances, we matched Gwamegi in number of Steiner points.

2 Algorithm

Let us first outline the idea behind our algorithm. Since a non-obtuse triangulation is a Delaunay triangulation (the local Delaunay condition is respected by the inscribed angle theorem), our algorithm maintains a (constrained) Delaunay triangulation (CDT) that gets modified successively. Whenever a obtuse triangle is present, the algorithm makes a modification by removing, relocating, or adding a Steiner point and updating the triangulation accordingly. More precisely, the algorithm operates in rounds, and in each round we consider a set of candidates for local changes and choose the most promising one. In each round, the input is the original instance and the current set of Steiner points, which have been added in the previous rounds. We compute a set of candidate actions, of which there are three types: (i) the insertion of a new Steiner point, (ii) the relocation of an existing Steiner point, and (iii) the replacement of two adjacent Steiner points with a single Steiner point. For

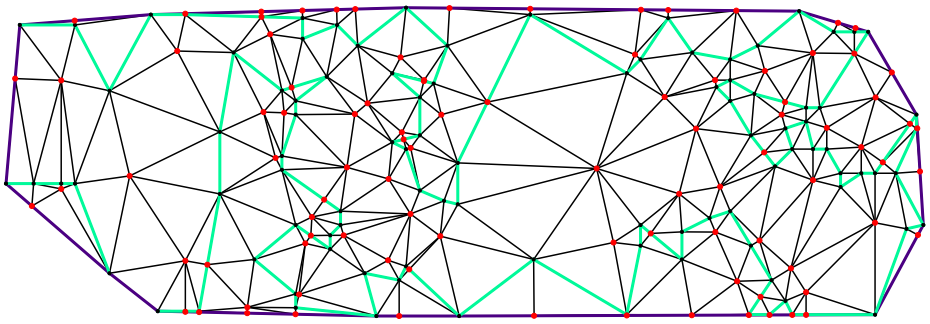

Figure 1 A non-obtuse triangulation produced by our implementation. Here, as in the rest of the paper, the region to be triangulated is enclosed by the fat curve, the given vertices are black, and the constraint edges are green. The Steiner points are red.

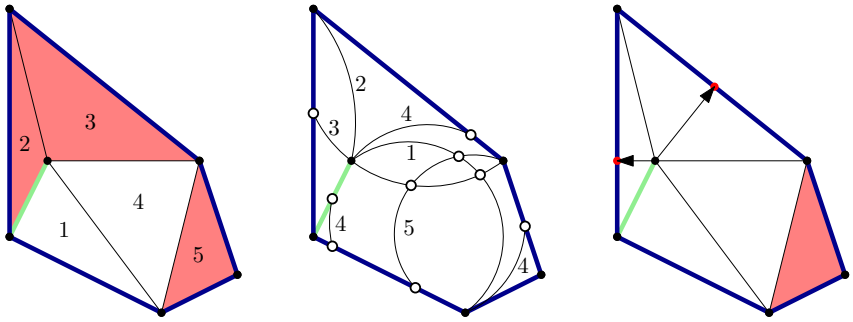

Figure 2 *left:* CDT with obtuse triangles marked in red; *middle:* its `circleArrangement`; *right:* the two `altitudeDrop` points of the two upper obtuse triangles and its resulting CDT.

each action, we compute the resulting triangulation after applying the action. Each of the resulting triangulations is evaluated using a cost function (given in Section 2.3, Equation (1)), which involves the number of Steiner points and the number of obtuse triangles of different types. The output produced by the round is the triangulation that minimizes the cost. The process terminates when the CDT has no obtuse triangles left. In particular, our algorithm produces a non-obtuse triangulation whenever it terminates.

The way in which we insert a new Steiner point is inspired by the work of Erten and Ungör [9, 8, 7]. They described a general approach to finding triangulations avoiding small or large angles, where new Steiner points are chosen as optimal points along the Voronoi diagram (see [7, Section 2.1]). We extend this idea to a visibility-constrained Voronoi diagram [14] which takes into account the constraints of the PSLG.

2.1 Primitives

We first describe the geometric primitives that we are basing our algorithm on:

- `altitudeDrop`: Given an obtuse triangle, compute the unique point on the longest side that splits the obtuse triangle into two right-angled triangles (Figure 2, right).
- `polygonCenter`: Given a simple polygon, compute a center point such that connecting each vertex of the polygon with the center point results in a non-obtuse triangulation of the polygon, or decide no such point exists. Such a point can be computed as follows: Observe that for any two points p and q, a point x forms a non-obtuse triangle pqx if and only if x lies inside the slab defined by the two hyperplanes rooted at p and q with normal $q - p$ and outside the disk centered at $\frac{p+q}{2}$ with radius $\frac{\|q-p\|}{2}$. Pick any point in the intersection of these sets defined by all consecutive pairs of vertices p and q on the boundary of the polygon (Figure 3).
- `visibilityVoronoi`: Given a CDT, compute the visibility-constrained Voronoi diagram (sometimes called bounded Voronoi diagram) [14]. (Figure 4, top right).
- `clippedCircumcircle`: Let T be a triangle in a CDT and C its circumcircle. The disk bounded by C may be partitioned into multiple pieces by the constraints of the CDT. Compute the piece of the partition containing T (Figure 4, bottom left).
- `circleArrangement`: Given a CDT, compute first the `clippedCircumcircle` for each triangle, then the arrangement of these clipped circumcircles (Figure 2, middle).

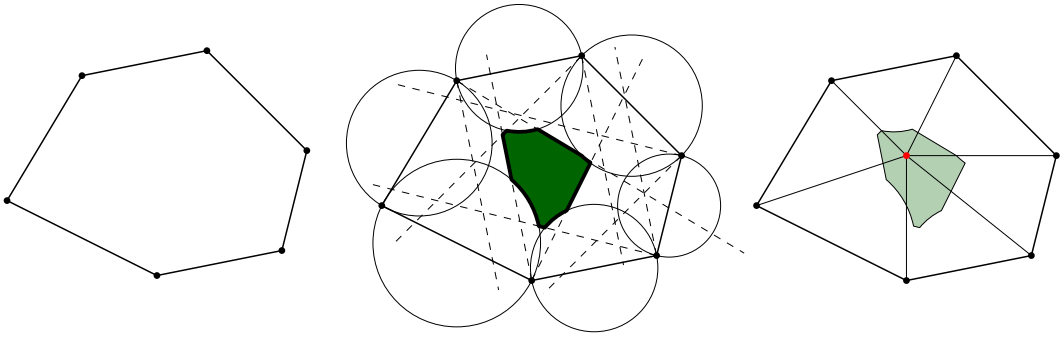

Figure 3 Illustration of the computation of the `polygonCenter` primitive.

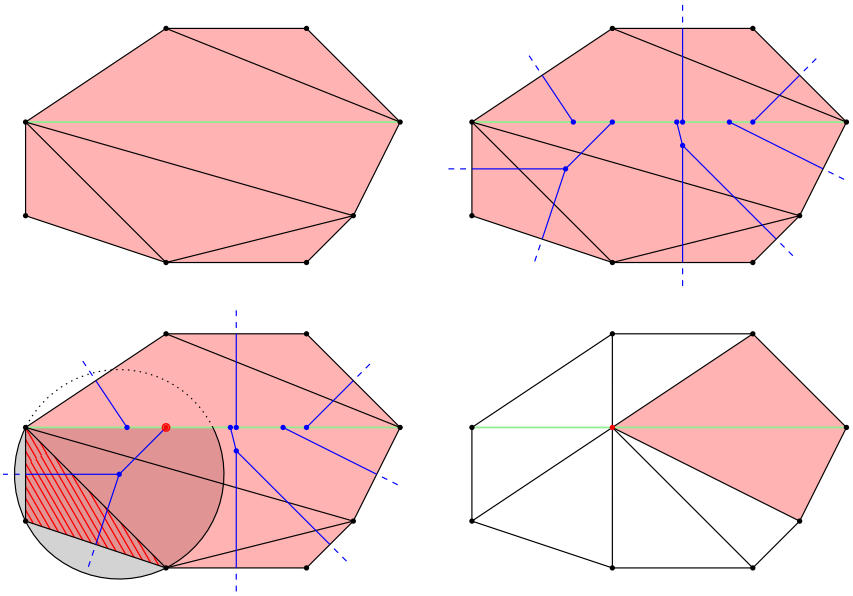

Figure 4 Center identification in the style of Erten and Ungör [9, 8, 7], from the visibility-constrained Voronoi diagram [14].

2.2 Action Generation

In this section we build on the geometric primitives we just introduced, and describe in more detail the three types of candidate actions that the algorithm evaluates for a provided CDT $\mathcal{D}$, which together form the action set $\mathcal{A}(\mathcal{D})$ of $\mathcal{D}$. Every Steiner point, triangle, and edge of $\mathcal{D}$ and every cell in the `circleArrangement` of $\mathcal{D}$ has at most one action associated to it. Every action includes two steps: the insertion, relocation or deletion of Steiner points and ensuring that the maintained triangulation is a CDT. We now describe the types of actions.

Insertion. Let T be a triangle in $\mathcal{D}$. If T is non-obtuse already, then it has no action associated to it. Hence, let T be obtuse instead. If the longest side of T (opposite the unique obtuse angle in T) is a constrained edge of $\mathcal{D}$, the candidate action associated to T adds the unique point described by the `altitudeDrop` primitive. If instead the longest side of T is not constrained, the candidate action associated to T adds the point v in the `clippedCircumcircle` of T that lies on an edge e of the `visibilityVoronoi` of $\mathcal{D}$ and maximizes the distance to the points of $\mathcal{D}$ defining e (see Figure 4). This point v

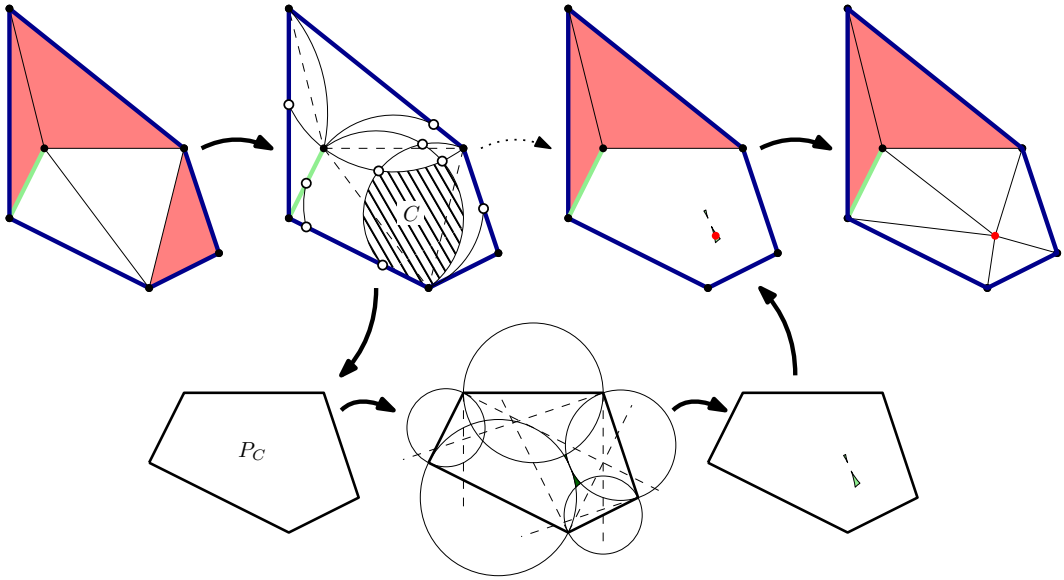

Figure 5 Center identification by choosing a cell C from the `circleArrangement` and computing the `polygonCenter` of its corresponding polygon P_C.

can efficiently be identified via a local search in the `visibilityVoronoi` diagram. We observe that v maximizes the distance to all other points in the CDT while still lying in the `clippedCircumcircle` of T. This guarantees that its insertion into the CDT results in the removal of T from the CDT, accompanied by an intuitively increased likelihood that only few angles of triangles incident to v are obtuse (c.f. [9, 8, 7]).

Next, let C be a cell in the `circleArrangement`. Let $\{T_1, \ldots\}$ be the set of all triangles whose `clippedCircumcircle` contains C. By classical Delaunay arguments, the union of triangles in $\{T_1, \ldots\}$ defines a polygon P_C. We note that the CDT resulting from adding a point $v \in C$ is obtained by replacing the edges of $\mathcal{D}$ in P_C with the segments vp for every vertex p of P_C. In particular, if at least one triangle in $\{T_1, \ldots\}$ is obtuse and the `polygonCenter` v of P_C lies in C, then adding v to the CDT ensures that the number of obtuse triangles in the CDT strictly decreases. Thus, if at least one T_i is obtuse and the `polygonCenter` of P_C exists, the candidate action associated to C adds this `polygonCenter` (see Figure 5), otherwise no action is associated to C.

Relocation. Let v be a Steiner point of $\mathcal{D}$. If v is not part of an obtuse triangle, v has no action associated to it. Hence, let v be part of some obtuse triangle instead. Let P be the polygon resulting from the union of all triangles that v is a part of. Assume the `polygonCenter` of P exists, otherwise v has no action associated to it. The action associated to v moves v to the `polygonCenter` of P.

Deletion. Let e be an edge in $\mathcal{D}$ defined by two Steiner points v and w. The union of all triangles that v or w are a part of forms a polygon P. Assume the `polygonCenter` of P exists, otherwise e has no action associated to it. The action associated to e removes the two points v and w from $\mathcal{D}$ and adds the `polygonCenter` of P.

2.3 Evaluation

The evaluation function of a CDT $\mathcal{D}$ consists of two parts: A naive evaluation function and an algorithm that improves the accuracy of the naive evaluation.

Naïve evaluation. We say an obtuse triangle T in $\mathcal{D}$ *supersedes* another obtuse triangle T' in $\mathcal{D}$ if the longest side of T is either of the shorter two sides of T' (Figure 6 shows superseded-superseding triangle pairs). We expect superseded triangles to be influenced by whatever action is associated to its superseding triangle. An example of this phenomenon can be seen in Figure 4. Hence, we argue that handling non-superseded obtuse triangles should be prioritized and therefore the cost of non-superseded obtuse triangles should be higher than that of superseded (obtuse) triangles. The evaluation function we use is

$$\text{eval}(\mathcal{D}) := \#\text{Steiner points} + 1.1 \cdot \#\text{superseded } \triangle\text{'s} + 3.1 \cdot \#\text{non-superseded } \triangle\text{'s}. \tag{1}$$

Figure 6 shows a run of the algorithm, including the actions that were applied and the value of the evaluation function. Note that we did not pursue optimizing the constants in (1).

Probabilistic state-graph evaluation. To improve the rather naïve evaluation function, we endow the evaluation function with a depth parameter $k \geq 0$, akin to the notion of minimax searching [12] over a game-state graph of a single player game, and define

$$\text{eval}_k(\mathcal{D}) := \begin{cases} \min_{A \in \mathcal{A}(\mathcal{D})} \text{eval}_{k-1}(\mathcal{D}_A) & \text{if } k > 0 \\ \text{eval}(\mathcal{D}) & \text{if } k = 0 \end{cases} \tag{2}$$

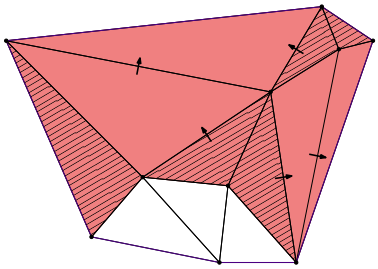
where $\mathcal{D}_A$ is the CDT resulting from $\mathcal{D}$ when applying the action A from the action set $\mathcal{A}(\mathcal{D})$. Even after extensive optimization efforts, we found that even with k as small as 3 the execution time was quite slow. Hence, instead of evaluating $\text{eval}_{k-1}(\mathcal{D}_A)$ for every A in the action set of $\mathcal{D}$, we randomly draw a sample S of actions from $\mathcal{A}(\mathcal{D})$ (with a bias towards more promising moves determined by $\text{eval}_0(\mathcal{D}_A)$) computing $\min_{A \in S} \text{eval}_{k-1}(\mathcal{D}_A)$.

2.4 Solution Merging

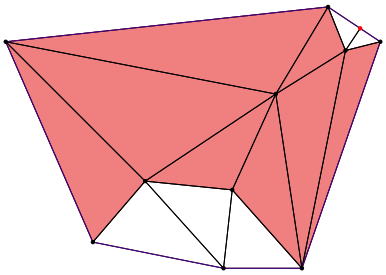
We observed that, due to the probabilistic nature of the evaluation function, different solutions to the same instance often had a similar number of Steiner points but looked vastly different locally. This motivates merging different solutions by sampling a circle and replacing every Steiner point inside this circle from one solution with the Steiner points of the other solution. Note that merging two solutions might result in a CDT that has obtuse triangles. Thus, we apply our algorithm to these CDTs obtaining a new solution with potentially less Steiner points. Repeated application of this merging step reduced the number of Steiner points by as much as 30% for some instances (see Figure 7).

3 Implementation, Experiments, and Examples

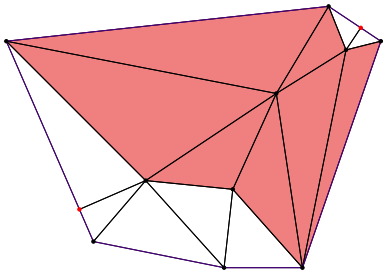
Code and Hardware. Our implementation is in python. In the later stages of the competition we ran our solver on ten nodes of the Marvin cluster of the University of Bonn, each with 1024GB of RAM and 96 threads at 2.10GHz using around 300 000 CPU hours. We did not find any improved solution in the last two weeks of the competition.



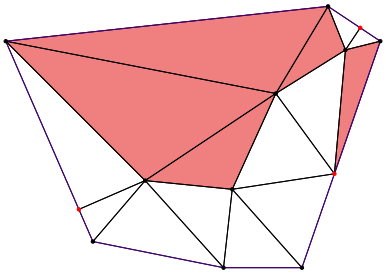
(a) Initial CDT with hatched non-superseded triangles and how triangles are superseded. $\mathrm{eval}(\mathcal{D}) = 19.9$, $\mathrm{eval}_3(\mathcal{D}) = 14.5$.



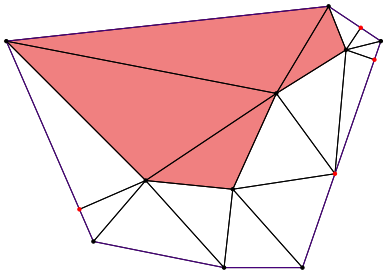
(b) '`altitudeDrop`' insert action. $\mathrm{eval}(\mathcal{D}) = 17.8$, $\mathrm{eval}_3(\mathcal{D}) = 12.4$.



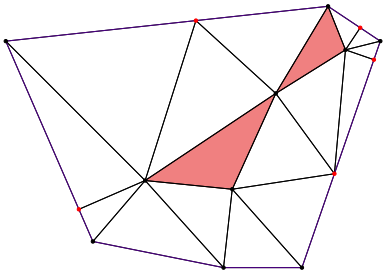
(c) '`altitudeDrop`' insert action. $\mathrm{eval}(\mathcal{D}) = 15.7$, $\mathrm{eval}_3(\mathcal{D}) = 11.2$.



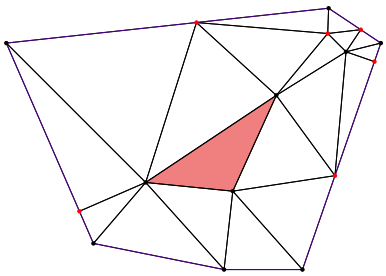
(d) '`visibilityVoronoi`' insert action. $\mathrm{eval}(\mathcal{D}) = 14.5$, $\mathrm{eval}_3(\mathcal{D}) = 9.1$.



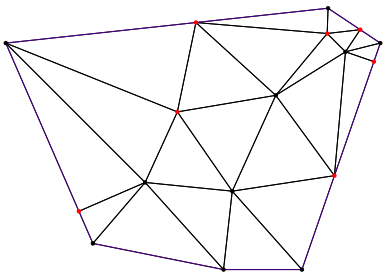
(e) '`altitudeDrop`' insert action. $\mathrm{eval}(\mathcal{D}) = 12.4$, $\mathrm{eval}_3(\mathcal{D}) = 7$.



(f) '`polygonCenter`' insert action. $\mathrm{eval}(\mathcal{D}) = 11.2$, $\mathrm{eval}_3(\mathcal{D}) = 7$.

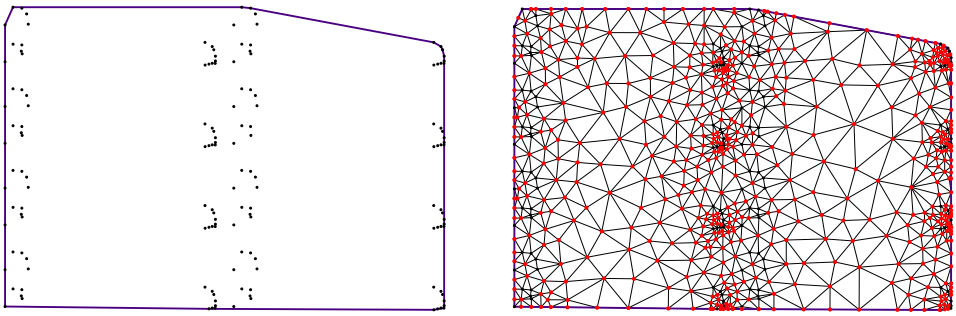


(g) '`polygonCenter`' insert action. $\mathrm{eval}(\mathcal{D}) = 9.1$, $\mathrm{eval}_3(\mathcal{D}) = 7$.



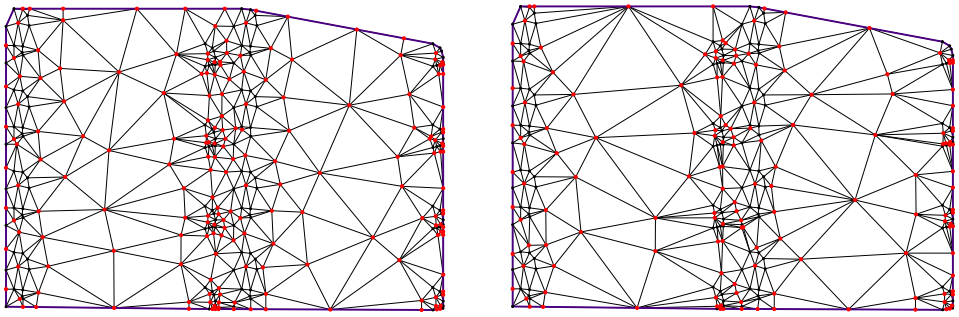
(h) Terminal '`polygonCenter`' insert action. $\mathrm{eval}(\mathcal{D}) = 7$, $\mathrm{eval}_3(\mathcal{D}) = 7$.

Figure 6 Maintained CDT of instance '`point-set_10_c04b0024`' (consisting of 10 points, 6 polygon edges and 0 inner edges) throughout the execution of the local search with depth 0, with all obtuse triangles marked in red. Execution time: 10 seconds. Final number of Steiner points: 7.



(a) Instance '`point-set_150_982c9ab3`' with 150 points, 13 polygon- and 0 inner edges.

(b) Baseline solution via [8, 7, 6] and rounding of coordinates with 573 Steiner points.



(c) Best found solution via probabilistic local search and depth 3 with 190 Steiner points.

(d) Solution via merging and re-solving of existing solutions with 151 Steiner points.

Figure 7 Solution comparison of instance '`point-set_150_982c9ab3`'.

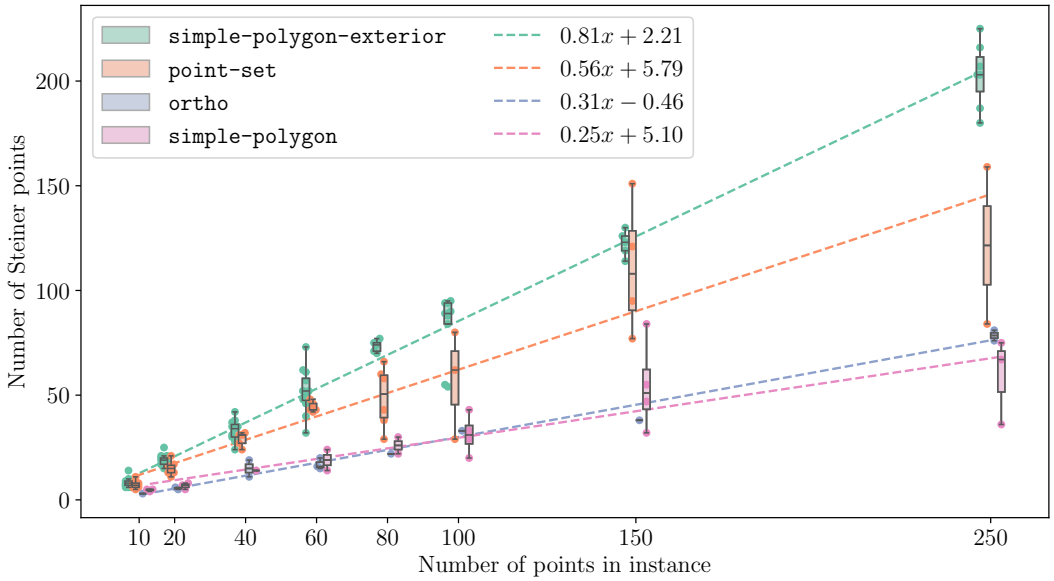


Figure 8 Relationship between solution size and input complexity over different instance types.

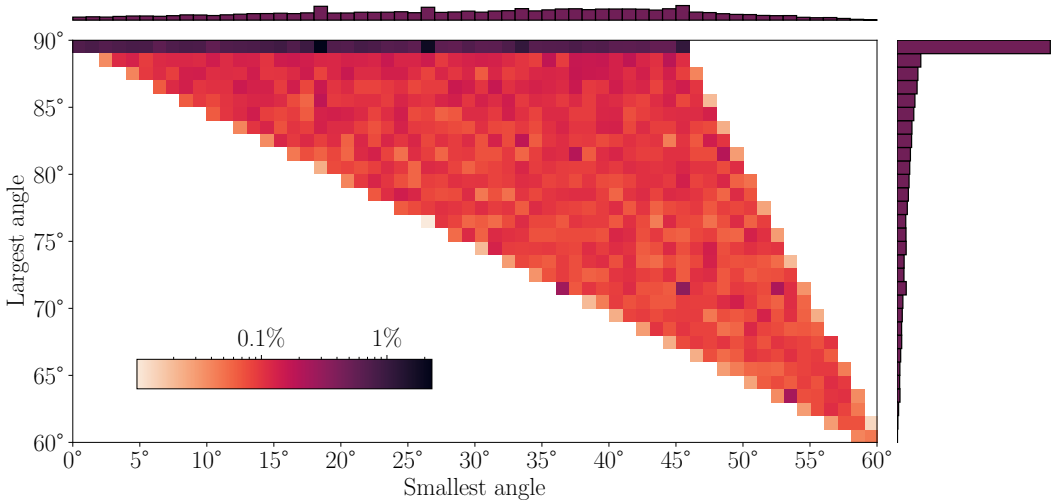

Figure 9 Average distribution of smallest and largest angles, of all triangles in all solutions.

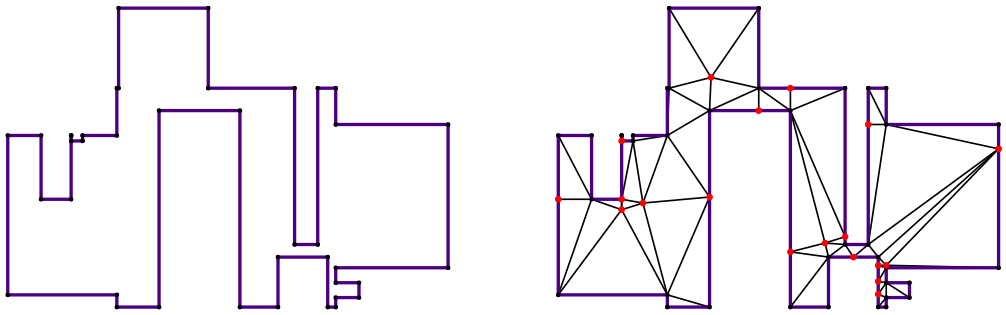

Figure 10 Instance '`ortho_40_56a6f463`' and a solution with 19 Steiner points.

Solutions. The provided instances fall into various types: (i) `ortho`, consisting of rectilinear simple polygons (Figure 10), (ii) `simple-polygon`, consisting of simple polygons (Figure 11), (iii) `point-set`, consisting of the convex polygons with points in its interior (Figures 13 and 14), and (iv) `simple-polygon-exterior`, consisting of convex polygons with points and additional constraints in its interior (Figures 12 and 15). Our algorithm performs well on all instances types; no manual intervention or distinction is necessary for our approach. The number of Steiner points in our solutions compared to the number of input points in each type suggests that the total number of Steiner points is roughly linear in the input complexity and increases depending on the number of points and constraints in the interior of the PSLG, see Figure 8. We observe that a large fraction of triangles computed by our algorithm are right triangles (see Figure 9, right). All other angles in our solutions (determined by largest and smallest angle) appear to be roughly equally distributed (see Figure 9).

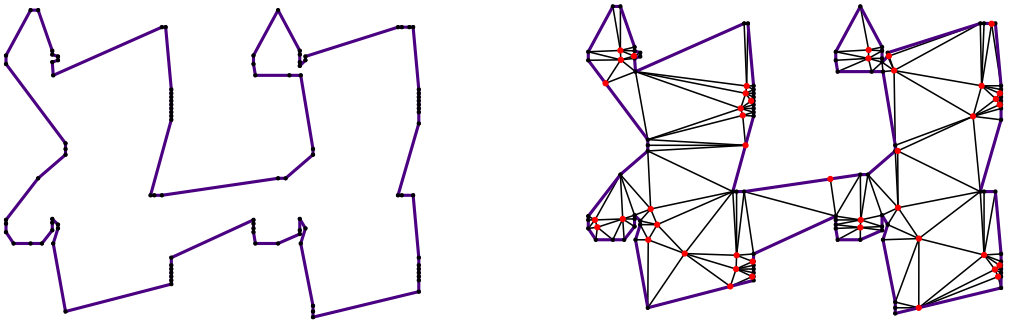

Figure 11 Instance '`simple-polygon_100_cb23308c`' and a solution with 43 Steiner points.

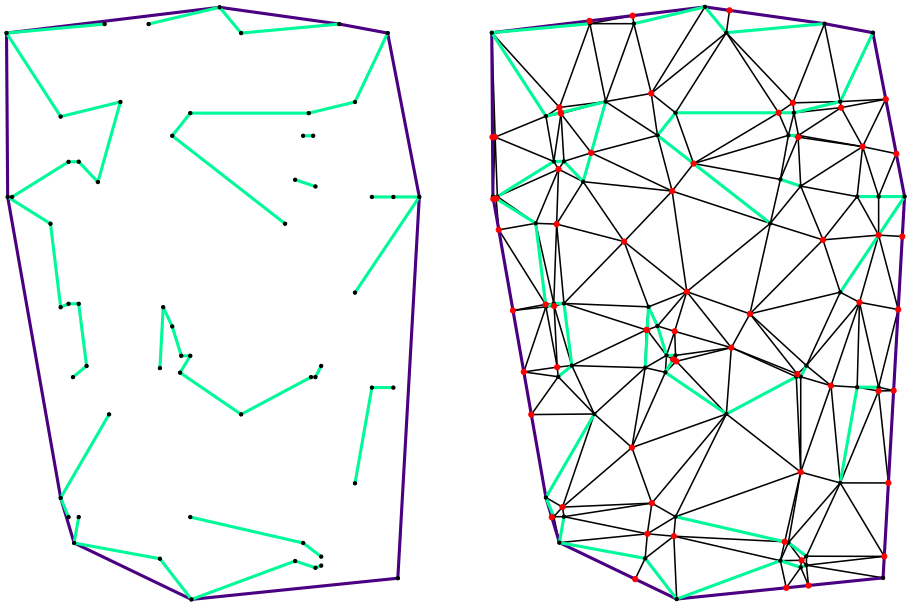

Figure 12 Solution to '`simple-polygon-exterior-20_60_8221c868`' with 62 Steiner points.

Abstract

In this year's CG challenge, the task was to compute a non-obtuse triangulation of given planar regions while minimizing the number of Steiner points. Our team (Gwamegi) used two approaches. The first approach incrementally adds Steiner points on the grid defined by the input points in the planar regions, while maintaining a Delaunay triangulation. The second approach is an iterated local search, which runs insertion and deletion steps alternatingly. In the insertion step, we add a new Steiner point inside a maximal convex subpolygon in the current triangulation. In the deletion step, we remove a number of Steiner points packed in a small region. We use both our approaches to obtain non-obtuse triangulations for all 150 instances. We use our second approach to reduce the number of Steiner points from the non-obtuse triangulations. We have successfully computed non-obtuse triangulations using a sufficiently small number of Steiner points for all instances.

1 Introduction

Triangulation is a well-studied topic in computational geometry. It is a subdivision of a planar geometric object into triangles. Such an object is a point set possibly with constraint edges [7, 13], a polygon [10, 11], or a planar straight-line graph (PSLG) [6]. In this year's CG

challenge, the task was to compute a non-obtuse triangulation of given PSLGs minimizing the number of Steiner points. This paper introduces the approaches of our team (Gwamegi) for the challenge. See also the survey [9] by the challenge organizers and another team's approach [1].

Finding triangulations under various optimality criteria has been well studied, including max-min angle triangulations (called Delaunay triangulations) [4, 12], high aspect ratio triangulations [14], and min-sum side length triangulations (called minimum weight triangulations) [3, 5]. Among them, Delaunay triangulation is the most popular with its various application areas such as mesh generation and path planning [2, 15]. Note that any non-obtuse triangulation (every triangle is acute or right) is Delaunay.

The challenge problem can be formulated as follows.

▶ **Problem 1.** *Given a problem instance $I = (V, R, E)$, where V is a set of points in $\mathbb{R}^2$, R is a simple polygon to be triangulated whose vertex set is a subset of V, and E is the set of constraint edges each connecting two distinct points in V, find a minimum-sized set $S \subset R$ of Steiner points and a non-obtuse triangulation of R with vertex set $V \cup S$ and respecting E.*

There were 150 instances, five types in total. Figure 1 illustrates the instance types.

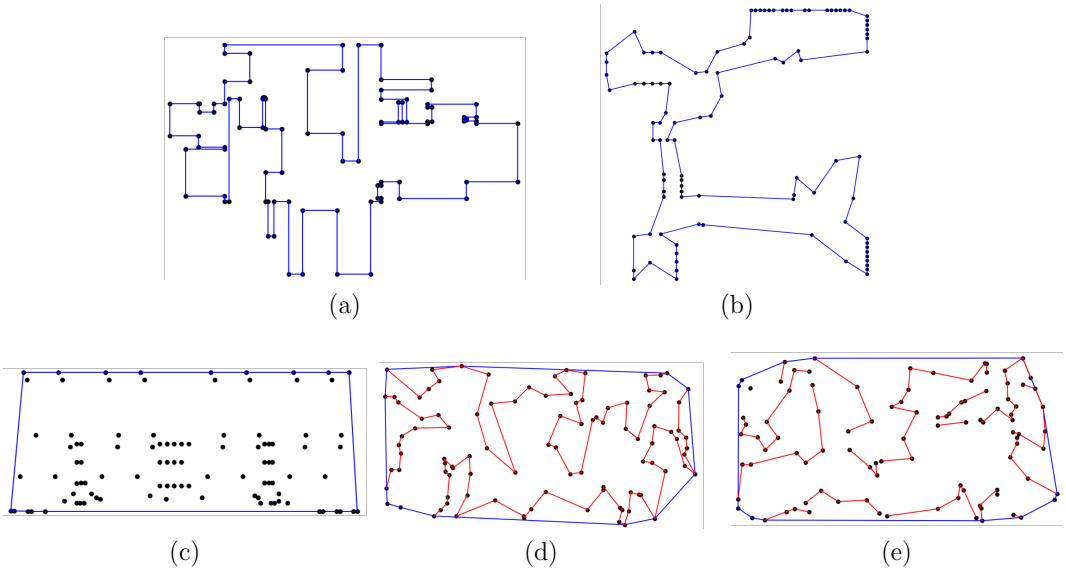

Figure 1 Example instance per type. Blue segments form the boundary of R. Red segments are constraint edges E. Type (a) ortho, (b) simple-polygon, (c) point-set, (d) simple-polygon-exterior, and (e) simple-polygon-exterior-20.

2 Algorithms

We used two approaches to compute non-obtuse triangulations: (1) incremental algorithm on a grid and (2) iterated local search. For all instances of type ortho and some instances of type point-set and type simple-polygon, we used our first approach. For the other instances, we used our second approach. After computing non-obtuse triangulations for all instances, we again used our second approach to reduce the number of Steiner points for each of them.

Let $\mathsf{DT}(V, R, E)$ be a Delaunay triangulation of R with point set V, respecting E. If there is more than one such Delaunay triangulation, we let $\mathsf{DT}(V, R, E)$ to be one with the minimum number of obtuse triangles. In our approaches, we maintain $\mathsf{DT}(V \cup S, R, E)$ while updating the set S of Steiner points. We say that S is a *feasible solution* of $I = (V, R, E)$ if $\mathsf{DT}(V \cup S, R, E)$ is a non-obtuse triangulation.

2.1 Incremental algorithm on a grid

We introduce our incremental algorithm. It was mostly used for instances of type ortho. For a type ortho instance $I = (V, R, E)$, R is an orthogonal polygon (any edge is vertical or horizontal), V is the vertex set of R, and $E = \emptyset$. Define $x(p)$ and $y(p)$ as the x- and y-coordinate of a point $p \in \mathbb{R}^2$, respectively. Let $X = \{x(p) \mid p \in V\}$ and $Y = \{y(p) \mid p \in V\}$, and let $S_G = \{p \in R \mid x(p) \in X, y(p) \in Y\}$ be the *grid points* of I. The set $S_G \setminus V$ is an obvious feasible solution of I. However, its size can be $\Omega(|V|^2)$. In the following, we show how to find a moderately-sized feasible solution $S \subset S_G$.

Starting with $S = \emptyset$, we compute $\mathsf{DT}(V \cup S, R, E)$ in each step. If it is non-obtuse, S is a feasible solution, and we are done. Otherwise, we pick a random obtuse triangle in $\mathsf{DT}(V \cup S, R, E)$. Let p be its obtuse vertex. The angle interval defined by p contains at least one of the four axis-aligned directions from p: $+x$, $+y$, $-x$ and $-y$. Without loss of generality, assume that it contains the $+y$-direction as in Figure 2, and let $\vec{r}$ be the ray emanating from p and going towards the $+y$-direction. Let q be a point moving from p along $\vec{r}$. During the movement of q, if $y(q) = y(v)$ for a vertex v of the triangle containing q and $q \neq p$, it stops, and we add q to S. It is easy to see that q always stops before moving out of R. We repeat the procedure until S becomes feasible.

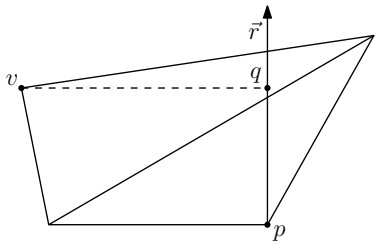

Figure 2 Point q moves from p along $\vec{r}$. It stops when $y(q) = y(v)$ for a vertex v of the triangle containing q.

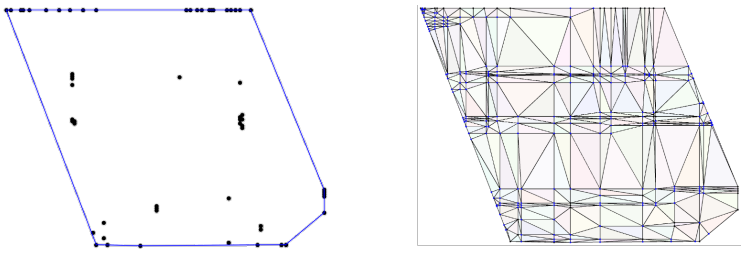
Table 1 shows that the above algorithm uses no more Steiner points than the size of V, for type ortho instances.

Table 1 $|V|$ is the size of the instances. $|S|$ is the average number of Steiner points added, when we executed the algorithm five times for each instance of type ortho.

$\lvert V\rvert$	10	20	40	60	80	100	150	250
$\lvert S\rvert$	3.0	9.3	23.6	38.4	45.4	74.6	125.2	184.9

We can apply the algorithm to some instances of type point-set and simple-polygon by invoking MakeNonObtuseBoundary procedure whenever we add a new Steiner point. MakeNonObtuseBoundary finds an obtuse triangle from $\mathsf{DT}(V \cup S, R, E)$ having its hypotenuse on the boundary of R, and adds the projection from the opposite vertex onto the hypotenuse to S. It repeats until there is no such obtuse triangle. See Figure 3.



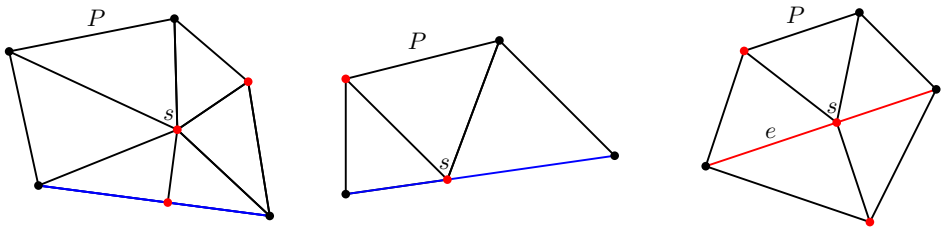
(a) (b)

Figure 3 (a) Instance point-set_60_27bc003d of type point-set and (b) its feasible solution obtained by our incremental algorithm.

2.2 Iterated local search

We introduce our local search algorithm. Starting from $S := \emptyset$, the algorithm runs *insertion steps* and *deletion steps* alternatingly to update S.

Unlike the incremental algorithm in Section 2.1, our local search algorithm may place non-grid Steiner points in the insertion step. We first observe the following. Let $I = (V, R, E)$ be an instance. Consider a feasible solution S of I. Fix a point $s \in S$, and let $T(s)$ be the set of triangles in $\mathsf{DT}(V \cup S, R, E)$ with s as a vertex. Since all triangles in $T(s)$ are non-obtuse, their union is a convex polygon P. The interior of P does not contain any constraint edge if and only if s does not lie on any constraint edge. See Figure 4(a, b). If s lies on some $e \in E$, then $P \cap e$ is an edge connecting two vertices of P, and P does not contain any other constraint edge. See Figure 4(c). Based on the observation, we consider the following.



(a) (b) (c)

Figure 4 Union P of $T(s)$. Black points are the given points in V, and red points are the Steiner points. (a) s lies in the interior of P and s does not lie on any $e \in E$. (b) s lies on the boundary of P. (c) s lies on some $e \in E$.

▶ **Problem 2.** *Given a convex polygon P, find a point $s \in P$ such that $\triangle spq$ is non-obtuse for any edge $\overline{pq}$ of P. Additionally, if a diagonal e of P is given, s must lie on e.*

Fix an edge $\overline{pq}$ of P and consider the triangle $\triangle spq$ for a point $s \in P$. We have $\angle spq \leq \pi/2$ and $\angle sqp \leq \pi/2$ if and only if s lies in the strip L perpendicular to $\overline{pq}$, with each bounding line going through p and q, respectively. We have $\angle psq \leq \pi/2$ if and only if s lies outside the disk D having $\overline{pq}$ as its diameter. See Figure 5(a). Summing up, $\triangle spq$ is non-obtuse if and only if s lies in $\mathcal{R}(\overline{pq}) := L \setminus D$, and $s \in P$ is a solution of Problem 2 if and only if it lies in the intersection of $\mathcal{R}(\overline{pq})$'s for every edge $\overline{pq}$ of P. See Figure 5(b). A similar subprocedure was previously introduced by Erten and Üngör [8], and it was also used in the team Naughty NOTers' approach [1], named as polygonCenter. If a diagonal e is given additionally as in

the problem statement, we check if such intersection of $\mathcal{R}(\overline{pq})$'s intersects e. We solve its generalized version, Problem 3, defined as follows, because there may be no solution for Problem 2. Let V_P be the set of vertices of P, and let $E_P \coloneqq \{e \cap P \mid e \in E\}$.

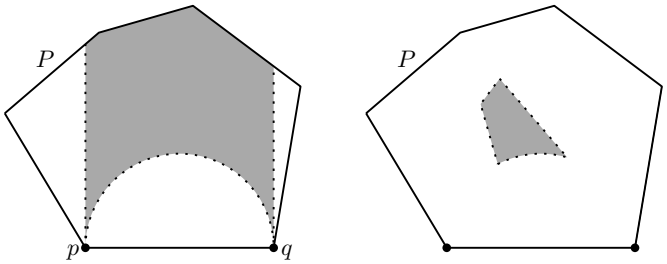


Figure 5 (a) $\mathcal{R}(\overline{pq}) \cap P$. (b) The intersection of $\mathcal{R}(\overline{pq})$'s for every edge $\overline{pq}$ of P.

▶ **Problem 3.** *Given a convex polygon P and a set of constraint edges E_P in P, find a point $s \in P$ minimizing the number of obtuse triangles in $\mathsf{DT}(V_P \cup \{s\}, P, E_P)$.*

To solve Problem 3, we need to define the following sets.

- $\mathcal{D}$: the set of circles, each having an edge of P as its diameter.
- $\mathcal{L}$: the set of lines, each perpendicular to an edge of P and going through one of its endpoints.
- $\mathcal{C}$: the set of circumcircles of the triangles in $\mathsf{DT}(V_P, P, E_P)$.

Consider the arrangement $\mathcal{A}$ of $\mathcal{D} \cup \mathcal{L} \cup \mathcal{C} \cup E_P$ in P. For each cell of $\mathcal{A}$, the number of obtuse triangles is the same. Thus we aim to find a vertex v of $\mathcal{A}$ minimizing the number of obtuse triangles in $\mathsf{DT}(V_P \cup \{v\}, P, E_P)$.

Since we are using exact arithmetic, it consumes too much time and space to exactly compute vertices of $\mathcal{A}$. So instead, we approximate each point with another point at close range with simpler coordinates. For each vertex of $\mathcal{A}$ that does not lie on any constraint edge, we approximate both its x- and y-coordinate using quantized values represented as $i \cdot q$ for some integer i and a fixed parameter $q \in \mathbb{Q}$. For each vertex of $\mathcal{A}$ lying on a constraint edge, we approximate only one of its coordinates with the quantized values, to ensure that the approximated point also lies on the constraint edge. We start with $q = 1$ and make it smaller whenever the algorithm gets stuck. From the approximated points, we choose one minimizing the number of obtuse triangles. If there are multiple such points, we choose a point at random. Let $\mathsf{AddPoint}(P)$ be the corresponding subprocedure.

In the insertion step, we first compute $\mathsf{DT}(V \cup S, R, E)$. If it is non-obtuse, we are done. Otherwise, we pick an obtuse triangle t in $\mathsf{DT}(V \cup S, R, E)$ at random. Then we compute a maximal convex polygon P which is the union of some triangles in $\mathsf{DT}(V \cup S, R, E)$ containing t. This is done by maintaining a convex polygon P, starting from $P = t$ and adding triangles incident to P until there is no triangle t' such that $P \cup t'$ is convex. Finally, we add a point to S obtained from $\mathsf{AddPoint}(P)$. During each insertion step, we repeat the above several times.

In the deletion step, we randomly choose a Steiner point p, and remove every Steiner point (including p itself) within distance $r \cdot d$ where r is a parameter that increases as time goes by, and d is the distance between p and its closest Steiner point.

We store the current solution as the best solution whenever the number of obtuse triangles decreases, or the number of Steiner points decreases while the number of obtuse triangles remains the same. In each iteration, we start from the best solution and apply the insertion and the deletion steps alternatingly. Figure 6(a) illustrates a deletion step, and Figure 6(b) illustrates a non-obtuse solution obtained by running an insertion step afterwards.

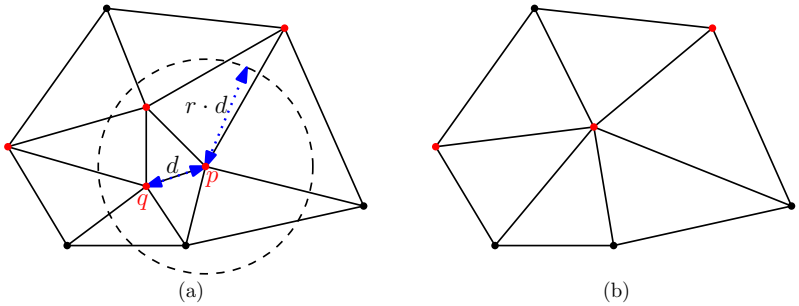

Figure 6 (a) Given a Steiner point p, we remove every Steiner point whose distance from p is at most $r \cdot d$, for some parameter r and the distance d between p and its closest Steiner point q. (b) Applying a deletion step and an insertion step in order reduces the number of Steiner points by two.

3 Results

We implemented our algorithms in Python 3. We used two servers: (i) 4.40GHz Intel Core i5 12400F CPU with 32GB RAM, and (ii) 4.70GHz AMD Ryzen 9 7900 CPU with 32GB RAM.

We now discuss the results. We have found non-obtuse triangulation for all 150 instances. We ranked first on 34 instances including 4 exclusive ones, see Figure 7. We ranked second in almost all the other instances, including 35 instances where we used only one more Steiner point than the best solution. As a result, we ranked second among 19 teams, and reached the top among the junior teams.

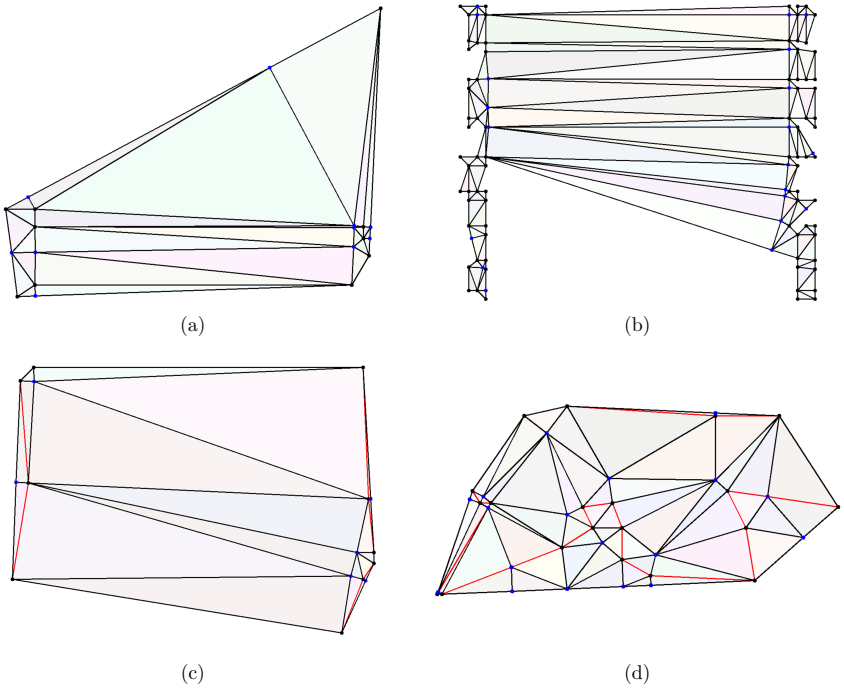

Figure 7 Our exclusive best solutions: (a) point-set_10_f999dc7f, (b) simple-polygon_80_7b8f6c4c, (c) simple-polygon-exterior_10_a5f0f2fc, and (d) simple-polygon-exterior_20_92dcd467.

We analyze our results by the types and the sizes of the instances. We achieved the highest average score for instances of ortho types. See Figure 8(a). We got higher scores for smaller instances than for the larger instances. See Figure 8(b).

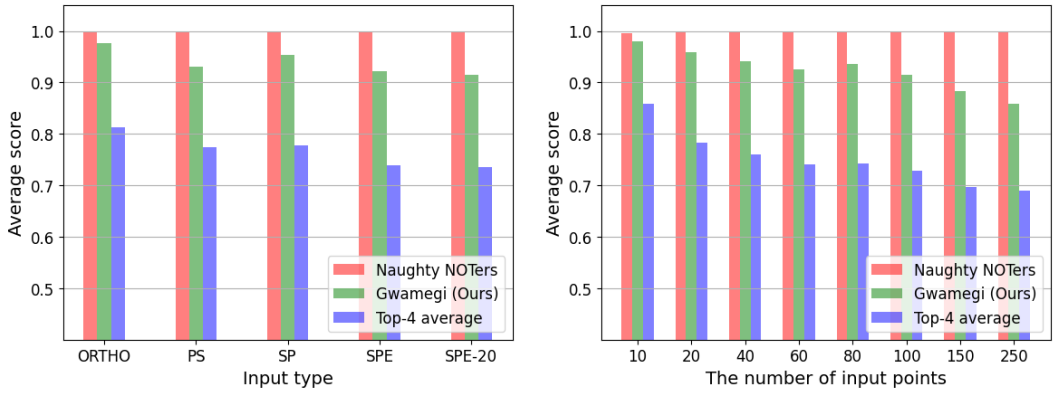

Figure 8 Average score compared with Naughty NOTers [1] and with top four teams (Naughty NOTers, Gwamegi, KITriangle, and Obtuse Terminators). We write ORTHO for ortho type instances, PS for point-set type instances, SP for simple-polygon type instances, SPE for simple-polygon-exterior type instances, and SPE-20 for simple-polygon-exterior-20 type instances. (a) Average score per input type. (b) Average score per number of input points.

Abstract

We present AmoebotSim 2.0, a simulation environment for the geometric amoebot model of programmable matter that supports the reconfigurable circuit and joint movement extensions of the model. In the geometric amoebot model, we consider systems of simple computational entities called *amoebots* in a regular triangular grid environment. We are interested in distributed algorithms that solve coordination and shape formation problems. The *reconfigurable circuit* and *joint movement* extensions of the model allow the amoebots to communicate over greater distances and perform more complex movements, overcoming some limitations of the original model. AmoebotSim 2.0 is an open-source simulation environment that supports these extensions and provides a rich graphical interface, flexible simulation features, an extensive API, and comprehensive documentation.

1 Introduction

Programmable matter envisions materials that can change their physical properties like shape, elasticity, conductivity, and color in a programmable fashion and react autonomously to external influences [10]. Potential application areas include minimally invasive medical treatment, maintenance, exploration, and manufacturing. We typically view such materials as systems of many identical nano-scale computational entities with minimal individual movement and communication abilities.

We consider the *geometric amoebot model* [5, 4], where a set of n entities, called *amoebots*, is placed on the nodes of the infinite equilateral triangular grid graph (see Fig. 1a). The set of occupied nodes must be connected and every node can be occupied by at most one amoebot. By performing an *expansion*, an amoebot occupying one node can expand its body onto an adjacent unoccupied node. An expanded amoebot can *contract* into either of the two occupied nodes. By repeated expansion and contraction, the amoebots can move along the edges of the grid. Two amoebots occupying adjacent nodes can sense each other and exchange simple messages. The amoebots are controlled by anonymous, identical finite state machines with a constant number of states that is fixed by the algorithm. We consider a *fully synchronous* execution model where time proceeds in discrete rounds and in each round, all amoebots are activated simultaneously.

The *reconfigurable circuit* extension [6] allows amoebots to construct communication networks by placing *pins* on the amoebots' borders (see Fig. 1b). The pins of adjacent amoebots connect to form communication channels. Each amoebot can internally connect arbitrary disjoint subsets of its pins into *partition sets*. Using partition sets as nodes and connections between pins of adjacent amoebots as edges, we define a graph. We call the connected components of this graph *circuits*. Amoebots can use circuits as communication channels on which they can broadcast primitive signals called *beeps*. A beep carries no information about its origin and is always received by all amoebots on a circuit. Using circuits, many coordination problems can be solved in polylogarithmic time [6, 9, 8, 2].

The *joint movement* extension [7] enables amoebots to perform more complex movements by pushing and pulling each other during expansions and contractions (see Fig. 1c). By combining their local movements, amoebots can rapidly reconfigure and move their structure.

In this paper, we present AmoebotSim 2.0, a visual simulator for algorithms in the geometric amoebot model that supports both model extensions. The source code is available on GitHub[2], and there is a website[3] showcasing the main features, some example simulations, and a browser-based demo. The simulator was developed for the Unity[4] game engine, which provides a platform for a highly interactive user interface and efficient rendering of complex simulations. The project can only be opened and executed within Unity's editor. Our simulator was inspired by AmoebotSim [3], a simulator for the original amoebot model. The main difference between the two simulators is that AmoebotSim uses a sequential execution model, while the extensions supported by our simulator require a synchronous model.

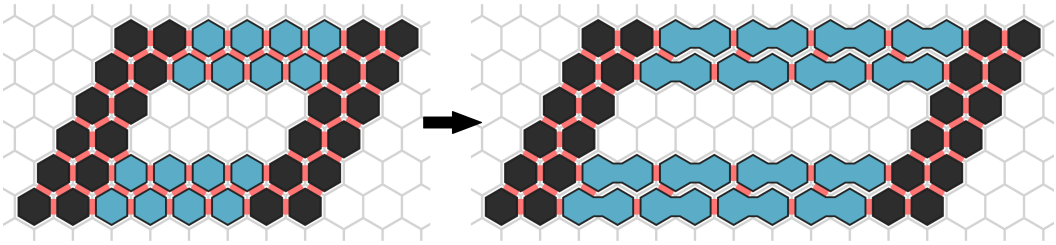
(b) Reconfigurable circuit extension.



(c) Joint movement extension.

Figure 1 (a) Contracted and expanded amoebots (blue) in the triangular grid. Adjacent amoebots are connected by red edges. (b) The reconfigurable circuit extension. Amoebots are drawn as hexagons, pins are black circles on their borders and partition sets are drawn as black circles inside the hexagons. The partition sets are connected to the pins they contain. Partition sets in the same circuit have lines of the same color. (c) Amoebots before and after a joint movement.

2 Features

User Interface. The simulator's user interface (see Fig. 2) consists of a central viewport showing the amoebot structure, a top toolbar with visualization options and general controls, a bottom toolbar with simulation controls, a collapsible log, and two collapsible side panels. The left panel displays the state variables of a selected amoebot, which can be edited while the simulation is paused, and the right panel either displays advanced visualization settings or algorithm parameters, depending on the current mode. When launched, the simulator starts in *initialization mode*, where the algorithm can be selected and the amoebot structure is initialized. Starting the simulation switches to *simulation mode*, where the simulation controls are enabled and the selected algorithm is executed.

Visualization Options. Visualizing amoebot states and complex circuit configurations is the main task of AmoebotSim 2.0. Therefore, each amoebot can control its color, the colors of its circuits, and the placement of its partition sets. Using the top toolbar, the amoebot visualization can be switched between three different modes, and circuits and joint movement bonds can be toggled off. To visualize the dynamics of a simulation, all movements are animated and beeps are highlighted with a flashing effect. The animation speed can be adjusted and the animations can be turned off if desired. Additional UI elements like lines and arrows can be drawn on top of the amoebots to display structures like spanning trees.

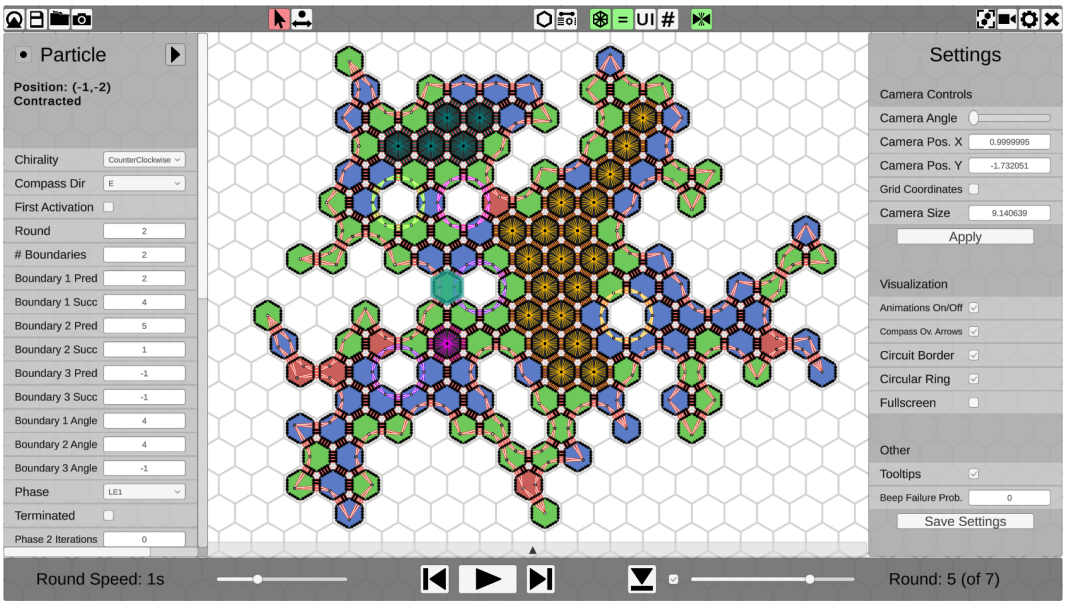


Figure 2 The AmoebotSim 2.0 user interface.

Algorithm Development. Algorithms are developed as C# classes that inherit from a base class and implement or override certain methods and fields. The simulation environment provides an algorithm creation tool that generates a functional template file with one click. Inheriting from the base class allows the simulator to detect the algorithm class by reflection, so no further registration in the core system is necessary. The base class and additional utilities provide a variety of methods and constants for all possible amoebot actions and information retrieval, e. g., discovering neighbors, manipulating direction values, setting up pin configurations, performing movements, etc. An algorithm can also be developed as a *subroutine*, allowing it to be reused by other algorithms and subroutines. A library of subroutines for some basic algorithms like leader election and boundary identification is provided. In addition to the documentation comments annotating all API source code, a comprehensive documentation with installation and usage instructions is hosted on GitHub.

Initialization. Every algorithm can implement an initialization procedure with custom parameters to place and initialize the amoebots. Using a global view of the structure, developers can establish any initial conditions, e. g., elect a leader amoebot, ensure hole-freeness, and provide input data. Afterwards, the amoebot structure can be edited manually by using the top toolbar and left side panel to add, remove, move, and edit amoebots.

Simulation History. The simulator records all rounds of a simulation. Using the bottom toolbar, any part of the recorded history can be reviewed and replayed. The history can also be cut off after the selected round so that the next rounds can be simulated again, possibly leading to a different outcome if the algorithm is randomized or some amoebot states were edited. Simulations can be stored in JSON files and loaded later.

Abstract

Metric spaces defined within convex polygons, such as the Thompson, Funk, reverse Funk, and Hilbert metrics, are subjects of recent exploration and study in computational geometry. This paper contributes an educational piece of software for understanding these unique geometries while also providing a tool to support their research. We provide dynamic software for manipulating the Funk, reverse Funk, and Thompson balls in convex polygonal domains. Additionally, we provide a visualization program for traversing the Hilbert polygonal geometry.

1 Introduction

Thompson, Funk, reverse Funk, and Hilbert are closely related distance measures that apply to points in the interior of a convex body (see Section 2 for definitions). The Hilbert metric has applications in convex approximation [1, 2, 16], real analysis [9], linear algebra [10], clustering [12], and machine learning [15] and has been the subject of recent study for this reason [4–7, 11]. The Funk, reverse Funk, and Thompson metrics are comparatively unexplored but all share similarities with the Hilbert metric [13, 14].

In this paper, we present new dynamic software for manipulating the Funk, reverse Funk, and Thompson balls in convex polygonal domains. Additionally, we provide visualization software for traversing the Hilbert polygonal geometry. Our code is predominantly written in Javascript and is available at `https://github.com/nithin1527/funk-geo-visualizer`. To use the software, please go to `https://funk-geo-visualizer.vercel.app/`. For more information on the usage, please see the README on the GitHub repository or watch the accompanying video available at `https://www.youtube.com/watch?v=IeRIO25iK-o`.

2 Definitions

Throughout, Ω refers to a convex polygon in $\mathbb{R}^2$ with m sides. Let $\partial\Omega$ denote its boundary and let $\operatorname{int}\Omega$ refer to its interior. When clear, we omit explicit reference to Ω.

▶ **Definition 1** (Funk weak metric). *Given two distinct points $p, q \in \operatorname{int}\Omega$ in $\mathbb{R}^2$, let q' denote the intersection of the ray from p through q with $\partial\Omega$. Define the* Funk weak metric *to be:*

$$F_\Omega(p,q) \;=\; \ln \frac{\|p-q'\|}{\|q-q'\|},$$

where $F_\Omega(p,p) = 0$.

The above definition is also sometimes called the *forward Funk metric*. Note that the Funk weak metric is asymmetric. Its reverse, the *reverse Funk metric*, is defined ${}^rF_\Omega(p,q) = F_\Omega(q,p)$ [13]. Define the *Funk ball* centered at a point p of radius r, denoted $B_F(p,r)$ (note the subscript refers to the distance function), to be the set of points $q \in \operatorname{int}\Omega$ such that $F_\Omega(p,q) \le r$. The reverse Funk ball is defined analogously. These are scaled homotheties of Ω (see Figure 1(b) and (c)).

▶ **Lemma 2.** *The open forward Funk ball of radius r around a point p is the image of Ω under Euclidean homothety around the point p with dilation factor of $(1 - e^{-r})$ [13].*

▶ **Lemma 3.** *The open reverse Funk ball of radius r around a point p is the image of Ω under Euclidean homothety around the point p with dilation factor of $(e^r - 1)$ [13].*

The *Hilbert metric* can be defined as the average of the forward and reverse Funk metrics [13].

▶ **Definition 4** (Hilbert metric). *Given two distinct points p, q in a convex polygonal $\Omega \subset \mathbb{R}^2$ we define the* Hilbert metric *to be:*

$$H_\Omega(p,q) \;=\; \frac{1}{2}(F_\Omega(p,q) + {}^rF_\Omega(p,q)),$$

Note that the Hilbert metric is a proper metric, obeying the identity of indiscernibles, symmetry, and the triangle inequality. Hilbert balls are polygons with at most $2m$ sides (see Figure 1(a)). For a characterization of Hilbert balls see "Balls in the Hilbert Polygonal Geometry" by Nielsen and Shao [11].

The notion of the Hilbert metric gave rise to the definition of another metric by A.C. Thompson in 1963 called the *Thompson metric* [14] on convex cones. The formulation of this metric can be generalized through the Funk metric.

▶ **Definition 5** (Thompson metric). *Given two distinct points p, q in a convex polygonal $\Omega \subset \mathbb{R}^2$ we define the* Thompson metric *to be:*

$$T_\Omega(p,q) \;=\; \max(F_\Omega(p,q), {}^rF_\Omega(p,q)),$$

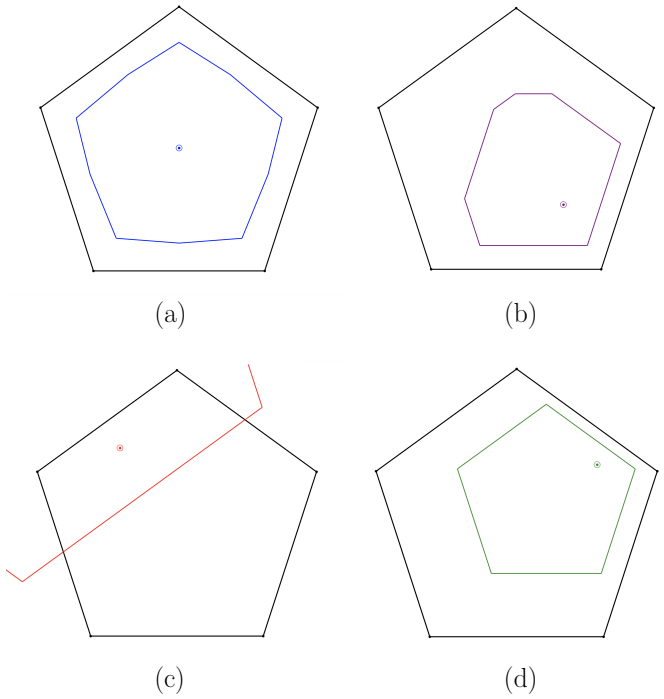

Figure 1 The Hilbert (a), Funk (b), Reverse Funk (c), and Thompson (d) balls around a point.

Note that the identity of indiscernibles and triangle inequality clearly carry over from the Funk metric. The symmetry of the Thompson metric follows from the fact that it is the maximum of the forward and reverse of a weak metric.

The Thompson ball (see Figure 1(d)) is the intersection of the forward and reverse Funk balls. Since both these balls are convex (as they are homotheties of Ω intersected with Ω [13]), computing the Thompson ball reduces to calculating the intersection of two convex polygons. This can be done linearly in the complexity of the polygons. Hence, we get:

▶ **Lemma 6.** *The Thompson ball around a point p with radius r has at most $2m$ sides and is the intersection of the forward and reverse Funk balls around p with radius r.*

Proof. This follows from the fact that each segment of the Funk balls can contribute at most once to the complexity of the Thompson ball by convexity. ◀

Thompson balls have a property that sets them apart from many other metrics.

▶ **Observation 7.** *Thompson balls are not pseudo-disks (see Figure 2(a)).*

We believe the following to be a new result.

▶ **Lemma 8.** *A Thomspon ball of radius r centered at p can be nested between two Hilbert balls of radius $0.5r$ and r centered at p (see Figure 2(b)).*

Proof. Given a convex body $\Omega \subset \mathbb{R}^d$, for every point $p \in \Omega$ and radius $0 < r$, we will show:

$$B_H(p, r/2) \subset B_T(p, r) \subset B_H(p, r).$$

To prove that $B_T(p, r) \subset B_H(p, r)$, we must show that the Thompson distance from p to a point on the boundary of the ball is greater than or equal to the Hilbert distance. This follows directly from the definition of the Hilbert and Thompson metric distances:

$$H(a, b) = \frac{1}{2}(F(a, b) + F(b, a)) \leq 2 \cdot \frac{1}{2}(\max(F(a, b), F(b, a)) = T(a, b)).$$

To prove that $B_H(p, r/2) \subset B_T(p, r)$, we must show that the Thompson distance from p to a point on the boundary of the ball is less than or equal to the Hilbert distance. This follows from the fact that if $H(a, b) = \frac{1}{2}r$ then $\frac{1}{2}(F(a, b) + F(b, a)) = \frac{1}{2}r$ so $F(a, b) + F(b, a) = r$ and so $T(a, b) = \max(F(a, b), F(b, a)) \leq r$. ◀

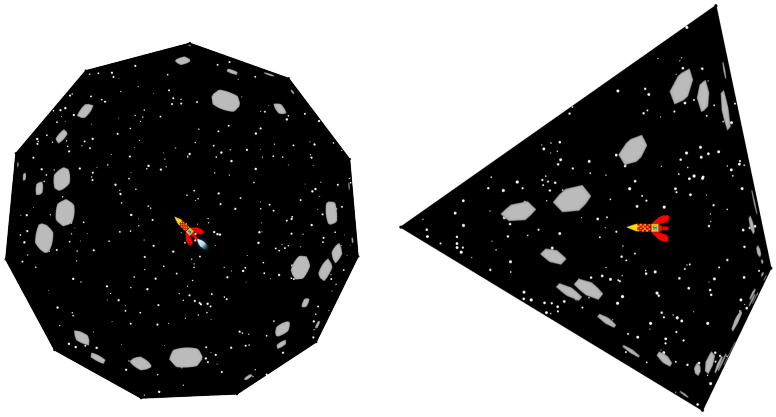
Figure 2 (a) Thompson balls are not pseudo-disks, (b) a Thompson ball of radius 1 between two Hilbert balls of radii 1/2 and 1.

3 Traversing the Hilbert Geometry



(a) (b)

Figure 3 (a) Travelling in a hendecagon and (b) after travelling some distance in the square.

We provide a visualization software for inserting Hilbert balls into a user-specified Hilbert polygonal geometry, and then traveling around that geometry (see Figure 3). In order to give users the ability to move in the Hilbert geometry, we implement a projective mapping that first affinely shifts Ω so that its centroid is at the origin O. Then, using a map ϕ_v, we map $O + v$ to the centroid $\phi_v(\Omega)$ where v is an accumulated displacement vector. This mapping is given by:

$$\phi_v(p) \;=\; \frac{p}{1+\langle p, v\rangle},$$

where p is an arbitrary point [8].

However, this projective mapping often deforms Ω into very skinny forms. To handle this situation, we first capture the approximate John ellipsoid of the original shape scaled with the Mahalanobis distance. After movement, we calculate the new approximate John ellipsoid with respect to the projection of the vertices of Ω. Then, we map the new John ellipsoid to the unit circle using a Cholesky decomposition. Lastly, we map the unit circle to the original approximate John ellipsoid to center the new geometry. Since all the maps we use are affine maps, they preserve the Hilbert metric. For more information on the mapping used, see the README on the GitHub repository.

Abstract

There are many structures, both classical and modern, involving point-sets and polygons whose deeper understanding can be facilitated through interactive visualizations. The Ipe extensible drawing editor, developed by Otfried Cheong, is a widely used software system for generating geometric figures. One of its features is the capability to extend its functionality through programs called Ipelets. In this media submission, we showcase a collection of new Ipelets that construct a variety of geometric structures based on point sets and polygons. These include quadtrees, trapezoidal maps, beta skeletons, floating bodies of convex polygons, onion graphs, fractals (Sierpiński triangle and carpet), simple polygon triangulations, and random point sets in simple polygons. All our Ipelets are programmed in Lua and are freely available.

1 Introduction

We present several **Ipelets** for sets of points and polygons in the $\mathbb{R}^2$ plane. These Ipelets include computing quadtrees, trapezoidal maps, onion decompositions, random point sampling in polygons, beta skeletons, floating bodies, the Sierpiński carpet and triangle fractals, and simple polygon triangulations. Some of these are also implemented in CGAL [9]. All the Ipelets are programmed in Lua and are freely available at `https://github.com/nithin1527/onion-soup`. To install an Ipelet, download the file and place it in the `ipelets` subfolder of your Ipe folder.

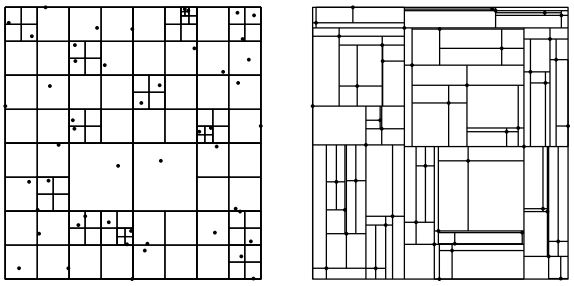
2 Points

In this section, we describe the geometric structures that our Ipelets compute on points. There are a few Ipelets available that already build geometric structures on point sets, such as Voronoi diagrams [5, 14] and Delaunay triangulations [5]. We contribute to this with the additions of the following Ipelets.

2.1 Quadtrees

A quadtree is a data structure used to recursively divide two-dimensional space into four regions/nodes, usually named northwest, northeast, southwest, and southeast [6, Ch. 14]. A point quadtree is a specific type of quadtree in which each node houses a point and its four regions are determined by dividing its region into four sub-regions, with the point itself as the center (see Figure 1(b)). A point-region quadtree is another type of quadtree in which each node represents a region of space with a certain maximum capacity of points, such that points are only housed in leaf nodes (see Figure 1(a)). The importance of quadtrees arises from their enabling of efficient operations on data points in two-dimensional space. Consequently, their applications include areas of image representation/processing, mesh generation, and two-dimensional collision detection [6, 16]. We contribute an Ipelet for generating both these types of quadtrees, and we produce the array format for its contents in a copyable form.

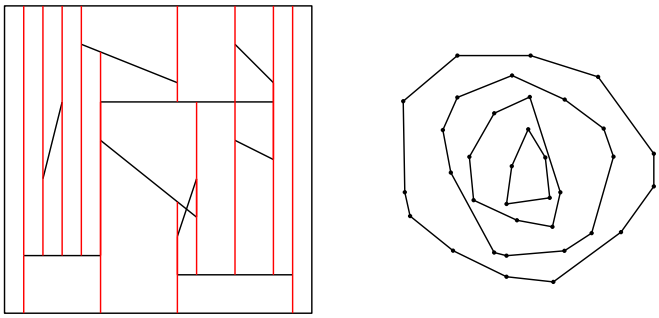


(a) (b)

Figure 1 (a) Point-region quadtree and (b) point quadtree.

2.2 Trapezoidal Maps

Given a collection of line segments, a trapezoidal map is a subdivision of the plane that respects these segments [6, Ch. 6.1]. The trapezoidal map is created by shooting vertical rays up and down from each of the endpoints of the segments until the vertical line intersects another segment or the bounding box (see Figure 2(a)). In practice, trapezoidal maps allow users to perform planar point location, with respect to the trapezoids that make up the map, in $O(\log(n))$ time. This finds applications in many areas, including geographic information systems, computer-aided design, among others [6, 16]. We provide an Ipelet which, given a set of line segments and an optional bounding box, computes a trapezoidal map of these line segments. It also provides a method for copying the details of the map in an array format.



(a) (b)

Figure 2 (a) Trapezoidal map of a set of segments and (b) an onion decomposition of a point set.

2.3 Onion Decompositions

▶ **Definition 1** (Onion Decomposition). *Given a finite set of points $P \subset \mathbb{R}^n$, the onion decomposition of P is the nested sequence of convex sets $\{C_0, C_1, \ldots, C_m\}$, where:*
(1) *C_i is the convex hull of P_i.*
(2) *$P_0 = P$ and $P_i = P \setminus \bigcup_{j=0}^{i-1} C_j$, for $i \geq 1$.*
(3) *P_m is the last P_i containing any points.*

This is the sequence of convex polygons that result by repeatedly taking the convex hull of the set, and then removing these points from the set [15, Ch. 4] [3] (see Figure 2(b)). Onion decompositions of points have found a variety of uses in robust statistics [1, 7] and fractional cascading [4]. We provide an Ipelet that allows users to select a point set and generate its onion decomposition in the plane.

2.4 Beta Skeletons

▶ **Definition 2** (Beta Skeleton). *Given a set of points (vertices) V and a parameter $\beta \in \mathbb{R}^+$, the beta skeleton of the set of points is the graph $G = (V, E)$ where: There exists an edge $\{v_1, v_2\} \in E$ if and only if for all $v_3 \neq v_1, v_2$, the angle $\angle v_1 v_3 v_2$ is smaller than θ, where:*

$$\theta = \begin{cases} \arcsin \frac{1}{\beta} & \text{if } \beta \geq 1, \\ \pi - \arcsin(\beta) & \text{if } \beta \leq 1. \end{cases}$$

Note that the Gabriel graph and the relative neighborhood graph (RNG) of the point set arise as special cases when $\beta = 1$ and $\beta = 2$, respectively. The beta skeleton [18, Ch. 32] has applications ranging from machine learning [19] to astronomy [10].

3 Polygons

In this section, we describe the geometric structures that our Ipelets compute on polygons, for more, see "Ipelets for the Convex Polygonal Geometry" [13].

3.1 Floating Body

Given a convex body $\Omega \subset \mathbb{R}^d$, a *cap* is the intersection of Ω with a halfspace H. Letting h denote the bounding hyperplane of H, the *base* of the cap is $h \cap \Omega$. When $d = 2$, the *area* of a cap is its Lebesgue measure.

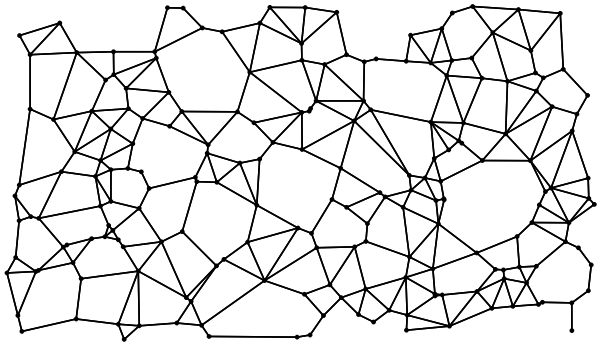


Figure 3 Beta skeleton for a point set for $\beta = 1$, which is equivalent to the Gabriel graph.

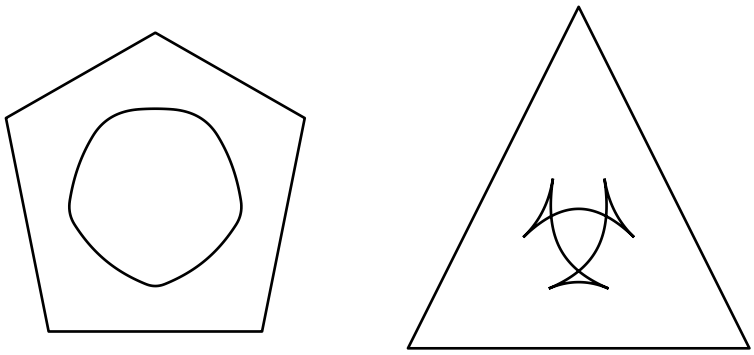
▶ **Definition 3** (Dupin Floating Body). *Given a convex body $\Omega \subset \mathbb{R}^n$ and $\delta \in [0, 1]$, the Dupin floating body, F_δ, is the (possibly non-convex) body defined by the set of points that are the centroids of the bases of all caps that cut off a volume of $\delta \cdot \mathrm{vol}(\Omega)$ [2, Ch. 3].*

▶ **Definition 4** (Convex Floating Body). *Given a convex body $\Omega \subset \mathbb{R}^n$ and $\delta \in [0, 1]$, the convex floating body K_δ is the intersection of all halfspaces whose defining hyperplanes cut off a set of volume $\delta \cdot \mathrm{vol}(\Omega)$ from Ω [2, Ch. 3] [17].*

Generally, the Dupin floating body need not be convex (see Figure 4(b)), but when it is convex it equals the convex floating body [2]. We provide an Ipelet for generating the Dupin floating body in arbitrary convex polygons (see Figure 4). For the purposes of the Ipelet we take δ as the percentage of the area of the given polygon in $\mathbb{R}^2$ to cut away with caps. Floating bodies are used for understanding the boundary structure of convex sets through affine surface area [17].

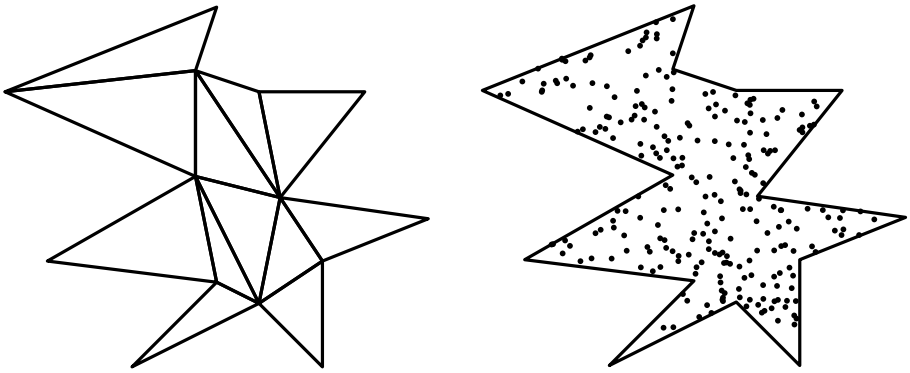


(a) (b)

Figure 4 Two examples of the Dupin floating body, (a) convex and (b) non-convex.

3.2 Polygon Triangulations and Point Sampling

Polygon triangulations are a ubiquitous tool in computer science [6, Ch. 3]. One application of such triangulations is that it allows efficient point sampling inside non-convex polygons. To do this, points are randomly chosen from inside the triangles (weighted by area) using barycentric coordinates. We provide an Ipelet which, given a polygon, decomposes it into a triangulation (based on code by Nils Olovsson [12]) and randomly places a user specified amount of points in it using this method.



(a) (b)

Figure 5 (a) Triangulating a simple polygon and (b) randomly sampling points in it.

3.3 Sierpiński Triangle and Carpet

The Sierpiński Triangle and Carpet [11, Ch. 1] are two self similar fractals defined on simple polygons. They are known for having a few interesting properties, such as Lebesgue measure 0 and Haussdorf dimensions $\log_2(3)$ and $\log_3(8)$. They contain uncountably many points.

Incremental and Interactive PQ- and PC-Trees

Simon D. Fink

Abstract

PQ-trees [2, 3] (and their more general variant PC-trees [13, 17]) are a well-known data structure for representing the set of linear (or for PC-trees, circular) orders respecting a given set of consecutivity constraints. Each such constraint is specified by a set of elements and requires that these elements appear consecutively in the linear (or circular) order; thus, they disallow the set to be interleaved with its complement. The main operation supported by these data structures is thus the so-called *update*, which takes as input a set that forms an additional constraint, and in response changes the tree in order to restrict the represented orders to those satisfying the new constraint. Interpreting a given tree is straightforward: leaves represent the underlying elements, while inner nodes either allow the order of their subtrees to be reversed (Q/C-nodes) or to be arbitrarily permuted (P-nodes). However, the way this structure and the set of represented orders change under updates is less intuitive. We present an interactive web app that allows users to specify sets of consecutivity constraints in the form of a 0/1-matrix and then calculates and visualizes the corresponding PQ- or PC-tree. The constraints can then be changed dynamically while observing how this changes the structure of the tree and the set of represented orders. Through this interactive exploration, we hope to make PQ- and PC-trees more accessible to a wider audience.

1 Background

PQ- and PC-trees have applications in many graph drawing problems related to planarity [3, 17] and its variants, such as Level Planarity [6] and Cluster Planarity [9], as well as other layout problems such as NodeTrix [15] or the geometric Segment Intersection Representation problem [11]. More broadly, they are also used for solving variants of the Travelling Salesperson Problem [4], in Computational Biology (such as for Genome Ordering [14]) and to solve the Consecutive Ones Problem on 0/1-matrices [3, 13], which has many applications, for example in the analysis of preferences in Computational Social Choice [8].

A *PQ-tree* T is a rooted tree the represents a set of linear orders on some ground set X [2, 3]. The leaves of T are exactly the elements of X, while its inner nodes are labelled as either P-node or Q-node; see Figure 1(b). A *P-node* allows arbitrarily permuting its incident subtrees, while a *Q-node* comes with a fixed order of its incident subtrees that may

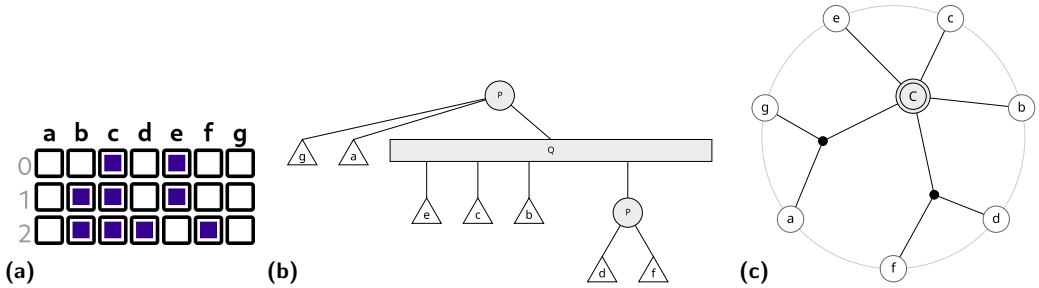

Figure 1 **(a)** A binary matrix representing the elements $X = \{a, b, c, d, e, f, g\}$ as its columns and the three consecutivity restrictions $\{c, e\}, \{b, c, e\}, \{b, c, d, f\}$ through its three rows. **(b)** A PQ-tree representing all linear orders satisfying the restrictions from (a). **(c)** A PC-tree representing all circular orders satisfying the restrictions from (a). Images generated by the portfolio website.

only be reversed. All orders of leaves obtained by making these changes at the inner nodes are the linear orders *represented* by the PQ-tree T. Similarly, a *PC-tree* T is an unrooted tree that represents a set of circular orders on some ground set X [13, 17]. In addition to being unrooted, its only further difference to a PQ-tree is that Q-nodes are called *C-nodes*, but otherwise behave the same in only allowing their fixed order or the reversal thereof; see Figure 1(c). As there is no designated root, the leaf orders obtained from a PC-tree can be circularly shifted, yielding circular instead of linear orders. It has been shown that still, both kinds of trees are actually linear-time equivalent [12].

A *trivial* PQ- or PC-tree consists only of a single inner P-node and represents all permutations of its leaves X. Any tree can be obtained from the trivial one by applying a sequence of *update* operations to it. Each update takes as input a subset $A \subset X$ and changes the tree such that the represented orders are restricted to those in which A is consecutive. If there are no represented orders where A is consecutive, the *null-tree* representing an empty set of orders is returned. The update operation can be implemented to run in $O(|A|)$ time [2, 17], although (as we discuss at the end of this paper) this algorithm is far from trivial to implement or explain [1, 7, 10].

In this way, consecutivity restrictions are represented as a family of subsets of X. This family can be represented as a binary 0/1 matrix, where each column corresponds to an element of X, and each consecutivity restriction corresponds to a row in the matrix, requiring exactly its 1-entries to be consecutive; see Figure 1(a). Note that the problem of finding orders satisfying all consecutivity constraints can now be seen as reordering the columns of the matrix such that all ones are (circularly) consecutive, which is also known as the (Circularly) Consecutive Ones Problem [3, 13].

2 Our Portfolio

We use the matrix representation in our portfolio to allow interactively specifying constraints. After the user changes the matrix, the PQ- or PC-tree displayed next to it is automatically updated to represent the desired orders. The columns of the matrix can be reordered manually through drag and drop, or automatically on clicking a button, such that the matrix has the (Circularly) Consecutive Ones Property. Additionally, the website displays how many admissible orders there are and also provides an explicit enumeration of them. In case of a no-instance (where no order satisfies the consecutivity restrictions), we highlight the first restriction that would yield a null-tree, and display the tree obtained from the

restrictions up to right before that point. This makes it easy to verify which elements of the next restriction cannot be made consecutive. A guided tour further provides a tutorial explaining the PQ- and PC-tree data structures and how the website can be used. Allowing to interactively explore PQ- and PC-trees and their relationship to consecutivity-constrained orders, we hope to make this data structure more accessible to a wider audience. We also provide visually-pleasing automatic visualizations that can, e.g., easily used for scientific work building on these structures; see Figure 1.

For PQ-trees, we use a simple top-down tree layout, while the layout of the circular and unrooted PC-trees is slightly more involved. Here, we use a Tutte drawing [16], fixing the leaves in an order admissible by the tree on a circle and then using the force-based approach to draw the inner nodes within the circle. Chiu, Eppstein and Goodrich suggested to assign weights to edges to further improve the aesthetics of Tutte drawings [5]. They use the formula a/r^i, where a is some scaling constant, r is the weighting parameter, and i is the minimum distance of the edge to a leaf. As the scaling is applied linearly to all weights and thus does not influence the resulting drawing, we set $a = 1$ in our implementation and only allow the user to tune the r value to their liking. Interestingly, while the authors suggested r values of 3 and 5 in their paper [5], we find values of 1 or slightly below to better suit the (rather small) graphs we draw.

Future improvements to the website could also allow interactively changing the displayed order right within the currently visualized tree according to the P- and Q/C-node rules. Furthermore, an interactive tour through the individual steps used to update a PQ- or PC-tree could further help in understanding this algorithm. Note that the update of PQ-trees is through a rather involved recursive matching and application of 9 different "templates" [2], resulting in an algorithm that is famously hard to implement correctly [7, 10]. The update on PC-trees streamlines this to an update in one go, although its correct linear-time implementation is still rather challenging [1, 10]. Thus, some trade-offs for simplicity of explanation will need to be made when interactively executing these algorithms, as is e.g. also done by the static explanation of the update we currently link to [1].

Abstract

This paper introduces a set of tools built to help researchers design algorithms for modular robots. These tools can brute force solutions to specific reconfigurations, visualize movements of modular robots, and can be used to design specific configurations of robots. Multiple models of modular robots are supported, and can be added by users.

1 Introduction

In *Modular Robotic Systems* (MRS) a "robot" consists of several small independent robotic units (called *modules*) that can move around each other (re-configure) to change the overall shape of the robot. This gives the system flexibility to adapt to different situations and resilience since modules are interchangeable. In many MRS models, a *configuration* of the system is a polyform composed of lattice-aligned modules. A *move* transforms a configuration C into another configuration C', where C and C' differ by the position of a single module m. A sequence of configurations $C^0, C^1, C^2, C^3, \ldots$ where each C^{i+1} is obtained by applying a single move to C^i is called a *reconfiguration sequence*. The *single backbone condition* [6] is often required, to move a module m in a configuration C, $C \setminus \{m\}$ must be connected.

A moving module must not collide with a stationary module. The *free space requirements* define the local arrangement of modules required to prevent collisions. Many models are defined by their free space requirements, such as sliding [5, 7] or pivoting [3, 8] cubes. These two models and their 2D analogs (sliding and pivoting squares) are the focus of this paper. Their free-space requirements are shown in Figure 1.

A model is *universal* if any configuration can be reconfigured into any other. Clearly, MRS models that admit universal reconfiguration are particularly desirable. However, this is not a common property, and small changes in free space requirements can affect whether a MRS model is universal or not. For example, the sliding square and cube models are universal [2, 5], while the pivoting square model is not. Further, it is PSPACE-complete to decide whether two given configurations can even be reconfigured into each other [1].

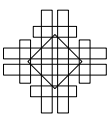

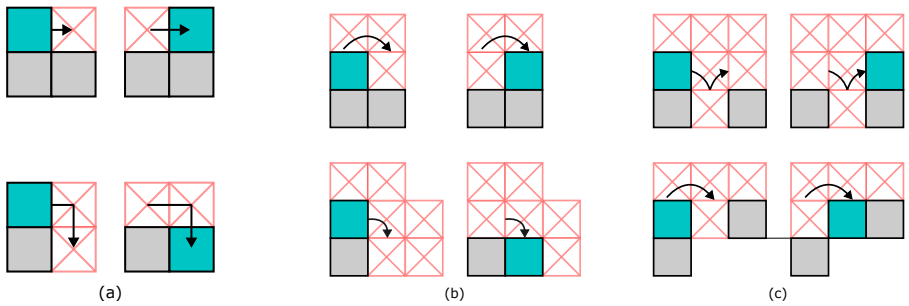

Figure 1 Free space requirements different movement models. Cubes with x's must be empty, the blue cube is the moving module. (a) sliding cube model (b) the restricted pivoting cube (c) "leapfrog" and "monkey" moves from [1].

Contribution. This paper introduces three new tools built to ease this process. A user can define a modular robot model and define starting and ending configurations and then via brute-force search (taking exponential time), find the shortest reconfiguration sequence between them. This can not only find optimal reconfiguration sequences but also be used to verify the correctness of a meta-module.[1] This work would be presented at CG Week via a live demonstration. At the time of writing this is an active research project, hence the software maybe updated, the linked GitHub will have updated documentation.

2 Software

Tiler. Our tool "3D Tiler" is a web-based application designed to create and manipulate 3D polyforms, inspired by the SVG Painter by Erik Demaine[2]. It supports the cube and rhombic dodecahedron lattices. The tool provides a variety of controls for users to interact with their designs. Layer controls allow users to move up or down layers and highlight the current layer, while color controls enable changing the color. The interface is illustrated in Figure 2. Additionally, 3D Tiler offers export options to JSON and OBJ formats, facilitating the sharing and utilization of designs in other applications. Importing designs from JSON files is also supported, making collaboration and modification straightforward.

Pathfinder. We built a tool "Pathfinder" which finds the shortest reconfiguration sequence between two configurations. Move definitions (free space requirements), and initial and final configurations are specified as input JSON files. A variety of cube/square models, as well as rhombic dodechahedra are supported "out of the box" and users can specify their own models.

It natively supports two search algorithms to explore and find shortest paths in the configuration space. We are given initial and final configurations[3] together with a description of the allowed moves[4]. The pathfinder tool uses a shortest path algorithm to incrementally build the configuration graph G. At each step, starting with the initial configuration, we

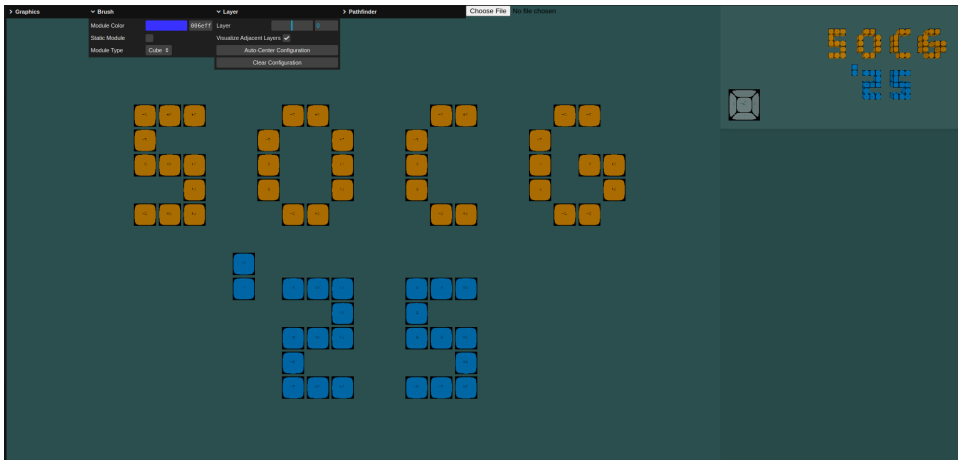

Figure 2 3D Tiler interface.

check whether each non-cut, non-static module has a valid move, each producing a new configuration added to G, which we then recurse into, in an order specified by the selected shortest path algorithm. Once a move generates the desired configuration, a file is produced for use in the visualization tool demonstrating the corresponding reconfiguration sequence.

BFS. New states are added to a queue and processed in a FIFO order. Each new state is kept in a hash table, so states can be checked if they have been previously visited. While a state is being processed, all new states reachable from the current state are generated and added to the queue. When the hash for the current state matches the hash for the final state, the algorithm terminates and returns the path from the start state to the end state.

A* search. A* search algorithm was implemented with various heuristics to improve search times. This search works almost identically to BFS, with the only difference being the use of a priority queue to store adjacent states. States are then processed in an order based on their depth added to a weight assigned to them by a heuristic. The advantages of the A* search are most clear when testing scenarios in 3D space, where the number of possible moves is far greater, and the heuristic tends to avoid irrelevant configurations.

Visualization. "WebVis" is an interactive, browser-based tool to visualize configurations and move sequences, as well as help to conceptualize potential new meta-module configurations. The tool takes a "scenario" file as input, which specifies a reconfiguration sequence and additional data such as module color, size, and shape. There are controls available to step forward and backward through the move sequence, change the animation speed, load in example scenarios, move the camera, and change the camera projection scheme (perspective versus orthographic). Details of input file specification can be found on the project wiki.

3 Results and Discussion

Pivoting to Sliding Meta-module. We analyzed the meta-module shown in Figure 3 made of pivoting square modules which simulate a sliding square module, demonstrating its correctness. The animation of the reconfiguration shown can be found in the repository.

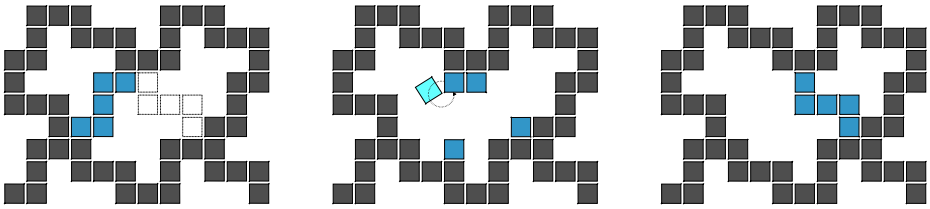

Figure 3 An initial, intermediate, and final configuration in the pivoting square model.

Heuristics. Table 1 shows the differences between search algorithms utilized.

Table 1 Search methods used on the initial and final configurations in Figure 3. All methods found a path of length 14.

Search Method:	BFS	A* (Manhattan Distance)	A* (Symmetric Difference)
Duplicate States Avoided:	148407	40783	58172
Unique States Visited:	24770	13114	14820
Average Time:	1123.67ms	455.33ms	756.67ms

Rhombic Dodecahedron Pivoting Model. In the young researchers' forum at SOCG 2023 Akitaya & Stock [4] showed that Rhombic Dodecahedral Modular Robots admit *super-rigid* configurations (Fig. 4), meaning that there are rigid configurations that remain rigid even with the addition of helper modules. Although the claims in [4] were proven, the proof requires a lot of casework, a technique prone to error. With our tool, we verified the validity of their results.

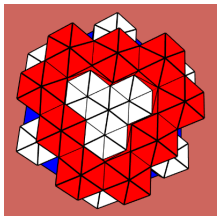

Figure 4 An example of a super rigid configuration from [4].
