We have implemented a differential interpreter that supports more constructs than present in the formalization. In addition to integer and boolean values, we also support string values. In the same vein, the language supports more than just the addition operator. It can call arbitrary operators based on an operator interface which requires an `init` function and an `inc` function:

```
1 trait Operator[T, U]:
2   def init(x: T): U
3   def inc(dx: Change[T]): Change[U]
```

The type `Change[T]` marks a change of value type `T`. Note that operators themselves can keep track of local state that is required for implementing efficient incremental operators. Additionally, the language enables first-order function calls of user-defined top-level functions. Each function ranges over its own local store.

One major difference is that the language supports a mutable 2-dimensional table ranging over integers which is global to all functions. To this end, the language supports a table-write statement $\textbf{table}[i, j] = e$ and a table-read expression $\textbf{table}[i, j]$. Note that we currently assume that the indices cannot change between the initialization and a differential run. This is a restriction we want to address in the future work.

6.3 Applying Optimizations

To enable efficient differential execution, we implemented various optimizations. We describe optimizations in the formalization as overlapping rules, where we decide manually which rule to apply. Our implementation always applies the optimization rule whenever possible. One could imagine that there are multiple applicable optimization rules. This leads to *optimization strategies* which select the optimization rule to apply at a given point at execution time. We want to investigate optimization strategies in future work.

We implemented the short-circuiting optimizations from Section 5.1 by preemptively computing read/written variables within statements and expressions. Because our language supports a 2-dimensional global table, this analysis extends to tracking table cell accesses. Building on the branch switching optimization from Section 5.3, we handle table operations efficiently:

```
def bellmanFord(numNodes: Int, src: Int): Unit {
  decl i: Int, u: Int, v: Int, w: Int
  i = 1
  repeat numNodes {
    table[0, i] = Int.Max
    i = i + 1
  }
  table[0, src] = 0
  repeat numNodes - 1 {
    u = 1
    repeat numNodes {
      v = 1
      repeat numNodes {
        w = table[u, v]
        if (w != 0 && table[0, v] > table[0, u] + w) {
          table[0, v] = table[0, u] + w
        } else {
          skip
        }
        v = v + 1
      }
      u = u + 1
    }
  }
}
```

Figure 5 Bellman-Ford Algorithm implemented in our language.

```
if (c) {
  table[i, j] = e1
} else {
  table[i, j] = e2
}
```

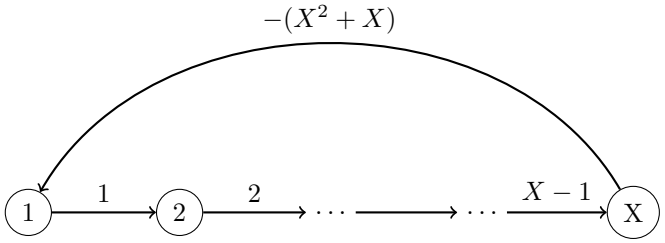
When branches differ only in their expressions (e_1 vs e_2), we can avoid expensive table diffing operations by directly computing $\Delta t[(i,j) \mapsto v_2 \ominus v_1]$ where $\sigma \vdash e1 \Rightarrow v_1$ and $\sigma \oplus \Delta\sigma \vdash e2 \Rightarrow v_2$.

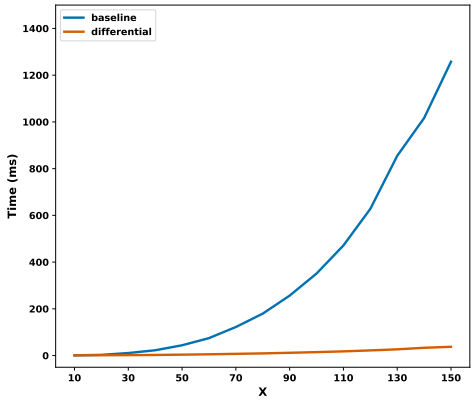
7 Case Study: Shortest-Path with Bellman-Ford Algorithm

To evaluate how precise change descriptions enable efficient incremental computation of dynamic algorithms, we implemented the Bellman-Ford single-source shortest-path algorithm [6] in our language (Figure 5). Our implementation represents the graph using an adjacency matrix stored in a global 2-dimensional table, with shortest path weights from source node `src` to node i stored at indices $(0, i)$.

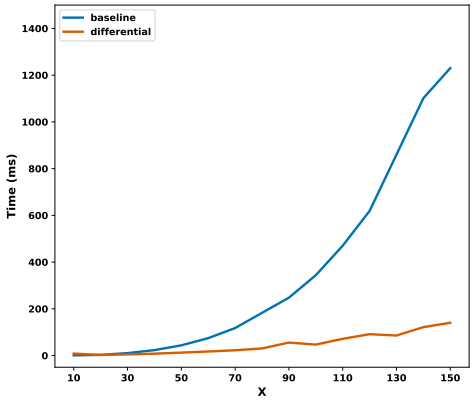
7.1 Setup

To evaluate our differential interpreter, we designed a graph structure that exhibits interesting incremental behavior. The graph is a cycle where we can configure its size by setting the number of nodes $X \in \{10, 30, \ldots, 130, 150\}$:





(a) Differential vs Baseline - Change (i).



(b) Differential vs Baseline - Change (ii).

Figure 6 Running times of Differential Interpretation and Normal Interpretation. Differential execution achieves significant speedups by avoiding redundant work.

The weight of the back edge $X \to 1$ is chosen to introduce new shortest paths, ensuring that small input changes can trigger significant output changes. We compute shortest paths starting from node 1 for different values of X and evaluate two types of changes:

(i) Adding an edge $1 \to (X-1)$ with weight 10^9. This introduces an alternative path that does not affect the shortest path solution.

(ii) Adding six edges forming cross-connections: $1 \to (X-1)$, $2 \to (X-2)$, $6 \to (X-2)$, $(X-5) \to 6$, $(X-3) \to 3$, and $(X-1) \to 2$, each with weight 10^9. Despite creating multiple new paths, these additions do not affect the shortest path solution.

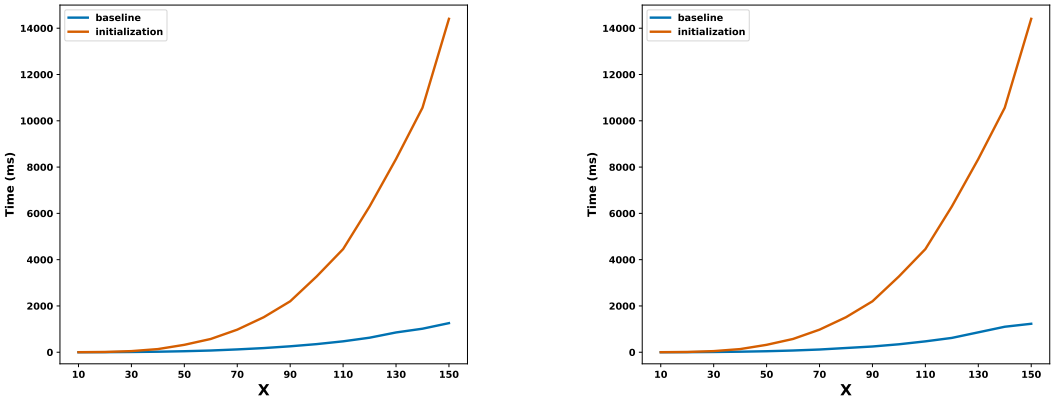
We conducted experiments on an Apple M4 Pro chip with 24GB memory running 64-bit OSX 15.1.1 and OpenJDK 23.0.1. Using the JMH benchmarking framework[3], we performed 5 warmup runs followed by 10 measurement runs for each configuration.

7.2 Results

In Figure 6, we compare the running times of differential interpretation against normal interpretation on the patched input. On the left we show the running times for change (i) and on the right we show them for change (ii). The differential interpreter outperforms normal interpretation for change (i). While Bellman-Ford has a time complexity of $O(X^3)$, the differential interpreter can skip most iterations because we employ an optimization that skips loop iterations when the changed table entries are not affected by the iteration. Since change (i) modifies just a single table entry without introducing new shortest paths, we can skip almost all iterations, yielding significant running time savings. The same benefits apply to change (ii), though to a lesser degree as fewer iterations are skippable.

A second critical optimization avoids diffing when branch switches occur, significantly reducing the differential interpreter's running time. Without this optimization, all branch switches for the inner if statement within the nested repeat loops would require diffing the old and new result tables, incurring an $O(X^2)$ cost. Instead, we apply constant-time updates to the current delta table.

[3] `https://github.com/openjdk/jmh`



(a) Initialization vs Baseline – Change (i).

(b) Initialization vs Baseline – Change (ii).

Figure 7 Running times of Initializing Interpretation and Normal Interpretation. The initial run incurs substantial overhead due to caching.

To evaluate stability over extended use, we executed 40 consecutive changes (Change (ii)) on graphs of varying sizes (10-150 nodes). We measured performance at five points in this sequence (1st, 10th, 20th, 30th, and 40th change), with 5 warmup and 10 measurement runs per point. After filtering outliers using the interquartile range (IQR) method, our analysis confirms that execution times remain consistent across the change sequence for each graph size. The Coefficient of Variation (CV), which measures relative variability as standard deviation divided by mean, is remarkably low (average 8%, maximum 13%), indicating that our differential approach maintains stable performance throughout extended use without degradation. While execution times scale with graph size as expected, the consistent performance within each size category demonstrates that repeated incremental updates do not compromise efficiency, further justifying the one-time initialization cost.

In Figure 7 we compare the running times of the initializing interpreter to normal interpretation on the initial input. On the left we show the running times for change (i) and on the right for change (ii). The graphs show that initialization requires significantly more time than normal interpretation. Normal interpretation takes roughly 1.5s for processing the initial graph where $X = 150$. In contrast, the initialization interpreter requires roughly 15s, a 10x increase. This overhead comes from caching states by inserting entries into hash tables. This overhead is an implementation artifact that we believe can be substantially reduced through engineering improvements and smarter caching strategies.

These results demonstrate that differential interpretation of dynamic algorithms like Bellman-Ford is feasible and can achieve order-of-magnitude speedups, provided we have: 1) optimizations that reduce work by skipping unaffected program fragments, enabled by precise change descriptors, and 2) efficient caching strategies to minimize initialization overhead. Additionally, reducing initialization time remains an important area for improvement.

8 Related Work

Incremental computation has been extensively studied, with various approaches aiming to efficiently update outputs in response to changes in inputs. In this section, we discuss work related to our approach, namely dynamic algorithms, incremental computing by selective recomputing, incremental computing by differential updating, and the incremental lambda calculus.

Dynamic algorithms are designed to handle arbitrary changes to inputs by maintaining data structures that can be efficiently updated [19]. They achieve efficiency through carefully designed update operations that maintain complex invariants specific to each problem domain, as demonstrated in problems like dynamic planar convex hulls [8, 20] and dynamic minimum spanning trees [14, 16]. While these algorithms can offer optimal incremental performance for specific problems, their development requires significant effort and domain expertise [22].

Our approach differs by embedding incrementality into the language semantics rather than relying on specialized data structures. Where dynamic algorithms require manual development of update operations for each problem, our differential semantics provides a systematic approach to deriving incremental behavior for programs written in our imperative language. This language-based approach demonstrates how incremental computation can be treated as a fundamental programming language feature rather than a specialized algorithmic concern.

Selective recomputing techniques aim to reuse previous results by identifying and rerunning only the affected parts of a computation when inputs change [10, 22]. Early methods like function memoization [21, 1] cache function calls and reuse results, but they struggle with programs that have internal state or complex control flow.

Self-adjusting computation [5, 4], representing the state-of-the-art in selective recomputing, introduces sophisticated dependency tracking using dynamic dependency graphs to identify precisely which computations need to be redone. Their change propagation algorithm then selectively recomputes only the affected portions of these dependency graphs. This approach has been enhanced to improve efficiency through data structure-level dependency tracking [3] and extended to handle imperative features [2], but maintains the core mechanism of dependency tracking. Despite these advances, the fundamental dependency tracking approach and its inherent disadvantages remain unchanged. *Adapton* [13] extends this line of work with demand-driven evaluation and better support for cyclic dependencies, but still faces similar overhead challenges from maintaining complex runtime structures.

Where selective recomputation focuses on identifying which computations to redo through dependency information, our differential semantics takes a fundamentally different approach by directly modeling how changes propagate through program constructs. This direct modeling enables more efficient handling of control flow changes: instead of rebuilding and traversing complex dependency graphs when loop bounds or conditions change, our semantics directly computes the precise differential effect of the modified control flow. The key distinction is that while self-adjusting computation and its extensions determine *what* to recompute, our differential semantics specifies *how* changes transform program states through the language semantics itself.

The incremental lambda calculus (ILC) [9, 11] provides a theoretical foundation for incrementalizing purely functional programs through type-directed program transformation. For each function f, it derives a derivative function f' that computes output changes from input changes, executing these derivative programs using standard semantics.

Our approach differs fundamentally from ILC by providing a differential semantics that directly executes programs on changes without requiring program transformation. This distinction has important practical implications – optimizing our differential semantics requires only modifying semantic rules, while ILC must optimize its program transformation process to generate more efficient derivative code. Another obvious difference between our approaches is that while ILC provides powerful techniques for incrementalizing higher-order functional programs, our differential semantics offers direct support for imperative features.

Differential updating originated in databases to maintain materialized views efficiently [7]. For each relational operator, they derive rules that translate changes to input relations into changes to output relations, avoiding full recomputation. View maintenance systems formalize these as delta rules [12] with algebraic properties that ensure correctness: a delta rule applied to input changes must produce the same result as recomputing with updated inputs. This approach has been particularly successful for Datalog, where differential evaluation enables efficient incremental maintenance of recursive views [18].

Our work shares the fundamental insight of deriving change-propagation rules but applies it to programming language constructs rather than relational operators. Like database approaches, we ensure correctness through algebraic properties, but our properties focus on language-level operations rather than relational algebra. This enables incrementalization of general-purpose programs while maintaining the mathematical rigor of differential database techniques.

Differential dataflow [17] extends dataflow systems to support incremental updates through data provenance tracking. While effective for data-parallel computations, it requires programs to be expressed in a restricted dataflow model. Our approach provides similar benefits for general imperative programs through language-level change tracking, making incremental computation accessible to mainstream programming.

9 Conclusion

This paper presents differential semantics, which exploits precise change information rather than using all-or-nothing selective recomputing. Rather than treating incrementality as a separate concern, we embed it directly in the programming language through semantic rules that precisely track and propagate changes. Our key contributions include a type-safe theory of changes that ensures semantic consistency, a differential semantics for an imperative language that handles both data and control flow changes, and a set of verified optimizations that make this approach practical. Through our implementation as a differential interpreter, validated on the Bellman-Ford algorithm, we demonstrate that our approach enables order-of-magnitude speedups compared to recomputation. These results establish that principled language design can make incremental computation both automatic and efficient. Future work could extend these foundations to richer language features like functions and recursion, moving toward general-purpose languages where incrementality is the default rather than a specialized capability.

GSOHC: Global Synchronization Optimization in Heterogeneous Computing

Soumik Kumar Basu
Department of Computer Science and Engineering, IIT Hyderabad, India

Jyothi Vedurada
Department of Computer Science and Engineering, IIT Hyderabad, India

Abstract

The use of heterogeneous systems has become widespread and popular in the past decade with more than one type of processor, such as CPUs, GPUs (Graphics Processing Units), and FPGAs (Field Programmable Gate Arrays) etc. A wide range of applications use both CPU and GPU to leverage the benefits of their unique features and strengths. Therefore, collaborative computation between CPU and GPU is essential to achieve high program performance. However, poorly placed global synchronization barriers and synchronous memory transfers are the main bottlenecks to enhanced program performance, preventing CPU and GPU computations from overlapping.

Based on this observation, we propose a new optimization technique called *hetero-sync motion* that can relocate such barrier instructions to new locations, resulting in improved performance in CPU-GPU heterogeneous programs. Further, we propose GSOHC, a compiler analysis and optimization framework that automatically finds opportunities for hetero-sync motion in the input program and then performs code transformation to apply the optimization. Our static analysis is a context-sensitive, flow-sensitive inter-procedural data-flow analysis with three phases to identify the optimization opportunities precisely. We have implemented GSOHC using LLVM/Clang infrastructure. On A4000, P100 and A100 GPUs, our optimization achieves speedups of up to 1.8x, 1.9x and 1.9x over the baseline, respectively.

1 Introduction

Heterogeneous computing is a programming paradigm that uses more than one type of processor, such as a CPU, in conjunction with accelerators, such as GPUs (Graphics Processing Units) and FPGAs (Field Programmable Gate Arrays). In a wide range of applications, CPUs and GPUs are both used, and both have strengths and limitations, which are essential for high-performance computing. Over the decades, several compiler optimizations [45, 6, 38] have been proposed to improve the performance of CPU programs. In the same vein, numerous recent research works [12, 33, 51, 1, 2] have developed new analyses and optimizations to enhance only GPU (device) side performance in the CPU-GPU heterogeneous applications. Nevertheless, CPU- and GPU-only optimization strategies are incapable of realizing the full

Figure 1 Sample CUDA code snippet showing blocking calls, host- and device-side computations.

potential of heterogeneous computing. For example, a GPU can remain idle during memory copy to CPU, and specialized global optimizations [23, 4, 27] are needed to improve overall performance by efficiently managing host-to-device data transfers.

In a similar vein, heterogeneous systems suffer from another important global performance problem: the CPU being idle after launching the kernel and allocating the task to the GPU, resulting in the underutilization of processors. The importance of this problem has been revealed through several manual optimization efforts [7, 46, 55, 47] of several domain-specific heterogeneous applications (efficiently distributing the workload between CPU and GPU). Further, in a performance study by White III et al. [53], manual optimization of CPU-GPU computation overlap yielded significantly better performance than most other optimization methods, such as communication-computation overlap etc. A poorly placed synchronization statement or blocking call is most often the reason for the CPU idleness in a heterogeneous system since it prevents CPU and GPU computations from overlapping.

Optimization Opportunities and Associated Challenges. Consider a sample example in Figure 1. There are two device kernel launches from the CPU function `main`, one at Line 10 and the other at Line 16. A device kernel is a function that runs asynchronously with CPU code on multiple cores of a GPU (in SIMT [20] fashion), and we refer to its computations as *device-side computations*. Programmers must explicitly add synchronization calls (e.g. `cudaDeviceSynchronize` call at Line 19) in their code to ensure that CPU-side computations halt until the device-side computations are complete. Further, memory transfers (e.g. `cudaMemcpy` calls at Lines 11, 15, and 17) also act as synchronization/blocking calls in the CUDA programming model. We can see that the host-side computation at Line 13 is not dependent on the device-side kernel computation at Line 10, as it does not use variables `u`, `d_u` and `size1`. Nevertheless, the host-side computation still awaits for completion of the device kernel due to the poorly placed synchronous data-transfer call at Line 11, resulting in suboptimal performance. As a result, as shown in Figure 2 (above the horizontal dotted lines), the program takes $t_2 - t_0$ time to execute the program statements from Line 10 to

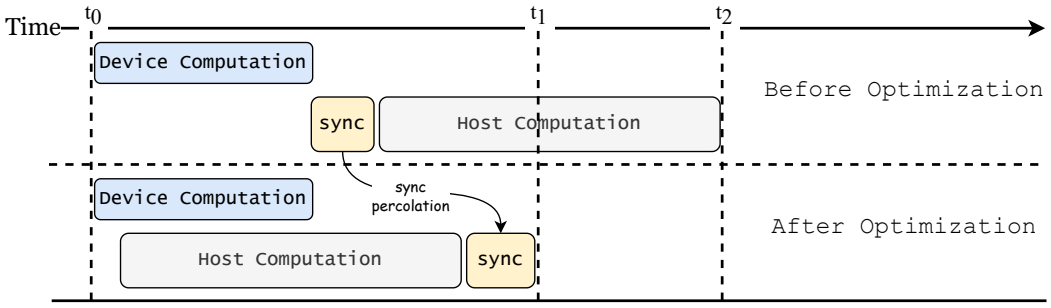

Figure 2 Execution of host- and device-side computations before and after hetero-sync motion.

Line 13. Alternatively, if the barrier is relocated after the host-side computation (say, from Line 11 to Line 14), the CPU will not wait for the kernel to complete, resulting in parallel execution of host- and device-side computations. Figure 2 (below the horizontal dotted lines) indicates that the time will then reduce from $t_2 - t_0$ to $t_1 - t_0$. This single synchronization statement relocation has opened a new avenue for optimizing program execution time. We call this optimization *hetero-sync motion*.

Manually identifying the target location for hetero-sync motion on a given synchronization statement is challenging. Firstly, for the synchronization statement at Line 11, it is required that the relocation target cannot be a successor of Line 15, which uses the variable `d_u`. Further, alias relationships between variables should be taken into account when performing this verification. Secondly, for the synchronization statement at Line 17, simply checking for data dependency may result in incorrectly moving it to Line 5, which is not guaranteed to get executed in all program paths, unlike the source location (this may also result in redundant or spurious data transfers). Thirdly, for the synchronization statement at Line 19, although it has no argument variables, to find its target location, we need to consider the farthest successor in the execution path for performance without violating previous synchronization dependencies. Fourthly, a kernel call (Line 16) can be associated with several synchronization calls (Line 17 and Line 19), and the challenge is to relocate all these synchronizations to the most suitable target location. The code snippet in Figure 3a from the `xlqc` benchmark program, which computes Coulomb and exchange matrices for quantum chemistry simulations, exemplifies such challenges in real-world applications. Here, `memcpy` operations at Lines 8 and 13, though dependent on Line 26, cannot be directly moved because doing so would make them conditional on the for loop at Line 19 resulting in correctness issues or multiple executions that degrade performance. Therefore, we need a dedicated analysis that addresses these challenges precisely and efficiently.

Furthermore, real-world programs exhibit the complexity of finding optimal target locations for synchronization statements across functions. Consider the code snippet in Figure 3b, from `CLINK` [11] (Compact LSTM INference Kernel), which performs efficient sequence prediction by minimizing memory and computation overhead in Long Short-Term Memory (LSTM) models. The synchronous `memcpy` call at Line 8 (along with `cudaDeviceSynchronize` call at Line 6) can be moved outside the `lstm_n5` function and placed after Line 19, thereby overlapping the kernel computation (at Line 5) with `init` (at line 18). Identifying such optimization opportunities requires a thorough analysis of call sites, precise mapping of function arguments, and context- and flow-sensitive analysis, posing significant challenges even for experienced developers. Moreover, the subsequent transformation requires adjusting function definitions, callsite arguments, and relocating instructions across functions, as seen

(b) Code snippet from `clink` [11].

Figure 3 Code snippet demonstrating opportunities in hetero-sync motion. The yellow box highlights synchronization statements, while the blue triangle (▶) marks the destination location.

in this example, where the `memcpy`'s arguments at Line 3 must be moved to the `main` (caller) function and passed as arguments to the `lstm_n5` (source) function. Further, the `memcpy` statement in `lstm_n5` function is invoked from two contexts (Lines 16 and 19), leading to the percolation of synchronization statements from both contexts to the target location. To address these complexities and reduce programming overhead, we propose an automated framework, GSOHC, to identify and move synchronization statements to optimal target locations, streamlining the code transformation process.

Existing Approaches and the Need for a New Solution. Hetero-Sync Motion optimization is analogous to compiler optimizations [42, 19, 16, 41, 17, 43] that relocate inefficient synchronization in the context of alternative programming paradigms such as MPI (Message Passing Interface) and CPU TLP (Thread-Level Parallelism). However, these approaches are inadequate to address the problem of hetero-sync motion due to the semantic differences in synchronization operations: (1) APIs such as `cudaMemcpy` in CPU-GPU heterogeneous programs perform both synchronization and data-transfer operations, unlike `wait` calls in TLP or MPI paradigms that only handle synchronization, (2) by default, synchronization statements in CUDA execute in the default stream, and data transfer begins only after all previous CUDA calls are completed, whereas MPI `wait` calls wait for the completion of a specific communication call based on the corresponding `request_ID` (similar to TLP). Using TLP approaches [42, 19, 43] for hetero-sync motion may percolate *sync* calls into divergent branch paths (e.g., moving Line 17 to Line 5 and Line 25 in Figure 1) resulting in redundant

execution of data transfers that may adversely affect the correctness and performance of a CPU-GPU program. On the other hand, MPI approaches [16, 41, 17] require a one-to-one pairing of `wait` calls with non-blocking communication calls, and handling each pair separately through data dependence checks; whereas, in CPU-GPU heterogeneous systems, the challenge lies in consolidating multiple synchronization calls surrounding a single kernel call into one target location. Further, previous works [23, 27, 4, 26, 30] have focused on CPU-GPU global optimization problems through techniques such as multi-kernel computation overlap and data transfer–kernel computation overlap using hybrid runtime and compile-time approaches. However, they do not address the synchronization relocation challenges posed by hetero-sync motion. Therefore, new static data-flow analysis approaches are needed to address synchronization bottlenecks in CPU-GPU heterogeneous programs by analyzing the flow of multiple synchronization calls and their associated data.

GSOHC. In Figure 2, below the horizontal dotted line, we can see how GSOHC pushes the synchronization statement after the host-side computation, facilitating overlap between host-side and device-side computations, thereby enhancing overall program performance. GSOHC does not optimize the host-side nor device-side computations, but it improves performance by only pushing the barrier to a successor program point in the execution path. Our static analysis is a context-sensitive, flow-sensitive inter-procedural data-flow analysis with three phases to identify the optimization opportunities precisely: (1) identifies the poorly placed synchronization statements in the code and maps them to target location sets (not unique since dependencies can be found in multiple program points in different execution paths), (2) updates the mapped location sets based on the control flow and contextual information, and (3) unifies the location sets so that each synchronization statement in a given context is mapped to a unique location.

We implemented our framework using LLVM/Clang infrastructure [36, 31]. GSOHC takes the input program in LLVM/IR format and produces the optimized IR with overlapping host-side computation and device-side computation, resulting in performance improvement. The key contributions of this work are as follows:

- A novel idea of hetero-sync motion optimization that relocates synchronization statements from a source location to a target location to improve performance in CPU-GPU heterogeneous programs.
- A novel compiler framework with three stages, including an interprocedural, context- and flow-sensitive data-flow analysis pass to identify optimization opportunities and determine optimal target locations for synchronization statements.
- A transformation pass that automatically relocates barrier statements to an optimal location so that host-side and device-side computations can overlap. Implementation of both passes in the LLVM infrastructure.
- An extensive evaluation of our approach and comparison with the base code. On A4000, P100, and A100 GPUs, our optimization achieves up to 1.8x, 1.9x, and 1.9x speedups over baseline, respectively.

2 Formalization and Overview

In this section, we discuss some preliminaries that are required to explain our static analysis in Section 3, and then we formally define our hetero-sync motion optimization.

We use the programming language in Figure 4 for our formalization. While we use this language to simplify our presentation, our implementation (see Section 5 for details) works on LLVM IR. It is easy to correlate every analysis step discussed in this paper with LLVM

Program $\mathcal{P}$	=	$s;\ m^+$
Method m	=	$\mathcal{H}(\vec{v})\{s_h\} \mid \mathcal{D}(\vec{v})\{s_d\}$
Host statement s_h	=	**call** $\mathcal{H}(\vec{e}) \mid sync \mid s \mid s_d \mid$ **return** v
Device statement s_d	=	**call** $\mathcal{D}(\vec{e}) \mid s$
Synchronization call $sync$	=	**call** $global_sync_api(\vec{e})$
Expression e	=	$v \mid c \mid e_1 \oplus e_2 \mid \neg e \mid e_1 \vee e_2 \mid e_1 \wedge e_2 \mid e_1 \otimes e_2$
Statement s	=	$v := e \mid$ **if**(e) s **else** $s \mid$ **while**(e) **do** $s \mid s; s \mid$ **skip**

$v \in$ **Variable** $\quad c \in$ **Constant** $\quad \vec{v} = (v_1, v_2, \ldots v_n)$

$\oplus \in \{+, -, \times, \div\} \quad \otimes \in \{<, >, \leq, \geq, =, \neq\} \quad \vec{e} = (e_1, e_2, \ldots e_n)$

Figure 4 Syntax of the input program.

IR instructions. Our implementation supports full LLVM IR, including pointer operations, though we do not show them in Figure 4. Furthermore, we consider heterogeneous computing systems with a CPU and a single GPU setup. Although our ideas are generic, we use the CUDA [8] programming model whenever we discuss concrete semantics.

The program $\mathcal{P}$ is a heterogeneous program consisting of statements and methods that can run on a CPU or a GPU. $\mathcal{D}(\vec{v})$ represents a method whose body of statements gets executed on a GPU (device) [1]. $\mathcal{H}(\vec{v})$ represents a method executed on a CPU (we do not specify the return type for simplicity). The statement *sync* denotes function calls that serve as global barriers to synchronize CPU and GPU. In CUDA programming model, $global_sync_api(\vec{e})$ can represent `cudaMemcpy` or `cudaDeviceSynchronize` calls. In addition, variable accesses v, expressions e, assignment statements ($v := e$), branch and loop instructions, etc., are all standard programming constructs. We now formally define some terminology that is required to introduce hetero-sync motion optimization.

▶ **Definition 1** (Device-side Computation). *We say an operation d is* device-side computation *if it resides within the body of a method $\mathcal{D}$ executed on a device (using multiple threads in SIMT fashion).*

▶ **Definition 2** (Host-side Computation). *We say an operation h is* host-side computation *if it resides within the body of a method $\mathcal{H}$ executed on a host (using one or more threads in SIMD or MIMD or SISD fashion).*

▶ **Definition 3** (Synchronization Call, *sync*). *In a heterogeneous program $\mathcal{P}$, a program point or statement s_i within a host-side method $\mathcal{H}$ is called a* synchronization call *(or sync) if it invokes dedicated APIs that cause $\mathcal{H}$ to wait at s_i until all device-side methods $\mathcal{D}_1, \mathcal{D}_2, \ldots, \mathcal{D}_n$ launched prior to s_i complete execution.*

For example, `cudaMemcpy` call (Line 17, Figure 1) and `cudaDeviceSynchronize` call (Line 19, Figure 1) are synchronization calls.

The goal of GSOHC is to identify large regions of code with host-side computations that are independent of a *sync* and result in overlap with device-side computations, maximizing performance through concurrent execution.

▶ **Definition 4** (Data Dependence). *Given two program statements s_i and s_j in a heterogeneous program $\mathcal{P}$, we say s_j is* data dependent *on s_i or vice versa iff*

$$(rd(s_i) \cap wr(s_j)) \cup (wr(s_i) \cap wr(s_j)) \cup (wr(s_i) \cap rd(s_j)) \neq \phi$$

where $rd(s_i)$ gives the set of variables read by statement s_i and $wr(s_i)$ gives the set of variables written by statement s_i.

[1] We use "GPU" and "device" interchangeably and, similarly, "host" and "CPU" in this paper.

For example, in Figure 1, Line 17 is data dependent on Line 5, since Line 5 reads and writes to the same data array that is written by Line 17.

▶ **Definition 5** (Statement Region, Ω). *In a program $\mathcal{P}$ with Inter-procedural Control Flow Graph $ICFG(\mathcal{P})$, a* statement region $\Omega(p_i, p_j)$ *is the sequence of program statements between two program points p_i and p_j (excluding p_i and p_j), where the basic block of p_j is a successor of the basic block of p_i in $ICFG(\mathcal{P})$.*

▶ **Definition 6** (Safe Region, $\mathcal{R}$). *A statement region $\Omega(p_i, p_j)$ is a* safe region, *$\mathcal{R}(p_i, p_j)$, if no statement in $\Omega(p_i, p_j)$ is data-dependent on the statement at p_i.*

▶ **Definition 7** (Refined Safe Region, $\mathcal{K}$). *A* refined safe region, *$\mathcal{K}(p_i, p_j)$ is derived from a safe region $\mathcal{R}(p_i, p_k)$ (represented as $\mathcal{R}(p_i, p_k) \vdash \mathcal{K}(p_i, p_j)$) iff:*

$$(p_i \textit{ dominates } p_j) \wedge (p_j \textit{ post-dominates } p_i) \wedge (p_j \textit{ dominates } p_k)$$

While $\mathcal{R}$ considers only data dependency, $\mathcal{K}$ considers both data dependency (from $\mathcal{R}$) and control dependency (via dominance relations). A statement p_i *dominates* p_j if all paths from the entry node to p_j pass through p_i, and p_j *post-dominates* p_i if all paths from p_i to the exit node pass through p_j.

▶ **Definition 8** (Unified Safe Region, $\mathcal{U}$). *A* unified safe region, *$\mathcal{U}(p_i, p_j)$ corresponds to a unique refined safe region, $\mathcal{K}(p_i, p_m)$, from the set of refined safe regions for p_i $\{\mathcal{K}_1(p_i, p_1)$, $\mathcal{K}_2(p_i, p_2)$, $\mathcal{K}_3(p_i, p_3)$, …, $\mathcal{K}_n(p_i, p_n)\}$ iff:*

$$\exists m \forall s,\ m, s \in \{1, \ldots, n\} \mid (p_m \textit{ dominates } p_s)$$

While the refined safe region $\mathcal{K}$ addresses control and data dependencies, multiple regions for p_i may result in redundant executions of a *sync* call along a path. The unified region $\mathcal{U}$ uniquely updates and unifies these regions for p_i.

▶ **Definition 9** (Hetero-Sync Motion). *Given a program point p_{src} with a sync call in a host-side method $\mathcal{H}$, if $\mathcal{U}(p_{src}, p_{dst})$ is a unified safe region, relocating the sync from p_{src} to p_{dst} to enable concurrent execution of a host-side statement $s_h \in \mathcal{U}(p_{src}, p_{dst})$ and a device-side computation statement s_d is called as* Hetero-Sync Motion.

Since *sync* calls block host-side and device-side computations from overlapping, our optimization *Hetero-Sync Motion* aims to move the *sync* call from program point p_{src} to p_{dst} to enable concurrent execution and improve performance.

▶ **Example.** In Figure 1, Ω(Line 17, Line 5) is an example of a statement region, which is also a safe region i.e., $\mathcal{R}$(Line 17, Line 5). Since Line 5 does not post-dominate Line 17, it cannot form a refined safe region. Hence, Line 17 and Line 3 form a refined safe region, i.e., $\mathcal{K}$(Line 17, Line 3). Similarly, another refined safe region is $\mathcal{K}$(Line 17, Line 23). The unified safe region becomes $\mathcal{U}$(Line 17, Line 3), indicating that hetero-sync motion optimization percolates the *sync* from source Line 17 to target Line 3.

Overview. Figure 5 depicts the pipeline of our GSOHC. Given a program $\mathcal{P}$ as input, GSOHC performs hetero-sync motion optimization (see Definition 9) on $\mathcal{P}$ and produces an optimized program $\mathcal{P}_{opt}$ automatically. GSOHC consists of two major components: a top-down inter-procedural context- and flow-sensitive data-flow analysis pass to identify the opportunities for hetero-sync motion optimization and a transformation pass to optimize the input code using the analysis results. Further, our static analysis framework follows

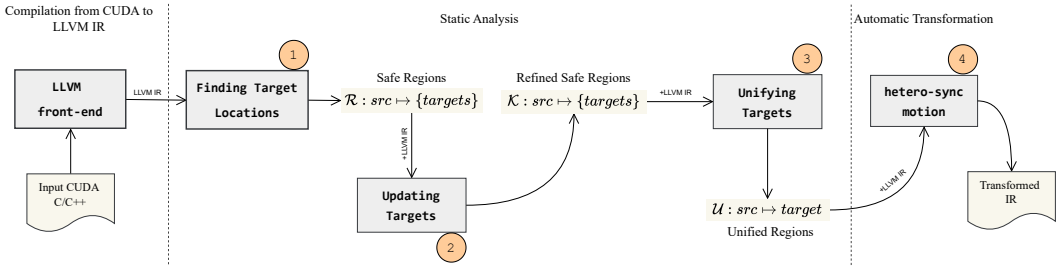

Figure 5 Complete pipeline of GSOHC.

a three-stage approach. The first stage identifies target location sets for poorly placed synchronization statements, represented as safe regions (see Definition 6). The second stage updates these safe regions to maintain the control-flow dependency between the source and target locations to form refined safe regions (see Definition 7). The third stage unifies each target location set into a single, unified safe region (see Definition 8), ensuring each *sync* statement is mapped to a unique location. Finally, the transformation pass relocates *sync* statements from source to target locations, to enhance the performance of the input programs. We will discuss the different stages of the analysis pass in Section 3 and then discuss the transformation pass in Section 4.

3 Static Detection of Hetero-Sync Motion Opportunities

Our static analysis for identifying opportunities of hetero-sync motion optimization takes a program $\mathcal{P}$ as input and outputs a map $\mathcal{M}$, which maps a *sync* statement to a set of target statement(s) in $\mathcal{P}$. The *sync* statement representing a global barrier call (see Definition 3) in $\mathcal{P}$ is considered as a source location, and the corresponding target location (singleton set at the end) is identified by our static analysis based on the concept of unified safe region (Definition 8). We will discuss the three stages of our static analysis in the following sections: finding target location sets (Section 3.1), updating target location sets (Section 3.2), and unifying target location sets (Section 3.3).

3.1 Finding Target Location Sets

The key idea is to perform a top-down context- and flow-sensitive inter-procedural data-flow analysis to identify the hetero-sync motion optimization opportunities in the form of safe regions (see Definition 6). Specifically, our analysis reports for each *sync* statement at p_{src} [2] a set of target locations, which is a collection of p_{dst} program points corresponding to safe regions identified in multiple execution paths.

Figure 6 shows the transfer function rules of our static analysis for statements in the language described in Figure 4. The first rule shows that if a program statement s is a synchronization call (see Definition 3), the analysis collects the variables that are read and written by s into sets $\mathbf{R}$ and $\mathbf{W}$, respectively, and then inserts s into the set Σ. In this paper, we refer to the sets $\mathbf{R}$ and $\mathbf{W}$ as the *read* set and the *write* set, respectively, representing the variables that are read from and written to by the *sync* statements. Likewise, we refer to Σ

[2] We use the words "source statement" and *sync* interchangeably, and, similarly, the words target and destination in this paper.

[SYNCHRONIZATION CALL]

$$\frac{s : \textbf{call } \mathit{global_sync_api}(\vec{e}) \quad e_i \in \vec{e}}{\mathbf{R}^s_{out} := \mathbf{R}^s_{in} \cup \texttt{rd}(e_i) \quad \mathbf{W}^s_{out} := \mathbf{W}^s_{in} \cup \texttt{wr}(e_i) \quad \Sigma^s_{out} := \Sigma^s_{in} \cup \{s\} \quad \mu^s_{out}[s] := \{s\}}$$

[HOST FUNCTION CALL]

$$\frac{s : \textbf{call } \mathcal{H}(\vec{e}) \quad s_1 : \texttt{entryPoint}(\mathcal{H})}{\mathbf{R}^{s_1}_{in} := \mathbf{R}^s_{in} \quad \mathbf{W}^{s_1}_{in} := \mathbf{W}^s_{in} \quad \Sigma^{s_1}_{in} := \Sigma^s_{in} \quad \mu^{s_1}_{in} := \mu^s_{in} \quad \Gamma := \Gamma \cdot s}$$

[ASSIGN]

$$\frac{s : v := e \quad var \in \texttt{rd}(e) \quad w \in \mathbf{W}^s_{in} \quad r \in \mathbf{R}^s_{in} \quad (var \odot w \ \vee \ v \odot w \ \vee \ v \odot r)}{\mathbf{R}^s_{out} := \emptyset \quad \mathbf{W}^s_{out} := \emptyset \quad \Sigma^s_{out} := \emptyset \quad \forall src \in \Sigma^s_{in} \ \mu^s_{out}[src] := \{s\}}$$

[DEVICE FUNCTION CALL]

$$\frac{\begin{array}{c} s : \textbf{call } \mathcal{D}(\vec{e}) \quad e_i \in \vec{e} \quad v_r \in \texttt{rd}(e_i) \ v_w \in \texttt{wr}(e_i) \quad w \in \mathbf{W}^s_{in} \quad r \in \mathbf{R}^s_{in} \\ (v_r \odot w \ \vee \ v_w \odot w \ \vee \ v_w \odot r) \end{array}}{\mathbf{R}^s_{out} := \emptyset \quad \mathbf{W}^s_{out} := \emptyset \quad \Sigma^s_{out} := \emptyset \quad \forall src \in \Sigma^s_{in} \ \mu^s_{out}[src] := \{s\}}$$

Figure 6 Transfer function rules for our flow- and context-sensitive static analysis. Here, $\texttt{rd}(e)$ and $\texttt{wr}(e)$ denote the sets of variables read and written by the expression e, respectively. Further, the target map μ stores each *sync* statement with its corresponding set of target locations.

as the *synchronization* set, which stores the *sync* statements. In the rule, $\mathbf{R}^s$ represent the flow-sensitive instance of the data-flow fact $\mathbf{R}$ at program point s, while sets $\mathbf{R}^s_{in}$ and $\mathbf{R}^s_{out}$ represent the data-flow facts flowing to and from statement s (similarly for $\mathbf{W}$, Σ and μ). Note that for the simplicity of the design of our static analysis, we have assumed that each basic block in an ICFG contains a single program statement.

As the analysis aims to identify an optimization opportunity in the form of safe region $\mathcal{R}(p_{src}, p_{dst})$, the first rule involves identifying the start of a safe region at the program point s [3] (i.e., s represents p_{src} here). This rule also initializes the target locations (end of safe regions) of s by adding itself to the set $\mu^s[s]$, which other rules can update later. We refer to μ as *target* map, which stores the mapping of a *sync* statement to the set of target locations where it can be percolated.

▶ **Example.** In Figure 7, `cudaMemcpy` call at Line 19 reads from `arr_gpu` and writes to `arr_output_gpu`. Hence, the read set and the write set are {`arr_gpu`} and {`arr_output_gpu`}, respectively. Further, the synchronization set includes Line 19, and the target map μ maps Line 19 to itself, i.e. μ[Line 19] = {Line 19}.

The second rule handles host function calls. As the analysis is inter-procedural, it analyzes the callee host function at each call site. It first propagates the data-flow facts from the call site to the entry point of the callee and appends the call site to the *call-string* Γ, which stores the function calling context (i.e., caller-callee sequence as a string) and then analyzes the callee. In our analysis, we restrict the length of the call-string to 4.

[3] Whenever we refer to a program statement, we refer to it in a given calling context Γ, i.e. $s \equiv (\Gamma, s)$.

```
1  void foo(...,arr_output_gpu,...)
2  {
3      /*entry point of function foo*/
4      int *x = malloc(n * sizeof(int));
5      ...
6      if(pred){
7          for(i=0;i<n;i++){
8              x[i] = arr_output_gpu[i];
9          }
10     }
11     ...
12     return;
13 }
14 void main(){
15     ...
16     /* Device-side computation */
17     cuda_kernel<<< grid,block >>>(..., arr_gpu);
18     /* barrier */
19     cudaMemcpy(arr_output_gpu, arr_gpu, size, cudaMemcpyDeviceToHost);
20     ...
21     foo(...,arr_output_gpu,...);
22     ...
23 }
```

Figure 7 Sample code with hetero-sync motion optimization opportunity.

▶ **Example.** In Figure 7, the function `main` invokes function `foo` at Line 21. Hence, the data-flow facts at the call site are propagated to the entry point of function `foo` (Line 4). The corresponding read set, write set, synchronization set, and target map for Line 4 are: $\mathbf{R}^s_{in} = \{\texttt{arr_gpu}\}$, $\mathbf{W}^s_{in} = \{\texttt{arr_output_gpu}\}$, $\Sigma^s_{in} = \{\text{Line 19}\}$, and $\mu^s_{in} = (\text{Line 19}, \{\text{Line 19}\})$. The analysis also appends the call site (Line 21) to the call-string Γ, i.e. $\Gamma := \Gamma$. Line 21.

The next rule addresses the assignment instruction $v := e$ involving RAW (Read-After-Write), WAR (Write-After-Read), and WAW (Writer-After-Write) dependencies. The analysis checks for any variable *var* read in expression e (i.e., $var \in \texttt{rd}(e)$) that aliases with variable w in the write set ($\mathbf{W}^s_{in}$) of the propagated *sync* statements at the program point s, thereby detecting a RAW dependency, represented as $var \odot w$. Here, $x \odot y$ indicates that x and y may refer to the same memory location (i.e. potential aliases). Further, for the variable v written in the assignment statement s, the analysis checks for WAR and WAW dependencies by examining the alias relationship between v and the variables in the set $\mathbf{R}^s_{in} \cup \mathbf{W}^s_{in}$. If a dependency exists, it creates a mapping from the propagated *sync* statements in μ^s to s, marking s as the target. This indicates the end of a safe region $\mathcal{R}$ for a *sync* statement and, thus, an optimization opportunity for hetero-sync motion optimization has been found. Note that the analysis terminates the safe regions for all the *sync* calls that reach s because after the code transformation, even if a single *sync* relocates to s, it becomes a blocking call for the host, and hence it would not be beneficial to extend the safe region of other propagated synchronization calls. Therefore, the analysis reinitializes the data structures $\mathbf{R}^s$, $\mathbf{W}^s$, and Σ^s to identify new optimization opportunities in the unanalyzed code.

▶ **Example.** In Figure 7, the assignment statement at Line 8 reads from array `arr_output_gpu`, which was previously written at Line 19. Due to this RAW data dependence, the analysis updates the target set for Line 19 in map μ to {Line 8}, i.e., $\mu[\text{Line 19}] := \{\text{Line 8}\}$, followed by the re-initialization of other data-flow facts ($\mathbf{R}$, $\mathbf{W}$, and Σ).

The fourth rule addresses device function calls. Since *sync* statements cannot be percolated into device functions, there is no need to analyze the code in these functions. This rule checks the data dependency between the function arguments passed at the calling context and the data-flow facts propagated to that program point. The effect of this rule is similar to that of an assignment statement (discussed above).

For all other program statements, the analysis directly copies the data-flow facts for propagation, i.e., $\mathbf{R}^{s}_{out} := \mathbf{R}^{s}_{in}$ (Similarly for $\mathbf{W}$, Σ, and μ). Upon completing the analysis of a function f, the framework consolidates the data-flow facts from each **return** statement s_r of f and propagates them to each successor *succ* of the corresponding call site in the caller function (found in the call-string Γ). That is, $\mathbf{R}^{succ}_{in} := \mathbf{R}^{succ}_{in} \cup \mathbf{R}^{s_r}_{out}$ (Similarly for $\mathbf{W}$, Σ, and μ). The call site is then removed from the call-string Γ.

▶ **Example.** The data flow facts corresponding to the `return` statement (Line 12, Fig. 7) in function `foo` are copied to the successor (Line 22) of the call site (of function `foo`).

Our analysis handles branches and loops by performing join operations on data-flow facts at control-flow merge points. The confluence operator of the analysis is a union, meaning the data-flow facts at the entry of a basic block (*in* sets) n in a CFG are the union of the *out* sets of all predecessors of n.

3.2 Updating Target Location Sets

After the analysis in the previous step terminates, GSOHC retrieves the target location set for each *sync* statement (from map μ^s at the main function's exit statement s) and provides this information in map $\mathcal{M}$ as input to the current step. The target location sets computed in the previous step respect data dependencies but do not account for control-flow dependencies. For example, consider the *sync* call at Line 19 in Figure 7. The analysis in the previous step identifies the data dependency between the write to `arr_output_gpu` in `cudaMemcpy` call at Line 19 and the read of the same variable at Line 8 (in function `foo`, called at Line 21). Hence, it terminates the safe region at Line 8 and maps this as a target location for the *sync* call at Line 19. However, relocating `cudaMemcpy` synchronization call from Line 19 to Line 8 would make its execution conditional on the value of `pred`, unlike in the original program where it executes on all paths. Thus, this step validates the target mappings $\mathcal{M}$ reported by the previous step and updates invalid target locations with valid ones by checking control-flow dependency through Algorithm 1.

For each *sync* statement *src* (source) and its corresponding target location *dst* (destination), Algorithm 1 validates if *src* dominates *dst* and *dst* post-dominates *src*, establishing a *dom-pdom* relationship. If validation fails, the algorithm iteratively identifies the farthest successor s_t from *src* that satisfies the dom-pdom relationship, updating s_t as the target location and thus establishing a refined safe region (see Definition 7) from *src* to s_t. We propose a context-sensitive, demand-driven algorithm for determining inter-procedural dom-pdom relationships between source and destination instructions. Our approach utilizes the transitivity property of dominance (if s_a dominates s_b and s_b dominates s_c, then s_a dominates s_c) and extends LLVM's intra-procedural dom-pdom tree analysis [34] to handle inter-procedural relationships. Further, unlike previous work [18] that exhaustively computes dominance relationships for all node pairs in the Inter-procedural Control Flow Graph (ICFG), our targeted analysis efficiently focuses only on the specific dom-pdom relationships required for our framework.

To present our algorithm, we extend the source and destination call-strings, Γ_{src} and Γ_{dst}, by appending the source instruction and destination instruction, respectively. We refer to this augmented data structure as *contextual path* $\mathbb{K}$. For example, the source and destination contextual paths are $\mathbb{K}_{src} = \langle sc_1,\ sc_2,\ \ldots,\ sc_n \rangle$, and $\mathbb{K}_{dst} = \langle dt_1,\ dt_2,\ \ldots,\ dt_m \rangle$, where each sc_i or dt_i is a function call, and sc_n and dt_m are the *src* and *dst* instructions, respectively.

Algorithm 1 Updation of Target Locations.

Input: source src, target dst, call-strings Γ_{src}, Γ_{dst}
Output: updated target statement s_t

```
1  Procedure updateTarget
2      K_src, K_dst ← Γ_src.src, Γ_dst.dst
3      n, m ← |K_src|, |K_dst|
4      com_i = max_{1≤i≤min(n,m)}{enclosingFn(sc_i) = enclosingFn(dt_i)}
5      s_extd ← exitDominance(K_src, com_i, n)
6      if s_extd ≠ K_src[com_i] then
7          s_r ← exitNode(enclosingFn(s_extd))
8          s_t ← validateRelocation(s_extd, s_r)
9          return s_t
10     if K_src[com_i] dom K_dst[com_i] ∧ K_dst[com_i] pdom K_src[com_i] = False then
11         s^s_com ← K_src[com_i]
12         s^d_com ← K_dst[com_i]
13         s_t ← validateRelocation(s^s_com, s^d_com)
14         return s_t
15     s_entd ← entryDominance(K_dst, com_i, m)
16     s_e ← entryNode(enclosingFn(s_entd))
17     if s_entd pdom s_e = False then
18         s_t ← validateRelocation(s_e, s_entd) return s_t
19     return dst
```

To determine inter-procedural dom-pdom relationships, we require a reference point within the contextual paths of both the source and destination instructions. We call this reference point the Nearest Common Caller (NCC) function, which is the function where the backward paths from src and dst in their respective contextual paths first meet. We refer to the index in a contextual path corresponding to the NCC function as the NCC index. The NCC index com_i is the maximum index where the functions in the contextual paths $\mathbb{K}_{src}$ and $\mathbb{K}_{dst}$ are same (formally defined at Line 4, Algorithm 1). Using the NCC function as a reference point, the algorithm effectively models the source and destination as if they were inlined within this common context. For instance, in Figure 8a, function $\texttt{f}_1$ is the nearest common function to both src and dst, thereby establishing it as the NCC function. Similarly, in Figures 8b, 8c, and 8d, functions `foo`, `foo`, and `main` are the respective NCC functions.

Algorithm 1 transitively establishes dom-pdom relationships across the entry and exit points of the functions involved in the paths from src to dst that pass via the NCC function, ensuring that src instruction can be safely propagated across function boundaries. This task can be divided into three phases, each addressing dominance at critical points in the paths: (1) Exit Dominance (Lines 5 - 9), (2) Common Dominance (Lines 10 - 14), and (3) Entry Dominance (Lines 15 - 19). In the ICFGs shown in Figure 8, the paths for Exit Dominance, Common Dominance, and Entry Dominance are highlighted in green, red, and blue, respectively. Notice that, together, these paths form a path from src to dst through the NCC function.

Exit Dominance. First, we verify if src ($\mathbb{K}_{src}[n]$) dominates the exit node of its enclosing function f_{src}, ensuring that the refined safe region for src can be extended to the call site invoking f_{src} in the caller function. The `exitDominance` function (Line 1, Algorithm 2)

Algorithm 2 `exitDominance` and `entryDominance`.

```
1  Function exitDominance(𝕂_s, index, n)
2      for i ← n to index + 1 by 1 do
3          s_r ← exitNode(enclosingFn(𝕂_s[i]))
4          if 𝕂_s[i] dom s_r = False then
5              return 𝕂_s[i]
6      return 𝕂_s[index]
7  Function entryDominance(𝕂_d, index, m)
8      for i ← index + 1 to m by 1 do
9          s_e ← entryNode(enclosingFn(𝕂_d[i]))
10         if 𝕂_d[i] pdom s_e = False then
11             return 𝕂_d[i]
12     return 𝕂_d[n]
```

iterates backwards from the last statement in $\mathbb{K}_{src}$, checking if each statement in the contextual path dominates the exit node of its enclosing function. If all these dominances hold, `exitDominance` returns the instruction at the NCC index in $\mathbb{K}_{src}$, establishing a refined safe region for *src* up to $\mathbb{K}_{src}[com_i]$. For example, in Figure 8c, the source function `bar` is invoked by `fun`, which is further called by the destination function `foo`, making `foo` the NCC function. The `exitDominance` function validates the dominance relationship between the source node `S` and the exit node `T` of `bar`, and then between node `Q` and node `U`. If all dominances hold, `exitDominance` returns the instruction at the NCC index (node `O`), indicating that the refined safe region can be established from node `S` to node `O`. (Similarly, in Figures 8a and 8b if nodes `D` and `L` dominate nodes `E` and node `M`, respectively, safe regions are established up to NCC indices `B` and `J`.) If a statement at index i fails to dominate the exit node of its enclosing function f, `validateRelocation` (Algorithm 3) finds a valid target location within f by iterating from $\mathbb{K}_{src}[i]$ to the farthest successor that satisfies the dom-pdom relationship. In Figure 8c, if node `Q` does not dominate node `U`, `validateRelocation` finds a valid target location along the path from `Q` to `U`. Note that if *src* is within the NCC function, i.e., $\mathbb{K}_{src}[com_i] = src$ as shown in Figure 8d, the `exitDominance` function has no effect, as it directly returns $\mathbb{K}_{src}[com_i]$, the instruction at the NCC index, without iterating through the loop. The algorithm proceeds to the Common Dominance phase only when a refined safe region for *src* is established up to the instruction at the NCC index ($\mathbb{K}_{src}[com_i]$).

Common Dominance. This phase verifies the dom-pdom relationship between the instructions $\mathbb{K}_{src}[com_i]$ and $\mathbb{K}_{dst}[com_i]$ at the NCC index to confirm whether the refined safe region for *src* can extend from $\mathbb{K}_{src}[com_i]$ to $\mathbb{K}_{dst}[com_i]$. If validation fails, the algorithm invokes the `validateRelocation` function to find a valid target location on the path from $\mathbb{K}_{src}[com_i]$ to $\mathbb{K}_{dst}[com_i]$ within the NCC function. If successful, the algorithm proceeds to the Entry Dominance phase. For example, in Figure 8a, if nodes `B` and `F` satisfy the dom-pdom relationship, the refined safe region for *src* can be extended into function $\mathtt{f}_3$. Similarly, in Figure 8d, if nodes `W` and `X` satisfy the dom-pdom relationship, the refined safe region extends into `foo` through the Entry Dominance phase.

Algorithm 3 Validation of Target Location Set.

```
1  Function validateRelocation(stmt s_n, stmt s_i)
2      worklist ← {s_n}; s_c ← s_i
3      repeat
4          b ← first(worklist)
5          worklist ← worklist − {b}
6          if b = s_i then
7              break
8          if s_n dom b ∧ b pdom s_n then
9              s_c ← b
10         foreach succ ∈ successor(b) do
11             if succ is not visited then
12                 worklist ← worklist ∪ {succ}
13     until worklist = ∅;
14     return s_c
```

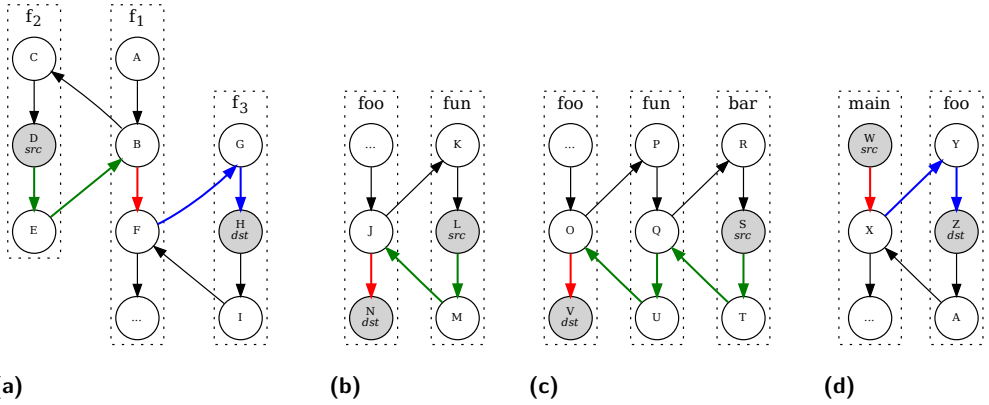

Figure 8 Examples for Exit Dominance, Common Dominance and Entry Dominance phase.

Entry Dominance. This phase verifies if an instruction s_d inside a callee function f_d (of the NCC function) post-dominates the entry node of f_d such that the refined safe region for *src* can be extended up to s_d. The `entryDominance` function (see Line 7, Algorithm 2) iterates through the destination contextual path $\mathbb{K}_{dst}$ to validate if each statement in the contextual path post-dominates the entry node of its enclosing function. If all these post-dominances hold, the algorithm establishes a refined safe region from *src* up to *dst*. For example, in Figure 8a, the refined safe region is extended till node `H` if `H` post-dominates the entry node `G`. Similarly, in Figure 8d, the refined safe region for *src* is established till node `Z` if `Z` post-dominates `Y`. If any statement at index i fails to post-dominate the entry node N of its enclosing function f, `validateRelocation` finds a valid target location within f by iterating from N to the farthest successor in f that satisfies the dom-pdom relationship. Note that, if *dst* resides within the NCC function, i.e., $\mathbb{K}_{dst}[com_i] = dst$, as shown in Figure 8b, `entryDominance` has no effect, as it simply returns $\mathbb{K}_{dst}[com_i]$, without iterating through the destination contextual path. Finally, `entryDominance` and Algorithm 1 terminate by returning the instruction up to which the refined safe region is established for the given *src*.

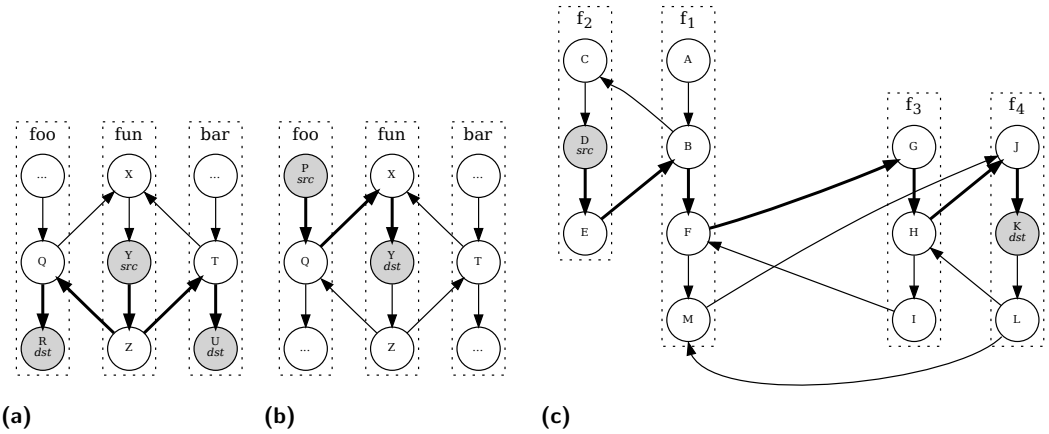

Figure 9 Locations of *src* and *dst* in inter-procedural hetero-sync motion, with paths from *src* to *dst* highlighted in bold.

▶ **Example.** In Figure 7, source *src* is Line 19 and target *dst* is Line 8, and the contextual paths are $\mathbb{K}_{src} = \langle$Line 19$\rangle$ and $\mathbb{K}_{dst} = \langle$Line 21, Line 8$\rangle$. Since, `enclosingFn`$(\mathbb{K}_{src}[1]) =$ `enclosingFn`$(\mathbb{K}_{dst}[1]) =$ `main`, the function `main` becomes the NCC function. Here, the Exit Dominance phase has no effect as *src* belongs to the NCC function (Line 19). In the Common Dominance phase, Line 19 and Line 21 satisfy the dom-pdom relationship, confirming that refined safe region can be extended into `foo`. In the Entry Dominance phase, *dst* (Line 8), however, does not post-dominate the entry node of `foo`. Hence, `validateRelocation` identifies Line 5 as the farthest successor from the entry node, which satisfies the dom-pdom relationship, establishing the refined safe region as $\mathcal{K}$(Line 19, Line 5) and setting Line 5 as the new destination.

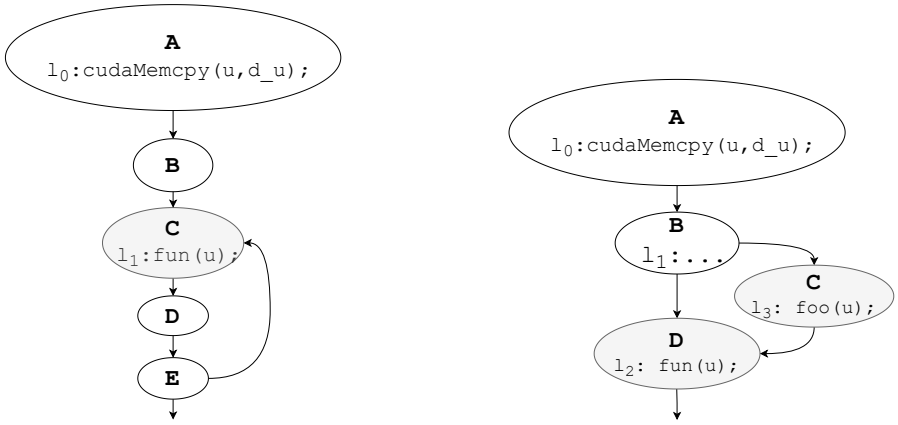
Updating Target Locations Across Contexts. After identifying a *dst* for an *src* in a specific context by means of a refined safe region, we verify its safety across different contexts. For a *src* in a method m, the *dst* location can fall into one of the three cases (see Figure 9): (1) *dst* inside a caller of m (2) *dst* inside a callee of m, and (3) *dst* inside a function f where m and f are called by NCC function.

The first case is safe because each invocation of the source function in different contexts maps *src* to a specific destination(s), such that the effect of percolation remains valid across all contexts when percolated to the respective caller functions. The example in Figure 9a demonstrates this with source function (`fun`) being invoked from two contexts (node `Q` in `foo` and node `T` in `bar`). The source instruction at context `Q` has a destination at node `R`, while at context `T`, the destination is `U`. Thus, percolating *src* to the caller functions ensures its execution along both paths: `Q` → `X` → `Y` → `Z` → `Q` → `R`, and `T` → `X` → `Y` → `Z` → `T` → `U` (as in the original program before optimization).

In the second case, relocating *src* to a callee can be unsafe in some cases. For example, in Figure 9b, `fun` is called from two different contexts in functions `foo` and `bar`. Percolating *src* (the *sync* statement) from `P` (in `foo`) to `Y` (in `fun`) enables computation in node `X` to run in parallel with kernels launched above `P` along the path `P` → `Q` → `X` → `Y` → `Z` → `Q` but introduces unintended memory transfers along path `T` → `X` → `Y` → `Z` → `T`, causing correctness issues. Hence, we percolate *sync* from *src* to the farthest node, whose enclosing function is invoked from a single callsite. In Figure 9b node `Q` is the farthest location from *src* (node `P`), with the enclosing function (`foo`) invoked from a single call site.

Algorithm 4 Updating Targets based on Context.

Input: $\mathbb{K}_{dst}$, com_i
Output: s_t
1 **Procedure** *updateTargets*
2 $n \leftarrow |\mathbb{K}_{dst}|$
3 **foreach** $j \leftarrow com_i$ **to** $n-1$ **by** 1 **do**
4 $s_{call} \leftarrow \mathbb{K}_{dst}[j]$
5 $f \leftarrow$ `getCallee`(s_{call})
6 $s_t \leftarrow s_{call}$
7 **if** *numCallSites*$(f) > 1$ **then**
8 **break**



(a) (b)

Figure 10 Example of two CFGs showing the necessity of loop-based updation and unification.

In the third scenario, where *src* and *dst* reside in functions that lack a direct caller-callee relationship, direct percolation from *src* to *dst* can be unsafe in some cases. For instance, in Figure 9c where function $\texttt{f}_1$ invokes functions $\texttt{f}_2$, $\texttt{f}_3$, and $\texttt{f}_4$ at nodes `B`, `F`, and `M`, respectively, and $\texttt{f}_3$ further invokes $\texttt{f}_4$ at node `H`. The *sync* at `D` in $\texttt{f}_2$ cannot be directly percolated to `K` in $\texttt{f}_4$ due to invocations of $\texttt{f}_4$ from different callsites. Like in the previous case, we percolate *sync* to the farthest node from *src* (node `D`), which is `H` in Figure 9c, where the enclosing function ($\texttt{f}_3$) is called from a single callsite.

Algorithm 4 updates target statements using contextual information by iterating over the destination contextual path from the NCC index com_i and checking whether the callee function at each index is invoked from a single callsite. If a callee at a callsite s_{call} is invoked from multiple callsites, the algorithm updates the target to s_{call} (Line 6), preventing the percolation of *sync* statements to such callee functions. For example, in Figure 9c, with NCC function $\texttt{f}_1$ and destination contextual path $\langle$`F`, `H`, `K`$\rangle$, the algorithm updates the destination to node `H` as the function $\texttt{f}_3$, called at callsite `F`, is invoked from a single callsite, whereas function $\texttt{f}_4$, called at `H`, is invoked from two distinct callsites (nodes `H` and `M`).

Updating Target Locations based on Loops. We now discuss another kind of updating process with an example. Suppose, in Figure 10a, the analysis identifies l_1 in basic block `C` as the optimal target location for the synchronization statement `cudaMemcpy` at statement l_0

```
1  void foo(float *arr_output_gpu)
2  {
3      float *arr_gpu, int size;
4      ...
5      cuda_kernel<<< grid,block >>>(..., arr_gpu); /* Device-side computation */
6      cudaMemcpy(arr_output_gpu, arr_gpu, size, cudaMemcpyDeviceToHost); /* barrier */
7  }
8  void bar(float *arr_output_gpu)
9  {
10     ...
11     for(int i=0; i<n; i++)
12         sum+=arr_output_gpu[i];
13 }
14 void main(){
15
16     float *arr_out_gpu, *cpu_arr;
17     foo(arr_out_gpu);
18     cpu_func(cpu_arr);
19     bar(arr_out_gpu);
20     ...
21 }
```

Figure 11 Sample code showing the challenges in automated transformation.

in basic block `A` (due to data dependency on `u`). While `A` *dominates* `C`, and `C` *post-dominates* `A`, relocating *sync* from l_0 to l_1 may incur performance overhead as `C` is a loop-header. A loop-header dominates its loop and is the target of a back edge forming the loop. The statement l_0, which gets executed once when it resides in `A`, would get executed in multiple iterations after optimization if placed in `C`. Thus, we mark l_0 to move to `B` since it is the farthest successor from the source (`A`) with the same loop scope as `A`.

At the end of this phase, the *sync* instructions and their updated target locations are stored in the map $\mathcal{M}$. This map is then passed to the next phase for further processing.

3.3 Unifying Target Location Sets

After the previous two steps, $\mathcal{M}$ may still map a single *src* (*sync* statement) to multiple destination locations. For example, in Figure 10b, the *sync* statement l_0 in basic block `A` has dependent statements l_3 in `C` and l_2 in `D`, both using variable `u`. While the first step identifies a set of target locations $\{l_2, l_3\}$, the second step refines it to $\{l_2, l_1\}$, replacing l_3 with l_1 in basic block `B` because l_1 post-dominates l_0, unlike l_3. However, since both l_1 and l_2 are on the same execution path, relocating *sync* to both l_1 and l_2 can cause redundant memory transfers, degrading performance. We address this issue in the current phase of our framework by unifying all the target locations that are found and updated by the previous two steps into a single target location. Here, we again use the inter-procedural dominance relationship to solve the problem. Among all the target location statements given by the previous step, GSOHC automatically selects the statement that dominates all the other statements in them. In Figure 10b, since basic block `B` dominates basic block `D`, the final set of target locations will contain only statement l_1. That is, GSOHC outputs a unique target location for a given *sync* statement in the form of a unified safe region (see Definition 8) for performing hetero-sync motion.

4 Code Transformation for Hetero-Sync Motion

The transformation pass takes the map $\mathcal{M}$ and a source program in IR format as inputs and outputs an optimized IR (see Figure 5). The map $\mathcal{M}$ associates a unique target location for a *sync* statement in a given context. When the target location is within the same

function as *sync*, the *sync* can be moved directly before the target statement. However, if the source and target locations are in different functions, direct percolation of the *sync* is infeasible due to the unavailability of argument variables in the target scope. For example, in Figure 11, the *sync* statement at Line 6 in function `foo` blocks potential overlap between kernel computation (Line 5) and host-side function (Line 18). According to our analysis step, the correct location for *sync* to achieve maximum computation overlap is Line 10. Since arguments for the *sync* call are defined locally in `foo` (Line 3), relocation requires transforming the IR to preserve these definitions across functions.

To address percolations across functions, GSOHC transforms the LLVM IR based on three different cases. Firstly, where the source and target functions lack a direct callee-caller relationship, *sync* argument variable definitions are first relocated to the NCC function (see Section 3), added to formal and actual argument lists of the source and target functions and then, the *sync* statement is percolated to the target instruction. In Figure 11, variables `arr_gpu` and `size`, defined at Line 3, are shifted from `foo` to the NCC function `main`, appended to parameter lists, appended to the actual arguments at call sites (Lines 17 and 19) and the *sync* is subsequently moved to the target location. Secondly, if the target is in the caller of the source function, the caller (target function) becomes the NCC function. Therefore, unlike the first case, the *sync* arguments do not need to be added to the formal and actual argument lists of the target function before percolating the *sync*. Thirdly, if the *sync* is in the caller of the target function, the caller (source function) becomes the NCC function. Similar to the second case, here, the argument variables of *sync* do not need to be added to the source function's formal and actual argument lists. Figure 7 demonstrates an example where hetero-sync motion requires transformation detailed in the third case, where the argument variables of *sync* (`arr_gpu` and `size`) at Line 19 are added as formal and actual arguments of the target function `foo`, prior to percolating the *sync* to Line 5.

5 Evaluation

This section investigates the following research questions to evaluate our hetero-sync motion optimization and GSOHC's capability in identifying and performing this optimization.

RQ1. Can GSOHC precisely identify opportunities for hetero-sync motion?

RQ2. How efficient are GSOHC's analysis and transformation passes?

RQ3. What is the impact of hetero-sync motion on the execution time of input benchmarks?

Implementation. GSOHC consists of two primary components: (1) inter-procedural flow- and context-sensitive static analysis to identify hetero-sync motion opportunities, (2) automated code transformation to perform the optimization. We have implemented our analysis and transformation passes using LLVM/Clang-14.x [36, 31] infrastructure. An open-source GPGPU compiler, `gpucc` [54] embedded with LLVM/Clang-14.x, converts CUDA programs into LLVM IR. Our custom analysis pass works on the SSA (Static Single Assignment) representation obtained using `-mem2reg` flag (which promotes memory references into register references, resulting in a "pruned" SSA). In addition, we use LLVM's intra-procedural Dominator and Post Dominator Tree [34], and Loop Info wrapper [35] passes.

Experimental Setup. We run our experiments on NVIDIA RTX A4000 (Ampere), NVIDIA Tesla P100 (Pascal) and NVIDIA A100 (Ampere) GPUs. Table 1 details the system specifications. This multi-generational GPU selection validates the robustness of our framework, enables analysis of performance variations due to communication and computation differences, and provides insights into its scalability across architectures.

Table 1 System configuration.

GPU	NVIDIA RTX A4000 (16 GB)	NVIDIA P100 (16 GB)	NVIDIA A100 (84 GB)
CPU	64 × AMD EPYC CPU @ 2.20GHz	20 × Intel(R) Xeon(R) Silver CPU @ 2.20GHz	64 × Intel(R) Xeon(R) Gold CPU @ 3.50 GHz
OS	Ubuntu 22.04 LTS	Debian GNU/Linux 11	Ubuntu 22.04 LTS
CPU RAM	128 GB	189 GB	84 GB

Benchmarks. To rigorously evaluate GSOHC with respect to diverse real-world scenarios, we use benchmark programs from benchmark suites: PolyBench [21], Rodinia [10], CUDA Sample SDK [44], and HeCBench [25]. Although (many) host-side computations in these benchmarks verify the results produced by GPU processors, they also exhibit complex control flows, encompassing nested loops, branches and aliasing behaviours, and offer rich inter-procedural opportunities replicating real-world challenges. For example, in the `entropy` program [57], a host-side function computes entropy for each matrix element using a 5×5 window with three nested loops, performing local histogram computation and probability evaluation using a logarithmic operation. Section 6 provides an in-depth analysis of CPU computations and various optimization opportunities in real-world programs. PolyBench, Rodinia and CUDA Sample SDK are widely-used GPU benchmark suites used in recent research works [2, 1, 26], while HeCBench is an extensive collection of heterogeneous computing benchmarks written in CUDA [9], HIP [5], SYCL [29], and OpenMP [14] across domains like physics, linear algebra, and machine learning (sourced from other standard suites such as Rodinia [10], PolyBench [21], N-body simulation [48], Hetero Mark [52], CUDA Sample SDK [44], etc.).

From these benchmark suites, we identified 56 benchmark programs (listed in Table 2) that contain opportunities for our hetero-sync motion optimization, excluding those without kernel or `global_synchronization` calls or with fewer device-side or host-side computations. Note that our framework can also analyze programs that have no hetero-sync motion opportunities and correctly report their absence, ensuring no false positives.

5.1 RQ1: Hetero-Sync Motion in Practice

We found 361 optimization opportunities from 56 benchmark programs for performing hetero-sync motion.

The results of our static analysis are shown in Table 2. The second column lists the number of lines in the LLVM IR file corresponding to each benchmark program. In the third column, O_f represents the number of manually found optimization opportunities. Our static analysis successfully identified all the optimization opportunities in the benchmarks, resulting in zero false negatives. For example, in the `xlqc` [58] program (from HecBench), the code computes Coulomb and exchange matrices for quantum chemistry simulations by first calculating their primitive forms on the GPU and transferring the results to host memory. On the CPU, two 2D contracted matrices are initialized, and GPU-computed primitive matrices are aggregated into these contracted matrices, which are then stored in GNU Scientific Library (GSL) data structures. GSOHC identifies an opportunity for hetero-sync motion here, where the performance can be enhanced by overlapping GPU computations with CPU initialization of the contracted matrices.

We have observed that many of our benchmark programs (around 48%) have synchronization barriers spanned across different functions. Using an intra-procedural analysis would have caused to miss many opportunities in this scenario. Moreover, optimization opportunities that span across different functions are much harder to identify manually (see Section 1). To address this, we designed an inter-procedural, flow- and context-sensitive static analysis framework that enables practical and effective hetero-sync motion.

Further, we thoroughly tested our analysis and transformation phases. For each benchmark program, we recorded the source and corresponding target location sets at each phase of our static analysis and manually verified them. We ran each program five times before and after transformation with identical inputs, confirming identical outputs. We also manually inspected the transformed IRs to ensure correctness of the transformation pass.

5.2 RQ2: Efficiency of GSOHC

This section presents the time taken by our analysis and transformation passes for the benchmark programs. In Table 2, the last column (T_{an}) shows the analysis time in milliseconds. Our analysis time ranges from a few milliseconds to 291 milliseconds (measured on the CPU node associated with the RTX A4000 GPU, see Table 1). Further, our transformation pass takes only a few microseconds, requiring three steps: (1) adding variables to function argument lists and callsite modifications, (2) declaring variables in the common caller, and (3) percolating *sync* to the target location.

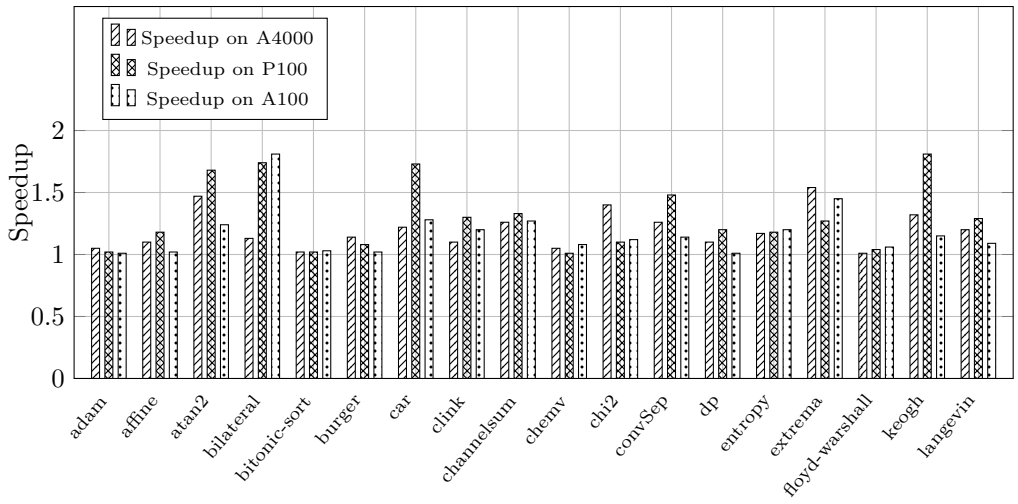
Although the benchmark programs have similar lines of code, the analysis time for the `shuffle` benchmark is significantly higher due to its greater number of hetero-sync motion opportunities and more complex control flow (with more loops, branches, and function calls). On the other hand, though benchmark `extrema` has 40 optimization opportunities, the control flow in it is much simpler (1D loops, fewer function calls and fewer branches with no nesting), resulting in a shorter analysis time. The data flow analysis may require multiple iterations over the loop body, with new flow information in each iteration, taking longer to converge to a fixed point. Therefore, the analysis time is more influenced by the number and location of opportunities rather than program size.

5.3 RQ3: Effectiveness of Hetero-Sync Motion

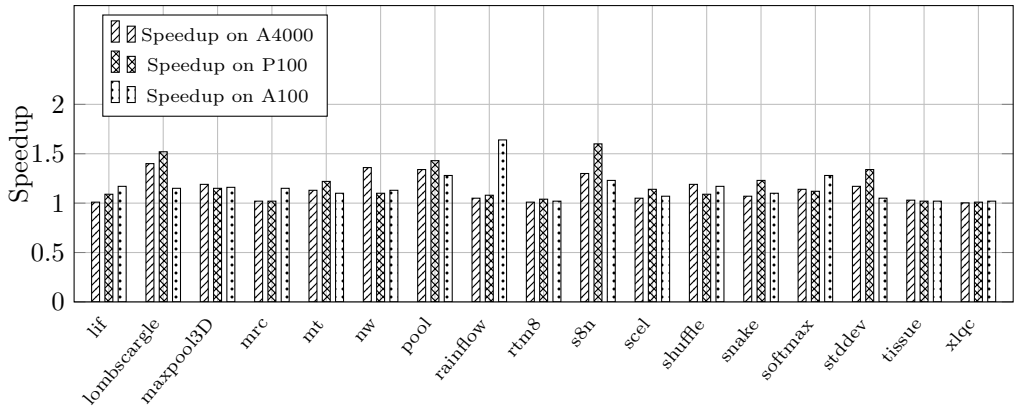
Figure 12a, 12b and 12c show the performance improvements achieved by hetero-sync motion on different benchmarks run on RTX A4000, P100 and A100 machines. We executed each benchmark program five times before and after optimization and then reported their arithmetic mean execution times. Our hetero-sync motion optimization achieves substantial performance gains on all machines, with geomean speedups of approximately 1.15x, 1.17x, and 1.13x with standard deviations of 0.19, 0.20 and 0.15 (and up to 1.8x, 1.9x and 1.9x speedups on A4000, P100 and A100, respectively) and a geometric mean performance improvement of around **11**%, reaching up to **34**%.

In many cases, the reduction in total execution time is also significant. Specifically, 36 benchmarks demonstrated performance improvements exceeding 500 milliseconds on the P100 machine, with 29 of these benchmarks showing improvements of over 1 second (11 benchmarks having improvements over 10 seconds). Given that the total running times of these programs are only a few seconds, hetero-sync motion optimization is notably impactful. The benchmarks with higher execution times also have higher improvements in execution time. As detailed in Figure 12b, the most pronounced improvement was observed in the `snake` benchmark from the HeCbench suite, where the execution time was reduced from 368.5 seconds to 230.6 seconds, yielding a 1.6x speedup and an overall reduction of 137.9 seconds. Further, the transformed code results in the best performance if T_{host}, the execution time of identified host-side computations, and T_{dev}, the execution time of identified device-side computations, are significant and are comparable to one another such that they can hide each other's latency. Thus, benchmarks such as `extrema`, `bilateral`, and `atan2` with significant overlaps show approximately 1.5x to 1.7x speedup with the optimization.

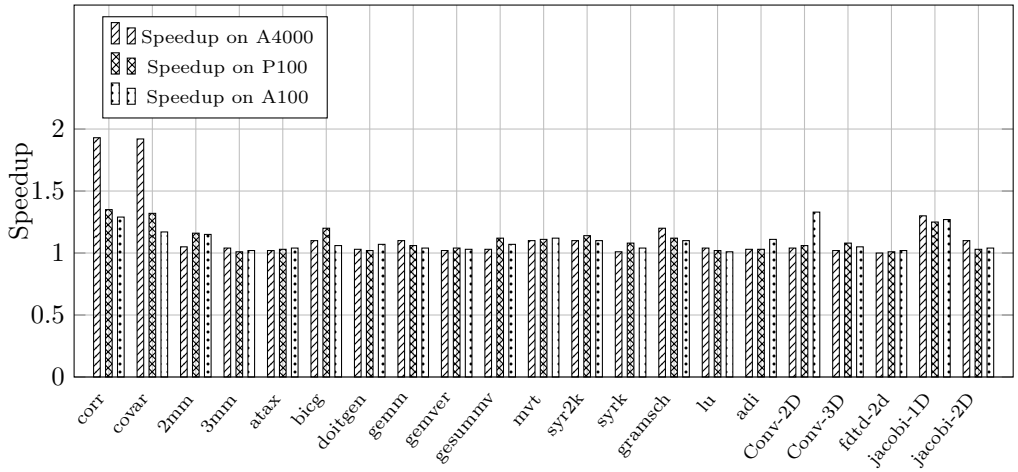
On the other hand, if T_{host} highly dominates T_{dev} or vice versa, the optimized code is constrained by the dominated time and does not result in significant performance gains. Thus the performance gains of less than 1.06x in specific benchmarks can be attributed to an imbalanced load distribution between CPU and GPU computations. For example, in `3mm`, `gemm` (from Polybench), and `bitonic-sort`, `lif` (from HeCBench), the CPU-side computations take significantly longer time than device-side computations. Thus, the optimized code takes almost as long as the CPU-side computation, resulting in smaller speedups. Further, we describe an interesting case in `floyd-warshall` benchmark program where it does not exhibit performance improvement post-optimization. In this case, the synchronization statement is a `cudaMemcpy` call present outside of a loop. However, additional `cudaMemcpy` calls within the loop, occurring before each kernel invocation, cause the kernel to block at each iteration. Since these synchronization calls are not loop-invariants, they cannot be moved outside the loop. Furthermore, relocating the *sync* statement from outside the loop body to a program point beyond the CPU computation may result in minimal overlap between host and device computation (particularly in the final iteration of the loop), yielding negligible speedup.



(a) Speedup achieved by hetero-sync motion on HeCBench.



(b) Speedup achieved by hetero-sync motion on HeCBench (contd.).



(c) Speedup achieved by hetero-sync motion on PolyBench.

Figure 12 Speedup achieved by hetero-sync motion on various benchmark programs.

```

Figure 13 Hetero-Sync Motion optimization opportunitites in real-world codes. For brevity, `cudaMemcpyDeviceToHost` is abbreviated as `DtoH` and `cudaMemcpyHostToDevice` as `HtoD`.

6 Case Study

Building upon the evaluation in Section 5 that demonstrates GSOHC's effectiveness, this section explores the broader applicability of hetero-sync motion in real-world open-source applications. We have surveyed several top-rated CUDA/C++ projects on GitHub and highlighted relevant opportunities in Figure 13. We present these case studies separately from the broader benchmark evaluation to provide a focused analysis of opportunities identified in specific real-world applications and to highlight practical insights that may otherwise be obscured in larger-scale evaluations. Note that certain real-world opportunities are embedded within large frameworks (rather than stand-alone programs) and benchmark suites that lack the necessary testing environment, such as readily available datasets. As a result, even though our static analysis pass is capable of effectively identifying these opportunities, we could not include them in our empirical evaluation. We first present intra-procedural opportunities, then inter-procedural opportunities.

Intra-procedural Opportunities. `GraphFlow` [22] (see Figure 13a), a CUDA/C++ deep learning framework, facilitates symbolic and automatic differentiation, supports dynamic computation graphs, and provides GPU-accelerated tensor and matrix operations, along with implementations of various state-of-the-art graph neural networks. An opportunity for hetero-sync motion optimization exists here when a code segment (in `GraphFlow`) uses GPU-based matrix multiplication for gradient computation. This code initiates two kernel launches. The first (Line 3) computes the gradient for the first matrix and synchronously transfers (Line 4) the result back to the host, which is followed by a CPU computation (Line 9) transposing the first matrix into a temporary data structure, which is then transferred to the device

memory along with the second matrix. The second kernel launch (Line 15) then performs matrix multiplication, updating the gradient for the second matrix, which is subsequently copied back to the host. In this case, performance can be further improved by overlapping the first kernel's computation with the CPU transposition of the first matrix. However, this optimization is currently restricted by the synchronous host-device data transfer immediately after the first kernel launch in the original implementation.

Inter-procedural Opportunities. We now discuss the `GCOL` and `GCON` programs from ScoR [13] benchmark suite. Both are CUDA/C++ applications focused on GPU-accelerated graph colouring and graph connectivity algorithms, respectively. Because these two applications share similar programming patterns, we will only discuss `GCOL` (see Figure 13b) in detail. The program operates in three phases within a loop that continues until all colour assignments are conflict-free. In the first phase, a GPU kernel (Line 17) is launched to assign initial colours to the vertices, while in the second phase, the code launches another GPU kernel (Line 22) to verify whether no adjacent vertices share the same colour. Lastly, a third GPU kernel (Line 26) is invoked to forbid specific colours from being assigned to prevent conflicts. Between consecutive phases, a host-side function is called (at Line 21) to partition the graph data for the next GPU kernel computation. However, `cudaDeviceSynchronize` calls (Lines 18 and 23) and synchronous data transfer operations (Lines 20 and 24) after each GPU kernel prevent overlap between the CPU's data partitioning and GPU computations, limiting potential performance improvements. This points to a hetero-sync motion optimization opportunity, especially since the CPU computation for workload division is encapsulated in a separate host function (distinct from that of the source function having *sync* call), indicating the need for inter-procedural optimization.

We further discuss real-world opportunities found in a GPU-based recursive filtering application called `gpufilter` [3] (not shown). An opportunity for hetero-sync motion optimization exists in a code segment that invokes three different host-side functions to perform different Gaussian filtering on an input image. Each function first computes the coefficients and weight vectors, followed by the creation of transformation matrices, which include generating zero and identity matrices, transposed convolution matrices, and performing matrix-vector multiplications. These transformation matrices are transferred to the device memory, followed by multiple GPU kernel launches to apply the filtering operations. Finally, the filtered image is transferred back to the host memory. The synchronous data transfer from device to host limits the overlap between the GPU filtering process and the CPU computation of transformation matrices for subsequent filtering, indicating an area for hetero-sync motion optimization.

7 Related Work

Global Optimizations in Heterogeneous Computing. GSOHC relocates synchronization calls on the host side to maximize the overlap between host and device computations. In this context, we refer to global optimizations as those approaches that target host-side code but improve interactions between CPU and GPU in heterogeneous systems, leading to overall better performance. CGCM [23] improves program performance by managing CPU-GPU communication through compiler optimizations and runtime libraries, breaking cyclic communication patterns by transferring data to the GPU early and retrieving only when necessary. Kessler et al. [27] proposed a static-analysis technique to reduce the number of data transfer messages between CPU and GPU by analyzing dependence graphs over kernel

calls, reordering operand arrays in memory, and merging memory allocations of adjacent operands. Ashcraft et al. [4] developed a compiler technique for automatically scheduling data transfers from CPU to GPU and vice-versa based on data used within the kernel to reduce the number of bytes transferred, leading to performance improvement.

Apart from the above-mentioned static analysis-based approaches, architectural-based or run-time-based approaches also have been proposed to address global performance issues in heterogeneous systems. HUM [26] has provided a run time technique that leverages CUDA Unified Memory to overlap `H2Dmemcpy` time with host or kernel computation, resulting in an overall program speedup. Kim et al. [30] have proposed a software-hardware-based approach to improve the performance of workloads that have multiple dependent GPU kernels by automatically overlapping the execution of such kernels and exploiting implicit pipeline parallelism. As there have been many similar attempts to improve the performance of heterogeneous programs, we cite a survey paper [37] that summarizes the efforts of numerous research papers. Unlike GSOHC, which enhances program performance through hetero-sync motion increasing CPU-GPU compute overlap, these approaches achieve performance through other dimensions such as multi-kernel computation overlap, data transfer overlap, and communication optimizations.

Synchronization Optimization. In the field of compilers, there is a large body of work [41, 19, 39, 42, 16, 15, 17, 50, 49, 43, 56, 24, 40] on reducing synchronization overheads in the context of various programming paradigms, including Thread Level Parallelism (TLP) programs, Task Parallel programs, and MPI (Message Passing Interface) programs.

Hetero-Sync Motion is analogous to the synchronization optimization proposed by Nicolau et al. [42, 43] for efficient placement of `post` and `wait` methods in a `non-DOALL` loop increasing the degree of Thread Level Parallelism (TLP) in CPU programs. Because they focus on the percolation of synchronization calls with only blocking properties, they fail to consider the control-flow dependency of inserted `wait` calls resulting in duplicate `wait` calls (and code explosion). This can lead to correctness and performance issues in heterogeneous CPU-GPU systems because synchronization calls such as `cudaMemcpy` have both blocking and data transfer properties. In contrast to this approach, our proposed framework efficiently manages such scenarios with a dedicated static analysis.

Our work on hetero-sync motion optimization can be compared to works by Danalis et al., Nguyen et al. and Das et al. [16, 41, 17], that proposed code motion techniques to improve computation-communication overlap in the MPI programming model. However, these approaches require matching between communication and blocking calls, can percolate only a single blocking or non-blocking call at a time, and are limited in their ability to extend percolation beyond another `MPI` call. Since a GPU kernel call can have multiple synchronization calls surrounding it, and synchronization calls (by semantics) wait for all previous kernel calls to finish in CPU-GPU heterogeneous systems, GSOHC requires a data-flow analysis to facilitate the percolation of multiple synchronization calls together to an optimal program point. Furthermore, as in the case of TLP, `MPI_wait` calls are mere blocking calls, unlike the ones with data transfer in our case.

A number of past works have also proposed transformation techniques for addressing synchronization overheads and improving program performance. Sarkar et al. [50] provided an approximation algorithm to select an ordering of the fork operations and determine the placement of join operations in a given program, allowing independent computations to run simultaneously and thereby improving the overall parallelism. Zhu et al. [56] provided a code motion compiler optimization technique to reduce the communication overhead

caused by remote reads/writes (accessing dynamically allocated data structures) in parallel C programs. Their analysis determines the optimal communication mode (blocking or pipelined) and propagates remote writes in the program that may be subject to coalescing. Diniz et al. [19] aimed at redundant lock elimination to reduce lock overheads through the percolation of synchronization calls in a parallel program. Unfortunately, however, their approach may reduce the overall parallelism of a given program. Nandivada et al. [39] proposed optimizations such as `finish` elimination, loop chunking and `forall`-coarsening to reduce the number of synchronization operations in X10 programs. Nayak et al. [40] introduces ScopeAdvice, a tool designed to detect over-synchronization in CUDA programs, enabling performance optimization by analyzing memory access and synchronization traces using NVIDIA's NVBit library. The cuSync framework [24] provides fine-grained tile-level synchronization to address GPU underutilization caused by uneven tile distribution when the number of computation tiles is not a multiple of the GPU's execution units, enabling concurrent execution of independent tiles with user-defined synchronization policies. While we also address synchronization statements to improve performance, unlike these approaches that directly reduce synchronization overheads, our focus is on percolating synchronization calls to enhance CPU-GPU computation overlap in CUDA programs.

In summary, the existing works on synchronization optimization are inadequate to address the problem of hetero-sync motion due to the semantic differences in synchronization operations. To the best of our knowledge, our work is the first to focus on automatic synchronization motion optimization in CPU-GPU heterogeneous systems.

Static Analyses for Optimizating Device Code in Heterogeneous Computing. Recent efforts [51, 2, 1] focus on accelerating CUDA programs by improving GPU kernels (device-side computations) through static analysis and compiler optimization approaches. DARM [51] presents a static analysis-based framework that identifies and automatically merges divergent blocks in a CFG to reduce the effects of thread divergence in device computation. GPUDrano [1] automatically identifies uncoalesced memory accesses in a GPU kernel code using data flow analysis. GPU Block Independence Analysis [2] represents a static analysis framework that can automatically identify whether a GPU kernel code is independent of the block size, allowing the compiler to tune block size to improve performance. As GSOHC, they are all built on LLVM [31], a general framework for building compilers. These optimizations differ from ours, but they can be effectively combined with GSOHC to improve the performance of the input program further.

Load Balancing of Heterogeneous Workloads. The optimal performance due to hetero-sync motion is attained when the input workload to the source program is load-balanced across various architectures in a heterogeneous system. This can be attributed to our framework's ability to optimize the source code in a manner that allows/improves concurrent execution of host-side and device-side computations. The performance study conducted by White et al. [53] shows that their manually optimized CPU-GPU implementation with workload distributed between CPU and GPU results in better performance. Lee et al. [32] proposed a run time technique that enables the effective utilization of available CPU and GPU computing resources in a heterogenous system through a workload distribution module and a global scheduling queue. Khalid et al. proposed Troodon [28], a machine learning-based framework that automatically schedules jobs to CPU and GPU in a load-balanced way, increasing throughput with high device utilization.

8 Conclusion

We have developed a novel compiler analysis and optimization framework, GSOHC that automatically analyzes CPU-GPU heterogeneous programs and relocates poorly placed synchronization barriers within them. This optimization, which we named hetero-sync motion, facilitates overlapping CPU and GPU computations, thereby improving program performance. GSOHC consisting of three distinct phases employs an interprocedural context- and flow-sensitive data-flow analysis to accurately identify optimization opportunities in the input programs. We have also performed an evaluation of our framework on 56 benchmark programs drawn from several widely-recognized benchmark suites. Our evaluation shows that our static analysis can successfully identify all the actual optimization opportunities within these benchmark programs. Furthermore, our evaluation confirms significant performance improvements in the optimized code, underscoring the practical impact of our approach.

Quantifying Cache Side-Channel Leakage by Refining Set-Based Abstractions

Jacqueline L. Mitchell
University of Southern California, Los Angeles, CA, USA

Chao Wang
University of Southern California, Los Angeles, CA, USA

Abstract

We propose an improved abstract interpretation based method for quantifying cache side-channel leakage by addressing two key components of precision loss in existing set-based cache abstractions. Our method targets two key sources of imprecision: (1) imprecision in the abstract transfer function used to update the abstract cache state when interpreting a memory access and (2) imprecision due to the incompleteness of the set-based domain. At the center of our method are two key improvements: (1) the introduction of a new transfer function for updating the abstract cache state which carefully leverages information in the abstract state to prevent the spurious aging of memory blocks and (2) a refinement of the set-based domain based on the finite powerset construction. We show that both the new abstract transformer and the domain refinement enjoy certain enhanced precision properties. We have implemented the method and compared it against the state-of-the-art technique on a suite of benchmark programs implementing both sorting algorithms and cryptographic algorithms. The experimental results show that our method is effective in improving the precision of cache side-channel leakage quantification.

1 Introduction

Cache side-channel attacks, whereby adversaries gain information about secret data by examining the footprint of program execution in the CPU cache, pose a significant threat to computer security. Cache side-channel attacks have been demonstrated in many critical infrastructure systems, ranging from cryptographic software in embedded devices [13, 30, 29, 1, 21, 19] to cloud computing applications where an adversary only needs remote access to the victim's hardware to successfully launch the attacks [5, 22, 6, 28]. Various techniques have been proposed to mitigate such attacks, including *constant-time programming* [16] along with verification techniques for proving the constant-time property [2, 4].

However, completely eliminating side-channel leakage is a challenging task since it may result in too much computational overhead [8]; it may also be infeasible for certain applications where some information leakage is required [24, 18, 27]. This motivates the development of mathematically rigorous techniques for *quantifying* side-channel leakage, to

allow programmers to audit the degree of leakage in software code. While the pioneering work of Doychev et al. [12, 11] show that abstract interpretation [9] using a set-based cache abstract domain is well-suited for quantifying cache side-channel leakage, the main limitation is the loss of precision in the quantification results.

To overcome this limitation, we propose a new method for improving the precision of abstract interpretation based static program analysis for quantifying cache side-channel leakage. Static program analysis based on abstract interpretation has the advantages of being sound, generally performant, and not requiring artificially-bounded loop iterations as in unsound alternative techniques based on bounded model checking [20] or symbolic execution [7]. However, these advantages of abstract interpretation may come at the cost of precision loss. There are two key sources of precision loss in the context of cache side-channel quantification. The first source is spuriously aging memory blocks in the cache while applying the so-called *abstract transfer function* which interprets memory-accessing instructions during the analysis. It does this by taking as input an abstract cache state and returning another abstract state which overapproximates the effect of accessing a memory block on any (concrete) cache state represented by the input abstract cache state. The second source of imprecision is the spurious aging of memory blocks due to the inability to express and leverage disjunctive invariants about the abstract cache states with respect to the control flow of a program (in other words, the incompleteness of the set-based abstract domain). Our new method is designed to mitigate these two key sources of precision loss.

At the center of our method is a novel abstract transfer function for the set-based abstract domain and an automatic lifting of the domain to more accurately capture invariants about the cache state. In this work, we have applied our method in the context of the abstract domain used by CacheAudit [11], a state-of-the-art tool for quantifying cache side-channel leakage. We denote this domain as $\mathcal{C}^\sharp$. An abstract state in the $\mathcal{C}^\sharp$ domain associates each memory block with a set of possible ages, which describes the possible positions for a memory block within the cache. The ages also determine how cache states are updated under a given replacement policy, as the result of interpreting a memory-accessing instruction. During an analysis step where abstract interpretation is used to compute the resulting abstract cache state after an access to memory, we say that a memory block b is *spuriously aged* to an age a if a is in the set of possible ages for b, and yet there is no valid concrete cache state in which b is of age a in the ground truth. In some cases, applying the best abstract transformer [9], which concretizes the abstract cache state to yield a set of concrete cache states, updates each concrete cache state according to a replacement policy, and then re-abstracts the set of updated concrete states into a new abstract cache state, can mitigate spurious aging. However, even if the best abstract transformer is used, a memory block may still be spuriously aged with respect to the collecting semantics, due to the incompleteness of $\mathcal{C}^\sharp$. Consider two abstract cache states C and C' that arise due to a difference in the control flow of a program (perhaps corresponding to two different branches of an if-statement). Even if the best abstract transformer does not age b to a in both C and C', this may not be true of their abstract union; we later provide an example in Section 4. This imprecision arises due to $\mathcal{C}^\sharp$'s inability to express disjunctive invariants at the level of variations in control flow.

To address the first source of precision loss, we propose to carefully leverage information in the abstract state regarding the ages of other memory blocks when deciding to age block b, to more accurately update the abstract cache state for each memory-accessing instruction. Instead of deciding to age b only based on b's age and the age of the accessed memory block, we use the ages of all the memory blocks in the cache to prevent the spurious aging of many

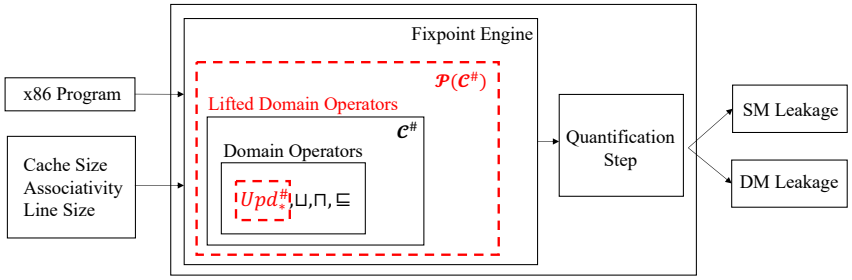

Figure 1 Our method for quantifying cache side-channel leakage based on abstract interpretation. SM corresponds to a shared memory adversary, where an attacker can observe which memory blocks are in the cache. DM corresponds to a disjoint memory adversary, where an attacker can observe which cache lines are occupied in the cache, but not the specific memory blocks occupying them.

memory blocks. As we describe later, we prove our improved transfer function improves upon the baseline transfer function by refining it in such a way that removes cases of spurious aging.

To address the second source of precision loss, we propose to parsimoniously leverage disjunctions of abstract cache states that arise due to variations in control flow. This technique can be implemented as a refinement of $\mathcal{C}^\sharp$, based on the powerset domain introduced by [3]. The powerset domain can refine any abstract domain by lifting its operators (partial order, join, meet, widen) to operate on a lifted version of the abstract domain, whose elements are a member of the *powerset* of elements of the abstract domain.

Figure 1 shows the overall flow of our method. The input to our method consists of a program P and the cache parameters. The program P is represented in x86 binary code. The cache parameters specify the total cache size, the associativity, and the cache line size. The output of our method is the cache side-channel leakage measured in bits, for two kinds of adversaries, explained in the following. The adversary type is either Shared Memory (SM) or Disjoint Memory (DM). At the end of a program's execution, the SM adversary is able to observe the placement of memory blocks in the final cache state, along with which memory blocks are in the various locations. In contrast, the DM adversary is only able to observe which locations of the cache are occupied in the final cache state, but not the specific memory blocks that occupy them. We note that other types of adversaries are possible; we have simply chosen these adversaries to empirically evaluate our techniques. The techniques are not specific to the two adversaries in the sense that other cache analyses may also depend on such set-based abstractions. Internally, our method consists of two innovative components, shown as the new transfer function $Upd^\sharp_*$ and the lifted domain which uses disjunctions, highlighted in red, dashed boxes in Figure 1.

We have evaluated our method on a suite of 29 benchmark programs, which are implementations of various sorting algorithms and cryptographic algorithms. The baseline that we use for comparison is CacheAudit [12]. We compared the two methods on all benchmark programs, with various cache settings and adversary types. In addition to a side-by-side comparison of our method against CacheAudit, we also conducted an ablation study by enabling each of the two new techniques and then comparing the performance. The goal is to check how effective each of the two techniques is in isolation across various cache configurations, and see if they have a synergistic effect when being used together. The experimental results show that, overall, our method significantly outperforms the state-of-the-art method. Furthermore, both of the two new techniques proposed in this paper are effective, and together, they have a synergistic effect.

In summary, this paper makes the following contributions:

- We propose a new method for more accurately quantifying cache side-channel leakage based on abstract interpretation.
- We introduce two novel techniques in our method. The first leverages a new abstract transfer function to prevent spurious aging of memory blocks in the cache during the analysis. The second leverages disjunctions parsimoniously to prevent spurious aging of memory blocks due to the incompleteness of $\mathcal{C}^\sharp$.
- We prove soundness and enhanced accuracy properties of the two novel techniques.
- We implement the method and demonstrate its advantages over the state-of-the-art technique on a suite of 29 benchmark programs.

The remainder of this paper is organized as follows. After providing the technical background in Section 2, we illustrate the limitations of prior work in Section 3 using an example. Then, we present our method in Section 4 and prove the soundness and accuracy properties. We present the experimental results in Section 5. After reviewing the related work in Section 6, we give our conclusion in Section 7.

2 Background

Unlike classic program analysis techniques that focus on functional properties, e.g., control and data flows of a program, quantifying side-channel leakage also requires the modeling and analysis of non-functional properties such as the cache state. Here, we introduce the components required for abstractly modeling cache behavior.

2.1 Modeling the Cache

A cache is used to bridge the latency gap between the fast CPU and the slow main memory, to reduce the overall execution time of a program. A cache is often divided into cache sets, each of which is further divided into cache lines, where each cache line has a fixed size. Formally, a cache with the size S, the associativity n, and the line size L is organized into $m = S/(L \cdot n)$ cache sets. Each cache set consists of n cache lines. Each cache line holds a contiguous block of L bytes. Throughout the paper, let $\mathcal{B}$ refer to the set of memory blocks under consideration.

Each memory block in $\mathcal{B}$ belongs to one cache set. We define the function $set : \mathcal{B} \to \{0, \ldots, m-1\}$ that maps each memory block $b \in \mathcal{B}$ its cache set $set(b) \in \{0, \ldots, m-1\}$. Given $b_1, b_2 \in \mathcal{B}$, the condition $set(b_1) = set(b_2)$ means that the two memory blocks map to the same cache set, whereas $set(b_1) \neq set(b_2)$ means that they map to different cache sets. When $set(b_1) \neq set(b_2)$, the two memory blocks map to different cache sets, and thus do not interfere with each other.

A concrete cache state c maps each memory block in $\mathcal{B}$ to a specific age in the set $\mathcal{A} = \{0, ..., n\}$ (recall, n is the associativity of the cache). Formally, $c : \mathcal{B} \to \mathcal{A}$, where $c(b) = n$ means that the block is outside of the cache, and $0 \leq c(b) \leq n-1$ means the block is inside the cache. The ages of memory blocks are determined by the so-called *cache replacement policy*. For example, with the popular LRU (least-recently used) policy, the age of a memory block b is determined by the number of other memory blocks accessed from the last time that b was accessed during program execution.

Let $\mathcal{C}$ be the set of concrete cache states. From a concrete cache $c \in \mathcal{C}$, executing an instruction that accesses a memory block $w \in \mathcal{B}$ leads to a new cache state $Upd(c, w) \in \mathcal{C}$. Here, $Upd : \mathcal{C} \times \mathcal{B} \to \mathcal{C}$ is called the transfer function.

▶ **Definition 1.** *The transfer function $Upd(c, w)$ for an LRU cache state $c \in \mathcal{C}$ and accessed memory block $w \in \mathcal{B}$ is defined as follows:*

$$Upd(c, w) := \lambda b \in \mathcal{B}. \begin{cases} c(b) & \text{when } set(b) \neq set(w) \\ c(b) & \text{when } set(b) = set(w) \wedge b \neq w \wedge c(b) = n \\ c(b) & \text{when } set(b) = set(w) \wedge b \neq w \wedge c(b) > c(w) \\ c(b) + 1 & \text{when } set(b) = set(w) \wedge b \neq w \wedge c(b) < c(w) \\ 0 & \text{when } set(b) = set(w) \wedge b = w \end{cases}$$

That is, the age of any memory block in a different cache set remains unchanged, as indicated by $set(b) \neq set(w)$. Within the same cache set, the age of the accessed memory block ($b = w$) is set to 0, the age of any memory block previously younger than the accessed block ($c(b) < c(w)$) increases by 1, and the age of any other memory block remains unchanged. In particular, $c(b) = n$ means the memory block b is already outside of the cache, and remains there upon an access to w. We note that following the LRU policy, any two memory blocks which belong to the same cache set cannot have the same age.

2.2 Abstract Interpretation of the Cache

Recall that $\mathcal{A}$ is a set of possible ages. Let $\mathcal{P}(\mathcal{A})$ be the powerset (set of all subsets) of $\mathcal{A}$, such that any element in $\mathcal{P}(\mathcal{A})$ represents a set of ages. Following Doychev et al. [11], we define the abstract cache state as a function $C : \mathcal{B} \to \mathcal{P}(\mathcal{A})$ that maps a block $b \in \mathcal{B}$ to a set of ages $C(b) \in \mathcal{P}(\mathcal{A})$. This is in contrast with the concrete state $c : \mathcal{B} \to \mathcal{A}$, which maps b to a single age $c(b)$.

Let $\mathcal{C}^\sharp$ be the set of abstract cache states. From an abstract cache state $C \in \mathcal{C}^\sharp$, executing an instruction that accesses a memory block $w \in \mathcal{B}$ leads to a new abstract cache state $Upd^\sharp(C, w) \in \mathcal{C}^\sharp$. Here, $Upd^\sharp : \mathcal{C}^\sharp \times \mathcal{B} \to \mathcal{C}^\sharp$ is called the abstract transfer function. Before defining $Upd^\sharp$, we need to define $C \downarrow_{w \mapsto c_w}$, which is a restriction of the abstract cache state C such that the age of block w is set to $c_w \in C(w)$. That is, $C \downarrow_{w \mapsto c_w}$ is an underapproximation of C where, since w occupies the age c_w, no other block can have the same age c_w, unless $c_w = n$ (meaning that w is outside of the cache), as is true in LRU caches. In the following, we define the abstract transfer function for a cache which follows the LRU replacement policy.

▶ **Definition 2.** *The abstract transfer function $Upd^\sharp(C, w)$ for a cache state $C \in \mathcal{C}^\sharp$ and accessed memory block $w \in \mathcal{B}$ is defined as follows [11]:*

$$Upd^\sharp(C, w) := \lambda b \in \mathcal{B}. \begin{cases} C(b) & \text{when } set(b) \neq set(w) \\ O_n\langle w \rangle \cup O_>\langle w \rangle \cup O_<\langle w \rangle & \text{when } set(b) = set(w) \wedge b \neq w \\ \{0\} & \text{when } set(b) = set(w) \wedge b = w \end{cases}$$

where $O_n\langle w \rangle \cup O_>\langle w \rangle \cup O_<\langle w \rangle$ computes a set of ages of block $b \in \mathcal{B}$ for each possible age $c_w \in C(w)$:

- $O_n\langle w \rangle := \bigcup_{c_w \in C(w)} \{c_b \mid c_b = n \wedge c_b \in C \downarrow_{w \mapsto c_w} (b)\}$ *has the ages equal to n,*
- $O_>\langle w \rangle := \bigcup_{c_w \in C(w)} \{c_b \mid c_b > c_w \wedge c_b \in C \downarrow_{w \mapsto c_w} (b)\}$ *has the ages older than c_w,*
- $O_<\langle w \rangle := \bigcup_{c_w \in C(w)} \{c_b + 1 \mid c_b < c_w \wedge c_b \in C \downarrow_{w \mapsto c_w} (b)\}$ *increments ages younger than c_w.*

The sets $O_n\langle w \rangle$, $O_>\langle w \rangle$ and $O_<\langle w \rangle$ in Definition 2 directly correspond to the three cases $c(b) = n$, $c(b) > c(w)$ and $c(b) < c(w)$ in Definition 1.

Abstract Domain ($\mathcal{C}^\sharp$): The universe is the set of abstract cache states. Element $\top$ (top) is a state $C \in \mathcal{C}^\sharp$ such that $\forall b \in \mathcal{B} \,.\, C(b) = \mathcal{A}$. Element $\bot$ (bottom) is a state $C \in \mathcal{C}^\sharp$ such that $\forall b \in \mathcal{B} \,.\, C(b) = \{\}$.

Partial Order ($\sqsubseteq_{\mathcal{C}^\sharp}$): Given two abstract cache states $C, C' \in \mathcal{C}^\sharp$, the ordering relation $C \sqsubseteq_{\mathcal{C}^\sharp} C'$ holds if and only if $\forall b \in \mathcal{B} \,.\, C(b) \subseteq C'(b)$.

Join ($\sqcup_{\mathcal{C}^\sharp}$): Given two abstract cache states $C, C' \in \mathcal{C}^\sharp$, the join is defined as $C \sqcup_{\mathcal{C}^\sharp} C' := \lambda b \in \mathcal{B} \,.\, C(b) \cup C'(b)$.

Meet ($\sqcap_{\mathcal{C}^\sharp}$): Given two abstract cache states $C, C' \in \mathcal{C}^\sharp$, the meet is defined as $C \sqcap_{\mathcal{C}^\sharp} C' := \lambda b \in \mathcal{B} \,.\, C(b) \cap C'(b)$.

Figure 2 The abstract domain $\mathcal{C}^\sharp$ and its partial order, join, and meet operators.

For example, consider $C = \{a \mapsto \{0,1\}, b \mapsto \{1,4\}, c \mapsto \{0,2,4\}\}$, accessed memory block b, and $n = 4$. We have $C \downarrow_{b \mapsto 1} := \{a \mapsto \{0\}, b \mapsto \{1\}, c \mapsto \{0,2,4\}\}$ because, when the age of b is 1, the age of a can no longer be 1. However, $C \downarrow_{b \mapsto 4} := \{a \mapsto \{0,1\}, b \mapsto \{4\}, c \mapsto \{0,2,4\}\}$ because multiple blocks can have the age 4 (meaning they are outside of the cache). Finally, $\mathit{Upd}^\sharp(C, b)$ returns the abstract cache state $\{a \mapsto \{1,2\}, b \mapsto \{0\}, c \mapsto \{1,2,4\}\}$.

2.3 The Baseline Algorithm

The baseline algorithm for quantifying cache side-channel leakage using abstract interpretation consists of two steps. The *analysis step* uses the abstract transfer function to compute an abstract cache state at each program location, to overapproximate the set of concrete cache states at that location. The *quantification step* leverages the abstract cache state C at the program exit point to compute the total number of concrete cache states, which is an upper bound of the information leakage (measured in bits).

The Analysis Step. An iterative procedure using abstract interpretation and the domain operations of $\mathcal{C}^\sharp$ is used to compute an abstract cache state at each program location. The procedure assumes that all memory blocks are outside of the cache initially, i.e., $\forall b \in \mathcal{B} \,.\, C(b) = \{n\}$. Then, it applies the abstract transfer function to the abstract cache state C at each program location to compute a new abstract cache state C'. Then, it conducts standard fixpoint iteration with the abstract transfer function and the domain operations. Fixpoint iteration is required to ensure that the abstract cache computed for each program location is an invariant, i.e., that it soundly overapproximates the set of possible concrete cache states at a given program location.

Figure 2 shows the abstract domain $\mathcal{C}^\sharp$ and its partial order ($\sqsubseteq_{\mathcal{C}^\sharp}$), join ($\sqcup_{\mathcal{C}^\sharp}$) and meet ($\sqcap_{\mathcal{C}^\sharp}$) operators. Consider abstract cache states $C_1, C_2, C_3, C_4 \in \mathcal{C}^\sharp$ as examples. If $C_1 = \{a \mapsto \{0,1\}, b \mapsto \{1,2\}\}$ and $C_2 = \{a \mapsto \{0,1,4\}, b \mapsto \{1,4\}\}$, then $C_1 \sqcup_{\mathcal{C}^\sharp} C_2 = \{a \mapsto \{0,1,4\}, b \mapsto \{1,2,4\}\}$ and $C_1 \sqcap_{\mathcal{C}^\sharp} C_2 = \{a \mapsto \{0,1\}, b \mapsto \{1\}\}$. However, if $C_3 = \{a \mapsto \{0\}, b \mapsto \{1\}\}$ and $C_4 = \{a \mapsto \{1\}, b \mapsto \{0\}\}$, then $C_3 \sqcap_{\mathcal{C}^\sharp} C_4 = \{a \mapsto \{\}, b \mapsto \{\}\}$, which equals the bottom element of $\mathcal{C}^\sharp$, $\bot$. The domain operations are used in the process of fixpoint iteration. For instance, when control flow paths in the program merge, the analysis must combine abstract states using the join operator ($\sqcup_{\mathcal{C}^\sharp}$), to remain a conservative overapproximation of the true set of cache states. Furthermore, the partial order $\sqsubseteq_{\mathcal{C}^\sharp}$ is used to detect if a fixpoint has been reached.

The Quantification Step. The abstract cache state C at the program exit point is used to compute the number of concrete cache states. This is accomplished by first mapping C from the abstract domain $\mathcal{C}^\sharp$ to the concrete domain $\mathcal{P}(\mathcal{C})$. Let $\gamma_{\mathcal{C}^\sharp}$ be the concretization

function, and $\gamma_{\mathcal{C}^\sharp}(C)$ be the set of concrete cache states. The cardinality $|\gamma_{\mathcal{C}^\sharp}(C)|$ represents the number of concrete cache states. In this case, $log_2|\gamma_{\mathcal{C}^\sharp}(C)|$ represents the maximum amount of information leakage measured in bits, according to Shannon's information theory.[1] We note that in our work, we assume that the leakage of each bit is equally valuable to the attacker, which motivates our use of Shannon entropy, as in CacheAudit [11].

▶ **Definition 3.** *The concretization function* $\gamma_{\mathcal{C}^\sharp} : \mathcal{C}^\sharp \to \mathcal{P}(\mathcal{C})$ *computes the set* $\gamma_{\mathcal{C}^\sharp}(C)$ *of concrete cache states for the abstract cache state* C *as follows:* $\gamma_{\mathcal{C}^\sharp}(C) :=$

$$\begin{aligned}\{c \in \mathcal{C} \mid\ & \forall b \in \mathcal{B} : c(b) \in C(b) \wedge \\ & \forall b_1, b_2 \in \mathcal{B} : set(b_1) = set(b_2) \wedge b_1 \neq b_2 \implies c(b_1) \neq c(b_2) \vee c(b_1) = c(b_2) = n \wedge \\ & \forall b_1 \in \mathcal{B} : 0 < c(b_1) < n \implies \exists b_2 \in \mathcal{B}.\ set(b_1) = set(b_2) \wedge (b_1 \neq b_2) \wedge c(b_2) = c(b_1) - 1\}\end{aligned}$$

The first condition $\forall b \in \mathcal{B} : c(b) \in C(b)$ takes the Cartesian product of the set of possible ages for each memory block $b \in \mathcal{B}$, while the last two conditions eliminate the obviously-invalid concrete cache states, according to the following two properties of LRU caches:

- ***No-collision within each cache set:*** If a cache line (age) is assigned to a memory block, it cannot be assigned to another memory block that belongs to the same cache set. Thus, if b_1 and b_2 belong to the same cache set ($set(b_1) = set(b_2)$) and $b_1 \neq b_2$, then $c(b_1) \neq c(b_2) \vee c(b_1) = c(b_2) = n$, meaning that the two blocks are either in different cache lines (ages) or are both outside of the cache.
- ***No-gap within each cache set:*** If a younger cache line (age) is available, an older cache line cannot be assigned to a memory block in a given cache set. Thus, when $c(b_1) \in \{1, ..., n-1\}$, there exists $b_2 \in \mathcal{B}$ such that $set(b_1) = set(b_2) \wedge (b_1 \neq b_2) \wedge c(b_2) = c(b_1) - 1$.

3 Limitations of Prior Work

While the baseline algorithm presented in Section 2 represents the state of the art, it has two main limitations in terms of the precision of its abstract transfer function and abstract domain. In this section, we use an example program to illustrate these limitations and then motivate our work on developing the new method.

3.1 The Example Program

Figure 3 shows the example program, which has a while loop containing an if-else statement. While the program has many variables, only four of them (a, b, c, and d) are being read. The two branches of the if-else statement differ in that the then-branch reads b and d whereas the else-branch reads c and d. This difference is sufficient to demonstrate the limitations of prior work and the advantages of our new method.

The Assumptions. For the sake of demonstration, we assume that all program variables in Figure 3 map to the same cache set. Furthermore, the cache set has only 4 cache lines. Finally, each variable occupies an entire cache line. With all of these assumptions, we have $\mathcal{B} = \{a, b, c, d\}$, $set(a) = set(b) = set(c) = set(d)$ and $n = 4$.

The reason why we focus only on these four variables is because, here, we assume that the cache is a *read-through, write-direct* cache as in Intel CPU's Data Direct I/O technology. That is, data is first read from main memory into the cache on a read operation, but when

[1] The Shannon entropy $H = \Sigma_c\ p(c)\ log_2 \frac{1}{p(c)}$ is maximized when each concrete cache state $c \in \gamma_{\mathcal{C}^\sharp}(C)$ has an equal probability $p(c) = \frac{1}{|\gamma_{\mathcal{C}^\sharp}(C)|}$, thus reducing H to $log_2 \frac{1}{p(c)} = log_2|\gamma_{\mathcal{C}^\sharp}(C)|$.

```
1  void foo (unsigned int d) {
2    unsigned int a, b, c, g, h = 0;
3
4    d = a + d; //read {a,d}
5
6    while (d >= 1 && d < 5) { //read {d}
7      if (d < 3) { //read {d}
8        h = b + 1; //read {b}
9        d--; //read {d}
10     }
11     else {
12       g = c + 1; //read {c}
13       d--; //read {d}
14     }
15   }
16
17 }
```

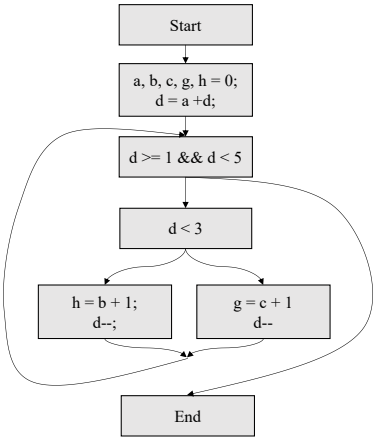

Figure 3 A program on the left-hand side and its control flow graph on the right-hand side.

writing data, it is directly written to the main memory without first updating the cache, effectively bypassing the cache for writes and prioritizing direct access to system memory. This aims to minimize unnecessary memory accesses. Under these assumptions, only read operations change the cache state.

Ground Truth. At the end of the program execution, there are only three valid concrete cache states: $c_1 = \{a \mapsto 1, b \mapsto 4, c \mapsto 4, d \mapsto 0\}$, $c_2 = \{a \mapsto 3, b \mapsto 1, c \mapsto 2, d \mapsto 0\}$, and $c_3 = \{a \mapsto 2, b \mapsto 1, c \mapsto 4, d \mapsto 0\}$. These three concrete cache states correspond to the following set of executions. State c_1 corresponds to the case where the body of the while loop is never entered, leaving c and b uncached (having age 4). State c_2 corresponds with executions in which the while loop is entered, and both branches of the if-statement are executed. (We note that due to the guards of both the while-loop and the if-statement, the then-branch is always executed after the else-branch when both are executed (when $d \geq 3$ at the beginning of the program), causing the cache line age of b to be younger than the cache line age of c. State c_3 corresponds to the case where only the then-branch of the if-statement is executed (when $d < 3$ at the beginning of the program), causing c to be uncached. With three possible concrete cache states, there is a maximum leakage of $\log_2(3)$ bits.

Baseline Algorithm. The abstract cache state at the last location of the program computed by the baseline algorithm in Section 2 is $C_{Last} := \{a \mapsto \{1,2,3,4\}, b \mapsto \{1,2,4\}, c \mapsto \{1,2,3,4\}, d \mapsto \{0\}\}$, which corresponds to 14 possible concrete cache states, where $|\gamma_{\mathcal{C}^\sharp}(C_{Last})| = 14$ (for reference, all 14 concrete cache states are featured in the appendix of the extended version [15]). This leads to a maximum leakage of $\log_2(14)$ bits, which is significantly higher than the ground truth $\log_2(3)$. As mentioned earlier, the baseline algorithm has two sources of imprecision, one of which is in the abstract transfer function $Upd^\sharp$ and the other is in the abstract domain $\mathcal{C}^\sharp$.

3.2 Imprecision of Abstract Transfer Function $\mathrm{Upd}^\sharp$

To see the imprecision in $Upd^\sharp$, consider the following abstract state C, which occurs prior to the third fixpoint iteration (using loop unrolling) of the while loop in Figure 3 using the baseline algorithm. That is, $C := \{a \mapsto \{2,3\}, b \mapsto \{1,2,4\}, c \mapsto \{1,2,4\}, d \mapsto \{0\}\}$.

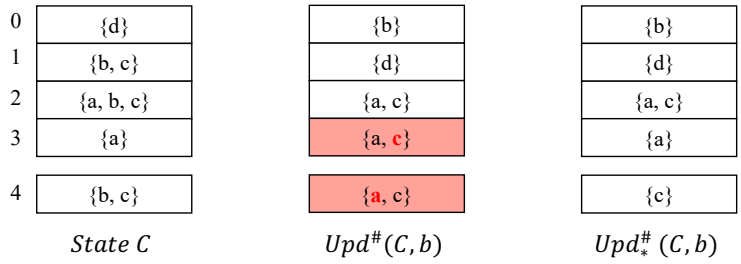

Figure 4 Differences in (baseline and new) abstract transfer functions, applied to abstract cache state $C \in \mathcal{C}^\sharp$ and the accessed memory block $b \in \mathcal{B}$.

The inverse of C, which maps from ages to memory blocks (variables), is shown in the left-most state of Figure 4.

Given abstract cache state C, consider the case of accessing (reading) variable b. As a result, the transfer function will return the abstract cache state $Upd^\sharp(C, b) := \{a \mapsto \{2, 3, 4\}, b \mapsto \{0\}, c \mapsto \{2, 3, 4\}, d \mapsto \{1\}\}$. Note that, due to spurious aging, the age 4 has become possible for a, and that the age 3 has become possible for c. However, according to the ground truth, there is no valid concrete cache state where a is outside of the cache, and there is no valid concrete cache state where c occupies the third cache line either.

In this work, we want to design a new transfer function $Upd^\sharp_*$ to eliminate such contradictory cache states. Intuitively, $Upd^\sharp_*(C, b)$ works as follows: when considering incrementing $3 \in C(a)$ to 4, $Upd^\sharp_*$ capitalizes on the fact that when a is of age 3, the set of variables with possible ages younger than 3 are $\{b, c, d\}$, as seen in the leftmost abstract cache state in Figure 4. Because there are only three such variables, and b is one of them, b must be younger than a when a is of age 3. Thus, it is unnecessary to increment $3 \in C(a)$ to 4 when accessing b, as b will already be younger than a. Similarly, $2 \in C(c)$ is not incremented to 3. Therefore, $Upd^\sharp_*(C, b) := \{a \mapsto \{2, 3\}, b \mapsto \{0\}, c \mapsto \{2, 4\}, d \mapsto \{1\}\}$, which corresponds to the rightmost abstract state in Figure 4. We shall explain more formally in Section 4.1 that, by replacing $Upd^\sharp$ with $Upd^\sharp_*$ in the iterative procedure used to analyze the program in Figure 3, our method will compute a better final abstract cache state, $C_{Last} := \{a \mapsto \{1, 2, 3\}, b \mapsto \{1, 2, 4\}, c \mapsto \{1, 2, 4\}, d \mapsto \{0\}\}$, which corresponds to seven (instead of 14) concrete cache states at the end of program execution.

3.3 Imprecision of Abstract Domain $\mathcal{C}^\sharp$

To understand the limitation of the $\mathcal{C}^\sharp$ domain, consider the final abstract cache state $C_{Last} := \{a \mapsto \{1, 2, 3\}, b \mapsto \{1, 2, 4\}, c \mapsto \{1, 2, 4\}, d \mapsto \{0\}\}$ computed at the exit point of the example program in Figure 3 by using $Upd^\sharp_*$. As mentioned earlier, this abstract cache state corresponds to seven concrete cache states. Compared to the ground truth, which has three concrete cache states c_1, c_2 and c_3 (defined in the previous subsection), the abstract cache state C_{Last} has 4 more (spurious) concrete cache states shown below: $c_4 = \{a \mapsto 3, b \mapsto 2, c \mapsto 1, d \mapsto 0\}$, $c_5 = \{a \mapsto 2, b \mapsto 4, c \mapsto 1, d \mapsto 0\}$, $c_6 = \{a \mapsto 1, b \mapsto 4, c \mapsto 2, d \mapsto 0\}$, and $c_7 = \{a \mapsto 1, b \mapsto 2, c \mapsto 4, d \mapsto 0\}$. These spurious cache states are due to the fact that $\mathcal{C}^\sharp$ is not capable of precisely capturing disjunctive invariants that arise due to variations in control flow.

Specifically, these spurious states result from an inability of $\mathcal{C}^\sharp$ to distinguish between when the while loop is entered or not, and whether the else branch is entered at least once in the program in Figure 3. To see why, consider the final abstract cache state C_{Last}, where 1 is

a possible age for a, 0 is a possible age for d, 2 is a possible age for c, and 4 is a possible age for b, thus allowing the concrete cache state $c_6 = \{a \mapsto 1, b \mapsto 4, c \mapsto 2, d \mapsto 0\}$. However, a is of age 1 only when the loop is not entered, but c being in the cache indicates that c was accessed in Line 12 of the program, and that the loop body was entered.

In this work, we want to remove these spurious states by leveraging the finite powerset framework of Bagnara et al. [3], which computes a bounded set of states (instead of a single state) at each program location. We shall explain in Section 4.2 that, in the context of cache side-channel analysis, this is accomplished by lifting the abstract domain $\mathcal{C}^\sharp$ to the powerset domain $\mathcal{P}(\mathcal{C}^\sharp)$ where each element has a cardinality of less than or equal to K. In practice, the bound K may be a small number, e.g., $K = 10$.

For the example program in Figure 3, $K = 3$ would be sufficient. That is, by using an abstract domain whose elements consist of a set of at most three elements of $\mathcal{C}^\sharp$ (as opposed to a single abstract state) to conduct fixpoint iteration with a lifted version of $Upd^\sharp_*$, we end up with the following abstract state: $\{\{a \mapsto \{1\}, b \mapsto \{4\}, c \mapsto \{4\}, d \mapsto \{0\}\}, \{a \mapsto \{3\}, b \mapsto \{1\}, c \mapsto \{2\}, d \mapsto \{0\}\}, \{a \mapsto \{2\}, b \mapsto \{1\}, c \mapsto \{4\}, d \mapsto \{0\}\}\}$, which corresponds to the three valid concrete cache states in the ground-truth.

We also emphasize that maintaining disjunctive invariants is able to prevent spurious aging caused by merging two abstract cache states. To see this, consider the following minor modification of code: suppose that the statement `h = g` is added between lines 8 and 9, indicating that g is read at that program location, in the then-branch of the if-statement. In the *first* iteration of analyzing the code with loop unrolling, the abstract states to be merged at the end of the if-statement are $C_{Then} := \{a \mapsto \{3\}, b \mapsto \{2\}, c \mapsto \{4\}, d \mapsto \{0\}, g \mapsto \{1\}\}$ and $C_{Else} := \{a \mapsto \{2\}, b \mapsto \{4\}, c \mapsto \{1\}, d \mapsto \{0\}, g \mapsto \{4\}\}$. Then, consider in the next iteration accessing variable b; $Upd^\sharp(C_{Then}, b) := \{a \mapsto \{3\}, b \mapsto \{0\}, c \mapsto \{4\}, d \mapsto \{1\}, g \mapsto \{2\}\}$. $Upd^\sharp(C_{Else}, b) := \{a \mapsto \{3\}, b \mapsto \{0\}, c \mapsto \{2\}, d \mapsto \{1\}, g \mapsto \{4\}\}$. Notice that in either case, a is not aged to 4. Now consider $C_{Both} := C_{Then} \sqcup_{\mathcal{C}^\sharp} C_{Else} = \{a \mapsto \{2, 3\}, b \mapsto \{2, 4\}, c \mapsto \{1, 4\}, d \mapsto \{0\}, g \mapsto \{1, 4\}\}$. We can see that $Upd^\sharp(C_{Both}, b)$ ages a from 3 to 4. Thus, maintaining disjunctive invariants (avoiding merging C_{Then} and C_{Else}) at this point can also prevent spurious aging. As we describe in more detail in Section 4, $Upd^\sharp_*$ is also unable to prevent spurious aging in this case, necessitating disjunctive invariants.

4 Our Method

We now present the two new techniques of our method for overcoming limitations of prior work. The first is a new abstract transfer function that prevents spurious aging of memory blocks in the cache. The second is a technique that lifts the abstract domain $\mathcal{C}^\sharp$ of states to *sets* of abstract cache states, to prevent spurious combinations of cache states.

4.1 The Abstract Transfer Function $Upd^\#_*$

Given an abstract cache state $C \in \mathcal{C}^\sharp$ and the accessed memory block $w \in \mathcal{B}$, we want to define $Upd^\#_*(C, w)$ such that it is significantly more accurate than the baseline $Upd^\sharp(C, w)$ defined in Section 2.3. Here, the focus is on eliminating contradictory cache states due to spurious aging of memory blocks, to tighten the gap between $Upd^\sharp$ and the *best abstract transformer* for $\mathcal{C}^\sharp$, which concretizes the abstract state C using $\gamma_{\mathcal{C}^\sharp}$, applies the concrete update function Upd to each concrete state, and abstracts the resulting set of concrete states.

4.1.1 The Intuition

To this end, recall that for the example program in Figure 3, when b is the accessed memory block and $C := \{a \mapsto \{2,3\}, b \mapsto \{1,2,4\}, c \mapsto \{1,2,4\}, d \mapsto \{0\}\}$, the spurious aging of a to 4 and the spurious aging of c to 3 will occur in $Upd^\sharp(C,b)$ when considering the case where b is of age 4 in C, meaning that, previously, b was outside of the cache.

Increasing the age of a from 3 to 4 is *spurious aging* because, when a is of age 3, to avoid a gap in the cache, the younger cache lines (with ages 0, 1, and 2) must hold b, c and d. Since the age of b is either 1 or 2, accessing b should not increase the age of a from 3 to 4. Increasing the age of c from 2 to 3 is also *spurious aging* because, when c is of age 2, to avoid a gap in the cache, the younger cache lines (with ages 0 and 1) must hold b and d. Since the age of b must be 1, accessing b should not increase the age of c from 2 to 3.

Leveraging the above reasoning, we want the new transfer function to return $Upd^\sharp_*(C,b) := \{a \mapsto \{2,3\}, b \mapsto \{0\}, c \mapsto \{2,4\}, d \mapsto \{1\}\}$. It is more accurate than $Upd^\sharp(C,b)$ as shown by the middle and right-most states in Figure 4 where the spurious ages in $Upd^\sharp(C,b)$ are highlighted in red. In fact, this is the best result that any transfer function can possibly achieve; that is, even if we concretize the abstract state C, apply $Upd(c,b)$ for every concrete state c, then re-abstract these concrete states, we will get the same abstract state. However, applying the aforementioned "best" abstract transformer will not be computationally efficient. In the subsections that follow, we introduce two core components of our new transfer function, $Upd^\sharp_*$, defined in Definition 4, to capitalize on the intuition.

4.1.2 The Function $Var(C, c_b, b)$

We first define $Var : \mathcal{C}^\sharp \times \mathcal{A} \times \mathcal{B} \to \mathcal{P}(\mathcal{B})$ as a function that takes an abstract cache state $C \in \mathcal{C}^\sharp$, an age $c_b \in \mathcal{A}$, and a memory block $b \in \mathcal{B}$ as input and returns the set of memory blocks belonging to the same cache set as b which are possibly younger than c_b in C. Formally, $Var(C, c_b, b) := \{b' \in \mathcal{B} \mid \exists c'_b \in C(b') \;.\; c'_b < c_b \wedge set(b) = set(b')\}$.

For example, consider $C := \{a \mapsto \{2,3\}, b \mapsto \{1,2,4\}, c \mapsto \{1,2,4\}, d \mapsto \{0\}\}$ (for the ease of demonstration, we assume that all memory blocks map to the same cache set). If $c_b = 3$, the set of memory blocks that are possibly younger are $\{a,b,c,d\}$; thus, we have $Var(C,3,b) = \{a,b,c,d\}$. However, if $c_b = 2$, we have $Var(C,2,b) = \{b,c,d\}$.

Given memory block c of age 2, we use $Var(C,2,c)$ to represent the set of memory blocks (in the same cache set as c) which are possibly younger than 2 in C, and then use $Var(C,2,c) \setminus \{c\}$ to remove the memory block c itself. To decide if another block b (such that $set(b) = set(c)$) may be younger than c, we check $b \in Var(C,2,c) \setminus \{c\}$. For our running example, where $Var(C,2,c) = \{b,c,d\}$ and $Var(C,2,c) \setminus \{c\} = \{b,d\}$, the check passes, meaning that b may be younger than c (when c is of age 2).

To summarize, the above discussion shows that, in general, the condition $w \in Var(C, c_b, b) \setminus \{b\}$ checks if block $w \in \mathcal{B}$ may be younger than block $b \in \mathcal{B}$, when b is of age $c_b \in C(b)$ and $set(b) = set(w)$. In the next subsection, we show how to convert this "may" information into "must" information, to understand when a memory block b *must* be younger than a certain cache line age.

4.1.3 The Cardinality $|Var(C, c_b, b) \setminus \{b\}|$

Since $Var(C, c_b, b) \setminus \{b\}$ is the set of blocks in the same cache set which are younger than $b \in \mathcal{B}$, when b is of age $c_b \in C(b)$, the cardinality of the set is the number of such younger blocks. When $|Var(C, c_b, b) \setminus \{b\}| \leq c_b$, to avoid gaps in the cache, the younger cache lines (of

ages $0, \ldots, c_b - 1$) must be filled with these younger blocks. Thus, if $w \in Var(C, c_b, b) \setminus \{b\}$ also holds, the age of block w is younger than the age of block b, when b is of age c_b. Thus, accessing block w should not increase the age of block b when b is of age c_b.

The above condition holds in the running example when b is the accessed memory block and a is of age 3. Since $Var(C, 3, a) \setminus \{a\} = \{b, c, d\}$ and $|Var(C, 3, a) \setminus \{a\}| = 3$, both conditions $|Var(C, 3, a) \setminus \{a\}| \leq 3$ and $b \in (Var(C, 3, a) \setminus \{a\})$ hold, meaning that the age of b is younger than the age of a, when a is of age 3. Thus, accessing b should not increase the age of a, when a is of age 3. We emphasize that if the condition $|Var(C, 3, a) \setminus \{a\}| \leq 3$ does not hold, i.e., $|Var(C, 3, a) \setminus \{a\}| > 3$, we would not be able to ascertain that b must be younger than 3. This comes down to the "pigeon-hole" principle, where we know that if there are 4 variables for 3 possible cache lines, then b is not guaranteed to be younger than 3.

4.1.4 The Algorithm for Computing $Upd^\sharp_*(C, w)$

We define $Upd^\sharp_*(C, w)$ by revising the sets $O_>\langle w\rangle$ and $O_<\langle w\rangle$ shown in Definition 2 for $Upd^\sharp$.

▶ **Definition 4** ($Upd^\sharp_*$). *The abstract transfer function $Upd^\sharp_*(C, w)$ for cache state $C \in \mathcal{C}^\sharp$ and accessed memory block $w \in \mathcal{B}$ is defined as follows:*

$$Upd^\sharp_*(C, w) := \lambda b \in \mathcal{B}. \begin{cases} C(b) & \text{when } set(b) \neq set(w) \\ O_n\langle w\rangle \cup O_>\langle w\rangle \cup O_<\langle w\rangle & \text{when } set(b) = set(w) \wedge b \neq w \\ \{0\} & \text{when } set(b) = set(w) \wedge b = w \end{cases}$$

where $O_n\langle w\rangle \cup O_>\langle w\rangle \cup O_<\langle w\rangle$ computes a set of ages of block $b \in \mathcal{B}$ for each possible age $c_w \in C(w)$:

- $O_n\langle w\rangle := \bigcup_{c_w \in C(w)} \{c_b \mid c_b = n \wedge c_b \in C \downarrow_{w \mapsto c_w} (b)\}$ *has the ages equal to n,*
- $O_>\langle w\rangle := \bigcup_{c_w \in C(w)} \{c_b \mid (c_b > c_w \vee (\ |\mathbf{Var(C, c_b, b) \setminus \{b\}}| \leq \mathbf{c_b} \wedge \mathbf{w} \in \mathbf{Var(C, c_b, b) \setminus \{b\}}\ )) \wedge c_b \in C \downarrow_{w \mapsto c_w} (b)\}$ *has the ages older than c_w,*
- $O_<\langle w\rangle := \bigcup_{c_w \in C(w)} \{c_b + 1 \mid (c_b < c_w \wedge (\neg(\ |\mathbf{Var(C, c_b, b) \setminus \{b\}}| \leq \mathbf{c_b} \wedge \mathbf{w} \in \mathbf{Var(C, c_b, b) \setminus \{b\}}\ )) \wedge c_b \in C \downarrow_{w \mapsto c_w} (b)\}$ *represents the effect on ages younger than c_w.*

The sets $O_>\langle w\rangle$ and $O_<\langle w\rangle$ are revised such that, when the **highlighted** condition in $O_>\langle w\rangle$ is satisfied, we avoid incrementing the age of block b. The condition holds when the number of variables (excluding b) younger than c_b is less than or equal to c_b, and the accessed block w is one of the younger blocks. This is to prevent the spurious aging of block b.

For the example in Figure 3, in particular, the newly added conditions to $O_>\langle b\rangle$ and $O_<\langle b\rangle$ avoid the spurious aging of a from 3 to 4 and c from 2 to 3, as shown in Figure 4. Thus, by replacing $Upd^\sharp$ with $Upd^\sharp_*$ in the iterative procedure, the final abstract cache state at the end of the program in Figure 3 becomes $\{a \mapsto \{1, 2, 3\}, b \mapsto \{1, 2, 4\}, c \mapsto \{1, 2, 4\}, d \mapsto \{0\}\}$, which corresponds to seven (instead of 14) concrete cache states.

4.1.5 The Soundness Property

This technique is sound in that it computes an overapproximation of the concrete cache states. Recall that $Upd(c, w)$ is the concrete transfer function for a concrete cache state c and the accessed memory block w, and $\gamma_{\mathcal{C}^\sharp}$ is the concretization function. To streamline notation in the following sections, we denote Upd_w as a function which takes as input a concrete cache state, and returns the cache state after having accessed w. (This can be thought of as currying the w argument in Definition 1).

To prove soundness, we will show that $Upd^\sharp_*$ subsumes the result of the best abstract transformer. To prove this, we first explicitly define the corresponding abstraction function $\alpha_{\mathcal{C}^\sharp} : \mathcal{P}(\mathcal{C}) \to \mathcal{C}^\sharp$, which takes as input a set of *concrete* cache states and returns an *abstract* cache state overapproximating the set.

▶ **Definition 5** ($\alpha_{\mathcal{C}^\sharp}$). *Let S denote some set of concrete cache states. Then, $\alpha_{\mathcal{C}^\sharp}(S) := \lambda b \in \mathcal{B}.\{c(b) \mid c \in S\}$*

We now state the formal claim of soundness in the following theorem:

▶ **Theorem 6.** *$Upd^\sharp_*$ is sound in that, for any $w \in \mathcal{B}$ and $C \in \mathcal{C}^\sharp$, $\alpha_{\mathcal{C}^\sharp} \cdot Upd_w \cdot \gamma_{\mathcal{C}^\sharp}(C) \sqsubseteq_{\mathcal{C}^\sharp} Upd^\sharp_*(C, w)$.*

Proof. In the interest of space, we defer the full proof to the appendix of the extended version [15], and instead provide a proof sketch here. In the following, let b refer to some memory block in $\mathcal{B}$ whose ages are being updated a result of accessing memory block w.

1. We prove the soundness of $Upd^\sharp_*$ by showing that it subsumes the result of the best abstract transformer.
2. We show this by proving that if there is some concrete state c' that is the result of applying Upd_w to some state $c \in \gamma_{\mathcal{C}^\sharp}(C)$, where $c'(b) = a'$, then $a' \in Upd^\sharp_*(C, w)(b)$.
3. If $b = w$, then for all concrete states $c \in \gamma_{\mathcal{C}^\sharp}(C)$, $c(b) = 0$. It is clear to see that $0 \in Upd^\sharp_*(C, w)(b)$.
4. Otherwise, if $b \neq w$, there are three cases. First, if there is some state c, where $c(b) = n$, then $c'(b) = n$. It is clear from the definition of $Upd^\sharp_*$, that $n \in Upd^\sharp_*(C, w)(b)$ (Case $O_n\langle w\rangle$). Second, we show that if there is a concrete state c where block b is older than w, that $c(b) \in Upd^\sharp_*(C, w)(b)$ (Case $O_>\langle w\rangle$). Third, we show that if there is a concrete state c where b is younger than w, then $c(b) + 1 \in Upd^\sharp_*(C, w)(b)$ (Case $O_<\langle w\rangle$).
5. By showing that 3-4 hold, we have proved our claim. ◀

4.1.6 The Accuracy Property

We now argue that $Upd^\sharp_*$, as defined in Definition 4, is a refinement of $Upd^\sharp$, as defined in Definition 2. More formally stated, $\alpha_{\mathcal{C}^\sharp} \cdot Upd_w \cdot \gamma_{\mathcal{C}^\sharp} \sqsubseteq Upd^\sharp_*(\cdot, w) \sqsubseteq Upd^\sharp(\cdot, w)$. We now present the key theorem, describing the refinement relationship between the two transformers.

▶ **Theorem 7.** *The abstract transformer $Upd^\sharp_*$ is always more precise than, or equal to the abstract transformer $Upd^\sharp$.*

Proof. To show this, we will proceed by demonstrating that given abstract cache state C, and a memory block w to be accessed, for all $b \in \mathcal{B}$, $Upd^\sharp_*(C, w)(b) \subseteq Upd^\sharp(C, w)(b)$. We will proceed by cases.

1. **Case $\mathbf{set(b) \neq set(w)}$.** In this case, $Upd^\sharp_*(C, w)(b) = C(b)$ and $Upd^\sharp(C, w)(b) = C(b)$ by their respective definitions. Thus, $Upd^\sharp_*(C, w)(b) \subseteq Upd^\sharp(C, w)(b)$ follows immediately.
2. **Case $\mathbf{set(b) = set(w)}$.** In the case where w and b belong to the same cache set, we split up the proof into the following two cases:
   a. $\mathbf{w = b}$. In this case, memory block b is the block being accessed. Therefore $Upd^\sharp_*(C, w)(b) = \{0\}$ and $Upd^\sharp(C, w)(b) = \{0\}$, by definition. Thus, the subset relationship follows immediately.
   b. $\mathbf{w \neq b}$. In this case, we will use $O^*_n\langle w\rangle$, $O^*_>\langle w\rangle$, $O^*_<\langle w\rangle$, and $O_n\langle w\rangle$, $O_>\langle w\rangle$, $O_<\langle w\rangle$ to refer to the corresponding components of $Upd^\sharp_*$ and $Upd^\sharp$, respectively. For the sake of brevity, let $\mathbf{M}$ refer to the predicate $\mathbf{|Var(C, c_b, b) \setminus \{b\}| \leq c_b \wedge w \in Var(C, c_b, b) \setminus \{b\}}$. To prove the claim, we will show that $O^*_n\langle w\rangle \cup O^*_>\langle w\rangle \cup O^*_<\langle w\rangle \subseteq O_n\langle w\rangle \cup O_>\langle w\rangle \cup O_<\langle w\rangle$.
   It follows by definition that $O^*_n\langle w\rangle \subseteq O_n\langle w\rangle$.
   To see why $O^*_<\langle w\rangle \subseteq O_<\langle w\rangle$, it can be shown that for any c_b, c_w, that $\{c_b + 1 \mid (c_b < c_w \wedge \neg\mathbf{M}) \wedge c_b \in C\downarrow_{w\mapsto c_w}(b)\} \subseteq \{c_b + 1 \mid (c_b < c_w) \wedge c_b \in C\downarrow_{w\mapsto c_w}(b)\}$. This simply follows from the fact that $c_b < c_w \wedge \neg\mathbf{M} \implies c_b < c_w$.

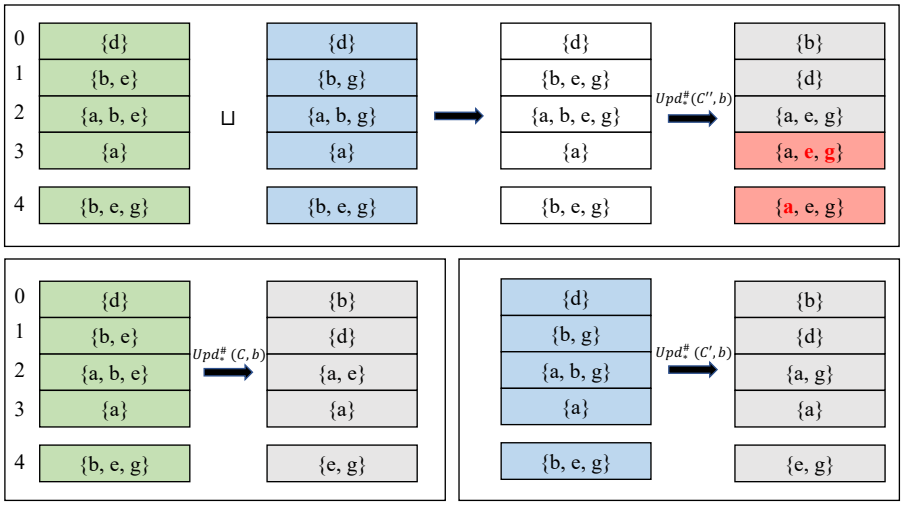

Figure 5 Merging two cache states which leads to spurious aging.

Finally, it can be shown that $O^*_>\langle w\rangle \subseteq O_>\langle w\rangle$. Let $c_b \in O^*_>\langle w\rangle$. Then, either of the two conditions hold:

i. $\exists \mathbf{c_w} \,.\, \mathbf{c_b} > \mathbf{c_w}$. If $c_b > c_w$ holds, then $c_b \in O_>\langle w\rangle$, by definition of $Upd^\sharp$.
ii. **M**. If **M** holds, then this implies that $w \in Var(C, c_b, b) \setminus \{b\}$. This in turn implies that there exists some c'_w such that $c'_w < c_b$. If this is the case, then $c_b \in \{c_b \mid (c_b > c'_w) \wedge c_b \in C \restriction_{w \mapsto c'_w} (b)\}$. Therefore, $c_b \in O_>\langle w\rangle$, by definition.

Given the fact that $O^*_n\langle w\rangle \subseteq O_n\langle w\rangle$, $O^*_>\langle w\rangle \subseteq O_>\langle w\rangle$, and $O^*_<\langle w\rangle \subseteq O_<\langle w\rangle$, it follows that $O^*_n\langle w\rangle \cup O^*_>\langle w\rangle \cup O^*_<\langle w\rangle \subseteq O_n\langle w\rangle \cup O_>\langle w\rangle \cup O_<\langle w\rangle$.

Therefore, in any case, $Upd^\sharp_*(C, w)(b) \subseteq Upd^\sharp(C, w)(b)$. ◀

4.2 Refining the $\mathcal{C}^\sharp$ Abstract Domain

We now present the technique for extending the abstract domain to a finite powerset domain, through the framework of Bagnara et al. [3] to improve the precision of the analysis.

4.2.1 The Intuition

We first use examples to illustrate the benefit of maintaining disjunctive invariants and show how to instantiate the framework in the context of cache analysis, which leverages it to maintain a set of elements of $\mathcal{C}^\sharp$, rather than a single element of $\mathcal{C}^\sharp$.

▶ **Example 8.** As an example of why refining $\mathcal{C}^\sharp$ is useful, consider the example in Figure 5, a case where $Upd^\sharp_*$ is unable to prevent precision loss. For both the blue and green abstract cache states, when applying $Upd^\sharp_*(\cdot, b)$ on both states individually (the bottom row of the figure), we can see that it is not possible for a be age 4, nor is it possible for e or g to be age 3. However, this is not the case in their abstract join. We emphasize that applying the best abstract transformer on the joined state does not prevent this either. This indicates an imprecision of the abstract domain $\mathcal{C}^\sharp$ as opposed to sub-optimality of $\mathcal{C}^\sharp$'s operators. Thus, it is desirable to keep these two abstract states separate. More explicitly, it is desirable to have an abstract domain which maintains a set of elements of $\mathcal{C}^\sharp$, e.g. $\{C, C'\}$.

Cache-Based Merging Operator ($\Omega_R^{\mathcal{C}^\sharp} : \mathcal{VC}^\sharp \to \mathcal{VC}^\sharp$). $\Omega_R^{\mathcal{C}^\sharp}$ takes in an abstract state S and merges any two elements of S if they have the same abstract **cache** state.

Subsumption Operator ($\Omega^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} : \mathcal{VC}^\sharp \to \mathcal{VC}^\sharp$). $\Omega^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$ takes in an abstract state S and removes elements of S if they are subsumed by some other state in S. $\Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}(S) \mapsto S'$, where $S' := S \backslash \{s \in S \mid s = \bot_{\mathcal{VC}^\sharp} \vee \exists s' \in S. s \sqsubset_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s'\}$.

Figure 6 The subsumption and merging operators with respect to $\sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$ and $\sqsubseteq_{\mathcal{C}^\sharp}$.

Furthermore, the refinement can be conducted when a main-channel (program values) analysis is conducted simultaneously with a side-channel (cache states) analysis. We refer to the abstract domain used in the main-channel analysis as $\mathcal{V}^\sharp$. Let $\mathcal{V}$ be some numerical abstract domain which approximates a numerical domain ($\mathcal{P}(\mathbb{Z})$) (for instance, $\mathcal{V}$ may be the domain of intervals or a domain of integer-valued sets). Let V be the set of program variables. Then, we assume $\mathcal{V}^\sharp := V \to \mathcal{V}$ is the abstract domain for the set of variables in the program which consists of maps from variables to an abstract value representation $\mathcal{V}$.

In this case, the abstract domain to be refined is the abstract domain which has elements of tuples of an abstract state in $\mathcal{V}^\sharp$ and an abstract state in $\mathcal{C}^\sharp$. The respective abstract domain operators are applied, independently, pointwise. The domain is denoted by $\mathcal{V}^\sharp \times \mathcal{C}^\sharp$.

In fact, refinement at the level of both the program value and cache abstractions can be useful, because if the value abstractions are more precise, then certain paths in the control of the program (and subsequently, memory accesses) may be eliminated, possibly leading to abstract cache states that are more precise. We write the rest of the section with this in mind (and it corresponds to the set-up in our evaluation). Therefore, in the remainder of this section we consider the concrete domain to be $\mathcal{P}(V \to \mathbb{Z}) \times \mathcal{P}(\mathcal{C})$.

4.2.2 The Finite Powerset Domain

In this section, we introduce the finite powerset domain. We first begin by introducing relevant notation and operators.

The maximum number of abstract states of type $\mathcal{V}^\sharp \times \mathcal{C}^\sharp$ allowed in the aforementioned set, denoted k, is pre-defined by the user. We refer to elements of such a set as disjuncts. In our case, the finite powerset framework can be thought of taking $\mathcal{V}^\sharp \times \mathcal{C}^\sharp$, which approximates $\mathcal{P}(V \to \mathbb{Z}) \times \mathcal{P}(\mathcal{C})$, and replacing it with an abstract domain which still approximates $\mathcal{P}(V \to \mathbb{Z}) \times \mathcal{P}(\mathcal{C})$, but using a *set* of abstract values in $\mathcal{V}^\sharp \times \mathcal{C}^\sharp$, that is, an element of the powerset of $\mathcal{V}^\sharp \times \mathcal{C}^\sharp$, $\mathcal{P}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$. With a slight abuse of notation, let $\mathcal{V}^\sharp \times \mathcal{C}^\sharp := \langle \mathcal{V}^\sharp \times \mathcal{C}^\sharp, \sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}, \bot_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}, \top_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}, \sqcup_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}, \sqcap_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} \rangle$ denote the abstract domain $\mathcal{V}^\sharp \times \mathcal{C}^\sharp$, along with its operators. We say that an element $S \in \mathcal{P}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$ is *non-redundant* with respect to $\sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$ if and only if $\bot_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} \notin S$ and $\forall s_1, s_2 \in S. s_1 \sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s_2 \implies s_1 = s_2$. Non-redundancy ensures that a set of abstract states does not contain unnecessary elements that are already represented by other elements in the set.

A *subsumption operator* serves to normalize an element $S \in \mathcal{P}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$ by removing redundant elements. The formal definition of the subsumption operator is in Figure 6. The $\Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$ operator removes redundant states based on both abstract program states and abstract cache states. The $\Omega_R^{\mathcal{C}^\sharp}$ operator merges abstract states which share the same abstract *cache* states; we emphasize that $\Omega_R^{\mathcal{C}^\sharp}$ does not remove any states based on redundancy, it simply merges abstract states which share the same abstract *cache* states. As we will see later on, the subsumption operator is used in the definition of the join, meet, and widening operators, while $\Omega_R^{\mathcal{C}^\sharp}$ is used in the definition of the join operator.

Let $\mathcal{P}_{fn(k)}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp, \sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp})$ denote the set of all elements of $\mathcal{P}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$ which have a cardinality of at most k. Formally, $\mathcal{P}_{fn(k)}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp, \sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}) := \{S \in \mathcal{P}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \mid |S| \leq k\}$, where every element S is non-redundant according to $\sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$. With this in place, we now formally define the finite powerset domain:

▶ **Definition 9** (Finite Powerset Domain $\mathcal{VC}^\sharp$). *Let* $\mathcal{VC}^\sharp := \langle \mathcal{P}_{fn(k)}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp, \sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}), \sqsubseteq_{\mathcal{VC}^\sharp}, \bot_{\mathcal{VC}^\sharp}, \top_{\mathcal{VC}^\sharp}, \oplus_{\mathcal{VC}^\sharp}, \sqcap_{\mathcal{VC}^\sharp} \rangle$ *denote the finite powerset domain. Here,* $\bot_{\mathcal{VC}^\sharp} = \emptyset$ *and* $\top_{\mathcal{VC}^\sharp} = \{\top_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}\}$. $\sqsubseteq_{\mathcal{VC}^\sharp}$ *is defined as:* $S \sqsubseteq_{\mathcal{VC}^\sharp} S' \iff \forall s \in S : \exists s' \in S'.s \sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s'$*, as in [3].* $S \oplus_{\mathcal{VC}^\sharp} S'$ *is defined to be* $\Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}(S \cup S')$.

$\mathcal{VC}^\sharp$ *is related to the concrete domain* $\mathcal{P}(V \to \mathbb{Z}) \times \mathcal{P}(\mathcal{C})$*, with the following concretization function:* $\gamma : \mathcal{VC}^\sharp \to (\mathcal{P}(V \to \mathbb{Z}) \times \mathcal{P}(\mathcal{C}))$*, where* $\gamma(S) \mapsto \bigcup\{(v, c) \in \gamma_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}(s) \mid s \in S\}$.

In summary, Definition 9 states that the lifted abstract domain $\mathcal{VC}^\sharp$ consists of sets of elements of $\mathcal{V}^\sharp \times \mathcal{C}^\sharp$, where $S \in \mathcal{VC}^\sharp$ is lower than $S' \in \mathcal{VC}^\sharp$ w.r.t. the partial order $\sqsubseteq_{\mathcal{VC}^\sharp}$ if every element in S is subsumed by some element in S', according to $\sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$. $\mathcal{VC}^\sharp$ relates to the concrete domain via the concretization function γ that takes an abstract element S and returns the union of the concretization of each element of S w.r.t. $\mathcal{V}^\sharp \times \mathcal{C}^\sharp$.

We now introduce each of the necessary domain operations for $\mathcal{VC}^\sharp$. We begin by introducing the lifted versions of the abstract transfer functions and the meet operator, and relegate join to its own subsection.

Abstract Transfer Functions. For both instructions that impact program values as well as the abstract cache state, we lift the application of the transfer function to be element-wise. Let $s[C]$ and $s[V]$ denote the cache abstraction and value abstraction components, respectively. Let $T_{\mathcal{V}^\sharp}$ be a transfer function that affects the abstract state corresponding to the program values. Then, the lifted version for $\mathcal{VC}^\sharp$ is a function such that $S \mapsto \Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}\{(T_{\mathcal{V}^\sharp}(s[V]), s[C]) \mid s \in S\}$. Similarly, let $T_{\mathcal{C}^\sharp}$ be a transfer function that affects the part of the abstract state corresponding to the abstract cache state. Then, the lifted version for $\mathcal{VC}^\sharp$ is a function such that $S \mapsto \Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}\{(s[V], T_{\mathcal{C}^\sharp}(s[C])) \mid s \in S\}$.

The Meet Operator. Meet is defined by taking the pairwise meet w.r.t. $\sqcap_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$. Specifically, if $S, S' \in \mathcal{VC}^\sharp$, then $S \sqcap_{\mathcal{VC}^\sharp} S'$ is defined as $\Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}(\{s \sqcap_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s' \mid s \in S, s' \in S'\})$. We note that this set may be larger than k. In this case, we can view the meet operator as replacing Line 1 of the algorithm for join (Algorithm 1) with $\Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}(\{s \sqcap_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s' \mid s \in S, s' \in S'\})$. The justification for the validity of the meet operator is in the appendix of the extended version [15].

Now, in the next section, we introduce our join operator.

4.2.3 The Join Operator

We now present the abstract **join** operator, which is the key novelty of our technique. In effect, this will replace the role of $\oplus_{\mathcal{VC}^\sharp}$ in Definition 9 to ensure that the number of disjuncts remains at most k when the join operator is applied by the analysis. Typically, deciding how to maintain and manage the disjunctive components in techniques like trace-partitioning [23], disjunctive completion [10], and the finite powerset framework is a key challenge in effectively implementing these techniques. In order to do so, we first consider when it is necessary to maintain certain disjuncts to prevent spurious aging:

▶ **Example 10.** Consider the two following abstract cache states for a fully-associative cache (all blocks map to one cache set) which can store four memory blocks (associativity = 4): $C = \{d \mapsto \{0, 1\}, b \mapsto \{1, 2, 4\}, c \mapsto \{0, 1, 2\}, a \mapsto \{3\}\}$ (green) and $C' = \{d \mapsto \{0\}, b \mapsto$

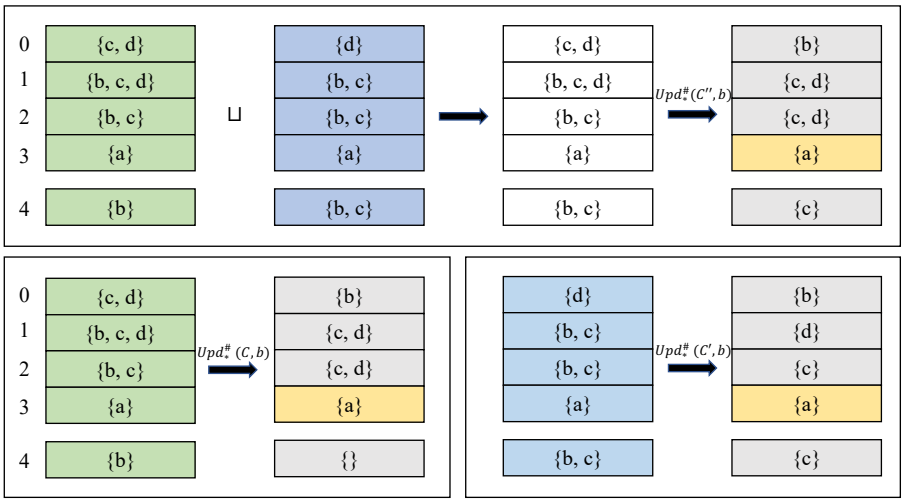

Figure 7 Merging two cache states does not cause spurious aging.

$\{1,2,4\}, c \mapsto \{1,2,4\}, a \mapsto \{3\}\}$ (blue), depicted in Figure 7. We can see that upon an access to variable b, $Upd^{\sharp}_{*}$ will not increment $3 \in C(a)$ to 4, meaning that a is definitely in the cache.

We can also see that this is true for their abstract join $C'' = C \sqcup_{\mathcal{C}^{\sharp}} C' = \{d \mapsto \{0,1\}, b \mapsto \{1,2,4\}, c \mapsto \{0,1,2,4\}, a \mapsto \{3\}\}$, where $4 \notin Upd^{\sharp}_{*}(C'', b)(a)$. In this example, we can see that merging the blue and green cache states did not impact the ability of $Upd^{\sharp}_{*}$ to prevent spuriously aging a from 3 to 4. Despite neither abstract state being subsumed by the other, the reason why $Upd^{\sharp}_{*}$ is able to prevent spurious aging on the union of both states is that the set of concrete cache states represented by the blue abstract state is a subset of the concrete states represented by the green state. This, combined with the fact that $Upd^{\sharp}_{*}$ prevents a from spuriously aging in either state, means that the same holds for the joined state.

The scenario referred to in Example 10, is a sufficient, but not necessary condition. To see why, consider another example, in which the set of valid concrete states of C and C' do not subsume one another, as in the following example:

▶ **Example 11.** Consider the two following abstract cache states: $C = \{d \mapsto \{0,1\}, b \mapsto \{1,2,4\}, c \mapsto \{0,2\}, a \mapsto \{2,3\}\}$ and $C' = \{d \mapsto \{0,1\}, b \mapsto \{0,2,4\}, c \mapsto \{1,3\}, a \mapsto \{2,3\}\}$. We can see that the set of concrete states represented by C and C' are not subsumed by one-another. (For example, $\{c \mapsto 0, d \mapsto 1, b \mapsto 2, a \mapsto 3\} \in \gamma_{\mathcal{C}^{\sharp}}(C)$, but is not in $\gamma_{\mathcal{C}^{\sharp}}(C')$ and $\{d \mapsto 0, c \mapsto 1, b \mapsto 2, a \mapsto 3\} \in \gamma_{\mathcal{C}^{\sharp}}(C')$, but is not in $\gamma_{\mathcal{C}^{\sharp}}(C)$.) However, in their abstract join, $C'' = \{d \mapsto \{0,1\}, b \mapsto \{0,1,2,4\}, c \mapsto \{0,1,2,3\}, a \mapsto \{2,3\}\}$, the following concrete state becomes possible: $\{b \mapsto 0, d \mapsto 1, c \mapsto 2, a \mapsto 3\}$, which is not a valid cache state in either C or C'. But, $Upd^{\sharp}_{*}(C'', b)$ is still able to avoid spuriously aging a from 3 to 4.

The scenarios described by Example 10 and Example 11 are in contrast with the example in Figure 5. In the Figure 5 example, a concrete cache state which is not possible in either cache state becomes possible in their abstraction union, and a memory block was spuriously aged as a result. In the case of Example 10 no new (valid) concrete cache state is introduced by the result of the join of the two abstract states. However, in Example 11, a new concrete cache state is introduced by the result of their join, but spurious aging was prevented. Having such a wide range of possibilities motivates the search for understanding when to merge abstract cache states, and when not to. If computational resources were no limit, only

merging abstract cache states such that $\gamma_{\mathcal{C}^\sharp}$ is *distributive* over the two cache states is ideal, meaning that no infeasible concrete cache states will be introduced. However, this is not applicable in practice due to being too costly, for two reasons. The first is that the number of disjuncts needed to be maintained may be very large (perhaps infinite in certain cases, depending on the control flow of the program, taking us out of the scope of the finite powerset construction), and the second is that checking the abstract states by concretizing them each time may lead to a large computational overhead.

Therefore, instead, we aim to maintain a reasonable number of disjunctions while retaining some precision, by carefully merging abstract states. To do so, we introduce our join operator to replace $\oplus_{\mathcal{VC}^\sharp}$ in Definition 9.

The Algorithm for Join. The abstract join is parameterized by the maximum number of disjuncts allowed, as well as a similarity relation $\sim_R$, to merge states when the number of allowed disjuncts is exceeded. The similarity relation takes in two states $s, s' \in \mathcal{V}^\sharp \times \mathcal{C}^\sharp$ and returns true or false, depending on whether they should be merged.

Algorithm 1 Join Operation $\oplus^*_{\mathcal{VC}^\sharp}\langle k : \mathbb{N}^+, \sim_R : (\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \times (\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \to \{\texttt{tt}, \texttt{ff}\}\rangle$.

Input: $S, S' \in \mathcal{VC}^\sharp$ // $\oplus^*_{\mathcal{VC}^\sharp} : \mathcal{VC}^\sharp \times \mathcal{VC}^\sharp \to \mathcal{VC}^\sharp$
Output: Joined state set S''
1. Set $S'' := \Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}(S \cup S')$
2. **if** $|S''| \leq k$ **then**
   return S''
3. **else**
   a. Set $S'' := \Omega_R^{\mathcal{C}^\sharp}(S'')$
   b. **if** $|S''| \leq k$ **then**
      return $\Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}(S'')$
   c. **else**
      i. **while** $|S''| > k$ **and** $\exists s_1, s_2 \in S'' : s_1 \sim_R s_2$ **do**
         Merge states s_1 and s_2 where $s_1 \sim_R s_2$
      ii. **while** $|S''| > k$ **do**
         Arbitrarily merge any pair of states
      iii. return $\Omega_R^{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}(S'')$

The join operator begins by combining the disjuncts in S, S' and removes redundant elements w.r.t. the value and cache abstractions. If, after doing this step, the cardinality of the resulting set is less than or equal to k, we stop. This choice is motivated by the fact that preserving disjunctive information that differs on the value domain may lead to more precise control-flow information, and thus, possibly result in fewer spurious memory accesses. Otherwise, the join operator aims to merge elements which share the same abstract cache states, using $\Omega_R^{\mathcal{C}^\sharp}$. After this, the subsumption operator is applied to ensure non-redundancy. If the number of disjuncts are within limit, the join operator returns the resulting abstract state. However, if the number of disjuncts still exceeds the number of those which are allowed, the join operator merges pairs of states which satisfy $\sim_R$. Merging via $\sim_R$ is done as much as possible until the number of disjuncts remaining are at most k. If all states satisfying $\sim_R$ have been merged pairwise and the number of disjuncts exceeds k, then states are merged arbitrarily pairwise, until the number of disjuncts is at most k. After this is complete, the subsumption operator is applied to ensure non-redundancy. We show that the join operator is valid in the appendix of the extended version [15]. In the next section, we discuss the possibilities for $\sim_R$.

4.2.4 The Merging Strategies

Recall that in Example 11, the concrete cache state $\{b \mapsto 0, d \mapsto 1, c \mapsto 2, a \mapsto 3\}$ is captured by the abstract cache state C'', but not by C or C', but we can still prevent the spurious aging of a from 3 to 4 by applying $Upd^\sharp_*$ to the abstract state C''. The key factor in $Upd^\sharp_*(C'', b)$ being able to avoid spuriously aging a from 3 to 4 is that the set of variables younger than age 3 (excluding a) is the same across C, C', C'' – the set being $\{d, b, c\}$. This corresponds with the second condition from the definition of $O_>\langle w\rangle$ in $Upd^\sharp_*$. Thus, it is of interest to preserve that property whenever we can.

To this end, we consider a condition under which merging two abstract states preserves the ability of $Upd^\sharp_*$ to prevent spurious aging of a given memory block when accessing some memory block w on the two abstract states separately. Specifically, we consider when two abstract cache states C and C' can be merged such that if $Upd^\sharp_*(C, w)$ and $Upd^\sharp_*(C', w)$ do not age a memory block b from t to $t+1$, then $Upd^\sharp_*(C \sqcup_{\mathcal{C}^\sharp} C', w)$ does not age memory block b from t to $t+1$, where t is some possible cache line age between 1 and $n-1$. If they satisfy the property that the set of memory blocks who have ages younger than t are the same in C and C', then if $Upd^\sharp_*(C, w)$ and $Upd^\sharp_*(C', w)$ do not spuriously age block b from t to $t+1$, then $Upd^\sharp_*(C'', w)$ where $C'' = C \sqcup_{\mathcal{C}^\sharp} C'$ does not age block b from t to $t+1$ spuriously.

We first introduce a helper function used in the proceeding Lemma that formalizes the aforementioned property. Let $\max_{<t}(A)$ be a function that takes a set of integers (A), and returns the maximum value that is less than t. If no such value exists, it returns $-\infty$. For example, $\max_{<4}(\{1,2,3,4\})$ returns 3, while $\max_{<5}(\{5,6,7\})$ returns $-\infty$. We now state the Lemma:

▶ **Lemma 12.** *Let $C, C' \in \mathcal{C}^\sharp$. Let $w \in \mathcal{B}$ be the memory block being accessed. Let $t \in \{1, ..., n-1\}$ be some cache line age, where n is the associativity of the cache. If for each $b \in \mathcal{B}$, $\max_{<t}(C(b)) = \max_{<t}(C'(b))(\star)$, then, if $Upd^\sharp_*(C, w)$ and $Upd^\sharp_*(C', w)$ do not age b from t to $t+1$, then $Upd^\sharp_*(C \sqcup_{\mathcal{C}^\sharp} C', w)$ does not age b from t to $t+1$.*

Proof. For the proof, please refer to the appendix of the extended version [15]. ◀

Lemma 12 yields two key corollaries for our purposes. The first states that if the universe of concrete cache states are partitioned using a set of abstract cache states based on groups of states which satisfy $(\star)$ pairwise, then there will be no spurious aging of memory blocks caused by combining states with the abstract join operator. The second one states a special case of the lemma, which prevents memory blocks from being spuriously uncached as a result of combining states with the abstract join operator. (We note that there is still possible imprecision due to the gap between $Upd^\sharp_*$ and the best abstract transformer.)

▶ **Corollary 13.** *Merging abstract cache states based on the strategy of only merging abstract cache states C, C' that satisfy the following formula $\forall t \in \{1, ..., n-1\}.\forall b \in \mathcal{B}. \max_{<t}(C(b)) = \max_{<t}(C'(b))$ will result in no block being spuriously aged, purely due to combining abstract cache states with the join operator.*

Proof. If only pairs of disjuncts which satisfy this property are merged, then for any block $b \in \mathcal{B}$, if b is not aged in either disjunct, then it will not be aged in their abstract union. This corresponds to the case where there is no precision loss due to using the $\mathcal{C}^\sharp$ abstract domain compared to $\mathcal{P}(\mathcal{C}^\sharp)$. ◀

▶ **Corollary 14.** *If $t = n-1$, then merging based on the aforementioned strategy will prevent a memory block from becoming possibly uncached as a result of merging two abstract states.*

Proof. This is just a special case of Lemma 12, where $t = n-1$. ◀

Egli-Milner Partial Order $\sqsubseteq_{EM}$ ($\sqsubseteq_{EM}$: $\mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \times \mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \to \{\texttt{tt}, \texttt{ff}\}$). The Egli-Milner partial order is defined as follows: $S \sqsubseteq_{EM} S' \iff S = \emptyset \vee (\forall s \in S \,.\, \exists s' \in S' \,.\, s \sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s' \wedge \forall s' \in S'.\exists s \in S.s \sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s')$.

k-Collapsor ($\Uparrow_k$: $\mathcal{P}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \to \mathcal{VC}^\sharp$). Given $S \in \mathcal{VC}^\sharp$ such that S is non-redunandant according to $\sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$, a k-Collapsor $\Uparrow_k (S)$ yields $S' \in \mathcal{VC}^\sharp$ such that $S \sqsubseteq_{EM} S'$ and, moreover, $|S'| \leq k$.

∇-Reduction Map ($\Omega^\nabla : \mathcal{P}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \to \mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$). The ∇-Reduction map is defined recursively: $\Omega^\nabla(S) := ite(\exists s, s' \in S \,.\, s \sqsubset_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s', \Omega^\nabla((S \setminus \{s, s'\}) \cup \{s \nabla_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} s'\}), S)$.

Widen for $\mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$ ($_k\nabla_P : \mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \times \mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp) \to \mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$). Given $S, S' \in \mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$ such that $S \sqsubset_{\mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)} S'$, $S_k \nabla_P S' := \Omega^\nabla(S \cup S'')$, where $S'' := \Uparrow_k (S')$.

Widen for $\mathcal{VC}^\sharp$ ($_k\nabla_P : \mathcal{VC}^\sharp \times \mathcal{VC}^\sharp \to \mathcal{VC}^\sharp$). Given $S, S' \in \mathcal{VC}^\sharp$ such that $S \sqsubset_{\mathcal{VC}^\sharp} S'$, $S_k \nabla_P S'' := \Omega^\nabla(S \cup S'')$, where $S'' := S' = \Uparrow_k (S')$, by virtue of $|S'| \leq k$, as it is a member of $\mathcal{VC}^\sharp$.

Figure 8 Details of the widening operator.

The two corollaries could lead to two different merging strategies to serve as similarity relations in the definition of the abstract join operator. The first being to prevent the spurious aging of any memory block as a result of merging two abstract cache states, and the second being to prevent any block from becoming spuriously uncached in the same scenario. While the two merging strategies have properties that are desirable, they have their limitations in terms of their utility in practice. First, it may require many disjuncts to be able to merge only according to the strategy suggested by Corollary 13. Second, using the strategy suggested by Corollary 14, the number of disjuncts required may be large, but furthermore, the user is forced to pick a specific t $(n-1)$.

Therefore, in practice, we merge two states according to the following similarity relation: $\forall b \in \mathcal{B}. \max_{\neq n}(C(b)) = \max_{\neq n}(C'(b))$. That is, if there is no memory block whose maximum (non-associativity) age differs between C and C', then we merge the two abstract states.

The goal is to encourage falling into either of the two cases where Lemma 12 indicates that the merging will not lead to spurious aging, while still keeping the number of disjunctions manageable by enforcing less stringent requirements than suggested by either Corollary 13 or Corollary 14. Of course, many other relations could be used, including strategies based on the syntax and semantics of the program, which we intend to explore in future work.

4.2.5 The Widening Operator

Finally, the last domain operation to be defined is the widening operator. A widening operator serves to enforce termination of analyses which use abstract domains with infinitely increasing chains, or to speed up the analysis, regardless of the abstract domain. Given that $\mathcal{C}^\sharp$ has finite height, no widening is required for it. However, $\mathcal{V}^\sharp$ abstracts program values and therefore may not be of finite height; thus we must introduce a widening operator for $\mathcal{VC}^\sharp$.

One way to instantiate a widening operator for the finite powerset domain is the through the use of a *cardinality-based* widening [3], which is what we do in our instantiation of the framework. The formal details of the cardinality-based widening (written as slight adaptations from the details in [3]) are shown in Figure 8. In a nutshell, cardinality-based widening ensures termination by first ensuring that the cardinality of the *widening* argument is bounded by a fixed (user-specified) size k. Then, a reduction map, which takes a set of elements and removes and replaces pairs of elements where one strictly subsumes the other by the widening of these two elements, is applied in a recursive manner until the set no longer changes. Together, the two form a ∇-connected extrapolation heuristic [3], which lifts the base-level widening $\nabla_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$ to the powerset domain, while preventing unbounded growth, guaranteeing termination.

In the case of the finite powerset domain of non-redundant (w.r.t. $\sqsubseteq_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp}$) sets *without* a restriction on the cardinality sets (whose elements are denoted, with a slight abuse of notation, by $\mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$ in Figure 8), the two steps are accomplished by a using a k-Collapsor ($\Uparrow_k$) and the reduction map Ω^∇. The k-Collapsor takes an element of $\mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$, S, and returns an element $S' \in \mathcal{P}_{fn}(\mathcal{V}^\sharp \times \mathcal{C}^\sharp)$, such that $|S'| \leq k$ and $S \sqsubseteq_{EM} S'$. The Elgi-Milner partial order ($S \sqsubseteq_{EM} S'$) means that for two sets S, S', every element in S is overapproximated by an element in S' AND every element in S' overapproximates some element in S. There are many ways to define a k-Collapsor [3], but it is worth noting that our join operator defined in Algorithm 1, can be used to define a k-Collapsor, e.g., $S \mapsto S \oplus^*_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} S$. By construction, the resulting set is of size less than or equal to k. Furthermore, since elements of S are merged, every element in the resulting set subsumes some element in S, enforcing $S \sqsubseteq_{EM} S \oplus^*_{\mathcal{V}^\sharp \times \mathcal{C}^\sharp} S$.

In our abstract domain, $\mathcal{VC}^\sharp$, where each set is restricted to be of size at most k, the widening operator for $\mathcal{VC}^\sharp$ can be defined as shown at the bottom of Figure 8. That is, the k-Collapsor is the identity function, as all elements in the domain are bounded by cardinality k. The termination and soundness guarantees follow from the results established in [3].

5 Experiments

We have implemented our method in a static program analyzer designed for quantifying cache side-channel leakage. Our analyzer is written in OCaml and built upon the CacheAudit analysis framework, the state-of-the-art tool for computing upper bounds of cache side-channel leakage via abstract interpretation. Our techniques are implemented as functors for the existing CacheAudit abstract domains, transforming the existing abstract interpreter to gain precision in the key ways we identified.

5.1 Experimental Setup

We conducted all experiments on a computer with an Intel Xeon W-2245 CPU and 128 GB RAM, running Ubuntu 20.04 operating system. The experiments were designed to answer the following questions:

- **RQ1**. Do the upper bounds computed by our method improve upon the state-of-the-art?
- **RQ2**. Do the two innovative techniques presented in Section 4 have a synergistic effect in practice?

Our benchmark consists of 29 C programs that implement a variety of sorting algorithms and cryptographic functions. For every sorting algorithm, we introduce a "structured" version, meaning that the elements of the arrays to be sorted are data structure types, consisting of several other components: character arrays and integers. This set-up reflects real-world applications of algorithms that carry some "informational payload".

Each sorting algorithm was assumed to run on an array of size 24. While loop unrolling is not strictly necessary for abstract interpretation based methods, it was required for certain programs (independent of the technique used), and thus, we allowed a loop unrolling limit of 1024 for those programs, as recommended by the tool. We limit the maximum number of disjunctions to 10.

5.2 Results for Answering RQ1

To answer RQ1, i.e., do the upper bounds computed by our method improve upon the state-of-the-art, we compare the results of our method and the existing method on all 29 benchmark programs. The results are shown in Table 1. Column 1 shows the name of the

Table 1 Comparing existing methods (**B** [11]) and our new method (**NM**) on a 32KB cache with associativity 8 and line size 32.

benchmark program. Columns 2-4 compare leakage quantification results for two types of adversaries: SM stands for the shared-memory adversary and DM stands for the disjoint-memory adversary. In general, the leakage for DM is smaller than or equal to the leakage for SM. In both cases, the quantification results of the existing and new methods are measured in bits – a smaller number means a better result (less leakage). In Column 4, the ✔symbol means that our method obtains a better result, and the ✔symbol means that our method obtains the best-possible result (e.g., when the leakage is already 0). Columns 5-6 compare the total analysis time in seconds. In general, we find that in most cases the running time is about twice as long compared to the baseline methodology. This is expected due to the extra domain operations required due to refining the $\mathcal{C}^\sharp$ domain to use *sets* of abstract states.

Table 1 shows that the new method obtains either better or the best-possible quantification results on 13/15 benchmark programs that implement various sorting algorithms. For example, the quantification results for *cocktailsortstruct* and *shellsort* are the best-possible because

the leakages obtained by our method are equal to 0. On the other 2/15 benchmark programs (*gnomesort* and *shellsortstruct*), the new method obtains quantification results that are as good as those of the existing method. As for the benchmark programs that implement cryptographic algorithms, the new method obtains either better quantification results on 9/14 of them, and obtains the same results as the existing method on 5/14 of them. We note that the results are also dependent on the cache configuration used. For example, using a $32K$ cache with associativity 16, and line size 32, on *sosemanuk* and *hc-128*, in particular, the precision of the leakage improves by close to 10 bits and 13 bits by using our method, corresponding to elimination of 1024 and 8192 spurious cache states, respectively. Overall, the results show that the upper bounds computed by our method improve upon the state-of-the-art significantly.

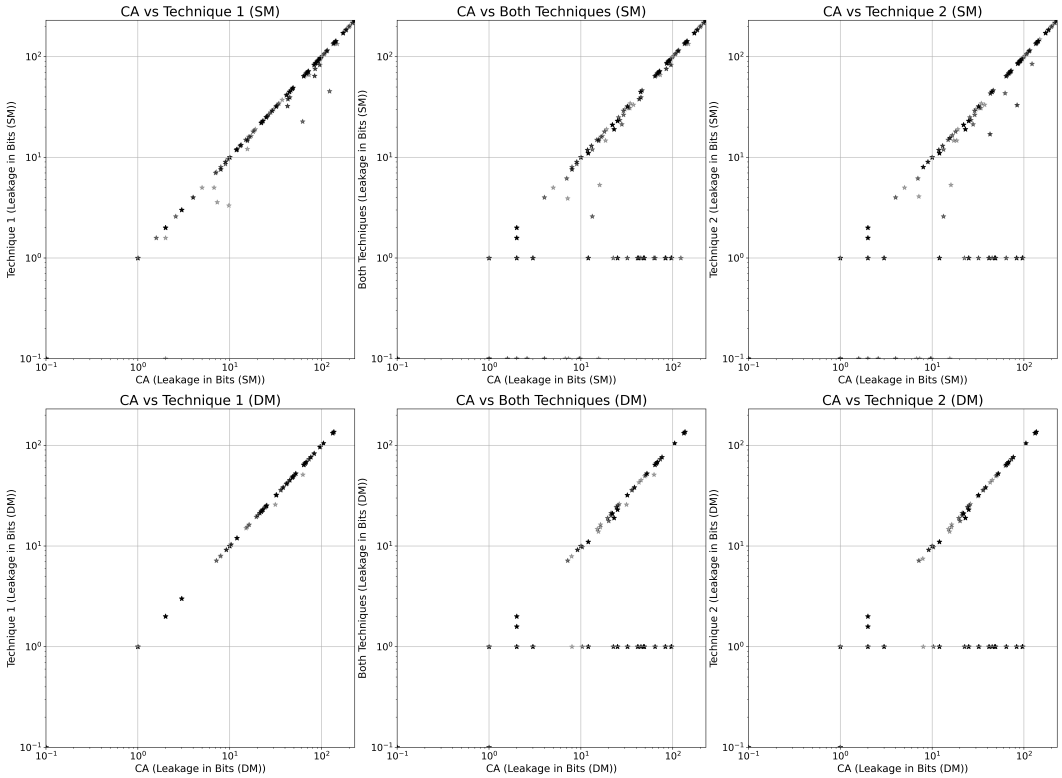

Figure 9 Evaluating the impact of the two new techniques in our method, by comparing them against the existing method. CA is the existing method (CacheAudit), Technique 1 is the first new technique in our method (the new abstract transfer function), Technique 2 is the second new technique in our method (refining the $\mathcal{C}^\sharp$ domain), and Both Techniques is our method with both of the two new techniques. The scatter plots on top are for the SM adversaries, while the scatter plots at the bottom are for the DM adversaries. In all of these scatter plots, points below the diagonal line ($y = x$) are winning cases for our method against the existing method.

5.3 Results for Answering RQ2

To answer RQ2, i.e., do the two techniques presented in Section 4 have a synergistic effect in practice, we conducted an ablation study, by enabling each individual technique and comparing it against the state-of-the-art. These comparisons were conducted on all 29 benchmarks programs, with various cache settings. That is, we set the cache size S to 4KB,

8KB, 16KB, 32KB and 64KB, the associativity n to 4, 8, and 16, and the cache line size L to 32 and 64 bytes. While we recognize that 16 is not a common associativity for real-world caches, our goal was to stress-test our abstract transformer under higher associativities. The results are shown as scatter plots in Figure 9. In each scatter plot, the x-axis is the leakage (in bits) obtained by the state-of-the-art method, and the y-axis is the leakage (in bits) obtained by our method (with one or both techniques enabled). Thus, the diagonal line represents the cases where our method is tied with the existing method, whereas points below the diagonal line are winning cases for our method.

In Figure 9, the two scatter plots on the left-hand side show the effectiveness of the new abstract transfer function. While most of the points are on the diagonal line, meaning that the two methods are tied, there are some points that are significantly below the diagonal line, indicating the effectiveness of the proposed technique for these cases. The two scatter plots on the right-hand side show the effectiveness of using disjunctions. Many of the points are below the diagonal line, which are the winning cases for our method. The two scatter plots in the middle show that using both the new abstract transfer function and leveraging disjunctions together perform very well, with even more points below the diagonal line.

Table 2 Evaluating the impact of the two new techniques in our method on the benchmark program *scatter_gather_openssl_1_0_2* using various cache settings. S is the cache size in bytes, n is the associativity level, and L is the cache line size in bytes.

Cache Setting (S, n, L)	Leakage Quantification			Time (s)		
	Technique-1 (SM / DM)	Ours (both) (SM / DM)	Technique-2 (SM / DM)	Tech-1	Ours (both)	Tech-2
(4096, 4, 32)	64.3 / 64.3	1.0 / 1.0	33.0 / 1.0	5	6	3
(4096, 4, 64)	32.3 / 32.3	1.0 / 1.0	17.0 / 1.0	3	3	3
(4096, 8, 32)	45.2 / 45.1	1.0 / 1.0	84.7 / 1.0	8	9	3
(4096, 8, 64)	22.6 / 22.6	1.0 / 1.0	43.3 / 1.0	5	5	4
(8192, 4, 32)	83.3 / 83.3	1.0 / 1.0	1.0 / 1.0	3	4	2
(8192, 4, 64)	41.9 / 41.9	1.0 / 1.0	1.0 / 1.0	2	2	2
(8192, 8, 32)	64.3 / 64.3	1.0 / 1.0	33.0 / 1.0	5	5	2
(8192, 8, 64)	32.3 / 32.3	1.0 / 1.0	17.0 / 1.0	3	3	3
(16384, 4, 32)	97.0 / 97.0	1.0 / 1.0	1.0 / 1.0	3	4	3
(16384, 4, 64)	49.0 / 49.0	1.0 / 1.0	1.0 / 1.0	2	2	3
(16384, 8, 32)	83.3 / 83.3	1.0 / 1.0	1.0 / 1.0	3	4	2
(16384, 8, 64)	41.9 / 41.9	1.0 / 1.0	1.0 / 1.0	2	2	3
(32768, 4, 32)	97.0 / 97.0	1.0 / 1.0	1.0 / 1.0	4	6	2
(32768, 4, 64)	49.0 / 49.0	1.0 / 1.0	1.0 / 1.0	2	4	1
(32768, 8, 32)	97.0 / 97.0	1.0 / 1.0	1.0 / 1.0	3	3	3
(32768, 8, 64)	49.0 / 49.0	1.0 / 1.0	1.0 / 1.0	2	3	2
(64512, 4, 32)	97.0 / 97.0	1.0 / 1.0	1.0 / 1.0	5	5	2
(64512, 4, 64)	49.0 / 49.0	1.0 / 1.0	1.0 / 1.0	3	3	3
(64512, 8, 32)	97.0 / 97.0	1.0 / 1.0	1.0 / 1.0	4	5	2
(64512, 8, 64)	49.0 / 49.0	1.0 / 1.0	1.0 / 1.0	2	4	1

We also collected detailed results of the experimental comparison, which are shown in Table 2. Various cache settings were used in the experiments, as shown in Column 2. For brevity, we only show these detailed results for a representative benchmark program named *scatter_gather*.

Overall, the results show that each of the two techniques is effective in isolation; furthermore, when the two techniques are used together, they often have a synergistic effect in terms of improving the precision of leakage quantification.

6 Related Work

As mentioned earlier, the most closely related work is that of Doychev et al. [11], which we regard as the baseline algorithm for quantifying cache side-channel leakage. The key difference in our work is a new abstract transfer function and a disjunctive refinement for increasing the precision of abstract interpretation.

Doychev et al. [11] support other adversaries, including trace-based and timing adversaries. Given that our abstractions fundamentally improve the precision of the abstract cache states in an abstract domain that is specialized for quantification, we expect that our techniques will help improve quantification results on downstream static analyses that rely on abstract cache states.

Kopf et al. [17] target cache-based adversaries, and conduct quantification via counting formulae, combined with an abstract interpreted-based static analysis. They recognize that trace partitioning [23] during the static analysis led to increased precision in the quantification results. However, trace-partitioning was conducted by manual program transformation, whereas our method is automated via abstract interpretation to parsimoniously leverage disjunctive information. Beyond abstract interpretation, which is a *sound* analysis technique, there are methods based on alternative analysis techniques such as bounded modeling checking [20] or symbolic execution [7]. However, their results may not be sound.

There are also methods targeting other kinds of adversaries. In the case of trace-based adversaries, it is assumed that a malicious attacker may observe the sequences of memory accesses throughout program execution; thus, quantification techniques aim to compute an upper bound on the number of distinct memory access traces possible. Various tools have been developed to compute an upper bound for the number of possible distinct memory access traces. Ma et al. [20] introduce an abstraction known as differential set that tracks, for each memory access, all possible addresses that might be accessed by that operation or its "sibling" operations in other control flows. Their abstraction is combined with bounded model-counting to compute a sound upper bound of information leakage. Other works leverage techniques such as symbolic execution to compute these upper bounds.

Beyond quantification, there are methods for cache hit/miss classification [26, 25, 14]. In particular, Touzeau et al. [25] combine abstract interpretation with model checking to classify memory accesses in LRU caches as "always hit", "always miss", or "definitely unknown". Touzeau et al. [26] also introduce a method that represents cache states using anti-chains of minimal/maximal elements rather than full state sets, thus enabling efficient computation while preserving precision. Gysi et al. [14] introduce symbolic techniques to count cache misses without having to enumerate all memory accesses, making the analysis practical through a hybrid approach that combines symbolic computation with selective enumeration. However, these works are not designed for quantifying cache side-channel leakage.

7 Conclusion

We have presented a method for significantly improving the precision of abstract interpretation based static analysis for quantifying cache side-channel leakage. The method uses a new abstract transfer function to prevent spurious aging and abstract domain refinement during the analysis step, which uses disjunctions parsimoniously to prevent spurious combinations of cache states. Our experimental evaluation on benchmark programs consisting of sorting

and cryptographic algorithms shows that the method is more accurate in quantifying cache side-channel leakage than the state-of-the-art technique. Furthermore, both of the two new techniques in our method contribute to the performance improvement.

Abstract

Dynamic program analyses help in understanding a program's runtime behavior and detect issues related to security, program comprehension, or profiling. Instrumentation platforms aid analysis developers by offering a high-level API to write the analysis, and inserting the analysis into the target program. However, current instrumentation platforms for WebAssembly (Wasm) restrict analysis portability because they require concrete runtime environments. Moreover, their analysis API only allows the development of analyses that observe the target program but cannot modify it. As a result, many popular dynamic analyses present for other languages, such as runtime hardening, virtual patching or runtime optimization, cannot currently be implemented for Wasm atop a dynamic analysis platform. Instead, they need to be built manually, which requires knowledge of low-level details of the Wasm's semantics and instruction set, and how to safely manipulate it.

This paper introduces Wastrumentation, the first dynamic analysis platform for WebAssembly that supports intercession. Our solution, based on source code instrumentation, weaves the analysis code directly into the target program code. Inlining the analysis into the target's source code avoids dependencies on the runtime environment, making analyses portable across Wasm VMs. Moreover, it enables the implementation of analyses in *any* Wasm-compatible language. We evaluate our solution in two ways. First, we compare it against a state-of-the-art source code instrumentation platform using the WasmR3 benchmarks. The results show improved memory consumption and competitive performance overhead. Second, we develop an extensive portfolio of dynamic analyses, including novel analyses previously unattainable with source code instrumentation platforms, such as memoization, safe heap access, and the removal of NaN non-determinism.

1 Introduction

WebAssembly (Wasm) [13] has become a compilation target for many high-level languages such as C, C++, and Rust, thanks to its portability and predictable performance [31]. It was originally designed as a binary instruction set for the web and is currently supported by all major browsers.

Wasm offers predictable performance through its compact program representation, enabling efficient loading, validation and execution as parts of the program are being loaded. To safely execute untrusted code, it features control-flow integrity (ensuring programs cannot

jump to unintended code locations), a modular system with strict encapsulation and type safety, and a sandboxed linear memory layout that isolates data from code and prevents unauthorized memory access [13].

Although Wasm was designed with built-in security and efficient mechanisms, it does not inherently address questions of software quality. For example, recent research reports performance issues in server-side Wasm applications [14] and memory safety issues [18, 23]. Dynamic analysis tools are increasingly being leveraged for Wasm to enhance security [9, 2], improve program comprehension [20, 30, 26, 39] and enable profiling [21].

To implement dynamic analyses, developers often rely on code transformation tools or general-purpose analysis platforms. In the context of Wasm, transformation tools like Brewasm [5] and WasmManipulator [29] allow developers to instrument the target program code by injecting additional Wasm instructions implementing the analysis. However, this approach requires a deep understanding of the instruction set and how it can be manipulated, such that the injected instructions uphold type safety and do not unintentionally interfere with the target program.

Alternatively, developers can use a general-purpose dynamic analysis framework for Wasm, either Wizard [38], or Wasabi [19]. These frameworks provide developers with a high-level API to implement analyses while avoiding unintentional analysis interference and ensuring type-safe instrumentation. Wizard's instrumentation framework is implemented within the Wizard execution engine. The integration at the level of the execution engine allows the instrumentation code to be turned on and off at runtime. Wasabi on the other hand instruments the target program with hooks that call into a JavaScript analysis which co-exists with the instrumented input program. Unfortunately, analyses implemented with these frameworks are restricted to concrete runtime environments. Wizard's instrumentation executes only on top of the Wizard engine, while Wasabi requires a JavaScript Virtual Machine (VM) along the Wasm VM. Moreover, analyses implemented with Wizard and Wasabi can only observe a program execution but not modify it, i.e. they do not support intercession. As a result, a wide range of dynamic analyses cannot be implemented with these frameworks, including runtime hardening [27, 18], virtual patching [34, 42], or runtime optimization [34, 43].

This paper presents Wastrumentation, the first general-purpose framework for dynamic analysis of WebAssembly that supports intercession and is portable among the many Wasm environments through its design as a source code instrumentation platform. To avoid the requirement of a JavaScript VM to be present for the instrumentation, Wastrumentation exposes its instrumentation API as a Wasm application binary interface (ABI). Furthermore, targeting a Wasm ABI has the benefit that any language that compiles to Wasm can be used to implement the analysis. Wastrumentation then merges both the target program and the analysis implementation as one Wasm program, making the instrumentation portable to any Wasm VM. To enable the construction of dynamic analyses requiring intercession, the instrumentation API of Wastrumentation enables the analysis to alter or skip operations happening at the target program side.

In summary, the main contributions of the paper are:

- We develop a novel instrumentation approach for Wasm programs to deploy dynamic analyses through source code rewriting featuring an instrumentation ABI akin to state-of-the-art high-level APIs but language-agnostic and extended with support for intercession.
- We show the usefulness of Wastrumentation by building an extensive portfolio of dynamic analyses, including a variety of existing analyses from Wasabi, as well as the implementation of three novel dynamic analyses that require intercession support, previously

unattainable with existing source code instrumentation platforms for Wasm. These analyses cover the domains of runtime optimization (memoization analysis), security (safe-heap analysis) and program repair ("DeNaN" analysis).
- We conducted a performance evaluation of Wastrumentation for the developed dynamic analyses on real-world programs from the Wasm-R3 benchmark suite [1], which shows improved memory consumption and competitive performance overhead compared to the state-of-the-art source code instrumentation platform, Wasabi [19].

2 Approach

This section describes our source code instrumentation platform for dynamic analysing Wasm applications. We first introduce Wastrumentation from the point of view of the analysis developer. Section 2.1 shows how to build a dynamic analysis atop of Wastrumentation, and Section 2.2 details the analysis API. Then, we turn our attention to the platform itself. Section 2.3 shows its architecture and gives an overview of the design choices. Section 2.4 details the transformations at the Wasm level where the instrumentation code is injected.

2.1 Developing a Dynamic Analysis with Wastrumentation

We now explain Wastrumentation from the perspective of an analysis developer implementing a concrete dynamic analysis. To this end, we present the "DeNaN" dynamic analysis, a novel dynamic analysis inspired by the "`--denan`" pass from the Wasm compiler framework Binaryen [10]. The "DeNaN" analysis ensures determinism among different Wasm VMs regarding floating point operations, as the Wasm language specification for "NaN Propagation"[1] does not enforce a canonical floating-point NaN representation. To address this, the "DeNaN" analysis replaces all runtime floating-point NaN values with a deterministic value 0.0.

To implement the "DeNaN" analysis, all Wasm instructions that may operate on runtime floating-point values must be intercepted. For each intercepted instruction, the analysis distinguishes between integer types (`i32`, `i64`), which are unaffected by NaN propagation, and floating-point type (`f32`, `f64`). Integer values remain unchanged, while floating-point NaN values must be replaced with 0.0. The relevant Wasm instructions include:
- Stack operations: `const`, pushes a constant on the value stack.
- Local and global variable operations: `local.get`, `local.set`, `global.get`, `global.set`, a "get" reads from a variable or global and pushed onto the value stack, a "set" does the opposite.
- Memory operations: `load`, `store`, a "load" reads from linear memory to the value stack, a "store" does the opposite.
- Arithmetic operations: `unary`, `binary`, operates on value(s) atop of the value stack.
- Function calls: passing arguments and receiving results for local, imported or exported functions.

Listing 1 shows a Rust implementation of the "DeNaN" analysis using the Wastrumentation API. Each Wastrumentation analysis implements *traps* that allow developers to register for specific Wasm events. The "DeNaN" analysis registers traps corresponding to the aforementioned instructions (Sections 2.1–2.1): `const_`, `local`, `global`, `load`, `store`, `unary`, `binary` and `apply`. The traps are defined using the `advice!` macro and are invoked by the instrumentation platform when corresponding events occur.

[1] WebAssembly 2.0 Specification – NaN Propagation (accessed on 28 Nov 2024).

The analysis instructs each trap function to capture each involved runtime value `v` and replace `v` with the result of `v.denan()`. It implements the method `denan` for Wasm values as an extension trait for the type `Value` (Sections 2.1–2.1). In Rust, extension traits allow to extend types with additional methods. This analysis declares the extension trait `Denan` (Section 2.1) and implements it for the type `Value` (Section 2.1) to allow invoking `denan` on Wasm values.

The implementation of `denan` (Section 2.1) matches on the type of the value. Integer values (matching `WasmType::I32` or `WasmType::I64`) are left untouched (Section 2.1). Floating point values (matching `WasmType::F32` or `WasmType::F64`) are cast to Rust's respective floating point type. On this floating type the method `is_nan` is called to intercept NaN instances. If `is_nan()` identifies a NaN instance, the value is replaced with 0.0, otherwise, it is returned unchanged (Section 2.1 and Section 2.1).

Listing 1 The Rust implementation of the "DeNaN" analysis. This analysis replaces all NaN floating-point values with 0.0 to ensure deterministic NaN-propagation across Wasm VMs.

```

    apply (func: WasmFunction, args: MutDynArgs, ress: MutDynResults) {
         args.update_each_arg(|_index, v| v.denan());
         func.apply();
         ress.update_each_res(|_index, v| v.denan()); } }
trait Denan { fn denan(self) -> Self; }
impl Denan for Value {
    fn denan(self) -> Self {
        use WasmType::{I32, I64, F32, F64};
        match self.type_() {
            I32 | I64 => self,
            F32 => self.as_f32().is_nan().then(|| 0_f32.into()).unwrap_or(self),
            F64 => self.as_f64().is_nan().then(|| 0_f64.into()).unwrap_or(self),
        } }}
```

2.2 Dynamic Analysis API

Table 1 shows the trap functions supported by Wastrumentation to build dynamic analyses. The table shows the high-level conceptual API, referring to Wasm constructs such as "location", "operator" and "operand". The trap functions are named after their corresponding program event. Each trap function gets as arguments details on the corresponding Wasm instruction and its code location. Such a conceptual API can then be implemented for a concrete high-level language that compiles to Wasm. Currently, our platform offers a Rust and AssemblyScript implementation of that API to implement dynamic analysis. The concrete language API is mapped onto the low-level Wasm instrumentation ABI by Wastrumentation at instrumentation time. The actual ABI for the conceptual API in Table 1 is specificied in Appendix A in [25].

Table 1 The dynamic analysis API supported by Wastrumentation. The columns show the trap name, the arguments provided to the trap, the type of value the trap must return and the implementation to ensure a transparent execution.

Trap name	Typed arguments	Return Type	Transparent Base
`if-then`$_{pre}$, `if-then-else`$_{pre}$	c:$type_{bool}$, input:$i32$, arity:$type_{i32}$, l:Loc	$type_{bool}$	c
`br`	l:$label$, l:Loc	$\emptyset$	
`br-if`	c:$type_{bool}$, l:$label$, l:Loc	$type_{bool}$	c
`br-table`	t:$i32$, effective-target:$label$, d:$label$, l:Loc	$type_{i32}$	t
`select`	c:$type_{bool}$, l:Loc	$type_{bool}$	c
`call`$_{pre}$, `call`$_{post}$	fn:idx_{func}, l:Loc	$\emptyset$	
`call-indirect`$_{pre}$	fn-idx:$i32$, tbl:idx_{tbl}, l:Loc	$type_{i32}$	fn-idx
`call-indirect`$_{post}$	tbl:idx_{tbl}, l:Loc	$\emptyset$	
`unary`	op:$unary$, o:$type_{val}$, l:Loc	$type_{val}$	op.apply(o)
`binary`	op:$binary$, l:$type_{val}$, r:$type_{val}$, l:Loc	$type_{val}$	op.apply(l, r)
`const`	v:$type_{val}$, l:Loc	$type_{val}$	v
`local`	v:$type_{val}$, i:idx_{local}, l:op_{local}, l:Loc	$type_{val}$	v
`global`	v:$type_{val}$, i:idx_{global}, g:op_{global}, l:Loc	$type_{val}$	v
`load`	i:idx_{load}, o:$offset_{store}$, op:op_{load}, l:Loc	$type_{val}$	op.perform(i, o)
`store`	i:idx_{store}, v:$type_{val}$, o:$offset_{store}$, op:op_{store}, l:Loc	$\emptyset$	op.perform(i, v, o)
`memory-size`	s:$type_{val}$, i:idx_{memory}, l:Loc	$type_{val}$	s
`memory-grow`	a:$type_{val}$, i:idx_{memory}, l:Loc	$type_{val}$	i.grow(a)
`block`$_{pre}$, `loop`$_{pre}$	input:$i32$, arity:$type_{i32}$, l:Loc	$\emptyset$	
`if-then`$_{post}$, `if-then-else`$_{post}$, `block`$_{post}$, `loop`$_{post}$, `drop`, `return`	l:Loc	$\emptyset$	
`apply`	f:$Function$, args:$Arguments$, ress:$Results$,	$\emptyset$	f.apply()

Our high-level API is inspired by Wasabi's instrumentation API, but it supports *intercession*, i.e. the ability of the analysis to modify the target program. This has two major implications for the design of the instrumentation API. We need to conceive (1) how the analysis controls the target program given the built-in safety and security characteristics of Wasm (detailed in Section 2.2.1), and (2) how the analysis can forward the intercepted operation to the target Wasm program (detailed in Section 2.2.2). The column "Transparent Base" in Table 1 denotes the operation that the analysis can call to forward the intercepted operation (captured at the trap function) to the target program.

2.2.1 Intercession: Modifying the Target Program

Dynamic analyses written on Wastrumentation can not only observe all the runtime behaviour of a target application but also control it. More concretely, analyses can change *part of* the target program behavior during the execution of the trap function. To illustrate this, consider the trap function `const_` that intercepts pushing a constant on the Wasm value stack. This trap function receives two arguments: the constant value `v` that would be pushed and the source code location `l` of the instruction. Wastrumentation allows the analysis to decide what value is pushed on the stack when the control flow returns to the target program by using the return value of the trap function. For example, the "DeNaN" analysis (cf. Section 2.1) uses this to alter the constant value `v` to a deterministic NaN value.

Generally, the API of Wastrumentation uses the return value of trap functions to alter the behavior of the target instruction. Whereas this is not always applicable (due to reasons further explained in Section 2.4), Table 1 shows when a return value dictates (part of) the target program behavior in the column "Return Type". Below, we further outline how the analysis is in control once a trap function is invoked.

- Intercession of control flow: For the trap functions `if`$_{\texttt{pre}}$, `if-then-else`$_{\texttt{pre}}$ `select`, and `br-if`, the return value dictates control flow of the branch expression as a boolean. For the trap function `br-table` the return value dictates the target label that control-flow will jump to. The return value of the trap function `call-indirect`$_{\text{pre}}$ determines the index in the function table of the instruction that will be invoked.
- Intercession of value stack manipulation: The following trap functions intercept instructions that push on the value stack: `unary`, `binary`, `const`, `local`, `global`, `load`, `store`, `memory-size` and `memory-grow`. The return value of the corresponding trap function is used as the outcome value that will be pushed on the stack.
- Introspection only: Aside for general intercession, the following trap functions cannot influence their respective instruction: `br`, `call`$_{\text{pre}}$, `call`$_{\text{post}}$, `call-indirect`$_{\text{post}}$, `block`$_{\text{pre}}$, `loop`$_{\text{pre}}$, `if`$_{\text{post}}$, `if-then-else`$_{\text{post}}$, `block`$_{\text{post}}$, `loop`$_{\text{post}}$, `drop` and `return`. This is due to how the respective program events do not depend on runtime information (eg. `br`) or report the termination of a program event (eg. `if-then-else`$_{\text{post}}$).
- Intercession of function application: The trap function `apply` can control a Wasm function application. When a function application takes place, this trap receives two pointers. The former points to an array containing the function arguments, and the latter points to the array containing the function results. This trap can alter the passed arguments before the function application takes place, and it can alter the return values before the control flow returns to the caller. Furthermore, this trap function is in control of whether the function application takes place at all.

2.2.2 Forwarding Intercepted Operations Back to the Target Program

Even if an analysis does not need to modify the target program, it remains responsible for the execution of intercepted program events. For example, if the trap function `const_` must remain transparent then the unaltered argument `v` must be the return value of the trap function. For the traps involved, the analysis is thus responsible for ensuring that the target operation takes place within the execution of the trap function. As mentioned before, Table 1 shows within the column "Transparent Base" the functions to be called within the trap function to forward the intercepted operation back to the target program.

Actually, the functions in the column "Transparent Base" represent the *continuation* of the intercepted operation that yields a return value. This design enables the analysis developer to add analysis code around the continuation of the intercepted operation and decide either to call the continuation or skip it altogether. This is most notable for the program events "apply" and "memory-grow". For "apply" the analysis controls function applications. This may further imply calling recursive functions. For "memory-grow", the return value either points to the next allocated page in linear memory or -1 if no allocation could be performed. This enables the analysis to artificially limit the available memory by not calling the memory to growth continuation and early returning with -1. For all other operations, the transparent base continuation is side-effect free and has no significant impact on analysis code that may go before or after the continuation.

2.3 Wastrumentation Design

Figure 1 depicts at a high-level the instrumentation process of Wastrumentation. We first describe the input provided to Wastrumentation, followed by the instrumentation process and the additional code that is generated. Then we elaborate on how the different modules are merged into a single output program. The numerical labels in the figure allow us to reference to visual elements in the following text.

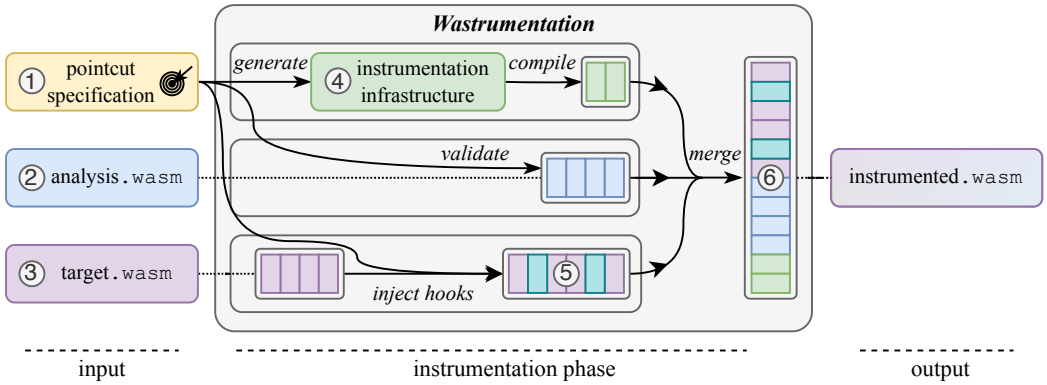

Figure 1 High-level overview of the architecture of Wastrumentation.

Input and Pointcut specification. In what follows, we adopt the pointcut specification terminology from aspect-oriented programming (AOP) to describe Wastrumentation inputs and their relationship. Note, however, that our implementation is limited compared to AOP, as our pointcut specification only supports static instruction targeting. As Figure 1 depicts, the input for Wastrumentation consists of the pointcut specification ①, the analysis program ②, and the target program to instrument ③. The pointcut specification enables selective instrumentation, by declaring the set of program instructions I and the set of functions of interest F within the target program. For example, the Rust implementation of the "denan" analysis in Listing 1 can be compiled to a Wasm module ②, along with a pointcut specification to target all implemented traps $I = \{const, local, global, load, store, unary, binary, apply\}$, and restrict instrumentation to the Wasm functions 4, 5, and 6 of the input program, $F = \{4, 5, 6\}$.

Instrumentation Process. For a given pointcut specification, Wastrumentation validates that the analysis module implements the trap functions corresponding to the specified target program instructions I. This validation takes place by iterating over the set I and validating that each corresponding trap function is exported by the analysis with the proper signature. If validation fails, Wastrumentation aborts the current instrumentation. If validation succeeds, Wastrumentation rewrites the identified instructions I within target functions F to inject hooks to placeholder analysis functions ⑤, according to the strategy explained in Section 2.4.

On-demand Instrumentation Code Generation. Some hooks pass compound data structures to traps functions that go beyond what the primitive number types of Wasm (i32, i64, i64, f64) can represent. For example, the *apply* trap function receives an array of Wasm arguments passed to the intercepted function call (cf. Section 2.4). Wastrumentation will generate additional instrumentation infrastructure as a new module ④. This infrastructure is generated on-demand, based on the input modules at hand. The module is responsible for managing such complex data structures, leaving the other modules untouched.

Bundling and Output. The final phase of Wastrumentation *bundles* the intermediate Wasm modules as a single instrumented module ⑥. To *bundle* these modules, Wastrumentation leverages the tool `wasm-merge` that is provided as part of the Binaryen tools [10]. This tool acts like a linker where multiple modules are merged into one. In doing so, `wasm-merge` replaces module imports that cross-reference other modules' exports with inline references to local functions in the resulting Wasm binary.

Preserving the Program State Space. Injecting analysis code into a target program comes with the challenge of preserving its original behavior. Any changes made during rewriting must not be observable for the input program. This requirement is critical to prevent deviations that could, for example, hide the program from a security analysis. The applied changes during instrumentation cannot interfere with the program state, including its memory, value stack, or call stack. This is unique to Wastrumentation. Other tools, e.g. Wasabi and Wizard, avoid this complexity because their analysis operates in a separate address space within the JavaScript interpreter or at the level of the Wasm interpreter, respectively. Our solution to preserve the input program state departs from the following properties of Wasm.

No Reflection. Wasm disallows runtime reflection regarding program code, the value stack, or the call stack [13]. This ensures that program code cannot inadvertently observe nor modify these components. Consequently, at execution time, the original input program code within the instrumented module remains unaware of the additional instrumentation code structure, values on the value stack and activation records on the call stack.

Separation of Linear Memory. Each memory load and write instruction in the instrumented module is statically tied to a unique memory view. When bundling the different code units (the target program, the analysis module, and additional instrumentation code), Wastrumentation leverages `wasm-merge` to assign distinct memory regions to each code unit. This separation leverages the Wasm standardized Multi-Memory proposal [12]. Multi-Memory enables to statically associate a unique memory index for every memory-related Wasm-instruction. This allows each module to operate exclusively on its unique linear memory index, ensuring complete isolation at runtime.

Figure 2 shows the statically enforced memory separation of merged program modules before and after program bundling. In the figure, the memory-relevant instructions such as `i32.load` and `i32.store` have a static memory index and a dynamic value that dictates the offset in the memory. Whereas each module has instructions addressing on its own set of linear memories, the instrumented module will contain the input program addressing the first indices of linear memory, followed by instrumentation and analysis modules operating at an on-demand decided memory index.

We ensure that the input program remains at its own offset, as external interoperation with the linear memory might make assumptions in the memory index, such as is the case for the widely adopted Wasm System Interface[2].

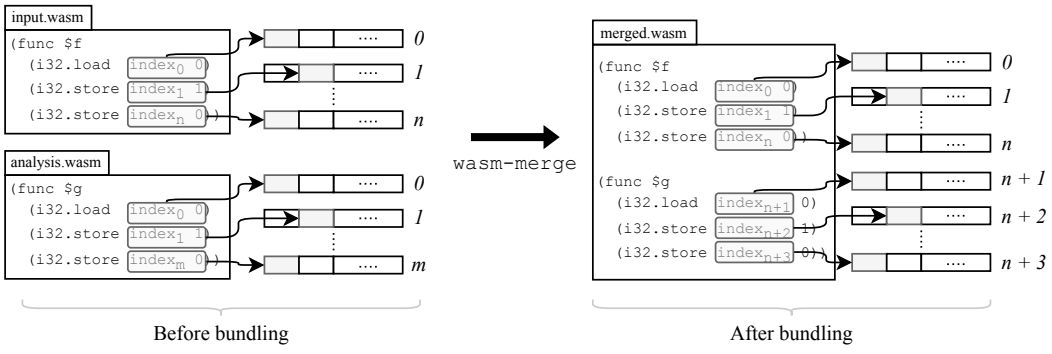

Figure 2 Visualization of the multi-memory access model before and after transformation.

```
(module ;; input analysis
  (func $apply (type $f_base:i32 $buf_sig:i32 $buf_sigtype:i32 $c_arg:i32 $c_res ⇒ void:i32)
    (; pre apply analysis code ;)
    (call $apply_base $f_base $buf_sig)
    (; post apply analysis code ;))
  (import "instrumented_input" "apply_base") (func $apply_base (param i32 i32)))
```

2.4 Instrumentation through Transformation

In what follows we detail the transformation strategy taken by Wastrumentation of the input program. The transformation follows two distinct patterns, one for function applications and another more general pattern for all other operations.

2.4.1 Function Application Instrumentation

The API of the "apply" trap receives a pointer to the *continuation function* and a pointer to a buffer containing the runtime arguments and results. The continuation function represents the next step in the execution flow. For the apply hook, this is the original function being intercepted. As Section 2.2.2 explains, the "apply" trap is responsible for calling the *continuation function* to allow a transparent execution of the target program. Inspired by the CLOS auxiliary "`around:`" method definition [3], the analysis code can (a) manipulate the arguments *before* the *continuation*, (b) determine *when* or *if at all* the function application takes place and (c) manipulate the results *after* the function application.

Listing 2 shows the minimal transparent analysis as a Wasm program that instruments function applications. The only implementation is the trap definition $*apply* (Section 2.4.1) that receives five arguments. The first argument (f_{base}) is a pointer to the *continuation function*. The second and third arguments (buf_{sig}, $buf_{sigtype}$) are pointers to buffers that contain the arguments and results for the current intercepted function application. The last two arguments (c_{arg}, c_{res}) dictate the number of arguments and results for that call respectively (to bound the value access of buf_{sig}, $buf_{sigtype}$). Section 2.4.1 calls the continuation, which may be preceded or succeeded with additional analysis code that is left out of the listing for brevity. Since the implementation of $\$apply_{base}$ resides in the transformed target program, the analysis must declare it as a function import (Section 2.4.1).

Listing 3 shows the input program for the transformation, containing a single function definition $\$f$. Whereas the transformation generalizes to any input set of function definitions, we restrict the example transformation to that of $\$f$ for brevity. Some intentional design considerations that influenced the transformation approach are the following:

- The analysis must be notified of all function applications of a target function, including (a) internal function applications through `call` or `call_indirect` statements local to the target module, (b) external function applications that may stem from the host and (c) for target functions that have no implementation details specification but are defined through an import statement.
- The API of the $*apply* trap is polymorphic for the target function application signature. This design choice enables low coupling between the analysis and the target input program, as the analysis program needs not to monomorphize the $*apply* trap implementation per signature as shown in [19]. Consequently, the analysis implementation must dispatch on function-specific behavior at runtime which may incur a performance penalty.

Listing 4 shows the input program result after transformation. The transformation of target function $\$f$ from Listing 3 results in two definitions $\$f_{original}$ (Section 2.4.1) and $\$f$ (Section 2.4.1). It is transparent to client code of $\$f$ (both internal and external to the Wasm

Listing 3 An input program candidate for dynamic analysis on function applications.

```
(module ;; input program
  (func $f (export "f") (type f_i^m ⇒ f_o^n) body_f))
```

module) since after transformation $\$f$ preserves its identity[3], its signature and its export declaration. However, $\$f$ will now call the trap $\$apply$ defined in Listing 2 with the required information.

In preparation for the call to $\$apply$, $\$f$ first stores arguments and runtime types to buffers (Sections 2.4.1–2.4.1) that $\$apply$ may manipulate at will. Next, $\$f$ yields control flow to $\$apply$ (Section 2.4.1), after which the results are loaded from the buffers (Sections 2.4.1–2.4.1) and eventually $\$f$ returns. The arguments to $\$apply$ (Section 2.4.1) are 0, the function pointer to the continuation function index in the table $\$table_{base-functions}$, the pointers $\$buf_{sig}$ and $\$buf_{sigvalues}$ pointing to the value- and types-buffers respectively and the the number of arguments m and results n.

If the trap $\$apply$ in Listing 2 calls the continuation $\$apply_{base}$, in Listing 4 the applicable continuation is resolved at runtime with the function pointer argument $\$f_{base}$ that is looked up in the function table $\$table_{base-functions}$ (Section 2.4.1). The call to the resolved applicable continuation $\$f_{base}$ loads the arguments from the buffer $\$buf_{sig}$ (Section 2.4.1) and calls $\$f_{original}$ (Section 2.4.1), after which the results are stored to $\$buf_{sig}$ (Section 2.4.1) and control is yielded to the post-analysis code in the trap $\$apply$.

Listing 4 The input program from Listing 3 after the instrumentation phase.

```
(module ;; input program, instrumented
  (func $f_original (type f_i^m ⇒ f_o^n) body_f)
  (func $f (export "f") (type f_i^m ⇒ f_o^n)
    (local $buf_sig i32) (local $buf_sigtype i32)
    ;; push values on stack
    (local.get 0) (local.get 1) ... (local.get m)
    ;; store args & types to instr-module-heap from value stack
    (local.set $buf_sig (call $alloc-vals-f_i^m-f_o^n))
    (local.set $buf_sigtype (call $alloc-typs-f_i^m-f_o^n))
    ;; call analysis apply
    (call $apply 0 $buf_sig $buf_sigtype m n)
    ;; retrieve results from instr-module-heap onto value stack
    (call $free-vals-f_i^m-f_o^n)
    (call $free-typs-f_i^m-f_o^n))
  (func $f_base (type $buf_sig:i32 ⇒ void)
    ;; retrieve args from instr-module-heap onto value stack
    (call $load-args-f_i^m-f_o^n (local.get $buf_sig))
    ;; call original body
    (call $f_original)
    ;; store results to instr-module-heap from value stack
    (call $store-results-f_i^m (local.get $buf_sig)))
  (import "analysis" "apply" (func $apply (type i32 i32 i32 i32 i32 ⇒ void)))
  (import "instr" "alloc-vals-f" (func $alloc-vals-f_i^m-f_o^n (type f_i^m ⇒ i32)))
  (import "instr" "alloc-typs-f" (func $alloc-typs-f_i^m-f_o^n (type void ⇒ i32)))
  (import "instr" "load-args-f" (func $load-args-f_i^m-f_o^n (type i32 ⇒ f_i^m)))
  (import "instr" "store-results-f" (func $store-results-f_i^m (type i32 ⇒ f_o^n)))
  (import "instr" "free-vals-f" (func $free-vals-f_i^m-f_o^n (type i32 ⇒ void)))
  (import "instr" "free-typs-f" (func $free-typs-f_i^m-f_o^n (type i32 ⇒ void)))
  (table $table_base-functions [$f_base] funcref)
  (func (export "apply_base") (param $f_base i32) (param $buf_sig i32) ;; => void
    (call_indirect $table_base-functions (type i32 ⇒ void) $f_base)))
```

[3] Identifiers are defined as alphanumeric tokens prefixed with a $-sign. In practice, Wasm functions are defined by an index as an i32-value, so a function name is actually a number that dictates its index.

The buffers used to communicate the runtime arguments and results between the function application, the analysis trap and the continuation function are handled by an external "instrumentation" module. This "instrumentation" module can orchestrate its linear memory while leaving the linear memory of the input program and the analysis code untouched. Functions to allocate and free memory, to load and store values in the buffers are imported in the instrumented module (Sections 2.4.1–2.4.1) and can be imported by the input analysis, though the pre- and post-analysis code is left out.

2.4.2 General Program Operation Instrumentation

All other instructions follow more concise rewrite strategies by Wastrumentation. These rewrite strategies rewrite each target operation into instructions that prepare context information on the value stack, followed by a call to an associated analysis trap function.

Table 2 summarizes the rewrite strategy, grouping instructions with similar rewrite patterns. The "Original instruction" column lists the unaltered instructions, while the "Rewritten instruction" column shows the instrumented result. The trap function is denoted as "$trap" for brevity but is specific to each instruction, such as "$return" for "return" or "$br" for "br".

As shown in Table 1, each trap function also receives the instruction's location. To provide this information, two constants (function index and instruction offset) are pushed on the stack before each trap call. These details are omitted from Table 2 for simplicity.

Maintaining the transformed program's well-typed property is essential. Thus the instrumented hooks must preserve the type correctness, including their interaction with the VM stack. Therefore, the analysis may modify the values handled by the target program, but it cannot alter their types. For instance, the rewrite of $t.\mathsf{const}\ c$ involves pushing the constant onto the value stack, followed by a call to the trap function "$const". This trap function receives the constant, returning a value of the same type while controlling its final value. Similarly, instructions like $t.unop$ and $t.binop$ are replaced with trap function calls that take the instruction operands and compute the resulting value on behalf of the program. The operands are available on the stack as they must have been for the original instruction.

For control-flow-related instructions such as "br-if", "br-table", and "select", the rewrite introduces a preceding trap function that controls the dynamic control flow. For "br-if" and "select," this is an `i32` value representing the condition. For "br-table," it is an `i32` value selecting a branch label from the statically predefined table associated with the instruction.

Instructions like "if-then-else", "if-then", "call-indirect", "call", "block", and "loop", include both pre- and post-trap functions. This design allows the analysis to trace the flow of execution per instruction, as additional instrumented code can be executed in between. For "if-then-else" and "if-then," the pre-trap function may modify the boolean condition controlling the flow. In contrast, trap functions for "return" and "drop" are observational, i.e. unable to alter control flow. For instructions like "local-get," "global-get," "local-set," "local-tee," "global-set," and "global-tee," the trap functions can alter the values being read or written to the respective variables.

3 Implementation

We implemented Wastrumentation in Rust and modularized the platform across different crates for improved maintainability and reusability. The core crate, as described in Figure 1, is responsible for transforming an input program based on a given analysis specification and pointcut specification. This crate consists of 5,118 lines of Rust code.

Table 2 The transformations applied by Wastrumentation.

Original Instruction	Rewritten instruction	Transformation description
	const	
t.const *c*	*t*.const *c*	Push constant on top of stack (TOS).
	call $trap	Call trap with constant, return value is result.
	unary, binary	
		Operands are on TOS, will be args to trap.
t.unop	*call* $trap	Call trap, return value is instruction result.
	br, br-if, br-table, select	
	(i32.const *l*)	Serialize target label ("br").
	call $trap	Call trap, passing serialized target label.
br *l*	br *l*	Return value of trap can change control flow for "br-if" and "br-table" and "select".
	if-then-else, if-then	
	(*call* $trap$_{pre}$ (i32.const *n*) (i32.const *m*))	Call pre-trap with blocktype arity: *n* input values on stack, *m* result values on stack.
if *blocktype* *instr**	if *blocktype* *instr**	Return value of pre-trap can alter control flow.
	(*call* $trap$_{post}$)	Call post-trap.
else	else	
instr*	*instr**	
	(*call* $trap$_{post}$)	Call post-trap.
end	end	
	call-indirect, call	
	i32.const *x*	Push f-idx ("call") or tbl-idx ("call-indirect").
	(*call* $trap$_{pre}$)	Trap does not take call args, only context.
call_indirect *x y*	call_indirect *x y*	To view or alter args / results, use trap *apply*.
	(*call* $trap$_{post}$ (i32.const *x*))	Call post-trap.
	block, loop	
	(*call* $trap$_{pre}$ (i32.const *n*) (i32.const *m*))	Call pre-trap with blocktype arity.
block *blocktype* *instr**	block *blocktype* *instr**	
end	end	
	(*call* $trap$_{post}$ (i32.const *n*) (i32.const *m*))	Call post-trap with blocktype arity.
	return, drop	
	call $trap	Call trap before instruction.
return	return	Trap can only observe, not alter semantics.
	local-get, global-get	
local.get *x*	local.get *x*	Push value on the value stack.
	(*call* $trap (i32.const *x*))	Call trap, return value is instruction result.
	local-set, local-tee, global-set, global-tee	
	(*call* $trap)	Instruction argument is TOS, call trap.
local.set *x*	local.set *x*	Trap may alter argument for instruction.

The core crate accepts only Wasm modules as analysis inputs, as explained in Section 2.3. However, these analyses must adhere to the analysis ABI (see Appendix A in [25]), which is typically not written by hand. To facilitate interaction with this ABI, we developed a domain-specific language (DSL) that exposes the high-level API described in Section 2.2. The primary and most mature implementation of this DSL is written in Rust as a set of Rust macros, and it is used in our evaluation (in Section 4). We also have a less mature implementation written in AssemblyScript as an AssemblyScript library, demonstrating the language agnosticism of the analysis ABI. The Rust DSL comprises 1,943 lines of code, and the AssemblyScript DSL, which currently only partially abstracts the low-level ABI, consists of 450 lines of code. Figure 3 illustrates how the analysis, along with the DSL implementation, is compiled into a Wasm module that serves as input for Wastrumentation. Note that once an analysis is compiled to a Wasm module, the trap functions must adhere to the statically typed signature in the ABI (Appendix A in [25]), or otherwise, Wastrumentation will reject the analysis.

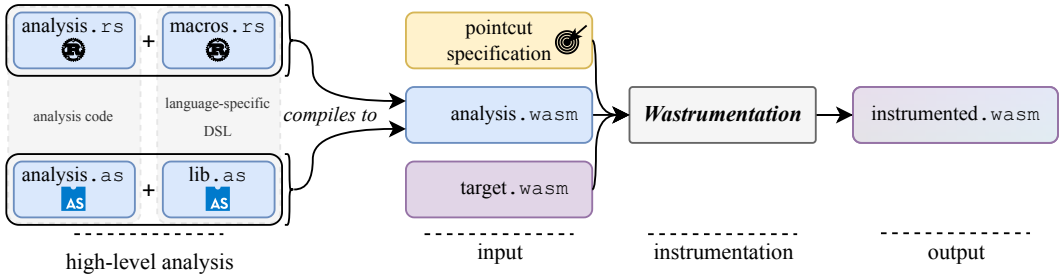

Figure 3 Overview of implementing analyses for Wastrumentation using a high-level language.

Rust and AssemblyScript are also supported for generating the instrumentation infrastructure. The code to generate the instrumentation infrastructure in either language amounts to a total of 4,451 lines of Rust code. Note that other languages can be supported, as long as a Rust-wrapper library can built around them, that implements the compiler interface used by Wastrumentation to compile the high-level program to a Wasm module.

4 Evaluation

We evaluate our work to check whether Wastrumentation is suitable for building dynamic analyses for Wasm applications. To this end, we assess the practicality and performance of our approach. We conduct several experiments to answer the following research questions (inspired by the ones found to evaluate other instrumentation platforms [19, 33, 35, 8, 38]):

RQ1. Does Wastrumentation aid the development of dynamic analyses compared to state-of-the-art approaches?
RQ2. Do the instrumented Wasm programs remain faithful to their original execution?
RQ3. How much does the code size increase after transformation?
RQ4. What is the runtime overhead due to instrumentation?
RQ5. What is the memory overhead due to instrumentation?

4.1 Methodology

We performed our experiments on two machines. The first is a server running Ubuntu 24.04.1 LTS (GNU/Linux 6.8.0-48-generic x86_64). The server has an AMD Ryzen 9 7950X processor (16 cores, 32 threads, 4.5–5.7GHz) and 128GB of main memory. The second machine is an Apple Mac Mini, with an M4 processor (4 performance and 6 efficiency cores) and 24GB of main memory.

We employed WasmR3 [1] commit 299be52, as target for a set of dynamic analyses. This benchmark suite includes 27 programs and serves as a reference for "realistic and standalone Wasm benchmarks" based on a 2024 record-reduce-replay pass of real-world programs.

To compare our approach to three state-of-the-art tools operating at three different levels:

- We use Wasabi to compare our approach to another source code instrumentation platform. We patched it to be compatible with WebAssembly 2.0 programs, commit ee2fb70
- We use Binaryen v122 to compare to a bytecode rewriting framework.
- We use Wizard [38] commit 1810b61 (compiled with Virgil [37] commit e64483e) to compare to a VM-level Wasm instrumentation framework.

In terms of runtimes, we execute Wasabi on Node V22.5.1, and we execute standalone Wasm programs on Wasmtime V30.0.2 and the aforementioned version of Wizard.

To avoid skewed results due to the VM warmup time or noise from other processes on the system, we compute the median of 30 executions of the target Wasm program for each individual runtime instance. When deploying an analysis with an instrumentation platform, we target every function of the input program and enable instrumentation for every program operation that the analysis depends on.

4.2 RQ1: Evaluating the Development of Dynamic Analysis Using Wastrumentation

To evaluate how Wastrumentation aids the development of dynamic analyses compared to state-of-the-art approaches, we implemented twelve dynamic analyses summarized in Table 3. The analysis code is written in Rust.

Table 3 The dynamic analyses implemented in Wastrumentation. We include the type of hooks and lines of code for the analyses in Wastrumentation and Wasabi. Those cells marked with ✗ correspond to analyses not possible to implement in Wasabi. The hooks used in [a] ("Basic Block Profiling") are `if_then_else, if_then, call pre, call_indirect pre, block pre, loop_ pre`, in [b] ("Branch Coverage") `if_then_else, if_then, br_if, br_table, select` and in [c] ("DeNaN") `apply, unary, binary, const_, local, global, load, store`.

Analysis Name	Hooks		Lines of code	
	Wasabi	Wastrumentation	Wasabi (JavaScript)	Wastrumentation (Rust)
Instruction Mix	all	all (introspection)	62	81
Basic Block Profiling	`begin`	6[a]	11	33
Instruction Coverage	all	all (introspection)	16	52
Branch Coverage	`if, br_if, br_table, select`	5[b]	21	30
Call Graph	`call_pre`	`call pre`	29	52
Dynamic Taint	all	all (introspection)	272	500
Memory Access Tracing	`load, store`	`load, store`	99	107
Cryptominer Detection	`binary`	`binary`	10	32
Forward	all	all	26	33
Denan	✗	8[c]	✗	35
Safe Heap	✗	`load, store`	✗	69
Memoization	✗	`apply`	✗	82

The first eight analyses in Table 3 ("Instruction Mix", "Basic Block Profiling", "Instruction Coverage", "Branch Coverage", "Call Graph", "Dynamic Taint", "Memory Access Tracing", "Cryptominer Detection") are analyses we ported from Wasabi [19][4]. We use the Wasabi analysis implementations available on the latest commit 21a322b in their public repository. The lines of code for the ported implementation in Rust remain in the same order of magnitute than those implemented in JavaScript for Wasabi. The main reason for the code size increase is to conform with the Rust type system and borrow checker (e.g., strict typing, synchronize on mutable global state). The ported analyses show that Wastrumentation does not sacrifice in terms of its ability to implement existing analyses.

The latter four analyses in Table 3 ("Forward", "DeNaN", "Safe Heap", "Memoization") are new analyses. More concretely, we implemented "Forward" in both platforms, and the last three are novel analyses that require intercession (which is not supported in Wasabi). We describe those analyses in what follows.

[4] Due to space constraints, the code for those analyses is included in the artifact. The semantics of the analyses are the same as they were implemented for Wasabi for the evaluation [19].

- **Forward**. This analysis implements all trap functions without altering the original program (cf. Table 1, column "Transparent Base"). It provides insight into the instrumentation platform's minimum performance overhead as no additional analysis code is included. Section 4.3 also uses it as a reference analysis to validate that input programs remain faithful to their execution semantics after instrumentation.
- **Denan**. This analysis replaces all `NaN`-floating point values in the program with the floating point value zero. The analysis is inspired by the "`--denan`" instrumentation pass from Binaryen. Section 2.1 showed our implementation and Section 4.2.2 compares it to the ad-hoc implementation in Binaryen.
- **Safe Heap**. This analysis checks for incorrect heap access. It is inspired by the "`--safe-heap`" instrumentation pass from Binaryen. Listing 5 shows its implementation and Section 4.2.2 compares it to the ad-hoc implementation in Binaryen. For every load or store operation, the analysis checks null dereferencing, reading past available memory and usage of addresses with incorrect memory alignment (Sections 4.2–4.2).
- **Memoization**. This analysis implements a memoization strategy of pure functions [24]. Its goal is to cache the outcome of pure function applications to save on repeated computation efforts. Section 4.2.1 details our implementation.

For didactical purposes, we omit (1) synchronization primitives on global state, (2) type casting and (3) method invocations for type conversion in Listing 5 and Listing 6.

Listing 5 Implementation of Binaryen's "`--safe-heap`" pass in Wastrumentation.

```
use wastrumentation_rs_stdlib::*;

const WASM_PAGE_SIZE:i64 = 65_536;
fn bounds(idx:i64,byts:i64,ofst:i64) {
 // strict_add: assert no overflow
 let last_idx_byte =
  idx.strict_add(byts).strict_add(ofst);
 assert!((last_idx_byte != 0) &&
  (last_idx_byte <=
   (base_memory_size(0)) *
    WASM_PAGE_SIZE)); }

// turn size into bitmask (‘-1‘), then
// assert mask-region is zero-only (‘&‘)
fn alignment(idx:i64, size:i64) {
 // size == 4 (_32) | 8 (_64)
 assert!(idx & (size - 1) == 0); }

advice! {
 load (i:LoadIndex,o:LoadOffset,
       op:LoadOperation,l:Loc) {
  bounds(i,op.target_size(),o.offset());
  alignment(i,op.target_size());
  op.perform(&i,&o)
 }
 store (i:StoreIndex,v:WasmValue,
        o:StoreOffset,op:StoreOperation,
        l:Loc) {
  bounds(i,op.target_size(),o.offset());
  alignment(i,op.target_size());
  op.perform(&i,&v,&o); } }
```

Listing 6 A dynamic analysis implementation that caches the result of stateless function.

```
use std::collections::HashMap;
use wastrumentation_rs_stdlib::*;

struct Key{fn_idx:i32,ags:Vec<Byte>}
static mut CACHE:HashMap<Key,Vec<Value>>
 = HashMap::new();

fn cache_hit(key:&Key) -> bool {
 CACHE.contains_key(&key) }

fn cache_retrieve(
 key:&Key, results:&mut Results) {
 CACHE.get(&key).unwrap().into_iter()
  .enumerate().for_each(|(i, v)|
   results.set_res(i, v.to_owned()));
}

fn cache_insert(key:Key, rss:&Results) {
 let rss = rss.rss_iter().collect();
 CACHE.insert(key, rss);
}

advice! { apply (
 fnc:WasmFn, ags:Args, rss:Results) {
  let ags = ags.map(to_bytes).collect();
  let key = Key {fn_idx: fnc.idx, ags};
  if cache_hit(&key) {
   cache_retrieve(&key, &mut rss);
  } else {
   fnc.apply();
   cache_insert(key, &rss); } } }
```

4.2.1 The Memoization Analysis

We now discuss the details of the memoization analysis. Listing 6 shows its implementation in Wastrumentation. The analysis maintains a global hashmap as *cache* where it associates a function index and its arguments with the results for that function call (Sections 4.2–4.2). The analysis targets the *apply* trap since only function applications will be memoized (Section 4.2). The trap implementation computes the cache key (Sections 4.2–4.2) and returns the associated result values if the key is stored in the cache. If the cache had no associated entry for the computed key, the function application continues and the computed result is stored in the cache for successive function applications (Sections 4.2–4.2).

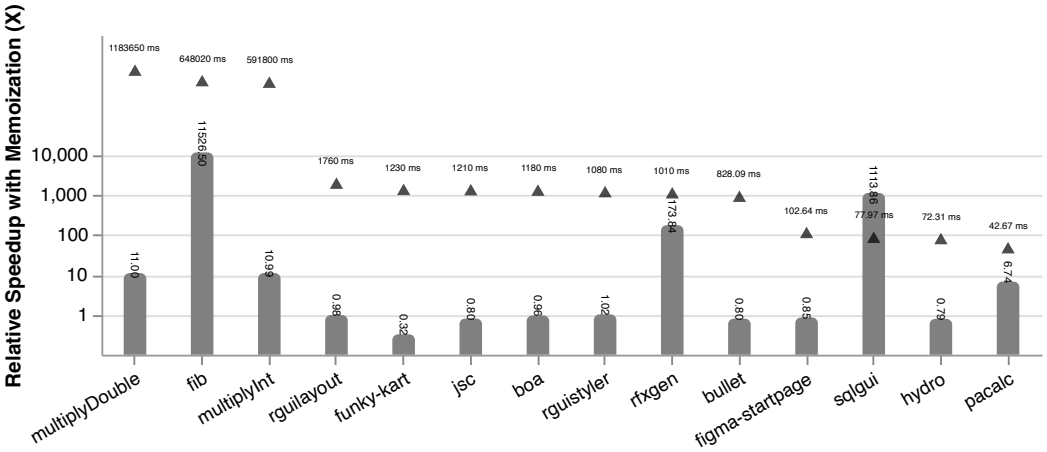

Figure 4 Execution times after instrumentation with the memoization analysis. The programs are sorted by their absolute runtime in miliseconds (▲) from left to right. The bar charts indicate the relative speedup on a logarithmic scale.

To assess the effectiveness of the memoization analysis, we conduct an experiment to check whether it would benefit the programs in the WasmR3 benchmark suite executed on Wasmtime. We first perform a static analysis phase to identify the programs with pure functions which could be good candidates for memoization. This phase identified 14 candidate programs (out of the 27) featuring pure functions. Figure 4 plots the measured runtimes of those programs and their instrumented variants. Our results show that the analysis can incur a performance penalty for some programs, and it can speed up others. The performance penalty ranges from 1.02x slowdown (rguilayout) to 3.10x slowdown (funky-kart), while the speed-up ranges from 1.02x speedup (rguistyler) to 1,1526.50x speedup (fib). This experiment shows that such analyses can be developed at low cost for exploration, and yield the potential to then be ported within concrete VM implementations if they offer promising results.

4.2.2 Comparison to Bytecode Rewriting Frameworks

As mentioned before, state-of-the-art dynamic analysis platforms for Wasm do not support intercession, but bytecode rewriting frameworks such as Binaryen [10] and Walrus [32] do. We observe that Binaryen v122 offers six instrumentation passes: "`--safe-heap`", "`--denan`", "`--instrument-locals`", "`--instrument-memory`", "`--log-execution`", "`--trace-calls`". Out of the six, all offer support for intercession except for "`--log-execution`" . Unfortunately, the "`--denan`" analysis is the only instrumentation pass that rewrites the input program into a variant that can execute standalone. All other instrumentation passes rewrite the target

program such the host must implement a part of the analysis, eg. what to perform when observing reads or writes into locals for the "`--instrument-locals`" pass. This couples the analysis with host-provided functionality. Titzer et al. developed in [38] two standalone ad-hoc analyses, "branches" and "opcodes", in the Walrus bytecode rewriting framework. To further evaluate RQ1, we compare the implementation of these three ad-hoc analysis implementations ("DeNaN", "branches", and "opcodes") that can execute standalone with an equivalent analysis on Wastrumentation.

When comparing the implementation of a given analysis on Wastrumentation to an ad-hoc solution, we observe three main limitations of bytecode rewriting frameworks.

Higher implementation effort. We observe repeated efforts of constructing the low-level Wasm constructs and injecting these within the target program when using bytecode rewriting frameworks. This most notably affects the code size of the analyses: "DeNaN" (195 LoC on Binaryen, 35 on Wastrumentation), "branches" (291 LoC on Walrus, 24 on Wastrumentation), and "opcodes" (242 LoC on Walrus, 81 on Wastrumentation). The lines of code for analyses in Wastrumentation are smaller since the transformation efforts are reused among analyses as they happen within Wastrumentation and Wasm-Merge.

Semantic abstraction loss. We observe a notable loss of high-level semantic expressiveness in bytecode rewriting systems because analysis implementations are restricted to low-level, elementary operations due to the lack of access to rich abstractions, such as complex data structures and a strong type system. For example, "DeNaN" analysis is limited to changing a value to 0 while the "branches" and "opcodes" increment a fixed set of global counters by 1. The other analyses implemented by Binaryen ("`--safe-heap`", "`--instrument-locals`", "`--instrument-memory`", "`--log-execution`", "`--trace-calls`") avoid additional complexity by forcing the analysis developer to implement more complex data structures within the host, such as logging infrastructure, hashmap dictionaries, or debugging infrastructure. In contrast, implementing the analyses on a general-purpose analysis platform is easier since developers do not need to manipulate Wasm instructions nor ensure the type safety of the analysis code. In Wastrumentation, developers can implement the analysis using a high-level API and in a high-level language like Rust. This reduces the complexity of the analysis by raising the abstraction level, allowing for a compiler to type-check, validate, and optimize the analysis code.

Lack of Separation of Concerns. We observe the analysis logic is tightly interwoven with the transformation pass, resulting in reduced modularity and maintainability. This means that instructions such as 'increment a counter' (analysis code) are scattered among instructions such as 'extend target body with increment' (transformation code). Wastrumentation decouples these concerns by treating the analysis implementation as a unit separate from the instrumentation phases. As a result, it becomes easier to maintain, comprehend, and evolve the semantics of the analysis independently from instrumentation.

Finally, we would like to note that the Binaryen instrumentation pass "DeNaN" is incomplete. The implementation of the "`--denan`" pass in Binaryen documents does not support the instrumentation of `local.get`, as doing so "would cause problems if we ran this pass more than once (the added functions use gets, and we don't want to instrument them)" [11]. Since Wastrumentation decouples instrumentation from the analysis implementation, the instrumentation of `local.get` operations do not run the risk that analysis code and its instructions of `local.get` are instrumented too.

Table 4 Violated assertions when deploying the Forward analysis using Wastrumentation on the Wasm official test suite.

	Tool	Execution Stage	Warning	# Modules	# Assertions
(1)	Wastrumentation	Transformation	Expected type f64, got f32	1	0
(2)	Wasm-Merge	Transformation	Unknown misc operation	8	36
(3)	Wasmtime	Runtime	Uninitialized element	4	4
(4)	Wasmtime	Runtime	Equality assertion failure	2	2
(5)	Wasmtime	Validation	Undeclared func. reference	2	8

4.3 RQ2: Evaluating the Faithful Execution

We take an experimental approach to validate that input programs remain faithful to their execution semantics after instrumentation. We validate that instrumented programs maintain structural integrity and correct execution semantics across (a) the 4,082 programs in the official Wasm test suite and (b) the 27 programs in the WasmR3 benchmark suite.

To validate the faithful execution of the 4,082 programs from the official Wasm test suite, we instrumented them with the "Forward" analysis (presented in Section 4.2). This analysis targets every supported trap without altering the semantics of the original program. The official Wasm test suite includes 26,632 assertions. We disabled those that assert failures (i.e., assertions that expect an invocation to trap)[5], as the goal of the experiment is to show that the "Forward" analysis does not alter successful tests. Disabling assertions on failures ensures proper execution of subsequent assertions. Otherwise, an exception in the input program halts the module's execution, preventing the instrumentation code from being notified and unable to clean up its internal state[6]. While the forward analysis is stateless, the instrumentation infrastructure remains stateful with respect to the apply trap (cf. Listing 4). For this reason, we disable failure assertions to retain all success assertions.

For the remaining 21,392 assertions, Wastrumentation has a success rate of 99.77%, with only 50 assertions failing across 17 modules. Table 4 categorizes the failures by the tool reporting the failure (Wastrumentation, Wasm-Merge, or the Wasmtime runtime), the stage at which the failure occurred (Transformation, Validation, or Runtime), the reported warning, the number of affected modules, and the number of affected assertions.

Failure (1) stems from `wasabi-wasm` [17], the underlying transformation library used by Wastrumentation which fails to infer the types of the input program. Failure (2) originates from Wasm-Merge, which cannot identify an input operation. We suspect this can be solved by enabling more feature flags provided by Wasm-Merge as they enable more Wasm instructions. Failure (3) results from uninitialized elements (static declared Wasm memory segments), which Wastrumentation does not directly manipulate. This issue could be addressed with further investigation into the serialization of our transformed module or the merge step. Failure (4) is a runtime failure caused by disabling previous assertions after they failed, violating the expected state. Finally, failure (5) requires more investigation.

In a second experiment, we verify Wastrumentation using the 27 programs of the WasmR3 benchmark suite across all 12 analyses listed in Table 3. For each input program in the WasmR3 and each analysis, we used `wasm-validate`, a Wasm binary validation tool, to verify the structural integrity of the code after instrumentation. The results showed no errors reported by `wasm-validate` for any of the analyses, confirming that Wastrumentation produces valid Wasm code that fully adheres to the requirements of the Wasm binary format.

[5] The following assertions (including count) were disabled: "assert_invalid" (1,476), "assert_trap" (2,388), "assert_exhaustion" (15), "assert_malformed" (1,277), "assert_unlinkable" (84).

[6] A proposal for Wasm exception handling is not yet standardized. If it were standardized, a set of exceptions could be accommodated by the instrumentation platform to clean up the analysis state.

4.4 RQ3: Evaluating Code Size Increase

We now compare the code size increase of Wastrumentation with respect to the state-of-the-art source code instrumentation platform Wasabi. To compare binary output size after instrumentation for both platforms, we computed $s = \frac{\mathsf{code{-}size}_{\mathsf{wasabi-instrumented}}}{\mathsf{code{-}size}_{\mathsf{wastrumentation-instrumented}}}$. This ratio s indicates where Wastrumentation-instrumented programs require fewer bytes ($s > 1$) or when Wasabi-instrumented programs require fewer bytes ($s < 1$).

We calculated the s ratio for each instrumentation of the WasmR3 benchmark suite using the dynamic analyses supported by both platforms. More concretely, the dynamic analyses used are the first eight analyses in Table 3 along with an adapted version of the "Forward" analysis. To ensure a fair comparison, we modified our "Forward" analysis to only include hooks that are compatible with Wasabi.

Note that, for Wasabi, the analysis logic is implemented on the JavaScript side, whereas, in Wastrumentation, it is embedded as Wasm code within the instrumented binary. Since JavaScript and Wasm serve different execution models and cannot be directly compared, we exclude the JavaScript analysis implementation from the code size comparison for Wasabi's instrumented programs to ensure a fair evaluation.

4.4.1 Results

Figure 5 shows the ratio s for each instrumentation in the cross-product. In cases where Wasabi failed to instrument a specific input program, we leave the cell blank as no ratio can be computed. Additionally, Figure 6 shows the size of the input programs prior to any instrumentation. The code size increases for each platform individually are presented in Appendix B in [25].

Out of a total of 180 successful ratios, 140 indicate the output Wasm module code generated by Wastrumentation is smaller, while the remaining 40 favor Wasabi. The analyses "Basic Block Profiling", "Branch Coverage" and "Call Graph" tend to favor Wasabi, which aligns with the low number of target operations in these analyses (6, 5 and 1, respectively). For the other analyses, which involve a larger number of traps, the size ratio generally favor Wastrumentation, resulting in smaller binary sizes compared to Wasabi.

The noticeable "red stripe" for the input program "game-of-life" indicates a significant advantage for Wasabi's instrumentation. This is largely due to the significant difference in binary sizes among the input programs. Whereas "game-of-life" has an uninstrumented size of just 1.199 bytes, the other input programs range from 38.965–22.264.896 bytes. This suggests that Wastrumentation introduces a relatively larger size overhead for smaller programs compared to Wasabi, which may be expected as this metric counts for Wastrumentation the additional analysis code, whereas it does not count the JavaScript analysis code for Wasabi.

4.5 RQ4: Evaluating the Runtime Overhead of Wastrumentation

To assess the runtime overhead of Wastrumentation, we performed 4 experiments. The first experiment evaluates the runtime overhead for Wastrumentation for its load, validate and execution of the "Forward" analysis. The second experiment computes the execution overhead of Wastrumentation for the 12 analyses discussed in Table 3. The third experiment compares the runtime overhead to the Wasabi source code instrumentation platform. Lastly, we compare the performance overhead to state-of-the-art bytecode rewriting frameworks.

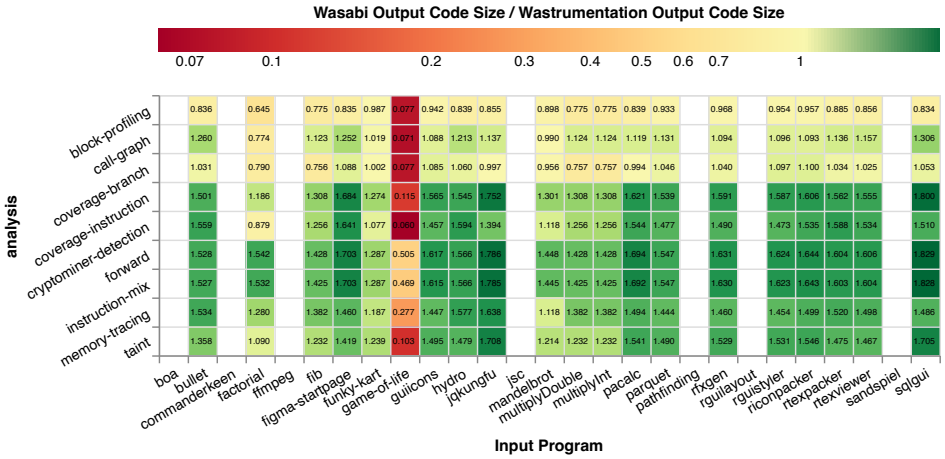

Figure 5 Code size ratio of Wasabi-over Wastrumentation-analyzed programs.

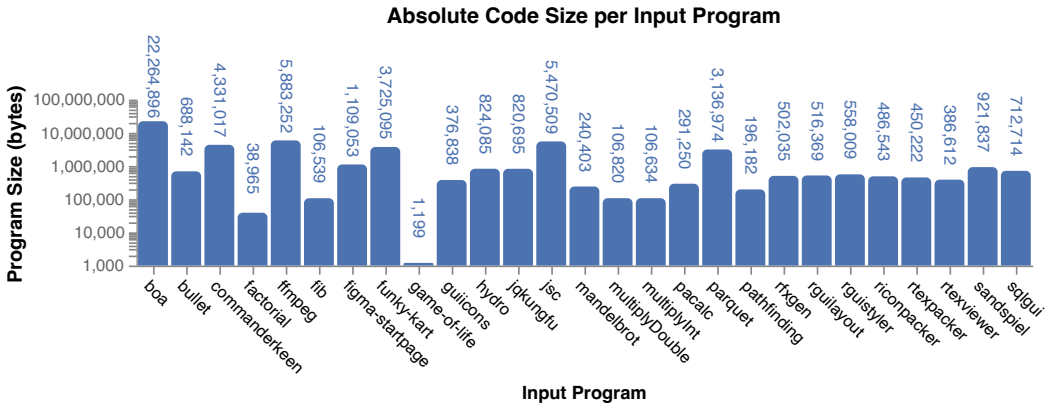

Figure 6 Code size of input programs from the WasmR3 benchmark suite.

4.5.1 Load, Validate and Execute Time

In this section, we evaluate the cost of loading, validating and executing programs for each stage for the input programs of the WasmR3 input suite when instrumenting with the "Forward" analysis. Figure 7 plots the overhead for each stage for 20 instrumented input programs with Wastrumentation. The overhead is computed using the Wizard engine. The median is computed for both the uninstrumented and instrumented variant over 30 runs. For the remaining input programs, 5 timed out, and 2 could not execute.

We observe that the relative increase for loading and validating an instrumented variant correlates with the absolute code size increase from Section 4.4. This is because both phases require reading the input program into the execution engine and performing a static validation on it. For loading, this is in the range 1.13–5.37, for validating in the range 1.84–5.65.

Second, we observe that the increase in execution time spent for the input programs differs significantly depending on the input program. We further ported 10 analyses other than "Forward" to Wastrumentation for further comparison, however other analyses execution failed with the message "`!trap[MEM_OUT_OF_BOUNDS]`". We believe this error does not originate for the "Forward" analysis since it does not reserve additional linear memory in that analysis code. To the best of our knowledge, this may point out a regression for the Wizard baseline engine, since no such exceptions occurred when executing the same experiments on other execution engines such as NodeJS, Wasmtime, and Wasmer.

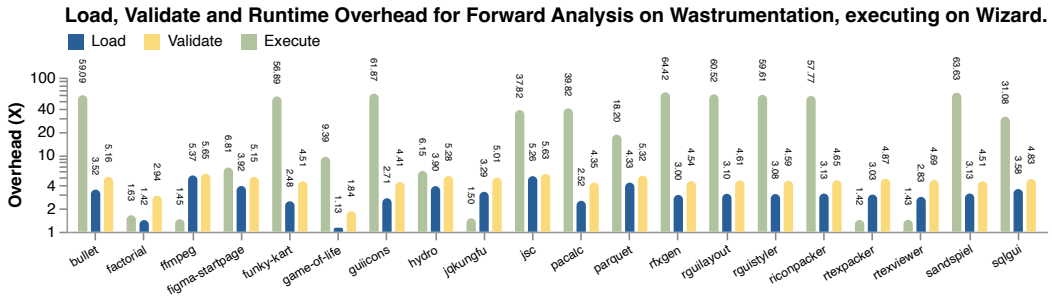

Figure 7 Overhead for loading, validating and executing time after instrumenting WasmR3 programs with the "Forward" analysis on Wastrumentation, executing on Wizard.

4.5.2 Setup for NodeJS experiments

To determine the runtime overhead of Wastrumentation, we compute the ratio o as the performance of instrumented execution relative to uninstrumented execution. An o value of 2 means instrumentation slows the execution time down by a factor of 2.

To compare the performance overhead for Wastrumentation and Wasabi, we computed a ratio p as the execution time of a Wasabi-instrumented module relative to the execution time of a Wastrumentation-instrumented module. A value $p > 1$ indicates Wastrumentation-instrumented execution requires less time to complete, and a value of $p < 1$ indicates Wasabi-instrumented execution requires less time to complete. For example, a p value of 0.5 means that "Wasabi is twice as fast at runtime to analyse the program", while a p value of 2 means that "Wastrumentation is twice as fast at runtime to analyse the program".

Similar to Section 4.4, we compute the ratio's o and p for the programs in WasmR3 using the analyses supported by both platforms. We profile the execution of uninstrumented and instrumented programs using the performance observation API from NodeJS "perf_hooks". The recorded times do not include the program loading from main memory or the verification or compilation of the module. As mentioned in Section 4.1, we calculate the median of 30 executions of the program within a single NodeJS instance. During our experiments, the execution of an instrumented program was limited to a timeout of 300 seconds.

4.5.3 Runtime overhead of Wastrumentation

Figure 8 shows the results for the overhead ratio o. The white cells indicate missing data, either due to the instrumented execution exceeding the timeout (T) or due to raising an uncaught exception (MD). In total, 51 combinations timed out, while 1 raised an uncaught exception ("memory-tracing" for the input program "pathfinding").

The results show that the instrumentation overhead for Wastrumentation ranges from 1x–514.0x. The analyses "coverage-instruction" and "taint" generally incur a higher overhead of 5.5x–514.0x and 12.85x–376.9x, respectively. These analyses are, however, heavy-weight as they implement all traps and maintain heap-allocated data structures that grow during the target program execution (a coverage hashmap and growable vectors, respectively). Nevertheless, Wastrumentation's overhead aligns with expectations for similar source code instrumentation platforms such as Wasabi [19], Jalangi [33] and Aran [6].

4.5.4 Comparison to Wasabi

Figure 9 shows the results for p ratio used to compare the runtime overhead for Wastrumentationand Wasabi. Note that figure only plots 20 input programs, as 7 input programs could not be instrumented by Wasabi so no ratio could be computed. The white cells indicate missing data, labeling T for "timeout", followed by the platform "M" (Wastrumentation), "S" (Wasabi) or "M&S" (both). For a total of 180 combinations where both Wastrumentation and Wasabi yield a valid instrumented module, 140 combinations yield a measurement. For 31 combinations both Wastrumentation and Wasabi timeout. For Wastrumentation an additional 3 combinations timeout and for Wasabi an additional 6. The performance overhead individually per platform for additional reference are further detailed in Appendix C in [25].

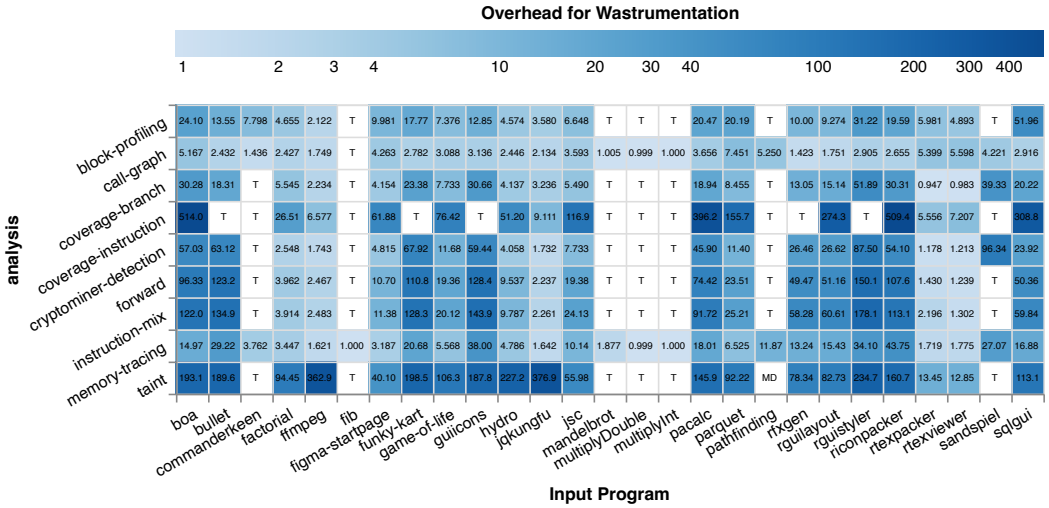

Figure 8 Execution overhead for instrumenting programs using Wastrumentation. Instrumentation is done for the cross-product of shared dynamic analyses and the WasmR3 benchmark suite.

The results of this experiment show that the distribution does not favor any particular instrumentation platform. Overall, the most suitable platform is determined by the specific input program, rather than the type of analysis applied. For example, for some input programs ("figma-startpage"–"hydro") Wastrumentation incurs a notable lower overhead across all analyses, while for other input programs ("jqkungfu", "rtexpacker", "rtexviewer") the opposite holds. Some notable outliers are ["jqkungfu","taint"] where Wasabi-instrumented execution is 17.5x faster and the "memory-tracing" analysis for "bullet", "funky"-kart, "guiicons", "ffxgen", and "rguistyler" where Wastrumentation is >9.0x faster than Wasabi.

To coroborate that our findings are consistent across virtual machines, we also deployed the "Forward" analysis for Wastrumentation on Wasmtime. Appendix D in [25] plots our findings, and confirms that across NodeJS and Wasmtime the overhead for the "Forward" analysis remains within the same order of magnitude.

4.5.5 Comparison to bytecode rewriting systems

Lastly, we compare the performance overhead of Wastrumentation with that of analyses implemented in bytecode rewriting systems. To this end, we compute the overhead of the bytecode rewriting analyses that we ported to Wastrumentation as described in Section 4.2.2.

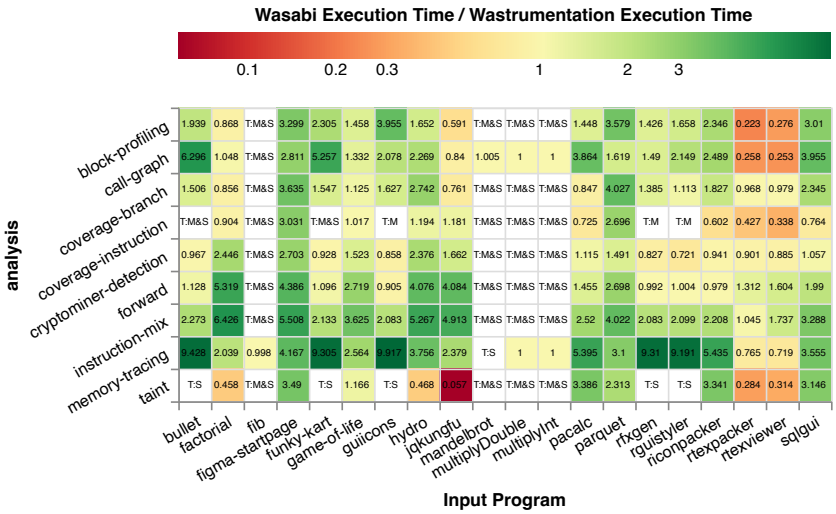

Figure 9 Execution time ratio of Wasabi-analyzed programs over Wastrumentation-analyzed programs.

Figure 10 plots the performance overhead for various input programs of the WasmR3 benchmark suite. For all analyses and input programs, the runtime overhead of bytecode rewriting is one or two orders of magnitude lower. These results are confirmed by earlier experiments, as pointed out by Titzer et al. [38].

The performance advantage of bytecode rewriting systems stems from two aspects. First, bytecode rewriting systems allow developers to have more fine-grained control over which specific locations to inject instrumentation code statically. Second, they can directly inline the analysis within the target operations. In contrast, Wastrumentation, requires runtime dispatching on generic operations. For example, our "binary" trap encapsulates 76 different instructions requiring additional dispatch at runtime.

4.6 RQ5: Evaluating the Memory Overhead of Wastrumentation

We now assess the runtime memory overhead incurred by Wastrumentation and compare it to Wasabi. To evaluate the memory overhead, we used the "Forward" analysis on the WasmR3 benchmark suite for both platforms. We measured the runtime memory using Node.js's built-in `process.memoryUsage()` method after executing each program. The memory overhead for each instrumented program was calculated relative to an uninstrumented baseline, representing the increase in memory usage (expressed as x times more memory usage).

4.6.1 Results

Figure 11 shows the results for each input program. For Wasabi, memory overhead could not be computed for the seven programs that failed to be instrumented, and these programs show no value in the figure. We observe that Wastrumentation's memory overhead ranges from 1.01x to 37.65x, while the memory overhead for Wasabi ranges from 1.03x to 12.34x. We suspect that the higher memory overhead in Wasabi is due to Node.js JIT employing more memory, as the analysis is written in JavaScript, but further experimentation is needed to quantify this hypothesis.

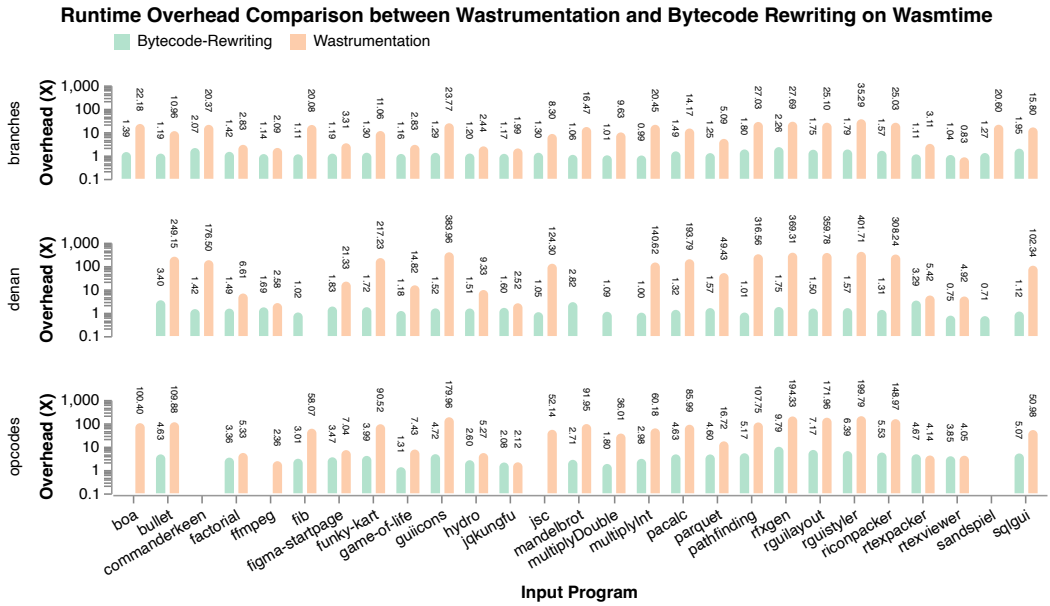

Figure 10 Performance overhead comparison between Wastrumentation and bytecode rewriting systems across various input programs from the WasmR3 benchmark suite.

In the context of Wasm programs, runtime memory is often a limited resource, particularly in environments such as cloud-based platforms or microcontrollers. As a result, minimizing memory overhead is critical for ensuring efficient execution. These results indicate that Wastrumentation may be better suited for deployment in memory-constrained environments.

5 Related Work

In recent years, WebAssembly has become a popular target for dynamic analysis. These analyses span various domains, including security [2], taint tracking [9, 36], program comprehension [20, 30, 26, 39], and profiling [21]. This section compares Wastrumentation to other instrumentation platforms for Wasm and discusses closely related work beyond Wasm.

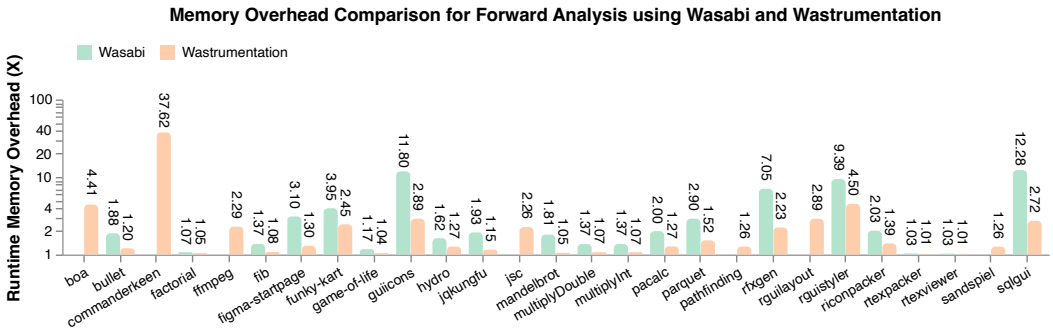

Figure 11 Runtime memory overhead of programs analyzed with Wasabi and Wastrumentation using the "Forward" analysis on the WasmR3 benchmarks. Baseline runs uninstrumented on NodeJS.

5.1 Instrumentation Platforms for WebAssembly

As mentioned before, there exist several tools that enable code transformation and instrumentation for Wasm binaries, Brewasm [5], WasmManipulator [29], and Binaryen [10]. These tools facilitate code injection by providing low-level APIs to modify the input program binary code. However, the analysis developer is responsible for the correctness of the transformation.

Wasabi [19] was the first dynamic analysis platform for Wasm, enabling developers to implement analysis against a high-level instrumentation API and ensuring a correct transformation. The analyses are written in JavaScript by implementing functions that execute code for specific program events of interest. Wasabi achieves instrumentation through source-level code rewriting, generating an instrumented version of the target program that calls the analysis code at runtime. Like Wasabi, Wastrumentation also performs source code instrumentation. In contrast, Wastrumentation does not require a specific language for the analysis, as long as the language can compile to Wasm. Moreover, analyses can operate in environments outside the web, where the Wasm VM may run without a JavaScript VM.

Wizard [38] follows a different instrumentation approach than that of Wasabi and Wastrumentation. Wizard is a Wasm VM with built-in support for instrumentation. In Wizard, analyses are implemented as instrumentation "probes". These probes are developed as extensions to classes within the Wizard VM, which upon execution of a target program will invoke the relevant probe. Wizard focuses on minimizing instrumentation overhead through features that VM-level instrumentation can benefit from, e.g., dynamically adapting analysis code during execution and JIT intrinsification of instrumentation code. However, with this approach, applications executed in the Wizard VM are the only ones that could be analysed. In contrast, dynamic analyses implemented with Wastrumentation do not have additional requirements for the runtime environment, making them portable to any Wasm VM.

5.2 Instrumentation Platforms Supporting Intercession

Dynamic analysis frameworks supporting intercession have been explored for languages other than Wasm. The GraalVM [41] is a polyglot VM that supports instrumentation and dynamic language execution. GraalVM's Truffle framework [40] enables high-performance instrumentation and runtime adaptation [7]. This capability has been used for building a taint analysis platform [16, 15]. In contrast to GraalVM, Wastrumentation performs the instrumentation ahead of time, allowing the instrumented program to run on any Wasm VM, at the cost of not being able to disable instrumentation once the program is executed.

Pin [22], Valgrind [28], and DynamoRIO [4] are dynamic binary instrumentation frameworks for native code analysis. Valgrind provides tools like Memcheck, Callgrind, and Helgrind, which allow intercession and monitoring of x86, ARM, and other instruction set architectures. Its approach of translating code into an intermediate representation enables detailed runtime analysis, including memory checking and profiling. Wastrumentation differs from these approaches for its target domain of applications. The distinct semantics of Wasm, such as its static strong type system and lack of reflection, challenge instrumentation.

6 Conclusion

This paper presented Wastrumentation, a general-purpose source code instrumentation platform for Wasm. Developers can build dynamic analyses using a high-level API that compiles to the Wasm application binary interface supported by Wastrumentation. As a result, analyses can be implemented in *any* language that compiles to Wasm. The platform

then merges the target program and the analysis code into a single Wasm program. The resulting instrumented code can be run in *any* Wasm VM. The high-level API allows for implementing analysis requiring intercession, e.g., altering or skipping operations at the target program. Our evaluation with real-world applications from the WasmR3 benchmark suite shows a competitive performance overhead compared to the state-of-the-art source code instrumentation platforms. We also implemented three novel analyses requiring intercession, which were unattainable with existing source code instrumentation platforms for Wasm.

In future work, we aim to improve the platform's modularity so that analyses that do not need intercession do not incurr any performance costs. Currently, it is not possible to eliminate intercession when it is not needed. We also aim to explore a more fine-grained specification language, enabling analysis developers to specify precisely what needs to be instrumented. This could further reduce performance overhead and the binary size of the instrumented application. Finally, we aim to gain more experience and insights in intercession analyses and explore ways to prevent them from compromising overall integrity or efficiency, e.g., detect analyses that pollute the target linear memory or impose a significant overhead.

Fair Termination of Asynchronous Binary Sessions

Abstract

We study a theory of asynchronous session types ensuring that well-typed processes terminate under a suitable fairness assumption. Fair termination entails *starvation freedom* and *orphan message freedom* namely that all messages, including those that are produced *early* taking advantage of asynchrony, are eventually consumed. The theory is based on a novel *fair asynchronous subtyping* relation for session types that is coarser than the existing ones. The type system is also the first of its kind that is firmly rooted in linear logic: fair asynchronous subtyping is incorporated as a natural generalization of the cut and axiom rules of linear logic and asynchronous communication is modeled through a suitable set of *commuting conversions* and of *deep cut reductions* in linear logic proofs.

2012 ACM Subject Classification Theory of computation → Type structures; Theory of computation → Linear logic; Theory of computation → Program analysis

Keywords and phrases Binary sessions, fair asynchronous subtyping, fair termination, linear logic

1 Introduction

Session type systems [32, 33, 35] have become a widespread formalism for ensuring a variety of safety and liveness properties of communicating processes through static analysis. Session types specify the *sequences* of messages that can be sent over a channel, and the type system makes sure that (1) well-typed processes comply with this protocol specification and that (2) the peer endpoints of the channel are used according to compatible protocols.

Many session type systems are defined for a synchronous calculus or language even if the actual underlying communication model is meant to be asynchronous. The point is that synchronous theories of session types are simpler and easier to work with and most if not all properties of a synchronous session type system hold even if the actual communication model is asynchronous. However, awareness of the communication model can help relaxing the type system and thus enlarging the family of well-typed processes. This observation has led to the study of *asynchronous subtyping relations* for session types [40, 39, 11] allowing processes to *anticipate* output messages with respect to the protocol specification they are expected to comply with, provided that anticipated outputs *do not depend* on incoming messages. This apparent violation of the protocol specification enabled by asynchronous subtyping is harmless precisely because output actions are non-blocking in an asynchronous setting.

The available session type systems based on asynchronous subtyping focus on the enforcement of safety properties but struggle at ensuring liveness properties of many simple communication patterns. As an illustration of such patterns consider a server that, in order

licensed under Creative Commons License CC-BY 4.0

to fulfill a request received from a session x, splits the request into an arbitrary number of tasks handled by a separate worker and then gathers the partial results to answer the client. We might be interested in establishing whether the client eventually receives a response.

To be more concrete, let us model the server as the term

$$x \triangleright \{\mathsf{req} : (y)(\mathit{Split}\langle x, y\rangle \mid \mathit{Worker}\langle y\rangle)\}$$

which indicates the input of the request followed by the spawning of a *Split* process and of a *Worker* process connected by a new session y.

The *Split* process is modeled by the following definitions:

$$\mathit{Split}(x, y) = y \triangleleft \mathsf{task}.\mathit{Split}\langle x, y\rangle \oplus y \triangleleft \mathsf{stop}.\mathit{Gather}\langle x, y\rangle \tag{1}$$

$$\mathit{Gather}(x, y) = y \triangleright \{\mathsf{res} : \mathit{Gather}\langle x, y\rangle, \mathsf{stop} : \mathsf{wait}\ y.x \triangleleft \mathsf{resp}.\mathsf{close}\ x\} \tag{2}$$

according to which the server sends to the worker a non-deterministically chosen number of tasks followed by a stop on session y, it then gathers from the worker an arbitrary number of results followed by a stop, and finally sends back to the client a response on session x.

One possible modeling of the worker process is according to the definition

$$\mathit{Worker}(y) = y \triangleright \{\mathsf{task} : y \triangleleft \mathsf{res}.\mathit{Worker}\langle y\rangle, \mathsf{stop} : y \triangleleft \mathsf{stop}.\mathsf{close}\ y\} \tag{3}$$

so that the worker sends a result for each task it receives. The eye-catching aspect of *Worker* is that it does not interact according to the "complementary" protocol implemented on the server side, at least not in the sense that is usually intended in (synchronous) session type theories. Indeed, while the server first sends all the tasks *and then* gathers all the results, the worker eagerly sends one result after receiving each task.

In an asynchronous setting, the fact that *Worker* sends some messages earlier than expected is not an issue since output actions are non-blocking. However, we would like to be sure that these early results do not keep accumulating and are eventually consumed by *Gather*. There is nothing in the modeling of *Split*, *Gather* and *Worker* that prevents this from happening, but *we can prove the eventual consumption of every* result *only under the assumption that sooner or later Split will send* stop *to Worker*. If we broaden our viewpoint, we see that the same assumption is necessary to prove that the client interacting with the server does not starve. While the server is running, the client is awaiting for a response from session x. In order to *prove* that the client will eventually receive a response, we have to assume that *Worker* will terminate the session y, which in turn requires the assumption that *Split* will eventually send stop to *Worker*. In general, the proof of any non-trivial liveness property that concerns the eventual production or consumption of a message on a certain session may require the assumption that every other session eventually terminates. For this reason, ensuring the eventual termination of sessions should be a primary goal of any session type system aimed at enforcing liveness properties. As we have seen in the discussion above, proving the eventual termination of a session may require some *fairness assumptions* like the fact that *Split* will eventually stop sending tasks. For this reason, in the literature such eventual termination property is referred to as *fair termination* [30, 26, 2].

In this work we study a theory of asynchronous session types and an associated session type system ensuring that well-typed processes are fairly terminating under a suitable fairness assumption. The fair termination of processes entails the fair termination of the sessions they operate on, hence that all messages produced – including those sent earlier than expected – are eventually consumed and that all processes waiting for a message eventually receive one. In other words, the very same type system prevents *process starvation* and ensures the absence of *orphan messages*. Related works achieve these goals only partially:

- The theories of asynchronous session types developed by Mostrous *et al.* [40, 39], Chen *et al.* [11] and Ghilezan *et al.* [29] require that every output can be only anticipated with respect to finitely many inputs. Since there is no finite upper bound to the number of tasks that *Split* can produce, each early res produced by *Worker* anticipates an unbounded number of inputs leaving *Worker* out of reach for the aforementioned theories.
- Bravetti, Lange and Zavattaro [8] study an asynchronous subtyping relation for session types that allows early outputs to anticipate an unbounded number of inputs. However, their subtyping relation disallows any *covariance* of outputs, which is needed to account for the fact that the behavior of *Worker* is *more deterministic* than the behavior expected by *Gather*. Indeed, while *Gather* expects to receive an arbitrary number of results, *Worker* produces exactly as many results as the number of tasks it receives from *Split*.
- None of the aforementioned works provides guarantees on the eventual fulfillment of the client's request, either because they do not make sure that every session eventually terminates [11, 29] or because they do not take multiple sessions into account [29, 8].
- Ciccone, Dagnino and Padovani [14, 16, 13] study session type systems ensuring the fair termination of sessions, but their works are based on synchronous communication models that do not support any form of output anticipation like the one exemplified by *Worker*.

The theory of asynchronous session types that we propose in this paper addresses all these limitations. In addition, we also make the following technical contributions:

- We define a *fair asynchronous subtyping relation* for session types that is coarser than those in the literature for the family of eventually terminating session types. Unlike many existing fair/asynchronous subtyping relations [39, 14, 13, 8] our subtyping relation is *closed under duality*. This property is key for proving the type system sound.
- We give the first *fair asynchronous semantics* of session types using a labelled transition system (LTS) defined by *bounded coinduction* [1, 18]. The adoption of this semantics allows us to characterize fair asynchronous subtyping in a way that is structurally the same as the one for the well-known synchronous subtyping defined by Gay and Hole [28].
- Our theory of asynchronous session types with fair asynchronous subtyping is the first one where the process model and the type system are rooted in linear logic [45, 10, 37]. We incorporate fair asynchronous subtyping in the type system as generalized forms of the cut and linear logic axiom thanks to the aforementioned closure under duality. Also, instead of introducing explicit message buffers, we model asynchronous communications by means of suitable *commuting conversions* and *deep cut reductions* in linear logic proofs.

Structure of the paper. Section 2 describes our calculus of asynchronous processes and the properties we enforce. Section 3 introduces the semantics of asynchronous session types while Section 4 studies fair asynchronous subtyping and its properties. Section 5 describes the type system and Section 6 illustrates some common usage patters of fair asynchronous subtyping. Section 7 shows how our LTS can be easily tailored to characterize various asynchronous subtyping relations that appear in the literature and compares them with our subtyping relation. Section 8 discusses related work in more detail and Section 9 recaps and outlines future work. Proofs and additional technical material are provided in the full paper [43].

2 A Calculus of Asynchronous Processes

In this section we present syntax and semantics of a calculus of asynchronous processes called CaP and we formulate the safety and liveness properties that our type system guarantees. At the surface level, CaP closely resembles other calculi of binary sessions based on linear logic

Table 1 Syntax of CaP.

P, Q	::=	**Process**	|	done	termination
	$x \leftrightarrow y$	link	|	$A\langle \overline{x} \rangle$	invocation
|	close x	signal output	|	wait $x.P$	signal input
|	$x \lhd \mathsf{a}.P$	tag output	|	$x \rhd \{\mathsf{a}_i : P_i\}_{i \in I}$	tag input
|	$x(y)[P].Q$	channel output	|	$x(y).P$	channel input
|	$P \oplus Q$	choice	|	$(x)(P \mid Q)$	composition

such as CP [45] or μCP [37]. The main differences between CaP and these calculi are that CaP supports general recursion, it includes a non-deterministic choice operator and above all it models asynchronous communication by giving a non-blocking semantics to output actions, which essentially act like message buffers.

The syntax of *processes* is shown in Table 1 and makes use of an infinite set of *channels* ranged over by x, y and z, a set Tags of *tags* ranged over by a, b, ... and a set of *process names* ranged over by A, B, etc. The terminated process, which performs no actions, is denoted by done. The term $A\langle \overline{x} \rangle$, where $\overline{x}$ is a possibly empty sequence of channels, represents the *invocation* of the process named A. We assume that for each such invocation there exists a unique global definition of the form $A(\overline{x}) = P$ that gives meaning to the name A. We also assume that all invocations occur guarded by a prefix or by a non-deterministic choice. The term $x \leftrightarrow y$ models a *link*, that is a process that forwards every message received from x to y and vice versa, effectively unifying the two channels. Links are typical of calculi based on linear logic since their typing rule correspond to the axiom of the logic. The terms close x and wait $x.P$ model processes that respectively send and receive a termination signal on x. Note that close x has no continuation, as is the case in most calculi based on linear logic, whereas wait $x.P$ continues as P. The term $x(y)[P].Q$ models a bifurcating session: it creates a new channel y, sends y on x, forks a new process P that uses y, and then continues as Q. The process $x(y).P$ waits for a channel y from x and then continues as P. The terms $x \lhd \mathsf{a}.P$ and $x \rhd \{\mathsf{a}_i : P_i\}_{i \in I}$ model processes that respectively send and receive a tag. The sender selects one particular tag a to send. The receiver continues as P_i depending on the tag a_i that it receives. In the examples we sometimes use tags as an abstract representation of more complex messages, such as requests or tasks. The term $(x)(P \mid Q)$ models the parallel composition of two processes P and Q connected by the channel x. We often refer to this term as a *cut*, since its typing rule coincides with the cut rule of linear logic. Finally, the term $P \oplus Q$ models the non-deterministic choice between P and Q.

It is known that links in conjunction with bifurcating sessions can be used to encode *session delegation*, whereby processes exchange an *existing* (rather than new) channel z on x. This behavior can be modeled by a term of the form $x(y)[y \leftrightarrow z].P$. As we will see in Section 6, CaP links also act as *explicit casts* enabling useful forms of subsumption.

The notions of *free* and *bound* channels for processes are defined as expected with the proviso that a process of the form $x(y)[P].Q$ binds y in P but not in Q. We identify processes up to renaming of bound channels and we write $\mathsf{fn}(P)$ for the set of channels occurring free in P. Also, for every global definition $A(\overline{x}) = P$ we assume $\mathsf{fn}(P) = \{\overline{x}\}$.

We have anticipated that CaP adopts an asynchronous communication model. In practice this would be implemented by FIFO buffers storing messages that have been produced but not consumed. In CaP, we model asynchrony giving a non-blocking semantics to the output actions $x(y)[Q].P$ and $x \lhd \mathsf{a}.P$. That is, we allow the continuation P to reduce and/or

interact with other sub-processes even if the prefix has not been consumed. In a sense, we consider the prefixes $x(y)[Q]$ and $x \lhd \mathsf{a}$ as *floating messages* or parts of a *buffer* associated with channel x. In general, we call *buffer* any term generated by the following grammar:

Buffer $\quad \mathcal{B}_x ::= [\,] \mid x \lhd \mathsf{a}.\mathcal{B}_x \mid x(y)[P].\mathcal{B}_x$

A buffer is either empty, represented by a *hole* $[\,]$, or a tag a sent on x followed by a buffer for x, or a fresh channel y (with associated process P) sent on x and followed by a buffer for x. Note that the annotation x in the metavariable $\mathcal{B}_x$ is meant to *bind* the channel on which the messages in the buffer have been sent. Therefore, having at our disposal a buffer $\mathcal{B}_x$, we can write $\mathcal{B}_y$ for the buffer that has the same structure as $\mathcal{B}_x$ but where x has been replaced by y. Buffers vaguely resemble *reduction contexts*, except that they allow us to place a hole *behind* output prefixes since these are meant to be non-blocking. Hereafter we write $\mathcal{B}_x[P]$ for the process obtained by replacing the hole in $\mathcal{B}_x$ with P.

The operational semantics of CaP is given by a structural pre-congruence relation $\sqsupseteq$ and a reduction relation $\to$, both defined in Table 2. In simple words, structural pre-congruence relates processes that are essentially equivalent except for the order of independent actions, while reduction describes communications and the resolution of non-deterministic choices.

We can roughly classify the rules for structural pre-congruence in four groups. The first group contains [S-CALL], [S-LINK] and [S-COMM], which capture expected properties of process invocations, links and parallel compositions: a process invocation $A\langle \overline{x} \rangle$ is indistinguishable from P if $A(\overline{x}) = P$; a link $x \leftrightarrow y$ is indistinguishable from $y \leftrightarrow x$; a cut $(x)(P \mid Q)$ is indistinguishable from $(x)(Q \mid P)$, that is parallel composition is commutative.

The second group of rules contains [S-WAIT], [S-CASE] and [S-JOIN]. These rules allow an input action on some channel y to be extruded from a cut on x when $x \neq y$. The purpose of these transformations is to move inputs on y close to outputs on y, so as to enable interactions

in the session y. These transformations correspond to well-known rearrangements of linear logic proofs (for example, they are sometimes referred to as *external reductions* [3, 25]), except that in CaP we allow the input prefix to be found *within an arbitrary buffer* $\mathcal{B}_x$, coherently with the intuition that (output) actions in a buffer are non-blocking. The side condition $z \notin \mathsf{fn}(\mathcal{B}_x)$ in [S-JOIN] makes sure that free occurrences of z in $\mathcal{B}_x$ are not accidentally captured by the binding prefix. Since we consider processes (and buffers) modulo renaming of bound names and there is an infinite supply of names, the bound z can always be renamed so as to enable this process transformation.

The third group of rules contains [S-PULL-0], [S-PULL-1] and [S-PULL-2]. These rules are similar to those of the second group, except that they allow whole *buffers* of messages on y to float through cuts on x when $x \neq y$. [S-PULL-2] is simple and speaks for itself while [S-PULL-1] deals with the case in which the name x bound by the cut occurs in the process P associated with a fresh channel z sent on $y \neq x$. In this case the cut as a whole becomes associated with z. In principle we should also specify the side condition $x \notin \mathsf{fn}(Q)$, but this condition holds for well-typed processes when $x \in \mathsf{fn}(P)$. The rule [S-PULL-0] covers a somewhat peculiar case of [S-PULL-2], whereby a buffer $\mathcal{B}_x$ can be extruded from the cut on x because there is a link $x \leftrightarrow y$ that acts as a forwarder from x to y. Note that the extruded buffer $\mathcal{B}_x$ turns into $\mathcal{B}_y$, so as to reflect the forwarding effect of the link.

The fourth and final group of rules contains [S-PULL-3] and [S-PULL-4]. These rules allow buffers for different channels to be permuted. Again [S-PULL-3] deals with the special case in which a channel x occurs in the process P associated with a fresh channel z.

In the definition of structural pre-congruence there are some glaring omissions (*e.g.* associativity of parallel composition) and very few rules are invertible. This is not because the missing rules would be unsound, but because they turn out to be unnecessary for proving that well-typed processes are deadlock free and fairly terminating.

Base reductions consist of [R-CHOICE], [R-CLOSE], [R-SELECT] and [R-FORK] which respectively model the reduction of a non-deterministic process, the termination of the session x and the consumption of tags and channels sent on channel x. The rules are almost standard, except that [R-SELECT] and [R-FORK] allow input actions on x to operate from within arbitrary buffers for x. The buffers represent asynchronously sent messages that do not block subsequent actions. At the logical level, these interactions correspond to *deep cut reductions* in a sense that resembles *deep inference* [31], whereby logical rules can be applied deep within a context. Unlike [R-SELECT] and [R-FORK], there is no buffer around $\mathsf{wait}\ x.P$ in [R-CLOSE]. This rule implies that a session cannot be closed unless all the messages (asynchronously) produced therein have also been consumed. Note that this property is enforced by the type system and is not meant to be checked at runtime. Rules [R-CUT], [R-BUFFER] and [R-STR] propagate reductions across cuts and buffers and close them by structural pre-congruence.

Hereafter we write $\to^*$ for the reflexive, transitive closure of $\to$. We write $P \to$ if $P \to Q$ for some Q and $P \not\to$ if not $P \to$.

We can now formally define the safety and liveness properties we are interested in.

▶ **Definition 1** (deadlock freedom). *We say that P is* deadlock free *if for every Q such that $P \to^* Q \not\to$ we have $Q \sqsupseteq \mathsf{done}$.*

Deadlock freedom is an instance of safety property. A deadlock-free process either reduces or it is (structurally pre-congruent to) done. For example, the process $\Omega() = \Omega\langle\rangle \oplus \Omega\langle\rangle$ is deadlock free (we have $\Omega\langle\rangle \to \Omega\langle\rangle$) whereas $(x)(\mathsf{close}\ y \mid \mathsf{wait}\ x.\mathsf{done})$ is deadlocked. When a deadlock-free process stops reducing, it contains no pending actions and all of its sessions have been closed. In particular, all the messages in buffers have been consumed.

The liveness properties we are interested in are related to *termination*, of which there exist several variants. A *reduction sequence* of P is a sequence $(P_0, P_1, \dots)$ such that $P_0 = P$ and $P_i \to P_{i+1}$ whenever $i+1$ is not greater than the length of the sequence. A *run* is a maximal reduction sequence, in the sense that either it is infinite or the last process in the sequence (say P_n) does not reduce (that is, $P_n \not\to$). We say that P is *weakly terminating* if it has a finite run, that P is *terminating* if every run of P is finite, and that P is *diverging* if every run of P is infinite. For example, $\Omega\langle\rangle \oplus \mathsf{done}$ is weakly terminating but not terminating, $\mathsf{done} \oplus \mathsf{done}$ is terminating, and $\Omega\langle\rangle$ is diverging. Note that here we call "termination" the mere inability to reduce further and not the fact that a process has become done. For example, done, close x and $(x)(\mathsf{close}\ y \mid \mathsf{wait}\ x.\mathsf{done})$ are all terminated (they do not reduce), but only done is also deadlock free. So it really is the combination of deadlock freedom (Definition 1) and some termination property that we wish to enforce with our type system.

The termination property we target in this work is called *fair termination* [30, 26, 2]. Fair termination consists of those processes such that all of their infinite runs are considered to be unrealistic or *unfair* and therefore can be ignored insofar termination is concerned. We could say that these processes may diverge in principle, but they terminate in practice. Clearly, fair termination depends on a *fairness notion* that discriminates *fair* runs from *unfair* ones. Among all fairness notions, here we consider a particular instance of *full fairness* [44].

▶ **Definition 2.** *A run is* fair *if it contains finitely many weakly terminating processes.*

Remember that a run is a *maximal* reduction sequence of a process. So, along a fair run the process only has finitely many chances to terminate. This can happen either because the run is finite (the process eventually terminates) or because the run contains a diverging process (at some point termination is no longer possible). For example, the infinite run $(\Omega\langle\rangle \oplus \mathsf{done}, \Omega\langle\rangle, \dots)$ is fair because only the first process in it is weakly terminating. We find it useful to also look at the *negation* of the notion of fair run: an *unfair run* is necessarily infinite and contains infinitely many weakly terminating processes. In other words, an unfair run describes a computation along which termination is always reachable, but it is never reached as if the process is avoiding it on purpose. For example, if $A() = A\langle\rangle \oplus \mathsf{done}$ then the infinite run $(A\langle\rangle, A\langle\rangle, \dots)$ is unfair because done is always reachable but never reached.

▶ **Definition 3.** *We say that P is* fairly terminating *if every* fair *run of P is finite.*

For example, $A() = A\langle\rangle \oplus \mathsf{done}$ is fairly terminating whereas $\Omega\langle\rangle \oplus \mathsf{done}$ is not because it has an infinite fair run. There are two reasons why full fairness is a suitable fairness assumption in our setting. First, full fairness has been shown to be the *strongest* conceivable fairness assumption [44], which means that it allows us to target the *largest* family of fairly terminating processes. Second, it has been observed [12] that this family admits the following alternative characterization which does not mention fair runs at all.

▶ **Theorem 4.** *P is fairly terminating iff each Q such that $P \to^* Q$ is weakly terminating.*

The relevance of this characterization rests in the fact that it provides the key proof method for the soundness of our type system. Indeed, suppose that the type system ensures that well-typed processes *weakly* terminate. We expect the type system to also enjoy subject redution, namely the property that well-typed processes always reduce to well-typed processes. But then, using the right-to-left implication in Theorem 4, the very same type system also ensures that well-typed processes fairly terminate.

▶ **Example 5.** Consider the *Split* process defined in (1). We derive

$$\mathit{Split}\langle x, y\rangle \to y \lhd \mathsf{task}.\mathit{Split}\langle x, y\rangle \to \cdots \to (y \lhd \mathsf{task})^n.\mathit{Split}\langle x, y\rangle$$

where $(y \lhd \mathsf{task})^n$ denotes n subsequent $y \lhd \mathsf{task}$ prefixes, using repeated applications of [R-CHOICE] and [R-BUFFER]. Notice how the messages pile up as the process reduces and also that, at any time, the process may reduce to $(y \lhd \mathsf{task})^n.y \lhd \mathsf{stop}.\mathit{Gather}\langle x, y\rangle$ which is weakly terminating.That is, $\mathit{Split}\langle x, y\rangle$ is fairly terminating by Theorem 4. We also have

$$(y)(\mathit{Split}\langle x, y\rangle \mid \mathit{Worker}\langle y\rangle) \to^* (y)((y \lhd \mathsf{task})^n.\mathit{Split}\langle x, y\rangle \mid (y \lhd \mathsf{res})^m.\mathit{Worker}\langle y\rangle)$$

for every n and m, indicating that *Split* has produced $m+n$ tasks and *Worker* has consumed only m of them. Since *Split* can always send stop and consume all the res messages produced by *Worker*, we also have

$$(y)((y \lhd \mathsf{task})^n.\mathit{Split}\langle x, y\rangle \mid (y \lhd \mathsf{res})^m.\mathit{Worker}\langle y\rangle) \to^* x \lhd \mathsf{resp.done} \not\to$$

indicating that $(y)(\mathit{Split}\langle x, y\rangle \mid \mathit{Worker}\langle y\rangle)$ too is fairly terminating by Theorem 4. ⌟

3 Asynchronous Session Types

3.1 Syntax

Session types are generated by the productions below

Session type $\quad S, T ::= \mathbf{1} \mid \bot \mid \oplus\{\mathsf{a}_i : S_i\}_{i\in I} \mid \&\{\mathsf{a}_i : S_i\}_{i\in I} \mid S \otimes T \mid S \parr T$

and adhere to the usual interpretation given to propositions of multiplicative additive linear logic (MALL) [10, 45]: the constants $\mathbf{1}$ and $\bot$ describe processes respectively sending and receiving a termination signal; the additive connectives $\oplus\{\mathsf{a}_i : S_i\}_{i\in I}$ and $\&\{\mathsf{a}_i : S_i\}_{i\in I}$ describe processes sending and receiving a tag a_i and then behaving according to S_i; the multiplicative connectives $S \otimes T$ and $S \parr T$ describe processes exchanging a channel of type S and then behaving according to T.

Compared to the usual linear logic propositions, we observe the following differences:

- The additive connectives are n-ary instead of binary and make use of explicit tags for improved generality and readability. In each additive connective $\oplus\{\mathsf{a}_i : S_i\}_{i\in I}$ and $\&\{\mathsf{a}_i : S_i\}_{i\in I}$ we assume that the set I is finite and that the tags a_i are pairwise disjoint.
- The additive constants $\mathbf{0} \stackrel{\text{def}}{=} \oplus\{\}$ and $\top \stackrel{\text{def}}{=} \&\{\}$ are defined as degenerate (empty) versions of the additive connectives instead of being built-in.
- The productions shown above are meant to be interpreted *coinductively*. That is, we consider session types the possibly infinite *regular* trees built using the above productions. We define possibly infinite session types as solutions of equations of the form $S = \cdots$ where the metavariable S may occur (guarded) on the right hand side of "=". It is a known fact that every such finite system of equations admits a unique regular solution [17].

The *dual* of a session type S, denoted by $S^\bot$, describes the mirrored protocol of S and is corecursively defined by following equations:

$$\mathbf{1}^\bot = \bot \qquad \oplus\{\mathsf{a}_i : S_i\}_{i\in I}^\bot = \&\{\mathsf{a}_i : S_i^\bot\}_{i\in I} \qquad (S \otimes T)^\bot = S^\bot \parr T^\bot$$
$$\bot^\bot = \mathbf{1} \qquad \&\{\mathsf{a}_i : S_i\}_{i\in I}^\bot = \oplus\{\mathsf{a}_i : S_i^\bot\}_{i\in I} \qquad (S \parr T)^\bot = S^\bot \otimes T^\bot$$

We say that the session types of the form $\mathbf{1}$, $\oplus\{\mathsf{a}_i : S_i\}_{i\in I}$ and $S \otimes T$ are *positive*, whereas the session types of the form $\bot$, $\&\{\mathsf{a}_i : S_i\}_{i\in I}$ and $S \parr T$ are *negative*. Positive session types describe protocols that begin with an *output action*, whereas negative session types describe protocols that begin with an *input action*. We write $\mathsf{pos}(S)$ and $\mathsf{neg}(S)$ to state that S is positive and negative, respectively.

Table 3 Labelled transition system for asynchronous session types.

$$[\text{MUST-}\mathbf{1}]\ \frac{}{\mathbf{1} \xrightarrow{!*} \mathbf{1}} \qquad [\text{MUST-}\otimes]\ \frac{}{S \otimes T \xrightarrow{!S} T} \qquad [\text{MAY-}\otimes]\ \frac{T \xrightarrow{?\sigma} T'}{S \otimes T \xrightarrow{?\sigma} S \otimes T'}$$

$$[\text{MUST-}\bot]\ \frac{}{\bot \xrightarrow{?*} \bot} \qquad [\text{MUST-}\parr]\ \frac{}{S \parr T \xrightarrow{?S} T} \qquad [\text{MAY-}\parr]\ \frac{T \xrightarrow{!\sigma} T'}{S \parr T \xrightarrow{!\sigma} S \parr T'}$$

$$[\text{MUST-}\oplus]\ \frac{}{\oplus\{\mathsf{a}_i : S_i\}_{i\in I} \xrightarrow{!\mathsf{a}_k} S_k} \qquad [\text{MAY-}\oplus]\ \frac{\forall i \in I : S_i \xrightarrow{?\sigma} T_i}{\oplus\{\mathsf{a}_i : S_i\}_{i\in I} \xrightarrow{?\sigma} \oplus\{\mathsf{a}_i : T_i\}_{i\in I}} \qquad [\text{FAIR-}\oplus]\ \frac{\exists k \in I : S_k \xrightarrow{?\sigma} T_k}{\oplus\{\mathsf{a}_i : S_i\}_{i\in I} \xrightarrow{?\sigma} \oplus\{\mathsf{a}_i : T_i\}_{i\in I}}$$

$$[\text{MUST-}\&]\ \frac{}{\&\{\mathsf{a}_i : S_i\}_{i\in I} \xrightarrow{?\mathsf{a}_k} S_k} \qquad [\text{MAY-}\&]\ \frac{\forall i \in I : S_i \xrightarrow{!\sigma} T_i}{\&\{\mathsf{a}_i : S_i\}_{i\in I} \xrightarrow{!\sigma} \&\{\mathsf{a}_i : T_i\}_{i\in I}} \qquad [\text{FAIR-}\&]\ \frac{\exists k \in I : S_k \xrightarrow{!\sigma} T_k}{\&\{\mathsf{a}_i : S_i\}_{i\in I} \xrightarrow{!\sigma} \&\{\mathsf{a}_i : T_i\}_{i\in I}}$$

3.2 Fair Asynchronous Semantics

We define the labelled transition system (LTS) for session types using the rules in Table 3. Labels of the transition system can be of the form $?\sigma$ (input of a message of type σ) or $!\sigma$ (output of a message of type σ) where σ is a *message type* of the form $*$ (the type of a termination signal), a (the singleton type of the tag a) or S (the session type of a channel). Hereafter we use σ and τ to range over message types and α and β to range over labels.

Before we describe the rules in detail, we must point out two unusual but important aspects of the LTS. First of all, the LTS is specified as a *Generalized Inference System* (GIS for short [1, 18]). A GIS consists of two sets of rules, those that are meant to be interpreted coinductively (the singly-lined rules in Table 3) and those that are meant to be interpreted inductively (the singly-lined rules plus the doubly-lined rules in Table 3). If we call $\xrightarrow{\alpha}_{\mathsf{ind}}$ the relation that is defined by the inductive part of the GIS, then the actual relation $\xrightarrow{\alpha}$ being defined is the largest one included in $\xrightarrow{\alpha}_{\mathsf{ind}}$ that satisfies the singly-lined rules in Table 3. The interested reader may refer to the literature for a thorough presentation of GIS [1, 18], but the examples we are about to discuss should suffice to clarify the nature of transitions.

The other unusual aspect of the LTS is that a transition $S \xrightarrow{\alpha} T$ is not an indication of what a process complying with S necessarily does, but rather of what the process is allowed or able to do. In particular, a transition $S \xrightarrow{!\sigma} T$ means that a process complying with S is allowed to output a message of type σ, even though S may be negative. We say that this is an *early output transition* because it describes an output that may occur ahead of time. Dually, a transition $S \xrightarrow{?\sigma} T$ means that a process complying with S is eventually able to input a message of type σ, even though S may be positive. We say that this is a *late input transition* because it describes the consumption of a message that may occur later on.

The axioms [MUST-*] are used to derive what we call *immediate transitions*. These are the expected transitions of session types, whereby no input is late and no output is early. For technical reasons it is convenient to have transitions also for $\mathbf{1}$ and $\bot$. In this way we do not have to distinguish $\mathbf{1}$ and $\bot$ from other non-terminated protocols when defining our notions of generalized duality (Definition 8) and subtyping (Definition 12).

The rules [MAY-*] deal with late inputs and early outputs. As an example, consider the session type $S = \&\{\mathsf{a} : \oplus\{\mathsf{c} : T\}\}$ for which we may derive the transition sequences

$$S \xrightarrow{?\mathsf{a}} \oplus\{\mathsf{c} : T\} \xrightarrow{!\mathsf{c}} T \qquad \text{and} \qquad S \xrightarrow{!\mathsf{c}} \&\{\mathsf{a} : T\} \xrightarrow{?\mathsf{a}} T$$

The sequence on the left, obtained by [MUST-&] followed by [MUST-⊕], is an ordinary one: actions are performed according to the syntactic structure of the type. The sequence on the right, obtained using [MUST-⊕], [MAY-⊕] and [MUST-&], is peculiar to the asynchronous setting: it describes a situation in which the output !c may be performed earlier than the input ?a. Since communication is asynchronous and c is going to be sent anyway, a process complying with S might choose to send it *early*, before waiting for a. Note that this is just a possibility: a process strictly adhering to the transition sequence on the left would still comply with S.

A dual reasoning applies to late inputs. If we consider the type $S' = \oplus\{\mathsf{a} : \&\{\mathsf{c} : T'\}\}$ we may derive the transition sequences

$$S' \xrightarrow{!\mathsf{a}} \&\{\mathsf{c} : T'\} \xrightarrow{?\mathsf{c}} T' \qquad \text{and} \qquad S' \xrightarrow{?\mathsf{c}} \oplus\{\mathsf{a} : T'\} \xrightarrow{!\mathsf{a}} T'$$

Again, the sequence on the left is standard. The sequence on the right, obtained using [MUST-&], [MAY-&] and [MUST-⊕], says that a process complying with S' is able to consume a c message, even though this will happen only after the process has sent a. The fact that the input action is late cannot cause issues, since both the outgoing a and the incoming c are sent asynchronously with a non-blocking operation.

As it is clear looking at the rules [MAY-⊕] and [MAY-&], late inputs and early outputs concerning a branching session type must be derivable for every branch: a message may be sent early (before an input) only if it is independent of the input; a message may be received late (after an output) only if it is independent of the output. For example, if we take $S = \&\{\mathsf{a} : \oplus\{\mathsf{c} : S_1\}, \mathsf{b} : \oplus\{\mathsf{c} : S_2, \mathsf{d} : S_3\}\}$ then we can derive

$$S \xrightarrow{!\mathsf{c}} \&\{\mathsf{a} : S_1, \mathsf{b} : S_2\} \quad \text{and also} \quad S \xrightarrow{?\mathsf{b}} \oplus\{\mathsf{c} : S_2, \mathsf{d} : S_3\} \xrightarrow{!\mathsf{d}} S_3 \quad \text{but not} \quad S \xrightarrow{!\mathsf{d}} S'$$

no matter what S' could be. A process complying with S may send c early, before receiving either a or b, since the output of c is allowed regardless of the input. On the contrary, the output d is allowed only if the input is b and so it cannot be anticipated before the input. Symmetrically, if we consider the session type $T = \oplus\{\mathsf{a} : \&\{\mathsf{c} : T_1\}, \mathsf{b} : \&\{\mathsf{c} : T_2, \mathsf{d} : T_3\}\}$, we may derive

$$T \xrightarrow{?\mathsf{c}} \oplus\{\mathsf{a} : T_1, \mathsf{b} : T_2\} \quad \text{and also} \quad T \xrightarrow{!\mathsf{b}} \&\{\mathsf{c} : T_2, \mathsf{d} : T_3\} \xrightarrow{?\mathsf{d}} T_3 \quad \text{but not} \quad T \xrightarrow{?\mathsf{d}} T'$$

The (late) input transition c is enabled because the process is able to receive c regardless of the tag a or b that it sends. On the contrary, the input transition on d is enabled only if the process sends b.

A subtler case of late input is illustrated by the session type $S_1 = \oplus\{\mathsf{a} : S_1, \mathsf{b} : \&\{\mathsf{c} : S_2\}\}$, which describes the behavior of a process that sends an arbitrary number of a's or a b and then waits for a c. Since the singly-lined rules in Table 3 are interpreted coinductively, we can derive $S_1 \xrightarrow{?\mathsf{c}} S_1'$ where $S_1' = \oplus\{\mathsf{a} : S_1', \mathsf{b} : S_2\}$ by means of the following *infinite* derivation:

$$\dfrac{\dfrac{\vdots}{S_1 \xrightarrow{?\mathsf{c}} S_1'}\,[\text{MAY-}\oplus] \qquad \dfrac{}{\&\{\mathsf{c} : S_2\} \xrightarrow{?\mathsf{c}} S_2}\,[\text{MUST-}\&]}{S_1 \xrightarrow{?\mathsf{c}} S_1'}\,[\text{MAY-}\oplus] \tag{4}$$

The transition $S_1 \xrightarrow{?\mathsf{c}} S_1'$ says that a process complying with S_1 performs a late input of c. Compared to the other examples of late inputs, this one looks more questionable and for a good reason: it may be the case that a process sending an *infinite* sequence of a's complies with S_1. So, claiming that such process is eventually able to input a c may lead to a message remaining orphan. In this work, however, we *assume* that a well-typed process complying with S_1 will also be *fair*, in the sense that it will eventually stop sending a's and will send the b ensuring that the c message is consumed. The same assumption is made, in dual form, for early outputs. For example, the session type $T_1 = \&\{\mathsf{a} : T_1, \mathsf{b} : \oplus\{\mathsf{c} : T_2\}\}$ performs the early output transition $T_1 \xrightarrow{!\mathsf{c}} T_1'$ where $T_1' = \&\{\mathsf{a} : T_1', \mathsf{b} : T_2\}$. That is, a process complying with T_1 is allowed to send c early because it is guaranteed to eventually receive a b message.

The infinite derivation that we have just shown in (4) reminds us that we must be careful in the use of coinduction for defining the LTS. Indeed, an unconstrained use of coinduction would allow us to derive early/late transitions that do not correspond to any "real" action of a session type, solely using [MAY-*] rules. Consider for example the infinite session type $S = \oplus\{\mathsf{a} : S\}$, which allows sending a neverending sequence of a's. It is easy to derive $S \xrightarrow{?\sigma} S$ for every σ by an infinite derivation consisting of [MAY-$\oplus$] rules only, despite the protocol described by S does *not* enable any input transition! Of course we want to make sure that, whenever we derive a late/early transition, this is justified by the use of at least one [MUST-*] rule somewhere in the derivation. This is the reason why the LTS is defined through a GIS and not simply by the (coinductively interpreted) singly-lined rules in Table 3. On the one hand, we want to make sure that that a late/early transition is enabled along *every* branch of a session type. This is an *invariant property* enforced by the [MAY-*] rules. On the other hand, we want to make sure that there exists at least one branch along which the transition eventually originates for real. This is a *well-founded property* enforced by the [MUST-*] rules. As it has already been observed elsewhere [15], GIS are a convenient way of defining relations like $\xrightarrow{\alpha}$ that mix invariant and well-founded properties at the same time. The effect of defining the LTS as a GIS is that, whenever we build a (possibly infinite) derivation for $S \xrightarrow{\alpha} T$ using the singly-lined rules, we must also be able to find, *for each* judgment $S_i \xrightarrow{\alpha_i} T_i$ in this derivation, a *finite* derivation for $S_i \xrightarrow{\alpha_i}_{\mathsf{ind}} T_i$. In (4) this is achieved easily, as shown below:

$$\dfrac{\dfrac{}{\&\{\mathsf{c} : S_2\} \xrightarrow{?\mathsf{c}}_{\mathsf{ind}} S_2}\,[\text{MUST-}\&]}{S_1 \xrightarrow{?\mathsf{c}}_{\mathsf{ind}} S_1'}\,[\text{FAIR-}\oplus]$$

Notice the key role of [FAIR-$\oplus$] in building this *finite* derivation for $S_1 \xrightarrow{?\mathsf{c}}_{\mathsf{ind}} S_1'$. Since S_1 is an *infinite* session type, we would not be able to find a finite derivation for $S_1 \xrightarrow{?\mathsf{c}}_{\mathsf{ind}} S_1'$ if we insisted on using [MAY-$\oplus$] only, since this rule requires us to derive the late input transition in *every* branch of the session type. Instead, according to [FAIR-$\oplus$] it suffices to find *one* branch along which we can eventually derive the late input transition directly. In the literature on GIS the doubly-lined rules are called *corules*. Here, we have called them [FAIR-$\oplus$] and [FAIR-&] because they somehow capture the fairness assumption of the LTS: whenever we derive late/early transitions in a looping session type like S_1 and T_1, the fairness assumption makes sure that the conversation eventually follows a branch leading out of the loop.

There is one exception to what we have just said about transitions being eventually derived by [MUST-*] rules. Recalling that $\mathbf{0} = \oplus\{\}$ and $\top = \&\{\}$, by [MAY-$\oplus$] and [MAY-&] we can easily derive $\mathbf{0} \xrightarrow{?\sigma} \mathbf{0}$ and $\top \xrightarrow{!\sigma} \top$ for every σ. These derivations are trivially valid for the GIS since they are finite. We might be tempted to flag these cases as pathological. After

all, the protocol $\mathbf{0}$ describes an unrealistic process that is able to *input anything* and the protocol $\top$ describes a uncontrollable process that may *output anything*. While it is true that such behaviors are practically useless, we will see in Section 4 that the derivability of these transitions for $\mathbf{0}$ and $\top$ has an important impact in the resulting subtyping relation, for which $\mathbf{0}$ and $\top$ will play the role of least and the greatest element.

Hereafter, we let φ and ψ range over finite sequences of labels, we write $\xrightarrow{\alpha_1 \cdots \alpha_n}$ for the composition $\xrightarrow{\alpha_1} \cdots \xrightarrow{\alpha_n}$, we write $S \xrightarrow{\alpha}$ if $S \xrightarrow{\alpha} T$ for some T and $S \not\xrightarrow{\alpha}$ if not $S \xrightarrow{\alpha}$.

3.3 Properties of Asynchronous Session Types

To substantiate the claim that each transition derivable by the GIS is "real" (*i.e.* it originates from the syntax of the session type), we prove that every input/output transition can be derived by the application of an axiom in Table 3 after every maximal, strongly fair sequence of immediate outputs/inputs. Strong fairness is a weaker assumption implied by the full fairness of Definition 2 [44]. Formally, a (possibly infinite) sequence of transitions $S_0 \xrightarrow{\alpha_1} S_1 \xrightarrow{\alpha_2} \cdots$ is *strongly fair* [26, 44] if, whenever some S' occurs infinitely often in the sequence $S_0 S_1 \cdots$ and $S' \xrightarrow{\alpha} T'$, then also T' occurs infinitely often in the same sequence. Intuitively, a strongly fair sequence of transitions does not discriminate those transitions that are enabled infinitely often. For example, if $S = \oplus\{\mathsf{a} : S, \mathsf{b} : T\}$, the infinite sequence $S \xrightarrow{!\mathsf{a}} S \xrightarrow{!\mathsf{a}} \cdots$ of transitions is strongly unfair, because the transition $S \xrightarrow{!\mathsf{b}} T$ is infinitely often enabled but never performed. On the contrary, if $S = \oplus\{\mathsf{a} : S\}$, then the infinite sequence $S \xrightarrow{!\mathsf{a}} S \xrightarrow{!\mathsf{a}} \cdots$ of transitions is strongly fair.

▶ **Theorem 6.** *Let α be the label of an input/output transition. Then $S \xrightarrow{\alpha}$ if and only if every maximal, strongly fair sequence of immediate output/input transitions $S \xrightarrow{\alpha_1} S_1 \xrightarrow{\alpha_2} \cdots$ is finite and ends in some T such that $T \xrightarrow{\alpha}$ is derivable by an axiom in Table 3.*

Note that, in the statement of Theorem 6, we cannot require the transition $T \xrightarrow{\alpha}$ to be immediate because of the phony early/late transitions enabled by $\mathbf{0}$ and $\top$.

We are accustomed to think that session types are used to describe race-free interactions, but we have seen examples of session types that simultaneously enable both input and output transitions. When this happens, such transitions are independent and do not interfere with each other. We formalize this fact by establishing a diamond property for session types.

▶ **Proposition 7.** *If $S \xrightarrow{?\sigma} S'$ and $S \xrightarrow{!\tau} S''$, then $S' \xrightarrow{!\tau} T$ and $S'' \xrightarrow{?\sigma} T$ for some T.*

4 Fair Asynchronous Subtyping

We define the subtyping relation for asynchronous session types in three steps. First of all, we formalize what we mean by *correct asynchronous composition* between the session types describing the protocols implemented by two processes using the two endpoints of a session. In many session type systems, this notion coincides with session type duality. Since we have to take asynchrony into account, duality alone is too strict so we need a notion of correct composition using the LTS defined in Section 3. Once this notion is in place, asynchronous subtyping can be defined as the relation that preserves correct asynchronous composition. This relation is "sound" by definition, but its properties can be intrinsically difficult to grasp. The final step will be to provide a *precise* (*i.e.* sound and complete) alternative characterization of asynchronous subtyping that sheds light on its properties.

The definition of correct asynchronous composition is given below.

▶ **Definition 8.** *We say that* $\mathcal{R}$ *is a* correct asynchronous composition *if* $(S,T) \in \mathcal{R}$ *implies:*
1. *either* $\mathsf{pos}(S)$ *or* $\mathsf{pos}(T)$*;*
2. *if* $S \xrightarrow{!\sigma} S'$ *and* $\sigma \in \{*\} \cup \mathsf{Tags}$*, then* $T \xrightarrow{?\sigma} T'$ *and* $(S',T') \in \mathcal{R}$*;*
3. *if* $T \xrightarrow{!\sigma} T'$ *and* $\sigma \in \{*\} \cup \mathsf{Tags}$*, then* $S \xrightarrow{?\sigma} S'$ *and* $(S',T') \in \mathcal{R}$*;*
4. *if* $S \xrightarrow{!S_1} S_2$*, then* $T \xrightarrow{?T_1} T_2$ *and* $(S_1,T_1) \in \mathcal{R}$ *and* $(S_2,T_2) \in \mathcal{R}$*;*
5. *if* $T \xrightarrow{!T_1} T_2$*, then* $S \xrightarrow{?S_1} S_2$ *and* $(S_1,T_1) \in \mathcal{R}$ *and* $(S_2,T_2) \in \mathcal{R}$*.*

We write $\bowtie$ *for the largest correct asynchronous composition.*

In words, Items 2–5 state that (S,T) forms a correct composition if, whenever one of the two types performs a (possibly early) output transition $!\sigma$, the other type is able to respond with a (possibly late) compatible input transition $?\tau$ and the continuations remain correct. In general this is not enough to guarantee progress because early outputs are only allowed but not mandatory. For example, the types $\&\{\mathsf{a} : \oplus\{\mathsf{b} : \mathbf{1}\}\}$ and $\&\{\mathsf{b} : \oplus\{\mathsf{a} : \bot\}\}$ satisfy Items 2 and 3, but two processes strictly adhering to these protocols (*i.e.* without performing early outputs) would starve. Item 1 requires that at least one of the two types is positive, namely that at least on one side of the session the outputs are guaranteed to be immediate. This is enough to ensure progress. For example, we have $\&\{\mathsf{a} : \oplus\{\mathsf{b} : \mathbf{1}\}\} \bowtie \oplus\{\mathsf{a} : \&\{\mathsf{b} : \bot\}\}$ as well as $\oplus\{\mathsf{b} : \&\{\mathsf{a} : \mathbf{1}\}\} \bowtie \oplus\{\mathsf{a} : \&\{\mathsf{b} : \bot\}\}$.

It is easy to see that $\bowtie$ is symmetric and that duality implies correctness:

▶ **Proposition 9.** *$S^\bot \bowtie S$ holds for every session type S.*

Other properties of $\bowtie$ are more surprising. For example, if $S = \&\{\mathsf{a} : S, \mathsf{b} : \oplus\{\mathsf{c} : \mathbf{1}\}\}$ and $R = \oplus\{\mathsf{a} : R\}$, we have that $S \bowtie R$ does *not* hold because of the early output transition $S \xrightarrow{!\mathsf{c}}$ to which R is unable to respond. The lack of compatibility between S and R is due to the fact that (the process behaving as) S makes a *fairness assumption* on the behavior of the process it is interacting with. More precisely, a process complying with S assumes that sooner or later a b message will be received, finally enabling the output of c. In anticipation of this, the process may decide to perform an early output of c, but in doing so it would generate an orphan message when interacting with another process adhering to R, which is not honoring this fairness assumption. It is also easy to see that $\mathbf{0} \bowtie S$ holds for every S and that $\top \bowtie S$ implies $S = \mathbf{0}$. These properties of $\mathbf{0}$ and $\top$ follow directly from the [MAY-$\oplus$] and [MAY-&] rules that we have commented in Section 3.

▶ **Example 10.** Let $!\mathsf{a}.S$ stand for $\oplus\{\mathsf{a} : S\}$ and $(!\mathsf{a})^n.S$ stand for $!\mathsf{a} \ldots !\mathsf{a}.S$ with n $!\mathsf{a}$ prefixes. Consider the session types $S = \oplus\{\mathsf{task} : S, \mathsf{stop} : T\}$ and $T = \&\{\mathsf{res} : T, \mathsf{stop} : \bot\}$ and $U = \&\{\mathsf{task} : \oplus\{\mathsf{res} : U\}, \mathsf{stop} : \oplus\{\mathsf{stop} : \mathbf{1}\}\}$ which respectively describe the behaviors of *Split*, *Gather* and *Worker* of Section 1 on the channel y. It is easy to establish that

$$\mathcal{S} \stackrel{\text{def}}{=} \{(S, (!\mathsf{res})^n.U) \mid n \in \mathbb{N}\} \cup \{(T, (!\mathsf{res})^n.!\mathsf{stop}.\mathbf{1}) \mid n \in \mathbb{N}\} \cup \{(\bot, \mathbf{1})\}$$

is a correct asynchronous composition hence $S \bowtie U$. ⌟

We can now define fair asynchronous subtyping semantically using *Liskov's substitution principle* [38] where the property being preserved is session correctness (Definition 8).

▶ **Definition 11** (fair asynchronous subtyping)**.** *We say that* S *is a* fair asynchronous subtype *(or just* subtype*) of* T*, notation* $S \leqslant T$*, if* $R \bowtie T$ *implies* $R \bowtie S$ *for every* R*.*

Paraphrasing, this definition says that a process using a channel x according to T can be safely replaced by a process using x according to S when S is a subtype of T. Indeed, the peer process, which is assumed to use the same channel x according to some session type R such that $R \bowtie T$, will still interact correctly after the substitution has taken place.

A few subtyping relations are easy to figure out. For example, we have $\mathbf{0} \leqslant S$ and $S \leqslant \top$ for every S because of the properties of $\mathbf{0}$ and $\top$ that we have pointed out above. It is also easy to see that $\oplus\{\mathsf{a} : \&\{\mathsf{b} : S\}\} \leqslant \&\{\mathsf{b} : \oplus\{\mathsf{a} : S\}\}$ holds in an asynchronous setting. After all, the process that behaves according to $\oplus\{\mathsf{a} : \&\{\mathsf{b} : S\}\}$ is sending a tag a that also the process that behaves according to $\&\{\mathsf{b} : \oplus\{\mathsf{a} : S\}\}$ *may* anticipate. Note that the inverse relation $\&\{\mathsf{b} : \oplus\{\mathsf{a} : S\}\} \leqslant \oplus\{\mathsf{a} : \&\{\mathsf{b} : S\}\}$ does not hold, despite the fact that $\oplus\{\mathsf{a} : \&\{\mathsf{b} : S\}\}$ and $\&\{\mathsf{b} : \oplus\{\mathsf{a} : S\}\}$ perform exactly the same transitions, because $\&\{\mathsf{a} : \oplus\{\mathsf{b} : S^{\perp}\}\}$ forms a correct asynchronous composition with $\oplus\{\mathsf{a} : \&\{\mathsf{b} : S\}\}$ but not with $\&\{\mathsf{b} : \oplus\{\mathsf{a} : S\}\}$ (Item 1 of Definition 8 is violated).

The above notion of subtyping is sound "by definition", but provides little information concerning the shape of related session types. To compensate for this problem, we also give a sound and complete coinductive characterization of $\leqslant$, which relates directly to Definition 8.

▶ **Definition 12** (coinductive asynchronous subtyping)**.** *We say that $\mathcal{S}$ is a* coinductive asynchronous subtyping *if $(S,T) \in \mathcal{S}$ implies:*

1. *either* $\mathsf{pos}(S)$ *or* $\mathsf{neg}(T)$*;*
2. *if $T \xrightarrow{?\sigma} T'$ and $\sigma \in \{*\} \cup \mathsf{Tags}$, then $S \xrightarrow{?\sigma} S'$ and $(S',T') \in \mathcal{S}$;*
3. *if $S \xrightarrow{!\sigma} S'$ and $\sigma \in \{*\} \cup \mathsf{Tags}$, then $T \xrightarrow{!\sigma} T'$ and $(S',T') \in \mathcal{S}$;*
4. *if $T \xrightarrow{?T_1} T_2$, then $S \xrightarrow{?S_1} S_2$ and $(S_1,T_1) \in \mathcal{S}$ and $(S_2,T_2) \in \mathcal{S}$;*
5. *if $S \xrightarrow{!S_1} S_2$, then $T \xrightarrow{!T_1} T_2$ and $(S_1,T_1) \in \mathcal{S}$ and $(S_2,T_2) \in \mathcal{S}$.*

Items 2–5 of Definition 12 specify the expected requirements for a session subtyping relation: every input transition of the supertype T must be matched by an input transition of the subtype S and the corresponding continuations should still be related by subtyping; dually, every output transition of the subtype S must be matched by an output transition of the supertype T and the corresponding continuations should still be related by subtyping. Interestingly, these items are essentially the same found in analogous characterizations of *synchronous subtyping for session types* [28], modulo the different orientation of $\leqslant$ due to our viewpoint based on the substitution of processes rather than on the substitution of channels.[1] However, the clauses of Definition 12 are not mutually exclusive, because the same session type may perform both input and output transitions. Also, session types related by subtyping need not start with the same type constructor. In this respect, Item 1 makes sure that the smaller session type can only anticipate (and not postpone) outputs, as argued above.

Definition 12 is a sound and complete characterization of $\leqslant$.

▶ **Theorem 13.** *$\leqslant$ is the largest coinductive asynchronous subtyping.*

Using Definition 12 and Theorem 13 we can prove some significant properties of $\leqslant$:

- (input contravariance) $\&\{\mathsf{a}_i : S_i\}_{i\in I} \leqslant \&\{\mathsf{a}_i : S_i\}_{i\in J}$ if $J \subseteq I$ by Item 2;
- (output covariance) $\oplus\{\mathsf{a}_i : S_i\}_{i\in I} \leqslant \oplus\{\mathsf{a}_i : S_i\}_{i\in J}$ if $I \subseteq J$ by Item 3;
- (output anticipation) $\oplus\{\mathsf{a}_j : \&\{\mathsf{b}_i : S_{ij}\}_{i\in I}\}_{j\in J} \leqslant \&\{\mathsf{b}_i : \oplus\{\mathsf{a}_j : S_{ij}\}_{j\in J}\}_{i\in I}$. Note that the inverse relation does not hold, despite these two session types have exactly the same transitions, because of Item 1.

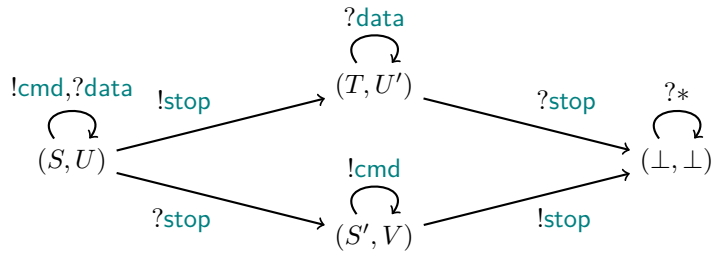
There are exceptions to output covariance and input contravariance when one of the two types specifies a non-terminating protocol. The next example illustrates one of such cases.

[1] The interested reader may refer to Gay [27] for a comparison of the two viewpoints.

▶ **Example 14.** Consider $S = \&\{\mathsf{a} : S, \mathsf{b} : \oplus\{\mathsf{c} : \mathbf{1}\}\}$ and $T = \&\{\mathsf{a} : T\}$. Despite S is a subtype of T for other session subtypings [28, 39, 11, 8], we have $S \not\leqslant T$ because $S \xrightarrow{!\mathsf{c}}$ and $T \not\xrightarrow{!\mathsf{c}}$. To see the reason why admitting this relation could cause a problem, consider a process that complies with the protocol $R = \oplus\{\mathsf{a} : R\}$. Such a process would output infinitely many a's and would not expect to input anything. Still, if we consider $S' = \&\{\mathsf{a} : S', \mathsf{b} : \mathbf{1}\}$ we have that $\oplus\{\mathsf{c} : S'\} \leqslant S$ holds. That is, a process complying with $\oplus\{\mathsf{c} : S'\}$ performs immediately the early output in S. By transitivity of $\leqslant$ (whose validity is implied by Theorem 13), we would also have $\oplus\{\mathsf{c} : S'\} \leqslant T$. Now the problem is clear: $R \bowtie T$ holds, but a process complying with R would not be able to handle the incoming c message if we composed it with a process complying with $\oplus\{\mathsf{c} : S'\}$. ⌟

The cases in which co/contra variance does not hold have no impact on the typeability of CaP processes: since our type system ensures the fair termination of well-typed processes, protocols like T in Example 14 are not inhabited. We will see in Section 7 that $\leqslant$ includes other subtyping relations supporting full co/contra variance for the family of fairly terminating session types, those that always allow the protocol to end.

▶ **Example 15.** We borrow a scenario from Bravetti, Lange and Zavattaro [8] to showcase an interesting example of fair asynchronous subtyping. Imagine a system made of a ground station and a satellite such that, at each flyby, the satellite sends data from the previous orbit and receives commands to execute in the next one. In principle, the ground station should follow the protocol $U = \&\{\mathsf{data} : U, \mathsf{stop} : V\}$ where $V = \oplus\{\mathsf{cmd} : V, \mathsf{stop} : \bot\}$. However, since the flyby window may be short, it makes sense to implement the ground station so that it communicates with the satellite in full duplex by anticipating the output of the commands. In this case, the ground station follows the protocol $S = \oplus\{\mathsf{cmd} : S, \mathsf{stop} : T\}$ where $T = \&\{\mathsf{data} : T, \mathsf{stop} : \bot\}$. Is this implementation correct? We can answer in the affirmative by proving $S \leqslant U$ with the diagram below, which represents a coinductive asynchronous subtyping containing the pair (S, U). In the diagram we also use the types $S' = \oplus\{\mathsf{task} : S', \mathsf{stop} : \bot\}$ and $U' = \&\{\mathsf{res} : U', \mathsf{stop} : \bot\}$.



Note that S allows for the anticipation of an unbounded number of outputs before an unbounded number of inputs. ⌟

We now list a few properties of $\leqslant$. First of all, we establish that $\leqslant$ is closed by duality.

▶ **Proposition 16.** *If $S \leqslant T$, then $T^\perp \leqslant S^\perp$.*

Proof. By Theorem 13 it suffices to show that if $\mathcal{S}$ is a coinductive asynchronous subtyping, then so is $\mathcal{S}^\perp \stackrel{\text{def}}{=} \{(T^\perp, S^\perp) \mid (S, T) \in \mathcal{S}\}$. This follows immediately from Definition 12. ◀

Then, we show how to characterize $\bowtie$ solely in terms of $\leqslant$.

▶ **Theorem 17.** *$S \bowtie T$ if and only if $S \leqslant T^\perp$*

Finally, we observe that similarly to the other asynchronous session type theories correct composition is undecidable. The source of undecidability follows from the possibility to use communicating buffers to model unbounded memories like tapes of Turing Machines [36] or queues of Queue Machines [6].

▶ **Theorem 18.** *Given two types S and T, the problem of checking $S \bowtie T$ is undecidable.*

As a direct consequence of Theorems 17 and 18, we have that checking $S \leqslant T$ is also an undecidable problem. Despite these negative results, the coinductive characterizations of correctness (Definition 8) and subtyping (Definition 12) are useful to prove that these relations hold in specific cases, as done in Examples 10 and 15.

5 Type System

In this section we describe the type system for CaP ensuring that well-typed processes weakly terminate, besides being free from communication errors and deadlocks. Theorem 4 then allows us to conclude that the very same type system also ensures fair termination when we make the fairness assumption stated in Definition 2. The type system is based on the proof rules of MALL but also includes typing rules for the non-logical process forms, namely termination, process invocation and non-deterministic choice.

5.1 Measuring Processes and Type Annotations

It is a known fact that infinitary proof systems for linear logic (*e.g.* μMALL [3, 25]) require validity conditions to enjoy the cut elimination property. As a consequence, the infinitary type system for CaP requires validity conditions to ensure the (weak) termination property. We implement these validity conditions using the technique of Dagnino and Padovani [19] and decorate types and typing judgments with quantitative information that estimates the amount of effort required to terminate a process. It is natural to measure such effort in terms of *number of reductions* of that process (Table 2). Since most reductions arise from session interactions and each session interaction involves a process outputting a message on a channel (with a *positive* type) and a process inputting a message from the same channel (with a *negative* type) we count the number of process forms representing outputs to establish the number of reductions that are necessary to normalize a process. In the presence of branching processes (those whose behavior depends on a tag received from a channel), we can tentatively compute an upper bound for terminating *each* branch.

Let us use the definitions in Section 1 to walk through this approach on increasingly complex examples. To start, consider the process *Gather*, which we repeat here for convenience:

$$Gather(x, y) = y \triangleright \{\mathsf{res} : Gather\langle x, y\rangle, \mathsf{stop} : \mathsf{wait}\ y.x \triangleleft \mathsf{resp.close}\ x\}$$

Now suppose that n is the measure associated with *Gather* and note that *Gather* is a branching and recursive process. The res branch does not contain any output actions, whereas the stop branch performs two outputs on x. Therefore, n should satify the relations $n \geq n$ (for the res branch) and $n \geq 2$ (for the stop branch) whose least solution is $n = 2$. That is, *Gather* weakly terminates by performing at most two outputs. Note that the actual number of interactions performed by *Gather* depends on the number of received res messages and may be larger than 2. However, these received messages are accounted for in the measure of the sender, while the measure 2 we give to *Gather* only accounts for the messages sent by *Gather*.

If we now consider the process

$$Split(x,y) = y \lhd \mathsf{task}.Split\langle x,y\rangle \oplus y \lhd \mathsf{stop}.Gather\langle x,y\rangle$$

we have to measure a non-deterministic choice. Since non-deterministic choices are performed autonomously by a process and we are interested in proving that processes *weakly* terminate, we can measure a non-deterministic choice by considering the branch with the least measure and the additional reduction due to [R-CHOICE]. So, in this case, the measure of *Split* – say m – must satisfy the equation $m \geq 1 + \min\{1+m, 3\}$ where $1+m$ is the measure of the left branch and 3 is the (least) measure of the right branch, having already established that *Gather* can be given measure 2. The least least solution of this constraint is $m = 4$.

A more challenging process to measure is

$$Worker(y) = y \rhd \{\mathsf{task} : y \lhd \mathsf{res}.Worker\langle y\rangle, \mathsf{stop} : y \lhd \mathsf{stop}.\mathsf{close}\ y\}$$

in which each task input is immediately followed by a res output. If we try to measure *Worker* following the same reasoning applied to *Gather*, we end up looking for some n satisfying the system of inequations $n \geq 1+n$ (for the task branch) and $n \geq 2$ (for the stop branch). Since no n satisfies these inequations, we have to refine our measuring strategy or else *Worker* would end up being ill typed. This is precisely what happens in some type systems ensuring the fair termination of sessions [14, 12] which is unfortunate because *Worker* is not ill behaved after all: the fairness assumption we are making ensures that the number of tasks will be finite, albeit unbounded. Likewise, the number of results will be finite but unbounded as well. The problem is that we are unable to find a *single* measure for *Worker* that accounts for all possibilities.

We refine our measuring technique allowing the measure of *Worker* to *depend* on the tags it receives. We realize this dependency by annotating tags with measures that are charged to senders and discharged from receivers. To see this mechanism at work in the case of *Split* and *Worker*, consider the following annotated session types:

$$S = \oplus\{\mathsf{task}^1 : S, \mathsf{stop}^0 : T\} \tag{5}$$

$$T = \&\{\mathsf{res}^0 : T, \mathsf{stop}^0 : \bot\} \tag{6}$$

$$U = \&\{\mathsf{task}^1 : \oplus\{\mathsf{res}^0 : U\}, \mathsf{stop}^0 : \oplus\{\mathsf{stop}^0 : \mathbf{1}\}\} \tag{7}$$

The annotations in task^1 and stop^0 mean that a process like *Split*, which complies with S, is *charged* by 1 unit of measure whenever it sends task and by 0 when it sends stop. This measure is charged *in addition* to the cost of the output it is performing and accounts for the cost of sending the result in *Worker*. Since this cost is already charged on *Split*, it can be *discharged* from the task branch of *Worker* when we compute its measure, as shown by U. This way we end up solving for *Worker* the equations $n \geq n$ (for the task branch) and $n \geq 2$ (for the stop branch) whose least solution is $n = 2$. In principle we have to reconsider the measure we gave to *Split* to account for the 1 unit that is now charged for each output of task, but since the measure of *Split* was determined by the stop branch (which has a null annotation) it remains unchanged.

From now on we consider a refinement of the session types presented in Section 3 where tags are annotated with natural numbers. These annotations do not interfere in any way with the properties and characterizations of session types we have presented there and in Section 4, with the proviso that wherever we have written matching message types in Sections 3 and 4 we mean that measures also match. In particular, Definition 8 entails that the amount of measure charged on one side of the session matches the amount of measure discharged from

Table 4 Typing rules for CaP.

$$[\textsc{done}]\ \frac{}{\mathsf{done} \vdash^n \emptyset} \qquad [\textsc{call}]\ \frac{P \vdash^n \overline{x : S}}{A\langle \overline{x} \rangle \vdash^{m+n} \overline{x : S}}\ A(\overline{x}) = P \qquad [\mathbf{1}]\ \frac{}{\mathsf{close}\ x \vdash^{1+n} x : \mathbf{1}} \qquad [\bot]\ \frac{P \vdash^n \Gamma}{\mathsf{wait}\ x.P \vdash^n \Gamma, x : \bot}$$

$$[\textsc{choice}]\ \frac{P \vdash^{n_1} \Gamma \qquad Q \vdash^{n_2} \Gamma}{P \oplus Q \vdash^{1+n_k} \Gamma} \qquad [\otimes]\ \frac{P \vdash^m \Gamma, y : S \qquad Q \vdash^n \Delta, x : T}{x(y)[P].Q \vdash^{1+m+n} \Gamma, \Delta, x : S \otimes T} \qquad [\parr]\ \frac{P \vdash^n \Gamma, y : S, x : T}{x(y).P \vdash^n \Gamma, x : S \parr T}$$

$$[\oplus]\ \frac{P \vdash^n \Gamma, x : S_k}{x \lhd \mathsf{a}_k.P \vdash^{1+n+m_k} \Gamma, x : \oplus\{\mathsf{a}_i^{m_i} : S_i\}_{i \in I}} \qquad [\&]\ \frac{\forall i \in I : P_i \vdash^{n+m_i} \Gamma, x : S_i}{x \rhd \{\mathsf{a}_i : P_i\}_{i \in I \cup J} \vdash^n \Gamma, x : \&\{\mathsf{a}_i^{m_i} : S_i\}_{i \in I}}$$

$$[\textsc{link}]\ \frac{}{x \leftrightarrow y \vdash^{1+n} x : S, y : T}\ S^\bot \leqslant T \qquad [\textsc{cut}]\ \frac{P \vdash^m \Gamma, x : S \qquad Q \vdash^n \Delta, x : T}{(x)(P \mid Q) \vdash^{m+n} \Gamma, \Delta}\ S \bowtie T$$

the other side of the session (like for S and U above) and the clauses of Definition 12 entail that matching actions in session types related by subtyping carry the same measure. In principle, it would be possible to relax these constraints and allow some variance of measure annotations. Since we do not have concrete examples that take advantage of this further refinement, we spare the additional complexity.

5.2 Typing Rules

The typing rules for CaP are shown in Table 4. Judgments have the form $P \vdash^n \Gamma$ where P is the process being typed, n is its measure and Γ is a *typing context*, namely a partial function that maps channels to types. We let Γ and Δ range over typing contexts, we write $\emptyset$ for the empty context, $x : S$ for the singleton context that maps x to S, and Γ, Δ for the union of Γ and Δ when they have disjoint domains. The typing rules shown in Table 4 are meant to be interpreted coinductively, hence a process is well typed provided there is a (possibly infinite) derivation built using those rules. The structure of the rules is essentially the same of other session type systems based on (classical) linear logic [45, 37, 19], so we will mainly focus on those aspects of the rules that are new or different in our setting.

The rule [done] states that the terminated process can have any measure and is well typed only in the empty context.

The rule [call] states that a process invocation is well typed in a context $\overline{x : S}$ if so is its definition in the same context. Recall that a typing derivation can be infinite in the case of recursive processes and note that the measure of the invocation may be larger than that of its definition, allowing some measure to be discarded from one invocation to the next. This is not strictly necessary for the soundness of type system, but it is sometimes convenient to obtain simpler typing derivations.

The rules [$\mathbf{1}$] and [$\bot$] deal with session termination in the expected way. The measure of close x is strictly positive whereas the measure of wait $x.P$ coincides with that of P since the measure n in a typing judgment $\Gamma \vdash^n P$ only accounts for the outputs performed by P.

The rules [⊗] and [⅋] deal with the communication of channels. The measure of a channel output $x(y)[P].Q$ accounts for both the measure of P (the process being spawned that uses one end of the fresh session y) and the measure of Q, while the additional unit of measure accounts for the output being performed. The measure of a channel input $x(y).P$ simply coincides with that of the continuation process.

The rules [⊕] and [&] deal with the communication of tags. The measure of a tag output $x \lhd \mathsf{a}.P$ accounts for the measure of the continuation P and of the measure annotation m associated with a in the type of x, while the additional unit of measure accounts for the output being performed. The measure of a tag input $x \rhd \{\mathsf{a}_i : P_i\}_{i \in I}$ is the residual measure of each branch after the measure annotation m_i associated with a_i in the type of x has been discharged. Note that a tag input may in general provide more branches than those actually occurring in the type of x. As a special case, [&] also captures the introduction rule for $\top$ in MALL. In particular, we have $x \rhd \{\} \vdash^n \Gamma, x : \top$ for every n and every Γ.

The rule [CHOICE] deals with non-deterministic choices in the expected way. The rule does not specify which branch of a non-deterministic choice determines the measure of the whole choice. Since the typeability of a process rests on its measurability, the obvious strategy is to pick the continuation with the smallest measure (*cf.* Section 5.1).

The rule [LINK] is a generalization of the axiom in MALL. It allows the unification of x and y provided that $S^\perp \leqslant T$ (or equivalently $T^\perp \leqslant S$, by Proposition 16) where S is the type of x and T is the type of y. As we will see in Section 6, this formulation of the link typing rule allows us to capture some recurring usage patterns of subtyping. A link has a strictly positive measure since it accounts for one [R-LINK] reduction.

Finally, the rule [CUT] rule ensures that the processes P and Q connected by the new session x use the channel correctly requiring $S \bowtie T$ to hold where S is the type of x as used by P and T is the type of x as used by Q. Note that this correctness condition can be equivalently expressed in terms of subtyping with the relation $S \leqslant T^\perp$ by Theorem 17. The measure of the composition is the combination of the measures of P and Q.

▶ **Example 19.** Let us build a typing derivation for the server $x \rhd \{\mathsf{req} : (y)(\mathit{Split}\langle x, y\rangle \mid \mathit{Worker}\langle y\rangle)\}$ using the types S, T and U defined in Equations (5)–(7). It is convenient to also use the type $V = \oplus\{\mathsf{resp}^0 : \mathbf{1}\}$. Table 5 shows the typing derivations for the *Split*, *Gather* and *Worker* processes. Note that the measures obtained for these processes coincide with those previously inferred in Section 5.1. From $S \bowtie U$ (Example 10) we derive

$$\dfrac{\dfrac{\dfrac{\vdots}{\mathit{Split}\langle x, y\rangle \vdash^4 x : V, y : S} \quad \dfrac{\vdots}{\mathit{Worker}\langle y\rangle \vdash^2 y : U}}{(y)(\mathit{Split}\langle x, y\rangle \mid \mathit{Worker}\langle y\rangle) \vdash^6 x : V}\,[\text{CUT}]}{x \rhd \{\mathsf{req} : (y)(\mathit{Split}\langle x, y\rangle \mid \mathit{Worker}\langle y\rangle)\} \vdash^6 x : \&\{\mathsf{req}^0 : V\}}\,[\&]$$

confirming that the server is well typed. ⌟

5.3 Properties of Well-Typed Processes

We conclude this section presenting a series of results showing the main properties of well-typed processes, starting from the preservation of typing under reductions (*i.e.* subject reduction) which underlies most of the subsequent results. Subject reduction is formulated in a slightly non-standard way because the typing context may become "smaller" – *i.e.* "more precise" – according to the subtyping relation $\leqslant$ after each reduction. This is a consequence of the formulation of the rule [LINK], where the types of x and y need not be dual to each other, but can be related by subtyping. In the statement of Theorem 20, we write $\leqslant$ for the pointwise extension of subtyping to typing contexts.

Table 5 Typing derivations for *Split*, *Gather* and *Worker*.

$$\dfrac{\dfrac{\vdots}{Gather\langle x,y\rangle \vdash^2 x : V, y : T} \quad \dfrac{\dfrac{\dfrac{}{\mathsf{close}\ x \vdash^1 x : \mathbf{1}}\,[\mathbf{1}]}{x \lhd \mathsf{resp}.\mathsf{close}\ x \vdash^2 x : V}\,[\oplus]}{\mathsf{wait}\ y.x \lhd \mathsf{resp}.\mathsf{close}\ x \vdash^2 x : V, y : \bot}\,[\bot]}{y \rhd \{\mathsf{res} : Gather\langle x,y\rangle, \mathsf{stop} : \mathsf{wait}\ y.x \lhd \mathsf{resp}.\mathsf{close}\ x\} \vdash^2 x : V, y : T}\,[\&]}{Gather\langle x,y\rangle \vdash^2 x : V, y : T}\,[\textsc{call}]$$

$$\dfrac{\dfrac{\dfrac{\vdots}{Split\langle x,y\rangle \vdash^4 x : V, y : S}}{y \lhd \mathsf{task}.Split\langle x,y\rangle \vdash^6 x : V, y : S}\,[\oplus] \quad \dfrac{\dfrac{\vdots}{Gather\langle x,y\rangle \vdash^2 x : V, y : T}\,[\textsc{link}]}{y \lhd \mathsf{stop}.Gather\langle x,y\rangle \vdash^3 x : V, y : S}\,[\oplus]}{y \lhd \mathsf{task}.Split\langle x,y\rangle \oplus y \lhd \mathsf{stop}.Gather\langle x,y\rangle \vdash^4 x : V, y : S}\,[\textsc{choice}]}{Split\langle x,y\rangle \vdash^4 x : V, y : S}\,[\textsc{call}]$$

$$\dfrac{\dfrac{\dfrac{\vdots}{Worker\langle y\rangle \vdash^2 y : U}}{y \lhd \mathsf{resp}.Worker\langle y\rangle \vdash^3 y : \oplus\{\mathsf{resp}^0 : U\}}\,[\oplus] \quad \dfrac{\dfrac{}{\mathsf{close}\ y \vdash^1 y : \mathbf{1}}\,[\mathbf{1}]}{y \lhd \mathsf{stop}.\mathsf{close}\ y \vdash^2 y : \oplus\{\mathsf{stop}^0 : \mathbf{1}\}}\,[\oplus]}{y \rhd \{\mathsf{task} : y \lhd \mathsf{resp}.Worker\langle y\rangle, \mathsf{stop} : y \lhd \mathsf{stop}.\mathsf{close}\ y\} \vdash^2 y : U}\,[\&]}{Worker\langle y\rangle \vdash^2 y : U}\,[\textsc{call}]$$

▶ **Theorem 20** (subject reduction). *If $P \to Q$, then $P \vdash^n \Gamma$ implies $Q \vdash^m \Delta$ for some $\Delta \leqslant \Gamma$.*

In general it is not possible to establish an order relationship between m (the measure of the process after the reduction) and n (the measure of the process before the reduction) because of the rule [CHOICE]. However, when $P \to$ it is always possible to reduce P so that its measure strictly decreases. This is the key reasoning for the forthcoming termination results.

While deadlock freedom (Definition 1) is usually taken for granted for session type systems based on linear logic, where it is a straightforward consequence of cut elimination, its proof for CaP is more elaborated because of the deep cut reductions that model asynchrony. In particular, all of the reduction rules of Table 2 except [R-CLOSE] take into account the presence of message buffers. The commuting conversions dealing with message buffers play a key role in rearranging the structure of processes so as to guarantee deadlock freedom in the presence of asynchronous communications.

▶ **Theorem 21** (deadlock freedom). *If $P \vdash^n \emptyset$, then P is deadlock free.*

Theorem 21 holds for closed processes (those well typed in the empty context), but its proof is based on a more general *productivity* result [43] that applies to open processes as well. Intuitively, a productive process is always able to reduce or it is structurally precongruent to another process that exposes some actions on a free name.

Next we have two termination results. The first one ensures that well-typed processes are weakly terminating, namely that they have (at least) one finite run.

▶ **Theorem 22** (weak termination). *If $P \vdash^n \Gamma$, then P is weakly terminating.*

Weak termination is a liveness property and, as such, its proof is based on a well-founded argument. The quantity n is one of the components of a lexicographically ordered pair that serves as basis for the induction. The other component of the pair measures the depth of the

"unguarded" top-level structure of the process which is guaranteed to be finite because of the guardedness restriction we have assumed on processes in Section 2. This component is needed to cope with the typing rules [CALL] and [CUT] for which the measure of the premise(s) is not necessarily smaller than the measure in the conclusion of the rules.

Theorem 22 can be strengthened to a termination result for *deterministic* processes, those that do not contain non-deterministic choices.

▶ **Theorem 23** (termination). *If P is deterministic and $P \vdash^n \Gamma$, then P is terminating.*

The combination of Theorem 22 with Theorem 21 also guarantees the absence of *orphan messages*. Indeed, suppose that P is a well-typed closed process and $P \to^* Q$ where Q contains non-empty buffers. By Theorems 21 and 22 we know that $Q \to^* \sqsupseteq \mathsf{done}$. Since in a closed process messages cannot simply disappear and the only way of consuming them is by means of the reductions [R-CLOSE], [R-FORK] and [R-SELECT], we know that all the messages in Q have been received.

Finally, using the proof principle stated in Theorem 4 we obtain, as a straightforward corollary of Theorem 22, that well-typed processes are *fairly terminating* (Definition 3).

▶ **Corollary 24.** *If $P \vdash^n \Gamma$, then P is fairly terminating.*

6 Subtyping Usage Patterns

A typical usage of subtyping is to make sure that processes occurring in different branches of a non-deterministic choice $P_1 \oplus P_2$ or of a tag input $x \rhd \{\mathsf{a}_i : P_i\}_{i \in I}$ can be typed in the same typing context. Indeed, the typing rules [CHOICE] and [&] require each P_i to be typed in the same typing context (with the exception that in [&], the type of x can be different in each branch), but there are cases in which this requirement is overly restrictive.

As an example, consider a variation of the scenario depicted in Section 1 in which the worker behaves either as $\mathit{Worker}\langle y \rangle$ (as defined as in Equation (3)) or as $\mathit{BatchWorker}\langle y \rangle$ that first gathers all tasks and then sends back all the results. The $\mathit{BatchWorker}\langle y \rangle$ version can be modeled by the equations

$$\mathit{BatchWorker}(y) = y \rhd \{\mathsf{task} : \mathit{BatchWorker}\langle y \rangle, \mathsf{stop} : \mathit{SendResults}\langle y \rangle\}$$
$$\mathit{SendResults}(y) = y \lhd \mathsf{res}.\mathit{SendResults}\langle y \rangle \oplus y \lhd \mathsf{stop}.\mathsf{close}\ y$$

for which it is easy to obtain a derivation $\mathit{BatchWorker}\langle y \rangle \vdash y : S^\perp$ where S is defined as in Equation (5). Ideally, we could express the server using a non-deterministic choice, thus:

$$x \rhd \{\mathsf{req} : (y)(\mathit{Split}\langle x, y \rangle \mid (\mathit{Worker}\langle y \rangle \oplus \mathit{BatchWorker}\langle y \rangle))\}$$

however, this process turns out to be ill typed because $\mathit{Worker}\langle y \rangle$ and $\mathit{BatchWorker}\langle y \rangle$ use the channel y according to different types. Moreover, it should be clear that there is no one-size-fits-all session type that can be associated with y.

We can exploit the relation $U \leqslant S^\perp$ to make $\mathit{Worker}\langle y \rangle$ (which complies with U defined in Equation (7)) look like a process that complies with $S^\perp$. In many type systems with subtyping, this is simply achieved with an application of the *subsumption rule*. The type system we have presented for CaP does not have a subsumption rule, but this rule is derivable thanks to the formulation of [LINK]. In our specific example, we can derive

$$\dfrac{\dfrac{}{z \leftrightarrow y \vdash z : U^\perp, y : S^\perp}\,[\text{LINK}] \qquad \dfrac{\vdots}{\mathit{Worker}\langle z \rangle \vdash z : U}}{(z)(z \leftrightarrow y \mid \mathit{Worker}\langle z \rangle) \vdash y : S^\perp}\,[\text{CUT}]$$

to obtain an implementation of the streaming worker that complies with $S^\perp$. Now we derive

$$(z)(z \leftrightarrow y \mid \mathit{Worker}\langle z\rangle) \oplus \mathit{BatchWorker}\langle y\rangle \vdash y : S^\perp$$

to obtain a well-typed worker. Incidentally, this example also illustrates the reason why Theorem 20 is formulated so that, when $P \to Q$, the typing context of Q may be smaller (according to $\leqslant$) than the typing context of P. Indeed we have $(z)(z \leftrightarrow y \mid \mathit{Worker}\langle z\rangle) \oplus \mathit{BatchWorker}\langle y\rangle \to (z)(z \leftrightarrow y \mid \mathit{Worker}\langle z\rangle) \to \mathit{Worker}\langle y\rangle$ and we would not be able to obtain a typing derivation for $\mathit{Worker}\langle y\rangle \vdash y : S^\perp$.

Another typical usage pattern for links is the implementation of *delegation*, whereby the endpoint of an existing session is exchanged through another session. Because of our formulation of [LINK], in our type system this mechanism also enables a form of substitution principle for channels so that a channel of type T can be safely used where a channel of type S is expected if $S \leqslant T$ (the reason why this formulation of the substitution principle may seem to go in the wrong direction is again due to the fact that we adopt the viewpoint whereby session types describe processes rather than channels).

To illustrate this usage pattern, consider the typing derivation

$$\dfrac{\dfrac{}{y \leftrightarrow z \vdash^1 y : U, z : T}\,[\textsc{link}] \quad \dfrac{\vdots}{P \vdash^n \Gamma, x : V} \quad \dfrac{\vdots}{Q \vdash^m \Delta, x : W, y : S}}{\dfrac{x(y)[y \leftrightarrow z].P \vdash^{n+1} \Gamma, x : U \otimes V, z : T}{(x)(x(y)[y \leftrightarrow z].P \mid x(y).Q) \vdash^{n+m+1} \Gamma, \Delta, z : T}\,[\textsc{cut}]}\,[\otimes] \quad \dfrac{x(y).Q \vdash^m \Delta, x : S \parr W}{}\,[\parr]$$

which concerns the composition of a process $x(y)[y \leftrightarrow z].P$ that delegates z to another process $x(y).Q$. Note that the sender delegates a channel of type T while the receiver expects to receive a channel of type S. In order for the cut to be well typed we must have $U \otimes V \bowtie S \parr W$, that is $U \bowtie S$ and $V \bowtie W$. The application of [LINK] requires $U^\perp \leqslant T$, that is $T^\perp \leqslant U$ by Proposition 16. From this relation and $U \bowtie S$ we deduce $T^\perp \bowtie S$ by definition of $\leqslant$. Using Theorem 17 we obtain $T^\perp \leqslant S^\perp$, that is $S \leqslant T$.

7 Comparison With Other Subtyping Relations

In this section we provide a more detailed comparison between $\leqslant$ and some connected subtyping relations appeared in the literature. We show that $\leqslant$ is coarser than these relations when we focus on the family of *First-order Fairly-terminating Session Types* (FFST). Fairly terminating session types are those describing protocols that can always eventually terminate. The reason why this family is relevant for us is that *fairly terminating session types are the only inhabited types in our type system*: since well-typed processes are fairly terminating (Corollary 24), they only use sessions that can always eventually terminate. For simplicity we also focus on *first-order* session types (without the multiplicative connectives $\otimes$ and $\parr$) because the handling of higher-order communications varies substantially depending on whether the type system is based on linear logic or not.

To carry out the comparison between $\leqslant$ and the other subtyping relations we define two restricted versions of the transition relation $\xrightarrow{\alpha}$. We write $\overset{\alpha}{\longmapsto}$ for the relation inductively defined by the [MUST-*] rules and we write $\overset{\alpha}{\Longmapsto}$ for the relation inductively defined by the [MUST-*] and [MAY-*] rules. So we have $\overset{\alpha}{\longmapsto} \subset \overset{\alpha}{\Longmapsto} \subset \xrightarrow{\alpha}$ but the relation $\overset{\alpha}{\longmapsto}$ only allows *immediate transitions* and $\overset{\alpha}{\Longmapsto}$ differs from $\xrightarrow{\alpha}$ because early outputs and late inputs can only be preceeded by a bounded number of inputs and outputs, respectively. For example, if $S = \&\{\mathsf{a} : S, \mathsf{b} : \oplus\{\mathsf{c} : \mathbf{1}\}\}$ and $T = \&\{\mathsf{a} : T, \mathsf{b} : \mathbf{1}\}$, we have $S \xrightarrow{!\mathsf{c}} T$ and $S \overset{!\mathsf{c}}{\Longmapsto}$.

We define fairly terminating session types thus:

▶ **Definition 25.** *We say that S is* fairly terminating *if, for every maximal strongly fair sequence $S = S_0 \overset{\alpha_1}{\longmapsto} S_1 \overset{\alpha_2}{\longmapsto} S_2 \overset{\alpha_3}{\longmapsto} \cdots$ starting from S, there exists k such that $S_k \in \{\mathbf{1}, \bot\}$.*

Gay and Hole [28] introduced the first *synchronous subtyping relation* for session types. We qualify this relation as "synchronous" because it does not allow any form of output anticipation. However, it supports unconstrained output covariance and input contravariance as shown in its characterization below, which uses immediate transitions only.

▶ **Definition 26.** *We write $\leqslant_{\mathsf{s}}$ for the largest relation such that $S \leqslant_{\mathsf{s}} T$ implies:*

1. *either* $\mathsf{pos}(S)$ *or* $\mathsf{neg}(T)$*;*
2. *if $T \overset{?\sigma}{\longmapsto} T'$ then $S \overset{?\sigma}{\longmapsto} S'$ and $S' \leqslant_{\mathsf{s}} T'$;*
3. *if $S \overset{!\sigma}{\longmapsto} S'$ then $T \overset{!\sigma}{\longmapsto} T'$ and $S' \leqslant_{\mathsf{s}} T'$.*

Mostrous *et al.* [40, 39] studied the first *asynchronous subtypings* for session types. Chen *et al.* [11] subsequently refined the relation of Mostrous and Yoshida [39] so as to avoid orphan messages. The resulting relation has been shown to be the largest one included in the original asynchronous subtyping that is closed under duality [7]. Using our LTS we can characterize the asynchronous subtyping relations in this line of research by the following definition.

▶ **Definition 27.** *We write $\leqslant_{\mathsf{a}}$ for the largest relation such that $S \leqslant_{\mathsf{a}} T$ implies:*

1. *either* $\mathsf{pos}(S)$ *or* $\mathsf{neg}(T)$*;*
2. *if $T \overset{?\sigma}{\longmapsto} T'$ then $S \overset{?\sigma}{\Longmapsto} S'$ and $S' \leqslant_{\mathsf{a}} T'$;*
3. *if $S \overset{!\sigma}{\longmapsto} S'$ then $T \overset{!\sigma}{\Longmapsto} T'$ and $S' \leqslant_{\mathsf{a}} T'$.*

Like $\leqslant_{\mathsf{s}}$, also $\leqslant_{\mathsf{a}}$ supports unconstrained contravariance of inputs and covariance of outputs but the clauses (2) and (3) are more genereous because early/late transitions enable the anticipation of outputs. For example, $\oplus\{\mathsf{a} : \&\{\mathsf{b} : S, \mathsf{c} : \&\{\mathsf{d} : T\}\}\} \leqslant_{\mathsf{a}} \&\{\mathsf{b} : \oplus\{\mathsf{a} : S\}, \mathsf{c} : \&\{\mathsf{d} : \oplus\{\mathsf{a} : T\}\}\}$. However, the use of $\overset{\alpha}{\Longmapsto}$ (instead of $\overset{\alpha}{\longmapsto}$) in Definition 27 means that anticipated outputs can only be preceeded by a bounded number of inputs. If we consider $S = \&\{\mathsf{b} : S, \mathsf{c} : \mathbf{1}\}$ and $T = \&\{\mathsf{b} : T, \mathsf{c} : \oplus\{\mathsf{a} : \mathbf{1}\}\}$ we have $\oplus\{\mathsf{a} : S\} \not\leqslant_{\mathsf{a}} T$ because $S \overset{!\mathsf{a}}{\longmapsto}$ and $T \overset{!\mathsf{a}}{\Longmapsto}$. Note that clause (2) incorporates the condition of Chen *et al.* [11] that guarantees orphan-message freedom: if the subtype S anticipates an output and T starts with an input, *i.e.* $S \overset{!\sigma}{\longmapsto}$ and $T \overset{?\tau}{\longmapsto}$ for some σ and τ, then clause (2) guarantees that S performs a corresponding late input transition.

The use of $\overset{\alpha}{\Longmapsto}$ is both a strength and a limitation of $\leqslant_{\mathsf{a}}$. It is a strength because, just like $\leqslant_{\mathsf{s}}$, the *property that $\leqslant_{\mathsf{a}}$ prevents orphan messages holds regardless of any fairness assumption.* It is a limitation in the sense that, as we have seen since Section 1, there are contexts in which it is desirable to work with a coarser asynchronous subtyping relation. To overcome this limitation, Bravetti *et al.* [8] have characterized a *fair asynchronous subtyping relation* which, in our setting, translates to the use of $\overset{\alpha}{\longmapsto}$ instead of $\overset{\alpha}{\Longmapsto}$, as shown below.

▶ **Definition 28.** *We write $\leqslant_{\mathsf{fa}}$ for the largest relation such that $S \leqslant_{\mathsf{fa}} T$ implies:*

1. *either* $\mathsf{pos}(S)$ *or* $\mathsf{neg}(T)$*;*
2. *if $T \overset{?\sigma}{\longmapsto} T'$ then $S \overset{?\sigma}{\longmapsto} S'$ and $S' \leqslant_{\mathsf{fa}} T'$;*
3. *if $S \overset{!\sigma}{\longmapsto} S'$ then $T \overset{!\sigma}{\longmapsto} T'$ and $S' \leqslant_{\mathsf{fa}} T'$ and $T \overset{\varphi!\tau}{\longmapsto}$ implies $S \overset{!\tau}{\longmapsto}$ for every sequence φ of input labels.*

Note that the clauses (2–3) of Definition 28 are not symmetric, implying that $\leqslant_{\mathsf{fa}}$ is not closed under duality. While clause (2) supports input contravariance, differently from all the other considered subtypings *clause* (3) *disallows output covariance altogether*. If we take $S = \oplus\{\mathsf{task} : S, \mathsf{stop} : T\}$, $T = \&\{\mathsf{res} : T, \mathsf{stop} : \bot\}$ and $U = \&\{\mathsf{task} : \oplus\{\mathsf{res} : U\}, \mathsf{stop} : \oplus\{\mathsf{stop} : \mathbf{1}\}\}$ from Example 10, we have $U \not\leqslant_{\mathsf{fa}} S^\bot$ because $S^\bot \xmapsto{?\mathsf{stop}} \xmapsto{!\mathsf{res}}$ but $U \xmapsto{?\mathsf{stop}} \not\xmapsto{!\mathsf{res}}$. This formulation of clause (3) is due to the fact that $\leqslant_{\mathsf{fa}}$, unlike $\leqslant_{\mathsf{s}}$, $\leqslant_{\mathsf{a}}$ and $\leqslant$ as well, is meant to preserve fair session termination (at the type level) which requires a controlled form of output covariance that Bravetti *et al.* [8] have conservatively approximated in this way. The next example shows that removing the additional conditions in clause (3) may compromise fair termination.

▶ **Example 29.** Consider the session types $S = \&\{\mathsf{play} : \oplus\{\mathsf{win} : S, \mathsf{lose} : S\}, \mathsf{quit} : \mathbf{1}\}$ and $U = \oplus\{\mathsf{play} : \&\{\mathsf{win} : \oplus\{\mathsf{quit} : \bot\}, \mathsf{lose} : U\}\}$ where S specifies the behavior of a slot machine that allows players to play an unbounded number of games and U specifies the behavior of a player who plays relentlessly until he wins a game. Not only do we have $S \bowtie U$, but also the composition of S and U is fairly terminating in the sense that, at each stage of the interaction between player and slot machine, it is always possible to extend the interaction so that the player wins. If we now consider an *unfair* implementation of the slot machine such that its actual behavior is described by the session type $T = \&\{\mathsf{play} : \oplus\{\mathsf{lose} : T\}, \mathsf{quit} : \bot\}$, we have that $T \leqslant S$ and therefore $T \bowtie U$ still holds, but the composition of T and U is no longer fairly terminating. Therefore $T \not\leqslant_{\mathsf{fa}} S$ and rightly so. In our setting, preserving fair session termination at the type level is not so important because the type system is able to enforce fair termination at the process level anyway thanks to its logical foundation. ⌟

▶ **Theorem 30.** *For FFST session types we have* $\leqslant_{\mathsf{s}} \subset \leqslant_{\mathsf{a}}$ *and* $\leqslant_{\mathsf{a}} \subset \leqslant$ *and* $\leqslant_{\mathsf{fa}} \subset \leqslant$.

8 Related Work

Asynchronous subtyping. The asynchronous subtyping relations for binary session types defined in the literature [39, 11, 8] are formulated syntactically using *input contexts* to identify the output actions in the larger session type that have been anticipated in the smaller session type. The work of Ghilezan *et al.* [29] considers multiparty sessions: in their setting a smaller session type can anticipate outputs also w.r.t. outputs sent to a different partner. This is achieved by considering also appropriate *output contexts*. We follow a different approach: once we have defined a LTS for session types that captures their asynchronous semantics (Definitions 11 and 12), we are able to provide a characterization of $\leqslant$ that is essentially the same as the one for synchronous subtyping (Definition 26).

It is worth pointing out that there is no contradiction in the fact that our subtyping relation turns out to be coarser than others that have been proved *complete* [9] or *precise* [11, 29]. The point is that the completeness of a subtyping relation for session types is always relative to a notion of correct session composition. Depending on this notion, the induced subtyping relation may vary. Our subtyping relation is coarser than $\leqslant_{\mathsf{a}}$ [39, 11] because it relies on a fairness assumption that enables a larger degree of output anticipation and it is coarser than $\leqslant_{\mathsf{fa}}$ [8] because it is not meant to preserve fair session termination and therefore it allows (almost) unconstrained output covariance.

Asynchronous subtyping relations for session types are known to be undecidable [36, 6, 7] and $\leqslant$ is no exception (Theorems 17 and 18). Despite the proof technique adopted to prove our undecidability results is similar to those used in other papers [6, 8], we could not directly derive our results from the undecidability of other relations because $\leqslant$ is coarser.

A synchronous version of fair subtyping for session types has been studied by Padovani [41]. This relation is stricter than $\leqslant$ because it does not allow early outputs and it is meant to preserve fair session termination. Unlike the other fair/asynchronous subtyping relations for session types (with the exception of the orphan message free subtyping of Chen *et al.* [11]), $\leqslant$ is closed under duality (Proposition 16).

Fair session termination. Type systems ensuring the fair termination of binary sessions have been studied by Ciccone, Dagnino and Padovani [14, 16, 42, 13]. These works are all based on a synchronous communication model. The technique adopted in this paper for measuring processes is essentially the same presented by Dagnino and Padovani [19] which in turn is an elaboration of resource-aware session type systems [22, 21, 23]. Fair termination is a weaker form of termination [30, 2, 26]. Session type systems enforcing the termination of well-typed processes are typically based on linear logic [45, 37] where termination is a direct consequence of the cut elimination property of the logic.

Logical approaches to asynchrony and subtyping. The literature on asynchronous sessions is mostly based on calculi that are not connected to linear logic and where buffers are modeled explicitly. A notable exception is the work of DeYoung *et al.* [24] which presents a type system based on linear logic for an asynchronous calculus of sessions. In that work, asynchrony is intended as the fact that outputs are non-blocking, but no anticipation is allowed. The basic idea is the same used in the encoding of binary session into the linear π-calculus [20]: session communications make use of explicit continuation channels and outputs can be spawned as soon as they are produced leaving the sender process free to reduce further.

The deep cut reductions of CaP bear some similarities with *deep inference* [31], whereby logical rules (including the cut) may operate on "deep" fragments of a proof derivation. At this stage we are unable to say whether there is a more meaningful connection between our modeling of asynchrony and deep inference.

The use of links to incorporate subtyping in the type system echoes the approach studied by Horne and Padovani [34] who give a *coercive semantics* to subtyping in a logical setting: a subtyping relation $S \leqslant T$ corresponds to a forwarder process (*i.e.* a link) that consumes a channel of type $S^\perp$ and operates on a channel of type T. In CaP, the availability of the native link is fundamental since buffers may grow arbitrarily and the forwarder process is neither finitely representable nor finitely measurable in general.

9 Concluding Remarks

Sessions are meant to enable the compositional enforcement of safety and liveness properties of communicating processes. However, most liveness properties concerning one particular session – like the fact that a given message is eventually produced or consumed – can only be ensured if one makes the assumption that every other session eventually terminates. For this reason, the eventual termination of sessions is of primary importance. From the property that a session eventually terminates, other properties of interest usually follow "for free" as a straightforward consequence of session typing.

In this paper we have introduced a new theory of asynchronous session types that ensures the eventual termination of every session under a full fairness assumption. As a consequence, every produced message is guaranteed to be eventually consumed and every process waiting for a message is guaranteed to eventually receive one. This theory improves previous ones in a number of ways: we define a novel fair asynchronous subtyping relation that supports the

anticipation of outputs before an unbounded number of inputs, output covariance and that is closed under duality; we extend the soundness properties to multiple, possibly interleaved and dynamically created sessions; we base our theory on a calculus of asynchronous processes whose features, types and typing rules are rooted in linear logic.

Clearly, the undecidability results about the correctness of session composition and of fair asynchronous subtyping are an obstacle to the applicability of the presented theory. While decidable approximations of these notions have been presented in the literature [5, 8, 4], they cover relatively small families of session types. In future work we envision the possibility to define sound (but necessarily incomplete) algorithms for checking correct composition and subtyping inspired by the coinductive characterizations of correct session composition and of fair asynchronous subtyping introduced in this paper.

We also conjecture that our semantic approach to subtyping based on an LTS with early/late transitions scales smoothly to the multiparty setting where it may lead to simpler characterizations of (fair) asychronous subtyping relations. It may be interesting to verify the validity of this conjecture in future work.

Reusing Highly Optimized IR in Dynamic Compilation

Abstract

Virtual machines (VMs) with dynamic compilers typically specialize compiled code to the state of the running VM instance and thus cannot reuse the code between multiple runs of the same application. The JIT compiler must recompile the same methods for each run of the application separately, which can prolong the application's warmup time. We propose a technique to reduce compilation time by reusing a highly optimized intermediate representation (IR). We achieve this by tracing compiler-interface calls during compilation. The validity of the specializations in the IR is verified during a replay stage, and the replay also facilitates the relocation of runtime object references. The IR is stored on a compilation server, which can compile it to machine code and provide the code to local or remote VM instances. We implemented a compilation server with IR caching for GraalVM, a high-performance production-grade Java Virtual Machine (JVM). We present an evaluation based on four industry-standard benchmark suites. In each suite, our approach reduces compilation time by 23.6% to 36.8% and warmup time by 13.1% to 21.2% on average while preserving peak application performance.

1 Introduction

Modern virtual machines (VMs) achieve high application performance by leveraging optimizing dynamic compilers. After a VM starts, the application typically experiences a warmup phase [2] until the performance-sensitive methods are compiled at the highest optimization level. The VM usually has to repeat these compilations for each run of the application. The latency of the compilation tasks is one of the factors contributing to the application's cold start. This problem is amplified when many VM instances execute the same application, such as in horizontally scaled deployments with demand-based elasticity and in serverless computing [5].

The goal of our work is to reuse compilation results from a past run of the same application on the same VM version and platform. For brevity, we refer to a single run of the application as a *VM run*, and we want to reuse compilations from a *source VM instance* in a *target VM instance*. Reusing past compilation results reduces the work performed by the JIT compiler in a VM run (compilation time). Depending on the workload's sensitivity to the latency of

Listing 1 An example where the compiler may specialize the compiled `log` method to the state of the running VM instance.

```
1  class Logger {
2      static final int level = Integer.parseInt(System
3          .getProperty("logLevel"));
4
5      static final PrintStream stream = createStream();
6
7      static void log(int logLevel, String message) {
8          if (logLevel >= level) {
9              stream.println(message);
10         }
11     }
12 }
```

compilation tasks, we can also reduce the time it takes for the application to reach peak performance (warmup time). However, it is challenging to reuse the code compiled by a highly optimizing compiler because the compiled code is specialized to the source VM instance.

To illustrate how a dynamic compiler tailors code to the source VM instance, consider the `log` method in Listing 1. The compiler may read the value of the `level` field at compilation time and embed its value in the machine code. Similarly, the compiler can read the value of the `stream` field, obtaining an object address that it can embed in the generated code.

These transformations improve performance by moving computation from run time to the compilation stage, but they pose a challenge to code reuse. For example, the compiled code implicitly assumes that the `level` field holds a particular value. The field's value could differ in another VM run, rendering the code incorrect for reuse. Moreover, the reference to the Java object constant obtained from the `stream` field requires relocation before we can reuse the code in another VM run. We give an overview of more problems with code reuse in Section 2.

The main idea of our paper is that the specializations of the code to the state of the running VM can be valid even in future VM runs of the same application. We can reuse compilation results from the source VM instance in the target VM instance, provided that it is possible to validate that the reused code would behave correctly in the target VM instance and relocate the references to VM objects. Both issues are solved by recording and replaying a *compilation trace*. To reduce the overall compilation time with this technique, we also need to ensure that validation succeeds for enough compilation units when the source and target VM instances execute the same application. We achieve this by modifying the compiler and caching the optimized intermediate representation (IR) rather than the compiled code because the IR is less specific to the target VM instance and easier to patch.

To reuse the IR compiled for method `log`, we must verify that the transformations performed during the original compilation for the source VM instance are correct in the target VM instance. Therefore, during compilation in the source VM instance, we record the calls from the compiler to the VM that query the VM's state, obtaining a compilation trace such as the one in Listing 2. In the target VM instance, we replay these calls to validate that they produce compatible results, and we use the computed VM object references as relocations. `%2` is a *trace variable* that stands for the `level` field, which we obtained as index `32` into the constant pool of the `Logger` class. The field's value read by the compiler was `4`,

Listing 2 A snippet of a compilation trace captured during a compilation of the `log` method from Listing 1.

```
1                                (%0 is the Logger#log method)
2  declaringClass(%0) = %1       (%1 is the Logger class)
3     getBytecode(%0) = ...      (the result is binary data)
4  lookupField(%1,32) = %2       (%2 is the Logger#level field)
5    isFinalField(%2) = true
6  readFieldValue(%2) = 4
7  lookupField(%1,48) = %3       (%3 is the Logger#stream field)
8    isFinalField(%3) = true
9  readFieldValue(%3) = %4       (%4 is a Java object constant)
10 isConstantNull(%4) = false
```

which we can validate in the target VM instance. The value read from the `stream` field is an object constant stored in trace variable `%4`, which we can use for relocation. We explain compilation tracing and replay in Section 3.

We implemented the approach for GraalVM [28]. GraalVM is the HotSpot [29] Java Virtual Machine (JVM), where the C2 compiler [35] is replaced with the high-performance GraalVM compiler. Based on the GraalVM compiler, we created a compilation server [18, 19, 1, 24] capable of compiling code for local and remote client VM instances over the network. The server can also cache the IR intended for reuse and compile the stored IR into machine code. Thanks to this design, multiple client VMs can share and benefit from the IR cache. To minimize the overall compilation latency, the client VMs employ a *hybrid compilation* strategy: they offload only large compilations where the server can leverage the IR cache. All other compilations are completed using the VM's local JIT compiler. We describe the design in Section 4.

We evaluate the approach on the DaCapo 23.11 MR1 [3], Renaissance 0.15 [39], and ScalaBench 0.1.0 [44] benchmark suites. Compared to the unmodified GraalVM baseline, hybrid compilation using a co-located compilation server with a pre-populated IR cache decreases compilation time by 23.6% to 36.8% and warmup time by 13.1% to 21.2% in every evaluated suite on average. We verified using the DaCapo suite that the benefits of our approach remain substantial when the server and the client VM are separated by a local network. We present the evaluation in Section 5 and describe the related work in Section 6.

Although we focus on the context of a modern JVM, the key concepts of the approach and the challenges faced by our implementation are likely transferable to other similar platforms. Specifically, the technique to cache and reuse the optimized IR assumes that there is a well-defined and interceptable interface between the VM and the compiler and that the compiler starts with an IR that is not overly specific to the target VM instance (other than references to VM objects). We believe these assumptions to be a common design element of environments with dynamic compilation, though other technical details can also influence the practicality of the approach.

In summary, we contribute the following:

- An approach to reuse highly optimized IR by compilation tracing and replay.
- A case study on a production-grade VM outlining the changes to the compilation pipeline to leverage the approach to achieve an overall improvement in compilation metrics.
- An empirical evaluation on industry-standard benchmarks, which shows that the technique reduces compilation time and can improve warmup time while preserving the application's peak performance.

Listing 3 A class with a method whose compiled code may not be reusable.

```
1 class Filter {
2     static final Options options = getOptions();
3
4     void filter(Collection<Integer> numbers) {
5         Predicate<Integer> isOutlier =
6             (n) -> n > options.threshold;
7         numbers.removeIf(isOutlier);
8     }
9 }
```

2 Reusability of Optimized Code

The code compiled by an optimizing dynamic compiler is usually not reusable across VM runs. This section summarizes the obstacles to code reusability in a modern JVM [37], with practical examples from the HotSpot JVM [29]. These challenges are caused by dynamic code loading and by optimizations that specialize the code to the state of the target VM instance, which are concepts relevant to many modern VMs.

2.1 Equivalence of Loaded Classes

A dynamic compiler tailors the code to the definitions of the loaded classes at a given time. To reuse code compiled for a source VM instance, we must ensure that the classes on the target VM instance are equivalent to the classes loaded by the source VM instance. However, a modern JVM may generate classes at runtime and modify the bytecode for optimization purposes. An application can trigger class loading at any time, so we must not expect that the target VM has precisely the same set of loaded classes.

For example, consider the `filter` method in Listing 3. In the HotSpot JVM, the first execution of the method runs the initialization code for the lambda expression [27], which loads a dynamically generated class representing the function object instance. We must ensure that even the generated classes have compatible definitions between VM runs. However, the generated class is assigned a name that is not stable between VM runs [6]. In addition, HotSpot modifies an operand of a bytecode instruction to link it with a function object factory. As a result, the bytecode of the `filter` method may also differ between VM runs.

2.2 Specialization to Application State

The compiler may evaluate loads from static final fields and even final instance fields if the receiver is a constant. This transformation removes a potentially expensive operation from the code and may also enable other optimizations. For example, in the body of the lambda expression in Listing 3, the compiler may fold the load of the `options` field. If `threshold` is a final instance field, the compiler can fold the load of this field as well. Although these specializations improve code quality, they restrict reusability. In future VM runs, the values of the static and instance fields could differ, rendering the compiled code incorrect for reuse.

2.3 Speculations and Assumptions

The compiler's optimization decisions may involve speculation [11] based on the application's past behavior and profiling feedback. These speculations and assumptions narrow the scope where the compiled code is applicable, but they may improve performance.

For example, the call to the `removeIf` method in Listing 3 produces a null pointer exception if the call's receiver is `null`. If such a situation never occurred previously, the compiler may speculatively omit the exception-throwing branch and instead emit a deoptimization [16]. This allows the compiler to focus only on the likely execution paths, but such compiled code is only beneficial if `removeIf` is not invoked with a null argument.

The compiler can make assumptions about the loaded classes. For example, `List` is an interface with possibly multiple implementations, making the `removeIf` call indirect. However, if only a single implementation is loaded, the compiler converts the call to a direct one and records the assumption about the interface having a single implementation. The VM invalidates the compiled code when it loads another implementation of the `List` interface. Such assumptions limit the reusability of the code, but they typically improve performance.

Lastly, the compiled code may contain implicit assumptions about the VM's state. For example, in Java, classes have static initializers [25], which the runtime invokes when a class is first referenced. If a class is already initialized, the compiled code does not need to check its initialization status. However, such code may not be reusable in another VM run, where the same classes might not yet be initialized.

2.4 Coupling with VM State

The compiler may encode absolute addresses, relative addresses, and offsets of various VM objects in the compiled code. These values usually change between VM runs, making the compiled code not directly reusable. For example, the call to the `removeIf` method in Listing 3 is compiled with the callee's address embedded in the machine code.

We could attempt to reuse the code by finding relocations for the referenced VM objects and patching their values in the machine code. Java objects have identities, so we must relocate them with identical objects to preserve the program's correctness. However, patching the values in the machine code is difficult because accessing the replacement value may require a different instruction sequence than the one emitted initially.

3 Compilation Tracing and Replay

Although dynamic compilers tailor code to the running VM, these specializations can often remain valid even in future VM runs, much like past profiles can inform future optimization decisions. To capture all dependencies of the compilation result on the state of the running application and source VM instance, we record the compiler's calls through the VM's compiler interface, yielding a compilation trace. In the target VM instance, where we want to reuse the compilation, we replay the compilation trace to validate that the compilation is compatible with the actual state of the running application and to compute relocations for VM object references.

Figure 1 shows a summary of compilation tracing, which this section explains in detail. In a *tracing stage*, we compile a method in a source VM instance up to a *point of reuse* to obtain the compilation unit's optimized IR (step 1). We use the compilation trace (2) to replace VM object references in the IR with trace variables (3). Lastly, we store the IR (4) along with the compilation trace in the IR cache (5). The IR depicted in Figure 1 is that of the `log method` from Listing 1. Interpreting the IR semantics is not essential to understanding the approach; Figure 1 uses Graal IR [10] as an illustration.

In a *replay stage*, we retrieve the compilation trace from the IR cache (step 6) to replay the trace in a target VM instance and validate the results. If the validation succeeds (7), we retrieve the cached IR (8) and replace the references to trace variables in the IR with references to VM objects (9). Finally, we compile the IR to machine code (10) and prepare it for execution on the target VM.

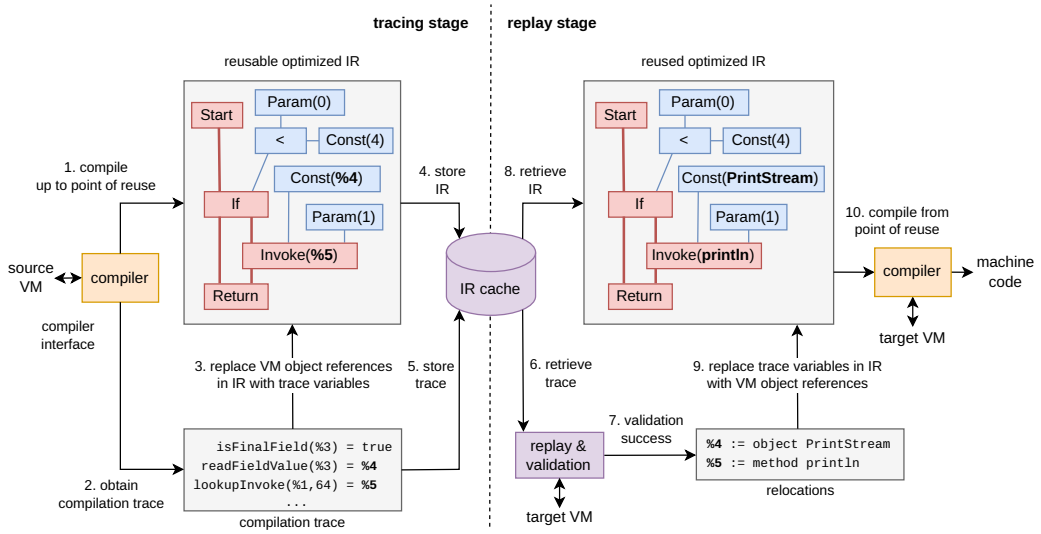

Figure 1 Overview of compilation tracing and replay. The IR format is based on Graal IR [10]; thick lines are control-flow edges, thin lines are data-flow edges.

3.1 Point of Reuse

We cache partial compilation results (the optimized IR) [37] instead of the final compiled code because it is less specialized to the state of the target VM instance. To enable IR reuse, we trace the compiler-interface calls in the compiler passes up to the designated point of reuse. The compiler can resume the compilation pipeline starting from the point of reuse in order to compile the cached IR to machine code.

The point of reuse should be as late as possible in the compilation pipeline to minimize the amount of work necessary to finish the compilation. However, it must be early enough so that references to VM objects can be relocated. If the point of reuse is early enough so that it is still possible to optimize the IR, the transformations that make the IR overly specific to the running VM instance can be deferred [37] until after the point of reuse. With these transformations deferred, the compiled machine code can benefit from specialization to the target VM instance while keeping the cached IR reusable.

In summary, the advantages of caching the IR are that

(i) patching the IR is easier than the compiled code,

(ii) we avoid all coupling introduced by late compiler passes after the point of reuse, and

(iii) transformations that introduce coupling to the source VM instance can be deferred until after the point of reuse.

3.2 Tracing

Compilation tracing records inputs to the compiler that influence a method's compilation. Therefore, the trace contains all assumptions about the application's and VM's state. Moreover, the trace captures the origin of every VM object reference that appears in the IR.

In the tracing stage, we run the compilation pipeline up to the point of reuse, obtaining an IR and an associated compilation trace. The compilation trace is a list of the compiler's queries sent to the VM with their arguments and results.

A value in the compilation trace may be a literal or a trace variable substituting a VM object. For example, the bytecode of the compiled methods and the values of primitive constants are embedded in the trace as literals. In Figure 1, trace variable `%4` substitutes a Java object constant obtained by reading the value stored in field `%3`. Trace variable `%5` substitutes a VM's representation of a method.

After obtaining the IR and the compilation trace, we replace all references to VM objects in the IR with the trace variables. Finally, we store the IR and the compilation trace in the IR cache.

3.3 Replay

In the replay stage, we retrieve the IR and the associated compilation trace from the IR cache. The goal is to verify that we can safely reuse the IR without causing the application to misbehave and to finish compiling the IR to machine code.

We replay the trace by iterating over the individual operations. For each operation, we first replace the trace variables in the argument list with the instances of VM objects they substitute. After that, we execute the operation in the target VM and examine its return value. If the trace's result is a trace variable referenced for the first time, then the return value of the operation defines the value of that trace variable. Otherwise, we validate that the return value is compatible with the result captured in the trace. Compatibility can be verified by checking that the results are equal or with an operation-specific check, as we explain in Section 4.

If the validation fails for an operation, we cannot use the IR for the target VM instance at this time. If the validation succeeds, all trace variables have assigned values. We proceed by substituting the trace variables in the IR with their values. Finally, we run the rest of the compilation pipeline, starting from the IR and obtaining the machine code for the target VM instance.

4 Implementation

Compilation tracing serves as a blueprint for validating the reusability of prior compilation results. To improve the overall compilation time using this approach, we must ensure that the cached IR is generally reusable, and we need a mechanism to share it among multiple VMs that might execute on different machines.

We implemented compilation tracing in GraalVM [28]. GraalVM is the HotSpot JVM [29] where the GraalVM compiler replaces the C2 compiler [35]. On top of this, we created a compilation server [19, 24] capable of IR caching, allowing local or remote VM instances to share a single IR cache.

Figure 2 shows an overview of our design, which this section explains in detail. In a *training run* (left side of Figure 2), a source VM instance executes an application and offloads compilation tasks to the compilation server (step 1). The server queries information from the source VM instance (2), caches the compilation result (3), and returns the compiled code to the source VM (4).

A subsequent run of the application may be executed as a *replay run*, which is sketched on the right side of Figure 2. In a replay run, the target VM obtains a compilation trace from the server (step A1), replays and validates it (A2), and returns the computed relocations to the server (A3). The server compiles the cached IR (A4, A5) and returns the compiled code to the target VM (A6). Compilation tasks that the target VM decides not to offload to the server are completed using the VM's local JIT compiler (step B1).

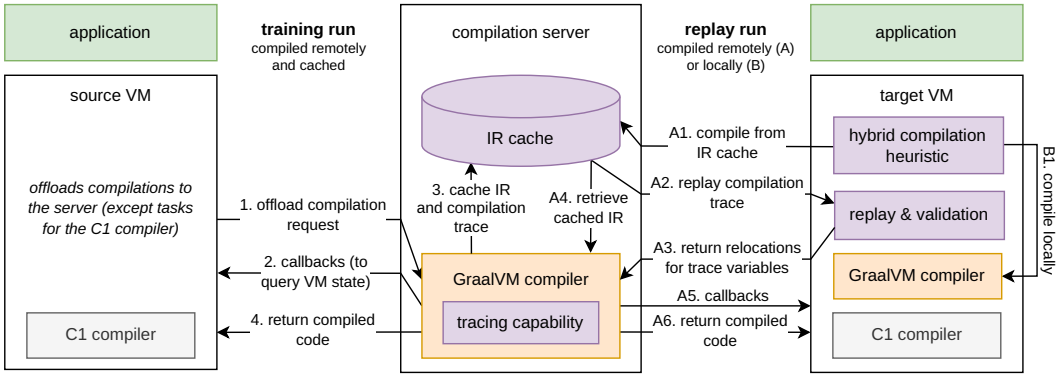

Figure 2 Overview of the implementation with a compilation server.

The compilation server is a standalone Java application that uses the GraalVM compiler as a library. The compilation client is implemented as an additional entry point of the GraalVM compiler, with some modifications and additions to the compiler and the VM's compiler interface.

4.1 Practical Compilation Tracing

We implemented compilation tracing by instrumenting the classes comprising the VM's compiler interface, creating wrapper classes with a compatible interface. The traced operations generally align with the granularity of the compiler-interface [40] calls exposed by the VM. A key challenge of compilation tracing is handling information that varies between VM runs, such as the bytecode, profiles, and dynamically generated classes.

Reusing Graal IR. The GraalVM compiler's compilation pipeline is divided into two stages: the front end and the back end. The front end parses the bytecode into a sea-of-nodes-based IR [10], optimizes it, and lowers the IR to a control-flow-graph-based representation for the back end. The compiler performs the majority of the optimization effort in the front end. Based on our measurements (Section 5), the compiler spends on average about 81% of the time in the front end, 14% in the back end, and 5% in the garbage collector triggered after compilation or waiting for the VM to prepare the compiled code for execution. We cache and reuse the IR at a point relatively late in the front end – before the compiler lowers portable address nodes to machine-specific nodes. This allows us to patch the IR with VM-specific information and defer the folding of field loads after the point of reuse (Section 4.2), while still saving a significant portion of compilation time.

Tracing Profiling Information. The IR stored in the cache is compiled using profiles recorded by the source VM instance. When the target VM instance reuses the IR from the cache, the compiled code should be performant and unlikely to deoptimize [16] in the future. Therefore, the cached IR should ideally be compiled using accurate and mature profiles.

After a target VM instance starts, we want to reuse IR as early as possible to leverage the performance of the compiled code. By reusing cached IR early in an application's lifecycle, we can potentially benefit from the fact that the profiles used to compile the IR may more accurately characterize the application's future behavior than the profiles collected by the target VM instance up to that point. For this reason, the replay stage does not verify the

Listing 4 Encoding of the operation that returns the recorded receiver types.

```
1 getReceiverTypes(%0, 42) = {
2   com.example.Map/com.example.Main: %1,
3   com.example.Set/com.example.Main: %2,
4 }
```

equivalence of profiling information between the source and target VM instances, and the compilation trace does not capture any profiling information other than receiver-type profiles. Receiver-type profiles are used during replay to locate some VM objects.

Receiver-Type Profiles. The VM records the types of receiver objects at virtual call sites to guide the inlining [38] heuristics. The compiler queries the receiver-type profiles from the VM, and the receiver types may be referenced in subsequent operations. Therefore, we must assign trace variables to the recorded receiver types. We do this by capturing the receiver-type profiles in the compilation trace.

Listing 4 illustrates the encoding of these profiles in the form of globally unique type identifiers mapped to trace variables. In the example, the `getReceiverTypes` operation returns the receiver types for a particular call site identified by the bytecode offset 42. The recorded receiver types are `com.example.Map` and `com.example.Set` assigned to trace variables `%1` and `%2`, respectively.

Since multiple class loaders may load a class with the same name, the globally unique identifier of a type comprises the class name and an identification of the type's class loader. We identify the class loader using the heuristic introduced by JITServer [19]: the loader's identifier is the name of the first class it loaded. In the above example, `com.example.Main` is the class loader's identifier.

In the replay stage, the goal is to map the trace variables to the respective types identified by the globally unique name. If we cannot find a type (it may not be loaded yet), the replay cannot continue and ends with a validation failure.

Dynamically Generated Classes. During execution, the VM may dynamically generate classes whose class name is not a stable identity across VM runs. For example, the HotSpot JVM loads generated classes to support lambda expressions and other core features. These generated classes are loaded as *hidden classes* [6], which are intentionally designed not to be discoverable by name, and their VM-assigned names vary between VM runs. The VM may compile the methods of hidden classes, and they may also appear in profiles and get inlined. To successfully validate compilation traces referencing hidden classes, we create stable class names based on a digest computed from the binary data that defines the hidden class and also from the Java objects passed to the static initializer of the hidden class.

Additionally, the code of an application may dynamically generate classes without using the hidden class feature. We can successfully reuse the compilations referencing these classes if their definitions are stable between VM runs and their class names uniquely identify them. However, these conditions are not always satisfied: for example, the Catalyst Optimizer [13] from the Apache Spark framework generates and assigns the exact same name to every generated class. Our prototype does not support such a use case and experiences validation failures. The problem could be fixed by adding a digest of the class definition to the class name.

Bytecode Modification. The VM can modify the operands of some bytecodes for optimization purposes in a way that is not stable across runs. The compiler may use these values as arguments in compiler-interface calls. To ensure the replayability of the compilation trace, we do not embed any VM-specific operand values in the compilation trace. Instead, we use an indirection specifying where to find the actual value in the target VM instance.

For example, our compiler interface offers an operation called `lookupInvoke`, which takes a class and index argument and returns the representation of the method invoked at that index. The compiler may obtain the index from an operand of a bytecode instruction and call the `lookupInvoke` operation with the operand value. In the compilation trace, we encode the operand value indirectly using the expression `operandValue(%0, 16)`.

```
lookupInvoke(%1, operandValue(%0, 16)) = %2
```

During replay, we find the concrete index as the value in the bytecode of the `%0` method at bytecode offset 16. Then, we can replay the `lookupInvoke` operation with the concrete argument value specific to the target VM instance.

Lastly, we must also validate that the bytecode of a particular method on the target VM instance matches the bytecode of this method on the source VM instance. We do this by comparing a canonicalized version of the bytecode, which does not contain any VM-specific values.

4.2 Improving IR Reusability

To improve the overall compilation time using our approach, we need to increase the chances that the IR stored in the cache passes validation so that we can reuse it. To this end, we validate the results of some operations with less strict checks than equivalence. Moreover, we use heuristics to defer optimizations that could break the IR's reusability.

Relaxed Validation Checks. We reuse the cached IR even if it is more general than required by the target VM instance. Specifically in the context of Java, if the cached IR leverages an assumption about the loaded classes (e.g., only a single implementation of an interface is loaded), we must check that the assumption holds in the target VM instance. However, if such a fact holds in the target VM instance but the cached IR does not leverage it, we consider this a validation success. Such a situation is expected when the cached IR is more mature than the state of the target VM instance.

Similarly, classes, methods, and fields in Java have initialization stages [25]. To facilitate IR reuse, we only require that a class, method, or field is in the same or later initialization stage on the target VM instance as in the source VM instance.

Patterns Preventing Reuse. If the compiler specializes the IR to computed constants whose values could change between VM runs, the IR may not be reusable. For example, consider the `ThreadLocal` implementation [4] shown in Listing 5. When a `ThreadLocal` instance is initialized, the `threadLocalHashCode` field is assigned a value based on a global counter. If a thread-local value is stored in a static final field, the thread-local's hash code is likely to differ between VM runs. The compiler may embed this field's value into methods that manipulate the thread-local value, leading to non-reusable IR and replay failures. In OpenJDK, the `ClassValue` implementation [41] also uses the same pattern, and similar patterns may appear in the code of applications. We can mitigate these problems using deferred optimization.

Listing 5 A snippet of the `ThreadLocal` implementation in OpenJDK (simplified).

```
class ThreadLocal {
    final int threadLocalHashCode = next.getAndAdd(INCREMENT);
    static AtomicInteger next = new AtomicInteger();
}
```

Deferred Optimization. We can allow the compiler to fold loads of computed constants while keeping the IR reusable by deferring [37] this optimization to the replay stage. In the context of Java, if we know that a particular field like the one in Listing 5 hinders reusability, we do not allow the compiler to fold a load of this field in the tracing stage. The compiler folds the field load in the replay stage when the VM-specific value of the field is known.

Deferring the folding of all fields is a disruptive change that leads to performance degradation [37]. Therefore, we target only fields that may cause validation failures. Our prototype implementation uses a simple condition: if the field's type is `int` and its name contains `hash`, we defer the folding. A more refined approach could select these fields based on past observations: if validation fails due to mismatching values read from a field, the field's folding would be deferred in future tracing stages.

4.3 Remote Compilation

We implemented a compilation server [19, 1, 24] with the capability to reuse the IR from past compilations. This allows multiple client VMs to share a single IR cache. Figure 2 shows a summary of the design. We implemented remote compilation and IR caching only for the top-tier GraalVM compiler since the low-tier C1 compiler [20] completes compilation tasks quickly and with a lower optimization level. To minimize compilation latency, the client VMs utilize hybrid compilation, in which a heuristic decides whether a method should be compiled by the VM's local JIT compiler or using the cached IR on the server.

Compilation Server. In a remote compilation setup, a client VM sends compilation requests to the server. The server compiles methods for the client VM's platform, utilizing only the information provided by the client. It is usually not possible to pack all the necessary information [19] in the forwarded compilation request. Instead, the server queries the client's VM state via remote callbacks. We employ aggressive caching and prefetching to minimize the number of remote callbacks. After completing the compilation, the server returns the compiled code to the client VM.

Training Run. The compilation server starts with an empty IR cache, which gets populated by a client VM that connects in training mode. In a training run, the compilation server handles requests with compilation tracing enabled. When the compilation pipeline reaches the point of reuse, the server stores the compilation trace and copies the IR into the cache. After that, the server completes the rest of the compilation pipeline and returns the compiled code to the client VM.

The IR cache is indexed by a symbolic representation of the compilation request. This symbolic representation comprises the fully qualified name, arguments, and the return value of the method to be compiled and the entry point if it is an on-stack-replacement (OSR) [12] compilation.

Replay Run. In a replay run, the client VM either chooses to compile locally or issues a remote compilation request. The decision is based on a server-provided list of compilation requests and other conditions, which we summarize later. In case of a remote compilation, the server looks up a cached compilation result in the IR cache and transfers the stored compilation trace to the client VM. The client VM replays and validates the trace. If validation succeeds, the client replies with the computed mapping of trace variables to VM objects. The server substitutes the trace variables with the VM object references in the IR, completes the compilation, and returns the compiled code. In case of a validation failure, the client VM completes the compilation request using its local JIT compiler instead.

The client VM must also handle recompilations. A recompilation of a method previously compiled from the cached IR may occur after deoptimization [16] or a violated assumption about the class hierarchy. In such a case, we cannot reuse the same IR to get a usable compilation result and prevent endless deoptimization. For this reason, the client VM handles recompilations by compiling from scratch using the local JIT compiler.

Permanent and Transient Validation Failures. Retrying to replay a compilation trace that previously failed can improve the latency of some compilation tasks. As explained above, the VM compiles a method using the local JIT compiler if the validation of a compilation trace fails. However, the code compiled by the local JIT may get invalidated later, and the VM may reissue an identical compilation request. We attempt to replay and validate the compilation trace again if the reason for the past failure is an uninitialized or unresolved class, unresolved field, or an uninitialized method. We consider these failures to be *transient* because they may be resolved by the VM performing the required initialization [25]. We consider other kinds of validation failures to be *permanent*, and the client VM never retries to replay the same compilation trace again.

Hybrid Compilation. To improve the overall compilation time, client VMs offload only the compilation requests where the IR cache is expected to bring a benefit. If there is no expected benefit, the client VM should avoid increasing compilation latency by communicating with the server. We estimate the potential savings based on the time the server spent compiling the bytecode to the reusable IR in the training run, which we refer to as the *pre-compilation time*. The pre-compilation time is an upper-bound estimate of the time a client VM can save by compiling the cached IR on the server rather than locally from scratch. Therefore, at the beginning of a replay run, the client VM obtains a list of compilation requests from the server for which the server has cached IR and the pre-compilation time above a client-provided threshold.

In the evaluated prototype, we set the pre-compilation time threshold to 20 milliseconds. The optimal threshold value depends on the workload, the communication latency between the client and the server, and the computing resources available to the client and server.

In summary, a client VM offloads a compilation request to the server if and only if all conditions are satisfied:

(i) The compilation request is in the server-provided list.

(ii) There was no previous attempt to complete this compilation request that ended with a permanent validation failure.

(iii) This compilation request was not already completed using the cached IR.

5 Evaluation

The goal of this section is to understand how hybrid compilation impacts the performance characteristics of standard Java and Scala workloads. We evaluate the workloads from major benchmark suites [3, 39, 44]. To ensure that the improvements are not achieved by offloading work to an additional machine or allocating more resources to the JIT compiler, we run the compilation server co-located on the same machine as the client VM, and we do not increase the number of concurrent compilation tasks. We first show the impact on key compilation metrics reported by the HotSpot JVM [29]. Then, we analyze the impact on peak performance and warmup time. Lastly, we evaluate how successful our prototype is in reusing and validating the cached IR and explain the reasons for the observed validation failures.

In a setup where a client VM connects to a remote server, the network latency adds to the compilation latency. For this reason, we consider low-latency environments (e.g., a fast local network) the most appropriate deployment option. The benefits would likely diminish in environments with higher latency. To demonstrate that the presented improvements are applicable to deployments on the local network, we also conduct experiments using the DaCapo benchmarks [3] where the client VM connects to a dedicated remote compilation server through the local network. We do not increase the number of concurrent compilation tasks to keep the results comparable to the co-located and baseline setups.

Notes on Performance Evaluation. Every benchmark suite we evaluate contains multiple benchmarks. The harness of every suite executes a benchmark by iterating a fixed workload multiple times in a dedicated JVM instance. The *iterations* usually get progressively faster as the VM warms up. The harness repeats the workload until it executes for at least the preset duration (e.g., 12 minutes). Due to the inherent non-determinism of the JVM, we also need to execute each benchmark for multiple VM runs [14]. The key metrics we evaluate are the wall-clock time it takes to complete an iteration (*iteration time* or *duration*) and the timestamps of their completion since the start of the JVM instance (*iteration timestamp*). In the rest of the section, we always aggregate absolute metric values using the arithmetic mean and relative metric values (ratios) using the geometric mean.

Hardware and Software. We executed the experiments on 20 identical blade servers, each equipped with an Intel Xeon CPU E3-1230 v6 (with four cores) and 32 GB of main memory. The blades are located in the same enclosure with separate 1 Gbps Ethernet network cards connected through a dedicated network router. We disabled hardware multithreading and power management. The blades run Fedora Linux 35 with kernel version 5.16.11.

We implemented our prototype on top of a development version of GraalVM Enterprise based on a development version of OpenJDK 22. We use the same binaries and the same JVM options for the modified and baseline runs, using additional JVM options to enable the remote JIT functionality. This avoids the potential variance introduced by the ahead-of-time compilation of the compiler itself. In every benchmark run, we use a JVM option to disable compressed class pointers (`-XX:-UseCompressedClassPointers`) because our prototype does not implement patching the compression parameters in the cached IR. We disable isolation between compiler threads (`-XX:JVMCIThreadsPerNativeLibraryRuntime=0`) to enable data sharing required by the client's compilation threads. In addition, we prevent the VM from shutting down the compiler runtime after a period without compilation activity (`-XX:JVMCICompilerIdleDelay=0`) to avoid potentially costly reinitialization of the runtime

for the client. The options `-Xms12G` and `-Xmx12G` set a fixed Java heap size, and we use the default garbage collector (`-XX:+UseG1GC`). Lastly, we use options to enable selected counters and timers in the GraalVM compiler to collect compilation statistics.

We use modified versions of the DaCapo 23.11 MR1 [3] harness and the ScalaBench 0.1.0 [44] harness to collect additional statistics. We execute the Renaissance 0.15 [39] benchmark suite with additional plugins to collect the same statistics. All DaCapo benchmarks are executed using the default workload size. We execute the ScalaBench benchmarks with default or larger sizes, selected to ensure the iterations are not excessively short. We exclude the workloads incompatible with OpenJDK 22.

5.1 Compilation Metrics

Experimental Setup. We measure the compilation metrics described below by running each benchmark for 12 minutes. On our platform, 12 minutes is typically sufficient time for the VM to warm up and then perform multiple iterations with peak performance. We manually verified that the tested benchmarks warmed up in the first 6 minutes of the run by plotting the iteration durations. For each benchmark, we repeat 30 VM runs of the baseline setup and the same number of VM runs with the hybrid setup that uses the cached IR for selected compilations. The client VM with hybrid compilation connects to a server running either on the same machine or a remote machine. In the *co-located* setup, the server runs on the same machine. In the *remote* setup, the compilation server runs on a dedicated machine, and all client VMs connect through the local network. Since the server is a Java application, we warm it up[1] with three unmeasured training and replay runs. Before each measured run of the client VM, we populate the IR cache of the compilation server with a single 12-minute training run of the same benchmark. To capture the potential variability between training runs, we do not reuse one training run for multiple replay runs.

Metrics. We collect the metrics reported by the JVM using the option `-XX:+CITime`. *Compilation time* is the sum of the wall-clock durations of all compilation tasks. Therefore, for the client VM with hybrid compilation, the compilation time metric includes the time spent on communication and serialization, as well as any failed attempts to reuse the cached IR. *Compiled bytecodes* is the total size of the bytecodes compiled in every compilation task, comprising the bytecode size of the root method and inlinees. *Compiled methods* is the total number of completed compilation tasks. Although we cache the IR only for the top-tier GraalVM compiler and not the C1 compiler [20], we report the sums of values for both compilers to present a complete picture. For multiple benchmark runs in the same setup, we report the arithmetic average of each metric value.

Statistical Evaluation. To ensure that the reported averages are not excessively impacted by random fluctuations, we used bootstrapping to compute 99% confidence intervals for all relative compilation and performance metrics reported in the paper. We did this by resampling with replacement from the VM runs of every benchmark in a particular setup. Because the confidence intervals are narrow relative to the reported effect size for every metric except peak performance, where the change is insignificant, we omit them from the presentation to enhance readability.

[1] We could avoid the server's warmup by compiling it ahead of time, similarly to how the GraalVM compiler is built.

Table 1 Compilation metrics in DaCapo benchmarks with a co-located server (lower is better).

benchmark	compilation time		compiled bytecodes		compiled methods	
	baseline	hybrid	baseline	hybrid	baseline	hybrid

Table 2 Changes in compilation metrics for every benchmark suite (lower is better).

benchmark suite	server setup	compilation time	compiled bytecodes	compiled methods
DaCapo	co-located	**−36.8**%	**−11.9**%	**−3.7**%
Renaissance	co-located	**−23.6**%	**−8.6**%	**−3.5**%
ScalaBench	co-located	**−35.9**%	**−9.8**%	**−4.3**%
DaCapo	remote	**−31.8**%	**−11.0**%	**−3.3**%

Results. Table 1 lists the compilation metrics for the individual DaCapo benchmarks with a co-located compilation server. The columns marked *baseline* show the arithmetic average of a metric value for all baseline runs of the given benchmark. The columns marked *hybrid* show the change in the arithmetic average of a metric value for the hybrid runs relative to the baseline. Hybrid compilation significantly reduces compilation time for every benchmark from 15.2% up to 59.3%. The size of the compiled bytecodes decreases by 3.4% to 21.7%, and the number of compiled methods decreases by up to 8.2%.

Table 2 summarizes the changes in compilation metrics in every evaluated suite. We aggregate the metric values for a benchmark suite as the geometric mean of the relative metric values of the individual benchmarks. In the setup with a co-located compilation server, the overall decrease in compilation time ranges between 23.6% and 36.8%, the size of the compiled bytes decreases by between 8.6% and 11.9%, and the number of compiled methods decreases by between 3.5% and 4.3%. The overall improvements in the DaCapo suite with a remote server are substantial but slightly lower than those in the co-located setup.

Discussion. The drop in compilation time is large in all benchmark suites, which is a result of multiple factors. The cached IR directly decreases compilation time by reducing the amount of work performed. As an indirect effect, faster compilations can lead to fewer compilation tasks being scheduled. This is because compilation tasks for the JIT compilers are scheduled when method invocation and loop back-edge counters overflow. By speeding up the compilation tasks, the compiled methods (including inlined methods) are executed via the compiled code that does not increment the counters. Consequently, these counters have fewer opportunities to overflow, and fewer compilation tasks may be scheduled. The data shows that both the total size of the compiled methods and their number decreased significantly, which is evidence of less work scheduled for the JIT compilers.

Another indirect effect that can save compilation time is the higher maturity of the cached IR, i.e., the compilations may have a lower chance of deoptimizing [16] on an assumption or speculation [11] and requiring a recompilation. This is because the cache stores the last completed compilation of a method from the training run, and, potentially, the IR may not contain speculations or assumptions that are bound to be violated later during the VM run.

During development, we found that our prototype can sometimes suffer from an excessive number of recompilations. This happens when the compiler deoptimizes from a compiled method to an earlier block in the control-flow graph, and the VM executes the bytecode instruction that triggered the deoptimization as part of a more mature compiled method rather than in the interpreter. Consequently, the VM fails to update the profiles for future recompilations. Our prototype can trigger this problem due to the presence of compiled code of varying maturity (from the IR cache and locally compiled). Changing how speculations are tracked in the IR [11] could improve the results, and we reported the issue to the GraalVM compiler developers. A few runs of the DaCapo `luindex` benchmark in the remote setup seem to suffer from excessive recompilation, inflating the difference between the co-located and remote setups. Without `luindex`, the compilation time savings in the remote setup are 33.6% instead of 31.8%.

The improvements vary between the benchmarks because multiple variables determine the success of our approach. For example, some benchmarks use code patterns that lead to non-reusable code, which we analyze later. In some workloads, the VM often compiles different methods across two VM runs, leading to cache misses. Lastly, compilation units differ in their size, and IR caching may benefit larger compilations more.

The difference between the co-located and remote setups can likely be attributed to the communication latency. A possible mitigation for this problem is hiding the latency by increasing the number of concurrent compilation tasks [18, 19].

5.2 Performance Metrics

We use the measurement data collected from the experiment introduced above to analyze how our approach impacts peak performance and warmup time.

Peak Performance. The quality of the code compiled by a dynamic compiler is sensitive to factors such as the timing of compilation tasks. Therefore, we consider it a good practice to confirm that performance is unaffected. We measure the peak performance in terms of the average iteration time when the VM is warmed up. We acknowledge that the workloads may not reach a single steady state [2], and variation in iteration time is expected. As a pragmatic choice, we compute the arithmetic average of the durations of iterations completed after the 6-minute mark since VM start (lower is better). Note that the workloads typically warm up in the first 6 minutes of the run on our platform.

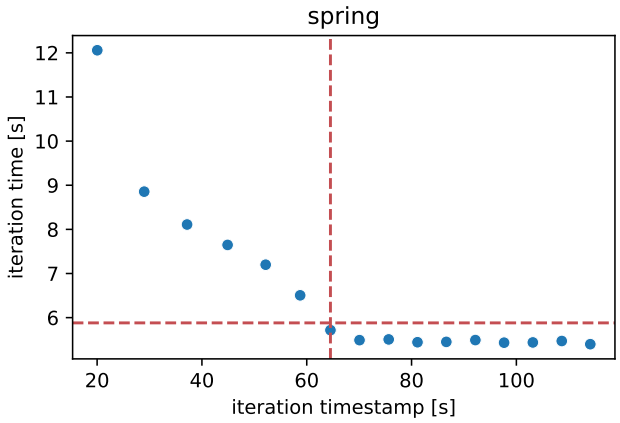

Figure 3 Iterations from the beginning of a baseline run of the DaCapo `spring` benchmark, highlighting the warmup threshold (horizontal line) and the warmup time (vertical line).

Warmup Time. There are multiple options for precisely defining warmup, but there is no standard and straightforward option. Related work [19] uses 90% of peak throughput as the threshold to consider an application warmed up. Since we evaluate benchmarks consisting of multiple workload iterations, we define warmup time as the timestamp of the first iteration where the iteration time is below a warmup threshold. We compute the warmup threshold analogously to the related work [19] as 1/(90%) of the mean iteration time after the 6-minute mark (the peak performance metric). We performed a sensitivity analysis to verify that the overall results vary by no more than a few percent with values of the warmup threshold parameter between 1/(80%) and 1/(95%). Due to performance anomalies that we explain below, we exclude the `scala-kmeans` and `gauss-mix` benchmarks from the warmup time evaluation in the Renaissance suite.

To visualize our warmup detection method, Figure 3 plots the iteration timestamps and durations of the DaCapo `spring` benchmark from the start of a single run. The horizontal line is the computed warmup threshold. The vertical line marks the computed warmup time.

Benchmarks with high iteration times present a potential problem for our and similar warmup detection methods. Because we determine warmup only after an iteration completes, we risk overestimating small changes in warmup time that occur within an iteration. This concern is reduced in benchmarks with low iteration times. We verified that restricting the evaluation to 25% of the benchmarks with the lowest baseline iteration time yields similar overall results.

We encountered these performance anomalies that are relevant to warmup detection:

1. high variance in iteration time within a VM run (in DaCapo `xalan` and other benchmarks),
2. the application experiences a small but continuous speedup (in DaCapo `fop` and other benchmarks),
3. slowing down after the first iteration (in DaCapo `kafka`), and
4. large shifts in performance (in Renaissance `scala-kmeans` and `gauss-mix`).

These anomalies occur in both the baseline and hybrid setups. We manually inspected plots similar to Figure 3 to verify that the problems caused by the first three anomalies are mitigated by the warmup threshold. In DaCapo `kafka`, the first iteration is already below the warmup threshold, so the warmup detection yields reasonable results. The performance shifts in Renaissance `scala-kmeans` and `gauss-mix` cause significant variance in the measured

Table 3 Performance metrics in DaCapo benchmarks with a co-located server (lower is better).

benchmark	warmup time		iteration time

Table 4 Changes in performance metrics for every benchmark suite (lower is better).

benchmark suite	server setup	warmup time	iteration time
DaCapo	co-located	**−17.4**%	**−0.3**%
Renaissance	co-located	**−13.1**%	**−0.2**%
ScalaBench	co-located	**−21.2**%	**0.0**%
DaCapo	remote	**−17.3**%	**−0.2**%

warmup time. In multiple runs, warmup is detected at the point of a performance drop occurring several minutes into the run, which can substantially impact the average warmup time. The performance shifts may be caused by inlining instability [36], which is a known compiler issue that manifests in these benchmarks. For the above reasons, we consider these benchmarks unsuitable for comparing warmup time between two systems, and we exclude them when computing the overall warmup change in the Renaissance suite. The DaCapo and ScalaBench suites do not experience performance shifts of this nature.

Results. Table 3 lists the performance metrics for the individual DaCapo benchmarks with a co-located compilation server. As before, we show the absolute values for the baseline runs and the relative values for the hybrid runs. Our approach improves the warmup time for almost all DaCapo benchmarks. The peak performance of the hybrid runs is usually close to the baseline, with few minor deviations in both directions.

Table 4 summarizes the changes in performance metrics for every evaluated setup. In the setup with a co-located server, the overall decrease in warmup time is between 13.1% and 21.2%. The iteration time of the hybrid setup does not significantly deviate from the baseline. The overall warmup improvement in the DaCapo suite with a remote server is similar to that of the co-located setup.

Discussion. Our approach significantly improves warmup time in most workloads, which we likely achieve primarily by reducing the latency of compilation tasks. When compilation latency is reduced, the VM can start executing efficient code earlier. However, due to the nature of dynamic compilation, compilation time reductions do not transfer linearly to warmup improvements. Just by changing the latencies of compilation tasks, we also impact the collected profiles, the methods selected for compilation, and, consequently, how the compiler optimizes code. Lastly, compilation speed is only one of the many factors that influence warmup.

The presented approach aims not to degrade peak performance. In the vast majority of benchmarks, there is no significant impact, and the overall change is also small. However, in individual benchmarks, our approach can change when a particular method is compiled (compared to the baseline), which in turn impacts profiles and optimization. In the Renaissance suite, a small number of workloads are susceptible to performance changes in either direction. These changes are likely caused by inlining instability [36].

5.3 Analysis of IR Reusability

We evaluate the success of our prototype in reusing the cached IR based on the relative size of the bytecode compiled from the cache, which we refer to as the cache hit rate. We also analyze the reasons for the observed validation failures and discuss the options for improving IR reusability in future work.

Cache Hit Rate. In every 12-minute run of the hybrid setup, we compute the cache hit rate as the ratio of the bytecode size of the compilation tasks served from the IR cache and the total bytecode size of all compilation tasks. We use the geometric mean to aggregate the metric.

In the co-located setup, the cache hit rate is about 69% in the DaCapo suite, 64% in the Renaissance suite, and 77% in the ScalaBench suite. In the DaCapo suite with a remote server, the cache hit rate is 71%.

The results show that the majority of the compiled bytecodes originate from the IR cache. The client VMs never reach a cache hit rate of 100% in any of the runs since we deliberately try to compile small methods using the local JIT compiler to keep compilation latency low. The other factors that decrease the cache hit rate are cache misses, recompilations, and validation failures.

Transient Validation Failures. The evaluated benchmarks experience a varying number of validation failures. *Transient failures* are the most common type of validation failures, comprising between 89% and 96% of the validation failures in every evaluated benchmark suite. As explained before, they are caused by the cached IR referencing a class that is not yet loaded by the target VM or referencing a class, method, or field that is in an earlier initialization stage than required to reuse the IR. These failures occur in almost every benchmark because we attempt to reuse mature IR as early as possible. The average number of transient failures varies between benchmarks. DaCapo `eclipse` experiences these failures most frequently, averaging more than 250 failures per run.

Permanent Validation Failures. All other types of validation failures are permanent and together comprise between 4% to 11% of the observed failures in every benchmark suite. The vast majority of Renaissance workloads are affected by permanent failures. In contrast, about half of the DaCapo benchmarks and the vast majority of ScalaBench benchmarks do not experience permanent failures at all.

Class hierarchy mismatch is a permanent failure that occurs when a class hierarchy query on the target VM returns an incompatible result. For example, it occurs when an interface has a single loaded implementation during the tracing stage but multiple loaded implementations during the replay stage. This kind of failure occurs in most Renaissance benchmarks and in about a third of DaCapo benchmarks, but only a low number of compilation tasks are affected on average: no DaCapo benchmark experiences more than 4 of these failures per run.

The *field value mismatch* permanent validation failure occurs when the compiler folds a read of a static final field and the value differs from the expected one. The failure occurs in most Renaissance benchmarks and in about a third of the DaCapo benchmarks. The `cassandra` benchmark is the most affected in the DaCapo suite, experiencing about 13 such failures on average.

Lastly, *type definition mismatch* and *method definition mismatch* are permanent failures occurring due to an incompatible definition of a class or a method. For example, an incompatible class may have different fields, and an incompatible method may have different bytecodes. These failures occur frequently in only a few of the benchmarks. In the Renaissance `dec-tree` benchmark, these incompatibilities are caused by the classes generated by the Catalyst Optimizer [13] from the Apache Spark framework. As we explained previously, our prototype cannot distinguish between the multiple generated classes in this case since they all share the same class name.

Mitigating Validation Failures. We invested a substantial engineering effort to minimize the number of validation failures, and there are still options for further improvement. One of the problems with our prototype is recording the compilation trace also for the expanded inlining candidate methods [38], even if these candidates are not ultimately inlined. There is an opportunity to avoid the validation failures caused by the inlining candidates, which we could achieve by filtering out the operations irrelevant to the inlined methods.

We could mitigate many of the transient validation failures by loading pre-initialized classes [47], which is a planned but so far unrealized feature of the OpenJDK project Leyden [15]. The client VM could trigger the loading of a pre-initialized class when the class is first referenced in a compilation trace. Pre-initialization requires caching [48] the values of the static final fields, which would also mitigate the failures caused by field value mismatch. Together, these features would open up the option for eagerly compiling [18] the cached IR and prefetching the code compiled at the highest optimization level.

6 Related Work

Reusing Compilation Results. Shared Class Cache (SCC) [17] is a technology to improve startup and warmup performance in the OpenJ9 JVM. SCC stores preprocessed class data in a memory-mapped file, and it can also store compiled code. Reusability of the code is achieved by compiling it with a lower optimization level [19] and patching the compiled machine code [8]. Due to the lower performance of the cached code, the JIT compiler must recompile the hottest methods to reach peak throughput. SCC uses a process similar to

compilation tracing to establish the provenance of VM objects [9], such as methods and classes. However, the mechanism is not used to facilitate specializing the code for the running VM instance. In our approach, we leverage compilation tracing almost without any restrictions on the optimizations that can be applied. Thus, the code compiled from our IR cache achieves peak performance and does not require recompilation. ShareJIT [46] and ShMVM [7] are systems similar to SCC that facilitate sharing code compiled with reduced optimization level on a single machine. `jaotc` [21, 22] was a tool to precompile Java class files ahead of time to native code for the HotSpot JVM.

Pečimúth et al. [37] explain the reasons why highly optimized code is not reusable in GraalVM. The authors suggest caching the IR and making it reusable by deferring all optimizations that potentially specialize the IR to the running VM. However, this approach reduces peak performance in many workloads. In our work, we instead let the compiler perform the optimizations that specialize the IR to the VM, and we employ compilation tracing to facilitate IR reuse without sacrificing peak performance.

The Truffle language implementation framework [45] can store the compiled code along with other data structures in a file [31] to improve warmup in future VM runs. The guest language running in this mode (e.g., JavaScript) must satisfy specific conditions. For example, the language implementation cannot speculate on object identity, since it would lead to a guaranteed deoptimization. The approach we present does not have this restriction because replaying the compilation trace allows us to relocate object references in the IR.

Ř+ [26] is a system to reuse compiled code for the R language. In Ř+, the compiler tracks its assumptions and stores them along the compiled code. The code repository may contain multiple versions of the same function, each fit to a different context. At run time, calls are dispatched to the appropriate version based on the current context. Although the HotSpot JVM does not perform such contextual dispatch, our IR cache could potentially benefit from storing multiple versions of a method. For example, the most mature version of a method is sometimes not usable early in the application's lifetime due to assumptions about the loaded classes.

Remote Compilation. JITServer [19, 18] is a remote JIT compilation server for the OpenJ9 JVM. The design of our compilation server, with callbacks for VM runtime information and the caching of their results, is inspired by JITServer. JITServer leverages compiled-code caching based on OpenJ9's SCC [17] infrastructure. Therefore, the code loaded from the cache requires recompilation at the highest optimization level. The main use case presented by the authors is remote compilation for resource-constrained containers in cloud data centers. Resource-constrained containers benefit from the offloading of compilation tasks to a remote server and achieve warmup improvements even without requiring code caching. The compilation server running on another, non-constrained machine effectively extends the computing resources available to the VM running in a container. JITServer can hide the latency of the offloaded compilation tasks by issuing more concurrent compilation tasks. It can also trigger remote compilation eagerly and prefetch [18] the compiled code to the client VMs.

In contrast, our work focuses on reusing the IR compiled at the highest optimization level without needing recompilation to reach peak performance. We decrease the compilation latency by reusing the cached IR. We present an evaluation where the compilation server is co-located with the client without increasing the number of concurrent compilation tasks or dedicating more computing resources to JIT compilation.

Cloud Native Compiler [1] is a production-grade compilation server that can reuse profiles from past JVM runs. However, there is little technical information available. The compilation server for Jikes RVM by Lee et al. [24] is an earlier work in which compilation tasks are served in a single request without callbacks. However, this is difficult to achieve in a modern JVM due to the dynamicity of the runtime and method inlining.

Improving Warmup. OpenJDK project Leyden [15] is a comprehensive effort addressing the startup and warmup phase of Java applications via various techniques, such as storing compiled code in class-data archives [42], ahead-of-time loading of classes in the linked [23] or initialized [47] state, and other techniques that may require new language features. OpenJDK project CRaC [30] mitigates warmup time by checkpointing running Java applications (creating snapshots), which can then be restored. However, the checkpointed application must manage resources such as open files and sockets, so the process is not transparent to the programmer. Jump-Start [34] is a technique that improves warmup by sharing profiling information for the HipHop VM, which eliminates the overhead of collecting profiles.

Ahead-of-Time (AOT) Compilation. Native Image [32] builds native executables by compiling Java class files ahead of time with the closed-world assumption (i.e., classes cannot be loaded at run time). AOT compilation can eliminate warmup but may impact peak performance. The performance of dynamic languages like JavaScript often depends on speculation and runtime feedback, so AOT compilers [43, 33] usually cannot produce as efficient code as JIT compilers.

7 Conclusion

This paper introduces a novel technique to reuse highly optimized IR in dynamic compilers. We do this by tracing the arguments and results of compiler-interface calls, allowing us to verify that the assumptions made during a compilation of reusable IR hold in a particular target VM instance. Using this approach, we can relocate the IR's VM object references and compile the IR for the target VM instance. A compilation server caches the IR from previous runs of the application and can compile it to machine code for local or remote client VMs. An empirical evaluation based on the GraalVM compiler and industry-standard benchmark suites shows that the approach reduces compilation time by 23.6% to 36.8% and warmup time by 13.1% to 21.2% in each suite without hindering peak performance.

Lightweight Diagramming for Lightweight Formal Methods: A Grounded Language Design

Abstract

Tools such as Alloy enable users to incrementally define, explore, verify, and diagnose specifications for complex systems. A critical component of these tools is a visualizer that lets users graphically explore generated models. As we show, however, a default visualizer that knows nothing about the domain can be unhelpful and can even actively violate presentational and cognitive principles. At the other extreme, full-blown custom visualization requires significant effort as well as knowledge that a tool user might not possess. Custom visualizations can also exhibit bad (even silent) failures.

This paper charts a middle ground between the extremes of default and fully-customizable visualization. We capture *essential* domain information for *lightweight* diagramming, embodying this in a language. To identify key elements of lightweight diagrams, we ground the language design in both the cognitive science research on diagrams and in a corpus of 58 custom visualizations. We distill from these sources a small set of orthogonal primitives, and use the primitives to guide a diagramming language called Cope-and-Drag (`CnD`). We evaluate it on sample tasks, three user studies, and performance, and find that short `CnD` specifications consistently improve model comprehension over the Alloy default. `CnD` thus defines a new point in the design space of diagramming: a language that is lightweight, effective, and driven by sound principles.

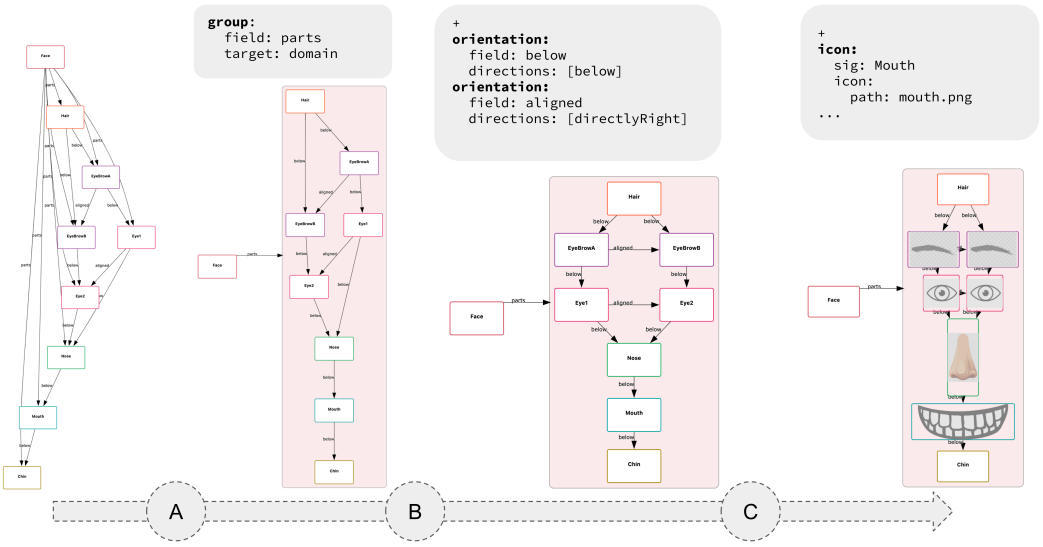

Figure 1 Cope-and-Drag is a language built to support lightweight diagramming for lightweight formal methods. A small set of orthogonal primitives allows users to incrementally refine model-finder output into more effective diagrams. This figure shows how to incrementally refine an instance describing a face using (A) grouping, (B) orientation, and (C) icons.

1 Introduction

In *lightweight formal methods*, proposed by Jackson and Wing [15] and realized in tools such as Alloy [16], users build formal models iteratively, exploring the design space as they go.

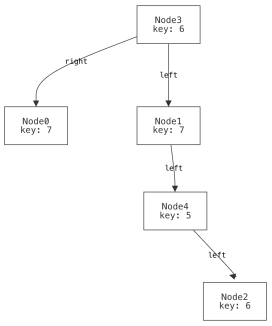
Alloy specs consist of sig[nature]s (sets of atoms), fields (relations between sigs), and descriptions of system behavior. Whereas traditional verification tools are inert without properties, Alloy users can begin reasoning with *just* system descriptions. Alloy uses a (SAT) solver to automatically generate instances that satisfy the spec, presenting them most commonly visually (e.g., Figure 2). This makes using Alloy as close an analog to programming as most formal methods tools get. Unlike a user of a proof assistant (where one must at least somewhat manually construct a proof) or model checker (which requires properties to verify), an Alloy user can enter a spec (akin to a program) and just click "Execute", and see a sequence of examples. This modality, in fact, goes beyond that of a typical programming language, as the user doesn't need to provide specific inputs to see output.

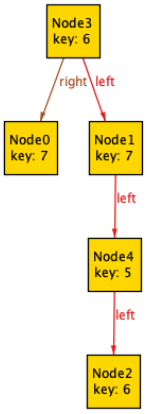
This immediacy and ability to work in the absence of properties has two benefits. First, users can spot ways in which the output does not conform to their intent and improve their specification. Second, seeing these violations suggests desirable and undesirable *properties*, which can then be formalized and verified – addressing the important and often neglected question of where properties come from. Thus, realizing lightweightness hinges heavily on the quality of visualizations.

Alloy and its recent sibling tool Forge [32] visualize relations as graphs. Alloy comes with a default GUI tool [16]. Forge uses Sterling [11] to render interactive graphs in a web browser (Sterling can visualize Alloy instances as well). Both the Alloy default and Sterling are generic, in that they do not embody any knowledge of the domain being modeled, which makes them largely indistinguishable from the perspective of our work: e.g., see Figure 2c and Figure 2b. While obtaining these visualizations requires zero effort from users, research shows that users struggle to make sense of them as models grow in size and complexity [24].

```
sig Node {
  // one key per Node
  key    : one Int,
  //At most one left/right child
  left   : lone Node,
  right  : lone Node
}

pred binary_tree {
  all disj n1, n2: Node | {
    n1 in n2.^(
     left + right + ~left + ~right)
  }
  all n: Node | {
    n not in n.^(left + right)
    some n.left => n.left != n.right
    lone parent: Node | {
      n in parent.(left+right)
   }
  }
}
run {binary_tree} for exactly 5 Node
```





(a) Alloy spec. **(b)** Sterling output. **(c)** Alloy Visualizer output.

Figure 2 Alloy spec of a binary tree, without any properties, alongside a generated instance (visualized by Alloy Visualizer). `Node` is a sig that defines a set of atoms, while fields `left`, `right`, and `key` describe relations between nodes. Predicate `binary_tree` imposes constraints on these fields.

Sterling also provides support for custom JavaScript visualizations. They can be narrowly crafted to a domain, and can be quite visually attractive (e.g., [32, Figure 11]; Figure 11b). By being programmable (in addition to being interactive), they can be applied repeatedly and consistently to all output. However, these custom visualizations suffer from a dual problem. As we discuss in Section 2.4, users must: know the details of drawing libraries, which are orthogonal to formal methods; expend a great deal of effort; and not inadvertently run afoul of visual design principles. Furthermore, custom visualizations suffer from a critical mode of *silent failure* when the specification and visualization disagree on model invariants. Silent failures, we argue, are especially dangerous for lightweight formal methods (Section 4).

In contrast, we want customization to not only be programmable but also: be lightweight; avoid complex library over-dependence; embody good visual design principles; and prevent failure modes. By embodying these in a programming language, we can be confident that *all* programs written in that language enjoy these desirable traits. Thus, this paper views the visualization task as a *language design problem*.

We therefore present a new language, Cope-and-Drag (`CnD`), for this purpose. `CnD` is driven both top-down, by cognitive science principles of visualization, and bottom-up, by manually distilling ideas from dozens of actual visualizations (Section 2). The resulting language is small, requires little annotation, and can be used incrementally (Section 3). `CnD` is designed to avoid the critical failure mode instead of silently rendering a misleading diagram (Section 4). We show through experiments that the features of the language result in visualizations that are more effective than the default visualizer (Section 5). `CnD` is embedded in an open-source tool that serves as a substitute visualizer for Alloy and Forge, available at `https://github.com/sidprasad/copeanddrag/tree/ecoop-2025`.

While this work falls in the realm of recent language designs for visual output, we show why this work is novel (Section 6) and particularly well-suited to the important domain of lightweight formal methods (Sections 3.3 and 4). Furthermore, this work or its extensions can also apply to other formal methods tools that employ diagramming (Section 6.3).

Vocabulary

- A **specification** (or, in the lightweight spirit, *spec*) is a formal description of a system's behavior (e.g., Alloy or Forge code).
- An **instance** is a concrete assignment of values to variables that satisfies the constraints and properties defined by the spec (e.g., a model generated by SAT, lifted to the domain).
- A **bad-instance** is an instance that fails to satisfy part of the *implicit* spec that the author is *trying* to write. A bad instance reflects a discrepancy between what the explicit spec currently represents and what the author intends it to represent. We use the colloquial word "bad" intentionally, since it is human judgment that identifies such a discrepancy. The discovery and extirpation of bad-instances while driving towards the implicit spec is a key part of the lightweight formal methods process.
- A **default-graph** is a directed-graph visualization produced by the Alloy Visualizer [16] or Sterling [11] (without customization). These graphs are agnostic to the domain being modeled. (While there are differences between the two tools, discussed in Section 6.1, for the purposes of this paper, Alloy and Sterling graphs are effectively the same, so we refer to them by the same general label.)
- A **triad** is a three-part figure that consists of default-graph output, `CnD` output, and the corresponding `CnD` source code. We use triads extensively in the supplement.

Supplemental Material

A powerful aspect of `CnD` diagrams is their interactive nature. While we include screenshots in this paper, we also provide interactive versions in supplementary material. Any diagram name that appears in a blue box, as in **name**, has an interactive variant available through a Docker image. Instructions for running the Docker are in the supplement readme (`supplement.pdf`). Instructions on accessing the exact survey instruments used in Section 5.2 are available in the supplement as well.

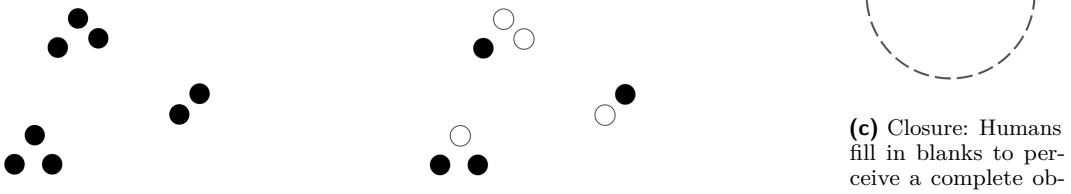
2 Diagramming Language Design

Languages can be designed from many perspectives, such as personal taste, carefully subjecting every feature to a user study, or programmer opinion, which can be broadly expressed or narrowly targeted. While these all have their validity, we focus on *grounded* design: designs that are derived from, and can be substantiated by, external artifacts.

There are roughly two ways to proceed. One is bottom-up: start with a large collection of desired artifacts, cluster their commonalities and differences, identify their principal dimensions, and use those to inform the design. Another is top-down: start with general principles established by experts (usually based on prior grounded efforts) and concretize them into operations. Because these approaches complement each other well, we use both methods. We start top-down, distilling key principles from the diagramming literature (Section 2.1), and then examine a corpus of concrete examples in the context of these principles (Section 2.2). We then align these perspectives to derive a set of diagramming primitives that are both theoretically grounded and practically applicable in the context of lightweight formal methods (Section 2.3).

2.1 Top Down

We begin our language design by drawing on established principles in cognitive science, visualization, and diagramming.



(a) Proximity: Our minds perceive a connection between objects in close spatial proximity.

(b) Similarity: Objects sharing the same color, shape, or size are perceived as related.

(c) Closure: Humans fill in blanks to perceive a complete object. While this diagram consists of a set of disconnected dashes, a viewer perceives a circle.

Figure 3 Examples of the Gestalt principles of proximity, similarity, and closure.

2.1.1 Visual Principles

A diagram is a visual representation that uses shapes and symbols to convey information or ideas. In this role as an information presentation tool, effective diagrams rely on perceptual properties common in information visualization, the most relevant (and best established) of which relate to pre-attentive processing and the Gestalt principles [5].

Pre-Attentive Processing. Pre-attentive processing is a cognitive function that allows humans to quickly detect certain visual features (e.g., color, shape, and size) of objects without conscious effort. This rapid processing can both help and hinder understanding.

The Stroop effect, for instance, demonstrates that the brain often automatically processes text, such as in word recognition, faster than stimuli such as color [43] and spatiality [49]. In the context of diagrams, this means that understanding is hindered when visual elements conflict with textual content (e.g., laying out a binary tree's `left` children to the right and `right` children to the left). Other common features that might cause undesirable pre-attentive processing include irrelevant visual elements [45], unnecessarily overlapping lines [39], or ambiguous labeling [5, 22]. Effective diagrams, therefore, use visual features to highlight important information while being mindful of extraneous cognitive load [44]. For example, Figure 5 leverages different colors to help viewers quickly distinguish between Alloy identifiers and `CnD` keywords.

Gestalt Principles. The Gestalt principles [17, 41, 48] describe how humans perceive and organize visual information, grouping objects that are close together (proximity), share attributes (similarity), form complete shapes (closure), follow a continuous path (continuity), stand out from a background (figure-ground), appear balanced (symmetry), or move together (common fate).[1] These principles play a crucial role in visual design, user interface design, and data visualization, helping to create more intuitive and easily comprehensible visual representations. Figure 3 illustrates some of these principles.

The Gestalt principles so accurately describe human perception, and leveraging pre-attentive processing is so inherently effective, that they both underpin many diagramming conventions, even when their influence is not explicitly acknowledged. For a more detailed description of how these principles apply to visualization, see [5, page 8].

[1] While these principles were originally formulated by Wertheimer in 1912 [48], we authors are more familiar with Spillman's English translation [41] and Koffka's framing in the field of psychology [17].

2.1.2 Diagramming Principles

While visualizations focus on displaying information, diagrams act as cognitive tools that facilitate deeper comprehension and analysis of complex systems [20, 22, 46]. A diagram's effectiveness stems not only from its visual appeal, but also from its ability to organize information in a way that facilitates efficient cognitive processes [20]. These processes depend on the task one is trying to perform.

Subway maps, for example, leverage the observation that semantic similarity is intuitively tied to spatial proximity [14]. By grouping together stations that are functionally related (e.g., transfer points or lines serving the same neighborhoods), they serve as effective diagrams for planning public transportation routes. However, this layout is poorly suited for understanding the actual geographic distances between stations, as the map distorts spatial relationships in favor of simplifying the navigation task.

Thus, while a "good" diagram must be well laid out, it must also relate well to the *problem* it is designed to address [5, 22]. Diagrams are of help when they:

1. Leverage spatial metaphors and natural correspondences in the source domain [20, 46].
2. Convey patterns and relations in the source domain in spatial terms [14, 20].
3. Group together all information that will be used together [14, 20].

2.1.3 Core Diagramming Operations

From the above literature, we identify that users require the following operations in order to create effective diagrams:

Relative Positioning. Users should be able to specify the relative positions of diagram elements. This allows diagram elements to be spatially arranged to reflect the underlying structure of the domain, relating to the Gestalt principles of continuity, closure, and proximity. Placing graph elements consistently in relation to others can imply diagrammatic flow, groupings, and even underlying shapes. We identify two key aspects of relative positioning:

1. *Directional relationships* between diagram elements. For example, specifying that elements should be placed above, below, to the left, or to the right of one another.
2. *Angular flow* to describe element positions. For example, specifying that elements should be arranged in a circle, or that they should form a shape.

Grouping. Users should be able to group related diagram elements together. Leveraging the Gestalt principle of proximity, grouping related elements together can help users to better understand the relationships between them. This also allows diagrammers to group together elements that will be used together, reducing extraneous cognitive load. Grouping relationships in interactive diagrams can also help users reason about higher-level structures and relationships, leveraging the Gestalt principle of common fate.

Styling. Users should be able to control some visual aspects of how diagram elements are rendered. We identify two ways in which users might want to style their diagrams: theming and iconography. Theming involves influencing the aesthetic properties of diagram elements, such as the color, size, and shape of elements. This allows users to create diagrams that tap into the Gestalt principles of similarity and figure-ground.

Iconography, on the other hand, involves the use of pictorial elements in diagrams that themselves carry semantic meaning, e.g., representing an eye with an image instead of the word "eye" (Figure 1). Icons and symbols in diagrams can tap into pre-attentive processing, allowing users to quickly understand what a diagram element represents without needing to examine the diagram in detail.

With these primitives, diagrammers should be able to create artifacts that:

- Focus on important parts of the problem.
- Are tools for knowledge presentation. That is, they offer insight into instances of the spec being explored.
- Act as tools for knowledge discovery. That is, they show key aspects of bad-instances of the spec.

2.2 Bottom Up

While the top-down approach provides a theoretical foundation for our language design, much of the literature draws on abstract principles that may not be directly applicable to the formal methods domain.

To study how these principles manifest in practice, we contacted the Forge [32] team, who kindly gave us access to anonymized data on visualizations that students created in their upper-level undergraduate course on formal methods, as well as the results of a follow-up survey on students' visualization experiences. Students had given permission for this use.[2]

Figure 4 A student-drawn diagram illustrating the layout of their spec. This layout relies on relative positioning, grouped elements, and iconography.

The dataset contained anonymized retrospective comments on 58 final group projects (21 from 2022, 21 from 2023, and 16 from 2024), most of which were written in Forge, and visualized either as default-graphs or using D3 [3] to customize Sterling. As a result, we were able to gain insight into how two methods of visualization work for users who have roughly a semester of experience with formal modeling.

Projects covered a wide range of domains, from games like Solitaire to cryptographic protocols and group theory. Each project involved a code submission (a spec and optional visualization) as well as a recorded presentation or written summary explaining the domain being modeled, the design decisions made, and an optional demonstration of the visualization.

Most projects (47 total, 81 %) involved some kind of custom visualization (typically relying on Sterling's D3 integration). We examined these projects to determine how the principles we derived from the cognitive science literature were reflected in the visualizations students created. We also included projects in our analysis that did not include a custom visualization, but where authors were especially clear about wanting a custom visual component even if they did not have one, e.g., by presenting a hand-drawn diagram (e.g., Figure 4) or by manually rearranging nodes of the Sterling default-graph in their presentation.

[2] Some of these visualizations are shown in figure 11 of [32].

In our analysis, we found that:

- 44 projects (75 %) involved custom visualizations that had clear representation salience and minimal visual clutter. Each atom in the model was represented by at most one element in the visualization, and each element in the visualization corresponded to an important aspect of the model.
- 41 visualizations (70 %) communicated semantic relationships between elements via their relative orientation. Examples include the grid layout of cells when visualizing the games Minesweeper and Battleships, and the relative positions of nodes in red black trees.
- 19 visualizations (33 %) grouped nodes together inside explicit shapes to imply relatedness. Examples include piles of cards in the card game Solitaire, player hands in the game Chopsticks, and sets of elements in group theory.
- 4 visualizations (7 %) conveyed spec semantics by laying out diagram elements to imply shapes or directionality. Examples include the cyclic order of player turns in the card game Coup and travel paths in a map routing algorithm.

The Forge team also shared anonymized results of a survey. Students explained that they created custom visualizations due to the large, unstructured instances presented by the default-graphs. Specific issues included: too many edges and nodes, complicated states, and overlapping components. Their custom visualizations hid unnecessary information, conveyed key aspects of the source domain, and could even act as useful debugging tools.

While the decisions made by students may not fully represent those of experienced formal methods practitioners, they do provide valuable insight into some key aspects of the modeling process. While working on open-ended projects, students had to carry out real steps a practitioner would take: choose a domain they were interested in and knowledgeable about, formally model it, debug the models, and effectively communicate their output.

2.3 Top-Down and Bottom-Up Alignment

Our analysis of student projects suggests that diagramming principles from the cognitive science literature (Section 2.1), such as reducing cognitive load and highlighting important information, are very much applicable in the context of lightweight formal methods. Across a diverse range of domains, student visualizations preserved domain-specific spatial relations, grouped together related elements, and encoded spec semantics in terms of spatial layout and directionality. They also draw attention to a key additional requirement in the context of formal methods: support for bad-instances. We discuss this in further detail in Section 4.

2.4 The Pain Barrier to Custom Visualization (with D3)

We have motivated the value of custom visualizations. However, they come at a heavy price. Not only do users need familiarity with JavaScript, but D3 – one of the most influential online visualization libraries [2] – is notorious for its steep learning curve, API verbosity, and low-level operations [2, 28]. It is also worth noting that both JavaScript and D3 are entirely orthogonal learning objectives to someone learning or performing formal methods.

The nature of D3 also means that Sterling-with-D3 scripts are often enormous relative to the specs they are built to visualize. For example, the code for the river-crossing visualization in the Sterling demo [10] is *four times* longer than the spec (148 lines vs. 35 lines). It can also be difficult during maintenance and debugging to understand which parts of their D3 code correspond to which parts of the spec. Furthermore, a typical custom visualization is an "all-or-nothing" proposition: until enough of the visualization has been written, the user gets

Program ::= Constraint* Directive*

Constraint ::= CyclicConstraint
| OrientationConstraint
| GroupingConstraint

CyclicConstraint ::= Field FlowDirection

OrientationConstraint ::= Field Direction+
| Sig Direction+

GroupingConstraint ::= Field Target

FlowDirection ::= clockwise | counterclockwise

Direction ::= above | below | left | right
| directlyAbove | directlyBelow
| directlyLeft | directlyRight

Target ::= domain | range

Directive ::= PictorialDirective
| ThemingDirective

PictorialDirective ::= Sig Icon

ThemingDirective ::=
Attribute | Color
| Projection | VisibilityFlag

Icon ::= path height width

Attribute ::= Field

Color ::= SigName color

Projection ::= Sig

VisibilityFlag ::= hideDisconnected
| hideDisconnectedBuiltIns

Figure 5 Abstract syntax of Cope-and-Drag. Identifiers from the source Alloy spec are in orange, while `CnD`-specific keywords are in blue.

no benefit at all. This critically violates the "pay as you go" flavor that is characteristic of lightweight formal methods. It also makes it difficult to iterate, debug, and maintain custom visualizations, discouraging the use of D3 for exploratory diagramming tasks.

In Section 2.2, we have already indicated that some students used paper drawings or manually dragged boxes to simulate what they wanted. In the same survey in which students praised the value of custom visualizations, 37 respondents (44%) did not use JavaScript/D3 *at all*. These students primarily identified the complexity of D3 and the need to use JavaScript as a significant barrier to building custom visualizations, reporting difficulty learning JavaScript and D3, having enough time, starting, and finishing, corroborating past findings [2].

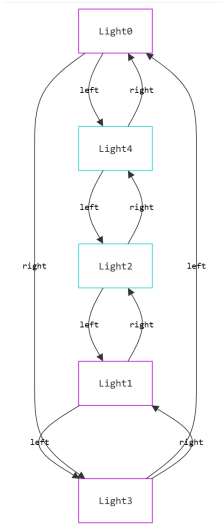
We thus see that the potential for custom visualization is undermined by the current tooling, which is onerous and often too daunting for users. (We discuss other drawing systems and languages in Section 6.) This observation demands a better, lightweight way of capturing the *essential* elements of diagrams that draws on the above principles and examples.

3 The Cope-and-Drag System

Cope-and-Drag (`CnD`) is a lightweight diagramming language designed for use with Alloy-like languages. The tool's name is inspired by the cope-and-drag casting process in metallurgy, reflecting its adaptable approach to diagram creation. `CnD` implements the diagramming operations identified in Section 2, and applies them to directed graphs with the goal of improving upon default-graphs. These generated diagrams support user interactions *while maintaining consistency with the diagram spec*. Thus, `CnD` not only facilitates diagram creation, but also supports *faithful* interactive exploration of instances being visualized.

3.1 `CnD` Primitives

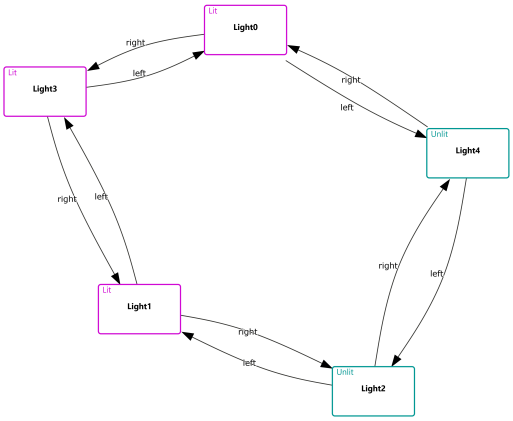
`CnD` primitives operate upon Alloy/Forge sigs (which are essentially types) and their fields. These primitives fall into two categories: directives and constraints. Directives are used to specify the visual representation of a sig or field. Constraints are used to specify the relationships between visual representations. The resultant diagrams are interactive, allowing



(a) Default-graph.

```
constraints:
  - cyclic:
      field:  left
      direction: clockwise
```

(b) `CnD` spec featuring a `cyclic` constraint. Identifiers from the source Alloy spec are in orange.



(c) `CnD` diagram.

Figure 6 ring-lights triad, contrasting a default-graph with `CnD` for an instance of a puzzle involving 5 lightbulbs arranged in a ring. The default misleadingly positions the nodes in a line. Supplement Figure 1 presents a larger version of the diagrams.

users to drag nodes around and explore the spec, while ensuring that the visual representation remains consistent with the specified constraints. For instance, if a constraint specifies that `A` must be to the left of `B`, a user will not be allowed to drag `B` to the left of `A` (ab). In cases where constraints cannot be satisfied, no diagram is produced (Section 3.2).

Each `CnD` primitive is designed to fulfill a specific requirement identified in Section 2.

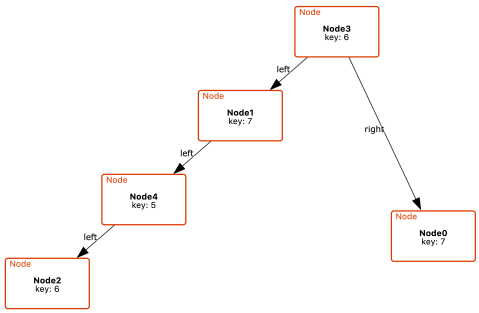
Relative Positioning: Cyclic and Orientation Constraints. Cyclic and Orientation constraints are used to specify the *relative positioning* (Section 2.3) of diagram elements.

Cyclic constraints lay out atoms related by a sig field along the perimeter of a notional circle, suggesting they form a shape. If a field does not define a complete cycle, each connected subset is arranged on the circle's perimeter based on a depth-first exploration of the field. Atoms in the relation can be positioned either clockwise (the default) or counterclockwise. Figure 6 presents a triad. The `CnD` diagram arranges nodes in a circle, in accordance with the spec, because the `CnD` program includes a `cyclic` constraint. The default-graph, lacking this domain-specific information, arranges nodes in a line. A user would need to carefully read the edge labels or the underlying spec to discover that the nodes have a cyclic relationship.

Orientation constraints specify the placement of atoms in a diagram instance relative to one another. These constraints can be applied between sig types (e.g., all atoms of type `A` must be to the left of those of type `B`) or along sig fields (e.g., atoms related by the `child` field must be placed downward). For example, the orientation constraints in Figure 7a are at the heart of a `CnD` program for binary tree instances produced by Figure 2. Supplement Figure 2presents a triad with the full `CnD` spec and a default-graph. The default produces a Stroop effect, putting the left child on the right and vice versa. Users have no way to prevent this effect.

```
- orientation:
    field: left
    directions: [left, below]
- orientation:
    field: right
    directions: [right, below]
```

(a) CnD spec.



(b) CnD diagram.

Figure 7 bt CnD spec and diagram for binary tree instances produced by Figure 2.

Grouping Constraints. Grouping constraints specify that atoms related by a sig field should be grouped together spatially. Groups can be created based on either the range (default) or domain of the sig field. Grouping goes beyond merely associating atoms: CnD replaces the individual edges between the group source and target atoms with a single edge, and places grouped atoms within a bounding box. Groups cannot intersect unless one is entirely subsumed by another.[3]

Figure 8 shows the CnD-rendered state of a river-crossing puzzle, using groups to indicate shores. This picture significantly reduces the number of edges; it also shows which entities are on the same shore, thereby avoiding confusion because near and far shore entities are interleaved in the default-graph version. A careful look at the default Sterling visualization of a similar river crossing spec in the Forge paper [32, Figure 5, left] shows that it too exhibits a Stroop effect.

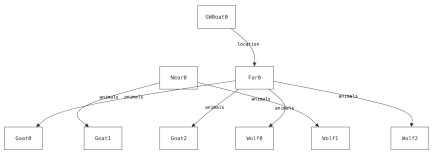
In general, grouping constraints allow users to focus on higher-level structures and relationships without being overwhelmed by individual connections.

Directives. Directives allow users to control the visual aspects of how atoms of a particular sig type are rendered.

Pictorial directives specify that atoms of a particular sig must be represented by a specific icon (with or without a textual label as well). These icons help to visually situate the output in the domain being modeled, making the output less uniformly textual and exploiting pre-attentive processing. Two examples are the facial features in Figure 1 and the fruit in Figure 14.

CnD also supports a subset of the theming directives made available by the Alloy Visualizer and Sterling. Attribute directives display a field relation as a label on atoms of a particular sig type. Sig color directives associate specific colors with atoms of a certain sig type. Projection directives allow diagrams to focus on the atoms of a particular sig and their directly connected relations, hiding all other elements. Users can also hide disconnected atoms, depending on the provenance of their sig type, by using the `hideDisconnected` and `hideDisconnectedBuiltIns` visibility flags.

[3] The requirement that groups not intersect is a technical limitation of the WebCola library [8] used by CnD. Overlapping groups affect the computation of bounding boxes and convex hulls. Group bounding boxes, as determined by WebCola, are also not guaranteed to be minimal, and can sometimes be larger than necessary.



(a) Alloy Visualizer interleaves near and far shore entities.

```
constraints:
  - group:
      field:  animals
      target: domain
```

(b) CnD spec.

Figure 8 rc Alloy Visualizer and CnD representations of a river-crossing puzzle instance.

3.2 When Constraints Cannot be Satisfied

All CnD constraints are hard constraints, and thus *must* be satisfied for a diagram to be produced. Constraints might not be satisfied for one of two reasons:

1. A single CnD constraint definition could be inherently unsatisfiable. For example a constraint that requires the same field to be laid out both leftwards and rightwards:

   ```
   - orientation: {field:  next , directions: [right, left]}
   ```

   This represents a bug in the CnD spec, and can be identified statically. In this case, CnD produces an error message in terms of the constraints that could not be satisfied.

   ```
   Inconsistent orientation constraint:
   Field next cannot be laid out with directions: right, left.
   ```

   Checking for inconsistencies is a relatively simple process: CnD just needs to ensure that the same field is not laid out in conflicting directions.
2. Some constraints may be individually satisfiable, but become contradictory when laying out a specific instance. This is akin to a dynamic error, as it depends on the structure of the instance being visualized. For example, consider the constraints:

   ```
   - orientation: {sigs : [ X ,  Y ], directions: [below]}
   - orientation: {sigs : [ Y ,  Z ], directions: [below]}
   - orientation: {sigs : [ Z ,  X ], directions: [below]}
   ```

   If an instance's elements form a cyclic dependency, the constraints become unsatisfiable. However, an instance may lack atoms of, say, Z, in which case the constraints are satisfiable. CnD identifies these inconsistencies by treating layout as a linear optimization problem. Constraint primitives are incrementally added to the Cassowary linear constraint solver [1]

to ensure that a satisfying layout exists. `CnD` stops at the first indication that constraints cannot be satisfied, and provides an error message in terms of the currently added constraints and instance atoms (e.g., Figure 10).

In both these cases, `CnD` does *not* produce a diagram. Instead, it provides an error message explaining that the constraints could not be met. If all constraints can be satisfied, `CnD` relies on the WebCola library [8, 9] to produce a diagram.

3.3 The Lightweightness of `CnD`

Having described the design of `CnD`, we now briefly justify calling it "lightweight".

Critically, `CnD` *refines* a default-graph output. Thus, the user can apply it incrementally: the empty `CnD` program still produces output, indeed, the exact same output as Sterling. (We discuss this design principle in more detail in Section 8.) Users can thus decide which aspects of the output most need refinement (just as they already do with Alloy Visualizer directives) and apply these rules incrementally. Furthermore, it is easy to turn a rule on or off, to see whether it has the desired effect. This incremental input refinement does not, however, imply incremental output refinement. Adding a new rule to a `CnD` program a new rule may change the layout substantially. Enforcing minimal output changes requires implicit constraints, which can obscure bad instances (Section 4) or introduce unintended Stroop effects (Section 2.1).

`CnD` programs also tend to be very brief. There is only a small number of primitives (constraints and directives) in the language (Section 3.1). Because these primitives apply to sigs and fields, there is an upper-bound on how many we can write, and this is independent of the size of the *operational* part of the spec.

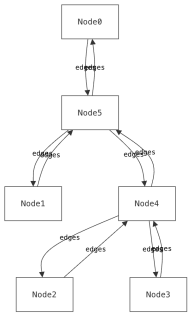
`CnD` output is also "lightweight" in another sense: the language offers few bells-and-whistles, and the output is not necessarily pretty. We view the path from a `CnD` program to a full-fledged custom visualization as akin to that from an Alloy or Forge spec to a correct-by-construction spec verified by a proof assistant. The goal is not to produce diagrams that are attractive, but rather ones that are functionally useful and do not confuse, mislead, or otherwise abuse cognitive principles.

3.4 Where do `CnD` Programs Belong?

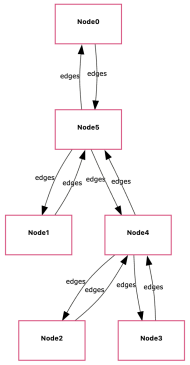
A design question is where to write a `CnD` program. Is it part of the spec, or does it live separately from the spec? This partially depends on whether it even makes sense to have more than one `CnD` program for a spec.

We argue that it is not only possible but also sensible to have multiple views on instances of the same spec. As an example, suppose a user is modeling a self-stabilizing protocol for a distributed system. Depending on the goal, they might want to use a ring to show network topology (e.g., Figure 12b), a DAG to examine hierarchies, or groups to explain permissions. No one view is more privileged than the other. They might even switch between these as they explore and debug different aspects.

In our current implementation, the `CnD` program resides in the visualizer. This is for three more reasons beyond the one given above. First, it is easy to explore commands incrementally even for a given instance (which follows Ma'ayan et al.'s recommendation [22]). Second, the same visualizer works with both Alloy and Forge (and any other tools that use the same protocol), providing portability of these ideas. Finally, it saves us the effort of modifying the implementations of Alloy and Forge.



(a) Default-graph.



(b) undirected-tree CnD, from an empty program.

Figure 9 Default Alloy and default CnD outputs for an undirected tree spec.

That said, CnD programs are not completely separate from the spec; they are really a *spatial refinement* of the spec. Therefore, it would be meaningful to extend the spec languages to include (and name) each of these views. The "static" checking that CnD provides (Section 3.2) is then arguably part of the act of checking the spec itself. The user interface could then provide a menu of these pre-defined views, which were presumably chosen by the domain expert, while enabling the user of the spec to write their own views as well (as they currently can).

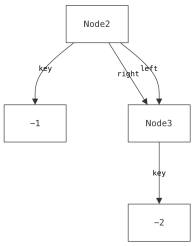
3.5 Visual Details

Whenever possible, CnD diagrams also encode a set of visual principles designed to reduce cognitive load and enhance user comprehension. Graph edges are laid out in a way that minimizes crossings and with as few bends as possible [39]. To reduce edge ambiguity, CnD also ensures that arrowheads are not incident on the same point of a node. We see an example of this in Figure 9, whose CnD program is empty, so the CnD output embodies only the above principles relative to the default-graph: observe the absence of overlapping edge labels. In addition, in CnD output, atoms of each sig are assigned a unique color by default, making salient the type of each node in the diagram. This is not visible in Figure 9 because all the atoms belong to the same sig, but we see it in several outputs such as Figures 1, 12a, and 12c (whose CnD programs do not include any coloring directives).

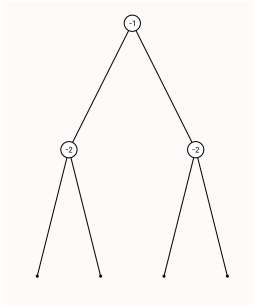
4 Bad-Instances: When Custom Visualizations Can Fail Silently

As we have discussed in Section 1, unlike tools like verifiers – which are inert in the absence of a property – lightweight formal methods can consume *just* a spec and show concrete instances of it. (Researchers have shown how to leverage non-instances as well [12, 26].) This helps bootstrap the formalization process by surfacing latent properties.

In practice, the modeling process is a series of incremental efforts that produces several incorrect specs before reaching an acceptable spec. Incorrect specs are the source of what we dub *bad-instances*: instances that do not align with the informal spec that the user is trying to formally model. It is critical for a visualizer to faithfully render bad-instances, since the user needs to see them and realize that the spec is incorrect.



(a) Default-graph.



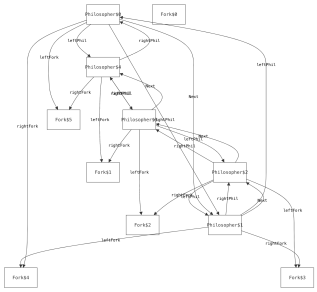
(b) Sterling-with-D3.

Error: The instance being visualized is inconsistent with layout constraints.

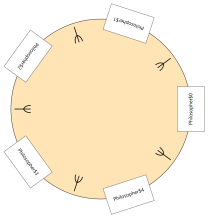
Constraint:
`ENSURE: Node3 is to the left of Node2`
conflicts with the following constraints:
`ENSURE: Node2 is above Node3`
`ENSURE: Node2 is to the left of Node3`
`ENSURE: Node2 is above Node3`

(c) **bt-dag** `CnD` reports an error.

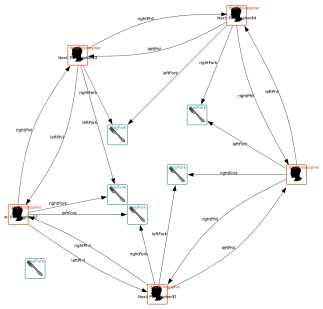
Figure 10 Outputs for a bad-instance of a binary search tree spec. The instance is a DAG with two nodes. The custom Sterling visualization misleadingly draws a tree.



(a) Default-graph (6 forks).



(b) Sterling-with-D3 (5 forks).



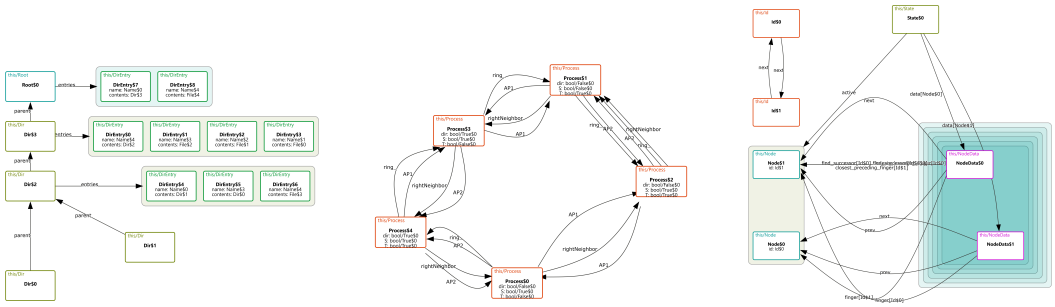
(c) **phil-inv** `CnD` (6 forks).

Figure 11 Outputs for a bad instance of a dining-philosophers spec. The instance has 6 forks but only 5 philosophers. Only `CnD` shows the extra fork and a roughly circular layout.

Faithful rendering is not an issue with default-graphs: for all their weaknesses described earlier in this paper, to their credit, instances and bad-instances alike are displayed as directed graphs, with no information lost or hidden (except as stated in an explicit user directive). In contrast, a custom visualization needs to be sensitive to bad-instances and not misrepresent them or, worse, accidentally suppress the way in which they are bad (so the user may never discover that the spec is flawed). Nelson et al. [32] discuss this in their study of custom Sterling-with-D3 visualizations. They find that as users modify their spec, domain-specific visualizations would behave unexpectedly, leading to confusion and frustration for users.

This problem is not limited to students. Consider these two examples writen by people who are expert in both formal modeling and Sterling:

- A common underconstraint when modeling a binary search tree is to forget to enforce that a node's left and right children are distinct. Figure 10 shows the result of applying an expert-authored visualization to a bad instance: a DAG. The custom visualizer is not robust to this possibility and thus masks an important failure. The default-graph reveals the underlying structure, while `CnD` does even better, displaying an error message about the inconsistency between the bad-instance and diagramming constraints.
- An expert-authored visualization of the dining philosophers problem from the Sterling website [10] also fails silently when presented with bad-instances. A common underconstraint when modeling the dining philosophers problem is not ensuring that the number



(a) filesystem. (b) ring-orientation. (c) chord.

Figure 12 CnD diagrams for three example specs.

of forks equals the number of philosophers. As shown in Figure 11, the expert-written visualization presents the bad-instance as an instance, hiding the presence of an extra fork. The default-graph hides no information, but the lack of semantically meaningful layout means that the sixth fork is not particularly salient. The CnD diagram, in contrast, arranges the domain in a meaningful way, and adds icons to distinguish philosophers from forks, making the extra fork easier to see.

Of course, an attentive visualization author can protect against some of these issues with checks, preconditions, and assertions. Besides being onerous and easy to overlook, these suffer from a more fundamental problem: they are limited by the author's assumptions of what can go wrong. That is, they can only handle *known* unknowns: faulty specs that the author thinks of. However, these would probably be turned into properties in the first place. Problems that the author does not think about (*unknown* unknowns) – the very kind for which lightweight formal methods are ideal – are, by definition, impossible to account for, and may well result in misleading or deceptive visualizations. This problem is especially salient in educational contexts, where it is well-documented that experts (if they provide visualizations) suffer from blind spots [29, 30] about what mistakes students might make.

CnD strikes a happy medium between generic and custom visualization. Because it only refines the generic output, it does not hide information. Because the refinements encode domain information, bad instances either fail noisily (Figure 10) or produce a structured diagram (Figure 11). We report on a user study involving bad-instances in Section 5.2.3.

5 Evaluation

We now evaluate CnD. Our evaluation has three parts. In Section 5.1, we examine its ability to generate visualizations for new domains. In Section 5.2, we provide empirical data on the effectiveness of the generated diagrams. Finally, in Section 5.3, we discuss CnD's performance when generating various diagrams.

5.1 Examples

It is unsurprising that CnD can capture well the demands of the examples in Section 2.2, given that these were effectively the "training set." We instead need a distinct "test set." For that, we use examples from the Alloy Models repository, a publicly available community-maintained collection of specs (`github.com/AlloyTools/models`). It is unclear how to *comprehensively*

study these; instead, we chose a sample of specs for domains that were sufficiently different from one another and that we understood well (for which we could therefore meaningfully write `CnD` programs) and assess their effect.

Filesystem. Figure 12a shows a generic filesystem rendered in `CnD`. It uses an orientation constraint to lay out directories hierarchically, and a combination of grouping and orientation constraints to lay out entries in the same directory. Entry contents and names are shown as attributes. Supplement Figure 4presents a triad contrasting the default-graph and the `CnD` program that refined the graph.

Ring Orientation. Figure 12b shows how we can visualize instances of an Alloy spec for the self-stabilization problem in distributed systems [7] for a ring of processes. A cyclic constraint is used to convey the circular topology of processes, while boolean flags are shown as attributes. Supplement Figure 5presents a triad.

Chord. Figure 12c visualizes an instance of the Chord [42] distributed hash table protocol. This diagram groups active nodes together, and lays out the previous node seen by a node to its direct left. Finally, it uses grouping constraints to show the results of the `find_successor` and `find_predecessor` operations. (The multiple subsuming rectangles in this diagram are a limitation of the WebCola library used by `CnD`, and are used to indicate subsumed groups. One could imagine alternate implementations that collapse these groups into a single rectangle.) Supplement Figure 7 presents a triad.

5.2 User Studies

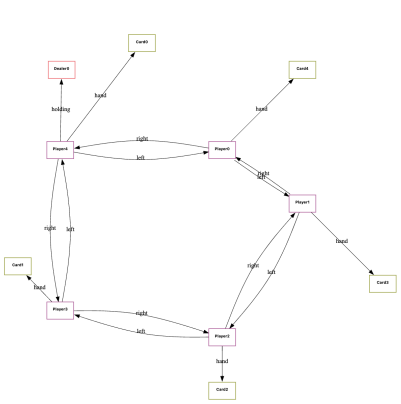
We now present user studies that examine the effectiveness of `CnD`:
Q1. Do `CnD` specs help users understand the instances being explored (Section 5.2.1)?
Q2. Can pictorial directives further enhance spec understanding (Section 5.2.2)?
Q3. Do `CnD` diagrams make salient key aspects of bad-instances (Section 5.2.3)?
We use the default-graph as a baseline for comparison, for three reasons. First, it is what a user would get by default. Second, it is a fixed entity (up to the choice of specific visualizations), whereas the set of possible custom visualizations is limitless and our choices might be biased. Finally, as noted in Section 4, it does not suppress problems with bad-instances.

For all three studies, we recruited participants from the Prolific platform's pre-defined pool of users identified as having "computer programming skills". Each participant was compensated USD 5 for about 15 minutes of time, and no individual took part in more than one study. Our study was deemed to not be human subjects research by our review board; we nevertheless took reasonable safeguards to protect the participants. The full versions of the study diagrams are available in the supplement.

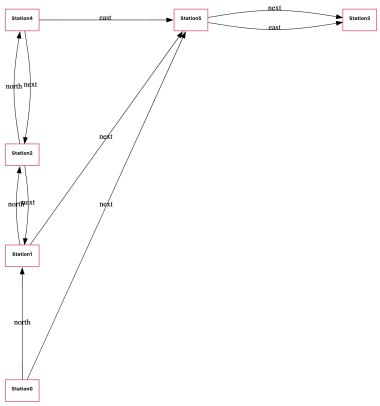
5.2.1 Instance understanding

In order to better understand how `CnD` diagrams offer insight into spec instances, we designed three specs, each of which lends itself well to one kind of `CnD` constraint.

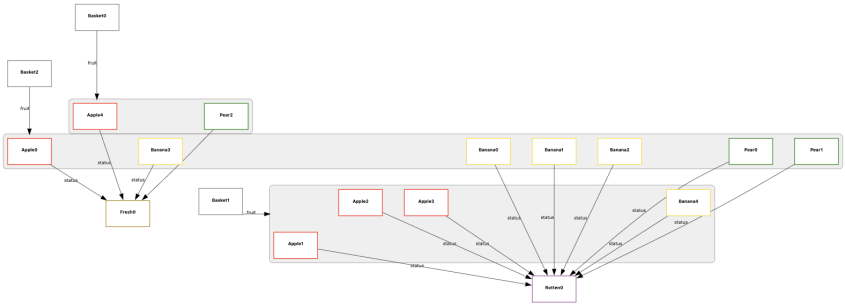
- Cards (Figure 13a): This scenario tested the efficacy of cyclic constraints by asking participants questions about the movement of player roles across rounds of a card game.
- Subway (Figure 13b): This scenario tested the efficacy of orientation constraints by asking participants questions about the relative geographical positions of subway stations.
- Fruit (Figure 13c): This scenario tested the efficacy of grouping constraints by asking participants questions about the relative distribution of fruit across baskets.



(a) cards diagram.



(b) subway diagram.



(c) fruit diagram.

Figure 13 CnD outputs for the three Q1 user study scenarios (Section 5.2.1).

Users were shown one instance of the spec. For each spec, we developed 2–3 questions that would exercise the user's understanding of the instance they were shown. The specs avoided details that would enable a user to answer the questions based on prior knowledge rather than the instance itself.

Each participant (n = 38) was randomly assigned 2 scenarios, one visualized using the default-graph and the other using CnD with *only* the associated constraint. Participants shown CnD diagrams were significantly more likely to get questions correct than those shown default-graph visualizations (62.75 % vs 48.04 % correct, $Z = 2.11$, $p < 0.05$), with a small-to-medium effect size ($d = 0.26$). Participants took approximately the same amount of time to complete the tasks (mean time on task: 105.3s for CnD, 100.46s for default-graph, $t = -0.81$, $p = 0.22$).

5.2.2 Pictorial directives

In order to test the efficacy of pictorial directives, we conducted a second study extending the Fruit scenario described in Section 5.2.1. While the scenario remained unchanged, participants (n = 30) were assigned one of two variations of the fruit diagram: one with CnD's default node representation (Figure 13c) and one with images of fruits on certain nodes (Figure 14). (Supplement Figure 8presents both diagrams together.)

Table 1 Scenarios used to study the effectiveness of `CnD` constraints on spec understanding.

Scenario	Constraint	Correct Answer Percent		Mean Time on Task	
		default-graph	`CnD`	default-graph	`CnD`
cards	Cyclic	28 %	36 %	161.96s	128.81s
subway	Orientation	31 %	56 %	84.02s	121.73s
fruit	Grouping	69 %	74 %	60.15s	70.32s

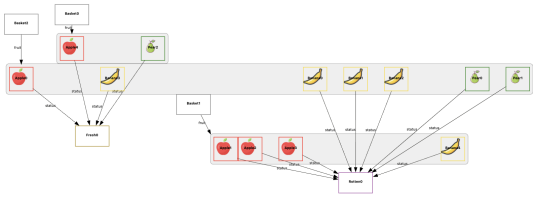


Figure 14 fruit-icons diagram for the Q2 user study (Section 5.2.2).

Participants shown the diagram with pictorial directives answered questions correctly more often, and faster than those shown the diagram without them (86.67 % vs 73.33 % correct, mean time-on-task: 56.76s vs 68.55s). However, these were not statistically significant at a 95 % confidence level (correctness: $Z = 1.60$, $p = 0.11$, time-on task: $t = -0.96$, $p = 0.34$).

Participants were then shown the fruit scenario with three different diagram styles: default-graph, default `CnD`, and `CnD` with pictorial directives, and asked to rank them in order of preference. Participants tended to rank the `CnD` with icons diagram highest (mean rank 1.45), followed by the `CnD` with default nodes (mean rank 2.00), and then the default-graph (mean rank 2.57). This difference in ranking was statistically significant (Friedman $Q = 19.27$, $p = 6.55e - 5$). A pairwise comparison showed that the ranking for `CnD` with icons was significantly higher than that of the default-graph ($p = 3.4e - 5$). Participants identified that the `CnD` with icons diagram conveyed the same information as `CnD` with default nodes, but still showed a slight preference for the former ($p = 0.07$). Their feedback praised the "clarity" of the "structured layout", and that the icons "made relationships more visible and easy to understand" and their absence made it "harder to visualize the elements quickly", while default-graph had "complex" layout and made it "difficult to find what they are looking for".

5.2.3 Bad-Instances

To identify *bad* instances, the participant must have some intuitive sense of what constitutes a *good* instance. To avoid the confound of training (which some participants may do only half-heartedly), we picked two situations that users are likely to be able to implicitly judge: the game Tic-Tac-Toe and a human face (Figure 1 (B), *excluding* the icons (C), which we felt would introduce a confound). For each scenario, we constructed a valid and invalid instance and visualized them using the default-graph and `CnD`. The Tic-Tac-Toe instances are shown in Figure 15, while the face instances (similar to Figure 1) are in Supplement Figure 10.

Out of n = 40 participants, half of them saw `CnD` diagrams for Tic-Tac-Toe and default-graph diagrams for the Face scenario, while the other half saw the reverse. For each scenario, participants were first shown a diagram of a good instance, asked to judge its validity, and then asked a follow-up question about the scenario that required them to parse the diagram's structure. This helped build familiarity with the model, scenario, and diagramming style.

Table 2 Scenarios used to study the understanding of bad-instances.

Scenario	Good Instance	Bad Instance
Tic-Tac-Toe	3x3 grid of Xs and Os representing a Tic-Tac-Toe board (**ttt**).	9 node graph marked with Xs and Os that do not form a grid (**ttt-inv**).
Face	Facial features arranged to match a human face (**face**).	Facial features arranged to align one eyebrow with the eyes (**face-inv**).

Participants were then shown a diagram of a bad-instance, and asked to judge its validity. (To be clear, participants did not *know* they were being shown instances in this order: they were simply passing judgment on two diagrams. But we showed the valid instance first to avoid confusing them.)

We divide responses into two groups:

- Validity judgments: The participant asserted that the bad-instance diagram was either valid or invalid. Participants who said it was invalid were asked to explain why, while those who asserted it was valid were asked the same follow-up question as before.
- Uncertain responses: The participant was unsure about the diagram's validity. These participants were asked why they were uncertain.

Uncertain Responses. It is tricky to interpret uncertainty. If a user is spot-checking a spec, uncertainty may arouse their suspicions, leading them to investigate further. On the other hand, if a user is browsing a spec, they may simply move on to the next instance. However, we did not examine this in depth because relatively few participants expressed uncertainty about validity. Only 5 participants (12.5 %, mean time = 37.84s) were unsure about the validity of `CnD` diagrams, while 3 participants (7.5 %, mean time = 29.52s) were not sure about the validity of default-graphs.

Validity Judgments. Participants were significantly more likely to identify bad-instances and correctly explain *why* they were bad when shown `CnD` diagrams than when shown the default-graphs (71.43 % vs 43.24 %, $p = 0.03$, $\chi^2 = 4.73$). Participants also made these validity judgments faster with `CnD` (mean of 58.06s vs. 69.82s), but this difference was not statistically significant ($p = 0.37$, $U = 568.00$).

5.2.4 Threats to Validity

Several factors may limit the generalizability and interpretation of our findings. While study participants had prior programming experience, this does not imply familiarity with formal methods, Alloy, or instance visualization. Effects on understanding could differ for users with more experience in these areas [24]. We believe, however, that this wide pool of participants might help indicate `CnD`'s utility across several kinds of programmers.

While we attempted to control for domain expertise by selecting scenarios that were either novel (Sections 5.2.1 and 5.2.2) or universally familiar (Section 5.2.3), different kinds of expertise could affect understanding. For instance, the ability to interpret a diagram might be different if the interpreter is also the author of the spec.

The relatively simple and well-understood nature of study scenarios might also limit how well our results generalize to "real world" formal methods scenarios. A bad instance, for example, might be less salient when dealing with more complex or less familiar domain.

Finally, as with any online study, there are inherent threats related to participant engagement and motivation, which could influence the outcomes. We believe that these limitations do not invalidate our findings, but they do warrant caution in interpreting the results as directly applicable to experienced Alloy users in real-world settings.

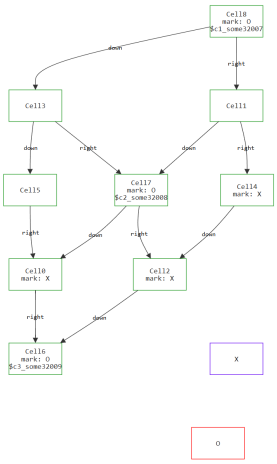
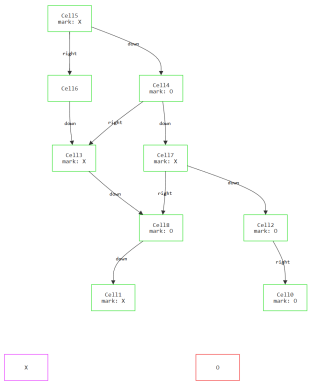
(b) `ttt-inv` `CnD` bad-instance.



(c) default-graph good-instance.



(d) default-graph bad-instance.

Figure 15 Good and bad Tic-Tac-Toe instances from the Q3 bad-instance study (Section 5.2.3).

5.3 Performance

The Cassowary solver used by `CnD` to determine constraint satisfaction is guaranteed to find a solution if one exists [1]. This means that for any set of constraints that admit a valid visualization, `CnD` will always produce a solution. To assess performance, we measured the average time (over 50 runs) taken to generate diagrams for all 20 scenarios referenced in this paper and supplementary material. All measurements were performed on a 2.30 GHz processor (AMD Ryzen 7) with 16GB memory. With the exception of `chord`, `face`, and `face-inv`, which took 0.98s, 1.03s, and 1.06s, all the others took half a second or less. All times are within range for interactive use. Constraint solving took under 50ms in each case; the rest of the time was spent on graph layout. Supplement Section 4 presents full numbers.

6 Related Work

CnD sits between default visualizations, which lack domain-specific semantics, and programmatic tools, which require users to define every aspect of the diagram from scratch:

1. Generic visualizers support all instances (Section 6.1). While they are flexible and broadly applicable, their lack of domain-specific insight can lead to confusing visualizations (Section 3.1).
2. Drawing and diagramming tools offer users fine-grained control over visualizations, enabling them to craft detailed domain-specific diagrams (Section 6.2). This control demands significant effort. Users have to manage the nuts-and-bolts of diagram creation, dealing not only with domain-level constructs, but also actual "drawing" primitives (e.g., lines, shapes, points).

6.1 Default-graph Visualizers

The Alloy Visualizer [16] is the default visualizer for Alloy instances. It generates directed graph visualizations of the spec instance, with nodes representing atoms and edges representing relations between them. Users are provided a range of theming options, such as being able to change the color or shape of graph nodes or hide nodes via projection. When Alloy's magic-layout feature [40] is enabled, it can even adjust its theming and layout heuristically. Users, nevertheless, struggle to make sense of these as specs grow in size and complexity [24].

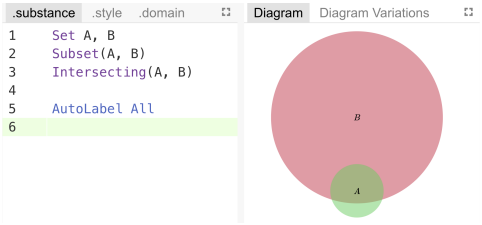
Sterling [11] is a web-based variant of the Alloy Visualizer that is designed to make large instances more comprehensible. Nodes and edges are laid out hierarchically, in an effort to reduce cognitive load, and layouts are consistent across instances, making the differences between them more salient.

We group both these tools together as default-graphs – generic visualizers that do not encode any domain-specific knowledge about the spec being visualized. Although both Alloy and Sterling provide numerous theming options, users cannot exercise control over *layout* decisions. On the other hand, the simple node-edge representation makes clear how domain constructs map to visual elements (*representation salience*), preserves domain terminology (*vocabulary correspondence*), and remains robust to bad-instances.

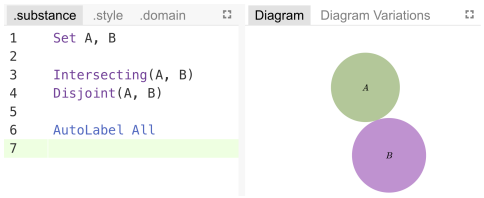
Of the prior work on Alloy visualization, CnD is most related to Couto et al. [6], which proposes *layout managers* for Alloy. For example, one might say that parking spaces should be arranged in a linear order with corresponding cars above. This work covers a larger set of primitives than CnD, such as grid and tree layouts. However, orientation appears to be defined by a single relation for each sig, which prevents expressing, e.g., the bidirectional layout of Figure 9. It is also unclear how layout managers compose (Figure 1) and how conflicts (Section 3.2) would be resolved. These works are thus complementary, with Couto et al. focused on expressive breadth, and CnD on composition and bad-instance discovery.

6.2 Drawing and Diagramming Tools

Sterling-with-D3. In addition to its default layout, Sterling also allows users to define custom visualizations using the D3 visualization library [3]. D3 is a powerful, expressive JavaScript library that gives users a great deal of control over the appearance of their diagrams. This enables diagrams that use a wide range of domain-specific visual encodings to represent relationships between entities. This complexity, however, comes at a cost. We observe barriers to adoption of D3 in Section 2.4.



(a) Penrose diagram of a bad-instance. Set A is a subset of set B in the spec but not in the visualization because the style file assumes that intersecting sets cannot subsume one another.



(b) Penrose diagram of a nonsensical instance in which sets A and B are declared to be intersecting and disjoint. This produces output with no indication of an error.

Figure 16 Two misleading Penrose diagrams.

Penrose. Penrose [51] is a domain-specific language designed to build diagrams of mathematical objects. The language's design is informed by both Gestalt principles (Section 2.1.1) and the diagramming tool requirements described by Ma'ayan et al. [22].

Penrose introduces a structured approach to the diagramming process by requiring users to separate the content of their diagram from how it is drawn. Diagrams, therefore, are constructed as three sub-programs: domain, substance, and style. The domain specifies the rules of the mathematical object being diagrammed, the substance specifies the instance of the object being visualized, and the style specifies how the object should be visualized. This separation of concerns makes Penrose a very powerful diagramming language, with the ability to generate diagrams across a wide range of domains.

Penrose substances and domains can be thought of as analogous to specs in formal modeling languages. A Penrose domain is similar to an Alloy spec, while a Penrose substance corresponds to an instance of that spec. In contrast, "style files" are more akin to programs. Users must describe how diagram elements should be constructed from rendering primitives (e.g., lines, shapes, points) before they can write higher-level constraints on how these elements should be laid out. Given the choice of rendering primitives, a user may even have to specify the order in which higher-level constraints are applied.

This represents a heavy up-front cost. A user must have already built the diagram from the ground up before they can begin to add layout constraints relevant to their domain.

Penrose's heavy up-front cost disincentivizes its use as an exploratory tool. The Penrose directed graphs demo,[4] for instance, involves nearly 150 lines of style code, including 13 constraints, 4 constraint application phases, and complex visualization calculations (e.g., for the angle of incidence of arrowheads on nodes). Much of this would have to be re-written if the shape of nodes were to change from circles to, say, squares.

After spending significant time on the nuts-and-bolts of rendering, a Penrose user might plausibly still find themselves looking at a misleading visualization for one of two reasons:

1. Since users have to build visualizations from scratch, Penrose diagrams may be brittle to bad-instances (Section 4). We show an example of this in Figure 16a, based on the Penrose Euler Diagrams demo.[5]
2. Penrose's numerical optimization problem is designed to always try to find a solution. This means that the system can, misleadingly, generate diagrams even when some user-specified constraints are not satisfied (Figure 16b).

[4] https://github.com/penrose/penrose/tree/main/packages/examples/src/box-arrow-diagram
[5] https://penrose.cs.cmu.edu/try/?examples=set-theory-domain%2Ftree-euler

BlueFish. Bluefish [37] is a declarative diagramming framework inspired by the principles of component-based UI frameworks. The core Bluefish primitive is the *relation*, which is used to capture semantic associations between diagram elements. Bluefish is particularly well suited to diagramming because these relations are composable and extensible. For example, relations are a natural way to define a diagram where elements overlap with one another.

However, Bluefish relations are defined in terms of concrete diagram elements, rather than abstracting over their types. As a result, an author who wishes to *dynamically* populate relations must fall back on Bluefish's host language (JavaScript). This is especially pertinent in the context of model-finding tools, like Alloy and Forge, where the exact elements appearing in an instance (or bad-instance) are not known in advance, and where the author may be unfamiliar with JavaScript.

6.3 Diagramming for Formal Methods

We note that multiple other formal methods tools also provide some form of diagramming. While in some cases very powerful, we are not aware of any of them providing *lightweight* diagramming in the manner of `CnD`.

Pro B. The Pro B [21] suite provides multiple tools (e.g., BMotionWeb [19] and VisB [47]) for visualizing traces. Moreover the Alloy2B [18] project can translate a rich subset of Alloy to B, meaning that Pro B can be used for some Alloy visualizations. For example, BMotionWeb [19] enables interactive, domain-specific visualizations. Creating these visualizations requires some knowledge of web programming. In VisB [47], users modify attributes of a base SVG image by linking elements of the image to aspects of the underlying spec.

Lean. The Lean [27] proof assistant provides domain-specific visualizations for structures like graphs, trees, etc. [25, 31] and for proofs as well [50]. Creating new visualizations with these libraries requires either familiarity with JavaScript (as Sterling does) or with a diagramming tool such as Penrose (Section 6.2).

GUPU. GUPU [33] is a pedagogic tool for visualizing Prolog substitution via domain-specific *viewers*. Students can use these graphical tools alongside tailored feedback and testing capabilities to better understand Prolog solutions. GUPU's viewers are written in Prolog [34], and are capable of generating sophisticated diagrams. Unlike `CnD` specs, however, GUPU viewers are heavyweight. Authors must invest significant time to get started, specifying each diagram construct, the minutiae of layout, and reconstructing the relationships between diagram elements. This is a significant barrier to entry: custom viewers presented by the GUPU authors [34] are Prolog programs that are much more complex than the Prolog programs they visualize.

6.4 Layout Tools

`CnD` builds heavily on two libraries for layout:

- WebCola [8] is a JavaScript library designed to support constraint-based graph layout [9]. WebCola constraints are specified in terms of a graph's nodes, and can be used to control node alignment, separation, and grouping. These constraints, however, are always "soft". This means that WebCola will always generate a layout, even if the constraints are not satisfied. Nevertheless, WebCola is still useful for layout, so `CnD` uses WebCola *after* constraints are deemed consistent and satisfiable (see Section 3.2).

- DAGRE is a JavaScript library for generating directed graph layouts, organizing nodes into hierarchical layers to minimize edge crossings and improve readability [36]. While DAGRE allows users to exercise some control over graph layout (e.g., specifying the direction of graph flow and node separation), users are unable to control the layout of individual nodes or edges. DAGRE's focus on hierarchical layout means that it is not well suited to more general graph layouts (e.g., cyclic graphs). Taking inspiration from Sterling, `CnD` uses DAGRE if no layout constraints are specified.

7 Limitations

Since `CnD` acts as a refinement on default-graphs, it inherits many of the same limitations. For instance, layout constraints may not be applicable to non-functional, non-hierarchical relations. Consider the example of an undirected tree, where each edge between nodes takes the form of a symmetric relation (Figure 9). Any orientation constraint on symmetric relations is necessarily inconsistent, so `CnD` cannot enforce a layout based on tree edges.

Furthermore, `CnD` constraints cannot add *new* information not reflected in the default-graph (though pictorial directives can). The instance in Figure 9 does not contain any information on which node is the parent of another. Thus, `CnD` alone cannot dictate which node is visualized as the root of the tree. Doing so without building a custom visualization requires somehow indicating the root the tree by, for instance, a field or sig in the spec.

A silver lining here, however, is that the worst-case scenario for `CnD` is the default-graph. As we have shown in Section 3.5, even in the absence of any `CnD` primitives, its output likely leads to less cluttered, more informative diagrams than the default-graph. Thus, `CnD` diagrams should not be less useful than default-graphs.

8 Discussion

Once we strip away the finery, the effectiveness of many custom visualizations boils down to a small number of key spatial relationships. We found that these relationships can be captured by a small set of primitives, which we encoded into a lightweight, declarative language. We discuss some of the lessons we have learned from this work below.

"Useful but not Pretty" diagrams. While many visualization tools and frameworks focus on drawing, with an emphasis on high visual quality, much of the value of a diagram comes from its ability to preserve key semantic relationships. Cope-and-Drag diagrams are often less visually appealing than those generated by D3 or Penrose, but help effectively communicate the model's structure while avoiding the pitfalls of focusing too much on aesthetic concerns.

Diagramming by Refinement: Specifications versus Programs. There is a fundamental divide between the practices of writing programs and writing specs. In personal communication, Daniel N. Jackson (the lead architect of Alloy) once explained to the last author the difference between a program and a spec: the empty program exhibits no behaviors, while the empty spec admits all behaviors. Roughly speaking, growing a program typically leads to additional behaviors, whereas growing a spec (by writing constraints) typically leads to fewer behaviors.

We believe a similar divide applies to diagramming. The Alloy Visualizer behaves like a spec: the default visualizer shows everything. As this paper has noted, this genericity and domain-independence causes problems (Section 2.2) but also has virtues (Section 4). At

the other extreme are systems like D3. By providing full control, they can address some of the weaknesses we have noted (Sections 6.1 and 7). However, the user gets nothing for free: every piece of output requires programmer effort. That puts them on the program end of the program–spec split. Systems like Penrose also fall at this end, even though they provide more structure to the program and thus enable some separation of concerns.

In this typology, `CnD` is "spec," not "program." It consciously alters the default-graph output, with the empty `CnD` program leaving the output unchanged. Adding constraints and directives shapes and sometimes limits the amount of output and the number of specs or instances that can be displayed. Thinking of diagramming as spatial refinement also provides design insight, both into where a `CnD`-like spec can live (Section 3.4) and how errors can be handled by analogy to types (Section 3.2).

Floors and Ceilings: The Value of Lightweightness. Another useful typology is that introduced by the Scratch programming language [23], of *floors* and *ceilings*. Scratch presents itself as having a low floor and high ceiling: it's very easy to start programming but there is little limit to how sophisticated a program one can write. Without dwelling on Scratch's claims, we can view the systems we have discussed through the same lens. Default-graphs have the lowest floor of all – one needs to do nothing to obtain output – but also have a very low ceiling. Systems like D3 and Penrose have an arbitrarily high ceiling, but also an elevated floor (which in D3 is known to cause difficulties for some users; we are not aware of much evidence either way about Penrose). We would classify `CnD` as having the lowest of floors (since the program can be empty, still producing default-graph output), but also a moderate ceiling: it does some things very well, but other things (Section 7) poorly relative to a custom visualization.

Showing Erroneous Output. In Section 3.2 we discuss how `CnD` handles errors. In particular, in both cases, it refuses to produce a diagram. This avoids creating output that might mislead the user. However, it is unclear that this option is ideal. The entire premise of this paper is that seeing visual output is useful for knowledge discovery, including for spotting problems. Similarly, there are situations where producing "bad" output can quickly help a user spot why a bug in the *`CnD` program* (or, more subtly, its relationship to the spec). Providing no output at all cuts off that avenue.

For this reason, we believe it would be worthwhile to investigate a mode where we produce visual output even in the case of errors, but make salient which elements should have prevented any output from occurring. We believe there are important algorithmic, cognitive, and presentational considerations. Algorithmically, we have constraints that cannot be satisfied; we have to somehow identify constraints to break to even generate output, and then label which parts of the output are invalid. Cognitively, there are surely factors that influence which constraints to choose (which may not always be the "smallest"). Presentationally, we have to both make salient that the user is viewing an invalid instance and highlight which parts of are invalid.

Accessibility for the Visually-Impaired. Like the vast majority of data-visualization tools, the Alloy Visualizer relies primarily on modalities that are inaccessible to visually-impaired users [13]. `CnD` does not reduce the accessibility of the Alloy Visualizer. However, the encoding of essential spatial relationships in `CnD` specifications presents an opportunity to improve how visually-impaired users are able to interact with default output. In particular, the `CnD` constraints may lead to improved output: e.g., exploiting spatial audio effects for sonification [4, 35, 52].

Conclusion. `CnD` is not meant to be a last word in the diagramming conversation, but rather an interesting point in the design space. It is unclear how to make the ceiling for `CnD` much higher, at least not without "lifting" the floor. This is very difficult in the current design (which consciously modifies default-graph output) and may cause problems such as masking bad-instances. Instead, we believe there is value to having other languages that can provide other floor–ceiling ranges.

Abstract

As Python is increasingly being adopted for large and complex programs, the importance of static analysis for Python (such as type inference) grows. Unfortunately, static analysis for Python remains a challenging task due to its dynamic language features and its abundant external libraries. To help fill this gap, this paper presents PoTo, an Andersen-style context-insensitive and flow-insensitive points-to analysis for Python. PoTo addresses Python-specific challenges and works for large programs via a novel hybrid evaluation, integrating traditional static points-to analysis with concrete evaluation in the Python interpreter for external library calls. We evaluate the analysis with two clients: type inference and call graph construction. This paper presents PoTo+, a static type inference for Python built on PoTo. We evaluate PoTo+ and compare it to two state-of-the-art Python type inference techniques: (1) the static rule-based Pytype and (2) the deep-learning based DLInfer. Our results show that PoTo+ outperforms both Pytype and DLInfer on existing Python packages. This paper also presents PoToCG, a call-graph construction analysis for Python built on PoTo. We compare PoToCG to PyCG, the state of the art for this problem, and show that PoTo produces more complete and more precise call graphs.

1 Introduction

Points-to analysis is a fundamental static analysis that determines what objects a reference variable may point to. It has a wide variety of applications (aka. *client* analyses), including call graph construction, type inference, debugging, and security vulnerability detection. Essentially all interesting questions one could ask about a program require some form of points-to information and points-to analysis has been studied extensively in the context of mainstream languages such as C, C++, Java, and JavaScript. Surprisingly, points-to analysis for Python has received less attention, despite Python's popularity.

This paper presents PoTo, an Andersen-like point-to analysis for Python. Andersen's analysis [2] is a classical flow-insensitive, context-insensitive, and inclusion-constraint-based analysis. It computes a points-to graph Pt where the nodes are reference variables and heap objects, and the edges represent points-to relations. For example, an edge $x \rightarrow o$ represents that x points to heap object o (i.e., reference x stores the address of o), and $o_1 \xrightarrow{f} o_2$ represents that field f of o_1 points to o_2.

While PoTo leverages well-known techniques, it also adapts to the unique challenges of Python: complex syntax and module system, dynamic semantics, and ubiquitous use of external libraries whose code is unavailable. First, our solution presents principled translation from Python source into the 3-address code intermediate representation demanded by points-to analysis. It specifies explicitly which Python features are handled precisely and faithfully to the feature semantics and which are handled approximately via a default interpretation; due to the complexity of Python, handling is unsound. Second, a novelty of PoTo is *hybridization*. We observe that many expressions, particularly ones stemming from external libraries and built-in functions, are available for *concrete evaluation* but are unavailable for standard *abstract evaluation* by virtue of their code being unavailable. Therefore we *concretely evaluate* the expressions and propagate the concrete objects through the points-to graph. This yields more information during inclusion constraint resolution and improves program coverage.

We evaluate PoTo on concrete type inference and call graph construction. We choose type inference because there has been significant interest in the problem in recent years. In addition to traditional approaches such as Pytype [12], there has been significant advance in deep-learning-based approaches, e.g., [1, 30, 46]. PoTo+ is the type inference client that largely draws types from PoTo's result: given $Pt(x)$ computed by the points-to analysis, the type of x is the union of the types of objects $o \in Pt(x)$. We compare PoTo+ against (1) Pytype [12], arguably the most advanced rule-based type inference tool, and (2) DLInfer [46], a state-of-the-art deep-learning-based tool, on a benchmark suite of Python packages ranging from 3,556 to 285,515 lines of code. Our results show that PoTo+ is comparable to Pytype and both techniques outperform DLInfer in terms of coverage (i.e., percentage of variables for which a type is reported) and correctness of inferred types. Furthermore, PoTo scales better than Pytype. Call graph construction is a classical client of points-to analysis. We build PoToCG based on PoTo and compare it to PyCG [34], the leading call graph construction analysis for Python. The results show that PoToCG constructs more complete and more precise call graphs compared to PyCG and it scales better.

The contributions of our work are as follows:

- PoTo, the first Andersen-style points-to analysis for Python.
- Hybridization weaving concrete and abstract evaluation.
- Evaluation on two clients of points-to analysis: type inference and call graph construction.

Ultimately, we hope that this work contributes to tools that make Python developers more productive and Python code more robust.

2 Problem Statement and Overview

The problem at hand is to design an Andersen-style points-to analysis for Python and *scale the analysis to large real-world Python packages*. Andersen's points-to analysis is a classical static analysis problem. It is a whole-program flow-insensitive and context-insensitive analysis that tracks flow of values via inclusion constraints. E.g., an assignment statement `x = y` triggers an inclusion constraint $Pt(\mathtt{y}) \subseteq Pt(\mathtt{x})$ indicating that the points-to set of `y` flows to the points-to set of `x`.

There are numerous challenges for Andersen's analysis and more generally static analysis for Python. First, Andersen's analysis is defined over a 3-address code intermediate representation (IR) serving as the foundation for the inclusion constraints. Translation from high-level C, C++, Java, and JavaScript code into 3-address code is well-studied and there are mature tools that provide the translation, notably LLVM [20], Soot [41], WALA [17], and Doop [36]. Surprisingly, static analysis for Python is largely ad-hoc AST-based analysis with each new work (e.g., [12, 46]) embedding its own interpretation of Python AST constructs and translation (if any) of those constructs into a 3-address code IR. Translating Python AST constructs into a 3-address code IR is challenging due to (1) Python's complex syntax and dynamic semantics and (2) Python's rich module system and scoping issues arising from it. Python allows for reflection and metaprogramming, subclassing conditioned on runtime values, complex With statements and context managers, and many other features [47] that are difficult or impossible to handle soundly in a static semantics. Even a construct such as Subscript, e.g., `a[index_expr]`, is non-trivial in the sense that its canonical interpretation as element access of a list-like structure is unsound (we choose the canonical interpretation for both Subscript and Attribute; a more faithful but also more complex interpretation would be to treat `__getitem__` and `__getattr__` as virtual calls). A principled analysis therefore must choose a subset of constructs to interpret precisely. We present a minimal syntax that specifies a subset of Python, and for that subset we present a precise interpretation that is faithful to the Python construct's semantics. All other Python AST constructs are abstracted by a fall-through structure *Other* and receive a default interpretation that can be both over-approximate and unsound. Going forward we sometimes refer to precisely-interpreted constructs as *interpreted* and to *Other* as *uninterpreted*. A key goal is to describe the points-to analysis as completely as possible, grounding the syntax and specifying interpretation semantics for both kinds of constructs, while at the same time abstracting away unnecessary detail. Section 3 specifies interpreted and uninterpreted constructs and their semantics, and makes it clear that we support memory-accesses and nested functions. It also explicitly lists the features under *Other*, e.g., generator expressions and With statements.

Another challenge is use of external libraries. Whole-program static analysis generally assumes that library code is available. However, Python has a particularly extensive ecosystem of open-source libraries; it is a dynamically-typed language where library interfaces usually lack type annotations; Python libraries and their interfaces are often rapidly evolving; and libraries are often at least partially implemented in C instead of Python. We address this with a novel hybridization technique that weaves concrete and abstract evaluation during 3-address code generation and constraint resolution.

While to the best of our knowledge we are the first to present a points-to analysis for Python, the problem has been studied extensively in mainstream languages, notably C, C++, Java, and JavaScript. (We detail related work in Section 6.) JavaScript is a dynamically typed language, as is Python. However, JavaScript poses unique challenges and program analysis aims to address these challenges: event-driven nature of applications, interaction with the DOM, runtime construction of object property strings, and runtime creation and deletion of object properties. None of these is a significant issue for Python, which increasingly is a general-purpose language used to build libraries and applications similarly to Java. We therefore model Andersen's analysis after Java's analysis, extracting and analyzing a Java-like subset of Python. Python presents new challenges though, including lack of a 3-address code IR, missing external libraries, and first-class functions and classes.

Consider the example in Figure 1, adapted from DLInfer, a recent paper on neural type inference for Python. Our analysis has two core phases (PoTo), followed by a client phase:

```python
import re

def url_regex():
  regex_cache = None
  if regex_cache is None:
    regex_cache = re.compile(r"p"
        )
  return regex_cache

def str_validator(value):
  if isinstance(value,str):
    return value.value
  else:
    return value

def validate(value):
  url = str_validator(value)
  m = url_regex().match(url)
  if m.end() != len(url):
    raise Exception(m.end())

def main():
  validate("p abcd")
```

(a) Python source.

```python
import re # External import

def url_regex():
  regex_cache = None
  regex_cache=(const,<class 're.Pattern'>,...)
  url_regex_ret = regex_cache

def str_validator(value):
  str_validator_ret = value.value
  str_validator_ret = value

def validate(value):
  url = str_validator(value)
  t1 = url_regex()
  t2 = t1.match
  m = t2(url)
  t3 = m.end
  t4 = t3()
  t5 = len(url)
  t6 = (const,<class 'Exception'>,...)
  t7 = m.end
  t8 = t7()
  t9 = t8(t7)
```

(b) 3-address code for (a), excluding `main`.

Figure 1 Illustrating example, adapted from DLInfer [46].

1. $x = \text{object}$ *new assignment*
2. $x = y$ *copy propagation*
3. $x.f = y$ *field write*
4. $x = y.f$ *field read*
5. $x = y(z)$ *closure call*

Figure 2 3-address code statements.

Phase 1: Python source ⟶ 3-address code
Phase 2: 3-address code ⟶ Points-to graph
Phase 3 (client): Points-to graph ⟶ Concrete type inference or call graph

Phase 1 takes as input Python source code and produces 3-address code; this phase works at the granularity of a function. Phase 2 processes the 3-address statements as inclusion constraints computing the points-to graph. The two phases are intertwined – roughly, the analysis starts at the main function and immediately invokes Phase 1 on main generating 3-address code for main; it then invokes Phase 2 to solve the 3-address code for main. As new functions become reachable, the analysis invokes 3-address code generation, then it proceeds to solve the constraints until the points-to graph reaches a fixpoint. As expected, one can implement many client analyses on top of the points-to results. Phase 3 focuses on concrete (i.e., non-polymorphic) type inference and call graphs as client analyses.

The first phase does principled translation of Python AST constructs into the standard 3-address statements shown in Figure 2. For example, the Python source in Figure 1(a) Line 17 translates into the 3-address sequence of statements in Figure 1(b) Lines 14–16. A

novelty in our treatment is the weaving of concrete evaluation into 3-address code translation and later constraint resolution. During translation, the analysis concretely evaluates every expression in its enclosing import environment. If evaluation succeeds, translation returns the resulting constant; otherwise, it proceeds recursively and returns the corresponding 3-address code statements. For example, in Figure 1(a) Line 6, the right-hand-side evaluates into a concrete object: `(const,<class 're.Pattern'>,...)` in Figure 1(b) Line 5 (we write a concrete object as a triple of `const`, the object type, and its value, with the value typically elided). As is standard for flow-insensitive analysis, the translation ignores control flow and basic blocks. Each function in Figure 1(b) is a straight-line sequence of 3-address statements. Suffix `_ret` indicates the function's return value (e.g., `str_validator_ret`).

The second phase of the analysis solves the 3-address statements as inclusion constraints, incorporating (1) class and function objects as first-class values, and (2) concrete evaluation. The analysis maintains *abstract objects* (constructed from code in the package under analysis) and *concrete objects* (constructed from concrete evaluation). Abstract objects, in turn, fall into three categories: *meta-class* objects, *meta-func* objects (more precisely closure objects), and *data* objects. The analysis maintains an abstract reference environment, which is the package-under-analysis environment, and uses it to resolve names defined in the package.

When processing a call or a field access statement, the analysis retrieves each object in the points-to set of the receiver variable. Roughly speaking, if the function object at the call is an abstract one, the analysis proceeds with abstract evaluation. If it is a concrete one, it attempts concrete evaluation. For example, in `url = str_validator(value)`, the analysis examines the points-to set of `str_validator` and retrieves the abstract function object representing the `str_validator` function. This triggers abstract evaluation and (standard) addition of the points-to set of `str_validator_ret` (the special return variable) to the points-to set of the left-hand-side variable `url`. Eventually, the points-to set of `url` becomes {`(const, <class 'str'>, 'p abcd')`}. Concrete evaluation of `t2 = t1.match` returns the concrete closure object corresponding to the match function, and finally concrete evaluation of `m = t2(url)` returns a concrete `re.Match` object. The hybrid analysis infers concrete types for identifiers `url` and `m`, respectively `<class 'str'>` and `<class 're.Match'>`, while Pytype reports only the fall-through type Any for both.

3 Syntax and Semantics

Recent work defines syntax for a subset of Python and a corresponding interpretation semantics for the purpose of weakest precondition inference [32]. A notable idea in this work is the separation of Python constructs into interpreted and uninterpreted ones. In this paper, we follow the idea of separating constructs into interpreted and *Other* but differ in important ways as our goal is interprocedural flow- and context-insensitive points-to analysis rather than weakest precondition inference. Unlike [32], we track object creation and flow of values and construct a call graph on the fly. Flow-insensitive points-to analysis demands a different set of interpreted constructs and a different interpretation.

Section 3.1 defines the syntax for the purposes of flow-insensitive points-to analysis, Section 3.2 defines the interpretation that generates 3-address code, and Section 3.3 presents Andersen-style constraint resolution, highlighting Python-specific semantics.

3.1 A Minimal Python Syntax

Figure 3 specifies the syntax which grounds the analysis. An expression e can be a constant c (`42` or `"foo"`), a variable (`x`), an attribute access (`x.foo`), a subscript access (`x["bar"]`), a list, a tuple, a dictionary, a list comprehension (`[2*x for x in range(10)]`), a dictionary

e ::= $c \mid x \mid e.x \mid e[e] \mid e(e,...,e)$	const | Name | Attribute | Subscript | Call
$\mid [e,...,e] \mid \{e\text{: }e,...,e\text{: }e\} \mid (e,...,e)$	List | Dictionary | Tuple
$\mid [e \text{ for } x,...,x \text{ in } e \text{ if } e]$	ListComp
$\mid \{e\text{:}e \text{ for } x,...,x \text{ in } e \text{ if } e\}$	DictComp
$\mid e \ op \ e \mid e \ cop \ e$	BinOp | Compare
$\mid Other\ (e,...,e)$	*All other Python AST expressions*
s ::= pass $\mid x = e \mid e.x = e \mid e[e] = e$	Pass | Assign
$\mid s \ ; \ s \mid$ for e in e: s	Suite | For
$\mid$ def $f(x,...,x)$: s ; return e	FunctionDef | Return
$\mid$ class $C(e,...,e)$: s	ClassDef
$\mid Other\ (s,...,s)$	*All other Python AST statements*
i ::= import p (as x)? | from p import x (as x)?	Import | ImportFrom
$\mid i \ ; \ i$	
m::= $i \ ; \ s$	Module

Figure 3 Syntax of a subset of Python. The non-terminal names on the right are based on the official Python abstract syntax tree (AST); e.g., the AST node for a statement sequence is Suite.

comprehension (`{x:f(x)for x in range(x)}`), a binary operation or a compare operation. All other Python expressions are under *Other* $(e_1,...,e_n)$ and receive the default interpretation; their AST nodes are BoolOp, NamedExpr, UnaryOp, Lambda, IfExp, Set, SetComp, GeneratorExp, Await, Yield, YieldFrom, FormattedValue, JoinedStr, Starred, and Slice.

A statement s can be pass, the assignment of either a variable (`x = 42`), an attribute (`x.foo = 42`), or a subscript (`x["bar"] = 42`), a sequence, a loop, a function definition, or a class definition. All other Python statements are captured under *Other* $(s_1,...,s_n)$ and receive the default interpretation; their AST nodes are Delete, TypeAlias, AugAssign, AnnAssign, AsyncFor, While, If, With, AsyncWith, Match, Raise, Try, TryStar, Assert, Global, Nonlocal, Break, and Continue. This default interpretation is often all that is needed. For example, Break and Continue are irrelevant to flow-insensitive analysis. As another example, for If statements, the default interpretation descends into the AST node of the children and processes them. As illustrated in Figure 1, this is adequate for flow-insensitive analysis. To simplify the presentation, we leave out the syntax of complex left-hand-side expressions in assignments (e.g., `a, *(b, c)= (1, (2, 3), 4)`), variable-length arguments, and keywords arguments. We use deconstruct-and-bind preprocessing to reduce these into sequences of assignments as in Figure 3. For example, `a, *(b, c)= (1, (2, 3), 4)` reduces into a sequence including `a = 1`, `b = (2, 3)` and `c = 4`.

A module m starts with a sequence of import i, import p or from p import x, with an optional alias name (as x), followed by a statement. A package under analysis is a sequence of modules.

3.2 3-address Code Generation

3-address-code translation takes as input the Python source (i.e., AST) of a function and produces a sequence of 3-address-code statements of the form in Figure 2.

```
# Initialize Γ0:
Γ0 = [], Φ = {}
for ⟨module M: i; s⟩ in package under analysis
    for ⟨class C(...): ...⟩ in s: Γ0 ← [(M.C, t)] + Γ0, t is fresh
    for ⟨def f(...): ...⟩ in s: Γ0 ← [(M.f, t)] + Γ0, t is fresh
    # Imports from p import x' as x are implicit assignments
    for x = ... in s: Γ0 ← [(M.x, t)] + Γ0, t is fresh
# Next, compute class hierarchy H and MRO:
H ← C3(Γ0) # H maps (⟨class C(...): ...⟩, f) to ⟨def f(...): ...⟩
# Interpret main and add to worklist:
Φ[⟨def main(...): s⟩] ← I(s, [])
W ← {⟨def main(...): s⟩} # Entry point
# Interpret module initializers and add to worklist:
for ⟨module M: ...⟩ in package under analysis
    Φ[⟨def M.module_init(...): i; s⟩] ← I(i; s, [])
    W ← {⟨def M.module_init(...): i; s⟩} # Entry points
# Solve constraints in reachable functions:
while W ≠ ∅
   ⟨def f(...): ...⟩ ← remove function from W
    for c in Φ[⟨def f(...): ...⟩][1]: W ← W + c.solve()
```

Figure 4 Worklist algorithm.

3.2.1 Environment and Interpretation Functions

The analysis interprets expressions and statements in an *abstract* reference environment split into two components: Γ and Γ_0. Γ is a *local* reference environment associated to the enclosing function. It is a map of (id,t) tuples where id is a local and t is the *analysis variable* representing the local. Γ_0 is the *global* reference environment mapping identifiers for module-level constructs to analysis variables representing those constructs. In addition, there is an *external* environment, Γ_{ext}, necessary for concrete evaluation. We analyze imports and group them into two categories: (1) internal imports are relative imports (e.g., `from ..metrics import get_scorer`) and ones referencing the analysis package, and (2) the remaining external imports (e.g., `import re`). External imports comprise Γ_{ext}.

The interpretation of a statement $\mathcal{I}(s, \Gamma)$ returns a pair (Γ', S) where Γ' is the augmented local environment resulting from the interpretation of s into 3-address code, and S is *the sequence of 3-address statements* corresponding to s. E.g., $\mathcal{I}(\mathsf{x} = \mathsf{y.f.g}, [(\mathsf{y}, \mathsf{t1})])$ returns the augmented environment [(x,t2), (y,t1)] and the following sequence of 3-address statements: t4 = t1.f; t3 = t4.g; t2 = t3. Here t1 and t2 are the analysis variables associated with local variables y and x respectively (in code examples we sometimes ignore analysis variables and use the source-level identifier directly). We leave Γ_0 and Γ_{ext} implicit in the writeup as they are uniquely defined for each statement under interpretation.

The interpretation of an expression $\mathcal{I}(e, \Gamma)$ returns a pair (V, S) where V is *a set of analysis variables* and S is the sequence of 3-address statements corresponding to e. E.g., $\mathcal{I}(\mathsf{y.f.g}, [(\mathsf{y}, \mathsf{t1})])$ returns fresh variable t3 and the sequence of 3-address statements t4 = t1.f; t3 = t4.g.

Φ is the environment of interpreted functions: a mapping from a function definition (Python AST FunctionDefs in the implementation) to a pair (Γ, S), where Γ is the local reference environment resulting from the translation of the function definition and S is the sequence of 3-address statements corresponding to the function body.

The analysis uses the worklist algorithm in Figure 4.

3.2.2 Global Environment Initialization

The analysis first initializes a global environment Γ_0 that contains mappings for identifiers of module-level constructs, $M.f$ (functions), $M.C$ (classes), and $M.x$ (identifier definitions) to their corresponding analysis variables. The scope of these constructs spans the entire package, hence the analysis augments the environment and makes these constructs available during 3-address code generation. This is similar to the *let rec* construct in functional programming which extends the scope for let-bound identifiers across all right-hand-side expressions. Initialization does not interpret functions, classes and right-hand-side of assignments; these are interpreted during reachability analysis.

3.2.3 Class Hierarchy Analysis

Next, the analysis computes the class hierarchy H using the C3 linearization algorithm for method resolution with multiple inheritance [4]. H is a mapping from a pair of class definition $\langle$class C(...): ...$\rangle$ and function name f to the corresponding function definition $\langle$def f(...): ...$\rangle$ resulting from a lookup in the *Method Resolution Order* (MRO) of C. Additionally, the step creates a (meta-cls, $\langle$class C(...): ...$\rangle$) object for each module-level class definition and associates the corresponding analysis variable t to that object. In other words, this step creates an initial set of points-to edges which allows for data object creation during the second phase of the analysis.

3.2.4 Iteration

As it is customary for whole-program analysis, the analysis starts from a main function. It translates main and all module initializers into 3-address code (the calls to $\mathcal{I}(s, [])$) and adds them to the worklist. The analysis removes a function from the worklist and processes the 3-address statements c for that function. The call $c.solve()$ solves the semantic constraints associated to c which has side effects on the 3-address code environment Φ and points-to graph Pt. A call statement triggers interpretation and placement on the worklist of the callee function and it is an invariant that when a function is removed from the worklist, its three address code is available in Φ.

The call $c.solve()$ returns a minimal set of functions that are affected by solving constraint c. For example, if c is the 3-address code statement t1 = t2 and solving it changes the points-to graph of t1, *solve* returns the enclosing function of the statement. A change in the points-to graph due to t1.f = t2 returns all functions in Φ, as the effect of new objects added to Pt(o.f), where o is an object in the points-to set of t1, may propagate to arbitrary functions.

3.2.5 Interpretation of statements and expressions

The definition of the interpretation function is presented in Figures 5 and 6. Interpretation of statements is in the abstract while interpretation of expressions weaves concrete and abstract evaluation. Below we highlight the most interesting points.

3.2.5.1 Statements

Consider interpretation of assignment $x = e$. If the variable x appears in a module initializer, we retrieve the analysis variable from Γ_0 (imports also create implicit global assignments). Otherwise, we only augment the local environment with a fresh variable if the variable x is not in the current environment. We target flow-insensitive points-to analysis, and thus, a Python sequence `x = 1; x = "a"` gives rise to 3-address code sequence t1 = 1; t1 = "a" and fails to distinguish that `x` is an integer at the first assignment and a string at the second.

\end{aligned}
$$

Figure 6 From Python expressions and imports to 3-address-code. Given an environment Γ, the interpretation function for an expression $\mathcal{I}(e, \Gamma) = (V, S)$ returns a set of analysis variables V and the 3-address code S. M is the expression's enclosing module, and Γ_{ext} is its external environment. Γ_0 is the global environment.

The interpretation of a loop for x in e: s reduces to a sequence of assignment $x = e$ followed by s. The assignment binds identifier x before descending into the interpretation of s.

A function definition in a module initializer has an entry $M.f$ in Γ_0. Otherwise, i.e., if this function is nested into another function, we augment the local environment with f and return the augmented environment. Function definition gives rise to a "new" statement, assigning the abstract meta-func object to t. Class definitions have no effect during interpretation. Module-level class definitions are processed during class hierarchy analysis.

Note also that we ignore static reference environments for nested functions, which is unsound in general. A function value may flow to arbitrary points of the program and it is interpreted into 3-address code when it is called (detailed in calls in Section 3.3); however, interpretation happens in the empty environment rather than the actual static reference environment and references coming from enclosing scopes evaluate to empty sets.

For uninterpreted statements, the algorithm descends into each sub-statement and extracts the corresponding 3-address code. This does not "glue" components according to the statement's semantics. However, recursive descent processes all nested assignments and calls; it augments the environment and generates 3-address code that captures value flow.

3.2.5.2 Expressions

Recall that a key feature of our analysis is concrete evaluation and that concrete evaluation happens both during 3-address code generation and constraint resolution. We employ the following heuristic for 3-address code generation, as the rules for expression interpretation in Figure 6 detail. For simple expressions (i.e., variables), we first attempt resolution in the abstract environment: first Γ then Γ_0. If it fails, we attempt concrete evaluation. For all other expressions (i.e., complex expressions), we first attempt concrete evaluation in Γ_{ext}, and if it fails to produce a concrete object we proceed with interpretation in the abstract.

The interpretation of a variable (first rule in Figure 6) first searches the local environment Γ (i.e., the enclosing function), and then the global environment Γ_0 if the first lookup fails. If lookup in Γ_0 fails as well, it attempts concrete evaluation. If concrete evaluation succeeds and returns a concrete object, $\mathcal{I}(x, \Gamma)$ returns x and an object creation statement. The last clause aims at built-in functions, e.g., `len` and enables reporting of built-in callees. The reader may have noticed here that we reuse the original variable name as an analysis variable, but create a new concrete instance of the built-in function object. Thus, there are as many concrete instances representing `len` as there are (static) calls to `len` in the code. Our implementation does not optimize this case yet, but it is trivial to get rid of such redundant concrete objects.

For remaining expressions, including *Other*, the analysis first tries concrete evaluation, and if it succeeds, it returns the new analysis variable t along with the assignment of the concrete object to t. If an expression does not evaluate (which is the common case), interpretation continues recursively in the abstract environment. For example, `np.array(arg)` matches Call in Figure 6. Concrete evaluation fails with a NameError as `arg` is a local program variable; interpretation proceeds in the abstract. It recurses into Attribute `np.array` and this time it does evaluate to the numpy function. Interpretation of the call expression returns ({t1}, {t2 = (const, <... builtin ...>,...); t1 = t2(t3)}) where t3 is the analysis variable for `arg`.

Subscript expressions treat [] as a special field in the abstract, which is standard in points-to analysis. To interpret a list in the abstract, we create a new list object and generate subscript assignments to populate the list. Tuple, set, and dictionary are analogous.

For uninterpreted expressions we return the union resulting from the interpretation of each sub-expression when concrete evaluation fails.

3.2.5.3 Import

Finally, to interpret imports in module initializers (last rule of Figure 6), we first find the enclosing module M' of imported construct x', and then look up for the representative analysis variables t1 and t2 corresponding to the imported construct $M'.x'$ and the alias x in the current module M. Statement t2 = t1 propagates the value (e.g., a function definition, a class definition) from module M' to M. For example, consider statement `from cerberus.platform import _get_args as get_args` in module M. Lookup of `cerberus.platform._get_args` yields t1 which points to the function def of __get_args. Lookup of M.get_args yields t2 and t2 = t1 ensures the def propagates to t2 and references to get_args in M find that function def.

For simplicity, the rule treats x' as a module-level construct, however, it can be a module. E.g., `errors` in `from cerberus import errors` is a module and code can access module-level constructs as in `errors.DocumentErrorTree`. We handle this case in the attribute rule: if lookup of e in Γ during $\mathcal{I}(e, \Gamma)$ yields no result, the analysis maps $e.f$ to a module-level-construct identifier $M.C$, $M.f$ or $M.x$, and searches Γ_0 to retrieve the corresponding analysis variable (the step is not shown in the rule to avoid the complexity of lookup failure).

3.3 Constraint Resolution

As mentioned earlier, the analysis maintains abstract objects and concrete objects. Abstract objects are explicitly grouped into *data objects*, *function objects*, and *class object*:

(data, ⟨class C(...): ...⟩)	*an abstract data object*
(meta-func, ⟨def f(...): ...⟩)	*an abstract function object*
(meta-cls, ⟨class C(...): ...⟩)	*an abstract class object*
(const, ty, v)	*a concrete object*

The 3-address statements are as specified in Figure 2. These statements induce constraints that populate a points-to graph Pt. The nodes in the points-to graph are analysis variables as well as objects o of the above kinds. The edges represent the points-to relation. E.g., there could be an edge from variable t to an object o, and this is denoted as $\{o\} \subseteq Pt(t)$ or equivalently as $t \rightarrow o$. There could be a field edge indicating that field f of o_1 points to o_2 and this is denoted as $\{o_2\} \subseteq Pt(o_1.f)$ or equivalently as $o_1 \xrightarrow{f} o_2$.

The rules for new assignment, copy propagation and field write are largely standard (except for their returns) and we elide them from the presentation. We elaborate on the rules for field read $t_1 = t_2.f$ and function call $t_1 = t_2(t_3)$ as they illustrate Python-specific semantics and concrete evaluation.

3.3.1 Indirect read

The rule in Figure 7 examines each object in the points-to set of receiver variable t_2 and does case-by-case analysis on the object type. E.g., if it is an abstract data object of some user-defined class, the analysis searches the class hierarchy (MRO) to determine the function referenced by $o.f$, forms the closure by binding *self* to the receiver object o and adds the closure object to the points-to set of left-hand-side t_1. If the object is a concrete object, the analysis evaluates the field access returning a new concrete object and adding it to the points-to set of t_1. Here, and in Calls, we restrict the number of times a statement is evaluated successfully. The restriction, currently set to 2, is not only an optimization but also necessary for termination, otherwise the analysis would keep creating distinct concrete objects at the same statement during fixpoint iteration.

solve for $t_1 = t_2.f$ in $\langle$def f'(...): ...$\rangle$ with Γ_{ext} :
  for $o \in Pt(t_2)$
    case o **of**
      (data, $\langle$class C(...): ...$\rangle$) $\rightarrow$
        $\langle$def f(self, p): ...$\rangle \leftarrow H[(\langle$class C(...): ...$\rangle, f)]$
        $Pt(t_1) \leftarrow Pt(t_1) + \{$(meta-func, $\langle$def f(self, p): ...$\rangle)\}$
      (meta-cls, $\langle$class C(...): ...$\rangle$) $\rightarrow$
        $\langle$def f(self, p): ...$\rangle \leftarrow H[(\langle$class C(...): ...$\rangle, f)]$
        $Pt(t_1) \leftarrow Pt(t_1) + \{$(meta-func, $\langle$def f(self, p): ...$\rangle)\}$
      (const, ...) $\rightarrow Pt(t_1) \leftarrow Pt(t_1) + \{eval(o.f, \Gamma_{ext})\}$
    $Pt(t_1) \leftarrow Pt(t_1) + Pt(o.f)$ # *when f is an object field, add its points-to set*
  return $\{\langle$def f'(...): ...$\rangle\}$ if $Pt(t_1)$ changed else $\{\}$

Figure 7 Indirect read. Solving $t_1 = t_2.f$ in enclosing function $\langle$def f'(...): ...$\rangle$ with Γ_{ext}.

The last line returns the enclosing function f' to the worklist if there is a change to the points-to set of t_1, as the change may trigger changes to other points-to sets in f'.

3.3.2 Call

Figure 8 details the rule for calls. There are two cases at the top level, an abstract object or a concrete object as function value. For an abstract object, we do case-by-case analysis. If o is a data object, it queries the hierarchy to retrieve the corresponding ___call___ function – this is the function that is being called. If it is a meta class object, this leads to the retrieval of the constructor. If it is a meta function, there are two cases: a closure where self is already bound to a receiver, or the function is just a value with a null reference environment.

Once the analysis identifies the function to be called at this site, it checks if an interpretation of this function into 3-address code already exists. If it does not we interpret it. Notably, we interpret the AST of the function in the empty environment (i.e., only parameters are bound). This means that a first-class function does not carry its static reference environment and the analysis introduces unsoundness. While it is possible to extend the analysis with such bindings, this will complicate the code, while we believe in practice it will have limited impact (based on looking at Python code and our results). A notable departure from standard Java analysis is that there is no explicit new A() site. Different meta class objects may flow to receivers of calls accounting for data object creation (but the number of meta class objects is bounded and thus the number of data objects instantiated at the call is finite).

Once the callee function is interpreted, the analysis propagates points-to sets from actual arguments t_3 to formal parameters p and return values to the left-hand-side of the call t_1. In case of a concrete receiver, if the analysis finds concrete arguments for all parameters, it executes the function.

4 Results

We evaluate our Andersen-style points-to analysis, PoTo, on two clients: type inference (Section 4.1) and call graph construction (Section 4.2). However, points-to analysis has a wide variety of applications and we envision other clients as well. The analysis can be run on any Python package. It starts at a provided entry function and computes a points-to graph containing information on reachable variables and their inferred types. To thoroughly analyze a library package, a set of entry functions are needed. We follow DLInfer, a neural type inference for Python, and use the same 10 Python packages from their experiment available

solve for $t_1 = t_2(t_3)$ in $\langle$def f'(...): ...$\rangle$ with Γ_{ext} :

with DLInfer's artifact. The 10 packages range in size from 3,556 LOC to 285,515 LOC (see Table 1). These packages contain rich test cases which suit our need of diverse entry points. We use each function in a package's test directory as an entry point. For five of the packages (cerberus, mtgjson, pygal, sc2, and zfsp), we additionally create custom entry functions targeting remaining unreachable public functions. For the other five packages (anaconda, ansible, bokeh, invoke, and wemake_python_styleguide), we only use default test suites.

4.1 Type Inference

To target unreachable methods for the purposes of type inference, we enhance the analysis. We achieve this by performing a shallow analysis that collects built-in type information and type annotations from assignment and return statements. For example, consider an assignment with a built-in type: `rules = set(schema.get(field, ()))`. The shallow analysis infers that `rules` can be of type `set`. This has impact when the method is unreachable from PoTo's entry points, as it creates a key and infers a type for the `rules` local variable. The final results, called PoTo+, are stored as a dictionary of *keys* to their inferred types. A *key* is a tuple of (module name, function name, variable name), describing the variable and its

scoping information. Keys largely correspond to local variables (including arguments and returns) in a package and are an abstraction for flow-insensitive analysis, the target of our work. The remainder of this section uses the terms keys and variables interchangeably.

We compare the results of PoTo+ against four other type inference techniques. Three of these are based on the recent neural type inference work DLInfer [46]: DL-ST, DL-DY, DL-ML. We make use of the result files available with DLInfer's artifact [45]. DL-ST is their ground truth information, which is a combination of running the Pysonar2 static tool and extracting type information [42]. DL-DY is a set of dynamic type information obtained from executing the test suites. This dynamic set contains only variables whose type can be collected only this way, meaning that this is the set difference of the actual dynamic run and DL-ST set [46]. Lastly, DL-ML is the result of DLInfer's machine-learning approach. We aggregate each DLInfer result in the same way as our analysis, which is a dictionary of keys to their types. We choose DLInfer for several reasons: (1) DLInfer is recent work in a top conference, (2) it compares with several state-of-the-art deep-learning techniques: Type4Py [27], Typilus [1], PYInfer [9], and DeepTyper [15], (3) DLInfer infers types for local variables, not only parameters and returns, and (4) its artifact [45] includes full Python packages along with analysis results allowing for a comparison over the same code base.

In addition to DLInfer, we also compare our result to Pytype, a prominent static type checking and type inference tool [12]. To get type information for all variables, we instrument the package by inserting Pytype's command `reveal_type(var)` for each local variable at the end of a function, and run Pytype on each file in the package directory. The types are then collected and combined to be the inferred result of Pytype. This process takes time to complete but only needs to be done once. This is a departure from standard use of Pytype as baseline for type inference work, which uses Pytype's result on parameters and returns only (e.g. [29]); Pytype can infer types for local variables as well and we make use of this in our comparison.

Our evaluation considers 4 research questions:

RQ1: How high is the coverage of PoTo+ compared to other type inference techniques?
RQ2: To what extent are the types from PoTo+ equivalent to those from other techniques?
RQ3: If the types do not match those from other techniques, which one is correct?
RQ4: Does the time to run PoTo+ scale well and how does it compare to Pytype?

To answer RQ1, we measure the percentage of total keys in a package for which our analysis reports types against the percentage of total keys for which the four other type inference techniques report types (more detail on methodology in Section 4.1.1). Our analysis collects types for a *larger percentage of total keys* compared to the four other techniques. To answer RQ2, we compare our inferred types to those inferred by each of the four other techniques, measuring the equivalence in term of total match, partial match, and mismatch (more detail in Section 4.1.2). Our inferred types *largely match with Pytype's*. While there is some match with DLInfer, there is disagreement in many keys.

To answer RQ3, we inspect a sample of mismatches according to the result from RQ2 for each pair comparisons: PoTo+ vs. Pytype, PoTo+ vs. DL-*. We found that in the few cases where there is a mismatch with Pytype, Pytype is correct in all cases. A mismatch with DL-* is nearly always a correct result by PoTo but an incorrect result by DL-*. The conclusion from RQ1-RQ3 is that *traditional techniques outperform a state-of-the-art neural technique* for the task of type inference. Lastly, for RQ4, we compare the total time to run PoTo (with dozens of entry functions for the smaller packages and thousands for the larger ones) to the time to run Pytype to collect reveal-type information. On all but one package, ansible, PoTo outperforms Pytype significantly.

Table 1 Statistics for the dataset.

Package	Files		LOC		Keys
	Total	Test Dir	Total	Test Dir	
cerberus	45	32	6,694	3,011	966
mtgjson	54	2	6,912	58	1,378
pygal	78	24	13,780	3,208	2,439
sc2	69	6	11,205	603	5,970
zsfp	54	7	3,556	207	1,345
anaconda	370	9	90,207	587	21,183
ansible	1,445	961	285,515	174,296	22,346
bokeh	1,133	280	131,931	43,316	14,978
invoke	133	65	26,159	9,878	3,474
wemake	403	291	55,841	32,798	3,184

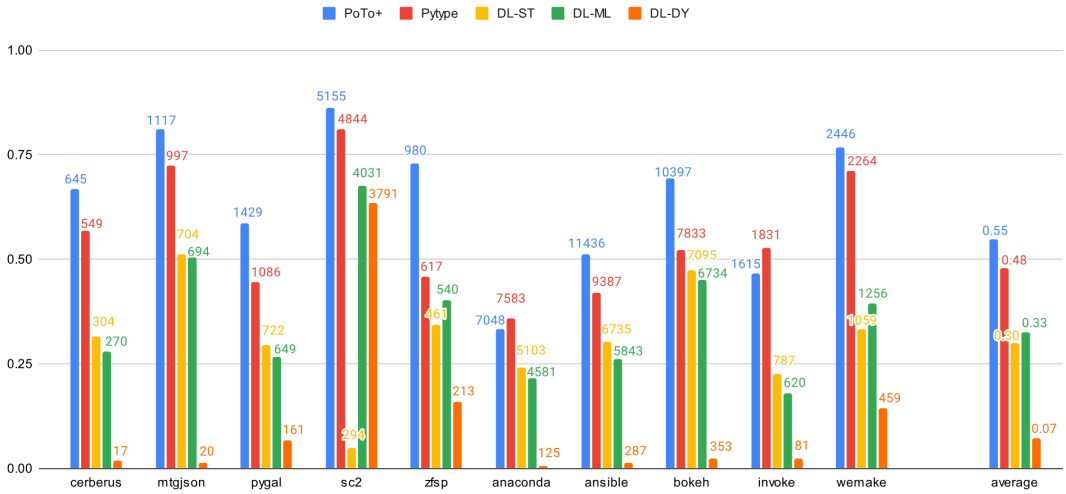

Figure 9 Coverage percentages of non-empty keys to total keys (RQ1).

4.1.1 Coverage (RQ1)

Table 1 shows the statistic of all 10 packages. We are interested in inferring types for the core package and exclude test files from our reports. The total keys include all variables, function arguments, and function return types. They serve as an upper limit of possible variables (or keys) for each package.

Figure 9 shows the percentages of non-empty keys to the total keys for each package. Non-empty keys are ones for which the analysis (ours or other techniques) gives type information; empty keys are variables in total keys for which the analysis gives no information. In the case of Pytype, a key is designated as empty if its inferred type is the trivial `Any` type. The numbers above each bar are the numbers of non-empty keys. For the five packages (cerberus, mtgjson, pygal, sc2, and zfsp) where we add custom entry functions, PoTo+ covers more non-empty keys than other techniques, followed closely by Pytype. For the remaining packages where we only use default test suites, we have slightly worse coverage than Pytype on anaconda and invoke, reflecting worse test coverage by the underlying test suites. PoTo+ still has the highest average coverage percentage.

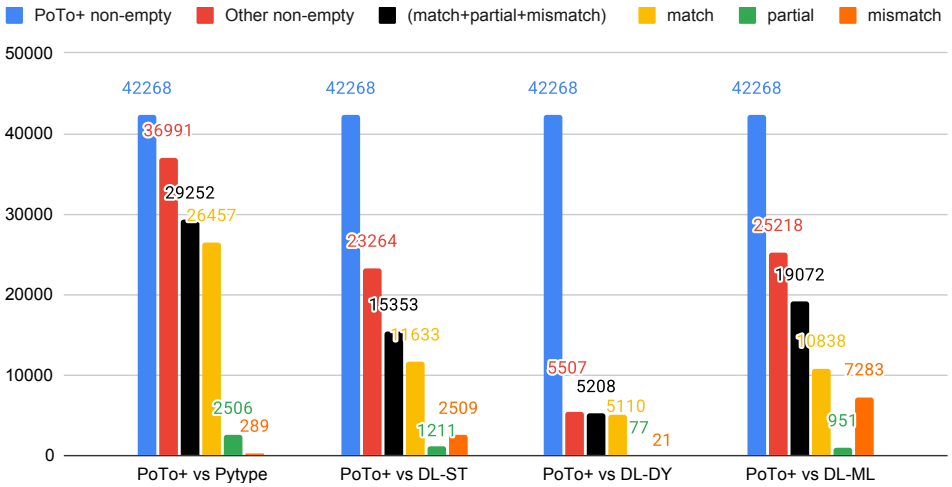

Figure 10 Equivalence comparison between PoTo+ and other type inference techniques (RQ2). Black bars (sums) show the number of keys for which both techniques report types. Numbers are summation of all 10 packages.

4.1.2 Equivalence (RQ2)

Next, we measure the similarity of inferred types. For each variable in a package, our analysis and the other type inference techniques can either have information on this variable, and the information is the set of its inferred types, or have no information, i.e., an empty set.

For built-in containers such as `dict`, `list`, `set`, and `tuple`, we compare only the top-level part and deem that they match if they are the same container types. The main reason for this shallow comparison is to facilitate processing and comparison as each type inference technique infers and reports types in different forms. For example, DLInfer reports only the type of a container, e.g., `dict`. Pytype reports parametric information, e.g., `Dict[str, int]`, but not always, while PoTo+'s inferred types come from abstract and concrete objects, e.g., `{'rename_handler': <class 'int'>}`. PoTo can collect parametric information, but it requires significant processing and raises issues on reporting types for polymorphic containers.

Matching is automatic but some comparisons require manual verification because of rendering of PoTo concrete objects. For example, PoTo+'s `1970-01-01` matches with DL-ST's `datetime.date` type. Another example is a match between PoTo+'s `<function <lambda> at 0x109297520>` and Pytype's `Callable[[Any],Any]`.

We are interested in 3 groups of equivalence: total match, partial match, and mismatch, where partial match is when the two sets of types have non-empty intersection and mismatch is an empty intersection. Figure 10 shows these as summation across the 10 Python packages. In addition, Figure 10 shows bars with the total number of non-empty keys by PoTo+ next to bars with the total number of non-empty keys by the other technique; for convenience it draws a bar that sums match, partial match and mismatch, i.e., the set of keys for which both techniques report a type. On all Python packages, PoTo+ shares the most non-empty keys with Pytype, and has high numbers of total matching. DL-ST and DL-ML have some matching and partial matching with our analysis, but also contain many keys that are mismatches. The discrepancy is discussed in Section 4.1.3. For the sc2 package, almost all common keys between PoTo+ and DL-ML are mismatches. The mismatches are due to simple assignments of class attributes in /sc2/ids/ directory, e.g. `NULL = 0`, `RADAR25 = 1`, `TAUNTB = 2`. Our analysis, Pytype, and DL-DY correctly infer the types as integer, but DL-ML labels all

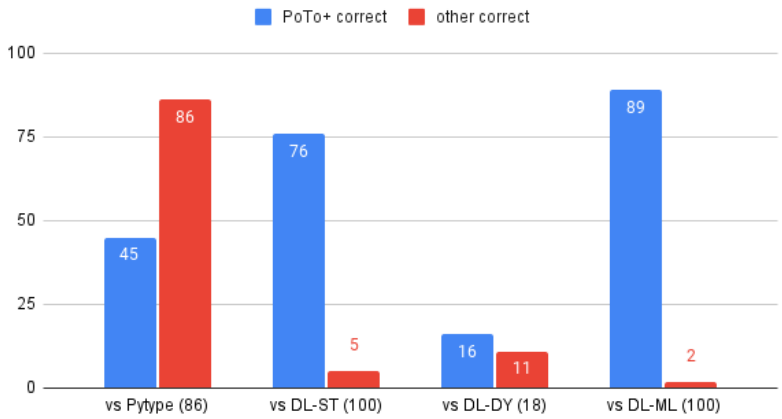

Figure 11 Correctness comparison between PoTo+ and other techniques (RQ3). Numbers in parentheses are # of samples. This figure zooms in on a sample of the mismatched keys from Figure 10; for Pytype there are 289 mismatched keys which is less than 1% of all variables.

of them as `num` which is incorrect as it is not a type. There are 3,791 such assignments out of 3,984 common keys between PoTo+ and DL-ML in the sc2 package. Lastly, DL-DY has low coverage of types information, and most of them are a total match with our analysis.

Figure 10 shows that PoTo+ reports a larger number of types compared to the other techniques; for example, for Pytype, there are 29,252 keys for which both report type information (the black bar) and there are 13,016 keys for which PoTo+ reports a type but Pytype does not. In contrast there are 7,739 keys for which Pytype reports a type but PoTo+ is empty. Appendix A.1 includes per benchmark versions of this figure.

4.1.3 Correctness (RQ3)

To carry out the comparison we manually examine a sample of 10 non-match keys for each package and each pair of comparisons, i.e., PoTo+ vs. Pytype, PoTo+ vs. DL-ST, PoTo+ vs. DL-DY, and PoTo+ vs. DL-ML. In cases where there are fewer than 10 non-match keys, we exhaustively examine all of them, (e.g., there are only 8 non-matches between PoTo+ and Pytype for pygal, so there are 8 instead of 10 keys for pygal). There are only 18 total non-matches keys for PoTo+ vs. DL-DY. For the remaining 3 techniques, the total is slightly under 300 samples. Results are shown in Figure 11.

4.1.3.1 PoTo+ vs. Pytype

Comparison with Pytype shows that a mismatch usually means that PoTo+ is incorrect while Pytype is correct. Of the 86 pairs we examined, PoTo+ is correct 45 times, while Pytype is correct 86 times, because Pytype handles a larger set of Python features precisely, while PoTo defaults to Other, thus polluting points-to sets. For example, PoTo does handle list and dictionary comprehensions precisely, but defaults to Other on set comprehensions. Consider the example: `rampPoints = {p for p in rampDict if rampDict[p]}`. Recall that handling of Other propagates points-to sets of `p`, `rampDict` and `rampDict[p]` into `rampPoints`. This leads to PoTo+ reporting type `[dict, bool]` as `p`'s set is empty and `rampDict`'s set contains a single dictionary object of `Point` object keys, and bool values (it is straightforward to add handling of set comprehensions and other features to PoTo to improve matching).

Table 2 Running times for PoTo and Pytype (RQ4).

Package	PoTo	Pytype	Package	PoTo	Pytype
cerberus	51s	4m22s	anaconda	1m59s	1h21m40s
mtgjson	1m39s	15m39s	ansible	6h23m07s	6h14m59s
pygal	1m48s	1h00m17s	bokeh	1h41m16s	10h15m41s
sc2	52s	40m29s	invoke	1m32s	20m45s
zsfp	11s	7m28s	wemake	3m25s	9m17s

For the majority of cases where both are correct, PoTo+ reports a concrete type while Pytype reports a type parameter. For example, PoTo+ reports correctly `[dict, None]`, i.e., an optional dictionary for the return type of `_normalize_purge_unknown` in the cerberus package; while Pytype reports type variable `[_T0]` and this is correct with respect to Pytype's type system which allows for polymorphic functions.

4.1.3.2 PoTo+ vs. DL-ML, DL-ST and DL-DY

Of the 100 pairs we examine for PoTo+ vs. DL-ML, PoTo+ is correct 89 times, while DL-ML is correct 2 times. We mark PoTo+ incorrect conservatively – essentially, when the result is partially correct but not sound and not complete, we mark it incorrect. One common source of incorrect result for DL-ML was the `num` types mentioned earlier. Another source is usage of the function name instead of the function's return type at call assignments. Consider the following example from package pygal: `background = lighten('#e6e7e9',7)`. DL-ML reports type `[lighten]` for `background`, while PoTo+ correctly reports `[str, tuple]`. Yet another source of incorrect results is over-reliance on `dict` types. For example, in the wemake package: `AnyFunctionDef=Union[ast.FunctionDef,ast.AsyncFunctionDef]`, PoTo+ correctly infers type `[typing.Union[...]]` for `AnyFunctionDef` (via concrete evaluation). DL-ML infers `[dict]`.

Of the 100 samples we examine for PoTo+ vs. DL-ST, PoTo+ is correct 84 time and DL-ST is correct 5 times. There are no `num` types, as they are correctly assigned `int`; however, we observe similar patterns of function name instead of return type, and over-reliance on `dict`.

There are only 18 total mismatches for PoTo+ vs. DL-DY; 8 from ansible and 10 from bokeh. PoTo+ is correct 16 times and DL-DY is correct 11 times. Most cases are from accessing a dictionary or calling a function such as `children = kwargs.get('children')` or `typ = type(obj)`. On 5 occasions, DL-DY infers types that appear wrong such as `type`.

4.1.4 Scalability of PoTo (RQ4)

Table 2 show the running times of PoTo (total time for thousands of entry functions) and of Pytype. We run on a commodity Mac book Pro with 2.4 GHz 8-Core Intel Core i9 and 32 GB of Memory (one of our development machines). The "+" phase (type inference) is instantaneous and type aggregation and processing are negligible. We do not include these in the timing. In both cases, execution is IO-dominated, as PoTo writes points-to results into pkl files and Pytype's reveal-type reveals types by printing special error message.

PoTo runs in 1–3 minutes for all but the two largest packages, bokeh and ansible. Pytype is significantly more expensive ranging between 4 and 81 minutes on those packages. Without the reveal-type instrumentation Pytype runs 30% faster than with; thus, its underlying static analysis is expensive and PoTo still outperforms Pytype. PoTo runs slower than Pytype on ansible because ansible has nearly 500 test file (we filtered out ones that do not reference ansible packages from the 961 original ones to speed up testing) and many hit the same bottleneck of ansible code in the points-to analysis.

4.2 Call Graphs

To strengthen the case for applicability of PoTo, we evaluate it on another classical client of points-to analysis: call graph construction. We call the client PoToCG. We compare PoToCG to PyCG, the leading Python call graph construction analysis [34]. Unfortunately, PoToCG and PyCG are two different analyses, with different goals, and comparing them is non-trivial. PoToCG is a standard whole-program reachability analysis [3, 33, 23], whose goal is as follows: given a *main function* and a package, compute the smallest, i.e., most precise, call graph of reachable functions. PyCG, on the other hand, takes a set of files as input and computes a call graph that aims to include every call site in these files. Both graphs are unsound, by virtue of being analyses of Python, and both techniques aim to minimize the number of missing call graph nodes and edges. Nevertheless, PyCG is still the best Python call-graph analysis to compare to representing the state-of-the-art, and we made the comparison as apples-to-apples as possible modulo the different nature of the two approaches. We do not expand PoToCG to unreachable functions for this comparison, because such an expansion would entail a brand new call graph analysis that is antithetical to the reachability analysis inherent in Andersen-based call graph construction. Instead, we report on the number of reachable functions in PoToCG compared to PyCG, then we zoom in on the PoToCG-reachable functions and compare the quality of the PoToCG call graph for those functions compared to PyCG.

The research questions we address are as follows:

RQ5: How does PoToCG compare to PyCG in terms of reachable functions?

RQ6: For the PoToCG-reachable functions, how *complete* and how *precise* is the PoToCG call graph compared to PyCG?

We construct the PoToCG call graph by traversing call 3-address statements $x = y(z)$ in PoTo reachable functions and examining the points-to set of y. Meta-func objects represent abstract functions and lead to callees in the package. Concrete objects lead to callees that are either built-in functions (e.g., `len`) or external library functions (e.g., `re.sub`).

Consider function `UnconcernedValidator.__init__` in benchmark cerberus containing the following statement: `self.document_error_tree = errors.DocumentErrorTree()`. It gives rise to a corresponding 3-address-code call statement $x = y(z)$. Analysis variable y's points-to set contains meta-func abstract object `cerberus.errors.DocumentErrorTree.__init__`. Thus, we record a call graph edge from caller `UnconcernedValidator.__init__` to callee function `cerberus.errors.DocumentErrorTree.__init__` (this edge is missing from the PyCG results). PoToCG handles calls to built-in functions as well by recording the concrete object corresponding to the built-in function, e.g., `len`, `int`, etc. PyCG captures built-in callees as well. We aggregate results across all test cases, as in the type inference client.

Unfortunately, PyCG ran only on the five smaller packages – cerberus, pygal, mtgjson, sc2, and invoke. It did not terminate on any of the remaining packages. (PoToCG terminates on them.) To run PyCG, all files in a package are passed to PyCG as entry points. The five packages that terminated took 30 seconds to a few minutes, which are about the same as PoToCG as shown in Table 2. The other packages timed out after two hours per package.

Table 3 shows function coverage of PoToCG and PyCG (RQ5). The top three rows provide the raw statistic of each package we produced by scanning its Python AST. For the result of both techniques (row 4 and 5), we are interested in functions that have at least one outgoing edge or one incoming edge in their respective call graphs, meaning that we exclude isolated empty functions. Except for invoke, which relies entirely on its test suite (we did not write additional tests for it), PoToCG achieves relatively good coverage: 49% for cerberus, 72% for

Table 3 Function coverage of PoToCG and PyCG (RQ5). * indicates that the number is unusual due to non-existent callees, i.e., callees that do not correspond to function definitions.

Functions	cerberus	pygal	mtgjson	sc2	invoke
Total functions	200	354	237	567	782
Funcs without a call stmt	38	83	32	256	111
Funcs with call stmt	162	271	205	311	671
Funcs in PoToCG	91	218	211	266	99
Funcs in PyCG	161	816*	259	412	738
Funcs in PoToCG but not in PyCG	5	26	0	15	2
Funcs in PyCG but not in PoToCG	75	624	48	161	641
Funcs in both. Same # of edges	37	88	86	168	50
Exactly the same set of edges	29	71	57	123	37
Different set of edges	8	17	29	45	13
Funcs in both. #Edges: PoToCG > PyCG	43	54	76	67	33
Funcs in both. #Edges: PyCG > PoToCG	6	50	49	16	14

Table 4 Edges in PoToCG reachable functions (RQ6).

Edges	cerberus	pygal	mtgjson	sc2	invoke
True positive PoToCG	**339**	**599**	**679**	**438**	**260**
True positive PyCG	192	398	550	351	220
False positive PoToCG	**1**	**0**	**0**	**0**	**0**
False positive PyCG	12	813	116	4	6

pygal, 91% for mtgjson, and 77% for sc2. We measure coverages by percentages of functions in PoToCG that have call statements, to total functions with call statements. PyCG numbers for pygal and mtgjson exceed the upper bound of total functions, because PyCG reports caller and callee nodes that cannot be mapped to actual function definitions, e.g., `pygal.etree.etree.fromstring.findall.node.serie.get.split.append`. PyCG includes each module as a node as it can potentially have call edges. PyCG also maps functions in `__init__.py` files differently. For example, function `safe_load()` in `invoke/vendor/yaml3/__init__.py` has its path as `invoke.vendor.yaml3.safe_load`. We adjust PoToCG to accommodate these cases.

Table 4 zooms in on the functions that are both in PoToCG and PyCG for which the two techniques report *different sets of callee functions* (RQ6). These are the bottom three lines in Table 3 surrounded with a solid rectangle. We examined all the edges in these functions. We classified a caller-callee edge as *true positive* when reaching a specific call statement in the caller would indisputably lead to the callee for some receiver (when there is a receiver); this is the case for the `DocumentErrorTree` constructor example above. We classified an edge as *false positive* otherwise. In practice, essentially all false positives were in PyCG where the reported callee could not be mapped to a function definition in the package or in an external library. One can see in Table 4 that PoToCG reports considerably better call graphs for the functions it reaches – it reports a much larger number of true positive callees compared to PyCG as well as virtually no false positives, while PyCG reports a large number of false positives for two of the benchmarks. Therefore, PoTo's call graph is more complete and more precise for the functions it reaches. We observed that when reported callees could be

mapped to function definitions, both PoToCG and PyCG's callees were true positives. The reason why PyCG had a large number of false positives was that it reported many callees that did not correspond to function definitions.

We consider cases that highlight PoToCG's better recall (i.e., soundness) and better precision. PoToCG's better recall is due to its flow analysis as in the following example:
`validator = self._get_child_validator(..); mapping[field] = validator.normalized(..)`
In this example, the analysis must infer that a `Validator` object flows to the `validator` variable. PoTo infers that the analysis variable corresponding to `validator` points to a Validator object and correctly infers a call edge to `cerberus.base.UnconcernedValidator.normalized`. In contrast, PyCG leaves this call empty.

Another reason for PoToCG's better coverage is concrete evaluation. Consider
`result = validator.normalized(...); mapping[field] = value_type(result.values())`
In the above code, an empty concrete dictionary flows to the analysis variable corresponding to `result` and concrete evaluation deduces that the `values` member function is called. In contrast, PyCG does not infer a callee at this call.

As mentioned previously, PyCG reports hundreds of non-existent callees as in the following example: `pygal.util.decorate.serie.node`. Here, `decorate` is a function in the `util` module. We surmise PyCG infers `decorate` to return an object that has a field `serie`; however, it is not clear how that access path corresponds to an actual function definition in the pygal package. Another example is `pygal.graph.public.PublicApi.svg.serie.node`. We observed large numbers of such false positive callees in the pygal and mtgjson benchmarks but nearly none in the remaining benchmarks. In contrast, PoToCG reports were precise – if the call is reached then the reported function will be called.

Overall, we observed that recall (i.e., soundness) rather than precision is a more pressing issue for all analyses. PoToCG has better recall overall for the functions it reaches as detailed in Table 4, however, in the absence of ground truth it is difficult to judge how complete PoTo's call graph is. We did not observe precision issues in either analysis results, other than PyCG reporting non-existent callees. We further examined several applications and their hierarchies and we could not easily identify a call site that would have benefitted from a context- or object-sensitive analysis. For example, in pygal, a charting library and one of the larger applications in the suite, classes encapsulated predominantly string and numerical values, as opposed to complex objects; superclasses contained nearly all the functionality; and there were no setter and getter functions. As a specific case, one class hierarchy had root `class Style` which defined several class-level string and numerical fields representing colors and fonts. It also defined a function `get_colors` which formatted color strings to interact with CSS. Subclasses of `Style` added a small number of string or numerical class-level fields and defined no functions. Appendix A.2 gives an example where PoTo shows a clear advantage over an object-sensitive analysis. We conjecture that Python applications use class hierarchies differently from Java although further studies are needed. We consider PoTo a necessary baseline. Improved precision, possibly via context-sensitive, is a promising direction for future work in Python program analysis.

5 Threats to Validity

Section 4.1.3 discusses correctness comparison that depends on limited samples out of thousands of mismatches. To mitigate this, we collect all 18 mismatches against DL-DY, plus 10 samples per packages for all packages across 3 other techniques, resulting in total of 300 hand-labeled examples with broad coverage.

The analysis relies on unit tests for entry points, thus presuming the existence of test suites and good test coverage of the test suites. To increase coverage, we added custom entry-points for 5 of the packages; notably, coverage remains robust even for those large packages where we used only the existing test suites.

Lastly, PoTo is a hybrid analysis that alternates between concrete and abstract evaluation, and it employs semantic choices to deal with Python's complexity. This makes the analysis unsound by design, but it is the typical kind of trade-off made by most real-world static analysis [24]. Our results with two client analyses show that PoTo compares favorably against respective state-of-the-art techniques, thus validating its trade-offs.

6 Related Work

This section discusses prior work related to each of the three contributions stated in Section 1.

Points-to analysis. At its core, PoTo is an implementation of Andersen's points-to analysis [2], but unlike the original, it works for Python and is hybridized with concrete evaluation. The only other points-to analysis for Python we have found is in Scalpel [22]; however, Scalpel's analysis is not based on Andersen's, does not use concrete evaluation, and the paper lacks empirical results. Few static analyses have been shown to work on real-world Python programs, including PyCG [34] (which finds call graphs) and Tree-sitter [8] (which is limited to syntactic queries) [8]. Neither PyCG nor Tree-sitter does points-to analysis, nor do they use concrete evaluation. This paper empirically compares PoToCG against PyCG.

Outside of Python, work on points-to analysis and related alias and value-flow analysis dates decades back. Chatterjee et al. [6] describe a context-sensitive points-to analysis for C++, Rountev et al. [33] present an Andersen-style analysis for Java, and Fähndrich et al. [10] define a context-sensitive points-to analysis for C, among many other works. Siu and Xue [38] and Shi et al. [35] present scalable value-flow analysis over LLVM IR. Jang and Kwang [18] define the first Andersen-like points-to analysis for JavaScript and Sridharan et al. [37] improve Andersen's analysis with better reasoning about property accesses. These analyses work over established 3-address code IR in LLVM, Wala, and Soot. In contrast, we needed to construct 3-address code for points-to analysis from Python AST constructs.

Recent works on points-to analysis for Java (e.g., [25], [19]) focus on context- and object-sensitivity to improve precision. Our analysis is a context-insensitive and flow-insensitive baseline; we envision that the 3-address code and hybridization will serve as a foundation for building context- and flow-sensitive analysis for Python in the future.

Hybridization weaving concrete and abstract evaluation. PoTo uses concrete evaluation to solve the problem of analyzing Python programs that use external libraries. Two other works hybridize abstract (i.e. static) with concrete (i.e. dynamic) analysis for Python: PyCT [7] (which does concolic testing) and Rak-amnouykit et al.'s analysis [32] (which finds weakest preconditions). Neither is based on points-to analysis, nor has been used for type inference.

Looking back outside of Python, the idea of combining static and dynamic analyses has a long history in program analysis of Java and JavaScript. Hirzel et al. [16] hybridize Andersen's analysis with dynamic analysis to handle Java's dynamic class loading. Grech et al. [13] define a hybrid analysis for Java that takes whole heap snapshots and integrates them into the analysis. Wei and Ryder [43] present blended analysis for JavaScript that collects traces of execution then uses static analysis to reason about flow of tainted values. Tripp et al.'s analysis for JavaScript [40] addresses the problem of modeling the DOM; it

runs a dynamic analysis to concretize the external environment, followed by a static analysis in the concrete environment. Similarly, Laursen et al. [21] do a dynamic pre-analysis followed by a static analysis that uses runtime results; they target property access in JavaScript, a notorious issue in JavaScript codes [5]. Our analysis differs from all these works as it targets Python. It presents a novel blend of static and dynamic interpretation – it weaves concrete evaluation in both 3-address code generation and constraint resolution and elevates concrete objects to first-class status in the analysis. Park et al. [28]'s analysis of JavaScript does concrete execution of selected functions using carefully constructed objects; this is similar to our usage, however, their goal is to improve precision, while our goal is to improve soundness.

We view Toman and Grossman's Concerto [39] as most closely related to our work. Concerto is a combined concrete and abstract interpretation framework. It considers concrete state (for framework code) and abstract state (for application code) and allows calls from one domain into the other. Concerto is a theoretical framework, while we focus on Python and develop 3-address code generation and a specific analysis, Andersen's points-to analysis.

Type inference and call graph analysis for Python. PYInfer [9] and DeepTyper [15] use deep learning for Python type inference, and several other works combine deep learning with simple static analysis [1, 27, 29, 30, 44, 46]. This paper empirically compares PoTo+ against the latest of those, DLInfer [46], chosen because it compares with several earlier works and its artifact [45] has points-to sets for 10 real-world Python programs. A handful of other works use static analysis for Python type inference [11, 12, 14, 26]. Unlike PoTo+, none of these use points-to analysis nor concrete evaluation. In addition to DLInfer, this paper also empirically compares PoTo+ against Pytype [12], which is based on static analysis. We chose Pytype as a second baseline because it is widely used in practice and, like PoTo+, handles real-world Python programs [31]. Even though call-graph analysis is a popular client for points-to analysis in other languages, for Python, it has received little attention from the academic community. The main work is PyCG [34], and thus, we chose it as a baseline.

Instead of hybridizing static analysis with concrete evaluation, several works hybridize static analysis with machine-learning (ML). Xu et al. present a static type inference for Python augmented with ML for guessing types based on variable names [44]. Typilus uses static analysis to build a Python program dependency graph, then uses a graph neural network for type inference [1]. TypeWriter performs deep-learning (DL) type inference, then uses a static type checker to repair hallucinations [30]. Type4Py [27], HiTyper [29], and DLInfer [46] are primarly DL type inferences for Python, assisted by simple static analyses.

7 Conclusions

This paper presents PoTo, the first Andersen-style points-to analysis for Python. PoTo works on real-world Python programs, which use dynamic features as well as external packages for which source code is often missing (and which often involve non-Python code). To handle external packages, PoTo introduces a novel hybridization of Andersen's static analysis with dynamic concrete evaluation. In terms of clients, this paper presents PoTo+, a type inference built upon PoTo. While several recent papers explore deep learning for Python type inference, our results indicate that (at least as of now) static analysis solves this problem with superior coverage and correctness. This paper also presents PoToCG, a call-graph analysis built upon PoTo that performs better than the state-of-the-art for Python.

A Appendix

A.1 Per-application Equivalence Comparisons including Bars for Non-Empty Variables

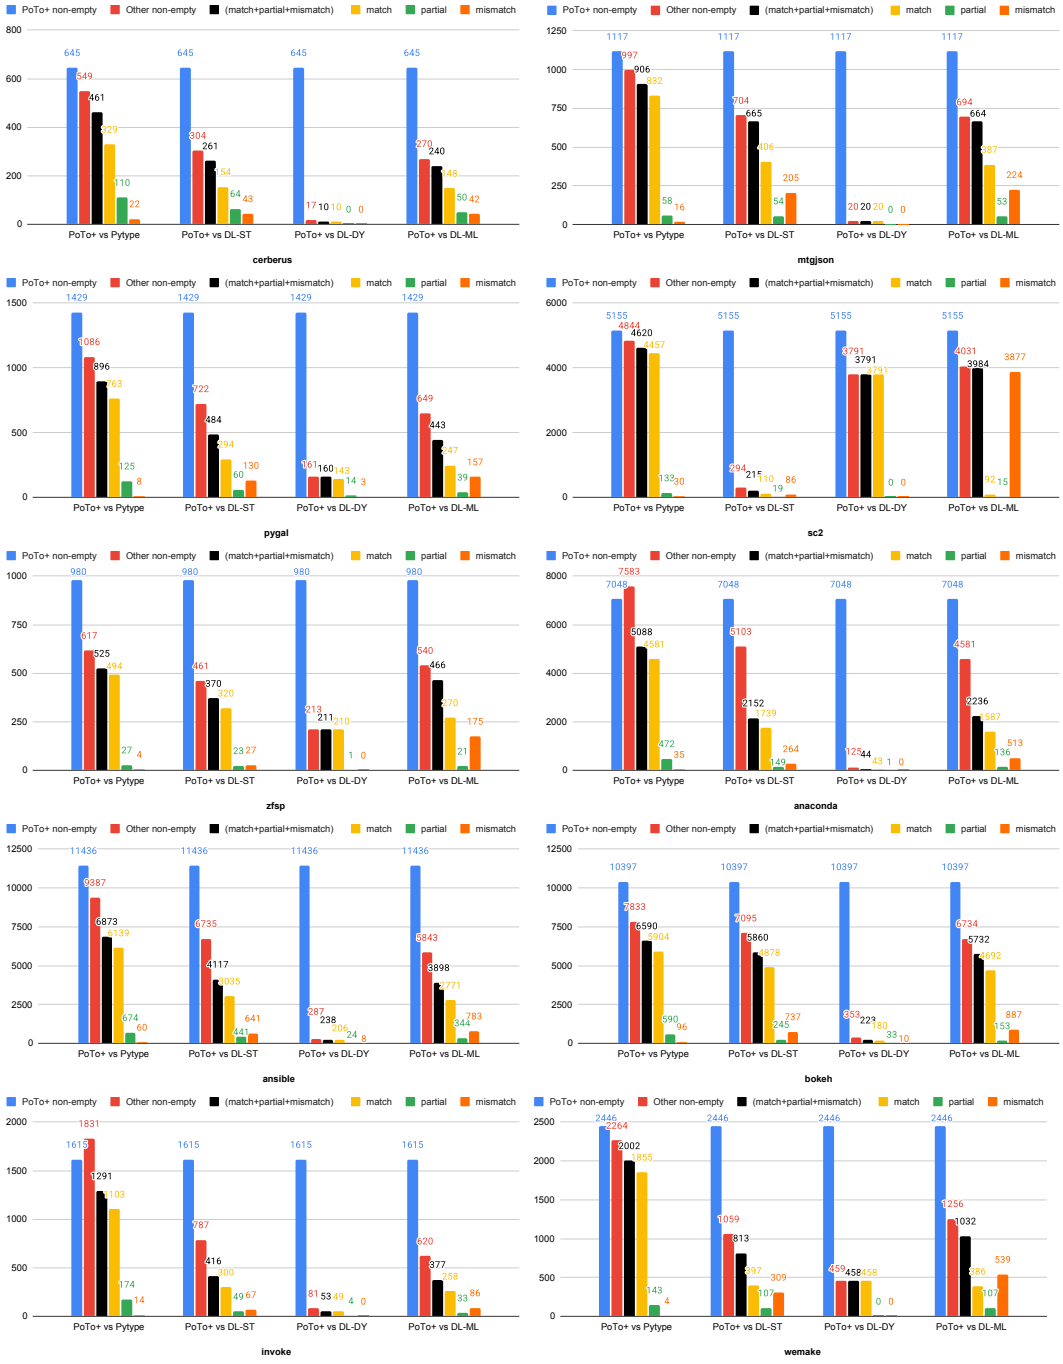

Figure 12 Equivalence comparison between PoTo+ and other type inference techniques (RQ2) for each individual package.

A.2 Difficult-to-Analyze Call Sites

```
1  class PublicApi:
2     ...
3     def render(self):
4       self.setup()
5       self.svg.render()
6
7  class BaseGraph(PublicApi):
8     ...
9     def setup(self):
10      self.svg = Svg(self)
11
12 class Line(BaseGraph):
13    ...
14    # Defines several new functions
15    # Does not override render or setup
16
17 # A test:
18 line1 = Line()
19 line1.show_legend = False
20 line1.fill = True
21 line1.pretty_print = True
22 line1.no_prefix = True
23 line1.x_labels = ['a', 'b', 'c']
24 line1.add('_', [1, 2, 3])
25 line1.render()
26
27 line2 = Line(show_legend=False, fill=True, pretty_print=True, no_prefix=True,
       x_labels=['a', 'b', 'c'])
28 line2.add('_', [1, 2, 3])
29 line2.render()
```

The listing shows an excerpt of a hierarchy from pygal. The majority of functionality is in base classes `PublicApi` and `BaseGraph` and the initialization context for graphing objects (e.g., line) consists largely of boolean, string, and numerical values. In this example the two line objects are initialized with the same values, as the test case tests their equivalence, but the important point is the types of encapsulated objects (booleans and lists of strings or integers), not the values themselves.

The call at line 5 illustrates a performance advantage of PoTo over a 1-object-sensitive analysis. Clearly, PoTo resolves the call to `Svg.render()`. A 1-object-sensitive points-to analysis will replicate functions `render` and `setup` per each one of the line objects hoping to distinguish between the two initialization contexts. However, replication is redundant as field `svg` is initialized in each replica of `setup` to the same `Svg` object, which flows into each replica of `render`; the analysis therefore discovers the same call target twice. While this is one example and we do need further studies, we observed similar flows in pygal and other applications – initialization context is of values of simple types that have no impact on the flow of objects and no impact on the call graph.

Reusing Caches and Invariants for Efficient and Sound Incremental Static Analysis

Abstract

Static analysis by means of abstract interpretation is a tool of choice for proving absence of some classes of errors, typically undefined behaviors in C code, in a sound way. However, static analysis tools are hardly integrated in CI/CD processes. One of the main reasons is that they are still time- and memory-expensive to apply after every single patch when developing a program. For solving this issue, incremental static analysis helps developers quickly obtain analysis results after making changes to a program. However, existing approaches are often not guaranteed to be sound, limited to specific analyses, or tied to specific tools. This limits their generalizability and applicability in practice, especially for large and critical software. In this paper, we propose a generic, sound approach to incremental static analysis that is applicable to any abstract interpreter. Our approach leverages the similarity between two versions of a program to soundly reuse previously computed analysis results. We introduce novel methods for summarizing functions and reusing loop invariants. They significantly reduce the cost of reanalysis, while maintaining soundness and a high level of precision. We have formalized our approach, proved it sound, implemented it in Eva, the abstract interpreter of Frama-C, and evaluated it on a set of real-world commits of open-source programs.

1 Introduction

Abstract interpretation [10, 9] is a sound flow-sensitive static analysis technique that allows the user to prove absence of programming errors, such as undefined behaviors in C code. To be precise enough, it is also usually implemented as a context-sensitive analysis, i.e., the analyzer relies on the function context (such as values of arguments and global variables) when analyzing a function call. However, soundness and preciseness come at a cost: Abstract interpretation can be time- and memory-expensive when analyzing real-world programs. It is not necessarily an issue when analyzing a program once, but it can prevent developers from introducing such a static analysis technique in a CI/CD process to check that their changes do not introduce bugs: Even a seemingly minor syntactic change can have a huge impact on the behavior of the software.

Incremental analyses are one way to reduce the cost of analyzing software after a change by reusing as many results as possible from the analysis of a previous version when analyzing the new version of the code. However, providing a sound flow- and context-sensitive incremental analysis is hard: existing approaches are either unsound [22, 27] or limited to specific classes of analyses [35, 16] or tied to specific analysis tools [1, 33, 28]. This paper presents a generic abstract-interpretation based approach for incremental flow- and context-sensitive analysis which is sound, and supports unbounded memory locations. Our approach is based on soundly reusing analysis results from previous analysis runs and is designed to be is applicable to most existing abstract interpreters. For each type of analysis result to be reused, we provide the conditions under which soundness is guaranteed. Such conditions typically involve program matching, which is the process of determining whether two parts of a program are equivalent or not. We consider two different types of analysis results: Function summaries and loop invariants. For function summaries, we propose a new way to summarize the effect of the analysis of a function in order to avoid re-analyzing the body of a function when the context of the analysis is the same. Our function summaries are soundly reusable and always precise for functions that have not been impacted by the modification of the program. For loop invariants, we propose a way to accelerate the analysis of loops by reusing the loop invariants from a previous analysis of the loop. Loop invariants are always soundly reusable even if the loop has been modified, but they may introduce imprecision in the analysis. However, we provide a way to limit the loss of precision and show that in practice, only little imprecision are introduced. Both approaches are complementary and can be used together to accelerate a static analysis, either an ongoing one or an incremental one.

Both approaches are formalized and proved sound. They have been implemented in Eva [6], the abstract interpreter of Frama-C [3, 19], an analysis framework for C code. This implementation has been evaluated on a set of real-world commits of open-source programs: The evaluation shows that our incremental analysis is much more time-efficient than the original analysis when analyzing two successive commits, while remaining precise in practice. Therefore, we think that such an incremental analysis helps integrate sound static analyzers in CI/CD process.

Contributions

- An approach for summarizing functions and reusing the summaries in subsequent analyses;
- An approach for reusing loop invariants in subsequent analyses;
- A formalization and a proof of soundness for both approaches for an imperative language with dynamic allocations;
- An experimental evaluation on real-world commits of open-source C programs for both approaches.

The rest of the paper is organized as follows. Section 2 presents the background on abstract interpretation. Section 3 presents an example to illustrate our approach for reusing function summaries and loop invariants. Section 4 introduces a representative programming language and its formal semantics. Using this language, Sections 5 and 6 formalize our approaches for function summaries and loop invariants, respectively. Section 7 presents an implementation and evaluation of both approaches. Section 8 discusses related work. Section 9 concludes the paper and discusses future work.

2 Elements of Abstract Interpretation

This section introduces the basic elements of abstract interpretation that are used in the rest of the paper. Abstract interpretation [10, 9] is a general theory of sound approximation of program semantics. It is based on the idea of computing an over-approximation of the set of possible states of a program using abstract domains, and provides a formal guarantee that the computed over-approximation is sound, i.e., it contains all possible states of the program. More formally, starting from a so-called concrete semantic domain $\mathcal{D}$, which can express the properties of interest (such as the set of memory states, to prove non-reachability of erroneous states), but is too difficult to compute with, abstract interpretation introduces the concept of abstract domain $\mathcal{D}^\sharp$ where the elements of $\mathcal{D}^\sharp$ are sound approximations of the elements of $\mathcal{D}$. The domains $\mathcal{D}$ and $\mathcal{D}^\sharp$ are partially ordered by a relation $\sqsubseteq$ and $\sqsubseteq^\sharp$. We also define the concretization function $\gamma : \mathcal{D}^\sharp \to \mathcal{D}$ as a monotonic function that maps an abstract element to a concrete element. We require that the abstract domain provides a sound approximation of the concrete join $\sqcup$ and meet $\sqcap$ operators, such that for all $x^\sharp, y^\sharp$ in $\mathcal{D}^\sharp$, $\gamma(x^\sharp) \sqcup \gamma(y^\sharp) \sqsubseteq \gamma(x^\sharp \sqcup^\sharp y^\sharp)$ and $\gamma(x^\sharp) \sqcap \gamma(y^\sharp) \sqsubseteq \gamma(x^\sharp \sqcap^\sharp y^\sharp)$. Moreover, the least upper bound $\top^\sharp$ (resp. greatest lower bound $\bot^\sharp$) of a set of abstract elements, when it exists, approximates the least upper bound $\top$ (resp. greatest lower bound $\bot$) of the corresponding set of concrete elements. A semantic operator is a function over domains. Abstract interpretation often requires computing fixpoints of semantic functions, e.g. in case of loops or recursive functions. They can be computed by iterating an abstract operator over an abstract domain. The convergence of the iteration sequence in the abstract domain is guaranteed by the use of a widening operator $\nabla^\sharp$ [10]. Formally, if $f : \mathcal{D} \mapsto \mathcal{D}$ is a monotonic operator over a complete concrete lattice $(\mathcal{D}, \sqsubseteq)$ and $f^\sharp : \mathcal{D}^\sharp \mapsto \mathcal{D}^\sharp$ is a sound abstraction of f, then the limit of the iteration sequence $x_0^\sharp = \bot^\sharp$, $x_{n+1}^\sharp = x_n^\sharp \nabla^\sharp f^\sharp(x_n^\sharp)$ converges in finite time to a stable iterate $x^\sharp$, which is a sound approximation of the least fixpoint lfp $f \sqsubseteq \gamma(x^\sharp)$. The existence of lfp f and the soundness of the approximation are guaranteed by Tarski's theorem [11, 34]. Moreover, the abstract operator $f^\sharp$ is not required to be monotonic, and does not necessarily admit a least fixpoint. We can settle for an abstract post-fixpoint $f^\sharp(x^\sharp) \sqsubseteq^\sharp x^\sharp$. Moreover, any post-fixpoint is an inductive invariant and the least fixpoint is the least invariant, so the limit of the iteration sequence is also an invariant. Figure 1 presents an interval abstract domain $\mathcal{I}_\mathbb{Z}^\sharp$, which represents values of integers as a pair of bounds, and a widening operator for fast and sound convergence of the iteration sequence.

3 Motivating Example

This section introduces an example that illustrates our contributions. Consider the following (buggy) C program that stores squares' size in an array before computing their area.

$$\mathcal{I}_{\mathbb{Z}}^{\sharp} \triangleq \{\ [a,b] \mid a \in \mathbb{Z} \cup \{-\infty\}, b \in \mathbb{Z} \cup \{+\infty\}, a \leq b\ \} \cup \{\bot_{\mathcal{I}_{\mathbb{Z}}}^{\sharp}\}$$

$$[a,b]\ \nabla_{\mathcal{I}_{\mathbb{Z}}}^{\sharp}\ [c,d] \triangleq \left[\begin{cases} a & \text{if } a \leq c \\ -\infty & \text{otherwise} \end{cases}, \begin{cases} b & \text{if } b \geq d \\ +\infty & \text{otherwise} \end{cases} \right]$$

Figure 1 Interval abstract domain and associated widening operator.

```
1  #define LEN 100
2  int area(int n) { return n + n; /* bug: should be 'n * n' */ }
3  void main() {
4    int sizes[LEN], areas[LEN];
5    for(int i = 0; i < LEN; i++)
6      sizes[i] = i;
7    for(int i = 0; i <= LEN; i++)  /* bug: should be 'i < LEN' */
8      areas[i] = area(sizes[i/2]);
9  }
```

This program contains one functional bug at line 2 and one undefined behavior at line 8 because of an incorrect test at line 7. Any modern abstract interpreter handling C code, such as Astrée [23], the Eva [4, 6] plugin of Frama-C [3, 19], Mopsa [24], or Polyspace [21], is able to analyze such a code instantaneously and reports one alarm. This alarm is raised when writing into the array `areas[100]`. Indeed, the loop at line 7 iterates one time too many, which results in an out-of-bound access. Such modern analyzers often implement function summaries that allow them to avoid analyzing twice a function under the same analysis context. An analysis context of a function is an over-approximation of the memory state at the call site, including the values of the arguments.

In our example, running an interval analysis with a standard widening operator allows the analyzer to converge in four iterations and to only analyze the function `area` twice instead of four times (i.e., one for each loop iteration). Indeed, for each loop iteration, the analysis context of the function call at line 8, in which `sizes` is omitted because it does not change throughout the analysis, is: $\{i \mapsto [0,0]; areas[i] \mapsto uninit; n \mapsto [0,0]\}$ at iteration 1, $\{i \mapsto [0,1]; areas[i] \mapsto [0,0]; n \mapsto [0,0]\}$ at iteration 2, $\{i \mapsto [0,100]; areas[i] \mapsto [0,100]; n \mapsto [0,50]\}$ at iteration 3 (with widening), and $\{i \mapsto [0,100]; areas[i] \mapsto [0,100]; n \mapsto [0,50]\}$ at iteration 4. We observe that the analysis of the function `area` depends on the value of its argument n (which is given by the value of array `sizes` at index `i/2`), and not on the value of the array `areas`. By assuming a sound over-approximation of the variables needed to analyze the function `area`, an analyzer can build a function summary that restricts the values of the state of the analysis before the call to `area` to the values of the variables needed to analyze the function. Such a state is then used to avoid the analysis of the body of the function again if the values of the needed variables are the same. The function summary in this case contains the state of the analysis before the call (denoted as input state $I^{\sharp}$) to function `area`, the state of the analysis after the call (denoted as output state $\mathcal{O}^{\sharp}$) to `area`, and the set (or sets) of variables needed to analyze the function. For example, the function summary for the call at line 8 after the first loop iteration is $\{I^{\sharp} = \{n \mapsto [0,0]\}; \mathcal{O}^{\sharp} = \{areas[i] \mapsto [0,0]\}; R^{\sharp} = \{n\}; W^{\sharp} = \{areas[i]\}\}$, where $R^{\sharp}$ (resp. $W^{\sharp}$) is the set of variables read (resp. written) by the function `area`. When analyzing the same function again during the second loop iteration, the value of the read variable n does not change, so the analyzer can reuse the function summary to avoid

reanalyzing the body of function `area`: It directly computes the state of the analysis after the call to function `area` from the output state $\mathcal{O}^\sharp$ and the written variables $W^\sharp$. Our first contribution consists in formalizing such function summaries for soundly reusing them when possible in order to speed up the analysis.

If such an analyzer is part of a CI/CD process, the developers would easily detect the runtime error at line 7 and fix it by submitting the following patch:

```
- for (i = 0; i <= LEN; i++)
+ for (i = 0; i < LEN; i++)
```

Analyzing the code again will allow them to prove that there is no more out-of-bound access in the program. However, for large programs, this analysis can be time-consuming, which may prevent its use in a CI/CD process. Indeed, it would require to run a new analysis from scratch for every program change, even minimal ones. This paper explains how to reuse previously computed function summaries from a previous analysis in order to prevent abstract interpreters from reanalyzing the body of the function `area` when reanalyzing the (almost) same program after a small patch. In fact, the analysis of the call to `area` was already done prior to the patch for the call contexts $\{n \mapsto [0,0]\}$ and $\{n \mapsto [0,50]\}$. The context $\{n \mapsto [0,0]\}$ can be directly reused when analyzing the patched version, so the analyzer only needs to analyze the call for the context $\{n \mapsto [0,49]\}$.

Later, the functional bug at line 2 will also be fixed by the following commit:

```
- int area(int n) { return n + n; }
+ int area(int n) { return n * n; }
```

Modifying the function `area` results in invalidating all function summaries inferred for this function and for all functions that call it. Therefore, the analyzer will analyze again from scratch the functions `area` and `main`.

Our second contribution consists in reusing previously computed loop invariants to speed up the analysis of both loops in our running example in order to speed up the analysis even when no function summaries can be soundly reused. Indeed, prior to the patch for the functional bug, the analyzer has already computed the loop invariants for the loops at lines 5 and 7. If $arr[a,b] \mapsto [i,j]$ denotes *the array arr contains values in the interval* $[i,j]$ *for any index in the interval* $[a,b]$, these invariants are $\{sizes[0,99] \mapsto [0,99]; areas[0,99] \mapsto uninit; i \mapsto [0,99]\}$ and $\{sizes[0,99] \mapsto [0,99]; areas[0,99] \mapsto [0,198]; i \mapsto [0,99]\}$, respectively. Reusing them will allow the analyzer to converge faster by starting the iteration from the previously computed fixpoint for this loop instead of the least element $\bot^\sharp$. This optimization allows the first loop to converge in one iteration only as the fixpoint has not changed, while the second loop will converge in two iterations as the value of $areas[0,49]$ still needs to stabilize to $[0,2401]$ ($2401 = 49 \times 49$).

Together, our contributions allow analyzers to reduce the analysis time significantly when submitting small patches that fix bugs or introduce new features on large programs (see Section 7). Therefore, they help integrate such analyzers in a CI/CD process.

4 Language and Semantics

Figure 2 presents our language. It is an imperative language containing basic control flows (sequences, conditionals and loops), assignments, function calls and dynamic allocations, which allocate new memory locations of type integer at a given allocation site μ. Expressions consist of integer constants, variables, dereferences, addresses of a variable, and basic n-ary

$$
\begin{array}{lll}
\textbf{expr} & e ::= c & c \in \mathbb{V} \\
& \mid *e & \text{(dereference)} \\
& \mid \&x & \text{(address of } x\text{)},\ x \in \mathbb{X} \\
& \mid \diamondsuit(e_1, \ldots, e_n) & \diamondsuit \in \{+, -, *, /\} \\
\textbf{stmt} & s ::= *e_1 \coloneqq e_2 & \text{(assignment)} \\
& \mid *(\&x) \coloneqq \text{malloc}_\mu & \text{(allocation)},\ \mu \in \mathbb{L} \\
& \mid s_\alpha ; s_\beta & \text{(sequence)} \\
& \mid f(\vec{e}) & \text{(function call)} \\
& \mid \textbf{if}\ (e \bowtie 0)\ \textbf{then}\ s_\alpha\ \textbf{else}\ s_\beta & \text{(conditional)} \\
& \mid \textbf{while}\ (e \bowtie 0)\ \textbf{do}\ s & \text{(loop)} \\
\textbf{fun} & f ::= f(\vec{x})\{s\} & \text{(function definition)} \\
& \bowtie \in \{=, \neq, <, >, \leq, \geq\} & \text{(relational operator)}
\end{array}
$$

Figure 2 Syntax of our language.

arithmetic operators over integers. Functions are defined with a unique name f, a list of formal parameters $\vec{x}$, and a body of statements s. Variables denote integers or memory locations.

Notations

We denote $\mathbb{X}$, the finite set of all variables and formal parameters of functions; $\mathbb{L}$, the finite set of allocation sites; $\mathbb{H} = \mathbb{L} \times \mathbb{N}$, pairs of allocation site and the number of allocations at this site that represents a memory block dynamically allocated in the heap; $\mathbb{A} = \mathbb{X} \uplus \mathbb{H}$, the set of all possible memory locations; $\mathbb{V} = \mathbb{Z} \uplus \mathbb{A}$, the set of all possible values (either an integer or a memory location) assignable to a variable; and $\mathbb{M} : \mathbb{A} \rightharpoonup \mathbb{V}$, a memory state that maps a memory location to some (concrete) value. $\mapsto$ is the update operator that assigns a value to a memory location in a memory state, such that $m[a \mapsto v]$ denotes the memory state $m \in \mathbb{M}$ that maps the location $a \in \mathbb{A}$ to the value $v \in \mathbb{V}$ and other elements $a' \in \text{dom}(m)$ to their previous value $m(a')$. $|$ is the restriction operator that removes the keys of a mapping, such that $m|_A$ is the memory state m restricted to the set A of memory locations. Additionally, we denote $e^\sharp$ an element of an abstract domain. Furthermore, the formal parameters of a function are given by params : $\textbf{fun} \to \mathcal{P}(\mathbb{X})$, the body of the function by body : $\textbf{fun} \to \textbf{stmt}$ and the local variables of the function by locals : $\textbf{fun} \to \mathcal{P}(\mathbb{X})$.

Assumptions and limitations

We do not handle pointer arithmetic: $[\![\diamondsuit]\!]$ is only defined for integers. Assignments can only write a memory location by dereferencing it. So, assigning some expression e to a variable $x \in \mathbb{X}$ is written $*(\&x) = e$. Every malloc_μ expression is assumed to be unique and $\mu \in \mathbb{L}$ identifies the allocation site. A same malloc_μ can be called multiple times during the execution of a program (typically, when written in a loop). In such a case, it generates multiple memory blocks at different addresses. Without loss of generality, all variable names are assumed to be unique, including formal parameters of defined functions. Functions have no return value: They can be simulated by passing to the function a reference to a variable

in which the function stores its result. Recursive function calls are also not supported, we already have functions, unbounded loops and unbounded memory allocation, so the support of recursive calls does not bring theoretical difficulties. It is just a technical limitation of the formalization and is left for future work.

4.1 Concrete Semantics

Figures 3 and 4 define the concrete semantic functions for expressions and statements, respectively. The semantics for expressions, $\mathbb{E}[\![\mathbf{expr}]\!]$, maps a concrete memory state to a concrete value. The semantics for statements, $\mathbb{S}[\![\mathbf{stmt}]\!]$, maps a concrete memory state to another concrete memory state: $\mathbb{S}[\![\mathbf{stmt}]\!]$ computes the state of the program reached at the end of the execution of a statement. The concrete semantics is deterministic and $\mathbb{S}[\![\mathbf{stmt}]\!]$ is a partial function to handle undefined operations such as divisions by zero or reading uninitialized memory locations. A function call is done by binding the value of the evaluation of the arguments to the formal parameters in the memory state, executing the body of the function, removing the formal parameters from the memory state at the end of the function execution, and returning this memory state. The semantics for dynamic allocations relies on a next operator: for a location site $\mu \in \mathbb{L}$ and a memory state $m \in \mathbb{M}$, $\text{next}(\mu, m)$ returns the first free memory block in $\mathbb{H}$ at this call site, which is formally defined as follows:

$$\text{next}(\mu, m) \triangleq \langle \mu, \min\{i \in \mathbb{N} \mid \langle \mu, i\rangle \notin \text{dom}(m)\}\rangle.$$

This definition and the concrete semantics for dynamic allocations imply that the first memory block allocated at μ is $\langle \mu, 0\rangle$, the second one is $\langle \mu, 1\rangle$, and so on.

$$\begin{aligned}
\mathbb{E}[\![\mathbf{expr}]\!] &: \mathbb{M} \to \mathbb{V} \\
\mathbb{E}[\![c]\!]m &\triangleq c,\ c \in \mathbb{Z} \\
\mathbb{E}[\![*e]\!]m &\triangleq m(\mathbb{E}[\![e]\!]m) \\
\mathbb{E}[\![\&x]\!]m &\triangleq x,\ x \in \mathbb{X} \\
\mathbb{E}[\![\diamondsuit(e_1, ..., e_n)]\!]m &\triangleq \diamondsuit(\mathbb{E}[\![e_1]\!]m, ..., \mathbb{E}[\![e_2]\!]m)
\end{aligned}$$

Figure 3 Concrete semantics for expressions.

4.2 Abstract Domains

Value Abstract Domain

We abstract the concrete values $\mathbb{V}$ by an abstract domain $\mathbb{V}^\sharp$, such that $(\mathbb{V}^\sharp, \sqsubseteq^\sharp_{\mathbb{V}})$ is a partial order abstracting the concrete domain $(\mathcal{P}(\mathbb{V}), \subseteq)$ featuring a monotonic concretization function $\gamma_{\mathbb{V}} : \mathbb{V}^\sharp \to \mathcal{P}(\mathbb{V})$ and a widening operator $\nabla^\sharp_{\mathbb{V}}$. To construct such an abstract value domain, we need to abstract both integer values and memory locations.

The abstract domain $(\mathbb{Z}^\sharp, \sqsubseteq^\sharp_{\mathbb{Z}})$ for integer values is left unspecified. We just assume a concretization function $\gamma_{\mathbb{Z}} : \mathbb{Z}^\sharp \to \mathcal{P}(\mathbb{Z})$ and a widening operator $\nabla^\sharp_{\mathbb{Z}}$. For instance, this abstract domain is the interval domain in our running example. The set of variables is finite, so variable sets can be abstracted by its powerset $(\mathcal{P}(\mathbb{X}), \subseteq)$. An abstract heap address represents a set of concrete heap addresses [17]. Consequently, memory updates on abstract heap addresses are done by merging the new value with the previous value, which is called a

$$
\begin{aligned}
\mathbb{S}[\![\mathbf{stmt}]\!] &: \mathbb{M} \rightharpoonup \mathbb{M} \\
\mathbb{S}[\![*e_1 := e_2]\!]m &\triangleq m[\mathbb{E}[\![e_1]\!]m \mapsto \mathbb{E}[\![e_2]\!]m] \\
\mathbb{S}[\![*(\&x) := \mathrm{malloc}_\mu]\!]m &\triangleq \text{let } \langle \mu, n\rangle := \mathrm{next}(\mu, m) \text{ in} \\
&\quad\; m[\mathbb{E}[\![\&x]\!]m \mapsto \langle \mu, n\rangle][\langle \mu, n\rangle \mapsto 0] \\
\mathbb{S}[\![f(\vec{e})]\!]m &\triangleq \text{let } \vec{x} := \mathrm{params}(f) \text{ in} \\
&\quad\; \text{let } \vec{y} := \mathrm{locals}(f) \text{ in} \\
&\quad\; \text{let } m_{\mathrm{ret}} := \mathbb{S}[\![\mathrm{body}(f)]\!](m[\vec{x} \mapsto \mathbb{E}[\![\vec{e}]\!]m]) \text{ in} \\
&\quad\; m_{\mathrm{ret}}|_{\mathrm{dom}(m_{\mathrm{ret}}) \setminus (\vec{x} \cup \vec{y})} \\
\mathbb{S}[\![s_\alpha; s_\beta]\!]m &\triangleq (\mathbb{S}[\![s_\beta]\!] \circ \mathbb{S}[\![s_\alpha]\!])m \\
\mathbb{S}[\![\mathbf{if}\ (e \bowtie 0)\ \mathbf{then}\ s_\alpha\ \mathbf{else}\ s_\beta]\!]m &\triangleq \mathbf{if}\ (\mathbb{E}[\![e]\!]m \bowtie 0)\ \mathbf{then}\ \mathbb{S}[\![s_\alpha]\!]m\ \mathbf{else}\ \mathbb{S}[\![s_\beta]\!]m \\
\mathbb{S}[\![\mathbf{while}\ (e \bowtie 0)\ \mathbf{do}\ s]\!]m &\triangleq \mathrm{lfp}(F)(m) \\
&\quad \text{where } F(f)(m) \triangleq \begin{cases} f(\mathbb{S}[\![s]\!]m) & \text{if } \mathbb{E}[\![e]\!]m \bowtie 0 \\ m & \text{otherwise} \end{cases}
\end{aligned}
$$

Figure 4 Concrete semantics for statements.

weak update. The induced precision loss with weak updates can be compensated by using more sophisticated techniques to summarize heap addresses [18]. The idea is to allow some abstract heap addresses to represent a singleton concrete heap address and allow *strong updates* on such addresses. We choose to represent abstract heap addresses $\mathbb{H}^\sharp_k : \mathbb{L} \times \mathbb{N}_{\leq k}$ as a pair of allocation site $\mu \in \mathbb{L}$ and a natural number smaller or equal than k.

Such a technique is based on *k-limiting* [20] and *allocation site* [2]. The natural number k is used to limit the maximum number of generation of strong abstract heap addresses on a given site before over-approximating further allocations with a weak abstract heap address. Such limit k will be referred as $\mathrm{k_{lim}}$ or k for subscript in the rest of the paper. More precisely, we want to represent the first k allocations on a site μ with a dedicated abstract heap address $\langle \mu, k\rangle$ for all $0 \leq k < \mathrm{k_{lim}}$, and all further allocations with an abstract heap address $\langle \mu, \mathrm{k_{lim}}\rangle$. Consequently, when an abstract heap address represents a singleton concrete heap address, the update on this address is a strong update: the new value replaces the previous one. Otherwise, if an abstract heap address potentially represents multiple concrete heap addresses, the update is a weak update: the new value is merged with the previous one, which is the case for $\langle \mu, \mathrm{k_{lim}}\rangle$. Formally, the abstract value domain $\mathbb{V}^\sharp$ is defined as follows:

$$
\begin{aligned}
\mathbb{V}^\sharp &\triangleq \mathbb{Z}^\sharp \times \mathcal{P}(\mathbb{H}^\sharp_k) \times \mathcal{P}(\mathbb{X}) \cup \{\top^\sharp_{\mathbb{V}}, \bot^\sharp_{\mathbb{V}}\} \\
\gamma_{\mathbb{V}} &: \mathbb{V}^\sharp \to \mathcal{P}(\mathbb{V}) \\
\gamma_{\mathbb{V}}(\top^\sharp_{\mathbb{V}}) &\triangleq \mathbb{V} \\
\gamma_{\mathbb{V}}(\bot^\sharp_{\mathbb{V}}) &\triangleq \emptyset \\
\gamma_{\mathbb{V}}(z^\sharp, h^\sharp, x^\sharp) &\triangleq \gamma_{\mathbb{Z}}(z^\sharp) \cup \gamma_{\mathbb{H}}(h^\sharp) \cup x^\sharp \\
&\quad \text{where } \gamma_{\mathbb{H}}(h^\sharp) \triangleq \bigcup \{\gamma_h(\langle \mu, n\rangle) \mid \forall \langle \mu, n\rangle \in h^\sharp\} \\
&\quad \text{where } \gamma_h(\langle \mu, n\rangle) \triangleq \begin{cases} \{\langle \mu, n\rangle\} & \text{if } n < k \\ \{\langle \mu, j\rangle \mid \forall j \geq k\} & \text{if } n = k. \end{cases}
\end{aligned}
$$

The definitions of operators $\sqsubseteq^\sharp_{\mathbb{V}}$, $\sqcup^\sharp$, $\sqcap^\sharp$ and $\nabla^\sharp$ are omitted, but defined pointwise and extended to $\top^\sharp_{\mathbb{V}}$ and $\bot^\sharp_{\mathbb{V}}$ such that the former is the greatest element of $\mathbb{V}^\sharp$ and the latter is its least element for the partial order $\sqsubseteq^\sharp$.

Non-relational Memory Abstract Domain

We derive the abstraction $\mathbb{M}^\sharp$ of $\mathbb{M} : \mathbb{A} \rightharpoonup \mathbb{V}$ from the abstract value domain $\mathbb{V}^\sharp$ by mapping each memory location in the finite set of abstract memory locations $\mathbb{A}^\sharp_k : \mathbb{X} \uplus \mathbb{H}^\sharp_k$ to an abstract value $\mathbb{V}^\sharp$. The abstract memory domain $\mathbb{M}^\sharp$ is thus a partial mapping from abstract memory locations to abstract values. The operations $\sqsubseteq^\sharp, \nabla^\sharp, \sqcup^\sharp, \sqcap^\sharp$ are defined pointwise, and the least element $\bot^\sharp_{\mathbb{V}}$ is used when one of the operands is undefined . The least element $\bot^\sharp$ (resp. the greatest element $\top^\sharp$) maps each memory location in $\mathrm{dom}(\mathbb{M}^\sharp)$ to the least element $\bot^\sharp_{\mathbb{V}}$ (resp. the greatest element $\top^\sharp_{\mathbb{V}}$) of the abstract value domain. The concretization function γ takes into account possible undefined memory locations. Formally, the abstract memory domain is defined as follows:

$$\mathbb{M}^\sharp \triangleq (\mathbb{A}^\sharp_k \rightharpoonup \mathbb{V}^\sharp)$$
$$\gamma : \mathbb{M}^\sharp \to \mathcal{P}(\mathbb{M})$$
$$\gamma(M^\sharp) \triangleq \left\{ m \in \mathbb{M} : \left\{ \begin{array}{ll} m(\langle a, n\rangle) \in \gamma_{\mathbb{V}}(M^\sharp(\langle a, n\rangle)) & (1) \\ m(\langle a, n\rangle) \in \gamma_{\mathbb{V}}(M^\sharp(\langle a, k\rangle)) & (2) \\ m(x) \in \gamma_{\mathbb{V}}(M^\sharp(x)) & (3) \end{array} \right. \middle| \; \forall a : j_a \in \mathbb{N} \right\}$$

where (1) $\forall \langle a, n\rangle \in \mathrm{dom}(M^\sharp)$ and $n < k$ and $n < j_a$
(2) if $\langle a, k\rangle \in \mathrm{dom}(M^\sharp)$ and $k \leq n \leq j_a$
(3) $\forall x \in \mathbb{X}$ and $x \in \mathrm{dom}(M^\sharp)$

4.3 Abstract Semantics

Figures 5 and 6 present the abstract semantics of our language, which computes an over-approximation of the concrete semantics. The abstract semantics for expressions, $\mathbb{E}^\sharp[\![\mathbf{expr}]\!]$, maps an abstract memory to an abstract value, while the abstract semantics for statements, $\mathbb{S}^\sharp[\![\mathbf{stmt}]\!]$, maps an abstract memory to another abstract memory. $\mathbb{S}^\sharp[\![\mathbf{stmt}]\!]$ computes an over-approximation of the possible states reached at the end of the executed statement. Function $\phi_{\mathbb{Z}} : \mathbb{Z} \to \mathbb{Z}^\sharp$ (resp. $\diamondsuit^\sharp$) is assumed to be a sound abstraction of integer constants (resp. unary operators) given by the abstract domain $\mathbb{Z}^\sharp$ for integer values. We assume given a sound abstraction of relational operators $\bowtie^\sharp_e$: $\mathbb{M}^\sharp \to \mathbb{M}^\sharp$ and its negation $\not\bowtie^\sharp_e : \mathbb{M}^\sharp \to \mathbb{M}^\sharp$ such that for all non-relational abstract elements $M^\sharp \in \mathbb{M}^\sharp$ and all concrete memory states $m \in \mathbb{M}$, if $\mathbb{E}[\![e]\!]m \bowtie 0$ then $m \in \gamma(\bowtie^\sharp_e (M^\sharp))$, and its negation if $\mathbb{E}[\![e]\!]m \not\bowtie 0$ then $m \in \gamma(\not\bowtie^\sharp_e(M^\sharp))$.

The abstract semantics of an assignment performs an abstract memory update, which is either a strong update when the written address is precise, or a weak update when it is not. The formal definition of such a memory update is as follows:

▶ **Definition 1** (Memory Update). *Given an abstract memory $M^\sharp \in \mathbb{M}^\sharp$, a set of abstract memory locations $X \in \mathcal{P}(\mathbb{A}^\sharp_k)$ and an abstract value $v^\sharp \in \mathbb{V}^\sharp$, the update of $M^\sharp$ with X is defined as follows:*

$$\forall X \in \mathcal{P}(\mathbb{A}^\sharp_k), \forall v^\sharp \in \mathbb{V}^\sharp :$$
$$M^\sharp[X \rightsquigarrow v^\sharp] \triangleq \begin{cases} M^\sharp[a^\sharp \mapsto v^\sharp] & \text{if } X = \{a^\sharp\} \wedge \\ & (a^\sharp \in \mathbb{X} \vee (a^\sharp = \langle \mu, n\rangle \wedge n < k)) \\ & \text{strong update} \\ M^\sharp[\forall a^\sharp \in X. a^\sharp \mapsto v^\sharp \sqcup^\sharp_{\mathbb{V}} M^\sharp(a^\sharp)] & \text{otherwise weak update} \end{cases}$$

$$

Soundness Requirements of Abstract Semantic Functions

The concrete semantic functions are implicitly lifted to sets. We require that the abstract semantic functions are sound abstractions of the corresponding concrete semantic functions. This is expressed by the following soundness criterion: $\forall M^\sharp \in \mathbb{M}^\sharp$, $\mathbb{S}[\![\mathbf{stmt}]\!]\gamma(M^\sharp) \subseteq \gamma(\mathbb{S}^\sharp[\![\mathbf{stmt}]\!]M^\sharp)$ and $\mathbb{E}[\![\mathbf{expr}]\!]\gamma(M^\sharp) \subseteq \gamma_{\mathbb{V}}(\mathbb{E}^\sharp[\![\mathbf{expr}]\!]M^\sharp)$.

Set of Abstract Read, Written and Allocated Memory Locations

We define the set of abstract memory locations used in expressions, read in statements, written in statements, and allocated in statements. These sets are used in the definition of function summaries and loop invariants. They are defined inductively over the semantics of statements. These locations are collected and propagated throughout each evaluation of an expression and a statement. We only present here the important cases of these definitions. The others are defined in a straightforward manner.

▶ **Definition 4** (Set of abstract memory locations used in expressions). *The set of abstract memory locations used in an expression* ***expr*** *is the set of memory locations which might change the result of the abstract evaluation of the expression.*

$$
\begin{aligned}
\Upsilon^\sharp[\![\boldsymbol{expr}]\!] &: \mathbb{M}^\sharp \to \mathcal{P}(\mathbb{A}_k^\sharp) \\
\Upsilon^\sharp[\![\&x]\!]M^\sharp &\triangleq \emptyset \\
\Upsilon^\sharp[\![*e]\!]M^\sharp &\triangleq \mathit{let}\ Y := \Upsilon^\sharp[\![e]\!]M^\sharp \cup \mathbb{E}^\sharp[\![e]\!]M^\sharp\ \mathit{in} \\
&\qquad \mathit{let}\ X := \mathbb{E}^\sharp[\![*e]\!]M^\sharp\ \mathit{in} \\
&\qquad\quad \begin{cases} Y & \mathit{if}\ |X| = 1 \\ & \wedge\ (\forall a^\sharp \in X : a^\sharp \in \mathbb{X} \vee (a^\sharp = \langle \mu, n \rangle \wedge n < k)) \\ X \cup Y & \mathit{otherwise} \end{cases} \\
\Upsilon^\sharp[\![\diamondsuit(e_1, ..., e_n)]\!]M^\sharp &\triangleq \bigcup_{\forall i \in [1,n]} \Upsilon^\sharp[\![e_i]\!]M^\sharp
\end{aligned}
$$

▶ **Definition 5** (Set of abstract read memory locations in statements). *An abstract memory location $a^\sharp$ is read by a statement* ***stmt*** *if its abstract value $M^\sharp(a^\sharp)$ is accessed by the computation of $\mathbb{S}^\sharp[\![\boldsymbol{stmt}]\!]M^\sharp$.*

$$
\begin{aligned}
\mathit{Read}^\sharp[\![\boldsymbol{stmt}]\!] &: \mathbb{M}^\sharp \to \mathcal{P}(\mathbb{A}_k^\sharp) \\
\mathit{Read}^\sharp[\![*e_1 := e_2]\!]M^\sharp &\triangleq \Upsilon^\sharp[\![e_1]\!]M^\sharp \cup \Upsilon^\sharp[\![e_2]\!]M^\sharp \\
\mathit{Read}^\sharp[\![*(\&x) := \mathit{malloc}_\mu]\!]M^\sharp &\triangleq \emptyset \\
\mathit{Read}^\sharp[\![f(\vec{e})]\!]M^\sharp &\triangleq \mathit{let}\ M_1^\sharp := M^\sharp[\mathit{params}(f) \mapsto \mathbb{E}^\sharp[\![\vec{e}]\!]M^\sharp]\ \mathit{in} \\
&\qquad \Upsilon^\sharp[\![\vec{e}]\!]M^\sharp \cup \mathit{Read}^\sharp[\![\mathit{body}(f)]\!]M_1^\sharp \setminus \mathit{locals}(f) \setminus \mathit{params}(f)
\end{aligned}
$$

▶ **Definition 6** (Set of abstract memory locations modified in statements). *An abstract memory location $a^\sharp$ is written by a statement* ***stmt*** *if it is a lvalue in an assignment statement.*

$$
\begin{aligned}
\mathit{Write}^\sharp[\![\boldsymbol{stmt}]\!] &: \mathbb{M}^\sharp \to \mathcal{P}(\mathbb{A}_k^\sharp) \\
\mathit{Write}^\sharp[\![*e_1 := e_2]\!]M^\sharp &\triangleq \mathbb{E}^\sharp[\![e_1]\!]M^\sharp \\
\mathit{Write}^\sharp[\![*(\&x) := \mathit{malloc}_\mu]\!]M^\sharp &\triangleq \{x\} \\
\mathit{Write}^\sharp[\![f(\vec{e})]\!]M^\sharp &\triangleq \mathit{let}\ M_1^\sharp := M^\sharp[\mathit{params}(f) \mapsto \mathbb{E}^\sharp[\![\vec{e}]\!]M^\sharp]\ \mathit{in} \\
&\qquad \mathit{Write}^\sharp[\![\mathit{body}(f)]\!]M_1^\sharp \setminus \mathit{params}(f) \setminus \mathit{locals}(f)
\end{aligned}
$$

▶ **Definition 7** (Set of abstract allocated memory locations in statements). *An abstract memory location $a^\sharp$ is allocated by a statement* ***stmt*** *if it is the result of a call to the allocation function.*

$$Alloc^\sharp[\![\textbf{\textit{stmt}}]\!] : \mathbb{M}^\sharp \to \mathcal{P}(\mathbb{A}_k^\sharp)$$
$$Alloc^\sharp[\![*(\&x) := malloc_\mu]\!]M^\sharp \triangleq \{next^\sharp(\mu, M^\sharp)\}$$
$$Alloc^\sharp[\![f(\vec{e})]\!]M^\sharp \triangleq Alloc^\sharp[\![body(f)]\!](M^\sharp[params(f) \mapsto \mathbb{E}^\sharp[\![\vec{e}]\!]M^\sharp])$$

▶ **Example 8.** Given a statement $x := \text{malloc}_\mu; *x := y$ (written in C-like for simplicity) and an abstract memory $M^\sharp$ such that $M^\sharp = \{\langle\mu, 0\rangle \mapsto 0, y \mapsto 1\}$, if $k_{\text{lim}} = 1$ we have:

$$\mathbb{S}^\sharp[\![.]\!]M^\sharp = M^\sharp[x \mapsto \langle\mu, 1\rangle, \langle\mu, 1\rangle \mapsto 1]$$
$$Read^\sharp[\![.]\!]M^\sharp = \{x, y, \langle\mu, 1\rangle\}, Write^\sharp[\![.]\!]M^\sharp = \{x, \langle\mu, 1\rangle\}, Alloc^\sharp[\![.]\!]M^\sharp = \{\langle\mu, 1\rangle\}$$

We have to consider $\langle\mu, 1\rangle$ as read because it is a weak memory location, thus its value is read during a weak update.

▶ **Definition 9** (Projection). *Given a set of memory locations $X^\sharp \in \mathcal{P}(\mathbb{A}_k^\sharp)$ and an abstract memory $M^\sharp \in \mathbb{M}^\sharp$, the projection of $M^\sharp$ on $X^\sharp$ is defined as:*

$$M^\sharp \downarrow X^\sharp \triangleq \lambda x. \textit{if } x \in X^\sharp \textit{ then } M^\sharp(x) \textit{ else } \top^\sharp$$

Memory locations are omitted from the abstract memory after a projection if their value is $\top^\sharp$ for the sake of readability.

5 Incremental Analysis with Function Summaries

This section introduces a summarization technique that allows abstract interpreters to avoid reanalyzing the body of a function when calling it within the same analysis context. We first introduce the program matching process that identifies the unmodified functions across two program versions. We then present and formalize the concept of function summaries and how they can be soundly reused to speed up incremental static analysis.

Given two program versions P_{new} and P_{old}, we aim to identify the functions that have not changed between the two versions. We consider two functions f_{new} and f_{old} to be similar if their ASTs have the same shape, they have the same instructions, the set of global variables they access are the same and have not been modified, and the functions they call are similar. Although simple, this matching process is sufficient for our purpose and allows us to identify a significant number of functions that have not changed between two versions of a program.

▶ **Example 10.** Consider the following program:

```
1 int a = 0;
2 void f() { a = 0; }
3 void g() { a = 1; }
4 void main() { f(); g(); }
```

Let us consider two different patches (a) and (b) that are applied independently to the program:

```
- int a = 0;
+ int a = 1;
```

(a)

```
- void f() { a = 0; }
+ void f() { a = 1; }
```

(b)

Applying patch (a) directly changes the value of the global variable a. Therefore, the functions `f`, `g` and their caller `main` are considered different from their previous versions. In contrast, applying patch (b) only changes the body of the function `f`, which impacts its caller `main` but not the function `g` that is independent of `f`. Therefore, the function `g` is considered similar to its previous version by the matching algorithm. Such a matching process is efficient (with regard to the number of functions that are considered similar) when the changes are localized, i.e., when they do not modify global variables accessed by many functions or when they do not change functions that are called by many other functions. More sophisticated techniques exist to identify similar functions or programs for more complex changes [13, 15], such as detecting variable renaming. However, these are beyond the scope of this work and are left for future research.

After identifying the functions that have not changed between two program versions, we aim to reuse the function summaries for these functions to speed up an incremental analysis. We now introduce the concept of function summaries and how they can be soundly reused to avoid reanalyzing the body of a function. In essence, a function summary is a pair of input/output abstract memory states $(\mathcal{I}^\sharp, \mathcal{O}^\sharp)$ that represent the analysis of a function's body. The input state $\mathcal{I}^\sharp$ is the abstract memory state before executing the body of the function and the output state $\mathcal{O}^\sharp$ is the abstract memory state after executing the body of the function. We consider $\mathcal{I}^\sharp$ as the analysis context of f that contains the abstract values of the function's arguments. By storing $(\mathcal{I}^\sharp, \mathcal{O}^\sharp)$ in a cache, we can reuse the output state $\mathcal{O}^\sharp$ when analyzing the same function body with an equivalent input state $\mathcal{I}^\sharp_{\text{new}}$, such as $\mathcal{I}^\sharp_{\text{new}} = \mathcal{I}^\sharp$. However, such a reusability condition is too restrictive and results in many cache misses because the input abstract memory state $\mathcal{I}^\sharp$ contains memory locations that are not necessarily needed to analyze function f. The following example illustrates this issue.

▶ **Example 11.** Consider the following program:

```
1 void f(int *p) { *p = 1; }
2 void main() {
3   int a = 0;
4   f(&a);
5 }
```

At line 4, the analysis infers $(\mathcal{I}^\sharp_4 = \{a \mapsto 0,\ p \mapsto \{\&a\}\}, \mathcal{O}^\sharp_4 = \{a \mapsto 1, p \mapsto \{\&a\}\})$ as the summary of `f`. A developer then applies the following patch that adds two more calls to `f`:

```
4   f(&a);
5 + f(&a);
6 + f(&a);
```

The incremental analysis of the program identifies that function `f` has not changed between both versions of the program, so it tries to reuse the summary of the first call to function `f` at line 4 when analyzing the second call to function `f` at line 5 and the third call to `f` at line 6. Indeed, the effect of the analysis of function `f` for every call is identical as the value of variable a does not impact the analysis of function `f`. However, the reusability condition $\mathcal{I}^\sharp_{\text{new}} = \mathcal{I}^\sharp$ does not hold at line 5 since $\{a \mapsto 1\} \neq \{a \mapsto 0\}$, the first mapping being part of the input state $\mathcal{I}^\sharp_5$ at line 5 and the second one being part of $\mathcal{I}^\sharp_4$. Consequently, the analyzer should analyze the body of `f` again and compute a new summary for the call at line 5, while it could be soundly reused in this case. Therefore, the above-mentioned reusability condition is too restrictive and leads to a lot of cache misses, although correct. Additionally, the abstract input and output states can be quite large for a real-world program, leading to significant

memory overhead. In this example, it is worth noting that, when analyzing the third call to function `f` at line 6, the reusability condition holds at line 5, so the summary can be reused for this particular call.

We propose a more relaxed condition for reusing function summaries. The new condition needs to verify only (a sound over-approximation of) the read memory locations $R^\sharp$ of the function in order to update the values of (a sound over-approximation of) the written memory locations $W^\sharp$. More precisely, given a statement stmt that does not allocate new memory locations, then its analysis summary is a tuple $(\mathcal{I}^\sharp \downarrow R^\sharp, R^\sharp, \mathcal{O}^\sharp \downarrow W^\sharp, W^\sharp)$: When analyzing stmt with a new input state $\mathcal{I}^\sharp_{\text{new}}$, we only check whether $\mathcal{I}^\sharp_{\text{new}}$ and $\mathcal{I}^\sharp$ are equal for the values restricted to $R^\sharp$. If so, we can reconstruct the output state $\mathcal{O}^\sharp_{\text{new}}$ by merging the values of written memory locations $W^\sharp$ of $\mathcal{O}^\sharp$ with the values of unmodified memory locations $\text{dom}(\mathcal{I}^\sharp_{\text{new}}) \setminus W^\sharp$ of $\mathcal{I}^\sharp_{\text{new}}$. The assumption that stmt does not allocate new memory locations is relaxed later in this section to handle dynamic memory allocation. More formally, if the condition $\mathcal{I}^\sharp_{\text{new}} \downarrow R^\sharp = \mathcal{I}^\sharp \downarrow R^\sharp$ holds before analyzing stmt, then its output state $\mathcal{O}^\sharp_{\text{new}}$ is $\mathcal{O}^\sharp \downarrow W^\sharp \sqcap^\sharp (\mathcal{I}^\sharp_{\text{new}} \downarrow (\text{dom}(\mathcal{I}^\sharp_{\text{new}}) \setminus W^\sharp))$.

▶ **Example 12.** Consider again Example 11. We can infer the following analysis summary of function `f` at line 4, along with its set of read and written memory locations.

$$(\mathcal{I}^\sharp_4 \downarrow R^\sharp_4 = \{p \mapsto \{\&a\}\},\ R^\sharp_4 = \{p\},\ \mathcal{O}^\sharp_4 \downarrow W^\sharp_4 = \{a \mapsto 1\},\ W^\sharp_4 = \{a\}).$$

It is worth noting that $\{a \mapsto 0\}$ is not part of the read input state anymore. When analyzing the call to function `f` at line 5 after having patched the code, we must only check whether $\{a \mapsto 1, p \mapsto \{\&a\}\} \downarrow \{p\}$ is equal to $\{p \mapsto \{\&a\}\}$. By definition of the projection, the condition indeed holds. Therefore, we can build the output state $\{a \mapsto 1\} \sqcap^\sharp (\{a \mapsto 0, p \mapsto \{\&a\}\} \downarrow \{p\})$, which is $\{a \mapsto 1, p \mapsto \{\&a\}\}$.

This relaxed condition allows us to reuse the analysis summary of the first call to function `f` at line 4 when analyzing the second call at line 5. It still allows for reusing it at line 6 as well. Additionally, the memory overhead of the incremental analysis is now reduced since the function summary only stores the projected values of the input and output states.

Extension to Dynamic Memory Allocation

In the case of programs that dynamically allocate memory on the heap, the condition of summary reuse on read memory locations is not sufficient to ensure soundness. Consequently, to preserve soundness, functions that allocate memory dynamically and every caller of these functions will not benefit from summaries.

▶ **Example 13.** Consider for instance the following program:

```
1 void f(int **p) { *p = malloc(sizeof(int)); }
2 void main() {
3     int *a;
4     f(&a);
5     f(&a);
6 }
```

Let μ be the allocation site at the call of malloc_μ in function `f`. We infer the following summary for the analysis of function `f` at line 4:

$$(\mathcal{I}^\sharp_4 \downarrow R^\sharp_4 = \{p \mapsto \{\&a\}\},\ R^\sharp_4 = \{p\},\ \mathcal{O}^\sharp_4 \downarrow W^\sharp_4 = \{a \mapsto \langle \mu, 0 \rangle\},\ W^\sharp_4 = \{a\})$$

When analyzing the call to function `f` at line 5, we check the condition on read memory locations and find that it holds. Therefore, the reconstructed output state is $\{a \mapsto \langle \mu, 0\rangle, \langle \mu, 0\rangle \mapsto Z_0^\sharp\}$. This output state is only correct if we assume that the number of allocations allowed on the site μ is 1, i.e., assuming the call to `f` at line 5 would not generate a new memory location. However, if we assume that $k \geq 2$, the reconstructed output for the call to function `f` at line 5 is incorrect, since the analysis of this call should have generated a new memory location $\langle \mu, 1\rangle$ and updated the value of a to the correct address $\langle \mu, 1\rangle$.

The issue with dynamic memory allocation comes from the condition on read memory locations: It does not capture the allocation of new memory locations. To address this issue, we need to verify that, given an abstract input state $\mathcal{I}^\sharp_{\text{new}}$, we would allocate or reuse the same abstract memory locations (def. 7) as with the saved input state $\mathcal{I}^\sharp$. More formally, we want to verify that the value of the next$^\sharp$ function is the same when applied to $\mathcal{I}^\sharp_{\text{new}}$ and $\mathcal{I}^\sharp$ for each allocation site μ of a given statement. Such a verification is only necessary when a statement stmt dynamically allocates memory, i.e., when $A^\sharp \neq \emptyset$.

▶ **Example 14.** Consider Example 13 again. We can infer the following summary for the analysis of function `f` at line 4, along with the set of read, written and allocated memory locations.

$$(\mathcal{I}_4^\sharp \downarrow R_4^\sharp = \{p \mapsto \{\&a\}\},\ R_4^\sharp = \{p\},\ \mathcal{O}_4^\sharp \downarrow W_4^\sharp = \{a \mapsto \langle \mu, 0\rangle\},\ W_4^\sharp = \{a\},$$
$$\mathcal{O}_4^\sharp \downarrow A_4^\sharp = \{\langle \mu, 0\rangle \mapsto Z_0^\sharp\},\ A_4^\sharp = \{\langle \mu, 0\rangle\})$$

When analyzing the call to function `f` at line 5, we also need to verify whether the input state allocates the same memory locations as the saved input state, i.e., $\forall \langle \mu, _\rangle \in A_4^\sharp,\ \text{next}^\sharp(\mu, \mathcal{I}_4^\sharp) = \text{next}^\sharp(\mu, \mathcal{I}_5^\sharp)$. The above condition holds only if the number of allocations allowed on the site μ is 1 or no allocation has been made on the site μ with the saved input state $\mathcal{I}_4^\sharp$.

The following theorem expresses the soundness property related to function summaries.

▶ **Theorem 15** (Safe approximation of the computation of a statement)**.** *Given a statement* ***stmt****, a previously computed abstract state* $\mathbb{S}^\sharp[\![\textbf{\textit{stmt}}]\!]\mathcal{I}^\sharp_{old} = \mathcal{O}^\sharp_{old}$*, reusing the analysis summary of* ***stmt*** *with a new abstract input state* $\mathcal{I}^\sharp_{new}$ *is a safe approximation of the computation of* ***stmt*** *if* $\mathcal{I}^\sharp_{new}$ *and* $\mathcal{I}^\sharp_{old}$ *agree on the values of the read memory locations and the set of memory locations allocated by* ***stmt*** *with* $\mathcal{I}^\sharp_{old}$ *is the same as the set of memory locations allocated by* ***stmt*** *with* $\mathcal{I}^\sharp_{new}$*. More formally, let* $\mathcal{I}^\sharp_{old}, \mathcal{I}^\sharp_{new} \in \mathbb{M}^\sharp$ *be two abstract input states, and let* $R^\sharp := Read^\sharp[\![\textbf{\textit{stmt}}]\!]\mathcal{I}^\sharp_{old}, W^\sharp := Write^\sharp[\![\textbf{\textit{stmt}}]\!]\mathcal{I}^\sharp_{old}$, $A^\sharp := Alloc^\sharp[\![\textbf{\textit{stmt}}]\!]\mathcal{I}^\sharp_{old}$, *and* $\mathcal{O}^\sharp_{old} := \mathbb{S}^\sharp[\![\textbf{\textit{stmt}}]\!]\mathcal{I}^\sharp_{old}$*:*

$$\begin{aligned} &\textit{if } \mathcal{I}^\sharp_{new} \downarrow R^\sharp = \mathcal{I}^\sharp_{old} \downarrow R^\sharp \textit{ and } \forall \langle \mu, _\rangle \in A^\sharp, next^\sharp(\mu, \mathcal{I}^\sharp_{new}) = next^\sharp(\mu, \mathcal{I}^\sharp_{old}) \\ &\textit{then } \mathbb{S}[\![\textbf{\textit{stmt}}]\!]\ \gamma(\mathcal{I}^\sharp_{new}) \\ &\quad \subseteq \gamma((\mathcal{O}^\sharp_{old} \downarrow (W^\sharp \cup A^\sharp)) \sqcap^\sharp (\mathcal{I}^\sharp_{new} \downarrow (dom(\mathcal{I}^\sharp_{new}) \setminus (W^\sharp \cup A^\sharp)))). \end{aligned}$$

Proof. The interesting part of the proof consists of showing that only the values of written and allocated memory locations are modified by the computation of a statement. This means that the values of memory locations that are neither written nor allocated are left unmodified. Additionally, the values of written and allocated memory locations must over-approximate the values of the corresponding memory locations in the concrete computation. The complete proof is available in the extended version. ◀

6 Incremental Analysis with Loop Invariant Reuse

The previous section has shown that, whenever one of the conditions about statements and input states is not satisfied, we need to recompute the function summaries for a given function. This section now shows how we can reuse loop invariants to accelerate the analysis of loops, even if no function summary is available or is reusable. Such an approach was already used in [23] to accelerate the analysis of loops when analyzing nested loops, but without formal details, nor proofs, nor detailed experimental evaluation. This approach works for incremental and non-incremental analyses. We first introduce the program matching process that identifies the loop invariant for reuse. We then show how such an invariant accelerates the analysis of loops and how we can limit the loss of precision induced by such reuse. Finally, we show the soundness and termination of the approach.

Given two program versions P_{new} and P_{old}, we aim to identify similar loop statements in both versions. To this end, we syntactically sort its loops in every function, and we match the loop of index n in function `f` in P_{new} with the loop of same index n in the function with the same name `f` in P_{old}. This matching might be incorrect, typically when one loop statement has been removed and another one has been added in the same function. However, it suffices to reuse some loop invariants from the previous analysis. Furthermore, an incorrect matching does not impact soundness, as demonstrated later in this section.

▶ **Example 16.** Consider the following program and its associated patch:

```
1  void loop() {
2    int i = 0;
3  - while (i < 10)
4  + while (i < 11)
5      i++;
6  }
7  void main() { loop(); }
```

In this example, the loop statement in function `loop` has been modified by changing its upper bound from 10 to 11. Although the loop's condition on both versions of the program are syntaxically different, we consider them as similar since they appear in the same function in the same order. We now know that such a modification invalidates the summaries computed for functions `loop` and `main`. However, we can still reuse the invariant computed for the loop statement in the original analysis of function `loop` in order to accelerate the analysis of the patched version. We now show how we can reuse its loop invariant. Assume the use of the interval domain, as defined in Fig. 1 for the abstract domain of the integer values, and the use of the standard widening operator over intervals at the loop head in order to accelerate convergence when computing the fixpoint. The analysis of the program before the modification of the loop statement is as follows:

$$\text{let } M^\sharp = \{i \mapsto [0,0]\} \text{ in } \mathbb{S}^\sharp[\![\textbf{while } (i<10) \textbf{ do } i := i+1;]\!]M^\sharp \triangleq \bowtie^\sharp_{i<10}(\text{lim } F^\sharp)$$
$$\text{where } F^\sharp(\mathcal{I}^\sharp) \triangleq \mathcal{I}^\sharp \nabla (M^\sharp \sqcup^\sharp \mathbb{S}^\sharp[\![i := i+1;]\!] \circ \bowtie^\sharp_{i<10} \mathcal{I}^\sharp)$$

We start the iteration with the initial abstract state $\bot^\sharp$, and then iterate the abstract semantics of the loop until reaching a post fixpoint. Here are the obtained abstract states:

$$F^{\sharp 0} \triangleq \bot^\sharp \nabla (\{[0,0]\} \sqcup^\sharp \bot^\sharp) = \{[0,0]\}$$
$$F^{\sharp 1} \triangleq \{[0,0]\} \nabla (\{[0,0]\} \sqcup^\sharp \{[1,1]\}) = \{[0,+\infty]\}$$
$$F^{\sharp 2} \triangleq \{[0,+\infty]\} \nabla (\{[0,0]\} \sqcup^\sharp \{[1,10]\}) = \{[0,+\infty]\}$$

The iteration sequence converges to the invariant $[0, +\infty]$ in three iterations. Now, we apply the patch to the program and analyze the modified version. Our strategy for loop invariant reuse consists in starting the iteration sequence with the invariant previously computed (which we will refer to as $\mathcal{I}^\sharp_{\text{prev}}$) instead of starting it from the initial abstract state $\bot^\sharp$. With such a strategy, the iteration sequence of the analysis of the loop for the modified program is as follows: $F^{\sharp 0} \triangleq (\mathcal{I}^\sharp_{\text{prev}} = \{[0, +\infty]\}) \nabla (\{[0, 0]\} \sqcup^\sharp \{[1, 11]\}) = \{[0, +\infty]\}$. The iteration sequence converges to the invariant $[0, +\infty]$ after a single iteration: We successfully reduced the number of iterations needed to converge to the invariant by reusing $\mathcal{I}^\sharp_{\text{prev}}$. Such a reduction might seem not important at a first glance since it "only" removes two iterations, but their accumulation becomes significant when analyzing large programs as shown in Section 7, since such fixpoint computations are frequent and time-consuming.

We now show the impact of reusing loop invariants on the precision of the analysis. We know that the invariant computed for a loop statement in the previous analysis is a sound over-approximation of the concrete least fixpoint. Consequently, it contains values that are not necessarily used by the loop statement. However, such values might have changed in the new version of the program, and reusing the invariant might propagate imprecise values. To limit such an imprecision, we only reuse the values of memory locations that are used inside the loop. Such memory locations are defined as follows:

▶ **Definition 17** (Set of abstract used memory locations).

$$Used^\sharp[\![\textbf{\textit{stmt}}]\!]M^\sharp \triangleq Read^\sharp[\![\textbf{\textit{stmt}}]\!]M^\sharp \cup Write^\sharp[\![\textbf{\textit{stmt}}]\!]M^\sharp \cup Alloc^\sharp[\![\textbf{\textit{stmt}}]\!]M^\sharp.$$

Given a former invariant $\mathcal{I}^\sharp_{\text{prev}}$, an abstract input state $M^\sharp$ and a loop statement **stmt**, we reduce the invariant $\mathcal{I}^\sharp_{\text{prev}}$ to $\mathcal{I}^\sharp_{\text{red}}$ in the following way:

$$\text{let } U^\sharp = Used^\sharp[\![\textbf{stmt}]\!]M^\sharp \text{ in } \mathcal{I}^\sharp_{\text{red}} \triangleq (\mathcal{I}^\sharp_{\text{prev}} \downarrow U^\sharp) \sqcap^\sharp (M^\sharp \downarrow (\text{dom}(M^\sharp) \setminus U^\sharp)).$$

Reducing $\mathcal{I}^\sharp_{\text{prev}}$ to $\mathcal{I}^\sharp_{\text{red}}$ lets us also reduce the memory space used when storing invariants in the cache. This reduction is important when analyzing large programs.

▶ **Example 18.** Suppose we are analyzing the loop statement **while** $(i < 10)$ **do** $i := i + 1$ with the invariant $\mathcal{I}^\sharp_{\text{prev}} = \{i \mapsto [0, +\infty], j \mapsto [1, 1]\}$. Suppose the initial abstract state before the loop is $M^\sharp = \{i \mapsto [0, 0], j \mapsto [0, 0]\}$, where the value of j differs from $\mathcal{I}^\sharp_{\text{prev}}$. We would like to reuse $\mathcal{I}^\sharp_{\text{prev}}$ to accelerate the analysis of the loop, but we would also like to avoid propagating the value of j, as its value would make the analysis less precise.

Initially, the iteration sequence of the analysis of the loop converges to the invariant $\{i \mapsto [0, +\infty], j \mapsto [-\infty, 1]\}$, since the widening operator would replace the lower bound of j with $-\infty$ because j is unstable and decreasing. We show the part of the iteration sequence that propagates the value of j:

$$F^{\sharp 1}(\{j \mapsto [1, 1]\}) \triangleq \{j \mapsto [1, 1]\} \nabla (\{j \mapsto [0, 0]\} \sqcup^\sharp \{j \mapsto [1, 1]\}) = \{j \mapsto [-\infty, 1]\}.$$

However, by forgetting the value of j from $\mathcal{I}^\sharp_{\text{prev}}$, the iteration sequence of the analysis of the loop converges to the invariant $\{i \mapsto [0, +\infty], j \mapsto [0, 0]\}$. The idea is to reuse only the values of memory locations used by the statement. The reduced invariant is as follows:

$$\begin{aligned}\mathcal{I}^\sharp_{\text{red}} =& (\{i \mapsto [0, +\infty], j \mapsto [1, 1]\} \downarrow \{i\}) \sqcap^\sharp (\{i \mapsto [0, 0], j \mapsto [0, 0]\} \downarrow \{j\}) \\ =& \{i \mapsto [0, +\infty], j \mapsto [0, 0]\}\end{aligned}$$

Nevertheless, some imprecision cannot be avoided when reusing loop invariants. Consider the following example:

▶ **Example 19.** Suppose we analyzed the loop statement **while** $(i < 10)$ **do** $i := i + 1$ where the initial abstract state is $M_1^\sharp = \{i \mapsto [0, 0]\}$ and we obtained the invariant $\mathcal{I}^\sharp_{\text{prev}} = \{i \mapsto [0, +\infty]\}$. We now analyze the same loop with $\mathcal{I}^\sharp_{\text{prev}}$ but with a different initial abstract state $M_2^\sharp = \{i \mapsto [1, 1]\}$, where the value of i differs from the two abstract states. The analysis of the loop converges to the invariant $\{i \mapsto [0, +\infty]\}$ when reusing $\mathcal{I}^\sharp_{\text{prev}}$, which is less precise than the invariant $\{i \mapsto [1, +\infty]\}$ that we would have obtained if we had started the iteration sequence from $\bot^\sharp$. Such an imprecision is inevitable when starting the iteration sequence from a correct but less precise invariant, i.e., $\{i \mapsto [1, +\infty]\} \sqsubseteq^\sharp \mathcal{I}^\sharp_{\text{prev}}$.

Finally, we show the soundness and termination of the approach.

▶ **Theorem 20** (Soundness and Termination)**.** *For any loop statement* ***while*** $(e \bowtie 0)$ ***do*** s*, abstract state* $M^\sharp$ *and invariant* $\mathcal{I}^\sharp$*, the limit of the iteration sequence of the analysis of* ***while*** $(e \bowtie 0)$ ***do*** s *starting from* $\mathcal{I}^\sharp$ *and such that* $\bowtie^\sharp_e(lim\ F^\sharp)$ *where* $F^{\sharp 0} = \mathcal{I}^\sharp \nabla (M^\sharp \sqcup^\sharp \mathbb{S}^\sharp[\![s]\!] \circ \bowtie^\sharp_e \mathcal{I}^\sharp)$ *is sound and always terminates.*

Proof. The iteration sequence starting from an abstract state $\bot^\sharp$ is known to converge to a sound approximation of the concrete least fixpoint. However, we can start the iteration sequence from an arbitrary abstract state $\mathcal{I}^\sharp$: As long as the stability test $F^\sharp(\mathcal{I}^\sharp) \sqsubseteq^\sharp \mathcal{I}^\sharp$ which verifies if the invariant is a post-fixpoint is correct, the invariant $\mathcal{I}^\sharp$ is a sound approximation of the concrete least fixpoint, regardless of the steps of the iteration sequence. ◀

In summary, this approach is complementary to function summaries, as it does not require any condition to be satisfied to reuse the previous invariant. We have shown that reusing the previous invariant makes the analysis faster by reducing the number of iterations before reaching a stable iterate but may lose precision for some cases. Section 7 will show that, in practice, reusing loop invariants significantly accelerates the analysis of loops and does not impact the precision of the analysis.

7 Implementation and Evaluation

This section presents our implementation of the proposed techniques for function summaries and loop invariants, built on top of the Eva [4, 6] plug-in of Frama-C [3, 19]. It is evaluated on a benchmark of open-source C programs. The incremental version of Frama-C and the set of programs used for the evaluation are available as supplementary material.

7.1 Implementation

The Eva plug-in already computes function summaries without support for dynamic memory allocation through the Memexec [37] cache. Moreover, Frama-C already provides a mechanism to store analysis results in a dedicated file [5]. Last, Frama-C also provides an abstract syntax tree (AST) diff tool to compare the ASTs of two relatively similar programs. In our work, we first extended the Memexec cache to support dynamic memory allocation and to compute and store loop invariants. Then, the saved function summaries and loop invariants are reloaded in subsequent analysis runs after comparing the abstract syntax trees of the analyzed programs. Finally, function summaries impacted by the changes are invalidated before running the analysis.

7.1.1 Function Summaries

Eva's Memexec computes and stores function summaries after analyzing a function with a new analysis context. Additionally, Memexec does not bound the number of summaries stored in the cache. We extended Memexec to support dynamic memory allocation by storing the abstract set of memory locations allocated by the function in the summary. However, the reusability condition differs slightly from the one presented in Section 5. In fact, Eva features a mechanism to deallocate memory locations. To do so, Eva removes the memory location from the abstract state when it is freed. More precisely, suppose that we want to analyze a statement $*\&x = \text{malloc}_\mu$ with an abstract input state $M^\sharp$, and we are given a set $A^\sharp$ of memory locations already allocated on the site μ. If Eva finds a memory location $\langle \mu, n \rangle$ in $A^\sharp$ that has been freed, i.e., $\langle \mu, n \rangle \notin \text{dom}(M^\sharp)$, then Eva reuses the memory location $\langle \mu, n \rangle$ instead of generating a new one. This mechanism is particularly useful for avoiding generating new memory locations when the same memory location is allocated and deallocated repeatedly, typically in a loop. It enhances the precision of the analysis by delaying as much as possible the generation of weak memory locations. We leverage this mechanism to reuse function summaries by checking whether the set of allocated memory locations $A^\sharp$ generated by the analysis of the function is reusable or not given a new abstract input state $\mathcal{I}^\sharp_{\text{new}}$, i.e., $A^\sharp \sqcap \text{dom}(\mathcal{I}^\sharp_{\text{new}}) = \emptyset$. This condition is sound with respect to the current handling of dynamic memory allocation in Eva. However, the formal proof of the soundness of this condition is left for future work.

7.1.2 Loop invariants

Contrary to function summaries, Eva had no mechanism to reuse loop invariants. Therefore, we extended it to do so: First, we modified AST Diff to build the correspondence between the loops of the functions of both programs. Then, we added a cache of loop invariants for each loop statements of each function in Memexec. The reusability condition of loop invariants presented in Section 6 states that any loop invariant can be soundly reused. We are left with the task of finding the loop invariant to reuse when multiple invariants are stored in the cache. Finding such an invariant is challenging because, although every choice maintains soundness, it has an impact on the performance and the precision of the analysis. More precisely, we want to find the closest invariant to the one we are looking for. To do so, we decided to store separately new invariants when the analysis of the current function is done with a new analysis context. The analysis context is defined here as the callstack and the abstract values of the argument of the function. When, the same analysis context is encountered, the new invariant is merged using the abstract join $\sqcup^\sharp$ operator with the one stored in the cache.

7.2 Evaluation

Research questions

We evaluate our implementation to address the following research questions:

RQ1: Is incremental analysis more time-efficient than a full analysis?

RQ2: What is the impact of incremental analysis on max memory usage and on-disk storage?

RQ3: What is the impact of incremental analysis on the precision of the analysis?

RQ4: What is the effect of cache loading and AST comparison on analysis time?

Table 1 Program description.

Program	# Commit	LoC	Function	Loop	Diff Summary
PolarSSL	41	28K	818-822	293-302	52 files, 887 (+), 259 (−)
Monocypher	107	7K	660-823	210-244	147 files, 15348 (+), 3395 (−)
Chrony	119	25K	206-265	125-162	109 files, 10754 (+), 1698 (−)

Experimental Setup

Our experiments focus on analyzing three real-world programs: PolarSSL [1], Monocypher [2] and Chrony [3], issued from the Open Source Case Studies (OSCS) [4]. Table 1 shows the total number of commits analyzed, the average number of lines of code (LoC), the minimum and maximum number of functions and loops in the program, and the summary of the diff between the first and last commit. The diff summary shows the total number of files modified, the total number of lines added and removed. All programs, written in C, were already pre-configured and modified to be analyzable with Eva for a classical non-incremental analysis. For our evaluation, we simulate a development scenario where developers modify the source code of these programs and push the changes to the repository. The commits consist of real modifications made by the developers of both projects. Each code commit triggers an analysis run in the continuous integration (CI) pipeline. The analysis process reuses function summaries and loop invariants computed during the previous analysis run. Every commit includes modifications affecting the source code. The code source in OSCS contains annotations made by the maintainers of the repository. These annotations are mandatory to guide the analysis of Eva and ensure it completes in a reasonable time. We extracted these annotations as a patch and applied them to each commit before running the analysis. Since a commit involves changes to the source code, we need to ensure for each commit that the patch applies correctly, that Frama-C can parse the modified code, and that Eva's analysis completes successfully. We took the maximum set of commits that successfully passes these checks for each program. Adding the commits where any of these checks failed would involve changes to the annotations or even the analysis parameters for each additional commit. No additional code annotations were needed for the incremental analysis. Our experiments are executed on a machine with an Intel Core i7-12800H CPU clocked at 2.4 GHz and 64 GB of RAM. The machine runs Manjaro Linux 6.6. We used Frama-C version 28.1 extended with our development for incremental analysis. The analysis parameters were set to the values already used in OSCS for non-incremental analysis. We also set the maximum number of allocation per site k_{lim} to 2 with `-eva-mlevel 2` option and we disabled the possibility of `malloc` to fail with `-eva-no-alloc-returns-null` option.

7.3 Results

To answer the research questions RQ1–RQ4, we evaluate the performance and precision of our approach by focusing on criteria such as analysis time, memory consumption, and number of alarms generated on six different analysis settings for each version of PolarSSL,

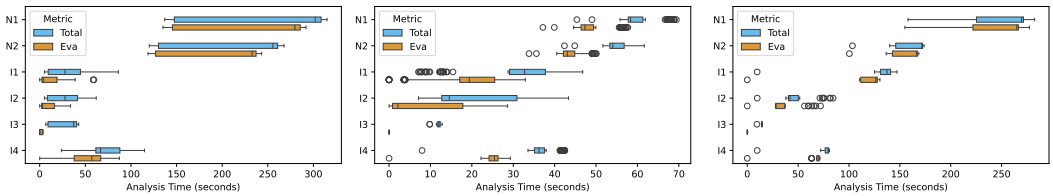
Table 2 Analysis settings.

Setting	Type	Version Reused	Approach
N1	Full	None	Summaries
N2	Full	None	Summaries, Invariants
I1	Incremental	Immediate previous	Summaries
I2	Incremental	Immediate previous	Summaries, Invariants
I3	Incremental	Same version	Summaries, Invariants
I4	Incremental	First version	Summaries, Invariants



(a) Monocypher. **(b)** Chrony. **(c)** PolarSSL.

Figure 8 Analysis time measurement results.

Monocypher and Chrony as shown in Table 2. Full Analyses (N1 and N2) are used as a reference for the comparison with Incremental Analyses (I1, I2, I3, and I4). Even though N1 and N2 do not reuse any previous results, they still benefit from summaries and invariants computed during the ongoing analysis. Incremental Analyses (I1 and I2) reuse the results of the immediate previous version of the program when they are available. For the first version of the program, we run a full analysis similar to N1 (resp. N2) for I1 (resp. I2). The first analysis results are then reused by the second version, and so on. The difference between N1 and N2 (resp. I1 and I2) is the reuse of loop invariants. It allows us to evaluate the impact of reusing loop invariants on the analysis results. Incremental Analysis (I3) sets the limit of the maximum efficiency that can be achieved by our approach. We run first a full analysis of each version of the programs and then we incrementally analyze each version with itself. Therefore, no changes are made to the programs and all summaries and invariants are reused. Incremental Analysis (I4) sets the limit of the minimum efficiency that can be achieved by our approach. We run first a full analysis on the first version (v_0) of the programs and then we incrementally analyze each version ($v_1, ..., v_n$) with the results from the first version (v_0). The analysis of v_0 reusing the results of v_0 represents the best case scenario, whereas the analysis of v_n reusing the results of v_0 where n is the last version of the program represents the worst case scenario. Figure 8 shows the analysis time measurement for each program and analysis setting. We separate the total analysis time from Eva's analysis time. The latter is the abstract interpretation per se while the former includes the time spent on parsing the program, loading the cache and computing the impact of changes. Eva's analysis correctly represents the impact of the approach on the analysis time. The difference between the two metrics represents the overhead of incremental analysis and can be further reduced by optimizing cache loading and program matching. Circles represent outliers, i.e., data points that are significantly different from the rest of the data. Outliers such as sub-second Eva analysis time are not removed from the box plot as they are not considered as anomalies. We only remove the analysis of the first versions of each program in I1 and I2 because they cannot reuse any previous results and therefore they are not relevant. Figure 9 shows the

Figure 9 Impact of invalidated function summaries on analysis time.

Table 3 Summary of analysis results across programs and analysis settings.

	Analysis Setting	Total Alarms	Total Iter.	Max Mem. (MB)	Cache Load(s)	AST Diff.(s)	Cache Size(MB)
P	N1	29097	839265	1161			89.40
	I1	∼	**1.17x**	0.42x	7	4	0.63x
	N2	∼	1.62x	1.01x			1.01x
	I2	0.99x	4.00x	0.50x	5	4	0.68x
M	N1	25356	14478001	2981			130.42
	I1	0.99x	24.46x	0.64x	7	2	0.65x
	N2	**1.01x**	1.34x	0.94x			0.98x
	I2	**1.01x**	35.22x	0.64x	7	2	0.63x
C	N1	404748	1402787	1249			100.75
	I1	0.99x	1.81x	0.76x	2	4	0.85x
	N2	0.99x	1.6x	0.97x			0.99x
	I2	0.99x	6.9x	0.77x	2	4	0.90x

relationship between the number of invalidated function summaries and the analysis time. It also indicates the impact of the changes made to the program by the amount of invalidated summaries. Table 3 presents a comprehensive comparison between a full analysis and an incremental analysis across several performance metrics. We use N1 as the reference for the comparison with the other analysis settings (I1, N2 and I2). We display the ratio (Full Analysis / Incremental Analysis) for most cases except cache loading and AST Diff time. Cases with a significant difference are highlighted in bold. Cases annotated with ∼ indicate that the value is the same as the reference. Cases without values indicate a non-applicable metric. The first column indicates the program analyzed with **P** for PolarSSL, **C** for Chrony, and **M** for Monocypher. The second column indicates the analysis setting. The third column shows the total number of alarms generated by the analysis of all versions. The fourth column shows the total number of iterations required before convergence of all versions. The fifth column shows the peak memory usage. The sixth and seventh columns show the average time spent on loading the cache and computing the impact of changes, respectively. The last column shows the maximum size of the cache file.

RQ1: Time Efficiency

Figure 8 shows that Incremental Analysis I1 (resp. I2) is faster than Full Analysis N1 (resp. N2) for all programs. The efficiency of reusing function summaries alone is shown by N1 and I1. The further reduction in analysis time when reusing loop invariants is shown by

the differences N2-N1 and I2-I1. Moreover, Table 3 shows a significant reduction of the total iteration required to converge to a fixpoint when reusing loop invariants. Additionally, we observe some cases with Chrony where I1 is slower than N1. This is due to the invalidation of a large number of summaries. Consequently, the analysis does not benefit from previous results and the total analysis time increases due to the overhead of loading the cache and computing the impact of changes. Moreover, we observe that Incremental Analysis I1 is slower than Full Analysis N2 for PolarSSL. The number of iterations required to converge shown in Table 3 is higher for I1 than N2. This indicates that reusing function summaries is not always sufficient and the combination of summaries and loop invariants is necessary to achieve the best performance. We observe in Figure 8 for I3 that Eva's analysis time is instantaneous as no summaries are invalidated. Consequently, the total analysis time is only spent on loading the cache and computing the impact of changes. We observe in Figure 9 for I4 that the analysis time increases as the number of invalidated summaries increases. However, I4 is still more time-efficient than N2 in most cases. Nevertheless, the number of invalidated summaries is still not the best indicator – although better than the raw commit diff – to predict the outcome the analysis time. Indeed, the analysis time of each function can be different depending on its complexity. For example, the analysis of a function with a large number of loops or having deeply nested function calls is more time-consuming than the analysis of a logging function. The significant reduction in analysis time shows the efficiency of our incremental approach, making it highly suitable for use in CI/CD environments where quick feedback on code changes is essential.

RQ2: Max Memory Usage and On-Disk Storage

Table 3 shows that Incremental Analysis uses more memory than Full Analysis for all programs. This increase in memory usage is expected as we trade memory for time efficiency. Additionally, adding summaries and invariants to the cache increases the size of the dedicated file on disk. However, we believe that the increase in memory consumption and on-disk storage of Incremental Analysis is still acceptable and worth the time efficiency gained as they remain stable during the analysis. Moreover, the number of summaries and invariants we store is currently unbounded, thus, it is possible to modify this strategy and dynamically adjust this number in case of memory issues.

RQ3: Precision

We compare the total number of alarms generated by each analysis setting to N1 to assess the precision of our approach. We observe three different cases in Table 3: First, all incremental analysis settings I2 for all programs generated more alarms than N1. This behavior is expected as the reuse of loop invariants might introduce imprecision in the analysis. Although, we observe only a very slight increase in the number of alarms. Second, the number of alarms generated by I1 for Chrony and Monocypher also increases compared to N1. This increase is directly related to the reuse of function summaries involving dynamic memory allocation (summaries of function without dynamic memory allocation are not impacted). More precisely, we found that reusing summaries that contain weak memory locations introduces imprecision in the analysis in some cases because a full Eva analysis could have reused a strong memory location instead. This behavior is related to the definition of the next function which does not take into account memory deallocation, therefore, when the maximum number of allocation per site k_{lim} is reached, the function next always points to the last weak memory location. Third, the number of alarms generated by N2 and I2 for Monocypher decreases compared

to N1. Although unexpected, this behavior is related to the non-monotonicity property of widenings. More precisely, the reuse of loop invariants during the analysis of loops leads to the generation of more precise values. The non-monotonicity property of widening is studied in [9], and we have therefore an experimental evidence of its impact on real-world programs instead of crafted examples. Overall, this indicates that the incremental approach maintains a high level of precision, ensuring that the incremental approach is about as good as the non-incremental approach.

RQ4: Cache Loading and Program Matching

Table 3 shows that the overhead of loading the cache and computing the impact of changes is acceptable. The actual cases where such overhead is significant are when Eva's analysis time is very fast. Nonetheless, there is still room for improvement such as a partial or deferred cache loading and the use of more efficient program matching algorithms.

Summary

Overall, our approach offers substantial benefits in terms of time efficiency, with an acceptable memory usage and on-disk storage cost, and a slight overhead in loading the cache and computing the impact of changes. The analysis remains precise enough and even more precise in some cases. The reuse of loop invariants further enhances performance. These results suggest that incremental analysis is a valuable technique for improving the efficiency of static analysis in CI/CD environments.

Threats to Validity

We identify the following threats to the validity of our results: We reuse mostly the same analysis parameters as the ones already configured for a non-incremental analysis. Therefore, the effects of changing these parameters have not been explored: Our results could vary significantly when modifying them. Even though we conduct our experiments on three real-world programs, the generalizability of our results to other programs remains uncertain. The specific characteristics of these programs could influence the results, making their applicability to other programs unknown.

8 Related work

Incremental static analysis is a technique that has gained significant attention in recent years due to the need for fast and efficient analyses of large growing codebases. This technique speeds up non-incremental analyses by reusing previous analysis results and avoiding redundant work. This section reviews the current state of the art in incremental static analysis by abstract interpretation and highlights the gap that our work fills.

Incremental Modular Analysis. Modular analyses [12], based on summaries [7, 36, 35, 22, 27, 8] enable incremental analysis by analyzing only the modules that are affected by the changes in the program. Work in [35] proposes an approach to make modular static analysis incremental by exploiting dependencies between modules. They show that the dependencies computed during the analysis can be used to bound the impact of a change. Compared to this work our approach is more generic and does not require the original analysis to be modular. Work in [16] proposes a modular incremental analyzer capable of performing fine-grain incremental analysis across modular program partitions. However, their approach

assumes that the program is represented as Constrained Horn clauses and the analysis is done on the Horn clause representation. Compared to this work, our approach is more generic and does not require an intermediate representation far from the original program. Commercial tools like Coverity [22] and Infer [27] support modular incremental analysis on large codebases. However, they do not provide a soundness guarantee, which makes them unsuitable for critical software. In particular, Infer only shows the new alarms that are generated by the changes in the code after the analysis. More precisely, Infer only analyses the functions that are impacted by the changes in the code, and it does not guarantee that the analysis is sound. A shared problem with modularity through summaries is the loss of precision induced by the formalism used. A safe modular analysis implies a summary capable of representing all possible call contexts. However, computing a precise summary is costly, which leads to a trade-off between precision and cost. Our approach is inspired by summaries and guarantees safety while maintaining a high level of precision in the analysis.

Incremental Analysis Framework. Recent work has incrementalized several classes of program analyses. For instance, [1] focuses on dataflow analyses but is limited to distributive lattices, which rules out interval abstract domains. Frameworks such as IncA [33, 31, 32] provide a DSL for defining incremental analyses and algorithms to maintain analysis results. IncA translates the user-defined analysis to an intermediate representation such as graph-patterns and Datalog. It supports incremental control flow and points-to analysis for mbedrr C [33], and strong-update points-to, string, and constant propagation analyses for Java [31, 32]. Code modifications rely on a given AST changes notification, e.g., from IDEs. The incremental strategy maintains results across changes and provides real-time feedback. However, correctness and efficiency depend on the limitations and assumptions of the underlying Datalog solver, which analysis developers must satisfy. For instance, [33] do not support recursive user-defined aggregation, which limits analysis results to powerset lattices only. Later work [31] removes such limitations by providing a new algorithm and the use of widenings for infinite-height lattice, but imposes monotonicity over the aggregation operator and are only efficient for intra-procedural analyses. Work in [32] loosen the monotonicity requirement, although still imposes it in some cases and is efficient for inter-procedural analyses. In contrast, our approach does not target user-defined program analyses, but rather incrementalizes the abstract interpretation framework itself. We do not depend on the underlying abstract domains as long as they are non-relational. Abstract domains only need to be a poset, not a CPO nor a lattice, and abstract operators need not be monotonic – which they are often not, due to widenings and reductions. Moreover, our approach does not incrementally maintain analysis results given a set of changes, but rather runs the analysis of a program with a completely new AST and only reuses previous results when possible. This approach is more suitable for existing whole program analysis frameworks, such as Frama-C [3], Mopsa [24] and Astrée [23], where incrementality has not been considered. Other recent work focuses on incrementalizing existing frameworks. Works in [28, 29] incrementalize a generic local fixpoint solver: They show that the data structures used in the solver can be exploited to limit the part of the program that needs to be reanalyzed. They also support on-demand analyses [14] for which, given a specific query to the analyzer, it only computes the necessary dependencies to answer the query. Work in [30] proposes a new operational semantics that reifies abstract interpretation on a directed acyclic graph. It shows that the dependencies between the nodes in the graph can be exploited to invalidate only the nodes that are affected by the change in the program. Compared to these works, we provide a generic framework that can be built on top of any existing abstract interpreter instead

of incrementalizing a particular framework. Reusing fixpoints for incremental analysis is also a common technique used in incremental analysis. For instance, [26] matches pre- and post-change programs and reuses fixpoints for matched parts. It ensures soundness by reanalyzing the entire program, making it conservative–imprecision from mismatches may propagate. Our method limits fixpoint reuse to loops in modified functions or when function summaries cannot be reused, minimizing imprecision propagation.

Cache Reuse. Caching is pervasive and mandatory in practice for any large scale analysis. Abstract interpreters such as Mopsa [24, 25] and Astrée [23] use caching for function and fixpoint iteration in order to accelerate interprocedural and multi-threaded analyses. The Eva [4] plugin of Frama-C [3] also uses caching for function summaries, which did not support dynamic memory allocation before our extension. However, the reuse of the cache is limited to the ongoing analysis and are not designed to be soundly reused across different analyses. Compared to these works, we provide the conditions under which the cache can be reused or invalidated across different analysis.

9 Conclusion and Future Work

This paper presented a sound, generic approach to incremental static analysis based on reusing results from previous analysis runs. We introduced two complementary approaches: one for computing and reusing function summaries–precise and sound when functions are not affected by changes–and another for reusing loop invariants, which remain sound even when loops are modified, though potentially less precise. Combined, these two approaches can be used to significantly accelerate the analysis of large software. They are beneficial for both ongoing analysis and incremental analysis. They are suitable for critical software and for CI/CD approaches. We have implemented our approach in the Eva plugin of Frama-C and evaluated it on a set of open source programs. Our evaluation shows that our approach can significantly reduce the analysis time of these programs, while maintaining a high level of precision. Our next steps include extending function summaries to handle relational domains. As seen in the semantics of the language, function summaries only compute the set of memory locations inductively from the syntax. However, such a set cannot include by definition the set of memory locations that are related to each other. We already implemented a solution to this problem within Eva. More precisely, we compute the transitive closure of the relation between the read memory locations given by each relational domain used in the analysis. The next step is to formalize this solution and to prove its correctness. Additionally, we plan to extend our formalization to handle more features of the C language, such as pointer arithmetic, recursive function calls and memory deallocations. Moreover, we plan to use more sophisticated techniques for the program matching techniques, allowing us to reuse more analysis results. Finally, we plan to take into account changes in the parameters of the analysis. That is, static analyzers are often used after the initial development phase, typically by a separate team whose goal is to certify the absence of runtime errors. To do so, the analysis parameters are finely tuned incrementally to improve the precision. Since the cost of this process is an order of magnitude higher than the cost of the initial analysis, we aim to adapt our approach to this methodology of incremental tuning of the analysis parameters. However, not only is it crucial to avoid any loss of precision resulting from incrementality, as it currently the case, but we also aim to improve the precision of the analysis.

Abstract

In object-oriented languages, dynamic object reclassification is a technique to change the class binding of an object at runtime. Current approaches express when and how to reclassify inside the program's business code, while maintaining internal consistency. These approaches are less suited for programs that need to be consistent with an external context, such as autonomous systems interacting with a knowledge base. This paper proposes declarative dynamic object reclassification, a novel technique that provides a separation of concerns between a program's business code and its adaptation logic for reclassification, expressed via a knowledge base. We present Featherweight Semantically Reflected Java, a minimal calculus for declarative dynamic object reclassification that enables the programmer to define consistency both internally (using a type system) and externally (using declarative classification queries). We use this calculus to study how internal and external consistency interact for declarative dynamic object reclassification. We further implement the technique by extending SMOL, a language for reflective programming via external knowledge bases.

1 Introduction

In traditional object-oriented programming [54, 56], the behaviour of an object instantiated from a class is defined by the methods and properties of that class. However, in many real-world applications, both the object's state and the context in which it operates can change over time. Dynamic object reclassification [15, 16] and typestate-oriented programming [2, 20] are techniques within class-based object-oriented programming that enable *dynamic* class binding of objects at runtime, allowing objects to change their class while retaining their identity. These powerful programming abstractions are particularly useful when an object's context changes over time, and the object needs to adapt to the new context. When the class-binding of objects is dynamic, affected objects need to remain *consistent* with their expected capabilities. For example, consistency becomes critical for dynamic software updates in asynchronous, IoT-driven ecosystems where the local processing of class re-binding may get delayed [34].

Previous approaches to such programming abstractions (e.g., [2, 8, 13–16, 20, 26]) handle the requirements for the reclassification process internally: programs describe classes and reclassification within the same language. This results in (1) a notion of consistency that does not capture the program's context, (2) an operational and low-level view of the conditions for reclassification, and (3) a lack of separation of concerns between describing object behaviour and object reclassification. In contrast, autonomous and self-adaptive systems in, e.g., robotics and digital twins, typically need to adapt to a context represented by external knowledge bases containing information about both the environment and the system itself [7, 42].

This paper proposes a novel approach to dynamic object reclassification, which shifts the reclassification process from ensuring internal consistency, with an operational view of the adaptation logic, to ensuring external consistency, with a declarative view of the adaptation logic. The approach combines three main elements:

Knowledge Base: The context of the program is modelled as an external knowledge base, i.e., a logical representation of facts. This knowledge base evolves independently of the program and can be queried for Boolean results (*"is a certain formula implied by the knowledge base?"*) or retrieval (*"which values satisfy a given formula?"*).

Semantic Reflection expresses that a program can query its own state in context of the knowledge base; this is enabled by a process of lifting the runtime state of a program into the knowledge base [38].

Declarative Object Reclassification is defined via reclassification queries to the knowledge base. The first query defines when an object is *consistent* with a particular class; i.e., it is a *membership* or *classification* query. The second query that defines how to instantiate an object's fields when reclassifying an object into a particular class; i.e., it is a state *retrieval* query. These queries make use of semantic reflection, as they uniformly access both the lifted program state and the context in the knowledge base.

In combination, restrictions on queries and on class inheritance ensure that reclassification preserves type safety. In short, the main contributions of this paper are as follows:

- We propose a declarative dynamic object reclassification technique that uses (1) reflection of the program state into a knowledge base, and (2) the additional context of an external knowledge base, to provide an interface for reclassification queries that encapsulates the adaptation logic from the programmer.
- We formalise our technique in Featherweight Semantically Reflected Java (FSRJ), a novel minimal core calculus in the spirit of Featherweight Java [31], which supports semantic reflection into knowledge bases.
- We prove type soundness for FSRJ and give a precise characterisation of *program coherence*, describing the conditions under which reclassification queries ensure type safety.
- We provide a prototype implementation of declarative dynamic object reclassification as an extension of SMOL [38], a language for self-adaptive digital twins [40] based on Knowledge Graphs [29], including a static check for program coherence.
- We evaluate our prototype implementation by application to GreenhouseDT, an open-source digital twin of a mini-greenhouse [41].

The remainder of this paper is structured as follows: Section 2 illustrates declarative dynamic object reclassification with an example before Section 3 describes Featherweight Semantic Reflected Java, the minimal calculus for reflection into a knowledge base and subsequent object reclassification, as well as the type system. Section 4 describes the implementation in the SMOL language and Section 5 the evaluation on a self-adaptative digital twin. Finally, Section 6 discusses related work and Section 7 concludes with a discussion.

Java

```java
class Plant { int id; String species; }
abstract class Pump {
  int id; int gpioPin; Plant plant;
  void pump(){ ... }; /* uses gpioPin and waters the plant */
}
class NormalPump extends Pump { ... /* methods */ }
class OverheatingPump extends Pump { int maximal; ... /* methods */ }
class Main() {
  Plant pl = new Plant(1, "Ocimum basilicum");
  Pump pu = new NormalPump(2, 7, pl);
  void loop() { while (true) { pu.pump(); System.wait(1); } }
  public static void main(String[] args) { new Main().loop(); }
}
```

Figure 1 Greenhouse digital twin, without domain knowledge and dynamic object reclassification.

2 Overview

This section introduces the programming challenges that we address with declarative dynamic object reclassification, and motivates different technical aspects of our solution. To ease readability in the examples in this section and in the formalisation of Section 3, programs are given with a Java-like syntax and knowledge bases in first-order logic (FOL).

2.1 Programming Challenges

Motivating Scenario. Let us consider as a running example a digital twin of a greenhouse which contains plants and water pumps. These are monitored through sensors measuring their physical *properties*: the height, oxygen level and soil moisture for each plant and the temperature for each pump. Each plant has an associated pump that waters the plant according to a watering profile. The concrete watering profile depends on the stage of the plant (e.g., seedling or mature plant) and the level of functionality of the pump. We first consider a simple configuration of the example in Sections 2 and 3, with one pump, two plants and a temperature monitor for the pump (see Figure 1); we later consider a larger configuration in Section 5, with three pumps, three plants and monitoring more properties.

In the digital twin, each plant is modelled by a `Plant` object and each pump by a `Pump` object. The `Plant` class contains the plant's identifier and scientific `species` name, so further information about the plant can be retrieved from a *domain knowledge base*. The `Pump` class contains the pump's identifier, a reference `pl` to the plant it is watering and a reference `gpioPin` to the output pin needed to operate the physical pump. The `pump` method implements the watering profile for the pump, which depends on the stage of the plant and whether the pump is fully operational or not: A pump is either operating normally (`NormalPump`) or overheated and in need of maintenance (`OverheatingPump`). To avoid overheating, an `OverheatingPump` should run at reduced power. Let us further assume that sensors (not specified here) update a *synchronisation knowledge base* containing the current state of the greenhouse. Thus, our program can retrieve information about the greenhouse from the knowledge base as needed.

The physical entities in the greenhouse evolve over time (e.g., a pump may threaten to overheat). The objects in the digital twin need to adapt their behaviour in accordance with the evolution of the physical entities they are twinning. To address this kind of problem, we propose a dynamic object reclassification technique that is *declarative*; i.e., the adaptation logic for reclassification is derived in the knowledge base. We now introduce a knowledge base for our example, and extend our program with constructs to interact with this knowledge base.

Knowledge Bases and Consistency. A knowledge base is used to organise and make contextual information accessible via an API. To keep the presentation abstract, we here represent knowledge in terms of first-order logic formulas and structure the knowledge base for our digital twin as follows: (1) *domain knowledge* about plants and pumps, see Figure 2a, including the description of the physical pumps and plants in the greenhouse (the so-called domain objects); and (2) *synchronisation knowledge* about the current value of the properties of these domain objects, see Figure 2b. Observe how *consistency* here comes into play: a `Pump` object in the digital twin should be classified in the subclass of `Pump` implementing the watering policy that is appropriate for the current stage of the pump domain object it twins and controls.

We use patterns from ontologies and knowledge representation to model domain knowledge, represent domain objects and domain classes as constants (nullary predicates), and prefix all predicates concerning the domain by `ctx_`. The *membership* of a domain object (e.g., `ctx_o`) in a domain class (e.g., `ctx_C`) is expressed by a binary predicate $\texttt{ctx_in}(\texttt{ctx_o}, \texttt{ctx_C})$. the *value* x of a property `ctx_prop` for a domain object y by the predicate $\texttt{ctx_prop}(y, x)$. For instance, the temperature x of a pump y is expressed by the predicate $\texttt{ctx_temp}(y, x)$.

The formulas **E1**–**E4** in Figure 2a express general knowledge about pumps; the remaining formulas specific knowledge about domain objects (here, one plant and one pump). Formula **E1** states that a pump (`ctx_Pump`) is operating normally (`ctx_NormalPump`) if its temperature is ≤ 50°C, and **E2** that a pump is in danger of overheating (`ctx_OverheatingPump`) if its temperature is > 50°C. Formulas **E3** and **E4** express that the property `ctx_id` uniquely identifies a domain object and that each pump can have only one temperature. The remaining formulas describe the plant and pump in our greenhouse, represented by constants `ctx_plant` and `ctx_pump`; `ctx_Plant` is the domain class of all plants. The last formula states that the pump `ctx_pump` has some temperature. The synchronisation knowledge base, in Figure 2b, contains, for each non-constant property `ctx_prop` of the system, an axiom that states the current value of `ctx_prop`. It contains a formula that states the actual temperature of `ctx_pump`.

To express consistency, we need to relate the `Pump` program objects to the current state of the actual pumps in the greenhouse, as represented by the `ctx_Pump` domain objects. To this aim, we represent the program code and its runtime configuration as knowledge bases. Figure 2c illustrates how the code in Figure 1 can be represented by a *code knowledge base*: predicate $\mathsf{isCls}(x)$ express whether x is a program program class; and $\mathsf{subclass}(x, y)$ express whether x is a subclass of y.

The representation of a program configuration in a knowledge base is known as *semantic lifting* [38], and uses a function defined in terms of the language to serialise runtime configurations into a *lifted-heap* knowledge base, where: $\mathsf{isObj}(x)$ express whether x is a program object (reference); $\mathsf{instOf}(x, y)$ whether x is an object instance of class y; $\mathsf{in}(x, y)$ whether x is an object instance of a subclass of y; and $\texttt{C_f}(x, y)$ express whether x is an object in class a `C` and its field `f` has value y. Figure 2d shows the lifted runtime configuration of the program in Figure 1 after execution of the expression `new Main()` in Line 14 and field initialisation in Lines 11 and 12: here, the program object ι_1, which is stored in `pl`, is an instance of program class `Plant` and ι_2 is an instance of program class `NormalPump`; and $\texttt{Pump_plant}(\iota_2,\iota_1)$ states that the field `plant` in ι_2 of program class `Plant` has value ι_1.

Observe that the fact **D1** $\texttt{ctx_in}(\texttt{ctx_pump}, \texttt{ctx_OverheatingPump})$ can be derived in the knowledge base in Figure 2 (by instantiating the universal quantifier in the axioms **E2** and **E3** with `ctx_plant`), which shows that the lifted runtime configuration in Figure 2d (stating that ι_2 is an instance of `NormalPump`) is *not consistent* with the context. To enable

$(\mathbf{E1})\ \forall x.\ \mathsf{ctx_in}(x, \texttt{ctx_NormalPump}) \Leftrightarrow \big(\mathsf{ctx_in}(x, \texttt{ctx_Pump}) \wedge \exists y.\ \texttt{ctx_temp}(x, y) \wedge y \leq 50\big)$,

$(\mathbf{E2})\ \forall x.\ \mathsf{ctx_in}(x, \texttt{ctx_OverheatingPump}) \Leftrightarrow \big(\mathsf{ctx_in}(x, \texttt{ctx_Pump}) \wedge \exists y.\ \texttt{ctx_temp}(x, y) \wedge y > 50\big)$,

$(\mathbf{E3})\ \forall x, y, z.\ (\texttt{ctx_id}(x, z) \wedge \texttt{ctx_id}(y, z)) \Rightarrow x \doteq y$,

$(\mathbf{E4})\ \forall x, y, z.\ (\texttt{ctx_temp}(x, y) \wedge \texttt{ctx_temp}(x, z)) \Rightarrow y \doteq z$,

$\mathsf{ctx_in}(\mathsf{ctx_plant}, \texttt{ctx_Plant})$, $\mathsf{ctx_in}(\mathsf{ctx_pump}, \texttt{ctx_Pump})$,

$\mathsf{ctx_id}(\mathsf{ctx_plant}, 1)$, $\mathsf{ctx_id}(\mathsf{ctx_pump}, 2)$, $\exists x.\mathsf{ctx_temp}(\mathsf{ctx_pump}, x)$

declarative dynamic object reclassification, we need to connect program objects (e.g., ι_1 and ι_2) and classes (e.g., `Pump`, `NormalPump` and `OverheatingPump`) to corresponding domain objects (e.g., `ctx_plant` and `ctx_pump`) and classes (e.g., `ctx_Pump`, `ctx_NormalPump` and `ctx_OverheatingPump`) in the knowledge base. In particular, we face the following challenges:

Ch1: How can we relate program objects with the external knowledge base, and define *external consistency*, i.e., consistency between program and external knowledge base?

Ch2: How can we program reactions to changes in the consistency of the relation between program and knowledge base?

Ch3: How can we ensure that establishing external consistency does not break internal consistency, i.e., the typing of the program?

Knowledge Bases as Interoperability Layers. While our approach is general to dynamic reclassification, it is worth commenting on the role of the knowledge base, which is motivated by digital twins. In digital twins, the focus is not on highly complex low-level control, but on modularity, composition, and semantic interoperability of different components, where knowledge bases are widely used [42, 60]. Often, all communication between the program and the physical component is handled via the knowledge base. The program is acting as a controller *and* a coordinating component that acts on data that has been already ingested into the knowledge base. This approach, which lends to blackboard architectures [25], also motivates our terminology of *external consistency*: The program is consistent with an external component (namely the physical twin), as described by the synchronization knowledge base. From a model-based perspective, this corresponds to *intermodel consistency* (see, e.g., Feichtinger et al. [19]), in contrast to internal, or intramodel, consistency, which corresponds to type soundness.

Extended Java code

```
1  class Plant { int id; String species; }
2  abstract class Pump classifies λself. ctx_in(self, ctx_Pump) {
3    int id; int gpioPin; Plant plant;
4    void pump(){ ... }; /* uses gpioPin and waters the plant */
5  }
6  class NormalPump extends Pump
7    links λself. ctx_in(self, ctx_Pump) ∧ ∀x. Pump_id(self, x) ⇒ ctx_id(self, x)
8    classifies λself. ctx_in(self, ctx_NormalPump) { ... /* methods */ }
9  class OverheatingPump extends Pump
10   links λself. ctx_in(self, ctx_Pump) ∧ ∀x. Pump_id(self, x) ⇒ ctx_id(self, x)
11   classifies λself. ctx_in(self, ctx_OverheatingPump)
12   retrieves λself, maximal. ∃x. ctx_profile(self, x) ∧ ctx_maximalPower(x, maximal)
13   { int maximal; ... /* methods */ }
14 class Main {
15   Plant pl = new Plant(1, "Ocimum basilicum");
16   Pump pu = new NormalPump(2, 7, pl);
17   void loop() { while (true) { adapt(pu);  pu.pump(); System.wait(1); } }
18   public static void main(String[] args) { new Main().loop(); }
19 }
```

(a) The greenhouse digital twin programmatic part with `links`, `classifies`, `retrieves` and `adapt`.

$$\forall y.\ \mathsf{instOf}(y, \mathsf{NormalPump}) \Rightarrow \big(\mathsf{ctx_in}(y, \mathsf{ctx_Pump}) \wedge \forall x.\ \mathsf{Pump_id}(y, x) \Rightarrow \mathtt{ctx_id}(y, x)\big),$$
$$\forall y.\ \mathsf{instOf}(y, \mathsf{OverheatingPump}) \Rightarrow \big(\mathsf{ctx_in}(y, \mathsf{ctx_Pump}) \wedge \forall x.\ \mathsf{Pump_id}(y, x) \Rightarrow \mathtt{ctx_id}(y, x)\big)$$

(b) Linkage knowledge base. Tautologies from the default `links` clauses of `Plant` and `Main` are omitted.

Figure 3 The greenhouse digital twin programmatic part and the linkage knowledge base.

2.2 Declarative Dynamic Object Reclassification

Based on the knowledge base and scenario above, we now illustrate the mechanisms in the programming language to connect the program with its context at runtime, shown in Figure 3. The formalisation and properties for these mechanisms will be explored in Section 3.

Linkage. To address the first part of challenge ***Ch1***, we propose to dynamically add knowledge about the dynamically created objects of the program's runtime state to the knowledge base. Technically, we add to each non-`abstract` class `C` a `links` clause with a single-parameter λ-predicate $\lambda self.\phi$ to express that $\forall x.\mathtt{instOf}(x, \mathtt{C}) \Rightarrow \phi[self := x]$ is added to the knowledge base (the λ-predicate $\lambda self.\mathtt{true}$ here acts as default). At runtime, dynamically created objects are lifted into the lifted-heap knowledge base by adding a fact about their class membership, e.g., $\mathtt{instOf}(\iota, \mathtt{C})$ for some object ι (cf. Section 2.1). In Figure 3 (Section 2.1), the program class `NormalPump` declares its objects to be members of domain class `ctx_NormalPump` and the domain id (`ctx_id`) and program id (`Pump_id`) to be the same. Similarly for `OverheatingPump` (Section 2.1). Linkage connects the objects of `C` to the context, using domain terminology (i.e., predicate symbols). Figure 3b shows the *linkage knowledge base* containing the added axioms. The first states that every program object that is an instance of `NormalPump`, is also a pump (i.e., a `ctx_Pump` in the domain context), and that the ids are the same. The same states the same for `OverheatingPump`. This links the program object to the domain knowledge, as one can use *domain* axioms (such as **E1** and **E2**) to reason about the *program* objects. This is done as follows. From the lifted heap in Figure 2d, we derive that ι_2 is member of `ctx_OverheatingPump` as follows: By lifting, we have $\mathsf{instOf}(\iota_2, \mathtt{NormalPump})$ and by linkage, $\mathtt{ctx_id}(\iota_2, 2)$. Since `ctx_id` uniquely identifies an object (cf. **E3**), $\mathtt{ctx_pump} \doteq \iota_2$. Applying this equality in the formula $\mathtt{ctx_in}(\mathtt{ctx_pump}, \mathtt{ctx_OverheatingPump})$ (**D1**, see above), we obtain $\mathtt{ctx_in}(\iota_2, \mathtt{ctx_OverheatingPump})$.

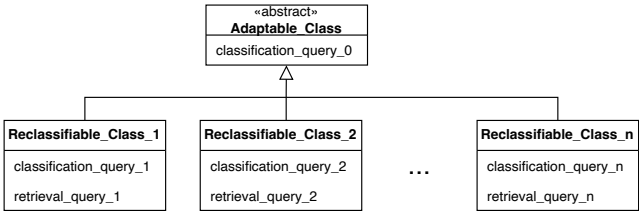

Figure 4 The structure of a class hierarchy for declarative dynamic object classification.

Consistency Declaration. To address the second part of challenge ***Ch1***, we propose to characterise in the knowledge base when an object should belong to a particular class. To this aim, we let objects change between *reclassifiable* subtypes of an *adaptable* (abstract) class. Technically, we add a `classifies` clause with a single-parameter λ-predicate to these classes. If this λ-predicate holds when instantiated for a program object of the given program class, the program object is considered consistent with its context. In our example (see Figure 2), ι_2 is *not* consistent. The only classes with a `classifies` clause are

1. *adaptable* classes, i.e, `abstract` classes that extend classes with no `classifies` clause; and
2. *reclassifiable* classes, i.e., all the subclasses of the adaptable classes (introduced in point 1), that must be non-`abstract` and have no subclasses.

Remark that, as illustrated in Figure 4, each reclassifiable class must (1) directly inherit from an adaptable class; (2) not be inherited from; and (3) have only reclassifiable sibling classes.

Reclassification Queries. Reclassification is the process of changing the program class of an inconsistent program object to a program class that makes the program object consistent. To address challenge ***Ch2***, we provide language support for programming such reclassification. The expression `adapt`(e) (Section 2.1) takes a program object that must be an instance of a reclassifiable class as argument, and checks whether this program object is consistent with the context; if this is not the case, it is reclassified. This is done by searching the knowledge base for a sibling to its current program class in the class hierarchy, that would make the object consistent. For the running example (see Figure 2), this would be the `OverheatingPump` class. Remark that the `adapt` expression is an explicit mechanism to ensure external consistency, but far from the only one. External consistency can also be established implicitly, either lazily, whenever an object is accessed, or periodically in the background, akin to a garbage collector.

To support state transfer for the reclassified object to the fields of its new program class, the programmer adds a `retrieves` clause to each reclassifiable class. This clause provides a λ-predicate with one parameter for the object in question and one for each field declared in the class. We can then infer values from the knowledge base that make the λ-predicate hold. Consider the `OverheatingPump` in Figure 3a: the reclassification query (Section 2.1) first retrieves the profile of the given pump, and then the maximal power it can use when in this stage.

Ensuring Consistency and Type Soundness. To address challenge ***Ch3***, let us observe that it is crucial that the dynamic operations on the knowledge base maintain satisfiability of the knowledge base – otherwise, the program's interactions with the knowledge base would allow incorrect information to be inferred, potentially violating type soundness. Technically, we first ensure that reclassifiable classes are not used as types; e.g., a variable of type `OperationalPump` is not allowed, as it may cause an error when accessed after reclassification. Both this restriction and the structure illustrated in Figure 4 are enforced by the type system; they guarantee that no unsafe access is possible.

Prg ::=	$\mathcal{K}$ $\overline{\texttt{CD}}$ e	Program
$\mathcal{K}$ ::=	$\{\overline{\phi}\}$	Knowledge base
CD ::=	`class` C [`extends` C] [Links] [Adapt] {$\overline{\texttt{FD}}$ $\overline{\texttt{MD}}$}	Class
FD ::=	T f;	Field
T ::=	C | `int`	Type
MD ::=	MH {`return` e;}	Method
MH ::=	T m($\overline{\texttt{T}}$ $\overline{\texttt{x}}$)	Method header
e ::=	x | n | e.f | e.m($\overline{\texttt{e}}$) | `new` C($\overline{\texttt{e}}$) | e.f = e | `null` | `adapt`(e)	Expression
Links ::=	`links` $\lambda z.\phi$	Linkage
Adapt ::=	`classifies` $\lambda z.\phi$ [`retrieves` $\lambda z\overline{z}.\phi$];	Adaptation

Figure 5 FSRJ syntax, where ϕ ranges over first-order logic (FOL) formulas, `C` over class names, `f` over field names, `T` over types (i.e., class names and the basic type `int`), `m` over method names, `x` over local variables (i.e., formal parameters to methods) and z over term variables (so $\lambda z.\phi$ is a unary λ-predicate and $\lambda z\overline{z}.\phi$ a λ-predicate of arity ≥ 1).

To ensure that the interaction between the program and the knowledge base does not introduce errors, we introduce a notion of *program coherence* roughly expressing that

1. every lifted object of a reclassifiable class can be classified as member of the adaptable superclass;
2. every lifted object that is member of an adaptable class can also be classified as member of one of the reclassifiable subclasses; and
3. the `retrieves` λ-predicate associates a value of the correct type to each field.

We say that an object is *hot* to mean that a method invoked on the object has an activation record on the stack, and *cold* otherwise. In the next section we will see that program coherence ensures that reclassification of cold objects is always successful.

3 FSRJ: Featherweight Semantically Reflected Java

This section provides a formal account of programming with semantic reflection in terms of *Featherweight Semantically Reflected Java (FSRJ)*, a minimal core calculus for class-based object-oriented languages with semantic reflection. Our purpose with FSRJ is to formalise the interplay between program execution, semantic reflection and the querying of knowledge bases for dynamic object reclassification. FRSJ is a variant of Featherweight Java (FJ) [31].[1]

3.1 FSRJ Syntax

The syntax of FSRJ is given in Figure 5. We let $\overline{\cdot}$ represent (possibly empty) sequences and $[\cdot]$ represent optional elements. Operations on sequences of pairs are abbreviated in a similar way; e.g., $\overline{\texttt{C}}$ $\overline{\texttt{f}}$ is shorthand for $\texttt{C}_1$ $\texttt{f}_1, \ldots, \texttt{C}_n$ $\texttt{f}_n$. The empty sequence is denoted by $\bullet$ and the length of a sequence $\overline{\texttt{e}}$ is denoted by $\#(\overline{\texttt{e}})$. The set of program variables includes the reserved name `this`, which cannot be used as a name of a field or a method's formal parameter.

In FSRJ, a program Prg consists of a knowledge base $\mathcal{K}$, a list of class definitions $\overline{\texttt{CD}}$ and a main expression e. The knowledge base $\mathcal{K}$, called the *domain knowledge base* of Prg, is set of FOL formulas. A class definition `class C [extends D]` [Links] [Adapt] {$\overline{\texttt{FD}}$ $\overline{\texttt{MD}}$} consists of

[1] FSRJ does not technically extend FJ because cast-expressions are excluded; these are orthogonal to semantic reflection and object reclassification. Further, FSRJ is imperative (it features a field assignment expression), has no implicit root class (`Object`), and classes in FSRJ need not have a superclass and have an implicit constructor which initialises all the fields.

a class name C, an optional clause `extends D` to express inheritance (so D is the immediate superclass of C), an optional linkage clause Links = `links` $\lambda z.\phi$, an optional adaptation clause Adapt = `classifies` $\lambda z.\phi$ [`retrieves` $\lambda z\overline{z}.\psi$] (where, in turn, the `retrieves` part is optional), a list of field definitions $\overline{\texttt{FD}}$ and a list of method definitions $\overline{\texttt{MD}}$. The *knowledge base*, formalising the context in which the program executes, is detailed in Section 3.2. The *linkage clause* expresses that every instance o of C is logically linked by $\lambda z.\phi$; i.e., given the address ι of o, the formula $\phi[z := \iota]$ holds in the context of the program. The *adaptation clause* expresses that if C has the immediate superclass D, then every instance o of an immediate subclass of D is reclassifiable to C by $\lambda z.\phi$ and $\lambda z\overline{z}.\psi$; i.e., given the address ι of o, if the formula $\phi[z := \iota]$ holds in the context of the program then there exist values $\overline{v}$ for the fields of C such that the formula $\psi[z\overline{z} := \iota\overline{v}]$ holds in the context of the program. Types T include names of declared classes and the basic type `int`. Field and method declarations are standard; the fields declared in a class are added to the ones declared in its superclasses, and are assumed to have distinct names (i.e., no field shadowing is allowed). Method names are assumed to be unique in the class; i.e., no method overloading is allowed. It is, however, possible to override methods from the superclass. All fields and methods are public, and each class has an implicit constructor that takes a parameter for each field (inherited or defined) in the class and initialises all the fields.

We assume that the elements of lists of named entities (i.e., class definitions, field definitions, method definitions, method formal parameter declarations) have different names. To simplify the presentation, we use a program Prg as a mapping from class names C to the corresponding class definitions CD; and use a class definition CD as a mapping that maps field and method names to field and method definitions, may map the keyword `extends` to the name of its superclass D, may map each of the keywords `links` and `classifies` to a unary λ-predicate of arity one and the keyword `retrieves` to a λ-predicate of arity $n+1$, where n is the number of fields (defined or inherited) in the class. We assume that programs Prg satisfy the following *well-formedness conditions:*

1. For a class name C appearing anywhere in Prg, we have $\texttt{C} \in \texttt{dom(Prg)}$.
2. There are no cycles in the transitive closure of the immediate `extends` relation.

The *subclassing* relation $<:$ is the reflexive and transitive closure of the immediate `extends` relation. The *subtyping* relation $\leq$ extends $<:$ by adding reflexivity on basic types, i.e., $\texttt{int} \leq \texttt{int}$.

In the sequel, we let the metavariable a range over names and the metavariable AD over definitions. The lookup of the definition of a field or method a in a class C is denoted by `aDef(C)(a)`. For each class in `dom(Prg)`, the function `aDef(C)` is defined as follows:

$$\texttt{aDef(C)(a)} = \begin{cases} \texttt{Prg(C)(a)} & \text{if } \texttt{a} \in \texttt{dom(Prg(C))} \\ \texttt{aDef(D)(a)} & \text{if } \texttt{a} \notin \texttt{dom(Prg(C))} \text{ and } \texttt{Prg(C)(extends)} = \texttt{D} \end{cases}$$

Given a field definition `FD = T f` and a method definition $\texttt{MD} = \texttt{T m } (\overline{\texttt{T}}\ \overline{\texttt{x}})\ \{\cdots\}$, let `signature(FD)` denote the type T of field f and `signature(MD)` the type $\overline{\texttt{T}} \to \texttt{T}$ of method m.

▶ **Example 1** (Greenhouse digital twin in FSRJ). Let us consider the encoding of the Greenhouse example (Figure 3a) in FSRJ. Sequential composition, which is not part of the syntax of FSRJ, can be encoded. For $\texttt{e}_1;\cdots;\texttt{e}_n$ of $n \geq 1$ expressions, define an auxiliary class `Encode` with a method $\texttt{T}_n$ `sqT1_T2_...Tn` $(\texttt{T}_1\ \texttt{x}_1, ..., \texttt{T}_n\ \texttt{x}_n)$ `{ return` $\texttt{e}_n$`;}`, where $\texttt{T}_i$ is the type of $\texttt{e}_i$ $(1 \leq i \leq n)$. Namely, $\texttt{e}_1;\cdots;\texttt{e}_n$ can be expressed as `new Encode().sqT1...Tn(`$\texttt{e}_1, ..., \texttt{e}_n$`)`.

Then, if we ignore the keyword `abstract`, consider `void` as syntactic sugar for `int`, consider the string literal `"Ocinum basilicum"` as syntactic sugar for an integer literal, and consider `System.wait(1)` as syntactic sugar for `new System().wait(1)` where `System` is a

class providing a method `int wait(int x) {...}`, we have that the Java-like code fragment in Figure 3a can be turned into an FSRJ code fragment by replacing the code of the class `Main` (in lines 16-21) by the following FSRJ code:

FSRJ

```
class Main { Plant pl; Pump pu;
 int loop(){ return new Encode().scPump_Plant_int_int_int(pu.plant=this.pl,
                    adapt(pu), pu.pump(), System.wait(1), this.loop(); }
} // Main expression:
new Main(new Plant(1,"Ocinum basilicum"), new NormalPump(2,7,null)).loop()
```

3.2 A FOL Representation of Knowledge Bases

To avoid the technicalities of knowledge representation languages in FSRJ, the knowledge base $\mathcal{K}$ of an FSRJ program is given as a set of closed FOL formulas over a given signature. Formally, signatures and formulas over signatures are defined as follows.

▶ **Definition 2** (Signatures). *A* signature *is a set of predicate symbols* $\Sigma = \Sigma_0 \cup \Sigma_1 \cup \Sigma_2$*, where* Σ_0 *is a set of 0-ary predicate symbols (constants),* Σ_1 *a set of unary predicate symbols, and* Σ_2 *a set of binary predicate symbols (relations). Let* c *range over* Σ_0*,* P *over* Σ_1 *and* R *over* Σ_2*.*

▶ **Definition 3** (FOL formulas and terms over a signature). *Let term variables* z *range over constants in a signature* Σ*. The* formulas ϕ *and* terms t *over* Σ *are defined as follows:*

$$\phi ::= \neg\phi \mid \phi \vee \phi \mid \phi \wedge \phi \mid \phi \oplus \phi \mid \phi \Rightarrow \phi \mid \phi \Leftrightarrow \phi \mid \exists z.\ \phi \mid \forall z.\ \phi \mid P(t) \mid R(t,t) \mid t \doteq t$$
$$t ::= z \mid c$$

Thus, in a λ*-predicate* $\lambda z\overline{z}.\psi$, $z\overline{z}$ is a (non-empty) list of term variables and ϕ a FOL formula. We denote by $\mathsf{FV}(t)$ the free variables in a term t and by $\mathsf{FV}(\phi)$ the free variables in a formula ϕ. The *substitution* $\phi[z := t]$ replaces all free occurrences of the term variable z by the term t in the formula ϕ (we omit its inductive definition here). Given a knowledge base $\mathcal{K}$ and a formula ψ, we let $\mathcal{K} \Rightarrow \psi$ abbreviate $\big(\wedge_{\phi\in\mathcal{K}}\ \phi\big) \Rightarrow \psi$.

Recall that the semantics of FOL with equality defines the values of terms to be individuals of a domain with an identity-relation, and the values of (well-formed) formulas to be truth values [4]. Thus, the semantics of a formula over a signature Σ is defined relative to an equality-model $\mathcal{M} = \langle \mathcal{D}, \mathcal{I}, \approx \rangle$ and a variable assignment β that maps term variables to elements in the domain $\mathcal{D}$, such that: (1) the interpretation $\mathcal{I} : \Sigma \to \mathcal{D}^n$ maps symbols in Σ_2 to binary relations over $\mathcal{D} \times \mathcal{D}$, symbols in Σ_1 to unary predicates over $\mathcal{D}$, and symbols in Σ_0 to distinct elements in $\mathcal{D}$; and (2) the interpretation $\mathcal{I}(\doteq)$ is the equality-relation $\approx$ on $\mathcal{D}$. In the following definition of satisfiability, we omit the operators $\forall$, $\wedge$, $\oplus$ (which denotes exclusive or), $\Rightarrow$ and $\Leftrightarrow$, since their semantics can be derived by the semantics of the other operators.

▶ **Definition 4** (Satisfiability). *Let* Σ *be signature,* $\mathcal{M} = \langle \mathcal{D}, \mathcal{I}, \approx \rangle$ *an equality-model such that* $\mathcal{I} : \Sigma \to \mathcal{D}$*, and* β *a variable assignment. The values of terms* t *with respect to* β *in* $\mathcal{M}$*, denoted* $[\![t]\!]_{\mathcal{M},\beta}$*, are defined by* $[\![z]\!]_{\mathcal{M},\beta} = \beta(z)$ *and* $[\![c]\!]_{\mathcal{M},\beta} = \mathcal{I}(c)$*. The relation* $\mathcal{M}, \beta \models \phi$*, expressing that a formula* ϕ *is* satisfied *by* $\mathcal{M}$ *and* β*, is defined inductively as follows:*

$$\begin{array}{ll}
\mathcal{M},\beta \models \neg\phi & \textit{iff } \mathcal{M},\beta \not\models \phi \\
\mathcal{M},\beta \models \phi_1 \vee \phi_2 & \textit{iff } \mathcal{M},\beta \models \phi_1 \textit{ or } \mathcal{M},\beta \models \phi_2 \\
\mathcal{M},\beta \models \exists x.\ \phi & \textit{iff } \mathcal{M},\beta[x \mapsto d] \models \phi \textit{ for some } d \in D \\
\mathcal{M},\beta \models P(t) & \textit{iff } [\![t]\!]_{\mathcal{M},\beta} \in \mathcal{M}(P) \\
\mathcal{M},\beta \models R(t_1,t_2) & \textit{iff } \big([\![t_1]\!]_{\mathcal{M},\beta}, [\![t_2]\!]_{\mathcal{M},\beta}\big) \in \mathcal{M}(R)
\end{array}$$

A formula ϕ over Σ is (1) satisfiable *if $\mathcal{M}, \beta \models \phi$ holds for some $\mathcal{M}$ and β, and (2)* valid*, denoted $\models \phi$, when ϕ is satisfiable for every $\mathcal{M}$ and variable assignment.*
A knowledge base $\mathcal{K}$ is satisfiable/valid if $\wedge_{\phi \in \mathcal{K}} \phi$ is satisfiable/valid.
Given a knowledge base $\mathcal{K}$ and a formula ψ, we write $\mathcal{K} \models \psi$ as shorthand for $\models \mathcal{K} \Rightarrow \psi$.

▶ **Example 5** (Domain knowledge base for the Greenhouse digital twin in FSRJ)**.** The domain knowledge base for the FSRJ Greenhouse digital twin is given in Figure 2a.

3.3 Program Typing

In this section we present the type system for FSRJ, detailing especially on the language aspects related to knowledge bases, semantic reflection and dynamic object reclassification.

The function `type`, that extracts the type from a field or method definition, is defined by: `type(T f) = T` and `type(T m(`$\overline{\texttt{T}}$ $\overline{\texttt{x}}$`){···}) =` $\overline{\texttt{T}} \to$ `T`. The lookup of the type of a field or method `a` in the program is defined b:y `aType(C)(a) = type(aDef(C)(a))`. With respect to reclassification, we say that a class `C` ∈ `dom(Prg)` is:

- *standard*, written Std(`C`), if (1) `links` ∈ `dom(Prg(C))`; (2) `classifies` ∉ `dom(Prg(C))`; (3) `retrieves` ∉ `dom(Prg(C))`; and (4) if `C` has a superclass, then this superclass is standard (i.e., if `Prg(C)(extends) = B` for some `B`, then Std(`B`)).
- *adaptable*, written Adp(`C`), if (1) `links` ∉ `dom(Prg(C))`; (2) `classifies` ∈ `dom(Prg(C))`; (3) `retrieves` ∉ `dom(Prg(C))`; and (4) if `C` has a superclass, then this superclass is standard (i.e., if `Prg(C)(extends) = B` for some `B`, then Std(`B`)).
- *reclassifiable*, written Rcl(`C`), if (1) `links` ∈ `dom(Prg(C))`; (2) `classifies` ∈ `dom(Prg(C))`; (3) `retrieves` ∈ `dom(Prg(C))`; and (4) `C` has a superclass which is adaptable (that is, `Prg(C)(extends) = B` and Adp(`B`), for some `B`).

By inspecting the program, it is possible to check that there are no cycles in the transitive closure of the `extends` relation; that, for each class `C` in `dom(Prg)`, the names of the fields in `C` are distinct from the names of inherited fields; that each class is either standard, or adaptable, or reclassifiable; and that each adaptable class has at least a subclass (which is necessarily reclassifiable). We write `sane(Prg)` to express that the program `Prg` satisfies the well-formedness conditions in Section 3.1 and that the following sanity conditions:

1. $\texttt{C}_1 <: \texttt{C}_2$ implies that, for all method names `m`, if $\texttt{aType}(\texttt{C}_2)(\texttt{m})$ is defined, then $\texttt{aType}(\texttt{C}_1)(\texttt{m}) = \texttt{aType}(\texttt{C}_2)(\texttt{m})$.
2. $\texttt{C}_1 <: \texttt{C}_2$ and $\texttt{C}_1 \neq \texttt{C}_2$ imply that, for all field names `f`, if $\texttt{f} \in \texttt{dom}(\texttt{Prg}(\texttt{C}_1))$ then $\texttt{f} \notin \texttt{dom}(\texttt{Prg}(\texttt{C}_2))$.
3. For every `C` ∈ `dom(Prg)`, exactly one of Std(`C`), Adp(`C`) or Rcl(`C`) holds.
4. For every `C` ∈ `dom(Prg)`, if Adp(`C`) then there exists `D` ∈ `dom(Prg)` s. t. `Prg(D)(extends) = C`.
5. Reclassifiable class names are not used as field types, as method parameters or return types.

The typing rules and field lookup rule for FSRJ are given in Figure 6. Rule T-knowledge enforces that the domain knowledge base consists of closed formulas. The typing of expressions is standard, except for rule T-new, which enforces new objects to be typed either by an adaptable or a standard class, and rule T-adapt, which enforces the `adapt`-expression and the argument of `adapt` to be typed by an adaptable class `C`. This allows the argument of `adapt` to be dynamically reclassified to any subclass of `C`.

The typing of `links` clauses ensures that the linkage formula only contains one free variable z, which ensures that the formula can be closed by instantiating z. Similarly, the typing of the `adapts` clause ensures that the free variables of the `classifies`- and `retrieves`-formulas

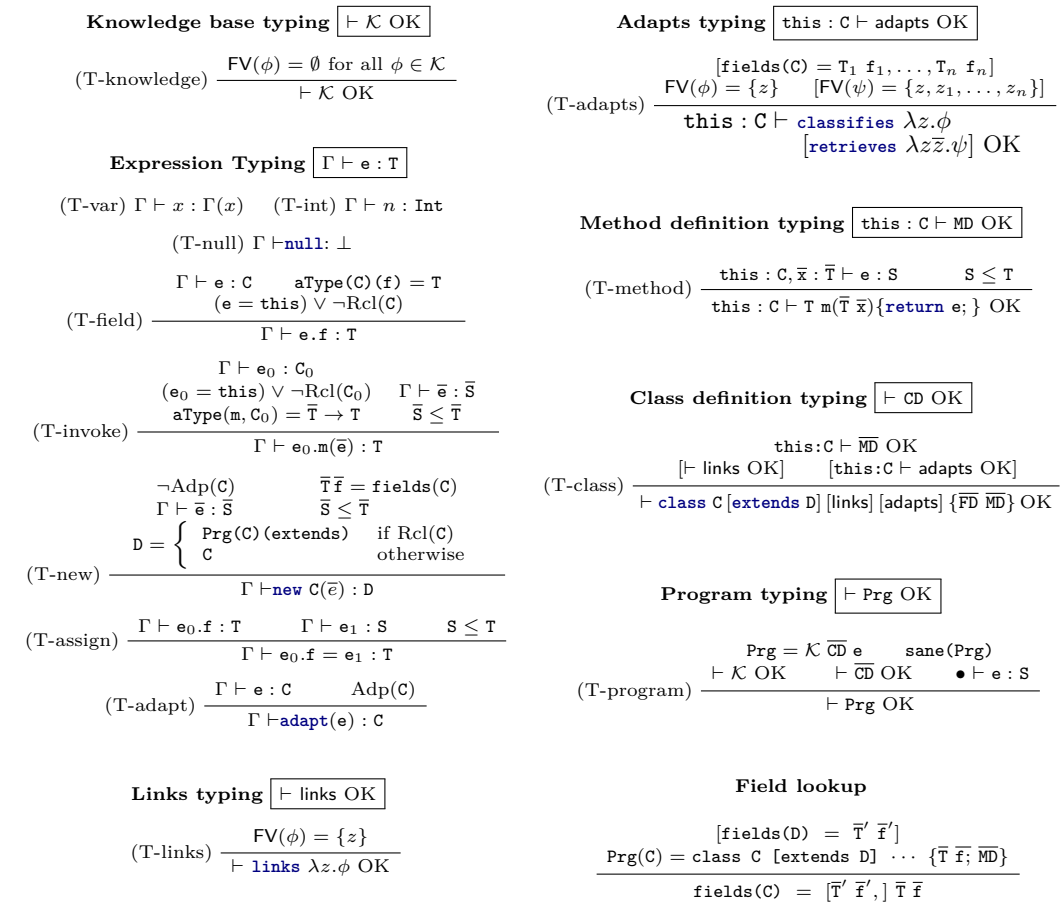

Figure 6 FSRJ: typing rules and field lookup rule.

are known. The typing rules for method and class definitions and for programs are standard recursively checking the different syntactic elements; the latter rule additionally checks that the program is sane. In the type system, the auxiliary function `fields(C)` retrieves all field definitions of a given class `C` in the program `Prg`, including the inherited ones. To type the `null` value, we use the special type $\bot$, which is not a class name, not part of the program and a subtype of any class name. In the sequel, we use the following convention:

- the metavariable `T` denotes either a non-reclassifiable class name or `int`; and
- the metavariable `S` denotes either a non-reclassifiable class name, `int` or $\bot$.

We say that a program `Prg` is well-typed to mean that $\vdash$ `Prg` OK holds.

▶ **Lemma 6** (Syntactic guarantees for well-typed programs). *Let* $\vdash$ *`Prg` OK. Then `sane(Prg)` and if* `new C(...)` *appears in `Prg` then `C` is not adaptable.*

3.4 Code, Linkage and Program Knowledge Bases

The purpose of this section is to explain how to formalise program-specific knowledge bases in FOL. Given a well-typed program $\mathsf{Prg} = \mathcal{K}\,\overline{\mathtt{CD}}\,\mathtt{e}$ with domain knowledge base $\mathcal{K}$, we first define a knowledge base $\mathcal{K}^{\mathsf{code}}$ that reflects part of the code of `Prg` in FOL. The knowledge base $\mathcal{K}^{\mathsf{code}}$ includes general axioms and symbols common to all FSRJ programs, as well as knowledge specifically derived from `Prg`, such as knowledge about declared classes and fields.

$A1$. $\forall x.\ (x \doteq \mathsf{int}) \oplus (x \doteq \mathsf{null}) \oplus \mathsf{isInt}(x) \oplus \mathsf{isObj}(x) \oplus \mathsf{isCls}(x)$,
$A2$. $\forall x.\ \mathsf{isCls}(x) \Leftrightarrow (\mathsf{isStd}(x) \oplus \mathsf{isAdp}(x) \oplus \mathsf{isRcl}(x))$
$A3$. $\mathsf{isInt}(n)$ for all $n \in \mathbb{Z}_k$
$A4$. $\mathsf{isCls}(\mathtt{C})$ for all $\mathtt{C} \in \mathit{Cls}$
$A5$. $\mathsf{isStd}(\mathtt{C})$ for all $\mathtt{C} \in \mathit{Cls}$ such that $\mathrm{Std}(\mathtt{C})$
$A6$. $\mathsf{isAdp}(\mathtt{C})$ for all $\mathtt{C} \in \mathit{Cls}$ such that $\mathrm{Adp}(\mathtt{C})$
$A7$. $\mathsf{isRcl}(\mathtt{C})$ for all $\mathtt{C} \in \mathit{Cls}$ such that $\mathrm{Rcl}(\mathtt{C})$
$A8$. $\forall x.\ \left(\wedge_{n \in \mathbb{Z}_k} \neg(x \doteq n)\right) \Rightarrow \neg\mathsf{isInt}(x)$
$A9$. $\forall x.\ \left(\wedge_{\mathtt{C} \in \mathit{Cls}} \neg(x \doteq \mathtt{C})\right) \Rightarrow \neg\mathsf{isCls}(x)$
$A10$. $\forall x, y.\ \mathsf{subclass}(x, y) \Rightarrow (\mathsf{isCls}(x) \wedge \mathsf{isCls}(y))$
$A11$. $\mathsf{subclass}(\mathtt{C}, \mathtt{C}')$ for all $\mathtt{C}, \mathtt{C}' \in \mathit{Cls}$ such that $\mathtt{C} <: \mathtt{C}'$
$A12$. $\neg\mathsf{subclass}(\mathtt{C}, \mathtt{C}')$ for all $\mathtt{C}, \mathtt{C}' \in \mathit{Cls}$ such that $\mathtt{C} \not<: \mathtt{C}'$
$A13$. $\forall x, y.\ \mathsf{compatible}(x, y) \Leftrightarrow \exists z.\ \mathsf{subclass}(x, z) \wedge \mathsf{subclass}(y, z) \wedge \mathsf{isAdp}(z)$
$A14$. $\forall x, y.\ (\mathsf{instOf}(x, y) \vee \mathsf{in}(x, y)) \Rightarrow (\mathsf{isObj}(x) \wedge \mathsf{isCls}(y))$
$A15$. $\forall x.\ \mathsf{isObj}(x) \Rightarrow \exists y.\ \mathsf{isCls}(y) \wedge \mathsf{instOf}(x, y) \wedge \neg\mathsf{isAdp}(y)$
$A16$. $\forall x, y, z.\ (\mathsf{instOf}(x, y) \wedge \mathsf{instOf}(x, z)) \Rightarrow (y \doteq z)$
$A17$. $\forall x, y.\ \mathsf{in}(x, y) \Leftrightarrow \exists z.\mathsf{instOf}(x, z) \wedge \mathsf{subclass}(z, y)$
$A18$. $\forall x, y.\ \mathsf{hasType}(x, y) \Leftrightarrow (\mathsf{in}(x, y) \vee (\mathsf{isInt}(x) \wedge (y \doteq \mathsf{int})) \vee ((x \doteq \mathsf{null}) \wedge \mathsf{isCls(y)}))$
$A19$. $\forall x.\ \mathsf{in}(x, \mathtt{C}) \Leftrightarrow \exists y.\ \mathtt{C_f}(x, y)$ for all $\mathtt{C} \in \mathit{Cls}$ and $\mathtt{C_f} \in \mathit{Fls}(\mathtt{C})$
$A20$. $\forall x, y, z.\ (\mathtt{C_f}(x, y) \wedge \mathtt{C_f}(x, z)) \Rightarrow (y \doteq z)$ for all $\mathtt{C} \in \mathit{Cls}$ and $\mathtt{C.f} \in \mathit{Fls}(\mathtt{C})$
$A21$. $\forall x, y.\ \mathtt{C_f}(x, y) \Rightarrow \mathsf{in}(x, \mathtt{C}) \wedge \mathsf{hasType}(y, \mathtt{type(C_f)})$ for all $\mathtt{C} \in \mathit{Cls}$ and $\mathtt{C.f} \in \mathit{Fls}(\mathtt{C})$

Figure 7 The code knowledge base.

▶ **Definition 7** (Code knowledge bases). *Given a well-typed FSRJ program* Prg *with domain knowledge base $\mathcal{K}$ over the signature Σ, let $\mathit{Cls} =$ `dom(Prg)` be the set of class names in* Prg*, $\mathit{Fls}(\mathtt{C})$ the set of qualified field names* `C.f` *declared (not inherited) in class* `C`*,* `type(C.f)` *the type of the field* `C.f`*, and $\mathbb{Z}_k = \{z \mid -k \leq z \leq k\}$ (where k is natural number) a set of integers. We denote by Σ^{code} the following signature (where subscripts denote the arity of non-constant symbols):*

$$\mathbb{Z}_k \cup \{\mathsf{int}, \mathsf{null}\} \cup \mathit{Cls} \cup \{\mathtt{C_f}_2 \mid \mathtt{C.f} \in \mathit{Fls}(\mathtt{C})\}$$
$$\cup\{\mathsf{isInt}_1, \mathsf{isObj}_1, \mathsf{isCls}_1, \mathsf{isStd}_1, \mathsf{isAdp}_1, \mathsf{isRcl}_1, \mathsf{subclass}_2, \mathsf{in}_2, \mathsf{compatible}_2, \mathsf{instOf}_2, \mathsf{hasType}_2\}$$

and (without loss of generality) assume that $\Sigma \cap \Sigma^{\mathsf{code}} = \mathbb{Z}_k \cup \{\doteq\}$. The code knowledge base $\mathcal{K}^{\mathsf{code}}$ of Prg *is the set consisting of the formulas over Σ^{code} in Figure 7.*

We briefly discuss the formulas of $\mathcal{K}^{\mathsf{code}}$. Axiom $A1$ expresses that each element in the domain must be either the type name `int`, the value `null`, an integer value, an object or a class; and $A2$ that each class is either standard, adaptable or reclassifiable. Axioms $A3$ declare that each constant $n \in \mathbb{Z}_k$ is an integer and $A4$ declare that each constant $\mathtt{C} \in \mathit{Cls}$ is a class. Axioms $A5$–$A7$ declare the kind (standard, adaptable, reclassifiable) of each constant $\mathtt{C} \in \mathit{Cls}$. Axioms $A8$ express that each integer in the domain is mapped to a constant $n \in \mathbb{Z}_k$ and $A9$ that each class in the domain is mapped to a constant $\mathtt{C} \in \mathit{Cls}$. Axioms $A10$–$A12$ express that the subclass relation relates classes to classes and capture the $<:$ relation of `Prg`. Axiom $A13$ expresses that two (reclassifiable) classes are compatible if and only if they are both subclasses of the same adaptable class. Axiom $A14$ expresses that both the instOf and the in relations relate objects with classes. Axioms $A15$ and $A16$ declare that each object is an instOf of exactly one non-adaptable class. Axiom $A17$ declares that an object is in a class if and only if it is an instOf of a subclass of that class. Axiom $A18$ declares that only null,

integers and objects have types, and which are their types. Axioms $A19$–$A21$ express that the predicate `C_f` models the field `f` of objects of any subclass of `C`, each object has exactly the fields (declared or inherited) in its class, and each field contains exactly one value of the declared type.

▶ **Example 8** (Code knowledge base for the Greenhouse digital twin in FSRJ)**.** A subset of the code knowledge base for the FSRJ program in Example 1 (namely, the subset containing axioms A4 and A11) is given in Figure 2c.

We define the linkage knowledge base to express that each object satisfies the predicate specified by the `links` clause of its class.

▶ **Definition 9** (Linkage knowledge bases)**.** *Let* Prg *be a well-typed FSRJ program with domain knowledge base $\mathcal{K}$ over Σ. Let $Cls = \mathit{dom(Prg)}$. The* linkage knowledge base $\mathcal{K}^{\mathsf{link}}$ of Prg *is the set of formulas over the signature $\Sigma \cup \Sigma^{\mathsf{code}}$ defined by $\forall x.\ \mathsf{instOf}(x, \mathtt{C}) \Rightarrow \phi[z := x]$ for all $\mathtt{C} \in Cls$ and $\mathit{Prg}(\mathtt{C})(\mathtt{links}) = \lambda z.\phi$.*

▶ **Example 10** (Linkage knowledge base for the Greenhouse digital twin in FSRJ)**.** The linkage knowledge base for the FSRJ program of Example 1 is given in Figure 3b.

Observe that by combining Σ and Σ^{code}, predicates in $\mathcal{K}^{\mathsf{link}}$ may express connections between an FSRJ program's runtime values (e.g., instances of a class `C`) and the domain knowledge base. We define a knowledge base that comprises the three knowledge bases defined above:

▶ **Definition 11** (Program knowledge bases)**.** *Let* Prg *be a well-typed FSRJ program with domain knowledge base $\mathcal{K}$ over the signature Σ. The program knowledge base of* Prg *is the knowledge base $\mathcal{K}^{\mathsf{Prg}} = \mathcal{K} \cup \mathcal{K}^{\mathsf{code}} \cup \mathcal{K}^{\mathsf{link}}$ over the signature $\Sigma \cup \Sigma^{\mathsf{code}}$.*

▶ **Lemma 12** (Satisfiability of the program knowledge base)**.** *For every well-typed program* Prg *with domain knowledge base $\mathcal{K}$ over the signature Σ. If $\mathcal{K}$ is satisfiable, then the knowledge base $\mathcal{K}^{\mathsf{Prg}} = \mathcal{K} \cup \mathcal{K}^{\mathsf{code}} \cup \mathcal{K}^{\mathsf{link}}$ over the signature $\Sigma \cup \Sigma^{\mathsf{code}}$ is satisfiable.*

3.5 Program Coherence

This section considers requirements on FSRJ programs `Prg` to ensure that reasoning with the program knowledge base $\mathcal{K}^{\mathsf{Prg}}$ is in fact meaningful for declarative object reclassification. These requirements are needed to ensure type soundness; even with a satisfiable domain knowledge base, linking axioms can make the knowledge base incoherent (e.g., define a linkage predicate to introduce false into the knowledge base). Below, let $\lambda z.\phi^{\mathtt{C}} = \mathtt{Prg}(\mathtt{C})(\mathtt{classifies})$ and $\mathrm{Children}(\mathtt{C}) = \{\mathtt{D} \in \mathtt{dom}(\mathtt{Prg}) \mid \mathtt{Prg}(\mathtt{D})(\mathtt{extends}) = \mathtt{C}\}$ for classes `C`. We say that a well-typed program `Prg` with domain knowledge base $\mathcal{K}$ over a signature Σ is *coherent* if:

Coh1: $\mathcal{K}$ is satisfiable. This requirement ensures that models exist for the domain knowledge base.

Coh2: $\mathcal{K} \cup \mathcal{K}^{\mathsf{code}} \models \mathcal{K}^{\mathsf{links}}$. This requirement ensures that the user-defined linkage axioms exclude no interpretation that satisfies the union of the domain and code knowledge bases $\mathcal{K} \cup \mathcal{K}^{\mathsf{code}}$; thus ensuring that each object satisfies the linkage predicate of its class.

Coh3: In every model satisfying $\mathcal{K}^{\mathsf{Prg}}$, for every object x instance of a reclassifiable subclass of an adaptable class `C`, the classification predicate $\phi^{\mathtt{C}}$ of `C` must hold for x:

$$\mathcal{K}^{\mathsf{Prg}} \models \forall x.\ \mathsf{in}(x, \mathtt{C}) \Rightarrow \phi^{\mathtt{C}}[z := x], \text{ for all } \mathtt{C} \in Cls \text{ such that } \mathsf{isAdp}(\mathtt{C}).$$

This requirement ensures that the classification-predicates in the knowledge base respect the subclass hierarchy in the program.

Coh4: In every model satisfying $\mathcal{K}^{\mathsf{Prg}}$, for every object x in an adaptable class $\mathtt{C}$, classification predicate $\phi^{\mathtt{D}}$ of one of its subclasses $\mathtt{D}$ must hold for x:

$$\mathcal{K}^{\mathsf{Prg}} \models \forall x.\ \mathsf{in}(x,\mathtt{C}) \Rightarrow \bigvee_{\mathtt{D}\in\mathrm{Children}(\mathtt{C})} \phi^{\mathtt{D}}[z:=x],\ \text{for all}\ \mathtt{C} \in \mathit{Cls}\ \text{s.t.}\ \mathsf{isAdp}(\mathtt{C}).$$

This requirement ensures that for every instance of a subclass of $\mathtt{C}$, the classification query of at least one of the subclasses of $\mathtt{C}$ always holds.

Coh5: In every model satisfying $\mathcal{K}^{\mathsf{Prg}}$, for every object x in an adaptable class $\mathtt{C}$ and subclass $\mathtt{D}$ of $\mathtt{C}$, the `retrieves` predicate of $\mathtt{D}$ must hold for x when its `classifies` predicate holds:

$$\mathcal{K}^{\mathsf{Prg}} \models \forall x.\big(\mathsf{in}(x,\mathtt{C}) \wedge \phi^{\mathtt{D}}[z:=x]\big) \Rightarrow \Big(\big(\exists \overline{y}.\psi^{\mathtt{D}}[z\overline{z}:=x\overline{y}]\big) \wedge \big(\forall \overline{y}.\psi^{\mathtt{D}}[z\overline{z}:=x\overline{y}] \Rightarrow \mathsf{hasType}(\overline{y},\overline{\mathtt{T}})\big)\Big),$$

for all $\mathtt{C},\mathtt{D} \in \mathit{Cls}$ such that $\mathsf{isAdp}(\mathtt{C})$ and $\mathsf{subclass}(\mathtt{D},\mathtt{C})$

where $\lambda z,\overline{z}.\psi^{\mathtt{D}} = \mathtt{Prg(D)(retrieves)}$, $\mathtt{fields(D)} = \overline{\mathtt{T}}\ \overline{\mathtt{f}}$ (for some $\overline{\mathtt{f}}$), and $\mathsf{hasType}(\overline{y},\overline{\mathtt{T}})$ is shorthand for $\mathsf{hasType}(y_1,\mathtt{T}_1) \wedge \cdots \wedge \mathsf{hasType}(y_n,\mathtt{T}_n)$. This requirement ensures that a reclassified object can be instantiated correctly.

Conditions ***Coh1*** and ***Coh2*** are basic requirements on the domain knowledge base $\mathcal{K}$ and the linkage axioms. They ensure that reasoning over the combined knowledge base is possible. In contrast, ***Coh3***–***Coh5*** are required for type soundness (cf. Theorem 22): first ***Coh3*** ensures that subclassing in the program and the knowledge base are aligned; then ***Coh4*** ensures that reclassification always succeeds in finding a target class $\mathtt{D}$; and finally ***Coh5*** ensures that values for the fields in the target class $\mathtt{D}$ can always be retrieved in the knowledge base and respect the declared types of the fields of class $\mathtt{D}$ in the program.

3.6 Heap Lifting, Synchronisation and Operational Semantics

To model the operational semantics of FSRJ, we introduce the concepts of *address* (of an object in a heap), *stack*, *values*, *object*, *heap*, *lifted-heap knowledge base*, *environment*, *synchronisation knowledge base*, *overall knowledge base*, *runtime expressions* and *runtime configurations*. *Addresses*, ranged over by the metavariable ι, are elements of the denumerable set I. *Stacks* are sequences $\overline{\iota}$, recording the addresses of objects on which methods under execution have been invoked (the address of the object of the most recent invocation is rightmost). *Values*, ranged over by the metavariable v, are either addresses, integers, or the special value `null`. *Objects* are tuples $\langle \mathtt{C}, \overline{\mathtt{f}} = \overline{v}\rangle$, where $\mathtt{C}$ is the class of the object, $\overline{\mathtt{f}}$ the names and $\overline{v}$ the values of the fields. A heap $\mathcal{H}$ maps addresses to objects; the empty heap is denoted by $\emptyset$. A value v occurs in $\mathcal{H}$ if $v \in \{\iota, \overline{v}\}$ for some $\mathcal{H}(\iota) = \langle \mathtt{C}, \overline{\mathtt{f}} = \overline{v}\rangle$, where $\iota \in \mathtt{dom}(\mathcal{H})$.

▶ **Definition 13** (Heaps for well-typed programs). *A heap $\mathcal{H}$ for a well-typed FSRJ program* Prg *is a mapping from addresses to objects such that*

- $\{\iota \mid \iota \text{ occurs in } \mathcal{H}\} = \mathtt{dom}(\mathcal{H})$, *and*
- $\mathcal{H}$ *only contains instances of non-adaptable classes defined in* Prg.

The following definition formalises the concept of *lifting a heap* into a knowledge base.

▶ **Definition 14** (Lifted-heap knowledge base). *Given a heap $\mathcal{H}$ for a well-typed FSRJ program* Prg*, the* lifted-heap knowledge base $\mathcal{K}^{\mathsf{heap}}(\mathcal{H})$*, which lifts $\mathcal{H}$ to FOL, is the set consisting of the following formulas over the signature $\Sigma^{\mathsf{heap}}(\mathcal{H}) = \Sigma^{\mathsf{code}} \cup \mathtt{dom}(\mathcal{H})$:*

*L*1. $\mathsf{instOf}(\iota,\mathtt{C})$ *for all* $\iota \in \mathtt{dom}(\mathcal{H})$ *such that* $\mathcal{H}(\iota) = \langle \mathtt{C}, \mathtt{f}_1 = v_1, \ldots, \mathtt{f}_n = v_n\rangle$

*L*2. $\mathsf{C_f}_j(\iota, v_j)$ *for all* $\iota \in \mathtt{dom}(\mathcal{H})$ *and for all* $\mathsf{C_f}_j$ *such that* $\mathcal{H}(\iota) = \langle \mathtt{C}, \mathtt{f}_1 = v_1, \ldots, \mathtt{f}_n = v_n\rangle$, $\mathtt{C} <: \mathtt{C}_j$, $\mathtt{C}_j.\mathtt{f}_j \in \mathit{Fls}(\mathtt{C}_j)$ *and* $1 \le j \le n$

*L*3. $\forall x.\ \big(\bigwedge_{\iota\in\mathtt{dom}(\mathcal{H})}(x \neq \iota)\big) \Rightarrow \neg\mathsf{isObj}(x)$

The following definition formalises the concept of stating the values of the current properties of the physical assets into a knowledge base.

▶ **Definition 15** (Environment and synchronisation knowledge base)**.** *An environment $\mathcal{E}$ for a well-typed FSRJ program* Prg *is a reference to a mapping that provides suitable current values for the properties of the assets described in the domain knowledge base of* Prg*. The* synchronisation knowledge base $\mathcal{K}^{\mathsf{sync}}(\mathcal{E})$ *of* Prg *provides a witness for each formula* $\exists x.\mathsf{ctx_prop}(\mathsf{ctx_asset}, x)$ *in $\mathcal{K}$ which states that the property* ctx_prop *of the asset* ctx_asset *has some value x.*

We now define a knowledge base that combines the two knowledge bases defined above, which model the dynamic part of the system (the program heap and the current values of the properties physical assets, respectively) with the domain and code knowledge base, which model the static part of the system (domain knowledge and the structure of the code, respectively). The combined knowledge base is operationalised in the operational semantics of FSRJ (see rules R-adapt-y and R-adapt-n in Figure 8).

▶ **Definition 16** (Overall knowledge base)**.** *Given a heap $\mathcal{H}$ and an environment $\mathcal{E}$ for a well-typed FSRJ program* Prg*, the* overall knowledge base $\mathcal{K}^{\mathsf{overall}}(\mathcal{H}, \mathcal{E}) = \mathcal{K}^{\mathsf{Prg}} \cup \mathcal{K}^{\mathsf{heap}}(\mathcal{H}) \cup \mathcal{K}^{\mathsf{sync}}(\mathcal{E})$ *of* Prg*, over the signature $\Sigma^{\mathsf{Prg}} \cup \Sigma^{\mathsf{heap}}(\mathcal{H})$, represents domain knowledge, code, heap and value of the asset properties for the program* Prg *with heap $\mathcal{H}$ and environment $\mathcal{E}$.*

We briefly discuss the formulas of $\mathcal{K}^{\mathsf{heap}}(\mathcal{H})$. The axiom $L1$ introduces individuals ι as instances of classes `C` (Axiom $A14$ of Definition 7 then allows us to infer `isObj(`ι`)`). Axiom $L2$ populates the relation `C_f` for all fields `f` of the classes `C`. Axiom $L3$ states that only addresses from the heap can be considered as objects in the knowledge base $\mathcal{K}^{\mathsf{overall}}(\mathcal{H}, \mathcal{E})$ (thus, $L3$ is similar to the closure axioms $A8$ and $A9$ for integers and classes in Figure 7).

▶ **Example 17** (Lifted-heap and synchronisation knowledge bases for the Greenhouse digital twin in FSRJ)**.** The lifted-heap and synchronisation knowledge bases for the FSRJ program in Figure 3a and Example 1 after the first execution of the `pu.plant=this.pl` expression in the body of the `loop` method, are given in Figures 2b and 2d, respectively.

Recall that (by Lemma 12) the program knowledge base $\mathcal{K}^{\mathsf{Prg}}$ of a well-typed program Prg is satisfiable. The following theorem shows that, if $\mathcal{K}^{\mathsf{Prg}}$ satisfies conditions ***Coh1*** and ***Coh2*** for program coherence (see Section 3.5), then its extension $\mathcal{K}^{\mathsf{overall}}(\mathcal{H}, \mathcal{E})$ with a lifted-heap knowledge base $\mathcal{K}^{\mathsf{heap}}(\mathcal{H})$ and synchronization knowledge base $\mathcal{K}^{\mathsf{sync}}(\mathcal{E})$ for Prg remains satisfiable (thus, reasoning over $\mathcal{K}^{\mathsf{overall}}(\mathcal{H}, \mathcal{E})$ is possible).

▶ **Theorem 18** (Satisfiability of the overall knowledge base)**.** *Let $\mathcal{H}$ be a heap and $\mathcal{E}$ an environment for the well-typed program* Prg *with domain knowledge base $\mathcal{K}$ is over the signature Σ, and let $\mathcal{K}^{\mathsf{Prg}} = \mathcal{K} \cup \mathcal{K}^{\mathsf{code}} \cup \mathcal{K}^{\mathsf{link}}$ be the program knowledge base of* Prg*. If $\mathcal{K}$ is satisfiable and $\mathcal{K} \cup \mathcal{K}^{\mathsf{code}} \models \mathcal{K}^{\mathsf{links}}$, then the overall knowledge base $\mathcal{K}^{\mathsf{overall}}(\mathcal{H}, \mathcal{E})$ is satisfiable.*

Runtime expressions are ranged over by e. Their syntax is obtained from the syntax of expressions (cf. Figure 5) by removing variables `x` (recall that `this` is a variable) and adding addresses ι and `ret`-expressions (of the form `ret`(e), that represent the execution of a method). A *runtime configuration* (*configuration*, for short) is a triple consisting of a heap, a stack and a runtime expression, i.e., $\mathcal{H} \mid \bar{\iota} \mid e$. The reduction relation has the form $\mathcal{H} \mid \bar{\iota} \mid e \to \mathcal{H}' \mid \bar{\iota}' \mid e'$, where the configuration $\mathcal{H} \mid \bar{\iota} \mid e$ gets reduced to $\mathcal{H}' \mid \bar{\iota}' \mid e'$ in one step. A configuration $\mathcal{H} \mid \bar{\iota} \mid e$ that cannot be reduced is called a *normal form*. The initial configuration of a program is $\emptyset \mid \bullet \mid$ `e`, where `e` is the main expression of the program. Remark that configurations only

Evaluation context

$$E ::= [] \mid E.\texttt{f} \mid E.\texttt{m}(\overline{e}) \mid \texttt{v.m}(\overline{v}, E.\overline{e}) \mid \texttt{new C}(\overline{v}, E, \overline{e}) \mid \texttt{v.f} = E \mid \texttt{ret}(E) \mid \texttt{adapt}(E)$$

Congruence rule

$$\frac{\mathcal{H} \mid \overline{\iota} \mid e \to \mathcal{H}' \mid \overline{\iota}' \mid e'}{\mathcal{H} \mid \overline{\iota} \mid E[e] \to \mathcal{H}' \mid \overline{\iota}' \mid E[e']}$$

Figure 8 FSRJ operational semantics: computation rules, method body lookup, evaluation context, and congruence rule.

include stacks to ensure that the operational semantics can model that execution gets stuck when the reclassification of an object on which a method under execution has been invoked is attempted (i.e., that a configuration that is going to perform such a reclassification is a normal form).

The reduction system for FSRJ is given in Figure 8. The reduction rules use the auxiliary function `mBody(m,C)` (for method body lookup) and the *congruence rule* (which uses evaluation contexts) are also given in Figure 8. The rules R-field, R-new and R-assign for field access, object creation and assignment are standard. Rule R-invoke pushes the address of the called object to the stack and a `ret`-expression that stems from method lookup for the called method in the class of the called object, as the new runtime expression. Here, actual parameters and the self-reference are inlined by substitution on the runtime expression. Rule R-ret then pops the object address from the stack, returning the computed value as the new runtime expression.

In FSRJ an object is hot (see Section 2) if and only if its address occurs on the stack. Both rules for dynamic object reclassification, R-adapt-y and R-adapt-n, check whether an object needs to be reclassified and cause the execution to get stuck if an attempt to reclassify a hot object is made. Rule R-adapt-y applies if the object needs to be reclassified (i.e., it cannot be classified as a member of its current class); rule R-adapt-n applies otherwise. We now explain the interaction between execution and the knowledge base in these rules. Both rules check whether the object ι of class `D` is cold and, if so, lift the heap $\mathcal{H}$ to construct the knowledge base $\mathcal{K}^{\text{overall}}(\mathcal{H}, \mathcal{E})$. If the classification predicate ϕ of `D` holds when instantiated with ι, then rule R-adapt-n is applied and the object is not reclassified. Otherwise rule R-adapt-y is applied. Recall from Axiom $A13$ of Definition 7 that two classes are compatible if they have the same superclass. Thus, the premises of rule R-adapt-y identify a class $\texttt{D}'$ that is compatible with `D`, for which the classification predicate ϕ' holds when instantiated with ι. The last premise ensures that the **`retrieves`**-predicate ψ' of $\texttt{D}'$ holds for values $\iota, \overline{v}'$, and the resulting heap on the right-hand side binds ι to an object of class $\texttt{D}'$ in which the fields $\overline{\texttt{f}}$ are bound to $\overline{v}'$.

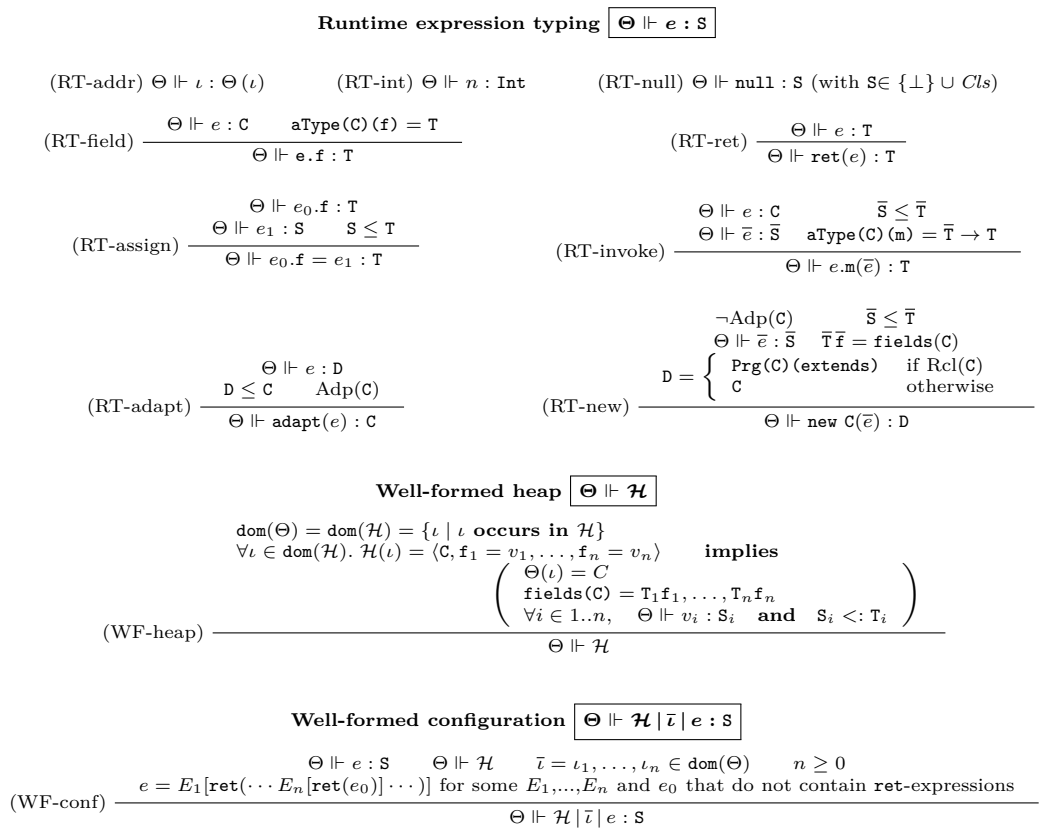

Figure 9 FSRJ run-time typing: runtime expressions, well-formed heaps and configurations.

3.7 Type Soundness for Coherent Programs

In order to prove type soundness for coherent FSRJ programs by a subject reduction theorem and a progress theorem for the small-step operational semantics, we need to formulate a type system for runtime expressions. Expressions containing either a *stupid selection*, i.e., a field selection `null.f` or a method invocation `null.m(...)`, or a *stupid reclassification*, i.e., an object reclassification `adapt(null)`, are not well-typed according to the FSRJ (source level) type system. However, a runtime expression without stupid selections and stupid reclassifications may reduce to a runtime expression containing stupid selections or stupid reclassifications. Therefore, the type system for runtime expressions contains a rule for assigning to the value `null` either the type $\bot$ (like in the source level typing) or any class name.

The type rules for runtime expressions are shown in Figure 9 (left); these rules are of the form $\Theta \Vdash e : \mathtt{S}$, where the environment Θ is a finite (possibly empty) mapping from addresses to class names. Figure 9 (bottom) also presents the notions of *well-formed-heaps* and *well-formed configurations*. The notion of well-formed heap ensures that the environment Θ maps all the addresses in the heap into the class of the corresponding object and that, for every object stored in the heap, the fields of the object contain appropriate values. The notion of well-formed configuration ensures that the heap is well-formed, that the addresses in the stack are defined in the heap, that the runtime expression is well-typed and has a structure that is compatible with the stack – this last check is performed by exploiting evaluation contexts for FSRJ runtime expressions (see Figure 8).

Then, type soundness can be proved by using the standard technique of subject reduction and progress theorems [50]; however, we need to account for declarative object reclassification.

▶ **Lemma 19** (From expression typing to runtime expression typing). *If* $\bullet \vdash e : T$*, then* $\bullet \Vdash e : T$*.*

We now consider subject reduction for the execution of semantically reflected programs. Here, program coherence (Section 3.5) and Theorem 18 (which assumes ***Coh1*** and ***Coh2*** and is independent from ***Coh3***–***Coh5***) are crucial for the case of R-adapt-y:

- an inconsistent (i.e., not satisfiable) knowledge base, or
- a consistent knowledge base that satisfies ***Coh1***–***Coh4*** and does not satisfy ***Coh5*** because the retrieved values for the fields have a wrong type

would allow us to, e.g., infer erroneous values for `retrieves` λ-predicates (see the premise $\mathcal{K}^{\mathsf{overall}}(\mathcal{H}, \mathcal{E}) \models \psi'[z\overline{z} := \iota\overline{v}']$ of rule R-adapt-y), potentially leading to typing errors for runtime configurations after reclassification. Lifting a heap that is not well-typed, could make the knowledge base inconsistent (see Condition L2 in Definition 14 and Axiom A21 in Figure 7). Thus, well-typed runtime configurations ensure consistent overall knowledge bases, which in turn (together with ***Coh5***) ensure that (whenever rule R-adapt-y does not get stuck) dynamic object reclassification produces well-typed runtime configurations.

▶ **Theorem 20** (Subject reduction). *If* $\Theta \Vdash \mathcal{H} \,|\, \overline{\iota} \,|\, e : S$ *and* $\mathcal{H} \,|\, \overline{\iota} \,|\, e \to \mathcal{H}' \,|\, \overline{\iota}' \,|\, e'$ *then there exists* $\Theta' \supseteq \Theta$ *such that* $\Theta' \Vdash \mathcal{H}' \,|\, \overline{\iota}' \,|\, e' : S'$ *for some* S' *such that* $S' \leq S$*.*

Progress relies on program coherence, but not on consistency of the knowledge base. Concretely, ***Coh3***–***Coh5*** guarantee that there exists a class $\mathtt{D}'$ such that the following three premises of rule R-adapt-y hold:

$$\mathcal{K}^{\mathsf{code}} \models \mathsf{compatible}(\mathtt{D}, \mathtt{D}') \qquad \mathcal{K}^{\mathsf{overall}}(\mathcal{H}, \mathcal{E}) \models \phi'[x := \iota] \qquad \mathcal{K}^{\mathsf{overall}}\mathcal{H}, \mathcal{E}) \models \psi'[z\overline{z} := \iota\overline{v}']$$

The last case in the statement of the theorem states that the adaptation of hot objects gets stuck (cf. ***DC3*** in Section 4).

▶ **Theorem 21** (Progress). *Let* $\mathcal{H} \,|\, \overline{\iota} \,|\, e$ *be a well-typed normal form. Then*

1. *either* e *is a value and* $\overline{\iota} = \bullet$*; or*
2. *for some evaluation context* E *we can express* e *as*
   a. *either* $E\,[\mathtt{null.f}]$ *for some* $\mathtt{f}$*, or*
   b. $E\,[\mathtt{null.m}(\overline{v})]$ *for some* $\mathtt{m}$ *and* $\overline{v}$*, or*
   c. $E\,[\mathtt{null.f} = v]$ *for some* $\mathtt{f}$ *and* v*, or*
   d. $E\,[\mathtt{adapt}(\mathtt{null})]$*, or*
   e. $E\,[\mathtt{adapt}(\iota)]$ *for some* $\iota \in \overline{\iota}$*.*

Type soundness follows from Lemma 19 and Theorems 20 and 21. After Theorem 20, this theorem is a second place where consistency (needed only for Theorem 20) and program coherence (needed for Theorem 21) interact: We need the overall knowledge base $\mathcal{K}^{\mathsf{overall}}(\mathcal{H}, \mathcal{E})$ to be consistent so that ***Coh3***–***Coh5*** indeed select the correct class $\mathtt{D}'$ to reclassify.

▶ **Theorem 22** (Type soundness). *Let* $\mathtt{Prg} = \mathcal{K}\,\overline{CD}\,\mathtt{e}_0$ *be well-typed and coherent FSRJ program such that* $\bullet \vdash \mathtt{e}_0 : T_0$*, and* $\emptyset \,|\, \bullet \,|\, e_0 \to^* \mathcal{H} \,|\, \overline{\iota} \,|\, e$ *with* $\mathcal{H} \,|\, \overline{\iota} \,|\, e$ *being a normal form. Then* e *is*

1. *either an integer* n *and* T_0 *is* `int` *and* $\overline{\iota} = \bullet$*; or*
2. $\mathtt{null}$ *and* T_0 *is either* $\bot$ *or a class name and* $\overline{\iota} = \bullet$*; or*
3. *an address* ι *such that* $\mathcal{H}(\iota) = \langle C, \cdots \rangle$ *with* $C \leq T_0$ *and* $\overline{\iota} = \bullet$*; or*
4. *an expression containing either* $\mathtt{null.f}$ *or* $\mathtt{null.m}(\overline{v})$ *or or* $\mathtt{null.f} = v$ *or* $\mathtt{adapt}(\mathtt{null})$ *or* $\mathtt{adapt}(\iota)$ *for some* $\mathtt{f}, \mathtt{m}$*,* $\overline{v}$*,* v *and* ι *such that* $\iota \in \overline{\iota}$*.*

4 Discussion: Design Choices, Implementation and Performance

This section discusses design choices for declarative dynamic object reclassification. We first consider overall design choices for the declarative reclassification mechanism (as reflected in FSRJ), then design choices related to the implementation of declarative dynamic object reclassification (as reflected in our prototype implementation), and finally the implementation itself.

4.1 Overall Design Choices

Our main goal with declarative dynamic object reclassification is to realise a separation of concerns and decoupling between the *application logic*, which describes program behaviour within a given context, and the *adaptation logic*, which describes how the behaviour of the program changes according to context changes. To focus on the basic interaction between adaptation and application logic, we aimed for a simple programming construct for dynamic object reclassification and considered the following design choices:

DC1: The adaptation logic is expressed in a declarative way, leveraging domain knowledge.
DC2: The application logic is expressed by standard class-based object-oriented code.
DC3: Adaptation works on (cold) objects in isolation and hot object adaptation gets stuck.

Concerning ***DC1***, to focus on the general mechanisms of semantic reflection and declarative dynamic object reclassification, FSRJ formalises the knowledge base as a set of FOL formulas. Observe that FSRJ does not impose any restrictions on queries to the knowledge base. For example, `classifies`-predicates may depend on the class of other objects; thus, the reclassification of one object may lead to another object becoming inconsistent. We believe that this flexibility is convenient in a digital twin setting; e.g., a change of requirement monitor for a plant may trigger a change in the controller for the water pump. An alternative design choice would be to restrict queries to, e.g., only depend on the external context (i.e., the domain and synchronisation knowledge). In this case, we avoid the reclassification of one object triggering the reclassification of another, but we could potentially reclassify one object too early, violating the program logic (e.g., changing the watering policy before changing the humidity monitor in the greenhouse). Furthermore, self-adaptation in FSRJ is not deterministic: an object may be reclassifiable to more than one class. If determinism is desired, one can add the additional constraint that the classification queries of its reclassifiable subclasses of all adaptable classes are pairwise disjoint.

Concerning ***DC2***, it can be worth observing that (1) the `links`, `classifies` and `retrieves` clauses could be expressed as, e.g., program annotations or even in a separate file; (2) typing just enforces a programming pattern that treats an adaptable class as an abstract class and its reclassifiable subclasses as final classes that cannot be used as types; and (3) the `adapt` expression could be implemented as a library function.

Concerning ***DC3***, there are several ways to relax this restriction. First, the reclassification of a hot object could be delayed until the object becomes cold (this raises the issue of whether the ordering between delayed adaptations of different objects should be preserved). Second, the `adapt` expression could be replaced or complemented by a class-level adaptation expression to trigger the adaptation of all objects of a class. Third, the `adapt` expression could be externalised; e.g., replaced or complemented by an adaptation triggered by the runtime system, which performs adaptation on all objects of adaptable classes, and delays adaptation for hot objects until they become cold. Relaxing ***DC3*** suggests several interesting directions for further work, including

- a type and effect system [3,57] to ensure that hot object adaptation cannot occur;
- coordinated adaptation of object aggregates (i.e., groups of interconnected objects);
- reclassifiable classes extended by other reclassifiable classes (cf. [15,20]); and
- adaption of hot objects, e.g., the expression `adapt(this)` (cf. [15,20]) or a method defined in a class `C` with an expression `adapt(e)` where `e` has type `C` (cf. [16]).

For the last point, the adaptation logic could depend on the values of fields in the target object; when the object is cold, reclassification might rely on these values satisfying some class invariant (following a program verification methodology, e.g., [1,48]). So, hot object adaptation should require to devise a suitable invariant that the object must satisfy when, e.g., a specific occurrence of the expression `adapt(this)` is executed. For this reason, we decided that even rule R-adapt-n gets stuck on hot objects.

4.2 Implementation and Performance

Implementation. To interact with context in an implementation, we need to be able to check entailment and satisfiability of first-order formulas, and to retrieve witnesses when evaluating the satisfiability of λ-predicates (for `retrieves`-queries). Whereas such functionality is available in, e.g., satisfiability modulo theory solvers, the querying mechanism for declarative dynamic object reclassification would additionally benefit from decidability and availability of formalised domain knowledge. Hence, we consider two possibilities: ontology-based knowledge graphs and logic programming for ***DC2***.

Knowledge Graphs are widely used triple-based data formalisms with numerous variants, of which the RDF/OWL stack is well-suited for reclassification. First, these knowledge graphs are used in numerous industrial ontologies and is an established, core technology for autonomous systems, e.g., in digital twins or robotics [7, 42]. Thus, they enable reuse and provide general knowledge across industries, especially in engineering. Second, these knowledge graphs have a foundation in Description Logics [5], which are decidable fragments of FOL with efficient reasoners and advanced tool-supported pragmatics for non-experts [28].

Logic Programming is widely used and perhaps more rooted in programming and artificial intelligence than knowledge graphs, and also used for autonomous systems [7,32]; numerous implementations are available for knowledge representation and reasoning, e.g., Golog [45]. Logic programming has several variants, such as Prolog-style languages or Answer Set Programming [10,46], which easily produce the witnesses we need for our queries. Logic programming is based on rules that encode domain knowledge, and powerful reasoning engines to achieve high efficiency. However, they are less prevalent for ontologies (i.e., general knowledge with few or no individuals), and seem better suited for concrete planning tasks.

We aim to leverage domain knowledge for self-adaptation in autonomous systems, e.g., digital twins. Observe that FSRJ's knowledge base and queries fit into Description Logic (specifically, the logic $\mathcal{SROIQ}$ underlying OWL 2 [30]). In particular, program coherence (Section 3.5) here maps to *decidable reasoning operations*: ***Coh1*** expresses satisfiability of a $\mathcal{SROIQ}$ knowledge base, ***Coh2*** the entailment of two sets of $\mathcal{SROIQ}$ axioms, and ***Coh3***–***Coh5*** the entailment of a subconcept relation from a set of axioms. In Description Logic syntax, we have $\exists \mathsf{in}.\{\mathtt{C}\} \sqsubseteq \mathsf{cl}_{\mathtt{C}}$ (***Coh3***) and $\exists \mathsf{in}.\{\mathtt{C}\} \sqcap \mathsf{cl}_{\mathtt{C}} \sqsubseteq \bigsqcup_{\mathtt{D}} \mathsf{cl}_{\mathtt{D}}$ (***Coh4***), where $\mathsf{cl}_{\mathtt{C}}$ is the classification concept of class `C`. ***Coh5*** is a special case of type checking knowledge graph access under semantic reflection [39]. Hence, our implementation uses knowledge graphs that connect to existing ontologies.

Further, an implementation of declarative dynamic object reclassification needs to realise semantic lifting to integrate program and knowledge base, and dynamic reclassification via `adapt`-expressions. For these reasons, our implementation is based on SMOL [38], an interpreted research language used to explore connections between programming languages and knowledge graphs, that natively supports heap lifting into a knowledge base. The language is restricted to Description Logics and OWL-based knowledge graphs. The backend uses HermiT [24] for reasoning and Apache Jena (`https://jena.apache.org/`) for graph data management. SMOL was designed to support semantic reflection for the implementation of digital twins [40], but has not yet offered direct programmatic support for reclassification as proposed in this paper.

Our implementation, extending SMOL, goes slightly beyond the design decisions of FSRJ concerning minimality. The main differences are: (1) an explicit constructor that is called after reclassification to establish the classification predicate of the new class; (2) `links`, `classifies` and `retrieves` clauses are inherited; and (3) a more elaborate lifting mechanism, which can be encoded in the one of FSRJ. The constructor ensures a form of reclassification stability, while inheritance of classification predicates ensures a form of behavioural subtyping corresponding to ***Coh3*** (see Section 3.5). Our implementation supports both the `adapt`-expression of FSRJ and an option for reclassification to be triggered periodically by the runtime system. For static program analysis, we exploit the decidability of description logics underlying knowledge graphs to ensure program coherence. Figure 10 gives the SMOL version of our running example, as well as the knowledge graph used as the knowledge base.

Performance. The most expensive operations of FSRJ are on the lifted heap. Experimental results [35] that compare querying a description logic knowledge base with lifted heaps to querying a representation of the same knowledge expressed in program code, show that reasoning in the description logic knowledge base scales significantly better than reasoning with the knowledge represented in the program, both for more complex knowledge bases (i.e., more possible classification targets) and for more elements (i.e., more constants or individuals in the knowledge graph). The direct representation in the program only performs better for simple (<10 classification targets) and small (<2000 individuals) knowledge graphs. Further, remark that heap lifting in SMOL does not generate a full knowledge base every time the lifted heap is accessed. Instead it uses *virtualisation* [59]: the implementation determines which parts of the knowledge base are relevant for a query, and only generates this part.

5 Evaluation of the Prototype Implementation

To evaluate the prototype implementation of declarative dynamic object reclassification, we aim to demonstrate that the reclassification works in practice as expected from the calculus. Concretely, we consider the following research questions:

RQ1: Does derivation in the knowledge base identify the correct class for reclassification?
RQ2: Does derivation in the knowledge base instantiate state correctly during reclassification?

These RQs address essential aspects of the declarative reclassification process, namely that the `classifies`-and `retrieves`-predicates are resolved correctly in the knowledge base at runtime.

Experimental Design and Setup. This evaluation is based on GreenhouseDT [41], an open-source digital twin exemplar of a mini greenhouse developed in SMOL as a sensor-driven system that controls the temperature and humidity on different shelves of a greenhouse, as

OWL

```
ctx:NormalOps EquivalentTo: ctx:Pump and (ctx:temp some xsd:double[<= 50.0])
ctx:Overheating EquivalentTo: ctx:Pump and (ctx:temp some xsd:double[> 50.0])
FunctionalDataProperty(ctx:id)
```

(a) General knowledge as OWL ontology.

SMOL

```
1 abstract class Pump (domain String id, Int GpioPin, Plant plant)
2   links "a ctx:Pump";
3 Unit pump() /* ... */ end end
4 class Normal extends Pump () classifies "<ctx:NormalOps>";
5   /* methods */ end
6 class Overheating extends Pump (Int maximal) classifies "<ctx:Overheating>";
7   retrieves "?this ctx:hasMaintananceProfile [ctx:hasMaximalPower ?maximal]";
8 /* methods */ end
```

(b) SMOL code.

RDF

```
1 ctx:pump1 a ctx:Pump;  ctx:id "2"; ctx:temp 52.5.  run:ob1 a prog:Seedling.
2 run:ob2 a prog:NormalPump; prog:id "2"; prog:GpioPin "7", prog:plant run:ob1.
3 run:ob2 smol:links [a ctx:Pump; ctx:id "1"].
```

(c) Lifting in RDF.

Figure 10 Instantiation of the pump in the Greenhouse digital twin in the SMOL implementation.

well as the soil moisture level of the plants on these shelves. The digital twin uses these sensor readings to determine the control policy of pumps (the actuators of the digital twin) for watering purposes. In our experiments, we focus on the behaviour of the actuators, i.e., the pumps used to water the plants, and use declarative object reclassification to dynamically determine which controller implementation to use for the pumps and to adopt the controller objects accordingly.

We extend GreenhouseDT to capture the following *condition-based maintenance scenario*: to ensure that pumps work properly:

1. the pumps need to operate within a given temperature range, and
2. the pumps should not exceed their expected life time in hours of operation.

If the temperature in an old pump exceeds the temperature thresholds, the pumps could get damaged. For that reason, we implement an extension of the motivating example discussed in Section 2, in which pumps can have one of the following distinct modes of behaviour: normal *operating* mode for pumps that work normally, *overheating* mode for pumps whose temperature is too high, *underheating* mode for pumps whose temperature is too low, and *maintenance* mode for pumps whose temperature is outside the operating range and that have exceeded the expected life span (and therefore need to be stopped). We model the different behavioural modes as reclassifiable subclasses of an adaptable class `Pump`. The exact values for the temperature and age thresholds depend on the type of pump considered; thus, the exact reclassification parameters differ, depending on the specifications of the different pumps. These extensions to the example are realistic as different actuators typically come with different specifications. The extensions also add complexity to the adaptation logic; it is easy to see that as this complexity increases, then a clear separation of concerns between the adaptation logic and the program logic also becomes increasingly attractive, as promoted in the approach of this paper.

Table 1 Pump states based on input temperature and reclassification cycles.

Pump ID	Model	Time (H)	Temperature	Expected Class	Actual Class
After Instantiation					
Pump 1	R385	0	5	Operational	Operational
Pump 2	WPS27	30	80	Overheating	Overheating
Pump 3	R365	3000	94	Maintenance	Maintenance
After First Reclassification					
Pump 1	R385	0	−5	Underheating	Underheating
Pump 2	WPS27	30	41	Overheating	Overheating
Pump 3	R365	2000	50	Operational	Operational
After Second Reclassification					
Pump 1	R385	2500	−5	Maintenance	Maintenance
Pump 2	WPS27	30000	41	Maintenance	Maintenance
Pump 3	R365	300	1	Underheating	Underheating

Our evaluation is performed in terms of two sets of experiments: in the first set, we provide different temperature measurements to evaluate how the system adapts pump controller objects in response to changes in the temperature. We considered scenarios with three pumps with different specifications, and three temperature measurements for each pump: one below the specified temperature range, one above the range and one within the range. In the second set, we additionally let the age of the pumps change to capture a more complex reclassification scenario. In this set, we expanded the previous scenarios with additional age update events that enable the reclassification. In the experiments, we opted to keep the knowledge base invariant; i.e., the actual components that constitute the greenhouse remain the same over time in the domain knowledge base, and only the behaviour of the pump controllers in the virtual layer of the digital twin will change and will require dynamic object reclassification in the digital twin. For ***RQ1***, we then inspected the class targeted by the reclassification in each experiment and, for ***RQ2***, the resulting object state.

Results. Table 1 illustrates the results from the experiments, comparing the expected class of each pump with the actual class after running `adapt`-expressions on objects with different pump specifications in the domain knowledge base in different scenarios. The actual class of each pump in the experiments is retrieved via the API, whereas the expected class of the pumps in the system is determined from the specifications of the different pumps, combined from constraints for the adaptation logic as expressed in the domain knowledge base, and the actual state of the objects in the system after the reclassification process.

To answer ***RQ1***, our experiments used different inputs to adapt the `Pump` objects in the model. When calling `adapt` on an object, the system changes the class of the object depending on the input event, the object state and the domain knowledge base. We checked that the reclassification process worked as formalised in FSRJ by comparing the returned class to the expected ones after running the `adapt` on the `Pump` objects. We ran the two sets of experiments described above on our prototype implementation, in all cases the dynamic object reclassification determined by the `classifies`-predicate selected the correct reclassifiable subclass of the `Pump` class.

To answer ***RQ2***, we ran the same sets of experiments as for ***RQ1***, and inspected the state of the `Pump` objects after the reclassification process, comparing the values of the fields to the expected ones. In all the conducted experiments, the actual state of the `Pump` objects was

consistent with the expected state, demonstrating that the system was able to derive correct values for the `retrieves`-predicates from the domain knowledge base at runtime. The second set of experiments showed that when considering more complex reclassification constraints, our prototype implementation was able to find a correct state.

Threats to Validity. The evaluation of the prototype implementation of declarative dynamic object reclassification has been done on a specific system, GreenhouseDT. Although the adaptation logic involves multiple classes in the knowledge base, the solutions to knowledge base queries have not been very complex. In particular, queries have deterministic solutions in our evaluation setup. We do not foresee particular challenges with non-deterministic queries, as any solution would then be correct (although not necessarily optimal). Furthermore, although the queries in our evaluation involve multiple constraints, they do not involve complex constraint solving (i.e., constraints with many variables). Although well-suited for knowledge representation, knowledge graphs are not particularly strong at complex constraint solving. As our prototype implementation relies completely on the decidable fragments of FOL available in knowledge graphs to answer the queries, the prototype implementation could potentially fail to address ***RQ2*** in cases where solutions might exist. Remark that we do not see this limitation of the prototype as a limitation of the proposed approach, as constraint solvers such as SMT could be integrated in a more refined query-answering mechanism.

6 Related Work

We focus this discussion of related research on two complementary aspects of our work: dynamic object reclassification techniques and programming with external domain knowledge. To the best of our knowledge, the combination of these aspects is novel to our paper.

There is a body of work on dynamic reclassification and related programming mechanisms (e.g., [2, 8, 13–16, 20, 26]), that addresses "self-extension" [13] and extensions of Java and use of the JVM [8, 14, 16, 26], to the design of novel programming languages [2, 20]. This line of work shares the following limitation: the requirements for the reclassification process are handled internally, as part of the program. In contrast, our paper proposes a novel approach to dynamic reclassification, in which we shift the reclassification process from ensuring internal consistency, with an operational description, to external consistency with a declarative description. This way, our work enables a separation of concerns between the adaptation logic and the application logic of the program, that has not been considered in previous work. In contrast to the works mentioned above, we have considered a very basic programming construct for dynamic object reclassification that does not require an advanced type (and effect) system.

Dynamic Software Updating (DSU) [27, 49, 51, 55] addresses runtime changes to the program code, such as software patching and task updates in real-time. DSU leverages techniques such as aspect-oriented programming [52], or changes Java program behaviour [49, 51] at the JVM or Bytecode level by modifying the code base or the instantiated objects, without halting execution. As code elements change, ensuring consistency becomes a major concern: new objects must allow the system to remain consistent with the specification. This can be solved by modifying old objects or by enforcing type renaming [27]. For DSU on asynchronous systems, statically collected type constraints can be enforced at runtime, delaying upgrades until they are type-safe [33]. Compared to reclassification mechanisms, including our work, DSU addresses externally triggered runtime changes to the program

code, while dynamic reclassification programmatically changes the class of objects based on changes in the heap or context, but does not modify the class table. Although software updates are triggered externally, DSU does not consider external consistency as done in our work.

Programming with external domain knowledge is common for self-adaptive systems [11, 44, 58] in, e.g., robotics [7, 9] and digital twins [17], but these systemic approaches generally lack the guarantees that can be provided by language abstractions. Semantic reflection, originally introduced in SMOL [38], has been used for many purposes in digital twins [40], including to repair external consistency by means of self-adaptive techniques [35–37, 40, 41], but so far the adaptation logic had to be programmed by hand. Semantic reflection has also been applied in digital twin architectures [23] to detect internal inconsistencies that trigger reconfigurations, and to drive domain-aware simulations [53]. Whereas this line of work exploits the lifting of runtime states, the self-adaptation has been concerned with the composition of components and not with changing their internal behaviour. In all cases, the adaptation logic was implemented manually without language or type support. Our work overcomes this limitation by means of linguistic support for declarative reclassification.

The adaptation and retrieval queries of our paper can be seen as a form of LINQ [47], used for reflection with knowledge bases for the underlying serialisation. We are not aware of previous applications of such techniques for reclassification. Golog [45] uses FOL to examine and pick elements from its own state and allows decidable model checking when restricted to description logics [6], but has no type or class system. The systems of Fagin et al. [18] and Calvanese et al. [12] include knowledge bases that can be manipulated and updated by the program through epistemic operators, but have no type or class system either. Here, restrictions to description logics gives tractable knowledge base revision [21, 22, 43]. We are not aware of other work on core calculi for semantically reflected programs, as studied in our paper.

7 Conclusion and Future Work

This paper presents declarative dynamic object reclassification and its formalisation in Featherweight Semantically Reflected Java, a minimal core calculus that formalises declarative reclassification in terms of interaction between a program's runtime configurations, domain knowledge and environment. We further show how to implement declarative dynamic object reclassification, and how to use these features in practice for adaptable digital twins. A key advantage of this approach is that developers can specify the reclassification process in a declarative way, disentangled from the business code, using queries to determine when and how an object should be reclassified. This makes it easier to reason about the reclassification process, and to ensure that the system remains consistent with an external context. Unlike previous approaches, declarative reclassification is based on external consistency; i.e., reclassification is driven by external domain knowledge, rather than by the internal state of the system. This makes our approach better suited for applications that must adapt to changes in the environment; it further provides a separation of concerns between the program's business code and its adaptation logic.

Some limitations and possible lines for future work are mentioned in Section 4. This paper does not address the issue of ensuring that the reclassification process is triggered at the right time; instead, reclassification is explicitly invoked. An implicit trigger might extend the range of applications for declarative reclassification; e.g., reclassification could be automatically triggered when certain conditions are met, at fixed time intervals, or during the lifting process.

Such systems would be more dynamic and responsive to changes in the environment. When doing so, it would be crucial to ensure that the system is "free" to act; e.g., the target objects are cold or wait until reclassification is safe. Such constraints point towards DSU and asynchronous update mechanisms; in fact, integrating such mechanisms with a declarative adaptation logic would be an interesting extension of our work. Another interesting line of work is to consider more flexible class hierarchies, e.g., by allowing adaptable subclasses or reclassifiable subclasses of reclassifiable classes, as well as static restrictions to ensure progress, such as type and effect systems to eliminate reclassification attempts on hot objects. Finally, this paper focused on adaptation of cold objects in isolation. In future work we would like to generalise declarative reclassification to reclassification of hot objects and to synchronised reclassification of multiple objects (e.g., all instances of a class or object aggregates) tagged for reclassification, while maintaining the separation of concerns and type soundness of the language.

Abstract

We present a design and implementation of an in-memory object graph store, dubbed ϵStore. Our key innovation is a storage model – epsilon store – that equates an object on the heap to a node in a graph store. Thus any object on the heap (without changes) can be a part of one, or multiple, graph stores, and vice versa, any node in a graph store can be accessed like any other object on the heap. Specifically, each node in a graph is an object (i.e., instance of a class), and its properties and its edges are the primitive and reference fields declared in its class, respectively. Necessary classes, which are instantiated to represent nodes, are created dynamically by ϵStore. ϵStore uses a subset of the Cypher query language to query the graph store. By design, the result of any query is a table (ResultSet) of references to objects on the heap, which users can manipulate the same way as any other object on the heap in their programs. Moreover, a developer can include (transitively) an arbitrary object to become a part of a graph store. Finally, ϵStore introduces compile-time rewriting of Cypher queries into imperative code to improve the runtime performance. ϵStore can be used for a number of tasks including implementing methods for complex in-memory structures, writing complex assertions, or a stripped down version of a graph database that can conveniently be used during testing. We implement ϵStore in Java and show its application using the aforementioned tasks.

1 Introduction

We present a design and implementation of an *in-memory object graph store*, dubbed ϵStore, which enables easy implementation of methods for complex structures, writing assertions over a set of objects on the heap, and substituting (as a lightweight alternative) a graph database in an application during the testing process.

(a) An example schema.

(b) Relational database model.

(c) Traditional graph database model.

(d) ϵStore model.

Figure 1 Comparison of different storage models for the schema in (a).

ϵStore introduces a novel storage model–epsilon storage–that equates an object on the heap to a node in a graph store. Figure 1 illustrates the differences among well-known storage models and epsilon storage; a schema (or class diagram) that is being instantiated is shown in Figure 1a. In ϵStore, any object on the heap (without changes) can be a part of a graph store (or even multiple stores), and vice versa, any node in a graph store can be accessed like any other object on the heap. Specifically, each node in a graph is an object (i.e., instance of a class). Its properties and its edges are the primitive and reference fields declared in its class, respectively. Necessary classes, which are instantiated to represent nodes, are created dynamically by ϵStore.

ϵStore uses a subset of the Cypher query language [22] to query the graph store; Cypher is a powerful yet concise declarative language popular in the space of graph databases [55]. In our design, the result of any query is a table (ResultSet [51]) of references to objects on the heap, which users can manipulate the same way as any other object on the heap in their programs. Moreover, a developer can include (transitively) an arbitrary object to become a part of a graph store. Processing, e.g., parsing, Cypher queries at runtime can be costly, thus, ϵStore includes support for query rewriting into imperative code at compile-time. Our experiments show query rewrites improving query end-to-end execution times by 5x.

We implemented ϵStore in Java. Our primary focus was to enable novel programming style and propose an efficient storage model. We demonstrate the uniqueness of ϵStore with three use cases. First, we demonstrate the use of ϵStore for concisely expressing complex assertions. Second, we show how ϵStore can be used for implementing various methods. Visualisation of object relations and their fields through graphs can simplify API design. We write methods for a dozen of widely-used data structures from popular libraries (e.g., Guava [21]), as well as methods for H2 [23], an in-memory relational database. We compare ϵStore with OGO [57] in terms of runtime performance. OGO is a framework for Java that allows using Cypher to query the heap. Third, we use ϵStore as a lightweight replacement for graph databases; using an in-memory database (or another form of an object store) is common during testing to save setup cost and runtime cost incurred if a full-blown database is used [6]. At the same time, we note that ϵStore is *not* meant to replace graph databases in production as that is not the primary intent for ϵStore. To estimate benefits of using

ϵStore instead of a graph database, if so desired, we use queries and datasets from the Social Network Benchmark (SNB) [1] of the Linked Data Benchmark Council (LDBC) [56]. LDBC is the most popular benchmark for graph databases. The LDBC SNB was designed to model a snapshot of the activity in a realistic social network. Finally, we evaluate the compile-time code rewriting capability of ϵStore, on the LDBC queries, by comparing its performance with the vanilla version of ϵStore.

Our results show versatility of ϵStore for various tasks and good performance in case a lightweight store is sufficient in the testing process.

The key contributions of this paper include:

- **Idea.** We introduce a novel storage model. Besides being used as a traditional object store (manipulated only via queries), our design enables a unique interoperability between imperative code and objects in a graph store. Results of queries are references to objects in a graph store, thus enabling further imperative processing of the results. Furthermore, any object, which is created by imperative code, can be included into a graph store without any intermediate abstraction and queried for complex relations.
- **Formalization.** We formalize the core of the proposed storage model and the set of API operations supported by ϵStore. We also define a mapping and describe the way instances of any existing class, map to nodes and edges, and can be queried.
- **Implementation.** We implemented ϵStore in Java thus using Java features to dynamically create and load classes that are necessary to represent nodes and their properties. We focus on enabling novel programming models. We also perform compile-time query rewriting into imperative code to reduce the runtime cost. Our implementation is publicly available on GitHub[1].
- **Evaluation.** We performed a three-pronged evaluation. First, we evaluated ϵStore on queries and datasets from the LDBC SNB. Second, we evaluated the power of ϵStore by comparing its execution of library methods of Java data structures, implemented as Cypher queries, with OGO. Finally, we evaluated the compile-time code rewriting capability of ϵStore on the LDBC SNB benchmark queries.

2 Example

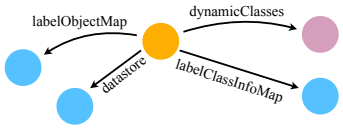
ϵStore is an in-memory graph store. We demonstrate several aspects of ϵStore using an example that showcases the following: (1) creation of a graph store, (2) creation of nodes and edges, (3) querying the graph store, and (4) capturing existing objects into a graph store. We also use this example to provide a brief introduction to the Cypher graph query language [22].

Schema. We use a subset of the LDBC SNB schema shown in Figure 1a to discuss the example. It contains two entities, `Person` and `Post`. The `Person` entity has two properties: `id` of type `long` and `firstName` of type `String`. The `Post` entity has properties: `id` of type `long` and `content` of type `String`. A `Person` can be in a relation (`LIKES`) with a `Post`.

Introduction to Cypher. Cypher is a declarative query language introduced by Neo4j and designed to be expressive when querying graph stores. The labelled property graph (LPG) data model uses nodes and relations to model data. A simple LPG modelling

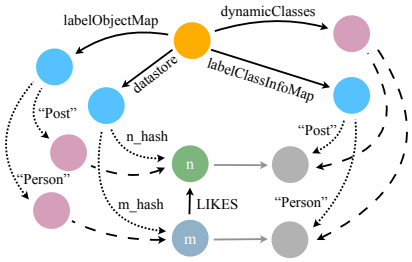
[1] `https://github.com/EngineeringSoftware/eStore`

```
1 /* Instantiate EpsilonStore instance **/
2 EpsilonStore  db = new EpsilonStore ("dbname");
```



(a) Creating an ϵStore instance with name *dbname*.

```
1 /* Add Person and Post nodes to EpsilonStore */
2 db.query(
3  "CREATE (m:`Person` {id: 112, firstName: 'Eve'}"
4  +"-[r:LIKES]->"
5  +"(n:`Post` {id: 481, content: 'About Databases'})"
6 );
```



(b) Insertion of objects without explicit schema (dynamically creating classes `Person` and `Post` at runtime with ASM).

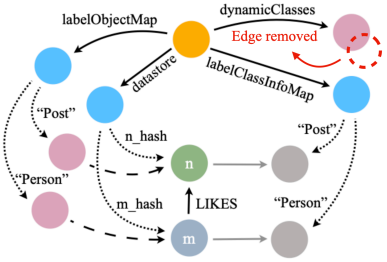
```
1 public class Person {
2     private long id;
3     private String firstName;
4     private Post[] LIKES;
5 }
```

(c) Person.java.

```
1 public class Post {
2     private long id;
3     private String content;
4
5 }
```

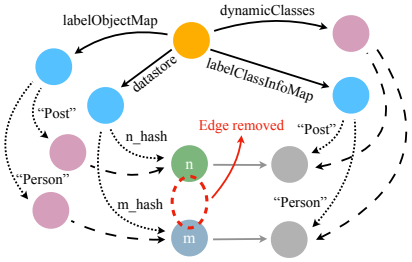
(d) Post.java.

```
1 /* Add Person and Post nodes to EpsilonStore */
2 Post post = new Post(481L, "About Databases");
3 Person person = new Person(112L, "Eve", post);
4 db.captureAll(person);
```



(e) Insertion of objects with pre-defined schema (using existing `Person` and `Post` classes).

```
1 /* Execute Cypher query to remove the LIKES edge */
2 db.query(
3  "MATCH (m:`Person` {id: 112})"
4  +"-[r:LIKES]->"
5  +"(n:`Post` {id: 481}) "
6  +"DELETE r"
7 );
```



(f) Deleting relations using Cypher queries.

Figure 2 An illustrative example to showcase ϵStore for creating a graph store, creating nodes and relations, capturing existing objects, and querying the state of the graph store. The left side of each sub-figure will show the code and the right side will show the corresponding state of the ϵStore instance.

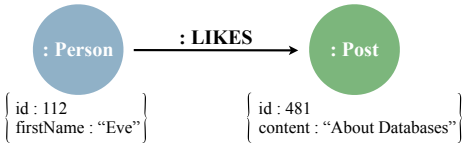


Figure 3 An example labelled property graph.

the schema in Figure 1a is given in Figure 3. In Cypher semantics, the data entities `Person` and `Post` are called *nodes*, and `LIKES` is called a *relation*. Both nodes and relations can have one or more *labels*. Labels function as types, and groups similar nodes and relations. In the example LPG, the `Person` entity has label *Person* and the `Post` entity has label *Post*. The relation between these nodes has the label *LIKES*. Both, nodes and relations, can have properties, which are a set of key-value pairs. The key-value pairs describe the property name and value. The `Person` node has properties *id* with value 112 and *firstName* with value "Eve". A node may have 0 or more relations and can have relations with the same label to different nodes. A relation may be non-directional, uni-directional or bi-directional. We now describe Cypher syntax. A node is generally represented in a Cypher query as `()` and we can optionally specify a variable to reference it in later clauses such as `(n)`. To match and return the node with label `Person`, we would write the Cypher query as `MATCH (n:`Person`{id:112, firstName:"Eve"}) RETURN n`. In a larger context, we can be more specific with the query: `MATCH (n:`Person`{id:112, firstName:"Eve"})-[:LIKES]->(m:`Post`{id:481, content:"About Databases"}) RETURN n`.

Creating the graph store. The ϵStore graph store is created by invoking the constructor of the `EpsilonStore` class with at least one argument to specify the name for the graph store as shown in Figure 2a. The constructor call also instantiates several reference fields of ϵStore. The *datastore* is a map that maps the *ID* of an object present in ϵStore to itself. It can be used to optimize queries through ID based lookups. The *dynamicClasses* is a list that stores the `java.lang.Class` instances created dynamically by ϵStore at runtime. The *labelClassInfoMap* is a map that maps fully qualified class names of classes of objects present in ϵStore to `ClassInfo` instances. The `ClassInfo` class of ϵStore is used to cache primitive and reference field information of a class such as type and name of fields and is used during query execution to access the fields of objects of that class. Finally, the *labelObjectMap* is a map that maps fully qualified names of classes of objects present in ϵStore, to list instances that store objects of the corresponding classes.

Inserting objects without explicit schema. Nodes in ϵStore can be any Java object. Nodes can be created using `CREATE` Cypher queries that instantiate objects of specified classes. If the specified class cannot be found in the classes loaded by the JVM, it is dynamically created by ϵStore. An example of such a query is given in Figure 2b. We refer to such object insertions into ϵStore as insertions *without* explicit schema.

The Cypher query in Figure 2b, as defined by the Cypher grammar, is a *single part query* with an update (`CREATE`) clause. The `CREATE` clause, syntactically, is made up of the token `CREATE` followed by a pattern. The pattern may be a single node pattern (`(n)`) or a multi-node pattern with relations (`(n)-[]->(m)-[]->(p)`) or multiple single node patterns (`(n),(m),(p)`). The pattern in our example is a two node pattern with relations `(:`Person`{...})-[:LIKES]->(:`Post`{...})`. The objective of the `CREATE` clause in ϵStore is to create instances and assign references between them based on the nodes and

relations specified in the pattern. Therefore, the query in Figure 2b creates an instance of type `Person` and an instance of type `Post` with the given properties. It then assigns the reference field `LIKES` of the `Person` instance with the `Post` instance. Assuming that the `Person` and `Post` classes are not present in the classes loaded by the JVM, ϵStore uses the byte code manipulation framework, ASM [7], to first dynamically create these classes.

The *node properties* are mapped to the primitive fields of these classes whereas the relations are mapped to their reference fields. All reference fields, created using class creation, are *Arrays* of type `Object` with the same name as the relation labels. This design decision allows support for one-to-many relations with the same label between nodes.

Inserting objects with explicit schema. ϵStore also supports inserting instances of existing classes using the `captureAll` API method as shown in Figure 2e. `captureAll` captures all references under reflexive transitive closure, and hence, all objects reachable from the captured object are also inserted into the store. The class definitions of `Person` and `Post` are given in Figure 2c and Figure 2d, respectively. The field *dynamicClasses* is empty since the classes of the objects inserted already exist and are not required to be created dynamically.

Data modification through queries. The objects captured into an instance of ϵStore can be modified using Cypher queries. The query (lines 3-6) in Figure 2f deletes the relation between two nodes. It is a single part query with two clauses, a reading (`MATCH`) clause and an update (`DELETE`) clause. The `MATCH` clause identifies a set of objects and their references that matches the specified pattern. The specified pattern is a two node relation pattern specifying the labels, properties and relations for the referrer and referee nodes. Since this pattern exists in our store, the variables `m,r,` and `n`, are mapped to the `Person` instance, the reference field `LIKES` of the `Person` instance, and the `Post` instance respectively. The `DELETE` clause on line 6 deletes all the objects mapped to the variable `r`. Therefore, the field `LIKES` of the referrer node is set to `null` which is shown as the edge being removed in the corresponding graph store state.

3 Graph Store

We first formalize our proposed storage model and the core operations supported by ϵStore (§3.1). We then discuss the mapping between Cypher semantics and Java semantics as implemented by ϵStore (§3.2), followed by a discussion on the API methods provided by ϵStore (§3.3). Finally, we highlight the key implementation details (§3.4).

3.1 Semantics

ϵStore requires no changes to the language syntax, compiler, or execution environment. Thus, we focus on formalizing the core operations of ϵStore such as capturing, deleting, and querying objects. We use big-step operational semantics in our formalization. This section clarifies these operations by providing precise definitions and illustrative examples for each of the rules.

Table 1 shows the key symbols used in our formalization. We define a type (τ) as a (type_name, set_of_fields) pair. Each field is a tuple: (name, type_name), and has a unique name within a type definition. To simplify discussion, we will assume that `int` and `string` are the only primitive types available: (int, $\emptyset$) and (string, $\emptyset$). We define a set type (Set, {}), as an untyped set of values. We also define a metadata type that will be used to describe a type: (Meta, {(name, string)}). We use Γ to denote a set of all available types at runtime.

Table 1 Definitions of key symbols used in our formalization of ϵSTORE operations.

Symbol	Definition
Ξ	The set of all objects available on the heap.
Γ	The set of all available types at runtime.
τ	A type definition ($\tau \in \Gamma$), consisting of a type name and a set of fields.
o	An object on the heap ($o \in \Xi$).
o^τ	A meta-type instance ($o^\tau \in \Xi$).
$\overline{o}$	An instance of ϵSTORE
fields(o)	The set of non-primitive field names belonging to object o.
meta(o)	Retrieves the meta-type instance (o^τ) of the object o.
type(v)	Retrieves the type (primitive) of the primitive value v.
new(τ)	Creates a new object instance of type τ.
ntype(L, f)	Creates a new type named L with a set of fields defined in f which is a tuple of field names and their types ($f = (n_1 : t_1, ..., n_k : t_k)$).
$o[p/v]$	Represents an object o with a set of primitive fields p assigned to a set of values v.
$o.name$	Retrieves the value of the field named $name$ of the object o.
$o.^\star name$	Set of references reachable under transitive closure from the field named $name$ of o via non-primitive fields.
$\Xi(o, f \leftarrow v)$	Assigns the value v to the field f of object o.

We use Ξ to denote all objects available on the heap, i.e., $\Xi = \{o_1, o_2, ..., o_n\}$. Each object ($o$) is an instance of a type (τ) and has a unique identifier. An object has a set of values, each corresponding to one field of the object's type. An access to a field (o.name) returns its current value, and a "star" access to a field ($o.^\star$name) returns a transitive closure, i.e., set of objects reachable via non-primitive fields starting from the given field. We use the following notation to update the field `f` of an object o to value v: $\Xi(o, f \leftarrow v)$.

For each type (τ) in a running program, there is an object (o^τ) on the heap, created by the execution environment, which is an instance of the Meta type (analogous to instance of `java.lang.Class` [47])).

An instance of ϵSTORE is simply an object on the heap ($\overline{o} \in \Xi$). We define the ϵSTORE type as (ϵSTORE, {(store, Set)}). Thus, objects in a graph store are the objects reachable via the store field of an ϵSTORE instance, i.e., $db = \overline{o}.^\star$store, and we have that $db \subset \Xi$. As a result of our design, it is trivial to have any object on the heap inserted into a graph store, to share objects across graph stores, and even to embed one graph store into another.

We define the following helper functions: meta(o) returns the metadata object for the given object; fields(o) returns the set of reference field names for the given object; new(τ) creates a new object (o) of the type τ on the heap and its corresponding set of primitive fields p and their values v is denoted by $o[p/v]$; ntype(L, f) makes a new type (named L) with field names and types defined in the tuple f (tuple of field names mapping to their corresponding types). type(v) returns a name of the primitive type for the given primitive value.

We now formally define the core high-level operations that can be performed on an ϵSTORE instance. In all cases, $o \in \Xi \wedge \overline{o} \in \Xi$ and we use the following configuration:

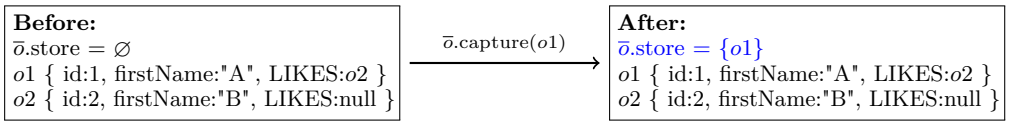
$\langle operation, \Xi, \Gamma \rangle$

For each rule, we first specify its big-step operational semantics, followed by a brief description of the rule, and finally an example showing the state of $\overline{o}$ and other relevant objects, before and after rule application. We assume that all objects used in these examples are instances of type `Person` and that this type exists in Γ unless specified otherwise. For each of the examples, the relevant changes in the after state are highlighted in blue.

▶ **Rule 3.1** (Capture).

$$\frac{\text{store}' = \overline{o}.\text{store} \cup \{o\}}{\langle \overline{o}.capture(o), \Xi, \Gamma\rangle \Downarrow \langle _, \Xi(\overline{o}, \text{store} \leftarrow \text{store}'), \Gamma\rangle}$$

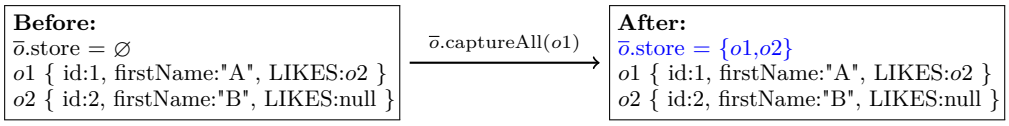
The `capture` rule defines the operation of inserting a single object o (present on the heap Ξ) into an ϵStore instance $\overline{o}$. The union in the premise ensures that if o already exists in $\overline{o}$, then no modifications occur to $\overline{o}$. In the example, we see that the ϵStore instance is empty and there exists an object o on the heap in the before state. After applying the `capture` rule, the ϵStore instance contains the the object $o1$.



▶ **Rule 3.2** (CaptureAll).

$$\frac{C = \overline{o}.\text{store} \cup \{o.^\star f | f \in \text{fields}(o)\} \cup \{o\}}{\langle \overline{o}.captureAll(o), \Xi, \Gamma\rangle \Downarrow \langle _, \Xi(\overline{o}, \text{store} \leftarrow C), \Gamma\rangle}$$

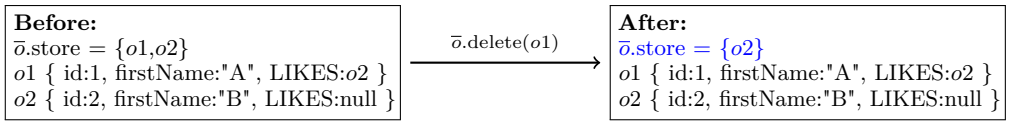
The `captureAll` rule is similar to the `capture` rule but here, the reference fields of the object o being captured are transitively visited and captured into $\overline{o}$ in addition to o. We see that in the premise of the rule, we first collect all the reference fields of o (fields(o)). Next, for every reference field (f), we collect the set of references reachable under transitive closure from o through that field ($o.^\star f$). This set is then unioned with o and the existing store of $\overline{o}$ to get the new store. In the example, we see that the store of $\overline{o}$ is initially empty and there are 2 instances of `Person` ($o1$,$o2$) with one referencing the other. On applying the rule to the referrer instance ($o1$), the store now contains both, the referrer and the referee instances.



▶ **Rule 3.3** (Delete).

$$\frac{\text{store}' = \overline{o}.\text{store} \setminus o}{\langle \overline{o}.delete(o), \Xi, \Gamma\rangle \Downarrow \langle _, \Xi(\overline{o}, \text{store} \leftarrow \text{store}'), \Gamma\rangle}$$

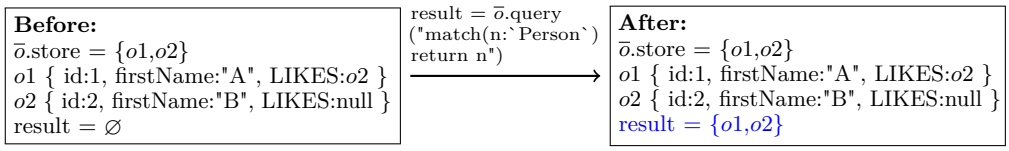
The `delete` rule is used to remove contained objects from ϵStore. In the premise, we remove the object o from the existing store to get the new store (store$'$). This is then used to update the store in the conclusion. If the object does not exist in the store then the store is unmodified after applying the rule. Deleting an object only removes that object from the store while its references that may be part of the store are not removed. In the example, the store initially contains two instances ($o1$,$o2$) with one referencing the other. On applying the rule to the referrer instance, only the referrer instance ($o1$) is removed in the after state of the store.



▶ **Rule 3.4** (Match).

$$\frac{C = \{o \mid o \in \overline{o}.^{\star}\text{store} \wedge \text{meta}(o).\text{name} = L\}}{\langle _ = \overline{o}.query(\text{“match \{a:}L\text{\} return a”}), \Xi, \Gamma\rangle \Downarrow \langle _ = C, \Xi, \Gamma\rangle}$$

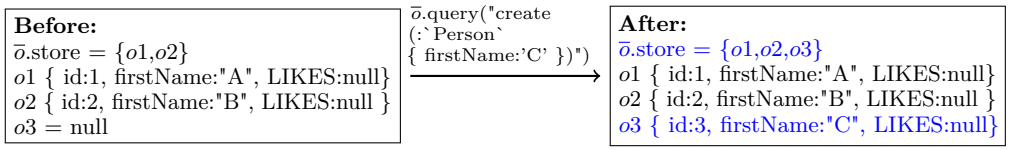
The `match` rule is used to query the store and retrieve stored objects matching one or more specified predicates. Although this rule supports complex predicates, we use a simple predicate to simplify its semantic description. We use the predicate of matching and retrieving all objects in the store whose type matches L. In the premise, we collect the set of all stored objects whose meta-type name matches L. This set is returned as the result of the query in the conclusion. In the example, the store initially contains two instances ($o1$,$o2$) both of type `Person`. The result is initially empty. On applying the rule to retrieve all stored objects of type `Person`, we see that the result now contains $o1$ and $o2$ which are the stored objects of type `Person`.



▶ **Rule 3.5** (Create with pre-defined schema).

$$\frac{L \in \Gamma \qquad o = new(L) \qquad o[p/v]}{\langle \overline{o}.query(\text{“create \{:}L\ \ \{p : v\}\}\text{”}), \Xi, \Gamma\rangle \Downarrow \langle \overline{o}.capture(o), \Xi, \Gamma\rangle}$$

The `create` rule with pre-defined schema is used to create and capture an object of a given existing type into an ϵSTORE instance. This rule uses the `CREATE` clause in the Cypher query. We use a simple example of creating an object of an existing type L with a field p and value v to describe its semantics. In the premise, we first create the object o of type L and update its field named p to value v. In the conclusion, we simply invoke the previously defined `capture` rule on the ϵSTORE instance with o as argument to capture it into the store. In the example below, the store initially contains 2 instances of type `Person` ($o1$, $o2$). After applying the rule, we see that the store now contains 3 instances of type `Person` and $o3$ is now `non-null`. We assign a “name” $o3$ to this created object only for the purpose of showing the before and the after states of applying the rule.

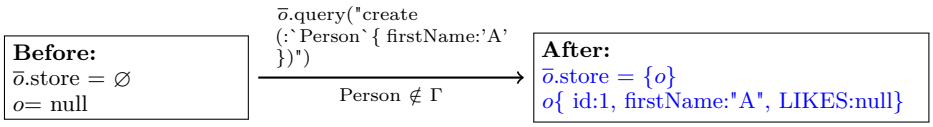


▶ **Rule 3.6** (Create without pre-defined schema).

$$\frac{L \notin \Gamma \qquad \tau = \text{ntype}(L, (\text{“}p\text{”} : type(v))\}) \qquad o = new(\tau) \qquad o[p/v]}{\langle \overline{o}.query(\text{“create \{:}L\ \ \{p : v\}\}\text{”}), \Xi, \Gamma\rangle \Downarrow \langle \overline{o}.capture(o), \Xi, \Gamma \cup \{\tau\}\rangle}$$

The `create` without pre-defined schema is used to create an object of non-existing type and capture it into the ϵSTORE instance. The query used is similar to `create` with pre-defined schema except, now the type L is assumed to not exist in the set of available runtime types

Γ. We use the same example used in create-with-pre-defined-schema rule to describe the semantics. In the premise, we first create a type L with a field named p with type matching that of the primitive value v. Next, we create an instance o of type L and update its field named p with value v. Finally, in the conclusion, we invoke the previously defined `capture` rule on the ϵSTORE instance with o as the argument, to capture it into the store. The newly created type is unioned into the set of available runtime types Γ. This ensures that new objects of this type can now be created by applying the create-with-pre-defined-schema rule instead. In the example below, the store is initially empty. On applying the rule under the assumption that the `Person` type does not yet exist, the store now contains an instance of type `Person` and the object o is `non-null`.



We will now use the operations we formalized to prove 2 properties about ϵSTORE. In the theorems that follow, σ represents the state of the ϵSTORE. $\sigma(o) = \perp$ denotes that the object o is absent from the store. We use the configuration $\langle operation, \sigma, \Gamma\rangle$ in our formal description of the theorems and their proofs.

▶ **Theorem 1** (Idempotency of Insertions). *Repeated insertions of the same object o into an ϵSTORE instance $\overline{o}$ yields an ϵSTORE instance state identical to inserting the object just once. We can formally state the theorem as $\forall\ o$, σ and $\sigma_0(o) \neq \perp$:*

$$\bigwedge_{i=0}^{n} (\langle \overline{o}.capture(o), \sigma_i, \Gamma\rangle \Downarrow \langle _, \sigma_{i+1}, \Gamma\rangle) \implies \sigma_{n+1} = \sigma_0$$

Equality of the states is defined using the standard definition for set equality i.e., $\sigma_{n+1} = \sigma_0 \iff (\sigma_{n+1} \subseteq \sigma_0 \wedge \sigma_0 \subseteq \sigma_{n+1})$.

Proof. We will use mathematical induction to prove this theorem.

1. **Base Case (i = 0):** Prior to capture, o is present in the store, i.e., $\sigma_0(o) \neq \perp$. When a capture operation is executed, the state transitions as follows:

   $$\langle \overline{o}.\text{capture}(o), \sigma_0, \Gamma\rangle \Downarrow \langle _, \sigma_1, \Gamma\rangle \qquad \text{where } \sigma_1 = \sigma_0 \cup \{o\} \text{ by rule } \texttt{capture}$$

   σ_1 denotes the updated state. We know that $\sigma_0 \cup \{o\} = \sigma_0$ since $\sigma_0(o) \neq \perp$. Therefore, $\sigma_1 = \sigma_0$ and the theorem holds for the base case.
2. **Inductive Step (i = n):** Consider an $(n-1)^{th}$ transition:

   $$\langle \overline{o}.\text{capture}(o), \sigma_{n-1}, \Gamma\rangle \Downarrow \langle _, \sigma_n, \Gamma\rangle$$

   Lets assume that the theorem holds for $i = (n-1)$ i.e., $\sigma_n = \sigma_0$. Now for the n^{th} transition, by the semantics defined in rule capture, $\sigma_{n+1} = \sigma_n \cup \{o\}$. However, by our assumption of the theorem holding for $i = (n-1)$, $\sigma_{n+1} = \sigma_0 \cup \{o\}$. By base case, we know that $\sigma_0 \cup \{o\} = \sigma_0$. Therefore, we can claim by mathematical induction that $\sigma_{n+1} = \sigma_0$ as required by the theorem. ◀

▶ **Theorem 2** (Persistence of Inserted Objects). *If an object o is inserted into the store at state σ, then o remains in the store in all subsequent states unless explicitly removed via a deletion operation. We can formally state the theorem as $\forall\ o$, σ and $\sigma_0(o) = \perp$:*

$$(\langle \overline{o}.capture(o), \sigma_0, \Gamma\rangle \Downarrow \langle _, \sigma_1, \Gamma\rangle) \bigwedge_{i=1}^{n} (\langle S_i, \sigma_i, \Gamma_i\rangle \Downarrow \langle S_i', \sigma_{i+1}, \Gamma_{i+1}\rangle) \implies \sigma_{n+1}(o) \neq \perp$$

where S_i (evaluates to S_i') is any ϵSTORE supported operation excluding the `delete` operation.

Table 2 Mapping of Cypher constructs to Java in ϵStore. "—" indicates unsupported features.

Group	Cypher Construct	Cypher Syntax	Class: Dynamically created	Class: Existing
Struct.	Node	`()`	`Object`	`Object`
	Relation	`()-[]-(),()-[]->(),()<-[]-()`	`Object[]`	`Object, Object[]`
		`()<-[]->()`	—	—
Misc.	Node Label	`(:<label>)`	Fully qualified class name	Fully qualified class name
	Relation Label	`()-[:<label>]-()`	Reference field name	Reference field name
	Node Properties	`({<name>:<value>,...})`	Primitive, String fields	Primitive, String fields
	Relation Properties	`()-[{<name>:<value>,...}]-()`	—	—
Property Values	Decimal Literal	`[Long.MIN_VALUE, Long.MAX_VALUE]`	`long`	`byte, short, int, long`
	Float Literal	`[-Double.MAX_VALUE, Double.MAX_VALUE]`	`double`	`float, double`
	Boolean Literal	`TRUE, FALSE`	`boolean`	`boolean`
	String Literal	`"<string>"`	`java.lang.String`	`java.lang.String`

Proof. We will use structural induction on the defined semantic rules to prove this theorem.

1. **Base Case (i = 0):** Prior to capture, o is not present in the store, i.e., $\sigma_0(o) = \bot$. When a capture operation is executed, the state transitions as follows:

$$\langle \overline{o}.\text{capture}(o), \sigma_0, \Gamma \rangle \Downarrow \langle _, \sigma_1, \Gamma \rangle \qquad \text{where } \sigma_1 = \sigma_0 \cup \{o\} \text{ by rule } \texttt{capture}$$

   σ_1 denotes the updated state. Thus, immediately after execution, o is present in the store or in other words $\sigma_1(o) \neq \bot$. Therefore, the theorem holds for the base case.
2. **Inductive Step (i = n):** Consider an $(n-1)^{th}$ transition:

$$\langle S_{n-1}, \sigma_{n-1}, \Gamma_{n-1} \rangle \Downarrow \langle S'_{n-1}, \sigma_n, \Gamma_n \rangle$$

   Lets assume that the theorem holds for $i = (n-1)$ i.e., $\sigma_n(o) \neq \bot$. Now for the n^{th} transition, the arbitrary statement S_n must be chosen from set of operations including capturing, creating or matching as per the requirements of the theorem. Since these rules do not specify any removal condition and were the same choice of operations available for the $(n-1)^{th}$ transition. We can claim by structural induction on the operational semantics, o persists in all transitions unless explicitly removed through deletion. Therefore we can conclude that $\sigma_{n+1}(o) \neq \bot$ as required by the theorem. ◀

3.2 Mappings

The mapping of semantics between Cypher and Java in ϵStore, is given in Table 2. The first column (Group) shows Cypher features [29] supported by ϵStore. The *Cypher Construct* and the *Cypher Syntax* columns describe the Cypher feature and its corresponding syntax when querying. We show the mapping between Cypher features and Java classes in two cases: (1) classes that are dynamically created by ϵStore (i.e., schema absent), and (2) already existing classes written by developers (i.e., pre-defined schema present). These are given by columns *Dynamically created* and *Existing*, respectively.

A Cypher *node* maps to any object in ϵStore for both dynamic and existing classes. If a *label* is specified for the node, then it maps to objects that are instances of the class with a *fully qualified name* matching the label.

For existing classes, a *relation* with a label maps to objects referred to by other objects with the reference field name matching the label. These referee objects can be elements of an array. For dynamic classes, relations always refer to the elements of an array of objects with the array reference field name matching the label. This allows an object to have relations with the same label to different objects. Relationships also support *directionality* which enforces a referrer-referee relation. ϵStore supports non-directional and uni-directional relations but not bi-directional owing to the limitation of its implementation language (Java).

```
1 public void capture(Object obj) throws EpsilonStoreException
2 public void captureAll(Object obj) throws EpsilonStoreException
3 public ResultSet query(String cQuery) throws EpsilonStoreException
```

Figure 4 ϵStore's API available via the `EpsilonStore` class. The `capture` method in Line 1 is used to capture a single object into ϵStore. The `captureAll` method in Line 2 is used to transitively capture all objects reachable from, and including, the argument `obj` into ϵStore. Line 3 shows the method to query ϵStore with the given Cypher query string `cQuery`.

Node properties map to an object's *primitive* or `java.lang.String` fields in ϵStore. The property values can be a decimal, floating point, string or boolean literal. To handle the range of values supported by Cypher, ϵStore defaults to mapping decimal and float properties to `long` and `double` fields for dynamic classes. Whereas for existing classes, these properties may map to `byte`, `short`, `int`, `long`, `float`, and `double` fields.

Finally, for an instance (o) of a class `C` (`C extends A`), we treat all the fields (those from `C` and `A`) in o the same.

3.3 API

ϵStore's API has three methods: (1) `capture`, (2) `captureAll`, and (3) `query` as shown in Figure 4. It is our intentional design choice to keep the interface simple. Furthermore, the architecture of ϵStore and the expressivity of Cypher allows most operations to be performed through queries.

Inserting data. The `captureAll` method given in Figure 4 line 2 is used to insert data into ϵStore by capturing all objects reachable from the given argument object `obj` under reflexive transitive closure. We use a Breadth First Search (BFS) [10] strategy to traverse the graph of object references reachable from the root object `obj`. `capture` method inserts only the given object into ϵStore.

Semantically, to capture an object in ϵStore translates to storing references to the object in the `EpsilonStore` instance's `labelObjectMap` and `datastore` fields as well as to store its primitive and reference field information (name and type) in `ClassInfo` instance present inside the `labelClassInfoMap` field.

The algorithm for capturing objects into ϵStore is given in Algorithm 1. We use a FIFO queue inside a loop to collect all the objects directly and indirectly reachable from the argument object through its reference fields during each iteration. In each iteration, we pop an object o' from the head of the queue (line 4), compute its hash (ID) (line 8) to check if it already exists in the ϵStore instance (lines 9-11), and add it to `datastore` if absent (line 12). We then get the fully qualified class name of the object's class (line 13), check if its mapped to a list in `labelObjectMap`, and append the object to the list if mapped (line 18). If not mapped, we then insert a new empty list for this key in `labelObjectMap` (line 15) and append the object. In addition, we also create a `ClassInfo` instance for the class of this object to cache its field information and insert it into the `labelClassInfoMap` field (line 16). Following this, we get the reference field objects of o' and insert them into the queue (line 22). The loop terminates when the queue is empty.

Querying. The `query` method is shown in Figure 4 line 3 and is used to query the ϵStore instance. It takes the Cypher query string `cQuery` as an argument and returns a `ResultSet` containing the result of the query: references to objects in the ϵStore instance.

Algorithm 1 Capturing objects.

Input: An object o to be inserted into ϵStore
Require: An empty FIFO queue q

```
1:  procedure CAPTUREALL(o)
2:      Append o to q
3:      while q is not empty do
4:          o' ← Pop head of q
5:          if o' is null then
6:              continue
7:          end if
8:          h ← getHashCode(o')
9:          if datastore[h] is not null then
10:             continue
11:         end if
12:         datastore[h] ← o'
13:         c ← getClassName(o')
14:         if labelObjectMap[c] is null then
15:             labelObjectMap[c] ← []
16:             labelClassInfoMap[c] ← new
                ClassInfo(c)
17:         end if
18:         Append o' to labelObjectMap[c]
19:         cInfo ← labelClassInfoMap[c]
20:         for all r := getRefFields(cInfo) do
21:             o'' ← getRefObject(cInfo, r, o')
22:             Append o'' to q
23:         end for
24:     end while
25: end procedure
```

Algorithm 2 Creating objects.

Require: Cypher query string $query$ and list of Java classloaders $cList$

```
1:  for all x := in Nodes of query do
2:      l ← Label of x
3:      pNames ← Property names of x
4:      pValues ← Property values of x
5:      pTypes ← inferTypes(pNames, pValues)
6:      c ← GETORMAKECLASS(l, pNames, pTypes)
7:      o ← CreateAndSetFields(c, pNames, pValues, pTypes)
8:      capture(o)
9:  end for

10: procedure GETORMAKECLASS(l, pNames, pTypes)
11:     if labelClassInfoMap[l] is not null then
12:         return getClass(labelClassInfoMap[l])
13:     else
14:         for all loader := cList do
15:             c ← findClassWithLoader(l, loader)
16:             if c is not null then
17:                 labelClassInfoMap[l] ← new ClassInfo(l)
18:                 return c
19:             end if
20:         end for
21:         c ← ASMCreateClass(l, pNames, pTypes)
22:         labelClassInfoMap[l] ← new ClassInfo(l)
23:         return c
24:     end if
25: end procedure
```

Data can also be inserted into ϵStore through Cypher `CREATE` queries. The algorithm for data insertion through queries is given in Algorithm 2. We describe the case when the Cypher query specifies the creation of a multiple single node pattern (`CREATE (n:label1 {...}), (m:label2), ...`). We start by iterating through all the node definitions in the Cypher query string and collect their labels, property names, property values, and their outgoing edge labels. For each property name and value pair, we infer the property type (line 5) using the mapping given in Table 2. Next, for each node definition, we invoke `GETORMAKECLASS` which either finds a class with a fully qualified name matching that node label or dynamically creates a class with the name matching the label and with its field definitions matching the node's property names and types. The `GETORMAKECLASS` procedure first checks (line 11) the `labelClassInfoMap` field for the class, matching the passed in label argument l and returns it if present (line 12). If absent, we attempt to find the class corresponding to the label by iterating through all the classes loaded into the JVM by all the available *classloaders* [12, 48] and return it if found (line 18). If this also fails, then ϵStore proceeds with dynamic class creation at runtime (line 21). We use the bytecode manipulation and analysis framework ASM [7] to dynamically generate the class. Once the class is found or created, we instantiate it (line 7) and set the fields of the instance to the collected property values. The instance is then captured into ϵStore.

The class instantiation procedure `CreateAndSetFields` checks for consistency of the inferred property types and the field definitions present in the class. An exception is thrown if the checks fail due to a type mismatch.

3.4 Implementation

Field access. Cypher queries may specify patterns in their clauses that require matching a node's properties (`MATCH (n {a:10})`) or its relationships (`MATCH ()-[:label]->()`). Executing these queries requires accessing the fields of objects. To optimize query execution and avoid the overhead of repeatedly retrieving the field name and type for every object,

we cache these field information in ϵStore's `ClassInfo` instances. Since fields are defined in an object's class in Java, it is sufficient to have one `ClassInfo` instance to cache the field information for all objects of that class. These `ClassInfo` instances are stored in ϵStore's `labelClassInfoMap` field. This field is a hashmap that maps a label to its corresponding `ClassInfo` instance. `ClassInfo` is an abstract class. We have two concrete implementations of it based on the approach used to retrieve the field values. We refer to these two implementations of ϵStore as ϵStore^r and ϵStore^u.

- **ϵStore^r** uses Java *reflection* [53] to retrieve the field values. This implementation contains a hashmap mapping field names to their corresponding `java.lang.reflect.Field` [50] instances, obtained using reflection. These `Field` instances are used to retrieve the field values.
- **ϵStore^u** uses Java's *unsafe* [41] API to retrieve the field values. This implementation contains a hashmap mapping field names to field offsets (type `long` values). These field offsets are used to retrieve the field values.

Storage. ϵStore stores inserted objects using their unique ID's and their labels (types).

- **Storing by label**. Every object in Java is an instance of a class which defines its type and the fully qualified name of this class is the *label* of the object. The `labelObjectMap` field is used for storing inserted objects based on their label. This field is a hashmap that maps labels to ordered lists of objects belonging to the corresponding labels. During query execution, if the query string specifies a label for a node to be matched, then since `labelObjectMap` stores objects by their labels, we can use it to efficiently search only a subset of the stored objects.
- **Storing by ID**. The ID is assumed to be unique for every inserted object and is by default computed internally by invoking the `identityHashCode` [46] method provided by `java.lang.System` package on the object. The `datastore` field is used for storing objects based on their ID. This field is a *hashmap* that maps the ID of an inserted object to itself. If the ID of an object being inserted is found to already exist in the `datastore` then the old object reference mapped to that ID in the `datastore` is replaced with the new object reference. During query execution, if the query string specifies a node and its ID then the `datastore` can be used to reduce the search space of stored objects and hence optimize query performance.

Our storage schemes are designed such that the storage structures require minimal update on insertion or removal of objects from ϵStore.

3.5 Code Rewriting

The vanilla version of ϵStore parses input queries and generates a query plan at runtime. We notice the overhead is significant, even multiple times greater than the time to actually execute the query. To reduce overhead, we introduce a code rewriting technique in ϵStore. The basic idea is to parse the query at compile time, then when building the query plan at compile time, we inject the query plan execution code directly into the query call site.

Specifically, we introduce a Java annotation to support this feature. When a method is annotated with this annotation, all the queries (passed as arguments to the `query` API described in Section 3.3) inside the method will be preprocessed by a handler. The handler reuses most part of the ϵStore engine; however, instead of executing the query plan and returning the result, it will aggregate imperative Java code of the query plan needed to be executed for the query and replace the query with corresponding imperative code at the call site. At runtime, only plain imperative Java code is executed. This way, we translate the declarative query into imperative code at compile time, and there is no overhead for parsing and building the query plan at runtime.

```
1 public class LinkedList<E>...{
2     transient Node<E> first; ...
3     private static class Node<E> {
4         ...
5         Node<E> next;
6         Node<E> prev; ...
7     } ...
8 }
```

(a) Snippet of the `LinkedList` class.

```
1 public void testAcyclicity(){
2     List<Long> list = new LinkedList<Long>(); ...
3     EpsilonStore  db = new EpsilonStore ("dbname");
4     db.captureAll(list);
5     assertTrue(db.query(
6       "MATCH (n:‘LinkedList$Node‘)-[:next*]->(n)"
7      +" RETURN COUNT(n) = 0").getBoolean(0));
8 }
```

(b) Checking *acyclicity* invariant on the `LinkedList` with ϵStore.

Figure 5 An example showing complex assertions with ϵStore.

4 Use Cases

We describe 3 use cases that are made possible as the result of our design. These examples showcase the unique programming style of equating objects (instances of classes) and nodes in ϵStore. Our examples include: (1) writing complex assertions for checking structural invariants, (2) implementing methods, and (3) using ϵStore as a lightweight graph store.

4.1 Runtime invariant checking with complex assertions

Structural invariants can be easily checked by writing complex assertions using ϵStore queries. We demonstrate this by checking the *acyclicity* invariant of a linked list.

A snippet of the `java.util.LinkedList` [13] class definition is given in Figure 5a. It contains an inner-class `Node`, whose instances are the `LinkedList` instance's nodes. The fully qualified class name of this inner-class in Java is `LinkedList$Node`. An instance of `Node` has a field `next` that holds a reference to its successor node in the list. The `next` field of a node can be `null` if it is the last node in the list. It also contains a field `prev` that holds a reference to its predecessor node.

The acyclicity invariant of a `LinkedList` imposes the condition that no node can be reachable from itself by strictly following only its successor or predecessor nodes. In other words, a `LinkedList` must be free of cycles. Figure 5b shows how such an invariant can be checked with ϵStore. The `LinkedList` instance `list` is first captured into an ϵStore instance using its `captureAll` API method (line 4). Next, we assert on the result of the Cypher query (lines 6-7), that checks for acyclicity of the captured `list`. The query contains a `MATCH` clause that matches a pattern in the captured graph of objects, where a `Node` instance contains a path to itself through 1 or more `next` edges. The `RETURN` clause returns `true` if such a pattern does not exist.

In this manner, an otherwise complex assertion can be concisely expressed using Cypher queries with ϵStore.

4.2 Implementing methods with Cypher queries

H2 is an open-source, lightweight relational database implemented in Java. H2 supports embedded in-memory mode, where it runs within the same JVM as the application. Thus, all the objects related to an H2 instance are on the heap. As a result, we can insert an instance of H2 into an instance of ϵStore. We can then query anything related to the H2 instance or data within that instance. Here, we show a way to query the metadata of an H2 instance.

Figure 6a shows how to get the schemas in an H2 database using the API provided by JDBC [52, 25]. Figure 6d shows the actual implementation of the `getSchemas` API by H2. It imperatively setups `result`, iterates over the schemas and insert them into the `result`.

```
Connection conn = DriverManager.getConnection(
    "jdbc:h2:mem:h2TestDb",
    "sa",
    ""
);
DatabaseMetaData meta = conn.getMetaData();
ResultSet schemas = meta.getSchemas();
```

(a) Getting *schemas* using JDBC API.

```
EpsilonStore  db = new EpsilonStore ("name");
Class h2db =
    Class.forName("org.h2.engine.Engine");
db.captureAll(h2db);
/* schemas names are the keys of
 * a ConcurrentHashMap
 */
ResultSet schemas = db.query(
  "MATCH (db: `org.h2.engine.Database`)"
  +"-[:schemas]->()-[:table]->()-[:key]->(k)"
  +"RETURN k");
```

(b) Getting *schemas* using ϵStore query.

```
ResultSet users = db.query(
   "MATCH (db: `org.h2.engine.Database`)"
   +"-[:usersAndRoles]->()-[:table]->()"
   +"-[:key]->(k) "
   +"RETURN k");
```

(c) Getting *users* using ϵStore query.

```
public ResultInterface getSchemas() {
  return getSchemas(null, null);
}
public ResultInterface getSchemas(String catalog,
  String schemaPattern) {
  checkClosed();
  SimpleResult result = new SimpleResult();
  result.addColumn(
      "TABLE_SCHEM", TypeInfo.TYPE_VARCHAR);
  result.addColumn(
      "TABLE_CATALOG", TypeInfo.TYPE_VARCHAR);
  if (!checkCatalogName(catalog)) {return result;}
  CompareLike schemaLike = getLike(schemaPattern);
  Collection<Schema> allSchemas =
      session.getDatabase().getAllSchemas();
  Value cValue =
      getString(session.getDatabase().getShortName());
  if (schemaLike == null) {
    for (Schema s : allSchemas)
      result.addRow(getString(s.getName()), cValue);
  } else {
    for (Schema s : allSchemas)
      if (schemaLike.test(s.getName()))
        result.addRow(getString(s.getName()),
        cValue);
  }
  // we ignore sorting for a fair comparison
  // result.sortRows(
  // new SortOrder(session, new int[] { 0 }));
  return result;
}
```

(d) H2 implementation for `getSchemas` JDBC API.

Figure 6 Querying metadata of H2. (a) Querying schemas using JDBC `getSchemas` API, (b) Querying schemas of a captured H2 instance with ϵStore, (c) Querying users of a captured H2 instance with ϵStore, and (d) H2's implementation of `getSchemas`.

Figure 6b shows how to get the same result by inserting the embedded H2 database into ϵStore and querying its metadata using Cypher. The idea here is to show how ϵStore can be easily used to implement some API methods in a concise and readable way, allowing developers to quickly experiment with new ideas and move fast. As another example, figure 6c shows how we can query all the users in an H2 database while JDBC only provide an API for getting current username.

4.3 Lightweight in-memory Graph Store

The ability to insert, delete, update and query objects in ϵStore and the support for the Cypher query language makes ϵStore a good candidate for testing when a graph database is needed. We demonstrate in section 5.4 that ϵStore can be used as a light-weight alternative in-place of graph databases by evaluating it on the LDBC SNB benchmark.

5 Evaluation

We evaluated ϵStore in three ways. First, we benchmarked ϵStore on the LDBC SNB [1] benchmark using Neo4j graph database as reference. Second, we re-implemented a number of imperative library methods of data structures using Cypher in ϵStore and compared its performance with OGO. Finally, we compared the query execution times of ϵStore with and without code rewriting, on the LDBC SNB benchmark. We answer the following questions:

RQ1: How does ϵStore perform as a lightweight graph store?
RQ2: How does ϵStore, when used for implementing methods, compare with OGO?
RQ3: How does ϵStore's code rewriting improve its performance?

We describe environment setup (§5.1), existing systems we use as baselines (§5.2), and the benchmarks (§5.3). Finally, we answer the research questions (§5.4-§5.6).

5.1 Experiment Setup

We built a Docker image for each system used in the evaluation (e.g., OGO) to ensure ease of repeatability of our evaluation experiments. All experiments are run inside Docker containers and averaged over 5 runs. We modified each system used in the evaluation to collect the same profile data. We use a single machine to run the experiments; the machine has an x86_64 11th Gen Intel(R) Core(TM) i7-11700K @ 3.60GHz server with 64GB of RAM and running a 64-bit Ubuntu 20.04.1 operating system. We use Java 17 throughout our experiments.

5.2 Existing Systems

We briefly describe the existing systems that we used in our evaluations.

Neo4j. Neo4j [28] is a graph database and arguably, the most popular one in the industry at the moment. It uses the LPG data model. Neo4j has two modes.

- Server Mode (Neo4j^s): In this mode, Neo4j operates as a database server and runs in a JVM separate from the test JVM which contains the benchmarking queries. We use the Neo4j Java driver [35] version 4.3.3 in the test JVM to send the benchmarking query strings to the Neo4j server. The driver implements the Bolt [30] protocol (similar to JDBC) to communicate with the server. We build Neo4j from source inside docker and load it with the LDBC SNB benchmark dataset. The loading of the datasets (CSVs describing nodes and relations) is done using Neo4j's batch import tool `neo4j-admin` [34].
- Impermanent Mode (Neo4j^i): In this mode, all data inserted into the database are stored in-memory and is non-persistent, and the database runs inside the JVM running the LDBC benchmark queries. This mode is only available in internal test-suites of Neo4j. The Docker image used for evaluation is the same as that built for the server mode. We first create an impermanent database by instantiating `GraphDatabaseService` [31] through dependency injection with `ImpermanentDbmsExtension` [32]. We then insert the LDBC SNB benchmark datasets into the database by using `CREATE` Cypher queries to create the corresponding nodes and relations through database transactions.

We include both, Neo4j^s and Neo4j^i as a point of reference in our evaluation of ϵStore on the LDBC SNB benchmark. We use Neo4j version 5.13.0 and default configuration for all modes of Neo4j in our experiments.

OGO. OGO [57], similar to LINQ [42], combines imperative and declarative (via Cypher) styles of programming. Namely, OGO sees the entire JVM heap (i.e., object graph) as a single graph and enables developers to query the heap (or a subset of it) using queries. We compare it with ϵStore for writing methods using queries on several data structures by replacing existing imperative implementations.

Table 3 shows some major differences between the existing systems we used in our evaluation and ϵStore. We categorize the feature differences into *Programmability* and *Database* features. Programmability features broadly include capabilities such as schema creation, querying runtime program state, manipulating objects on the heap and quickly implementing methods of library classes. These are (partially) supported by OGO and ϵStore. However, most graph databases lack all or most of these features. The database features include some

Table 3 Differences between traditional graph databases, OGO and ϵStore.

	Feature	GDBs	OGO	ϵStore
Programmability	Schema creation	✓	✗	✓
	Query program state	✗	✓	✓
	Heap manipulation	✗	✓	✓
	Method implementation	✗	✓	✓
	Code Rewriting	✗	✗	✓
Database features	Views [43]	✓	✗	✓
	Multi-tenancy [8]	✓	✗	✓
	In-memory	✓	✓	✓
	ACID [24]	✓	✗	✗

features found in traditional databases such as support for multiple views, multi-tenancy, in-memory or non-persistent storage, and ACID compliancy. Most graph databases support all or most of these features, while ϵStore focuses on support for multiple views, in-memory and multi-tenancy features. This table serves to highlight the differences in the design of traditional graph databases and ϵStore and thus their area of applicability.

5.3 Benchmarks

This section provides a brief description of the benchmarks used in our evaluation.

ϵStore as a graph store. To evaluate ϵStore as a graph store and answer RQ1, we use the SNB benchmark from LDBC [56]. LDBC provides both, various sized datasets for its benchmarks and the Cypher queries. The size of a dataset is measured using scale factor which is its uncompressed disk space (e.g., an uncompressed dataset that requires 10GB of disk space would have a scale factor of 10). The LDBC SNB was designed with the aim to model a snapshot of the activity in a realistic social network during a period of time. Table 4 shows the nodes and relationships that appear in the LDBC SNB benchmark and their variation with scale factors used in our evaluation namely, 0.1, 0.3, 1, 3 and 10. Higher scale factors can be supported since ϵStore is only limited by the memory available to the JVM which can be increased with the JVM option `-Xmx`. We observe that the frequency of some nodes (`Comment`) and relationships (`Person Likes Comment`) scale by order of magnitude for an order of magnitude increase in scale factor whereas that of others such as `Tagclass` and `Tagclass IsSubclassOf Tagclass` do not change with scale factor. Query execution time is affected by these different occurrence frequencies depending on the node and relationship labels appearing in it. We use all the queries from the LDBC SNB benchmark that are currently supported by ϵStore. Many queries use Cypher language features which are not implemented in ϵStore yet (§6). Table 5 gives a brief description of the used queries. The name of the query as it appears in the LDBC SNB benchmark documentation is shown in column 1. The queries all contain either a read (`MATCH`) clause or a read and an update (`CREATE`) clause. These read and update clauses contain either single node or two-node patterns. The pattern contained in the queries is given by columns 3, 4 and 5. Finally, a brief description of the queries is given in column 6. Generally, ignoring indexing schemes, we should expect the query execution time to scale with the number of operations performed and the frequency of occurrence of labels in its patterns. For example, Q^G_{SNB} contains the most occurring label (`Comment`) in the benchmark in its patterns and 2 clauses, and would be expected to take more time to execute than Q^D_{SNB} that involves less frequently occurring labels and just 1 clause.

Table 4 Node and relationship statistics for LDBC SNB benchmark across evaluated scale factors.

ϵStore as a heap manipulation engine. To evaluate ϵStore as an engine to modify objects on the heap and answer RQ2, we use data structures from three sources: Java Collections Framework (JCF) [49], Google Guava [21], and the Eclipse Collections [17] projects. We rewrote on average 2 library methods from each of these data structures to use Cypher queries (rather than the imperative implementation). Simply, for ϵStore, we insert the data structure into an instance of ϵStore and run a query that implements the same functionality as exiting imperative code.

5.4 ϵStore as a Lightweight Graph Store (RQ1)

We use query execution time and memory consumption during benchmarking on LDBC SNB benchmark to motivate ϵStore as a lightweight graph store.

Query execution time. In our early experiments, we noticed substantial variations in query execution times across several runs, which we attribute to the JVM environment. To stabilize the time, we perform the following steps. We first load the dataset for a given scale factor into the systems used in our evaluation. Next, we execute all the chosen LDBC queries for that benchmark in a randomized order. We call this as the 1^{st} set. Following this, we once again execute the same set of queries in another randomized order. We call this as the 2^{nd} set. The sets are executed back-to-back in the same JVM process. The profile data for an evaluation run is collected for every query execution in both the sets. However, when

Table 5 Description of the LDBC SNB benchmark queries used in our evaluation.

Query	Abbrv.	Start Node	Relation	End Node	Description
interactive-delete-query2	Q^A_{SNB}	Person	Likes	Post	Matches a pattern with a *Person* node pointing to a *Post* node through a relation *Likes*, deletes the relation and returns the count of *Likes* relation between the two nodes.
interactive-delete-query3	Q^B_{SNB}	Person	Likes	Comment	Matches a pattern with a *Person* node pointing to a *Comment* node through a relation *Likes*, deletes the relation and returns the count of *Likes* relation between the two nodes.
interactive-delete-query5	Q^C_{SNB}	Forum	HasMember	Person	Matches a pattern with a *Forum* node pointing to a *Person* node through a relation *HasMember*, deletes the relation and returns the count of *HasMember* relation between the two nodes.
interactive-short-query1	Q^D_{SNB}	Person	IsLocatedIn	Place	Matches a pattern with a *Person* node pointing to a *Post* node through a relation *IsLocatedIn* and returns properties of the two nodes.
interactive-short-query5	Q^E_{SNB}	Comment	HasCreator	Person	Matches a pattern with a *Comment* node pointing to a *Person* node through a relation *HasCreator* and returns properties of the *Person* node.
interactive-update-query2	Q^F_{SNB}	Person	Likes	Post	Matches a *Person* and *Post*, creates a relation *Likes* from *Person* to *Post* node and returns the count of *Likes* relation between the two nodes.
interactive-update-query3	Q^G_{SNB}	Person	Likes	Comment	Matches a *Person* and *Comment*, creates a relation *Likes* from *Person* to *Comment* node and returns the count of *Likes* relation between the two nodes.
interactive-update-query5	Q^H_{SNB}	Forum	HasMember	Person	Matches a *Forum* and *Person*, creates a relation *HasMember* from *Forum* to *Person* node and returns the count of *HasMember* relation between the two nodes.
interactive-update-query8	Q^I_{SNB}	Person	Knows	Person	Matches a *Person* and *Person*, creates a relation *Knows* from *Person* to *Person* node and returns the count of *Knows* relation between the two nodes.

reporting the profile data for a query for an evaluation run, we use the data from the 2^{nd} set and discard the 1^{st} set. Figure 7 shows a boxplot of the query execution time for the queries in the 1^{st} and 2^{nd} sets for ϵSTORE^r across 10 evaluation runs. It is observable that profile data for the queries collected from the 2^{nd} set has substantially lower variance than that collected from the 1^{st} set, and, hence, the query profile data are more stable across runs.

The collected profile data breaks down the total query execution time ($\mathbf{T_{tot}}$) into the query parsing time ($\mathbf{t_{Pa}}$), query plan generation time ($\mathbf{t_{Pl}}$), and query plan execution time ($\mathbf{t_{Ex}}$). We compute the sum breakdown time ($\mathbf{t_{Bd}}$) from the profile data as t_{Bd}=t_{Pa}+ t_{Pl}+ t_{Ex}. All times are reported in milliseconds unless otherwise stated.

Table 6 shows the results for LDBC SNB. Column 1 shows the query abbreviation. Column 2 shows the scale factor of the dataset. Columns 3-5 show the results for Neo4j^s, Neo4j^i, and ϵSTORE^r respectively. We initially hypothesized that using reflection to retrieve field values may degrade performance due to excessive runtime type-checking. To test our hypothesis, we decided to implement field access using reflection (ϵSTORE^r) and the unsafe API (ϵSTORE^u). However, we observed no significant performance difference between these two modes of ϵSTORE. Hence, for brevity, we omit showing ϵSTORE^u results in Table 6.

For each system, we show the query parsing time (t_{Pa}), query planning time (t_{Pl}), query plan execution time (t_{Ex}), sum breakdown time (t_{Bd}), and the total query execution (T_{tot}). We use bold text for T_{tot}, and we use gray background to show the best value (smallest T_{tot}) in each row. OOM indicates out of memory (when the physical memory requirement exceeds ~64GB). The T_{tot} of queries in general scales with scale factor of the datasets with the exception of some queries (e.g., Q^A_{SNB},Q^B_{SNB}), that operate on node labels containing very

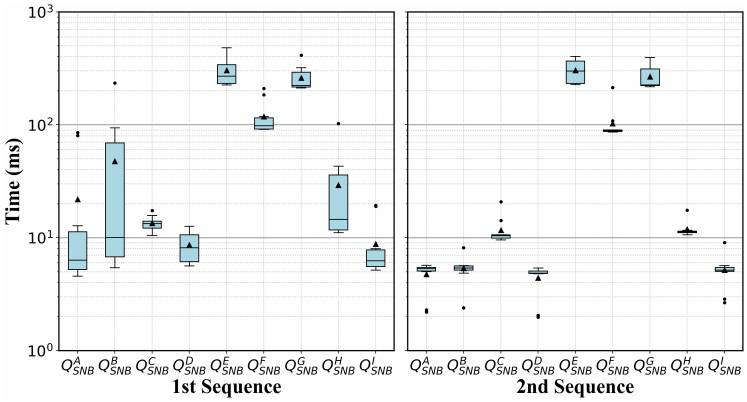

Figure 7 Query execution times for 1st and 2nd randomized sequence runs of ϵSTORE^r.

(b) SNB physical memory usage in GB.

Figure 8 Virtual and Physical memory usage in GB for LDBC SNB evaluation across scale factors. Query failures for exceeding memory are indicated by OOM.

few nodes. We can see that the T_{tot} of ϵSTORE is comparable or better than the production graph database for most of the queries. The graph database outperforms ϵSTORE for query Q^E_{SNB} because, Q^E_{SNB} matches referrer node with label containing the highest amount of nodes in the benchmark (20 million+ for SF 10). This shows that for testing purposes, where datasets are relatively smaller, ϵSTORE can be used as a lightweight graph store instead of a full fledged production graph database.

Memory usage. In addition to time, we also measured memory consumption for all the systems. We used pidstat [39] to collect memory consumption during evaluation runs. Figure 8 shows the peak memory usage for each system (one bar per system). The virtual and physical memory consumption in GB during running all the selected queries on the SNB for different scale factors is shown in Figure 8a and Figure 8b, respectively. We allow Neo4j^i and Neo4j^s to manage their own memory requirements [33], e.g., allocating page cache. We observe that the virtual memory usage of a system does not change significantly across scale factors of the SNB benchmarks. The physical memory usage, on the other hand, increases with increasing scale factors for all the systems. Neo4j^i requires the most physical and virtual memory and is OOM for the SNB scale factor 10 dataset. ϵSTORE^r consumes the least amount of virtual memory across the systems and is second only to Neo4j^s in terms of the least physical memory consumed. This is to be expected since ϵSTORE^r being in-memory,

Table 6 Total query execution time (T_{tot}) and its breakdown in milliseconds, for queries and datasets from the LDBC SNB benchmark. All reported times lower than 0.5 milliseconds are shown as 0. The maximum allocated physical memory for each evaluation run is 63GB.

stores all inserted data on RAM whereas Neo4j^s can store part of it on disk and can page it into RAM as and when required. We once again see that for smaller datasets, which is generally the case during testing, ϵStore's memory consumption is comparable or better than a production graph database.

> In summary, the query execution times and memory consumption of ϵStore is on par or better than that of a production graph database for small datasets. Since, smaller datasets are typically the norm in testing environments, ϵStore provides an excellent light-weight alternative to a full fledged graph database for testing.

5.5 Data-structure Performance (RQ2)

We reuse 5 of the data structures from Thimmaiah et al. [57] that were used to evaluate OGO. We also introduce 4 additional data structures from the Eclipse Collections project in our evaluation.

OGO supports two modes of operation, OGO^{Neo} and OGO^{Mem}. In both modes, the first step is to identify a subset of the heap that is relevant to the query. The 2 modes differ in the query engine used. OGO^{Neo} uses an external query engine (Neo4j) and OGO^{Mem} uses an in-memory query engine. We compared the 2 different modes of OGO with ϵStore by executing Cypher queries implementing imperative methods from data-structure libraries. We evaluated these queries for varying workloads (number of elements present inside the data structure). The results are shown in Table 7. We only report the total query execution time T_{tot} (in milliseconds) for each system. The data-structures are given in the first column.

Table 7 Total query execution time (T_{tot}) in milliseconds, for the *contains* or equivalent method reimplemented as Cypher query, on data structures for different modes of OGO and ϵStore. The time out (TO) duration used is 1 minute .

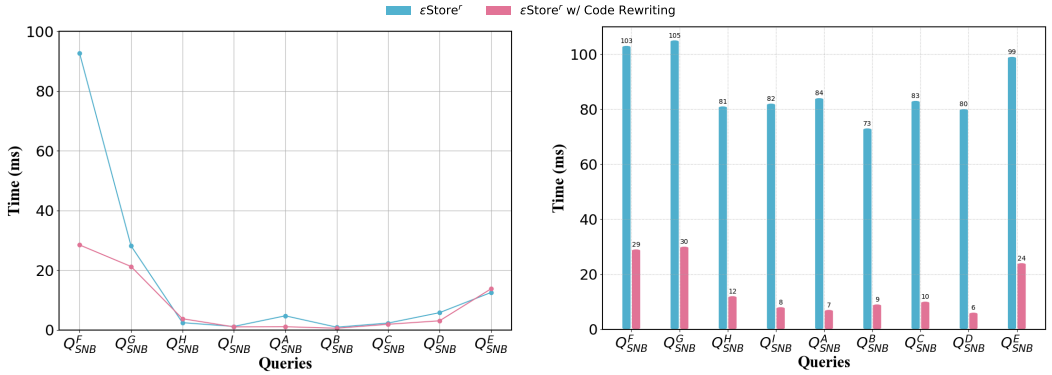
The second column shows the workload, and finally, columns three through six give the total query execution times for OGO and ϵStore. We fixed the query execution time out (TO) duration to be 1 minute. We clearly see that both the modes of ϵStore consistently outperform those of OGO by at least an order of magnitude. Larger workloads for most of the considered data structures result in TO for OGO.

OGO^{Neo} is significantly slower than ϵStore because of using an external query engine which incurrs a heavy overhead due to repeated serialization and deserialization of the heap subset. This overhead increases for higher workloads due to increase in the heap subset size. ϵStore is also faster than OGO^{Mem} by an order of magnitude on average. This is primarily due to 3 factors. The first is that both the modes of OGO rely on tagging [45] of objects (assigning a `long` identifier) in the heap to identify those relevant to the query. Since other JVM processes such as the garbage collector (GC) also use tagging, both modes of



(a) Sequence. **(b)** Standalone.

Figure 9 Total query execution time (T_{tot}) for LDBC SNB queries in milliseconds. In (a), each query is executed in sequence inside a single JVM process; in (b), each query is executed in a separate JVM process.

OGO execute every query by first iterating through the entire heap and tagging every object to 0. This tag initialization time grows linearly with the number of objects in the heap. The second factor is, ϵSTORE is implemented purely in Java and thus benefits from Just-In-Time (JIT) compilation whereas OGO^{Mem} uses an in-memory query engine implemented in C++. Finally, the third factor is in the identification of the heap subset in OGO. Both the modes rely on the JVMTI `FollowReferences` [44] method to identify the heap subset. The `FollowReferences` method takes a user provided callback as one of its arguments and visits every object starting from JNI roots following its chain of references, reporting them to the callback. Providing class filters to `FollowReferences` only controls what objects are reported but not what objects are visited. This overhead of visiting objects not relevant to the query increases with increase in heap size. This is unlike ϵSTORE which stores references to the objects that might be queried.

We only compare total query execution time and not lines of code (LOC) since, both OGO and ϵSTORE use Cypher to implement the data-structure methods.

> In summary, ϵSTORE outperforms both the modes of OGO for Cypher queries re-implementing imperative methods from data-structure libraries. OGO is on-average an order of magnitude slower or worse. This is due to ϵSTORE benefitting from JIT compilation due to its pure Java implementation and storing references to all the queryable objects. OGO, on the other hand, incurrs heavy overhead due to its need to identify the heap subset relevant to the query for every query execution.

5.6 Imperative Code Rewriting Performance (RQ3)

We evaluate the performance of the code rewriting using LDBC SNB queries on the smallest scale factor dataset (0.1).

Figure 9 shows the evaluation results. In Figure 9a, we run each query sequentially in the same JVM process. (The order to run these queries is determined by the test runner, we observe the same trend with other orders). We observe that the code rewriting technique speeds up the first two queries; and for the subsequent queries the execution time is similar. There are two main reasons for the results. First, we use ANTLR to parse the query and the start up takes time [4], thus the first query of ϵSTORE^r takes much longer time than others. Second, after the warm up, JIT compilation kicks in and the difference becomes negligible.

We further evaluate the execution time when each query runs in a separate JVM process and the result is shown in Figure 9b. This result is consistent with our previous conclusion.

In summary, parsing and generation of query plans adds nearly an order of magnitude to the execution time. We can significantly speed up query execution by removing this overhead by injecting query plan execution code into the query call site at compile time.

6 Limitations and Future Work

We document potential future directions in this section.

Query optimization. Our current implementation of the query engine only generates the physical plan and directly executes it. In the future, we could introduce a logical plan and construct a physical plan from it. This could allow us to reason about query execution strategies at a more abstract level.

ID collisions. ϵSTORE stores references to captured objects using their class names and their IDs. The object's hash code is used as its ID. However, it is possible for two or more distinct objects to share the same hash code. Currently, ϵSTORE does not support retaining multiple objects with identical hash codes; if a newly captured object shares a hash code with an existing object, the existing reference is overwritten by the new one. Although such situations are theoretically possible, we did not encounter them during our evaluation.

Programming languages. We implemented ϵSTORE in Java due to our familiarity with the language. Modifying types of fields or number of fields in Java is hard. Class redefinition would require bytecode modification and loading in the class with a different classloader and then managing two different versions of the same class within a single JVM. This restricts the types of queries we can support in eStore (e.g., we cannot add new edges, we cannot add new node properties etc.). Other languages like Python or Smalltalk might allow eStore implementations to be more flexible and versatile. We leave design of an in-memory object graph store for other languages as future work.

Concurrency semantics. We defined semantics assuming sequential program execution. It would be interesting to define semantics for concurrent programs when an object might be accessed both inside and outside a store (or multiple stores simultaneously). However, that is outside the scope of the current work.

Query languages. ϵSTORE currently supports a subset of Cypher, which is the most popular query language. Future work could explore supporting other known graph query languages, e.g., GraphQL [19], Gremlin, SPARQL, and AQL [5]. Integration with languages that support both imperative and declarative traversals, such as Gremlin, could be especially well suited for ϵSTORE's data representation.

Cache layer for graph databases. The efficient in-memory graph store model of ϵSTORE makes it suitable to be used as a cache layer for persistent graph databases like Neo4j. The new programming style brought by ϵSTORE can further enrich the interoperability between the applications and the graph databases. We leave for future work the exploration of this direction.

7 Related Work

In this section, we cover the most closely related work, which we organize into: (1) graph databases storage, (2) language integrated queries, (3) object relational/graph mappers.

Graph databases storage. Graph databases [3, 60, 2, 9] are a type of NoSQL database. One of the most popular graph databases is Neo4j, which we discussed in this paper. Many other (proprietary) options are available including TigerGraph [58], Neptune [27], Nebula [37], JanusGraph [38], VelocityDB [36], Kùzu [16] and Memgraph [40]. VelocityDB is an in-memory object database integrated with C# and can be extended as a graph database, but it still introduces extra layer(s) of storage model abstraction and uses a specific set of APIs instead of a query language like Cypher.

Language integrated queries. [11, 42, 20, 54] Microsoft LINQ [42] is an integration of query capabilities directly into C# language. LINQ supports various data sources, including collections (e.g., List), SQL database, XML documents, and streams. Unlike LINQ, ϵSTORE is an in-memory graph backed object store. Including an object into ϵSTORE enables queries on it similar to those on data structures using LINQ. Apache Commons OGNL [18] is an open-source Expression Language (EL) for Java. It provides its own expression syntax to navigate and manipulate Java object graphs. However, it is not designed as a graph store, and does not provide the same level of expressiveness as graph query languages. OGO generalizes the idea behind LINQ's data structure queries and enables querying the entire Java heap. Unlike OGO that supports querying the state of the heap, ϵSTORE focuses on implementing an in-memory graph backed object store.

Object relational/graph mappers. Object-relational mapping (ORM) [59] is used to convert data between a (relational) database and the heap. In a way, object relational mapping techniques create an object database that can be directly manipulated within the program. Example of ORM include Hibernate [26]. There are also Object-graph mappers (OGM) for graph databases, such as Neomodel [15] and Renesca [14] for Neo4j. ϵSTORE is a graph backed object store and thus requires no additional mapping into memory objects.

8 Conclusions

We presented ϵSTORE, the first in-memory graph backed object store. ϵSTORE brings a programming paradigm shift, as it equates nodes in a graph with objects on the heap and relations among nodes with reference fields. It uses dynamic class generation and loading to create necessary schema (classes) to represent nodes and their properties. A subset of Cypher is used for querying the store, and each query returns a table of references. Additionally, ϵSTORE can transitively include an object already on the heap into a store, which enables complex queries for data and relations on already existing object graphs. Our evaluation shows the benefit of our approach. Besides being used as an object graph store, we expect that the combination of graph store features, object store features, implementation of a graph as an object graph, and ability to capture object graphs into a store will introduce new programming styles.

Multiparty Asynchronous Session Types: A Mechanised Proof of Subject Reduction

Marco Carbone
IT University of Copenhagen, Denmark

Abstract

Session types offer a type-based approach to describing the message exchange protocols between participants in communication-based systems. Initially, they were introduced in a binary setting, specifying communication patterns between two components. With the advent of multiparty session types (MPST), the typing discipline was extended to arbitrarily many components. In MPST, communication patterns are given in terms of global types, an Alice-Bob notation that gives a global view of how components interact. A central theorem of MPST is subject reduction: a well-typed system remains well-typed after reduction. The literature contains some formulations of MPST with proofs of subject reduction that have later been shown to be incorrect. In this paper, we show that the subject reduction proof of the original formulation of MPST by Honda et al. contains some flaws. Additionally, we provide a restriction to the theory and show that, for this fragment, subject reduction does indeed hold. Finally, we use subject reduction to show that well-typed processes never go wrong. All of our proofs are mechanised using the Coq proof assistant.

1 Introduction

Session types provide a type-based framework for specifying how participants in a concurrent communication-based system exchange messages. These communication patterns, specified in a protocol language, are used for verifying the programs that implement them. The framework guarantees properties such as type safety (well-typed programs never go wrong), session fidelity (processes behave according to protocol descriptions), and in-session deadlock-freedom (protocols never get stuck). Originally, Honda et al. [30, 31] proposed *binary session types* where types (protocol specifications) describe only how pairs of processes exchange messages. Inspired by choreographic languages [9], Honda et al. later extended this concept to *multiparty session types* [32, 33], which generalise the framework to handle protocols with

arbitrarily many participants and asynchronous communication. This seminal work has driven significant progress in both the theory of communication-based systems [6, 11, 19, 39, 49] and their implementation in mainstream programming languages [1, 2, 20, 38].

Except for some cases [13, 35, 51], the correctness results of the theory of multiparty session types rely on paper proofs, which necessitate the omission of numerous details. Known pitfalls, such as incorrect results caused by issues with binders [21, 54], or unsound projection functions [51], often arise from overlooking technical details that are nearly impossible to catch in lengthy paper proofs.

A common way to make sure that all of these details are found, and to ensure that all proofs are correct, is to use interactive proof assistants like Isabelle [44], Coq [41], or Lean [42], to have all proofs machine-checked by a computer. Proof assistants have proven immensely successful and have been used to guarantee the correctness of a wide variety of foundational results in both mathematics [25, 26, 27, 28] and computer science [5, 36]. Nevertheless, attractive as these mechanisations are, they are also very difficult to implement. The original multiparty session types paper [32], recipient of the Most Influential Paper POPL 2008 award [40], should by all means be a prime candidate for mechanisation but has, because of the difficulty of the proofs, mostly been left untouched.

This paper mechanises the subject reduction theorem for the theory of multiparty asynchronous session types, as stated in the journal version of the original paper [33]. Subject reduction states that well-typed programs remain well-typed throughout their execution, as defined by their operational semantics. Subject reduction is one of the core theorems in the meta-theory, supporting key results such as type safety, session fidelity, and in-session deadlock-freedom. Although the proofs of the original paper are quite detailed, they are also lengthy and intricate. During our mechanisation efforts, however, we discovered that subject reduction, as presented in the original work, does not hold. In this paper, we provide a counterexample to the original theorem and present a new type system for which subject reduction does hold. Our proofs are fully machine-checked using the Coq proof assistant.

Multiparty Session Types. Multiparty session types use *global types*, a protocol specification language for describing the interaction patterns among multiple communicating participants. Interactions feature a sender and a receiver, generally called *roles*. For example, the following global type specifies the communication patterns between roles p, q, and r:

$$G = \mathsf{p} \to \mathsf{q}\colon 1\left\{ \begin{array}{l} l_1\colon \mathsf{q} \to \mathsf{r} : 2\langle \mathsf{bool} \rangle.\mathsf{end} \\ l_2\colon \mathsf{p} \to \mathsf{r} : 2\langle \mathsf{bool} \rangle.\mathsf{end} \end{array} \right\} \tag{1}$$

This global type describes a protocol where role p internally decides and informs role q over channel 1, whether to continue in branch l_1 or in branch l_2. If p picks branch l_1, role q, after receiving this label, must send a boolean to r over channel 2. Conversely, if q picks branch l_2, p must then send a boolean to r over the same channel 2. In both branches, the protocol terminates after p or q communicate with r. A channel in the protocol represents a private FIFO queue, shared between the three roles for communication. A global type describes asynchronous protocols, meaning that sends are non blocking, sent messages are immediately placed on a channel, and the sending process can continue executing while the message is in transit. In this example, role q must first receive label l_1 from p before sending a boolean on channel 2. However, if p chooses branch l_2, it can immediately send a boolean without waiting for q to read from channel 1. Global types are equipped with a *reduction semantics* that captures this asynchronous behaviour.

A key observation, relevant for the remainder of this work, is that, as in the original work, a global type dictates exactly which channels the roles communicate over, as can be seen from the explicit references to channels 1 and 2 in the example above. This practice

is often referred to as *explicit channels*, and contrasts with later work where the way roles use channels is implicit and therefore more restrictive. In the implicit channel setting, each pair of roles shares private channels that no other roles can access. Implicit channels are often used in the literature because they offer a convenient abstraction when full control over channel usage is not needed, and formal proofs are significantly simplified. Explicit channels are, however, more expressive and allow fine-grained control over which channels are actually used. This is particularly useful in applications where only a limited number of channels are available and must be shared among all roles. For example, AMQP [3], the Advanced Message Queuing Protocol, is a widely used message-oriented middleware protocol where communication takes place over named queues (channels), and where efficient use of limited shared resources is critical. Encoding implicit channels using explicit ones is straightforward and just a matter of allocating unique channels to all pairs of roles. This means that our results apply to both explicit and implicit channels, and not just to the explicit setting. It is also worth noting that using implicit channels requires allocating a channel (queue) for each ordered pair of roles, resulting in a quadratic number of channels.

While global types provide a holistic view of a protocol, the behaviour of its individual roles can be described as *local types*. Local types provide a local view of the protocol for each of its roles and can be obtained from global types by an operation known as *projection*. For example, the global type from Equation (1) can be expressed as the following collection of local types:

$$\mathsf{p} : 1 \oplus \left\{ \begin{array}{l} l_1 : \mathsf{end} \\ l_2 : !2\langle \mathsf{bool} \rangle.\mathsf{end} \end{array} \right\} \qquad \mathsf{q} : 1\& \left\{ \begin{array}{l} l_1 : !2\langle \mathsf{bool} \rangle.\mathsf{end} \\ l_2 : \mathsf{end} \end{array} \right\} \qquad \mathsf{r} : ?2\langle \mathsf{bool} \rangle.\mathsf{end} \tag{2}$$

The local type for p says that label l_1 or label l_2 must be communicated over channel 1 and if label l_2 is chosen then a boolean must be sent over channel 2. Dually, role q must be ready to receive label l_1 or l_2 on channel 1, and if label l_1 is selected, a boolean must be sent over channel 2. Finally, role r is ready to receive a boolean from channel 2. Similar to global types, collections of local types such as the one seen in Equation (2), are equipped with a semantics that captures the various communications that can be performed.

Protocols described as global types are executed as *sessions*. A session is an instance of a protocol with private channels where each role is implemented as an executable process, written in the multiparty session calculus, a model of computation for concurrent system based on the π-calculus [43]. The core idea of multiparty session types is that global types can be projected into local types which are then, via a type system, used to verify that a given implementation conforms to the specification provided by the global types. For example, multiparty session types ensure that the following parallel composition of processes can participate in a session that implements the global type from Equation (1):

$$\begin{array}{l} \overline{\mathsf{a}}[\mathsf{p}]_2(\mathfrak{s}).\overbrace{\mathfrak{s}[1] \lhd l_2; \mathfrak{s}[2]!\langle \mathsf{true} \rangle; \mathbf{0}}^{P} \quad | \\ \mathsf{a}[\mathsf{q}](\mathfrak{s}).\underbrace{\mathfrak{s}[1] \rhd \{l_1 : \mathfrak{s}[2]!\langle \mathsf{false} \rangle;\ \mathbf{0},\quad l_2 : \mathbf{0}\}}_{Q} \quad | \quad \mathsf{a}[\mathsf{r}](\mathfrak{s}).\underbrace{\mathfrak{s}[2]?(x); \mathbf{0}}_{R} \end{array} \tag{3}$$

The term above reads as follows: three processes are about to initiate a 3-party protocol on a, where a is a *shared name* denoting the name of the protocol in the calculus. The first process, prefixed with $\overline{\mathsf{a}}[\mathsf{p}]_2(\mathfrak{s})$, is requesting the initiation of a session featuring two queues (instantiating the channels specified in the global type), acting as p while the second and third process are performing a session accept, joining the session as roles q and r respectively. The binder $\mathfrak{s}$ is a placeholder for a session identifier that will be created at runtime. Process P denotes a process that, playing role p, first puts a label l_2 in the queue at channel 1 and

then puts the message true in queue at channel 2. Process Q awaits for a label on queue at channel 1 that determines its continuation. Finally, process R, playing role r, receives a value on the queue at channel 2. Initially, we synchronise over the prefixes $\overline{\mathsf{a}}[\mathsf{p}]_2(\mathfrak{s})$, $\mathsf{a}[\mathsf{q}](\mathfrak{s})$, and $\mathsf{a}[\mathsf{r}](\mathfrak{s})$, yielding the term

$$(\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})\left(\begin{array}{lll} \overbrace{\mathsf{s}^{\mathsf{p}}[1] \lhd l_2; \mathsf{s}^{\mathsf{p}}[2]!\langle\mathsf{true}\rangle;\mathbf{0}}^{P[\mathsf{s}^{\mathsf{p}}/\mathfrak{s}]} & | & \overbrace{\mathsf{s}^{\mathsf{q}}[1] \rhd \{l_1 : \mathsf{s}^{\mathsf{q}}[2]!\langle\mathsf{false}\rangle; \mathbf{0}, l_2 : \mathbf{0}\}}^{Q[\mathsf{s}^{\mathsf{q}}/\mathfrak{s}]} \quad | \\ \underbrace{\mathsf{s}^{\mathsf{r}}[2]?(x); \mathbf{0}}_{R[\mathsf{s}^{\mathsf{r}}/\mathfrak{s}]} & | \quad \mathsf{s}[1] :: \emptyset \quad | & \mathsf{s}[2] :: \emptyset \end{array}\right) \tag{4}$$

The operation generates the new session identifier s (the syntax $(\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})$ is a restriction binder), which we use to replace the binder $\mathfrak{s}$ with *located session identifiers* s^{p}, s^{q} and s^{r} for roles p, q, and r respectively. The two communication queues, represented by $\mathsf{s}[1]$ and $\mathsf{s}[2]$, where messages can be enqueued and dequeued, are shared between all participants and are initially empty. Role p, implemented by process $P[\mathsf{s}^{\mathsf{p}}/\mathfrak{s}]$, first sends label l_2 over channel 1 and then value true over channel 2, and reduces to the following term:

$$(\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})\Big(\mathbf{0} \quad | \quad Q[\mathsf{s}^{\mathsf{q}}/\mathfrak{s}] \quad | \quad R[\mathsf{s}^{\mathsf{r}}/\mathfrak{s}] \quad | \quad \mathsf{s}[1] :: l_2{}^{\mathsf{p}} \cdot \emptyset \quad | \quad \mathsf{s}[2] :: \mathsf{true}^{\mathsf{p}} \cdot \emptyset\Big) \tag{5}$$

where the label $l_2{}^{\mathsf{p}}$ and the value $\mathsf{true}^{\mathsf{p}}$, both annotated with the sending role p, have been enqueued on $\mathsf{s}[1]$ and $\mathsf{s}[2]$ respectively.

A Counter-Example to Subject Reduction. Subject reduction states that any term typed by a collection of local types (referred to as the *typing environment*), derived from a global type through projection, will remain typable after the process reduces. Since local types are equipped with a reduction semantics, the subject reduction theorem also states that the term obtained after reduction can be typed either by the same typing environment or by a modified environment, reflecting a reduction of local types. The original statement of subject reduction by Honda et al. can be informally stated as follows:

> *If P is well typed in a typing environment Δ, and P reduces to P' then either P' is well-typed in the original typing environment Δ, or in another environment Δ' such that Δ can reduce to Δ'*

The reduction on the environment Δ is crucial because it establishes a connection between the reductions performed by the processes and the protocol specification defined by the local types (which are derived from global types). Proving other results, such as session fidelity (processes behave according to protocol descriptions), heavily relies on the relationship between the reductions of processes and types. Unfortunately, the original theory by Honda et al. does not satisfy subject reduction. The key issue lies in the fact that some well-typed processes can reduce to well-typed terms in a way where their typing environments are not the same nor does the initial environment reduce to the latter. We demonstrate this with our running example.

Even though the process in Equation (3) has been reduced to the one in (4) and then to (5), this new process is still typable by the same local types in Equation (2), derived by means of projection from the global type in Equation (1). This is because the semantics of environments tracks interactions, which matches an output action on a channel with an input action on the same channel. So far only outputs have been performed, and the environment is thus unchanged. However, when process $R[\mathsf{s}^{\mathsf{r}}/\mathfrak{s}]$ (which is equal to $\mathsf{s}^{\mathsf{r}}[2]?(x);\mathbf{0}$) retrieves message $\mathsf{true}^{\mathsf{p}}$ from $\mathsf{s}[2]$, the term in Equation (5) reduces to

$$(\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})\Big(\mathbf{0} \quad | \quad Q[\mathsf{s}^{\mathsf{q}}/\mathfrak{s}] \quad | \quad \mathbf{0} \quad | \quad \mathsf{s}[1] :: l_2{}^{\mathsf{p}} \cdot \emptyset \quad | \quad \mathsf{s}[2] :: \emptyset\Big) \tag{6}$$

which reveals a problem. Here, the process $\mathsf{s}^{\mathsf{r}}[2]?(x); \mathbf{0}$, acting as role r, has consumed the boolean $\mathsf{true}^{\mathsf{p}}$ from the $\mathsf{s}[2]$ queue while ${l_2}^{\mathsf{p}}$ is still in the $\mathsf{s}[1]$ queue. In other words, the branching interaction between roles p and q described by the global type in Equation (1) has been executed out of order, since q has not yet received l_2, but the communication of a boolean from p to r in the l_2 branch has been completely performed. The problem with the original theory of multiparty session types is that the asynchronous semantics of processes allows $Q[\mathsf{s}^{\mathsf{q}}/\mathsf{s}]$ and $R[\mathsf{s}^{\mathsf{r}}/\mathsf{s}]$ to read from queues $\mathsf{s}[1]$ and $\mathsf{s}[2]$ respectively in any order. However, the semantics of the global type from Equation (1) requires that q (corresponding to process $Q[\mathsf{s}^{\mathsf{q}}/\mathsf{s}]$) reads from channel 1 (corresponding to queue $\mathsf{s}[1]$) before r (corresponding to process $R[\mathsf{s}^{\mathsf{r}}/\mathsf{s}]$) reads from channel 2 (corresponding to queue $\mathsf{s}[2]$).

Below (left) we show a global type that describes the remaining behaviour of the session, and we show (right) the environment derived from it.

$$\mathsf{p} \to \mathsf{q} : 1\left\{ \begin{array}{l} l_1 : \mathsf{end} \\ l_2 : \mathsf{end} \end{array} \right\} \qquad \mathsf{p} : 1 \oplus \left\{ \begin{array}{l} l_1 : \mathsf{end} \\ l_2 : \mathsf{end} \end{array} \right\}, \quad \mathsf{q} : 1 \& \left\{ \begin{array}{l} l_1 : \mathsf{end} \\ l_2 : \mathsf{end} \end{array} \right\}, \quad \mathsf{r} : \mathsf{end} \tag{7}$$

This environment types the process in Equation (6). The problem is that the two environments in Equations (2) and (7) are neither the same, nor can they be related by the semantics of local types, therefore breaking subject reduction.

A reasonable question to ask at this point is why, given how influential the work by Honda et al. is, has this not been noticed before? The answer is most likely twofold. Firstly, the proofs are very complex and have never been mechanised. Secondly, the original formulation of multiparty session types differs from most later work. In particular, they use explicit channels where all roles in a session share queues, as opposed to implicit channels, introduced by Bettini et al. [4], where each ordered pair of roles has a dedicated queue. Our counterexample hinges on the use of explicit channels since it would not have been possible to derive it with implicit channels.

This Work. We develop a theory of multiparty session types that mostly follows the original framework by Honda et al [32]. Our main results are threefold. First, as described above, we identify a counterexample to subject reduction, highlighting a flaw in the original meta-theory of multiparty asynchronous session types. Second, we fix this flaw and prove subject reduction of the amended calculus and its type system. Finally, we mechanise all of our results in the Coq proof assistant which significantly reduces the risk of errors on our part. We gradually introduce the prerequisites of our subject reduction proof throughout this paper.

Section 2 defines a process language that models communicating programs. These programs feature different types of communication operations, all based on the concept of sessions. They can start new sessions and subsequently use session channels to communicate within these sessions. The process language is formally defined as a process algebra, equipped with a standard notion of structural equivalence and reduction semantics.

Next, in Section 3, we define global and local types. Global types give a global abstraction of how a set of processes should behave within a given session. To describe how individual processes within a session should behave, global types can be transformed, by means of projection, into a set of local types (one for each process in the session), where each local type represents the behaviour of a specific process in a session. Both global and local types are equipped with a reduction semantics which specifies the behaviour enforced by the types. Using these reduction semantics, we state a projection theorem that establishes the correctness of the projection from global types to local types. However, due to the flexible definition of global types, some global types are not realisable, meaning that their semantics

does not correspond to that of their projection. To address this, we introduce the linearity property, which characterises those global types that can be correctly realised, similarly to the approach in the original framework [32, 33].

The last part of this article, in Sections 4 and 5, focuses on defining the type system for which we prove subject reduction. This does not follow the original framework precisely. In particular, our typing of queues (processes communicate via FIFO queues, one for each channel) takes a different approach which, despite being equivalent, facilitates the mechanisation work. For subject reduction to hold, we need to have an extra restriction on global types, which we call unstuckness. This restriction is what avoids bad situations such as that in the example above to happen. In addition to subject reduction, we also prove communication safety (type safety), which guarantees linearity – ensuring that there is never a race on a session channel – and error freedom in communications.

All proofs have been machine-checked in the Coq proof assistant, marking this as the first mechanisation of subject reduction for a general framework of asynchronous multiparty session types with explicit channels. Definitions and results in the paper are linked to the Coq code in our online repository. These links are marked with the symbol .

2 Multiparty Asynchronous Session Processes

Our process language is an extension of the π-calculus with the notion of session which forms the foundation for inter-process communication.

Syntax. Let $\mathscr{P}$ be a finite subset of the natural numbers which denotes a set of roles (ranged over by $\mathsf{p}, \mathsf{q}, \mathsf{r}, \mathsf{s}, \mathsf{t}$), let $\mathscr{L}$ be a set of labels (ranged over by l), and let I, J denote index sets of the form $\{1, \ldots, n\}$ for any natural number n. Moreover, let indices in an index set be denoted by i, j. We identify two distinct sets of atoms, *shared names*, ranged over by $\mathsf{a}, \mathsf{b}, \mathsf{c}$, and *session identifiers*, ranged over by $\mathsf{s}, \mathsf{t}, \mathsf{r}$. Note that both shared names and session identifiers are in sans-serif font. Multiparty asynchronous session processes are defined by the following grammar ( ):

$a ::= x \mid \mathsf{a}$	(shared names)	$s ::= \mathfrak{s} \mid \mathsf{s}^{\mathsf{p}}$	(session channels)
$v ::= \mathsf{a} \mid \mathsf{true} \mid \mathsf{false}$	(values)	$e ::= x \mid v \mid e \ \mathsf{and}\ e'$	(expressions)
$h ::= l^{\mathsf{p}} \mid v^{\mathsf{p}} \mid (\mathsf{s}^{\mathsf{q}})^{\mathsf{p}}$	(message)	$D ::= \{X_i(x\tilde{\mathfrak{s}}) = P_i\}_{i \in I}$	(declarations)

$P ::= \overline{a}\,[\mathsf{n}]_k(\mathfrak{s}).P$	(session request)	$\mid \mathsf{if}\ e\ \mathsf{then}\ P\ \mathsf{else}\ Q$	(conditional branch)
$\mid a[\mathsf{p}](\mathfrak{s}).P$	(session acceptance)	$\mid P \mid Q$	(parallel composition)
$\mid s[k]!\langle e\rangle; P$	(value sending)	$\mid \mathbf{0}$	(inaction)
$\mid s[k]?(x); P$	(value reception)	$\mid (\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})P$	(name hiding)
$\mid s[k]!\langle\langle t\rangle\rangle; P$	(session delegation)	$\mid (\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})P$	(session hiding)
$\mid s[k]?((\mathfrak{s})); P$	(session reception)	$\mid X\langle e, \tilde{s}\rangle$	(process call)
$\mid s[k] \lhd l; P$	(label selection)	$\mid \mathsf{s}[k] :: \tilde{h}$	(message queue)
$\mid s[k] \rhd \{l_i : P_i\}_{i \in I}$	(label branching)		

A shared name non-terminal $a, b, c, \ldots$ can be either a value variable, denoted by $x, y, z, \ldots$, or a shared name a. Located session non-terminals, denoted by $s, t, r, \ldots$, can be either a located session variable, denoted by $\mathfrak{s}, \mathfrak{t}, \mathfrak{r}, \ldots$, or a located session, denoted by $\mathsf{s}^{\mathsf{p}}, \mathsf{t}^{\mathsf{p}}, \mathsf{r}^{\mathsf{p}}$, where the roles ($\mathsf{p}$, q, and r) denote which role is currently using the session, i.e. which location it is being used at. Figure 1 gives an overview of the various names.

A multi-cast session request $\overline{a}\,[\mathsf{n}]_k(\mathfrak{s}).P$ requests to start a session on a, with roles $\{0, ..., \mathsf{n}\}$ and the requester acting as n. When a session eventually is initiated on a concrete shared name a, a fresh session identifier s is created. The requester acts as n by referencing variable

a	shared name	x	value variable	a	shared name non-terminal
s^{p}	located session	$\mathfrak{s}$	located session variable	s	located session non-terminal
s	session identifier	k	channel		

Figure 1 Naming of key elements.

channel $\mathfrak{s}$ in P which, during the execution, is substituted for a located session s^{n}. The natural number k declares how many channels (queues) will be created when the session is initiated and each queue is addressed as $\mathsf{s}[i]$ for $i \in \{1, ..., k\}$. The term $a[\mathsf{p}](\mathfrak{s}).P$ denotes the dual process that accepts a request on a, playing role p.

The construct $s[k]!\langle e\rangle; P$ denotes the sending of expression e (after its evaluation to a value) to the queue of session s addressed at $\mathsf{s}[k]$. The construct $s[k]?(x); P$ reads from $\mathsf{s}[k]$, with variable x binding the received value in the continuation P. The construct $s[k]!\langle\!\langle t\rangle\!\rangle; P$ denotes sending a session channel, an operation called delegation. The construct $s[k]?((\mathfrak{s})); P$ denotes receiving a session channel, an operation called session reception. In session reception, we bind a located session variable $\mathfrak{s}$ in the continuation P, similarly to the request and accept constructs. Branching communications are captured by $s[k] \lhd l; P$ and $s[k] \rhd \{l_i\colon P_i\}_{i\in I}$. The former selects a branch by communicating label l, while the latter reacts to a branch that another process has chosen (external choice).

The terms $(\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})P$ and $(\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})P$ respectively bind shared names and session identifiers in P. Free shared names and free session identifiers, denoted by $\mathsf{fn}(Q)$ and $\mathsf{fs}(S)$ respectively, are defined in a standard way. The process call $X\langle e, \tilde{s}\rangle$ invokes procedures stored in the declarations D. Declarations are identified by a name X, ranging over some set of declaration names, and have the form $X(x\tilde{\mathfrak{s}}) = P$, where the parameters x and $\tilde{\mathfrak{s}}$ are instantiated with a value and a list of distinct located sessions, respectively. The body P may include process names, thereby supporting recursion. The terminated process is denoted by $\mathbf{0}$.

A queue addressed at $\mathsf{s}[k]$ with messages $\tilde{h}$ is denoted by $\mathsf{s}[k] :: \tilde{h}$, and a message h is either a label, a value, or a session name. A message contains an annotation of the role that has sent the message, e.g., $\mathsf{s}[k] :: \mathsf{true}^{\mathsf{p}} \cdot \tilde{h}$ contains a message from p. Syntactically, variables cannot be messages in a queue. This is sensible because the semantics introduced next enforces that all variables are substituted for concrete terms before being put on a queue.

We define two types of *substitution*: one on value variables and one on located session variables. Both are denoted by the standard syntax $P[\mathsf{a}/x]$ and $P[\mathsf{s}^{\mathsf{p}}/t]$.

Reduction Semantics. We now give a reduction semantics for processes. First, we must define the structural congruence relation.

▶ **Definition 1** (Structural Congruence 🐓). *Structural congruence, denoted by $P \equiv Q$, is the smallest equivalence relation that satisfies the following rules:*

$$P \mid \mathbf{0} \equiv P \qquad P \mid Q \equiv Q \mid P \qquad (P \mid Q) \mid R \equiv P \mid (Q \mid R)$$

$$(\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})\ \mathbf{0} \equiv \mathbf{0} \qquad (\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})P \mid Q \equiv (\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})(P \mid Q) \quad \textit{when } \mathsf{a} \notin \mathsf{fn}(Q)$$

$$(\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})\ \mathbf{0} \equiv \mathbf{0} \qquad (\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})P \mid Q \equiv (\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})(P \mid Q) \quad \textit{when } \mathsf{s} \notin \mathsf{fs}(Q)$$

$$\frac{P \equiv Q}{(\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})P \equiv (\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})Q} \qquad \frac{P \equiv Q}{(\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})P \equiv (\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})Q}$$

$$
\begin{array}{rl}
\text{[Link]} & \Big(\prod_{\mathsf{i}=0}^{\mathsf{n}-1} \mathsf{a}[\mathsf{i}](\mathfrak{z}).P_{\mathsf{i}}\Big) \mid \overline{\mathsf{a}}\,[\mathsf{n}]_k(\mathfrak{z}).P_{\mathsf{n}} \;\to_D\; (\boldsymbol{\nu}\,\mathsf{s})\Big(\prod_{\mathsf{i}=0}^{\mathsf{n}-1} P_{\mathsf{i}}[\mathsf{s}^{\mathsf{i}}/\mathfrak{z}] \mid \prod_{j=1}^{k} \mathsf{s}[j] :: \epsilon\Big) \\
\text{[Send]} & \mathsf{s}^{\mathsf{p}}[k]!\langle e\rangle; P \mid \mathsf{s}[k] :: \tilde{h} \;\to_D\; P \mid \mathsf{s}[k] :: \tilde{h} \cdot v^{\mathsf{p}} \qquad \boxed{e \downarrow v} \\
\text{[Recv]} & \mathsf{s}^{\mathsf{p}}[k]?(x); P \mid \mathsf{s}[k] :: v^{\mathsf{q}} \cdot \tilde{h} \;\to_D\; P[v/x] \mid \mathsf{s}[k] :: \tilde{h} \\
\text{[Deleg]} & \mathsf{s}^{\mathsf{p}}[k]!\langle\!\langle \mathsf{t}^{\mathsf{q}} \rangle\!\rangle; P \mid \mathsf{s}[k] :: \tilde{h} \;\to_D\; P \mid \mathsf{s}[k] :: \tilde{h} \cdot (\mathsf{t}^{\mathsf{q}})^{\mathsf{p}} \\
\text{[SRec]} & \mathsf{s}^{\mathsf{p}}[k]?((\mathfrak{z})); P \mid \mathsf{s}[k] :: (\mathsf{t}^{\mathsf{r}})^{\mathsf{q}} \cdot \tilde{h} \;\to_D\; P[\mathsf{t}^{\mathsf{r}}/\mathfrak{z}] \mid \mathsf{s}[k] :: \tilde{h} \\
\text{[Label]} & \mathsf{s}^{\mathsf{p}}[k] \lhd l; P \mid \mathsf{s}[k] :: \tilde{h} \;\to_D\; P \mid \mathsf{s}[k] :: \tilde{h} \cdot l^{\mathsf{p}} \\
\text{[Branch]} & \mathsf{s}^{\mathsf{p}}[k] \rhd \{l_i \colon P_i\}_{i \in I} \mid \mathsf{s}[k] :: l_j{}^{\mathsf{q}} \cdot \tilde{h} \;\to_D\; P_j \mid \mathsf{s}[k] :: \tilde{h} \qquad \boxed{j \in I} \\
\text{[IfT]} & \mathsf{if}\ e\ \mathsf{then}\ P\ \mathsf{else}\ Q \;\to_D\; P \qquad \boxed{e \downarrow \mathsf{true}} \\
\text{[IfF]} & \mathsf{if}\ e\ \mathsf{then}\ P\ \mathsf{else}\ Q \;\to_D\; Q \qquad \boxed{e \downarrow \mathsf{false}} \\
\text{[Def]} & X\langle e, \tilde{\mathsf{s}}^{\mathsf{p}}\rangle \;\to_D\; P[v/x][\tilde{\mathsf{s}}^{\mathsf{p}}/\tilde{\mathfrak{z}}] \qquad \boxed{e \downarrow v \text{ and } \big(X(x\tilde{\mathfrak{z}}) = P\big) \in D} \\
\text{[Res}_{\boldsymbol{\nu}^{\mathsf{s}}}\text{]} & P \;\to_D\; P' \;\Rightarrow\; (\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})P \;\to_D\; (\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s})P' \\
\text{[Res}_{\boldsymbol{\nu}^{\mathsf{a}}}\text{]} & P \;\to_D\; P' \;\Rightarrow\; (\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})P \;\to_D\; (\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a})P' \\
\text{[Par]} & P \;\to_D\; P' \;\Rightarrow\; P \mid Q \;\to\; P' \mid Q \\
\text{[Str]} & P \equiv P' \text{ and } P' \;\to_D\; Q' \text{ and } Q' \equiv Q \;\Rightarrow\; P \;\to_D\; Q
\end{array}
$$

Figure 2 Reduction semantics for processes ( ).

The first line makes processes a commutative monoid over parallel composition with $\mathbf{0}$ as the unit element. The next two lines give the structural rules for name restriction, allowing the binder to be dropped when its scope is a terminated process, and allowing the scope to be extruded when this is capture-free. The rules in the last line ensure that $\equiv$ is a congruence with respect to the two restriction operators. Whilst this is not strictly necessary for the semantics, it will prove useful when we formulate communication safety in Section 5.

The reduction semantics for processes, denoted by $P \;\to_D\; P'$, is defined by the rules given in Figure 2. Rule [Link] initiates a session between $\{0, \ldots, \mathsf{n}\}$ roles. The request is made by n and the remaining processes accept on the same shared name a, declaring with $[\mathsf{i}]$ which role of the session they will perform as. The requester indicates by k how many queues will be initiated for the session. This information does not need to be shared with the other roles because the type system will ensure queue addresses $\mathsf{s}[k]$ are used correctly. The parallel composition of the accepting processes is defined using $\prod$ to denote parallel composition of a set of processes. We assume that the natural number n is greater than 0, i.e., there are at least two processes engaging in a session.

Rule [Send] puts a value at the end of a queue, annotating the value with the role p of the located session s^{p} it was sent on, and [Recv] reads from the front of the queue. Rules [Deleg] and [SRec] are the corresponding rules for delegation and session reception while [Label] and [Branch] are the corresponding rules for labels. Rules [IfT] and [IfF] are standard semantics for if-statements. Rule [Def] handles recursive calls by name by replacing the process variable X with its declaration in D, substituting x for the evaluation of e, and substituting $\tilde{\mathfrak{z}}$ for a list of located sessions. Rules [Res$_{\boldsymbol{\nu}^{\mathsf{s}}}$], [Res$_{\boldsymbol{\nu}^{\mathsf{a}}}$] and [Par] allow reductions to occur under restriction binders and parallel composition. Rule [Str] handles structural congruence.

▶ Remark 2 (Differences with the original work). We annotate a session identifier s with a role p, yielding a located session s^{p}. Such annotations have become a common practice in the literature. They were introduced as *polarities* for binary session types [22, 54], which address unintended limitations of the semantics. As in previous work [4, 17], we annotate messages with the sending role to indicate the sender of the message. This allows us to compare the specification of p against the messages it has enqueued and its remaining actions.

3 Global Types, Local Types, and Projection

Syntax. The syntax of global and local types is given as follows (🐓):

$$
\begin{array}{rcll}
G & ::= & \mathsf{p} \to \mathsf{q} : k\langle U\rangle.G \mid \mathsf{p} \to \mathsf{q} : k\{l_j : G_j\}_{j\in J} \mid \mu\mathbf{t}.G \mid \mathbf{t} \mid \mathsf{end} & \\
T & ::= & !k\langle U\rangle.T \mid ?k\langle U\rangle.T \mid k \oplus \{l_i : T\}_{i\in I} \mid k \,\&\, \{l_i : T_i\}_{i\in I} \mid \mu\mathbf{t}.T \mid \mathbf{t} \mid \mathsf{end} & \\
U & ::= & \mathsf{bool} \mid \mathsf{int} \mid G \mid T & \qquad \hat{\Delta} ::= \emptyset \mid \hat{\Delta},\ \mathsf{p} : T
\end{array}
$$

The global type $\mathsf{p} \to \mathsf{q} : k\langle U\rangle.G$ specifies a session with an interaction where p sends a message of type U to q via channel k, and G specifies the remaining session. The type $\mathsf{p} \to \mathsf{q} : k\{l_j : G_j\}_{j\in J}$ specifies a branching interaction where p sends a label l_i to q via k, and G_i specifies the remaining session. The constructs $\mu\mathbf{t}.G$ and $\mathbf{t}$ are used to write tail-recursive specifications such as $\mu\mathbf{t}.\mathsf{p} \to \mathsf{q} : k\langle U\rangle.\mathbf{t}$. Finally, end specifies the terminated session. A message type U is either a boolean, an integer[1], a global type or a local type. Global types are used as message types when communicating shared names and local types are used when communicating session channels.

The local type $!k\langle U\rangle.T$ (resp. $?k\langle U\rangle.T$) specifies a role that sends (resp. receives) a message of type U over channel k, with T representing the remaining actions. The type $k \oplus \{l_i : T\}_{i\in I}$ (resp. $k \,\&\, \{l_i : T_i\}_{i\in I}$) specifies sending (resp. receiving) a label l_i, with T_i being the subsequent actions. As for global types, $\mu\mathbf{t}.T$ and $\mathbf{t}$ allow tail-recursive specifications. Lastly, end is a terminated role.

We deal with recursive variables in a standard way and write capture-avoiding substitution as $G_1[G_2/\mathbf{t}]$ (resp. $T_1[T_2/\mathbf{t}]$). We assume that types are closed and contractive. Global and local types are contractive if, for any of its sub-expressions with shape $\mu\mathbf{t}_0.\mu\mathbf{t}_1...\mu\mathbf{t}_n.\mathbf{t}$, the body $\mathbf{t}$ is not $\mathbf{t}_0$ [47].

A *local type environment* $\hat{\Delta}$ is a map from roles to local types. For every p in the domain of $\hat{\Delta}$ (denoted by $\mathsf{dom}(\hat{\Delta})$), there is a unique entry $\mathsf{p} : T$ for some T.

Projection. Projection is a partial function which, given a global type and a role, attempts to generate a local type that captures the specification of this role in the global type. When the global type specifies behaviour that the role cannot implement, projection is undefined. Our mechanisation uses the projection function $\mathsf{proj}_{\mathsf{p}}(G)$ proposed by Tirore et al. [51], which is defined in Figure 3. The function $\mathsf{proj}_{\mathsf{p}}(G)$ is defined in terms of two auxiliary definitions: a translation function, denoted by $\mathsf{trans}_{\mathsf{p}}(G)$, and a projectability predicate, denoted by $\mathsf{projectable}_{\mathsf{p}}(G)$. The translation function is a total function which produces a local type representing the local behavior of the translated role. The projectability predicate checks that the global type specifies behavior that is possible to implement by the projected role.

[1] Our mechanization excludes the integer message type, as the expressiveness of the expression language is orthogonal to our focus. We include the integer type here solely to simplify examples with distinct message types.

$$\mathsf{gVar}(\mathsf{t}, G) \stackrel{\text{def}}{=} \begin{cases} \mathsf{gVar}(\mathsf{t}, G_1) \ \wedge \ \mathbf{t} \neq \mathbf{t}' & \text{if } G = \mu \mathbf{t}'.G_1 \\ \mathbf{t} \neq \mathbf{t}' & \text{if } G = \mathbf{t}' \\ \mathsf{True} & \text{otherwise} \end{cases}$$

$$\mathsf{trans}_{\mathsf{p}}(\mathsf{p}_1 \to \mathsf{p}_2 : k\langle U \rangle.G) \stackrel{\text{def}}{=} \begin{cases} !k\langle U \rangle.(\mathsf{trans}_{\mathsf{p}}(G)) & \text{if } \mathsf{p} = \mathsf{p}_1 \text{ and } \mathsf{p}_1 \neq \mathsf{p}_2 \\ ?k\langle U \rangle.(\mathsf{trans}_{\mathsf{p}}(G)) & \text{if } \mathsf{p} = \mathsf{p}_2 \text{ and } \mathsf{p}_1 \neq \mathsf{p}_2 \\ \mathsf{trans}_{\mathsf{p}}(G) & \text{if } \mathsf{p} \notin \{\mathsf{p}_1, \mathsf{p}_2\} \end{cases}$$

$$\mathsf{trans}_{\mathsf{p}}(\mathsf{p}_1 \to \mathsf{p}_2 : k\{l_j : G_j\}_{j \in J}) \stackrel{\text{def}}{=} \begin{cases} k \oplus \{l_j : \mathsf{trans}_{\mathsf{p}}(G_j)\}_{j \in J} & \text{if } \mathsf{p} = \mathsf{p}_1 \text{ and } \mathsf{p}_1 \neq \mathsf{p}_2 \\ k \ \& \ \{l_j : \mathsf{trans}_{\mathsf{p}}(G_j)\}_{j \in J} & \text{if } \mathsf{p} = \mathsf{p}_2 \text{ and } \mathsf{p}_1 \neq \mathsf{p}_2 \\ \mathsf{trans}_{\mathsf{p}}(G_1) & \text{otherwise} \end{cases}$$

$$\mathsf{trans}_{\mathsf{p}}(\mu \mathbf{t}.G) \stackrel{\text{def}}{=} \begin{cases} \mu \mathbf{t}.(\mathsf{trans}_{\mathsf{p}}(G)) & \text{if } \mathsf{gVar}(\mathsf{t}, G) \\ \mathsf{end} & \text{otherwise} \end{cases}$$

$$\mathsf{trans}_{\mathsf{p}}(\mathbf{t}) \stackrel{\text{def}}{=} \mathbf{t} \qquad \mathsf{trans}_{\mathsf{p}}(\mathsf{end}) \stackrel{\text{def}}{=} \mathsf{end}$$

$$\mathsf{proj}_{\mathsf{p}}(G) \stackrel{\text{def}}{=} \begin{cases} \mathsf{trans}_{\mathsf{p}}(G) & \text{if } \mathsf{projectable}_{\mathsf{p}}(G) \\ \text{undefined} & \text{otherwise} \end{cases}$$

$$\mathsf{proj_roles}(G, \ \{\mathsf{p}_1, \ \cdots, \ \mathsf{p}_n\}) \stackrel{\text{def}}{=} \begin{cases} \mathsf{p}_1 : \mathsf{proj}_{\mathsf{p}_1}(G), \ \cdots, & \text{if } \forall i \in \{1, \ \cdots, \ n\}. \\ \mathsf{p}_n : \mathsf{proj}_{\mathsf{p}_n}(G) & \mathsf{proj}_{\mathsf{p}_i}(G) \text{ is defined} \\ \text{undefined} & \text{otherwise} \end{cases}$$

$$\mathsf{full_proj}(G) \stackrel{\text{def}}{=} \mathsf{proj_roles}(G, \ \mathsf{roles}(G))$$

Figure 3 Projection ( ).

Translation is defined such that $\mathsf{trans}_{\mathsf{p}}(\mathsf{p}_1 \to \mathsf{p}_2 : k\langle U \rangle.\ G)$ produces the output $!k\langle U \rangle$ (resp. input $?k\langle U \rangle$) when the translated role is p_1 (resp. p_2), and translates the remaining global type as $\mathsf{trans}_{\mathsf{p}}(G)$. If the translated role does not occur in the interaction, translation simply ignores the interaction proceeds as $\mathsf{trans}_{\mathsf{p}}(G)$. The translation of a branching global type $\mathsf{trans}_{\mathsf{p}}(\mathsf{p}_1 \to \mathsf{p}_2 : k\{l_j : G_j\}_{j \in J})$ is similar when p occurs in the interaction. When p does not occur, translation chooses the first branch j_1 and proceeds as $\mathsf{trans}_{\mathsf{p}}(G_1)$. The auxiliary predicate $\mathsf{gVar}(\mathsf{t}, G)$ is used in the translation of $\mu \mathbf{t}.G$, and checks if $\mu \mathbf{t}$ can safely be added to $\mathsf{trans}_{\mathsf{p}}(G)$, without producing non-contractive local types. In particular, this predicate ensures that trans never produces non-contractive types like $\mu \mathbf{t}.\mathbf{t}$. Finally, $\mathsf{trans}_{\mathsf{p}}(\mathbf{t})$ (resp. $\mathsf{trans}_{\mathsf{p}}(\mathsf{end})$) returns $\mathbf{t}$ (resp. end).

On its own, the translation function is too permissive. E.g., the global type

$$\mathsf{p} \to \mathsf{q} \colon 1 \left\{ \begin{array}{l} l_1 \colon \mathsf{r} \to \mathsf{s} : 2\langle \mathsf{bool} \rangle.\mathsf{end} \\ l_2 \colon \mathsf{r} \to \mathsf{s} : 2\langle \mathsf{int} \rangle.\mathsf{end} \end{array} \right\}$$

$$\frac{}{\mathsf{p} \to \mathsf{q} : k\langle U\rangle.G \xrightarrow{\mathsf{p}\to\mathsf{q}:k\langle U\rangle} G}\ [\text{GR1}] \qquad \frac{j \in I}{\mathsf{p} \to \mathsf{q} : k\{l_i : G_i\}_{i\in I} \xrightarrow{\mathsf{p}\to\mathsf{q}:k\langle l_j\rangle} G_j}\ [\text{GR2}]$$

$$\frac{G_1 \xrightarrow{\ell} G_2 \qquad \mathsf{q} \notin \ell}{\mathsf{p} \to \mathsf{q} : k\langle U\rangle.G_1 \xrightarrow{\ell} \mathsf{p} \to \mathsf{q} : k\langle U\rangle.G_2}\ [\text{GR3}]$$

$$\frac{\forall i \in I.\ G_i \xrightarrow{\ell} G_i' \qquad \mathsf{q} \notin \ell}{\mathsf{p} \to \mathsf{q} : k\{l_i : G_i\}_{i\in I} \xrightarrow{\ell} \mathsf{p} \to \mathsf{q} : k\{l_i : G_i'\}_{i\in I}}\ [\text{GR4}] \qquad \frac{G[\mu \mathbf{t}.G/t] \xrightarrow{\ell} G'}{\mu \mathbf{t}.G \xrightarrow{\ell} G'}\ [\text{GR5}]$$

Figure 4 Semantics for global types ( ).

specifies that p sends l_1 or l_2 to q and depending on this choice, r has to send a boolean or an integer to s. The problem is that role r cannot know which choice was made, and its specification is thus not possible to implement. The projection of role r should therefore be undefined for this global type. As a total function, translation naively ignores this and translates the l_1 branch, producing the local type $!2\langle \mathsf{bool}\rangle.\mathsf{end}$. If role p chooses l_2, role r will incorrectly behave as if l_1 was chosen.

The problem in the example above is solved by letting the projection function, which we denote with $\mathsf{proj}_{\mathsf{p}}(G)$, be defined only when the projectability predicate $\mathsf{projectable}_{\mathsf{p}}(G)$ holds. In such case, the returned local type is computed as $\mathsf{trans}_{\mathsf{p}}(G)$. This predicate depends on a coinductive specification of projection that is not covered in this paper. For the definition of the projectable predicate and the coinductive specification we refer the reader to the paper where they were first introduced [51].

The bottom of Figure 3 defines the function full_proj which projects a global type over all its roles, and generates a local type environment $\hat{\Delta}$.

▶ Remark 3 (Differences with the original work.). Projection is notoriously complex to define correctly. Our mechanisation uses the projection by Tirore et al. [51], which, unlike that of Honda et al., handles μ-binders correctly and has been proven sound and complete in Coq with respect to the coinductive projection specification by Ghilezan et al. [24].

Semantics of Global Types, Local Types, and Environments. We define the semantics of global types as a labeled transition system, denoted by $G \xrightarrow{\ell} G'$. A label ℓ, called *interaction*, is formally defined as:

$$\mathcal{U} ::= U \mid l \qquad\qquad \ell ::= \mathsf{p} \to \mathsf{q} : k\langle \mathcal{U}\rangle$$

The syntactic category $\mathcal{U}$ is either a message type U or a label l, and an interaction $\mathsf{p} \to \mathsf{q} : k\langle \mathcal{U}\rangle$ is either the exchange of a message type or a label.

The semantics of global types is defined by the rules given in Figure 4. Rules [GR1] and [GR2] allow a global type to reduce by its first interaction. Rules [GR3] and [GR4] allow a global type to reduce by an interaction ℓ that occurs nested in one of its continuations, which makes the semantics asynchronous by allowing p to occur in ℓ. On the process level, this corresponds to p putting a message on the queue to be read by q, followed by p completing interaction ℓ with a different role before q receives the message. The completed interaction ℓ may not involve q because inputs are blocking. Rule [GR5] unfolds a μ-binder.

$$\frac{}{!k\langle U\rangle.T \xrightarrow{!k\langle U\rangle} T}\ [\text{LR1}] \qquad \frac{}{?k\langle U\rangle.T \xrightarrow{?k\langle U\rangle} T}\ [\text{LR2}]$$

$$\frac{j \in I}{k \oplus \{l_i : T\}_{i\in I} \xrightarrow{!k\langle l_j\rangle} T_j}\ [\text{LR3}] \qquad \frac{j \in I}{k \,\&\, \{l_i : T_i\}_{i\in I} \xrightarrow{?k\langle l_j\rangle} T_j}\ [\text{LR4}]$$

$$\frac{T \xrightarrow{\zeta} T' \quad \mathsf{ch}(\zeta) \neq k}{!k\langle U\rangle.T \xrightarrow{\zeta} !k\langle U\rangle.T'}\ [\text{LR5}] \qquad \frac{\forall i \in I.\ T_i \xrightarrow{\zeta} T_i' \quad \mathsf{ch}(\zeta) \neq k}{k \oplus \{l_i : T\}_{i\in I} \xrightarrow{\zeta} k \oplus \{l_i : T_i'\}_{i\in I}}\ [\text{LR6}]$$

$$\frac{T[\mu \mathbf{t}.T/\mathbf{t}] \xrightarrow{\zeta} T'}{\mu \mathbf{t}.T \xrightarrow{\zeta} T'}\ [\text{LR7}] \qquad \frac{T_1 \xrightarrow{!k\langle U\rangle} T_1' \qquad T_2 \xrightarrow{?k\langle U\rangle} T_2'}{\hat{\Delta},\ \mathsf{p} : T_1,\ \mathsf{q} : T_2 \xrightarrow{\mathsf{p}\to\mathsf{q}:k\langle U\rangle} \hat{\Delta},\ \mathsf{p} : T_1',\ \mathsf{q} : T_2'}\ [\text{LEnv}]$$

Figure 5 Semantics for local types ( ) and local type environments ( ).

The semantics of local types is a two-level labeled transition system: the first level gives semantics to local types T, denoted by $T \xrightarrow{\zeta} T'$, and the second level gives semantics to local type environments $\hat{\Delta}$, denoted by $\hat{\Delta} \xrightarrow{\ell} \hat{\Delta}'$. A label ζ, called *action*, is formally defined as:

$$\zeta ::= !k\langle U\rangle \mid ?k\langle U\rangle$$

An action is the sending or receiving of a message type or a label. We write $\mathsf{ch}(\zeta)$ (resp. $\mathsf{ch}(\ell)$) to extract the channel of a local label ζ (resp. global label ℓ).

Formally, we define the semantics of local types and typing environments by the rules given in Figure 5. Rules [LR1], [LR2], [LR3] and [LR4] allow a local type to reduce by its first action. Similar to the global type rules [GR3] and [GR4], rules [LR5] and [LR6] allow a local type to reduce by an action ζ that occurs nested in one of its continuations. These rules make the local type semantics asynchronous. A condition for reducing by a nested action ζ, is that ζ uses a different channel than the first action, i.e., $\mathsf{ch}(\zeta) \neq k$. The intuition is that the first action, which is an output, already has occurred and it has resulted in a value being put on channel k; but before this value has been received by another participant, another interaction has in the meantime completed on another channel k'. Interactions between local types is captured by the semantics of local type environments $\hat{\Delta} \xrightarrow{\ell} \hat{\Delta}'$, given by the single rule [LEnv]. An environment may reduce by $\mathsf{p} \to \mathsf{q} : k\langle U\rangle$ when it maps p and q to local types that can reduce by $!k\langle U\rangle$ and $?k\langle U\rangle$.

▶ Remark 4 (Differences with the original work). We define the semantics of local types differently from Honda et al. Unlike their semantics, ours includes the asynchronous rules [LR5] and [LR6]. Instead, Honda et al. achieve asynchrony by defining a relation that relates local types with permuted outputs; for example, $!k\langle U\rangle.!k'\langle U'\rangle.T$ is related to $!k'\langle U'\rangle.!k\langle U\rangle.T$. Similar to our asynchronous rules, this permutation is only allowed if $k \neq k'$. However, that by Honda et al. is a more restrictive semantics, as it misses cases where an output is preceded by a nested input on a different channel, thereby permitting the input to be placed in front of the output. For instance, with the types $!k\langle U\rangle;?k'\langle U'\rangle;T$ and $?k'\langle U'\rangle;!k\langle U\rangle;T$, for $k \neq k'$, our rule [LR5] with $\zeta = ?k'\langle U\rangle$ allows the output to be preceded by the input. Preceding an output with an input is essential for proving the equivalence between the semantics of global types and that of local type environments, a property known as the *Projection Theorem*. Consequently, their restrictive semantics means that their projection theorem (Lemma 5.11 [33]) does not hold. At the end of this section, we present a projection theorem for our semantics.

Linearity. The Honda et al. formulation of multiparty session types began an entire line of research, but to the best of our knowledge, all future work has adopted the *implicit* channels introduced by Bettini et al. [4]. Although they are more expressive, explicit channels are more complicated, allowing global types to contain races. For example, the global type:

$$\mathsf{p} \to \mathsf{q} : k\langle \mathsf{int} \rangle.\ \mathsf{r} \to \mathsf{q} : k\langle \mathsf{bool} \rangle.\mathsf{end} \tag{8}$$

is problematic because the two interactions $\mathsf{p} \to \mathsf{q} : k\langle \mathsf{int} \rangle$ and $\mathsf{r} \to \mathsf{q} : k\langle \mathsf{bool} \rangle$ share the same explicit channel k which introduces a race between p and r. The problem is that roles p, q, and r are freely using channel k without coordination. Hence, if r writes on channel k before p, it wins the race and a type error occurs when q receives bool while expecting int. Linearity of global types (not to be confused with standard linear types) is a property that rules out global types with interactions that introduce races. The main intuition behind linearity is that those interactions of a global type that share the same channel must have some causal dependency that avoids races. In the example, there is no causal dependency between the output of p and the output of q. However, the global type

$$\mathsf{p} \to \mathsf{q} : k\langle \mathsf{int} \rangle.\ \mathsf{p} \to \mathsf{r} : k'\langle \mathsf{string} \rangle.\ \mathsf{r} \to \mathsf{q} : k\langle \mathsf{bool} \rangle.\mathsf{end} \tag{9}$$

enforces a dependency between the output of p and the output of r: p first sends int on channel k and then sends string on k' while r has to receive string on channel k' before sending bool on channel k. Linearity checks that all execution paths of a global type enforce dependencies between interactions on the same channel, ensuring that no race can occur.

We first introduce the notion of a trace as:

▶ **Definition 5** (Trace 🐓). *A trace ρ of a global type G is a (possibly empty) sequence of interactions such that*

$$\frac{\mathsf{trace}\ \rho\ G}{\mathsf{trace}\ (\mathsf{p} \to \mathsf{q} : k\langle U \rangle \cdot \rho)\ (\mathsf{p} \to \mathsf{q} : k\langle U \rangle.G)} \qquad \frac{\mathsf{trace}\ \rho\ (G[\mu \mathbf{t}.G\ \mathsf{t}])}{\mathsf{trace}\ \rho\ (\mu \mathbf{t}.G)}$$

$$\frac{\mathsf{trace}\ \rho\ G_i}{\mathsf{trace}\ (\mathsf{p} \to \mathsf{q} : k\langle l_i \rangle \cdot \rho)\ (\mathsf{p} \to \mathsf{q} : k\{l_i : G_i\}_{i \in I})} \qquad \frac{}{\mathsf{trace}\ \epsilon\ G}$$

Intuitively, a trace records the interactions of a finite walk through the global type, starting from the first interaction and unfolding μ-binders when they occur. For example, the global type G in Equation (1) has traces $\mathsf{p} \to \mathsf{q} : 1\langle l_1 \rangle \cdot \mathsf{q} \to \mathsf{r} : 2\langle \mathsf{bool} \rangle \cdot \epsilon$ and $\mathsf{p} \to \mathsf{q} : 1\langle l_2 \rangle \cdot \mathsf{p} \to \mathsf{r} : 2\langle \mathsf{bool} \rangle \cdot \epsilon$. However, since a trace is a finite walk, also $\mathsf{p} \to \mathsf{q} : 1\langle l_1 \rangle \cdot \epsilon$ and $\mathsf{p} \to \mathsf{q} : 1\langle l_2 \rangle \cdot \epsilon$ are traces of G. We say $\mathsf{p} \to \mathsf{q} : k$ happens before $\mathsf{r} \to \mathsf{s} : k'$ in G if, for some ρ and ρ', we can derive:

$$\mathsf{trace}\ (\rho \cdot \mathsf{p} \to \mathsf{q} : k\langle \mathcal{U} \rangle \cdot \rho' \cdot \mathsf{r} \to \mathsf{s} : k'\langle \mathcal{U}' \rangle)\ G \tag{10}$$

We omit $\mathcal{U}$ and $\mathcal{U}'$ from the interactions as they provide no causal information. Given two interactions ℓ_1 and ℓ_2, we say that ℓ_1 and ℓ_2 are ordered if ℓ_1 happens before ℓ_2 or vice versa. Linearity asserts that ordered interactions that share the same channel must have dependencies between their inputs and outputs, which then guarantees the absence of races. Formally, we first define dependencies as:

▶ **Definition 6** (Input and Output Dependencies). *The interaction dependencies* $\mathsf{IO}, \mathsf{II}, \mathsf{OO}, \mathsf{IOOO} \subseteq \ell \times \ell$ (🐓) *and judgments* input dep ρ (🐓) *and* output dep ρ (🐓) *are defined as:*

$$\mathsf{p} \to \mathsf{q} : k\ \mathsf{IO}\ \mathsf{s} \to \mathsf{r} : k' \stackrel{\mathsf{def}}{=} (\mathsf{q} = \mathsf{s}) \qquad \mathsf{p} \to \mathsf{q} : k\ \mathsf{II}\ \mathsf{r} \to \mathsf{s} : k' \stackrel{\mathsf{def}}{=} (\mathsf{q} = \mathsf{s})$$

$$\mathsf{p} \to \mathsf{q} : k\ \mathsf{OO}\ \mathsf{s} \to \mathsf{r} : k' \stackrel{\mathsf{def}}{=} (\mathsf{p} = \mathsf{s}) \wedge (k = k') \qquad \ell_1\ \mathsf{IOOO}\ \ell_2 \stackrel{\mathsf{def}}{=} \ell_1\ \mathsf{IO}\ \ell_2 \vee \ell_1\ \mathsf{OO}\ \ell_2$$

$$\text{[I-Base]}\ \frac{\ell_1\ \mathsf{II}\ \ell_2}{\mathsf{input\ dep}\ \ell_1 \cdot \ell_2} \qquad \text{[I-Skip]}\ \frac{\mathsf{input\ dep}\ \ell_1 \cdot \rho \cdot \ell_3}{\mathsf{input\ dep}\ \ell_1 \cdot \ell_2 \cdot \rho \cdot \ell_3} \qquad \text{[I-Tail]}\ \frac{\mathsf{input\ dep}\ \ell_2 \cdot \rho \cdot \ell_3 \qquad \ell_1\ \mathsf{IO}\ \ell_2}{\mathsf{input\ dep}\ \ell_1 \cdot \ell_2 \cdot \rho \cdot \ell_3}$$

$$\text{[O-Base]}\ \frac{\ell_1\ \mathsf{IOOO}\ \ell_2}{\mathsf{output\ dep}\ \ell_1 \cdot \ell_2} \qquad \text{[O-Skip]}\ \frac{\mathsf{output\ dep}\ \ell_1 \cdot \rho \cdot \ell_3}{\mathsf{output\ dep}\ \ell_1 \cdot \ell_2 \cdot \rho \cdot \ell_3} \qquad \text{[O-Tail]}\ \frac{\mathsf{output\ dep}\ \ell_2 \cdot \rho \cdot \ell_3 \qquad \ell_1\ \mathsf{IOOO}\ \ell_2}{\mathsf{output\ dep}\ \ell_1 \cdot \ell_2 \cdot \rho \cdot \ell_3}$$

Interaction dependencies relate interactions by asserting different ways the same role can occur in both interactions, such as IO (input-output) meaning the input role of the first interaction is also the output role of the second interaction (cf. [32]). Likewise we have OO (output-output) and II (input-input) dependencies. Input and output dependencies are obtained by composing interaction dependencies. An input dependency is a sequence of IO dependencies that ends in II while an output dependency is a sequence of IOOO dependencies. We use these chains to show causal orderings between the roles in the first and last interactions of the chain. For the sake of presentation of rules [O-Base] and [O-Tail], we have defined the interaction dependency IOOO which simply states that there can be either an IO or an OO dependency.

We begin by examining each rule of input dependency to understand why they assert and preserve the ordering of inputs. The shortest input dependency is established by [I-Base], where the two inputs originate from the same role and are therefore ordered. Rule [I-Skip] reflects that chains do not need to include all interactions in the trace. Finally rule [I-Tail] extends an existing input dependency between ℓ_2 and ℓ_3 by adding ℓ_1 in front of ℓ_2 when it satisfies $\ell_1\ \mathsf{IO}\ \ell_2$. We can assume that the inputs of ℓ_2 and ℓ_3 are ordered and this is also the case between ℓ_1 and ℓ_3 if it is the case for ℓ_1 and ℓ_2. If the channels of ℓ_1 and ℓ_2 are different then the inputs are ordered because the input of ℓ_2 cannot intercept the output of ℓ_1. If the channels are the same, then there must exist input and output dependencies between ℓ_1 and ℓ_2, ensuring in particular that their inputs are ordered. More generally, input and output dependencies show that a specific pair of ordered interactions, with the same channel, have ordered inputs and outputs, by relying on this property to hold for all other ordered interactions with the same channel.

Next, we consider why the rules of output dependency preserve ordering of outputs. We start by the shortest output dependency built by [O-Base], relating the interactions by either OO or IO. The former ensures the ordering by having the same role in both outputs. IO preserves output dependency by blocking the output of the second interaction. Rule [O-Skip] is the corresponding skip. Finally, rule [O-Tail] allows output dependencies to be extended either by OO or IO, extending the ordering of the outputs between ℓ_2 and ℓ_3 by adding ℓ_1 in front, as long as the outputs of ℓ_1 and ℓ_2 are ordered as well. The argument for why output ordering is preserved is similar to that of rule [O-Base].

Linearity asserts dependencies between any ordered interactions with the same channel. Unlike Honda et al., we define linearity in terms of a weaker property, $\mathsf{linearHead}(G)$, which simplifies the decision procedure. This formulation only asserts the existence of dependencies when the first of the two interactions is also the first interaction in the trace.

We define linearity of a global type, $\mathsf{linear}(G)$, in terms of $\mathsf{linearHead}(G)$ in Figure 7. Intuitively, $\mathsf{linearHead}(G)$ checks if the first interaction is free of races and $\mathsf{next}(G)$ proceeds to the continuation of the global type. Due to global types having only finitely many distinct subterms, a consequence of μ-types being regular [47], only finitely many applications of the coinductive rule of linear is necessary before a previously encountered global type inevitably reappears, at which point the proof can circularly be closed.

$$|G| \stackrel{\text{def}}{=} \begin{cases} 1 + |G_1| & \text{if } G = \mu \mathbf{t}.G_1 \\ 0 & \text{otherwise} \end{cases} \qquad \mathsf{unfold_once}(G) \stackrel{\text{def}}{=} \begin{cases} G_1[\mu \mathbf{t}.G_1/t] & \text{if } G = \mu \mathbf{t}.G_1 \\ G & \text{otherwise} \end{cases}$$

$$\mathsf{unf}(G) \stackrel{\text{def}}{=} \mathsf{unfold_once}^{|G|}(G)$$

Figure 6 Calculating μ-height ( ) and unfolding global types ( ). Corresponding operations exist on local types (respectively and).

$$\mathsf{linearHead}(G) \stackrel{\text{def}}{=} \forall \ell_1\ \rho\ \ell_2.\ \ \mathsf{trace}\ (\ell_1 \cdot \rho \cdot \ell_2)\ G\ \rightarrow\ \mathsf{ch}(\ell_1) = \mathsf{ch}(\ell_2)\ \rightarrow \\ \mathsf{input\ dep}\ \ell_1 \cdot \rho \cdot \ell_2 \wedge \mathsf{output\ dep}\ \ell_1 \cdot \rho \cdot \ell_2$$

$$\mathsf{next}(G) \stackrel{\text{def}}{=} \begin{cases} \{G_1\} & \text{if } \mathsf{unf}(G) = \mathsf{p}_1 \to \mathsf{p}_2 : k\langle U \rangle.G_1 \\ \{G_i \mid i \in I\} & \text{if } \mathsf{unf}(G) = \mathsf{p}_1 \to \mathsf{p}_2 : k\{l_i : G_i\}_{i \in I} \\ \emptyset & \text{otherwise} \end{cases}$$

$$\frac{\mathsf{linearHead}(G) \quad \forall G' \in \mathsf{next}(G).\ \mathsf{linear}(G')}{\mathsf{linear}(G)}$$

Figure 7 Linearity of global types ( ).

The definition of the function $\mathsf{next}(G)$ uses the unfold operation $\mathsf{unf}(G)$ which we define in Figure 6. The definition uses μ-height, denoted by $|G|$, which is the number of top-level μ-binders occurring before another construct appears. For example, $|\mu \mathbf{t}.\mathsf{end}| = 1$ and $|\mathsf{p} \to \mathsf{q} : k\langle U \rangle.G| = 0$. We create an auxiliary function $\mathsf{unfold_once}(\cdot)$ which unfolds a single binder by turning $\mu \mathbf{t}.G$ into $G[\mu \mathbf{t}.G/\mathbf{t}]$ and define the unfolding operation for global types, denoted by $\mathsf{unf}(G)$, as the repeated application of $\mathsf{unfold_once}(G)$ μ-height times. The operation $\mathsf{unf}(T)$ can be similarly defined on local types and we elide its definition.

▶ **Theorem 7** (Decidability of Linearity). *The predicate* $\mathsf{linear}(G)$ *is decidable.*

Decidability of linearity can be reduced to a reachability problem on a graph induced by a global type with $\mathsf{next}(\cdot)$ as an adjacency list.

Projection Theorem. We have seen that interactions in a protocol can be described by $G \xrightarrow{\ell} G'$ and $\hat{\Delta} \xrightarrow{\ell} \hat{\Delta}'$. Naturally, we want to establish a correspondence between these two semantics with respect to the projection operation. Intuitively, if $\hat{\Delta}$ and $\hat{\Delta}'$ are derived from G and G', respectively, then $G \xrightarrow{\ell} G'$ holds if and only if $\hat{\Delta} \xrightarrow{\ell} \hat{\Delta}'$. However, this result is too strong due to recursion, which may unfold some terms during reduction, making projection slightly different. The issue lies in syntactic equality on local types being too restrictive to prove the projection theorem. Local types, however, can be more loosely related by a coinductive equality on their continuously unfolded terms:

▶ **Definition 8** (Coinductive equality). *Coinductive equality is a relation on local types defined by the following rules:*

$$\frac{\mathit{unf}(T) = \mathsf{end} \quad \mathit{unf}(T') = \mathsf{end}}{T \approx T'} \text{ [Eq-End]}$$

$$\frac{\mathit{unf}(T) = !k\langle U\rangle.T'' \quad \mathit{unf}(T') = !k\langle U\rangle.T''' \quad T'' \approx T'''}{T \approx T'} \text{ [Eq-!]}$$

$$\frac{\mathit{unf}(T) = ?k\langle U\rangle.T'' \quad \mathit{unf}(T') = ?k\langle U\rangle.T''' \quad T'' \approx T'''}{T \approx T'} \text{ [Eq-?]}$$

$$\frac{\mathit{unf}(T) = k \oplus \{l_j : T_j\}_{j\in J} \quad \mathit{unf}(T') = k \oplus \{l_j : T'_j\}_{j\in J} \quad \forall j \in J.\ T_j \approx T'_j}{T \approx T'} \text{ [Eq-}\oplus\text{]}$$

$$\frac{\mathit{unf}(T) = k \,\&\, \{l_j : T_j\}_{j\in J} \quad \mathit{unf}(T') = k \,\&\, \{l_j : T'_j\}_{j\in J} \quad \forall j \in J.\ T_j \approx T'_j}{T \approx T'} \text{ [Eq-\&]}$$

This relation checks the shape of the unfolded local types, and checks whether the same actions are specified, before proceeding to the continuations. Because of unfolding, it might require a circular proof to derive the equality. With an abuse of notation, $\hat{\Delta}_1 \approx \hat{\Delta}_2$ is the point-wise extension of $\approx$ to local type environments. Coinductive equality on continuously unfolded μ-types is decidable [47], and this has been mechanised [18]. Our mechanisation also includes a proof of the decidability of the relation $\approx$, which, to the best of our knowledge, is the first mechanisation for session types. Using this relation, we can state the following:

▶ **Theorem 9** (Projection). *Let G be a global type such that* $\mathsf{linear}(G)$ *holds and* $\mathsf{full_proj}(G)$ *is defined, then*

1. (🐓) *if $G \xrightarrow{l} G'$ then $\hat{\Delta}$ exists such that* $\mathsf{full_proj}(G) \xrightarrow{l} \hat{\Delta}$ *and* $\mathsf{proj_roles}(G', \mathsf{roles}(G)) \approx \hat{\Delta}$
2. (🐓) *if* $\mathsf{full_proj}(G) \xrightarrow{l} \hat{\Delta}$ *then G' exists such that $G \xrightarrow{l} G'$ and* $\mathsf{proj_roles}(G', \mathsf{roles}(G)) \approx \hat{\Delta}$.

▶ Remark 10 (Differences with the original work). The projection theorem of Honda et al. does not take into account that $\mathsf{roles}(G')$ may be a strict subset of $\mathsf{roles}(G)$. The set of roles in a global type can decrease after reduction if the reduced interaction involves a role that only occurs in that interaction. This results in an invalid environment reduction because the domain shrinks, exemplifying an innocent error that is hard to catch on paper.

4 Queue Types, Environment Decomposition, and Coherence

Queue types. Honda et al. handle the typing of queues using type contexts $\mathcal{T}$, which are local types with a hole $[\cdot]$. They decompose a local type T into a context $\mathcal{T}$ and another local type T', such that the applied context $\mathcal{T}[T']$ is related to T by a subtyping relation (see Definition 5.1 [33]). The type checking of a process against an environment $\hat{\Delta}$, may involve multiple of these decompositions. Mechanising this approach is non-trivial, and for convenience, we take a different approach: we type processes with an environment that contains local types that are decomposed *a priori*. We refer to this as a decomposed environment, denoted by $\hat{\Delta}; \hat{\mathcal{Q}}$. We formally define queue environments $\hat{\mathcal{Q}}$, and the queue types Q it contains, as:

▶ **Definition 11** (Queue type and Queue Environment). Queue types (🐓), *denoted by* $\mathtt{Q}$, *and* queue environments (🐓), *denoted by* $\hat{\mathcal{Q}}$ *, are defined as:*

$$\mathtt{Q} ::= \emptyset \mid (k, \mathcal{U}) \cdot \mathtt{Q} \qquad \hat{\mathcal{Q}} ::= \emptyset \mid \hat{\mathcal{Q}},\ \mathtt{p} : \mathtt{Q}$$

A queue environment $\hat{\mathcal{Q}}$ is a map from roles to queue types, and a queue type is a sequence of pairs. In each pair, the left component is always a channel, and the right component is either a message type U or a label l. A pair $(k, \mathcal{U})$ in the queue type models the presence of a message $\mathcal{U}$ in the queue at channel k, and the order of these pairs indicates the order in which these messages were sent. Queue types are given with respect to roles in the environment $\hat{\mathcal{Q}}$, and this environment describes the content of all queues in the session. Queue types are derived from local types using the following notion of path:

▶ **Definition 12** (Path 🐓). *A path, denoted by σ, is a (possibly empty) sequence of elements from the set $\mathcal{L} \cup \{\bot\}$, where $\mathcal{L}$ is the set of labels defined in Section 2.*

A path is similar to a trace, it represents a walk through the μ-type. Unlike traces, we use paths to decompose local types.

▶ **Definition 13** (Decomposition of Local Types 🐓). *The decomposition of local types, denoted by* $\mathsf{decomp} : \sigma \to T \to T \times Q$*, is defined as:*

$$\mathsf{decomp}_\sigma\ T \stackrel{\mathsf{def}}{=} \begin{cases} (T', (k, U) \cdot \mathtt{Q}) & \mathsf{unf}\ T = !k\langle U\rangle.T_1 \ \wedge\ \sigma = \bot \cdot \sigma' \ \wedge\ \mathsf{decomp}_\sigma\ T_1 = (T', \mathtt{Q}) \\ (T', (k, l_j) \cdot \mathtt{Q}) & \mathsf{unf}\ T = k \oplus \{l_i : T\}_{i \in I} \ \wedge\ \sigma = l_j \cdot \sigma' \ \wedge \\ & \mathsf{decomp}_\sigma\ T_j = (T', \mathtt{Q}) \quad \wedge\ j \in I \\ (\mathsf{unf}\ T, \emptyset) & \sigma = \emptyset \\ \text{undefined} & \text{otherwise} \end{cases}$$

With respect to a path, decomposition splits a local type into a pair consisting of a residual local type and a queue type. We overload notation, denoting the point-wise extension of decomposition onto environments as $\mathsf{decomp}_f\ \hat{\Delta}$, which splits the environment $\hat{\Delta}$, with respect to a path function $f : \mathscr{P} \to \sigma$, into a residual environment $\hat{\Delta}'$ and a queue environment $\hat{\mathcal{Q}}$.

▶ **Definition 14** (Decomposition of Environments 🐓). *Let the path function f be such that $\forall i \in \{1, \ldots, n\}.\ \mathsf{decomp}_{f(\mathsf{p}_i)}\ T_i = (T_i', \mathtt{Q}_i)$. Environment decomposition, denoted by* $\mathsf{decomp} : (\mathscr{P} \to \sigma) \to \hat{\Delta} \to \hat{\Delta} \times \hat{\mathcal{Q}}$*, is defined as:*

$$\mathsf{decomp}_f\ (\mathsf{p}_1 : T_1, ..., \mathsf{p}_n : T_n) \quad \stackrel{\mathsf{def}}{=} \quad \mathsf{p}_1 : T_1', ..., \mathsf{p}_n : T_n';\ \mathsf{p}_1 : \mathtt{Q}_1, ..., \mathsf{p}_n : \mathtt{Q}_n$$

▶ **Example 15.** The path function tracks, within a session, the messages that are in transit. Recall that the initial state of our running example from Section 1, Equation (4), has two empty queues. Because the queues are empty, the decomposition of the local types that type the three roles, should all produce the empty queue type $\emptyset$. This is achieved with the path function: $f(\mathsf{p}) = \emptyset$. After p has put a message on each of the two queues in Equation (5), the local type of p must be decomposed in a way that reflects the two outputs have been performed, and that the remaining roles have performed no outputs. We achieve this with the path function: $f(\mathsf{p}') = \mathsf{if}\ \mathsf{p}' = \mathsf{p}\ \mathsf{then}\ l_1 \cdot \bot\ \mathsf{else}\ \emptyset$. The decomposition of $G\!\upharpoonright_{\mathsf{p}}$ with respect to $f(\mathsf{p})$, where G is the global type in our running example, yields the residual local type end and queue type $(1, l_2) \cdot (2, \mathsf{bool})$.

Coherence. Honda et al. use a well-formedness condition on global types called coherence, which they define as a global type being linear and projectable, i.e., its projection is defined for all roles. Coherence is key to the soundness of Honda et al.'s work and other approaches based on global types, as it ensures that local behaviours are compatible [11, 49, 12] and correctly follow the global specification. However, coherence is not sufficient to rule out our counterexample. For this reason, we introduce an additional property to our definition of coherence, called unstuckness and denoted by $\mathsf{unstuck}\ (G)$.

$$\frac{}{\mathsf{p} \to \mathsf{q} : k\langle U\rangle.G \downarrow^1 \mathsf{p} \to \mathsf{q} : k\langle U\rangle}\ [\text{GB-1}] \qquad \frac{j \in I}{\mathsf{p} \to \mathsf{q} : k\{l_i : G_i\}_{i\in I} \downarrow^1 \mathsf{p} \to \mathsf{q} : k\langle l_j\rangle}\ [\text{GB-2}]$$

$$\frac{\mathsf{q} \notin \ell \quad G \downarrow^1 \ell}{\mathsf{p} \to \mathsf{q} : k\langle U\rangle.G \downarrow^1 \ell}\ [\text{GB-3}] \qquad \frac{\mathsf{q} \notin \ell \quad j \in I \quad G_j \downarrow^1 \ell}{\mathsf{p} \to \mathsf{q} : k\{l_i : G_i\}_{i\in I} \downarrow^1 \ell}\ [\text{GB-4}] \qquad \frac{G[\mu \mathbf{t}.G/t] \downarrow^1 \ell}{\mu \mathbf{t}.G \downarrow^1 \ell}\ [\text{GB-5}]$$

Figure 8 Barb relation for global types ( ).

The idea behind unstuckness is the following. The global type which specifies the counterexample is stuck because the only relevant rule, [GR4], is not applicable due to its restrictive premise, which requires universal quantification $\forall i \in I.\ G_i \xrightarrow{\ell} G_i'$. If this premise were relaxed to existential quantification $\exists i \in I.\ G_i \xrightarrow{\ell} G_i'$, then the global type would not be stuck. It is however not an option to relax the rule because it would break the Projection theorem. Instead, we define $\mathsf{unstuck}\ (G)$, which captures global types where the universally quantified premise implies the existentially quantified premise. The global type in the counterexample does not satisfy this property and is thus ruled out.

In order to define the unstuck predicate, we use the notion of barb, denoted by $G \downarrow^1 \ell$, formally defined by the rules in Figure 8. Intuitively, $G \downarrow^1 \ell$ holds whenever it is possible to derive that G can reduce by ℓ, in the relaxed setting where the existentially quantified premise is used in [GR4]. This lets us quantify over the labels for which reduction derivations must exist. This property must also be preserved by reduction, so we additionally assert that the reduced global type G' satisfies the property as well. For recursive global types, a derivation will not be finite, and the predicate is therefore coinductively defined:

▶ **Definition 16** (Unstuck). *We say a global type is unstuck if it satisfies the predicate* $\mathsf{unstuck}\ (G)$*, coinductively defined as:*

$$\frac{\forall \ell.\ G \downarrow^1 \ell \implies \exists G'.G \xrightarrow{\ell} G' \wedge \mathsf{unstuck}\ (G')}{\mathsf{unstuck}\ (G)}$$

We can finally introduce our stricter notion of coherence:

▶ **Definition 17** (Coherence). *The coherence of global types, local types and decomposed environments, denoted respectively by* $\mathsf{coherent}(G)$*,* $\mathsf{coherent}(L)$ *and* $\mathsf{coherent}(\hat{\Delta};\hat{\mathcal{Q}})$*, is defined as:*

- ( ) $\mathsf{coherent}(G)$ *holds iff* G *is projectable, linear and unstuck*
- ( ) $\mathsf{coherent}(\hat{\Delta})$ *holds iff there exists a coherent* G *whose full projection is* $\hat{\Delta}$
- ( ) $\mathsf{coherent}(\hat{\Delta};\hat{\mathcal{Q}})$ *holds iff there exists a coherent* $\hat{\Delta}'$ *and a function* f *such that* $\mathsf{decomp}_f\ \hat{\Delta}' = \hat{\Delta};\hat{\mathcal{Q}}$*.*

5 Typing System and Subject Reduction

This section introduces the type system for processes, connecting the concepts we have covered so far. This is formalised by the following typing judgement ( ):

$$\Gamma \vdash_{\mathcal{D}} P \triangleright_{\mathcal{C}} \mathcal{Q};\ \Delta$$

The intuitive meaning of the judgement is that process P is well-typed with values typed by the unrestricted environment Γ, including shared names, which Γ maps to global types. Ongoing sessions are typed by the two linear environments Δ and $\mathcal{Q}$. Process variables

are typed by $\mathcal{D}$, and the linear environment $\mathcal{C}$ ensures that each queue address is unique. Each entry $\mathsf{s}[k]$ in $\mathcal{C}$ acts as a unique token associated to a queue. We use $\mathcal{C}$ to ensure that queue addresses are unique across a process, e.g., $\mathsf{s}[k] :: \emptyset \mid \mathsf{s}[k] :: \emptyset$. Formally, we define these environments as

$$\text{(Unrestricted)} \quad \Gamma ::= \emptyset \mid \Gamma, a : G \mid \Gamma, x : U \qquad \mathcal{D} ::= \emptyset \mid \mathcal{D}, X : (U, \vec{T})$$

$$\text{(Linear)} \quad \mathcal{C} ::= \emptyset \mid \mathcal{C}, \mathsf{s}[k] \qquad \Delta ::= \emptyset \mid \Delta, s : T \qquad \mathcal{Q} ::= \emptyset \mid \mathcal{Q}, \mathsf{s}^{\mathsf{p}} : Q$$

The environment $\mathcal{Q}$ associates a queue type with each located session, recording what actions have been performed, while Δ associates a local type with each session channel, indicating what actions remain. $\mathcal{C}$ ensures that all queue addresses are disjoint. Note that the environments $\mathcal{Q}$ and Δ may specify multiple sessions, while $\hat{\mathcal{Q}}$ and $\hat{\Delta}$ specifies a single session.

▶ **Definition 18** (Session Filtering and Lifting). *The filtering of Δ by session identifier s, denoted by $\Delta(\mathsf{s})$, is the environment $\hat{\Delta}$ containing the local types of session s in Δ. Similarly, the filtering of $\mathcal{Q}$ by session identifier s, denoted by $\mathcal{Q}(\mathsf{s})$, is the environment $\hat{\mathcal{Q}}$ containing the local types of session s in $\mathcal{Q}$. These operations are always defined and return the empty environment when s is not present.*
Conversely, we define a lifting operation on $\hat{\Delta}$ and $\hat{\mathcal{Q}}$, denoted respectively by $[\hat{\Delta}]_{\mathsf{s}}$ and $[\hat{\mathcal{Q}}]_{\mathsf{s}}$, which yields environments Δ and $\mathcal{Q}$, corresponding to the initial environments where roles p have been replaced with located sessions s^{p}.

Using session filtering, we can extend the definition of coherence to $\Delta; \mathcal{Q}$.

▶ **Definition 19** (Coherence of $\Delta; \mathcal{Q}$ 🐓). *The coherence of the environment $\Delta; \mathcal{Q}$, denoted by $\mathsf{coherent}(\Delta; \mathcal{Q})$, holds iff for any session identifier s, $\Delta(\mathsf{s}); \mathcal{Q}(\mathsf{s})$ is coherent.*
When we, in stating the coherence of $\Delta; \mathcal{Q}$, want to refer to the underlying coherent environment Δ', whose decomposition yields $\Delta; \mathcal{Q}$, we write $\mathsf{coherent}(\Delta; \mathcal{Q})$ as Δ'.

The environments Δ, $\mathcal{Q}$ and $\mathcal{C}$ are linear, and this means different things for each. For Δ and $\mathcal{C}$, linearity carries the standard meaning: each entry in the environment must be used exactly once. In other words, entries cannot be duplicated, such that a local type in Δ is used to type two different processes. The linearity of $\mathcal{Q}$ is based on the partitioning of a queue type, which we explain next:

▶ **Example 20** (Partitioning a queue). Consider two queues with messages from the same p

$$\mathsf{s}[k] :: \mathsf{true}^{\mathsf{p}} \mid \mathsf{s}[k'] :: \mathsf{true}^{\mathsf{p}}$$

The queue type of p is $(k, \mathsf{bool}) \cdot (k', \mathsf{bool})$. We partition the queue type into two queue types, one for each queue, namely (k, bool) and (k', bool).

In the following definition, let $\mathsf{filter}\ f\ Q$ denote the queue type obtained by filtering out all those entries in the channels of Q that do not satisfy the predicate $f : k \to \{\mathsf{True}, \mathsf{False}\}$. Partitioning is then defined as:

▶ **Definition 21** (Partitioning 🐓). *Partitioning of a queue type by a predicate $f : k \to \mathsf{bool}$, denoted by $\mathsf{partition} : (k \to \{\mathsf{True}, \mathsf{False}\}) \to Q \to Q \times Q$, is defined as:*

$$\mathsf{partition}^f(Q) = (\mathsf{filter}\ f\ Q, \mathsf{filter}\ (\lambda k.\ \neg f(k))\ Q)$$

We write $(Q_0, Q_1) \hookrightarrow Q$ when there exists a predicate f such that $\mathsf{partition}^f(Q) = (Q_0, Q_1)$ and we point-wise extend this to environments, abusing notation by writing $(\mathcal{Q}_0, \mathcal{Q}_1) \hookrightarrow \mathcal{Q}$.

$$\frac{\Gamma(x) = S}{\Gamma \vdash x : S} \qquad \Gamma \vdash b : \mathsf{bool} \qquad \frac{\Gamma \vdash e : \mathsf{bool} \qquad \Gamma \vdash e' : \mathsf{bool}}{\Gamma \vdash e \text{ and } e' : \mathsf{bool}}$$

Figure 9 Typing rules for expressions ( ).

The terminated process $\mathbf{0}$ and the empty queue $\mathsf{s}[k] :: \emptyset$ are typed using the following definitions for terminated environments:

▶ **Definition 22** (Terminated Environments). *A local type environment is terminated, denoted by* $\mathsf{ends}(\Delta)$ *iff* $\forall(\mathsf{p} : T) \in \Delta.\ \mathit{unf}(T) = \mathsf{end}$. *A queue environment is terminated, denoted by* $\mathsf{ends}(\mathcal{Q})$ *iff* $\forall(\mathsf{s}^{\mathsf{p}} : Q) \in \mathcal{Q}.\ Q = \epsilon$

Typing Rules. The rules defining our type system can be found in Figures 9, 10, and 11. Figure 9 contains the typing rules for expressions. The typing rules for processes are split into two parts: the first part is presented in Figure 10, where all rules include the premise $\mathsf{ends}(\mathcal{Q})$, which is omitted in the figure to conserve space. [T-MCast] and [T-MAcc] type session request and accept, respectively. Roles are totally ordered, and the largest role of G is n which is assigned to the requesting process. The unfolding of its projection is inserted into Δ. [T-Send] and [T-Rcv] are the rules for sending and receiving. The session channel s is mapped to a local type in Δ and checked to correspond with the action of the process. In the typing of the subterm P, the s entry in Δ is updated to the unfolded continuation $\mathsf{unf}\ T$. [T-Deleg] and [T-SRec] type session delegation and reception. Similarly to the rules for send and receive, they perform the delegation of session channel s', which requires the type T_2 for s' in the environment to be coinductively equal to the carried type T_1 in the type of s. Here, coinductive equality is necessary to ensure the type system is closed under $\approx$. The rules [T-Sel] and [T-Branch] are similar to [T-Send] and [T-Rcv]. [T-IF] is the rule for if statements, which has no effect on the type environments. [T-Inact] and [T-QNil] are the rules for inaction and the empty queue, using the predicates $\mathsf{ends}(\Delta)$ and $\mathsf{ends}(\mathcal{Q})$ to check that the respective environments are terminated.

The remaining rules are in Figure 11, where the premises of all rules are explicitly stated. [T-Conc] types parallel composition and implements the split of the environments as discussed above. [T-NRes] and [T-CRes] are the rules for name and channel restriction. [T-NRes] introduces a coherent global type into Γ. [T-CRes] adds the decomposed environment $\hat{\Delta}; \hat{\mathcal{Q}}$ into $\Delta; \mathcal{Q}$ and extends $\mathcal{C}$ by a disjoint set of unique tokens $\{\mathsf{s}[k_i]\}_{i \in I}$. The tokens in $\mathcal{C}$ are used to ensure the uniqueness of queue addresses such that if $\mathsf{s}_k \in \mathsf{dom}\ \mathcal{C}$, then exactly one queue of shape $\mathsf{s}[k] :: \tilde{h}$ exists in the typed process. [T-QVal], [T-QSess], and [T-QSel] are type queues. A message is annotated by the role p that sent the message, which is used to identify the queue type in $\mathcal{Q}$ associated with the located session s^{p}, checking that k and $\mathcal{U}$ in the queue type correspond to the channel of the queue and the message it contains. [T-Var] is the rule for procedure call, calling procedure X with an expression and a list of distinct session channels. Here, we write $\tilde{s} : \tilde{T}$ to mean then environment with entries $(\tilde{s}_i : \tilde{T}_i)$ for $i \in \{1, .., |\tilde{s}|\}$, where $|\tilde{s}| = |\tilde{T}|$.

Our semantics uses a fixed set of definitions D in $\rightarrow_D$. We now show how to type them.

▶ **Definition 23** (Typing of declarations). *Declarations D are typed by the environment $\mathcal{D}$ whenever* $\mathsf{dom}\ D = \mathsf{dom}\ \mathcal{D}$ *and*

$$\forall X(x\tilde{\jmath}) = P \in D. \quad X : (U, \tilde{T}) \in \mathcal{D} \text{ implies } x : U \vdash_{\mathcal{D}} P \triangleright_{\emptyset} \tilde{\jmath} : \tilde{T};\ \emptyset$$

$$\frac{\Gamma \vdash a : G \quad \begin{array}{l}\mathsf{roles}(G) = \{0, \ldots, \mathsf{n}\} \\ \mathsf{channels}(G) = \{1, \ldots, k\}\end{array} \quad \Gamma \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \Delta, \mathfrak{s} : \mathsf{unf}(G\restriction_{\mathsf{n}});\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} \overline{a}\,[\mathsf{n}]_k(\mathfrak{s}).P \triangleright_{\emptyset} \Delta;\ \mathcal{Q}}\ [\text{T-MCast}]$$

$$\frac{\Gamma \vdash a : G \quad \mathsf{p} \in \mathsf{roles}(G) \quad \Gamma \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \Delta, \mathfrak{s} : \mathsf{unf}(G\restriction_{\mathsf{p}});\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} a[\mathsf{p}](\mathfrak{s}).P \triangleright_{\emptyset} \Delta;\ \mathcal{Q}}\ [\text{T-MAcc}]$$

$$\frac{\Gamma \vdash e : U \quad \Gamma \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \Delta, s : \mathsf{unf}(T);\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} s[k]!\langle e\rangle; P \triangleright_{\emptyset} \Delta, s :! k\langle U\rangle.T;\ \mathcal{Q}}\ [\text{T-Send}] \qquad \frac{\Gamma, x : U \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \Delta, s : \mathsf{unf}(T);\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} s[k]?(x); P \triangleright_{\emptyset} \Delta, s :? k\langle U\rangle.T;\ \mathcal{Q}}\ [\text{T-Rcv}]$$

$$\frac{T_1 \approx T_2 \quad s \neq s' \quad \Gamma \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \Delta, s : \mathsf{unf}(T);\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} s[k]!\langle\langle s'\rangle\rangle; P \triangleright_{\emptyset} \Delta, s :! k\langle T_1\rangle.T, s' : T_2;\ \mathcal{Q}}\ [\text{T-Deleg}]$$

$$\frac{\Gamma \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \Delta, s : \mathsf{unf}(T), t : \mathsf{unf}(T');\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} s[k]?((t)); P \triangleright_{\emptyset} \Delta, s :? k\langle T'\rangle.T;\ \mathcal{Q}}\ [\text{T-SRec}]$$

$$\frac{i \in I \quad \Gamma \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \Delta, s : \mathsf{unf}(T_i);\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} s[k] \lhd l_i; P \triangleright_{\emptyset} \Delta, s : k \oplus \{l_j : T_j\}_{j\in I};\ \mathcal{Q}}\ [\text{T-Sel}]$$

$$\frac{\forall i \in I \quad \Gamma \vdash_{\mathscr{D}} P_i \triangleright_{\emptyset} \Delta, s : \mathsf{unf}(T_i);\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} s[k] \rhd \{l_j : P_j\}_{j\in I} \triangleright_{\emptyset} \Delta, s : k \,\&\, \{l_j : T_j\}_{j\in I};\ \mathcal{Q}}\ [\text{T-Branch}]$$

$$\frac{\Gamma \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \Delta;\ \mathcal{Q} \quad \Gamma \vdash_{\mathscr{D}} Q \triangleright_{\emptyset} \Delta;\ \mathcal{Q} \quad \Gamma \vdash e : \mathsf{bool}}{\Gamma \vdash_{\mathscr{D}} \mathsf{if}\ e\ \mathsf{then}\ P\ \mathsf{else}\ Q \triangleright_{\emptyset} \Delta;\ \mathcal{Q}}\ [\text{T-If}]$$

$$\frac{\mathsf{ends}(\Delta_0) \quad \Gamma \vdash e : U \quad X : (U, \tilde{T}) \in \mathscr{D} \quad \Delta_1 \approx \tilde{s} : \tilde{T}}{\Gamma \vdash_{\mathscr{D}} X\langle e, \tilde{s}\rangle \triangleright_{\mathcal{C}} \Delta_0, \Delta_1;\ \mathcal{Q}}\ [\text{T-Var}] \qquad \frac{\mathsf{ends}(\Delta)}{\Gamma \vdash_{\mathscr{D}} \mathbf{0} \triangleright_{\emptyset} \Delta;\ \mathcal{Q}}\ [\text{T-Inact}]$$

Figure 10 Typing rules (🏃): all rules implicitly include the premise $\mathsf{ends}(\mathcal{Q})$.

▶ **Example 24** (Typing process definitions). Let D contain the single declaration $X(x\mathfrak{s}) = \mathfrak{s}[k]!\langle x\rangle; X\langle x, \mathfrak{s}\rangle$, which is typed by the environment $X : \mathsf{bool} \times \mathsf{unf}(T)$, where $T = \mu\mathbf{t}.!k\langle\mathsf{bool}\rangle.\mathbf{t}$. We name this environment $\mathscr{D}$ and to assert that D is typed by $\mathscr{D}$, we must show:

$$x : \mathsf{bool} \vdash_{\mathscr{D}} \mathfrak{s}[k]!\langle x\rangle; X\langle x, \mathfrak{s}\rangle \triangleright_{\emptyset} \mathfrak{s} : \mathsf{unf}(T);\ \emptyset$$

Which is derivable by [T-Send] and and [T-Var].

The example above highlights an important aspect of the type system. All local types in Δ are unfolded. Note for example that we put the unfolded local type in $\mathscr{D}$. This is necessary because all rules assume local types are unfolded, and we preserve this property by only introducing unfolded local types into Δ.

Subject Reduction. We now state the properties of the mechanised type system. We start with the substitution lemma, which is required by the subject reduction theorem to derive typings for value substituted processes $P[v/x]$ and located session substituted processes $P[\mathsf{s}^{\mathsf{p}}/t]$.

▶ **Lemma 25** (Substitution 🏃).
1. *If* $\Gamma, x : U \vdash_{\mathscr{D}} P \triangleright_{\mathcal{C}} \Delta;\ \mathcal{Q}$ *and* $\Gamma \vdash v : U$ *then* $\Gamma \vdash_{\mathscr{D}} P[v/x] \triangleright_{\mathcal{C}} \Delta;\ \mathcal{Q}$.
2. *If* $\Gamma \vdash_{\mathscr{D}} P \triangleright_{\mathcal{C}} \Delta, \mathfrak{s} : T;\ \mathcal{Q}$ *then* $\Gamma \vdash_{\mathscr{D}} P[\mathsf{s}^{\mathsf{p}}/\mathfrak{s}] \triangleright_{\mathcal{C}} \Delta, \mathsf{s}^{\mathsf{p}} : T;\ \mathcal{Q}$.

$$\frac{\Gamma \vdash_{\mathscr{D}} P \triangleright_{c_0} \Delta_0;\ \mathcal{Q}_0 \quad \Gamma \vdash_{\mathscr{D}} Q \triangleright_{c_1} \Delta_1;\ \mathcal{Q}_1 \quad (\mathcal{Q}_0, \mathcal{Q}_1) \hookrightarrow \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} P \mid Q \triangleright_{c_0, c_1} \Delta_0, \Delta_1;\ \mathcal{Q}} \text{ [T-Conc]}$$

$$\frac{\mathsf{ends}(\mathcal{Q}) \quad \mathsf{ends}(\Delta)}{\Gamma \vdash_{\mathscr{D}} \mathsf{s}[k] :: \emptyset \triangleright_{\mathsf{s}[k]} \Delta;\ \mathcal{Q}} \text{ [T-QNil]} \qquad \frac{\mathsf{coherent}(G) \quad \Gamma, \mathsf{a} : G \vdash_{\mathscr{D}} P \triangleright_C \Delta;\ \mathcal{Q}}{\Gamma \vdash_{\mathscr{D}} (\boldsymbol{\nu}^{\mathsf{a}}\mathsf{a}) P \triangleright_{\emptyset} \Delta;\ \mathcal{Q}} \text{ [T-NRes]}$$

$$\frac{\mathsf{coherent}(\hat{\Delta}; \hat{\mathcal{Q}}) \quad \Gamma \vdash_{\mathscr{D}} P \triangleright_{(c, \{\mathsf{s}[k_i]\}_{i \in I})} \Delta, [\hat{\Delta}]_{\mathsf{s}};\ \mathcal{Q}, [\hat{\mathcal{Q}}]_{\mathsf{s}}}{\Gamma \vdash_{\mathscr{D}} (\boldsymbol{\nu}^{\mathsf{s}}\mathsf{s}) P \triangleright_c \Delta;\ \mathcal{Q}} \text{ [T-CRes]}$$

$$\frac{\Gamma \vdash v : U \quad \Gamma \vdash_{\mathscr{D}} \mathsf{s}[k] :: \tilde{h} \triangleright_c \Delta;\ \mathcal{Q}, \mathsf{s}^{\mathsf{p}} : Q}{\Gamma \vdash_{\mathscr{D}} \mathsf{s}[k] :: v^{\mathsf{p}} \cdot \tilde{h} \triangleright_c \Delta;\ \mathcal{Q}, \mathsf{s}^{\mathsf{p}} : (k, U) \cdot Q} \text{ [T-QVal]}$$

$$\frac{\Gamma \vdash_{\mathscr{D}} \mathsf{s}[k] :: \tilde{h} \triangleright_c \Delta;\ \mathcal{Q}, \mathsf{s}^{\mathsf{p}} : Q}{\Gamma \vdash_{\mathscr{D}} \mathsf{s}[k] :: l^{\mathsf{p}} \cdot \tilde{h} \triangleright_c \Delta;\ \mathcal{Q}, \mathsf{s}^{\mathsf{p}} : (k, l) \cdot Q} \text{ [T-QSel]}$$

$$\frac{T_0 \approx T_1 \quad \Gamma \vdash_{\mathscr{D}} \mathsf{s}[k] :: \tilde{h} \triangleright_c \Delta;\ \mathcal{Q}, \mathsf{s}^{\mathsf{p}} : Q}{\Gamma \vdash_{\mathscr{D}} \mathsf{s}[k] :: (\mathsf{t}^{\mathsf{q}})^{\mathsf{p}} \cdot \tilde{h} \triangleright_c \Delta, \mathsf{t}^{\mathsf{q}} : T_0;\ \mathcal{Q}, \mathsf{s}^{\mathsf{p}} : (k, T_1) \cdot Q} \text{ [T-QSess]}$$

Figure 11 Typing rules (🐓): there are no implicit premises for these rules.

The lemma states that processes remain well-typed after variables are substituted for values and located session variables are substituted for located session identifiers. This lemma is necessary for proving the cases of subject reduction dealing with value and session reception.

We are now ready to state subject congruence and subject reduction:

▶ **Theorem 26** (Subject congruence and reduction). *Let P, P', and Q be processes, and Γ, Δ, Δ_0, and $\mathcal{Q}$ environments. Then,*

1. (🐓) *if $P \equiv Q$ and $\Gamma \vdash_{\mathscr{D}} P \triangleright_c \Delta;\ \mathcal{Q}$ then $\Gamma \vdash_{\mathscr{D}} Q \triangleright_c \Delta;\ \mathcal{Q}$*
2. (🐓) *if $\Gamma \vdash_{\mathscr{D}} P \triangleright_c \Delta;\ \mathcal{Q}$, $\mathsf{coherent}(\Delta; \mathcal{Q})$ as Δ_0, and $P \ \rightarrow_D \ P'$ then there exists $\Delta_1, \Delta', \mathcal{Q}'$ s.t. $\mathsf{coherent}(\Delta'; \mathcal{Q}')$ as Δ_1 and $\Gamma \vdash_{\mathscr{D}} P' \triangleright_c \Delta';\ \mathcal{Q}'$ and either $\Delta_0 = \Delta_1$ or there exists ℓ s.t. $\Delta_0 \xrightarrow{\ell} \Delta_1$*
3. (🐓) *if $\Gamma \vdash_{\mathscr{D}} P \triangleright_{\emptyset} \emptyset;\ \emptyset$ and $P \ \rightarrow_D \ P'$ then $\Gamma \vdash_{\mathscr{D}} P' \triangleright_{\emptyset} \emptyset;\ \emptyset$*

The theorem contains three statements: (1) typing is preserved by congruence; (2) typing is preserved by process reductions, relating environments either by equality or reduction; and, (3) typing is preserved by closed processes with no queues , which is a special case of (2). The proof of (1) proceeds by structural induction on the congruence relation, while the proof of (2), the core subject reduction result, is by induction on process reductions.

▶ Remark 27 (Differences with the original work). The type system enforces linear resource use by defining smaller resources as splits of larger ones, contrasting with Honda et al., who define larger resources as compositions of smaller ones. Our focus on splitting rather than composing is evident in several aspects of the type system. Firstly, the environment $\Delta; \mathcal{Q}$ provides an intuitive temporal split: queue types in $\mathcal{Q}$ indicate completed actions, while residual local types in Δ indicate remaining actions. Keeping these concepts distinct simplifies the definition of environment splitting, as Δ and $\mathcal{Q}$ split orthogonally. Secondly, queue types and residual local types are obtained by decomposition. Our definition allows us to avoid using the subtyping relation, unlike Honda et al. This is significant because introducing subtyping through a non-structural subsumption rule complicates reasoning about type derivations, particularly in proof assistants.

$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]?(x); P \mid \mathsf{s}^{\mathsf{q}}[k]?(x); Q) \qquad \mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]!\langle e\rangle; P \mid \mathsf{s}^{\mathsf{q}}[k]!\langle e'\rangle; Q)$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]?(x); P \mid \mathsf{s}^{\mathsf{q}}[k] \rhd \{l_j\colon Q_j\}_{i\in J}) \qquad \mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]!\langle e\rangle; P \mid \mathsf{s}^{\mathsf{q}}[k] \lhd l; Q)$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]?(x); P \mid \mathsf{s}^{\mathsf{q}}[k]?((\jmath)); Q) \qquad \mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]!\langle e\rangle; P \mid \mathsf{s}^{\mathsf{q}}[k]!\langle\!\langle t\rangle\!\rangle; Q)$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k] \rhd \{l_i\colon P_i\}_{i\in I} \mid \mathsf{s}^{\mathsf{q}}[k] \rhd \{l_j\colon Q_j\}_{j\in J}) \qquad \mathbf{error}(\mathsf{s}^{\mathsf{p}}[k] \lhd l;_1 P \mid \mathsf{s}^{\mathsf{q}}[k] \lhd l;_2 Q)$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k] \rhd \{l_i\colon P_i\}_{i\in I} \mid \mathsf{s}^{\mathsf{q}}[k]?((\jmath)); Q) \qquad \mathbf{error}(\mathsf{s}^{\mathsf{p}}[k] \lhd l; P \mid \mathsf{s}^{\mathsf{q}}[k]!\langle\!\langle t\rangle\!\rangle; Q)$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]?((\jmath)); P \mid \mathsf{s}^{\mathsf{q}}[k]?((\jmath)); Q) \qquad \mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]!\langle\!\langle t\rangle\!\rangle; P \mid \mathsf{s}^{\mathsf{q}}[k]!\langle\!\langle u\rangle\!\rangle; Q)$$

Figure 12 The **error** relation (🐓): violation of linearity (race on the same channel).

$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]?(x); P \mid \mathsf{s}[k] :: l_j{}^{\mathsf{q}} \cdot \tilde{h})$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]?(x); P \mid \mathsf{s}[k] :: (\mathsf{t}^{\mathsf{r}})^{\mathsf{q}} \cdot \tilde{h})$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k] \rhd \{l_i\colon P_i\}_{i\in I} \mid \mathsf{s}[k] :: v^{\mathsf{q}} \cdot \tilde{h})$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k] \rhd \{l_i\colon P_i\}_{i\in I} \mid \mathsf{s}[k] :: (\mathsf{t}^{\mathsf{r}})^{\mathsf{q}} \cdot \tilde{h})$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]?((\jmath)); P \mid \mathsf{s}[k] :: v^{\mathsf{q}} \cdot \tilde{h})$$
$$\mathbf{error}(\mathsf{s}^{\mathsf{p}}[k]?((\jmath)); P \mid \mathsf{s}[k] :: l_j{}^{\mathsf{q}} \cdot \tilde{h})$$

$$\frac{\mathbf{error}(P)}{\mathbf{error}((\nu^{\mathsf{a}}\mathsf{a})P)} \qquad \frac{\mathbf{error}(P)}{\mathbf{error}((\nu^{\mathsf{s}}\mathsf{s})P)} \qquad \frac{\mathbf{error}(P)}{\mathbf{error}(P \mid Q)}$$

Figure 13 The **error** relation (🐓): communication error and structural rules.

Communication Safety. We conclude this section by presenting communication safety, the property that states that a well-typed process never goes wrong. We first define a notion of error, in order to capture processes behaviour that we consider erroneous:

▶ **Definition 28** (**error**$_{\equiv}$ 🐓). *The relation* **error** *on processes is the minimal relation satisfying the rules in Figure 12 and Figure 13. Then,* $\mathbf{error}_{\equiv}(P)$ *is defined as* $\exists Q.\ P \equiv Q \wedge \mathbf{error}(Q)$.

The **error** relation captures situations in which processes cause a run-time error. Following the original work, we have categorised errors into two groups. The rules in Figure 12 address situations where linearity is violated. In session types, linearity ensures that there is never a race condition on a session channel. Such an error situation can arise in different ways, notably when two inputs or outputs competing on the same channel are ready to be executed (recall the notion of linearity of global types). The second type of error is a communication error, where a process reads from a queue a message of the wrong kind, e.g., it reads a label when a delegated session is expected. These cases are presented in Figure 13, along with three structural rules that permit lifting the relation under restriction or parallel composition.

The predicate $\mathbf{error}_{\equiv}(P)$ lifts the error relation to structural congruence in order to capture different structurally congruent processes. This design choice (as opposed to including a structural congruence rule in the definition of **error**) was made to simplify our mechanised proof of communication safety. Note that we can always rewrite a process into the form $(\nu x_1 \ldots x_n)(P \mid Q \mid R)$, where P and Q are the components to be checked for errors. Restriction rules are then applied to eliminate binders, and parallel rules are used to strip away the R component. We formally state communication safety as:

▶ **Theorem 29** (Communication Safety 🐓). *If* $\Gamma \vdash_{\mathcal{D}} P \triangleright_{\mathcal{C}} \Delta;\ \mathcal{Q}$ *and* $\mathsf{coherent}(\Delta; \mathcal{Q})$ *as* Δ_0 *then it is never the case that* $\mathbf{error}_{\equiv}(P)$.

From the previous theorem and subject reduction, we obtain the following:

▶ **Corollary 30** (Safety Preservation 🐓). *If* $\Gamma \vdash_{\mathcal{D}} P \triangleright_{\mathcal{C}} \Delta;\ \mathcal{Q}$, coherent$(\Delta;\mathcal{Q})$ *as* Δ_0, *and* $P \ \rightarrow_D \ P'$ *then it is never the case that* $\mathbf{error}_{\equiv}(P')$.

▶ Remark 31 (Differences with the original work). Our approach to defining communication safety differs from that of the original work by Honda et al. While we structurally define what constitutes an erroneous process and negate this property to derive safety, they define safety directly in terms of available redexes in the processes. In their approach to safety, when a redex is present in a session, session channels must occur linearly, and the messages read from queues must conform to the expectations of the receiving process. We departed from their non-structural approach in favour of an error predicate, as this proved more convenient for mechanisation, allowing us to perform induction on the predicate.

Given that the original formulation is not entirely formal, we have not mechanised the original definition nor demonstrated whether the two approaches are equivalent. However, it is worth noting that the use of an error predicate for defining safety is fairly standard and, for example, was employed in the original work on binary session types by Honda et al. [31].

6 Related Work and Discussion

Related Work. We discuss the most relevant related work, with a particular focus on mechanisations of session types.

Mechanisation of multiparty session types. Castro-Perez et al. [13] mechanise in Coq a trace equivalence between processes, coinductive local types and coinductive global types. Their processes, equipped with a trace semantics and no structural congruence, use implicit channels and are single-session without delegation; therefore, there is no multi-cast session request nor session acceptance and a process is always typed by a single global type. As a consequence, subject reduction is replaced by showing that processes and types have the same traces. Their process language is a domain specific language embedded in Coq. This allows a user to write a correct-by-construction process in Coq for each role of a session, and use Coq's extraction feature to extract executable OCaml code. The generated code has a transport API that allows interaction with external code. While their setting is more applied than ours, they also propose an elegant approach to representing session types as coinductive types that are coinductively related to unfolded μ-types. Castro-Perez et al. prove their definition of projection sound with respect to a coinductive specification of projection by Ghilezan et a. [24]. For a similar setting but with explicit channels, Tirore et al. [51] propose a projection for which both soundness and completeness hold: this is the projection that we adopt in our mechanisation.

Jacobs et al. [35] mechanise multiparty GV in Coq using the Iris framework [37]. Multiparty GV is an extension of the linear lambda calculus with multiparty asynchronous session types with implicit channels. Their language, equipped with a thread pool semantics and no structural congruence, features an n-ary fork operator that combines session initiation and process spawning, ensuring an acyclic topology, therefore ensuring progress [8]. This is unlike our setting where already existing processes can initiate sessions on shared names. Their methodology is significantly different from ours, and is based on separation logic [45, 46] and connectivity graphs [34]. They define an invariant on runtime configurations, ensuring well-typedness and buffer consistency. They then prove preservation of this invariant under operational semantics and show that configurations satisfying the invariant cannot deadlock.

Mechanisation of binary session types. Using the Iris framework, Hinrichsen et al. [29] introduce semantic typing for a variant of binary session types using logical relations. Gay et al. [23] compare duality definitions in an Agda mechanisation of binary session types.

Duality is the binary notion of compatibility used for binary session types, that is a special case of the multiparty notion of coherence. Gay et al. demonstrate that some definitions are unsound when type variables can appear in messages. Like them, our work does not take the equi-recursive view and we explicitly state when syntactic equality of μ-types is used and thus when to trigger unfoldings and when we use coinductive equality modulo unfolding. Castro-Perez et al. [14] mechanise in Coq a subject reduction theorem for the binary session type meta-theory given by Yoshida and Vasconcelos [54]. They use the locally nameless representation for variables by Charguéraud [15]. Like us, Castro-Perez et al. distinguish between variable and value session channels. Unlike our setting, theirs does not include recursion nor process call and definitions. Instead of process call, they use replication $!P$. Their definition of structural congruence lacks commutativity and transitivity which, although it makes some simple reductions impossible, simplifies substantially the subject reduction proof. Recently, Sano et al. [48] mechanised a version of binary session types that are in a Curry-Howard correspondence with linear logic [52]. They use linearity predicates, which enable the separate checking of linearity properties in the type system, allowing the typing judgement to focus solely on non-linear contexts.

Session types on paper. There is a vast literature on multiparty session types that builds on the original paper. An introduction was given by Yoshida and Gheri [53] and a comprehensive overview was given by Scalas and Yoshida [49] where they argue the inconvenience of using global types to define compatibility. It should be noted that, to the best of our knowledge, all later work uses implicit channels and, therefore, the counter example does not invalidate these results. However, as argued in the introduction, explicit channels are more expressive and particularly useful in applications where only a limited number of channels are available, e.g., AMQP [3]. A binary version of session types has also been applied to type a choreographic language, i.e., a synchronous process-level language with global interactions that features explicit channels [9, 10]. Like for global types, choreographies must undergo a well-formedness check, which resembles a more restrictive linearity analysis for global types.

Discussion. We discuss our contributions and potential further developments.

On the Mechanisation in Coq. Our mechanisation in Coq consists of over 20K lines of code and features several design choices to address the complexity of the theory of multiparty session types. For handling binders, we employed the *Autosubst2* library, developed in Stark's PhD thesis [50]. From a user-defined signature in higher-order abstract syntax (HOAS), Autosubst2 generates Coq code with an inductive definition that uses a de Bruijn representation, along with substitution operations on this datatype. We reuse the definitions in the work by Tirore et al [51] for representing global types, local types and the projection function. We reused their code off-the-shelf, significantly streamlining our development.

For representing typing environments, we adopted a straightforward approach using lists of pairs $(\text{name}, \text{type})$. Other common forms of representation include lists with indices or functions from names to types. We found our approach more convenient to use for parallel substitutions, which is the kind of substitution operation that Autosubst2 is based on. In particular, while low-level, it simplified context splitting for parallel composition rules, requiring only standard checks for linearity of name usage, as dictated by linear type systems. We believe this representation offers an accessible starting point for researchers aiming to mechanise session types. Finally, our work heavily relies on a combination of *inductive* and *coinductive* definitions, which we implemented using the Paco library [16], which proved invaluable for developing our mechanisation.

On Communication Safety, Session Fidelity, and Progress. Subject reduction serves as a critical internal lemma that can be used to prove many key results, including communication safety (also known as type safety), session fidelity, and progress. The primary goal of this paper is to prove subject reduction and uncover the issues in the original theorem by Honda et al., demonstrating its incorrectness; establishing communication safety, which ensures that well-typed processes do not exhibit wrong behaviour, was an additional achievement. On the other hand, other results, though highly interesting, lie beyond the intended scope of this work. Session fidelity expresses that communications within a session progress according to the global type. While we have not mechanised session fidelity as a formal theorem, addressing this remains a promising avenue for future research. Proving session fidelity would require augmenting the reduction semantics with labels to specify the communication performed and the channels involved, enabling a finer-grained analysis of interaction behaviours.

Another key result from Honda et al. is progress, which asserts that a well-typed single-session process never deadlocks. In our work, linearity of global types plays a crucial role in ensuring that interleavings of send and receive operations adhere to the global type. However, our counterexample raises questions about the implications of explicit channels and causality on progress. Investigating these implications and formally proving progress for our system would further strengthen our meta-theoretical framework.

Finally, our results offer a foundation for extending our work to mechanise more advanced properties of session-typed systems, particularly in multi-session scenarios. Explicit channels, as demonstrated by our counterexample, introduce non-trivial distinctions in causality that deserve further exploration.

Alternative Semantics for Global and Local Types. The counterexample highlighted the restrictiveness of the global type semantics. Later work on multiparty session types [49, 13] introduces a more flexible global type semantics that, in the context of implicit channels, is unrelated to the counterexample. This work suggests semantic definitions that could allow the unstuck predicate to be removed from the meta-theory.

Other Observations. The mechanisation revealed some inconveniences in the meta-theory. For example, the representation of a finished session channel is ambiguous; it can be represented either as not being contained in the environment or as being contained but mapped to `end`. We conjecture that it would simplify proofs to resolve this ambiguity by choosing only the non-presence representation in conjunction with a closure operation on sessions, as done by Caires et al. [7] and Wadler [52].

Another inconvenience is the use of global types as the basis for multiparty compatibility. Scalas and Yoshida [49] pointed out that more general notions of compatibility exist beyond global types. This broader perspective may not only provide a more encompassing definition of compatibility but also simplify proofs by eliminating the need for two specification languages in the meta-theory.

Abstract

Static analyzers have been successfully developed to detect runtime errors in many languages. However, the automatic analysis of functional languages remains a challenge due to their recursive functions, recursive algebraic data types, and higher-order functions. Classic type systems provide compositional methods that are in general not precise enough to prove the absence of runtime errors such as assertion failures. At the other end of the spectrum, deductive methods are more expressive but may require user guidance to prove invariants.

Our work describes a static value analysis by abstract interpretation for a higher-order pure functional language. This analysis provides a sound and automatic approach to discover invariants and prevent assertion and match failures. We have designed a compositional analysis: functions are analyzed only once, at their definition site, generating a summary of their behavior. The summaries can be viewed as input-output relations expressed with relational abstract domains. We present two new abstract domains. A first abstract domain summarizes recursive algebraic data types. A second abstract domain lifts existing disjunctive relational summaries to higher-order by formalizing them as domains able to abstract higher-order functions. Both abstractions are parameterized by the abstractions of basic types (strings, integers, ...). Thanks to this parametric nature, both domains can be combined, allowing the analysis of higher-order functions manipulating algebraic data types and, conversely, algebraic data types using functions as first-class values.

We have implemented this analysis in the open-source MOPSA platform. Preliminary evaluation confirms the precision of our approach on a set of 40 handwritten toy programs as well as 20 programs from the state-of-the-art Salto analyzer benchmark.

1 Introduction

Thanks to strong static typing, functional programming languages such as OCaml are safer than traditional imperative languages, as they "reduce the number of runtime errors [...] found in Java and C#" [29]. Still, well-typed functional programs can occasionally go wrong upon encountering runtime errors, such as out-of-bounds array accesses, arithmetic overflows, non-exhaustive pattern matching or uncaught exceptions. In this work, we aim at statically detecting such errors by developing a *compositional static value analysis* and targeting higher-order pure functional languages. Our approach is rooted in the abstract interpretation

framework, and leverages *relational abstract domains* to yield a high expressivity. In particular, we explore a new compositional value analysis that can yield better precision than classic type systems. The analysis is fully automated, contrary to more expressive approaches traditionally based on deductive verification.

Value analyses based on abstract interpretation have been mostly developed to target imperative programming languages [6, 9]. An ongoing research direction focuses on developing *compositional* (or function-modular) analyses. These analyses consist in analyzing functions once, at their definition site, to infer a summary; the summary is then applied to analyze each function call. These methods significantly improve scalability when a function is called multiple times, as summary applications are computationally cheaper than reanalyzing a function at every calling context. One difficulty faced by compositional analyses is precision loss: analyses need to produce a unique summary, correct for every possible input of the analyzed function. A key ingredient to achieve interesting precision levels is to rely on *relational abstract domains* which are able to express relationships between variables. Relational domains have been used extensively in previous works to create input-output relational summaries [26, 14, 17, 25]. However, relational domains are not always sufficient to make up for precision loss, for example when very distinct function behaviors are approximated as a single input-output relation. A second ingredient is the addition of partitioning [30, 7] to create a set of separated summaries for each function, each summary expressing different results on different inputs. Boutonnet and Halbwachs [8] developed a method to compute disjunctive relational summaries that express precise properties of first-order, numeric functions.

The static analysis of functional programs raises new challenges: analyzers need to handle features such as user-defined algebraic data types (ADTs), higher-order functions, partial application, recursive functions and polymorphism. This work presents a compositional analysis which leverages relational abstract domains, exploring a new precision-scalability tradeoff. The analysis supports a pure, monomorphic subset of OCaml, including recursive ADTs, as well as both recursive and higher-order functions.

We present in Figure 1 a motivating example. This program defines a custom algebraic data type, with one constructor containing functions. `to_fun` is a higher-order function, as its result is a function. The definitions of values `f1` and `f2` are performed through partial application. In the case of the program in Figure 1, our approach analyzes function `to_fun` once, at its definition site, and deduces a summary for this function. Under the hood, our compositional analysis relies on two new, key abstract domains: one abstracts user-defined algebraic data types, while the other abstracts higher-order functions. We rely on a cooperation between these two abstract domains to infer a precise, disjunctive [8], summary for `to_fun`. Handling partial applications is seamless, and our analysis is able to infer the following summaries for functions `f1` and `f2`: $\texttt{f1} : x \to 5, \texttt{f2} : x \to x + 4$. The analysis can then perform further applications to conclude that $\texttt{r1} = 5, \texttt{r2} = 9$ fully automatically. Note that both abstract domains can leverage arbitrary abstractions for leaf data types (integers, strings, ...). In particular, the summary of `f2` is expressed precisely thanks to the relational polyhedra domain [15].

In previous work, Lermusiaux and Montagu [27] implemented a value analysis for a large subset of OCaml, which includes recursive ADTs and higher-order constructs. However, this analysis is neither compositional nor relational. This simplifies the analysis of higher-order functions, which can be triggered by analyzing functions only when their parameters are known, at call site. In our example, a non-compositional analysis would analyze `to_fun` twice, when computing the abstract values of `r1` and `r2`. Bautista et al. [5] defined a compositional, relational analysis for a toy imperative language extended with non-recursive ADTs. In particular, their approach does not support recursive functions, nor higher-order ones.

```
type cstorfun = Cst of int | Fun of (int -> int)
let to_fun a =
  match a with
  | Cst n -> fun x -> n
  | Fun f -> f

let f1 = to_fun (Cst 5)
let f2 = to_fun (Fun (fun x -> x + 4))
let r1 = f1 4
let r2 = f2 5
```

Figure 1 Motivating OCaml program with key features from functional programming paradigm.

Contributions. This paper defines the following contributions:

- We introduce a domain summarizing recursive algebraic data types (ADTs). This domain is fully parametric in the abstraction of its base types (integers, strings, ...). Our domain supports relational abstractions.
- Independently, we define an abstract domain for higher-order functions, lifting previous work on disjunctive relational summaries [8]. This allows the creation of a compositional analysis for higher-order functions.
- We illustrate how the two abstract domains can mutually benefit from each other on an example, and provide a soundness statement about the overall analysis.
- We have implemented these domains in the MOPSA platform [22]. Thanks to this implementation, a preliminary evaluation confirms the precision of our approach on a set of 60 toy OCaml programs (handwritten or from previous work [27]).

Outline. Section 2 presents the syntax of a functional language with standard semantics. Section 3 provides background on compositional, relational analyses for the first-order case. Section 4 proposes an abstract domain for recursive algebraic data types, and Section 5 presents our method to analyze higher-order functions. Section 6 highlights the cooperation achieved by combining both abstract domains thanks to their parametricity. Section 7 presents our implementation, benchmarks, and experimental results. Section 8 presents related work and Section 9 concludes.

2 Syntax of the Considered Functional Language

In this section, we present the syntax of a generic functional language, on which we will define our analysis. Its key features are recursion, algebraic data types, and higher-order. We limit ourselves to a monomorphic higher-order language without side-effects. This language is described in Figure 2. $\mathbb{V}$ is the set of variables, $\oplus$ any operator of the language ($+$, $-$, $\times$, $/$, $=$, etc.). $\mathcal{E}$ is the set of expressions. $fv(e)$ is the set of free variables of expression e. Π, the set of patterns, contains the wildcard _, variables, integers, `when` clauses, and type constructors. Free variables from the same pattern are required to be disjoint, as is the case in OCaml: the same variable cannot be bound twice. Figure 3 describes the semantic domain of the language. $\mathbb{C}$ is the set of all possible constructors. Semantic values of the language $\mathcal{V}$ are integers, type constructors containing values, error ω and continuous functions from values to values, to which we add $\perp$ (for non-termination). Finally, Σ is the set of concrete

$$

$$\mathbb{E}[\![\cdot]\!] : \mathcal{E} \times \Sigma \to \mathcal{V}$$

Figure 3 Semantic domain of the functional language.

environments, associating a value to each variable. The concrete semantics of an expression e is $\mathbb{E}[\![e]\!] \in \Sigma \to \mathcal{V}$. It associates a semantic value to an expression in an environment. This semantics follows the standard for eagerly evaluated functional languages (such as OCaml). It is standard, and not detailed here.

We work under the hypothesis that programs are well-typed. The type inference works as usual on functional languages [20, 31]. This way, some situations where an expression evaluates to the error ω are statically detected. However, well-typedness is not enough to prevent all possible kinds of errors, such as assertion failures, or match failures in the presence of `when` clauses. Our analysis focuses on those. During the analysis, we use type information, as well as user-defined type definitions, to select relevant abstract domains.

To simplify presentation, `int` type represents mathematical integers: working on machine integers and statically detecting overflows would only require adding assertions when performing arithmetic operations. Similarly, even though the language is pure, we can still handle array bound checks with a simple translation of programs with arrays to array-less programs: array accesses are replaced with assertions that indices are within the array range, abstracting away the content of the array.

3 Compositional and Relational Analysis at First-Order

Since the concrete semantics is uncomputable, we propose an abstract semantics for our language. This section provides background on relational analyses, and compositional interprocedural analyses for first-order programs with integers and pairs. We start by introducing an abstract semantics compatible with numerical relational analyses through the introduction of symbolic expressions (Section 3.1), and then describe how this abstract semantics can be lifted to perform compositional analysis of recursive functions (Section 3.2).

The analyses we describe feature two notable strengths: their definition is *domain-modular* – i.e. fully parametric in the underlying abstract domains – and supports precise *relational* inference – allowing us to express relationships between variables. We believe that this approach, originally formulated by the authors of the MOPSA framework [22], provides greater expressivity than traditional static analysis definitions. However, this generic and domain-modular approach requires additional formalization efforts to define domains.

3.1 Relational Analysis

We define a computable abstract semantics $\mathbb{E}^\sharp[\![e]\!]$ of an expression e, based on abstract domains. It delegates the abstraction of an object of type τ (e.g. integers, pairs, and after Section 4, ADTs) to the abstract domain $\mathcal{D}_\tau$. We denote the union of those domains as $\mathcal{D}$. Usually, such a semantics takes as parameter an expression e and an abstract environment (abstracting the possible values of all the variables), and returns an abstract value representing the set of possible values of the expression (in the abstract domain corresponding to the type of the expression). However, this formulation cannot easily express a relationship between the value of the expression and those of the variables. Indeed, let us consider the program in Figure 4. A numerical domain such as the interval domain can abstract `x` and `y` independently, as $\texttt{x} \in [1, 10]$ and $\texttt{y} \in [2, 11]$, but cannot infer the relation `y = x + 1`. To overcome this limitation, we use an abstract numerical domain able to store relations between variables – e.g. the polyhedra domain [15]. However, expressing relations between numeric variables from the program, that is, `x` and `y`, is not sufficient to leverage those relational information to `pair`, since we have no way to express a relation between the second field of `pair` and `y`.

Following the works of Chevalier and Feret [10], Journault et al. [22], we introduce *intermediate variables* (also named ghost variables), in addition to the initial program variables. Here, we introduce two intermediate variables p_1 and p_2, which respectively represent the first and second fields of `pair`. In practice, we keep separate the set of program variables $\mathbb{V}$ and the set $\mathbb{V}_\mathbb{Z}$ of intermediate variables on which a (possibly relational) numerical domain will express semantic constraints. We then keep a map from program variables in $\mathbb{V}$ to their *abstract values* in $\mathcal{V}^\sharp$, which can either be an element of an abstract domain, or an intermediate variable. In our example, $\mathbb{V}_\mathbb{Z}$ is $\{x, y, p_1, p_2\}$ whereas $\mathbb{V} = \{\texttt{x}, \texttt{y}, \texttt{pair}\}$. The map is then $m = \texttt{x} \to x, \texttt{y} \to y, \texttt{pair} \to (p_1, p_2)$. The possible values of variables in $\mathbb{V}_\mathbb{Z}$ are then represented as an abstract element from a (possibly relational) abstract domain $\mathcal{D}_\mathbb{Z}$. If the chosen numerical domain $\mathcal{D}_\mathbb{Z}$ is the polyhedra domain – which can express conjunctions of linear constraints – we can infer: $d = 1 \leq x \leq 10 \wedge y = x + 1 \wedge p_1 = y \wedge 1 \leq p_2 \leq y \in \mathcal{D}_\mathbb{Z}$. Note that the relation between the second field of `pair` and `y` was not expressible without introducing p_2. Such intermediate variables will be especially useful when abstracting algebraic data types in Section 4.

An abstract environment in $\Sigma^\sharp$ is then the pair of a map $m \in \mathbb{V} \to \mathcal{V}^\sharp$ and an element of the possibly relational numerical domain $d \in \mathcal{D}_\mathbb{Z}$. Thus, $\sigma^\sharp = (m, d) \in \Sigma^\sharp$.

As a last step, we define *abstract expressions* $\mathcal{E}^\sharp$, a lifting of abstract values where numerical intermediate variables can instead be *numeric expressions* $\mathcal{E}_\mathbb{Z}$, that is, symbolic operations between intermediate variables and integers. The abstract semantics of an expression e is then: $\mathbb{E}^\sharp[\![e]\!] : \Sigma^\sharp \to \mathcal{E}^\sharp \times \Sigma^\sharp$. It evaluates an expression e in an environment and returns an abstract expression into a new environment. Let p be the program in Figure 4, and $\sigma_0^\sharp$ a starting environment with no information on program variables. The analysis of p is:

$$\mathbb{E}^\sharp[\![p]\!]\sigma_0^\sharp = (p_1, p_2), (\texttt{x} \to x, \texttt{y} \to y, \texttt{pair} \to (p_1, p_2), \\ 1 \leq x \leq 10 \wedge y = x + 1 \wedge p_1 = y \wedge 1 \leq p_2 \leq y)$$

```
1 let x = random 1 10 in
2 let y = x + 1 in
3 let pair = (y, random 1 y) in
4  pair
```

Figure 4 Example program motivating relational analysis.

Set of program variables	$\mathbb{V}$
Set of intermediate variables	$\mathbb{V}_{\mathbb{Z}}$
Union of non-numerical domains	$\mathcal{D}$
Numerical domain	$\mathcal{D}_{\mathbb{Z}}$
Abstract values	$\mathcal{V}^\sharp = \mathcal{D} \cup \mathbb{V}_{\mathbb{Z}}$
Abstract environments	$\Sigma^\sharp = (\mathbb{V} \to \mathcal{V}^\sharp) \times \mathcal{D}_{\mathbb{Z}}$
Concrete numerical environments	$\Sigma_{\mathbb{Z}} = \mathbb{V}_{\mathbb{Z}} \to \mathbb{Z}$
Numeric expressions	$\mathcal{E}_{\mathbb{Z}} ::= n \in \mathbb{Z} \mid v \in \mathbb{V}_{\mathbb{Z}} \mid e_1 \oplus e_2$, where $e_1, e_2 \in \mathcal{E}_{\mathbb{Z}}$
Abstract expressions	$\mathcal{E}^\sharp = \mathcal{D} \cup \mathcal{E}_{\mathbb{Z}}$
Abstract semantics of expr. e	$\mathbb{E}^\sharp[\![e]\!] : \Sigma^\sharp \to \mathcal{E}^\sharp \times \Sigma^\sharp$

Figure 5 Formalization of the abstract semantics.

The abstract expression (p_1, p_2) is a symbolic pair of intermediate variables $p_1, p_2 \in \mathbb{V}_{\mathbb{Z}}$, therefore $(p_1, p_2) \in \mathcal{E}_{\mathbb{Z}}$. Figure 5 summarizes all abstract sets.

Assignments. Our abstract environments are made of two components $(m, d) \in \Sigma^\sharp$: a map m from variables to abstract values and an element d of the relational domain. To define assignments in such an environment, we write:

- $m[\mathtt{x} \to v]$ the map $m \in (\mathbb{V} \to \mathcal{V}^\sharp)$ where variable $\mathtt{x} \in \mathbb{V}$ is now bound to the value $v \in \mathcal{V}^\sharp$;
- $\mathbb{E}^\sharp_{\mathbb{Z}}[\![x \to v]\!]d \in \mathcal{D}_{\mathbb{Z}}$ the result of the assignment in an element $d \in \mathcal{D}_{\mathbb{Z}}$ of variable $x \in \mathbb{V}_{\mathbb{Z}}$ to a value or a numeric expression v.

▶ **Definition 3.1** (Abstract assignment). *The abstract assignment of a program variable* $\mathtt{x} \in \mathbb{V}$ *with abstract value* $v \in \mathcal{V}^\sharp$ *in environment* $(m, d) \in \Sigma^\sharp$ *is then:*

$$(m, d)[\mathtt{x} \to v] = \begin{cases} \left(m[\mathtt{x} \to x], \mathbb{E}^\sharp_{\mathbb{Z}}[\![x \to v]\!]d\right) & \text{if } x : \texttt{int} \\ (m[\mathtt{x} \to v], d) & \text{otherwise} \end{cases}$$

Intuitively, the assignment is delegated to the numerical domain for integer variables, and it is a simple map update otherwise.

Join. We denote the join between two environments as $\sqcup^\sharp$, which lifts the join operators from underlying components. The join is defined pointwise between two maps in $\mathbb{V} \to \mathcal{V}^\sharp$: each variable maps to a join of its abstract values from both maps in the relevant domain. We rely on the join of the numerical abstraction for the second component of the abstract environment. Note that this join can be *heterogeneous* [24], if both elements are not defined on the same set of variables (this will be further developed in Section 4). The meet $\sqcap^\sharp$ is defined similarly.

Concretization. The concretization of an abstract environment is based on the concretization $\gamma_{\mathbb{Z}}$ of the numerical domain, and on the concretizations γ_τ of the domains $\mathcal{D}_\tau$ abstracting objects of type τ. Those domains can be relational, so the concretization of a value can depend on other variables' concretization, following a construction defined by Monat [32]. Consequently, γ_τ takes as parameter an element of the domain $\mathcal{D}_\tau$ *together with a concrete numerical environment* $\sigma_{\mathbb{Z}} \in \Sigma_{\mathbb{Z}}$.

▶ **Definition 3.2** (Environment concretization). *Given* $\sigma^\sharp = (m, d) \in \Sigma^\sharp$*, its concretization is:*

$$\gamma_{\Sigma^\sharp}(m, d) = \{\sigma \in \Sigma \mid \exists \sigma_{\mathbb{Z}} \in \gamma_{\mathbb{Z}}(d), \forall x \in \mathbb{V}, x : \tau, \sigma(x) \in \gamma_\tau(m(x), \sigma_{\mathbb{Z}})\}$$

This concretization thus depends on the concretizations for ground types (such as integers, strings, etc.), but also on the concretizations for functions and algebraic data types. Those will be defined in Section 4 and Section 5.

▶ Remark 3.3 (Implicit concretization signature). Even though the concretization γ_τ takes as parameter a *concrete environment*, we can lift this definition so that it takes as parameter an *abstract environment* by writing:

$$\gamma_\tau(e^\sharp, (m, d)) = \bigcup_{\sigma_{\mathbb{Z}} \in \gamma_{\mathbb{Z}}(d)} \gamma_\tau(e^\sharp, \sigma_{\mathbb{Z}})$$

We simply join concretizations for every concrete numerical environment abstracted by d. Our abstract semantics takes as input an abstract environment and returns an abstract value in an abstract environment. With this notation, given $e : \tau$ and $\sigma^\sharp \in \Sigma^\sharp$, we can write the concretization of the abstract semantics $\mathbb{E}^\sharp[\![e]\!]\sigma^\sharp \in \mathcal{D}_\tau \times \Sigma^\sharp$, and we can write $\gamma_\tau(\mathbb{E}^\sharp[\![e]\!]\sigma^\sharp)$. In particular, this will be useful when stating the soundness theorem (Section 6.2).

Error propagation. To simplify the presentation, errors are implicitly propagated: if a sub-expression evaluates to the error ω, then so does the whole expression.

3.2 Compositional Function Analysis

Since an important contribution of this article is to design a *compositional* analysis, we first introduce how we analyze first-order functions in a compositional fashion, before extending our analysis in Section 5 to higher-order.

Compositional analysis aims at over-approximating all the possible behaviors of a function at definition site. The function is analyzed once and for all, and we then store the result of the analysis, its *summary*. Since the language is pure, the function does not modify the environment (no side-effects). Its behavior can then be represented by a relation between its inputs and its output, using a relational domain.

Let $\mathcal{F}^\tau$ be the set of functions of type $\tau = \tau_1 \to \cdots \to \tau_{n+1}$. Since we are restricted to first-order in this section, τ_i are base types such as integers or pairs. Given a set V of variables for inputs and output, we denote $\mathcal{R}(V)$ as the abstract domain chosen to represent relations between those. It abstracts $\Sigma|_V$, i.e. concrete environments restricted to V. It is provided with its concretization $\gamma_r : \mathcal{R}(V) \to \Sigma|_V$, with a lifting $\lambda_r : \mathcal{R}(V) \to \Sigma^\sharp$ and with a projection operator proj_r such that $\text{proj}_r(\sigma^\sharp) \in \mathcal{R}(V)$ only keeps information on variables in V.

We denote the domain chosen for functions of type τ as $\mathcal{D}_\tau = \mathbb{V}^n \times \mathbb{V} \times \mathcal{R}(V)$. This way, a function is abstracted as: the names $x_1, \ldots, x_n$ of its formal inputs, a result variable, and a relation between those variables.

▶ **Definition 3.4** (Functions concretization). *The concretization* $\gamma_\tau : \mathcal{D}_\tau \times \Sigma_\mathbb{Z} \to \mathcal{F}^\tau$ *is:*

$$\gamma_\tau((x_1,\dots,x_n,r,p),_) = \{f : \tau \mid \forall(a_1,\dots,a_n) : \tau_1 \times \cdots \times \tau_n, \\ [x_1 = a_1] \cdots [x_n = a_n][r = f(a_1,\dots,a_n)] \in \gamma_r(p)\}$$

A function f is abstracted as $(x_1,\dots,x_n,r,p)$ if the relation between its inputs and its output can be described by p. $_ \in \Sigma_\mathbb{Z}$ is not used by the concretization, as the summary relies on its own relational abstract element p.

We now describe the transfer functions used by the compositional analysis.

Function definition. Intuitively, the analysis of functions needs to generate a summary valid for all inputs. Thus, the body is analyzed with the most general inputs: the inputs are initialized at $\top$, the domain maximum (meaning we have no information on their values). We project the result on input and output variables. This way, we get the most general input-output relation, usable at any call site. Note that relationality is critical there, enabling us to discover relevant information on the function behavior despite making no hypothesis on the values of the inputs.

$$\mathbb{E}^\sharp[\![\text{fun } x_1 \cdots x_n \to \mathit{body}]\!]\sigma^\sharp = \text{let } e^\sharp, \sigma_0^\sharp = \mathbb{E}^\sharp[\![\mathit{body}]\!]\sigma^\sharp[x_1 \to \top,\dots,x_n \to \top] \text{ in} \\ ((x_1,\dots,x_n), r, \text{proj}_r(\sigma_0^\sharp[r \to e^\sharp])), \sigma^\sharp$$

Recursive functions. For recursive functions, the concrete semantics has to compute a least fixpoint of the function concrete semantics F:

$$\mathbb{E}[\![\text{let rec } f = e_1 \text{ in } e_2]\!]\sigma = \text{ let } F(v) = \mathbb{E}[\![e_1]\!]\sigma[f \to v] \text{ in } \mathbb{E}[\![e_2]\!]\sigma[f \to \text{lfp}(F)]$$

We use a standard technique from abstract interpretation [12] to obtain a computable abstract semantics, in three steps. First, thanks to Kleene's theorem, we rewrite the least fixpoint as the union of iterations of the analysis of the function, starting from $f \to \bot$, i.e. $\text{lfp}(F) = \bigcup_{k\in\mathbb{N}} F^k(\bot)$. Second, we move to the abstract semantics by using an iteration from $f \to \bot_\tau$, but evaluate the function body in the abstract domain with F. Third, we use a widening operator ∇_τ instead of a join to enforce the convergence in finite time. The widening operator is a component-wise lift, similar to the definition of the join operator on abstract environments in Section 3.1.

$$\mathbb{E}^\sharp[\![\text{let rec } f = e_1 \text{ in } e_2]\!]\sigma^\sharp = \text{let } \bot_\tau = ((x_1,\dots,x_n), r, [r \to \bot][x_i \to \top]_{i\le n}) \text{ in} \\ \text{let } F : \mathcal{D}_\tau \to \mathcal{D}_\tau = v^\sharp \to \text{fst}(\mathbb{E}^\sharp[\![e_1]\!]\sigma^\sharp[f \to v^\sharp]) \text{ in} \\ \text{let } s = \nabla_\tau \bigcup_{k\in\mathbb{N}} F^k(\bot_\tau) \text{ in} \\ \mathbb{E}^\sharp[\![e_2]\!]\sigma^\sharp[f \to s]$$

This reasoning extends to mutually recursive functions by iterating on a vector of function abstractions.

Function application. When applying a function e_0 to inputs of abstract values $e_i^\sharp$, we intuitively combine the current environment and the summary relation p. Before the combination, both abstract environments need to be defined on the same set of variables. We rely on two auxiliary functions: `add_vars` : $\Sigma^\sharp \times \mathcal{P}(\mathbb{V}_\mathbb{Z}) \to \Sigma^\sharp$ which extends the definition domain of an abstract environment with a set of variables, and `dom` : $\Sigma^\sharp \to \mathcal{P}(\mathbb{V}_\mathbb{Z})$ which

provides the definition domain of an abstract environment. The combination also requires additional equality constraints $[x_i = e_i^\sharp]$ between formal arguments x_i and values $e_i^\sharp$. These equality constraints are delegated to the filter function[1] of the relevant abstract domain.

$$\begin{aligned}\mathbb{E}^\sharp[\![e_0 \ \dots \ e_n]\!]\sigma_0^\sharp = \ & \text{let } ((x_1,\dots,x_n),r,p),\sigma_0^\sharp = \mathbb{E}^\sharp[\![e_0]\!]\sigma^\sharp \text{ in}\\ & \text{let } \forall i \in [\![0,n-1]\!] \ e_{i+1}^\sharp,\sigma_{i+1}^\sharp = \mathbb{E}^\sharp[\![e_{i+1}]\!]\sigma_i^\sharp \text{ in}\\ & \text{let } \sigma_n^\sharp = \texttt{add_vars}(\sigma_n^\sharp,\texttt{dom}(p)) \text{ in}\\ & \text{let } p = \texttt{add_vars}(\lambda_r(p),\texttt{dom}(\sigma_n^\sharp)) \text{ in}\\ & r,(\sigma_n^\sharp \sqcap^\sharp p)[x_1 = e_1^\sharp,\dots,x_n = e_n^\sharp]\end{aligned}$$

Compositionality. A key observation on our abstract semantics is that the function is analyzed at *definition site*. Consequently, we analyze it only once. At any call site, we only instantiate the resulting summary with input values. At first-order, Boutonnet and Halbwachs [8] proved that such a *compositional analysis* leads to a more efficient analysis for a function used at many call sites. Therefore, it can help the analysis to scale up.

Note that the purity hypothesis is necessary here: abstracting functions as input-output relations is correct only because the function does not modify the memory state. To handle side-effects, we would need to modify this abstraction to track mutability of the memory state, e.g., using extra input-output arguments to functions to model the mutable part of the state. Keeping compositionality while overcoming this limitation is left for future work.

In conclusion, this section defined a compositional analysis for first-order functions, both relational and fully parametric in the choice of abstract domains used to represent ground types. These features will be at the core of our abstractions for ADTs and higher-order functions.

4 Abstracting Recursive Algebraic Data Types

Algebraic objects are basic blocks of functional languages. Lists, trees, abstract syntax trees, etc. are defined using algebraic data types. To analyze them, we need a specific domain for objects of user-defined type:

$$\texttt{type } \tau = C_1 \text{ of } \tau_{1,1} * \cdots * \tau_{1,m_1} \mid \cdots \mid C_n \text{ of } \tau_{n,1} * \cdots * \tau_{n,m_n}$$

This section defines an abstraction for user-defined algebraic data types which is fully parametric in the abstraction of base types (integers, strings, etc). We illustrate our construction on integer base types, as these are very common, and many numerical abstractions already exist to serve as parameter. It also allows us to show that our analysis can be relational when parameterized with relational base domains. This relationality is a crucial factor to make compositional analyses precise, as exemplified in Section 4.3.

4.1 Parametric Relational Domain with Symbolic Variables

4.1.1 Domain

Let n be the number of constructors and m_i the number of fields of constructor C_i. Let $\mathbb{C}_\tau = \{C_i \mid 1 \leq \mathtt{i} \leq n\}$ be the set of constructors of type τ. Let $\mathbb{T}_\tau$ be the set of finite concrete objects of type τ. For recursive types, $\mathbb{T}_\tau$ can be infinite. To provide a computable

[1] The filter function models the effect of a test or a guard in the domain, by selecting environments satisfying a conditional – here, $[x_i = e_i^\sharp]$

abstract semantics, we chose to summarize (or "smash") together all the elements of a given field that are nested in an abstract data type. For instance, when abstracting a list of integers, a single abstract integer variable will be used to represent all the possible values of all the elements of the list. More generally, infinite sets of unbounded data-structures can be abstracted using a finite number of dimensions – here, one per field.

We construct systematically an abstraction for values of type τ from existing abstractions for values of types $\tau_{i,j}$ used in the definition of τ. However, in order to avoid cyclic definitions in the case of recursive types, we start from given domains $\mathcal{D}^\sharp_{\tau_{i,j}}$ defined only when $\tau_{i,j} \neq \tau$. The case of recursive types is well-founded, as is the case of user-defined types using fields of previously defined user-defined types. For simplicity, this definition omits the case of mutually recursive types, which does not pose additional theoretical issues.

▶ **Definition 4.1** (ADTs domain). *We derive domains $\mathcal{D}^\sharp_{i,j}$ used to abstract the value of the j-th field of the i-th constructor as follows:*

$$\mathcal{D}^\sharp_{i,j} = \begin{cases} \mathcal{P}(\mathbb{C}_\tau) & \text{if } \tau_{i,j} = \tau \\ \mathbb{V}_\mathbb{Z} & \text{if } \tau_{i,j} = \texttt{int} \\ \mathcal{D}^\sharp_{\tau_{i,j}} & \text{otherwise} \end{cases}$$

Finally, values of type τ are abstracted in $\mathcal{D}^\sharp_\tau$, defined as follows:

$$\mathcal{D}^\sharp_\tau = \prod_{\substack{1 \leq i \leq n \\ 1 \leq j \leq m_i}} (\mathcal{D}^\sharp_{i,j})^\perp \times \mathcal{P}(\mathbb{C}_\tau)$$

Intuitively, $\mathcal{D}^\sharp_\tau$ abstracts an object x of type τ as $((g_{i,j})_{i,j}, \mathscr{C})$ such that:

- $g_{i,j} \in (\mathcal{D}^\sharp_{i,j})^\perp$ abstracts every j-th field of C_i nested in x;
- $\mathscr{C} \in \mathcal{P}(\mathbb{C}_\tau)$ is the set of possible constructors C_i for x.

$\mathcal{D}^\sharp_\tau$ delegates the abstraction of field (i,j) to $\mathcal{D}^\sharp_{i,j}$. If this field is recursive, $\mathcal{D}^\sharp_{i,j} = \mathcal{P}(\mathbb{C}_\tau)$, meaning that we only keep track of its possible start constructors. If this is an integer field, $\mathcal{D}^\sharp_{i,j} = \mathbb{V}_\mathbb{Z}$, meaning that we create a symbolic variable $x.i.j \in \mathbb{V}_\mathbb{Z}$, to represent every field (i,j) nested in x. The numerical domain can then infer relations between them. When the field is neither recursive nor an integer, we delegate the abstraction to the domain chosen to abstract objects of type $\tau_{i,j}$. In this case, $\mathcal{D}^\sharp_{i,j} = \mathcal{D}^\sharp_{\tau_{i,j}}$.

By smashing every constructor field in one summary variable, we use an abstraction of fixed size to represent unbounded objects of recursive type. This approach shares similarities with the approach of Gopan et al. [18]. They use a fixed number of dimensions to over-approximate numeric values in unbounded collections, to analyze e.g. dynamic arrays or heap-allocated structures. Summarization variables consequently abstract more than one object. Note that smashing is done at the variable allocation site: each variable of type τ defines a set of numerical variables – the abstraction is called *object-sensitive* [39].

▶ **Example 4.2.** Let us illustrate this abstraction on lists of integers, defined as:

```
type list = Cons of int * list | Nil
```

We use the interval domain (i.e., $\mathcal{D}_\mathbb{Z} = \mathbb{I}$) to abstract integers. The set of possible constructors is $\mathbb{C}_{\texttt{list}} = \{\texttt{Cons}, \texttt{Nil}\}$. The constructor `Cons` has two fields. The first one, containing integers, is represented by $\mathcal{D}^\sharp_{1,1} = \mathbb{V}_\mathbb{Z}$, that is, a numeric variable, abstracted in $\sigma^\sharp$ as an interval. The second, recursive, one is represented by $\mathcal{D}^\sharp_{1,2} = \mathcal{P}(\mathbb{C}_{\texttt{list}})$. The constructor `Nil` has no field to be represented. The global abstraction for lists of integers is then:

$$\mathcal{D}^\sharp_{\texttt{list}} = \left((\mathcal{D}^\sharp_{1,1})^\perp \times (\mathcal{D}^\sharp_{1,2})^\perp\right) \times \mathcal{P}(\mathbb{C}_{\texttt{list}}) = \left(\mathbb{V}^\perp_\mathbb{Z} \times \mathcal{P}(\mathbb{C}_{\texttt{list}})^\perp\right) \times \mathcal{P}(\mathbb{C}_{\texttt{list}})$$

4.1.2 Concretization

Let $\gamma_{\tau_{i,j}}$ be the concretization for $\mathcal{D}^\sharp_{\tau_{i,j}}$ when $\tau_{i,j} \neq \tau$. It is provided by the domain $\mathcal{D}^\sharp_{\tau_{i,j}}$.

▶ **Definition 4.3** (ADTs concretization). *We define* $\gamma_\tau : \mathcal{D}^\sharp_\tau \times \Sigma_\mathbb{Z} \to \mathcal{P}(\mathbb{T}_\tau)$. *For* $(g, \mathscr{C}) \in \mathcal{D}^\sharp_\tau$, $\sigma_\mathbb{Z} \in \Sigma_\mathbb{Z}$*:*

$$\gamma_\tau((g,\mathscr{C}),\sigma_\mathbb{Z}) = \left\{ x : \tau \;\middle|\; \exists i,\, x = C_i(x_{i,1},\ldots,x_{i,m_i}) \;\wedge\; C_i \in \mathscr{C} \;\wedge\; \forall j, x_{i,j} \in \begin{cases} \gamma_\tau((g,g_{i,j}),\sigma_\mathbb{Z}) & \text{if } \tau_{i,j} = \tau \\ \gamma_{\tau_{i,j}}(g_{i,j},\sigma_\mathbb{Z}) & \text{otherwise} \end{cases} \right\}$$

Since type τ is finite, recursion is well-founded ($x_{i,j}$ contains strictly less constructors than x). An object $x : \tau$ is abstracted as $(g, \mathscr{C})$ if:

- it starts with $C_i \in \mathscr{C}$,
- and every j-th field of C_i accessible in x
  - either starts with constructor in $g_{i,j} \subseteq \mathbb{C}_\tau$, in the recursive case ($\tau_{i,j} = \tau$),
  - or can be abstracted as $g_{i,j}$ otherwise.

$g_{i,j}$ represents every j-th field from C_i nested in x, while $\Sigma_\mathbb{Z}$ keeps track of numeric variables.

▶ **Example 4.4.** Following Example 4.2, we consider the integer list abstract value $(g, \mathscr{C}) = ((r, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}\})$ with numerical environment $\sigma_\mathbb{Z} = [r \to [1, 10]]$. Its concretization $\gamma_{\texttt{list}}((g, \mathscr{C}), \sigma_\mathbb{Z})$ is the set of non-empty lists containing integers between 1 and 10:

$$\{\, x : \texttt{int list} \mid x = \texttt{Cons}(h, q) \wedge h \in [1, 10] \wedge q \in \gamma_{\texttt{list}}(((r, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}, \texttt{Nil}\}), \sigma_\mathbb{Z})\}$$

Let us consider $l = \texttt{Cons}(1, \texttt{Cons}(4, \texttt{Cons}(10, \texttt{Nil})))$. We have $l \in \gamma_{\texttt{list}}((g, \mathscr{C}), \sigma_\mathbb{Z})$, meaning that $(g, \mathscr{C})$ is a correct over-approximation of l.

4.1.3 Lattice Operators

We now define lattice operators. Since our domain is relational, operators are defined on environments. As seen in Section 3, environments are pairs, composed of a map from program variables to objects from their abstract domains, together with an element from the numerical relational domain. We denote lattice operators for the numerical relational domain as $(\sqsubseteq_r, \cup_r, \cap_r, \nabla_r)$. We denote operators for $\mathcal{D}^\sharp_{i,j}$ as $(\sqsubseteq_{\mathcal{D}_{i,j}}, \cup_{\mathcal{D}_{i,j}}, \cap_{\mathcal{D}_{i,j}}, \nabla_{\mathcal{D}_{i,j}})$. We define an intermediate inclusion between two ADT abstractions, interpreted outside their abstract environment. We simply lift inclusions $\sqsubseteq_{\mathcal{D}_{i,j}}$.

▶ **Definition 4.5** (Environment-free inclusion). *For* $(g_1, \mathscr{C}_1)$, $(g_2, \mathscr{C}_2) \in \mathcal{D}^\sharp_\tau$ *abstract elements:*

$$(g_1,\mathscr{C}_1) \subseteq^\sharp_\tau (g_2,\mathscr{C}_2) \iff \mathscr{C}_1 \subseteq \mathscr{C}_2 \wedge \forall i,j, g^1_{i,j} \sqsubseteq_{\mathcal{D}_{i,j}} g^2_{i,j}$$

$(g_1, \mathscr{C}_1) \subseteq^\sharp_\tau (g_2, \mathscr{C}_2)$ then means that the non-numerical fields of $(g_1, \mathscr{C}_1)$ are more precise than those of $(g_2, \mathscr{C}_2)$. To compare numerical fields, we need to check inclusion on environments:

▶ **Definition 4.6** (Inclusion). *We define* $\sqsubseteq^\sharp : \Sigma^\sharp \to \Sigma^\sharp$*:*

$$(m_1,d_1) \sqsubseteq^\sharp (m_2,d_2) \iff \forall v : \tau, m_1(v) \subseteq^\sharp_\tau m_2(v) \wedge d_1 \sqsubseteq_r d_2$$

An environment (m_1, d_1) is more precise than (m_2, d_2) if for every program variable, the abstraction of this variable is more precise in m_1 than in m_2, and its abstraction for numerical variables, d_1, is more precise than d_2.

▶ **Example 4.7.** Following Example 4.2 on integer lists, we have for instance:

$$((x.1.1, \{\texttt{Nil}\}), \{\texttt{Cons}\}) \subseteq^\sharp_{\texttt{list}} ((x.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}\})$$

So we can deduce:

$$\begin{aligned}&(x \to ((x.1.1, \{\texttt{Nil}\}), \{\texttt{Cons}\}), \{3 \leq x.1.1 \leq 6\})\\ \sqsubseteq^\sharp\ &(x \to ((x.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}\}), \{2 \leq x.1.1 \leq 7\})\end{aligned}$$

To define the meet, join and widening operators, we also start by defining those operators on the environment-free ADT abstractions, that is, ignoring their numerical part. Similarly, we lift operators from domains $\mathcal{D}^\sharp_{i,j}$. Those operators are defined between objects giving the same name to their summarization variables.

▶ **Definition 4.8** (Environment-free operators). *For* $\square \in \{\cup, \cap, \nabla\}$, *for* $(g_1, \mathscr{C}_1), (g_2, \mathscr{C}_2) \in \mathcal{D}^\sharp_\tau$*:*

$$(g_1, \mathscr{C}_1)\ \square^\sharp_\tau\ (g_2, \mathscr{C}_2) = (g, \mathscr{C}_1\ \square\ \mathscr{C}_2) \text{ where } g \text{ is defined by } \forall i, j, g_{i,j} = g^1_{i,j}\ \square_{\mathcal{D}_{i,j}}\ g^2_{i,j}$$

$(g_1, \mathscr{C}_1)\ \square^\sharp_\tau\ (g_2, \mathscr{C}_2)$ performs a join (resp. meet or widening) between non-numerical fields by delegating the operation to the relevant domains. Afterwards, to perform the operation on numerical fields too, we need to perform it on environments:

▶ **Definition 4.9** (Operators). *For* $\square \in \{\cup, \cap, \nabla\}$,*we build* $\square^\sharp : \Sigma^\sharp \to \Sigma^\sharp$*:*

$$(m_1, d_1)\ \square^\sharp\ (m_2, d_2) = (v : \tau \to m_1(v)\ \square^\sharp_\tau\ m_2(v),\ d_1\ \square^\sharp_r\ d_2)$$

Performing an operation between two environments consists in performing it on each variable abstraction in both maps, pointwise, and between both numerical abstract elements.

Note that the inclusion test, meet, join, and widening for the numerical relational domain operate on *heterogeneous* environments, that is, environments that may be defined on different sets of variables. We rely on the technique from Journault et al. [24] to lift classic relational domains (such as polyhedra) to the case of heterogeneous environments.. The soundness proof of our operators is a direct consequence of their soundness proofs [21].

4.1.4 Constructor Transfer Function

We then define the transfer function of constructors. Given an abstract environment $\sigma^\sharp_0$ and a concrete expression $C_k(e_1, \ldots, e_n)$, we compute a sound abstraction $(g, \mathscr{C})$ in a new abstract environment:

$$\begin{aligned}
\mathbb{E}^\sharp[\![\ C_k(e_1, \ldots, e_n)\ ]\!]\sigma^\sharp_0 = {}& \text{let } \forall i \in [\![1, n]\!]\ v_i, \sigma^\sharp_i = \mathbb{E}^\sharp[\![e_i]\!]\sigma^\sharp_{i-1} \text{ in} && (1)\\
& \text{let } (g^0, _), \sigma^\sharp = \mathbf{fold}\left((g^0, \emptyset) \leftarrow (v_j)_{\tau_{k,j}=\tau}\right)\sigma^\sharp_n \text{ in} && (2)\\
& \text{let } g^0, \sigma^\sharp = \bigcirc_{j, \tau_{k,j} \neq \tau}\left(\mathbf{fold}(g^0 \leftarrow_{k,j} v_j)\right)\ \sigma^\sharp \text{ in} && (3)\\
& \text{let } g = \left(\begin{cases} g^0_{k,j} \cup \mathrm{snd}(v_j) & \text{if } i = k \wedge \tau_{k,j} = \tau \\ g^0_{i,j} & \text{otherwise} \end{cases}\right)_{i,j} \text{ in} && (4)\\
& (g, \{C_k\}), \sigma^\sharp
\end{aligned}$$

The abstract semantics of $C_k(e_1, \ldots, e_n)$ is an element of $\mathcal{D}^\sharp_\tau$. The only possible start constructor is C_k. We abstract its fields as g, which is computed as follows. First, we recursively compute abstractions for e_i in v_i (1). We then define $g^0 = (g^0_{i,j})_{i,j}$. We use the

fold operator, defined by Gopan et al. [18] for summarization variables of arrays and lifted there for ADTs. It folds inside every $g^0_{i,j}$ all abstractions for the j-th fields of C_i nested inside every recursive field abstraction v_j (2). After the first folding, $g^0_{i,j}$ abstracts possible values in the j-th field of C_i nested at a depth of at least 1 in x. Then, we need to update it with every possible values in j-th fields of C_i nested at *any depth* in x. First, we add non-recursive information at depth 0, that is, updating $g^0_{k,j}$ with j-th field of C_k at depth 0, v_j (3). To do so, we compose ($\bigcirc$), for every non-recursive field (k, j), the **fold** operator to add v_j as a possible abstract values for field $g^0_{k,j}$. Finally, the possible start constructors of e_j, that is, $\mathrm{snd}(v_j)$, are added as possible start constructors for the j-th field of C_k (4).

▶ **Example 4.10.** Following previous examples on integer lists, given $\sigma^\sharp \in \Sigma^\sharp$:

$$\mathbb{E}^\sharp[\![\texttt{Nil}]\!]\sigma^\sharp = ((r.1.1, \bot), \{\texttt{Nil}\}), \sigma^\sharp[r.1.1 \to \bot]$$
$$\mathbb{E}^\sharp[\![\texttt{Cons}(10, \texttt{Nil})]\!]\sigma^\sharp = ((r.1.1, \{\texttt{Nil}\}), \{\texttt{Cons}\}), \sigma^\sharp[r.1.1 \to \bot \cup_{\mathbb{I}} [10, 10]]$$
$$\mathbb{E}^\sharp[\![\texttt{Cons}(1, \texttt{Cons}(10, \texttt{Nil}))]\!]\sigma^\sharp = ((r.1.1, \{\texttt{Nil}, \texttt{Cons}\}), \{\texttt{Cons}\}), \sigma^\sharp[r.1.1 \to [1, 10]]$$

Note that we rely on type information to delegate abstraction of a given field to the relevant domain. We discuss related implementation details in Section 7.1.

4.1.5 Abstraction Precision

▶ **Example 4.11** (Abstraction of trees)**.** We start with $\sigma^\sharp_0$ an empty environment. As an illustration for this abstract domain, consider:

```
type tree = Node of tree * int * tree | Leaf of int
let x = Node(Node(Leaf(250), 100, Leaf(251)), 1, Leaf(252))
```

Here, $\mathbb{E}^\sharp[\![\texttt{Node}(\texttt{Node}, (\texttt{Leaf}(250), 100, \texttt{Leaf}(251)), 1, \texttt{Leaf}(252))]\!]\sigma^\sharp_0 = ((g, \mathscr{C}), \sigma^\sharp)$ with:

$$(g, \mathscr{C}) = ((\{\texttt{Node}, \texttt{Leaf}\}, x.1.2, \{\texttt{Leaf}\}, x.2.1), \{\texttt{Node}\})$$
$$\sigma^\sharp = ([x.1.2 \to v_{x.1.2}], [x.2.1 \to v_{x.2.1}], [v_{x.1.2} \to [1, 100]][v_{x.2.1} \to [250, 252]])$$

$$\gamma_{\texttt{tree}}((g, \mathscr{C}), \sigma^\sharp) = \{x \mid x = \texttt{Node}(t_1, n, t_2) \ \wedge \ n \in [1, 100] \\ \wedge\, t_1 \in \gamma_{\texttt{tree}}((g, \{\texttt{Node}, \texttt{Leaf}\}))t_2 \in \gamma_{\texttt{tree}}(g, \{\texttt{Leaf}\})\}$$

It abstracts the set of trees starting with `Node`, only growing to the left, where the content of `Leaf` fields are between 250 and 252, and the content of `Node` between 1 and 100.

Note that our summarization abstraction can quickly lose precision, even when the structure size is known statically. To limit this, we could keep track of `x`'s exact content and summarize only when needed for convergence (recursive call), or for a certain depth of `x`. Such features are not yet implemented. Note that though of identical type, `Node` and `Leaf`'s integer fields are summed up separately.

▶ **Example 4.12** (Relationality)**.** Consider this program manipulating integer variables `a` and `y` of unknown value:

```
let z = Cons(a, Nil) in
let x = if y <= 2*a + 1 then Cons(y, z) else Cons(2 * a + 1, z)
```

With the polyhedra domain of Cousot and Halbwachs [15], the analysis is able to infer relational properties:

$$
\begin{aligned}
z \to & ((z.1.1, \{\texttt{Nil}\}), \{\texttt{Cons}\}), [z.1.1 = a] \\
x \to & (((x.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}\}), [x.1.1 = z.1.1 \cup y][y \leq 2a+1][z.1.1 = a]) \cup^\sharp_{\texttt{list}} \\
& (((x.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}\}), [x.1.1 = z.1.1 \cup 2a+1][y > 2a+1][z.1.1 = a]) \\
\to & ((x.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}\}), [x.1.1 < 2a+1][z.1.1 = a]
\end{aligned}
$$

We can then prove: $x_{1,1} \leq 2a+1$, that is, every element of the list is smaller than $2a+1$, without assuming any bound on a. This relational aspect is crucial to infer input-output function summaries for generic inputs.

4.2 Pattern-Matching Abstract Semantics

Pattern-matching is a key construct to manipulate ADTs. We define their abstract semantics. We use as intermediate function $\texttt{match}^\sharp : \mathcal{V}^\sharp \times \Sigma^\sharp \times \Pi \to \Sigma^\sharp \times \Sigma^\sharp$. Given an abstract value $v^\sharp$, an abstract environment $\sigma^\sharp$ and a pattern p, it returns two abstract environments. The first is an over-approximation of environments from $\sigma^\sharp$, in which p and $v^\sharp$ can match. The second is an over-approximation of environments in which they cannot. We rely on a filter function $\mathcal{F}^\sharp$ from the numerical domain. It restricts an abstract environment to keep only those where a given boolean predicate evaluates to true. It is useful to model the `when` guards appearing in patterns:

$$
\begin{aligned}
\texttt{match}^\sharp(v^\sharp, \sigma^\sharp, p \texttt{ when } e_1) = \ & \text{let } \sigma^\sharp_0, \sigma^\sharp_{\neg,0} = \texttt{match}^\sharp(\sigma^\sharp, v^\sharp, p) \text{ in} \\
& \text{let } e^n_1, \sigma^\sharp_1 = \mathbb{E}^\sharp[\![e_1]\!]\sigma^\sharp_0 \text{ in} \\
& \left(\mathcal{F}^\sharp[\![e^n_1 \neq 0]\!]\sigma^\sharp_1\right), \left(\sigma^\sharp_{\neg,0} \cup^\sharp \mathcal{F}^\sharp[\![e^n_1 = 0]\!]\sigma^\sharp_1\right)
\end{aligned}
$$

Thus, $v^\sharp$ matches p `when` e_1 in environments where $v^\sharp$ and p match, and when e^n_1 is non-zero. The other cases are simpler.

$$
\begin{aligned}
\mathbb{E}^\sharp[\![\text{match } e_0 \text{ with } p_1 \to e_1 \mid \cdots \mid p_m \to e_m]\!]\sigma^\sharp = \ & \\
& \text{let } \sigma^\sharp_1, \sigma^\sharp_{\neg,1} = \texttt{match}^\sharp(\mathbb{E}^\sharp[\![e_0]\!]\sigma^\sharp, p_1) \text{ in} \\
& \text{let } e'_1 = \text{match } e_0 \text{ with } p_2 \to e_2 \mid \cdots \mid p_m \to e_m \text{ in} \\
& \begin{cases} \mathbb{E}^\sharp[\![e_1]\!]\sigma^\sharp_1 \cup^\sharp \mathbb{E}^\sharp[\![e'_1]\!]\sigma^\sharp_{\neg,1} & \text{if } m \geq 1 \\ \{\omega\}, \sigma^\sharp & \text{if } m = 0 \wedge \sigma^\sharp \neq \bot \end{cases}
\end{aligned}
$$

The abstract semantics of pattern matching is the abstract union of all interpretations of branches e_i, in an environment in which e_0 matches the pattern p_i but not the previous patterns p_j for $j < i$. We add $\{\omega\}$ (match failure) if some part of the environment did not match any pattern. Our analysis can thus target match failure, i.e. when no pattern caught the value of e_0. This is the case if $\sigma^\sharp \neq \bot$ when no pattern is left. To the best of our knowledge, this is the first value analysis handling `when` clauses in pattern-matching exploiting value information to precisely detect non-exhaustive pattern-matching. The OCaml compiler does warn on non-exhaustive pattern-matching but, since its analysis is not value-sensitive, it is more conservative. For the following program, it will issue a "non-exhaustive pattern matching" warning, whereas our analysis, knowing that `l` starts with `Cons`, can prove that no case is left unmatched:

```
let l = Cons(1, Nil) in let x = match l with Cons(h,Nil)-> h.
```

```
let rec filter_le inf l =
  match l with
  | Cons(h, q) when h > inf -> filter_le inf q
  | Cons(h, q) when h <= inf -> Cons(h, filter_le inf q)
  | Nil -> Nil
in
let x = Cons(0, Cons(5, Cons(11, Nil))) in
let y =  filter_le 4 x in
let hd = match y with Cons(h,q) -> h | Nil -> 0 in
assert(hd <= 4)
```

Figure 6 A recursive function manipulating recursive algebraic objects.

4.3 Example

Before defining a domain for higher-order functions, we show with an example how our compositional function analysis works together with our ADT summarization domain and the abstract semantics of pattern-matching. We consider the program in Figure 6. It defines a function `filter_le`. This function of type $\tau = \texttt{int} \to \texttt{list} \to \texttt{list}$ takes as inputs an integer *inf* and a list l and keeps only the elements of l that are lower than *inf*.

Let *body* be the body of the function `filter_le`. We analyze it with unknown inputs, in $\sigma^\sharp = [l \to \top][inf \to \top]$. Its abstract semantics is $F : v^\sharp \to \text{fst}(\mathbb{E}^\sharp[\![body]\!]\sigma^\sharp[f \to v^\sharp])$. To get the abstract semantics of the recursive function, we compute the abstract fixpoint of the body semantics (Section 3.2). Starting with `filter_le` at $\bot_\tau = ((inf, l), r, \sigma^\sharp[r \to \bot])$, we compute the fixpoint $\nabla_{n\in\mathbb{N}} F^n(\bot_\tau)$:

$$\begin{aligned}
F(\bot_\tau) &= \mathbb{E}^\sharp[\![\text{fun } l \ inf \ \to body]\!]\sigma^\sharp[\texttt{filter_le} \to \bot_\tau] \\
&= ((inf, l), ((r.1.1, \bot), \{\texttt{Cons}\}, \sigma^\sharp[r.1.1 \to \bot])) \cup^\sharp_\tau \bot \\
&= (\bot_\tau, \{\texttt{Cons}, \texttt{Nil}\}, \sigma^\sharp[r.1.1 \to \bot]) \\
F^2(\bot_\tau) &= F(((inf, l), (r.1.1, \bot), \{\texttt{Cons}, \texttt{Nil}\}, \sigma^\sharp[r.1.1 \to \bot])) \\
&= (((inf, l), (r.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}, \texttt{Nil}\}), \sigma^\sharp[r.1.1 \leq inf]) \\
F^3(\bot_\tau) &= F^2(\bot_\tau) \\
\nabla_{n\in\mathbb{N}} F^n(\bot_\tau) &= (((inf, l), (r.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}, \texttt{Nil}\}), \sigma^\sharp[r.1.1 \leq inf])
\end{aligned}$$

By iteratively computing the summary of the function, we are finally able to infer that the elements in the output list ($r.1.1$) are lower than input *inf*. We denote this result as V_1, assign it to `filter_le` and continue the analysis:

$$\mathbb{E}^\sharp[\![\text{let rec } \texttt{filter_le} = body \text{ in } e]\!]\sigma^\sharp = \text{ let } \sigma_1^\sharp = \sigma^\sharp[\texttt{filter_le} \to V_1] \text{ in } \mathbb{E}^\sharp[\![e]\!]\sigma_1^\sharp$$

We abstract the assignment into x:

$$\begin{aligned}
\mathbb{E}^\sharp[\![\texttt{Cons}(0, \texttt{Cons}(5, \texttt{Cons}(11, \texttt{Nil})))]\!]\sigma_1^\sharp = \ & \text{let } \sigma_2^\sharp = \sigma_1^\sharp[x.1.1 \to 0 \cup_\mathbb{Z} 5 \cup_\mathbb{Z} 11] \text{ in} \\
& ((x.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}\}), \sigma_2^\sharp = V_2, \sigma_2^\sharp \\
\mathbb{E}^\sharp[\![\text{let } x = \texttt{Cons}(0, \texttt{Cons}(5, \texttt{Cons}(11, \texttt{Nil}))) \text{ in } e_2]\!]\sigma_3^\sharp = \ & \text{let } \sigma_3^\sharp = \sigma_2^\sharp[x \to V_2] \text{ in } \mathbb{E}^\sharp[\![e_2]\!]\sigma_3^\sharp
\end{aligned}$$

We then abstract the assignment into y by applying `filter_le`.

$$\mathbb{E}^\sharp[\![\texttt{filter_le}\ 4\ x]\!]\sigma_3^\sharp = ((r.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}, \texttt{Nil}\}),$$
$$(\sigma^\sharp[r.1.1 \leq inf])[inf = 4][l = \sigma_3^\sharp(x)]$$
$$((r.1.1, \{\texttt{Cons}, \texttt{Nil}\}), \{\texttt{Cons}, \texttt{Nil}\}), \sigma^\sharp[r.1.1 \leq 4] = V_3, \sigma_4^\sharp$$

$$\mathbb{E}^\sharp[\![\text{let } y = \texttt{filter_le}\ 4\ x \text{ in } e_2]\!]\sigma_4^\sharp = \text{ let } \sigma_5^\sharp = \sigma_4^\sharp[x.1.1 \to 0 \cup_{\mathbb{Z}} 5 \cup_{\mathbb{Z}} 11][y \to V_3] \text{ in}$$
$$\mathbb{E}^\sharp[\![e_2]\!]\sigma_5^\sharp$$

We then evaluate $e_1 =$ match y with $\mid \texttt{Cons}(h, q) \to h \mid \texttt{Nil} \to 0$. We assign the result to hd.

$$\mathbb{E}^\sharp[\![e_1]\!]\sigma_1^\sharp = h, \sigma_5^\sharp[hd \leq 4]$$

Since $hd \leq 4$, the assertion is proven. More generally, the summary for `filter_le` proves that for any list l and integer inf, `filter_le` inf l is a list whose content is lower than inf. The analysis also proves that the pattern-matching inside the function body is exhaustive.

5 Higher-Order, Disjunctive Relational Summaries

In a higher-order setting, functions can be inputs or output of other functions. This is a key concept of functional programming, making programs harder to analyze. We consider the program from Figure 1 and highlight the benefits of compositional analyses on this example.

Non-compositional analysis. Different choices were made in the literature to analyze higher-order functions. A method giving precise results [27] is simply to defer the analysis of `to_fun`'s body until we know its parameters, or an abstraction of them. Consequently, the body analysis is performed at every call site. Thus, the definitions of `f1` and `f2` only trigger a store of their definition code. When we compute `r1` and `r2`, all inputs are known, yielding: $\texttt{r1} = 5, \texttt{r2} = 9$. This method is able to infer precise results for `r1` and `r2`, with the drawback that the function body is reanalyzed at each call site. This is costly, and hinders scalability.

Compositional analysis. To circumvent this cost, we can perform a compositional analysis, where a function is analyzed only once, at its definition site. This is how `filter_le` was analyzed in Section 4.3, at first-order. Since functions are abstracted as points in the polyhedra space, intuitively, manipulating them as first class values for higher order does not add further complexity. The function domain is simply based on the polyhedra one. We can analyze `to_fun` once and for all, supposing that we do not know anything about `f`'s behavior. We get $\texttt{r1} = \top, \texttt{r2} = \top$. This loss of information is due to a join of both possible cases from `to_fun`'s behavior. However, this is not inherent to compositional analysis, since the specification of `to_fun` is:

$$\texttt{to_fun}(c, x) = \begin{cases} n & \text{if } c = \texttt{Cst}(n) \\ f(x) & \text{if } c = \texttt{Fun}(f) \end{cases}$$

It is thus possible to describe `to_fun`'s behavior without a priori information on possible values for c, as long as *disjunctions* on those possible values are possible. The precision loss mentioned above was indeed due to the impossibility to express disjunctions when abstracting higher-order functions. This is why we focus in this section on lifting partitioning methods to higher-order.

5.1 Partitioning Function Summaries

Even at first-order, a similar precision loss occurs on very simple programs:

```
let binary x = if x > 0 then 10 else -10
```

By conducting a compositional non-relational analysis with the interval domain, we are only able to infer that the output is in $[-10, 10]$, a quite weak result. This comes from the fact that `binary` has two very distinct behaviors depending on the input value. Joining them induces a precision loss. The issue can be overcome by partitioning on the input [7], then keeping separate those behaviors: $\lambda x.(x > 0 \wedge res = 10) \vee (x \leq 0 \wedge res = -10)$. Note that relationality cannot, on its own, overcome this cause of imprecision. The polyhedra domain gives the same result as intervals on `binary`. However, Boutonnet and Halbwachs [8] successfully use relationality and partitioning together. Consider the following example:

```
let max x y = if x >= y then x else y
```

With the interval domain, even with partitioning, we cannot express anything interesting about `max`, whereas the polyhedra domain alone can only infer: $\lambda xy.x \leq res \wedge y \leq res$. But with *disjunctive relational summaries*, we can separate disjunct behaviors, then summarizing the maximum function with: $\lambda xy.(x < y \wedge res = y) \vee (x \geq y \wedge res = x)$. Maintaining multiple partitions is costly, so a key point of partitioning is to decide when to partition and when to merge different behaviors. Various heuristics were developed on that topic. Those methods are compatible with recursion. Indeed, Bourdoncle [7] and Boutonnet and Halbwachs [8] are able to give precise summaries for McCarthy 91 function.

We want to benefit from this precision improvement at higher-order. In a higher-order setting however, functions are first class values: they can be input or output of other functions, etc. As first class objects, they should be represented as abstract values. Compared to previous works at first-order, we then need to define the *abstract domain of functions*. To the best of our knowledge, this is the first presentation of disjunctive summaries as a domain abstracting functions complete with all its lattice operators, including join and widening.

5.2 Disjunctive Relational Summaries as a Domain on Functions

As in Section 3.2, we choose $(\mathcal{R}(V), \sqsubseteq_r^\sharp, \sqcup_r^\sharp, \sqcap_r^\sharp, \nabla_r^\sharp, \gamma_r, \mathrm{proj}_r, \lambda_r)$ a relational domain on V. This way, the formalization is independent of the chosen domain.

▶ **Definition 5.1** (Function domain). *Given a function type $\tau = \tau_1 \to \cdots \tau_n \to \tau_r$, we define $\mathcal{F}_\tau^\sharp$ the set of elements abstracting functions of type τ. Let n_i be the number of variables necessary to abstract an object of type τ_i.*

$$\mathcal{F}_\tau^\sharp = \{(V, r, (p_i)_{[\![1,m]\!]}) \mid V = (x_1, \ldots, x_n), \forall i, x_i \in \mathbb{V}^{n_i}, \forall i, j, i \neq j \Rightarrow x_i \neq x_j, r \in \mathbb{V}, \\ \forall i \in [\![1, m]\!], p_i \in \mathcal{R}(V \cup \{r\})\}$$

A function is thus abstracted as a triplet of: a n-tuple of input variables, an output variable, and a collection of m relations abstracting different cases in the function's behavior. We denote $(x_1, \ldots, x_n), r, (p_1, \ldots, p_m)$ as $\lambda x_1 \ldots x_n. \bigvee_{i=1}^{m} p_i(x_1, \ldots, x_n, r)$. For example, `let add x y = x + y` is abstracted as $((x, y), r, (r = x + y))$, written $\lambda xy.r = x + y$.

▶ **Definition 5.2** (Function concretization). *For* $\tau = \tau_1 \to \cdots \tau_n \to \tau_r$, $f = ((x_i)_{i\in[\![1,n]\!]}, r, (p_i)_{i\in[\![1,m]\!]}) \in \mathcal{F}^\sharp_\tau$, *the concretization is:*

$$\gamma_\tau(f, _) = \{f : \tau \mid \forall (a_1, \ldots, a_n) : \tau_1 \times \cdots \times \tau_n, \\ [x_1 = a_1] \cdots [x_n = a_n][r = f(a_1, \ldots, a_n)] \in \bigvee_{i=1}^{m} \gamma_r(p_i)\}$$

This concretization is simply an update of Definition 3.4, with a disjunction of relations instead of a unique one.

▶ **Example 5.3.** For $f^\sharp = \lambda x_1 x_2.(x_1 \leq x_2 \wedge r > 0) \vee (x_1 > x_2 \wedge r < 0)$, $\tau =$ `int` $\to$ `int` $\to$ `int`:

$$\gamma_\tau(f^\sharp, _) = \{f : \mathbb{N} \to \mathbb{N} \to \mathbb{N} \mid \forall x_1, x_2 \in \mathbb{N}, \\ x_1 \leq x_2 \implies f(x_1, x_2) > 0 \wedge x_1 > x_2 \implies f(x_1, x_2) < 0\}$$

That is, $f^\sharp$ represents all functions whose result is lower than 0 when the first input is the smallest, and greater than 0 otherwise.

We need to define comparison, join, meet, and widening operators on functions. Since we consider only well-typed programs, those operators will be defined for functions of identical type: in particular, they will have the same number of parameters. These definitions build upon relational domain operators.

Note that renaming the inputs or the output of the function does not change its concretization. Without loss of generality, we assume when comparing two functions that they use the same names for inputs or outputs (this can always be ensured by renaming). We then define abstract inclusion, meet, join, and widening operators on the functional domain:

▶ **Definition 5.4** (Inclusion). *For* $f = V, r, (f_i)_{[\![1,n_1]\!]}$, $g = V, r, (g_i)_{[\![1,n_2]\!]}$, *the inclusion* $\subseteq^\sharp$ *on* $\mathcal{P}^\sharp_n$ *is:* $f \subseteq^\sharp g \iff \forall i \in [\![1, n_1]\!], \exists j \in [\![1, n_2]\!], f_i \sqsubseteq^\sharp_r g_j$

f is included in g if every disjunct of f is included in a disjunct of g. This order is the classic order for disjunctive completion domains [1].

▶ **Example 5.5.** With this definition, given two functions of type `int -> int`:

$$x, r, \begin{cases} x > 1 \wedge r = 10 \\ x = 0 \wedge r = 10 \\ x < 0 \wedge r = \top \end{cases} \quad \subseteq^\sharp \quad x, r, \begin{cases} x \geq 1 \wedge r = 10 \\ x < 1 \wedge r = \top \end{cases}$$

▶ **Definition 5.6** (Meet). *Given* $f = V, r, (f_i)_{i\in[\![1,m_1]\!]}$ *and* $g = V, r, (g_i)_{i\in[\![1,m_2]\!]}$, *the abstract intersection of functions is defined as* $\sqcap^\sharp_f$*:*

$$f \sqcap^\sharp_f g = V, r, \left(\bigsqcup_{j=1}^{m_2} (f_i \sqcap^\sharp_r g_j) \right)_{i\in[\![1,n_1]\!]}$$

That is, given a disjunct f_i, we compute its meet with every disjunct g_j and then join them together, keeping n_1 partitions. Indeed, for performance reasons, we do not want to maintain all (quadratic) combinations of pairwise intersections. This method ensures that we keep the number of partitions used in the right argument. This abstraction of the meet is then not commutative. An alternative definition would partition with regard to the abstraction with the highest number of disjuncts, which would likely be more precise. An experimental study, left for future work, could be led to determine the best version.

▶ **Example 5.7.** Given two functions of type `int -> int` with different input partitioning:

$$n, r, \begin{cases} n \geq 0 \wedge 1 \leq r \leq 3 \\ n < 0 \wedge -3 \leq r \leq -1 \end{cases} \quad \sqcap_f^\sharp \quad n, r, \begin{cases} n \geq 1 \wedge 2 \leq r \leq 4 \\ n = 0 \wedge r = 3 \\ n < 0 \wedge -4 \leq r \leq -2 \end{cases}$$

$$= n, r, \begin{cases} (n \geq 1 \wedge 2 \leq r \leq 3) \sqcup_p^\sharp (n = 0, r = 3) \sqcup_p^\sharp \bot_p \\ \bot_p \sqcup_p^\sharp \bot_p \sqcup_p^\sharp n < 0 \wedge -3 \leq r \leq -2 \end{cases}$$

$$= n, r, \begin{cases} n \geq 0 \wedge 2 \leq r \leq 3 \\ n < 0 \wedge -3 \leq r \leq -2 \end{cases}$$

▶ **Definition 5.8** (Join). *Given $f = V, r, (f_i)_{i \in [\![1, n_1]\!]}$ and $g = V, r, (g_i)_{i \in [\![1, n_2]\!]}$, the abstract union of functions is defined as $\sqcup_f^\sharp$. We write $G_i = \{g_j \mid 1 \leq j \leq n_2 \wedge proj_r(g_j) \sqsubseteq proj_r(f_i)\}$ the set of g_j whose constraints on the inputs are included in the constraints of f_i, and $G^\neg = \{g_j \mid 1 \leq j \leq n_2 \wedge \forall 1 \leq i \leq n_1, g_j \notin G_i\}$ the set of g_j not included in any G_i.*

$$f \sqcup_f^\sharp g = V, r, (f_i \bigsqcup_{g_j \in G_i} g_j)_{i \in [\![1, n_1]\!]} \vee (g_j)_{j \in [\![1, n_2]\!] \wedge g_j \in G^\neg}$$

That is, we keep every disjunct f_i, and join them with disjuncts of g respecting their conditions on the input. We add disjuncts g_j that are compatible with no f_i. Similarly to the meet operator, we do not want to simply keep every disjunct, so as to limit their number.

▶ **Example 5.9.** Given two functions of type `int -> int`:

$$n, r, \begin{cases} n \geq 0 \wedge 1 \leq r \leq 3 \\ n < 0 \wedge -3 \leq r \leq -1 \end{cases} \quad \sqcup_f^\sharp \quad n, r, \begin{cases} n \geq 1 \wedge 2 \leq r \leq 4 \\ n = 0 \wedge r = 3 \\ n < 0 \wedge -4 \leq r \leq -2 \end{cases}$$

$$= n, r, \begin{cases} (n \geq 0 \wedge 1 \leq r \leq 3) \sqcup_p^\sharp (n \geq 1 \wedge 2 \leq r \leq 4) \sqcup_p^\sharp (n = 0 \wedge r = 3) \\ (n < 0 \wedge -3 \leq r \leq -1) \sqcup_p^\sharp (n < 0 \wedge -4 \leq r \leq -2) \end{cases}$$

$$= n, r, \begin{cases} n \geq 0 \wedge 1 \leq r \leq 4 \\ n < 0 \wedge -4 \leq r \leq -1 \end{cases}$$

Widening is defined the same way as join, replacing $\sqcup_p^\sharp$ with $\nabla_p^\sharp$. However, to ensure convergence, we also limit the number of disjuncts to a user-controlable constant. When performing widening, we join disjuncts when necessary to respect this limit, before delegating widening to the underlying domain.

In conclusion, we defined the set $\mathcal{F}_\tau^\sharp$ alongside its concretization, inclusion, join, meet, and widening operators, as an abstract domain for functions of type τ. We now explain how to apply a computed summary in $\mathcal{F}_\tau^\sharp$ at a call site, to evaluate the effect of a function call.

5.3 Function Application with Partitioning

Function summaries being now disjunctive, we need to update the semantics from Section 3.2:

$$\mathbb{E}^\sharp[\![e_0 \dots e_k]\!]\sigma^\sharp = \text{let } (x_1, \dots, x_n, r, (p_i)_{i\in[\![1,m]\!]}), \sigma_0^\sharp = \mathbb{E}^\sharp[\![e_0]\!]\sigma^\sharp \text{ in} \tag{5}$$

$$\text{let } \forall i \in [\![0, k-1]\!]\ e_{i+1}^\sharp, \sigma_{i+1}^\sharp = \mathbb{E}^\sharp[\![e_{i+1}]\!]\sigma_i^\sharp \text{ in} \tag{6}$$

$$\text{let } \forall i \in [\![1, m]\!]\ \sigma_{k,i}^\sharp = \texttt{add_vars}(\sigma_k^\sharp, \texttt{dom}(p_i)) \text{ in} \tag{7}$$

$$\text{let } \forall i \in [\![1, m]\!]\ p_i = \texttt{add_vars}(\lambda_r(p_i), \texttt{dom}(\sigma_n^\sharp)) \text{ in} \tag{8}$$

$$\text{let } \forall i \in [\![1, m]\!]\ p_i' = (p_i \sqcap^\sharp \sigma_{k,i}^\sharp)[x_j = e_j^\sharp]_{j\in[\![1,k]\!]} \text{ in} \tag{9}$$

$$\text{let } X = \{x_{k+1}, \dots, x_n\} \text{ in} \tag{10}$$

$$\begin{cases} \left(X, r, (\text{proj}_r(p_i'))_{i\in[\![1,m]\!]\wedge p_i'\neq\bot}\right), \sigma^\sharp & \text{if } k < n \\ r, (p_i')_{i\in[\![1,m]\!]\wedge p_i'\neq\bot} & \text{otherwise} \end{cases} \tag{11}$$

First, we compute the semantics of the function e_0 (5). Then we compute sequentially the semantics of its argument expressions e_1, …, e_k (6). As in Section 3.2, we extend p_i and $\sigma_k^\sharp$ to the same definition domain (7,8). We combine them and add to each function disjunct p_i the equality constraint between formal argument x_j and value $e_j^\sharp$ (9). X is the set of free formal arguments (not bound to an actual argument) in case of partial application (10).

Partial application comes naturally (case $k < n$ in (11)). When partially applying a function, we project the result on the set of remaining variables. The result is then a set of relations consisting in a disjunctive summary. It abstracts the function resulting from the partial application. When the application is total (otherwise in (11)), there is no remaining parameters: we simply change the format of the result. In both cases, we remove empty disjuncts $p_i' = \bot$, which correspond to unsatisfiable constraints on the inputs.

▶ **Example 5.10.** The summary of the function `max` is $(x, y), r, (x > y \wedge r = x) \vee (x \leq y \wedge r = y)$. Then partially applying it with one argument a, we get the abstraction:

$$\mathbb{E}^\sharp[\![\texttt{max}\ a]\!]\{a \geq 5\} = y, r, \{(a > y \wedge r = a \wedge a \geq 5) \vee (a \leq y \wedge r = y \wedge a \geq 5)\}$$

This way, we deduce that the function returns a result which is always greater than 5, and is y if it is greater than a and a otherwise.

5.4 Function Analysis with Partitioning

We update function analysis semantics from Section 3.2 to allow a disjunctive result:

$$\mathbb{E}^\sharp[\![\text{fun } x_1 \cdots x_n \to body]\!]\sigma^\sharp = \text{let } c_1, \dots, c_p = \texttt{get_preconditions}(body) \text{ in} \tag{12}$$

$$\text{let } \forall i \in [\![1, p]\!],\ e_i^\sharp, \sigma_i^\sharp = \mathbb{E}^\sharp[\![body]\!](\sigma^\sharp \wedge c_i)[x_j \to \top] \tag{13}$$

$$\text{and } s_i = \text{proj}_r(\sigma_i^\sharp[r \to e_i^\sharp]) \text{ in} \tag{14}$$

$$\left((x_1, \dots, x_n), r, (s_i)_{i\in[\![1,p]\!]}\right), \sigma^\sharp \tag{15}$$

The `get_preconditions` helper function scans the body to get a set of predicates $(c_1, \dots, c_p)$ suitable for partitioning (12). Then, we analyze the body of the function with each precondition c_i (13) and get a set of possible behaviors s_i (14). The function is then abstracted as the disjunction of those behaviors for the function (15). Note that we do not keep partitioned states *inside* the analysis of a recursive function, to avoid the risk of diverging

sets of partitions. Consequently, when applying a function inside the body of the recursive function, we immediately merge cases. also note that this definition is independent of the chosen `get_preconditions` partitioning heuristics.

We chose to use a heuristics, so called *local reachability*, introduced by Boutonnet and Halbwachs [8]. We try to partition regarding conditions controlling reachability to certain key points – branches in conditional branching or pattern matching. Note that finding those preconditions is a pre-analysis, performed just before analyzing the function itself. Consequently, when a function body we are either analyzing or pre-analyzing performs a function call, the abstract summary of the called function is already available (or it is set to bottom if this is the first iteration of a recursive call).

To sum up the method, the body of the function is pre-analyzed to decide a partitioning on the inputs. It starts with a precondition $I^\sharp$, which can be $\top$, and follows those steps:

1. Analyze the function body with an interprocedural analysis and note $r_i^\sharp$ the result at each reachable control point;
2. Choose a control point for which $r_i^\sharp \neq \bot$;
3. Choose an abstract value $s^\sharp$ which is complementable, i.e. its complementary can be expressed in the domain (note that $x \leq y$ as well as $x > y$ tests are always complementable for polyhedra on integers) such that $\text{proj}_r(r_i^\sharp) \sqsubseteq^\sharp s^\sharp$. We get disjuncts $I^\sharp \sqcap s^\sharp$ and $I^\sharp \sqcap \bar{s}^\sharp$.

We may iterate this algorithm to get more disjuncts and gain more precision.

6 Combining both Domains into an Analysis

Sections 4 and 5 presented, respectively, independent extensions of a first-order numeric analysis to algebraic data types and to higher-order functions. Thanks to their parametricity, we can combine these two extensions to analyze our target language from Section 2:

- Algebraic data types can contain higher-order values (i.e., functions). Indeed, the parametricity of the ADT abstraction supports functions as leaf data types, themselves represented by the higher-order part of our work.
- Function summaries from the higher-order section can express precise properties on ADTs they manipulate (including the case of recursive functions manipulating recursive ADT). Indeed, the abstract domain representing functions is parametric in the domain chosen to express relations between inputs and outputs (e.g., polyhedra).

We show how the resulting analysis performs on our example function `to_fun` and state its soundness theorem.

6.1 Analysis Cooperation Example

We choose as relational domain the polyhedra domain, combined with a domain stating the equality of functions. We analyze our example from the introduction. We recall its code:

```
1  let to_fun a =
2    match a with
3    | Cst n -> (fun x -> n) (* p1 *)
4    | Fun f -> f (* p2 *)
```

Pre-analysis by local reachability. We analyze the function with a classic relational analysis. We denote the control point after the first branch of the match as p_1 and the one after the second branch of the match as p_2. We denote possible constructors of a as a_c.

The analysis in p_1 gives us $r_1^\sharp = (x, r, r = n), [a_c = \{\texttt{Cst}\} \wedge a.1.1 = n] \neq \bot$. We see that $proj(\{a_c, a.1.1, a.2.1\}, r_1^\sharp) = [a_c = \{\texttt{Cst}\}]$ is complementable, of complementary $[a_c = \{\texttt{Fun}\}]$. Consequently, we get two disjuncts: $a_c = \{\texttt{Cst}\}$ and $a_c = \{\texttt{Fun}\}$.

Full analysis. Let *body* be the body of `to_fun`.

$$\mathbb{E}^\sharp[\![\text{fun } a \to body]\!]\sigma^\sharp = (a_c, a.1.1, a.2.1), r, \begin{cases} \mathbb{E}^\sharp[\![body]\!]\sigma^\sharp[a_c = \{\texttt{Cst}\}] \\ \mathbb{E}^\sharp[\![body]\!]\sigma^\sharp[a_c = \{\texttt{Fun}\}] \end{cases}$$

We analyze the first case. We have $\texttt{match}^\sharp(\sigma^\sharp[a_c = \{\texttt{Cst}\}], a, p_1) = \sigma^\sharp[a_c = \{\texttt{Cst}\}], \bot$ so:

$$\begin{aligned} \mathbb{E}^\sharp[\![body]\!]\sigma^\sharp[a_c = \{\texttt{Cst}\}] &= \mathbb{E}^\sharp[\![\text{fun } x \to n]\!]\sigma^\sharp[a_c = \{\texttt{Cst}\}] \cup^\sharp \bot^\sharp \\ &= (x, r', r' = n), [a_c = \{\texttt{Cst}\} \wedge a.1.1 = n] \end{aligned}$$

Similarly, for the second case:

$$\begin{aligned} \mathbb{E}^\sharp[\![body]\!]\sigma^\sharp[a_c = \{\texttt{Fun}\}] &= \mathbb{E}^\sharp[\![\text{fun } x \to n]\!]\sigma^\sharp[a_c = \{\texttt{Fun}\}] \cup^\sharp \bot^\sharp \\ &= f, [a_c = \{\texttt{Fun}\} \wedge a.2.1 = f] \end{aligned}$$

In the end, the semantics of `to_fun` is:

$$\mathbb{E}^\sharp[\![\text{fun } a \to body]\!]\sigma^\sharp = (a_c, a.1.1, a.2.1), r, \begin{cases} [a_c = \{\texttt{Cst}\} \wedge r = (x, r', r' = a.1.1)] \\ [a_c = \{\texttt{Fun}\} \wedge a.2.1 = f] \end{cases}$$

We denote this summary as s and bind `to_fun` to s in the environment. Note that this summary is as precise as in the concrete. We can evaluate `f_1 = to_fun Cst`(5) and `f_2 = to_fun Fun`$(\text{fun } x \to n)$:

$$\begin{aligned} \mathbb{E}^\sharp[\![\texttt{to_fun Cst}(5)]\!]\sigma^\sharp &= r, \sigma^\sharp[a_c = \{\texttt{Cst}\} \wedge r = (x, r', r' = a.1.1)] \\ &\quad [a_c = \{\texttt{Cst}\} \wedge a.1.1 = 5] \\ &= r, \sigma^\sharp[a_c = \{\texttt{Cst}\} \wedge a.1.1 = 5 \\ &\quad \wedge r = (x, r', r' = a.1.1)] \\ \mathbb{E}^\sharp[\![\texttt{to_fun Fun}(\text{fun } x \to n)]\!]\sigma^\sharp &= r, \sigma^\sharp[a_c = \{\texttt{Fun}\} \wedge a.2.1 = f] \\ &\quad [a_c = \{\texttt{Fun}\} \wedge a.2.1 = (x, r', r' = x + 1)] \\ &= r, \sigma^\sharp[a_c = \{\texttt{Fun}\} \wedge a.2.1 = (x, r', r' = x + 1) \\ &\quad \wedge r = a.2.1] \end{aligned}$$

In both cases, one of the summary disjuncts has an empty intersection with the environment, so it does not appear in the final state. Applying the summaries, we are able to infer $r_1 : 5, r_2 : 9$. In the end, we are able to recover the same precision as a non-compositional method (Section 5) while staying compositional. This way, we do not have to re-analyze `to_fun`'s body when computing r_1 and r_2, instead using the summaries inferred at call site. Additionally, we get a precise contract for `to_fun`, which is valid for every input.

6.2 Analysis Soundness

The analysis defined in this article is sound, i.e. the analysis of a program P over-approximates the reachable states of P. Section 3.1 defined the concretization of abstract environments (Definition 3.2) and the concretization of the abstract semantics of an expression (Remark 3.3).

▶ **Theorem 6.1.** *The abstract semantics* $\mathbb{E}^\sharp$ *is sound, i.e.:*

$$\forall \sigma \in \Sigma, \forall \sigma^\sharp \in \Sigma^\sharp, \forall e : \tau \in \mathcal{E}, \sigma \in \gamma_{\Sigma^\sharp}(\sigma^\sharp) \implies \mathbb{E}[\![e]\!]\sigma \in \gamma_\tau(\mathbb{E}^\sharp[\![e]\!]\sigma^\sharp)$$

Proof. The proof is by induction over the syntax of expression e. ◀

7 Experimental Evaluation

7.1 Implementation

The methods described in the article were implemented in MOPSA [22], an open source and multi-language platform to ease the development of abstract analyzers. Similarly to other static analyzers by abstract interpretation, such as Astrée [6], Frama-C [9], Infer [16], or Julia [40], MOPSA is based on a composition of several abstract domains. Compared to them, it goes further in terms of modularity, enforcing a finer level of granularity of abstractions. It encourages relational abstractions for all types and features powerful domain communication mechanisms (such as reduced products, cartesian products, expression rewriting) and supports the reuse of abstractions in the analysis of widely different languages (such as C [37, 23] and Python [33, 34, 35]). The core of the platform is composed of 22 000 LoC of OCaml.

We added 3 000 LoC to support OCaml analysis and to implement the algebraic data types and higher-order domains described in the article. Our analysis is fully automatic: it leverages typing information from the frontend – handled by the OCaml compiler – to automatically associate abstract domains to values, based on their types. The user sets a global precision level by selecting more or less expressive domains for base types (e.g., polyhedra or intervals for integers). Choosing the best precision/performance trade-off is a long-standing problem for the analysis of any language. It is not addressed by this paper.

In MOPSA, a configuration file describes how domains are combined to define an analysis. A configuration for our analysis is shown in Figure 7. Sequences delegate the analysis of an expression to the right-hand side domain when relevant. Reduced products perform reductions between both domain results. Cartesian products implement collaborations between domains. `ML.program` is the frontend, handling the import from the OCaml compiler. `ML.intraproc` handles conditionals and assertions. `ML.let_rec` computes an abstract fixpoint for recursive definitions of variables. Domains `ML.functions` (defined in Section 5.2) and `ML.adts` (defined in Section 4.1) depend on each other because of their parametricity. They share underlying domains for ground types, here strings and integers. MOPSA includes a Universal language, implementing ready-to-use abstractions for basic constructs. Here, integers are abstracted by the reduced product of the polyhedra domain `U.polyhedra` and the congruence domain `U.congruences`. `U.string` abstracts strings. The configuration could be defined using other domains for ground types as well. Our implementation is parametric in those domains.

On a technical note, our ADT domain required support for heterogeneous operations, that is, operations on environments defined on different sets of variables [24], which is the case when joining two match cases. Our functions' domain required adapting the already existing trace partitioning [30] for C-like languages on the platform. Sound operations on summarization variables from Gopan et al. [18] were already part of the platform and were leveraged when handling summarization variables of recursive algebraic data types.

7.2 Experiments

We tested our implementation on the examples from this article as well as 40 handwritten programs highlighting the precise handling of recursive functions manipulating algebraic data types, functions partitioning on algebraic constructors, partial application, algebraic data

types containing functions, etc. In particular, it inferred correct summaries for `filter_le` and `to_fun` functions. Additionally, we selected 20 programs from Salto's benchmarks [27] that are compatible with the current limitations of our approach, i.e. they do not contain modules, nor imperative features, nor polymorphism. Figure 8 displays the analysis time for an extract of our 60 programs. The first five programs are from Salto's benchmarks. The programs we consider are small: they consist in around a dozen lines each.

Precision. For most numerical recursive functions (e.g. `binomial`, `ackerman`, `mc91`), our relational compositional analysis gives results at least as precise as Salto's non-compositional and non-relational approach, but with only one analysis of the body. This illustrates how relationality and disjunctions can recover precision lost by compositionality, thus enhancing performance when the analyzed function is analyzed multiple times. Besides, for some functions, no precise invariant can be discovered without relationality – e.g. `rec_add`, or `numeric_loop3b` from Salto's benchmark. Our analysis was therefore of the same precision or better than Salto on 14 out of those 16 examples. Finally, as explained in Section 4.2 our analysis is the first to support `when` clauses, and to detect non-exhaustive pattern-matching.

Performance. All our tests were performed on a Intel(R) Core(TM) i7-8565U CPU 1.80GHz with 16 GB of RAM. The analysis for those small programs is lower than a second. The slowest analysis was for the `tak` function, making three recursive calls in its body. Those

runtimes are comparable to the analysis performed by Salto – less than a second. The runtime difference on the (small) benchmarks available is not significant enough to deduce that one analysis is faster, and to evaluate which part of our method results in a speed-up and which part in a slowdown. Moreover, Salto and MOPSA feature different abstractions beside compositionality that may impact the analysis time as well. A more thorough evaluation of runtime trade-offs is thus left for future work. Previous work by Boutonnet and Halbwachs [8] at first-order concluded that summary construction time is often negligible with regard to total analysis time. Besides, in our implementation, maintaining a summary is equivalent to storing it (they are immutable, as functions are currently pure). We optimistically hope that future work would draw a similar conclusion on higher-order programs.

Note that our method's interest goes beyond performance: it automatically generates *contracts* for higher-order functions. Therefore, it plays a role in proving not only the absence of runtime errors, but also refined properties on the program behavior, being able to automatically discover functions specifications.

8 Related Work

Type systems. To prove properties on functional programs, type systems are widely used. The simplest ones already prevent some errors, such as adding a function to an integer. More expressive type systems, used for program verification, include dependent types, and in particular refinement types. They have enjoyed a steady popularity over the years [44, 43], relying under-the-hood on SMT solvers to reason on properties, mainly numeric ones. Although formulated within the framework of abstract interpretation, we believe our work shares similarities, as it provides a compositional analysis and infers numeric invariants.

Deductive methods. Deductive methods, such as Cameleer [38] or F* [41], can prove precise properties, such as correctness with regard to a specification, but need often both user annotations and SMT solvers. It differs from our goal, a fully-automated and solver-free method, to infer semantic properties.

Non-value abstract interpretation analysis. Whereas many works approach static analysis of functional languages, they often focus on control flow analysis, which, as precised in Liang and Might [28], does not suffice to keep track of values through flow. Cousot and Cousot [13] define higher-order functions abstractions, e.g. as relations or as sets. They also formulate refinements, e.g. disjunctive completion. They are however mainly interested in comportment analysis such as strictness or termination. We use similar abstractions and refinements, but to define a value analysis. Besides, we support algebraic data types with an abstraction fully parametric in possibly relational domains. Montagu and Jensen [36] develop methods to infer a form of frame condition for pure functional higher-order languages, i.e. identifying equality relations between parts of algebraic values. They suffer from the same lack of information when applying an input function as we do. They are however limited to non-recursive types, and cannot handle complex numeric relations.

Abstract interpretation-based value analysis. In our experimental evaluation, we compared to Salto [27], a static value analyzer verifying OCaml programs. It supports a wider subset of the language, such as side-effects and modules. Their method differs from ours, being non-relational and non-compositional. Our compositional approach could be more scalable. Journault et al. [24] propose a relational abstract domain for trees but are limited to this

specific data structure. Bautista et al. [3], Bautista et al. [4] describe a relational abstraction for numeric algebraic values and infer structural equalities between non-numeric fields, but are limited to non-recursive objects. Valnet et al. [42] support recursion, but not higher-order.

Compositional analysis. Input-output relational analysis has been long studied, first applied to `while` programs [26]. Our method can be seen as an extension of symbolic relational separate analysis from Cousot and Cousot [14], extended to support ADTs and higher-order. This is a long-known method [14] to improve analysis scalability. Compositionality has been used in multiple settings: Farzan and Kincaid [17] use them to analyze independently decomposed parts of a program and Kincaid et al. [25] for inter-procedural analysis, analyzing procedures independently of their calling context, once and for all. Codish et al. [11] develop a compositional analysis for logic programs, therefore proving it useful in a declarative context. Bautista et al. [2, 5] define an ADT domain in an input-output analysis for non-recursive imperative programs. In the MOPSA platform [22], a prototype modular analysis was implemented for C programs manipulating strings [23]. To improve precision, Bourdoncle [7] expresses non-relational disjunctive summaries. Boutonnet and Halbwachs [8], on which we built upon, permit relationality. All those methods are however limited to first-order.

9 Conclusion and Future Work

This article presents two abstract domains, one tailored to handle recursive ADTs, and the other one to represent functions used as first-class values, as well as higher-order functions. Thanks to the parametricity of both domains, each domain can leverage the other, e.g. to abstract functions manipulating ADTs (and conversely). The combination of these two domains yields a compositional and relational analysis for a pure functional programming language. This analysis has been implemented into the MOPSA framework to analyze a pure subset of the OCaml language. Our preliminary evaluation shows the precision of our approach on 60 programs, including 20 benchmarks from Salto [27].

We now review the limitations of our approach and discuss future work. The language we have studied here is pure; extending our analysis to support references will be challenging. Our analysis focuses on a monomorphic functional programming language; we could rely, in future work, on the polymorphic equality domain from Montagu and Jensen [36] to handle polymorphism. Our current analysis does not detect arithmetic overflows: we believe this is an important, yet orthogonal concern. Our analysis is technically able to infer ranges of numerical variables and can thus detect overflows. However, our OCaml analysis does not support the wraparound semantics of overflows for now. To the best of our knowledge, there are no compositional value analysis currently tackling this issue, even in the case of first-order imperative languages. Previous work on compositional static analysis for first-order languages (e.g. Boutonnet and Halbwachs [8]) proved that compositionality is useful for scaling up. We postulate that similar speed-ups could be achieved in a higher-order setting with compositional analyses. While this article provides a contribution towards this goal by proposing a precise and compositional analysis, we have not evaluated its scalability in our preliminary experiments. We believe this work is a first step towards automatically proving functional properties (e.g., sorting [19]) in a functional setting with higher-order functions.

Mono Types – First-Class Containers for Datalog

Runqing Xu

Abstract

We propose mono types, a new abstraction for programming Datalog. Mono types behave like first-class containers that can be stored in relations and to which elements can be added decentrally. But, mono types are more than just containers: They provide a `read` operation that can yield any result as long as it monotonically grows with each added element and is independent of the order in which elements are added to the container. This design permits a wide range of mono types (e.g., sets, maps, and aggregations), yet guarantees mono types can be integrated into Datalog without jeopardizing Datalog's least fixed-point semantics. We develop a theory for mono types, which includes constructions for complex mono types, equivalence relation for mono types, and properties about semantics-preserving mono-type transformations. This theory ensures sound Datalog integration and justifies crucial compiler optimizations for mono types. Together, these techniques demonstrate that mono types provide abstraction without regret: We demonstrate in two case studies that programs become easier to write with mono types, while their performance also improves drastically.

1 Introduction

Datalog is a programming language for processing structured and cyclic data. Datalog's distinguishing feature is its efficient fixed-point semantics: A program runs until no more deductions are possible, exploiting that programs behave monotonically. Therefore, when processing graphs (as in data-flow or social-network analysis), Datalog programmers can forgo data structures for graph traversals (e.g., visited nodes, queues, stacks) and explicit termination conditions. Instead, the termination is managed by the fixed-point semantics. However, this does not mean all Datalog programs are equally efficient.

Consider a Datalog program that collects the variables shared between two syntax trees:

```
sharedVar(v) :- e1 = Plus(Plus(Var("x1"),Var("x2")),Var("y")),
                e2 = Plus(Var("y"),Plus(Var("z1"),Var("z2"))),
                hasVar(e1, v), hasVar(e2, v).
hasVar(e, v) :- ?Var(e,v).
hasVar(e, v) :- ?Plus(e,lhs,rhs), hasVar(lhs,v).
hasVar(e, v) :- ?Plus(e,lhs,rhs), hasVar(rhs,v).
```

Predicate `sharedVar` constructs two syntax trees `e1` and `e2`, computes their variables using `hasVar`, and returns those variables `v` that occur in both expressions. Predicate `hasVar` traverses the syntax tree to collect variables. We write `?Var(e,v)` to pattern match `e` as a `Var`, extracting the variable name `v`. In the end, `hasVar` computes a relation that associates each expression with each variable contained in the expression. Thus, `hasVar` will derive 8 tuples for each of `e1` and `e2`, even though they only contain 3 variables each. In general, an expression tree of size n will contain at most $(n+1)/2$ variables, yet `hasVar` computes up to $((n+1) \cdot log\,(n+1))/2$ tuples. That is, our program performs asymptotically worse than necessary.

The problem of our program is that it propagates variables along the tree, generating a separate tuple for an intermediate node. But the problem is more general than that. For example, consider a graph analysis of a social network, where we want to find Alice's most popular friend.

```
mostPopFriend(p, max((p, n))) :- n = count(connectedWith(p,_)).
mostPopFriend(p1, max((p, n))) :- connectedWith(p1, p2), mostPopFriend(p2, (p, n)).
main(p) :- mostPopFriend("Alice", (p, _)).
```

This program uses recursive aggregation to select the person `p` with the most connections `n`. Moreover, since `connectedWith` may span a cyclic graph, the program relies on Datalog's fixed-point semantics, producing a single most popular person in the end. Again this program derives many more tuples than necessary. Initially, `mostPopFriend` contains tuples `(p, (p,n))` for each person `p` and only gradually will the most connected person become known throughout the graph.

In this paper, we propose a Datalog extension that not only eliminates this overhead but also improves the programmability of Datalog. Specifically, we introduce *first-class containers for Datalog* that enable a new programming pattern: Rather than redundantly propagating information from one node to another, we can propagate a single container to collect all information. Conceptually, our containers are mutable collections that can grow over time. Let us revisit the first example:[1]

```
sharedVar(v) :- e1 = Plus(Plus(Var("x1"),Var("x2")),Var("y")),
                e2 = Plus(Var("y"),Plus(Var("z1"),Var("z2"))),
                hasVar(e1, v), hasVar(e2, v).
hasVar(e, v) :- col = new set[string], collectVar(e,col), read(col) = v.
collectVar(e, col) :- ?Var(e,v), col += v.
collectVar(e, col) :- ?Plus(e,lhs,rhs),collectVar(lhs,col),collectVar(rhs,col).
```

Our extension comprises three new constructs. First, we can create distinct containers such as `new set[string]` in `hasVar`. Second, we can add elements to the container such as `col += v` in `collectVar`. Third, we can read from a container `read(col)`. When executing this program, only the container needs to be propagated but not the variables, leading to considerably fewer tuples. But, actually, our containers are much more flexible than this example may suggest.

Our extension supports a wide variety of "containers", which only need to adhere to a single monotonicity property for a user-defined partial order $\sqsubseteq$.

$\forall c.\, \forall i.\, \mathsf{read}(c) \sqsubseteq \mathsf{read}(\mathsf{c} \mathrel{+}= \mathsf{i})$

[1] Datalog requires range-restrictedness: Each variable in the head of a rule must be positively bound in the body of the rule. In this paper, example Datalog programs sometimes violate range-restrictedness when a relation's head variable is intended to receive input from the relation's call-sites. This is the case for head variable `col` of `collectVar`, which is bound by the call in `hasVar`. Our Datalog code can be systematically rewritten to satisfy range-restrictedness using the magic set transformation. We take the liberty of showing the "wrong" code for readability.

That is, adding elements i to a container c will only increase the subsequent reads. This property is sufficient for ensuring that containers are compatible with Datalog's fixed-point semantics. For the `set` container from above, the monotonicity property holds because `read` produces the set of added elements. But we do not need to collect elements, we may also aggregate them. For example, a sum aggregation of natural numbers satisfies the monotonicity property: `read` produces the sum, which grows with every addition. Since monotonicity is the only constraint, we call our container extension *mono types*. Mono types not only can improve performance, they also provide a new form of abstraction. For example, in our social-network program, we can add people with their friendship count to a mono type, and separately decide which mono-type definition to use:

```
collectFriend(p, col) :- col += (p, count(connectedWith(p,_))).
collectFriend (p1, col) :- connectedWith(p1, p2), collectFriend(p2, col).
mostPopFriend(p, pop) :- max = new retain_max, collectFriend(p, max), read(max) = pop.
leastPopFriend(p, pop) :- min = new retain_min, collectFriend(p, min), read(min) = pop.
```

We first demonstrate the algebraic theory of mono types. A well-founded theory of mono types is crucial because violations of monotonicity will lead to undefined Datalog behavior. In particular, we develop mono-type constructions that enable us to develop complex mono types based on simpler ones. For example, a map mono `Map[K,V]` is parametric in a mono type for values `V` and combines all values that have the same key. This way we can construct mono types for multi maps `new map[K, Set[V]](new set)` or for grouped maxima `new map[K, int](new max)`. Our theory ensures that all map constructions yield valid mono types. We have formalized the algebraic theory of mono types and verified the correctness of mono-type constructions in the proof assistant Rocq, and the code is available open-source.[1]

We then show how mono types can be integrated into Datalog systems. Technically, we compile mono types to Datalog aggregations. However, this induces a considerable overhead for mono types that are containers, such as sets and maps. Therefore, we develop the theory of mono-type equivalence and mono-type functors, allowing us to convert between equivalent mono-type definitions. We use this theory to prove certain optimizations sound, and add them to our Datalog integration. Finally, we evaluate the programmability and performance of mono types using case studies. In summary, we present the following contributions:

- We develop and mechanize the algebraic theory of mono types and mono-type constructions in Rocq.
- We integrate mono types into Datalog by translation to user-defined aggregations.
- We formalize the theory of mono-type equivalence and mono-type functors and use it to develop sound compiler optimizations for the set and map mono types.
- We show that mono types improve Datalog's programmability and evaluate their performance.

2 A Theory of Mono Types

In the introduction, we have seen some motivating examples for using mono types: to collect values and to aggregate them. Since mono types can occur as part of Datalog's fixed-point semantics, it is important to ensure Datalog remains well-founded. To this end, we develop and formalize a specification for mono types and instantiate the specification with various examples. We then present generic constructions for mono types, allowing us to build up complex mono types from simpler ones. We have mechanized the theory of mono types and the constructions in Rocq and use Rocq's notation in our presentation.

[1] `https://gitlab.rlp.net/plmz/artifacts/mono-types-ecoop25`

2.1 Mono Types

Conceptually, mono types are stateful containers. However, mono-type containers are restricted in three important ways: First, elements can only be added to a mono type but never removed or replaced. Second, the content of a mono type can only be observed monotonically. And third, the observation of a mono type is independent with the order of added elements. We represent the interface of mono types as a type-level record in Rocq:

```
Record MonoAPI M I O `{PartialOrder O} : Type :=
{ create : M I O ;  add : M I O → I → M I O ;  read : M I O → O
; mono_law : forall m i, read m ⊑ read (add m i)
; ord_indep : forall m i1 i2, read (add (add m i1) i2) = read (add (add m i2) i1)
}.
```

Mono instances have type `M I O`, where `I` is the type of added inputs, and `O` is the type of the read observations. Mono instances can only be created through functions `create` and `add`, which means all mono instances are sequences:

$$\mathtt{m}_0 = \mathtt{create}, \qquad \mathtt{m}_1 = \mathtt{add}\ \mathtt{m}_0\ \mathtt{i}_1, \qquad \cdots \qquad \mathtt{m}_n = \mathtt{add}\ \mathtt{m}_{n-1}\ \mathtt{i}_n$$

Users can observe the state of a mono instance at any time using `read`, but with two restrictions:

(i) Reads on a later mono instance produce larger values than reads on an earlier mono instance from the same sequence:

$$\forall\, i, j.\quad i < j \implies \mathtt{read}\ \mathtt{m}_i \sqsubseteq \mathtt{read}\ \mathtt{m}_j$$

In the interface of mono types above, we ensure this property by requiring a monotonicity law `mono_law`. This law states that each individual `add` increases the observable output with respect to a fixed partial order for `O`.

(ii) Swapping the order of inputs does not affect the updated value of a mono instance:

$$\forall\, i_1, i_2.\quad \mathtt{read}\ (\mathtt{add}\ (\mathtt{add}\ \mathtt{m}_j\ i_1)\ i_2) = \mathtt{read}\ (\mathtt{add}\ (\mathtt{add}\ \mathtt{m}_j\ i_2)\ i_1)$$

We ensure the order independence through the law `ord_indep` in the interface.

The monotonicity law, order independence law, and the lack of any removal operations are the reason that mono types integrate well with Datalog as we will discuss below.

One notable omission from `MonoAPI` is the internal state of mono instances. While it is clear that mono types must use internal state to carry information from an `add` to a `read`, the internal state cannot be observed by users directly. Instead, the internal state is only accessible while defining a mono type, for which we provide a dedicated interface:

```
Record Mono ST I O `{PartialOrder O} : Type :=
{ init : ST ; add : ST → I → ST ; read : ST → O
; mono_law : forall (st : ST) (i : I), read st ⊑ read (add st i)
; ord_indep : forall s a1 a2, result (add (add s a1) a2) = result (add (add s a2) a1)
}.
```

In contrast to `MonoAPI`, interface `Mono` has an additional type parameter `ST`, which exposes the type of the internal state. Otherwise, the two interfaces are almost identical and each `Mono` gives rise to an implementation of `MonoAPI` by setting `M I O = ST` and using `init` for `create`. All our examples and constructions use the `Mono` interface, but it is important to remember that the internal state will not be visible to users of `MonoAPI`, which means we can exchange the implementation internals of a mono type without affecting users.

As first example, consider a mono type `nat_sum_mono` that computes the sum over naturals:

```
Definition nat_sum_mono : Mono nat nat nat :=
  {| init := 0 ; add s n := s + n ; read s := s |}.
```

For `nat_sum`, the internal state, input, and output all are of type `nat`. We start with an initial state `0`, add each new input to it, and allow the sum to be observed directly. This mono type satisfies the `mono_law` for the natural order of `nat`.

Our second example is `retain_max_mono`, which we used in Section 1 for the most popular person in a social network:

```
Definition retain_max_mono A : Mono (option (A, nat)) (A, nat) (option (A, nat)) :=
{| init := None
 ; add s i := match s, i with
   | None, _ ⇒ Some i
   | Some (a1,n1), (a2,n2) ⇒ if n1 >? n2 then Some (a1,n1) else Some (a2,n2)
   end
 ; read s = s
|}.
```

This mono type is more interesting and requires distinct types for input and output. The input is a pair `(A,nat)`, which can be understood as a weighted `A`. The mono type retains that input `A` with the highest weight. However, initially no `A` value is known yet, which is why we employ an option type for the internal state and output. Mono type `retain_max` satisfies the `mono_law` for the ordering where `None` $\sqsubseteq$ `Some` (a, n) for all a and n, and `Some` $(a_1, n_1) \sqsubseteq$ `Some` (a_2, n_2) if $n_1 \leq n_2$.

In both previous examples, the `read` function was a simple identity. We include `read` in our design because it allows us to isolate a post-processing step. For example, we can define a set mono that collects and produces a set of all inputs. However, internally this mono type uses a list representation for constant-time `add` and only converts the list to a set in `read`:

```
Definition set_mono1 A : Mono (list A) A (set A) :=
{| init := nil ; add s a := a :: s ; read s := set_from_list s |}.
```

The internal state has no obvious ordering, but the output set satisfies the `mono_law` based on the partial order $(\subseteq)$ of set inclusion. Technically, it is not necessary to isolate the `read` projection, but it makes mono types easier to define and reason about. In principle, we can merge the post-processing done by `read` into the other functions if we use the internal state to also retain the post-processed output:

```
Definition set_mono2 A : Mono (list A, set A) A (set A) :=
{| init := (nil, set_from_list nil)
 ; add st a := let (l,_) := st in (a :: l, set_from_list (a :: l))
 ; read st := let (_,s) := st in s
|}.
```

Here, the internal state contains both the list of inputs and the projected set representation. We update the projected set after each `add`, but only use it in `read`. For this particular mono type, we can actually improve the definition by fusing `add` and `set_from_list`:

```
Definition set_mono A : Mono (set A) A (set A) :=
  {| init := empty_set ; add s a := set_add a s ; read s := s |}.
```

This is our final mono type for sets (*set mono* for short). We start with an empty set and add input elements to that set directly. While we could have started with this mono type, note this: All three mono types implement the same `MonoAPI`. Semantically, the three mono types are interchangeable because they only differ in their internal state, which is not observable. We will exploit such interchangeability in Section 4 to optimize usages of mono types.

The set mono is actually a special case of an entire class of mono types. A bounded semi-lattice has a bottom element and a least upper bound operator `lub`. Each bounded semi-lattice uniquely determines a partial order:

$$\mathtt{a}_1 \sqsubseteq \mathtt{a}_2 \iff \mathtt{lub}\ \mathtt{a}_1\ \mathtt{a}_2 = \mathtt{a}_2$$

Each bounded semi-lattice gives rise to mono type, which satisfies the `mono_law`:

```
Definition lattice_mono A `(BoundedSemiLattice A) : Mono A A A :=
  {| init := bottom ; add := lub ; read a := a |}.
```

This is an important class of mono types because lattices are heavily exercised in Datalog. In particular, lattice-based aggregation [8, 13] allows Datalog programs to implement data-flow analyses over custom lattices. The lattice mono can also easily accomodate widening, for example, using a unary widening operator in `read`.

Lastly, we want to provide an example where the internal state of a mono type is not monotone, but the output is. Consider the following mono type where the internal state changes in accordance with the collatz function:

```
Definition collatz_fun n : {n : nat | 0 < n} := if is_even n then n / 2 else 3 * n + 1.
Definition collatz_mono A (n : {n : nat | 0 < n}) : Mono nat A bool :=
{| init := n ; add st _ := if st =? 1 then 1 else collatz_fun st ; read st := st =? 1 |}.
```

The `collatz_mono` starts at a given positive number `n`. At each call of `add`, we forward the state to the next collatz number, unless we already reached `1`. The output of the `collatz_mono` is `true` if the number of calls to `add` is equal to or exceeds the total stopping time of `n`, that is, if the sequence has reached `1` yet. For example, `collatz_mono 12` will exercise the following sequence for the first 9 calls of `add`: $12, 6, 3, 10, 5, 16, 8, 4, 2, 1$. Any subsequent call of `add` will keep the state at 1. Nonetheless, `add` is not monotone: the state fluctuates up and down indeterminately. However, the output of mono type satisfies `mono_law` for the order `false` $\sqsubseteq$ `true`.

2.2 Mono-Type Constructions

We have seen a number of mono types in the previous subsection. However, it is not necessary to construct mono types individually, including the necessary proof of `mono_law` . Instead, users can use generic constructions that we discovered for creating complex mono types from simpler ones. We start with constructions that compose multiple mono types.

Sum mono. In Section 1, we used a mono type to collect all variables in an expression tree. Consider we also want to collect the integer literals the tree contains. Of course, we could traverse the tree twice, once collecting variables and once collecting literals, but this entails a memory and run-time overhead. It is more efficient to use a single mono type that can collect both kinds of data. We can construct such a mono type using the sum construction:[2]

```
Definition sum_mono (m1 : Mono ST1 I1 O1) (m2 : Mono ST2 I2 O2)
  : Mono (ST1 * ST2) (I1 + I2) (O1 * O2) :=
{| init := (init m1, init m2)
 ; add s a := let (s1, s2) := s in match a with
              | inl a1  ⇒  (add m1 s1 a1, s2)
              | inr a2  ⇒  (s1, add m2 s2 a2)
              end
 ; read s := let (s1, s2) := s in (read m1 s1, read m2 s2)
|}.
```

A sum mono is parametric in mono types `m1` and `m2`, and it retains both of their internal states `ST1 * ST2`. The sum mono's input is the sum type `I1 + I2` and the `add` function dispatches to either `m1` and `m2`. We can use the sum mono in Datalog as follows:

[2] Note the record accessors in Rocq: `init m1`, `add m1`, and `read m1` refer to the respective fields of the mono-type record `m1`.

```
main(e) :- col = new sum(new set[string], new set[int]), collectInfo(e, col).
collectInfo(e,col) :- ?Var(e,v), col += (inl v).
collectInfo(e,col) :- ?Num(e,n), col += (inr n).
collectInfo(e,col) :- ?Plus(e,lhs,rhs),collectInfo(lhs,col),collectInfo(rhs,col).
```

Product mono. While the sum mono dispatches its input, a product mono obtains inputs for both contained mono types. For example, in a social network, we may want to find the most popular person while also collecting all people in a set. The product mono `new prod(new retain_max, new set[Person])` can deliver this behavior:

```
Definition prod_mono (m1 : Mono ST1 I1 O1) (m2 : Mono ST2 I2 O2)
  : Mono (ST1 * ST2) (I1 * I2) (O1 * O2) :=
{| init := (init m1, init m2)
 ; add s a := let (s1, s2) := s in let (a1, a2) := a in (add m1 s1 a1, add m2 s2 a2)
 ; read s := let (s1, s2) := s in (read m1 s1, read m2 s2)
|}.
```

Note how each input pair `(a1,a2)` is split up and forwarded to `m1` and `m2` in `add`. The definitions `init` and `read` are identical to the sum mono.

Input functors. We can also construct various mono types through functors. The simplest class of functors only affects the input of a mono type:

```
Definition fmap_input_mono (f : I2 → I1) (m : Mono ST I1 O) : Mono ST I2 O :=
  {| init := init m ; add s a := add m s (f a) ; read s := read m s |}.
```

This functor wraps a mono type and applies `f` to all inputs prior to processing. For example, we can use the functor to define mono types that fork their input:

```
Definition fork_mono (m1: Mono ST1 I O1) (m2: Mono ST2 I O2): Mono (ST1 * ST2) I (O1 * O2)
  := fmap_input_mono (fun a ⇒ (a,a)) (prod_mono m1 m2).
```

The fork mono is like a product mono, but both contained mono types expect the same input type `I`. We can use an input functor to duplicate a given input and use the standard product mono to do the composition.

Map mono. Finite maps are used ubiquitously in computing, and program analysis applications in Datalog are no exception. For example, even a flow-insensitive analysis usually tracks abstract values for each variable `map[string,V]`, where `V` forms a lattice and multiple entries for the same variable are joined. A flow-sensitive analysis computes such a map for each control-flow node `map[Node,map[string,V]]`. To support this important class of Datalog applications, we developed a construction for map monos:

A map mono accepts input pairs `K * V`, where `K` is a key and `V` is a value. However, it does not store the values for keys directly. Instead, all values associated with the same key are added to a mono type `m` with input `V`. The map mono then stores the state of `m` for each key:

```
Definition map_mono `{Bounded O} (m: Mono ST V O): Mono (map K ST) (K * V) (map K O) :=
{| init := empty_map
 ; add s ka := let (k, a) := ka in
               map_add_with s k (fun st ⇒ add m st a) (add m (init m) a)
 ; read s := map_map_values (read m) s
|}.
Definition map_add_with {K V} : map K V → K → (V → V) → V → map K V.
Definition map_map_values {K V1 V2} : (V1 → V2) → map K V1 → map K V2.
```

$$
\begin{array}{rrll}
p & \in & \mathit{Prog} & ::= \overline{r} \\
r & \in & \mathit{Rule} & ::= P(\overline{t}) \coloneq \overline{a}. \mid P(\overline{t}, \alpha(\overline{t})) \coloneq \overline{a}. \\
a & \in & \mathit{Atom} & ::= P(\overline{t}) \mid t = t \mid t \mathrel{+}= t@\overline{t} \\
t & \in & \mathit{Term} & ::= c \mid x \mid \textbf{new}\ M(\overline{m})@\overline{T} \mid \textbf{read}(t) \\
m & \in & \mathit{MonoTerm} & ::= \textbf{new}\ M(\overline{m}) \mid c
\end{array}
$$

$c \in \textbf{Val} \quad x \in \textbf{Var} \quad M \in \textbf{MonoType} \quad \alpha \in \textbf{AggOp}$

Figure 1 Datalog syntax extended with constructs for creating, adding to, and reading from a mono type.

Initially, the state of a map mono is the empty map; we initialize the state for new keys on demand in `add`. To this end, `add` uses a helper function `map_add_with s k f v` that adds key `k` to map `s`. If the key already exists in `s`, `map_add_with` uses `f` to update the old value using `add` of `m`. But if the key is new `s`, `map_add_with` inserts its value `v`. This is where `add` lazily initializes the entry for `k` with `init m` before adding `a` to it. The result of the map mono is another map, which contains the outputs of `m` for each key in the map.

To prove that `map_mono` produces valid mono types that satisfy the `mono_law`, we need to introduce a partial order on maps. The constraint `Bounded V` means `V` has a partial order and a bottom element.

```
Instance map_order {K V} `{Bounded V}: PartialOrder (map K V) :=
  { s1 ⊑ s2 := forall k, map_find_default k bottom s1 ⊑ map_find_default k bottom s2 }.
```

Function `map_find_default k v s` yields the value of `k` in `s`, or `v` if `s` does not contain `k`. This means we compare two maps by treating all undefined keys as being assigned to bottom. Thus, `s1 ⊑ s2` holds if for all keys `k` in `s1`, either `s1(k) = bottom` or `s2` also contains `k` and `s1(k) ⊑ s2(k)`. Based on this order, we prove `mono_law` for `map_mono` by induction on its internal state. We can now use the map mono to construct various useful mono types, such as:

```
Definition multi_map_mono K V := map_mono K (set_mono V).
Definition var_sign_mono := map_mono string (lattice_mono sign).
Definition stmt_var_interval_mono :=
  map_mono stmt (map_mono string (lattice_mono interval)).
```

The `var_sign_mono` can be used for a flow-insensitive sign analysis, tracking the sign of each variable. The `stmt_var_interval_mono` nests two map monos to track the range of each variable for each statement separately. These mono types can improve the programmability of Datalog.

3 Integrating Mono Types into Datalog

The theory from the previous section establishes that reading from a mono type yields monotonically growing observations about its state. In the present section, we explain how this property enables us to integrate mono types into Datalog. Syntactically, the integration is straightforward as shown in Figure 1 (you can ignore the parts in blue for now). This follows our examples from the paper: We add an atom $t \mathrel{+}= t$ to add a value to a mono type, **new** M to create a new mono instance, and **read**(t) to read the result of a mono type. The present section explains how these constructs can be integrated into Datalog semantically.

Our strategy for integrating mono types into Datalog is to treat them as a generalized form of aggregation. In Datalog, aggregation is often written as an annotation on the rule head:

```
R(x, α(y)) :- P(x, y).
P("a",1). P("a",2). P("b",1). P("b",3). P("c",10).
```

Here, α is an aggregation operator, `α(y)` is the aggregation results, and all bindings for `y` in the body of `R` are the aggregation inputs. Note that we obtain a separate aggregation result for each `x` in `R(x,α(y))`. For example, if α implements a sum aggregation, we obtain:

```
R("a",3). R("b",4). R("c",10).
```

This form of aggregation is prevalent in existing Datalog systems and we want to reuse it for mono types. However, mono types are first-class containers, and aggregation happens within each container. To embed mono types in Datalog, we have to solve 3 conceptual challenges first:

- The above example uses strings to distinguish aggregation results. Mono instances also need to be distinguishable, so that each one can provide their own aggregation result.
- The above example collects all aggregation inputs in a relation `P`. Mono instances also need to collect their inputs, even though they are provided through scattered calls of `add`.
- The above example uses a simple aggregation operator $\alpha : 2^{\texttt{int}} \to \texttt{Y}$ that takes a set of input elements of type `int` and yields a value of some type `Y`. Mono types use `add` and `read` functions to produce aggregation results, which does not fit the signature of α.

In the remainder of this section, we describe these challenges in detail and propose concrete solutions. In the end, we present translation rules that compile mono types to Datalog and give a declarative semantics for mono types.

3.1 Representing Mono Instances

Each instance of a mono type represents a distinct container. Adding an element to one mono instance may not affect other mono instances. That is, mono instances need to be identifiable and distinguishable. Consider the following example, reproduced from Section 1:

```
sharedVar(v) :- e1 = Plus(Plus(x1,x2),y), e2 = Plus(y,Plus(z1,z2)), hasVar(e1,v), hasVar(
    e2,v).
hasVar(e, v) :- m = new set[int], collectVar(e,m), read(m) = v.
collectVar(e, m) :- ?Var(e,v), m += v.
collectVar(e, m) :- ?Plus(e,lhs,rhs), collectVar(lhs,m), collectVar(rhs,m).
```

In our example, `sharedVar` invokes `hasVar` twice, once for `e1` and once for `e2`. Accordingly, `hasVar` must create two instances with `new set[int]`, one for each expression. In contrast to object-oriented programming languages, Datalog does not have side-effects, which is necessary for creating unique object IDs. We need a different approach.

Our solution is based on an observation: Predicate `hasVar` creates a distinct mono instance for each expression `e` provided as `input`. By default, the atoms that occur before `new set[int]` in the body of `hasVar` determine how many mono instances we need: one for each unique binding of variable `e`. In general, if a rule $P(\overline{t}) :- a_1, \ldots, a_n.$ has an atom a_i that contains **new** M, then we need a distinct instance of M for each substitution produced by $a_1, \ldots, a_{i-1}$. For each substitution $\sigma = \{X_1 \mapsto c_1, \ldots, X_k \mapsto c_k\}$ produced by $a_1, \ldots, a_{i-1}$, we uniquely represent the associated mono instance as a tuple $(c_1, \ldots, c_n)$. We also support a more explicit form **for** $\overline{t}$: **new** $M(\overline{m})$, which lists relevant variables explicitly and does not rely on the order of atoms in the rule. Note that nested mono constructors such as the two sets in `new sum(new set[string], new set[int])` are arguments to the surrounding `sum` mono; they are not values in Datalog and do not require a Datalog representation.

3.2 Collecting Mono-Type Inputs

Datalog aggregation is defined over relations: A relation collects all relevant aggregands to be processed by an aggregation operator. In contrast, the aggregands of mono types are scattered throughout the program: the invocations of `+=` determine the relevant aggregands, but there is no central relation that collects them. For example, consider again the following program from Section 2, where we add values to a mono type `m` in two different places:

```
main(e) :- m = new sum(new set[string], new set[int]), collectInfo(e, m).
collectInfo(e,m) :- ?Var(e,v), m += (inl v).
collectInfo(e,m) :- ?Num(e,n), m += (inr n).
collectInfo(e,m) :- ?Plus(e,lhs,rhs),collectInfo(lhs,m),collectInfo(rhs,m).
```

To enable aggregation for mono types, we must collect the aggregands in a relation. We found that we can use a magic set transformation to achieve this. A magic set transformation rewrites the Datalog program to collect the relevant arguments of a relation [16]. If we treat `m += a` as a call to a synthesized relation `Aggregand(m, a)`, we can use a magic set transformation to obtain the following rules:

```
Aggregand(m, a) :- ?Var(e,v), a = inl v.
Aggregand(m, a) :- ?Num(e,n), a = inr n.
```

These rules are derived from the previous program by copying the relevant atoms for each `m += a`. This way, the `Aggregand` relation enumerates the added aggregand values `a` for each mono instance `m`.

By collecting all added values in a relation, we implicitly submit to Datalog's set semantics. Specifically, even when executing `m += a` multiple times, relation `Aggregand` will only enumerate `(m,a)` $\in$ `Aggregand` at most once; multiple occurrences of the same tuple are collapsed. While this is fine for the set monos used in the example above, other mono types are less permissive. For example, consider we want to infer how often each variable occurs in an expression:

```
main(e) :- m = new map[string,nat](new nat_sum), collectInfo(e, m).
collectInfo(e,m) :- ?Var(e,v), m += (v,1).
collectInfo(e,m) :- ?Plus(e,lhs,rhs),collectInfo(lhs,m),collectInfo(rhs,m).
```

Even if an expression contains the same variable or numeric literal multiple times $x + y + x$, the `Aggregand` relation will only contain two tuples: `(m, ("x",1))` and `(m,("y", 1))`. That is, the second insertion of `(m, ("x",1))` does not show up, because Datalog employs its set semantics for the relation. As a consequence, we would incorrectly compute that both `"x"` and `"y"` only occur once in the expression.

This issue is well-known for aggregations in Datalog, and we adapt the standard solution [9]. To distinguish different occurrences of aggregands, we introduce auxiliary columns that help distinguish them. Figure 1 showed the necessary syntactic constructs in blue font. For our example, we can use the IDs of expressions for this purpose:

```
main(e) :- m = new map[string,nat](new nat_sum)@Exp, collectInfo(e, m).
collectInfo(e,m) :- ?Var(e,v), m += (v,1)@e.
collectInfo(e,m) :- ?Plus(e,lhs,rhs),collectInfo(lhs,m),collectInfo(rhs,m).
Aggregand(m, kv, id) :- ?Var(e,v), kv = (v,1), id = e.id.
```

Note how we augmented the mono construction with the type and the `add` call with the value of the auxiliary columns. For $x + y + x$ we obtain the following aggregands, assuming each variable has a distinct ID `Var#i`.

```
Aggregand(m, ("x",1), Var#1). Aggregand(m, ("y",1), Var#2). Aggregand(m, ("x",1), Var#3).
```

Importantly, aggregation will ignore the auxiliary columns. It will query `Aggregand(m, kv, _)` and call `add` for each individual entry. The next subsection explains how aggregation works in detail.

3.3 Mono Types as Generalized Recursive Aggregation

Conceptually, Datalog's aggregation operators are defined over sets of inputs and have the signature $\alpha : 2^{\mathtt{X}} \to \mathtt{Y}$. That is, given a set of inputs of type X, aggregation yields a single output of type Y. In practice, Datalog systems compute aggregation results iteratively and require aggregation operators of the following form: $\beta : \mathtt{Y} \times (\mathtt{X} \to \mathtt{Y} \to \mathtt{Y})$. An aggregation operator β defines an initial result β_1 that corresponds to $\alpha(\emptyset)$ and an update function β_2 that incorporates another input. Then, for $X = \{x_1, \ldots, x_n\}$, we have $\alpha(X) = \beta_2(x_n, (\ldots, \beta_2(x_1, \beta_1)))$.

As a first try, we could integrate mono types as iterative aggregation operators $\beta = (\mathtt{init}, \mathtt{add})$. The `read` function is then only applied after obtaining the mono-type state through aggregation. This leads to code of the following form, where `x` are mono-type inputs, `y` are mono-type states, and `z` are mono-type outputs:

```
Aggregand(m, v) :- ... .
Aggregate(m, β(x)) :- Aggregand(m, x).
P(z) :- Aggregate(m,y), read(y) = z.
```

But this approach faces a semantic issue: it does not work for recursive aggregation.

If recursive aggregation occurs the Datalog program (indirectly) feeds the output y of an aggregation back as input x. Many interesting use cases of aggregation require recursive aggregation, including program analysis and network analysis. For example, consider again the social-network analysis from Section 1, which finds the most popular friend:

```
mostPopFriend(p, max((p, n))) :- n = count(connectedWith(p,_)).
mostPopFriend(p1, max((p, n))) :- connectedWith(p1, p2), mostPopFriend(p2, (p, n)).
main(p) :- mostPopFriend("Alice", (p, _)).
```

This program uses recursive aggregation, because the second rule obtains an aggregation output `(p,n)` of `p2` and uses it as aggregation input for `p1`. Recursive aggregation is only well-defined if the aggregation operator is monotone: $\forall X.\, \forall Y.\, \alpha(X) \sqsubseteq \alpha(X \cup Y)$ for traditional aggregation, or $\forall x.\, \forall y.\, y \sqsubseteq \beta_2(x, y)$ for iterative aggregation.[3] Monotonicity of aggregation is important because new aggregation results *replace* prior aggregation results (in contrast to regular columns, which accumulate all derived values in a set). But our mono types do not guarantee monotonicity for the states aggregated by `add`; we only ensure monotonicity for the resulting outputs. This renders the above approach incorrect because the second column of `Aggregate(m,β(x))` does not grow monotonically. Consequently, we lose the property that every Datalog program has a minimal model, and a fixed-point does not need to exist.

We can fix the situation by considering mono types as generalized aggregation operators

$$\gamma : \mathtt{Y} \times (\mathtt{X} \to \mathtt{Y} \to \mathtt{Y}) \times (\mathtt{Y} \to \mathtt{Z}).$$

This directly corresponds to the interface of mono types, with $\gamma = (\mathtt{init}, \mathtt{add}, \mathtt{read})$ and extends iterative aggregation by incorporating the output projection `read`. While this may seem negligible, it significantly alters the semantics of Datalog programs using such aggregation:

[3] Note that the initial result β_1 does not need to be a least element because Datalog yields *no result* when there are no aggregands. Internally, Datalog embeds aggregations results in `option` Y and yields `None` initially, but `Some` y subsequently.

```
Aggregand(m, v) :- ... .
Aggregate(m, γ(x)) :- Aggregand(m, x).
P(z) :- Aggregate(m,z).
```

Compared to the first approach, `Aggregate` now contains output values `z` rather than internal states `y`. And since mono types guarantee monotonicity of the projected outputs through the `mono_law`, we can use them as a generalized form of aggregation. For example, this generalized aggregation is necessary to correctly embed the `collatz_mono` into Datalog, because its output is monotone even though its state fluctuates. We have used generalized aggregations in an existing Datalog system (see Section 5) and it was easy to replace β-aggregation by γ-aggregation.

3.4 Formal Translation and Mono Dispatch

The previous subsections explained the ideas for encoding mono types in Datalog. To make these encodings precise and reproducible, we provide a formal translation from Datalog with mono types to Datalog with aggregation. Figure 2 shows the translation rules, which we explain one by one subsequently. The reason we define the semantics of mono types through translation to recursive aggregation is that the semantics of recursive aggregation is well understood [9] and supported by modern Datalog engines.

A program consists of rules $r_1 \cdots r_n$, which we translate compositionally $[\![r_1]\!] \cdots [\![r_n]\!]$. However, to support mono types, we must also generate additional rules for each mono construction **new** $M(\overline{m})@\overline{U}$ in the program. Note that $\overline{U}$ are the types of the auxiliary columns used to distinguish different occurrences of added inputs as described in Subsection 3.2. For each mono construction, we derive three new rules:

- Aggregand: Collects all aggregands of a mono type, added through invocations of $m \mathrel{+}= t$. As explained in Subsection 3.2, we rely on a magic-set transformation to synthesize the rules for this predicate; our translation only indicates the head of these rules.
- $\mathsf{Aggregate}_{M(\overline{m})}$: Performs the aggregation for the fully instantiated mono type $M(\overline{m})$ in the head of the rule. The body of the rule draws the aggregation inputs from Aggregand, ignoring the auxiliary columns.
- Aggregate: Since different mono types can occur in the same program, we need to carefully select the correct aggregation operation (an issue we have ignored so far). To this end, we use Aggregate to *dispatch* over the current mono type. Specifically, if m is a mono instance of $M(\overline{m})$, we dispatch to $\mathsf{Aggregate}_{M(\overline{m})}$. Note that these dispatch alternatives must be generated statically to identify the predicate named $\mathsf{Aggregate}_{M(\overline{m})}$.

The rest of the translation is compositional; Figure 2 only shows the rules for rewritten atoms. First, consider the construction of a new mono instance of $M(\overline{m})$. We represent mono instances as algebraic data in Datalog: $m = !\mathsf{MonoVal}(M(\overline{m}), \overline{t})$ constructs a mono instance and $?\mathsf{MonoVal}(m, M(\overline{m}), \overline{t})$ deconstructs m again. Each mono instance contains its fully instantiated mono type $M(\overline{m})$ and a list of values computed by $\overline{t}$ that uniquely identifies each mono instance as explained in Subsection 3.1.

An add operation $m \mathrel{+}= t@\overline{u}$ translates to a call of relation Aggregand. The magic set transformation will use this call to generate a rule for Aggregand that enumerates the arguments of the call. Here, the terms $\overline{u}$ serve to distinguish different occurrences of t. Finally, we read the aggregation result of a mono instance by calling relation Aggregate.

This concludes the integration of mono types into Datalog. In the translated program, the aggregation operator $M(\overline{m})$ is both order-independent and monotonic under bag inclusion, based on the algebraic properties of mono types. Thus, our integration does not jeopardize

$$
\begin{array}{lcl}

\end{array}
$$

Figure 2 Formal translation of Datalog with mono types to Datalog with generalized aggregation.

the least-fixed point semantics of Datalog with recursive aggreation [13], as long as there is no infinite ascending chain in the aggregation domain. We can use our translation to execute Datalog programs with mono types in any Datalog engine that supports generalized aggregation, such as Viatra/IncA [17], Ascent [10], and Flix [8].

3.5 An Example of Mono-type Translation

Even with above translation rules, understanding the execution of Datalog programs with mono types can be challenging, especially for readers who are unfamiliar with recursive aggregation. To aid in comprehension, we present a concrete example of the translation and the execution of a Datalog program with mono types.

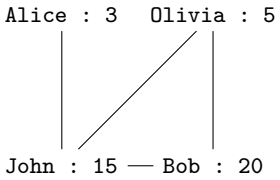
Consider a program that determines the number of followers for the most-followed user (we call it *maximum follower count* in the follows) in Alice's social network. This program uses a map mono, which associates each user's name with a `nat_max` mono, to track the maximum follower count for each individual.

```
visit(m) :- followers(p, n), m += (p,n).
visit(m) :- connected(p, q), visit(q,m), map = read(m), m += (p,map(q)).
main(f) :- m = new map[string, nat](new nat_max), visit(m), f = read(m)("Alice").
```

Here is the translation of above program. For simplicity, we use ... to leave the body generated by magic set transformation, and inline the $\mathsf{Aggregate}_{M(\overline{m})}$ rule as there is only one mono-type instance created.

```
visit(m) :- followers(p, n), Aggregand(m,p,n).
visit(m) :- connected(p, q), visit(q,m), Aggregate(m,map), Aggregand(m,p,map(q)).
main(f) :- m = !MonoVal(map_mono(nat_max)), visit(m), Aggregate(m,d), f = d("Alice").
Aggregand(m,p,n) :- ...
Aggregate(m,map_mono(nat_max)(p,n)) :- Aggregand(m,p,n).
```

We illustrate the execution of the translated program using a simple example in Figure 3. Figure 3a depicts a sample social network that includes Alice, where `Alice : 3` indicates that Alice has three followers. We detail the execution trace for both the `Aggregand` and `Aggregate` rules in Figure 3b. The aggregated argument of the `Aggregate` relation is a map that associates each user with the maximum follower count in her network. In the second iteration, John's maximum user count is updated by 20, which triggers the tuple `Aggregand(m, "Alice", 20)` derived in the third iteration. Besides, we can observe that the number of followers for each user in the map mono grows monotonically. We do not show the fourth iteration because no



(a) An instance of social-network.

	Aggregand(m,p,n)	Aggregate(m, d)
Iter. 1	(m, "Alice", 3), (m, "John", 15)*) (m, "Olivia", 5), (m, "Bob", 20)	(m, Map("Alice" -> 3, "John" -> 15, "Olivia" -> 5, "Bob" -> 20))
Iter. 2	(m, "Alice", 15), (m, "John", 20) (m, "John", 5), (m, "John", 3) (m, "Olivia", 15), (m, "Olivia", 20) (m, "Bob", 5), (m, "Bob", 15)	(m, Map("Alice" -> 15, "John" -> 20, "Olivia" -> 20, "Bob" -> 20))
Iter. 3	(m, "Alice", 20)	(m, Map("Alice" -> 20, "John" -> 20, "Olivia" -> 20, "Bob" -> 20))

*) We use `m` to represent the mono-type value `map_mono(nat_max)` for brevity.

(b) The execution trace of the translated program.

Figure 3 A concrete example of the execution of Datalog programs with mono types.

new tuples are derived and the program terminates. This example shows that performing mono add after mono read will lead to recursive aggregation in the translated program, but mono types abstract from the complications this involves.

4 Mono-Type Equivalence and Optimization

Mono-type aggregation can have a considerable performance overhead in Datalog systems because we are leaving the realm of Datalog's highly optimized relational algebra. In this section, we develop a theory for the equivalence of mono types that allows us to replace mono types without changing the semantics of a Datalog program. We then explain how this theory establishes optimizations for mono types and how they can reduce the need for aggregation in important cases.

4.1 Mono-type Equivalence

Intuitively, we consider two mono types to be equivalent if they produce the same outputs given the same sequence of inputs. There is no need to compare the states of mono types since they are invisible in the Datalog programs. For example, we introduced different version of the set mono in Section 2 (shown below): `set_mono1` uses a list internally and converts it to a set on `read`, while `set_mono` maintains a set of added elements internally and yields that set on `read`. These two mono types are equivalent because they produce the same sets as output, independent of states. However, sometimes we want to compare mono types that have different output types. For example, we would expect a multimap mono `map_mono K (set_mono V)` is equivalent to set of pairs `set_mono (K * V)`, because their output types `map K (set V)` and `set (K * V)` are isomorphic. Accordingly, we formalize the equivalence on mono types through a bidirectional embedding. A function f embeds mono type m_1 into m_2 if (i) f maps the initial output of m_1 to the initial output of m_2 and (ii) f is closed under `add`. That is, instead of running m_2, we can run m_1 and embed its outputs to obtain results equivalent to m_2. Two mono types then are *equivalent* if there exist embeddings in both directions. We formalized mono-type equivalence in `mono_equiv` below and proved it is a reflexive, symmetric, and transitive relation in Rocq:

```
Definition reachable (m : Mono ST I O) (st : ST) :=
  exists (l : list I), List.fold_left (add m) l (init m) = st.
Definition mono_embed (m1 : Mono ST1 I O1) (m2 : Mono ST2 I O2) (f : O1 → O2) : Prop :=
  f (read m1 (init m1)) == read m2 (init m2) ∧
  forall (s1 : ST1) (i : I), reachable m1 s1 → exists (s2 : ST2),
    reachable m2 s2 ∧ f (read m1 s1) == read m2 s2 ∧
    f (read m1 (add m1 s1 i)) == read m2 (add m2 s2 i).
Definition mono_equiv (m1 : Mono ST1 I O1) (m2 : Mono ST2 I O2)
    (f : O1 → O2) (g : O2 → O1) : Prop := mono_embed m1 m2 f ∧ mono_embed m2 m1 g.
```

We showed `mono_equiv` holds for the multimap mono `map_mono K (set_mono V)` and `set_mono (K * V)`. To this end, we defined embedding functions for their outputs and verified they satisfy `mono_embed`.

4.2 Mono-type Functors

With mono-equivalence in place, we can now study how to transform between equivalent mono types. If we inspect the specification of mono types and their equivalence relation, we can find two significant ways to transform between equivalent mono types. First, we can post-process the result of `read` to produce an alternative output. And second, we can post-process the result of `add` to produce (and maintain) an alternative state. We call both kinds of transformations *mono-type functors* and provide sufficient criteria to ensure they preserve equivalence. This means that no manual equivalence proof will be necessary for mono types where one is derived from the other through mono-type functors.

We design output functors to change the output type and value of a mono type. To this end, we specify `OutputFunctor`, which employs a function `f` to adjust the `read` operation and leave `init` and `add` untouched. The result of `OutputFunctor` is a new mono type whose output changed from type `O1` to `O2`. In order to preserve the `mono_law`, we require `f` to be a monotone function.

```
Definition OutputFunctor (f : O1 → O2) (_ : monotone f) (m : Mono ST I O1)
  : Mono ST I O2 := {| init := init m ;  add := add m ; read s := f (read m s) |}.
```

For example, we can derive a flattened version of the multimap mono:

```
Definition flatten_multimap {A B} : map A (set B) → set (A * B).
Definition flat_multimap_mono : Mono (map K (set V)) (K * V) (set (K * V)) :=
  OutputFunctor flatten_multimap _ (map_mono K (set_mono V)).
```

Observe how `flat_multimap_mono` yields outputs of type `set (K * V)` rather than `map K (set V)`. This way, output functors allow us to create many interesting mono types by projection of the output. For example, we can use output functors to obtain a mono that only contains the unique keys of a multimap, or only those entries that satisfy a filter function.

```
Definition multimap_keys_mono : Mono (map K (set V)) (K * V) (set K) :=
  OutputFunctor map_keys _ (map_mono K (set_mono V)).
Definition multimap_size_mono : Mono (map K (set V)) (K * V) nat :=
  OutputFunctor set_size _ flat_multimap_mono.
```

Here, the last example shows that we can stack applications of `OutputFunctor`: We use a flattened multimap and take its size. This way, `multimap_size_mono` computes the number of key-value pairs.

But, when are the resulting mono types equivalent to the original ones? We have proved that, if `f` has an inverse function `g`, the mono type generated from an output functor is equivalent to the original mono type. That is, the effect of `OutputFunctor` must be reversible:

```
Theorem ob_functor_equiv : forall (m: Mono ST I O1) f (f_mono: monotone1 f) g,
    bijective f g → mono_equiv m (OutputFunctor f f_mono m) f g.
```

Not all uses of `OutputFunctor` satisfy this property. But, we can use this lemma to guarantee a multimap mono is equivalent to its flattened version:

```
Definition unflatten_multimap : set (K * V) → map K (set V).
Lemma bij_flatten_multimap : bijective flatten_multimap unflatten_multimap.
Lemma flat_multimap_equiv : mono_equiv (map_mono K (set_mono V)) flat_multimap_mono.
```

State functor. We formulate state functors to derive new mono types that operate on a modified state. Unlike output functors, state functors use a pair of functions `f` and `g` that convert between `ST1` and `ST2` and back. This is necessary because the state is both argument and result of `add`. While `add` operates on `ST1` in the original mono type, we aim to derive `add` that operates on `ST2`. To this end, we map the argument state from `ST2` to `ST1` to apply the original `add`, and then map its result back to `ST2`. To ensure the resulting definition satisfies the `mono_law`, we require function `f ∘ g` to be both extensive and increasing in domain `ST1`. Moreover, we impose another restriction `indep` to guarantee the transformed mono types meet the `ord_indep` law.

```
Definition extensive (f : ST1 → ST1) (m : Mono ST1 I O) :=
  forall s : ST1, result m s ⊑ result m (f s).
Definition increasing (f : ST1 → ST1) (m : Mono ST1 I O) :=
  forall s1 s2 : ST1, result m s1 ⊑ result m s2 → result m (f s1) ⊑ result m (f s2).
Definition ord_indep_abs (f : ST2 → I → ST2) (g : ST2 → O) :=
  forall s a1 a2, g (f (f s a1) a2) = g (f (f s a2) a1).
Definition StateFunctor (f : ST1 → ST2) (g : ST2 → ST1) (m : Mono ST1 I O)
  (_ : extensive (f ∘ g) m) (_ : increasing (f ∘ g) m)
  (indep : ord_indep_abs (fun s a ⇒ f (add m (g s) a)) (read m ∘ g) : Mono ST2 I O :=
  {| init := f (init m) ; add s a := f (add m (g s) a) ; read s := (read m ∘ g) s |}.
```

The state functor derives mono types that operate on different states internally. For example, we can transform the multimap mono to use flattened sets as states:

```
Definition multimap_flat_state_mono : Mono (set (K * V)) (K * V) (map K (set V)) :=
  StateFunctor flatten_multimap unflatten_multimap _ _ (map_mono K (set_mono V)) _.
```

Note how the derived mono type uses sets of pairs internally, although its output is still a multimap for now. But is the resulting mono type also equivalent to the original one? We have proved that, if `f` is a bijection and `g` is its inverse, `StateFunctor` preserves the equivalence of mono types:

```
Theorem st_functor_equiv {ST1 ST2 I O} `{PartialOrder O, PartialOrder ST1,
  PartialOrder ST2} : forall (m: Mono ST1 I O) (f : ST1 → ST2) (g : ST2 → ST1),
    bijective f g → mono_equiv m (StateFunctor f g _ _ m _) id id.
```

Composing functors. We can compose mono-type functors by stacking them. The order in which we compose multiple `StateFunctor` or multiple `OutputFunctor` instances matters, because one transforms the output of the other. We have seen an example of this in `multimap_size_mono`, which stacks two `OutputFunctor`: The first converts a multimap to a set of pairs, the second counts the number of entries. Consequently, the order of their application cannot be changed.

The story is different when combining a `StateFunctor` with an `OutputFunctor`: One changes the state, the other changes the output. In that sense, we could try to apply them in any order. Indeed, we were able to prove that the order of their application is irrelevant for `mono_equiv`. Figure 4 shows the corresponding commuting diagram.

4.3 Optimization by Mono-Type Replacement

The equivalence relation `mono_equiv` indicates that we can use one mono type as a drop-in replacement for another mono type. Thus, if one implementation is more efficient than the other, we may opt for the better one. Mono-type functors help us establish such equivalences.

We illustrate the mono-type replacement for the multimap mono. So far, we have established a number of mono types that are provably equivalent to the multimap mono.

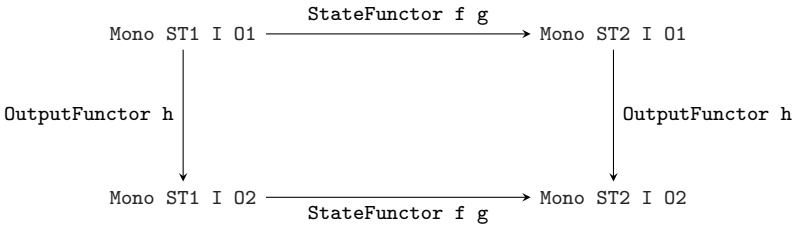


Figure 4 Commuting diagram for `OutputFunctor` and `StateFunctor` under `mono_equiv`.

```
Definition flat_multimap_mono : Mono (map K (set V)) (K * V) (set (K * V)) :=
  OutputFunctor flatten_multimap _ (map_mono K (set_mono V)).
Definition multimap_flat_state_mono : Mono (set (K * V)) (K * V) (map K (set V)) :=
  StateFunctor flatten_multimap unflatten_multimap _ _ (map_mono K (set_mono V)) _.
Definition flat_multimap_flat_state_mono : Mono (set (K * V)) (K * V) (set (K * V)) :=
  OutputFunctor flatten_multimap _ multimap_flat_state_mono.
```

The last mono type shown above composes the state functor used in `multimap_flat_state_mono` with an output functor. The implementation of this mono type is not efficient, because it is converting back and forth between maps and sets all the time. But its signature suggests a way forward: it uses a set of pairs both as state and output. This is interesting, because we have seen another mono type that admits this type:

```
Definition set_pair_mono : Mono (set (K * V)) (K * V) (set (K * V)) := set_mono (K * V).
```

Since the state and output functor have done most of the heavy lifting, it is easy to prove that the set mono on pairs is equivalent to the last multimap mono from above:

```
Lemma set_multimap_equiv : mono_equiv flat_multimap_flat_state_mono set_pair_mono id id.
```

Hence, we can replace any multimap mono by a set mono in Datalog programs. We can follow the same approach to prove further equivalences and use them to opt for more efficient mono types.

4.4 Optimization by Mono-Type Elimination

This paper introduces mono types as a new abstraction for Datalog programmers. However, not all mono types are necessary at run time because *Datalog provides some mono types as built-ins*. We can eliminate those mono types that are built into Datalog from the program.

First, most Datalog systems support a number of primitive aggregations functions, such as `count`, `max`, or `sum`. Of course, we can reuse them instead of using `nat_sum`, for example. But this is unlikely to affect the performance of the program much, because the built-in aggregations have to do the exact same work as our mono types and the aggregations resulting from them.

The second class of built-in mono types is much more important: Datalog has a number of relational mono types built-in. For example, Datalog relations essentially implement the `set_mono`: they collect tuples monotonically. If we can adopt such built-in relational mono types, we can eliminate the aggregation that the standard semantics of mono types imposes. Aggregation can have a considerable performance overhead in Datalog systems because we are leaving the realm of Datalog's highly optimized relational algebra. So this is likely to have a large performance impact.

Since the set mono is built into Datalog, we can optimize the translation rule:

if `mono_equiv` $M(\overline{m})$ (`set_mono` A) for some A:
$[\![\textbf{new}\ M(\overline{m})@(U_1, \ldots, U_k)]\!]_{agg} = \mathsf{Aggregate}_{M(\overline{m})}(m, t) :\!-\ \mathsf{Aggregand}(m, t, _).$
else:
$[\![\textbf{new}\ M(\overline{m})@(U_1, \ldots, U_k)]\!]_{agg} = \mathsf{Aggregate}_{M(\overline{m})}(m, M(\overline{m})(t)) :\!-\ \mathsf{Aggregand}(m, t, _).$

If $M(\overline{m})$ is equivalent to a set mono, the aggregation can be skipped: Note how the head of the generated rule simply forwards the aggregands. In contrast, other mono types have to aggregate the aggregands using $M(\overline{m})$. For example, we have established that the mono type for multimaps is equivalent to the mono type for sets. Therefore, multimaps do not require aggregation using the optimized translation rules.

We found another important relational mono type that is built into Datalog and which we call *functional relations*. A functional relation is a finite relation (i.e., set of tuples) with a functional dependency, meaning that some columns uniquely determine other columns. Datalog allows functional relations to aggregate the uniquely determined columns. Therefore, we can faithfully capture functional relations as the following mono type:

```
Definition fun_dep (s : set (A * B)) :=
  forall (a : A) (b b' : B), set_In (a, b) s → set_In (a, b') s → b = b'.
Definition funrel A B := {s : set (A * B) | fun_dep s}.
Definition funrel_mono K (m : Mono ST I O) : Mono (funrel K ST) (K * I) (funrel K O) :=
{| init := empty_set
 ; add s ka := let (k, a) := ka in
               funrel_add_with s k (fun st ⇒ add m st a) (add m (init m) a)
 ; read s := funrel_map_values (read m) s
|}.
```

Here, `funrel_add_with` uses the first function argument if `k` already is present in `s`, and the second the function argument for new `k`. Functional relations still require aggregation, but only on the uniquely determined columns rather than on all columns of the relation. We can exploit this in a dedicated translation rule:

if `mono_equiv` $M(\overline{m})$ (`funrel_mono` m') for some A:
$[\![\textbf{new}\ M(\overline{m})@(U_1, \ldots, U_k)]\!]_{agg} = \mathsf{Aggregate}_{M(\overline{m})}(m, k, m'(t)) :\!-\ \mathsf{Aggregand}(m, (k, t), _).$

Note how the generated rule simply propagates the first half of the input k, and only requires aggregation of the remainder t. But this only holds for mono types $M(\overline{m})$ that are equivalent to a `funrel_mono`. We were able to establish such equivalence for the map mono:

```
Theorem map_funrel_mono_equiv : forall (m : Mono ST I O)
  mono_equiv (map_mono K m) (funrel_mono K m) map_funrel funrel_map.
```

We prove this property by first applying output and state functors to `map_mono`, such that the resulting mono type has the same signature as `funrel_mono`. The remainder of the proof is manageable and only took a few hours to complete.

In conclusion, Datalog programs that use a map mono only need to use aggregation on the values of that map. Moreover, since `map_mono K1 (map_mono K2 m)` is equivalent to `map_mono (K1 * K2) m`, actually only the most-nested value type has to be aggregated. This has a significant performance impact as we will evaluate in the subsequent section.

5 Implementation, Case Studies, and Performance

We have implemented mono types as an extension of the IncA Datalog system [14] and made the code available open-source.[2] IncA supports generalized recursive aggregations over user-defined functions, which makes it well-suited for mono types. In particular, we added built-in support for set monos, map monos, and a number of primitive monos on strings and numbers. We also provide an interface for user-defined mono types, which we used to integrate lattice-based mono types for example. We integrated mono types as described in Section 3 by translating into Datalog with aggregation. The translation for set monos and map monos is configurable to activate or deactivate the optimization described in Subsection 4.3 and 4.4. Overall, the integration of mono types required 550 LoC for IncA.

Next, we evaluate the usability and performance of mono types using two case studies: dependency analysis and interval analysis, each with and without using mono types. Program analysis is a common use case for Datalog because of its least fixpoint semantics. We show that mono types significantly improve the performance of these analysis compared to pure Datalog code.

5.1 Dependency Analysis

We want to analyze the dependencies of a simple language with inter-dependent definitions. A program of the language consists of definitions that assign a name to an expression. Expressions are either numbers, additions, or variables:

$$\begin{array}{lll} \text{(programs)} & p & ::= \overline{d} \\ \text{(definitions)} & d & ::= \texttt{def}\ x = e \\ \text{(expressions)} & e & ::= n \mid x \mid e + e \end{array}$$

We represent the analyzed program as an abstract syntax tree (AST) which is encoded with algebraic data types in Datalog. Each variable refers to exactly one definition, as illustrated with subscripts in the following example:

```
def a1 = c3; def b2 = 2; def c3 = a1; def main4 = c3
```

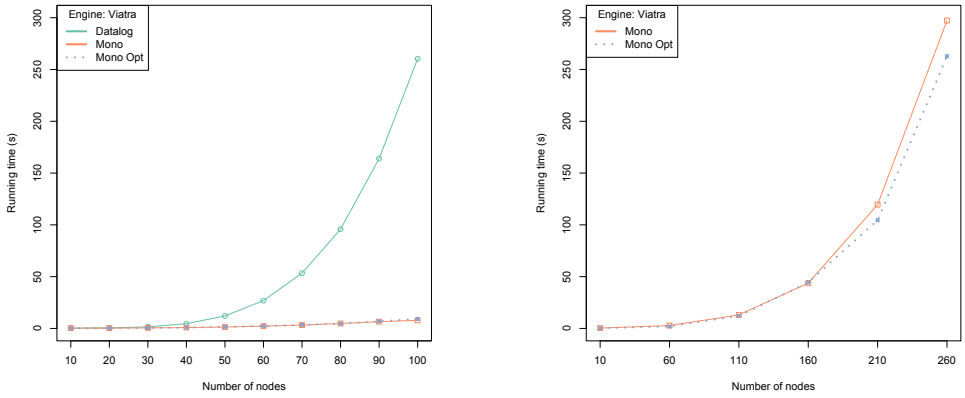
For a given definition, we compute all definitions it transitively depends on. In our example, `main`$_4$, `a`$_1$, and `c`$_3$ all transitively depend on `a`$_1$ and `c`$_3$, whereas `b`$_2$ is not used.

We implement this analysis in pure Datalog using three central relations:

```
edgesDefs(defs, from, to) :- ?Cons(defs, hd, tl), edgesDef(defs, hd, from, to).
edgesDefs(defs, from, to) :- ?Cons(defs, hd, tl), edgesDefs(tl, from, to).
edgesDef(defs, def, from, to) :- ?Def(def, _, e), refersTo(defs, e, to), from = def.
edgesDef(defs, def, from, to) :- ?Def(def, _, e), refersTo(defs, e, other),
                                 edgesDef(defs, other, from, to).
refersTo(defs, e, def) :- ?Var(e, name), findDef(defs, name, def).
refersTo(defs, e, def) :- ?Add(e, e1, e2), refersTo(defs, e1, def).
refersTo(defs, e, def) :- ?Add(e, e1, e2), refersTo(defs, e2, def).
```

We first traverse the list of all definitions in `edgesDefs`. For each definition, we compute all definitions it depends on using the two rules of `edgesDef`: A definition `def` depends on another definition `to` if (i) `def` contains a variable referencing `to`, or (ii) `def` contains a variable

[2] https://gitlab.rlp.net/plmz/inca-scala/-/tree/layered-ir/inca-ir/src/main/scala/inca/ir/extension/mono



(a) Viatra: Pure Datalog vs set mono.

(b) Viatra: Set mono vs optimized set mono.

Figure 5 Performance results for the dependency analysis.

reference to `other`, which in turn depends on `to`. An expression `e` refers to a definition `def` if `e` contains a variable with the name of `def`. We accomplish this using the `refersTo` relation to recursively traverses an expression.

We now rewrite this program with mono types. Instead of collecting and propagating edges in `edgesDefs` and `edgesDef`, we create a single mutable mono set and pass it around. That way, `edgesDef` can directly write reachable pairs of definitions into the mono set when they are discovered:

```
main(from, to) :- m = new set[(Def, Def)], edgesDefs(defs, m), read(m) = (from, to).
edgesDefs(defs, m) :- ?Cons(defs, hd, tl), edgesDef(defs, hd, m), edgesDefs(tl, m).
edgesDef(defs, def, m) :- ?Def(def, _, e), refersTo(defs, e, trg),
                          m += (def, trg), edgesDef(defs, trg, m).
```

The changes required to the original dependency analysis are minimal. And the program became simpler. For example, we now only need a single rule for `edgesDef` that registers a dependency edge `(def, trg)` and also recurs. Similarly, `edgesDefs` only needs one rule that asks for the dependencies of `hd` and recurs on `tl` at once. But, most importantly for this case study, mono types improved the performance significantly.

In Figure 5, we show the execution time for the dependency analysis for different sized cyclic graphs on Viatra [17]. Figure 5a reveals that using a set mono reduces the running time considerably compared to pure Datalog. This is because the analysis using pure Datalog code has to propagate edges in `edgesDefs` and `edgesDef`, which produces orders of magnitudes more tuples than the analysis using mono types. Using a mono set eliminates this overhead. To highlight the difference between the optimized (Mono opt) and non-optimized set mono (Mono), we ran additional tests with bigger input graphs. As shown in Figure 5b, the optimization of set monos yields around 10% performance gains. For graphs exceeding 200 nodes this difference becomes more evident. The optimization does not have a bigger impact because, internally, the state of the non-optimized set mono is represented by an immutable Scala set. The aggregation operation needs to add elements to this internal state, which is a constant time operation. Since we are only reading the set mono once, in the `main` relation, this aggregation only happens a single time. We have additionally translated the dependency analysis program into Soufflé [5] and Ascent [11]. Since neither of them supports user-defined aggregation, we can only compare the performance between plain Datalog and optimized set mono on these two engines. We found that the experimental results are almost identical

to Viarta, optimized set mono's running time is significantly less than plain Datalog. This experiment result confirms mono types are an effective and general optimization technique for Datalog.

5.2 Interval Analysis

We also implement a flow-sensitive interval analysis for the While language in Datalog as idiomatically as possible. We then rewrite it to use nested map monos. Both implementations share common relations to compute the control flow graph and abstractly evaluate expressions.

Based on the control flow graph, the pure Datalog version uses two mutually recursive relations `intervalBefore` and `intervalAfter`. These relations define the interval value for a variable before and after the execution of a specific statement. To compute `intervalAfter`, we distinguish two different cases. If the current statement is an assignment of the current variable `var`, then `aeval` computes the value of `var` after the assignment. In all other cases, we propagate the information from `intervalBefore`. Note how `aeval` requires a reference to the current statement so that it can query `intervalBefore` for the value of referenced variables in `exp`. To compute `intervalBefore` for a variable `var`, we join the intervals of `var` that are valid after any predcessor statement.

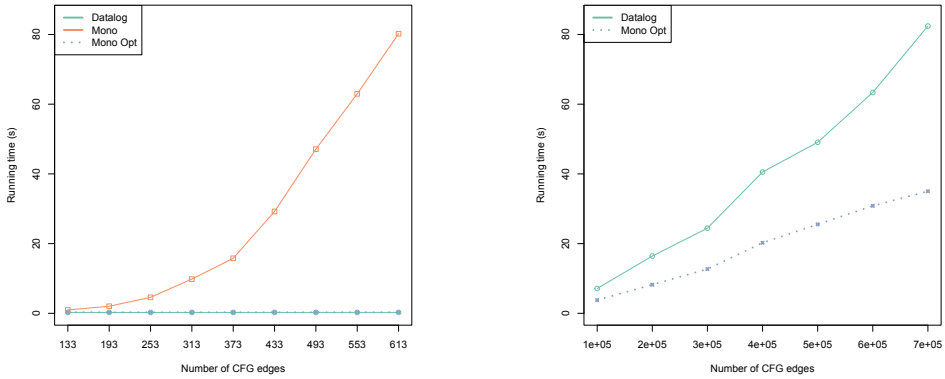
```
intervalAfter(stmt, var, iv) :- assignment(stmt, var, exp), aeval(stmt, exp, iv).
intervalAfter(stmt, var, iv) :- nonassignedVars(stmt, var), intervalBefore(stmt, var, iv).
aeval(stmt, exp, iv) :- ?Var(exp, v), intervalBefore(stmt, v, iv).
aeval(stmt, exp, iv) :- ...
predecessorIntervals(stmt, var, pred, iv) :- cflow(pred, stmt),
                                             intervalAfter(pred, var, iv).
intervalBefore(stmt, var, lub(iv)) :- predecessorIntervals(stmt, var, _, iv).
```

To implement the same analysis using mono types, we propagate a single nested mono map while traversing the control flow graph. The mono map yields a result of type `map[Stmt, map[Var, Interval]]`, which is the standard abstract domain used in flow-sensitive data-flow analysis: For each statement, we compute the abstract value of each variable. With this mono type, we do not need explicit aggregation in the Datalog code anymore. We initialize the nested mono map for the first statement in the analyzed code and then propagate it to all other statements. Note that we use the upper-case `Interval` for the type of interval values and the lower-case `interval` for the interval mono type.

```
traverse(stmt, m) :- isFirst(stmt), m = for stmt : new map[Stmt, map[Var, Interval]](
                                        new map[Var, Interval](new interval)].
traverse(stmt, m) :- cflow(pred, stmt), traverse(pred, m).
```

Similar to before, we need to handle two different cases when we process a statement. If the statement is an assignment of a variable `var` to some expression `exp`, we evaluate `exp` under an environment `env`. We obtain `env` from the map mono by first reading the mono type, which yields the full flow-sensitive analysis result as a nested map, and then performing a map lookup at `stmt`, which yields a variable map. This way, `aeval` does not depend on `intervalBefore` or the like, it simply reads variable values from the given environment. If the analyzed statement does not assign `var`, then we simply propagate its value to all successor statements:

```
transfer(stmt) :- traverse(stmt, m), assignment(stmt, var, exp), cflow(stmt, succ),
                  env = read(m)(stmt), aeval(env, exp, iv), m += (succ, (var, iv)).
transfer(stmt) :- traverse(stmt, m), nonassignedVars(stmt, var), cflow(stmt, succ),
                  env = read(m)(stmt), iv = env(var), m += (succ, (var, iv)).
aeval(env, exp, iv) :- ?Var(exp, v), iv = env(v).
aeval(env, exp, iv) :- ...
```



(a) Pure Datalog vs map mono.

(b) Pure Datalog vs optimized map mono.

Figure 6 Performance results for the interval analysis.

In our opinion, mono types enable a much cleaner definition of the interval analysis that is very close to the definitions found in program-analysis textbooks. In fact, the definition of `transfer` is most declarative: it describes equations that must hold for each statement. And since `transfer` is neither directly nor indirectly recursive, it can be understood as a specification without even considering a fixed-point semantics. Of course, solving this analysis problem still requires a fixed-point computation due to loops in the analyzed program. This is evident in the analysis definition implicitly: The values written to the map mono depend on the values read from the map mono, which will be translated into recursive aggregation. The mono type protected the programmer from this complication. But, is there a performance penalty for this abstraction?

Figure 6 shows the performance results for the interval analysis. On the left, we can see that the non-optimized mono version is orders of magnitude slower than using pure Datalog. But these are very small programs with only a few hundred CFG edges. We suspect that this slow down is due to the explicit map data structures that needs to be maintained by the non-optimized map mono. The optimization for map monos removes this overhead, by flattening the nested map mono and converting it to relations. Not only does this eliminate the overhead of the mono type abstraction, the optimized program actually scales much better to analyzing large programs. For example, to analyze programs with $\sim$ 700K CFG edges, the optimized map mono requires less than 40s whereas the pure Datalog version requires more than 80s. This clearly shows that mono types provide abstraction without regret.

6 Related Work

We develop and mechanize the theory of mono types and their properties in Rocq. To the best of our knowledge, we are the first to introduce a mutable, monotonic container abstraction for Datalog. However, in the context of distributed computing and parallel programming, monotone data types have been studied in the past, which we discuss below. Besides a thorough theoretical exploration, we also integrate and evaluate mono types using the IncA framework for Datalog. In recent years, numerous extensions and frontends for Datalog have been proposed in the literature. Some of these have features that are related to mono types, as the following discussion shows.

6.1 Datalog Dialects

Compared to all existing Datalog dialects, mono types bring three novel features. First, mono types generalize existing styles of aggregation, making aggregation more expressive. Second, mono types have a mechanized theory in Rocq, including constructions, functors, and an equivalence relation. And third, mono types behave like first-class containers that can be propagated and filled anywhere, which improves programmability and performance. In our discussion below, we focus on the first part, namely the expressiveness of aggregation. This is because no existing Datalog system has a mechanized aggregation theory nor supports anything like first-class containers.

Datafun [3] is a typed higher-order functional programming language that can express Datalog-style programs. Datafun supports aggregation over relations via the join operator of semi-lattices. Our mono types are a generalization of semi-lattices and permit `add` operations that are not computing a least upper bound, such as required for summation. Datafun's key feature is to track monotonicity with types by differentiating discrete and monotone variables. In contrast, we choose to develop and prove the theory of mono types in Rocq and use this foundation to let users design custom mono types. This is a classic trade-off between automation and expressiveness. Specifically, Datafun's type system has limited capabilities for establishing monotonicity and therefore only supports a few built-in semi-lattices, whereas our implementation supports user-defined mono types. Finally, Datafun ensures the termination of fixed-point computations by constraining them to finite semi-lattice types, which are tracked by its type system. With mono types, we do not guarantee termination but instead require the user to prevent infinite ascending chains, which is in conformance with lattice-based aggregation in existing Datalog systems. It would be interesting to study if Datafun can be faithfully extended to support mono types in place of semi-lattices while retaining its metatheory.

Flix [8] and IncA [13] are Datalog frameworks that support recursive aggregation over user-defined aggregation operators. While most aggregation operators in their case studies are semi-lattices, they can also express other monotonic operations, such as summation [15]. Mono types are more general still, because they support a post-processing through the `read` operation, and only the result of `read` must be monotonic. Since we deviated from the textbook semi-lattice aggregation, we established a theory of mono types formally in Rocq. Flix supports validating the monotonicity of user-defined aggregation operators using an SMT solver [7]. However, given the complexity of properties we needed to establish for mono types, it seems highly unlikely that an automated approach can establish the same guarantees. In particular, to enable optimizations of mono types, we had to prove a number of equivalences between mono types. These optimizations have a significant performance impact, as our evaluation shows. Existing Datalog systems cannot optimize aggregations.

BYODS [10] is a Datalog engine and dialect written in Rust with support for custom data structures to back Datalog relations. This not only improves performance, but also allows the user to extend the semantics of Datalog. Namely, BYODS represents relation as a triple $(D, \mathit{inj}, \gamma)$, where D is a lattice that represents the state of the custom relation. The injection function $\mathit{inj} : T \to D$ converts a tuple T to D, which can then be joined with the current state of the custom relation. And the concretization function $\gamma : D \to \mathcal{P}(T)$ extracts a set of tuples from the state of the custom relation. They have proved that if γ is a monotonic function, the custom relation will not break the fixed point semantics of Datalog. The custom relation is similar to mono types, as D can be seen as the state type, inj and γ are close to the `add` and `read` operation respectively. However, mono types do not require the state type to be ordered and the output of mono types is not limited to powersets. In

addition, BYODS can also be used to support user-defined lattices and recursive aggregations, which give rise to performing aggregation on map lattices. But they do not explore how to optimize aggregations, which requires an equivalence relation over user-defined types like ours. A promising future work is to combine BYODS with mono types to enable additional performance improvements after our optimizations.

Dedalus [2] introduces state to Datalog to reason about distributed systems. In particular, Dedalus introduces a notion of time to Datalog by annotating relations with a monotonically increasing timestamp. Each change happens at a specific point in time. To persist a fact over time, it is rederived in each subsequent iteration. Effectively, Dedalus evaluates Datalog over time, which enables strong updates by revoking or updating facts. While our mono types also introduce a notion of mutable state to Datalog, they do not permit strong updates. Even though we enforce no restriction on the state of a mono type, we require their output to grow monotonically to guarantee a unique minimal model. It is not obvious how we could support strong updates instead of monotone updates without conflicting with Datalog's fixed-point semantics. In general, mono types and Dedalus serve different purposes. Mono types provide a general purpose abstraction for Datalog to increase programmability and performance. Dedalus on the other hand, evaluates Datalog over time to reason about distributed systems.

6.2 Application of Monotonic Data Types

Conflict-free replicated data types (CRDTs) [12] is a framework for maintaining eventually consistent values in distributed systems. There are two types of CRDTs, operation-based CRDTs and state-based CRDTs. Mono types are more closely related to state-based CRDTs. Specifically, a state-based CRDT object consists of an initial state, a query method to read the current state, an update method to modify state, and a merge method to compute the least upper bound between local state and remote states. CRDT requires the state to grow monotonically after applying an update or merge method. Except for the merge method, we can find that state-based CRDTs and mono types exploit a similar design pattern. However, the monotonicity property serves different purposes in CRDTs and mono types. CRDTs require monotonicity to guarantee that all of the replicas reach the same state eventually. In contrast, mono types use monotonicity to ensure the well-definedness of recursive aggregation in Datalog [13].

Nevertheless, the similarity between CRDTs and mono types leads to a promising direction for future work: extending mono types to Datalog dialects that are used in the distributed system, such as Dedalus [2], Bloom [1], or Bloom^L [4]. Notably, Bloom^L allows passing lattice-based stateful objects across relations, and adopts similar ideas as mono types to collect the inputs of objects. However, mono types provide a more generalized form of lattice-based aggregation that differentiates between state and output, which is more flexible than Bloom^L. In addition, Bloom^L does not provide optimization for sets and maps.

LVars [6] (lattice vars) is a model for deterministic-by-construction parallel programming. Its interface only exposes a put operation (compute the `lub`) and a get operation (to read the state) to programmers. To guarantee determinism, LVars require the get operation to only return a state from a predefined threshold set Q, in which the `lub` of two distinct elements is $\top$ (the error state). With mono types, we do not need to associate a threshold set since we can rely on the eventual consistency of the fixed-point computation.

7 Conclusion

We propose mono types, a monotonic data structure for Datalog to improve its programmability and performance. Mono types support three essential operations: (1) we can instantiate them, (2) we can add elements to them, and (3) we can read monotonically increasing outputs from them. To guarantee well-defined behaviour for Datalog programs, we mechanize and prove the theory of mono types in Rocq. Given this theoretical foundation, we integrate mono types into Datalog by translating them to generalized aggregations over relations. We identify two central container mono types: set mono and map mono. Using a new concept of mono equivalence, we show that these containers are native to Datalog in the sense that we can profit from Datalog's set semantics to implement them. To validate the usability and performance improvements of mono types, we implement two case studies, a dependency analysis and an interval analysis. We show that mono types significantly improve the performance of these analysis compared to pure Datalog.

Abstract

Abstract interpretation provides a foundational framework for approximating program semantics by interpreting code through abstract domains using semantic functions over ordered sets along a program's control flow graph (CFG). To facilitate fixpoint computation in abstract interpretation, weak topological ordering (WTO) is an effective strategy for handling loops, as it identifies strategic control points in the CFG where widening and narrowing operations should be applied. However, existing abstract interpreters still face challenges when extending WTO computation in the presence of recursive programs. Computing a precise whole-program WTO requires full context-sensitive analysis which is not scalable for large programs, while context-insensitive analysis introduces spurious cycles that compromise precision. Current approaches either ignore recursion (resulting in unsoundness) or rely on conservative approximations, sacrificing precision by adopting the greatest elements of abstract domains and applying widening at function boundaries without subsequent narrowing refinements. These can lead to undesired results for downstream tasks, such as bug detection.

To address the above limitations, we present RecTopo, a new technique to boost the efficiency of precise abstract interpretation in the presence of recursive programs through interprocedural weak topological ordering (IWTO). Rather than pursuing an expensive whole-program WTO analysis, RecTopo employs an on-demand approach that strategically decomposes programs at recursion boundaries and constructs targeted IWTOs for each recursive component. RecTopo dissects and analyzes (nested) recursions through interleaved widening and narrowing operations. This approach enables precise control over interpretation ordering within recursive structures while eliminating spurious recursions through systematic correlation of control flow and call graphs.

We implemented RecTopo and evaluated its effectiveness using an assertion-based checking client focused on buffer overflow detection, comparing it against three popular open-source abstract interpreters (IKOS, Clam, CSA). The experiments on 8312 programs from the NIST dataset demonstrate that, on average, RecTopo is 31.99% more precise and achieves a 17.49% higher recall rate compared to three other tools. Moreover, RecTopo exhibits an average precision improvement of 46.51% and a higher recall rate of 32.98% compared to our baselines across ten large open-source projects. Further ablation studies reveal that IWTO reduces spurious widening operations compared to whole-program WTO, resulting in a 12.83% reduction in analysis time.

1 Introduction

Abstract interpretation [24, 22, 25] offers a framework for approximating program semantics by analyzing code through abstract domains and applying semantic functions over ordered sets along the program's control flow graph (CFG). The analysis converges to a conservative solution at a post-fixpoint, which is an over-approximation of the least fixpoint of the program's semantics. This least fixpoint is defined by a system of equations $a_1 = \Phi_1(a_1, a_2, \ldots, a_n),\ \ldots,\ a_n = \Phi_n(a_1, a_2, \ldots, a_n)$, where each a_i denotes the abstract states at control point i, and Φ_i represents the corresponding semantic function of a program.

For programs with acyclic control flows, fixpoint computation typically converges after a few iterations over the CFG. However, the presence of cycles introduces cyclic dependencies between program states, complicating the analysis when working with abstract domains characterized by unbounded or very deep lattice heights [27, 62]. In such domains, such as the standard interval domain [17], the iterative computation may require a prohibitively large number of steps to reach a post-fixpoint. Even worse, termination is not guaranteed, as a post-fixpoint may not be reached within a finite number of steps. To facilitate fixpoint computation in these domains, widening techniques [22, 24, 13] compute a safe (upper) approximation of the least fixpoint (a post-fixpoint, hereafter referred to as a fixpoint for simplicity). However, widening operations must be judiciously applied only at cycle points, as spurious widening at acyclic locations introduces precision loss due to over-approximation, which cannot be recovered through subsequent narrowing [11]. Bourdoncle's algorithm [13] provides an effective solution through weak topological ordering (WTO) for intraprocedural analysis, which efficiently identifies program loops and their nested structures while requiring only one widening point per loop. The WTO framework further enables sophisticated interleaved widening and narrowing strategies [10], where narrowing compensates precision that may have been lost during widening by incorporating invariants such as loop bounds and branching constraints. These advantages have made WTO a standard method for handling intraprocedural loops in many current abstract interpreters [15, 26, 19, 18].

While state-of-the-art abstract interpreters effectively leverage Bourdoncle's algorithm for loop analysis, they face difficulties when determining WTO for recursive function calls. Several approaches have been proposed for taming recursions and interprocedural abstract interpretation. For non-recursive functions, function inlining enables precise interprocedural analysis. However, this approach becomes infeasible for recursive functions due to potentially infinite inlining sequences in unbounded recursion. To address this, some tools adopt strong assumptions, employing either under- or over-approximation approaches. For example, Astrée [37] completely excludes the analysis of unbounded recursion, while IKOS [15, 40] conservatively assigns top values ($\top$) to variables in recursive contexts, effectively bypassing the analysis of recursive functions. To improve precision, tools such as Clam [34, 19] and CSA [18] analyze recursive function bodies but introduce many spurious widening operations

at function boundaries. Their effectiveness remains limited, as their WTO computations are confined to individual function scopes, preventing the creation of an effective interprocedural order for efficient fixpoint computation and subsequent narrowing to enhance precision. Consequently, both under-approximation and over-approximation approaches can produce undesirable outcomes for downstream tasks, such as bug detection.

Addressing these limitations necessitates an approach that incorporates both the analysis of recursive function bodies and guarantees termination properties. This requires an interprocedural weak topological ordering (IWTO) that establishes an efficient computation order across function boundaries, enabling minimal widening points and allowing narrowing strategies for precise handling of recursions. The primary challenge lies in accurately identifying the IWTO within the control flow graph, where multiple call sites of the same function can generate spurious recursive paths. These paths arise when call sites connect to prior invocations of the same function, potentially introducing unnecessary widening points and thereby compromising the precision of the analysis.

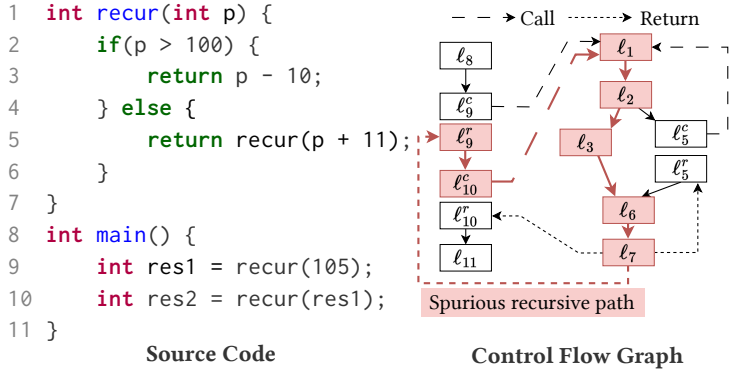

Figure 1 Spurious recursive path when analyzing McCarthy 91 function [43] (a library of mathematical theory of computation).

Figure 1 illustrates this challenge in the context of the McCarthy 91 function [43]. The function `recur` ($\ell_1 - \ell_7$) is a recursive function that takes an integer `p` as input and recursively invokes itself at ℓ_5 to increase `p`'s value until `p` is greater than 100. The main function invokes `recur` twice at ℓ_9 and ℓ_{10} respectively. In the control flow graph, each function invocation at location ℓ_n is decomposed into two distinct nodes: a call site ℓ_n^c and a corresponding return site ℓ_n^r (e.g., the call at ℓ_9 in the source program manifests as ℓ_9^c and ℓ_9^r in the control flow graph). The control flow edges are established such that each call site connects to its callee's entry point (e.g., $\ell_5^c \dashrightarrow \ell_1$, $\ell_9^c \dashrightarrow \ell_1$, and $\ell_{10}^c \dashrightarrow \ell_1$), while return edges link the callee's exit point to the corresponding return sites (e.g., $\ell_7 \dashrightarrow \ell_{10}^r$, $\ell_7 \dashrightarrow \ell_9^r$, and $\ell_7 \dashrightarrow \ell_5^r$). Note that, a spurious recursive path highlighted in red in the figure ($\ell_9^r \rightarrow \ell_{10}^c \dashrightarrow \ell_1 \rightarrow \ell_2 \rightarrow \ell_3 \rightarrow \ell_6 \rightarrow \ell_7 \dashrightarrow \ell_9^r$) arises due to the consecutive call to the function `recur` at ℓ_9 and ℓ_{10}, which may lead to a redundant widening operation at the spurious recursion and compromises analysis precision. While a fully context-sensitive analysis could theoretically eliminate such spurious paths through precise call-return matching, the exponential complexity of such an approach renders it impractical for real-world program analysis.

We present RecTopo, a new interprocedural fixpoint computation technique that computes interprocedural weak topological ordering (IWTO) in the presence of recursive programs, enabling recursions to be handled as efficiently and precisely as loops. Our approach

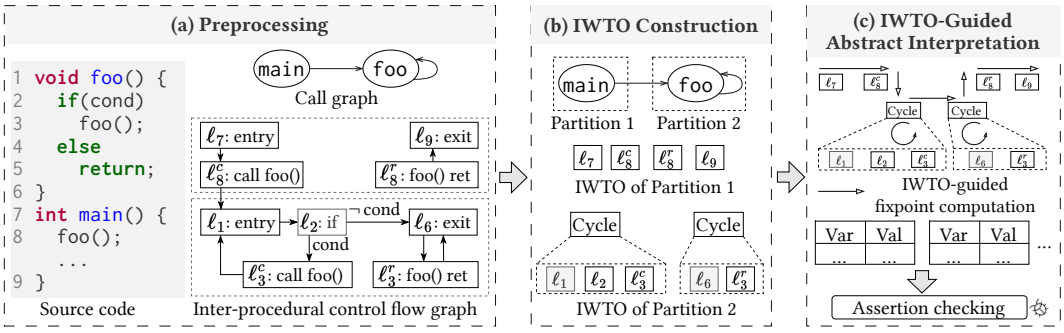

Figure 2 An overview of RecTopo framework.

systematically dissects programs into non-recursive and recursive components, avoiding the complexity of whole-program WTO construction. The framework first leverages Tarjan's strongly connected component algorithm [61] on the call graph to identify recursive function calling chains. Subsequently, on the CFG, it coalesces call sites of functions within the same recursive chain and assigns each recursion a unified IWTO. This principled decomposition enables the seamless integration of an efficient worklist algorithm with interleaved widening and narrowing operations for precise recursion analysis. Our approach also eliminates spurious interprocedural cycle, thus preventing spurious widening operations that would otherwise arise from distinct call sites of the same function.

Figure 2 illustrates the three-phase architecture of RecTopo, demonstrating how our framework systematically addresses the challenges of interprocedural analysis in the presence of recursions:

(a) Preprocessing: The framework begins by transforming the input program into LLVM's intermediate representation (LLVM-IR) [41]. This standardized representation provides a unified foundation for constructing both the interprocedural control-flow graph (ICFG) and the corresponding call graph.

(b) IWTO Construction: At the core of our approach lies a novel two-step IWTO construction process. First, we employ Tarjan's algorithm [61] on the call graph to identify and partition functions based on their recursive relationships. This partitioning is crucial as it enables us to isolate and group functions within the same recursive calling chain. Then, guided by these function partitions, we construct their corresponding IWTOs on the ICFG through iterative applications of Tarjan's algorithm. This strategic decomposition yields a precise IWTO for each recursion, providing an effective foundation for subsequent analysis phases while avoiding the complexity of whole-program WTO construction.

(c) IWTO-Guided Abstract Interpretation: The framework leverages the constructed IWTOs to perform precise abstract interpretation. By following the computed order, our analysis ensures effective convergence through strategic application of widening and narrowing operations at carefully selected points. This principled approach yields highly precise abstract states that serve as a foundation for various client analyses, such as buffer overflow detection, while maintaining analysis efficiency.

In summary, this paper makes the following major contributions:

- We introduce RecTopo, a new fixpoint computation approach for precise interprocedural abstract interpretation with enhanced efficiency. Our approach manages recursions precisely by leveraging interprocedural weak topological ordering (IWTO) and an interleaved strategy of widening and narrowing operations.

Table 1 Analysis domains and LLVM-like statement set.

- We introduce a scalable algorithm for constructing an IWTO for each recursion, designed to circumvent the high-cost construction of a whole-program weak topological ordering. This is accomplished by applying Tarjan's strongly connected component algorithm [61] on the call graph, which in turn guides the construction of IWTOs on the control flow graph.
- We comprehensively evaluate RecTopo's performance using 8312 programs from the NIST dataset and 10 real-world open-source projects. Experimental results show that RecTopo outperforms our baselines by achieving 31.99% higher precision and a 17.49% increase in recall rate on average. Furthermore, RecTopo shows an average precision improvement of 46.51% and a higher recall rate of 32.98% compared to baselines tools on ten open-source projects.

2 Background

This section provides the foundational knowledge of the language on which our abstract interpretation is based (see §2.1), as well as discussions on abstract interpretation (see §2.2) and weak topological ordering (see §2.3).

2.1 Language

Table 1 presents the analysis domains and LLVM-like statement set used in abstract interpretation. The set of program variables $\mathcal{V}$ is split into two disjoint subsets: $\mathcal{O}$, comprising *address-taken variables*, and $\mathcal{P}$, containing all *top-level variables*. Top-level variables $\mathtt{p}, \mathtt{q}, \mathtt{idx}, \mathtt{g} \in \mathcal{P}$ adhere to static single assignment (SSA) form and are subject to exactly one definition. Address-taken objects $\mathtt{o} \in \mathcal{O}$ can only be accessed through pointer dereferencing operations at Load/Store instructions. Constant values are initially bound to top-level variables through Cons instructions ($\mathtt{p} = \mathtt{c}$) that assign constants $\mathtt{c}$. Addr statements,

denoted as `p = &o`, allocate address-taken objects `o`, which may represent stack variables, global variables, or abstract heap objects. GEP enables structured access to composite objects: struct fields are accessed via constant offsets `fld`, while array elements use variable offsets `idx`. For field-sensitive analysis, RECTOPO employs a field-index-based strategy [12, 52], distinguishing struct fields through unique indices. COPY denotes a simple assignment of top-level variables/pointers. The PHI instruction, fundamental to SSA form, consolidates variable values at control flow merge points. BINARY and UNARY instructions represent arithmetic and bitwise operations, respectively. CALL and RETURN represents parameter passing and return value handling in function invocations.

2.2 Abstract Interpretation

Abstract interpretation offers a formalized framework for computing program semantics at each control point, represented as an abstract state specific to that point. The collection of all abstract states constitutes an abstract trace, denoted as σ (see Definition 2). The analysis iteratively updates σ by applying a semantic function – assumed to be monotonic to simplify the exposition – until reaching a fixpoint. This fixpoint yields a sound over-approximation of the program's behaviors.

▶ **Definition 1** (Concrete and Abstract Domains). *Let $\mathbb{C} = 2^{\mathcal{V}\to S}$ be the concrete domain, where S represents all possible runtime values. The abstract domain $\mathbb{A}$ forms a lattice $\langle \mathbb{A}, \sqsubseteq, \sqcap, \sqcup, \bot, \top \rangle$ with partial order $\sqsubseteq$. A Galois connection $\mathbb{C} \underset{\gamma}{\overset{\alpha}{\rightleftharpoons}} \mathbb{A}$ formalizes their relationship through abstraction function $\alpha : \mathbb{C} \to \mathbb{A}$ and concretization function $\gamma : \mathbb{A} \to \mathbb{C}$.*

▶ **Definition 2** (Abstract Trace $\sigma \in \mathbb{L} \to \mathbb{A}$). *An abstract trace maps control points to abstract states, where σ_L denotes the abstract state at control point $L \in \mathbb{L}$. Function $\sigma_L(x)$ yields variable x's abstract value at L. For a program statement ℓ, $\sigma_{\overline{\ell}}$ and $\sigma_{\underline{\ell}}$ represent the pre- and post-abstract states, respectively.*

Widening. The widening technique [24, 22] is introduced to ensure fixpoint termination and accelerate convergence by approximating infinite loop behavior. It involves choosing a subset of control points $\mathcal{L}' \subseteq \mathcal{L}$ as widening points. For each widening point $\ell_i \in \mathcal{L}'$, we use equation $\sigma_{\underline{\ell_i}} = \sigma_{\underline{\ell_i}} \nabla \Phi_i(\sigma_{\underline{\ell_1}}, \sigma_{\underline{\ell_2}}, \ldots, \sigma_{\underline{\ell_n}})$ instead of $\sigma_{\underline{\ell_i}} = \Phi_i(\sigma_{\underline{\ell_1}}, \sigma_{\underline{\ell_2}}, \ldots, \sigma_{\underline{\ell_n}})$ for fixpoint computation. In this equation, ∇ is a widening operator, which is formally defined on a poset $(\mathbb{A}, \sqsubseteq)$ that satisfies the following properties: (1) $\forall a, a' \in \mathbb{A}, a \sqcup a' \sqsubseteq a \nabla a'$ and (2) for an increasing chain $a_1 \sqsubseteq a_2 \sqsubseteq ... \sqsubseteq a_m$, the increasing chain $a'_1 \sqsubseteq a'_2 \sqsubseteq ... \sqsubseteq a'_m$ where $a'_1 = a_1$ and $a'_m = a'_{m-1} \nabla a_m$ eventually stabilizes. For example, the widening function on the integer interval domain $\mathcal{I} = \{[l, u] | l, u \in \mathbb{Z}\}$ is defined as: $[l_0, u_0] \nabla [l_1, u_1] = [\text{if } l_1 < l_0 \text{ then } -\infty \text{ else } l_0, \text{if } u_0 < u_1 \text{ then } +\infty \text{ else } u_0]$.

Narrowing. After the widening iteration converges to a fixpoint, a subsequent narrowing iteration, as described in [15, 24, 11, 39], aims to enhance the post solution through a downward fixpoint iteration. The narrowing operator Δ satisfies the following properties: (1) $\forall a, a' \in \mathbb{A}, a' \sqsubseteq a \implies a \Delta a' \sqsubseteq a$ and (2) for a decreasing chain $a_1 \sqsupseteq a_2 \sqsupseteq ... \sqsupseteq a_m$, the decreasing chain $a'_1 \sqsupseteq a'_2 \sqsupseteq ... \sqsupseteq a'_m$ where $a'_1 = a_1$ and $a'_m = a'_{m-1} \Delta a_m$ eventually stabilizes. For example, the narrowing operator on the integer interval domain $\mathcal{I}$ is defined as: $[l_0, u_0] \Delta [l_1, u_1] = [\text{if } l_0 = -\infty \text{ then } l_1 \text{ else } l_0, \text{if } u_0 = +\infty \text{ then } u_1 \text{ else } u_0]$.

2.3 Weak Topological Ordering (WTO)

WTO provides an arbitrary update of abstract states rather than strictly following the order of control points. This arbitrary update (also called *chaotic iteration* [20]) is proven not to affect the precision of fixpoint computation while having the potential to accelerate the convergence to the fixpoint [20, 21]. We first give some basic concepts of WTO and then delve into how WTO can be leveraged to enhance the precision of widening and accelerate the *chaotic iteration algorithm*.

▶ **Definition 3** (Hierarchical Ordering). *A hierarchical ordering of a set of elements V is a well-parenthesized permutation of V that does not contain consecutive "(".*

A hierarchical ordering of V induces a total order $\preceq$, a binary relation over the elements of V, where for any $v, w \in V$, either $v \preceq w$ or $w \preceq v$ holds, establishing a linear sequence. A *hierarchical component* is formed by a matching pair of "(" and ")", along with the sub-components or elements in V between them in the specified order. The hierarchical order could also be viewed as a tree, with leaf nodes representing the elements of V, and sub-trees (with non-leaf roots) representing hierarchical components. The first element of a hierarchical component is denoted as *component head*, which is highlighted using double underlining as $\underline{\underline{v}}$. The set of heads of the components containing the element v is denoted by $\omega(v)$. The depth of an element $v \in V$ is defined as $\delta(v) = |\omega(v)|$, which represents the depth of the leaf node corresponding to v in the tree.

▶ **Example 4.** "($\underline{\underline{1}}$ ($\underline{\underline{2}}$ 3))" is a valid hierarchical ordering of elements $\{1, 2, 3\}$. Both "($\underline{\underline{1}}$ ($\underline{\underline{2}}$ 3))" and "($\underline{\underline{2}}$ 3)" are hierarchical components with 1 and 2 being their respective component heads. The orders like "(1 ((2 3))" or "((1 2) 3)" are invalid hierarchical orders. The former is not *well-parenthesized*, and the latter contains consecutive "("s. Components have a hierarchical (nested) structure, meaning that one component can be a sub-component of another. For instance, "($\underline{\underline{2}}$ 3)" is a sub-component of "($\underline{\underline{1}}$ ($\underline{\underline{2}}$ 3))", thus $\omega(3) = \{1, 2\}$ and $\delta(3) = 2$.

▶ **Definition 5** (Weak Topological Ordering). *A weak topological ordering (WTO) of a directed graph $G = (V, E)$ is a hierarchical ordering of control points V such that for each edge $u \to v \in E$, $u \prec v \wedge v \notin \omega(u)$ or $v \preceq u \wedge v \in \omega(u)$. If an edge $u \to v$ satisfies $v \preceq u \wedge v \in \omega(u)$, $u \to v$ is called a back edge.*

▶ **Example 6.** One possible WTO of the intraprocedural control flow graph in Figure 3 is "1 ($\underline{\underline{2}}$ ($\underline{\underline{3}}$ 4) 5) 6". 2 and 3 are the WTO heads and $5 \to 2$ and $4 \to 3$ are back edges. It is clear that WTO precisely captures the nested loop structures within the graph. The inside loop is captured by "($\underline{\underline{3}}$ 4)" while the outside loop is "($\underline{\underline{2}}$ ($\underline{\underline{3}}$ 4) 5)".

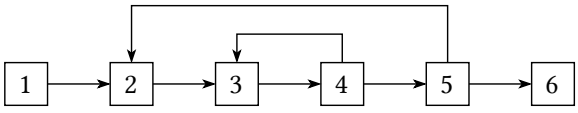

Figure 3 An example of control flow graph.

***WTO*-Guided Chaotic Iteration.** Given the explicit WTO of the control flow points, the chaotic iteration recursively computes a fixed point of the sub-components of each component in WTO every time the component reaches a fixed point [13]. WTO also provides an admissible set of widening points (the heads of WTO components) such that every loop in the program is cut by at least one widening point.

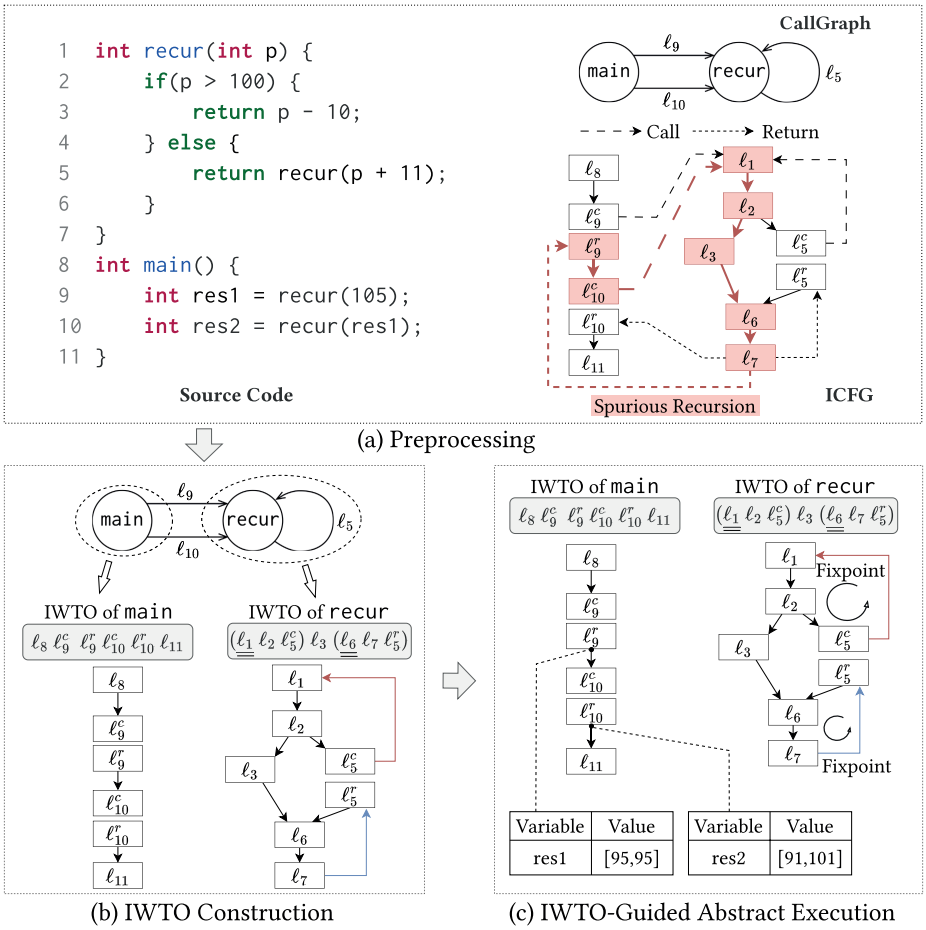

Figure 4 A motivating example by revisiting the example in Figure 1. It provides a detailed illustration of the phases of our framework, as shown in Figure 2.

***WTO* Construction.** WTO is constructed based on Bourdoncle's algorithm [32], which utilizes Tarjan's algorithm [61] to identify all strongly connected components (SCCs) in a directed graph. The algorithm repeatedly applies Tarjan's algorithm on the graph to break each found SCC into smaller SCCs until no further subdivision is possible. Each time an SCC is divided, smaller SCCs are ordered within the larger one in the WTO. The hierarchical structure of these components reflects the partial ordering of the WTO. Current abstract interpretation frameworks [15, 19, 18] compute WTO at the function level, applying the analysis intraprocedurally. However, the interprocedural fixpoint computation order remains implicit, as it is not guided by an interprocedural WTO structure.

3 Motivating Example

Figure 4 illustrates how RecTopo precisely determines the interprocedural fixpoint computation order and widening points by revisiting the example in Figure 1. We use the integer interval domain [17] to reason about its behaviors. The state-of-the-art analyzers, IKOS [15], Clam [19, 34] and CSA [18], all yield an imprecise top value $[-\infty, \infty]$ for `recur`'s return variable `res1` at ℓ_9 and `res2` at ℓ_{10}. In comparison, RecTopo derives a more precise result of $[95, 95]$ for `res1` and $[91, 101]$ for `res2`, demonstrating its precise interprocedural fixpoint computation order and widening strategies.

(a) Preprocessing. As shown in Figure 4(a), we first generate the call graph and interprocedural control flow graph (ICFG) of the analyzed program. In the call graph, we identify the function `recur` as a recursive function, and `main` as the caller. In the recursive function `recur`, we observe two distinct recursive calling paths: one from ℓ_1 to ℓ_5^c and another from ℓ_6 to ℓ_5^r. Note that, the cyclic path highlighted in red in the figure ($\ell_9^r \rightarrow \ell_{10}^c \dashrightarrow \ell_1 \rightarrow \ell_2 \rightarrow \ell_3 \rightarrow \ell_6 \rightarrow \ell_7 \dashrightarrow \ell_9^r$) is a spurious recursive path arising due to the consecutive call to the function `recur` at ℓ_9 and ℓ_{10}.

(b) IWTO Construction. Initially, we apply Tarjan's algorithm to the call graph, identifying two distinct function partitions: `main` and `recur`. Leveraging these partitions, we divide the original ICFG into two sub-ICFGs: one for `main` and another for `recur`. This division eliminates interprocedural edges between `main` and `recur`, as they are not part of the same recursive calling chain, according to the call graph's structure. Consequently, this approach removes the spurious recursion previously depicted in Figure 4(a) and prevents the redundant widening of this spurious recursion, thereby maintaining the precision as inlining-based methods for non-recursive functions. Furthermore, the true recursion within `recur` is comprehensively analyzed, resulting in an interprocedural weak topological ordering (IWTO) of "$(\underline{\underline{\ell_1}}\ \ell_2\ \ell_5^c)\ \ell_3\ (\underline{\underline{\ell_6}}\ \ell_7\ \ell_5^r)$" (where $\underline{\underline{\ell_1}}$ and $\underline{\underline{\ell_6}}$ are WTO heads). This analysis contrasts with approaches like IKOS [15], which typically omit the function body in recursive analyses, or Clam [19, 34] and CSA [18] which only perform widening on ℓ_1 and ℓ_7 without narrowing.

(c) IWTO-Guided Abstract Interpretation. The abstract interpretation illustrated in Figure 4(c) follows the order outlined in the IWTO constructed for the program. The execution begins at the `main` function and progresses through the call sites ℓ_9^c and ℓ_{10}^c. An interleaved widening and narrowing approach is employed to precisely approximate the behaviors of the two IWTO cycles within `recur`. Specifically, at the call site ℓ_9^c, the formal parameter `p` is initialized with the interval $[105, 105]$. As execution enters the first cycle $(\underline{\underline{\ell_1}}\ \ell_2\ \ell_5^c)$, a fixpoint is quickly reached with `p` remaining at $[105, 105]$, given that the path condition for the branch from ℓ_2 to ℓ_5^c is infeasible. Subsequently, at ℓ_3, the return value is calculated as $[95, 95]$. This value is then carried over to the second IWTO cycle $(\underline{\underline{\ell_6}}\ \ell_7\ \ell_5^r)$, where a fixpoint is again promptly achieved, resulting in a final return value of $[95, 95]$ for `res1`, much more precise compared to $[-\infty, \infty]$ for existing state-of-the-art tools [15, 19, 18]. Following this, the second invocation at ℓ_{10}^c uses the value of `res1`, $[95, 95]$, as the input for `p`, and re-engages with the IWTO of `recur`. In the first cycle, the initial widening operation expands `p` to $[95, \infty]$, followed by narrowing that refines the value to $[95, 111]$, which is subsequently propagated to ℓ_3 as $[101, 111]$. Consequently, upon returning to ℓ_{10}^r, the value of `res2` is determined to be $[91, 101]$, demonstrating consistently greater precision than IKOS, Clam and CSA.

4 RecTopo Approach

In this section, we introduce our approach for constructing interprocedural weak topological ordering in §4.1, followed by the algorithm for IWTO-guided abstract interpretation in §4.2. Additionally, we provide the proof of termination for our algorithm in §4.3.

4.1 IWTO Construction

The construction of IWTO consists of two stages. In the first stage (see §4.1.1), we perform program partitioning to divide the program into several function partitions (Definition 7). The second stage (see §4.1.2) involves constructing the IWTO on the ICFG for each resulting function partition from the first stage.

```
1  int main() {
2      recur1(20);
3      recur2(15);
4  }
5  int recur1(int i) {
6      if(i > 10)
7          return recur2(i - 1);
8      else
9          return i;
10 }
```

```
11 int recur2(int j) {
12     if(j > 10)
13         return recur1(j - 1);
14     else
15         return id(j);
16 }
17 // identity function
18 int id(int k) {
19     return k;
20 }
```

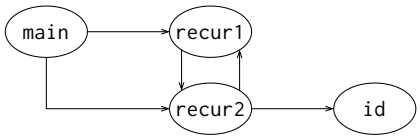

Figure 5 A recursion example and its call graph.

4.1.1 Program Partitioning

This stage aims to decompose the input whole program into several function partitions (see Definition 7) and identify all function partition entries (see Definition 8). The process of function partitioning segments the whole program analysis into manageable parts while ensuring that the functions within each recursive call are analyzed collectively and precisely. The identification of function partition entries is critical to guarantee that each IWTO is accurately constructed starting from the entry point as dictated by the program's call sites.

▶ **Definition 7** (Function Partition). *A function partition, denoted as* `FPar`*, consists of a set of functions that are directly or indirectly reachable from each other on the call graph.*

We apply Tarjan's algorithm [61] to the pre-built call graph of the analyzed program, identifying all strongly connected components (SCCs). Each SCC on the call graph corresponds to a distinct function partition. Non-recursive functions, being single-node SCCs, each forms an individual partition. For recursive functions, those within the same calling chain are aggregated into a single partition. Note that if a recursive function calls a non-recursive function, they are placed in separate partitions because the non-recursive function does not call back, meaning that they do not meet the criteria of mutual reachability required for placement in the same partition (Definition 7).

▶ **Definition 8** (Function Partition Entry). *For a function partition* `FPar`*, a function* $\texttt{f} \in \texttt{FPar}$ *is considered a function partition entry if and only if there exists a function* $\texttt{f}' \notin \texttt{FPar}$ *such that* $\texttt{f}'$ *calls* `f`*. In other words,* `f` *is an entry point to the partition* `FPar` *if it is invoked by at least one function outside of the partition.*

Function Partition Entries Identification. For each function `f` within a function partition `FPar`, we examine the predecessors of `f` on the call graph. If any predecessor $\texttt{f}'$ is found not to belong to `FPar`, then `f` is designated as a partition entry for that partition.

▶ **Example 9.** We illustrate the process of program partitioning with an example and its call graph in Figure 5. This example includes a mutual recursion between the functions `recur1` and `recur2`, invoked by `main` at locations ℓ_2 and ℓ_3, respectively. Additionally, the function `id` is called by `recur2` at location ℓ_{15}. Applying Tarjan's algorithm to this call graph results

Algorithm 1 IWTO construction algorithm.

```
   Input: G(V, E): ICFG of the program
          EMap: map from function partition to its partition entries
   Output: IMap: map from partition entry to IWTO
1  Function constructIMap(EMap, G):
2      IMap := {};
3      foreach (FPar → FParEns) ∈ EMap do
4          constructIWTO(FPar, FParEns, G, IMap);
5      return IMap;
6  Function constructIWTO(FPar, FParEns, G, IMap):
7      G_FPar(V_FPar, E_FPar) := ICFGPartition(G, FPar);          // Step 1
8      foreach v ∈ V_FPar do                                      // Step 2
9          if v is a non-recursive call site then
10             E_FPar := E_FPar ∪ (v, v.returnSite());
11     foreach entry ∈ FParEns do                                 // Step 3
12         entryICFGNode := Entry ICFG Node of entry;
13         IMap[entry] := Bourdoncle(G_FPar, entryICFGNode);
```

in three SCCs: {main}, {recur1, recur2}, and {id}. Each SCC corresponds to a distinct function partition. For the function partition {recur1, recur2}, both functions are identified as partition entries, as they are separately called by main at different locations.

4.1.2 IWTO Construction

For each function partition entry, we establish an interprocedural weak topological ordering (IWTO). As shown in Algorithm 1, the main function constructIMap (Lines 1-5) processes all function partitions of the analyzed program, alongside EMap, which maps each function partition to its function partition entries and aims to produce IMap, which maps each function partition entry to its respective IWTO. The subroutine constructIWTO defined at Lines 6-13 aims to construct IWTO for a specific function partition FPar and its associated entries FParEns. constructIWTO first extracts the subgraph corresponding to FPar on the ICFG, and then completes the extracted subgraph by connecting non-recursive calls and returns (Definition 10). Finally, based on the completed subgraph, it constructs an IWTO for each function partition entry and stores the results in IMap. The detailed steps of constructIWTO are outlined as follows:

Step 1: ICFG Partitioning. Given a function partition FPar, this step (Line 7) aims to extract the induced sub-ICFG corresponding to FPar from the ICFG of the entire input program. The resulting sub-ICFG is composed exclusively of ICFG nodes that are contained within a specific function from FPar.

▶ **Definition 10** (Recursive and Non-Recursive Call/Return Site). *A call site* $\ell^c\langle$caller, callee$\rangle$ *in the ICFG is defined as a recursive call site iff.* caller *and* callee *are in the same function partion. Else,* ℓ^c *is classified as a non-recursive call site. Each* ℓ^c *is associated with a corresponding return site* ℓ^r*, which facilitates the return from the callee function.*

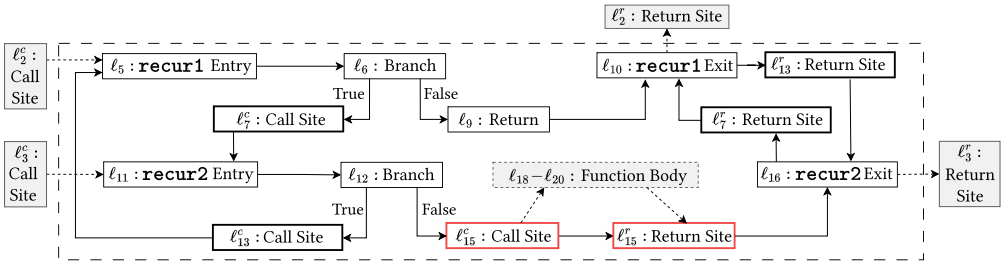

Figure 6 The sub-ICFG of function partition `recur1` and `recur2` by revisiting the example in Figure 5.

▶ **Example 11.** Figure 6 shows the sub-ICFG of function partition {`recur1`, `recur2`} for the code example in Figure 5. The call sites ℓ_7^c and ℓ_{13}^c are *recursive call sites* because their callee functions are recursive, and these calls occur within recursive functions (`recur1` and `recur2`). By comparison, the call sites ℓ_2^c and ℓ_3^c are considered *non-recursive* as they are located in the `main` function, which is not part of the recursion involving `recur1` or `recur2`. ℓ_{15}^c is also a *non-recursive call site* because its callee, `id`, is not a recursive function.

Step 2: Sub-ICFG Completion. This step (Lines 8-10) ensures that every node within the sub-ICFG extracted in Step 1 remains reachable from the entry of its corresponding function. During the ICFG partitioning in Step 1, all non-recursive return sites (Definition 10) become unreachable. This occurs because each non-recursive return site is initially linked to its corresponding call site via the callee function body; however, the callee function is excluded from the sub-ICFG because it does not belong to the current function partition. Therefore, we introduce an additional edge from each non-recursive call site directly to its respective return site.

Step 3: *IWTO* Construction. In this step (Lines 11-13), we employ Bourdoncle's algorithm [32] to build the IWTO for the completed sub-ICFG derived from Step 2. For each partition entry, denoted as `entry`, Bourdoncle's algorithm begins at the function entry node associated with the function partition entry, referred to as `entryICFGNode` in Algorithm 1. It then constructs an IWTO across the entire sub-ICFG, incorporating its interprocedural edges.

▶ **Example 12.** Let us revisit the example in Figure 5 and illustrate the three steps in Algorithm 1 used to construct the IWTO of the function partition {`recur1`, `recur2`}. In Step 1, we obtain an induced sub-ICFG shown in Figure 6, where call and return sites are delineated with bold outlines. Non-recursive call/return sites are denoted by ▭, whereas recursive call/return sites are indicated by ▭. In Step 2, since the ICFG nodes of `id` are excluded from the sub-ICFG in Step 1, the return site ℓ_{15}^r becomes unreachable from its call site. Consequently, we add an edge from the call site ℓ_{15}^c to its return site, ensuring reachability from the function entry within the sub-ICFG. Finally, in Step 3, we apply Bourdoncle's algorithm to the partition entries `recur1` and `recur2`, starting from their respective entry ICFG nodes, ℓ_5 and ℓ_{11}. Specifically, initiating from ℓ_5, we establish the IWTO as: "$(\underline{\underline{\ell_5}}\ \ell_6\ \ell_7^c\ \ell_{11}\ \ell_{12}\ \ell_{13}^c)\ \ell_9\ \ell_{15}^c\ \ell_{15}^r\ (\underline{\underline{\ell_{10}}}\ \ell_{13}^r\ \ell_{16}\ \ell_7^r)$". The IWTO starting from ℓ_{11} is outlined as: "$(\underline{\underline{\ell_{11}}}\ \ell_{12}\ \ell_{13}^c\ \ell_5\ \ell_6\ \ell_7^c)\ \ell_9\ \ell_{15}^c\ \ell_{15}^r\ (\underline{\underline{\ell_{16}}}\ \ell_7^r\ \ell_{10}\ \ell_{13}^r)$".

4.2 IWTO-Guided Abstract Interpretation

This section first presents the overall algorithm for fixpoint computation in §4.2.1, followed by an example set of feasible node-level interpretation rules that can be applied during the fixpoint computation in §4.2.2.

4.2.1 Abstract Interpretation Algorithm

Algorithm 2 presents the pseudo-code for IWTO-guided abstract interpretation, initialized by the `chaoticIteration` function (Line 1). This algorithm takes two inputs: a map linking each partition entry to its corresponding IWTO (`IMap`), as described in §4.1.2, and the program's entry function, `root` (e.g., the `main` function). Starting from `root`, which is a function partition entry (Definition 8), the function `handlePartition` iterates through the elements in its IWTO (Lines 5-9), processing each as either a single node (Line 7) or a cycle (Line 9), where cycles in the IWTO may represent either intraprocedural loops or recursive calls. For handling cycles, we apply the interleaved widening and narrowing strategy [10] to compute a fixpoint that considers both efficiency, achieved through widening, and precision, refined by narrowing.

The subroutine `handleNode`, detailed from Line 10 to Line 13 in Algorithm 2, processes individual nodes. At Line 11, the procedure begins by updating the abstract state node-wise, based on the semantics of the ICFG node. If this node is identified as a non-recursive call site (as defined in Definition 10), `handlePartition` is recursively invoked to process the corresponding callee function. Recursive call and return sites are treated similarly to normal intraprocedural nodes, as their analysis is integrated within the IWTO.

The algorithm for computing a fixpoint for a cycle is shown in the `stabilizeCycle` subroutine, delineated from Line 14 to Line 32 in Algorithm 2. It employs a while loop to continuously process the IWTO elements constituting the cycle. As mentioned in §2.3, each iteration of the loop begins by processing the component head of the IWTO using either widening or narrowing operations, outlined in Lines 18-27, followed by the process other IWTO components (Lines 28-32). The cycle commences with iterations where the widening operation is applied first (Lines 19-23) to the head node, aiming to accelerate the stabilization process. Once the widening has reached a fixpoint, where no changes in the abstract state are observed from one iteration to the next, the algorithm transitions to the narrowing phase (Lines 24-27). This phase refines the analysis's precision, following the methodologies proposed in [10]. The loop concludes when the narrowing phase also achieves a fixpoint, determined at Line 26, where a consistent abstract state is maintained post-narrowing from one loop iteration to the next.

4.2.2 Node-Level Interpretation Rules

Figure 7 demonstrates an example set of rules for handling each IWTO node, which can be applied at Line 11 in Algorithm 2. Note that these rules can be customized to perform other types of abstract interpretations, such as using different abstract domains or object sensitivity.

The interpretation of each node encompasses two fundamental steps: first, aggregating post-abstract states from predecessors to derive its pre-abstract state; second, transforming the pre-abstract state according to program semantics to obtain the post-abstract state. For interprocedural analysis, abstract states are aggregated via CallFlow and RetFlow rules, while intraprocedural states are gathered through the Sequence rule. Notably, CallFlow employs selective aggregation of abstract states from call sites: it blocks propagation from mismatching non-recursive call sites while allowing propagation from recursive call sites.

Algorithm 2 IWTO-guided abstract interpretation.

```
Input: IMap: map from partition entry to IWTO
       root: program entry function
Output: Abstract states of the program
1  Function chaoticIteration():                                  // Algorithm entry
2      handlePartition(dummyCall⟨_, root⟩);
3  Function handlePartition(callSite⟨caller, callee⟩):
4      IWTO := IMap[callee];
5      foreach elem ∈ IWTO do
6          if elem is a single node then
7              handleNode(callSite, elem);
8          else
9              stabilizeCycle(callSite, elem);
10 Function handleNode(pEntryCallsite, node):
11     Update abstract state of node;
12     if node is a non-recursive call site then
13         handlePartition(node);                                 // Inline
14 Function stabilizeCycle(pEntryCallsite, cycle):
15     head := cycle.getHead();                                   // Cycle head
16     increasing := true;
17     while true do
18         handleNode(pEntryCallsite, head);
19         if increasing then
20             Widen abstract state of head;                      // Widening
21             if abstract state of head not increasing then
22                 increasing := false;
23                 continue;
24         else
25             Narrow abstract state of head;                     // Narrowing
26             if abstract state of head not decreasing then
27                 break;
28         foreach elem ∈ cycle.getBody() do
29             if elem is a single node then
30                 handleNode(pEntryCallsite, elem);
31             else
32                 stabilizeCycle(pEntryCallsite, elem);
```

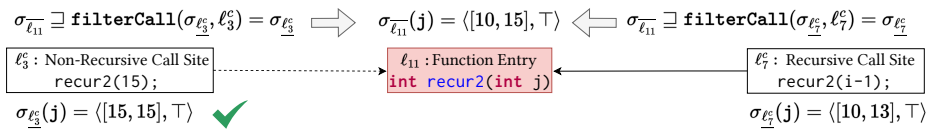
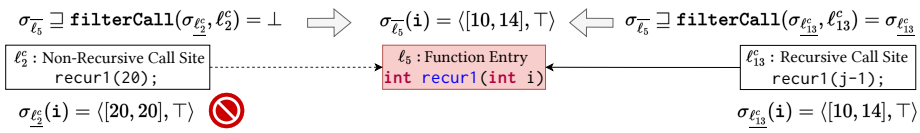
Figure 7 Rules for interpreting each node during abstract interpretation (Line 11 in Algorithm 2). $\ell@\texttt{caller} \hookrightarrow \ell'@\texttt{callee}$ and $\ell@\texttt{caller} \hookleftarrow \ell'@\texttt{callee}$ represent interprocedural control flows. The former indicates a flow from the CALL statement ℓ in `caller` to the entry ℓ' of the `callee` function, while the latter denotes a flow from the exit ℓ' of the `callee` back to the RETURN statement ℓ in `caller`. $\ell \overset{\texttt{cond}}{\hookrightarrow} \ell'$ denotes an intraprocedural control flow with path condition `cond`, whose value is null for unconditional flows. $a \sqsupseteq b$ represents $a := a \sqcup b$. $\mathtt{f}^{\#}$ is the abstract operator concerning the concrete operator `f`. $\alpha(\texttt{cond}(\mathtt{p}_i))$ abstracts the concrete values of $\mathtt{p}_i$ restricted by sequence condition `cond` based on Definition 1. $\mathtt{o.fld}_j$ represents the j^{th} field of the base object `o`.

▶ **Example 13.** Figure 8 illustrates this selective aggregation using the example in Figure 6, demonstrating the application of the CALLFLOW rule in deriving pre-abstract states for ℓ_{11} and ℓ_5. Consider the scenario where abstract interpretation progresses to invoking $\texttt{handlePartition}(\ell_3^c\langle\texttt{main}, \texttt{recur2}\rangle)$ to analyze the function partition $\{\texttt{recur1}, \texttt{recur2}\}$ from partition entry `recur2`. When deriving the pre-abstract state of ℓ_{11}, as shown in Figure 8a, both $\sigma_{\underline{\ell_7^c}}$ and $\sigma_{\underline{\ell_3^c}}$ are permitted to propagate. This is because ℓ_7^c is a recursive call site, whereas ℓ_3^c, while non-recursive, matches the current partition entry's call site, denoted as `pEntryCallsite` in Algorithm 2 at Line 10. Conversely, as shown in Figure 8b, when deriving the pre-abstract state of ℓ_5, $\sigma_{\underline{\ell_2^c}}$ is blocked because ℓ_2^c does not match `pEntryCallsite`, ℓ_3^c, whereas $\sigma_{\underline{\ell_{13}^c}}$ propagates due to the recursive nature of ℓ_{13}^c.

The RETFLOW rule facilitates the propagation of abstract states from a callee function's exit node to the corresponding return site. The SEQUENCE rule refines abstract values based on control flow edge conditions. Figure 9 demonstrates this refinement process for deriving the pre-abstract state of ℓ_{13}^c. Since the incoming edge from ℓ_{12} requires condition `i > 10` to hold, we refine the abstract value of `i` in $\sigma_{\underline{\ell_{12}}}$ by computing its meet with $[11, \infty]$.



(a) Deriving the pre-abstract state $\sigma_{\overline{\ell_{11}}}$ during running $\texttt{handlePartition}(\ell_3^c\langle \texttt{main}, \texttt{recur2} \rangle)$.



(b) Deriving the pre-abstract state $\sigma_{\overline{\ell_5}}$ during running $\texttt{handlePartition}(\ell_3^c\langle \texttt{main}, \texttt{recur2} \rangle)$.

Figure 8 Illustration of the CallFlow rule for deriving pre-abstract state of ℓ_{11} and ℓ_5 by revisiting the example in Figure 6.

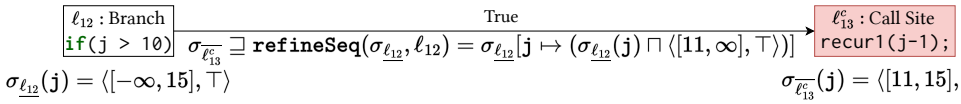


Figure 9 Illustration of the Sequence rule for deriving the pre-abstract state $\sigma_{\overline{\ell_{13}^c}}$ by revisiting the example in Figure 6.

The post-abstract state $\sigma_{\underline{\ell}}$ of node ℓ is derived from its pre-abstract state $\sigma_{\overline{\ell}}$ and the relevant statement. For pointer-free statements (Cons, Copy, Phi, Unary, Binary, Call and Return), we calculate the abstract value of the left-hand-side variable based on the right-hand-side values and relevant operators. For instance, given a Binary statement $\ell : \texttt{r} = \texttt{p} + \texttt{q}$ and $\sigma_{\overline{\ell}}(\texttt{p}) := \langle [1, 3], \top \rangle, \sigma_{\overline{\ell}}(\texttt{q}) := \langle [4, 7], \top \rangle$, we derive $\sigma_{\underline{\ell}}(\texttt{r}) := \langle [5, 10], \top \rangle$. Particularly, since Call and Return statements involve parameter and return value passing – essentially top-level variable assignments – we handle each assignment using the Copy rule for translation. For pointer-related statements (Gep, Load and Store), we utilize abstract values across interval and address domains to derive the post-abstract state. To elaborate, for Gep, we join all potential address values formed by adding a base address $\texttt{o} \in \gamma(\sigma_{\overline{\ell}}(\texttt{p}))$ with an offset $\texttt{j} \in \gamma(\sigma_{\overline{\ell}}(\texttt{idx}))$ to derive the conservative address value for the left-hand-side variable. As for Load, we join the abstract values $\sigma_{\overline{\ell}}(\texttt{o})$ of all possible addresses $\texttt{o} \in \gamma(\sigma_{\overline{\ell}}(\texttt{q}))$ to form the conservative abstract value of the left-hand-side variable. Lastly, for Store, we update the abstract value of every possible address $\texttt{o} \in \gamma(\sigma_{\overline{\ell}}(\texttt{p}))$. Particularly, when there are multiple addresses $\texttt{o} \in \gamma(\sigma_{\overline{\ell}}(\texttt{p}))$, we join the abstract value $\sigma_{\overline{\ell}}(\texttt{q})$ with each existing abstract value $\sigma_{\overline{\ell}}(\texttt{o})$ to form o's new abstract value conservatively. In contrast, when there is only one $\texttt{o} \in \gamma(\sigma_{\overline{\ell}}(\texttt{p}))$, it is safe to directly use $\sigma_{\overline{\ell}}(\texttt{q})$ as o's new abstract value, because the store must occur at o.

▶ **Example 14.** We revisit the example in Figure 5 to illustrate the IWTO-guided abstract interpretation. It starts with $\texttt{handlePartition}(\ell_0\langle _, \texttt{main} \rangle)$. The IWTO of main function is outlined as "$\ell_1\ \ell_2^c\ \ell_2^r\ \ell_3^c\ \ell_3^r\ \ell_4$". Both ℓ_2^c and ℓ_3^c are non-recursive call sites, which require invoking handlePartition to handle their callee functions. Take ℓ_3^c as an example. $\texttt{handlePartition}(\ell_3^c\langle \texttt{main}, \texttt{recur2} \rangle)$ follows the IWTO of function partition {recur1, recur2}, which is outlined as "$(\underline{\underline{\ell_{11}}}\ \ell_{12}\ \ell_{13}^c\ \ell_5\ \ell_6\ \ell_7^c)\ \ell_9\ \ell_{15}^c\ \ell_{15}^r\ (\underline{\underline{\ell_{16}}}\ \ell_7^r\ \ell_{10}\ \ell_{13}^r)$", to perform abstract interpretation. The first element of the IWTO, "$(\underline{\underline{\ell_{11}}}\ \ell_{12}\ \ell_{13}^c\ \ell_5\ \ell_6\ \ell_7^c)$", is a cycle, with ℓ_{11} being the head. To handle the cycle, the function stabilizeCycle is

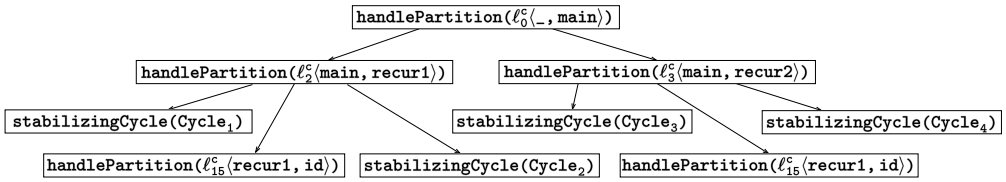

Figure 10 Recursion tree of algorithm 2 executing on the program presented in Figure 5.

invoked, which iteratively updates the abstract states of the nodes within the cycle. The iteration involves two stages, the widening stage and the narrowing stage. We elaborate on the widening and narrowing stages using the updating process of $\sigma_{\overline{\ell_{11}}}(\mathtt{j})$, as ℓ_{11} is the only widening point of the cycle. During the widening stage, it is initialized as $\langle[15, 15], \top\rangle$ in the first iteration. In the second iteration, it is first updated to $\langle[13, 15], \top\rangle$, and then widened to $\langle[-\infty, 15], \top\rangle$ (refer back to §2.2). The iteration then proceeds to the narrowing stage, during which $\sigma_{\overline{\ell_{11}}}(\mathtt{j})$ is updated to $\langle[10, 15], \top\rangle$, refining the value obtained in the widening stage. This refinement benefits from the adjustments made in the SEQUENCE rule while deriving the pre-abstract state of ℓ_7^c. With the conclusion of the narrowing stage, `stabilizeCycle` finalizes, and the abstract interpreter continues to address the remainder of the IWTO. After finalizing its handling of the entire IWTO, the abstract interpreter proceeds to addressing ℓ_3^r and concludes that the return value of this recursion, entering from ℓ_3^c, is exactly 10. This exact value also benefits from the refinement conducted by the SEQUENCE rule while deriving the pre-abstract state of ℓ_{15}^c.

4.3 Termination Analysis

This section aims to prove that Algorithm 2 is guaranteed to terminate, even in the presence of nested recursions and loops in the input program. Algorithm 2 begins with `chaoticIteration`, which calls `handlePartition` to handle the dummy call site to `root`, the program entry function. It then enters a mutual recursion among three functions: `handlePartition`, `handleNode` and `stabilizeCycle`. Due to the simplicity of `handleNode`, we inline it at the invoking sites in Lines 7 and 30 for the convenience of the proof. In order to model the recursion described in Algorithm 2, we introduce the concept of *recursion tree*.

▶ **Definition 15** (Recursion Tree). *The recursion tree, denoted as a triple $T = (N, E, r)$, models the invocation process of a running algorithm. The set N is non-empty and consists of nodes, where each $n \in N$ represents an instance of a function invocation with specific parameters during the recursive process. The set $E \subseteq N \times N$ comprises edges, where an edge $(n_1, n_2) \in E$ indicates that function n_1 calls n_2 during the recursion. The element $r \in N$ denotes the root node of T, representing the initial function that starts the recursive calls.*

▶ **Example 16.** Figure 10 demonstrates the recursion tree of Algorithm 2 as it executes on the program presented in Figure 5. The root node indicates that the recursion of Algorithm 2 begins with `handlePartition`($\ell_0^c\langle$_, `main`$\rangle$), where $\ell_0^c\langle$_, `main`$\rangle$ denotes a dummy call to the program entry, `main`. Additionally, the two edges of the root node indicates that it invokes each child subroutine once during execution.

Since all operations in the functions `handlePartition` and `stabilizeCycle` are trivial and guaranteed to terminate, the overall termination of the algorithm can be reduced to the termination of the recursive process. This is equivalent to stating that the recursion tree of Algorithm 2 contains a finite number of nodes for any input.

▶ **Lemma 17.** *The recursion tree of Algorithm 2 on any input has finite height.*

Proof. Consider a path (sequence of nodes) starting from the root node in the recursion tree. We will show that the number of nodes along this path is bounded by analyzing the invocations of two specific functions: `handlePartition` (referred as P nodes) and `stabilizeCycle` (reffered as S nodes). These are the only types of nodes present on the path, as we have inlined all `handleNode` invokations for simplicity.

First, we examine the subsequence of `handlePartition` calls, denoted as:

$$P_1(\ell_1^c\langle \texttt{caller}_1, \texttt{callee}_1\rangle), \ldots, P_m(\ell_m^c\langle \texttt{caller}_m, \texttt{callee}_m\rangle).$$

We use $FP(\texttt{f})$ to denote the unique function partition to which function `f` belongs. It follows that for all $i \in [1, m-1]$, $FP(\texttt{callee}_i) = FP(\texttt{caller}_{i+1})$. Consequently, for all $i < j$, $\texttt{caller}_j$ is reachable from $\texttt{caller}_i$ on the call graph. We aim to prove the following sub-conclusions. **Sub-conclusion 1**: For all $i \leq j$, $FP(\texttt{caller}_i) \neq FP(\texttt{callee}_j)$. Suppose this were not the case. Then, there would exists $i \leq j$ such that $FP(\texttt{caller}_i) = FP(\texttt{callee}_j)$, implying that $\texttt{caller}_i$ is reachable from $\texttt{callee}_j$. Furthermore, it follows that $\texttt{caller}_j$ would also be reachable from $\texttt{callee}_j$, which contradicts the definition of $\texttt{v}_j\langle \texttt{caller}_j, \texttt{callee}_j\rangle$ as a non-recursive call site (according to Definition 10). **Sub-conclusion 2**: For all $i < j$, $FP(\texttt{caller}_i) \neq FP(\texttt{caller}_j)$. This follows directly from Sub-conclusion 1 and $FP(\texttt{callee}_i) = FP(\texttt{caller}_{i+1})$. If $FP(\texttt{caller}_i) = FP(\texttt{caller}_j)$ for some $i < j$, it would contradict Sub-conclusion 1. **Sub-conclusion 3**: $m \leq |FPars|$, where $|FPars|$ denotes the number of function partitions in the program. If this were false, then there would exist at least one pair $i < j$ such that $FP(\texttt{caller}_i) = FP(\texttt{caller}_j)$, which would contradict Sub-conclusion 2.

Second, we examine a *continuous* subsequence of `stabilizeCycle` invocations,

$$S_1(\texttt{cycle}_1), \ldots, S_n(\texttt{cycle}_n).$$

For this sequence, the inequality $n < \texttt{cycle}_1\texttt{.depth}$ is established, where $\texttt{cycle}_1\texttt{.depth}$ denotes the depth of the $\texttt{cycle}_1$. This holds because $\texttt{cycle}_{i+1}$ is a sub-IWTO component of $\texttt{cycle}_i$. Furthermore, the number of continuous S subsequences is limited to length of the longest P subsequence on the path, which, as previously concluded, is $|FPars|$. Consequently, the total number of S nodes on the path is limited to $|FPars| \times maxCycleDepth$, where $maxCycleDepth$ is the maximum depth of all IWTO cycles.

Finally, since the path consists solely of P and S nodes, the length of the path is less than $|FPars| \times (maxWTOdepth + 1)$. ◀

▶ **Lemma 18.** *The recursion tree of Algorithm 2 for any input has finite degree.*

Proof. To establish this, we consider two cases. **Case 1:** For a $P(\ell^c\langle \texttt{caller}, \texttt{callee}\rangle)$ node, its degree is limited by the number of elements in `callee`'s corresponding IWTO. **Case 2:** For a $S(\texttt{cycle})$ node, its child nodes represent the invoked subroutines within the double-nested loop outlined in Algorithm 2 from Lines 17 to 32. The outer loop is guaranteed to terminate within h rounds [13], where h represents the height of the lattice when applying the widening operation. The inner loop is bounded by the number of elements in `cycle`. Thus, the degree of an S node is also finite.

In both cases, the degree of the nodes are limited, confirming that the recursion tree has finite degree. ◀

Proof. By Lemmas 17 and 18, both the height and the breadth of the recursion tree are limited. Consequently, the recursion tree contains a finite number of nodes, which implies the termination of Algorithm 2. ◀

5 Evaluation

In this section, we evaluate the performance of RecTopo, focusing on its precision improvement in abstract interpretation and its scalability when applied to large-scale programs. We conduct a comparative analysis between RecTopo and three state-of-the-art abstract interpreters, IKOS [15], Clam [19, 34] and CSA [18], in an assertion-checking client, buffer overflow detection.

Additionally, we perform an ablation study to assess the influence of the IWTO implementation on the overall effectiveness of RecTopo.

Our empirical evaluation addresses the following research questions:

RQ1 **Analysis Effectiveness:** How effective is RecTopo in detecting buffer overflow vulnerabilities compared to state-of-the-art tools when evaluated on standard NIST benchmarks?

RQ2 **Real-world Applicability:** To what extent can RecTopo scale to analyze real-world applications while maintaining its precision in bug detection?

RQ3 **Impact of IWTO:** What is the contribution of the IWTO technique to RecTopo's overall performance, particularly regarding precision improvements and computational overhead?

5.1 Datasets and Implementation

Datasets. We evaluate RecTopo using (1) a benchmark composed of 8312 programs from NIST [46], which includes comprehensive test cases of buffer overflow vulnerabilities, with 800 cases containing recursions, and (2) 10 popular open-source C/C++ projects across various application domains, with their statistics detailed in Table 2. These projects include `paste` [16] (file merger), `md5sum` [16] (file verifier), `YAJL` [4] (JSON parsing library),

Table 3 Comparison of tools using the NIST benchmark, with the recall and precision in percentages (%). "NIST (entire)" refers to the entire dataset, while "NIST (recursion)" specifies the test cases that have recursions.

Dataset	Metric	IKOS	Clam	CSA	RecTopo
NIST (entire)	Recall (%)	53.90	55.29	80.83	**80.83**
	Precision (%)	46.38	37.18	78.38	**85.97**
NIST (recursion)	Recall (%)	100.00	100.00	100.00	**100.00**
	Precision (%)	50.00	50.00	55.56	**95.24**

`8cc` [7] (C compiler), `libplist` [8] (Property List file handler), `MP4v2` [2] (MP4 file library), `RIOT` [3] (IoT operating system), `darknet`[1] (neural network framework), `tmux` [5] (terminal multiplexer) and `Teeworlds` [9] (online multiplayer game).

Implementation. The experiments are conducted on an Ubuntu 22.04 server with an eight-core 2.60GHz Intel Xeon CPU and 128 GB memory. The interprocedural control and value flow graphs are built upon LLVM-IR (with LLVM version 14.0.0) using the SVF library (version 2.9). The LLVM-IR represents program functions as global variables, further modeled as address-taken variables. The call graph is built by considering the points-to information to resolve indirect calls. Program loops/recursions are captured by IWTO, which is constructed using the algorithm described in Section 4.1 (Algorithm 1). The abstract value representation is implemented using Z3 expressions [45]. We utilize the interleaved widening and narrowing strategy as described in [10] to precisely handle recursions and intraprocedural loops. We detect buffer overflows at each `gep` instruction by comparing the offset size and the memory size, both of which are calculated based on interval and points-to information from abstract interpretation. For the baselines IKOS, Clam and CSA, we directly use their open-source implementations and their default settings (e.g., interval analysis) for detecting buffer overflows.

5.2 RQ1: NIST Benchmark

Table 3 presents the true positive rates and precision of RecTopo along with three baseline abstract interpreters in detecting buffer overflows [28, 29, 30] using the pre-labeled NIST benchmark, NIST (complete), and its subset containing test cases that includes recursive functions, NIST (recursion).

Comparison Results. For the complete NIST dataset, RecTopo consistently surpasses the baseline tools. It identifies, on average, 26.24% more buffer overflows than IKOS and Clam, while also achieving an average precision improvement of 44.19% over these tools. Its precision is also 7.59% higher than CSA. This performance underscores the robustness of RecTopo in interprocedural abstract interpretation. Moreover, the advantages of RecTopo are particularly notable in scenarios involving recursive functions, where it achieves a precision rate of 95.24% in detecting buffer overflows. In contrast, the average precision of IKOS, Clam and CSA in these test cases is only approximately 51.85%, 43.39% lower than RecTopo.

Result Analysis. The improved recall can be attributed to RecTopo's adoption of CSA's robust handling of core program features, such as loop handling, and precise external API modeling [18]. Here, we focus on analyzing the precision improvements in handling recursion

```c
int mc91(int p) {
    if(p > 100) {
        return p - 10;
    } else {
        int p1 = p + 11;
        int p2 = mc91(p1);
        int res = mc91(p2);
        return res;
    }
}
int main() {
    char buf[200];
    int idx = mc91(100);
    buf[idx] = 0;
}
```

(a) Recursive function.

```c
int sum = 0;
void adder(int num) {
    sum += num;
}
int main() {
    char buf[10];

    // call adder twice
    int m = 1;
    adder(m);
    int n = 2;
    adder(n);

    buf[sum] = 0;
}
```

(b) Multiple call sites.

Figure 11 False buffer overflows eliminated by RecTopo.

```c
int modNb(int n) {
    if (n - 9 >= 0)
        return n;
    else
        return modNb(n + 1);
}
int main() {
    char buf[10];
    int idx = modNb(0);
    buf[idx] = 0;
}
```

(a) Complex path condition.

```c
int sum(int n, int m) {
    if (n <= 0)
        return m + n;
    else
        return sum(n - 1,m + 1);
}
int main() {
    char buf[10];
    int idx = sum(9, 0);
    buf[idx] = 0;
}
```

(b) Variable correlations.

Figure 12 False positives of RecTopo.

through two representative code scenarios shown in Figure 11. A key contributing factor is RecTopo's construction of IWTO for recursive functions, which effectively guides the narrowing process by leveraging program path conditions. As demonstrated in Figure 11(a), the program accesses the `buf` buffer at ℓ_{14} with an offset `idx`, which is obtained from the return value of the `mc91(100)` function call at ℓ_{13}. RecTopo precisely determines `mc91`'s return value in the range $[91, 101]$. Consequently, it concludes that the buffer access at ℓ_{14} is safe. In contrast, all our baseline analyses report an overflow alarm here, incorrectly indicating that the value of `mc91(100)` could be anywhere within $[-\infty, \infty]$.

Another reason is that the IWTO construction approach effectively eliminates spurious recursions (widening points) arising from multiple call sites of the same function, such as the double call to `adder` in Figure 11(b). RecTopo accurately differentiates between these call sites, preventing misclassification of program points, $\ell_{12}, \ell_2 - \ell_4, \ell_{10}, \ell_{11}$, as part of a spurious recursion. This precision prevents RecTopo from widening the value of `sum` at the `adder` entry point (ℓ_2) to $[0, \infty]$. Consequently, RecTopo derives the precise value of `sum` at ℓ_{14} as $[3, 3]$, thereby eliminating a false overflow alarm.

Table 4 Comparing RecTopo with three open-source tools (IKOS, Clam and CSA), using ten popular applications. #TP and #FP are true positive and false positive, respectively. Time (secs) is running time.

Project	IKOS			Clam			CSA			**RecTopo**

False Positives of *RecTopo*. We further analyze RecTopo's false positives and identify two primary causes, as demonstrated in the examples in Figure 12. First, RecTopo compromises precision for efficiency in scenarios involving complex path conditions. A case in point is its failure to accurately interpret the path condition at ℓ_2 in Figure 12(a), resulting in an imprecise narrowing of the range of `n` after widening. This imprecision triggers the overflow alarm at ℓ_{10}. This issue primarily stems from the limitations of the abstract interpretation solver, which, although not a key contribution of RecTopo, affects its precision. Enhancing the solver's capability for precise path condition interpretation could rectify this. Another source of precision loss is RecTopo's inability to track relationships between variables. This limitation is illustrated in Figure 12(b), where the parameters `m` and `n` have a constraint that their sum at each call site remains constant. However, RecTopo's interval domain representation only allows for the independent storage of their abstract states, thus failing to capture their interrelation. As a result, when the parameter `m` is widened to $[0, \infty]$, RecTopo over-approximates `idx`'s range as $[0, \infty]$. Adopting a relational domain to articulate the constraints between program variables could overcome this limitation.

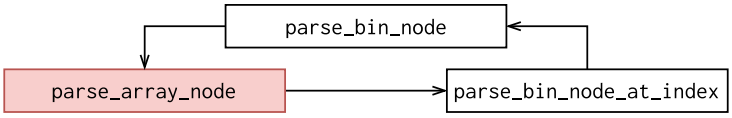
5.3 RQ2: Real-World Projects

Table 4 presents the experimental results for true positives, false positives and running time of RecTopo compared to the three existing tools (IKOS, Clam and CSA) on ten real-world projects.

Comparison Results and Analysis. RecTopo demonstrates superior performance across all metrics, successfully identifying 75 real bugs with a precision rate of 65.79%, representing 79.78% of all identified vulnerabilities. In contrast, IKOS and Clam achieve an average recall rate of only 30.32% among discovered bugs. The precision rates of the baseline tools average 19.28%, less than one-third of RecTopo's precision. Notably, RecTopo achieves these significant improvements while maintaining computational efficiency comparable to CSA.

```
1  static plist_t parse_array_node(struct bplist_data *bplist,
2                                  const char** bnode, uint64_t size)
3  {
4      plist_data_t data = plist_new_plist_data();
5      const char *index1_ptr = NULL;
6      ...
7      for (uint64_t j = 0; j < size; j++) {
8          index1_ptr = (*bnode) + j * bplist->ref_size;
9  +       if (index1_ptr < bplist->data ||
10 +           index1_ptr + bplist->ref_size >=
11 +           bplist->data + bplist->size) {
12 +               plist_free(node);
13 +               return NULL;
14 +       }
15         index1 = UINT_TO_HOST(index1_ptr, bplist->ref_size);
16     ...
17 }
```

Patch



Call Graph

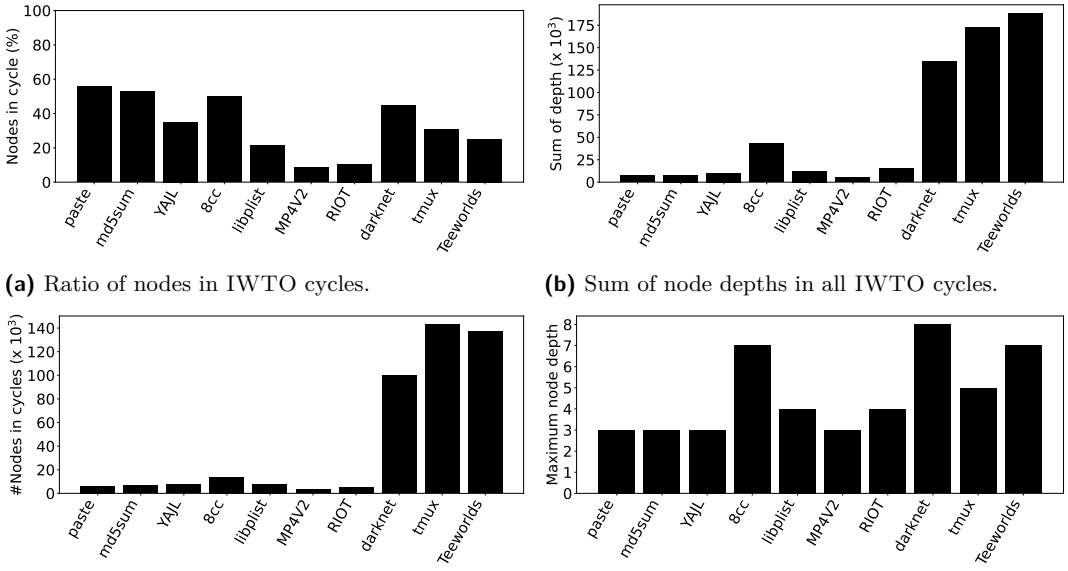
Figure 13 The patch and call graph of a real-world buffer overflow in `libplist` [8] found by our tool.

The markedly lower false positive rate of RecTopo can be attributed to its sophisticated abstract interpretation framework, guided by the IWTO approach. This methodology enables precise derivation of abstract states within recursive contexts through carefully orchestrated interleaved widening and narrowing operations on recursions.

Case Study. Figure 13 illustrates the patch [6] and call graph for a real-world buffer overflow identified by RecTopo in `libplist` [8], a portable C library to handle Property List files [53]. RecTopo and CSA initially find this bug, which is missed by Clam and IKOS. However, after the bug is patched, CSA erroneously continue to report it as a buffer overflow – resulting in false positives. By comparison, RecTopo accurately eliminates the false alarm after the bug is fixed.

The bug resides in the `parse_array_node` function, within a recursive calling chain as depicted in Figure 13. It is triggered at line ℓ_{15}, where the function `UINT_TO_HOST` accesses the address pointed by `index1_ptr` and reads an extra `bplist→ref_size` bytes. This bug arises because `bplist→ref_size`, the buffer access variable in the recursion, is not properly bounded, potentially allowing reads past the allocated buffer of `index1_ptr`, leading to a buffer overflow. When the issue is addressed by introducing a boundary check before ℓ_{15}, RecTopo stops reporting the problem, while CSA still signal a bug. This discrepancy is attributed to our utilization of widening and narrowing techniques within the recursive function partition, which precisely leverage path conditions to refine the abstract value of `bplist→ref_size`, thereby providing more accurate results and effectively eliminating the false positive.

Statistics. We present detailed statistics of IWTO across the ten real-world projects. Figure 14a illustrates the proportion of nodes residing in IWTO cycles for each program. The data reveals a substantial presence of nodes within IWTO cycles, ranging from 8.4% to



(a) Ratio of nodes in IWTO cycles.

(b) Sum of node depths in all IWTO cycles.

(c) Number of nodes in IWTO cycles.

(d) Maximum node depth in the IWTO.

Figure 14 Statistics of IWTO in real-world programs.

55.9%, with an average of 33.5%. Figure 14b depicts the aggregate depth of nodes (as defined in §2.3) across all IWTO cycles in each program. The data exhibits a near-linear growth pattern relative to program size. Given that the time complexity for cycle stabilization is linear with respect to the sum of node depths [13], this suggests that the overall time complexity for stabilizing IWTO cycles scales approximately linearly with program size. Figure 14c presents the number of nodes within IWTO cycles per program, while Figure 14d shows the maximum node depth in each program's IWTO. The data demonstrates that while the number of nodes in cycles increases linearly with program scale, the maximum depth remains relatively stable. This relationship explains the linear growth pattern observed in the aggregate node depth measurements.

5.4 RQ3: Ablation Analysis

This section presents a comprehensive ablation analysis of RecTopo, with a focus on evaluating its precision enhancements and scalability.

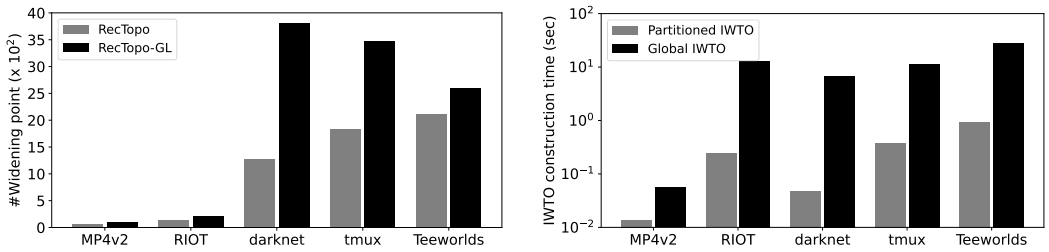
We compare RecTopo with two distinct variants: RecTopo-NR, which omits recursive calls by assigning a default top value; and RecTopo-GL, which integrates a whole-program global IWTO. This comparative analysis underscores the critical contributions of IWTO in enhancing both precision and scalability.

Table 5 presents the true positives, false positives and running time of RecTopo compared to its two variants (RecTopo-NR and RecTopo-GL) on real-world popular applications. The results demonstrate that the IWTO employed in RecTopo significantly enhances precision while incurring only a moderate increase in computational overhead.

Comparison with *RecTopo*-NR. RecTopo exhibits 60.41% higher precision than RecTopo-NR. This superior precision stems from RecTopo's ability to more precisely calculate the values of variables within recursive functions. In contrast, RecTopo-NR simplifies the process by assigning a generic top value to these variables.

Table 5 Comparing RecTopo with its two variants, RecTopo-NR and RecTopo-GL (described in §5.4), using ten popular applications. #TP and #FP are true positive and false positive, respectively. Time (secs) is running time.

Project	RecTopo-NR			RecTopo-GL			**RecTopo**		
	Report		Time	Report		Time	Report		Time
	#TP	#FP	(secs)	#TP	#FP	(secs)	#TP	#FP	(secs)
`paste`	3	13	8	3	32	15	3	0	12
`md5sum`	4	9	6	4	36	13	4	2	10
`YAJL`	3	62	3	3	97	12	3	0	9
`8cc`	3	85	30	3	108	44	3	5	38
`libplist`	5	119	39	5	230	52	5	8	49
`MP4v2`	1	131	11	1	193	23	1	0	16
`RIOT`	8	126	22	8	285	35	8	4	31
`darknet`	21	217	3168	21	914	4211	21	7	3725
`tmux`	12	253	727	12	1322	1247	12	5	983
`Teeworlds`	15	304	2491	15	1641	3416	15	8	3032
Total	75	1319	6505	75	4858	9068	**75**	**39**	7905



(a) (b)

Figure 15 (a) Comparing the number of widening points of RecTopo and RecTopo-GL on real-world programs and (b) Comparing IWTO construction time of partitioned and global IWTO on real-world programs.

This overly conservative approaches of RecTopo-NR results in broader intervals that frequently trigger false overflow alarms during buffer access. In terms of performance efficiency, RecTopo-NR leads in execution speed as it bypasses the body of recursive functions entirely.

However, the slight time advantage of RecTopo-NR does not compensate for the substantial precision gains achieved by RecTopo, reinforcing its effectiveness in balancing precision with performance.

Comparison with *RecTopo*-GL. RecTopo-GL implements a global whole-program IWTO that establishes connections between all call sites and their corresponding callee functions. The abstract interpretation within RecTopo-GL is managed by this singular IWTO, with each cycle processed with precision comparable to that of RecTopo. Despite this, RecTopo-GL demonstrates a reduction in precision by 64.27%, and it also operates 1.15× longer compared to RecTopo.

The reduced precision in RecTopo-GL can be primarily attributed to its redundant widening operations. As depicted in Figure 15a, RecTopo achieves a significant decrease in the number of widening points, with an average reduction of 58.99% and a peak reduction of

up to 81.56%. This substantial decrease in unnecessary widening throughout various program procedures directly contributes to the enhanced precision of RecTopo. Regarding scalability, the comparison of the time required to construct IWTO in RecTopo and RecTopo-GL highlights significant differences. Figure 15b clearly shows that constructing a whole-program IWTO in RecTopo-GL demands considerably more time – nearly 36 times longer – than the IWTO approach used in RecTopo. This comparison underscores the efficiency and practicality of the partitioned approach in handling scalability.

6 Related Work

Our discussion centers on areas closely related to RecTopo, specifically focusing on abstract interpretation, fixpoint computation, and recursion handling in program analysis.

Abstract Interpretation. Abstract interpretation [24, 27] serves as the theoretical foundation for numerous static analysis techniques, encompassing program verification [31, 15, 42, 66, 67], data-flow analysis [50, 51], and static bug detection [59, 60, 18, 55, 56, 63, 48]. These techniques are fundamentally designed to ensure both state over-approximation and analysis termination. Some approaches [48, 36] utilize sparse abstract interpretation framework that propagates abstract states through def-use chains instead of control flows. In contrast, our work operates within the context of control-point-based analysis. Note that this assumption is a design choice made to align with classical abstract interpretation formulations [13, 18, 20, 40, 47], though our approach is not fundamentally restricted to this scope. Weiss et al. [65] proposes database-backed analysis with graph algorithms to enhance both scalability and precision. More recently, Cheng et al. [18] developed cross-domain abstract interpretation to track correlations across different abstract domains. While significant, these approaches are orthogonal to our work.

Fixpoint Computation. Fixpoint computation, originally conceptualized by Cousot et al. [24], forms the theoretical cornerstone of abstract interpretation by providing conservative approximations of program runtime behaviors. For acyclic control flows, fixpoint computation typically terminates after a few iterations over the CFG. However, in the presence of cyclic control flows, the fixpoint computation may require an impractically large number of iterations to converge, or in the worst case, may never converge, especially when using abstract domains characterized by infinite or very large lattice heights. To address this issue, widening operators [23] are introduced to accelerate the fixpoint computation and ensure its termination. Since its introduction, Bourdoncle's algorithm [13] has remained the predominant approach for efficient fixpoint computation in abstract interpretation. Subsequent research has largely built upon this foundation, exploring various refinements such as interleaved widening and narrowing strategies to enhance precision [10, 11, 35, 33] and parallel computation techniques [40, 64, 44]. These advances, while valuable, are orthogonal to our focus on interprocedural fixpoint computation. Current interprocedural methods typically either inline callee functions [15], overlooking opportunities for interprocedural topological ordering, or disregard varying calling contexts [48, 47], potentially introducing superfluous widening operations.

Recursion Handling. In interprocedural static analysis, recursive program structures present significant challenges by potentially generating unbounded call stacks that can affect analyzer termination. Existing approaches address this challenge through various strategies: some

employ fixed-depth recursive call unrolling [59, 55, 56], while others explicitly bound the analysis of recursive calls [26, 37]. These approaches offer practical trade-offs between precision and analysis feasibility. More conservative methods focus on computing sound approximations of values within recursive structures [15, 18], prioritizing soundness while potentially sacrificing precision when analyzing recursions. Oh et al. [49] proposed techniques for eliminating spurious interprocedural cycles, though not specifically targeting recursion handling. Rival et al. [54] developed specialized methods for handling recursion in shape analysis, focusing primarily on precise approximation of recursive heap structures – an approach complementary to our work. Keidel et al. [38, 14] introduces a terminable big-step abstract interpretation approach even in the presence of loops and recursions. It achieves this by identifying recurrent call traces of the abstract interpreter itself during runtime. However, while this dynamic approach allows the application of widening on recursions, it currently does not support further narrowing to improve precision. Späth et al. [57] proposes a synchronized pushdown system that improves time complexity for recursive data structures. It operates within a pushdown framework, which differs from our abstract interpretation methodology. Stein [58] introduces a versatile framework for incremental and demand-driven tabulation-based abstract interpretation, utilizing dynamic summarization graphs to support sound analysis of recursion. While effective, it does not incorporate Bourdoncle's strategy, which could enhance efficiency in handling cycles.

7 Conclusion

This paper introduces RecTopo, a novel approach to fixpoint computation for precise interprocedural abstract interpretation. RecTopo utilizes interprocedural weak topological ordering to steer chaotic iterations across program procedures effectively. This strategy not only incorporates an interleaved widening and narrowing approach for accurately addressing recursions but also eliminates redundant widening caused by interprocedural dependencies. RecTopo demonstrates an average precision improvement of 46.51% and an increased recall rate of 32.98% when compared to baselines tools on ten open-source projects.

Abstract

The use of Large Language Models (LLMs) for code generation has gained significant attention in recent years. Existing methods often aim to improve the quality of generated code by incorporating additional contextual information or guidance into input prompts. Many of these approaches adopt process-oriented reasoning strategies, mimicking human-like step-by-step thinking; however, they may not always align with the structured nature of programming languages. This paper introduces **Chain of Grounded Objectives (CGO)**, a concise goal-oriented prompting approach that embeds functional objectives into prompts to enhance code generation. By focusing on precisely defined objectives rather than explicit procedural steps, CGO aligns more naturally with programming tasks while retaining flexibility. Empirical evaluations on HumanEval, MBPP, their extended versions, and LiveCodeBench show that CGO achieves accuracy comparable to or better than existing methods while using fewer tokens, making it a more efficient approach to LLM-based code generation.

1 Introduction

The advancement of Large Language Models (LLMs) has significantly transformed software development, particularly in natural language-driven code generation [35, 12]. These models enable developers to generate code from textual descriptions, reducing manual effort and expanding accessibility for non-experts. However, fully leveraging their potential requires addressing challenges related to output accuracy, motivating researchers to explore more structured and detailed prompts. In response, recent research has focused on enhancing the input to LLMs by incorporating additional context or guidance, and these methods can be classified according to the type of supplementary information provided:

[1] corresponding author

First, **example-based guidance** approaches involve supplying sample codes or problem-solution examples to guide LLMs; with few-shot prompting [4] being a typical example.

Second, **process-oriented reasoning**, focuses on guiding the model through the procedural steps required to solve a problem, essentially explaining "how" to reach a solution. Prompts like Chain of Thought [30] and self-planning [16] exemplify this approach by decomposing the problem-solving process into a sequence of logical steps. Based on our preliminary experiments, while effective, process-oriented reasoning can introduce unnecessary complexity in straightforward tasks, potentially leading to increased inference time and token consumption.

Third, **goal-oriented reasoning** focuses on specifying "what" needs to be achieved rather than prescribing "how" to achieve it. This includes prompting with input-output examples, specifications, or constraints, leaving the model to infer the optimal approach. Test-driven prompting [25, 21] is a representative example: the problem goal is defined by test cases, but such methods require code execution for validation, incurring computational overhead.

However, **is complex reasoning always necessary for effective code generation?** Instead of guiding LLMs through intricate reasoning steps, could a simpler approach – one that provides only clear and direct goals – lead to better results?

To explore this, we propose **Chain of Grounded Objectives (CGO)**, a concise goal-oriented reasoning approach that succinctly captures the objectives of a coding problem. CGO first prompts the LLM to analyze the given problem and autonomously generate a compact set of objectives outlining the functional requirements of the solution. These objectives are then incorporated as supplemental input to guide the final code generation step. Notably, they are expressed in a style similar to code comments, a format LLMs have extensively encountered during training. By presenting objectives in this grounded manner, CGO enhances compatibility with programming languages while prioritizing computational interpretability. Furthermore, since CGO introduces minimal additional information, it consumes fewer tokens than verbose, process-oriented prompts, making it a more efficient alternative.

By examining CGO's effectiveness and efficiency in comparison to existing reasoning techniques, we aim to determine whether concise goal-driven guidance can serve as a more practical alternative to complex procedural reasoning in code generation.

The key contributions of this study are as follows:

- **Chain of Grounded Objectives (CGO)** is introduced as a concise goal-oriented reasoning prompt technique that employs functional objectives to guide code generation.
- **Higher accuracy**: Experimental results on HumanEval and MBPP show that CGO outperforms existing prompting techniques.
- **Real-world applicability**: CGO also exhibits competitive performance on LiveCode Bench, a benchmark reflecting more realistic coding scenarios.
- **Efficiency**: Despite requiring fewer tokens, CGO maintains high-quality code generation relative to other prompt techniques.

2 Related Work

2.1 Code Generation Using LLMs

The development of pretrained language models has significantly influenced research in code generation. Models such as CodeT5 [29] and UnixCoder [8], which learn from both textual and code data, have demonstrated strong performance across various code generation

and understanding tasks. Furthermore, models like Codex, CodeGen, AlphaCode, and CodeGeeX have shown that incremental increases in model size can lead to improved performance, highlighting the importance of scaling model parameters in code generation models [6, 22, 19, 34].

Recently, open-source models have also made significant progress. Models such as LLaMA and Mistral [26, 15] provide researchers with accessible yet high-performing alternatives, while CodeLLaMA [27], specifically designed for code generation, has achieved strong performance in code-related tasks. Moreover, the emergence of small open-weight models like Deepseek and Qwen has further improved the efficiency of code generation models. Qwen [12] has released models optimized not only for general natural language processing (NLP) tasks but also for code generation, demonstrating performance comparable to some large proprietary models. Deepseek introduced various architectures, including Deepseek-R1 [9], which enhances Deepseek-V3 with efficient reinforce learning, excelling in benchmarks and competitive programming.

Additionally, proprietary models such as the GPT series, Gemini, and Claude continue to achieve state-of-the-art performance in code generation, demonstrating ongoing advancements in code understanding and generation capabilities [1, 24].

2.2 Prompting Strategies for Code Generation

The simplest way to generate code with LLMs is to input the coding problem directly and let the model produce a solution. However, as effective prompting has been shown to improve LLM performance, various studies have explored prompting techniques for code generation.

Example-based guidance approaches, such as few-shot prompting [4], provide example problem-solution pairs but have shown limited impact on code quality, according to our preliminary experiments. Process-oriented reasoning methods decompose the problem-solving process into a sequence of manageable steps. CodeCoT adapts CoT for code generation by refining intermediate steps to align with coding tasks [11], Structured Chain of Thought (SCoT) uses pseudocode as intermediate steps [18]. Self-Planning [16] prompts the model to create a detailed plan before generating code, effectively breaking complex problems into smaller, manageable subtasks. Goal-oriented reasoning includes methods like Test-Case-Driven Chain of Thought (TCoT) [25]. TCoT focuses on defining goals in the form of test cases to validate generated code through execution and iterative refinement. However, its reliance on execution-based feedback loop incurs computational costs.

3 Proposed Technique: CGO Prompting

In this study, we propose Chain of Grounded Objectives (CGO) prompting, a concise goal-oriented reasoning approach designed to enhance the performance of LLMs in automated code generation tasks. The core idea behind CGO is to provide functional objectives as additional input to guide the LLM. These objectives are presented in the form of comment-level representations that are likely familiar to the LLM based on its training data, such as structured natural language descriptions commonly found alongside code.

3.1 Motivation

CGO is grounded in the principle that learning-aligned prompting has been shown to be effective [28], and that providing flexible guidance rather than overly specific context can lead to improved generation performance [2]. Specifically, we adopt comment-style objectives

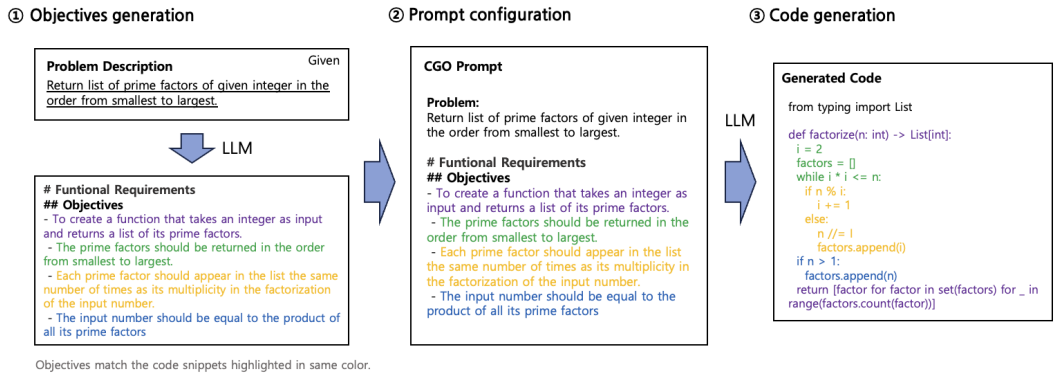

Figure 1 CGO's Workflow.

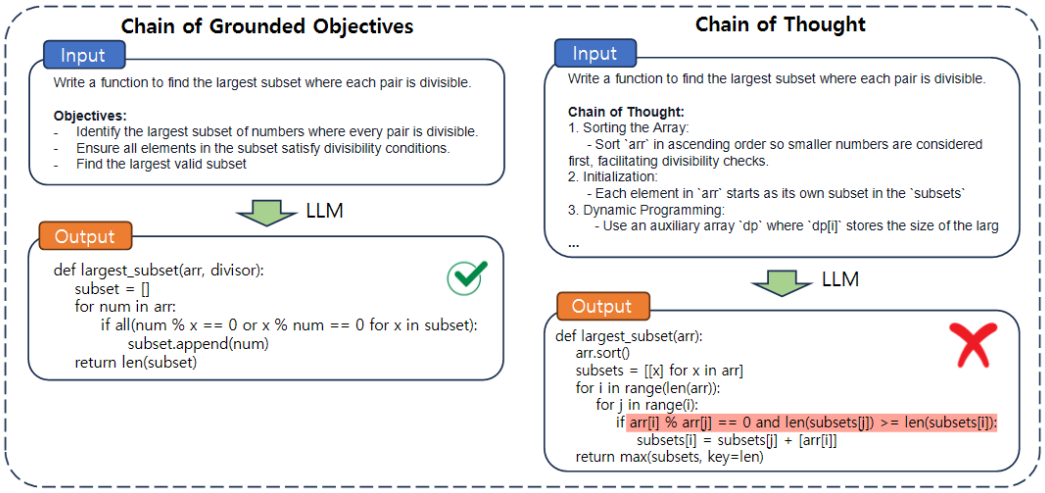

Figure 2 Code example generated with the Chain of Grounded Objectives and Chain of Thought.

based on the intuition that these resemble structured explanations commonly found in the training data of LLMs. Such structured explanations, including comments and documentation, generally describe intended functionality in a way that abstracts implementation details. By incorporating such familiar patterns, we expect that CGO prompting:

- Provides clarity to the LLM about the task requirements.
- Improves the model's ability to map functional objectives to code implementations.
- Leverage its training familiarity with structured descriptions to improve the overall quality of code generation.

Figure 1 illustrates the workflow of the CGO-based code generation process consists of two stages: (1) the "Objective Generation Stage", where the LLM generates functional objectives from the problem description, and (2) the "Code Generation Stage", where these objectives are used as additional context to guide the LLM in generating the code.

The CGO-based code generation process can be formally described as follows (detailed examples are provided in Tables 8):

(1) Objective Generation Stage

In the first stage, the LLM generates a set of functional objectives $O = \{o_1, o_2, \ldots, o_n\}$ based on the given problem description P.

$$O = \text{GenObj}(P) \tag{1}$$

Here, GenObj is a function that maps the problem description P to a set of objectives O, where each objective o_i represents a specific sub-goal, such as a functional requirement, that the final code is expected to achieve. The LLM is guided by a specifically designed prompt, such as *"Write **objectives** for the problem."* This step ensures that the model explicitly understands the key elements of the problem before generating code.

By framing functional objectives to reflect the developer's intent, this approach bridges natural language and code, using the LLM's reasoning to align with the developer's thought process.

(2) Code Generation Stage

In the second stage, the LLM synthesizes the final code C using both the problem description P and the objectives O as input. This process is represented by the function GenCode:

$$C = \text{GenCode}(O \mid P) \tag{2}$$

The notation $O \mid P$ indicates that while the objectives O are derived from the problem P, they are treated as additional context that supplements the original problem description. The function GenCode leverages this enriched context to generate code that not only solves the problem but also adheres to the specific goals outlined in O. This supports the LLM in developing a clear understanding of the problem's requirements, resulting in code that is both functionally correct and contextually appropriate.

The entire CGO-based code generation process can be represented by combining the two stages:

$$C = \text{GenCode}(\text{GenObj}(P) \mid P) \tag{3}$$

4 Evaluation

4.1 Experimental Setup

4.1.1 Benchmarks

Experiments were conducted on five datasets: HumanEval, MBPP-sanitized, their extended versions – HumanEval+ and MBPP+ – which include additional edge cases, and LiveCodeBench.

While HumanEval and MBPP-sanitized provide high-quality coding problems for evaluating LLMs, they primarily consist of standalone function implementations, making them relatively simple benchmarks. HumanEval+ and MBPP+ improve robustness assessment by incorporating more test cases, while LiveCodeBench better reflects real-world coding challenges by requiring a deeper understanding of problem contexts and constraints. These datasets support the evaluation of both fundamental code generation capabilities and performance in practical settings.

- **HumanEval**: A benchmark of 164 coding problems introduced by OpenAI, each comprising a natural language description, example function signatures, and an average of 7.7 test cases per problem.

- **MBPP-sanitized** [3]: A refined subset of MBPP, containing verified problems with a problem description, a reference solution, and three test cases for each instance.
- **HumanEval+ and MBPP+** [20]: Extended versions of HumanEval and MBPP with 80x and 35x more test cases, focusing on edge case robustness.
- **LiveCodeBench** [13] : A contamination-free and continuously evolving benchmark for evaluating LLMs on code generation. Each problem in LiveCodeBench includes a structured problem description, example inputs and outputs, and explicit constraints, making it more reflective of real-world programming tasks.

In this experiment, since MBPP-sanitized does not provide function signatures, the input prompt was adjusted to follow the **HumanEval-style** for consistency by extracting function headers from the ground-truth code. Examples of this formatting are shown in Table 7.

4.1.2 Baselines

We compared the proposed method with the following baseline approaches (detailed examples are provided in Tables 9 to 12):

- **Direct prompting**: Generates code solely from the problem description.
- **Few-shot**: Includes example problems and solutions to guide the model.
- **CodeCoT**: Utilizes Chain of Thought (CoT) with a one-shot example to generate intermediate steps and final code in two stages [11].
- **Zero-shot CoT**: A prompt that generates a CoT Reasoning process to solve the given problem without providing example CoT and incorporates it into code generation [17].
- **Self-Planning**: Extracts sub-tasks from the problem and generates a plan, which guides code generation in two stages [16].
- **Self-Pseudo**: Reflecting the design phase of the software development process, first define the problem requirements and then generate pseudocode based on them. Subsequently, use the generated pseudocode to write the final code in three stage.

4.1.3 Performance Evaluation

We compared the proposed CGO against six baseline reasoning methods in Section 4.1.2 using five LLMs: LLaMA3-8B-Instruct, LLaMA3-70B-Instruct, LLaMA3.1-8B-Instruct, LLaMA3.1-70B-Instruct, and GPT-3.5-Turbo. For all methods, both the intermediate reasoning steps and the final code generation were performed using *greedy sampling* (*temperature* = 0, *top-p* = 1), producing deterministic outputs at each stage. Further details of the experimental setup are provided in Appendix A.

Performance evaluation was conducted using *pass@k*, a widely adopted metric, along with *pass-ratio@n*, which provides a more fine-grained analysis of code generation performance. Further details regarding the metrics bellow are provided in Appendix B.

- *pass@k*: The probability of generating at least one correct solution among k attempts [6].
- *pass-ratio@n*: The average squared ratio of passed test cases across n generated solutions, emphasizing higher accuracy, as defined in [32].

Although *greedy sampling* typically produces the same output for a given prompt, minor variations may still occur due to factors such as floating-point precision errors and non-deterministic execution environments. To account for this, we repeated the experiment 10 times per problem. As a result, we set $k = 1$ for *pass@k*, while for *pass-ratio@n*, we used $n = 10$, averaging results across multiple runs.

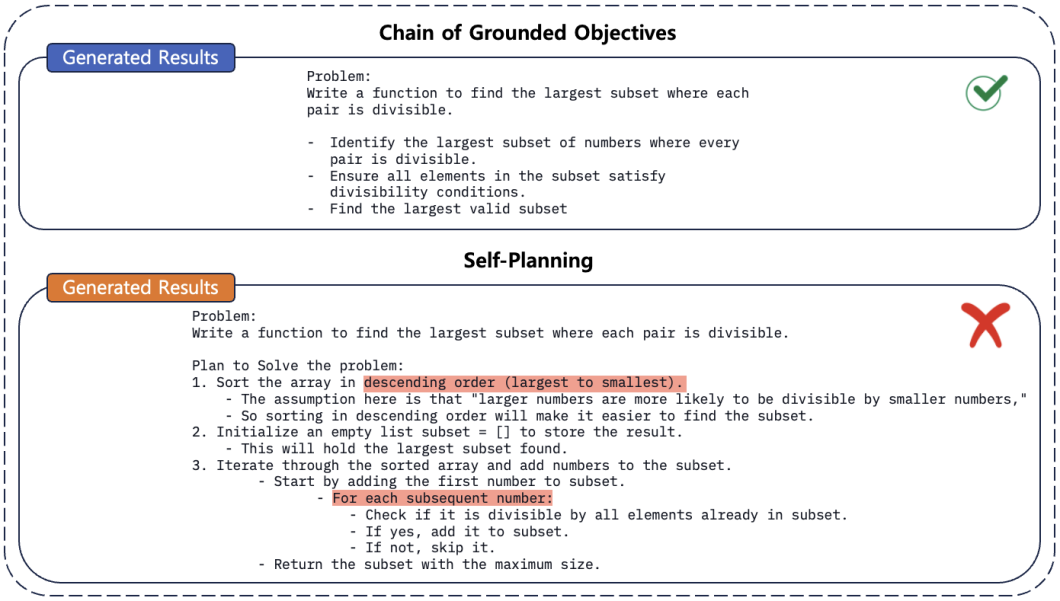

Figure 3 Context example generated with the Chain of Grounded Objectives and Self-Planning.

4.2 RQ 1: How Does CGO Perform Compared to Baselines?

In this section, we evaluate the correctness of generated code across four benchmarks: HumanEval, MBPP-sanitized, and their extended versions – HumanEval+ and MBPP+. Tables 1, 2, and 3 present the *pass@1* (for $n = 10$) and *pass-ratio@10* scores, comparing CGO with various baseline reasoning methods using three different LLMs: LLaMA3-8B-Instruct, LLaMA3-70B-Instruct, and GPT-3.5-Turbo.

LLaMA3-8B-Instruct (Medium-scale LLM)

Table 1 reports the results for LLaMA3-8B-Instruct, showing the accuracy of code generated using nine different methods: Direct prompting, 1-shot, 2-shot, 3-shot, CodeCoT, zero-shot CoT, self-planning, self-pseudo, and CGO. The results demonstrate that CGO outperformed all baseline reasoning methods across all benchmarks, achieving the highest *pass@1* and *pass-ratio@10* scores.

Interestingly, despite its widespread use in LLM prompting, few-shot prompting yielded surprisingly suboptimal performance, with inconsistent results across different benchmarks. While it showed improvements in MBPP-sanitized and MBPP+, it underperformed compared to direct prompting on the HumanEval benchmarks. Overall, it did not demonstrate a clear advantage over other reasoning methods, suggesting that few-shot prompting may be less effective for code generation than anticipated.

CodeCoT improved over few-shot prompting, demonstrating the benefits of leveraging CoT, but still fell 4.9 points behind CGO in *pass@1* (57.5 vs. 62.4) and 4.1 points in *pass-ratio@10* (61.3 vs. 65.4) on HumanEval. Across the evaluated benchmarks, Zero-shot CoT often outperformed CodeCoT; however, it still lagged behind CGO, suggesting that leveraging the model's inherent reasoning abilities may be more effective than manually constructing CoT examples for code generation.

While CGO and CoT share the general principle of decomposition, they differ in their underlying reasoning processes. CoT emulates a human-like, step-by-step reasoning, whereas CGO adopts a machine-oriented reasoning approach. This mechanistic approach facilitates a

Table 1 Comparison of the CGO prompt with various baselines using the LLaMA3-8B-Instruct across four benchmarks (HumanEval, HumanEval+, MBPP-sanitized, MBPP+), evaluated using *pass*@1(n=10) and *pass-ratio*@10.

Prompts	HumanEval		MBPP-sanitized		HumanEval+		MBPP+

Self-Pseudo	79.9	81.7	82.3	82.8	73.8	75.0	69.3	70.6
CGO	**80.3**	**83.2**	**83.3**	**83.7**	**74.6**	**75.7**	**70.4**	**71.1**

more direct alignment with automated code-generation tasks. Figure 2 presents an example of the intermediate outputs generated by CGO (objectives) and CoT (step-by-step reasoning), clearly demonstrating that CGO generates more concise intermediate results. While CoT's detailed, explanatory style is beneficial to some extent, Figure 3 shows that its emphasis on human-readable explanations introduces unnecessary verbosity, diverting focus from capturing essential functional objectives for code generation.

Among the evaluated baseline methods, self-planning achieved the highest performance, coming closest to CGO. While planning, like CoT, emphasizes procedural steps, it places less emphasis on strict step-by-step sequencing, which may contribute to its stronger performance.

Self-Pseudo follows a three-stage reasoning process, sequentially generating requirements, pseudo-code, and then the final implementation, aligning with typical software development procedures. However, its effectiveness was limited with LLaMA3-8B-Instruct, consistently recording lower scores than direct prompting (DP) across all four benchmarks. This suggests that incorporating software development process elements into code generation is less effective for an 8B-scale model, likely due to its limited capacity to process complex contextual dependencies.

Overall, CGO consistently outperformed all other methods, demonstrating that its concise, goal-oriented reasoning approach effectively enhances code generation accuracy across diverse benchmarks.

Table 3 Comparison of the CGO prompt with various baselines using the GPT-3.5-Turbo across four benchmarks (HumanEval, HumanEval+, MBPP-sanitized, MBPP+), evaluated using *pass*@1(n=10) and *pass-ratio*@10.

LLaMA3-70B-Instruct and GPT-3.5-turbo (Large-scale LLMs)

Tables 2 and 3 show the results for LLaMA3-70B-Instruct and GPT-3.5-Turbo, both of which have greater computational capacity than LLaMA3-8B-Instruct. With these larger models, the accuracy of all methods improved compared to LLaMA3-8B-Instruct, while the overall performance trends remained similar.

As in the previous results, CGO generally outperformed other methods across benchmarks, with self-planning achieving strong performance among baselines. Zero-shot CoT continued to perform better than CodeCoT in HumanEval, but unlike in LLaMA3-8B-Instruct, CodeCoT outperformed Zero-shot CoT in some MBPP-sanitized benchmarks, suggesting that its effectiveness may depend on the characteristics of the benchmark.

A notable difference from previous results is the performance of self-pseudo, which showed improvement with larger models. While it performed worse than direct prompting in LLaMA3-8B-Instruct, it achieved better results in HumanEval with larger models, in some cases approaching CGO. This suggests that larger models are better able to integrate multi-step reasoning, making the use of pseudo-code more effective. However, CGO still outperformed Self-Pseudo in terms of *pass-ratio@10*, indicating that while generating pseudo-code can be beneficial, CGO remains a more efficient and reliable approach.

Overall, CGO demonstrated strong performance across different model sizes, showing its effectiveness as a concise, goal-oriented reasoning approach for code generation.

4.3 RQ 2. Does CGO Effective in Real-World Programming Task?

To evaluate CGO's effectiveness in real-world programming scenarios, we compared its performance with baseline reasoning-based prompting techniques on LiveCodeBench. Table 4 presents the results based on *pass@1* and *pass-ratio@10* across LLaMA3.1-8B-Instruct, LLaMA3.1-70B-Instruct, and GPT-3.5-Turbo.

In this experiment, few-Shot prompting was excluded due to the longer problem descriptions in LiveCodeBench. Including additional examples for few-Shot prompting would exceed the context length limit of LLaMA3.1 models, making it impractical for evaluation.

Experimental results show that while CodeCoT outperformed Direct Prompting (DP), its performance improvement was not particularly significant compared to other baseline methods. This observation became more pronounced as the model size increased. These findings suggest that as the diversity of problem increases, incorporating appropriate examples into the code generation process becomes increasingly important.

Table 4 Comparison of the CGO prompt with baseline methods on LiveCodeBench, using 3 LLMs. Results is evaluated based on *pass*@1(n=10) and *pass-ratio*@10.

Prompts	LLaMA3.1-8B-Instruct		LLaMA3.1-70B-Instruct		GPT-3.5-turbo	
	pass@1	*pass-ratio*@10	*pass*@1	*pass-ratio*@10	*pass*@1	*pass-ratio*@10
Direct Prompting	26.0	32.1	41.5	48.8	35.5	44.1
CodeCoT	28.0	36.1	44.7	52.4	35.7	43.6
Zero-shot CoT	29.0	36.6	47.0	54.3	39.0	48.3
Self-Planning	**30.0**	**38.1**	48.3	56.0	38.3	47.6
Self-Pseudo	25.5	33.0	48.0	55.7	39.5	48.1
CGO	28.0	34.7	**49.0**	**56.1**	**40.75**	**50.2**

Table 5 Performance comparison of baselines and CGO across difficulty levels based on *pass*@1 and *pass-ratio*@10, using the GPT-3.5-Turbo.

Prompts	easy		medium		hard	
	pass@1	*pass-ratio*@10	*pass*@1	*pass-ratio*@10	*pass*@1	*pass-ratio*@10
Direct Prompting	60.56	67.83	22.61	32.73	20.00	28.00
Self-Planning	60.56	70.92	**28.57**	39.97	16.66	25.26
CodeCoT	60.56	67.79	25.00	34.71	16.66	22.12
Zero-shot CoT	**65.49**	**73.78**	27.97	39.02	17.77	25.99
Self-Pseudo	61.97	71.29	**28.57**	40.44	15.55	25.85
CGO	**65.49**	73.48	**28.57**	**40.55**	**24.44**	**31.58**

In contrast, zero-shot CoT demonstrated greater performance improvements compared to CodeCoT, and this tendency was consistently observed across all three models. This suggests that as problem complexity and diversity increase, leveraging the model's inherent capabilities to construct a Chain of Thought (CoT) reasoning process before code generation can be a more effective approach.

Conversely, self-planning recorded the highest performance on LLaMA3.1-8B-Instruct, achieving 30.0 in *pass@1* (30.0 vs. 28.0) and 38.1 in *pass-ratio@10* (38.1 vs. 34.7), outperforming CGO by 2.0 and 4.7 points. However, on LLaMA3.1-70B-Instruct and GPT-3.5-Turbo, Self-Planning showed lower performance compared to CGO.

Self-pseudo showed lower performance than DP on LLaMA3.1-8B-Instruct, consistent with the results observed in RQ 1. However, for the other two models, it demonstrated performance comparable to or higher than that of self-planning. This variation suggests that the effectiveness of the self-pseudo approach may depend on model size and capability. These findings indicate that incorporating the software development process into the code generation pipeline remains a valid approach, even in environments with diverse problem types such as LiveCodeBench.

CGO showed lower performance than self-planning and zero-shot CoT when using the LLaMA3.1-8B-Instruct model. However, in experiments using LLaMA3.1-70B-Instruct and GPT-3.5-Turbo, CGO achieved the highest performance compared to the baseline prompts. Notably, in GPT-3.5-Turbo experiments, CGO recorded 40.75 in *pass@1* (40.75 vs. 35.5) and 50.2 in *pass-ratio@10* (50.2 vs. 44.1), 4.25 and 6.1 points higher than DP, demonstrating significant improvements.

These results suggest that CGO's goal-oriented reasoning approach is also effective in real-world problem-solving when applied to larger models such as LLaMA3.1-70B-Instruct and GPT-3.5-Turbo, rather than smaller 8B-scale models. Furthermore, it confirms CGO's advantage over baseline prompts.

Table 6 Performance comparison of baselines and CGO across difficulty levels based on *pass*@1 and *pass-ratio*@10, using the LLaMA3.1-70B-Instruct.

Prompts	easy		medium		hard	
	pass@1	*pass-ratio*@10	*pass*@1	*pass-ratio*@10	*pass*@1	*pass-ratio*@10
Direct Prompting	69.71	72.69	30.95	40.31	16.66	22.60
Self-Planning	**80.99**	**85.33**	38.10	47.09	15.56	26.52
CodeCoT	79.58	83.32	32.74	42.02	12.22	23.19
Zero-shot CoT	79.58	83.17	33.93	43.60	**20.00**	**28.83**
Self-Pseudo	78.16	82.72	38.28	47.90	16.88	28.32
CGO	80.22	82.59	**39.88**	**49.46**	17.78	26.58

4.3.1 Performance Analysis of CGO Across Difficulty Levels

This subsection provides a more detailed analysis of Table 4, examining the performance of CGO and baseline prompts across different problem difficulty levels as defined by LiveCodeBench. Table 5 presents the results, categorizing problems into three difficulty levels: easy, medium, and hard. The results in Table 5 were obtained using GPT-3.5-Turbo, while Figure 4 provides a visual representation of these findings for better readability.

Easy problems showed relatively modest performance gains across most baselines. The self-planning approach matched the baseline in *pass@1* but demonstrated improvements in *pass-ratio@10*. Zero-shot CoT achieved one of the highest scores among all baselines, along with CGO, significantly outperforming DP. Other prompting techniques showed performance levels similar to DP, with only minor enhancements.

As problem complexity increased, the performance gap among baselines became more pronounced. On medium-level problems, self-planning achieved 28.57 in *pass@1* (28.57 vs. 22.61), outperforming DP by 4.95 points. Zero-shot CoT also demonstrated improvements over DP, reinforcing the advantages of autonomous reasoning before code generation. In contrast, CodeCoT exhibited the lowest performance, indicating the need for a more refined Chain of Thought (CoT) strategy.

Several methods, including CGO, self-planning, and self-pseudo, attained the same *pass@1* score (28.57). However, in terms of *pass-ratio@10*, CGO recorded the highest value (40.55), followed by self-pseudo (40.44) and self-planning (39.97). These results suggest that while different approaches may achieve similar *pass@1* scores, *pass-ratio@10* provides additional insight into solution quality by reflecting the proportion of generated code that successfully passes more test cases, thereby offering a more comprehensive measure of correctness.

Performance degradation was more apparent in hard problems, where most baselines underperformed compared to DP. Self-planning and CodeCoT showed lower *pass@1* scores compared to DP, and this pattern was consistent in *pass-ratio@10* as well. While zero-shot CoT led among the baselines, it still fell short of DP, revealing limitations in handling higher complexity tasks. self-pseudo saw the most significant performance drop, indicating its ineffectiveness in solving more challenging problems. In contrast, CGO achieved the highest performance across all baselines, with *pass@1* and *pass-ratio@10* scores of 24.44 and 31.58, respectively. These results represent a 4.44 and 3.58 improvement over DP, demonstrating CGO's effectiveness not only in lower difficulty levels but also in more complex problem-solving scenarios.

Table 6 shows the performance of the prompting methods, including CGO, across difficulty levels using the LLaMA3.1-70B-Instruct. CGO achieved strong performance on medium-difficulty problems – which constitute the majority of the benchmark – achieving the highest

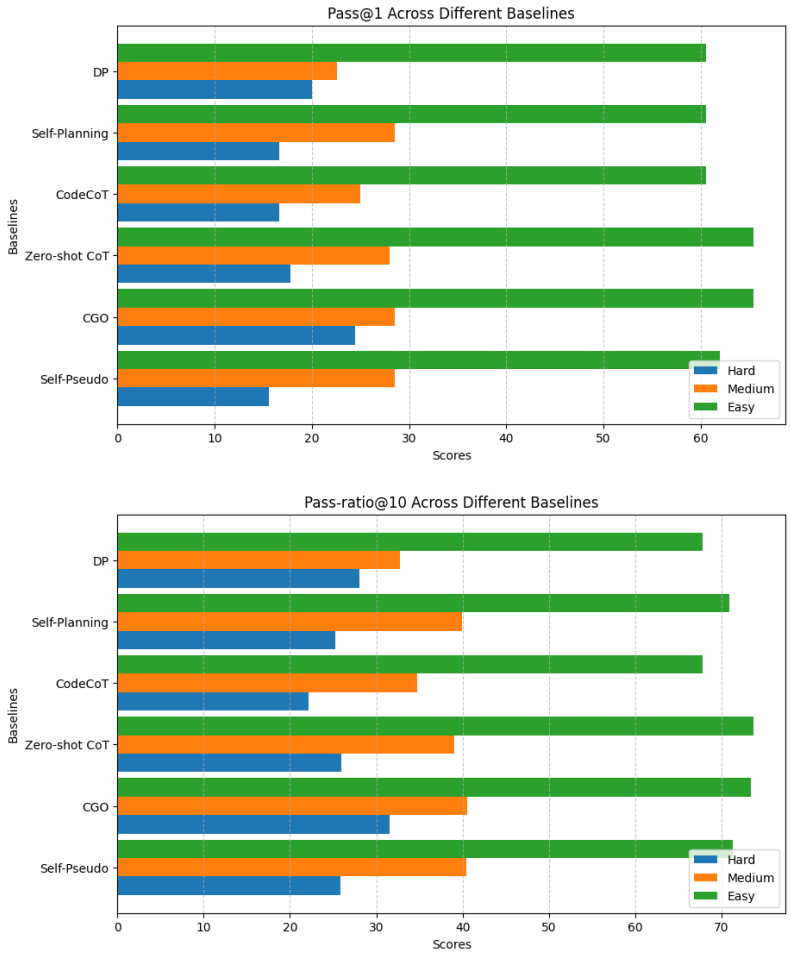

Figure 4 *pass@1* and *pass-ratio@10* scores by difficulty level on the GPT-3.5-turbo experiment.

scores of 39.88 for *pass@1* and 49.46 for *pass-ratio@10*, indicating its effectiveness in addressing problems of intermediate complexity. On easy and hard problems, although CGO did not attain the highest scores, it still ranked second in terms of *pass@1*, closely behind self-planning on easy problems and zero-shot CoT on hard problems, indicating a stable level of performance across different complexities.

The results show that CGO performs similarly to other baselines on easy, medium difficulty problems, while achieving better results on hard problems. This suggests that CGO's objective-driven approach provides useful guidance, particularly for more complex tasks. Further studies could investigate whether integrating CGO with other reasoning approaches improves performance, particularly on hard problems where additional structured reasoning may be advantageous.

4.4 RQ 3. Does CGO Resource-Efficient Compared to the Baselines?

All prompting methods examined in this study follow a multi-step reasoning process, where the LLM first autonomously generates intermediate supplementary content (e.g., objectives, plans, chain-of-thought, or pseudo-code) before generating the final code. While this additional content helps guide the code generation process, it also increases token generation, thereby

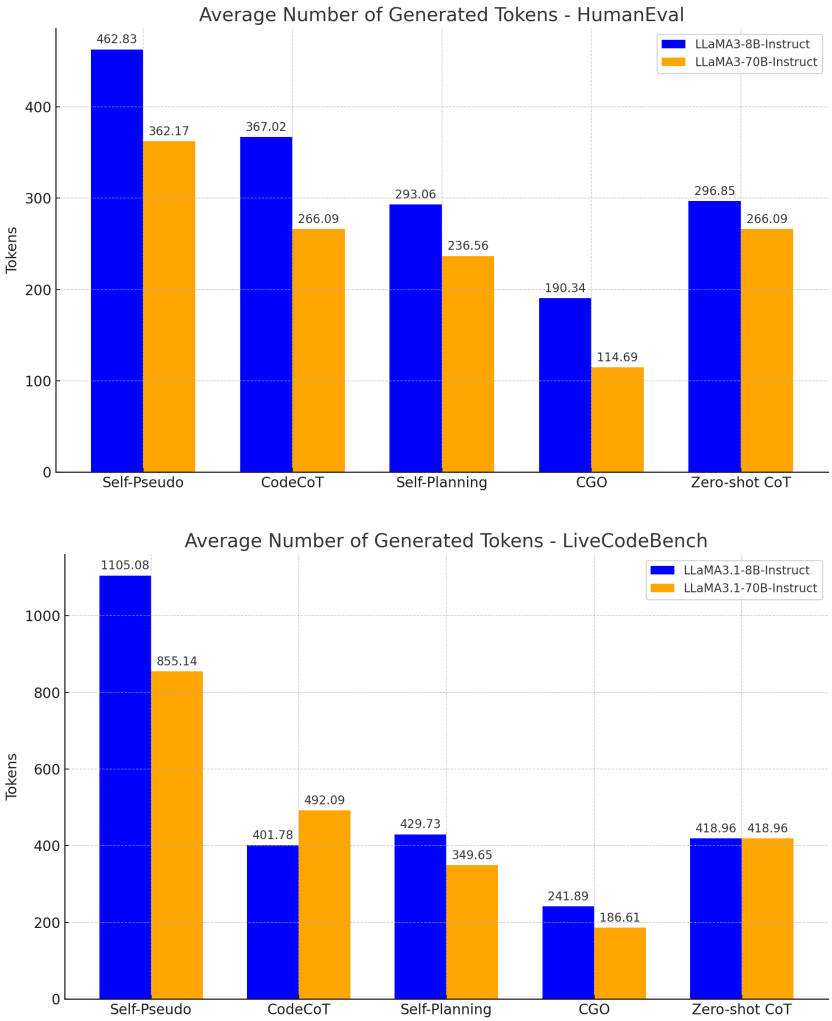

Figure 5 Average number of generated tokens by LLaMA3.1-8B-Instruct and LLaMA3.1-70B-Instruct on the HumanEval and LiveCodeBench across 5 baseline prompts (lower is better).

raising the computational cost of using LLMs. Since LLM inference cost scales with the number of generated tokens, it is essential to evaluate the trade-off between enhanced guidance and resource efficiency.

In this section, we evaluate the resource efficiency of each baseline by measuring the token count of the intermediate supplementary content generated by the LLM. Figure 5 presents the average token count across baselines on the HumanEval and LiveCodeBench benchmarks, serving as a proxy for computational cost. The results show that CGO consistently generates the fewest tokens, making it the most resource-efficient approach among the compared baselines.

On HumanEval, CGO produces 114.69 tokens on average for LLaMA3-70B-Instruct and 190.34 tokens for LLaMA3-8B-Instruct, significantly lower than other baselines. In contrast, self-pseudo requires the most tokens (462.83 for LLaMA3-8B-Instruct and 362.17 for LLaMA3-70B-Instruct), followed by CodeCoT and self-planning.

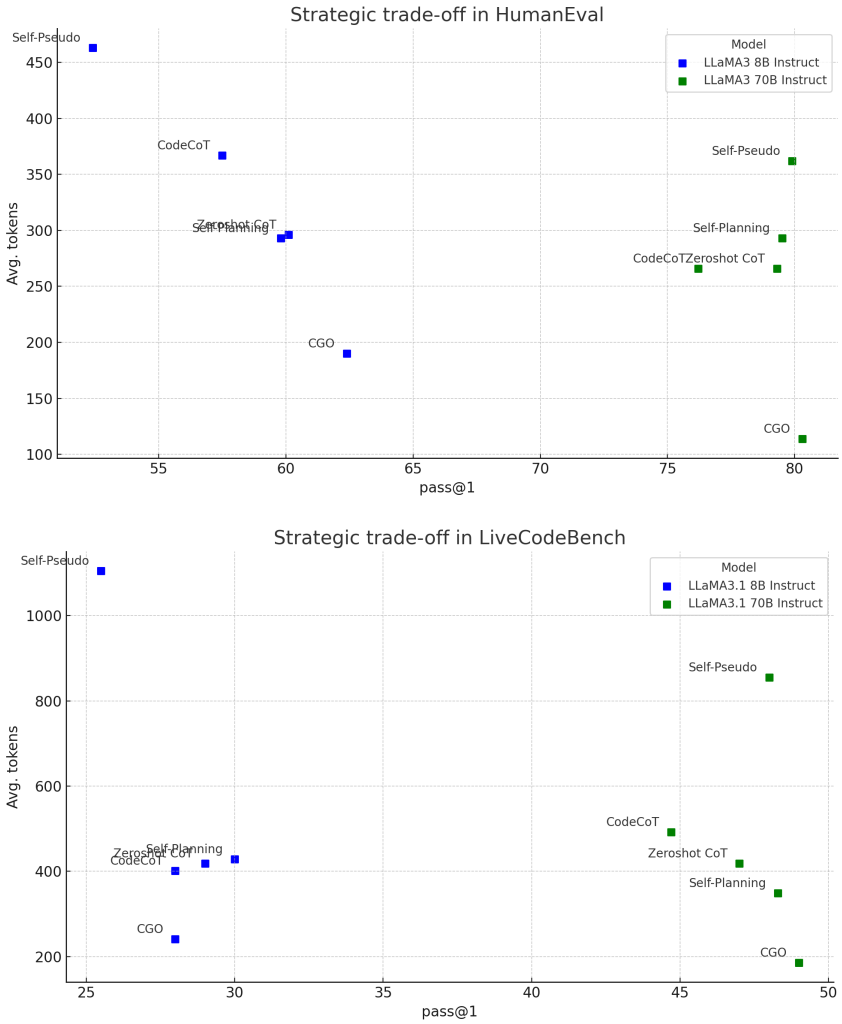

Figure 6 Strategic trade-off on the HumanEval and LiveCodeBench across 5 baseline prompts.

This pattern is observed on LiveCodeBench, where CGO remains the most efficient, generating 186.61 tokens for LLaMA3.1-70B-Instruct and 241.89 tokens for LLaMA3.1-8B-Instruct. self-pseudo again exhibits the highest token consumption (1105.08 and 855.14, respectively), with CodeCoT and self-planning also showing significantly higher token usage than CGO.

Interestingly, for most cases, the LLaMA3.1-8B-Instruct generates more tokens than the LLaMA3.1-70B-Instruct under the same benchmark and prompting technique. A possible explanation is that the larger LLaMA3.1-70B-Instruct, having a greater capacity to process and distill information, tends to generate more concise outputs. Consequently, it may require fewer tokens to convey the necessary details for code generation.

Overall, these findings highlight CGO as the most resource-efficient approach among the evaluated baselines. By emphasizing concise functional objectives, CGO achieves an effective balance between token usage and guidance quality, thereby minimizing computational overhead without compromising performance, as further demonstrated in Figure 6. Its primary

Table 7 Performance comparison of CGO and requirement-based prompting with the LLaMA3.1-70B-Instruct, evaluated on HumanEval and LiveCodeBench using *pass*@1 and *pass-ratio*@10.

Prompts	HumanEval		LiveCodeBench	
	pass@1	*pass-ratio*@10	*pass*@1	*pass-ratio*@10
CGO-original	**80.3**	83.2	**49.0**	56.1
CGO-variant	79.27	**83.9**	48.5	**56.19**

advantage lies in its ability to generate only the essential contextual elements required for code generation, making it particularly well-suited for scenarios where computational efficiency is a priority.

4.5 Wording Variations in CGO Prompting

The CGO approach does not strictly require the use of the word "objective" in its prompts. For example, terms such as "objective" and "requirement" convey similar meanings within the context of coding. To evaluate whether minor wording differences could significantly influence the effectiveness of the CGO approach, we conducted an experiment.

In this experiment, we compared two variations of prompt wording used during the intermediate output generation stage:

- Original Prompt: *"Write **objectives** to solve the problem"*
- Variant Prompt: *"Write **requirements** to solve the problem"*

We assessed the performance of code generation on the HumanEval and LiveCodeBench benchmarks. The experimental results are summarized in Table 7.

The results reveal negligible differences between the two prompt variants, with variations within approximately 1% in both *pass@1* and *pass-ratio@10* scores. These findings indicate that CGO's effectiveness is consistently good regardless of minor semantic differences in prompt wording, allowing developers the flexibility to choose synonymous terms without compromising performance.

4.6 Limitation

Our study demonstrates the efficiency and effectiveness of CGO, but certain aspects remain unexplored:

- **Model Selection**: The evaluation was conducted on five LLMs (LLaMA3-series, and GPT-3.5-Turbo), providing insights into CGO's effectiveness but not covering the full range of recent models. Future research will extend experiments to Qwen, DeepSeek, and other emerging LLMs to assess CGO's broader applicability.
- **Sampling Strategy**: We used greedy sampling for all experiments, ensuring deterministic outputs but not considering sampling-based approaches such as nucleus sampling. Since different sampling strategies can influence both output diversity and efficiency, future work will explore their impact on CGO.
- **Objective Generation**: CGO generates objectives using a zero-shot approach, which may lead to variations in format, detail, or clarity across different instances. Employing methods such as few-shot prompting or structured guidance could improve consistency and standardization in the objectives produced. Additionally, systematic evaluations involving human or automated approaches (e.g., "LLM-as-judge" [7]) would further help assess the quality and appropriateness of generated objectives.

- **Evaluation Methodology**: Our evaluation primarily focused on functional correctness and performance metrics. Additional criteria such as readability, maintainability, and robustness against edge cases need to be considered.

Addressing these aspects will further refine CGO and enhance its adaptability to different models and inference settings.

5 Conclusion

This paper introduced Chain of Grounded Objectives (CGO), a concise goal-oriented reasoning approach that succinctly captures the objectives of a coding problem. CGO autonomously generates comment-style objectives, aligning well with programming language conventions while offering clear guidance without excessive verbosity.

Empirical evaluations on HumanEval, MBPP-sanitized, and their extended versions (HumanEval+ and MBPP+) demonstrate that CGO consistently achieves high accuracy, outperforming baseline prompting techniques in *pass@1* and *pass-ratio@10*. These results indicate that CGO enables LLMs to generate correct solutions without requiring intricate reasoning steps.

On LiveCodeBench, CGO also demonstrated competitive performance, particularly on medium and hard difficulty problems, underscoring its applicability to real-world programming tasks. In addition to accuracy, CGO exhibited the highest efficiency, often reducing the number of intermediate tokens generated by more than half compared to baseline prompts. This reduction minimizes inference costs while sustaining competitive performance, making CGO a cost-effective approach for LLM-based code generation.

Overall, CGO presents a practical and efficient approach to guiding LLMs in code generation. Future work could investigate applying CGO to specialized reasoning models such as DeepSeek-R1 or OpenAI o3 to further evaluate and enhance its effectiveness.

A Experimental Details

In our experiments, we employed LLaMA-3 and LLaMA-3.1 based models, and GPT-3.5-Turbo-16k-0106. Both objective generation and code generation were carried out using greedy sampling with a temperature of 0 and a top-p of 1, following prior work [10, 5].

The MBPP prompts were standardized to align with the HumanEval format. To ensure consistency, function signatures were extracted directly from the ground-truth code. Examples of the standardized formatting are presented in Table 7.

To increase the diversity of outputs, we generated $n = 10$ objective samples per problem, which were subsequently used to guide the code generation process.

For the implementation of *Chain-of-Thought (CoT)* [23, 33] and *Self-Planning* strategies, reasoning chains were constructed based on code examples provided in the original Self-Planning approach. Instead of directly reusing existing reasoning sequences, we manually curated new examples tailored to our experimental configuration.

Few-shot prompting was realized by randomly selecting example problems and their corresponding solutions from the same dataset. Each problem description was labeled as *Input* and the corresponding solution as *Output*, which were incorporated into the prompt as reference examples.

The execution of the generated code was configured to run in Docker sandbox environment.

All experiments were conducted using the Huggingface [14] and LangChain, LangGraph libraries. All resources are publicly available on GitHub.

B Evaluation Details

We evaluated the experimental results using *pass@k* and *pass-ratio@n* metrics.

B.1 *pass@k*

The *pass@k* metric assesses the performance of an LLM in code generation by evaluating the execution outcomes of the generated code. For a given coding problem, *pass@k* indicates whether at least one of the k code solutions produced by the LLM successfully passes all associated test cases. A problem is deemed solved by the LLM if any of the k solutions satisfy this condition.

$$pass@k := \mathop{\mathbb{E}}_{problems}\left[1 - \frac{\binom{n-c}{k}}{\binom{n}{k}}\right] \tag{4}$$

B.2 *pass-ratio@n*

For a given solution indexed by i $(0 < i \leq n)$, $pass\text{-}ratio_i$ is computed as the square of the ratio between the number of passed test cases for solution i and the total number of test cases. Squaring this value assigns greater weight to solutions with higher pass ratios, thereby emphasizing solutions with greater accuracy.

$$pass\text{-}ratio_i = \left(\frac{\text{Number of passed test cases } i}{\text{Total number of test cases}}\right)^2 \tag{5}$$

The *pass-ratio@n* is calculated using the formula below. It represents the average *pass-ratio* of the n generated codes.

$$pass\text{-}ratio@n = \frac{\sum_{i=1}^{n} pass\text{-}ratio_i}{n} \tag{6}$$

HumanEval Prompt Example

```
def separate_paren_groups(paren_string: str) -> List[str]:
    """ Input to this function is a string containing multiple groups
        of nested parentheses.
    >>> separate_paren_groups('( ) (( )) (( )( ))')
    ['()', '(())', '(()())']
    """
```

MBPP-sanitized Prompt Example

```
def first_repeated_char(str1):
    '''Write a python function to find the first repeated character
       in a given string.'''
```

Figure 7 Examples of HumanEval-style Prompt (HumanEval, MBPP-sanitized).

Table 8 Examples of Objective and Code Generation Using CGO.

Problem Description Example

```
def separate_paren_groups(paren_string: str) -> List[str]:
    """ Input to this function is a string containing multiple
        groups of nested parentheses. Your goal is to
    separate those group into separate strings and return the
        list of those.
    Separate groups are balanced (each open brace is properly
        closed) and not nested within each other
    Ignore any spaces in the input string.
    >>> separate_paren_groups('( ) (( )) (( )( ))')
    ['()', '(())', '(()())']
    """
```

Objectives Generation Prompt

Write objectives to solve the problem.

Objectives Generation Examples

- Separate groups of nested parentheses should be identified and extracted from the input string.
- Ignore any spaces in the input string.
- Ensure that each extracted group is balanced (each open brace is properly closed).
- Extracted groups should not be nested within each other.

Generated Code

```
def separate_paren_groups(paren_string: str) -> List[str]:
    result = []
    stack = []
    current_group = ""

    for char in paren_string:
        if char == '(':
            stack.append('(')
            current_group += '('
        elif char == ')':
            stack.pop()
            current_group += ')'
            if not stack:
                result.append(current_group)
                current_group = ""

    return result
```

Table 9 Examples of Code Generation Using Few-shot.

Problem Description Example

```
def separate_paren_groups(paren_string: str) -> List[str]:
    """ Input to this function is a string containing multiple
        groups of nested parentheses. Your goal is to
    separate those group into separate strings and return the
        list of those.
    Separate groups are balanced (each open brace is properly
        closed) and not nested within each other
    Ignore any spaces in the input string.
    >>> separate_paren_groups('( ) (( )) (( )( ))')
    ['()', '(())', '(()())']
    """
```

Few-shot Examples

```
### Input
def minSubArraySum(nums):
    """
    Given an array of integers nums, find the minimum sum of any
        non-empty sub-array of nums.
    Examples:
        minSubArraySum([2, 3, 4, 1, 2, 4]) == 1
        minSubArraySum([-1, -2, -3]) == -6
    """

###Output
def minSubArraySum(nums):
    max_sum = 0
    s = 0
    ...
```

Few-shot Code Generation Prompt

Write python code for the problem.

Generated Code

```
groups = []
current_group = ""
for char in paren_string:
    if char == '(':
        current_group += char
    elif char == ')':
        current_group += char
        groups.append(current_group)
        current_group = ""
return groups
```

Table 10 Examples of Code Generation Using CodeCoT.

Problem Description Example

```
def separate_paren_groups(paren_string: str) -> List[str]:
    """ Input to this function is a string containing multiple
        groups of nested parentheses. Your goal is to
    separate those group into separate strings and return the
        list of those.
    Separate groups are balanced (each open brace is properly
        closed) and not nested within each other
    Ignore any spaces in the input string.
    >>> separate_paren_groups('( ) (( )) (( )( ))')
    ['()', '(())', '(()())']
    """
```

CoT Generation Prompt

Generate detailed comments for this code.

CoT Generation Examples

- The input string contains groups of nested parentheses separated by spaces.
- Split the input string by spaces to handle each group individually.
- Remove any extra spaces to ensure proper processing.
- Assume each group is balanced and valid.
- Iterate through groups, filtering out empty or invalid ones.
- Collect remaining valid groups into a list.
- Return the filtered list.
- This method assumes no nested validation beyond splitting.

Generated Code

```
groups = paren_string.split(' ')
filtered_groups = [group.strip() for group in groups if group.
    strip()]
return filtered_groups

print(separate_paren_groups('( ) (( )) (( )( ))'))  # Output:
    ['()', '(())', '(()())']
```

Table 11 Examples of Code Generation Using Self-Planning.

Problem Description Example

```
def separate_paren_groups(paren_string: str) -> List[str]:
    """ Input to this function is a string containing multiple
        groups of nested parentheses. Your goal is to
    separate those group into separate strings and return the
        list of those.
    Separate groups are balanced (each open brace is properly
        closed) and not nested within each other
    Ignore any spaces in the input string.
    >>> separate_paren_groups('( ) (( )) (( )( ))')
    ['()', '(())', '(()())']
    """
```

Plan Generation Prompt

Write plan for the problem.

Plan Generation Examples

(1) Preprocess the input string:
- **(a)** Remove all spaces to simplify processing.

(2) Initialize variables:
- **(a)** List `groups` to store the final balanced groups.
- **(b)** String `temp` to construct the current group.
- **(c)** Integer `balance` to track open and close parentheses.

(3) Iterate through the cleaned string:
- **(a)** Add the character to `temp`.
- **(b)** Adjust `balance` based on whether the character is `(` or `)`.
- **(c)** If `balance == 0`, add `temp` to `groups` and reset `temp`.

(4) Return the list `groups` containing all balanced groups.

Generated Code

```
cleaned_string = paren_string.replace(" ", "")
groups = []
temp = ""
balance = 0
for char in cleaned_string:
    temp += char
    if char == '(':
        balance += 1
    elif char == ')':
        balance -= 1
        if balance == 0:
            groups.append(temp)
            temp = ""

return groups
```

Table 12 Examples of Code Generation Using Pseudo-Code.

Problem Description Example

```
def separate_paren_groups(paren_string: str) -> List[str]:
    """ Input to this function is a string containing multiple
        groups of nested parentheses. Your goal is to
    separate those group into separate strings and return the
        list of those.
    Separate groups are balanced (each open brace is properly
        closed) and not nested within each other
    Ignore any spaces in the input string.
    >>> separate_paren_groups('( ) (( )) (( )( ))')
    ['()', '(())', '(()())']
    """
```

Pseudo-code

```
Function separate_paren_groups(input_string):
    Strip spaces from input_string
    Initialize result as empty list
    Initialize current_group as empty string
    Set balance = 0
    For each char in input_string:
        Append char to current_group
        If char is '(':
            increment balance
        If char is ')':
            decrement balance
        If balance == 0:
            Append current_group to result
            Reset current_group to empty string
    Return result
```

Generated Code

```
cleaned_string = paren_string.replace(" ", "")
groups = []
temp = ""
balance = 0
for char in cleaned_string:
    temp += char
    if char == '(':
        balance += 1
    elif char == ')':
        balance -= 1
        if balance == 0:
            groups.append(temp)
            temp = ""
return groups
```

Efficient Neural Network Verification via Order Leading Exploration of Branch-and-Bound Trees

Abstract

The vulnerability of neural networks to adversarial perturbations has necessitated formal verification techniques that can rigorously certify the quality of neural networks. As the state-of-the-art, branch-and-bound (`BaB`) is a "divide-and-conquer" strategy that applies off-the-shelf verifiers to sub-problems for which they perform better. While `BaB` can identify the sub-problems that are necessary to be split, it explores the space of these sub-problems in a naive "first-come-first-served" manner, thereby suffering from an issue of inefficiency to reach a verification conclusion. To bridge this gap, we introduce an order over different sub-problems produced by `BaB`, concerning with their different likelihoods of containing counterexamples. Based on this order, we propose a novel verification framework Oliva that explores the sub-problem space by prioritizing those sub-problems that are more likely to find counterexamples, in order to efficiently reach the conclusion of the verification. Even if no counterexample can be found in any sub-problem, it only changes the order of visiting different sub-problems and so will not lead to a performance degradation. Specifically, Oliva has two variants, including Oliva$^{\mathsf{GR}}$, a greedy strategy that always prioritizes the sub-problems that are more likely to find counterexamples, and Oliva$^{\mathsf{SA}}$, a balanced strategy inspired by simulated annealing that gradually shifts from exploration to exploitation to locate the globally optimal sub-problems. We experimentally evaluate the performance of Oliva on 690 verification problems spanning over 5 models with datasets `MNIST` and `CIFAR-10`. Compared to the state-of-the-art approaches, we demonstrate the speedup of Oliva for up to 25× in `MNIST`, and up to 80× in `CIFAR-10`.

1 Introduction

The rapid advancement of artificial intelligence (AI) has propelled the state-of-the-art across various fields, including computer vision, natural language processing, recommendation systems, etc. Recently, there is also a trend that adopts AI products in safety-critical systems, such as autonomous driving systems, in which neural networks are used in the perception module to perceive external environments. In this type of application, unexpected behaviors of neural networks can bring catastrophic consequences and intolerable social losses; given that neural networks are notoriously vulnerable to deliberate attacks or environmental perturbations [28, 18], effective quality assurance techniques are necessary in order to expose their defects timely before their deployment in the real world.

Formal verification is a rigorous approach that can ensure the quality of target systems by providing mathematical proofs on conformance of the systems with their desired properties. In the context of neural networks, formal verification aims to certify that a neural network, under specific input conditions, will never violate a pre-defined specification regarding its behavior, such as safety and robustness, thereby providing a rigorous guarantee that the neural network can function as expected in real-world applications. With the growing emphasis on AI safety, neural network verification has emerged as a prominent area of research, leading to the development of innovative methodologies and tools.

As a straightforward approach, exact encoding solves the neural network verification problem by encoding the inference process and specifications to be logical constraints and applying off-the-shelf or dedicated solvers, such as MILP solvers [47] and SMT solvers [23], to solve the problem. However, this approach can be very slow due to the non-linearity of neural network inferences and so they are not scalable to neural networks of large sizes. In contrast, approximated methods [44, 41, 49] that over-approximate the reachable region of neural networks are more efficient: once the over-approximation satisfies the specification, the original output must also satisfy; however, if the over-approximation violates the specification, it does not indicate that the original output also violates, and in this case it may raise a *false alarm*, i.e., a specification violation that actually does not exist.

To date, *Branch-and-Bound* (`BaB`) [5] is the state-of-the-art verification approach that overarches multiple advanced verification tools, such as $\alpha\beta$-Crown [51] and Marabou [52]. It is essentially a "divide-and-conquer" strategy, and is often jointly used with off-the-shelf approximated verifiers due to their great efficiency. Given a verification problem, it first applies an approximated verifier to the problem, and splits it to sub-problems if the verifier raises a false alarm, until all the sub-problems are verified or a real counterexample is detected, as a witness of specification violation. As application of approximated verifiers to sub-problems leads to less over-approximation, `BaB` can thus resolve the issue of false alarms of approximated verifiers and outperform their plain application to the original problem.

Motivations

As a "divide-and-conquer" strategy, `BaB` can produce a large space that consists of quantities of sub-problems, especially for verification tasks that are reasonably difficult. However, when exploring this space, the classic `BaB` adopts a naive "first come, first served" strategy, which ignores the importance of different sub-problems and thus is not efficient to reach a verification conclusion. Notably, different sub-problems produced by `BaB` are not equally important – with a part of the sub-problems, it is more likely to find a real counterexample that can show the violation of the specification, and thereby we can reach a conclusion for the verification efficiently without going through the remaining sub-problems.

Contributions

In this paper, we propose a novel verification approach Oliva, which is an **o**rder **l**eading **i**ntelligent **v**erification technique for **a**rtificial neural networks.

We first define an order called *counterexample potentiality* over the different sub-problems produced by BaB. Our order estimates *how likely* a sub-problem is to contain a counterexample, based on the following two attributes: **1.** the level of problem splitting of the sub-problem, which implies how much approximation the approximated verifier needs to perform. The less approximation there is, the more likely the verifier can find a real counterexample; **2.** a quantity obtained by applying approximated verifiers to the sub-problem, which is an indicator of *the degree* to which the neural network satisfies/violates the specification. By these two attributes, we define the counterexample potentiality order over the sub-problems, as a proxy to suggest their likelihood of containing counterexamples and serve as guidance for our verification approach.

Then, we devise our approach Oliva that exploits the order to explore the sub-problem space. In general, Oliva favors the sub-problems that are more likely to contain counterexamples. Once it can find a real counterexample, it can immediately terminate the verification and return with a verdict that the specification can be violated; even if it cannot find such a counterexample, after visiting all the sub-problems, it can still manage to certify the neural network without a significant performance degradation.

To exemplify the power of our order-guided exploration, we propose two variants of Oliva:

- Oliva^{GR} employs a greedy exploitation strategy, which always prioritizes the sub-problems that have a higher likelihood of containing counterexamples. This approach focuses on the most suspicious regions of the sub-problem space, and is likely to quickly expose the counterexamples such that the verification can be concluded quickly;
- To avoid overfitting of our proposed order, we also devise Oliva^{SA} inspired by simulated annealing [24], the famous stochastic optimization technique. The approach works similarly to simulated annealing: it maintains a variable called *temperature* that keeps decreasing throughout the process, which can control the trade-off between "exploitation" and "exploration". At the initial stage, the temperature is high, and so the algorithm allows more chances of exploring the sub-problems that are not promising; as the temperature goes down, it converges to the optimal sub-problem. As the exploration of the search space has been done at the early stage of the algorithm, it is likely to converge to the globally optimal sub-problems and thereby find counterexamples. In this way, we mitigate the potential issue of being too greedy, and aim to strike a balance between "exploitation" and "exploration" in the search for suspicious sub-problems.

Evaluation

To evaluate the performance of Oliva, we perform a large scale of experiments on 690 problem instances spanning over 5 neural network models associated with the commonly-used datasets `MNIST` and `CIFAR-10`. By a comparison with the state-of-the-art verification approaches, we demonstrate the speedup of Oliva, for up to 25× in `MNIST`, and up to 80× in `CIFAR-10`. Moreover, we also show the breakdown results of Oliva for problem instances that are finally certified and the instances that are finally falsified. Experimental results show that Oliva is particularly efficient for those instances that are falsified, which demonstrates the effectiveness of our approach.

For a verification problem whose result is unknown beforehand, it is always desired to reach the conclusion as quickly as possible. Given that verification of neural networks is typically time- and resource-consuming, our approach provides a meaningful way to accelerate

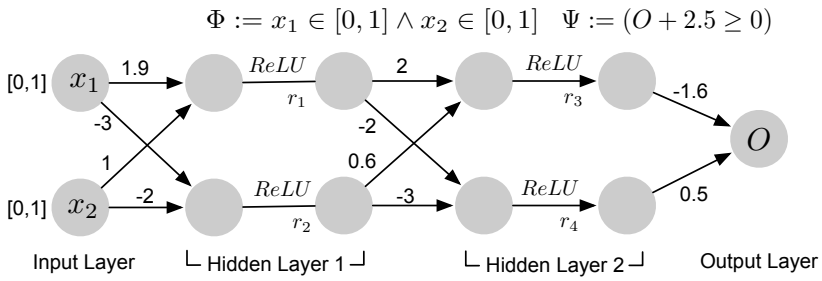

Figure 1 A neural network N and specification.

the verification process. While performing verification of neural networks with the aim of finding counterexamples sounds similar to approaches like testing or adversarial attacks, our approach differs fundamentally from those approaches, in the sense that, while those approaches deal with a single input each time and so they can never exhaust the search space, our approach deals with sub-problems that are finitely many, and so we can finally provide rigorous guarantees for specification satisfaction of neural networks.

Paper organization

The rest of the paper is organized as follows: §2 overviews our approach by using an illustrative example; §3 introduces the necessary technical background; §4 presents the proposed incremental verification approach; §5 presents our experimental evaluation results; §6 discusses related work. Conclusion and future work are presented in §7.

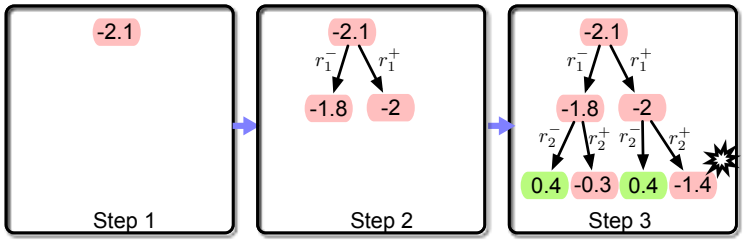
2 Overview of The Proposed Approach

In this section, we use an example to illustrate how the proposed approach solves neural network verification problems.

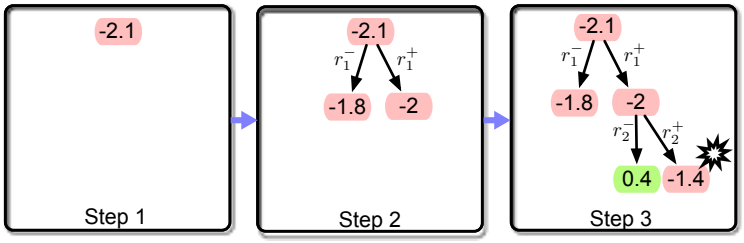
2.1 Verification Problem and BaB Approach

Fig. 1 depicts a (feed-forward) neural network N. It has an input layer, an output layer, and two *hidden layers* that are *fully-connected*, namely, the output of each hidden layer is computed by taking the weighted sum of the output of the previous layer, and applying the ReLU activation function. The output O of the neural network is computed by taking only the weighted sum of the output of the second hidden layer (without activation function). The weights of each layer are as labeled in Fig. 1. This neural network N is expected to satisfy such a specification: for any input $(x_1, x_2) \in [0,1] \times [0,1]$, it should hold that the output $O + 2.5 \geq 0$. Verification aims to give a formal proof to certify that N indeed satisfies the specification, or give a counterexample instead if N does not satisfy the specification.

As the state-of-the-art neural network verification approach, Branch-and-Bound (`BaB`) [5] has overarched several famous verification tools, such as $\alpha\beta$-Crown [51]. The application of `BaB` to neural network verification often relies on the combination with off-the-shelf verifiers, and a common choice involves the family of approximated verifiers. These verifiers can efficiently decide whether the neural network satisfies the specification, by constructing a convex over-approximation of neural network outputs: if the over-approximated output satisfies the specification, the original output must also satisfy; however, if not, it does not indicate that the original output also violates the specification, and so it may raise a *false alarm* that reports a specification violation that is actually not existent.



(a) BaB's process for verification.



(b) Oliva's process for verification.

Figure 2 Neural network verification problem and solution via BaB (BaB *vs.* Oliva).

BaB is introduced to solve this problem. It is essentially a "divide-and-conquer" strategy that splits the problem when necessary and applies approximated verifiers to sub-problems to reduce the occurrences of false alarms. In this context, a problem can be split by predicating over the sign of the input of a ReLU function (i.e., by allowing the ReLU's input to be positive or negative only), such that it can be decomposed to two linear functions each of which is easier to handle. BaB decides whether a (sub-)problem is needed to be split further, based on a value $\hat{p}$ returned from the approximated verifier. Intuitively, $\hat{p}$ indicates *how far* the specification is from being violated by the over-approximation of a (sub-)problem. If $\hat{p}$ is positive, it implies that problem has been verified and so there is no need to split it; otherwise, it implies that the problem cannot be verified, and so BaB needs to check whether it is a false alarm, by checking whether the counterexample reported by the verifier is a spurious one. Fig. 2a illustrates how BaB solves the verification problem in Fig. 1:

Step 1 – BaB first applies a verifier to the original verification problem, which returns a negative $\hat{p} = -2.1$. By validating the counterexample reported by the verifier, BaB identifies that it is a false alarm and decides to split the problem;

Step 2 – BaB splits the problem identified by the root node, and applies the verifier to the two sub-problems respectively. Again, it identifies that the verifier raises a false alarm for each of the sub-problems. Therefore, it needs to split both sub-problems;

Step 3 – Similarly, BaB applies the verifier in turn to the newly expanded sub-problems. It manages to verify two sub-problems (i.e., the two nodes both with $\hat{p} = 0.4$), and also identifies a false alarm (i.e., the node with $\hat{p} = -0.3$). In the node with $\hat{p} = -1.4$, BaB finds that the counterexample associated with this sub-problem is a real one; because having one such real counterexample suffices to show that the specification can be violated, BaB terminates the verification at this point with a verdict that the specification is violated.

2.2 The Proposed Approach

For a verification problem that is considerably difficult, BaB can often produce a space that contains a large number of sub-problems. However, as shown in Fig. 2a, the classic BaB explores these sub-problems by a naive "first come, first served" order, which ignores the difference of the sub-problems in terms of their importance, and thus can be very inefficient.

To bridge this gap, we propose an approach that explores the space of sub-problems guided by an order of importance of different sub-problems. Specifically, we identify the importance of different sub-problems by their likelihood of containing counterexamples, in the sense that the more likely a sub-problem contains counterexamples, it should be more prioritized in the exploration of the sub-problem space – once we can find a counterexample there, we can immediately terminate the verification and draw a conclusion. Even if it does not manage to find a counterexample in any problem, it just visits the sub-problems in a different order from the original BaB, so it still would not be much slower.

Fig. 2b demonstrates how our approach solves the same verification problem in Fig. 1.

- In early stages, Oliva works the same as BaB, i.e., it visits the (sub-)problems and obtains the same feedback $\hat{p}$ from the verifier, and based on that, it decides to split the (sub-)problems and apply verifiers to sub-problems;
- The difference comes from the rightmost plot of Fig. 2b, in which Oliva prioritizes the sub-problem that has $\hat{p} = -2$ rather than its sibling that has $\hat{p} = -1.8$ to expand. This is because $\hat{p}$ is a indicator that reflects how far the sub-problem is from being violated (based on the over-approximation performed by the verifier), and in this case $\hat{p} = -2$ signifies that this sub-problem has been violated *more* than the other and so it is more likely to find a counterexample there. Indeed, Oliva manages to find a real counterexample in one of its sub-problems, thereby terminating the verification immediately after that.

By this strategy, we manage to save two visits to sub-problems compared to BaB, each of which consists of an expensive problem solving process, and therefore, it reaches the conclusion of the problem more efficiently than BaB.

A variant of our approach inspired by simulated annealing

Essentially, our proposed approach changes the naive "breadth-first" exploration of the sub-problem space in the classic BaB to an intelligent way guided by the likelihood of finding counterexamples in different sub-problems. However, as this guidance consists of a total order over different branches, it may lose some chances of finding counterexamples in some branches that initially seem not promising.

To mitigate this issue, we also propose a variant of our approach, inspired by simulated annealing [24]. It works as follows: throughout the process, we maintain a temperature that keeps decreasing slowly, which is used to control the trade-off between "exploitation" and "exploration". Initially, when the temperature is high, our algorithm tends to explore the sub-problem space by assigning a considerably high probability to accept a sub-problem that is not promising; as temperature goes down, it converges to the optimal sub-problem; due to the exploration of the search space at the initial stage, the algorithm is likely to converge to the globally optimal sub-problems. In this way, we can mitigate the side-effect of being too greedy, and strike a balance between "exploitation" and "exploration".

3 Preliminaries

In this section, we first introduce the neural network verification problem, and then introduce the state-of-the-art verification approach called *branch-and-bound* (BaB).

3.1 Neural Network Verification Problem

In this paper, we consider feed-forward neural networks, as depicted in Fig. 1.

▶ **Definition 1** (Neural networks). *A (feed-forward) neural network $N : \mathbb{R}^n \to \mathbb{R}^m$ maps an n-dim input to an m-dim output (see Fig. 1 for an example). It accomplishes the mapping by alternating between affine transformations (parametrized by weight matrix W_i and bias vector B_i) and non-linear activation functions σ; namely, the output $\boldsymbol{x}_i$ of layer i ($i \in \{1, \ldots, L\}$) is computed based on the output $\boldsymbol{x}_{i-1}$ of layer $i-1$, as follows: $\boldsymbol{x}_i = \sigma(W_i \boldsymbol{x}_{i-1} + B_i)$. Here, the computation unit that computes each dimension of $\boldsymbol{x}_i$ is called a* neuron*; in each layer i, the number of neurons is equivalent to the number of dimensions of $\boldsymbol{x}_i$. Specially, $\boldsymbol{x}_0$ is the input and $\boldsymbol{x}_L$ is the output of the neural network. There could be different choices for the non-linear activation functions, such as ReLU, sigmoid and tanh; following many existing works [25], we adopt Rectified Linear Unit (ReLU) (i.e., $ReLU(x) = \max(0, x)$) as the activation function in our neural networks.*

Specifications are logical expressions that formalize users' desired properties about neural networks. In this paper, we adopt the following notation in Def. 2 as our specification formalism, and later we show that it can be used to formalize commonly-used properties, such as *local robustness* of neural networks.

▶ **Definition 2** (Specification). *We denote by a pair (Φ, Ψ) a* specification *for neural networks, where Φ is called an input specification that predicates over the input region, and Ψ is called an output specification that predicates over the output of a neural network. Specifically, we denote the output specification Ψ as follows: $f(N(\boldsymbol{x}_0)) > 0$, where $f : \mathbb{R}^m \to \mathbb{R}$ is a function that maps an m-dim vector to a real number.*

▶ **Definition 3** (Verification problem). *A verification problem aims to answer the following question: given a neural network N and a specification (Φ, Ψ), whether $\Psi(N(\boldsymbol{x}))$ holds, for any input $\boldsymbol{x}$ that holds $\Phi(\boldsymbol{x})$. A verifier is a tool used to answer a verification problem: it either returns* true*, certifying N's satisfaction to the specification, or returns* false *with a* counterexample *$\hat{\boldsymbol{x}}$, which is an input that holds $\Phi(\hat{\boldsymbol{x}})$ but does not hold $\Psi(\hat{\boldsymbol{x}})$.*

We now explain how our notations can be used to formalize a neural network verification problem against local robustness, which is a property often considered in the domain of image classification. Local robustness requires that a neural network classifier should make consistent classification for two images $\boldsymbol{x}$ and $\boldsymbol{x}_0$, where $\boldsymbol{x}$ is produced by adding small perturbations to $\boldsymbol{x}_0$. Formally, given a reference input $\boldsymbol{x}_0$, $\Phi(\boldsymbol{x})$ requires that the input $\boldsymbol{x}$ must stay in the region $\{\boldsymbol{x} \mid \|\boldsymbol{x} - \boldsymbol{x}_0\|_\infty \leq \epsilon\}$, where $\|\cdot\|_\infty$ denotes the ℓ^∞-norm distance metric and ϵ is a small real value, and $\Psi(N(\boldsymbol{x}))$ requires that $\min_{1 \leq i \leq m, i \neq i_l} (N(\boldsymbol{x})_{i_l} - N(\boldsymbol{x})_i) > 0$, where $N(\boldsymbol{x})_i$ denotes the i-th component of the output vector $N(\boldsymbol{x})$, and i_l is the label of $\boldsymbol{x}_0$ inferred by the neural network, i.e., $i_l = \arg\max_{1 \leq i \leq m} N(\boldsymbol{x}_0)_i$.

3.2 Branch-and-Bound (BaB) – State-of-the-Art Verification Approach

There have been various approaches proposed to solve the neural network verification problem. Exact encoding [23, 47, 7] formalizes the inference process and the specification of a neural network to be an SMT or optimization problem and solves them by dedicated [23] or off-the-shelf [47, 7] solvers. These approaches are sound and complete, but due to the non-linearity of neural network inferences, they suffer from severe scalability issues and cannot handle neural networks of large sizes. To resolve this issue, approximated approaches [42, 41, 44] over-approximate the output of neural networks by linear relaxation, and they can certify the satisfaction of specification if the over-approximated output satisfies the specification. These approaches are typically efficient and sound; however, they are not complete, i.e., they

may raise false alarms with spurious counterexamples, if the over-approximated output does not satisfy the specification. As the state-of-the-art, Branch-and-Bound (BaB) [5] employs approximated verifiers and splits the problem when necessary (i.e., if a false alarm arises in a problem), because by solving sub-problems it can improve the precision of approximation and reduce the occurrence of false alarms. BaB keeps problem splitting until all of the sub-problems are certified (such that the original problem can be certified) or a real counterexample is detected with a sub-problem (such that the original problem is falsified).

In the following, we explain the necessary ingredients and detailed workflow of BaB.

Approximated verifiers

Approximated verifiers, denoted as LpVerifier, are a class of verifiers that solve a verification problem by computing an over-approximation of the output region of neural networks – if the over-approximation satisfies the specification, it implies that the original output region must also satisfy it. Typically, LpVerifier can return a tuple $\langle \hat{p}, \hat{\boldsymbol{x}} \rangle$, where $\hat{p} \in \mathbb{R}$ is called a *verifier assessment*, which is a quantity that indicates *the extent* to which the over-approximated output satisfies the specification. Formally, given an LpVerifier, it can construct a region $\hat{\Omega} \supseteq \{N(\boldsymbol{x}) \mid \Phi(\boldsymbol{x}) = \mathsf{true}\}$, which over-approximates the output region of a neural network N; then, LpVerifier computes $\hat{p}$ as follows: $\hat{p} := \min_{\boldsymbol{y} \in \hat{\Omega}} f(\boldsymbol{y})$, where f is as defined in Def. 2. If $\hat{p}$ is positive, it implies that the original output also satisfies the specification, and so it can certify the satisfaction of neural networks. Conversely, if $\hat{p}$ is negative, LpVerifier deems that the specification is violated and provides a counterexample input $\hat{\boldsymbol{x}}$ as an evidence. However, due to the over-approximation, this reported violation of LpVerifier could be a false alarm and the counterexample $\hat{\boldsymbol{x}}$ may be a spurious one, i.e., the corresponding output $N(\hat{\boldsymbol{x}})$ of $\hat{\boldsymbol{x}}$ actually satisfies the specification. In this case, just based on the result of LpVerifier, we cannot infer whether N holds or violates the specification. This situation is referred to as the *completeness issue* of approximated verifiers.

There have been various approximation strategies that can be used to implement approximated verifiers, e.g., *DeepPoly* [44] and *ReluVal* [50], and mostly, the over-approximation is accomplished by using linear constraints to bound the output range of the non-linear ReLU functions. In particular, we assume that our adopted approximated verifiers hold the *monotonicity* property, namely, for two output regions of neural networks that hold $\Omega_1 \subset \Omega_2$, if we over-approximate them by using the same approximated verifier LpVerifier, the obtained over-approximation $\hat{\Omega}_1$ and $\hat{\Omega}_2$ hold that $\hat{\Omega}_1 \subseteq \hat{\Omega}_2$. While there can be different options of over-approximation strategies, our proposed approach is orthogonal to them, so we can adopt any approximated verifiers that hold our assumption about monotonicity.

Branch-and-Bound (BaB)

BaB is the state-of-the-art neural network verification approach, and has been adopted in several advanced verification tools, such as $\alpha\beta$-Crown [51] and Marabou [52]. It is essentially a "divide-and-conquer" strategy, that divides a verification problem adaptively and applies off-the-shelf verifiers (such as approximated verifiers) to solve the sub-problems. Because approximated verifiers often achieve better precision on sub-problems, BaB can thus overcome the weaknesses of the plain application of approximated verifiers to the original problem and resolve the issues of false alarms.

Before looking into the details of BaB, we first introduce ReLU specification, which is an important notion in the algorithm of BaB.

Algorithm 1 Branch-and-Bound (`BaB`) [5].

Require: A neural network N, an input specification Φ, an output specification Ψ, an approximated verifier `LpVerifier`$(\cdot)$, and a ReLU selection heuristic $\mathsf{H}(\cdot)$.
Ensure: A *verdict* $\in \{\mathsf{true}, \mathsf{false}\}$.

```
1:  Q ← {⊤}
2:  T ← ∅
3:  function BaB(N, Φ, Ψ, Q)
4:      if Empty(Q) then
5:          return true
6:      Γ ← Pop(Q)
7:      ⟨p̂, x̂⟩ ← LpVerifier(N, Φ, Ψ, Γ)
8:      T ← T ∪ {⟨Γ, p̂⟩}
9:      if p̂ < 0 then
10:         if Valid(x̂, N, Ψ) then
11:             return false
12:         else
13:             r_k ← H(Γ)
14:             for a ∈ {r_k^+, r_k^-} do
15:                 Push(Q, Γ ∧ a)
16:     return BaB(N, Φ, Ψ, Q)
```

▶ **Definition 4** (ReLU specification). *Let N be a neural network consisting of K neurons, and $\hat{x}_i \in \mathbb{R}$ $(i \in \{1, \ldots, K\})$ be the input for the ReLU function in the i-th neuron. An* atomic proposition `AP` *w.r.t. the i-th neuron is defined as either $\hat{x}_i \geq 0$ (written as r_i^+) or $\hat{x}_i < 0$ (written as r_i^-). Then, a ReLU specification Γ is defined as the conjunction of a sequence $\mathsf{Set}(\Gamma) := \{\mathtt{AP}_1, \ldots, \mathtt{AP}_{|\Gamma|}\}$ of atomic propositions, where each $\mathtt{AP} \in \mathsf{Set}(\Gamma)$ is defined w.r.t. a distinct neuron. $|\Gamma|$ is the number of atomic propositions in $\mathsf{Set}(\Gamma)$; specially if $|\Gamma| = 0$, Γ is denoted as $\top$. Moreover, we define a* refinement relation $\prec$ *over ReLU specifications, namely, given two ReLU specifications Γ_i and Γ_j, we say Γ_j refines Γ_i (denoted as $\Gamma_i \prec \Gamma_j$) if and only if $\mathsf{Set}(\Gamma_i) \subset \mathsf{Set}(\Gamma_j)$.*

By selecting a neuron i, we can split the ReLU function into two linear functions, each identified by a predicate r_i^+ or r_i^- over the input of ReLU. Thereby, a neural network verification problem boils down to two sub-problems, for each of which `LpVerifier` does not need to perform over-approximation for the ReLU function in the i-th neuron.

The workflow of `BaB` is presented in Alg. 1. In Alg. 1, we allow `LpVerifier` to take an additional argument, namely, a ReLU specification Γ, which identifies a sub-problem by adding the constraints in $\mathsf{Set}(\Gamma)$ to constrain the inputs of a number of selected ReLU functions. It uses a FIFO queue Q to maintain the problem to be solved, which is initialized to be a set that consists of $\top$ only, identifying the original verification problem.

i) First, it applies `LpVerifier` to the original problem (Line 7): if `LpVerifier` returns a positive $\hat{p}$, or a negative $\hat{p}$ with a valid counterexample $\hat{\boldsymbol{x}}$ (Line 10), then verification can be terminated with a verdict returned accordingly;

ii) In the case it returns a negative $\hat{p}$ with a spurious counterexample (Line 12), it divides the verification problem into two sub-problems. This is achieved by first selecting a neuron (i.e., a ReLU) in the network according to a pre-defined ReLU selection heuristics H (Line 13), and then identifying two sub-problems each identified by an additional constraint on the input of the selected ReLU function (Line 15).

iii) It applies `LpVerifier` to the new sub-problems respectively, and decides whether it needs to further split the sub-problem, following the same rule in Step ii. In Alg. 1, this is implemented by recursive call of the BaB function in Line 16.

In `BaB`, the ReLU selection heuristics H involves an order over different neurons such that it can select the next ReLU based on an existing ReLU specification. There has been a rich body of literature that proposes different ReLU selection strategies, such as DeepSplit [21] and FSB [10]. However, our proposed approach in §4 is orthogonal to these strategies and so it can work with existing strategies. In this work, we follow an existing neural network verification approach [48] and we adopt the state-of-the-art ReLU selection strategy in [21].

As a result of Alg. 1, it forms a binary tree $\mathcal{T}$ (see Line 2 and Line 8) that records the history of problem splitting during the `BaB` process. In this tree, each node $\langle \Gamma, \hat{p} \rangle$ denotes a sub-problem, identified by a ReLU specification Γ and the verifier assessment $\hat{p}$ returned by `LpVerifier` that signifies the satisfaction of the sub-problem.

▶ **Lemma 5** (Soundness and completeness). *The* `BaB` *algorithm is sound and complete.*

Proof. Soundness requires that if `BaB` returns `true`, the neural network must satisfy the specification. The soundness of `BaB` relies on that: 1) `LpVerifier` is sound; 2) the ReLU specifications identified by the leaf nodes of the `BaB` tree cover all the cases about the input conditions of the split ReLUs in the neural network.

Completeness requires that if `BaB` returns `false`, the neural network must violate the specification. The completeness of `BaB` relies on the fact that the counterexamples $\hat{\boldsymbol{x}}$ reported by `BaB` are all validated and so they must be real. Moreover, in the worst case if all neurons are split, the sub-problem will be linear and so a $\hat{\boldsymbol{x}}$ must be a real one if it exists.

Finally, `BaB` is guaranteed to return either `true` or `false` within a finite time budget, because the number of neurons in a neural network is finite. ◀

4 Oliva: The Proposed Verification Approach

As a "divide-and-conquer" strategy, `BaB` can produce a huge space that consists of quantities of sub-problems; however, as shown in Alg. 1, the existing `BaB` approach explores this space in a naive "first come, first served" manner (implemented by the *first-in-first-out* queue in Alg. 1 that stores the (sub)-problems to be solved), which can be very inefficient to exhaust the sub-problem space.

Our proposed approach involves exploring the `BaB` tree in an intelligent fashion, guided by the severity of different tree nodes. In §4.1, we showcase such a severity order, defined by the probability of finding counterexamples with a sub-problem. The intuition behind this order is that, by prioritizing sub-problems that are more likely to find counterexamples, we may quickly find a counterexample and thereby immediately terminate the verification. If we cannot find it after visiting all sub-problems, we achieve certification of the problem.

4.1 Counterexample Potentiality Order

We introduce an order over different sub-problems based on their probability of containing counterexamples. Given a node in `BaB` tree that identifies a sub-problem, we can infer this probability using the following two attributes:

Node depth. In a `BaB` tree, the depth of a node signifies the levels of problem splitting, and for more finely-split sub-problems, `LpVerifier` introduces less over-approximation. Because of this, if a node Γ with a greater depth is still deemed by `LpVerifier` as violating the specification (i.e., the verifier assessment $\hat{p}$ is negative), it is more likely that Γ indeed contains real counterexamples.

Verifier assessment. Given a node in BaB tree that identifies a sub-problem, its $\hat{p}$ returned by `LpVerifier` can be considered as a quantitative indicator of *how far* the sub-problem is from being violated. Due to our assumption about the monotonicity of `LpVerifier` in performing over-approximation, given a fixed `LpVerifier`, $\hat{p}$ is correlated to the original output region of the neural network. Therefore, in the case $\hat{p}$ is negative, the greater $|\hat{p}|$ is, there is a higher possibility that the original output region is closer to violation of the specification, and so it is more likely that the sub-problem contains a real counterexample.

Based on the above two node attributes, we define the suspiciousness of a BaB tree node, and then define a Counterexample POtentiality (CePO) order over different nodes.

▶ **Definition 6** (Suspiciousness of sub-problems). *Let Γ be a node of the BaB tree that has a verifier assessment $\hat{p}$ (with a counterexample $\hat{\boldsymbol{x}}$ if $\hat{p} < 0$). The suspiciousness $\mathsf{susp}(\Gamma) \in [0,1] \cup \{+\infty, -\infty\}$ of the node Γ maps Γ to a real number as follows:*

$$\mathsf{susp}(\Gamma) := \begin{cases} -\infty & \text{if } \hat{p} > 0 \\ +\infty & \text{if } \hat{p} < 0 \text{ and } \mathtt{valid}(\hat{\boldsymbol{x}}) \\ \lambda \frac{\mathtt{depth}(\Gamma)}{K} + (1-\lambda)\frac{\hat{p}}{\hat{p}_{\min}} & \text{otherwise} \end{cases}$$

where $\lambda \in [0,1]$ is a parameter that controls the weights of the two attributes, and K is the total number of neurons (i.e., ReLUs) in the network.

Intuitively, the suspiciousness of a node encompasses a heuristic that estimates the probability of the relevant sub-problem violating the specification. It is particularly meaningful in the case when $\hat{p} < 0$ and the counterexample is spurious, and set to be $+\infty$ if the sub-problem is provably violated, and $-\infty$ if the sub-problem is certified. By their suspiciousness, we define the CePO order over different nodes as follows:

▶ **Definition 7** (Counterexample potentiality (CePO) order). *Let Γ_1 and Γ_2 be two nodes in a BaB tree, and $\hat{p}_1$ and $\hat{p}_2$ be verifier assessments for Γ_1 and Γ_2, respectively. We define a CePO order $\sqsubset$ between the two nodes as follows:*

$$\Gamma_1 \sqsubset \Gamma_2 \quad \textit{iff} \quad \mathsf{susp}(\Gamma_1) < \mathsf{susp}(\Gamma_2)$$

The CePO order allows us to sort the nodes in BaB tree,[1] and so it can serve as a guidance to our verification approach in §4.2 and §4.3.

4.2 Oliva$^{\mathsf{GR}}$: Greedy Exploration of BaB Tree

The Oliva$^{\mathsf{GR}}$ algorithm, presented in Alg. 2, implements a greedy strategy that explores the space of BaB tree nodes guided by the CePO order. Compared to the classic BaB, it always selects the most suspicious node to expand, such that it can maximize the probability of finding counterexamples and thereby conclude the verification problem efficiently.

The algorithm begins with applying the approximated verifier `LpVerifier` to the original verification problem, identified by the ReLU specification ε (Line 2), which returns a tuple $\langle \hat{p}, \hat{\boldsymbol{x}} \rangle$ containing a verifier assessment $\hat{p}$, possibly followed by a counterexample $\hat{\boldsymbol{x}}$. The suspiciousness $\mathsf{susp}(\varepsilon)$ of the root node is then computed based on this assessment. At this point, if $\hat{p} > 0$ or if $\hat{p} < 0$ with a valid counterexample $\hat{\boldsymbol{x}}$, the algorithm can be immediately

[1] In the case if two nodes have the same suspiciousness, we simply impose a random order; in the case both are $-\infty$ or $+\infty$, the comparison is meaningless and so we do not need to sort them.

Algorithm 2 Oliva$^{\mathsf{GR}}$: The proposed greedy algorithm.

Require: A neural network N, input and output specification Φ and Ψ, an approximated verifier $\texttt{LpVerifier}(\cdot)$, a ReLU selection heuristic $\mathsf{H}(\cdot)$, and a hyperparameter λ.
Ensure: A *verdict* $\in \{\mathsf{true}, \mathsf{false}, \texttt{timeout}\}$

1: $\mathcal{T} \leftarrow \{\varepsilon\}$
2: $\langle \hat{p}, \hat{\boldsymbol{x}} \rangle \leftarrow \texttt{LpVerifier}(N, \Phi, \Psi, \varepsilon)$
3: $\mathsf{R}(\varepsilon) \leftarrow \mathsf{susp}(\varepsilon)$ ▷ a metric for child selection
4: **if** $\hat{p} < 0$ and $\texttt{not valid}(\hat{\boldsymbol{x}})$ **then**
5: **while** not reach termination condition **do**
6: GreedyBaB$(\varepsilon, N, \Phi, \Psi)$
7: **return** $\begin{cases} \mathsf{true} & \text{if } \mathsf{R}(\varepsilon) = -\infty \\ \mathsf{false} & \text{if } \mathsf{R}(\varepsilon) = +\infty \\ \texttt{timeout} & \text{otherwise} \end{cases}$
8: **else**
9: **return** $\begin{cases} \mathsf{true} & \text{if } \hat{p} > 0 \\ \mathsf{false} & \text{if } \hat{p} < 0 \text{ and } \texttt{valid}(\hat{\boldsymbol{x}}) \end{cases}$

10: **function** GreedyBaB(Γ, N, Φ, Ψ)
11: $r_k \leftarrow \mathsf{H}(\Gamma)$
12: **if** $\Gamma \cdot r_k^+ \in \mathcal{T}$ **then** ▷ check existence of children
13: $\Gamma^* \leftarrow \Gamma \cdot a^*$ s.t. $a^* \leftarrow \underset{a \in \{r_k^+, r_k^-\}}{\arg\max}\, \mathsf{R}(\Gamma \cdot a)$
14: GreedyBaB$(\Gamma^*, N, \Phi, \Psi)$
15: **else**
16: **for** $a \in \{r_k^+, r_k^-\}$ **do** ▷ $\mathcal{T}$ expansion via BaB.
17: $\langle \hat{p}, \hat{\boldsymbol{x}} \rangle \leftarrow \texttt{LpVerifier}(N, \Phi, \Psi, \Gamma \cdot a)$ ▷ apply `LpVerifier` with $\Gamma \wedge a$
18: $\mathsf{R}(\Gamma \cdot a) \leftarrow \mathsf{susp}(\Gamma \cdot a)$ ▷ compute R
19: $\mathcal{T} \leftarrow \mathcal{T} \cup \{\Gamma \cdot a\}$ ▷ add to the tree of $\Gamma \wedge a$
20: $\mathsf{R}(\Gamma) \leftarrow \underset{a \in \{r_k^+, r_k^-\}}{\arg\max}\, \mathsf{R}(\Gamma \cdot a)$

terminated with a conclusive verdict (Line 9). Otherwise, the algorithm enters its main loop where it iteratively calls GreedyBaB to split and verify the sub-problems until a termination condition is reached (Line 5-7). We elaborate on the termination condition later.

The GreedyBaB function implements the main process of tree exploration and problem splitting. By each of its execution, it selects the maximal sub-problem in terms of the CePO order in the tree and applies `LpVerifier` to its subsequent sub-problems with the aim of finding counterexamples. The function begins with selecting a ReLU r_k as a successor of the current node (Line 11) using the pre-defined ReLU selection heuristics H (see §3.2), and then it recursively calls GreedyBaB until it reaches the greatest node Γ, in terms of the CePO order, whose children are not expanded yet (Line 12-14). After reaching such a node Γ, it expands the children of Γ, by applying `LpVerifier` respectively to the two sub-problems identified by the children of Γ (Line 16-17). It also computes and records the suspiciousness of the newly expanded children (Line 18), and updates $\mathcal{T}$ that keeps track of the tree (Line 19). Lastly, the greater suspiciousness over the children are propagated backwards to ancestor nodes until the root (Line 20), serving as a reference for future node selection.

Termination condition

The main loop in Line 5 of Alg. 2 can be terminated on the satisfaction of any of the following three conditions:

- $\mathsf{R}(\varepsilon) = -\infty$: This implies that all leaf nodes have been verified successfully (i.e., $\hat{p} > 0$ for all leaves, otherwise by Line 20 $\mathsf{R}(\varepsilon)$ cannot be $-\infty$), allowing the algorithm to return a true verdict that certifies the specification satisfaction;
- $\mathsf{R}(\varepsilon) = +\infty$: This implies that a valid counterexample has been found in some leaf node, and so by Line 20 its suspiciousness of $+\infty$ can be back-propagated to the root node; in this case, the algorithm can be terminated with a false verdict;
- `timeout`: This occurs when the algorithm exceeds its allocated time budget without reaching either of the above conclusive verdicts.

The three termination conditions correspond to the three cases of return in Line 7.

4.3 Oliva$^{\mathsf{SA}}$: Simulated-Annealing-Style Exploration of BaB Tree

The greedy strategy in §4.2 exploits the CePO order in the exploration of `BaB` tree, so it can efficiently move towards the sub-problems that are more likely to find counterexamples. However, as it is a greedy strategy, in the case if the CePO order is not sufficiently precise, the verification process can be easily trapped into a local optimum, and miss the chances of finding counterexamples in other branches than the one suggested by the CePO order.

To bridge this gap, we propose an approach that adapts the classic framework of *simulated annealing*, which not only follows the CePO order, but also takes other branches into account. As a consequence, during the verification, it strikes a balance between "exploitation" of the suspicious branches and "exploration" of the less suspicious branches.

"Hill climbing" vs. "Simulated annealing"

Hill climbing is a stochastic optimization technique that aims to find the optimum of a black-box function. Due to the black-box nature of the objective function, it relies on sampling in the search space and selects only the samples that optimize the objective function as the direction to move. Therefore, this is a greedy strategy, similarly to our proposed approach Oliva$^{\mathsf{GR}}$ in §4.2. While Oliva$^{\mathsf{GR}}$ does not need to sample the search space, it can select the sub-problem that is more promising, and thereby move towards the direction that is more likely to achieve the objective. As a consequence, they both suffer from the issue of "local optima".

In the field of stochastic optimization, *simulated annealing* [24] is an effective approach to mitigate the issue of "local optima" in hill climbing. It is inspired by the process of *annealing* in metallurgy, in which the temperature is initially high but slowly decreases such that the physical properties of metals can be stabilized. In simulated annealing, there is also a temperature that slowly decreases throughout the process: when the temperature is initially high, it tends to explore the search space and assigns a considerably high probability to accept a sample that is not the optimal; as temperature goes down, it converges to the optimum that is likely to be the global one, thanks to the exploration of the search space at the initial stage.

Our proposed approach Oliva$^{\mathsf{SA}}$ adapts simulated annealing to our problem setting, and the core idea involves that, at the initial stage, we allow more chances of exploring the branches that are less promising. Then, after we have comprehensively explored the search space and obtained the information about the suspiciousness of different branches, we tend to exploit the branches that are more suspicious, namely, that are more likely to contain counterexamples.

Algorithm 3 Oliva$^{\mathsf{SA}}$: The proposed simulated annealing algorithm.

Require: A neural network N, input and output specification Φ and Ψ, an approximated verifier $\texttt{LpVerifier}(\cdot)$, a ReLU selection heuristic $\mathsf{H}(\cdot)$, and a hyperparameter λ.
Ensure: A *verdict* $\in \{\mathsf{true}, \mathsf{false}, \texttt{timeout}\}$

1: $\mathcal{T} \leftarrow \{\varepsilon\}$
2: $\langle \hat{p}, \hat{\boldsymbol{x}} \rangle \leftarrow \texttt{LpVerifier}(N, \Phi, \Psi, \varepsilon)$
3: $\mathsf{R}(\varepsilon) \leftarrow \mathsf{susp}(\varepsilon)$ ▷ a metric for child selection
4: $T \leftarrow T_{max}$ ▷ temperature
5: **if** $\hat{p} < 0$ and $\texttt{not valid}(\hat{\boldsymbol{x}})$ **then**
6: **while** not reach termination condition **do**
7: $T \leftarrow \alpha \cdot T$ ▷ T is decreased by $(1-\alpha)T$ in each iteration
8: $\text{SABaB}(\varepsilon, N, \Phi, \Psi)$
9: **return** $\begin{cases} \mathsf{true} & \text{if } \mathsf{R}(\varepsilon) = -\infty \\ \mathsf{false} & \text{if } \mathsf{R}(\varepsilon) = +\infty \\ \texttt{timeout} & \text{otherwise} \end{cases}$
10: **else**
11: **return** $\begin{cases} \mathsf{true} & \text{if } \hat{p} > 0 \\ \mathsf{false} & \text{if } \hat{p} < 0 \text{ and } \texttt{valid}(\hat{\boldsymbol{x}}) \end{cases}$

12: **function** $\text{SABaB}(\Gamma, N, \Phi, \Psi)$
13: $r_k \leftarrow \mathsf{H}(\Gamma)$
14: **if** $\Gamma \cdot r_k^+ \in \mathcal{T}$ **then**
15: $\Delta p \leftarrow \exp\left(\frac{\min \mathsf{R}(\Gamma \cdot a) - \max \mathsf{R}(\Gamma \cdot a)}{T}\right)$ s.t. $a \in \{r_k^+, r_k^-\}$
16: $\Gamma^* \leftarrow \Gamma \cdot a^*$ s.t. $a^* \leftarrow \begin{cases} \text{randomly choose } r_k^+ \text{ or } r_k^- & \text{if } \texttt{rand}(0,1) < \Delta p \\ \underset{a \in \{r_k^+, r_k^-\}}{\arg\max}\, \mathsf{R}(\Gamma \cdot a) & \text{otherwise} \end{cases}$
17: $\text{SABaB}(\Gamma^*, N, \Phi, \Psi)$
18: **else**
19: **for** $a \in \{r_k^+, r_k^-\}$ **do** ▷ $\mathcal{T}$ expansion via BaB.
20: $\langle \hat{p}, \hat{\boldsymbol{x}} \rangle \leftarrow \texttt{LpVerifier}(N, \Phi, \Psi, \Gamma \cdot a)$ ▷ apply `LpVerifier` with $\Gamma \wedge a$
21: $\mathsf{R}(\Gamma \cdot a) \leftarrow \mathsf{susp}(\Gamma \cdot a)$ ▷ compute R
22: $\mathcal{T} \leftarrow \mathcal{T} \cup \{\Gamma \cdot a\}$ ▷ add to the tree of $\Gamma \wedge a$
23: $\mathsf{R}(\Gamma) \leftarrow \underset{a \in \{r_k^+, r_k^-\}}{\arg\max}\, \mathsf{R}(\Gamma \cdot a)$

Algorithm details

The Oliva$^{\mathsf{SA}}$ algorithm is presented in Alg. 3. It also starts with checking the original verification problem (Line 2), and enters the loop of tree exploration if the original problem cannot be solved by `LpVerifier` (Line 5). However, compared to Oliva$^{\mathsf{SA}}$, it has a notable difference about the adoption of a temperature T (Line 4) which is a global variable that keeps decreasing in each loop of the algorithm (Line 7).

In the function SABaB, the temperature T is used when selecting the nodes to proceed. In the case if the children of the current node Γ have been expanded (Line 14), unlike Oliva$^{\mathsf{GR}}$ that always prefers the most suspicious child, Oliva$^{\mathsf{SA}}$ selects a child according to the policy adapted from the original simulated annealing:

- It first computes an acceptance probability Δp (Line 15), by which it determines whether the selection of a child that is less promising is acceptable. This probability Δp is decided by both the difference of "energy" (defined by the suspiciousness difference between two children) and the temperature T;
- In the original simulated annealing, a sample that is more promising can be accepted in any case, and a sample that is less promising can be accepted with the probability Δp. In our context, we adapt this policy as follows (Line 16):
  - If a random value in $[0, 1]$ is less than Δp, we randomly select a child from the two children of Γ with the same probability, despite the CePO order over the two children;
  - Otherwise, we select the more suspicious child following the CePO order.

The selected child will be used as the argument for the recursive call of SABaB, in order to proceed towards a node whose children are not expanded. After achieving such a node Γ, it expands the children of Γ (Lines 19-22) by applying `LpVerifier` to each child of Γ, recording their suspiciousness (Line 21) and updating the `BaB` tree (Line 22). Lastly, it back-propagates the greater suspiciousness over the children until the root (Line 23), similarly to Oliva$^{\mathsf{SA}}$.

This gradual transition from exploration to exploitation helps Oliva$^{\mathsf{SA}}$ to avoid premature convergence while ensuring an eventual focus on the promising branches. The termination conditions remain the same as in Oliva$^{\mathsf{GR}}$, checking for full verification ($\mathsf{R}(\varepsilon) = -\infty$), counterexample discovery ($\mathsf{R}(\varepsilon) = +\infty$), or timeout. However, by pursuing a higher coverage of the sub-problem space before being greedy, Oliva$^{\mathsf{SA}}$ increases the possibility of discovering counterexamples that might be missed by the purely greedy strategy of Oliva$^{\mathsf{GR}}$.

▶ **Theorem 8.** *Both* Oliva$^{\mathsf{GR}}$ *and* Oliva$^{\mathsf{SA}}$ *are sound and complete.*

Proof. The proofs of soundness and completeness of our approaches are similar to that of `BaB` in Lemma 5, so we skip the details. Intuitively, our approaches only introduce an order of visiting different nodes in `BaB` tree, but hold all the conditions that are necessary for the soundness and completeness of `BaB`. ◀

5 Experimental Evaluation

5.1 Experiment Settings

Baselines and Metrics

We compare the two versions of Oliva, namely, Oliva$^{\mathsf{GR}}$ and Oliva$^{\mathsf{SA}}$, with three state-of-the-art neural network verification tools $\alpha\beta$-Crown [59, 51], NeuralSAT [11], and `BaB`-baseline, as presented in §3.2. The settings of baseline approaches are detailed below:

- `BaB`-baseline is implemented based on the ERAN framework [41, 44], which employs LP-based triangle relaxation for bounding the output of ReLU functions, and utilizes DeepSplit [21] as the ReLU selection heuristics for selecting ReLU function to split, i.e., H in Alg. 1, Alg. 2, and Alg. 3.
- $\alpha\beta$-Crown [59, 51] is applied with its default branch-and-bound settings. Moreover, a balanced strategy kFSB from FSB [10] is selected as the ReLU selection heuristics for selecting the ReLU function to split.
- NeuralSAT [11] is applied with its default DPLL(T) framework and we select the stabilized optimization as the neuron stability heuristics for ReLU activation pattern search. Additionally, it is registered with a random attack [8, 56] to reject the easily detected violation instances at the early stage of verification processes.

Table 1 Benchmark details for the evaluation of verification.

Model	Architecture	Dataset	#Activations	# Instances	#Images
$\texttt{MNIST}_{\texttt{L2}}$	2 × 256 linear	MNIST	512	100	70
$\texttt{MNIST}_{\texttt{L4}}$	4 × 256 linear	MNIST	1024	78	52
$\texttt{OVAL21}_{\texttt{BASE}}$	2 Conv, 2 linear	CIFAR-10	3172	173	53
$\texttt{OVAL21}_{\texttt{WIDE}}$	2 Conv, 2 linear	CIFAR-10	6244	196	40
$\texttt{OVAL21}_{\texttt{DEEP}}$	4sub Conv, 2 linear	CIFAR-10	6756	143	53

For our approaches, the hyperparameters are set as follows: $\lambda = 0.5$ (see Def. 6), $T_{max} = 1$ (see Line 4 of Alg. 3) and $\alpha = 0.99$ (see Line 7 of Alg. 3); in RQ3, we study the impact of these hyperparameters on the performance of our approaches.

We apply each of the five approaches (including two proposed approaches and three baseline approaches) to each of the verification problems, and we adopt 1000 secs as our time budget, following the VNN-COMP competition [30]. If an approach manages to solve the problem (either verifies the problem or reports a real counterexample), we deem this run as a *solved* verification process, and record the time cost for reaching the verification conclusion. In particular, our $\mathsf{Oliva}^{\mathsf{SA}}$ is a stochastic approach, namely, its performance is subject to randomness. To compare its performance with other approaches, in Table 2, Table 3 and Fig. 5, we only show the performance of one random run; in Fig. 6, we particularly study the influence of randomness to $\mathsf{Oliva}^{\mathsf{SA}}$, by repeating each verification process for 5 times.

Our evaluation metrics include the number of instances solved by an approach and the time costs for each successful verification process. For comparison of two different approaches, we also compute the speedup rate, which is the ratio of the time costs of the two approaches.

Moreover, in order to understand whether our counterexample potentiality order works, we compare the performances of our tools with the baseline approach, respectively for the problems that are finally certified and the problems that are finally falsified. We further study the influence of the hyperparameters (including λ in Def. 6 and α that decides the change rate of temperature in Line 7 of Alg. 3) to the performances of our approaches. In the implementation of Oliva, we adopt the same approximated verifiers and ReLU selection heuristics as the BaB-baseline. The code and experimental data of Oliva are available online[2].

Datasets and Neural Networks

Our experimental evaluation uses two well-known datasets: MNIST, featuring images of handwritten digits for classification, and CIFAR-10, featuring images of various real-world objects like airplanes, cars, and animals, with networks tasked to identify each class. These datasets are standard benchmarks that have been widely used in the neural network verification community and adopted in the VNN-COMP [30], an annual competition in the community for comparing the performances of different verification tools. We evaluate two networks trained on MNIST that have fully-connected layers only, and three neural networks trained on CIFAR-10 that have both convolutional layer and fully-connected layers, with different network architectures, following common evaluation utilized in ERAN [32, 51] and OVAL21 [4, 5] benchmarks. More details of these benchmarks are presented in Table 1.

[2] https://github.com/DeepLearningVerification/Oliva

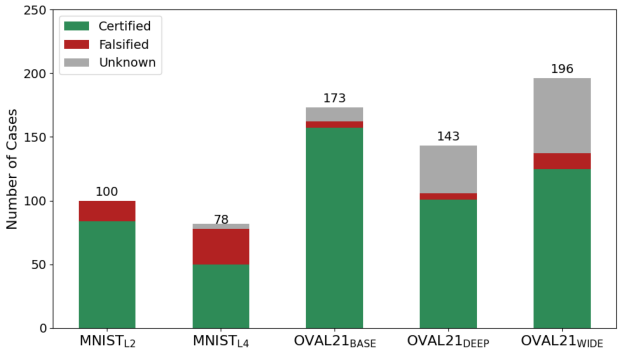


Figure 3 The distribution of Certified/Falsified/Unknown cases generated by `BaB`-baseline.

Specifications

In our experiments, all our neural network models are used for image classification tasks, and all the specifications adopted are about local robustness of the neural network models. Each input specification defines an ϵ as the threshold for perturbation; and each output specification requires the expected label to be matched by the original input of the model. In total, we collected 690 problem instances. Table 1 under the column "# Instances" displays the number of instances in each model, and "# Images" shows the number of different images covered by the different instances. Fig. 3 demonstrates the distribution of verification verdicts across the five models in our benchmark set, according to our experimental results. The green portion denotes tasks eventually verified ("Certified"), the red portion denotes tasks that were shown to violate the property ("Falsified"), and the gray portion corresponds to tasks that remained inconclusive ("Unknown").

In order to present a meaningful comparison, we need to avoid the verification problems that are too simple, for which the problem can be solved within a small number of problem splitting and so there is no need to expand the `BaB` tree too much. To that end, we perform a selection of parameters (i.e., ϵ in Def. 2) of input specifications, from a range of 0/255 to 16/255 under the L_∞ norm. Our approach involves a binary search-like algorithm to determine the proper perturbation values for each image, as follows:

1. Initially, we set 0/255 as the lower bound l and 16/255 as the upper bound u, and calculates the midpoint by taking $m = \frac{l+u}{2}$;
2. We apply `BaB`-baseline to the verification problem with m as the ϵ, and check the number of nodes in the `BaB` tree. If the tree size is greater than 1, we accept it as a candidate parameter and move to the next image; otherwise, based on the results of verification, we proceed to update m as like Step 1 and repeat Step 2 as follows:
   - If the specification is violated, it implies that ϵ is too large and so we set u to be m, and update m accordingly;
   - If the specification is satisfied, it implies that ϵ is too small and so we set l to be m, and update m accordingly.

This process continues until a pre-defined budget is exhausted.

Fig. 4 shows the distribution of node counts across all models for the verification instances. The distribution confirms that all instances involve multiple tree nodes, ensuring meaningful sub-problem selection. Notably, more than half of the tree sizes fall within the range of 100-1000 nodes, highlighting the importance of effective sub-problem selection. The complexity of most instances necessitates careful choice in verification instances.

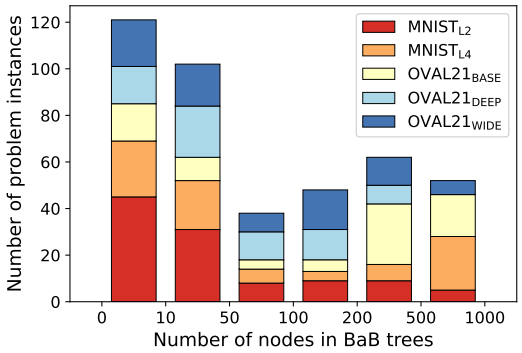

Figure 4 The distribution of the tree sizes generated by BaB-baseline.

Software and Hardware Setup

All experiments were conducted on an AWS EC2 instance running a Linux system with 16GB of memory and an 8-core Xeon E5 2.90 GHz CPU. All tools are developed in Python 3.9, and we used the GUROBI solver 9.1.2 [19] for the LP-based optimization. For each verification instance, we set a time budget as 1000 seconds which is consistent with VNN-COMP [30].

5.2 Evaluation

RQ1: Is Oliva more efficient than existing approaches?

In Table 2, we compare the performance of our approach with the state-of-the-art baseline approaches, BaB-baseline, $\alpha\beta$-Crown and NeuralSAT, across all our verification problems.

We observe that, Oliva shows evident improvement for benchmarks including OVAL21$_{BASE}$, OVAL21$_{DEEP}$ and OVAL21$_{WIDE}$. On the OVAL21$_{BASE}$, Oliva^{SA} solves 159 instances in an average of 155.29 seconds, far surpassing BaB-baseline (42 instances in 770.7 seconds) and $\alpha\beta$-Crown (58 instances in 641.7 seconds). For OVAL21$_{DEEP}$, Oliva^{GR} solves 92 instances, compared to 33 by BaB-baseline and 55 by $\alpha\beta$-Crown, while using less time (250.72 seconds compared to 552.24 seconds). The difference is even more pronounced for OVAL21$_{WIDE}$, where Oliva^{GR} solves 131 instances in an average of 240.16 seconds, greatly exceeding both BaB-baseline (40 instances in 733.73 seconds) and $\alpha\beta$-Crown (63 instances in 557.51 seconds).

For MNIST$_{L2}$ benchmarks that have simpler architectures compared to OVAL21, BaB-baseline performs well with 96 instances solved, while Oliva^{GR} achieves 99 solved instances with a faster average time (57.76 seconds). As the size of the network increases to MNIST$_{L4}$, $\alpha\beta$-Crown declines to 44 instances, while Oliva^{GR} achieves 67 solved instances with an average time of 146.31 seconds. These results highlight the effectiveness and efficiency of Oliva, compared to the baseline approaches.

Table 3 presents a pairwise comparison, in which each cell indicates the number of problem instances solved by the approach listed in the row, but not solved by the approach listed in the column. Namely, we can perform pairwise comparison between two approaches by comparing the values in a pair of cells symmetric to the diagonal of Table 3. Compared to baseline approaches, our approaches demonstrate superior performances, as indicated by the green area that shows the number of additional problems solved by our approaches by not by baseline approaches; in comparison, the numbers in the red area, that includes the number of problems solved by baseline approaches, but not solved by our approaches, are much less. By comparing the performances between Oliva^{GR} and Oliva^{SA}, we find that Oliva^{GR} slightly

Table 2 RQ1 – Overall comparison of different verification approaches, in terms of the number of solved problem instances and the time costs (in secs).

Model	BaB-baseline		$\alpha\beta$-Crown		Neuralsat		Oliva^{GR}		Oliva^{SA}	
	Solved	Time	Solved	Time	Solved	Time	Solved	Time	Solved	Time
$\texttt{MNIST}_{\texttt{L2}}$	96	126.41	87	51.32	99	32.37	95	96.79	99	57.76
$\texttt{MNIST}_{\texttt{L4}}$	65	194.74	44	428.03	54	392.04	67	146.31	53	142.72
$\texttt{OVAL21}_{\texttt{BASE}}$	42	770.7	58	641.7	70	621.21	154	184.96	159	155.29
$\texttt{OVAL21}_{\texttt{DEEP}}$	33	694.74	55	552.24	55	539.59	92	250.72	87	261.68
$\texttt{OVAL21}_{\texttt{WIDE}}$	40	733.73	63	557.51	65	533.01	131	240.16	112	288.0

Table 3 RQ1 – Pairwise comparison on the number of additional solved problem instances from all verification tasks. The number in each cell implies the number of problem instance solved by the approach of the row, but not solved by the approach of the column.

	BaB-Baseline	$\alpha\beta$-Crown	NeuralSAT	Oliva^{GR}	Oliva^{SA}
BaB-Baseline	0	80	59	8	13
$\alpha\beta$-Crown	111	0	11	23	39
NeuralSAT	126	47	0	30	46
Oliva^{GR}	271	255	226	0	40
Oliva^{SA}	247	242	213	11	0

outperforms Oliva^{SA}, in that it solves 40 additional problems than Oliva^{SA}, although there are 11 problems Oliva^{SA} solves but Oliva^{GR} does not do. That said, it also demonstrates the complementary strengths between different approaches, namely, there is no one global optimal approach that can solve all the problems, and so it is worthwhile to try different approaches when one approach does not work.

In Fig. 5, we take a further comparison between Oliva and BaB-baseline, and draw a scatter plot to show the individual instances for which Oliva outperform BaB-baseline. The x-axis represents the time taken by the BaB-baseline method in seconds, while the y-axis shows the speedup ratio of Oliva over BaB-baseline. This ratio is calculated as $\tau_{\text{BaB}}(i)/\tau_{\text{Oliva}}(i)$, where $\tau_{\text{BaB}}(i)$ and $\tau_{\text{Oliva}}(i)$ denote the time taken by BaB-baseline and Oliva on the instance i, respectively. The blue dots and orange crosses represent all of the individual problem instances. The red line is the threshold at $1\times$ speedup, above which the ratio distinguishes that Oliva outperforms than BaB-baseline.

Across all the models, it can be seen that a significant number of blue dots (Oliva^{GR}) and orange crosses (Oliva^{SA}) appear above the red line, indicating that Oliva outperforms the BaB-baseline. Notably, around the 1000-second mark on the x-axis, there are multiple instances where the speedup ratio is up to $80\times$, meaning that Oliva can solve these problems more than 80 times faster than the BaB-baseline. This trend is particularly evident in OVAL21 models ($\texttt{OVAL21}_{\texttt{BASE}}$, $\texttt{OVAL21}_{\texttt{DEEP}}$, and $\texttt{OVAL21}_{\texttt{WIDE}}$) that have relatively complex architectures.

In Table 4, we summarize the statistical information of speedup ratios of our approaches over BaB-baseline. Overall, the two variants of Oliva achieve consistent performance improvements, with median speedups exceeding 2 times and mean gain values around 7 times.

Similar to simulated annealing, our tool Oliva^{SA} is a stochastic approach that is subject to randomness. To analyze the impact of randomness on the performance of Oliva^{SA}, we conduct five independent attempts with all the verification problems and compare them with the deterministic Oliva^{GR}. Since Oliva^{SA} incorporates a simulated annealing approach that makes probabilistic decisions during sub-problem exploration, different runs may explore the verification space in different orders, potentially leading to variations in performance.

Figure 5 RQ1 – Comparison of time cost and speedup ratio of the two variants $\mathsf{Oliva}^{\mathsf{GR}}$ and $\mathsf{Oliva}^{\mathsf{SA}}$ of our proposed approach Oliva over BaB-baseline.

The results are presented in Fig. 6, in which we only present the problems that are either solved by $\mathsf{Oliva}^{\mathsf{GR}}$ or $\mathsf{Oliva}^{\mathsf{SA}}$. Overall, the performance comparisons between $\mathsf{Oliva}^{\mathsf{GR}}$ and $\mathsf{Oliva}^{\mathsf{SA}}$ are consistent across different attempts, and are concentrated in the 0.5-2× speedup bracket. This result suggests that the randomness in the simulated annealing approach does

Figure 6 The distributions of conclusive instances by the variant of Oliva^{SA}, in different speedups and time costs compared with Oliva^{GR}. The black dashed line indicates the performance of Oliva^{GR}: above the black dashed line, Oliva^{GR} outperforms Oliva^{SA}; below it, Oliva^{SA} performs better.

not substantially impact the effectiveness of Oliva^{SA}. Notably, in Fig 6c and Fig 6d, with the nature of the randomness, Oliva^{SA} exhibits the strength in finding solutions in the time cost of 100-600s that might be difficult to solve by the deterministic approach of Oliva^{GR}.

Figure 7 RQ2 – Comparison between BaB-baseline and Oliva for violated and certified verification problem instances.

RQ2: How effective is Oliva in handling violated and certified problem instances, respectively?

Fig. 7 shows the performance advantage of Oliva^{GR} and Oliva^{SA} over BaB-baseline across different verification tasks. For violated instances (i.e., confirmed counterexample by BaB-baseline and Oliva), Oliva^{GR} and Oliva^{SA} consistently demonstrate superior efficiency, evidenced by lower median time costs and smaller interquartile ranges across all models.

In Fig. 7a, Oliva shows notably lower median time costs and compressed interquartile ranges compared to BaB-baseline, indicating more consistent and faster execution. In $\texttt{OVAL21}_{\texttt{BASE}}$ and $\texttt{OVAL21}_{\texttt{DEEP}}$ (Fig. 7c and Fig. 7d), Oliva^{GR} and Oliva^{SA} sub-problem selection

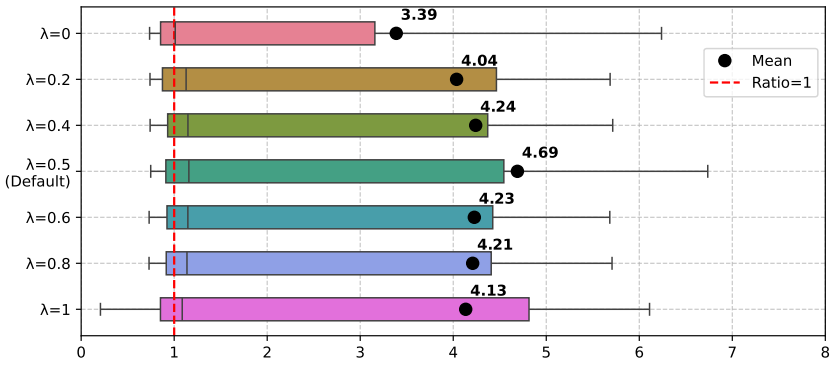

Figure 8 RQ3 – Speedup over BaB-baseline under different hyperparameter λ values on verification tasks with $\texttt{OVAL21}_{\texttt{WIDE}}$.

strategy is highly effective in problem instances where counterexamples exist. For $\texttt{OVAL21}_{\texttt{BASE}}$, Oliva^{GR} achieves a median speed-up ratio of approximately 2.5× for violated instances, and Oliva^{SA} with reaching up to 4× faster execution than BaB-baseline. Similarly, for $\texttt{OVAL21}_{\texttt{DEEP}}$, the median speed-up ratio is around 3×, with peak performance showing up to 5× acceleration.

In contrast, for certified instances (i.e., confirmed robust), two variants of Oliva are generally on par with the BaB-baseline, indicating that in these cases, the performance of Oliva is comparable with BaB-baseline, which does not introduce overhead costs. This is expected, because in BaB, most of the time consumption is devoted to the problem solving process for each sub-problem. While our proposed approach introduces little overhead in the selection of the sub-problems to proceed with, the overhead is almost invisible.

RQ3: How does the hyperparameter λ and α in the order influences the performance of Oliva?

Fig. 8 highlights the impact of the λ parameter on the speedup of Oliva^{GR} over BaB-baseline for the verification task on $\texttt{OVAL21}_{\texttt{WIDE}}$ model. In this experiment, we randomly select 20% of the instances, including 13 conclusive and 12 unknown cases, based on the BaB-baseline performance. The chosen instances are at varying levels of time consumption. This analysis examines λ values ranging from 0.0 to 1.0, and summarizes the speedup ratios of Oliva^{GR} under different λ values. The findings reveal that, first, the performances of Oliva^{GR} under different λ are relatively stable, mostly outperforming BaB-baseline. This implies that both of the attributes, including the level of problem splitting and the verifier assessment, are effective in guiding the space exploration. Moreover, the performance slightly improves as λ increases from 0.0 to 0.5, peaking at a speedup of 4.69. Beyond $\lambda = 0.5$, speedup declines, indicating 0.5 as the optimal value. In terms of the average improvement, the speedup vary from 3.39 to 4.69 and is not negligible, which emphasizes the importance of careful tuning of λ to maximize the efficiency of Oliva^{GR} in verification tasks.

Then, we settle $\lambda = 0.5$ as the default value to evaluate the temperature reduction parameter α, which ranges from 0.95 to 0.999, as suggested by [24]. Fig. 9 compares the speedup of Oliva^{SA} over Oliva^{GR}. The hyperparameter α determines the speed of "temperature" decreases during the verification processes, directly affecting the balances between exploration and exploitation. First, by the medians, we find that Oliva^{SA} under all α outperform Oliva^{GR}. Specifically, with $\alpha = 0.999$, Oliva^{SA} achieves better performance than Oliva^{GR} in average,

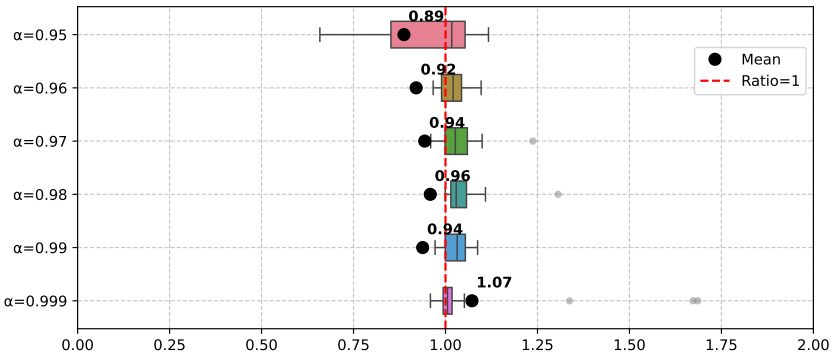

Figure 9 RQ3 – Speedup over Oliva$^{\text{GR}}$ under hyperparameter α values on verification tasks with $\texttt{OVAL21}_{\texttt{WIDE}}$.

which is a very slow cooling schedule (α close to 1) that allows the algorithm to thoroughly explore the search space early on before transitioning to exploitation. As α decreases, the temperature drops more rapidly, giving the algorithm less time to explore before converging on promising areas. The lower performance ratios seen with $\alpha = 0.95 - 0.98$ suggest that this faster cooling schedule may be too aggressive, causing Oliva$^{\text{SA}}$ to commit too quickly to certain branches of the verification tree without adequately exploring alternatives. By our inspection of experimental results, the relative low mean values are caused by some specific cases, for which Oliva$^{\text{SA}}$ does not perform well. Notably, when selecting $\alpha = 0.99$, while its mean ratio of 0.94 might seem underwhelming at a first glance, its median performance is notably strong compared to other α values, representing a balanced probability that allows sufficient exploration while maintaining steady progress toward exploitation. In practical verification tasks, as consistency can be as a valuable property, $\alpha = 0.99$ can thus be preferable despite its lower mean ratio.

6 Related Work

Neural Network Verification

Neural network verification has been extensively studied in the past few years, giving birth to many practical approaches [47, 23, 14, 22, 41, 44, 43, 29, 49, 39]. Approximated verifiers are perferable due to their efficiency, and many works aim to seek for tighter bounds for approximation refinement [2, 46, 40, 32, 31, 54, 27, 36, 15, 13, 9]. Some works aim to refine the approximation [55, 34, 20, 12, 60] by exploiting information from (spurious) counterexamples (known as CEGAR approach). In contrast, our approach does not aim to refine the approximation of the backend verifiers, but we estimate the probability of finding counterexamples in different sub-problems to efficiently explore the sub-problem space.

Problem Splitting Strategies in BaB

Problem splitting [38, 26, 16] is an important component in the `BaB` workflow, which is critical to the efficiency of verification [4]. Early research considers splitting input space by its dimensions [50, 1, 37]; however, that can lead to an exponential growth in the number of sub-problems w.r.t. the number of dimensions, which is intractable especially for applications that have high-dimensional data, such as image classification. More recently, many works start to perform problem splitting by decomposing ReLU functions, which can achieve

better performance [5] and scales better than input domain splitting. In these works, the ReLU selection strategy that decides the next neuron (i.e., the ReLU function) to be split is important and there emerge many effective strategies including DeepSplit [21] (which we adopted), BaBSR [5] and FSB [10]. Compared to those works, our approach is different and is orthogonal to them, because instead of selecting ReLU, we select the sub-problems to proceed with, which changes the naive breadth-first strategy of `BaB` in visiting the sub-problems. Notably, our work is in line with [57]; however, unlike [57] that targets incremental neural network verification, we target the problem of classic neural network verification, and we adopt a different stochastic optimization framework, i.e., simulated annealing.

Testing and Attacks

Testing is another effective quality assurance for neural networks, and it has also been extensively studied, such as [35, 33, 17, 45]. A similar line of works are adversarial attacks, that aim to generate adversarial examples [18, 3, 53, 58, 6] to fool the neural networks. While these approaches are efficient, they cannot provide rigorous guarantee on specification satisfaction, when they cannot find a counterexample, because they solve the problem by checking infinitely many single inputs in the input space. In comparison, our approach is sound, in the sense that if there does not exist a counterexample in the network, we can finally reach the certification of the network. This is because by our problem splitting, we deal with finitely many sub-problems.

7 Conclusion and Future Work

In this paper, we propose an approach Oliva with two variants Oliva^{GR} and Oliva^{SA} in order to achieve high efficiency of neural network verification. Oliva introduces a severity order over the sub-problems produced by `BaB`. This order, called counterexample potentiality, estimates the suspiciousness of each sub-problem in the sense how likely it contains a counterexample, based on both the level of problem splitting and the assessment from approximated verifiers that signify how far a sub-problem is from being violated. By prioritizing the sub-problems with higher counterexample potentiality, Oliva can efficiently reach verification conclusions – either finding a counterexample quickly or certifying the neural network without significant performance degradation. Specifically, our two variants of Oliva implement different strategies: *i*) Oliva^{GR} greedily exploits the most suspicious sub-problems; *ii*) Oliva^{SA}, inspired by simulated annealing, strikes a balance between exploitation of the promising sub-problems and exploration of the sub-problems that are less promising. Our experimental evaluation across 5 neural network models and 690 verification problems demonstrates that Oliva can achieve up to 80× speedup, compared to the state-of-the-art baseline approaches. Moreover, we also show the breakdown comparison for the certified problems and for the falsified problems, and we demonstrate that the performance advantages of the proposed approach indeed come from the strategy guided by counterexample potentiality.

To the best of our knowledge, our work is the first that exploits the power of stochastic optimization in neural network verification, by taking the sub-problems as the search space. In future, we plan to do more exploration in this direction, e.g., trying other stochastic optimization algorithms, such as genetic algorithms, and comparing the performances of different strategies, in order to deliver better verification approaches.

RacerF: Lightweight Static Data Race Detection for C Code

Tomáš Dacík
Faculty of Information Technology, Brno University of Technology, Czech Republic

Tomáš Vojnar

Faculty of Information Technology, Brno University of Technology, Czech Republic

Abstract

We present RacerF, a novel static analyser for thread-modular data race detection. The approach behind RacerF exploits static analysis of sequential program behaviour whose results are generalised for multi-threaded programs using a combination of lightweight under- and over-approximating methods. The tool is implemented as a plugin of the Frama-C platform and can leverage several analysis backends, most notably the Frama-C's abstract interpreter EVA. Although our methods are mostly heuristic without providing formal guarantees, our experimental evaluation shows that even for intricate programs, RacerF can provide very precise results competitive with more heavyweight approaches while being faster than them.

The research involved discussions with Julien Signoles from the Frama-C team at CEA that were supported by the project VASSAL: "Verification and Analysis for Safety and Security of Applications in Life" funded by the European Union under Horizon Europe WIDERA Coordination and Support Action/Grant Agreement No. 101160022.

Acknowledgements We appreciate discussions on the subject with Julien Signoles from the Frama-C team at CEA, France and with Adam Rogalewicz from FIT BUT, Czechia.

1 Introduction

Data races in concurrent programs belong among the most nasty bugs in computer programs: they are easy to cause, hard to spot during code inspection, and hard to catch by testing as they can manifest only very rarely. Due to this, a lot of effort has gone into designing as safe as possible libraries and languages for writing concurrent programs, but, on one hand, many programs are written using languages without such safety features (with the C language being a prominent example), and on the other hand, even in the safety-oriented languages such as Rust, unsafe programming is usually allowed and sometimes used, e.g., for performance reasons.

A lot of work has also been invested in designing various static as well as dynamic methods of finding data races and/or proving their absence. However, the complex behaviour of concurrent programs reflects in that such methods do often have problems with scalability

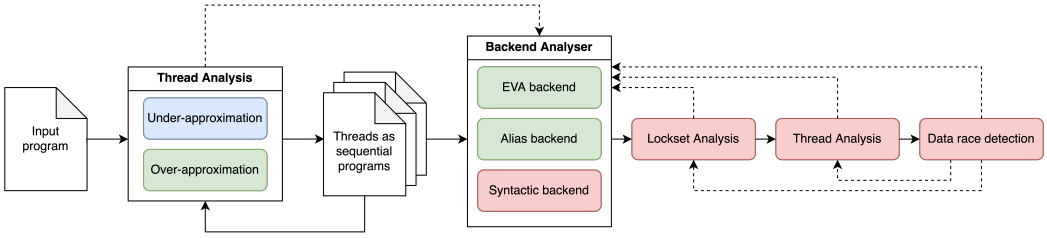

Figure 1 An overview of the workflow of RacerF. The phases with under- and over-approximation guarantees are marked by blue and green colour, respectively. The phases designed without guarantees are marked by red colour. The solid lines represent the workflow of individual analysis phases. The dashed lines represent queries on the results of other phases.

or precision. In this paper, we present a novel tool RacerF for thread-modular data race detection with the aim of providing a suitable balance between the scalability and precision of the analysis. We then also present our experience from running the tool and comparing it with several other data race detectors.

The approach implemented in RacerF relies on leveraging results of static analysis of the sequential behaviour of program threads for finding data races in multi-threaded programs. We use two strategies of combining information resulting from the analysis of the sequential behaviour of program threads: one under-approximates and one over-approximates the concurrent behaviour of the threads running in parallel. We combine these strategies to obtain a more precise analysis such that the under-approximation is used to find data races while the over-approximation is used to show their absence.

RacerF is implemented as a plugin of the Frama-C platform [10, 1] and is in particular designed for finding data races in C programs with POSIX threads (pthreads). RacerF can use several analysis backends implementing the underlying analysis of the sequential behaviour of program threads and differing in their precision and scalability. One of them is built on top of the Frama-C's value analysis plugin EVA based on abstract interpretation [6], one is purely syntactic, and the last one is based on Alias, Frama-C's plugin for may-alias and points-to analysis [5].

We have performed experiments with RacerF on a number of benchmarks coming both from the SV-COMP competition in software verification, which includes both synthetic benchmarks as well as benchmarks derived from real-world code, as well as on a number of student projects in an advanced course of operating systems. Although the approach behind RacerF is mostly heuristic without providing formal guarantees, our experimental evaluation shows that even for intricate programs, RacerF can provide very precise results competitive with more heavy-weight approaches while being faster than them.

Approach Overview

An overview of the workflow of RacerF is illustrated in Fig. 1. The core component is a *backend analyser* which answers several kinds of queries based on analysing individual threads as sequential programs (the general interface and several different backend analysers are described in Section 4). The *thread analysis* (Section 5) incrementally discovers new program threads and analyses them using the chosen backend analyser. Since the discovery of a new thread may add additional information, the process of thread discovery and their analysis using the backend analyser is repeated until a fixpoint is reached. Then, two helper

analyses are run to deal with checking whether two memory accesses may happen in parallel – a *lockset analysis* checks which accesses are guarded by which locks and an *active-threads analysis* checks when threads are created and joined (Section 6). Those analyses query results of the backend analysis, mainly for possible values of parameters of locking and threading functions. Finally, *data race detection* (Section 7) is performed. This phase checks memory accesses (using information provided by the backend analyser) and tracks whether they need to be protected and, if so, whether they indeed are. The detected issues are then classified into may- and must-data-races. Must-data-races are reported to the user, while an absence of may-data-races is used to claim program race-free.

Fig. 1 also depicts the approximation guarantees provided by the individual phases. Note that the combination of under- and over-approximating methods may seem problematic from the point of view of what can be guaranteed to hold for the produced results. However, we do not aim at providing guarantees in the sense of formal verification. Our aim is to achieve high efficiency and precision in practice even though some false alarms may be missed or some bugs not identified.

2 Related Work

RacerX [15] is a static analyser for C based primarily on a lockset analysis. The tool has been successfully used to find bugs in the kernels of several operating systems. Compared to our approach, RacerX uses a very simple pointer analysis for the representation of locks only. Further, RacerX uses many heuristics in individual analysis phases to deal with analysis mistakes while RacerF tries to achieve precision using careful ranking. RacerX is unfortunately not available for an experimental comparison. RacerD [4] is a compositional analyser implemented in the Infer framework. It provides scalability by analysing each function only once. Unlike us, RacerD targets Java programs with structural locking, assuming that all locking operations are balanced. Both RacerX and RacerD focus on under-approximation only. O2 [26] is another static checker building on the notion of origins unifying threads and events. The approach was implemented for C, C++, and Java/Android; and used to find many previously unknown bugs in real-world code. However, as we show in our experiments, it can still miss many data races in smaller but real-world programs.

On the other side, there are tools focused on soundness, rather than data race detection. Goblint [32] and Astrée [24, 27] rely on a thread-modular abstract interpretation to soundly over-approximate thread behaviour. The work [32] further proposes a way to handle common locking schemes in Linux driver devices. In our approach, we are not interested in the analysis of multithreaded programs in general and we can consequently afford more drastic approximations that seem to be sufficient for data race detection. We also focus on under-approximation to detect bugs.

As an alternative to static data race detection, various approaches based on *testing* and *dynamic analysis* can be used. A big challenge for these approaches is the fact that errors like data races can manifest in very rare behaviours only, which are difficult to catch, even through many repeated test runs. Coverage of such rare behaviours can be improved using approaches such as *systematic testing* [33] or *noise-based testing* [13, 17]. Another way is to use *extrapolating dynamic checkers*, such as [30, 14, 19], which can report warnings about possible errors even if those are not seen in the testing runs, based on spotting their symptoms. However, even though such checkers have proven quite useful in practice, they can, of course, still miss rarely occurring errors. Moreover, monitoring a run of large software

through such checkers may be quite expensive too.

Approaches based on *model checking*, i.e., exhaustive state-space exploration, can guarantee the discovery of all potentially present errors – either in general or at least up to some bound, often given in the number of context switches. However, so far, the scalability of these techniques is not sufficient to handle large industrial code, even when combined with methods such as *sequentialisation* [25, 28] or advanced techniques based on *automata* [12, 23] or *SMT encodings* [20, 21, 16]. Indeed, this shows up in our experiments too.

3 Preliminaries

We now introduce several basic notions that we use when describing the analysed programs and the analyses proposed.

Concurrency model. We primarily target C programs using threads and mutexes in the style of the POSIX threads (pthreads) execution model. We use the term *thread* to mean thread's entry point, i.e., an identifier of the function from which the given thread is started. In the examples, we shorten the calls of locking, unlocking, thread-creating, and thread-joining functions as `lock`(...), `unlock`(...), `create`(...), and `join`(...), respectively. We further implicitly assume that all locks are properly initialised and omit the arguments that are not relevant, e.g., we write just `create`(`t1`), where `t1` is an entry point, when the thread id, attributes, and argument are not relevant for the example.

The CValue domain and memory addresses. Throughout the paper, we frequently refer to the CValue abstract domain [6, 10] implemented in Frama-C and used by the abstract interpretation of EVA. We are primarily interested in the representation of memory addresses. A memory address is represented as a pair (b, o) where b is a *base address* (in the following referred to simply as a *base*) and o is an offset. Each variable (global, local, and also formal) has its associated base address. Dynamic allocations are modelled by creating so-called *dynamic bases* which come in two flavours – a *strong* dynamic base corresponds to the result of precisely one call to an allocation function; on the other hand, *weak* memory bases may represent multiple allocated addresses (typically, they are the consequence of allocations in loops). Offsets are represented by a dedicated integer domain, the details of which are not important for this paper. We use CValue.val for the domain representing possible values of a single variable and CValue.state for the domain representing program state, i.e., possible values for multiple variables. We use Addresses to denote the aforementioned set of memory addresses. In the rest of the paper, the operations *join* and *widening* as well as *top values* refer to those on the CValue domain.

Analysis contexts. We call an *analysis context* a triple $(thread, calls, stmt)$ consisting of a thread, a sequence of the latest n calls (each of them formed by a call site and the function called), and a program statement. Our data race analysis relies on various underlying analyses presented below to compute an abstract representation of thread states reachable by performing the given statement for each analysis context. Notice that a context holds no information about how the thread was created nor how its execution was interleaved with other threads. The empty call sequence is denoted by ε. The number n is a parameter of the analysis set to 1 by default to handle simple lock/unlock wrapper functions. We use Context to denote the set of all possible contexts.

\end{aligned}
$$

Figure 2 The interface of the backend analysis used by the proposed analysis of data races. The function analyse_thread performs the analysis of a thread as a sequential program given by its entry point, starting from the given initial state. The other functions answer queries based on the results computed by analyse_thread (specific for different backends). Note that the signatures do not include statements as those are already included in contexts.

4 Backend Analysis

Our data race analysis relies on a backend analysis of sequential program behaviour to get answers for several kinds of queries. Those include *function pointer resolution* (to determine which functions are to be analysed when and to determine thread entry points passed to thread create functions), getting *points-to information* (to determine targets of (un)lock operations, to perform escape analysis, and, most importantly, to determine on which addresses to look for data races), getting information on *memory accesses*, and characterizing *values of integer variables* (to determine whether offsets of two accesses overlap, and to check whether a trylock operation succeeds in the given branch of code).

To offer a selection of multiple backend analyses differing in their scalability, precision, and ease of use, we have implemented several such analyses. The interface a backend needs to implement is shown in Fig. 2. The function analyse_thread runs the analysis of a thread as a sequential program starting from the provided state of global variables and the thread's argument. Based on the results, the different queries are then answered.

Evolved Value Analysis (EVA) backend. This backend is based on EVA [6], a value analysis plugin of Frama-C based on abstract interpretation. EVA provides a combination of multiple abstract domains and an API to answer all the needed queries, and our backend is just a thin wrapper over EVA, which implements caching, simplification, and answering some trivial queries on its own. The interface in Fig. 2 is in fact inspired by the API of EVA, and the other backends mimic it. In particular, the EVA's API implements queries for call stacks which can be easily obtained from our contexts.

Syntactic backend. This backend provides a lightweight analysis based only on syntactical information in the style of RacerX [15] or RacerD [4]. The implementation of analyse_thread is simply an empty function and the functions state and value always return the top value. The function value_ptr searches the expression and extracts bases of the expected type. This is inspired by the insight that in some programs only global locks are accessed using `lock(&m)` and `unlock(&m)` (where `m` is a global variable), and it is thus sufficient to simply extract the base of `m`. The function memory_accesses is implemented similarly with a more detailed analysis of an expression to determine whether a base is being read or written to it. Finally,

```
1  void *t1(void *arg1) {
2    int *x = (int *)arg1;
3    (*x)++;
4  }
5
6  void *t2(void *arg2) {
7    int *y = (int *)arg2;
8    (*y)++;
9  }
10 int main() {
11   int data = 0;
12
13   create(t1, &data);
14   create(t2, &data);
15 }
```

Figure 3 An example of a program for which the Syntactic backend fails to find a data race.

function pointers are over-approximated by taking each function assigned in the program. In the case of thread entry points, this can be further refined by taking only functions matching the thread signature (i.e., `void *(*fn)(void *arg)` for pthreads).

Alias backend. The aim of the third backend is to provide a middle ground between the precision of the EVA and the scalability of the syntactic backend. It relies on another Frama-C plugin called Alias [5] which performs a may-alias analysis using a variant of the classical Steensgaard's algorithm [31]. For queries not related to pointer expressions (state and value), the top values are returned. For the other queries, since Alias does not have an API to answer our queries directly, we take the result of the syntactic backend and replace each base by a canonical representative of its alias equivalence class. In particular, for memory accesses, we ensure that a selected canonical address for an alias class is vulnerable to data races if such an address exists (e.g. because its base corresponds to a global variable or a local variable that escaped; see Section 7 for more details). Alias also does not allow starting with a user-supplied set of aliases (as expects the signature of our analyse_thread function). We therefore need to perform an additional saturation of the aliases set for all queries, as demonstrated by the example in the next paragraph. The Alias plugin is still relatively new (it lacks support, e.g., for the dynamic memory allocation) and thus our backend over it is also experimental.

▶ **Example 1.** The advantage of the Alias backend over the syntactic backend is demonstrated in Fig. 3. The program contains a data race on an address of the variable `data` that escapes its scope in the `main` function by passing it as an argument to the threads `t1` and `t2`. Both threads share the same code, which creates a local alias for this address. This is a very common pattern when thread arguments are used – since the type of the argument is generic `void*`, it needs to be casted to its actual type. The address is then written to by both threads using their local aliases. While the syntactic backend would not report any relevant access for data race detection, the Alias backend would compute aliases for `x` and `y` as $\{\texttt{x}, \texttt{arg1}\}$ and $\{\texttt{y}, \texttt{arg2}\}$, respectively. Our backend then performs a saturation of both sets by adding aliases $\{\texttt{arg1}, \&\texttt{data}\}$ and $\{\texttt{arg2}, \&\texttt{data}\}$, respectively. Finally, `&data` will be selected as a canonical base, because it is vulnerable to a data race.

5 Thread Analysis

In this section, we propose our approach on how to leverage an analyser for sequential programs to analyse programs with multiple threads. The design of our approach is based on the observation that answers to our queries described in Section 4 on objects relevant for our

Algorithm 1 Thread analysis.

Input : Program entry point main
Input : Initial values of global variables GlobalsVals ∈ Cvalue.state
Data : Initial states of threads $I : T \to$ Cvalue.state
Output : Thread-creation graph $G = (T, \to)$
Output : Results of analysis of sequential behaviour of the threads $R : T \to$ Result

1 $i = 0$
2 $G_0 = (\{\mathsf{main}\}, \emptyset)$ `// Initial graph containing main only`
3 $I_0 = \{\mathsf{main} \mapsto \mathsf{GlobalsVals}\}$ `// Initial state of the main thread`
4 $R_0 = \{\mathsf{main} \mapsto \mathsf{Backend.analyse_thread}(\mathsf{main}, \mathsf{GlobalsVals})\}$ `// Analyse main`
5 **do**
6 $\quad i = i + 1$
7 $\quad G_i = G_{i-1}$
$\quad$ `/* Update the graph with reachable threads. */`
8 $\quad$ **foreach** thread represented as a vertex p in G_{i-1} **do**
9 $\quad\quad$ **foreach** stmt s of the form $\mathsf{thread_create}(f)$ syntactically reachable by p **do**
10 $\quad\quad\quad children = \mathsf{Backend.functions}(R_{i-1}(p), (p, \varepsilon, s), f)$
11 $\quad\quad\quad G_i = G_i \cup \{p \xrightarrow{s} c \mid c \in children\}$
$\quad$ `/* Build equations wrt. the chosen approx. strategy. */`
12 $\quad \Phi_i = \mathsf{ConstructEquations}(G_i)$
$\quad$ `/* Solve the system of equations. */`
13 $\quad I_i = \mathsf{SolveEquations}(\Phi_i, I_{i-1})$
$\quad$ `/* Analyse each thread as a sequential program. */`
14 $\quad R_i = \{t \mapsto \mathsf{Backend.analyse_thread}(t, I_i(t)) \mid t \in \mathsf{dom}(I_i)\}$
15 **while** $G_{i-1} \neq G_i$
16 **return** G_i, R_i

analysis are often not too much affected by thread interleavings. We design two strategies for combining results of the analyses of the sequential behaviour of individual threads that under- and over-approximate the overall behaviour of the concurrent program consisting of the threads (not including behaviour possibly caused by errors in the code, i.e., for example undefined behaviour after a data race). Furthermore, these strategies can subsequently be combined to increase the precision of the resulting analysis by using under-approximation to find races while using over-approximation to show their absence. However, as we show in our experimental evaluation in Section 8, both of our strategies are often sufficiently precise on their own.

The core idea of our thread analysis is similar to that of the Frama-C's proprietary Mthread plugin described in [34]. Starting with the `main` thread, we iteratively build a thread-creation graph that captures the parent-child relationship among the so-far discovered threads. In each iteration, we add newly discovered threads and perform the analysis (potentially multiple times) of each thread as a sequential program (using the `analyse_thread` function of the selected backend). This is done by solving a system of equations over the initial states of the threads given by whose construction we describe below. However, before that, we first describe the graph construction algorithm.

The section is relevant mainly for our EVA backend and partly for our Alias backend. For the Syntactic backend, only the thread-creation graph construction is relevant (because no analysis of threads is performed).

5.1 Construction of the Thread-Creation Graph

The method is given in Algorithm 1. The output of the algorithm is (1) a thread-creation graph $G = (T, \to)$ where T is the set of all discovered threads and $\to$ is a labelled edge relation such that $p \xrightarrow{s} c$ means that the parent p creates a child c at the program statement s, and (2) a mapping $R : T \to \mathsf{Result}$ containing results of the analysis of the behaviour of each thread. The algorithm further operates with the mapping $I : T \to \mathsf{CValue.state}$ representing the initial states of discovered threads[1]. Once we derive a stable mapping I (i.e., a fixpoint of the thread's initial states), we have also reached a fixpoint of the results R, needed to answer all the queries issued by our analysis.

The algorithm starts with a graph that contains only the main thread whose initial state is given by the initial values of global variables. With this initial state, main is analysed on line 4.

In the main loop of the algorithm starting on line 5, the graph is updated by adding threads created from (syntactically) reachable statements. Notice that the evaluation of an expression f on line 10 is performed without using any calling context. This is because our analysis, in particular the system of equations in Sections 5.2 and 5.3, is not very sensitive to thread-create wrappers. Consequently, we can construct smaller graphs by distinguishing edges only by statements and not by calling contexts.

After a new iteration of the graph G_i is constructed, we build a system of equations, one for each discovered thread, given by G_i. Each of these equations describes how an initial state of a thread can be computed using initial states of other threads. Then, the system is solved using initial states from the previous iteration I_{i-1} to obtain new initial states I_i. The solution may need an application of widening operators – we provide more details on our implementation of the equation solving in Section 8. Based on the new initial states, we compute new results R_i on line 14.

This loop is repeated until the thread-creation graph stabilises. Overall, the algorithm runs two fixpoint computations – the outer updates the graph with new threads, while the inner (equation solving on line 13) performs analysis on the current graph, and can thus help to discover previously unknown threads in new iterations.

Below, we discuss how the aforementioned equations are constructed.

5.2 Under-Approximating Thread Analysis

We use the following under-approximated semantics of thread creation. A thread is started with the initial state corresponding to the join of initial states of its create statements, and its writes to global variables are not propagated to other threads. The creation of threads then roughly corresponds to calling its entry point in a "sandbox" that makes all of its actions invisible for other threads. Formally, given a thread-create graph G_i with edges $\to$, we compute the initial state of a thread t (other than `main` – the initial state of `main` is given by the initial states of global variables) as follows:

$$I(t) \triangleq \bigsqcup_{p \xrightarrow{s} t} \mathsf{let}\ R = \mathsf{Backend.analyse_thread}(p, I(p))\ \mathsf{in}\ \mathsf{Backend.state}(R, (p, \varepsilon, s)),$$

[1] In the implementation, the product $\mathsf{CValue.state} \times \mathsf{CValue.val}$ is used as the domain of the initial states to represent the values of global variables and the value of the thread's argument. However, for simplicity of the presentation, we may assume that the argument is simply included among the global variables.

```
1  int *g;
2  void *t1() {
3    g = malloc(...);
4  }
5  void *t2() {
6    (*g)++;
7  }
8  int main() {
9    create(t1); join(t1);
10   create(t2); create(t2);
11 }
```

(a)

```
1  int g = 1;
2  void *thread() {
3    lock(L);
4    if (g == 1) {
5      unlock(L); return NULL;}
6    g = 2;
7  }
8  int main() {
9    create(t1);
10   lock(L); g = 0; g = 1; unlock(L);
11 }
```

(b)

Figure 4 Examples of programs on which (a) the under- and (b) over-approximating thread analysis reports a false negative and a false positive, respectively.

i.e., we take all statements s creating t, and for each of them, we recompute the corresponding parent p and take its state at the statement s, returning the join of all those values. In this way, the creation of a thread does not affect its parent at all.

The motivation for this strategy is straightforward – for acyclic thread-creation graphs, it is enough to analyse each entry point only once (provided caching is used for the `analyse_thread` function). On the other hand, there are two main sources of possible imprecisions – thread interleavings are not taken into account, and parents do not see effects of their children. The latter can sometimes result in seemingly weird false negatives when performing data race detection, as demonstrated in Listing 4a. In the program, the `main` thread first creates a thread `t1` which allocates an integer value and then a thread `t2` (created twice) accesses this value without any synchronization. However, we cannot detect this data race using EVA[2] since in our under-approximated setting, `t2` will never see the allocation, and in such a situation, EVA will mark the memory access on line 6 as surely invalid and will not report any memory access for it.

5.3 Over-Approximating Thread Analysis

While for the under-approximating strategy, we assumed that no changes done by threads are propagated, in our over-approximating strategy, we assume that every thread can see all possible changes (even those that should be invisible due to some synchronization method). For this method to work correctly, we also need to perform a simple transformation of the analysed program, which we discuss, together with a motivation example, later in this section.

We compute the initial state of a thread t (here also including the `main` thread) as the join of the states our analysis has encountered so far. Formally, given a thread graph G_i with a set T of currently known threads, the initial values of global variables $V = \mathsf{GlobalsVals}$, and a set of all program statements Stmt, we proceed as follows:

$$I(t) \triangleq V \sqcup \bigsqcup_{s \in \mathsf{Stmt},\ t' \in T} \mathsf{let}\ R = \mathsf{Backend.analyse_thread}(t', I(t'))\ \mathsf{in}\ \mathsf{Backend.state}(R, (t', \varepsilon, s)),$$

i.e., we take the join of the states of all statements for each currently discovered thread.

[2] We could detect the memory access with the other backends that do not care about memory initialization.

```
1  atomic_int g;
2
3  void *t() {
4    g++;
5  }
6
7  int main() {
8    g = 0;
9    create(t);
10   if (g == 1)
11     ...
12 }
```

(a) Original program.

```
atomic_int g;

void *t() {
  g = (*) ? g : g+1;
}

int main() {
  g = (*) ? g : 0;
  create(t);
  if (g == 1)
    ...
}
```

(b) Transformed program.

Figure 5 An example of a program for which the over-approximating strategy fails to compute a sound over-approximation unless the program is transformed ($*$ denotes non-deterministic condition).

To solve such a system, more than one sequential analysis of each entry point and an application of widening is needed to converge[3] (cf. Section 8). Observe that the equations do not depend on edges of the thread-creation graph, just on its vertices.

As we also consider context switches that cannot happen due to synchronization (even those that cannot happen because a child was not yet created, e.g., when computing the initial state of the main thread and already using states of its children), we may later report false data races as demonstrated in Listing 4b. In this example, we will compute the initial state of `thread` to be $\{\mathsf{g} \mapsto \{0, 1, 2\}\}$. However, the value 0 is never visible to `thread` because the sequence of updates on line 10 (as well as the condition on line 4) is performed atomically, resulting in no change of g. Thus, the memory access on line 6, which would be flagged as a data race (together with one of the accesses on line 10), is in fact unreachable.

Although both examples in Fig. 4 are taken from publicly available benchmarks, we believe that they are quite rare in practice. Moreover, our strategies can be combined by allowing the under-approximation to only report errors and the over-approximation to only report that no error has been found. Otherwise, an unknown verdict will be reported, which would be also the case in both examples in Fig. 4.

5.3.1 Program transformation

The presented over-approximating strategy is not in itself sufficient to compute a sound over-approximation of multi-threaded behaviour as demonstrated on the program in Figure 5. In the example, we are particularly interested in the block inside the condition on line 10, which may contain some important event for our analyser. This code is unreachable when the main thread is analysed as a sequential program regardless of the initial state. Indeed, our over-approximation strategy would compute the initial state as $\{\mathsf{g} \mapsto [0, \mathsf{max_int}]\}$, but already on line 8, this state would be modified to $\{\mathsf{g} \mapsto [0, 0]\}$ and the over-approximation would be lost.

[3] We apply widening quite aggressively by performing it already after the second iteration to reach a fixpoint as soon as possible.

We solve the above problem using a simple source code transformation rather than modifying the internal state of the sequential analyser (so we do not need to make further requirements on the interface of our backends). The idea behind our solution is that it is sufficient to ensure that each program instruction is *extensive*, i.e., if S and S' are the sets of concrete states before and after the instruction, respectively, then $S \subseteq S'$. We modify all program instructions to be extensive using the following rules.

- An assignment $\mathtt{x} = \mathtt{y}$ is transformed into a non-deterministic choice between the old and the new value as $\mathtt{x} = (*)\ ?\ \mathtt{x} : \mathtt{y}$.
- A function call $\mathtt{f}(\mathtt{x}_1, \ldots, \mathtt{x}_n)$ where at least one of the arguments x_i is passed by reference is transformed into a condition which non-deterministically skips the call as $\mathtt{if}(*)\ \mathtt{f}(\mathtt{x}_1, \ldots, \mathtt{x}_n)$.

In the rest of the paper, we implicitly assume that all backend queries for a thread t are evaluated over the results $R_i(t)$ where R_i is the value returned by Algorithm 1.

6 Lockset and Active-Threads Analyses

This section presents two helper analyses for data race detection. Both are used to check whether a pair of contexts can happen in parallel – the *lockset analysis* checks this based on locks being held in the given contexts, and the *active-thread analysis* deals with creating and joining of threads.

6.1 Lockset Analysis

Lockset analysis is traditionally used to compute must- or may-locksets being held for each statement. Our lockset analysis is context-sensitive, path-insensitive, and it computes both must- and may-locksets simultaneously. It is inspired by the approach of RacerX described in [15], which, however, does not employ any advanced alias analysis and is not context-sensitive.

We represent locks by their concrete addresses, i.e., $\mathsf{Lock} = \mathsf{Address}$, and we define $\mathsf{Lockset} = 2^{\mathsf{Lock}}$. Our lockset analysis is implemented as a forward data flow analysis with the domain of locksets, computed for each thread in separation, starting with the empty lockset. On the intraprocedural level, we start to analyse a function with an entry lockset L_{entry} coming from the caller, and gradually update it using the following transfer function that, for a context c with a statement s, transforms the lockset L_{old} reached before executing s into a set of locksets $\mathcal{L}_{new}$ resulting from the execution of s as follows:

$$\mathcal{L}_{new} = \begin{cases} \{L_{old} \cup \{\ell\} \mid \ell \in \mathsf{Backend.value_ptr}(c, \mathtt{p})\} & \text{if s is } \mathtt{lock(p)}, \\ \{L_{old} \setminus \{\ell\} \mid \ell \in \mathsf{Backend.value_ptr}(c, \mathtt{p})\} & \text{if s is } \mathtt{unlock(p)}, \\ \{L_{old}\} & \text{otherwise.} \end{cases}$$

After applying the transfer function, if $\mathcal{L}_{\text{new}}$ is not a singleton set, we fork the analysis and continue with each element of $\mathcal{L}_{\text{new}}$ separately. As a result, we obtain the summary of a function f analysed in a context c in the form $(c, L_{entry}) \mapsto \mathcal{L}_{exit}$ where $\mathcal{L}_{exit}$ is the set of locksets at the return statements of all forked analysis runs inside f. Such summaries are then used for the interprocedural analysis. We also construct *statement summaries* $\mathcal{S}$ of the same form as for functions, i.e., mappings from pairs of an input context and a lockset to output sets of locksets. These are used for caching at the statement level and to implement the must- and may-lockset queries for a context c as

$$\mathsf{may_ls}(c) = \bigcup_{(c,L)\in\mathsf{dom}(\mathcal{S})} L \qquad \mathsf{must_ls}(c) = \bigcap_{(c,L)\in\mathsf{dom}(\mathcal{S})} L$$

Dealing with path explosion. As we represent locks using memory addresses and fork the analysis whenever we cannot precisely evaluate the parameter of a (un)locking operation, the set of traversed paths can easily explode. To tackle this problem, our transfer function selects only a small number of locks when the set $\mathsf{Backend.value_ptr}(c, \mathtt{p})$ is too large (currently, the threshold is set to three locks). This works in many practical cases because it is usually enough to differentiate the may- and must-cases through a few paths only. In the future, we would like to provide support for symbolic treatment of locks combined with may- and must-equality reasoning.

Our analysis does not support reentrant mutexes/semaphores but can handle non-blocking lock functions and read-write locks as discussed below.

Non-blocking locking functions. For non-blocking lock functions such as `trylock`, which does not block when the mutex is already locked, or `timedlock`, which blocks just for a limited time, we update the lockset with relevant locks for which we also track the variable used to store the return value of the corresponding call. Evaluation of a query $\mathsf{may_ls}(c)$ or $\mathsf{must_ls}(c)$ will then ask the backend for the state s computed for the context c through the query $s = \mathsf{Backend.state}(c)$, and filter out the locks for which the state s does not guarantee that the locking was (possibly or surely, depending on the query) successful. This guarantee will only be provided if the success of the locking was explicitly checked in the context c. This way we obtain a limited path-sensitivity for branching over expressions containing variables storing return values of lock operations. For the function `pthread_mutex_lock`, we assume that it is blocking (i.e., that it never fails), but the user can easily change the configuration to treat it as non-blocking.

Read-write locks. To support read-write locks, a lock object keeps additional information about whether it was obtained in the read- or write-mode. Based on this information, we modify the intersection of locksets, presented later on as the main operation used for data race detection, so that it contains only those locks which are present in both operands and at least in one of them in the write-mode. In other words, if two accesses are guarded only by a lock obtained in both cases in the read-mode, we will treat them as unprotected.

6.2 Active-Threads Analysis

The goal of this analysis is to deal with situations when two memory accesses cannot happen in parallel either because one happens before the thread of the other one is created, or because one happens after the thread of the other one is surely joined. We again compute this information in a thread-modular way by computing a *set of sets of threads* that may or must be active in parallel for each context, respectively. Two contexts are then may-parallel (must-parallel) if the thread of one of them is in the union (intersection) of sets computed for the other, and vice versa.

The sets of active threads are computed in a very similar way to how the lockset analysis is performed – just working with sets of threads instead of sets of locks, with the transfer functions for thread creation and joining analogous to those for locking/unlocking, and with the same way of handling the may- and must-queries. The set of thread entry points is usually small, and we thus do not need any special treatment to tackle path explosion unlike in the lockset analysis. One difference between the analyses is in the initial states. The lockset analysis of each thread is started with the empty lockset, but the active-threads analysis of a thread t starts with the union of all threads that may be active together with t

in some context of the parent of t (the analysis is thus run in the order given by a topological order on thread-creation relation, and for the very rare case of cyclic thread-creation graphs, we simply skip the analysis, providing trivial answers for queries based on it).

Thread identifiers. Another significant difference is the way in which threads are joined. While our analysis abstracts threads using their entry points, in the concrete semantics, they are manipulated using their *identifiers*. In many programs, however, the manipulation of identifiers is straightforward, and one can easily map identifiers to abstract threads and vice versa. Based on this observation, we assume that if an identifier expression of a created and joined thread is the same, then the thread is also the same. We have never encountered a situation when this would lead to a wrong analysis verdict.

7 Data Race Detection

Our data race detection does a forward traversal of the program and collects memory accesses consisting of a context (used for querying the results of lockset and active-thread analyses), a base address, and a symbolic offset (a set of intervals in the Cvalue domain that may be some simple value for backends different from EVA). We cluster memory accesses according to their bases to later check for data races only inside each of those clusters. This is justified by the following hypothesis about the memory model: it is not possible to get from one base to another by adding an offset. This hypothesis might not hold for some low-level C programs, but it is important for efficiency. Moreover, analysis of programs breaking this assumption is not even supported by EVA [8].

The tracking of accesses is inspired by [30]. For each cluster represented by its base, we track a state $s \in \{\mathsf{ReadOnly}\ o, \mathsf{Exclusive}\ o, \mathsf{Shared}, \mathsf{SharedMod}\}$ representing that a memory base is either read-only (ReadOnly) or modified (Exclusive) by a single thread o, read by several threads with none of them writing to it (Shared), or modified by distinct threads such that at least one of them writes to it (SharedMod). With each access to a memory base b by a thread t, the state of b is updated according to the transition graph in Fig. 6. When the analysis is finished, we keep only the memory bases marked as SharedMod or Exclusive o (when o is a thread created multiple times), and for each of them, we check each pair of accesses for a data race. The information about which threads are unique and which are created multiple times is computed during the thread analysis based on whether its create statement was visited once or multiple times.

Escape analysis. An important part of data race detection is discovering local bases that may escape their scope. Our syntactic backend assumes that dynamically allocated bases can always escape and static bases escape when their address is taken. Using the Alias and EVA backends, we enhance this by testing (for both static and dynamic bases) not only whether their addresses were taken, but also whether they were assigned to global variables.

May- and must-data-races. We distinguish two types of data races based on the confidence we have in them. For *may-data-races*, the below conditions need to be satisfied:

1. At least one of the accesses is a write access.
2. The accessing threads are either distinct or the same non-unique thread.
3. The offsets of the addresses may overlap (checked by a query over the CValue domain of intervals).

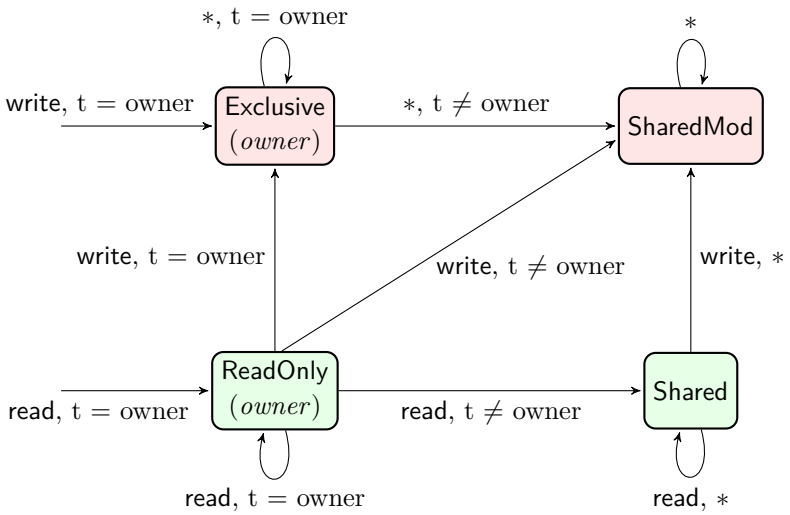

Figure 6 The transition graph for tracking states of memory bases. Each transition corresponds to a read or write memory access by a thread t. The symbol $*$ represents any access kind/thread. The states vulnerable to data races are marked in red.

4. The intersection of the may-locksets of the concerned contexts is empty (checked using the results of the lockset analysis).
5. The threads of both accesses may run in parallel (checked using the results of the active-threads analysis).

For *must-data-races*, we require the *must*-variants of Conditions 3–5 to hold. In addition, the following conditions are required to rule out races involving a memory access representing abstraction of multiple memory accesses:

6. The memory base is not *weak* (i.e., if it is dynamic, then it represents precisely one dynamic allocation) and it is not allocated in a non-unique thread.
7. The size of the access does not exceed the size of the type of the base.
8. The base is the only base being read/written to in its context.

Condition 6 ensures that we do not report must-races on bases obtained by abstracting and hence merging different calls to allocation functions. Condition 7 rules out races on possibly different indices to arrays (an access with an offset bigger than the size of the type of the base usually abstracts multiple accesses). Finally, Condition 8 handles situations when our context-sensitivity level is not sufficient to distinguish accesses to multiple bases.

Arrays and loop unfolding. To slightly relax the restrictiveness of Condition 7, we can perform a small number of unfoldings of each loop. This can help us report must data races on the accesses in unfolded cases. The loop unfolding is also useful for dealing with the creation of threads in loops – since our analyses are path-insensitive, they will also consider the infeasible path on which the cycle is never entered, and no thread is created. For memory accesses following the loop, the must variant of Condition 5 will thus not hold. Unfolding such loops at least once will fix this problem.

8 Implementation and Experimental Evaluation

The RacerF[4] analyser based on the above presented principles is implemented as a plugin of the Frama-C platform as a part of our bigger project for detection of concurrency bugs. The individual analyses are written as OCaml functors parametrised by a module implementing the backend analysis. We also provide a Python wrapper which runs a combination of under- and over-approximating analyses and also performs preprocessing (currently, the preprocessing is implemented outside of our analyser for technical reasons, thus the analyser is slowed a bit by the need of repeated parsing). To solve the systems of equations from Sections 5.2 and 5.3 we use the *chaotic iteration strategy with widenings* [7] implemented in the Ocamlgraph library [9]. The widening operators are those provided by the CValue domain.

Our implementation provides support for atomic and thread-local variables. The threading and locking functions (and their relevant properties) as well as atomic functions (such as gcc's `__atomic_store`) may be defined using configuration files.

We have conducted a series of experiments to support the following two hypotheses:

- Despite having no formal guarantees, RacerF can efficiently analyse intricate programs without sacrificing a precision. We validated this hypothesis on a collection of benchmarks from SV-COMP containing 1029 programs, many of them being intricate examples and corner cases contributed by participants to showcase capabilities of their tools.
- RacerF can detect data races in real-world programs for which other existing static analysers do not provide precise results (either because of too coarse approximation or running out of resources). We validated this hypothesis on a set of student programs from [18].

Experimental setup. Some data presented in experiments were taken from the results of SV-COMP 2025 [3]. All other experiments were run on a machine with 2.5 GHz Intel Core i5-7300HQ CPU and 16 GiB RAM, running Ubuntu 22.04 in a virtual machine limited to 10.7 GiB RAM. Our experiments were conducted using BenchExec [2], a framework for reliable benchmarking.

8.1 SV-COMP Benchmarks

The SV-COMP sub-category *NoDataRace-Main* is, to our knowledge, the largest publicly available data race benchmark. Many of its programs are small but intricate tests provided by the participants. Our main goal is to demonstrate the scalability of our approach and to also show that its heuristic nature does not compromise its precision even on those intricate examples. The benchmark also contains implementations of lock-free algorithms, which are out of the scope of our tool. We have implemented a single heuristic that detects active waiting (essentially a loop with an empty body) as a characteristic pattern for lock-free algorithms, and when it is present, returns an unknown result.

We compare with the five best-performing tools participating in SV-COMP 2025 [21, 22, 23, 29] (including $\text{RacerF}_{\text{sv-comp}}$, an older version of RacerF) and we also include $\text{RacerF}_{\text{under}}$ and $\text{RacerF}_{\text{over}}$ representing RacerF running with under- and over-approximating thread analysis only, respectively. We wanted to include also the O2 checker [26], but since its results were not good and all the other tools were configured specifically for this benchmark by their authors, we do not consider such a comparison fair.

[4] RacerF is available under the MIT license at `https://github.com/TDacik/Deadlock_and_Racer`.

Table 1 Results for the SV-COMP sub-category *NoDataRace-Main*. The columns represent true negatives, false positives, true positives, false negatives, out-of-resource (time or memory), score (as defined by SV-COMP rules, but excluding witness validation), and times (excluding timeouts) on local and competition machine, respectively.

	No race (794)		Races (235)					
Analyser	TN	FP	TP	FN	RO	Score	Time$_1$ [s]	Time$_2$ [s]
RacerF	674	4	105	0	0	1389	4620	–
RacerF$_{\text{over}}$	674	6	83	0	0	1335	3970	–
RacerF$_{\text{under}}$	680	4	105	6	0	1209	2710	–
RacerF$_{\text{sv-comp}}$	674	4	98	0	0	1382	3100	1300
Goblint	712	0	0	0	3	1424	–	2320
Deagle	685	0	203	1	43	1541	–	10k
UGemCutter	578	0	161	0	263	1317	–	152k
UAutomizer	609	0	121	0	274	1339	–	120k

The results are summarised in Table 1. Unlike the competition results [3], we present the results ignoring the witness validation. RacerF produced 4 false alarms, all of them on programs where a data race is ruled out by some intricate condition. Two of them are variants of a program where a data race does not manifest because an array being searched in parallel contains only zeros and a certain condition is thus never triggered which makes the potential racy access unreachable (which is the kind of behaviour that our tool cannot handle). The other two contain locking patterns that are beyond the scope of our lockset analysis.

We first focus on a comparison of the versions of RacerF. The difference between its newest version and the version competing in SV-COMP'25 lies mainly in improved escape analysis and preprocessing (loop unrolling in the under-approximating mode and assignment modification in the over-approximating mode). The changes show a positive impact on more reported data races but also a slowdown which is a consequence of preprocessing done in over-approximating mode. The slowdown mostly manifests for the active-thread analysis, which could be a performance bug in the implementation.

Interestingly, running RacerF in either the over- or under-approximating mode does not compromise its precision too much, leading to an additional 2 false positives (and 22 must-races classified just as may- and thus not reported) and 6 false negatives, respectively.

Compared to participants of SV-COMP'25, RacerF placed second in the competition ranking and third in our evaluation. Compared to Goblint, which never reports races, RacerF can produce correct results for more programs. Compared to model checker Deagle, which benefits from the fact that many programs are small and their loops can be fully unrolled, no version of RacerF ever runs out of time or memory.

Where RacerF shines is the ldv–linux–3.14–races benchmark subset containing 5 programs derived from the Linux kernel (all of them are race-free). None of the participants with a positive score can provide correct verdicts for those programs (except Goblint which handles one of them), but RacerF can correctly analyse each of them under two minutes.

8.2 Student Programs

To test our tool on more non-crafted programs, we performed an evaluation on a set of 116 student programs from [18]. The programs are rather short (around 100 – 300 LoC) and implement the same heavily concurrent algorithm parametric in the number of threads, but

Table 2 Results for student programs. The columns are true positives, false negatives, no race reported, race reported, out-of-resources, and time (excluding timeouts).

	Races (30)		Others (86)			
Analyser	TP	FN	NR	RR	OOR	Time [s]
RacerF	16	3	46	0	0	688
O2	7	23	86	0	0	54
Goblint$_{sv}$	0	3	46	0	0	41
Goblint	27	3	46	40	0	41
Deagle	3	1	6	0	78	1644

they differ in various intricate bugs (for their detailed discussion see [18]). We have identified 29 data races using dynamic analysers. However, there may be more that those tools missed. One additional race was discovered by all RacerF, O2, and Goblint. The issue could manifest only in a very rare situation when two threads simultaneously failed and called a clean-up function that assigns a global pointer without synchronization. The time limit was set to 60 seconds and the memory limit to 1GB.

We have compared with Goblint[5] and Deagle (version from SV-COMP'25) that performed better than us in SV-COMP, and with O2 (implemented in Coderrect[6]) that we selected as a recent representative of lightweight and scalable race detection tools.

The results are given in Table 2. As expected, since all the programs contain unbounded loops and also an unbounded number of threads is created, Deagle ran out of the resources on almost all programs and provided an answer in only 10 cases. Interestingly, Goblint and RacerF claimed *the same* 46 programs as race-free (but RacerF without providing any false positives). The three missed races by RacerF and Goblint are also the same and are caused by an undefined behaviour related to re-initialisation and destroying of mutexes that still may be used by some threads (neither of the tools supports detection of such problems). A detailed inspection suggests that both tools struggle with programs that use an array where each thread accesses only the element at its dedicated index.

Overall, RacerF achieves excellent precision on both sides. While O2 misses many races and Goblint reports many false alarms, RacerF is able to discover more than half of the races while not reporting any false alarms.

9 Conclusions and Future Work

We have presented a novel data race detector RacerF and performed a series of experiments indicating that RacerF achieves a nice compromise between precision and scalability both on crafted benchmarks and real-world programs. In the future, we would like to target other classes of concurrency bugs. We already have an implementation for deadlock detection based on top of our lockset analysis, which is not discussed in this paper. Another interesting direction is combination with dynamic approaches, e.g., guiding insertion of noise injection by results of static analysis.

[5] We use Goblint in the version from SV-COMP'25 but with the default configuration as the other available configurations did not improve the results and led to timeouts. Further, to provide more detailed results, we run Goblint via its SV-COMP wrapper that never reports detected races (Goblint$_{sv}$) as well as without it.

[6] The link `https://coderrect.com` from which we got version 1.1.3 is no longer available.

Type-Safe and Portable Support for Packed Data

Arthur Jamet
University of Kent, Canterbury, UK

Michael Vollmer
University of Kent, Canterbury, UK

Abstract

When components of a system exchange data, they need to serialise the data so that it can be sent over the network. Then, the recipient has to deserialise the data in order to be able to process it. These steps take time and have an impact on the overall system's performance.

A solution to this is to use **packed data**, which has a unified representation between the memory and the network, removing the need for any marshalling steps. Additionally, using this data representation can improve the program's performance thanks to the data locality enabled by the compact representation of the data in memory. Unfortunately, no mainstream programming languages support packed data, whether it's out-of-the-box or through a compiler extension.

We present `packed-data`, a Haskell library that allows for type safe building and reading of packed data in a functional style. The library does not rely on compiler modifications, making it portable, and leverages meta-programming to allow programmers to pack their own data types effortlessly.

We evaluate the usability and performance of the library, and conclude that it allows traversing packed data up to 60% faster than *unpacked* data. We also reflect on how to enhance the performance of library-based support for packed data.

Our implementation approach is general and can easily be used with any programming languages that support higher-kinded types.

1 Introduction

Components within a system may need to exchange data. Consequently, data needs to be sent in a format that is processable by the recipient. For example, web application programming interfaces (web APIs) usually serialise data using the Java-Script Object Notation (JSON) before sending it over the network. On the other hand, the receiver of the data has to deserialise the response into a processable object; only then will it be able to use the data. For example, a web client has to parse the JSON received before being able to, say, compute the average length of the usernames in a list.

The most common serialisation formats used for these kinds of interactions are JSON, XML and HTML. They all have a simple, human-readable syntax, and it is very easy to serialise and deserialise data with them. However, because of their syntax, these formats make the data considerably larger, leading to a higher memory footprint and longer transfer times. Additionally, de/serialisation has a cost and can impact the performance of large exchange-heavy systems.

Alternatively, such components could use a binary format to exchange data. For example, one could use Google's Protocol Buffers (Protobuf)[1], which generates code (for many languages) to serialise/deserialise data to/from a binary format. This leads to smaller payloads (compared to human-readable formats), and thus smaller transfer times. On the other hand, Cap'n Proto[2] allows using binary data as-is, without any marshalling steps, but its encoding leads to bigger buffers compared to Protobuf's.

Packed data is binary data that can be used as-is, safely and without any deserialisation step. Thus, it can be easily persisted to and read from the disk without any conversion cost. Additionally, the minimal layout information contained in the packed data leads to a smaller overhead compared to Cap'n Proto. Moreover, unlike objects in memory, packed data does not have pointers and nested fields are inlined within the parent structure. Consequently, the data locality enabled by the packed format can leverage better performance (e.g. using the L1 cache). This can help speed up programs that traverse large data trees, like compilers with abstract syntax trees (AST) or web browsers with document object models (DOM).

The current state-of-the art is Gibbon, a compiler that transforms programs that use pointer-based structures into programs that use this packed representation [14, 13, 9, 11]. Gibbon supports a small subset of the Haskell programming language, and compiles recursive functional programs operating on trees into C code operating on packed bytestrings. For example, Figure 1b shows the memory layout of a binary tree (defined in Figure 1a) for a C program. Gibbon's packed representation of that same tree (defined in Figure 1c) is given in Figure 1d: instead of containing pointers, the parent node contains its children directly, contiguously in memory.

Writing C code for traversing packed data by hand is not trivial, and requires raw and untyped pointer manipulations, leading to code that is hard to read and maintain. Figure 2 gives an example of such code, which computes the sum of the leaves in a packed tree. Using a specialised compiler like Gibbon can alleviate this concern by generating the tricky code automatically (and using a typed intermediate language that verifies packed data layout invariants [13]), but introducing a dependency on an experimental research compiler is not realistic for some software projects. Additionally, Gibbon supports only a small subset of Haskell, lacking many convenient features, and also requires whole-program compilation, making integration into larger programs awkward.

This data layout has another a drawback: it does not allow accessing members of a data structure easily. Since fields are inlined and can have variable sizes (e.g. for recursive data types), they do not have a predefined position (or offset) within the parent structure. For example, consider a tree similar to the one from Figure 1, but where the root node's children are swapped. We know that the leaf is *after* the node, but we do not know the node's size or where it ends. The only way to access the leaf would be to traverse the first child. Depending on the size of that tree, it can lead to catastrophic performance issues. One solution to this problem is to use *indirections*. In Gibbon, indirections are numbers inserted (when requested) in the packed buffer before each field of a data structure. These numbers represent the size in bytes of the field they precede [13]. Indirections make the packed data larger, but they help avoid useless traversals of (potentially big) preceding fields before getting to the target one.

While the benefits of packed data have been proven, Gibbon is one of the only compilers that use this data layout natively. But Gibbon is not the only tool to leverage a condensed data layout: we already mentioned high-level libraries like Cap'n Proto, which allows using packed

data as-is, and Protobuf, to pack/unpack data. On the compiler-level, the Glasgow Haskell Compiler (GHC) also supports packing data, through *compact normal forms* (CNF) [15], but we can't manipulate it (e.g. access a field) in this form. Packed data remains to be leveraged by mainstream programming languages. The performance improvements enabled by this data format remain limited to experimental research projects.

In this paper, we present a new effort of supporting packed data through a library. `packed-data` is a Haskell library for building and traversing packed data. Inspired by the example packed data interface from Bernardy et al.'s paper [4], the library contains a code generator that allows the programmer to easily use their own algebraic data types (ADT). We use Haskell in this paper, but our approach is not specific to the Haskell programming language. Thus, the library does not require any compiler modifications and can be implemented in any language with higher-kinded types. We present the design of this library along with a use-case for packed data (Section 2). Then, in Section 3, we evaluate the usability and performance of our library-based approach. Finally, we reflect on the limitations of our design in Section 4 and suggest improvements in Section 5.

The source code of `packed-data` is available on Hackage[3]. The package also includes the code of the benchmarks we present in Section 3.2.

Unless specified, all code snippets in this paper use the Haskell syntax.

2 The `packed-data` Library

In this section, we will go through and explain the features of the `packed-data` library. Then, we will give an example of a writing operation on packed data, and finally we will cover a use-case of packed data, implemented with the library.

2.1 Features

As its name suggests, `packed-data` allows creating and manipulating packed data. Since the library is implemented in Haskell, we leverage the language's type-system to guarantee that packed data manipulation is type-safe. Thus, any bad use of a packed buffer will be detected and rejected at compile-time. Additionally, we hide pointer arithmetic details behind a functional API. This allows programmers to use packed data like they would use data streams, instead of a raw and untyped memory buffer. The library also includes a code generator which generates all the necessary functions to pack, traverse and unserialize custom ADTs. Finally, `packed-data` allows programmers to choose whether indirections are inserted in the packed data.

2.1.1 Packing Data

Packing data can be done in two ways: by using an intermediate typed buffer, or by serializing an object that already exists.

Consider a `Tree` ADT isomorphic to the one defined in Figure 1c. The code sample in Figure 3a uses the `Needs` intermediary buffer and functions like `startNode` and `writeLeaf` (generated automatically for the `Tree` type, see Section 2.1.3). Alternatively, the code snippet in Figure 3b shows how to *pack* a tree using the `pack` function. The buffers produced by these two approaches are identical.

The `Needs` type represents intermediary buffers that *needs* to be written to, before one can use them as packed data. Its definition in Figure 4 is inspired by Bernardy et al.'s examples [4]. `Needs` has two types parameters: the first one is the list (denoted `'[...]`) of the types of the values that the buffer expects before being considered *ready*, and the second type argument is the types of the values packed in the buffer once reified. These parameters allow for type-safety when writing data and producing the final buffer. By using lists as type parameters, we can represent multiple values packed next to each other in a single buffer.

```
myPackedTree :: Packed '[Tree]
myPackedTree = finish needs
    where needs = withEmptyNeeds
        $
        do
            startNode
            writeLeaf 1
            startNode
            writeLeaf 2
            writeLeaf 3
```

(a) Using the "start" and "write" functions.

```
-- Defined in packed-data
pack :: Packable a =>
    a -> Packed '[a]
pack = ...

-- Generated automatically
instance Packable Tree where
    ...

myTree :: Tree
myTree = Node
        (Leaf 1)
        (Node (Leaf 2) (Leaf 3))

myPackedTree :: Packed '[Tree]
myPackedTree = pack myTree
```

(b) Using the "pack" function.

Figure 3 How to pack a value with `packed-data`.

For example, `Needs '[Int] '[Tree]` represents a buffer that *needs* a single integer, before it can be reified as a packed `Tree`. `Needs '[] '[Char, Int]` represents a buffer that is ready to be reified; it would contain a packed character, followed by a packed integer.

When a `Needs` is *ready* or *full* (i.e. its first type argument is an empty list `'[]`), we can produce the final packed buffer with `finish :: Needs '[] t -> Packed t`.

Finalised buffers take the form of a `Packed` value. This data type, defined in Figure 4 has a single type parameter which tells the type of values packed inside. For example, `Packed '[Tree, Tree]` is a buffer that contains two packed `Trees`.

```
newtype Needs p t = Needs ByteString

newtype Packed p = Packed ByteString
```

Figure 4 Definition of the "Needs" and "Packed" data type.

2.1.2 Traversing Buffers

We need a way to traverse packed data. To do so, we defined `PackedReader`, a computation modelling a cursor, *reading* from left to right. `PackedReader` is parameterised by the type of the `Packed` data to read, the type of the data after the cursor has been shifted, and the type of the value produced by the computation. For example, in Figure 5a, we define a function that computes the sum of two integers packed in the same buffer.

To illustrate the security that type-safety provides, consider the code snippet 5b, where we try to read a `Char` where the packed value is actually an integer. This code does not type-check, and an error will be raised at compile-time. This showcases how type-safety prevents programmers from reading values incorrectly and bad shifts of the `PackedReader`'s cursor.

`PackedReader` is actually an *indexed* monad, where the type parameters represents the state of the computation [2], i.e. the expected types of the data to traverse, and the types of the packed data after the cursor has been moved.

```
readInt :: PackedReader
    '[Int] r Int

sumInts :: PackedReader
    '[Int Int] '[] Int
sumInts = do
    i1 <- readInt
    i2 <- readInt
    return (i1 + i2)
```

(a) Reading Packed integers.

```
readChar :: PackedReader
    '[Char] r Char

example :: PackedReader
    '[Int, Int] '[] Int
example = do
    i1 <- readInt
    c <- readChar -- Type error
    return i1
```

(b) Invalid reading of packed values.

```
getSum :: Packed '[Int, Int] -> Int
getSum packed = runReader sumInts packed
```

(c) Execution of a PackedReader.

Figure 5 Reading packed values with `PackedReader`.

This allows us to leverage Haskell's type-system to ensure type-safe data manipulation, and the language's native syntax (e.g. `do`-notation) to give the code an imperative feel. To actually execute a `PackedReader` computation, we use the `runReader` function. An example is given in Figure 5c.

The code generator described in Section 2.1.3 provides a "case" function: a `PackedReader` which simulates pattern matching. Figure 6 is an example of a packed tree traversal, using the generated `caseTree` (defined in Figure 8b). This function computes the sum of the leaf values in a packed tree. The first lambda to pass (lines 4-7) is the function to execute if the packed tree is a `Leaf`, and the second one (lines 8-12) is for when the packed tree is a `Node`.

```
1  sumTree :: PackedReader '[Tree] '[] Int
2  sumTree =
3      caseTree
4          ( do
5              n <- reader
6              return n
7          )
8          ( do
9              left <- sumTree
10             right <- sumTree
11             return (left + right)
12         )
```

Figure 6 Computing the sum of the values in a Tree, using "caseTree".

2.1.3 Code Generator

Defining how to encode and decode packed data is a critical aspect of packed data manipulation. Since we deal with bytes, it is very easy to make mistakes, and tools like the type-system cannot be helpful here. `packed-data` takes away the programmer's responsibility to write encoding/decoding functions for their custom data types by providing a code generator.

Powered by Template Haskell [10], this code generator defines the following for a given ADT:

- An instance of the `Packable` typeclass, providing the `pack` function (seen in Figure 3b)
- An instance of the `Unpackable` typeclass, providing the `reader` function, to unpack a value from a packed stream.
- A "case" function, to simulate pattern matching on a packed object (see Section 2.1.2)
- A "transform" function, similar to "case"; it helps generate packed data out of `Packed` values (an example of its usage is given in Section 2.2)

The code generator's entry point also takes as parameter a list of flags, which change its behaviour. Currently, these flags only deal with indirections (described in Section 2.1.4).

To invoke the code generator, the programmer has to call the `mkPacked` function. An example is given in Figure 7.

```
$(mkPacked ''Tree [InsertFieldSize])
```

Figure 7 Invocation of the code generator.

2.1.4 Indirections

The code generator accepts two flags:

- `InsertFieldSize`: Inserts indirections before each field of the packed ADT.
- `SkipLastFieldSize`: Does not insert an indirection before the last field. We do not always need to jump over a final field, and not adding an indirection allows saving space in memory.

These flags will change the definition of the functions produced by the code generator. Figure 8 illustrates these changes. Notice in Figure 8a that each field is preceded by a `FieldSize` (a type alias to 32-bit integers we use as indirections), absent from the definition in Figure 8b, generated without passing indirection flags. This type transparency regarding indirections makes it easier to think about how to traverse a data structure: should we traverse everything to get to the nth field, or can we use indirections to jump there?

```
caseTree ::
    PackedReader '[FieldSize, Int] r a ->
    PackedReader '[FieldSize, Tree, FieldSize, Tree] r a ->
    PackedReader '[Tree] r a
```

(a) Definition of the "case" function for Trees, when the "InsertFieldSize" is on.

```
caseTree ::
    PackedReader '[Int] r a ->
    PackedReader '[Tree, Tree] r a ->
    PackedReader '[Tree] r a
```

(b) Definition of the "case" function for Trees, when no indirection flags are passed to the generator.

Figure 8 Changes on the API caused by indirections.

Consequently, code that manipulates packed data changes accordingly to the indirections flags given to the code generator. For example, consider Figure 9 where we traverse a binary tree to get its right-most value. In Figure 9a, we have to *read* each left sub-trees to get to the right one. This is not optimal, as it causes a complete traversal of that sub-tree. However, in Figure 9b, we *skip* over a field using the `FieldSize` that precedes it. One drawback is that we have to explicitly skip `FieldSize`s we do not care about (before an integer value for example).

```
getRightMost :: PackedReader '[Tree] r Int
getRightMost =
    caseTree
        readInt
        ( do
            _ <- readTree
            getRightMost
        )
```

(a) Traversing a tree, without indirections.

```
getRightMost :: PackedReader '[Tree] r Int
getRightMost =
    caseTree
        ( do
            skipFieldSize -- Skipping leading indirection
            readInt
        )
        ( do
            skipWithFieldSize -- Skipping the left subtree
            skipFieldSize -- Skipping the right subtree's indirection
            getRightMost
        )
```

(b) Traversing a tree, with indirections.

Figure 9 Tree traversals in `packed-data`.

2.2 Example: Incrementing values of a packed tree

The packed data produced by the library is immutable. Since we are working with pointers and raw memory access under the hood, giving writing abilities (even through a monad) would break the purity and referential transparency of the library's API. Writing inside a buffer used by multiple `Packed` values would impact each of these variables, possibly leading to corruption. Just like in functional languages, it is not possible to do in-place modifications on packed data; instead we have to duplicate it.

To do so, we can build a `Needs` value while traversing a packed value. This is what the generated "transform" function is for: it behaves similarly to the "case" function (in the sense that it helps with pattern matching on packed values, and it can be used recursively), but it forces its arguments to be `PackedReader`s that produce `Needs` values. It also helps the programmer by writing leading tags and inserting indirections when necessary.

Figure 10 gives an example of a function that takes a packed tree and produces another where all the leaf values are incremented by one. We use the `transformTree` function (line 3) instead of `caseTree`, as the former invokes the `startLeaf`/`startNode` functions for us and thus

helps keeping the code simple. The first `PackedReader` (lines 4-7) passed to `transformTree` reads the integer of a packed `Leaf` and calls the `write` function from the `Packable` typeclass. The second `PackedReader` (lines 8-12) calls the `incrementPacked` function recursively for each branch and builds back the packed `Node` using the `applyNeeds` function.

```
1  incrementPacked :: PackedReader '[Tree Int] r (Needs '[] '[Tree Int])
2  incrementPacked =
3      transformTree
4          ( do
5              n <- readInt
6              return (write (n + 1))
7          )
8          ( do
9              left <- incrementPacked
10             right <- incrementPacked
11             return (applyNeeds left >> applyNeeds right)
12         )
```

Figure 10 Incrementing values of a packed tree.

2.3 Use case: Web Server

To showcase the perks of using packed data, let's take the example of a very simple web API that has two endpoints "`/sum`" and "`/right-most`". These endpoints respectively compute the sum of the leaves' values and get the right-most value in a packed tree passed to the request body.

Using the Scotty web framework[4], we would implement the endpoints as in Figure 11a. The endpoints are very simple: we get the packed tree, call the corresponding function `sumTree` and `getRightMost` (from Figures 6 and 9a) and send back the result.

The most interesting part of these endpoints is how we get the packed tree (on lines 4 and 9): Scotty's `body` function returns the raw request's body as a *lazy* `ByteString`. However, a `Packed` value relies on a *strict* `ByteString`. Thus, we need to use the `toStrict` function to do the conversion. This operation is $\mathcal{O}(n)$, but considering that a JSON-based API would traverse the entire `ByteString` to parse JSON as well, this is acceptable. `unsafeToPacked` is a $\mathcal{O}(1)$ operation to cast a `ByteString` into a typed `Packed` value. Unlike a JSON-based API, we do not marshal the request body, saving both memory and time.

On the client side (Figure 11b), we enjoy a similar kind of optimisation, as the packed tree can be sent as-is (if the client already uses packed data). Additionally, both `fromPacked` and `fromStrict` (line 5) are $\mathcal{O}(1)$ operations, making the preparation of a request lightweight.

When running this server in parallel with one that uses *unpacked* trees and JSON, we notice that the former runs noticeably faster than the later (Proper benchmarks on packed vs. unpacked data are done in Section 3.2).

[4] `https://hackage.haskell.org/package/scotty`

```haskell
endpoints :: ScottyM ()
endpoints = do
    get "/sum" $ do
        packedTree <- unsafeToPacked . toStrict <$> body
        sum <- liftIO $ runReader sumTree packedTree
        response sum

    get "/right-most" $ do
        packedTree <- unsafeToPacked . toStrict <$> body
        rightMost <- liftIO $ runReader getRightMost packedTree
        response rightMost
```

(a) Handling packed data in a web REST API Server.

```haskell
request methodGet "/sum" [] reqBody
  where
    packedTree :: Packed '[Tree]
    packedTree = ...
    reqBody = fromStrict (fromPacked packedTree)
```

(b) Sending packed data to a web REST API.

Figure 11 Packed data in a web REST API.

3 Evaluation

To understand the impact of using the library to handle packed data, we evaluate it in two ways. First, we take a look at its usability and portability, by comparing how to manipulate packed data and unpacked data. Then, we look at the performance through a benchmark on simple tree traversals.

3.1 Practical considerations

Since computations on packed data are lifted, it imposes limitations on how code can be written. `packed-data` tries to fill the gap between Haskell's features and what one might want to do with packed information, without modifying the compiler. However, this approach has some shortcomings. Let's take a look at five aspects of our library-based approach to evaluate the usability of `packed-data`.

3.1.1 Type-safety and maintainability

`packed-data` provides a high-level and type-safe API for low-level data manipulation. It keeps the user from doing raw and unsafe pointer arithmetic by abstracting these operations behind a functional API.

As an example, consider Figures 6, 12 and 2 where we compute the sum of the leaves of a packed tree using `packed-data` and pointer arithmetic in Haskell and C. In the later cases, dereferencing and pointer arithmetic bloats the code with multiple operations on numeric values that are not very expressive. In both languages, the type-checker will not be able to detect any pointer misuse. On the other hand, when using `packed-data` (Figure 6), pointer arithmetic is hidden away behind functions like `reader`, `caseTree` and the `do` expressions,

which guarantee correct pointer manipulation. Therefore, our library makes code that manipulates packed data more readable, maintainable and memory-safe, compared to code that does raw pointer arithmetic.

```
sumPackedNonMonadic :: Ptr Word8  -> IO (Int, Word8)
sumPackedNonMonadic ptr = do
    tag <- peek ptr :: IO Word8
    let !nextPtr = ptr `plusPtr` 1
    case tag of
        0 -> do
            !n <- peek nextPtr
            let !nextPtr1 = plusPtr ptr 9
            return (n, nextPtr1)
        1 -> do
            (!left, !r) <- go (castPtr nextPtr)
            (!right, !r1) <- go r
            let !res = left + right
            return (res, r1)
        _ -> undefined
```

Figure 12 Summing the values in a tree using raw pointer manipulation in Haskell.

3.1.2 Portability

`packed-data` does not require modifying the compiler or the runtime system. This means that the library's code does not deal with the compiler's implementation details. Thus, `packed-data` can virtually be used with any modern version of GHC (as of today, the library has been tested with GHC versions 9.2 to 9.12). The library can be simply used as a third-party package, with no further constraints.

Not relying on the compiler's internal workings also means that `packed-data` could be reimplemented in other languages with similar type systems like Scala, Rust or TypeScript.

3.1.3 Code Generator's Applicability

Thanks to its code generator (powered by meta-programming), `packed-data` can be used with any user-defined algebraic data type, with the exception of unboxed types (denoted with a trailing `#`, like `ByteArray#`) and types that use them.

It also requires very little boilerplate code (see Figure 7 from Section 2.1.3). Using a Template Haskell entry point like `mkPacked` is a common approach used by other popular Haskell libraries like Aeson[5] for JSON encoding/decoding.

3.1.4 Generated Code and Flags

We saw in Section 2.1.4 that flags could change the definition of the functions created by the code generator, while the names of the generated functions do not change. But what if we wanted to call the code generator twice for the same ADTs, passing different flags? This would lead to the definition of two functions with the same name (e.g. `caseTree`) in the same

[5] `https://hackage.haskell.org/package/aeson`

module, which is not allowed in Haskell. A workaround would be to call the code generator separately in dedicated modules, so that the different definitions are split, and we can import these modules according to our needs.

Another thing to consider is that the `Packed` data type does not us tell whether indirections are present in the packed data. Therefore, if a user wants to build trees with and without indirections, it is up to them to use the correct "case" and "reader" functions generated with the correct flags.

We should also note that the same code cannot be reused with instances of the `Packable` typeclass generated with different indirection flags. Figures 8 and 9 illustrate this problem: because of the strong typing of the packed data, `PackedReader`s need to explicitly skip over indirections (with `skipFieldSize`) when they are present.

3.1.5 Pattern Matching

One of Haskell's strengths is its powerful pattern matching support. Unfortunately, its syntax is not overload-able, meaning that we can not use it to pattern match on packed data. As a solution, the code generator defines a "case" function which takes lambdas as parameter, one for each constructor of the ADT (an example is given in Figure 6).

However, an issue arises from not being able to use the standard syntax: we can't do nested pattern matching. In Haskell, we can pattern-match on a constructor's fields, while with our "case" functions, pattern matching only considers constructors.

`packed-data` is a portable solution that provides type-safety for packed data manipulation. It is flexible (with flags for the code generator) and can be easily integrated to most modern Haskell projects. Even though the API sticks to Haskell's functional and pure paradigm, it does not support features like nested pattern matching.

3.2 Performance

We evaluate the performance of `packed-data` by comparing the execution time of simple tree traversals with pointer-based Haskell, Gibbon, C and Golang. We focus on four kinds of full tree traversals: computing the sum of values in a tree, evaluating an AST for a simple arithmetic language, getting the right-most node and incrementing the leaves' values. Table 1 reports the execution times of these tree traversals.

We should note that we will not compare the size of the packed data with buffers created by Cap'n Proto. This is because `packed-data`'s serialisation format is very similar to Gibbon's, and Vollmer et al. have already demonstrated that the compiler's packing format is more space-efficient than Cap'n Proto [13]. For the same reason, we will not benchmark Cap'n Proto's traversals, as the same paper showcases that Gibbon's traversals are generally faster than Cap'n Proto. Thus, we can use Gibbon's performance to indirectly compare `packed-data` with Cap'n Proto.

For each benchmark, each tree is built symmetrically, meaning that a tree of "size" 1 will have $2^1 = 2$ leaves, a tree of "size" 5 will have $2^5 = 32$ leaves, etc. The C and Haskell code were benchmarked using the Criterion library[6](with Haskell's Foreign Function Interface (FFI) to invoke the C code with negligible overhead). The Gibbon code was compiled with the `-p` and `--no-gc` options to use a packed layout and disable garbage collection. The Golang

[6] `https://hackage.haskell.org/package/criterion`

code was benchmarked using the `testing` library[7]. Code was compiled using GCC 11.4, GHC 9.10, Golang 1.18 and the latest Gibbon version as of March 2025. All benchmarks were run on an Intel machine with two Xeon Gold 6244 CPUs at 3.60 GHz, with 32Gb of RAM, running Ubuntu 22.04 LTS.

In this section, we will ignore the benchmark cases prefixed with *Non-monadic*, we will get back to them in Section 4.

For summing the values in a tree, using `packed-data` can provide up to a 20% speed-up compared to native Haskell. It also beats C by running 15% faster. We can note that, for this specific scenario, having indirections slightly slows down the traversal (around 2%): we do not need them to optimise the traversal, so we skip over them, leading to additional smaller jumps.

Evaluating an AST is similar to summing the values of a tree, as it requires a full traversal of a tree, without skipping any fields. The AST used for this benchmark is one for a small arithmetic language with integer values, addition, subtraction, multiplication, and division. This means that we will not have to deal with two constructors/tags like for the previous benchmark (for leaves and nodes), but five (one for the value, and one for each arithmetic operation). Similarly to the previous benchmark, using `packed-data` provides a 60% speed-up compared to regular Haskell. The *Unpacking, then traverse* line shows the runtime for functions that unpacks the packed AST, and then evaluates it. This case shows that doing so leads to an 8.5x slowdown compared to native Haskell and illustrates the cost of unpacking a value before processing it, i.e. that `time(unpacking)+ time(eval_unpacked)> time (eval_packed)`.

The third benchmark focuses on getting the right-most value in a tree. Unlike the previous cases, here a lot of jumps will be done, as we do not need to go through each branch of the tree. However, using `packed-data`, the operation is 10000 times slower than regular Haskell, as we need to traverse the entire packed tree to reach the last value. But this benchmarks illustrates the benefits of indirections: when they are present, we can skip over subtrees, avoiding a lot of useless traversals. Indirections allow this computation to be only four times slower than unpacked Haskell.

In the final benchmark, we evaluate the performance of incrementing the leaves' values in a tree. Note that the C and Golang benchmarks increment the trees *in-place*, while the others create a new tree. Here, Haskell is much slower than C, since Haskell's functional paradigm forces such operations to produce an entirely new tree. In `packed-data`, this can be done by using the `traverse` function and calling the `finish` function. The performance of `packed-data` are surprisingly comparable with regular Haskell. This can be justified by the fact that `packed-data` only does one big memory allocation for the entire buffer, instead of one per tree node. In the *Unpacking, increment and repack* case, we deserialise the packed tree, increment the leave's values (using the same function as for the native Haskell case), and then repack the tree. The *Deserialise and increment, and repack* case produces an unpacked tree already incremented (i.e. the leave's values are incremented in the "case" function's lambdas) and then re-serialiases the tree. The latter case has better performance than the former, as it avoids an additional traversal and the creation of a new unpacked tree. Again, these last two cases show that it is faster to use unpacked data as-is, instead of deserialising it first, whether it is for read-only or writing operations.

As a final note, we observed via some preliminary benchmarking that the packed data approach appears to perform worse on Apple ARM devices, where the non-packed (pointer-chasing) code is generally faster. We speculate that this may be due to ARM either handling

①: Using NeedsBuilder. ②: Unpacking, increment and repack.
③: Deserialise and increment, and repack.

(d) Execution times for incrementing the values in a tree.

pointer-chasing within a tree better, or punishing unaligned access more severely. Full investigation of packed data performance on ARM architecture is future work. Regardless, even on ARM, there was a significant benefit to operating directly on packed data rather than the "unpack, process and repack" round-trip.

We conclude that `packed-data` can provide better performance than native Haskell, but not in every case. In the best scenarios, the speed-ups can reach 60%, compared to unpacked data, but in the worst scenarios, it is considerably slower (from 4 to 10000 times). In the next section, we speculate on why sometimes the library performs slower than native Haskell.

4 Reflection

We concluded in the previous section that the performance of `packed-data` were satisfactory. This can be explained by the fact that we make the most of the L1 cache and do not jump around using pointers. In this section we consider an alternative way of writing code in Haskell for packed data that can provide better performance than `packed-data`. This approach, however, is far less maintainable and safe.

In Haskell, monads are not defined at the compiler level, they are regular data structures defined in Haskell's `base` standard library. Therefore, even though they are a big part of the functional paradigm, they do not enjoy any dedicated compiler optimisation.

To manipulate packed data, `packed-data` uses two monads: `IO`, required to do any kind of low-level operation (like dereferencing a pointer using `peek`), and `PackedReader`, which provides the high-level API for packed data traversals.

Since monadic operations can be as optimised as any other kind of computation (e.g. through inlining), inevitably, using two monads on top of each other like `packed-data` must lead to some computing overhead.

We argued in Section 3.1.1 that `packed-data`'s API allowed for readable and type-safe code. Figure 13b is an example of what traversing packed data without `packed-data` would look like. It is safe to say that this code is way less pleasant to read and harder to maintain than with the library (Figure 13a). However, it does get rid of one level of computation induced by the `PackedReader` monad.

Benchmarks using this non-monadic approach are included in Table 1 and labelled as *Non-monadic*. In the summing and AST evaluation benchmarks, this approach yields slightly better performance (between 2 and 6% compared to the monadic approach). However, in the third benchmark, with indirections, it is 19% faster than its `packed-data` counterpart. But it is still 3.5 times slower than regular Haskell, possibly because this computation relies heavily on following indirections and jumping around in the serialized tree. This leads to an extensive use of the `IO` monad, slowing down the traversal.

This confirms that our monadic approach to packed data manipulation causes some kind of computing overhead. However, this is specific to Haskell. Implementations for other languages might not suffer from this, but they should be able to leverage similar performance enhancements. As future work, we could use staging and compile-time evaluation to eliminate that computing overhead.

5 Future Work

While `packed-data` is a working library, it can be improved in many ways; or it can serve as a stepping stone for further research on the topic. In this section, we enumerate possible future work that can be done on the library or in this research domain.

```
evalPacked :: PackedReader '[AST] r Int32
evalPacked =
    caseAST
        reader
        (opLambda (+))
        (opLambda (-))
        (opLambda (*))
        (opLambda div)
  where
    {-# INLINE opLambda #-}
    opLambda ::
        (Int32 -> Int32 -> Int32) ->
        PackedReader '[AST, AST] r Int32
    opLambda f = R.do
        left <- evalPacked
        right <- evalPacked
        R.return (f left right)
```

(a) Using `packed-data`.

```
evalPackedNonMonadic :: Packed (AST ': r) -> IO Int32
evalPackedNonMonadic packed = fst <$> go (unsafeForeignPtrToPtr fptr)
  where
    (BS fptr _) = fromPacked packed
    go :: Ptr Word8 -> IO (Int32, Ptr Word8)
    go ptr = do
        tag <- peek ptr :: IO Word8
        let !nextPtr = ptr `plusPtr` 1
        case tag of
            0 -> do
                !n <- peek nextPtr :: IO Int32
                return (fromIntegral n, plusPtr nextPtr (sizeOf n))
            1 -> opLambda (+) nextPtr
            2 -> opLambda (-) nextPtr
            3 -> opLambda (*) nextPtr
            4 -> opLambda div nextPtr
            _ -> undefined
    {-# INLINE opLambda #-}
    opLambda :: (Int32 -> Int32 -> Int32) -> Ptr Int32 -> IO (Int32,
       Ptr Word8)
    opLambda f ptr = do
        (!left, !r) <- go $ castPtr ptr
        (!right, !r1) <- go r
        let !res = left `f` right
        return (res, r1)
```

(b) Using pointer arithmetic.

Figure 13 Evaluating a packed AST.

Building packed data (through a `Needs` buffer) is slow (four times slower than building native objects). Internally, it relies on the `bytestring-strict-builder` library[8] which, in itself provides good performance[9]. However, as for packed data traversals, building packed data is implemented through a monad, `NeedsBuilder`. As discussed in Section 4, even though it provides a functional and type-safe API, such approach can cause some computing overhead. A future version of `packed-data` could focus on making the packing process faster.

`packed-data` only supports its own packing layout. However, some systems could take advantage of data packed with a custom or pre-defined layout. Take JSON for example: the client of an API that serves JSON data would not have to deserialise the server's response, and could use it as is. This is also applicable for web browsers and HTML, especially since web pages can be sizeable. A next step for `packed-data` would be to handle data packed with a more complex layout like JSON, HTML or CBOR[10].

We have seen that accessing a field in a packed structure is not a straightforward task: we have to either use indirections or traverse the preceding fields. We could draw inspiration from Chilimbi, Davison & Larus' work [5] and reorder fields according to their access pattern, moving the most accessed ones first in a packed structure [11]. This would help programs access "popular" fields more easily, with fewer jumps in the packed buffer.

In `packed-data`, indirections take the form of a 32-bit integer. We could definitely save some space in the packed buffer by choosing the size of this indirection accordingly to the following field. For example, we do not need a 32-bit indirection for a four-characters string, one byte would be enough. To go even further, some packed data do not need indirections at all, if their size can be guesses statically (e.g. a packed character will always be one byte, a 16-bit number two bytes, etc.). In that case, indirections are useless. We can avoid inserting them (reducing the size of the packed buffer) and deduce the size of that packed data by relying on the type-checker and a couple of typeclasses.

As mentioned in Section 3.1, we could also allow the same code on packed data to be reused whether the data has been packed with or without indirections.

Another area of improvement would be not to insert indirections in the packed buffer itself, but in a separate heap object. This would allow for packed data to be smaller and enable parallelism in tree traversals.

Finally, because of the data layout used by `packed-data`, memory access can be unaligned. This noticeably affects performance on ARM CPUs. In the future, `packed-data` could include a flag that forces the insertion of padding in the packed buffer, to align tags, indirections and fields.

The portability of `packed-data` across other languages remains theoretical. While its implementation does not rely on modifying the compiler or the runtime system, it does heavily rely on Haskell's type-system. It would be interesting to implement `packed-data` in an other typed language like Scala, TypeScript or Rust.

We concluded in Section 4 that our library-based approach in Haskell suffered from a computing overhead caused by the `IO` monad, blocking any possible future enhancement of the library's performance. Deeply-embedded domain-specific languages (EDSLs) could be a solution to this problem. EDSLs expose functions that do not actually execute an operation,

[8] `https://hackage.haskell.org/package/bytestring-strict-builder`
[9] `https://github.com/haskell-perf/strict-bytestring-builders`
[10] `https://cbor.io`

but instead produce an AST [12]. These ASTs can then be optimised [1] and compiled into a full-blown program in the host language or produce a standalone executable [3]. A few EDSLs have performance as their main objective [1], and to reach it, it's not uncommon to rely on a backend written in a lower-level language, like C [6].

To provide better performance, `packed-data` could be reimplemented as a deeply embedded DSL: at compile time, using Template Haskell, we could produce an AST and generate C code. Using Template Haskell's quotation feature, we could inject the call to that C code into the Haskell program, using the language's C FFI. This way, we would still have a type-safe and functional API, while enjoying C's fast performance [7]. Furthermore, this C code could be reused as a common backend for implementations of `packed-data` in other languages.

6 Conclusion

Exchanging data using a packed format can be faster than when using a human-readable format like JSON, as the recipients can use the serialised data as-is, avoiding any deserialisation step. Manipulating packed data can also help save computation time, as it avoids chasing pointers. However, this format is not easy to adopt, as most implementations require either compiler modifications or a dedicated compiler.

In this paper, we investigate library-based support for packed data through `packed-data`. This Haskell library provides a type-safe and functional API that allows packing data, processing it, and unpacking it. It relies on Template Haskell and Haskell's type-system, meaning that this library could virtually be implemented in any language that supports meta-compilation and higher-kinded types.

Our benchmarks show that the library can leverage better performance than native Haskell (up to 60%), but in some scenarios like getting the right-most value in a tree, `packed-data` (with indirections) is four times slower. This is due to a computation overhead caused by the monadic approach used in the implementation, as benchmarks show that "pure" pointer arithmetic-based implementations can provide more competitive performance.

While a library-based approach for packed data support is feasible and portable, there is a performance and usability tradeoff to consider. We think that `packed-data` would benefit from staging and compile-time optimisations, for example, through an EDSL, which would generate and call C code. This would help get rid of computing overhead caused by the host language, and could be reused to build a common backend used by implementations of similar libraries in other languages.

WebGlitch: A Randomised Testing Tool for the WebGPU API

Matthew K. L. Wong
Department of Computing, Imperial College London, UK

Alastair F. Donaldson
Department of Computing, Imperial College London, UK

Abstract

We report on our experience designing a new technique and tool for fuzzing implementations of WebGPU, a W3C standard JavaScript API for in-browser GPU computing. We also report on our experience using our WebGlitch tool to test industrial-strength implementations of WebGPU, leading to the discovery of numerous bugs. WebGPU enables programmatic access to a device's graphics processing unit (GPU) for in-browser GPU computing, and is being implemented by Google, Mozilla and Apple for inclusion in all of the major web browsers. Guaranteeing the security and reliability of WebGPU is crucial to avoid wide-reaching browser security vulnerabilities and to facilitate portability by ensuring uniform behaviour across different platforms. To that end – inspired by randomised compiler testing techniques – our approach to fuzzing creates random, valid-by-construction programs by continuously selecting a WebGPU API function, then recursively generating all requirements necessary for that API call to be valid based on careful modelling of the API specification. This is implemented as a new open source tool, WebGlitch, which we designed in consultation with engineers at Google who work on the Chrome WebGPU implementation. WebGlitch identifies bugs through sanitiser-boosted crash oracles, differential testing, and by identifying cases where valid-by-construction API calls lead to runtime errors. We present an evaluation showing that WebGlitch can find bugs missed by an existing WebGPU fuzzer, wg-fuzz, and across the broader WebGPU ecosystem: to date, WebGlitch has found 24 previously-unknown bugs (15 fixed so far in response to our reports). Among these, 17 bugs affected WebGPU implementations from Google, Mozilla, and the Deno project. WebGlitch found an additional 4 bugs in the shader compilers used by the graphics APIs that WebGPU interfaces with. The remaining 3 bugs affect the widely-used JavaScript runtimes Node.js and Deno. Fuzzing with WebGlitch also led us to identify an ambiguity in the specification of the WebGPU shading language, for which we proposed an amendment that was accepted by W3C and which has been adopted in the latest version of the specification. Analysing the line coverage of a WebGPU implementation by WebGlitch-generated programs revealed that WebGlitch covers code missed by wg-fuzz and the official conformance test suite. Our hope is that this report on the design of WebGlitch and its deployment in practice will be useful for practitioners and researchers interested in using API fuzzing to improve the reliability of industrial codebases.

1 Introduction

In this experience report we investigate the use of randomised testing techniques for improving the reliability of implementations of the WebGPU API.

WebGPU [58] is a new W3C standardised web application programming interface (API) that allows building websites that make programmatic use of a device's graphics processing unit (GPU) for real-time rendering and general-purpose computation. WebGPU abstracts away the intricacies of platform-specific graphics APIs, providing a unified, object-oriented JavaScript interface to execute commands on the GPU and configure render and compute passes, including the running of *shader programs*, which execute across the massively parallel hardware that GPUs offer. In practice, implementations of WebGPU conform to this interface by delegating WebGPU API calls to appropriate combinations of calls in lower level, platform-specific graphics APIs such as Direct3D [37], Metal [2], and Vulkan [25].

Three major WebGPU implementations are currently under development, by Google (for Chromium-based browsers, including Chrome and Edge), Apple (for Safari), and an implementation primarily by Mozilla (for Firefox) [51].

As a web standard, WebGPU will be enabled on billions of browser instances, so defects in implementations of the API that affect WebGPU-enabled content, or worse, exploitable vulnerabilities, have the potential to be wide-reaching. Since WebGPU requires interfacing with kernel-level graphics drivers, exploits can potentially bypass browser sandboxing features [49], and these bugs have the potential to be triggered by merely visiting a web page. Indeed, many high severity CVEs have been identified for an existing web graphics API, WebGL [40, 42, 41]. WebGPU's increased complexity over WebGL presents an even wider attack surface and makes it more difficult to test. While there is an official conformance test suite (CTS) [50], it is unrealistic for handwritten tests to cover all edge cases, especially as problems may arise due to both bugs in the WebGPU implementation itself and bugs in platform-specific shader compilers and graphics APIs.

API fuzzing can help cover these corner cases by randomly generating sequences of API calls [5, 44, 22, 21]. In this work, we investigate the use of API fuzzing for finding bugs in implementations of WebGPU. In consultation with engineers at Google who work on the WebGPU implementation in Chromium, we developed a Java-based open source command line tool, WebGlitch: a black box fuzzer for the WebGPU API. We report on our experience designing and implementing WebGlitch, and deploying it in practice to find bugs in production WebGPU implementations.

WebGlitch generates JavaScript programs that make intricate use of the WebGPU API. Generated programs can then be fed to a WebGPU implementation under test, also testing the downstream graphics API and graphics drivers on which the implementation depends.

We have designed WebGlitch to ensure that the WebGPU programs it generates by default are valid-by-construction, according to the WebGPU specification. This is important because programs generated in a naive fashion would be unlikely to yield programs featuring API calls that satisfy WebGPU's complex validation rules. Invalid API calls would only exercise a limited subset of the implementation under test. Another benefit of generating valid-by-construction programs is that it allows for the automatic detection of validation bugs, where valid calls to API functions are wrongly rejected.

To ensure rigorous testing of parts of WebGPU related to compiling and executing shaders, we have integrated WebGlitch with WGSLsmith, a state-of-the-art random generator of WebGPU shading language (WGSL) programs [13, 28].

WebGlitch constructs programs incrementally, iteratively choosing random API functions to generate until a pre-defined limit is reached. Many API functions require parameters that refer to objects that must have been created previously via other API calls. At each generation step, rather than being restricted to only using previously-generated objects as the receiver and parameters for an API call, WebGlitch uses an *on-demand* approach, as follows. An *arbitrary* API function is chosen at random. A suitable receiving object and parameters for the chosen function are then obtained via a combination of (a) using in-scope objects from previous calls (if available), and (b) recursively generating randomised calls to other API functions to yield a receiving object and suitable parameter arguments when needed. On-demand generation increases the probability of rich API functions that require complex arguments being invoked: taking the simpler approach of only allowing calls to API functions for which suitable arguments have already been generated would bias generation towards favouring simple functions requiring a small number of simple arguments.

To maximise the chances of finding bugs, WebGlitch uses multiple test oracles in conjunction: sanitiser-boosted crash oracles (using sanitisers such as AddressSanitizer [47], LeakSanitizer [20], and UndefinedBehaviorSanitizer [20]), differential testing [32], and confirming that no errors are thrown for a valid WebGPU program (hereafter termed the "validity" oracle). The validity oracle hinges on the fact that WebGlitch generates programs that are valid by construction.

Over a period of 5 months, at various stages during its development, we have used WebGlitch to test the Dawn WebGPU implementation from Google [19] and the wgpu implementation from (primarily) Mozilla [45], used in the Chromium and Firefox browsers, respectively. This has led to WebGlitch identifying 24 previously-unknown bugs, of which 17 affected WebGPU implementations, 4 affected shader compilers used in downstream graphics APIs, and 3 affected the JavaScript runtimes Node.js and Deno. In addition, WebGlitch independently identified 5 bugs that turned out to have already been reported.

As well as finding bugs in implementations of WebGPU, our testing efforts identified an ambiguity in the specification of WGSL related to overflow checking for numeric types. We clarified the intended semantics with engineers at Google who are leading the design of WGSL, and based on this discussion we proposed a clarification to its specification to resolve the ambiguity, which as been accepted and incorporated into its latest version [52].

We present a set of controlled experiments on Google's WebGPU implementation, comparing the lines of code covered by running the WebGPU CTS vs. by conducting a short fuzzing campaign using WebGlitch, and a comparable fuzzing campaign using an existing WebGPU fuzzer, wg-fuzz [48]. Our results show that both WebGlitch and wg-fuzz generated programs that covered lines missed by the CTS. WebGlitch was able to cover 1,530 lines not reached by wg-fuzz, despite supporting the generation of fewer WebGPU API functions outlined in the specification than wg-fuzz. These two fuzzers complement each other, with wg-fuzz being able to cover 5,180 lines missed by WebGlitch.

We also present a summary of the insights that we gained on API fuzzing from our fuzz testing campaign of WebGPU, which may be valuable for researchers and practitioners considering deploying API fuzzing in the future. A key point here is that although our approach allowed the detection of numerous previously-unknown bugs, our fuzzing campaign required frequent manual intervention because of both the evolving and layered nature of the WebGPU API.

In summary, the contributions of this paper are:

- The development of a technique for fuzzing WebGPU implementations, implemented as the WebGlitch open source tool.

- A report on the use of WebGlitch in practice to find bugs in industrial-strength implementations of WebGPU from Google and Mozilla, to find bugs in associated infrastructure including the Node.js and Deno JavaScript runtimes, and to resolve an ambiguity in the WebGPU shading language specification.
- The findings of a controlled experiment assessing the code coverage achieved by WebGlitch in comparison to the WebGPU CTS and another WebGPU fuzzer, wg-fuzz. Our results show that WebGlitch covers lines of code that are missed by wg-fuzz, and that there are potential gaps in the CTS.

Paper Structure

We first give background on the WebGPU ecosystem, including the way in which it interfaces with downstream graphics APIs and the shader compilation process (Section 2). We then discuss the design and implementation details of WebGlitch (Section 3), before presenting an overview of the bugs found by WebGlitch (Section 4). We also conduct a controlled study to evaluate the abilities of different tools – the WebGPU CTS, wg-fuzz, and WebGlitch – to exercise and test a WebGPU implementation (Section 5). We finish by discussing key insights and lessons learned from our work (Section 6), related work on API fuzzing and compiler testing (Section 7), and directions for future work (Section 8).

Availability

Our WebGlitch tool is available as open source [53], and an artifact accompanying the paper is available [56]. WebGlitch is exposed as a set of command line tools: a *generator* component that generates JavaScript program that uses WebGPU; a *runner* component that runs sets of generated programs on a target platform, and a separate *fault-finder* program that mines the logs produced by the runner component to check for bugs, which are then categorised by the test oracle that found them.

2 WebGPU Background

WebGPU is a powerful new API that allows web applications to leverage the GPU for demanding tasks such as data visualisation, producing high-quality renders for 3D design tools, and on-device machine learning [57]. The WebGPU API allows a JavaScript program to encode GPU commands in buffers, which are then sent to the GPU for execution [58]. For example, there are commands for setting up render and compute passes, wherein shader program execution can be configured. The entire API is object-oriented, and all API functions are invoked on some receiving WebGPU object.

There are three major WebGPU implementations currently in development: Dawn, developed by Google and used in the Chromium project, on which the Google Chrome and Microsoft Edge browsers are based [19]; wgpu [45], primarily developed by Mozilla and used in Firefox, and an implementation from Apple [8] as part of the WebKit browser engine on which Safari is based. The wgpu implementation is noteworthy in that it is written in and made for Rust, and it is not fully compliant with the W3C WebGPU standard to make its usage more idiomatic to the Rust language. The wgpu project is used as the core implementation of WebGPU functionality in Firefox. However, an additional layer above wgpu is required to map JavaScript WebGPU API calls to wgpu ones and to fully adhere to the specification [45]. Google and Apple's WebGPU implementations are both written in C++. Although WebGPU is designed to be used in-browser, bindings are also available to

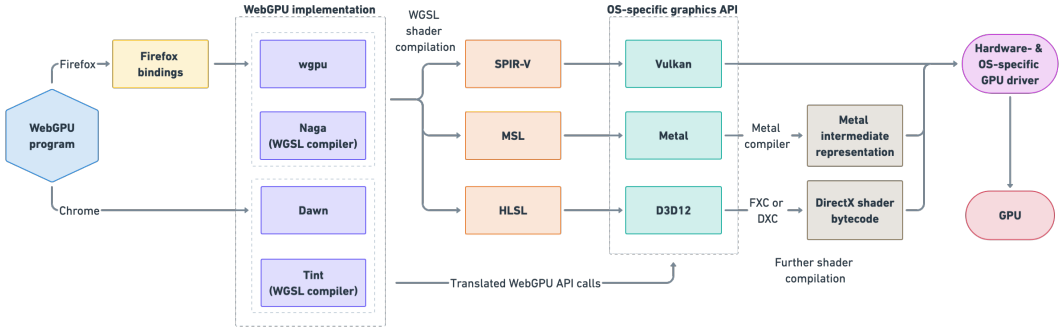

Figure 1 Simplified overview of the WebGPU architecture and WGSL compilation chain, created using information from wgpu and Chromium documentation [45, 49]. Tint is technically part of Dawn, but has been shown separately here for clarity. HLSL can be compiled by FXC [34] (deprecated) or DXC [35]. Apple's implementation in Safari, which only targets the Metal backend, has been excluded for clarity.

enable its use from JavaScript runtimes such as Node.js and Deno. As with Firefox, Deno [11] also uses wgpu as the core of its WebGPU implementation, building on top of it with its own independent implementation.

When a WebGPU API call is made in JavaScript, it is validated according to the correct usage defined in the WebGPU specification. If valid, it is then mapped on to one or more platform-specific graphics API calls (see Figure 1). At the time of writing, the APIs that are used in practice are: Direct3D 12 (D3D12) (for Windows) [37], Metal (for macOS, iOS, iPadOS) [2], and Vulkan (for Linux, Android) [25].

The downstream API calls made by the WebGPU implementation should be valid-by-construction. But bugs related to making these calls could mean that the lower-level API is used incorrectly, which can lead to undefined behaviour and crashes that could be exploited [36]. Even if there are no errors related to their usage, bugs within the implementation of these lower level APIs could be exploited through WebGPU programs. The major WebGPU implementations are also written in languages that allow for memory-unsafe code to be written (C++ and Rust[1]). As such, heap-use-after-frees and buffer overflows could be exploited for arbitrary remote code execution.

A key part of graphics programming is the issuing of shader programs for execution on GPU hardware. Because WebGPU provides an abstraction that is independent of any particular graphics API, it has its own associated shading language: WebGPU Shading Language (WGSL) [59]. Because the underlying graphics APIs expect shaders to be written in specific shading languages, such as HLSL (D3D12) [38], MSL (Metal) [3], and SPIR-V (Vulkan) [26], a WebGPU implementation must first compile a WGSL shader into the appropriate target language (Figure 1). This is accomplished using the WGSL compilers Tint (for Dawn) [19], Naga (for wgpu) [45], and wgslc (for Safari/WebKit). The resulting shader will then be further compiled by the shader compiler that ships with the driver for the user's GPU device to enable execution on the GPU hardware. Worryingly, bugs within the WGSL compilers themselves, as well as downstream compilers, have the potential to be exploited.

[1] Rust code that uses the "unsafe" feature of the language is not guaranteed to be memory-safe, and unsafe Rust is used in the wgpu project.

All these potential attack vectors combine to create a highly complex attack surface, similar to the one present in WebGPU's predecessor, WebGL [27]. This attack surface includes the WebGPU implementation and WGSL compiler used by a browser, alongside the lower-level platform-specific graphics API used by a device. However, the implementations of these APIs and their associated shader compilers are typically managed by third parties, resulting in a multi-layered attack surface that is difficult to test comprehensively.

Potential vulnerabilities have already been identified. These include an issue within the WebGPU implementation Dawn [49], an overflow bug in a downstream shader compiler [49], and several high-severity CVEs related to Tint [6].

3 Design and Implementation of WebGlitch

After an overview of how programs are generated by WebGlitch (Section 3.1), we explain how WebGPU API functions are represented (Section 3.2) and discuss the algorithm WebGlitch uses to generate valid-by-construction programs (Section 3.3). A worked example of this algorithm is then presented in Section 3.4 We then discuss how shaders are incorporated in generated programs (Section 3.5), and the test oracles that WebGlitch supports (Section 3.6). Finally, we present experimental results that give a ballpark estimate of the throughput of fuzzing using WebGlitch (Section 3.7).

3.1 WebGPU Program Generation Overview

To generate random WebGPU programs from scratch, WebGlitch incrementally adds new API calls to a skeleton JavaScript program. This skeleton contains components such as the main function and a helper function to load shaders. We refer to the program comprising all the calls that have been generated so far as a *partially-generated* program. At all times, WebGlitch keeps track of the state of the partially-generated program in order to generate valid API calls.

The following steps are repeated N times, for some fixed N that is provided as a parameter to the tool.

1. Choose a random API function, f, to call.
2. Select a receiver for f: an object on which f should be called. This may be an existing object resulting from a previous call, or may involve WebGlitch recursively generating additional API calls to bring a receiver of the right type into scope.
3. Issue any necessary function calls on the chosen receiver to bring it into a suitable state for a call to f to be valid.
4. Analyse the arguments required for the call to f. For primitive types and enumerated values, randomly choose a value from a set or range of valid ones. For other WebGPU objects, either find an in-scope object that satisfies the requirements, or generate one that does.

To illustrate step 3: suppose f needs to be called on a `GPUCommandEncoder` object with no active child passes. A `GPUCommandEncoder` is a WebGPU object that stores commands intended for execution on the GPU, such as render passes and compute passes. These "child" passes of a `GPUCommandEncoder` are considered "active" if the `end` method has not yet been invoked on it. If WebGlitch has selected a receiver representing a `GPUCommandEncoder` object with an active child pass, WebGlitch would need to invoke `end` on the child pass to bring the receiver into the necessary state.

Two programs generated using N repetitions of the above steps will have *roughly* the same size, because they will each feature N API function calls chosen via step 1. However, the sequence of functions that are called will likely be entirely different. Randomised recursive generation in steps 2–4 to fulfil the requirements of these calls will also lead to diversity.

The generation of a given call is guaranteed to terminate as there are a finite number of arguments per API function, and there are no cyclic dependencies between the requirements of functions in the API. In addition, WebGlitch uses a bound on the number of calls that will be generated, so generation is always guaranteed to terminate.

We now delve into the technical details of how this approach works, and our choice of this strategy for program generation.

3.2 Defining API Call Signatures and Requirements

Generation of valid WebGPU programs, which we describe in full in Section 3.3 below, hinges on a rigorous understanding of the signatures and requirements of API functions as defined in the prose specification.

Inspired by RESTler [5], an API-agnostic fuzzer which uses an interface definition language (IDL) to represent the structure of API functions, we designed a custom representation to specify the WebGPU API. This allowed us to add support for generating more basic API calls quickly. Each API function is specified via a JSON object, using a format that expresses characteristics shared by all API functions (e.g., number and types of arguments, and certain categories of requirements) to be expressed externally to the WebGlitch codebase (Figure 2). On execution, WebGlitch parses these definitions and uses the requirements they specify to guide its generation process. This decoupling of core API requirements from the source code of WebGlitch proved convenient during the development of the tool: it allowed additional functions to be made available to the tool, or early errors in our understanding of the API specification to be fixed without modifying or recompiling the WebGlitch source code.

```
"name": "writeBuffer",
"returnType": "none",
"properties": [{
  "buffer": {
    "type": "GPUBuffer",
    "conditions": {
      "same": ["GPUDevice"],
      "withAttributes": {
        "GPUBuffer.usage": ["GPUBufferUsage.COPY_DST"],
        "GPUBuffer.mapped": ["false"]
  }}}}
]
```

(a) Function to write data to a buffer on the GPU.

```
"name": "unmap",
"returnType": "none",
"conditions": {
  "withAttributes": {
    "GPUBuffer.mapped": ["true"]
  }
},
"setAttributes": {
  "this.mapped": ["false"]
}
```

(b) Function to return access to a buffer back to the GPU.

Figure 2 Examples of the JSON format for specifying WebGPU API functions and their requirements. Not all arguments have been listed for clarity. Some arguments require WebGPU objects, and their required state can be specified through the *withAttributes* field under the *conditions* field. These values can also be dynamic. The *setAttributes* field indicates that the function modifies the state of the object on which the function is called.

We populated these function requirements through careful analysis of the WebGPU specification [58], and updated them in response to occasional changes to the specification. Gathering such requirements was manual and could not be automated, as many API functions had unique constraints that required iterative updates to the JSON representation we used.

In addition to the general classes of requirements expressed in our JSON format, some API functions have more intricate requirements. Since extending our JSON representation to express such requirements was not straightforward nor elegant, information about them is "baked in" to WebGlitch – expressed in the logic of the WebGlitch source code. For example, creating a pipeline for rendering textures (through `createRenderPipeline`) can involve specifying various information about the vertex shader that will be used, which is difficult to express in a JSON representation.

Validation of WebGPU API function signatures was principally through practical testing against two implementations of WebGPU: Dawn and wgpu. As valid-by-construction programs are generated by default, when a WebGPU implementation under test rejects such a program this indicates that there is a bug in that implementation or a bug in the way the API function has been modelled in WebGlitch, which would be fixed iteratively. In cases where this was not clear from the specification, we consulted engineers at Google who work on Dawn.

3.3 Creating Valid Programs

WebGlitch constructs programs using an internal representation akin to an abstract syntax tree, but simpler because generated programs consist of a linear sequence of API calls.[2] Once generation is complete, the internal representation is pretty-printed as a JavaScript program.

Recall from the introduction and Section 3.1 that we have designed WebGlitch generate programs that are valid-by-construction: they always call WebGPU API functions on receiving objects that are in an appropriate state, passing the right number and types of arguments, with arguments satisfying any requirements described in the API specification.

The motivation for ensuring that generated programs are valid is as follows. When an *invalid* API call is made, minimal logic of the WebGPU implementation is executed: only the logic that checks for argument validity. Importantly, no functionality of the underlying graphics API will be invoked, and the WebGPU API call will not produce a meaningful result that can be used as input for subsequent functions.

We considered two approaches to generating valid-by-construction programs: a *conservative* approach, where an API function is selected to be invoked only if the partially-generated program has already created suitable WebGPU objects to fulfil the requirements of the selected function, and an *on demand* approach, where *any* API function can be selected to be invoked, with recursive generation being used to fulfil any missing requirements.

As already illustrated by the overview in Section 3.1, we opted for on-demand generation. Although the conservative approach is simpler, it suffers from the problem that many WebGPU functions have extensive requirements that must be satisfied in order for calls to be valid. It is unlikely that all such requirements will happen to be satisfied as a result of prior API calls in the partially-generated program. As a result, the most interesting and complex API functions would rarely be invoked in generated programs.

Once an API function has been selected at random, generation of a call to this function by WebGlitch can be split into two stages:

1. choose or create a random receiver object and ensure that it is in a suitable state for the function call;

[2] From the perspective of testing WebGPU implementations, there would be no value in including loops or conditional statements in generated JavaScript programs: such constructs would exercise the JavaScript engine, but would not exercise the WebGPU API in any additional depth, since e.g. a long linear sequence of calls can be used to call particular API functions multiple times.

2. for each function argument, choose a suitable value at random (for enumerated and numeric types), or choose or create a suitable WebGPU object at random and ensure that it is in a suitable state for the function call (for object arguments).

The state of a WebGPU object o is determined by the arguments passed into the function that created o, the state of the WebGPU object on which the constructing function was called, and any API calls that have been made on o since it was constructed.

In step 1 above, if a suitable receiver object with the required state is not available, WebGPU issues calls to construct one from scratch and bring it into a suitable state, or to bring an existing object into a suitable state. This process is recursive, because the creation of a required WebGPU object may require the creation of other WebGPU objects. We illustrate this via a worked example below.

Even if suitable receiver objects are already available for a call, WebGlitch randomly decides (via a configurable probability) whether to use one of these or generate a new receiver. The motivation for this is to reduce the probability that all API calls are made on the same or a small number of objects, which would limit program diversity.

Once a suitable receiver has been found or created, WebGlitch iteratively generates a valid value for each expected argument. For arguments with enumerated types, invalid values are determined by analysing the state of the receiver and object on which the constructor was called, and are filtered out. A value is chosen at random from the remaining subset. For arguments with numeric type, a random value is chosen within a valid minimum and maximum value. Certain numeric arguments may also need to be divisible by a constant value to be considered valid, in which case the randomly chosen value is rounded to the nearest divisible number within the range.

The most complex arguments to generate are other WebGPU objects, because their validity for a given call does not only depend on their type, but also on their state. The process of selecting or creating suitable arguments for a call is analogous to that for selecting or creating the receiving object for the call. However, in some cases the chosen receiving object can constrain the choice of valid arguments for the call. We illustrate this with a worked example in Section 3.4.

To support generation of valid programs, WebGlitch uses a symbol table (akin to that of a compiler) to track the types and states of objects in the partially-generated program throughout its generation. This includes relationships between parent and child objects (because new objects are created by invoking API functions on existing objects), and history of API calls that have been invoked on each object.

Allowing Invalid Function Calls

While there are several advantages to generating WebGPU programs that are guaranteed to be valid (as argued above), we deemed it also useful to equip WebGlitch with a mode where API calls within a program have some probability of being invalid, creating programs that are *nearly valid*. This enables the detection of instances where a WebGPU implementation's validity checks deviate from the specification or differ from those of another implementation.

To cater for this, WebGlitch can be configured with a percentage chance to bypass its internal validity analyses. WebGlitch can skip verifying both the receiver's state and the validity of the arguments passed into the API call, such that invalid WebGPU objects can also be passed as arguments in API calls further down.

3.4 Worked Example: Generating a Valid WebGPU API Call

To illustrate the above ideas, we show a call to the `writeBuffer` API function (Figure 3), which writes data into GPU memory, could be generated.

```
writeBuffer(GPUBuffer buffer, GPUSize64 bufferOffset, AllowSharedBufferSource data)
```

Figure 3 Signature of the `writeBuffer` method of the `GPUDevice` class. Optional arguments not shown for simplicity. GPUBuffer: a WebGPU object of type GPUBuffer. GPUSize64: an unsigned long long. AllowSharedBufferSource: an instance or view of a JavaScript ArrayBuffer or SharedArrayBuffer object. Adapted from [58].

Figure 4 shows what the partially-generated program might look like after all the ingredients required for the call to `writeBuffer`, and the call itself, have been generated. Being able to make this call depends on various WebGPU-specific constructs, including `GPUAdapter` (from which a WebGPU object representing the GPU is requested), `GPUDevice` (programmatic representation of a GPU), `GPUQueue` (handles executing GPU commands), and `GPUBuffer` (representing GPU memory) [58]. The specific details of these constructs do not matter much for the example.

```
const adapter = await navigator.gpu.requestAdapter();
const device = await adapter.requestDevice();
const queue = device.queue;
const buffer = device.createBuffer({
  mappedAtCreation: true
  size: 12
  usage: GPUBufferUsage.COPY_DST
});
const bufferOffset = 8;
const data = new Uint8Array([1, 2, 3, 4]);
queue.writeBuffer(buffer, bufferOffset, data);
```

Figure 4 WebGPU program to write data to a buffer.

Suppose WebGlitch is at the very start of creating a WebGPU program, so that the partially-generated program is empty, and suppose that the `writeBuffer` function is randomly selected. The receiver object for a call to this function must be a `GPUQueue`, but no such object exists in the (empty) partially-generated program. Because a `GPUQueue` is accessed via a property of a `GPUDevice`, and no `GPUDevice` is available in the empty program, WebGlitch issues a call to `requestDevice` to create a `GPUDevice`. However, `requestDevice` requires a `GPUAdapter` as its receiver, thus WebGlitch issues a call to `requestAdapter` to create a `GPUAdapter`. No additional generation work is required to call `requestAdapter` because it is invoked on the `navigator.gpu` property. The `navigator` object is part of the Document Object Model and provides access to the WebGPU API.

Armed with a `GPUQueue` object, `queue`, WebGlitch can now proceed to generate a call to `writeBuffer` on `queue`. In some cases, certain state-changing functions must be invoked on an object before a particular desired function can be called, but this is not the case for `writeBuffer`: it can be safely called on a freshly-created `GPUQueue` object. WebGlitch can therefore proceed to generate suitable parameters for the call to `writeBuffer`. Instructed by the JSON files in which requirements of WebGPU API functions are encoded, WebGlitch knows that `writeBuffer` requires a `GPUBuffer` created from the same `GPUDevice` from

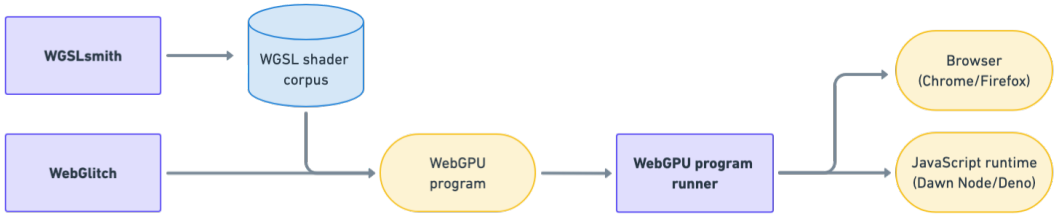

Figure 5 Overview of the WebGlitch workflow. The program runner configures the environment such that the same program generated by WebGlitch can be run within a browser and a JavaScript runtime.

which the `GPUQueue` was created, and with a size that is a multiple of 4. The buffer must also be allowed to be writeable, so it issues a call to `createBuffer` on `device` with the necessary arguments. The remaining arguments to `writeBuffer` also have restrictions (e.g., the `bufferOffset` parameter must be a multiple of 4 and the data to be written must fit within the offset and buffer size). Correspondingly, WebGlitch creates arguments that meet these requirements, employing randomisation where the requirements allow for a range of acceptable values.

Without taking care to generate valid programs by construction, it is very unlikely that even this relatively simple function would be called with valid arguments by chance.

3.5 Integrating Shader Programs

To exercise the portion of WebGPU related to shader compilation and execution, WebGlitch integrates with an existing WGSL shader generator, WGSLsmith [13, 28]. This combination leverages WGSLsmith's ability to construct a diverse range of shaders, which WebGlitch uses within the WebGPU API calls it generates (Figure 5). This results in WebGPU programs featuring a variety of GPU pipelines composed of randomised shader programs and configurations, which are ultimately executed in either a browser or JavaScript runtime environment. However, it is challenging to integrate shader programs and, by extension, WGSLsmith, into WebGlitch. API calls involving shaders often require specific arguments, such as for buffer sizes and bind group layouts, in order for them to be valid. It is difficult to automate this process without tooling to parse and understand WGSL shaders, which is challenging to get right. Rather than having WebGlitch invoke WGSLsmith during the program generation process, we instead used WGSLsmith to generate a corpus of shaders ahead of time, and manually determined the necessary bindings for these, encoding information about bindings in a JSON format that WebGlitch processes. The corpus of shaders used has varied over time: as discussed in Section 4.2 after finding that some shaders triggered interesting shader compiler bugs (which we reported), we removed them to avoid such bugs persistently occurring. We also removed some shaders due to changes in the WGSL specification which meant that certain features of WGSLsmith-generated shader programs were no longer valid.

3.6 Test Oracles

WebGlitch uses three test oracles to detect bugs: sanitiser-boosted crash oracles, the validity oracle, and differential testing. The validity oracle is enabled by default as long as the option to generate invalid programs is turned off. Straightforward crashes are also detected by default. The sanitiser-boosted crash oracle amounts to compiling the WebGPU

implementation under test with AddressSanitizer [47], which automatically enables LeakSanitizer [20], or UndefinedBehaviorSanitizer [20]. AddressSanitizer helps detect memory errors like out-of-bounds accesses and use-after-frees by making them more likely to cause a crash with a clear error message when they may otherwise go unnoticed. In a similar manner, UndefinedBehaviorSanitizer detects undefined behaviour like integer overflows and dereferencing a null pointer.

The differential testing oracle requires the user of WebGlitch to first execute the same set of generated WebGPU programs on different platforms and save the console output. We then use a script to parse and compare the results, flagging any discrepancies and notable error messages. WebGlitch then highlights programs which have unexpected differing outputs. The sanitiser-boosted crash oracle and validity oracle are straightforward to detect bugs with. Although differential testing is conceptually straightforward (run the same program on different implementations and check for differences), there are various nuances that must be considered when applying differential testing to WebGPU, which we now discuss.

Comparing Shader Outputs

One challenge is with accessing compute shader outputs, which are stored in GPU memory rather than main memory. Copying back and printing the results of every shader executed requires many additional API calls. But forcing every WebGPU program to always include these API calls would limit program diversity, and potentially prevent some bugs from being discovered. For these reasons, when invoking a compute shader WebGlitch makes a random choice as to whether each of the buffers associated with the compute shader should be copied back and printed.

Another issue applies to both graphics and compute shaders. While WebGPU contains very few implementation-dependent behaviours, the result of executing shaders can be different across different GPUs and drivers due to floating-point rounding [28]. Round-off error can lead to legitimate differences between results computed by shaders on different platforms, which could confound differential testing. As such, comparing outputs would require distance metrics and threshold values to identify differences [14], which is non-trivial. However, for compute shaders, this issue can be addressed using WGSLsmith [13, 28]. WGSLsmith only generates compute shaders and uses reconditioning [28] to avoid floating-point rounding. During reconditioning, all floating point operations are substituted with calls to functions that always return numeric values that can be represented exactly using the IEEE-754 standard. Implementation-dependent behaviours can also arise from "dynamic errors" in WGSL, which can be caused by out-of-bounds array accesses and unbounded loop iterations. WGSLsmith also avoid these behaviours are also by inserting checks on array bounds and loop iterations [28]. If WebGlitch were to be integrated with other shader generators, this would need special attention.

Comparing Error Messages

Recall that WebGlitch has a mode wherein validity checking has a configurable chance of being skipped for any receiver chosen and argument generated. In this case, we *do* expect to receive errors from the implementations under test. The type of error thrown for an invalid WebGPU API call is standardised in the WebGPU specification, so we can use differential testing to check for equivalent error output for a WebGPU program executed using different WebGPU implementations. A challenge here, however, is WebGPU does not standardise error message contents [58], so we parse and convert to an implementation-

independent representation for comparison. Different WebGPU implementations are also at varying degrees of completion [51], requiring manual analysis to determine the subset of API functions and arguments supported by all implementations for differential testing.

Differential Testing at WebGPU Program Runtime

A practical challenge is that it is difficult to directly differentially test WebGPU programs across multiple platforms as this would require platform-specific graphics APIs and drivers to be available simultaneously. To work around this, we run generated WebGPU programs separately on different platforms and log their outputs. The outputs are then parsed and compared post-execution by a separate program *FaultFinder*, which looks for discrepancies in outputs, error messages in valid programs, and crashes.

3.7 Throughput of WebGlitch

To provide an estimate of the throughput of fuzzing using WebGlitch, we used commit 29a4e87 to generate 1000 programs. We then executed each program against the Dawn implementation of WebGPU, targeting the Vulkan downstream graphics API via Node.js. Throughput was not measured on wgpu/Deno due to a bug that resulted in a Rust panic when executing almost every WebGPU program generated (Table 1, row 26). Experiments were performed on a machine with a 5.4 GHz Intel i7-13700K CPU, 64 GB DDR5 RAM, and an NVIDIA RTX 4080. They were run on Ubuntu 24.04. With default settings, WebGlitch took an average of 0.675 seconds to generate a WebGPU program. The majority of the time was spent on execution, which averaged 2.932 seconds.

4 Practical Impact on the WebGPU Ecosystem

To date, our use of WebGlitch has identified 29 bugs across the WebGPU ecosystem, consisting of 24 previously-unknown bugs and the independent discovery of 5 bugs that turned out to have already been reported.

Of the previously-unknown bugs, all have been reported, with 15 fixed following our submitted reports and 5 others confirmed.

We focused our testing efforts on two of the three major WebGPU implementations, Dawn (from Google and used by Chrome) and wgpu (primarily from Mozilla, and used in Firefox), on the major graphics APIs supported by Windows (D3D12), macOS (Metal) and Linux/Android (Vulkan).

We began by testing Dawn and wgpu through their JavaScript runtime bindings for Node.js and Deno, respectively. We then moved on to direct testing of the Chrome and Firefox browsers for completeness, because WebGPU is ultimately exposed to end users via browsers. Testing was conducted in-browser and within JavaScript runtimes on macOS,[3] Windows,[4] and Linux.[3]

Table 1 provides a summary of the 29 bugs identified by WebGlitch. The “Issue” column provides the ID of the bug in the issue tracker for the relevant project, with a hyperlink. The table is separated into specification issues, issues that might affect WebGPU support in Chromium and Firefox, shader compilation issues, issues impacting WebGPU bindings in Node.js and Deno, and JavaScript runtime bugs. WebGlitch was able to find bugs across

[3] MacBook Pro, Apple M2 Pro, 16 GB RAM
[4] Intel i7-13700K, 32 GB DDR5 RAM, NVIDIA RTX 4080

Table 1 Summary of all issues found by WebGlitch and the test oracles that found them. All "Duplicate" bugs marked with a * were first found by wg-fuzz. All other bugs classed as "Duplicate" were user-reported. FXC [34] is an HLSL shader compiler used in D3D12. The LLVMpipe driver from the Mesa 3D graphics library [33] allows for commands intended for execution on the GPU to be run on the CPU instead. Graphics libraries have been specified in parentheses for cases where bugs were specific to them. Otherwise, bugs affected all graphics libraries tested for that operating system (Linux: Vulkan, Windows: D3D11 with FXC & D3D12 with DXC, macOS: Metal).

	Issue	Type	Backend	Oracle	Description	Status
Issue affecting WGSL specification						
1	#4795	Ambiguity	N/A	Differential	Description of language behaviour when inferring types of numeric literals unclear	Fixed
Issues affecting Chromium (via Dawn)						
2	#350775867	Logic	All	Crash	Error message thrown for valid WebGPU program (exhibited only via Chrome)	Duplicate
3	#355605693	Logic	Windows	Validity	Validation error thrown for correct program	Confirmed
Issues affecting Firefox (via wgpu, or its Firefox integration)						
4	#1923237	Logic	All	Validity	Incorrectly throws error for valid program (exhibited only via Firefox)	Confirmed
5	#24798	Crash/hang	All	Crash	Crashes/hangs when specific buffer is created, followed by the destruction of a GPUDevice	Fixed
6	#24813	Logic	All	Differential	Fails to check that all WebGPU objects within a pass are from the same GPUDevice	Fixed
7	#24832	Logic	All	Differential	Missing check for GPUTextureView validity within a render pass	Fixed
8	#6040	Implementation lag	All	Validity	wgpu unknowingly lagging behind current WebGPU spec	Confirmed
9	#6041	Logic	All	Differential	Incorrect error message thrown	Fixed
Issues affecting shader compilation						
10	#6023	Logic	All	Differential	Naga: Implementation of constant evaluator deviates from WGSL specification	Fixed
11	#352496179	BSOD	Windows (FXC)	Crash	FXC: Poor performance of FXC resulted in 100% CPU and memory usage	Fixed
12	#42250583	Crash	Windows (FXC)	Crash	FXC: Valid HLSL code causes FXC to crash when paths with no side effects are encountered	Duplicate
13	#355603413	Crash	macOS	Crash	Metal shader compiler: Valid MSL involving division by 0 crashes Metal on Apple GPUs only	Confirmed
14	#372512081	ASan	Linux (LLVMpipe)	Sanitiser	LLVMpipe: Floating point exception	Unconfirmed
Issues affecting Node.js bindings for Dawn						
15	#346264226	Crash	All	Crash	Unreachable statement reached	Duplicate*
16	#346356636	Crash	All	Crash	Unreachable statement reached	Duplicate*
17	#346197748	Crash	All	Crash	Fatal error when making illegal API call	Duplicate*
18	#364871809	Crash	All	Crash	Fatal error when retrieving error message	Unconfirmed
19	#351644575	ASan	All	Sanitiser	Heap-use-after-free (object accessed after destruction)	Fixed
20	#355006329	LeakSan	All	Sanitiser	Not all resources freed on program exit	Fixed
Issues affecting wgpu integration in Deno						
21	#24806	Crash	All	Crash	Missing argument in error message constructor	Fixed
22	#24672	Logic	All	Differential	Fails to throw error message for invalid render/compute pass	Fixed
23	#24821	Logic	All	Differential	Arguments used in an unrelated render pass affects compute pass output	Confirmed
24	#25874	Logic	All	Validity	GPUAdapter incorrectly invalidated after specific API call	Fixed
25	#25870	Crash	All	Crash	Panics when destroyed texture used in render pass	Fixed
26	#28966	Crash	All	Crash	Panics when command encoder is finished	Unconfirmed
Issues affecting JavaScript runtimes (unrelated to WebGPU)						
27	#24575	LeakSan	All	Sanitiser	Deno leaks memory when JavaScript VM is exited	Fixed
28	#849	LeakSan	All	Sanitiser	Deno leaks memory when JavaScript VM is exited	Fixed
29	#54178	LeakSan	Linux	Sanitiser	Node.js leaks memory when "requiring" a non-existent module	Unconfirmed

the WebGPU ecosystem, including WebGPU implementations, WGSL compilers, the WGSL specification itself, downstream shader compilers, and JavaScript runtimes. Four new bugs (Table 1, rows 6, 7, 24, 25) were found by executing WebGPU programs containing invalid API calls, highlighting the importance of designing WebGlitch with a configuration that allows for invalid API calls in addition to its default mode where generated programs are valid-by-construction (see Section 3.3). The remaining bugs were all found through programs that were valid-by-construction. The range of sources within which bugs were detected demonstrates the importance of fuzz testing WebGPU in as many environments as possible.

We now elaborate on some of the bugs found by WebGlitch and their impact on the WebGPU ecosystem.

4.1 Specification Issue

WGSL is statically-typed and supports integer types of various bit-widths [59]. It also allows the bit-widths of certain numeric expressions to be left unspecified and inferred based on usage. This concept is referred to as *abstract numerics* [59]. The WGSL specification requires that expressions involving abstract numerics are checked at compile-time for overflow, so that a program is statically rejected if the value of an abstract numeric does not fall within the allowed range of values supported by a type of a specific bit-width.

To illustrate this, consider the first declaration in Figure 6. The abstract numeric expression `-1 * -2147483648` evaluates to `2147483648`, which is too large to be represented by the `i32` type (a 32-bit signed integer). The declaration should thus be rejected.

```
// Correctly rejected by Tint & Naga
const num1 : i32 = -1 * -2147483648

// Incorrectly rejected by Naga only
const num2 : i32 = -1 * i32(-2147483648)
```

Figure 6 We fixed a problem in the WGSL language specification where rules for implicit type casting were ambiguous. This was brought to light by the Naga compiler incorrectly rejecting the second declaration in this example.

In contrast, the second declaration should *not* be rejected. This is because the expression `i32(-2147483648)` specifies that `-2147483648` should be stored as a 32-bit signed integer, which is allowed because the value is in the representable range of the `i32` type. Overload resolution means that the abstract numeric argument `-1` is implicitly converted to an `i32` value (as an abstract numeric value is used with an `i32` value). The WGSL specification mandates two's complement semantics for `i32` operations, so the overall expression evaluates to `-2147483648`.

Differential testing between Dawn and wgpu revealed that the Tint shader compiler (used by Dawn) was behaving correctly, while the Naga shader compiler (used by wgpu) was incorrectly rejecting the second declaration [39].

However, when we investigated this discrepancy, it was not clear to us from the wording of rules about abstract numerics in the WGSL specification which of Tint or Naga were behaving correctly. Our understanding of the type-checking rules described above only came about after discussions with engineers at Google leading the development of the WGSL specification: they were not clear from the specification itself. We submitted a proposal to clarify this behaviour in the specification, which has since been accepted and incorporated [52]. After investigation, the bug in Naga stemmed from its constant evaluator rather than the way in which it handles type casting. A fix to then align the behaviour of Naga with the WGSL specification was submitted and accepted [55].

4.2 Bugs Affecting In-browser Execution

We found 13 previously-unknown bugs that affected either the core logic of a WebGPU implementation or downstream shader compiler behaviour. Although we found most of these bugs by fuzzing using JavaScript runtimes, rather than through in-browser fuzzing, they would affect any WebGPU workload that exercised these parts of the relevant WebGPU implementations, or that used shaders that would trigger the shader compiler bugs. Discussed below, we also found some bugs via in-browser testing that do not trigger via out-of-browser JavaScript runtimes, demonstrating the value of also conducting in-browser testing.

Bugs in the Implementation of API Functions

We found 8 bugs arising due to the incorrect implementation of API functions (7 of them previously-unknown); these are under the "Issues affecting Chromium (via Dawn)" and "Issues affecting Firefox (via wgpu, or its Firefox integration)" headings in Table 1. We now discuss a selection of these.

Two bugs were due to wgpu failing to reject invalid API calls related to configuring render passes (Table 1, rows 6, 7). One WebGlitch program generated by WebGlitch (shown in reduced form in Figure 7) caused wgpu to crash on macOS, and to hang on Linux and Windows.

```
const adapter = await navigator.gpu.requestAdapter();
const device = await adapter.requestDevice();
const buffer = device.createBuffer({
  mappedAtCreation: true,
  size: 12,
  usage: GPUBufferUsage.COPY_SRC
});
device.destroy();
```

Figure 7 Minimal test case causing wgpu to hang on Linux and Windows but crash on macOS.

Identifying the component responsible for this bug was difficult due to the layered architecture in use: it was initially detected while testing Deno, which builds on top of the Rust-native wgpu. As such, we had to manually translate the WebGPU program to a corresponding sequence of direct Rust API calls to confirm the bug was in wgpu.

Two bugs could *only* be triggered by in-browser fuzz testing with Firefox and Chrome – i.e. they could not be found by fuzzing against the Node.js and Deno runtimes.

For Firefox, this is expected: like Deno, Firefox uses wgpu, but builds on top of wgpu in a separate and non-trivial way to enable its use through the Firefox internal JavaScript engine. As such, bugs in this layer are only reachable by fuzz testing in Firefox; this is the case for the bug that we found (Table 1, row 4).

In the case of the bug found in Chrome, which led to an error being thrown for a valid WebGPU program (Table 1, row 2), it is unclear why it was not reachable through Dawn's Node.js bindings, and the cause of the bug is still under investigation.

Shader Compiler Bugs

In addition to the Naga bug discussed in Section 4.1 and Figure 6, we found 4 bugs affecting downstream shader compilers of specific graphics APIs, demonstrating the need to thoroughly test on a range of platforms.

One such bug (Table 1, row 13) affected the Metal compiler for Apple's Metal shading language. Recall from Section 2 that the WGSL compiler in a WebGPU implementation emits code for a downstream shading language. On macOS, we found that Tint, the WGSL compiler that ships with Dawn, generated Metal shading language code that caused the Metal compiler to fail. Determining that the problem was in the Metal compiler was non-trivial due to the layered nature of WebGPU: it is often unclear whether some invalid program was compiled by the WGSL compiler, or whether the source of the bug is further downstream. Moreover, this bug only affected shader compilation when targeting Apple GPUs – we found the crash did not happen when targeting Intel and AMD GPUs on Apple platforms, showing the importance of testing on different hardware configurations. To avoid repeatedly triggering this bug (which would impede the discovery of further bugs), we had to remove the offending shader from the corpus of shaders used by WebGlitch, something that we had to do for various shader programs that would reliably trigger compiler bugs.

4.3 Bugs Related to Runtime Bindings

A number of the previously-unknown bugs we found – 6 in total – turned out to relate to problems with the bindings between the Node.js and Deno JavaScript engines and the Dawn and wgpu implementations of WebGPU, and could not be triggered via in-browser execution (which does not use these bindings).

```
const adapter = await navigator.gpu.requestAdapter();
const device = adapter.requestDevice();
console.log(adapter.info);
```

Figure 8 Minimal test case where valid WebGPU program rejected by Deno.

While less serious in terms of impact than browser-related bugs, our reports of these problems improved the stability of these runtime bindings, and early fixes for some of these issues unblocked our work, allowing us to perform more intensive testing of Dawn and wgpu via these JavaScript runtimes without the binding-related problems masking the presence of other bugs.

Figure 8 shows a reduced test case that triggered a bug in Deno (Table 1, row 24). Our report led to this being raised in the wgpu project's weekly WebGPU meeting [54]. Within this test case, the `adapter.info` call was incorrectly rejected by Deno, throwing an error message that the `GPUAdapter` had been invalidated because a `GPUDevice` had been created from it.

In the Dawn bindings for Node.js we discovered a use-after-free (Table 1, row 19) and memory leak (Table 1, row 20). These were problematic for our fuzz testing campaign: even a trivial program Figure 9, which consists of just the entry point into the WebGPU API, triggered ASan and LeakSan errors Figure 9. Since these errors were thrown upon using the WebGPU API, we had to disable AddressSanitizer and LeakSanitizer while testing Dawn until engineers at Google fixed the problems. Because these bugs were limited to Dawn's Node.js bindings, which, understandably, are a lower priority compared than issues reproducible in Chrome, they took longer to address. As such, it temporarily blocked the discovery of a few other bugs in Dawn.

```
const adapter = await navigator.gpu.requestAdapter();
const device = await adapter.requestDevice();
```

(a) Minimal reproducible WebGPU program that raised repeated Sanitiser errors.

```
==87490==ERROR: AddressSanitizer: heap-use-after-free on address 0x00010d317d38 at pc 0x000127ec6a08 bp 0x00016b21e190 sp 0x00016b21e188

(b) Erroneous output detected by WebGlitch. The full error message has been excluded for brevity.

Figure 9 Minimal reproducible test case and console output for a bug raising ASan and LeakSan errors on Dawn node.

4.4 Bugs Affecting JavaScript Runtimes

Our testing led to the discovery of three previously-unknown bugs – all memory leaks – that affected the Node.js and Deno JavaScript runtimes and which turned out to be unrelated to WebGPU: they could be triggered by JavaScript programs that do not issue any WebGPU

API calls. We found such errors by running generated WebGPU programs against WebGPU implementations within JavaScript runtimes. When we reduced these programs to their minimal reproducible example, in each case we found that we could remove all WebGPU API calls while preserving the memory leak. This led to very simple JavaScript programs, e.g. a program that simply imports a module that cannot be found. The lack of any use of WebGPU indicated that such bugs lay within the underlying runtimes. One of the memory leak bug reports we submitted to Deno (Table 1, row 27) helped identify the root cause of an earlier, elusive memory leak that had been challenging to track down. Although this was not a WebGPU-related issue, and we did not set out to discover such types of issues, the impact of this bug was arguably more substantial than that of WebGPU-specific bugs as it affects all developers using Deno, not just those working with WebGPU.

5 Code Coverage Achieved by WebGlitch

To evaluate how thoroughly fuzzing with WebGlitch exercises a WebGPU implementation, we report on statement coverage on the Dawn codebase achieved via a short fuzzing campaign. We compare this to coverage achieved through fuzzing with wg-fuzz. This is the only other open source fuzzer we are aware of for the WebGPU API [48], and the coverage achieved by running the WebGPU conformance test suite (CTS) [50]. The WebGPU CTS is a fixed test suite to check if a WebGPU implementation conforms to the specification, ensuring coverage results gathered from it are comprehensive. We decided to focus on Dawn because at time of writing it is more mature than other open source WebGPU implementations.

Dawn already ships with tooling to measure coverage achieved by the CTS using llvm-cov [30]. To maintain a consistent environment for collecting coverage data, we generated 2000 WebGPU programs using each of WebGlitch and wg-fuzz, but in a format expected by the CTS, so that the Dawn coverage infrastructure could work with these programs as if they were CTS tests. We attempted using more WebGPU programs but found this led to an out-of-memory error as it exceeded the available RAM (32 GB) in our test system. However, analysis of coverage from one of these aborted experiments suggested that coverage had already saturated after 2000 programs.

Among the 2000 programs generated by each fuzzer, 1000 programs were valid by construction, and the remaining programs had a 10% chance for any given call to be invalid.

We then collected coverage data on the Dawn codebase separately by executing (a) the 2000 programs generated by WebGlitch, (b) the 2000 programs generated by wg-fuzz, and (c) the WebGPU CTS. Due to the randomised nature of WebGlitch and wg-fuzz, we repeated coverage collection for these tools three times, using three different sets of 2000 programs, and averaged the absolute percentage coverage values that we obtained. We then analysed the results to identify coverage gaps in the CTS: lines of code in Dawn covered by the WebGPU fuzzers but not by the CTS.

WebGlitch, wg-fuzz, and the CTS were able to cover 13.52%, 15.71%, and 28.00% of Dawn, respectively [56]. These values are all low because many parts of a WebGPU implementation are graphics API-specific, and it is not possible to execute the entirety of any WebGPU implementation on one machine; e.g. the macOS platform that we used for this experiment would only exercise the Metal back-end of Dawn. Even though the coverage of Dawn achieved by both WebGlitch and wg-fuzz is lower than that of the CTS, both fuzz testing tools successfully uncovered new bugs. Absolute coverage alone does not capture the distinction between deep, exploratory execution paths and broad functional coverage. As such, these fuzzing tools serve as a valuable complement to the CTS.

WebGlitch and wg-fuzz both achieve similar coverage, but the coverage achieved by wg-fuzz is slightly higher. This is likely because wg-fuzz covers all API functions, unlike WebGlitch which currently supports 75% of all WebGPU API functions. However, WebGlitch can generate many optional arguments that are not considered by wg-fuzz. Supporting these optional arguments required additional engineering to ensure that generated programs are still valid by construction. The use of these optional arguments will lead to different code paths being taken in the underlying WebGPU implementation under test. Despite WebGlitch supporting fewer WebGPU API functions, it managed to cover 1,530 lines that wg-fuzz missed and uncovered many bugs that wg-fuzz could not. Conversely, wg-fuzz covered 5,180 lines of Dawn that WebGlitch missed. Together, these tools complement each other.

Both WebGlitch and wg-fuzz were also able to cover lines of Dawn missed by the CTS, although most were related to formatting outputs. But among these lines of code was a Dawn function entirely missed by the CTS, and this function was linked to a correctness bug within Dawn that was identified by WebGlitch (Table 1, row 3). This underlines the value that fuzzing can play in identifying and filling coverage gaps in a CTS, as prior work on shader compiler fuzzing has demonstrated [15].

6 Insights and Lessons Learned

We now summarise a number of key lessons learned from our experience designing and deploying WebGlitch, which we hope will be insightful to other researchers and practitioners interested in API fuzzing.

On-demand Generation of API Calls Is Good for Bug Finding

Recall from Section 3 that WebGlitch takes an *on-demand* approach to API call sequence generation, whereby the conditions for a particular API function to be called are satisfied by issuing previous API function calls to create necessary ingredients. In contrast, the wg-fuzz fuzzer for WebGPU takes a more cautious approach where an API function is only selected for invocation if suitable prerequisite objects are already in scope.

WebGlitch uncovered many bugs (24) that wg-fuzz could *theoretically* find, but missed in practice due to its conservative approach: the probability of specific calls being generated is low. For example, the minimal reproducible test case for one identified bug (Table 1, row 23) consisted of a valid WebGPU program with 24 WebGPU API calls and 15 different WebGPU objects. It is already unlikely that a generated program will contain these 24 API calls in the required sequence, and the probability of generating such a program would be even lower when using a conservative approach that only invokes API functions using objects already available in the partially generated program. WebGlitch is capable of exercising API functions that require complex dependencies by creating these on-demand, and the success of WebGlitch at finding bugs in practice provides evidence that the tool is effective at exercising complex WebGPU implementations in depth.

Based on our experience, we recommend considering an on-demand approach when designing a generator of programs that make calls into an API whose functions have non-trivial prerequisites.

Fuzz Blockers Limit the Automated Nature of Fuzzing

Although much of the fuzz testing process can be automated (test case generation, execution, and analysis), our fuzz testing campaign required frequent manual intervention to make fuzzing productive. While using WebGlitch to find bugs is fully automatic, since WebGlitch

uses a black box approach, determining the root causes of bugs is still manual. This was mainly due to *fuzz blockers*, where "a fuzzer encounters the same bug very often, which blocks further fuzzing of downstream code" [12]. In our setting this corresponds to bugs in a WebGPU implementation (or bugs affecting a JavaScript runtime) that are extremely easy to trigger, manifesting so often that they make it hard to find deeper bugs. For example, we had to identify and remove certain shaders that had a high probability of triggering shader compiler bugs, or disable sanitisers until certain bugs were addressed by maintainers.

The issue of fuzz blockers is well known to fuzzing experts; e.g. Google's ClusterFuzz framework assigns a "Fuzz-blocker" label to a bug that is deemed to trigger so frequently that it hurts fuzzer performance [4], and indeed fuzz blockers were a real impediment to our work deploying WebGlitch in practice.

Finding the Root Cause of a Bug Within a Layered API Is Unclear

Generally, the standardization of WebGPU as JavaScript API makes the task of testing WebGPU implementations easier than it would otherwise be: a single generated WebGPU program can be executed across a range of operating systems and graphics drivers, potentially triggering bugs in any of the components shown in the layered diagram of Figure 1.

However, standardization also presents a challenge: when a test fails it can be hard to identify the source of the bug due to the layered nature of the API. Root-causing bugs requires a degree of detective work, e.g. ascertaining that a bug is likely to be Vulkan-specific because it triggers only when a Vulkan back-end is used, regardless of operating system or graphics driver, or ascertaining that a bug lies in an NVIDIA graphics driver by differentially testing across drivers from multiple vendors. This insight is likely to be relevant to fuzzing efforts for other APIs with diverse, layered implementations.

Testing Implementations of an Evolving Standard: A Challenge and an Opportunity

We also faced challenges due to the WebGPU API standard being incomplete during our fuzzing efforts. A benefit of fuzzing at this early stage was that we were able to find some issues with the specification of the API itself, prompting discussion and refinement. However, it meant that we had to actively work on keeping the fuzzer up-to-date with the evolving specification. We also had to be mindful of whether implementations under test were up-to-speed with the latest specification changes, otherwise updating the fuzzer to reflect the latest specification changes would waste developer time by identifying known issues where developers have not yet caught up with such changes. Similar observations were made in recent work on the deployment of compiler fuzzing techniques for WGSL, where early fuzzing of WGSL compilers uncovered an edge case unaccounted for by the specification, showcasing a benefit of applying fuzzing at an early stage, but where the evolving WGSL syntax introduced additional engineering overhead and posed similar challenges with differential testing [13].

This is a trade-off that should be borne in mind when deciding how early to commence a fuzzing effort for implementations of a new API.

Diversity of Testing Environments Is Important

Our work has benefited from the application of WebGlitch to WebGPU implementations in the context of a variety of browsers and operating systems.

However, it is likely that some bugs that WebGlitch would be capable of finding have gone undetected because the range of environments in which we were able to test is nevertheless limited. For example, some bugs affecting WebGPU are known to be specific to operating

system versions [1], or hardware-specific [18]. Any configuration that is left untested is a potential source of undiscovered bugs. This insight is particularly applicable to performance-critical APIs where it is likely that implementations of the API will leverage low level features of operating systems and hardware.

Supporting a new environment in the testing process is not always straightforward. For example, enabling sanitisers on macOS requires a particular environment variable to be set, but this variable is cleared prior to command execution for security purposes. Although there are workarounds, some can be fairly involved [46].

We are working with the WebGPU team at Google to deploy WebGlitch as part of ClusterFuzz, Google's continuous fuzzing infrastructure, which will ensure that fuzzing of WebGPU support in Chromium is conducted on a wide range of target platforms.

7 Related Work

WebGlitch generates valid-by-construction WebGPU programs from scratch, inspired the random C program generator Csmith [60]. Both these fuzzers are specific to a system under test. Many API fuzzers are more general [21, 23, 31, 5]. Among these, RESTler [5] is notable for generating syntactically correct calls by parsing an IDL and attempts to learn the sequences of calls required for validity by gathering and analysing the API call responses. FuzzGen [22], a fuzzer for C++ libraries, attempts to determine which sequences of API calls are valid by constructing a dependency graph of API calls based on analysis of a corpus of programs that use a given API. This is useful when a library's API has not been defined using an IDL. Although applicable to many different APIs, these fuzzers are unlikely to capture all nuances of any specific API, especially related to call validity.

Like Fuzzgen, the Randoop fuzzer for Java classes [43] also determines valid sequences of function calls at runtime. The design of WebGlitch is also similar to Randoop [43]: they both randomly choose a method to call and populate it with arguments created from previously generated calls. But rather than having prior knowledge of each API function's requirements, dependencies, and exactly how to construct each object like WebGlitch, Randoop executes the partially generated program as soon as it is created [43]. It then checks the result of executing the program against a set of pre-defined rules (e.g., a function should not throw an exception under certain conditions). If executing the partially-generated program did not throw any errors or violate any rules, then it is added to a corpus of partially-generated programs, otherwise it is discarded, unless the program threw an error while not violating any conditions, suggesting a potential bug. Randoop can then take objects created within these partially-generated programs and use them in another method call by extending the partially-generated program [43].

One drawback of this approach is that the search space for programs is large as Randoop does not have exact knowledge of which arguments are valid. Moreover, program generation can be inefficient as each time a method call is added, it must be executed to check if it is still valid. Most importantly, such an approach would not work well with the WebGPU API: the API contains many functions to configure the state of objects such as render/compute pipelines, buffers, and textures. However, errors are not always thrown immediately: it is possible to pass invalid configurations to an object, but if that object is never passed to the GPU for manipulation, no error is thrown. Given how unlikely it is that a partially-generated program within the corpus could be extended to include a valid call that passes objects to the GPU, most programs would fail to meaningfully exercise the underlying graphics

APIs. While this could potentially be addressed by adding extensive custom validation when executing programs, it would likely be more efficient to adopt a fuzzing approach that is tailored towards WebGPU instead.

One such example is wg-fuzz [48], which generates valid WebGPU programs from the ground up like WebGlitch, but takes a different approach to ensuring validity. It iteratively chooses random API calls to construct based on the state of the partially-generated program rather than first constructing all the API calls needed for a chosen call to be valid like WebGlitch. WebGlitch nevertheless found 25 bugs that wg-fuzz could not and rediscovered 3 that wg-fuzz had already reported (Section 4). That said, the two tools remain complementary, as wg-fuzz can cover some parts of Dawn that WebGlitch does not and vice versa (Section 5).

Fuzzing the WebGL and WebGPU ecosystems has not been limited to program generation from scratch. GLeeFuzz [44], which targets WebGL, uses an error message-guided mutation approach. GLeeFuzz is not aware of the validity of the programs it mutates, but uses the error messages thrown by mutant programs to guide its mutation. It uses error message diversity as a proxy for coverage, intensively exercising the call validation aspect of WebGL implementations. A GLeeFuzz-like technique would be interesting to investigate for WebGPU, but because its mutation-based approach primarily generates invalid programs, it would likely serve as a complement to WebGlitch, which focuses on generating valid programs.

GLFuzz [14] is a testing technique targeting compilers for the OpenGL shading language, a language similar to WGSL and used by the OpenGL, OpenGL ES and WebGL APIs [24]. GLFuzz uses metamorphic testing [7], wherein semantics-preserving mutations are applied to a seed program and the outputs of the original and mutant are compared for differences. Unlike WebGlitch, GLFuzz focuses solely on shader compiler testing and not on API testing.

There has also been work on fuzzing WebGPU's embedded shading language, WGSL, rather than the WebGPU API itself [6, 13, 28]. The WGSLsmith tool [13, 28] exclusively tests WebGPU shader compilers by generating random WGSL shader programs and detecting errors during compilation or execution of the shaders post-compilation. However, WGSLsmith exercises the WebGPU API in a limited way, as WGSL shaders are executed using a fixed WebGPU test harness. By contrast, WebGlitch makes extensive use of the broader WebGPU API in general and incorporates a fixed corpus of shaders into the API calls it generates, complementing WGSLsmith's shader-focussed approach. A recent paper [13] reports on the use of coverage-guided mutation-based fuzzing (via libFuzzer [29]) and black box fuzzing (via WGSLsmith and spirv-fuzz [17]) to directly test the Tint shader compiler in Google's Dawn WebGPU implementation, and to test tooling associated with SPIR-V, the Vulkan shading language. DarthShader [6] combines both program generation and mutation, fuzzing WGSL compilers in a coverage-guided manner. It has successfully found numerous bugs including several high severity CVEs affecting Chrome [6]. Part of its success can be attributed to its ability to mutate both the abstract syntax tree representation of a shader and its intermediate representation [6], enabling it to more effectively find bugs across different compilation stages. However, this approach is not directly applicable to the WebGPU API layer.

As discussed in Section 6, the WebGlitch and WGSLsmith projects both required manual effort to keeping the respective tools up-to-date with changes to the WebGPU specification. Furthermore, both tools tailored specifically to the WebGPU setting. Recent work has investigated Large Language Model (LLM)-based approaches that could potentially address these limitations [9, 10]. Both TitanFuzz [9] and FuzzGPT [10] use program generation techniques that can be applied to any API or programming language. TitanFuzz first gives a LLM step-by-step instructions to generate seeds, which are then mutated using an evolutionary algorithm to mask portions of the seed. This is then fed back to an LLM for

infilling, and mutants that execute without errors can then act as new seeds [9]. FuzzGPT extends TitanFuzz by either prompting or fine-tuning the LLM with code snippets from historical bugs to generate more unusual programs [10]. Both have been evaluated on the deep learning libraries PyTorch and TensorFlow, finding 21 and 27 new bugs, respectively via crash oracles and differential testing.

We speculate that the effectiveness of these LLM-based approaches on fuzzing for WebGPU may be more limited, due to the much smaller amount of WebGPU data available for training and/or fine-tuning compared with that for PyTorch and TensorFlow, and the fact that some existing training data may already be obsolete due to recent changes to the WebGPU standard [58]. These issues would also apply to generating WGSL shaders for use in such WebGPU programs. Given that WebGPU also requires complex setups of object states and buffers in specific sequences for calls to be valid, it would be more challenging for LLMs to produce valid programs that meaningfully exercise downstream graphics APIs (roughly a third of the programs generated by TitanFuzz were valid [9]).

As discussed in Sections 4.1 and 6, the deployment of fuzzing can identify problems not only in software but also in language specifications. WebGlitch was able to detect an area of ambiguity in the WGSL specification, and similar issues have been found before by WGSLsmith [13] and other fuzzers for the programming language Dafny [16].

8 Conclusions and Future Work

We have introduced a new method for fuzzing the WebGPU API that generates sequences of API calls that are valid-by-construction, based on careful modelling of the requirements of API functions, and an on-demand generation approach. We have implemented this in a new open source tool, WebGlitch, which has helped to find bugs across the WebGPU ecosystem – in the WGSL specification, the Dawn and wgpu implementations of WebGPU, the Node.js and Deno JavaScript runtimes, and various downstream shader compilers – in a manner that would be difficult to achieve with manually written tests alone.

Avenues for future work include testing of Apple's WebGPU implementation in WebKit/Safari once it is in a more complete state, as well testing on a broader range of hardware configurations (the importance of this is evidenced by the fact that one of our bugs was specific to Apple GPUs). Currently, WebGlitch supports around 75% of all functions in the WebGPU API; adding support for the full API would improve the thoroughness of testing and might increase bug-finding ability. In the meantime, WebGlitch is ready for browser development teams in industry to integrate into their testing processes to help identify bugs as early as possible.

Abstract

The widespread use of smartphones in daily life has raised concerns about privacy and security among researchers and practitioners. Privacy issues are generally highly prevalent in mobile applications, particularly targeting the Android platform – the most popular mobile operating system. For this reason, several techniques have been proposed to identify malicious behavior in Android applications, including the Mining Android Sandbox approach (MAS approach), which aims to identify malicious behavior in repackaged Android applications (apps). However, previous empirical studies evaluated the MAS approach using a small dataset consisting of only 102 pairs of original and repackaged apps. This limitation raises questions about the external validity of their findings and whether the MAS approach can be generalized to larger datasets. To address these concerns, this paper presents the results of a replication study focused on evaluating the performance of the MAS approach regarding its capabilities of correctly classifying malware from different families. Unlike previous studies, our research employs a dataset that is an order of magnitude larger, comprising 4,076 pairs of apps covering a more diverse range of Android malware families. Surprisingly, our findings indicate a poor performance of the MAS approach for identifying malware, with the F1-score decreasing from 0.90 for the small dataset used in the previous studies to 0.54 in our more extensive dataset. Upon closer examination, we discovered that certain malware families partially account for the low accuracy of the MAS approach, which fails to classify a repackaged version of an app as malware correctly. Our findings highlight the limitations of the MAS approach, particularly when scaled, and underscore the importance of complementing it with other techniques to detect a broader range of malware effectively. This opens avenues for further discussion on addressing the blind spots that affect the accuracy of the MAS approach.

1 Introduction

Mobile technologies, such as smartphones and tablets, have become fundamental to how we function as a society. Almost two-thirds of the world population uses mobile technologies [10, 33], with the Android Platform dominating this market and accounting for more than 70% of the *mobile market share*, with almost 2.5 million Android applications [1] (apps) available on the Google Play Store, in June 2023 [44]. As popularity rises, so does the risk of potential attacks, prompting collaborative efforts from both academia and industry to design and develop new techniques for identifying malicious behavior or vulnerable code in Android apps [45]. One popular class of Android malware is based on repackaging [6, 25], where a benign version of an app is infected with malicious code, e.g., to broadcast sensitive information to a private server [28], and subsequently shared with users using even official app stores.

The Mining Android Sandbox approach (MAS approach) was initially designed to construct sandboxes based on exploratory calls to sensitive APIs [20]. The MAS approach operates in two distinct phases. In the first phase (exploratory phase), automated test case generation tools are utilized to abstract the behavior of an app, focusing on recording calls to sensitive APIs (Application Programming Interfaces). Subsequently, during normal app execution (exploitation phase), the generated sandbox blocks any calls to sensitive APIs that were not observed during the exploratory phase. Prior studies [6, 13] have investigated the effectiveness of the MAS approach in detecting potential malicious behavior in repackaged apps. These studies have also conducted comparisons of the approach's performance by employing different test case generation tools during the exploratory phase, including Monkey [18], DroidBot [30], and Droidmate [22] – bringing evidence that DroidBot outperforms other test generation tools, uncovering many potential malicious behaviors.

Nonetheless, these previous studies have two main limitations. First, they use a small dataset of malware comprising only 102 pairs of original/repackaged versions of an app – which might compromise external validity. Second, their assessments do not investigate the impact of relevant features of the repackaged apps on the accuracy of the MAS approach for malware classification, including (a) whether or not the repackaged version is a malware, (b) the similarity between the original and the repackaged versions of an app, and (c) the malware family [2] when the repackaged version of an app is a malware. These limitations compromise a broader understanding of the MAS approach performance. We present more details about the MAS approach and related work in Section 2.

[1] In this paper, we will use the terms Android Applications, Android Apps, and Apps interchangeably, to refer to Android software applications

[2] Malware families (such as *gappusin*, *kuguo*, *dowgin*, etc.) are often used to classify malware in groups that share similar codebases, attack methods, and objectives [4].

To better understand the impact of these issues on previously published results, this paper presents a replication of the study conducted by Bao et al. [6]. We aim to verify the original study's findings by executing the test case generation tool DroidBot [30] in the same settings as the original research. Unlike the original study, here we use a curated dataset of app pairs (original/repackaged versions) significantly larger than the dataset used in Bao et al.'s study. Our new dataset contains 4,076 pairs of original and repackaged apps. We present more details about the datasets, data collection, and analysis procedures in Section 3.

Negative result. Our study reveals a significantly lower accuracy (F1-score of 0.54) of the MAS approach in comparison to what the MAS approach approach performs in the small dataset (F1-score of 0.90). Since an accuracy of 0.54 is unsatisfactory for a trustworthy malware classification technique, we conduct a set of experiments to understand the reasons for the lower accuracy in our dataset. Our further assessments reveal that the MAS approach fails to correctly classify most samples from a specific set of malware families, particularly those from the *gappusin* family (a particular adware class frequently appearing in repackaged apps). Out of the total of 1,337 samples within this family in our large dataset, the MAS approach failed to classify 1,170 samples as malware correctly. Accordingly, these families are responsible for substantially reducing the recall of the MAS approach. We detail the results of our experiments in Section 4. We also discuss the implications and possible threats to the validity of our study in Section 5 and present some final remarks in Section 6. The main artifacts we produced during this research are available in the paper repository.

2 Background and Related Work

There are many tools available that help developers reverse engineer Android bytecode [47]. For this reason, software developers can easily decompile trustworthy apps, modify their contents by inserting malicious code, repackage them with malicious payloads, and re-publish them in app stores, including official ones like the Google Play Store. It is well-known that repackaged Android apps can leverage the popularity of real apps to increase their propagation and spread malware [28]. As an example, in 2016 a repackaged version of the famous Pokémon Go app was discovered less than 72 hours after the game was officially released in the United States, Australia, and New Zealand [28]. The repackaged version, originated from an unofficial app store, gained full control over the victim's phone, obtaining access to main functions such as the phonebook, audio recorder, and camera.

Repackaging has been raised as a noteworthy security concern in Android ecosystem by stakeholders in the app development industry and researchers [23]. Indeed, there are reports claiming that about 25% of Google Play Store app content correspond to repackaged apps [46]. Nevertheless, all the workload to detect and remove malware from markets by the stores (official and non-official ones), have not been accurate enough to address the problem. As a result, repackaged Android apps threaten security and privacy of unsuspicious Android app users, beyond compromising the copyright of the original developers [24]. Aiming at mitigating the threat of malicious code injection in repackaged apps, several techniques based on both static and dynamic analysis of Android apps have been proposed, including the MAS approach for malware classification [20, 6].

2.1 Mining Android Sandboxes

A *sandbox* is a well-known mechanism to secure a system and forbid a software component from accessing resources without appropriate permissions. Sandboxes have also been used to build an isolated environment within which applications cannot affect other programs, the network, or other device data [32]. The idea of using sandboxes emerged from the need to test unsafe software, possible malware, without worrying about the integrity of the device under test [7], shielding the operating system from security issues. To this end, a sandbox environment should have the minimum requirements to run the program, and make sure it will never assign the program more privileges than it should have, respecting the *least privilege* principle. Within the Android ecosystem, sandbox approaches ensure the principle of the *least privilege* by preventing apps from having direct access to resources like device hardware (e.g., GPS, Camera), or sensitive data from other apps. Access to sensitives data like contact list or resources are granted through specific APIs, known as sensitive APIs, which are managed by coarse-grained Android permissions system [12].

The MAS approach [20] aims at automatically building a sandbox through dynamic analysis (i.e., using automatic test generation tools). The main idea is to grant permissions to an app based on its calls to sensitive APIs. Thus, sandboxes build upon these calls to create safety rules and then block future calls to other sensitive resources, which diverge from those found in the first exploratory phase. Using the Droidmate test generation tool [21], Jamrozik et al. proposed a full-fledged implementation of the MAS approach, named Boxmate [20]. Boxmate records the occurrences of calls to sensitive APIs and, optionally, the UI events (e.g., a button click) that trigger these calls. Therefore, it is possible to configure Boxmate to record events associated with each sensitive call as tuples (event, API), instead of recording just the set of calls to sensitive APIs. Jamrozik et al. argue that, in this way, Boxmate generates finer grain results, which might improve the accuracy of the MAS approach – even with the presence of reflection, a feature commonly used in malicious apps [29].

In fact, the MAS approach can be implemented using a mix of static and dynamic analysis. In the first phase, one can instrument an Android app to log any call to the Android sensitive methods. After that, one can execute a test case generation tool (such as DroidMate, DroidBot, or Monkey) to explore the app behavior at runtime, while the calls to sensitive APIs are recorded. This set of calls to sensitive APIs is then used to configure the sandbox. The general MAS approach suggests that the more efficient the test generation tool (for instance, code coverage), the more accurate the resulting sandbox would be.

2.2 Mining Android Sandbox for Malware Classification

Besides being used to generate Android sandboxes, the MAS approach can also be used to detect if a repackaged version of an Android app contains an unexpected (perhaps malicious) behavior [6]. In this scenario, the *effectiveness* of the approach is estimated in terms of the accuracy in which malicious behavior is correctly identified in the repackaged version of the apps.

The MAS approach for malware classification typically works as follows. In a first step (**instrumentation phase**), a tool instruments the code of the apps (both original and repackaged versions) to collect relevant information during the apps execution in later stages. Then, in a second step (**exploration phase**), the MAS approach collects a set S_1 with all calls to sensitive APIs the original version of an app executes while running a test case generator tool (like DroidBot). In the third step (**exploitation phase**), the MAS approach (a) collects a set S_2 with all calls to sensitive APIs the repackaged version of an app executes

while running a test case generator tool, and then (b) computes the set $S = S_2 \setminus S_1$ and checks whether S is empty or not. The MAS approach classifies the repackaged version as a malware whenever $|S| > 0$.

Previous research works reported the results of empirical studies that aim to investigate the effectiveness of the MAS approach for malware classification [6, 11]. For instance, Bao et al. found that, in general, the sandboxes constructed using test generation tools classify at least 66% of repackaged apps as malware in a dataset comprising 102 pairs of apps (original/repackaged versions) [6]. Actually, the mentioned work performed two studies: one pilot study involving a dataset of 10 pairs of apps (`SmallE`), in which the authors executed each test case generation tools for one hour; and a larger experiment (`LargeE`) involving 102 pairs of apps in which the authors executed the test case generation tools for one minute [6].

The authors also presented that, among five test generation tools used, DroidBot [30] leads to the most effective sandbox. Le et al. extend the MAS approach for malware classification with additional verification, such as the values of the actual parameters used in the calls to sensitive APIs [25], while Costa et al.[13] investigated the impact of static analysis to complement the accuracy of the MAS approach for malware classification. Their study reports that DroidFax [8], the static analysis infrastructure used in [6], classifies as malware almost half of the repackaged apps.

2.3 Android Malware Classification

The field of malware detection for the Android platform is fertile, with a significant number of secondary studies already published [41, 26, 48, 49]. In general, malware detection techniques are divided into static detection, dynamic detection, and hybrid detection [9]. Several studies have also conducted surveys on malware detection techniques and presented a review of them [31, 45, 35]. For instance, M. Odusami et al. [35] discuss various static analyses approaches that have been used in the literature to identify malicious behavior in Android apps. The authors present some works with permission and signature-based malware detection systems. They highlight that both approaches have a low false positive rate; however, they are very ineffective in detecting new malware. Although they could reveal possible malicious behaviors, the authors discuss several limitations of these approaches, as they are limited regarding code obfuscation and dynamic code loading.

The literature also presents surveys based on dynamic analysis, where malicious behavior is analyzed at runtime, exposing risks that are not detected by static analysis. As a malicious app "is alive", dynamic analysis adds another degree of analysis since it observes how Android apps interacts with the environment. However, if applied inappropriately, it may provide limited code coverage, which repeated executions can improve. Therefore, dynamic analysis's time cost and computation resources are higher when compared with static analysis. K. Tam et al. [45] presented several dynamic analysis studies based on Android architectural layers. The survey also exposed that dynamic analysis can be performed in emulator environments, real devices, or both. The authors discuss that the choice of environments is an important issue for analysis, as there are malware families that can detect emulated environments and do not exhibit malicious behaviors [42]. Finally, K. Tam et al. also exposed some works based on hybrid malware detectors and claim that these methods can increase code coverage and robustness, taking advantage of the best of each technique to find malicious behaviors.

Several studies have also explored Android malware detection approaches based on machine learning (ML) techniques, employing both static and dynamic analyses to extract features and train ML models [31]. Most of these approaches have demonstrated high accuracy (above 90%), effectively detecting previously unseen malware families with low

false positives rate [1]. However, some studies have identified limitations of machine learning approaches for Android malware classification. In their work, K. Liu et al. [31] highlighted challenges related to machine learning techniques, identifying several factors that could lead to biased results, such as the quality of the sample set. The authors argue that samples of poor quality, with a non-representative size or outdated samples, may yield promising results in experimental settings but might not perform similarly in a real environment [31]. Another critical aspect is the quality of the extracted feature dataset. The efficacy of machine learning approaches heavily relies on the selection of correct features and their extraction methods, particularly dynamic features. Moreover, in addition to the computational costs involved, other studies [14, 17] have indicated that machine learning approaches exhibit weaknesses when dealing with malicious apps that alter their behavior to mislead learning algorithms, which may restricts their applicability in real-world scenarios.

3 Experimental Setup

This research aims to develop a deeper understanding of the performance of the MAS approach for detecting malware. To this end, in this paper, we **replicate** the study by Bao et al. [6], which advocates for using the MAS approach for malware classification. However, in contrast to the original study [6], we use a dataset of repackaged apps that is an order of magnitude larger. Accordingly, we investigate the following research questions:

(RQ1) What is the impact of considering a larger and diverse dataset on the accuracy of the MAS approach for malware classification? Answering this question may help shed light on potential generalization issues in previous studies that empirically assess the MAS approach approach to malware classification.

(RQ2) What is the influence of the similarity between the original and repackaged versions of the apps on the performance of the MAS approach for malware classification? Answering this research question helps clarify whether the similarity between an original app and its repackaged version affects the MAS approach approach's performance in malware classification.

(RQ3) What is the influence of the malware family (e.g., *gappusin*, *kuguo*, *dowgin*) on the performance of the MAS approach for malware classification? Answering this research question may help identify potential blind spots in the MAS approach approach to malware classification, revealing possible extensions that could improve the detection of specific malware families.

In this section, we describe our study settings. First, we present our procedures to create our datasets (Section 3.1). Then, we describe the data collection and data analysis procedures (Sections 3.2 and 3.3).

3.1 Malware Dataset

To address our research questions, we contribute a dataset designed to meet two primary requirements. First, it should provide a comprehensive and up-to-date selection of Android repackaged apps. By "comprehensive", we mean at least an order of magnitude larger than the dataset used in the original study [6]. Given its comprehensiveness, we expect it to include a diverse range of malware families to ensure representativeness. Second, our dataset should be properly labeled, ensuring each sample includes key attributes such as similarity and malware family. This is particularly necessary to answer research questions RQ2 and RQ3.

3.1.1 Procedures for Building the Dataset

We curate our dataset in three main phases. In the first phase, we use two repositories of repackaged Android apps (RePack [28] and AndroMalPack [37]) to build the dataset we use in our research. RePack was curated using automatic procedures that extract repackaged apps from the Androzoo repository [2]. It comprises 18,073 apps, from which 2,776 are original versions of an app and the remaining ones are repackaged. RePack contains 15,297 pairs of original and repackaged Android apps, many repackaged versions of the same original app may coexist within the RePack dataset – note that all repackaged variants of a given app are derived from the same original version, as confirmed by their matching hash identifier. RePack is the leading dataset used in Android repackaged research [23], even though it only contains packages built until 2018. For this reason, we decided to include samples from the AndroMalPack dataset collected after 2018 in our research. Unlike RePack, AndroMalPack lacks information about the original apps, leading us to follow an existing heuristic [28] to identify the original versions of its repackaged apps, leading to a sample from the AndroMalPack dataset that contains 1,190 pairs (original/repackaged) of apps, all pairs satisfying our constraint of being collected after 2018. Altogether, our initial dataset contains a total of 16,487 pairs of apps.

In the second phase, we discarded some samples from our initial dataset because, during the execution of our experiments, we encountered recurrent issues related to the instrumentation of the apps using DroidFax [8]. Other problems occurred after the execution of the apps in the Android emulator, while analyzing the apps or their execution logs. More precisely, we encountered failures while instrumenting 919 original apps from our initial dataset, including both RePack and AndroMalPack. After removing these original apps from our dataset, we were left with 5,875 pairs (original/repackaged) of apps. Among these pairs, 430 repackaged apps could not be instrumented. Failures also occurred while analyzing either the original or repackaged version of 586 apps, resulting in a dataset containing 4,742 pairs. Failures at this phase were expected, as some malware samples employ evasion tactics, such as deliberately crashing test apps in simulated environments, to avoid detection [3]. Finally, we could not install five apps in the version of the Android emulator (API level 28) we used in our research. Compared to our experience building our dataset, a more significant percentage of failures has been reported in previous research [6]. Note that we did not apply any filters to increase the representation of certain malware families in our dataset.

Third, we queried the `VirusTotal` repository to identify original versions of apps labeled as malware. Samples with such labels were excluded from our dataset, as the MAS approach assumes that the original version of an app is not malware (otherwise, the repackaged versions might also exhibit malicious behavior). `VirusTotal` is a widely recognized tool that scans software assets, including Android apps, using over 60 antivirus engines [23]. Thus, we excluded 661 samples from our dataset that do not satisfy this constraint.

In the end, we are left with our final dataset (hereafter `LargeDS`) of 4,076 apps which we use in our study. To bring evidence that we were able to reproduce the results of previous research, we also consider in our research a small dataset (`SmallDS`) used in the original study [6]. This is the same dataset referenced in Section 2.2 as (`LargeE`).

3.1.2 Features of the Datasets

We queried the `VirusTotal` repository to find out which repackaged apps in our dataset have indeed been labeled as a malware. According to `VirusTotal`, in the `SmallDS` (102 pairs), 69 of the repackaged apps (67.64%) were identified as malware by at least two security engines.

Here, we consider a repackaged version of an app to be malware only if `VirusTotal` reports that at least two security engines identify malicious behavior within the asset. Although this decision aligns with previous research [50, 23], we assess its potential impact on our findings in Section 5. Considering the `LargeDS`, at least two security engines identified 2,895 out of the 4,076 repackaged apps as malware (71.02%). Again, in Section 5, we show that our results remain consistent across three additional scenarios: classifying a repackaged version of an app as malware if at least one, five, or ten `VirusTotal` engines flag it as malicious.

Classifying malware into different categories is a common practice. For instance, Android malware can be classified into categories like riskware, trojan, adware, etc. Each category might be further specialized in several malware families, depending on its characteristics and attack strategy – e.g., steal network info (IP, DNS, WiFi), collect phone info, collect user contacts, send/receive SMS, and so on [38]. According to the `avclass2` tool [40], the malware samples in the `SmallDS` come from 17 different families – most of them from the Kuguo (49.27%) and Dowgin (17.39%) families. Our `LargeDS`, besides comprising a large sample of repackaged apps (4,076 in total), contains 116 malware families – most of them from the Gappusin (46.18%) family. Despite being flagged as malicious by at least two security engines, unfortunately `avclass2` tool cannot correctly identify the family of 253 samples in our `LargeDS`.

We also characterize our dataset according to the similarity between the original and repackaged versions of the apps, using the SimiDroid tool [27]. SimiDroid quantifies the similarity based on (a) the methods that are either identical or similar in both versions of the apps (original and repackaged versions), (b) methods that only appear in the repackaged version of the apps (new methods), and (c) methods that only appear in the original version of the apps (deleted methods). Our `LargeDS` has an average similarity score of 90.39%, with the following distribution: 87 app pairs have a similarity score below 25%, 49 pairs fall between 25% and 50%, 353 apps between 50% and 75%, and 3,587 apps exceed 75%. The `SmallDS` has an average similarity score of 89.41%.

After executing our experiments, we identified the most frequently abused sensitive APIs called by the repackaged version of our samples. We observed that upon execution of all samples from our dataset (`SmallDS` and `LargeDS`), malicious app versions injected 133 distinct methods from sensitive APIs (according to the AppGuard [5] security framework). Malicious code often exploits these APIs to compromise system security and access sensitive data. Table 1 lists the 10 most frequently called methods from sensitive APIs that appear only in the repackaged versions of the apps.

We must highlight that the `LargeDS` samples come from different Android app stores. Most of our repackaged apps come from a non-official Android app store, Anzhi [34]. However, some repackaged apps also come from the official Android app store, Google Play.

3.2 Data Collection Procedures

We take advantage of the DroidXP infrastructure [11] for data collection. DroidXP allows researchers to compare test case generation tools for malicious app behavior identification, using the MAS approach. Although the comparison of test case generation tools is not the goal of this paper, DroidXP was still useful for automating the following steps of our study.

(Step1) **Instrumentation**: In the first step, we configure DroidXP to instrument all pairs of apps in our datasets (`SmallDS` and `LargeDS`). Here, we instrument both versions of the apps (as APK files) to collect relevant information during their execution. Under the hood, DroidXP leverages DroidFax to instrument the apps and collect static information about them. To improve the performance across multiple executions, this phase executes only once for each version of the apps in our dataset.

Table 1 Sensitive APIs that frequently appear in the repackaged versions of the apps. The *Occurrences* column gives the number of distinct repackaged apps that introduce a call to a sensitive method.

Method of Sensitive API	Occurrences
android.telephony.TelephonyManager: int getPhoneType()	311
android.telephony.TelephonyManager: java.lang.String getNetworkOperatorName()	297
android.location.LocationManager: java.lang.String getBestProvider(android.location.Criteria,boolean)	292
android.telephony.TelephonyManager: int getSimState()	284
java.lang.reflect.Field: java.lang.Object get(java.lang.Object)	277
android.net.NetworkInfo: java.lang.String getTypeName()	271
android.database.sqlite.SQLiteDatabase: android.database.Cursor query(java.lang.String,java.lang.String[],...,...,...,...,...)	270
java.lang.reflect.Field: int getInt(java.lang.Object)	250
android.net.wifi.WifiInfo: java.lang.String getMacAddress()	238
android.telephony.TelephonyManager: java.lang.String getNetworkOperator()	237

(Step2) **Execution**: In this step, DroidXP first installs the (instrumented) version of the APK files in the Android emulator we use in our experiment (API 28) and then starts a test case generation tool for executing both app versions (original and repackaged). We execute the apps via DroidBot [30], mainly because the original research we replicate here reports that DroidBot leads to the best accuracy of the MAS approach for malware identification. Since previous studies suggest that DroidBot's coverage nearly reaches its maximum within one minute [6], we run each app for three minutes. To mitigate the randomness inherent in test case generation tools, we repeat this process three times. To also ensure that each execution gets the benefit of running on a fresh Android instance without biases that could stem out of history, DroidXP wipes out all data stored on the emulator that has been collected from previous executions.

(Step3) **Data Collection**: After the execution of the instrumented apps, once again, DroidXP leverages DroidFax, this time to collect all relevant information (such as calls to sensitive APIs, test coverage metrics, and so on). We use this information to analyze the performance of the MAS approach for detecting malicious behavior.

3.3 Data Analysis Procedures

We consider that the MAS approach builds a sandbox that labels a repackaged version of an app as malware if there is at least one call to a sensitive API that (a) was observed while executing the repackaged version of the app and that (b) was not observed while executing the original version of the same app. If the set of sensitive methods that only the repackaged version of an app calls is empty, we conclude that the sandbox does not label the repackaged version of an app as malware. The set of sensitive APIs we use was defined in the AppGuard framework [5], which was based on the mapping from sensitive APIs to permissions proposed by Song et al. [16]. We triangulate the results of the MAS approach classification with the outputs of `VirusTotal`, which might lead to one of the following situations:

- **True Positive (TP)**. The MAS approach labels a repackaged version as malware and, according to `VirusTotal`, at least two security engines label the asset as a malware.
- **True Negative (TN)**. The MAS approach does not label a repackaged version as malware and, according to `VirusTotal`, at most one security engine labels the asset as a malware.
- **False Positive (FP)**. The MAS approach labels a repackaged version as malware and, according to `VirusTotal`, at most one security engine labels the asset as a malware.
- **False Negative (FN)**. The MAS approach does not label a repackaged version as malware, and according to `VirusTotal`, at least two security engines label the asset as a malware.

In Section 4 we compute *Precision*, *Recall*, and *F-measure* (F_1) from the number of true-positives, false-positives, and false-negatives (using standard formulae). We use basic statistics (average, median, standard deviation) to identify the accuracy of the MAS approach for malware classification, using both datasets – i.e., the `SmallDS` with 102 pairs of apps and `LargeDS` with 4,076 pairs. We use the Spearman Correlation [43] method and Logistic Regression [19] to understand the strengths of the associations between the similarity index between the original and the repackaged versions of a malware with the MAS approach accuracy – that is, if the approach was able to classify an asset as malware correctly. We also use existing tools to reverse engineer a sample of repackaged apps in order to better understand the (lack of) accuracy of the MAS approach.

Table 2 highlights the differences between the original study [6] and our replication study. In the best-case scenario, where no re-executions are required, our experiment would take at least 611 hours. In contrast, under the best conditions, the original experiment's execution would last 60 hours. This difference is one of the reasons we focus our research on DroidBot, the test case generation tool that demonstrated the best performance in the original study.

Table 2 Characterization of this replication study.

Study Feature	Original Study	Replication Study
Dataset	102 pairs of samples	4,076 pairs of samples
Execution time	One minute	Three minutes
Number of executions	Single execution	Three executions
Metrics	Malware prevalence	Precision, Recall, and F1-score
Test case generation tool	Six different tools (DroidBot with best performance)	DroidBot only

4 Results

In this section, we detail the findings of our study. We remind the reader that this replication study's primary goal is to better understand the strengths and limitations of the MAS approach for malware detection by replicating the work of Bao et al., using DroidBot as the test case generation tool. We explore the results of our research using two datasets: the `SmallDS` (102 app pairs), and `LargeDS` (4,076 pairs).

4.1 Exploratory Data Analysis of Accuracy

`SmallDS`. Considering the `SmallDS` (102 apps), the MAS approach for malware detection classifies a total of 69 repackaged versions as malware (67.64%). This result is close to what Bao et al. reported [6]. That is, in their original paper, the MAS approach using DroidBot classifies 66.66% of the repackaged version of the apps as malware [6]. This result confirms that we could reproduce the findings of the original study using our implementation settings of the MAS approach.

Finding 1. We were able to reproduce the results of existing research using our implementation of the MAS approach, achieving a malware classification in the `SmallDS` close to what has been reported in previous studies.

In the original study [6], the authors assume that all repackaged versions are malware and contain a malicious code. For this reason, the authors do not explore accuracy metrics (such as Precision, Recall, and F-measure (F_1)) – all repackaged apps labeled as malware are considered true positives in the original study. As we mentioned, in this paper we take advantage of `VirusTotal` to label our dataset and build a ground truth: In our datasets, we classify a repackaged version of an app as malware if, according to our `VirusTotal` query results, at least two security engines identify malicious behavior in the asset. This decision aligns with existing recommendations [50, 23]). The first row of Table 3 shows that the MAS approach achieves an accuracy of 0.90 when considering the `SmallDS`. Nonetheless, the MAS approach fails to classify seven assets as malware on the `SmallDS` correctly (FN column, first row of Table 3), and wrongly labeled the repackaged version of six apps as malware (FP column).

Table 3 Accuracy of the MAS approach in both datasets.

Dataset	TP	FP	FN	Precision	Recall	F_1
`SmallDS` (102)	63	6	7	0.91	0.90	0.90
`LargeDS` (4,076)	1,175	220	1,720	0.84	0.40	0.54

`LargeDS`. Surprisingly, considering our complete dataset (4,076 apps), the MAS approach labels a total of 1,395 repackaged apps as malware (34.22% of the total number of repackaged apps) – for which the repackaged version calls at least one additional sensitive API. Our analysis also reveals a **negative result** related to the accuracy of the approach: here, the accuracy is much lower in comparison to what we reported for the `SmallDS` (see the second row of Table 3): F_1 dropping from 0.90 to 0.54. This result indicates that, when considering a large dataset, the accuracy of the MAS approach using DroidBot drops significantly.

Finding 2. The MAS approach for malware detection leads to a substantially lower performance on the `LargeDS` (4,076 pairs of apps), dropping F1-score from 0.90 to 0.54 in comparison to what we observed in the `SmallDS`.

Therefore, the resulting sandbox we generate using DroidBot suffers from a significantly low accuracy rate when considering a large dataset. This is shown in the second row of Table 3. The negative performance of the MAS approach in the `LargeDS` encouraged us to endorse efforts to identify potential reasons for this phenomenon and motivated us to explore the research questions RQ2 and RQ3.

4.2 Assessment Based on Similarity Score

Figure 1 shows the Similarity Score distribution over the `LargeDS` we use in our research. Recall that the Similarity Score measures how similar an app's original and repackaged versions are. The complete dataset averages a Similarity Score of 0.90 (with a median of 0.98 and standard deviation of 0.18).

In this section we investigate how the Similarity Score influences the accuracy of the MAS approach – which might help us understand if it might explain the low small performance of the MAS approach in the `LargeDS`. To this end, we leverage Logistic Regression to quantify the relationship between Similarity Score and F1-score. This analysis excludes instances of true negatives (i.e., cases where the repackaged version is benign according to `VirusTotal` and the MAS approach correctly labels it as benign). As such, we test the following null hypothesis:

H_0 Similarity Score does not influence the accuracy of the MAS approach for malware detection.

The logistic regression results suggest that we should reject our null hypothesis (p-value $= 2.22 \cdot 10^{-16}$). This finding indicates that the accuracy of the MAS approach on `LargeDS` is influenced by the similarity between the original and repackaged versions of an app.

Finding 3. There is an association between the Similarity Score and the MAS approach performance, which means that the similarity between the original and repackaged versions of an app can explain the performance of the MAS approach for malware classification.

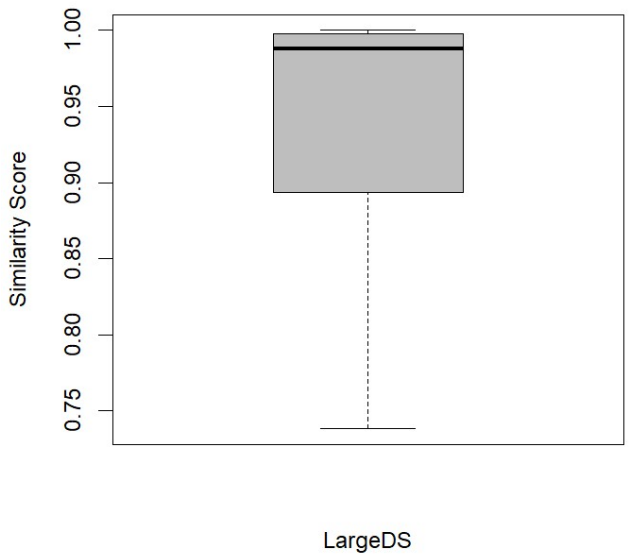

Figure 1 Similarity Score of the malware samples in the `LargeDS`. The boxplots in the figure do not show outliers.

To clarify the association between Similarity Score and accuracy, we use the *K-Means* algorithm to split the `LargeDS` into ten clusters – according to the Similarity Score. We then estimate the percentage of correct classifications for each cluster, as shown in Table 4. Note that the MAS approach achieves the highest percentage of correct classification (77.35%) for the second cluster (cId = 2), which presents an average Similarity Score of (0.56). Nonetheless, the cluster cId = 10, with a larger number of samples (1,302) and Similarity Score (0.99), presents a percentage of correct classifications of 26.5%. We can observe that as the average similarity rate decreases, there is a tendency toward greater accuracy in the MAS approach. Hence, the average similarity score could explain the poor performance of the MAS approach on the `LargeDS`, especially considering that most samples exhibit a high average similarity of 0.99.

4.3 Assessment Based on Malware Family

As we discussed in the previous section, the similarity assessment partially explains the low performance of the MAS approach on the `LargeDS`. Since the `LargeDS` covers a wide range of malware families, we investigate the hypothesis that the diversity of malware families in the `LargeDS` also contributes to the poor performance of the MAS approach on the `LargeDS`. Indeed, in the `LargeDS`, we identified a total of 116 malware families, though the most frequent ones are *gappusin* (1,337 samples), *revmob* (207 samples), *dowgin* (183 samples) and *airpush* (120 samples). Together, they account for 63.79% of the repackaged apps in our `LargeDS` labeled as malware according to `VirusTotal`.

This family distribution in the `LargeDS` is different from the family distribution in the `SmallDS` (used in the original study) – where the families *kuguo* (34 samples), *dowgin* (12 samples), and *youmi* (5 samples) account for 73.91% of the families considering the 69

Table 4 Characteristics of the clusters. Note there is a specific pattern associating the percentage of correct answers with the Similarity Score. For this analysis, we removed the true negatives in our dataset.

cId	Similarity Score	Samples	Correct Answers	%
1	0.42	42	30	71.42
2	0.56	181	140	77.35
3	0.68	131	98	74.81
4	0.80	170	104	61.18
5	0.88	263	83	31.56
6	0.91	236	129	54.66
7	0.95	167	51	30.54
8	0.97	150	67	44.67
9	0.98	421	112	26.60
10	0.99	1302	345	26.50

repackaged apps in the `SmallDS` for which `VirusTotal` labels as malware. Most important, in the `SmallDS`, there is just one sample from the *gappusin* family and no sample from *revmob* family, two of the most frequent families in our `LargeDS`. This observation leads us to the question: how does the MAS approach perform when considering only samples from the *gappusin* and *revmob* families?

The confusion matrix of Table 5 summarizes the accuracy assessment of the MAS approach considering only the *gappusin* and *revmob* samples in the `LargeDS`. To make clear, `VirusTotal` classifies as malware all repackaged versions in the *gappusin* and *revmob* family. It is worth noting that the MAS approach failed to classify correctly 1,170 (87.5%) samples of *gappusin* as malware. Similarly, 92 samples (44.44%) from *revmob* were not classified as malware. Furthermore, if we exclude the *gappusin* and *revmob* samples from the `LargeDS`, the recall of the MAS approach increases to 0.72, which, although improved, remains relatively low compared to the original studies.

Table 5 Confusion matrix of the MAS approach when considering only the samples from the *gappusin* and *revmob* family in the `LargeDS`.

Actual Condition	Predicted Condition	
	Benign	Malware
Benign (0)	TN (0)	FP (0)
Gappusin (1,337)	FN (1,170)	TP (167)
Revmob (207)	FN (92)	TP (115)

Finding 4. The MAS approach fails to correctly identify 87.50% of the samples from the *gappusin* family and 44.44% of the samples from the *revmob* as malware. Just like the Similarity Score, the presence of some malware families with a high false negative rate also influences the low recall of the MAS approach in the `LargeDS`

We further analyze the samples from the *gappusin* and *revmob* malware families in our dataset, given their relevance to the negative results presented in our paper. First, we examined the Similarity Score of the samples. Figure 2 shows a histogram of the Similarity Score for both families. Most repackaged versions are similar to the original ones, with an

average Similarity Score of 0.94, a median of 0.99, and a standard deviation (SD) of 0.16 for the *gappusin* family. For the *revmob* family, the average Similarity Score is 0.81, the median is 0.91, and the SD is 0.26.

We also reverse-engineered samples from both families. Due to the significant effort required for reverse engineering, we limited our analysis to a sample of 30 *gappusin* and 30 *revmob* malware samples, using the `SimiDroid`[3], `apktool` [4], and `smali2java` [5] tools. Considering this sample, the median Similarity Score is 0.99 and 0.90 for the *gappusin* and *revmob* families, respectively. Table 6 and Table 7 summarize the outputs of `SimiDroid` for these samples.

Regarding the *gappusin* malware, the similarity assessment of this sample of 30 apps reveals a few modification patterns when comparing the original and the repackaged versions. First, no instance in this *gappusin* sample dataset modifies the Android Manifest file to require additional permissions. In most cases, the repackaged version just changes the Manifest file to modify either the package name or the main activity name. Moreover, 29 out of the 30 samples in this dataset **modifies** the method `void onReceive(Context, Intent)` of the class `com.games.AdReciver`. Although the results of the decompilation process are difficult to understand in full (due to code obfuscation), the goal of this modification is to change the behavior of the benign version, so that it can download a different version of the `data.apk` asset. Figure 3 shows the code pattern of the `onReceive` method present in the samples. This modification typically uses a new method (`public void a(Context)`) in the repackaged versions, often introduced into the same class (`AdReceiver`). Since there are no additional calls to sensitive APIs, the MAS approach fails to correctly label the *gappusin* samples. This limitation holds regardless of our experimental choices, such as using the DroidBot tool (instead of more recent test case generation tools) or running the samples for three minutes.

Our assessment also reveals recurrent modification patterns that **delete** methods in the repackaged version of the apps. For instance, 20 repackaged apps in our *gappusin* sample of 30 malware remove the method `void b(Context)` from the class `com.game.a`. This class extensively uses the Android reflection API. Although it is not clear the real purpose of removing these methods, that decision simplifies the procedure of downloading a `data.apk` asset that is different from the asset available in the original version of the apps. Removing those methods might also be a strategy for antivirus evasion. For instance, although some usages of the class `DexClassLoader` might be legitimate, it allows specific types of attack based on dynamic code injection [15]. As such, antivirus might flag specific patterns using the Android reflection API suspect. Unfortunately, the MAS approach also fails to identify a malicious behavior with this type of change (i.e., changes that remove methods), again, regardless of the decisions we follow in our experiment. Listing 4 shows an example of code pattern frequently removed from the repackaged versions from the *gappusin* family.

In summary, our reverse engineering effort brings evidence that malware samples from the *gappusin* family neither modify the Android Manifest files nor call additional sensitive APIs. It acts as a downloader for further malicious app [4] – which reduces the ability of the MAS approach to classify a sample as a malware correctly. Both versions (original/repackaged) from the *gappusin* family have the same behavior for showing advertisements to the user, however, the repackaged version has additional call sites to the advertisement API and the advertisement sources are different.

(b) Similarity Score for the samples in the *revmob* family.

Figure 2 Histogram of the Similarity Score for the samples in the *gappusin* and *revmob* families.

Similar to the approach used for *gappusin* samples, we also reverse-engineered a random selection of 30 samples from the *revmob* family that were not detected by the MAS approach. As with the *gappusin* family samples, no instance from the *revmob* family modifies the Manifest file or inserts extra calls to sensitive APIs, making it harder for the MAS approach to label the samples as malware correctly. However, our reverse engineering reveals that all apps store a file with the extension ".so" (Shared Object files) in their lib directory. These files are dynamic libraries containing native code written in C or C++, and are often used by apps for performance reasons, when resource-intensive tasks need to be performed [39].

Unfortunately, creating malicious repackaged apps using ".so" files is also possible, as they can be replaced by a version containing harmful code [36]. The Shared Object files also allow for attacks based on dynamic code injection [15], considering that Android apps can use methods like `System.loadLibrary()` or `System.load()` to download malicious ".so" files from a remote server. Once on the device, malicious apps can use these files to interface with Java code in Android apps, via the Java Native Interface (JNI), performing malicious operations on low-level code and bypassing security mechanisms, like the MAS approach.

Our assessment confirms that all *revmob* samples contain Java code that loads a native library. In particular, to load these libraries, the samples use the `loadLibrary` method of the `System` class, which is called in the static constructor of the `mainActivity` class. The

```
public void onReceive(Context c, Intent intent) {
  SharedPreferences sp = c.getSharedPreferences(String.valueOf("com.")+"game."+"param",0);
  int i = sp.getInt("sn", 0) + 1;
  System.out.println("sn: " + i);
  if (i < 2) {
    mo4a(context);
    SharedPreferences.Editor edit = sp.edit();
    edit.putInt("sn", i);
    edit.commit();
  } else if (!new C0004b(context).f7h.equals("")) {
    String str1 = context.getApplicationInfo().dataDir;
    String str2 = String.valueOf(str1) + "/fi" + "les/d" + "ata.a" + "pk";
    String str3 = String.valueOf(str1) + "/files";
    String str4 = String.valueOf("com.") + "ccx." + "xm." + "SDKS" + "tart";
    String str5 = String.valueOf("InitS") + "tart";
    String str6 = "ff048a5de4cc5eabec4a209293513b6e";
    C0003a.m3a(context, str2, str3, str4, str5, str6);
    SharedPreferences.Editor edit2 = sp.edit();
    edit2.putInt("sn", 0);
    edit2.commit();
  }
}
```

Figure 3 Method introduced in 29 out of 30 *gappusin* malware we randomly selected from the LargeDS.

```
public static void m7a(Activity activity, String str, String str2, ... , String str5) {
  try {
    Class loadClass = new DexClassLoader(..., activity.getClassLoader()).loadClass(str3);
    Object newInstance = loadClass.getConstructor(new Class[0]).newInstance(new Object[0]);
    Method method = loadClass.getMethod(str4, new Class[]{Activity.class, String.class});
    method.setAccessible(true);
    method.invoke(newInstance, new Object[]{activity, str5});
  } catch (Exception e) {
    e.printStackTrace();
  }
}
```

Figure 4 Example of method that is typically removed from the repackaged apps of the *gappusin* family.

```
public class PZPlayer extends Cocos2dxActivity {
    // ...
    System.loadLibrary("game");
    // ...
}
```

Figure 5 Thie code links this java file into libgame shared library.

`loadLibrary` method takes "game" as an argument, and the code automatically searches the default lib directory for the `.so` file named (`lib+argument`). The "lib" directory contains the `libgame.so` file in all samples. Figure 5 presents the code pattern of the `mainActivity` class found in the samples from *revmob* family.

The `libgame.so` file contains compiled code written in C or C++, which is loaded into memory and linked to the apps at runtime. Although machine code is difficult to analyze, all the files include the `JNI_OnLoad` function, which the JNI implementation automatically uses to link Java methods and native functions. When we analyzed the ".so" file, we found that they all differ in size and content between the original and repackaged apps. It is possible that changes of interest occurred in the native `libgame.so` file and have gone unnoticed

Table 6 Summary of the outputs of the `SimiDroid` tool for the sample of 30 *gappusin* malware. (IM) Identical Methods, (SM) Similar Methods, (NM) New Methods, and (DM) Deleted Methods.

by the MAS approach. Again, since the MAS approach only considers differences in calls to sensitive APIs, it is unlikely to correctly classify these samples using other test case generation tools or by extending the execution time during its exploratory phase.

5 Discussion

In this section, we answer our research questions, summarize the implications of our results, and discuss possible limitations of our study that might threaten the validity of the results presented so far.

5.1 Answers to the Research Questions

The results we presented in the previous sections allow us to answer our three research questions, as we summarize in the following.

Table 7 Summary of the outputs of the `SimiDroid` tool for the sample of 30 *revmob* malware. (IM) Identical Methods, (SM) Similar Methods, (NM) New Methods, and (DM) Deleted Methods.

- **Performance of the MAS approach (RQ1).** Our study indicates that the accuracy of the MAS approach reported in previous studies [6, 13] does not generalize to a larger dataset. That is, while in our reproduction study (using the `SmallDS` of previous research) the MAS approach leads to an accuracy of 0.90, we observed a drop of precision and recall that leads to an accuracy of 0.54 in the presence of our `LargeDS` (4,076 pairs of original and repackaged versions of Android apps).
- **Similarity Analysis (RQ2).** Our results bring evidence about the association between the similarity of the original and repackaged versions of an app and the ability of the MAS approach to correctly classify a repackaged version of an app as a malware. Therefore, the similarity assessment is relevant for explaining the performance of the MAS approach to classify certain repackaged versions of an app as malware.
- **Malware Family Analysis (RQ3).** The results indicate that some families are responsible for the largest number of false negatives in the complete dataset. We specifically further investigate the *gappusin* and *revmob* families – a particular type of

Adware, designed to display advertisements while an app is running automatically. After reverse engineering a sample of 60 malware apps from *gappusin* and *revmob* family, we confirmed that the MAS approach cannot identify the patterns of changes introduced in the repackaged versions of the apps. The prevalence of the *gappusin* and *revmob* families in the Android malware landscape accounts for the poor performance of the MAS approach in malware classification on the large dataset.

5.2 Implications

Contrasting to previous research works [6, 25, 13], our results lead to a more systematic understanding of the strengths and limitations of using the MAS approach for malware classification. In particular, this is the first study that empirically evaluates the MAS approach considering as ground truth the outcomes of `VirusTotal` – a common practice in the malware identification research. This decision allowed us to explore the MAS approach performance using well-known accuracy metrics (i.e., precision, recall, and F_1 score). Contrasting with previous studies that assume that all repackaged versions of the apps were malware. Our triangulation with `VirusTotal` reveals this is not true. Although the MAS approach presents a good accuracy for the `SmallDS` ($F_1 = 0.90$), in the presence of a large dataset the MAS approach accuracy drops significantly ($F_1 = 0.54$).

We also reveal that some families in the `LargeDS` are responsible for a large number of false negatives, compromising the accuracy of the MAS approach. Altogether, the takeaways of this research are twofold:

- Negative result: the MAS approach for malware detection exhibits a much higher false negative rate than previous research reported.
- Future directions: Researchers should advance the MAS approach for malware detection by exploring more sophisticated techniques to differentiate between benign and malicious apps. In particular, since our reverse engineering results suggest that *gappusin* and *revmob* – two recurrent malware families – use the network to download new assets, new approaches might benefit from monitoring not only calls to sensitive APIs but also network traffic, as well as mining sensitive calls to native APIs embedded in `so` files. The versatility of the Java Native Interface (JNI) has introduced challenges. Malware authors increasingly use the native layer to hide malicious code, making both static and dynamic analysis more difficult. The current state of the art in sandbox mining overlooks native calls.

5.3 Threats to Validity

There are some threats to the validity of our results. Regarding **external validity**, one concern relates to the representativeness of our malware datasets and how generic our findings are. Indeed, mitigating this threat was one of the motivations for our research, since, in the existing literature on the MAS approach for malware classification, researchers had explored just one dataset of 102 pairs of original/repackaged apps. Curiously, for this small dataset, the performance of the MAS approach is substantially superior to its performance on our `LargeDS` (4,076 pairs of apps).

We contacted the authors of the Bao et al. original research paper [6], asking them if they had used any additional criteria for selecting the pairs of apps in their dataset. Their answers suggest the contrary: they have not used any particular app selection process that could explain the superior performance of the MAS approach for the `SmallDS`. We believe our results in the `LargeDS` generalize better than previous research work, since we have a more comprehensive collection of malware with different families and degrees of similarity.

Nonetheless, our research focuses only on Android repackaged malware. Thus, we cannot generalize our findings to malware that targets other platforms or uses different approaches to instantiate a malicious asset. Besides that, repackaging is a recurrent approach for implementing Android malware.

Regarding **conclusion validity**, during the exploratory phase of the MAS approach, we collected the set of calls to sensitive APIs the original version of an app executes, while running a test case generation tool (DroidBot). In the exploratory phase, the MAS approach assumes the existence of a benign original version of a given app. We also query `VirusTotal` to confirm this assumption, and found that the original version of seven (out 102) apps in the `SmallDS` contains malicious code. We believe the authors of previous studies carefully check that assumption, and this difference had occurred because the outputs of `VirusTotal` change over time [50], and a dataset that is consistent on a given date may not remain consistent in the future. Therefore, while reproducing this research, it is necessary to query `VirusTotal` to get the most up-to-date classification of the assets, which might lead to results that might slightly diverge from what we have reported here. Besides that, in the `LargeDS` we only consider pairs of original/repackaged apps for which `VirusTotal` classifies the original version as benign.

Regarding **construct validity**, we address the main threats to our study by using simple and well-defined metrics that are in use for this type of research: number of malware samples the MAS approach correctly/wrongly classify in a dataset (true positives/false negatives). We computed the accuracy results using precision and recall based on these metrics. In a preliminary study, we investigated whether or not the MAS approach would classify an original version of an app as malware, computing the results of the test case generation tools in multiple runs. After combining three executions in an original version to build a sandbox, we did not find any other execution that could wrongly label an original app as malware. Also, we label a repackaged version of an app as malware only if `VirusTotal` reports that at least two engines detect suspicious behavior in that asset. This decision might be viewed as either a weak or strong constraint and could raise concerns about construct validity. However, when we relax this constraint and label an asset as malware whenever at least one engine detects suspicious behavior, precision improves to 0.85, but recall drops to 0.39. Overall, the accuracy of the MAS approach remains almost unchanged ($F_1 = 0.53$) – still significantly lower than the precision of the MAS approach for `SmallDS`. We also evaluated accuracy by considering an asset as malware when at least five or ten `VirusTotal` security engines flagged it. As shown in Table 8, the results did not diverge significantly from what we have reported in this paper.

Table 8 Accuracy of the MAS approach at `LargeDS` (4,076 pairs) based on engines.

Engine(s)	TP	FP	FN	Precision	Recall	F_1
At least 01	1,222	220	1,900	0.85	0.39	0.53
At least 02	1,175	220	1,720	0.84	0.40	0.54
At least 05	1,087	220	1,578	0.83	0.40	0.54
At least 10	1,002	220	1,469	0.81	0.40	0.54

6 Conclusions

To better understand the strengths and limitations of the MAS approach for repackaged malware detection, this paper reported the results of an empirical study that replicates previous research works [6, 13]. The study utilizes a more diverse dataset compared to those used in previous research, with the aim of providing a more comprehensive evaluation

of the approach. To our surprise, compared to published results, the performance of the MAS approach drops significantly for our comprehensive dataset (F_1 score reduces from 0.90 in previous papers to 0.54 here). This result is partially explained by the high prevalence of specific malware families (named *gappusin* and *revmob*), whose samples are incorrectly classified by the MAS approach. We also report the results of a reverse engineering effort, whose goal was to understand the characteristics of the *gappusin* and *revmob* family that reduce the performance of the MAS approach for malware classification. Our reverse engineering effort revealed common changing patterns in the *gappusin* repackaged versions of original apps, which mostly use reflection to download an external apk asset for handling advertisements without introducing additional calls to sensitive APIs. Similarly, the *revmob* family does not include any additional calls to sensitive resources; however, it often uses JNI to interact with native code, which can be used to perform malicious operations at a low level, compromising the effectiveness of the MAS approach for malware identification. These negative results highlight the current limitations of the MAS approach for malware classification and suggest the need for further research to integrate the MAS approach with other techniques for more effective malware identification.

Shouting at Memory: Where Did My Write Go?

Vasileios Klimis
Queen Mary University of London, UK

Abstract

Non-Volatile Memory (NVM) promises persistent data, but verifying that promise on real hardware is challenging due to opaque caching and internal buffers like Intel's WPQ, which obscure the true state of writes. Traditional validation methods often fall short. This paper introduces a novel perspective: leveraging the subtle timing variations of memory accesses as a direct probe into write persistence.

We present a software technique, inspired by echolocation, that uses high-resolution timers to measure memory load latencies. These timings act as distinct signatures ("echoes") revealing whether a write's data resides in volatile caches or has reached the NVM persistence domain. This offers a non-invasive method to track write progression towards durability.

To reliably interpret these potentially noisy timing signatures and systematically explore complex persistence behaviours, we integrate this echolocation probe into an active model learning framework. This synergy enables the automated inference of a system's actual persistency semantics directly from black-box hardware observations. The approach is hardware-agnostic, adaptive, and scalable. Preliminary experiments on Intel x86 – a platform where persistence validation is notably challenged by the opaque Write Pending Queue (WPQ) – demonstrate the feasibility of our technique. We observed distinct latency clusters differentiating volatile cache accesses from those reaching the persistence domain. This combined approach offers a promising path towards robust and automated validation of NVM persistency across diverse architectures.

Category Pearl/Brave New Idea

Acknowledgements Special thanks to Andy Rudoff, Non-Volatile Memory Software Architect at Intel Corporation, for his insightful input on the development of the read-after-write timestamps mechanism. Gratitude is also extended to Glynn Winskel for his thoughtful feedback on the application of Event Structures in the intricate domain of memory persistency.

1 Introduction

Non-volatile memory (NVM) combines the speed of RAM with persistent data retention, providing reliable storage that survives power outages. The write-handling mechanisms of NVM are captured by formal *persistency* models, such as Px86 for Intel x86 architectures [37] and PArm for ARM architectures [38]. These models aim to align with architectural specifications, guiding developers in programming for NVM. However, they often lack extensive empirical validation to confirm their real-world applicability.

Empirical validation serves two key purposes. First, it ensures hardware vendors adhere to specified standards – an area with historical inconsistencies [2, 4]. Second, it provides a benchmark for testing whether theoretical persistency models align with actual hardware behaviour. This process ensures that models reflect observable behaviours while avoiding those that cannot occur on real machines, thus maintaining both soundness and completeness.

Persistency correctness is not merely academic but critical for system reliability. In practical applications – financial services, healthcare, industrial automation – the failure to respect persistency guarantees can undermine system integrity. For example, in financial

systems that rely on persistent storage, improper write ordering could violate transaction atomicity guarantees, potentially contributing to data inconsistencies if other safeguards fail. Healthcare systems with patient records might experience data loss or inconsistent state retrieval after power events. In safety-critical domains, such as automotive control systems, inconsistent recovery of calibration parameters or system state could lead to unpredictable behaviour during operation. While modern systems implement multiple layers of protection (transaction logs, checksums, reconciliation processes), the fundamental persistency guarantees of NVM serve as a critical foundation for these higher-level reliability mechanisms. Ensuring that persistency behaves as specified is therefore essential for building trustworthy systems across these domains.

Challenges in Validating Persistency Semantics. Validating persistent memory semantics involves significant challenges. A naive approach might involve inducing program crashes by abruptly powering off the system and retrieving data from Non-Volatile Memory (NVM) upon restart. However, this method only reveals the most recent write, leaving the order of prior writes uncertain. Moreover, frequent power cycling is impractical for comprehensive testing, and scheduling precise crashes proves nearly impossible.

Memory bus interception methods also face limitations, particularly with Intel x86 architectures [25]. This arises from the unique data pathway in Intel x86, where data destined for memory first pass through a battery-backed buffer called the *write-pending queue* (WPQ) in the memory controller [40] (see Figure 1). Since bus intercept observations occur after data have left the processor, they fail to accurately reflect the true order of data persistence.

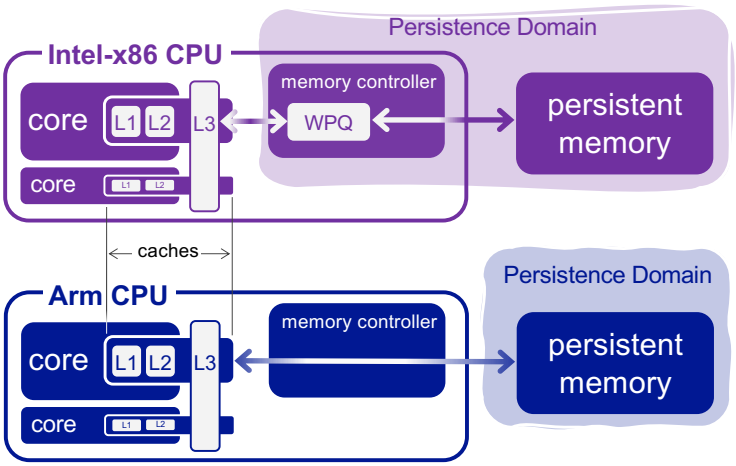

Figure 1 Persistency pathway in Intel x86 and ARM Systems.

In the realm of memory *consistency* models, empirical validation is a well-established practice. Tools like `litmus` [5] execute small multi-threaded tests, known as *litmus tests*, on target machines to examine the visibility and sequencing of writes across threads. This helps clarify the visibility and sequencing of writes among threads. However, unlike memory consistency, a `litmus`-like approach to validating persistency is impractical, as programs cannot directly detect data persistence. Stores may reside in various locations, such as caches, the Write-Pending Queue (WPQ), host memory, or in *Compute Express Link* (CXL) devices.

Representing Behaviour for Validation. Effectively validating NVM persistence – whether checking hardware compliance against specifications like Px86/PArm or diagnosing deviations – requires methods to precisely represent and compare expected versus observed behaviours. This involves capturing the complex interplay of concurrency, weak memory effects, and durability guarantees. While various formalisms exist for modelling concurrent systems (e.g., state machines, Petri nets [34], algebraic approaches [18]), representing the specific partial orders, fence semantics, and persistence states relevant to NVM validation poses unique challenges. Finding a formalism capable of clearly expressing both the specified model's predictions and the potentially divergent behaviours observed on real hardware is crucial for building robust validation techniques. We discuss our choice of formalism, *Event Structures* [44], in Section 5.

Contributions. Our work makes two key contributions:

1) **Introduction of Memory Echolocation Technique:** We introduce memory echolocation, a conceptually architecture-agnostic *timing analysis technique* that uses instruction latencies to non-invasively infer store locations. By analysing retrieval times, this approach identifies distinct timing patterns corresponding to memory hierarchy levels (e.g., caches, WPQ, NVM), revealing write progression towards persistence. Its effectiveness is demonstrated on Intel x86, a challenging platform for validation.
2) **Model-Learning Framework Leveraging Echolocation:** We propose a model-learning based validation framework that utilises memory echolocation (Contribution 1) for black-box observation. This framework enables the iterative refinement of persistency models based on observed timing data, facilitating scalable, adaptive, and more effective validation. It is grounded in *Event Structures* and incorporates persistency properties to accurately capture system behaviour.

2 Background

Non-Volatile Memory (NVM) technologies have introduced new challenges in the reliable management of persistent data. As NVMs retain data across power failures, system designers must ensure that updates to persistent state are crash-consistent – i.e., that data remains consistent even in the event of unexpected interruptions. Achieving this requires explicit reasoning about when writes leave volatile caches and become durable.

Modern architectures such as Intel-x86 and Arm support persistency through specialised instructions that transfer modified data from volatile cache layers to the persistent domain. These mechanisms enable fine-grained control over persist ordering, which is essential because contemporary processors employ multi-level caching for performance, decoupling program execution order from persistence visibility.

Illustrative Litmus Tests. To enforce correct persistency semantics, both Intel-x86 and Arm provide architectural primitives that explicitly govern data flushes to the persistent domain. The examples in Litmus Tests 1 and 2 illustrate minimal persistency patterns: if a crash occurs after y is assigned the value 1, then the programmer expects $x = 1$ to have been persisted, thereby ruling out states where $y = 1$ but $x = 0$.

Litmus Test 1: INTEL.	**Litmus Test 2:** ARM.
1: $x \leftarrow 1$	1: $x \leftarrow 1$
2: $clflush(x)$	2: $dc_cvap(x)$
3: $y \leftarrow 1$	3: $dsb(sy)$
	4: $y \leftarrow 1$

`upon recovery:` $y = 1 \Rightarrow x = 1$

Intel-x86 Persistency Semantics. The Intel-x86 persistency model is inherently buffered, allowing the *persist order* (the sequence in which writes are committed to persistent memory) to diverge from the *coherence order* (the sequence in which writes become visible to threads) [37]. For instance, in the sequence $x \leftarrow 1; y \leftarrow 1$, recovery states after a crash may include $x = 0, y = 0$, $x = 1, y = 0$, or $x = 1, y = 1$, but not $x = 0, y = 1$, which contradicts the program order. This discrepancy arises due to reordering of persist operations.

Intel-x86 offers instructions such as $clflush(x)$ to enforce persistence. This instruction flushes the cache line of x to the persistence domain. Variants such as *clflushopt* and *clwb* provide similar guarantees with differing performance characteristics: *clwb* retains the cache line, while *clflushopt* evicts it. These are non-blocking operations; they trigger persistence asynchronously.

Arm Persistency Semantics. The Arm architecture offers a comparable, though architecturally distinct, model [15, 38]. The instruction $dc_cvap(x)$ transfers data to the persistent domain, but requires a subsequent $dsb(sy)$ barrier to ensure visibility. These synchronisation mechanisms preserve persist order and enforce crash-consistency guarantees akin to those on Intel-x86, as demonstrated in Litmus Test 2.

Persistence Domains and Observability. The scope of the persistence domain – that is, the part of the memory hierarchy where data is guaranteed to persist across power failures – is determined by hardware architecture. On Intel-x86 systems, writes are considered persistent once they reach the memory controller (MC), often equipped with battery-backed buffers. Enhanced ADR (eADR) extends this domain to include L2 and L3 caches [40], further decoupling program execution from persistence observability.

In contrast, Arm architectures maintain a more confined persistence domain, which does not extend to the memory controller, allowing for more direct and observable control over write persistence.

Black-Box Model Learning. Validating persistency models requires a precise understanding of how write and flush operations interact under relaxed behaviours. However, target architectures often function as black boxes, concealing internal details such as persistence ordering and flush timing. These behaviours are instead inferred from observable outcomes of carefully orchestrated operation sequences.

Black-box model learning addresses this challenge by abstracting internal structures and focusing on input-output behaviours. This approach systematically issues crafted sequences of operations (e.g., writes, flushes) and observes the resulting persistence behaviour. Learning algorithms [6] iteratively construct state-transition models that approximate the system's persistency semantics.

For persistency validation, these learned models reveal how writes propagate to the persistence domain under varying conditions, enabling the detection of inconsistencies or undocumented behaviours. By systematically testing even opaque architectures, black-box learning provides a rigorous framework for evaluating complex, poorly understood persistency mechanisms [32].

Event Structures for Modelling Concurrent Behaviour. Persistent behaviours in concurrent programs are naturally expressed in terms of partial orders. *Event Structures* [44] offer a formal framework for modelling these behaviours. An event structure comprises a set of atomic events, a causality relation that expresses dependencies, and a conflict relation that defines mutual exclusions.

This representation is well-suited to reasoning about NVM persistency, which involves partially ordered interactions among writes, flushes, and fences. In this work, we adapt event structures to model the hypotheses explored during model learning. This enables precise specification and comparison of observed system behaviours with theoretical expectations. We present our specific adaptation of Event Structures for NVM persistency in Section 5.

3 Memory Echolocation

This section outlines a straightforward method for inferring store locations within the memory hierarchy, drawing metaphorical inspiration from the concept of *echolocation*. By leveraging timing analysis within the memory hierarchy, we can "map" where data is stored across different memory layers. By doing so, it avoids the need for intrusive approaches like crash-and-recovery, which disrupt system execution and involve directly inspecting memory contents.

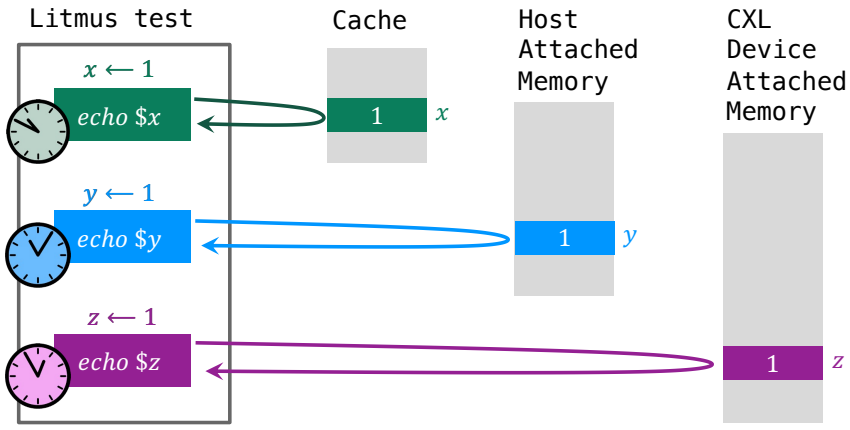

Figure 2 Memory Echolocation.

3.1 Echolocation-Inspired Insight

Echolocation, as observed in nature, involves emitting a signal and interpreting its returning echoes to infer the spatial arrangement of the environment. Our methodology mirrors this approach in the context of memory systems. By performing a store operation, we create a disruption in the memory hierarchy – analogous to emitting a signal. Subsequently, retrieving this data produces measurable latencies, or "echoes", that reveal the location and behaviour of the memory hierarchy components involved.

This analogy underscores the power of latency measurement as a diagnostic tool, revealing patterns of memory residency and transitions across architectural layers. The emitted "signal" in our case is the store operation, and the echoes are derived from the variability in memory access times observed during data retrieval.

3.2 Timing as a Mapping Tool

At the core of our approach is the precise measurement of memory access times. Once the initial store operation is performed, we measure the time required to fetch the data (Figure 2). These timing measurements serve as unique fingerprints of the specific memory layer where the data resides, offering a non-invasive mechanism to explore the memory hierarchy. For example:

- Extremely low latencies indicate L1 cache residency.
- Intermediate latencies may correspond to L2 or L3 caches.
- Longer latencies often point to the Write Pending Queue (WPQ) or main memory (RAM).
- In extended setups, latencies may also reveal accesses to emerging technologies like CXL-enabled memory.

Interpreting Latency Patterns. By correlating these retrieval times with the hierarchical levels of the memory system – such as L1/L2/L3 caches, Write Pending Queue (WPQ), main memory (RAM) and CXL – we can deduce where the stored value resides within the memory architecture. Shorter access times indicate cache residency, while longer delays suggest data retrieval from deeper layers like WPQ or RAM. These timing-based observations serve as a guide to "echo-map" the memory hierarchy, pinpointing the location of stored data with high precision.

4 Learning Persistency Models

Validating persistency semantics in modern systems is a complex and dynamic task, largely due to the intricate interactions between memory management, concurrency, and system failures. As systems grow in complexity, the number of potential states they can reach also increases. Traditional validation methods often fail to capture the full spectrum of behaviours that can emerge under different conditions. This is particularly true when dealing with non-deterministic behaviours, such as those triggered by crashes, race conditions, and the failure-recovery processes that involve complex memory state transitions.

To address these challenges and ensure more comprehensive validation process for persistency semantics, we propose integrating *model learning* techniques. This approach leverages the dynamic interplay between a knowledgeable *Persistency Learner* and an informative *oracle*, enabling automated and optimised validation tasks in a black-box setting. The learner formulates hypotheses about the system's persistency behaviour and tests them against the system through *Membership Queries* (MQ) and *Equivalence Queries* (EQ), receiving feedback from the oracle to validate or refine these hypotheses. This interactive, feedback-driven process enables the model to evolve continuously in real time, uncovering previously undetected edge cases, inconsistencies, and subtle aspects of persistency semantics that may have otherwise gone unnoticed.

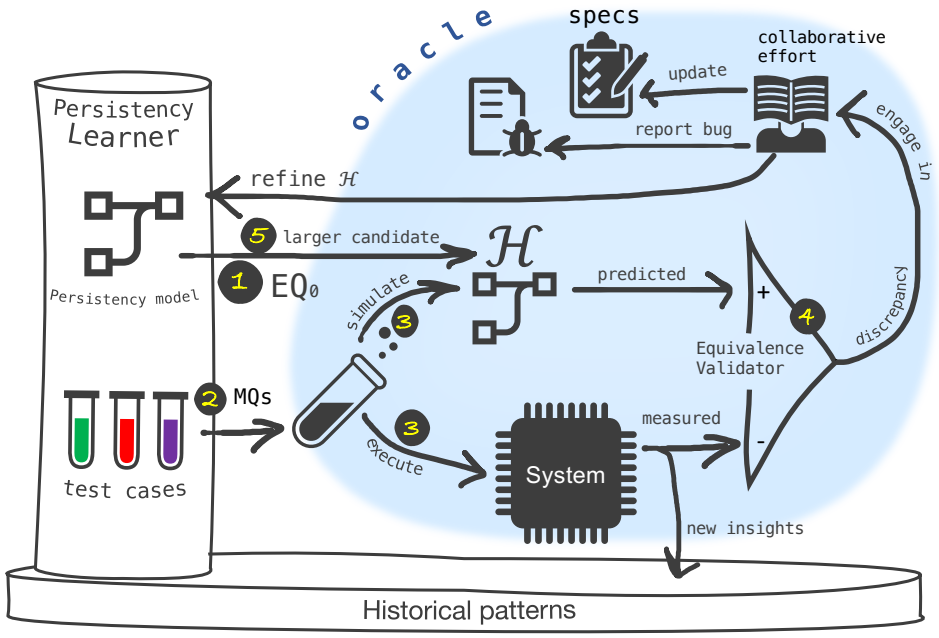

Figure 3 Cycle of the Model Learning Process for Persistency Semantics.

4.1 Persistency Model Learning in Action

The interaction between the learner and the oracle follows a systematic cycle, illustrated in Figure 3. To explore this process, consider a program P with two consecutive writes: $x \leftarrow 1$ followed by $y \leftarrow 1$. Following a crash and recovery, the values of x and y may vary, and the state $x = 0$ and $y = 1$ could appear, even though this state is never observable during normal execution. This inconsistency presents an opportunity for the model learner to refine its hypothesis about write persistency.

To reason about the persistency of writes in this example, we use a toy model built around the concept of a *persist buffer*. This buffer serves as an abstraction that captures the intermediate state of writes that are not yet persisted but are still available within the volatile memory hierarchy. The model incorporates the following elements:

- *Writes:* $w \in W$, where W is the set of all writes executed by the program.
- *Program Order:* The relation $\preceq_{po}$ captures the sequential order of writes in P, where $w_i \preceq_{po} w_j$ means w_i appears before w_j in the program.
- *Persist Buffer:* $\mathcal{B} = (w_1, w_2, \ldots, w_n)$, the ordered sequence of writes currently in the persist buffer, where $w_i \in W$ and $w_i \prec_{pb} w_j$ if write w_i occurs before w_j in the order within the buffer.
- *Persistence States:* A write w can be in one of two states:

$$\mathcal{P}(w) = \begin{cases} w^{\mathcal{P}} & \text{if } w \text{ has been persisted (written to persistent memory)} \\ w^{\mathcal{B}} & \text{if } w \text{ is still in the persist buffer (non-persistent)} \end{cases}$$

  Alternatively, we may use $w^{\neg\mathcal{P}}$ to denote $w^{\mathcal{B}}$.
- *Buffer Transitions:* A transition $\mathcal{B}^{(i)} \xrightarrow{w} \mathcal{B}^{(i+1)}$ represents a change in the contents of the persist buffer $\mathcal{B}$ when write $w \in W$ occurs, resulting in a new buffer state $\mathcal{B}^{(i+1)}$. The exact transformation is defined by specific persistence rules.

- *Crash and Echo Recovery:* X_{echo} represents a "soft crash" simulated using our non-invasive echolocation technique. Instead of a physical crash, this step involves probing the system using timed memory loads to infer the likely location (and thus persistence state) of relevant variables. It approximates the outcome of a crash-recovery cycle without disrupting the system. The specific mechanism for interpreting these probes is detailed in Section 6.

Initially, the model assumes that all writes are persisted immediately upon execution. This is captured by the following invariance rule for the persist buffer:

Immediate Persistence

$$\forall w \in W,\ \mathcal{B}^{(i)} \overset{w}{\hookrightarrow} \mathcal{B}^{(i)}$$

This simplistic assumption sets the stage for the learner to iterate and refine its understanding of the persistency model. The learning process unfolds as follows, with the numbering matching that in Figure 3:

1. **Initial Hypothesis:** The learner begins with the simplest hypothesis, assuming immediate persistence. This predicts $x = 1$ and $y = 1$ post-crash. The hypothesis is submitted as an *Equivalence Query (EQ)* to the oracle, which tests it against the actual System Under Learning (SUL).
2. **Targeted Test Case Generation:** To refine its understanding, the learner generates a test case (a Membership Query, MQ) to probe the system's crash recovery behaviour. The test involves executing a sequence of operations followed by the echolocation probe:

   $$\mathrm{TQ}_i : (x \leftarrow 1;\ y \leftarrow 1;\ \mathsf{X}_{echo})$$

   The effectiveness of echolocation hinges on using carefully constructed, simple test cases like TQ_i. For validating persistency semantics, we employ litmus tests which are kept intentionally small, typically involving only a few memory accesses and persistence-related instructions (flushes, fences). The echolocation probe (X_{echo}) is strategically placed *after* the sequence of operations whose outcome needs assessment, representing the timed load measurements for relevant variables (here, x and y). Complexity in these test cases must be minimised to avoid introducing extraneous micro-architectural effects that could obscure the primary latency signal related to data location. Echolocation is therefore suited for targeted microbenchmarks designed to probe specific persistency interactions, not for direct timing analysis within complex application code.
   The test case TQ_i is submitted as an MQ to observe the actual system behaviour as interpreted through the echolocation probe.
3. **Oracle Feedback:** The oracle executes the MQ on the SUL. Using the X_{echo} probe mechanism (detailed in Section 6), it determines the persistence state of the variables. Suppose the oracle concludes from the probes that x was non-persistent at the time of the simulated crash, while y was persistent. This translates to an observed 'recovered' state of $x = 0, y = 1$, which contradicts the learner's initial hypothesis. This counterexample (the test trace TQ_i and its observed outcome) is returned to the learner.
4. **Discrepancy Analysis and Model Refinement:** The learner revises its hypothesis to account for asynchronous persistence, acknowledging that writes pass through the persist buffer before being persisted, with reordering possible. The updated rule is expressed as follows:

Relaxed Persistence

$\forall w \in W,\ \mathcal{B}^{(i)} \overset{w}{\hookrightarrow} \mathcal{B}^{(i+1)}$ where $\mathcal{B}^{(i+1)} = \mathcal{B}^{(i)} \cup \{w\}$ and $\forall w' \in \mathcal{B}^{(i)}, w' \prec_{pb} w$

This rule accounts for the transient nature of writes in the persist buffer, allowing them to remain temporarily before being committed to persistent storage, with the persistence order potentially non-deterministic.

To accommodate controlled operations that enforce the immediate persistence of specific writes, the model is further refined with a dedicated rule for explicit flushes:

Explicit Flush Handling

$\forall w \in W$ where w modifies x and $w \preceq_{po}$ `CLFLUSH` x, `CLFLUSH` $x \implies w^{\mathcal{P}}$

5. **Iterative Hypothesis Testing:** The learner continues generating test cases (MQs or as part of EQs) to challenge the updated model. For instance:

   $\text{TQ}_{i+1} : (x \leftarrow 1;$ `CLFLUSH` $x;\ y \leftarrow 1;\ \mathsf{X}_{echo})$

   This test case examines whether the system flushes x to persistent memory before the write to y occurs. If the X_{echo} probe (following $y \leftarrow 1$) leads the oracle to conclude that x is persistent but y is not, the inferred recovered state would be $x = 1, y = 0$.

4.2 Algorithmic Implementation of Persistency Learning

Algorithm 3 outlines the iterative learning process at a high level, highlighting the roles of Membership Queries (MQs), Equivalence Queries (EQs), and the echolocation probe (X_{echo}). The algorithm addresses several practical considerations in model learning. It establishes explicit termination conditions through *maxIterations* and *convergenceThreshold* parameters. This ensures the learning process eventually terminates, even when a perfect model cannot be achieved due to system complexity or non-determinism. The *errorRate* tracking provides a quantitative measure of model quality, calculated as the proportion of test cases where the model's predictions differ from observed outcomes. Central to our approach is the *observationTable* T, which serves as a structured knowledge repository mapping test sequences to their observed outcomes. This table plays a crucial role in both generating test sequences for equivalence queries and constructing refined hypothesis models. The learning process has two distinct phases:

1. *Equivalence Query Phase*: The algorithm generates test sequences based on the current hypothesis and observation history. Each test is augmented with the echolocation probe and executed on the System Under Learning. Discrepancies between predicted and observed outcomes are collected as counterexamples. If no counterexamples are found, the current hypothesis is accepted as equivalent to the target model.
2. *Hypothesis Refinement Phase*: When counterexamples are found, the algorithm selects the most informative one to guide the generation of targeted membership queries. These queries explore specific aspects of the system's behaviour revealed by the counterexample. Results from these queries update the observation table, which is then used to construct a new hypothesis model.

The *HypothesisModel* H maintains rich state, tracking the abstract persist buffer content and the status of writes ($w^{\mathcal{P}}$ or $w^{\mathcal{B}}$). The *observed_outcome* and *predicted_outcome* represent the inferred set of persisted variable states (e.g., $x = 0, y = 1$) after a test sequence. The refinement process involves updating H's internal representation of buffering and persistence rules based on the observed outcomes stored in the observation table. This algorithm strikes a balance between theoretical soundness and practical applicability, accommodating the inherent challenges in learning models of complex persistency semantics in real-world systems.

Algorithm 3 Persistency Model Learning with Echolocation.

Require: SUL (System Under Learning, provides Oracle access)
Require: *maxIterations* (maximum learning iterations)
Require: *convergenceThreshold* (acceptable error rate)
Ensure: *HypothesisModel* H approximating SUL's persistency behaviour

Initialise H (e.g., based on "Immediate Persistence" rule)
Initialise *observationTable* $T \leftarrow \emptyset$ *// Explicitly define knowledge structure*
$iteration \leftarrow 0$
$errorRate \leftarrow 1.0$
while $iteration < maxIterations$ **and** $errorRate > convergenceThreshold$ **do**
// – Equivalence Query Phase –
  Generate test sequences T_{EQ} based on current H and *observationTable* T
  $counterexamples \leftarrow \emptyset$
  $totalTests \leftarrow 0$
  for each test sequence $t \in T_{EQ}$ **do**
    $t_{probe} \leftarrow t\,;\, \mathsf{X}_{echo}$ *// Append echolocation probe*
    $observed_outcome \leftarrow \text{Oracle}(SUL, t_{probe})$ *// Execute on SUL, interpret* X_{echo} *results (Sec 6.3)*
    $predicted_outcome \leftarrow H.\text{predict}(t)$
    $totalTests \leftarrow totalTests + 1$
    if $observed_outcome \neq predicted_outcome$ **then**
      $counterexamples \leftarrow counterexamples \cup \{(t, observed_outcome)\}$
  $errorRate \leftarrow |counterexamples|/totalTests$
  if $counterexamples = \emptyset$ **then**
    return H *// No discrepancies found*
// – Hypothesis Refinement Phase –
  Select most informative counterexample $ce = (t_{ce}, obs_{ce})$ from *counterexamples*
  Generate targeted Membership Queries Q_{MQ} based on ce and *observationTable* T
  for each query sequence $q \in Q_{MQ}$ **do**
    $q_{probe} \leftarrow q\,;\, \mathsf{X}_{echo}$
    $mq_outcome \leftarrow \text{Oracle}(SUL, q_{probe})$
    $T \leftarrow T \cup \{(q, mq_outcome)\}$ *// Update observation table*
  $H_{new} \leftarrow \text{constructHypothesis}(T)$ *// Build model from observation table*
  $H \leftarrow H_{new}$
  $iteration \leftarrow iteration + 1$
return H with annotation of achieved *errorRate*

5 Modelling Formalism

To formally model the complex interactions between concurrency, memory consistency, and NVM persistence guarantees, we adopt *Event Structures* [44]. This formalism provides a natural and expressive framework well-suited to the challenges of reasoning about persistency semantics, as detailed below.

5.1 Rationale for Choosing Event Structures

Event Structures [44] provide a principled foundation for modelling persistency for several key reasons:

True Concurrency and Causal Dependencies. Unlike interleaving models that artificially serialise concurrent operations, Event Structures directly represent concurrency through partial orders (*causality*) and mutual exclusion (*conflict*). This approach naturally captures non-total orderings inherent in weak memory models, particularly the complex interactions between memory operations, flushes, and fences in persistent memory systems.

Explicit Persistency Constraints. The core relations in event structures – causality, conflict, and concurrency – provide a natural framework for encoding the fine-grained behaviours specific to non-volatile memory systems. Causal dependencies represent ordering enforced by barriers, while conflict relations precisely capture requirements such as write persistence ordering (e.g., the "sfence" or dependent flush[1]), preventing executions that violate persistence rules.

Compositionality. Persistency guarantees operate at multiple levels of abstraction. Event Structures support modular reasoning, allowing models of individual instructions or components to be composed without needing a monolithic global state representation. This compositionality is essential for scaling verification to complex systems.

Leveraging these strengths, the next section provides our customised definition of *Persistent Event Structures*, tailored to the specifics of NVM operations and drawing parallels to concrete instruction sets like Intel x86 where relevant.

5.2 Persistent Event Structures

▶ **Definition 1** (Persistent Event Structure). *A* persistent event structure *for a program P over a set of persistent memory locations X and values V is defined as a tuple: $\mathcal{E}_P = (E, T, \theta, \preceq_{po}, \preceq_{hb}, \#, \succ_{rf}, \lambda)$, where:*

- *E is a finite set of events representing atomic memory operations;*
- *T is a set of threads, each executing a sequence of events;*
- *$\theta : E \to T$ maps each event to its issuing thread;*
- *$\preceq_{po} \subseteq E^2$ is the program order, a disjoint union of strict total orders on events within each thread. Specifically, for any $a, b \in E$, if $a \preceq_{po} b$, then $\theta(a) = \theta(b)$, meaning both events occur within the same thread. This relation enforces a sequential ordering of events within each thread.*
- *$\preceq_{hb} \subseteq E^2$ is the happens-before relation, a partial order (transitive, irreflexive, and antisymmetric) that extends program order ($\preceq_{po} \subseteq \preceq_{hb}$) and captures synchronisation effects across threads;*
- *$\# \subseteq E^2$ is the conflict relation, which captures mutual exclusivity between events that cannot occur together in the same execution due to resource contention (such as conflicting reads or writes to the same variable). The relation is irreflexive, symmetric and upward-closed with respect to happens-before order: $\forall e, e' \in E, e \# e' \wedge e \preceq_{hb} e_1 \wedge e' \preceq_{hb} e'_1 \Rightarrow e_1 \# e'_1$.*

[1] "Dependent flush" refers to the common pattern where the persistence guarantee of an asynchronous flush like `CLFLUSHOPT` or `CLWB` is made effective relative to subsequent code via an ordering instruction like `SFENCE`.

- $\succ_{rf} \subseteq E^2$ *is the resulting-from relation, where* $r \succ_{rf} w$ *means that the value read by event* r *was written by event* w*. This relation links each read operation to the specific write that provided its value.*
- $\lambda : E \to \mathcal{A}$ *labels each event with a memory operation from alphabet* $\mathcal{A}$*.*

The alphabet $\mathcal{A}$ of memory operations is structured hierarchically:

1. **Basic Memory Operations:**
   - *Initialisation Operation* $\mathbb{0}$, representing the initialisation of all locations in persistent memory appeared in the program, typically setting them to 0.
   - *Read Operations* $R = \{\mathtt{R}_x^v \mid x \in X, v \in V\}$, where $\mathtt{R}_x^v$ denotes reading the value v from x.
   - *Write Operations* $W = \{\mathtt{W}_x^v \mid x \in X, v \in V\} \cup \{\mathbb{0}\}$, where $\mathtt{W}_x^v$ denotes writing v to x, and $\mathbb{0} = \{\mathtt{W}_x^0 \mid x \in X\}$ represents the initialisation of all locations to zero. All writes are durable, meaning their effects *may* be observed after system recovery.
   - *Read-Modify-Write Operations* $RMW = \{\mathtt{RMW}_x^f \mid x \in X, f \in F\}$ denotes atomic updates to x using the function f. These operations atomically read the value of x, modify it using f, and write the result back to x, ensuring no interference from other threads during execution. Common atomic operations in Intel architectures include:
     - `lock xadd`: Atomic fetch-and-add. Adds a value to x and returns its previous value.
     - `lock cmpxchg`: Atomic compare-and-swap. Compares x with a specified operand and updates x if they match.
     - `lock or/and`: Atomic bitwise OR/AND. Performs a bitwise OR/AND operation on x.
     - `lock add`: Atomic addition. Adds a value to x and stores the result atomically.
2. **Synchronisation Operations:**
   - *Memory Fence* (FE_{mem}) ensures all preceding memory operations (loads and stores) complete before any subsequent ones. In Intel architectures, this is enforced via the `MFENCE` instruction.
   - *Store Fence* (FE_{store}) guarantees that all previous store operations complete before any subsequent stores. This is implemented in Intel architectures via the `SFENCE` instruction.
3. **Persistency Operations:**
   - *Regular Flush* $FL = \{\texttt{flush}\ x \mid x \in X\}$ writes back the cache line containing x to memory, ensuring that all pending writes to that cache line are asynchronously persisted. In Intel architectures, this is implemented via the `CLFLUSH` instruction.
   - *Optimised Flush* $FL_{opt} = \{\texttt{flushopt}\ x \mid x \in X\}$ also flushes the cache line containing x. However, it imposes different ordering constraints: a `flushopt` x operation is ordered only with respect to earlier writes to the same cache line; in contrast, a `flush` x operation is ordered with respect to all writes, regardless of their cache line. In Intel architectures, this functionality is provided by the `CLFLUSHOPT` instruction.
   - *Write Back* $WB = \{\texttt{wb}\ x \mid x \in X\}$ behaves like `flushopt` x but provides better performance; both persist the cache line of x, but `flushopt` x invalidates it, whereas `wb` x may retain it for reuse. Implemented in Intel architectures via the 'CLWB' instruction.

We define $W^{\mathcal{P}} \subseteq W$ as the subset of writes that have reached persistent memory. The initialisation is always persistent: $\mathbb{0} \in W^{\mathcal{P}}$.

The complete event alphabet is therefore:

$$\mathcal{A} = \underbrace{\{\mathbb{0}\} \cup R \cup W \cup RMW}_{basic\ memory\ operations} \cup \underbrace{\{FE_{mem}, FE_{store}\}}_{fences} \cup \underbrace{\{FL, FL_{opt}, WB\}}_{persist\ operations}$$

Refining the previously defined *resulting-from* relation over the event alphabet, we have:

$$R \times W \ \supseteq\ \succ_{rf} = \{(\mathtt{R}^v_x, \sigma) \mid x \in X, v \in V, f \in F, \sigma \in \{\mathbb{0}, \mathtt{W}^v_x, \mathtt{RMW}^f_x\}\}$$

meaning:

- $\mathbb{0}$ justifies reading *zero* from any location x;
- a write of v to x justifies reading v from x.

A refinement of the *program order* is the *adjacent program order* relation, $\preceq_{adj} \subseteq \preceq_{po}$, which captures the adjacency of events within the same thread. Formally, it is defined as:

$$a \preceq_{adj} b \iff a \preceq_{po} b \wedge \forall c \in E, (a \preceq_{po} c \wedge c \preceq_{po} b) \Rightarrow (c = a \vee c = b)$$

In other words, two events a and b are adjacent in the program order if there is no event c such that $a \preceq_{po} c \preceq_{po} b$ except for a and b themselves.

Events that are neither ordered by *happens-before* nor in *conflict* are considered concurrent. To formally capture the independence of events across different threads, we define the *concurrency* relation, denoted $\|$, as follows:

$$e_1 \parallel e_2 \iff \theta(e_1) \neq \theta(e_2) \wedge \neg(e_1 \preceq_{hb} e_2) \wedge \neg(e_2 \preceq_{hb} e_1) \wedge \neg(e_1 \# e_2).$$

The following example illustrates the application of event structures in this context.

Illustrative Example. Consider two concurrent processes, P_1 and P_2 (Figure 4), running on an Intel x86 architecture and interacting with the shared variable `ingredients`.

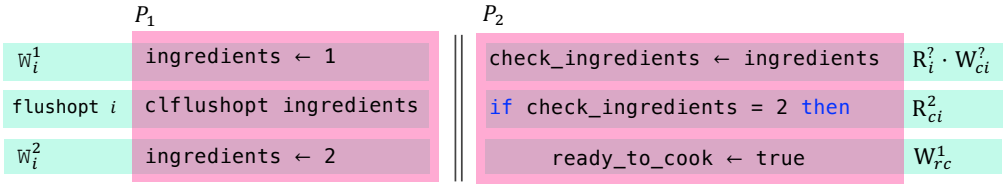

Figure 4 A 2-thread toy persistent program.

A natural expectation is that if `ready_to_cook` is `true`, then `ingredients` should be 2. However, due to the buffered persistence model of Px86, a crash and recovery may result in a state where `ready_to_cook` ← `true` persists while `ingredients` ← `2` does not.

The instruction `clflushopt ingredients` invalidates the cache line containing `ingredients` across the coherence domain, ensuring all cores either discard or update the cached copy. However, it does not enforce immediate persistence and may be reordered with later stores. Because of this, it is possible for the following sequence of events to occur:

1. P_1 writes `ingredients` ← `1` followed by `ingredients` ← `2`, but these updates remain in the cache and have not yet persisted.
2. P_2 reads `ingredients = 2`, sets the local variable `check_ingredients` to 2, and subsequently `ready_to_cook` ← `true`, with the latter being successfully persisted to memory.

3. Before P_1 executes `clflushopt ingredients`, the system crashes. As a result, the *persistent state* upon recovery can have:[2]

$$\texttt{ready_to_cook = true} \quad \wedge \quad \texttt{ingredients} = 0 \tag{1}$$

contradicting the program's expected logic: `ready_to_cook` $\implies$ `ingredients = 2`. This counterintuitive behaviour can, however, be avoided by using the stricter `clflush` instruction instead of `clflushopt`, as `clflush` prevents reordering with respect to any writes.

Representing persistent program behaviour with Event Structures. The semantics of a persistent event structure can be visualised using a directed acyclic graph. In the program shown in Figure 4, each instruction is mapped to a modelled *action*, highlighted next to it. These actions represent reads, writes and flushes in the program. Figure 5 (left) depicts the semantics of the concurrent execution of P_1 and P_2 as an event structure graph, where solid edges show *happens-before* order, dashed edges indicate *resulted-from*, and saw-like edges denote conflicts. When the right thread P_2 reads the value 2 from `ingredients`, which was written by the left thread P_1, P_1 passes a message to P_2. Under the Intel-x86 architecture, message passing ensures that the instruction writing the message ($\mathtt{W}_i^2$) is executed and ordered before the corresponding read instruction ($\mathtt{R}_i^2$) in P_2. This ordering is implicitly captured by the *resulted-from* relation, which links reads to their corresponding writes.

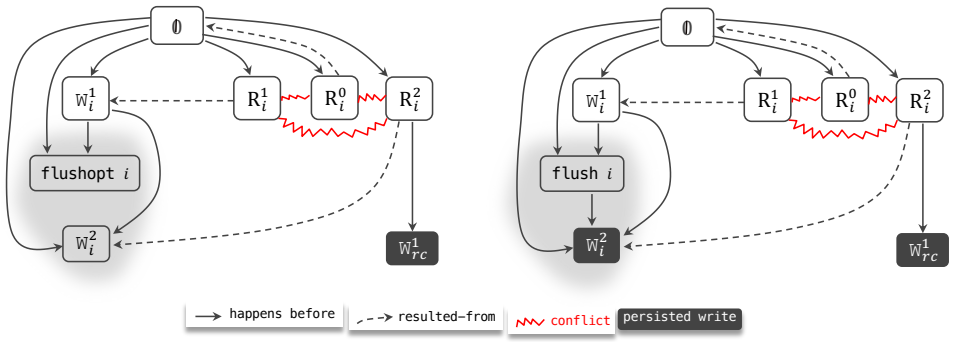

Figure 5 Event Structure semantics for the program in Figure 4, illustrating the *happens-before* relation with `flushopt` (left) and `flush` (right). The affected region of the graph is shaded to indicate where the changes occur.

Replacing `flushopt` i with `flush` i enforces a stricter *happens-before* ordering by introducing an additional edge from `flush` i to $\mathtt{W}_i^2$. As a result, this guarantees that whenever $\mathtt{R}_i^2$ is executed, i has already been persisted.

5.3 Alloy Encoding

We encode the semantics of persistent event structures using the Alloy modelling language [20], a declarative framework that expresses systems as relational structures. This encoding facilitates the analysis of program behaviour under diverse memory access patterns. The model is structured into a set of entities, each representing a distinct aspect of memory

[2] Upon recovery, the possible values are: `ready_to_cook` $\implies$ `ingredients` $\in \{0, 1, 2\}$, which accounts for all potential states.

semantics. Figure 6 illustrates the hierarchical relationships between these entities and their interconnections within the event structure. The corresponding Alloy code defining these entities is provided in Listing 1.

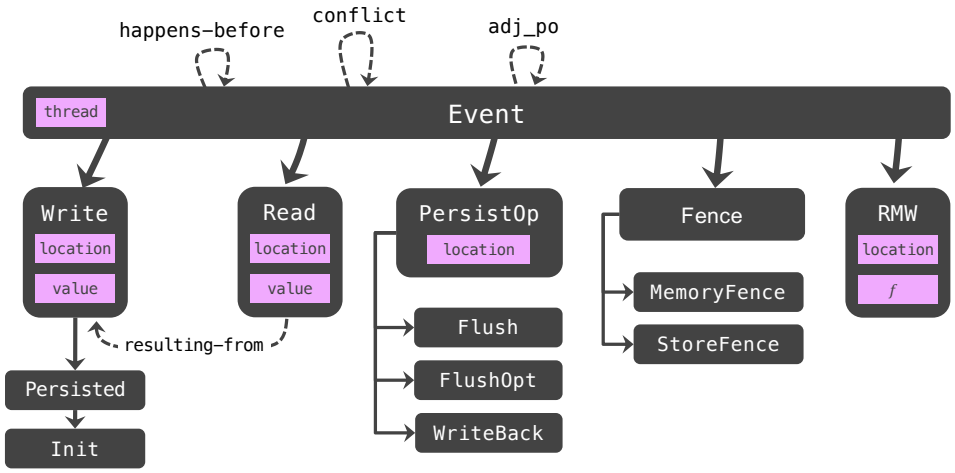

Figure 6 Hierarchical structure of entities (signatures) encoded in Alloy: black boxes represent memory operation events, with solid arrowed lines indicating inheritance. Coloured boxes represent relations that map the events within the outer black boxes to the corresponding entity indicated by the coloured box. Dashed arrow-headed lines denote event-to-event relationships.

Listing 1 Alloy specification for memory model.

```
abstract sig Thread {}
abstract sig Event {
    thread   : some Thread,
    adj_po   : set  Event,
    hb       : set  Event,
    conflict: set  Event,
    rf       : lone Event
}
sig Location {}
sig Write extends Event {
    location: set Location,
    value   : one Int
}
sig Read extends Event {
    location: one Location,
    value   : one Int
}
sig RMW, Fence extends Event {}
sig MemoryFence, StoreFence extends Fence {}
sig PersistOp extends Event {
    location: one Location
}
sig Flush, FlushOpt, WriteBack extends PersistOp {}
sig Persisted in Write {}
one sig Init in Persisted {}
```

In Alloy, memory events are defined as signatures, introducing new types in the model. The `Event` signature serves as the supertype, with specialised event types extending it via the `extends` keyword. Events are structured through relations that link their attributes to other entities (e.g., `Read` $\xrightarrow{rf}$ `Write`) or within the same entity (e.g., `Event` $\xrightarrow{hb}$ `Event`). These relationships are further constrained using facts – axiomatic formulae that Alloy assumes to be always true, shaping the space of possible examples and counterexamples generated by the Alloy analyser. For instance, to enforce that the relation *adjacent program order* (`adj_po`) applies only within the same thread, the following fact is defined:

Listing 2 An Alloy `fact`.

```
fact ProgramOrderScoped {
    all e1, e2: Event | e1 -> e2 in adj_po implies e1.thread = e2.thread
}
```

To illustrate how our Alloy model is executed to generate concrete instances, consider the following `pred`icate, `volatile`. It expresses conditions under which a write `w` could be considered volatile when event `e` occurs. The Alloy analyser systematically explores the model to find instances satisfying this predicate, revealing concrete memory event orderings that meet these constraints.

Listing 3 Checking volatility conditions in memory events.

```
pred volatile[w: Write, e: Event] {
    /* No Flush operation on the same location precedes e in the happens-before
       relation */
    no f: Flush | f.location = w.location and f -> e in hb
    /* No FlushOpt or WriteBack operation on the same location precedes w in hb
     * with a Fence event occurring between them */
    no f: FlushOpt + WriteBack, fence: Fence |
        f.location = w.location and f -> fence in hb and fence -> e in hb
}
```

By executing Alloy's `run` command with this predicate, we generate concrete executions that reveal scenarios where a write remains volatile. The analyser constructs instances that adhere to the specified constraints. One such instance, discussed in Figure 5, satisfies the `volatile` predicate and can be obtained by executing the following command, which explores possible executions within a bounded model of 7 events, 2 threads, and 3 memory locations:

```
run { some w: Write, e: Event | volatile[w, e] } for 7 Event, 2 Thread, 3 Location
```

6 Implementation and Feasibility Demonstration

As a foundational step, we developed a time-based measurement framework designed to explore memory access patterns, inspired by echolocation principles. This initial framework leverages high-resolution timestamps to analyse memory fetch latencies, enabling the identification of subtle timing variations. Central to this is the CPU's Time Stamp Counter (TSC), which provides the high-resolution timings necessary to observe micro-level memory access variations.

6.1 Measurement Technique

Our preliminary implementation, used to generate the latency data shown in Figure 7 and Table 1, employs a microbenchmark written in C (available at DOI 10.5281/zenodo.15045528). The core measurement technique involves timing individual memory load operations using the TSC. Specifically, we utilise the `rdtscp`[3] instruction, accessed via inline assembly, to obtain cycle counts immediately before and after the target memory load operation (e.g., `sum += array[i]` in our benchmark code).

[3] *Read Time-Stamp Counter and Processor ID* is an assembly instruction available on x86 processors that retrieves the current value of the CPU's time-stamp counter (TSC) along with the processor ID. This instruction offers a high-resolution timing mechanism often used for performance monitoring and benchmarking, and is partially serializing.

To prevent the compiler from optimising away the timed memory load, the target memory array (`array`) and the variable accumulating the result (`sum`) are declared `volatile`. Memory for the array is allocated using `posix_memalign` to ensure 64-byte alignment, minimising potential variations due to unaligned accesses.

The elapsed cycle count (end cycles - start cycles) for each load is then converted into nanoseconds. This conversion uses the CPU's clock frequency, which is determined dynamically at the start of the benchmark by parsing the 'cpu MHz' field from `/proc/cpuinfo` on the Linux test system. We acknowledge this frequency detection method is specific to the Linux environment.

In the specific experiment designed to populate the latency distribution (Figure 7), each timed load access to an array element `array[i]` was preceded by a write to that element and an explicit `clflush` instruction (also invoked via inline assembly) targeting its cache line. This was done to ensure that the subsequent timed load would likely fetch data from deeper levels of the memory hierarchy (e.g., L3, WPQ, DRAM) rather than potentially hitting in L1/L2 caches, allowing us to observe the full spectrum of access latencies. The benchmark performs numerous such timed accesses across a large memory region and repeats the entire measurement process multiple times. Individual nanosecond latency measurements are recorded (written to a CSV file in our implementation) to allow for detailed statistical analysis and visualization.

6.2 Feasibility Results

Our tests, carried out on an Intel® Xeon® E-2286G CPU (4.00 GHz, 14 cores) running Linux kernel version 4.18.0 on Red Hat Enterprise Linux 8, demonstrated that we could differentiate memory access latencies across various hierarchical levels based on these measurements. In Figure 7, we present a distribution plot based on approximately 25 million memory fetch operations. The observed latencies ranged from as low as 15 ns for the fastest L1 cache to up to 10,000 ns for the slowest swapped memory on disk. The vertical axis represents the order in which these memory accesses occurred, serving only to visualise the distribution of memory accesses across the entire dataset.

The fetch latencies are clearly segmented into six distinct zones, as highlighted by the shaded regions in the plot and detailed with range values in Table 1. These zones correspond to the hierarchical memory locations of the test system: L1 cache, L2 cache, L3 cache, Write Pending Queue (WPQ), DRAM, and swapped memory. This clear segmentation suggests the potential of our approach in profiling memory access patterns and indicates the reliability of timestamp-based latency measurements for inferring data location.

When measuring memory fetch latencies, the elapsed time includes not only the pure data fetch duration but also several overheads. These include the time required to issue the memory access command, the execution time of the memory access instruction itself, and the small but consistent cost of retrieving timestamps using the `rdtscp` instruction. Additionally, micro-architectural factors, such as cache coherence traffic, prefetcher activity, pipeline effects, resource contention, or cache invalidation caused by instructions like `clflush`, can contribute noise to the measured time. While these overheads and noise sources are present in the absolute measurements, they often remain relatively consistent or manifest as outliers across different fetches under controlled conditions.

For our purpose, which is to differentiate memory access locations within the hierarchy (e.g., cache, write pending queue, DRAM), the absolute latencies are less significant than the relative *differences* and distinct *clusters* observed between fetch times originating from different levels (Figure 7). These large differences tend to cancel out fixed overheads, allowing

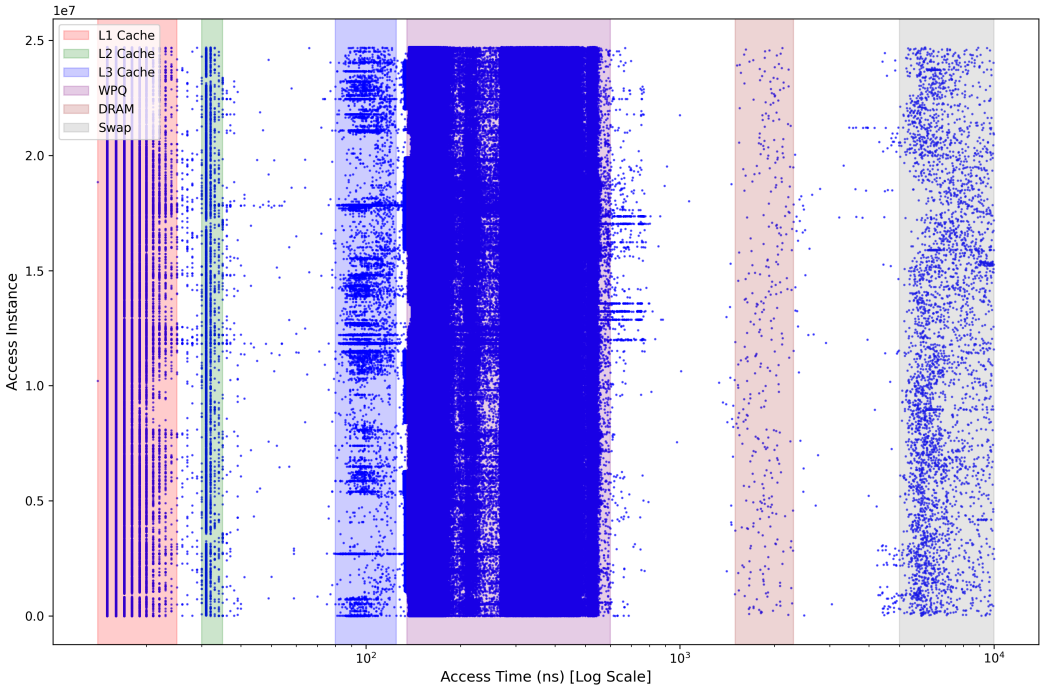

Figure 7 Memory Access Latencies Across Different Levels of the Hierarchy.

Table 1 Latency Ranges and Corresponding Memory Locations. The highlighted rows denote the persistence domain.

Latency Range [ns]	Memory Location	Description
10–25	**L1 Cache**	The closest and fastest memory tier to the CPU (64 KB per core), providing ultra-low latency for frequent data access.
30–35	**L2 Cache**	A slightly larger (256 KB) but slower memory cache near the CPU core, designed for rapid access to recently used data.
75–125	**L3 Cache**	A shared cache among multiple CPU cores, larger in size (12 MB) but slower due to increased complexity in access and coordination.
150–500	**Write Pending Queue (WPQ)**	A battery-backed buffer where data becomes persistent before it leaves the processor.
1500–2300	**Main Memory (DRAM)**	Represents direct access to DRAM, where latency is higher due to physical distance and slower access times compared to cache memory.
5000–10000	**Cached/Prefetched Swap Pages** and **Fully Swapped Memory on HDD**	Encompasses memory pages swapped to disk. Cached or prefetched pages (lower latency) are in RAM, while fully swapped pages (higher latency) require physical disk access.

us to reliably identify the memory hierarchy level from which the data is being fetched based on its characteristic latency range. This approach ensures that variations in fetch latencies used for inference are primarily attributable to the memory location itself rather than extraneous factors, although careful statistical analysis and threshold selection (see Section 8) are needed to handle ambiguity.

6.3 Application to Persistence Validation

The core idea of using echolocation for validation is to map the measured memory load latencies, discussed in the previous subsection, to an inferred persistence state for a given write. This allows us to approximate the outcome of a crash-recovery cycle non-invasively.

▶ **Definition 2** (Inferred Persistence State from Latency). *Let $L(w)$ be the latency measured by the echolocation probe for write w. Let $\mathcal{T}_{PD}$ be the experimentally determined minimum latency threshold indicating entry into the persistence domain, derived from the observed latency ranges (Table 1). On our test machine, $\mathcal{T}_{PD} \approx 150\,ns$, corresponding to the lower bound of WPQ access times. We define the inferred persistence state function $\hat{\mathcal{P}}$ as:*

$$\hat{\mathcal{P}}(w) = \begin{cases} w^{\mathcal{P}} & \text{if } L(w) \geq \mathcal{T}_{PD} \quad \textit{(Inferred Persistent)} \\ w^{\mathcal{B}} & \text{if } L(w) < \mathcal{T}_{PD} \quad \textit{(Inferred Non-Persistent)} \end{cases}$$

Crucially, to mitigate potential misinterpretation due to measurement noise near the threshold (as discussed in Section 8), we adopt a conservative approach when selecting $\mathcal{T}_{PD}$: it is aligned with the upper bound of non-persistent latency clusters plus a safety margin. This prioritises soundness (avoiding false positives for persistence). The oracle function within the model learning algorithm (Algorithm 3) uses this mapping $\hat{\mathcal{P}}$, based on the conservatively chosen $\mathcal{T}_{PD}$, to determine the definitive $w^{\mathcal{P}}$ or $w^{\mathcal{B}}$ state contributing to the observed_outcome from the raw latencies measured during the X_{echo} step.

With this mapping (Definition 2) established, we can validate correctness conditions required after a potential crash. For example, consider the litmus test from Figure 4 and its instrumented version in Figure 8. The expected post-crash condition is:

$$\texttt{ready_to_cook} \implies \texttt{ingredients} \in \{0, 1, 2\} \tag{2}$$

Validation of this condition relies on determining the state of `ready_to_cook` after the program sequence. Our approach uses the X_{echo} probe (executed after the write `ready_to_cook == true` in Figure 8) to measure $L(\texttt{ready_to_cook})$. The Oracle then applies Definition 2:

$$\text{if } \; L(\texttt{ready_to_cook}) \geq \mathcal{T}_{PD}, \; \text{ then } \; \hat{\mathcal{P}}(\texttt{ready_to_cook}) = \texttt{ready_to_cook}^{\mathcal{P}}$$

and the condition (Equation (2)) must hold for the validation to pass. Figure 8 illustrates how this check, driven by the echolocation-derived status, is conceptually embedded in the validation logic.

P_1

```
ingredients ← 1
clflushopt ingredients
ingredients ← 2
```

P_2'

```
check_ingredients ← ingredients
if check_ingredients = 2 then
    # Instrumentation check for persistence
    latency(ready_to_cook ← true) >= PERSISTENCE_THRESHOLD
          implies  ingredients ∈ {0, 1, 2}
```

Figure 8 Instrumented 2-Thread Program for Persistence Validation.

This implementation demonstrating the echolocation probe and its application concept represents a foundational step. As discussed in Section 10, future work involves implementing the full model learning framework and extending validation to more complex scenarios and diverse hardware.

7 Scope and Applicability

The previous sections introduced memory echolocation as a technique for non-invasively probing data location within the memory hierarchy (Section 6) and framed its use within a model learning cycle for validating persistency semantics (Section 4). This combined approach aims to provide a more robust, adaptable, and hardware-agnostic methodology compared to existing techniques. This section discusses the broader scope and applicability of this approach, particularly concerning different hardware architectures and potential extensions.

Hardware Agnosticism and Generality. A key advantage of our proposed methodology lies in its software-based nature. Unlike hardware bus interception methods, which require physical probes, platform-specific knowledge, and may be hindered by component integration (e.g., on SoCs) or internal buffering (like Intel's WPQ), echolocation relies solely on timing standard memory access instructions. This makes the fundamental probing technique portable across any architecture that provides a sufficiently high-resolution timer accessible from software (such as the TSC on x86, or equivalent counters on ARM, RISC-V, etc.). When coupled with the black-box model learning framework, which adapts based on observed outcomes, the overall approach offers a path towards a unified validation framework applicable across diverse hardware platforms, reducing the need for architecture-specific tooling.

Applicability to ARM Systems. While the challenge of the WPQ makes software-based validation particularly appealing for Intel x86, the echolocation technique offers significant advantages for ARM architectures as well:

- **Non-Invasiveness and Accessibility:** Echolocation avoids the cost, complexity, and potential physical impossibility of hardware bus probing, which is especially relevant for highly integrated ARM-based Systems-on-Chip (SoCs) commonly found in mobile, embedded, or IoT devices where physical access might be limited or impractical.
- **Unified Methodology:** It provides the same validation methodology used for other architectures, simplifying cross-platform testing, comparison, and tool development, rather than requiring different approaches (e.g., software for x86, hardware probes for ARM).
- **Future-Proofing:** As ARM architectures evolve, particularly in server or high-performance domains, they may incorporate more complex cache hierarchies, memory controllers with internal buffering, or technologies like CXL, potentially obscuring the exact persistence boundary from external probes, similar to the WPQ issue. Echolocation, being software-based, remains applicable regardless of these internal complexities.
- **Complementary Insights:** Even on ARM systems where bus snooping might be feasible, echolocation provides timing data reflecting the state *before* data necessarily reaches an externally snoopable point. This can offer complementary insights into buffering or ordering effects internal to the CPU core, cache hierarchy, or SoC interconnect.

Therefore, the motivation for using echolocation on ARM extends beyond merely bypassing a WPQ-like issue; its non-invasiveness, generality, and accessibility make it a valuable tool for validating persistency on these platforms.

Synergy of Echolocation and Model Learning. The proposed approach leverages the synergy between the two techniques. Echolocation provides the fine-grained, albeit potentially noisy, observational data about memory state transitions without system disruption. Model learning provides the structured framework (inspired by L^*, as discussed in Section 4) to systematically generate test cases (MQs, EQs), interpret the noisy observations from echolocation within the context of a hypothesis, identify discrepancies, and iteratively refine a model of the system's actual persistency behaviour. This allows for uncovering subtle or undocumented behaviours that might be missed by static analysis or purely hardware-based methods.

Potential for Broader Application. While this paper focuses on validating NVM persistency semantics, the underlying principles might be adaptable. The ability to infer data location in the memory hierarchy via timing could potentially be applied to study cache behaviour, coherence protocol actions, or even aspects of memory consistency, although these applications would require careful calibration, different instrumentation strategies, and potentially more sophisticated analysis techniques to deconvolve timing effects. These remain interesting avenues for future exploration.

Despite its promise, this methodology is not without challenges. The accuracy of echolocation can be affected by micro-architectural noise, and the completeness of model learning depends on the quality of test generation and the ability to explore relevant system states. The next section delves into these potential threats to validation and outlines mitigation strategies.

8 Threats to Validation

The proposed validation approach applies echolocation and model learning to systematically analyse persistency semantics. While promising, its robustness, accuracy, and generality must be scrutinised to strengthen its credibility.

8.1 Accuracy of Echolocation as a Proxy for Crash Behaviours

Echolocation is used to approximate memory access patterns occurring during recovery by analysing write echo times. As demonstrated in Figure 7, the access time zones are generally well-segmented for different memory regions. However, very few access times fall ambiguously between these zones, making it difficult to assign them definitively to a specific storage hierarchy. Such ambiguities may lead to misinterpretations of persistency behaviours.

Mitigation. To resolve this, we propose a two-pronged approach. First, *outlier detection* methods, such as the Local Outlier Factor (LOF) [11], can identify and potentially filter anomalous access times likely caused by transient system noise, improving the clarity of latency clusters. Second, to directly address the ambiguity of times falling near zone boundaries, we adopt the conservative threshold selection strategy detailed in Definition 2. By setting the persistence threshold $\mathcal{T}_{PD}$ based on the upper bound of non-persistent levels plus a margin, we explicitly trade off potentially missing some borderline persisted writes (completeness) for increased confidence that inferred persistence is correct (soundness), thus minimising misinterpretations arising from ambiguous timings.

8.2 Coverage of System States and Edge Cases

While the proposed validation approach uses model learning to penetrate the actual system and explore edge cases, some rare or complex execution paths, particularly those that are non-deterministic or timing-dependent, may remain untested, leading to incomplete coverage and potentially missing subtle persistency behaviours.

Mitigation. Our chosen modelling language, Alloy [20], helps mitigate coverage gaps through its exhaustive analysis within bounded scopes. By encoding the persistency semantics (including timing-related constraints where possible via ordering relations) derived from our model learning, Alloy can explore potential interleavings and states, including those leading to non-deterministic outcomes. Its relational logic is adept at exploring configurations that might expose subtle bugs related to concurrency or complex interactions, complementing the execution-based approach of model learning. Prior work [16, 24, 37, 38] confirms its utility in finding subtle memory model issues. Furthermore, the iterative nature of both Alloy model refinement (reacting to discrepancies found during validation) and the overarching model learning cycle (Section 4) helps systematically expand coverage as inconsistencies are uncovered and the model of system behaviour improves.

8.3 Assumptions in the Initial Model Hypothesis

The model learning process, as discussed in Section 4.1, begins with a simplistic initial hypothesis. While this serves as a foundation for systematic refinement, it may inadvertently introduce constraints or assumptions that bias subsequent learning steps. Such biases could narrow the exploration of the state space, leading to an incomplete or inaccurate understanding of the system's persistency semantics.

Mitigation. To minimise initial hypothesis bias, we adopt several strategies. First, the learning process can be initiated with different starting assumptions beyond simple immediate persistence (e.g., hypotheses incorporating relaxed ordering, different buffering behaviours). Second, we explicitly leverage existing formal persistency models from the literature (e.g., Px86 [37], PArm [38]) as initial hypotheses or baselines for comparison during the learning process on relevant platforms. This provides both a sanity check and ensures our learned models are contextualised against established specifications, adding rigor to the validation of our assumptions and conclusions.

Addressing these threats is crucial for realising the full potential of this validation approach. By systematically mitigating these risks, the methodology can be refined to deliver robust insights into persistency semantics across diverse systems.

9 Related Work

Memory Consistency Model Validation. Significant research has focused on empirically validating memory consistency models across architectures such as x86 [5, 41], IBM Power [39], and Arm [3], as well as GPUs [2] and hybrid CPU/FPGA systems [19]. Recent work extends these models to support features like virtual memory [42] and non-temporal accesses [36]. Traditional multi-threaded validation methods, while effective for consistency, struggle to validate *persistency* models, as they cannot distinguish between data retrieved from volatile caches and persistent memory.

Testing Persistent Programs. Tools such as PMTest [29], Pmemcheck [23], and PMAT [22] test persistent programs by embedding assertions to validate memory persistency guarantees dynamically. XFDetector [28] addresses pre- and post-crash instruction interactions, while PMFuzz [27] generates test cases to maximise path coverage, focusing on persistency-related operations. These tools generally rely on vendor-provided architectural specifications to evaluate whether a program violates persistency guarantees.

Event Structures for Modelling Relaxed Memory. The use of Event Structures (ES) to model systems with relaxed memory ordering guarantees has gained significant attention in recent research [13, 14, 21, 35]. These studies highlight the adaptability of ES in reasoning about concurrency, demonstrating their ability to effectively capture the complexities of weak-memory models across a wide range of architectures and scenarios.

Active Model Learning. Several algorithms have been proposed for learning models across different types of automata, as explored in various studies [1,7,10,12,17,31]. These algorithms can extend their capabilities to learning models of complex, distributed systems, including assemblies of communicating automata [9]. The versatility of these approaches makes them well-suited for testing intricate systems and ensuring the accuracy of persistency models.

Timing-Based Inference. Several studies have leveraged hardware performance counters to track memory access locality, primarily in DRAM [8, 26, 30, 33]. Our memory echolocation technique shares closer methodological similarities with CacheQuery [43], which employs timing-based measurements to detect cache side-channel vulnerabilities. However, our approach differs fundamentally in both objective and execution. While CacheQuery focuses on cache hierarchies to uncover security weaknesses, we extend timing-based inference to persistent memory systems, specifically analysing persistency properties rather than information leakage. Moreover, our method accounts for system-specific variations in persistence behaviour across different architectures, addressing challenges such as write-back buffers, ADR domains, and persistence ordering guarantees – factors beyond CacheQuery's security-oriented scope.

10 Conclusion and Future Work

This paper introduced a software-centric methodology aimed at overcoming persistent challenges in validating NVM semantics on real hardware. Our proposed approach uniquely combines fine-grained memory access timing analysis (*echolocation*) with the structured exploration capabilities of active model learning. We presented the core echolocation technique, demonstrating experimentally on an Intel x86 platform its feasibility for non-invasively distinguishing memory hierarchy levels, including the NVM persistence domain, based on load latency signatures. Furthermore, we outlined how these timing probes serve as the essential black-box observation mechanism within a proposed model learning framework, enabling the automated inference of persistency behaviours. While the full integration of the learning component remains future work, this synergistic approach, conceptually underpinned by *Event Structures*, represents a promising direction towards scalable, adaptive, and hardware-agnostic NVM validation.

10.1 Future Work

Adaptive Echolocation: Enhancing Robustness and Accuracy. As highlighted in our discussion of threats (Section 8), precise analysis using echolocation is complicated by inherent noise in modern systems arising from OS jitter, concurrent processes, architectural variability, micro-architectural interference (e.g., prefetchers, coherence traffic), and even thermal effects. To address this, future work will explore adaptive algorithms capable of dynamically adjusting to system state and filtering noise during real-time latency interpretation. Techniques potentially include online statistical filtering, change point detection, or lightweight machine learning models trained to recognise characteristic latency patterns amidst noise. The goal is to significantly improve the accuracy and reliability of inferred persistence states across diverse architectures, including complex emerging systems incorporating technologies like CXL-attached memory. Successfully learning distinctive latency patterns under varying conditions will enhance data residency detection, identify performance anomalies, and allow more confident prediction of memory state transitions.

Learning Event Structure Models of Persistency. Building on our proposed formalisation using Event Structures (Section 5), a key next step is developing algorithms to automatically infer these structures from echolocation observations. The input would consist of execution traces (sequences of operations generated by the learner) paired with their outcomes (inferred persistence states of relevant variables) obtained via the echolocation probe. The core challenge is to learn the specific causal ($\preceq_{hb}$) and conflict (#) relations that accurately model the target system's possibly undocumented or non-deterministic NVM persistency behaviour.

In conclusion, while the proposed approach represents a promising step forward in persistency validation, it is important to acknowledge that it is not a catch-all solution. The complexity and variability of memory subsystems pose ongoing challenges. Continued research will be essential to refining coverage of dynamic memory conditions beyond our current scope.

11 Data Availability Statement

The Alloy model discussed in Section 5.3, along with instructions for running it, is available on Zenodo (DOI 10.5281/zenodo.15045528). Additionally, we provide the fetch latencies plotted in Figure 7, along with the C script used to obtain them.

Contract Systems Need Domain-Specific Notations

Cameron Moy

Matthias Felleisen
PLT @ Northeastern University, Boston, MA, USA

Abstract

Contract systems enable programmers to state specifications and have them enforced at run time. First-order contracts are expressed using ordinary code, while higher-order contracts are expressed using the notation familiar from type systems. Most interface descriptions, though, come with properties that involve not just assertions about single method calls, but entire call chains. Typical contract systems cannot express these specifications concisely. Such specifications demand domain-specific notations. In response, this paper proposes that contract systems abstract over the notation used for stating specifications. It presents an architecture for such a system, some illustrative examples, and an evaluation in terms of common notations from the literature.

1 From General-Purpose to Domain-Specific Notations

Eiffel's contract system assumes that programmers can formulate Boolean expressions to articulate simple pre-conditions and post-conditions for methods [33, 34]. Such expressions suffice to state constraints that quotidian type systems cannot express. Here is an example, from Eiffel's documentation, of a method that sets the `seconds` field of a clock object:

```
set_seconds (s: INTEGER)
  require
     valid_argument_for_seconds: 0 <= s and s <= 59
  do
     seconds := s
  end
```

By monitoring the pre-condition, Eiffel's contract system can signal an error when control enters the method, not after `seconds` has been set and retrieved elsewhere. Eiffel's syntax has `require` and `ensure` keywords that cleanly separate specifications from implementations.

Findler and Felleisen [16] generalize Eiffel's design to modern, higher-order languages with first-class functions and objects. They realize that such a generalization necessitates creating wrappers around behavioral values. Here is the code for checking that a `derivative` function takes real-valued functions to real-valued functions:

```
(define (derivative unsafe-f)
  (define (check-real->real g)
    (lambda (x)
      (check-real (g (check-real x)))))
  (define f (check-real->real unsafe-f))
  (check-real->real (lambda (x) ... compute derivative ...)))
```

Programmers should never read, let alone write, such complex code. Contract systems, such as the one found in Racket [14, 19], therefore supply the familiar notation from type systems to eliminate these awkward and repetitive patterns:

```
(define/contract (derivative f)
  (-> (-> real? real?) (-> real? real?))
  (lambda (x) ... compute derivative ...))
```

In other words, developers may use the `->` notation as a shorthand for the tedious wrappers in the first version. In Eiffel, contract-specific notations are mere conveniences, but here the notation is essential – writing complex higher-order contracts without them is infeasible.

Moy and Felleisen [37] present an extension of higher-order contracts, dubbed *trace contracts*, that can express and monitor properties across multiple function and method calls. The idea looks straightforward: collect a trace of method-call events and check the trace with a functional predicate whenever it is updated.

Consider the HasNext property that Java programmers must respect when they use an iterator: each call to `next` must follow a call to `hasNext` [39]. A typical implementation would equip the class with an extra field to determine whether a violation has occurred:

```
class Iterator {
  private boolean canCallNext = false;

  public boolean hasNext() {
    this.canCallNext = true;
    ... method body ...
  }

  public Element next() {
    if (!canCallNext)
      throw new Exception("HasNext property violated");

    this.canCallNext = false;
    ... method body ...
  }
}
```

Comingling run-time checks with proper functionality in this way is a technique known as *defensive programming*. As Meyer [33, 34] argued long ago, comingling is bad for the person who maintains the implementation, bad for the person who programs to the interface, and bad for the person who wants to implement the interface differently.

By contrast, a contract system brings relief to all three groups. It enables the developer of an *interface* to state contracts for cross-cutting specifications and attach them to concrete implementations. A contract, independent of any particular implementation, confers two critical advantages:

1. Developers can program to interfaces that express constraints explicitly as code.
2. Contracts are compiled to run-time checks that monitor implementations of interfaces, so developers can trust that specification violations are reported in a timely fashion.

```
(provide
  (contract-out [an-iterator-object has-next/c]))

(define has-next/c
  (object-trace/c
   #:satisfies (re (star (seq 'has-next (opt 'next))))
   [has-next (->m boolean?) 'has-next]
   [next     (->m any/c)    'next]))

—— definition of the iterator ——
```

Figure 1 Checking the HasNext Property.

With trace contracts, the creator of an iterator class can express the HasNext property as a contract and gain all the benefits thereof. Figure 1 shows a module that exports an iterator object and, in doing so, attaches a contract that concisely states the HasNext property with the regular expression $(\texttt{hasNext}, \texttt{next}?)^*$ over the alphabet of method names. Other than the usual fully parenthesized syntax of Racket, the regular expression is rendered directly. The use of a problem-specific notation, here regular expressions, clarifies the developer's intent much better than comingled code, and permits the automated construction of dynamic checks. Each method, after the signature given by `->m`, is associated with an *event*. An event is a value to be added to the trace when that method is called. Here, the events are just atomic symbols: `'has-next` and `'next`.

Which brings us to a brave new idea: *contract systems should be abstracted over domain-specific notations for specifications*. In other words, it should be easy to plug in any number of domain-specific specification languages into a contract system. This paper illustrates the idea with *trace contracts* as the enforcement mechanism and a variety of *domain-specific specification languages*, which together yield domain-specific contracts (DSCs). The remainder of the paper describes DSCs and the underlying architecture in detail, shows how it works with a simple example (Section 2), presents a more sophisticated example from a real-world API (Section 3), describes a general plan for implementing DSCs in different host languages (Section 4), and evaluates a Racket implementation of DSCs (Section 5).

2 Domain-Specific Contracts in Action

Many interface specifications employ temporal terminology to constrain sequences of method calls. Consider the MapIterator property from Java's API [40]. This property states that an `Iterator`, created from a `Collection`, which is itself derived from a `Map`, cannot be used *after* the `Map` has been mutated. The word "after" suggests a temporal relationship – a need to look back at whether a mutating method of `Map` has previously been called.

An interface, therefore, should use a matching formal language, such as temporal logic, to state the property. Given that such statements tend to look at past events, Past-Time Linear Temporal Logic (PLTL) [31] is one suitable choice for stating the MapIterator contract. Indeed, the definition of satisfaction for PLTL formulas employs finite traces of past events – just like trace contracts.

PLTL comes with the primitive temporal operators $\bullet\,\phi$ (pronounced "previous") and $\phi\,\mathsf{S}\,\psi$ (pronounced "since"). Otherwise, PLTL looks like first-order logic. All other temporal operators, for example $\blacklozenge\,\phi$ (pronounced "once"), are derived notions. With these operators, an *invalid* sequence of method-call events is easy to express: `next` $\wedge\,\blacklozenge$ `mutate`. In prose, calling the `next` method of an iterator is invalid if the map has been mutated.

One contribution of this paper is a number of libraries, including one for PLTL, that developers can use in contracts. So, suppose a developer wishes to release a collections library that states and enforces the MapIterator property. Realizing this desire calls for three steps.

First, the developer imports the trace contract library and the PLTL library:

```
(require trace-contract)
(require logic/pltl)
```

Importing `trace-contract` brings in, among other forms, `object-trace/c`. As the introduction mentions, `object-trace/c` constructs an object contract that records a trace of method-call events. This trace is checked by a predicate every time a new element is added.

Second, the developer formulates and names the PLTL formula associated with the MapIterator property:

```
(define-pltl map-iterator-violation
  (∧ 'next (♦ 'mutate)))
```

Using the PLTL library, a developer can formulate the predicate as the above temporal formula, matching the informal prose found in Java's documentation. To use a named PLTL formula, a programmer must use the `pltl` form, which translates it to a (state) `machine` representation. A `machine` acts as a predicate over traces, i.e., it can check whether a trace satisfies or refutes a formula:

```
> (define s1 (list 'next 'next 'mutate 'next))
> (machine-accepts? (pltl map-iterator-violation) s1)
#true
```

Third, the developer combines a PLTL expression with `object-trace/c` to create an enforceable contract. Figure 2 shows a first attempt at such a contract for MapIterator. The three displayed definitions express a specification involving three methods across two classes, with an intervening class that bridges the gap. Two methods from the `Map` class – `remove` and `set` – mutate the `Map`. The intent with these contracts is that any iterator derived from a collection of keys becomes unusable when the underlying map is mutated. The `#:refutes` clause requests that the PLTL formula named `map-iterator-violation` is translated into a predicate over the trace of method-call events. If the contract ever discovers that the formula is satisfied, then the system signals a violation.

As is, these contracts are not quite right. An `object-trace/c` contract knows only about method calls for the current object. Therefore, `map-iterator/c` sees only calls to the `next` method and is unaware of any mutations to the underlying map.

Figure 3 shows how to adapt these contracts to inform the `map-iterator/c` contract of the other relevant method calls. To express this relationship, the contracts for collection and iterator objects become *functions* that accept the `map/c` contract itself. The `object-trace/c` form uses the keyword `this-contract` which, similar to `this` for objects, refers to the

```
(define map-iterator/c
  (object-trace/c
   #:refutes (pltl map-iterator-violation)
   [next (->m any/c) 'next]))

(define map-collection/c
  (object-trace/c
   [iterator (->m map-iterator/c)]))

(define map/c
  (object-trace/c
   [keys   (->m map-collection/c)]
   [remove (->m any/c void?)       'mutate]
   [set    (->m any/c any/c void?) 'mutate]))
```

Figure 2 First Attempt: Checking the MapIterator Property.

```
(define (map-iterator/c map/c)
  (object-trace/c
   #:refutes (pltl map-iterator-violation)
   #:include map/c
   [next (->m any/c) 'next]))

(define (map-collection/c map/c)
  (object-trace/c
   [iterator (->m (map-iterator map/c))]))

(define map/c
  (object-trace/c
   [keys   (->m (map-collection/c this-contract))]
   [remove (->m any/c void?)       'mutate]
   [set    (->m any/c any/c void?) 'mutate]))
```

Figure 3 Checking the MapIterator Property.

`object-trace/c` contract itself. While the `map-collection/c` function just passes this contract through to the `map-iterator/c` function, the latter actually makes use of it. The `#:include` clause informs the contract system that events from the trace for `map/c` are to be injected into the trace for `map-iterator/c`. Consequently, `map-iterator-violation`, which refers to the `'mutate` event, now works correctly in the `#:refutes` clause.

These contracts look simple, but the underlying property is sophisticated. Consider the scenario where an iterator is created, the underlying map is mutated, and then another iterator is created. It should be the case that the first iterator is invalidated, while the second one is usable. In other words, these two iterators require independent pieces of state. Some events, such as mutations to the underlying map, are shared with both. Other events, such as calls to `next`, are particular to a specific iterator and are not shared. All this careful state management is handled automatically.

Conversely, manually constructing defensive checks to correctly keep track of this information is difficult. Appendix A shows an implementation of defensive checks for MapIterator, similar to the defensive code shown in Section 1. The code is complex and takes several pages to explain. By contrast, Figure 3 is nearly self-explanatory.

3 Real Code Needs a Mixture of Domain-Specific Notations

Interfaces should be expressed as directly as possible, using the notation most appropriate for the property at hand. Sometimes a single interface benefits from mixing several domain-specific notations. The DSCs presented in this paper are flexible enough to allow a heterogeneous mixture of notations because they all compile to the same uniform mechanism for capturing and checking traces of events.

This section presents a series of contracts that ensure TCP sockets are used correctly. Consider an idealized TCP interface, similar to the one found in Java, which consists of four classes: a TCP manager, a TCP listener, an input stream, and an output stream. A TCP manager, when given a port number, is responsible for creating a TCP listener that deals with the given port. The purpose of a TCP listener is to accept client connections. For each connected client, a TCP listener produces an input and output stream for receiving and sending data, respectively.

Many languages, including Java, guarantee the following properties of TCP sockets:

- StreamClose. Input and output streams can be used until either the stream itself is closed or the underlying TCP listener is closed.
- PortExclusivity. At any point in the program, there can be at most one active TCP listener on each port.

The Java standard library uses defensive programming to enforce these properties.

Instead, DSCs can nicely express both properties, but they warrant two different notations. The StreamClose property can be expressed as a regular expression:

```
(define-re port-re
  (seq (star 'use) (opt (union 'close-stream `(close-listener
      ,_)))))
```

This regular expression accepts traces of method-call events that use a stream (input or output) until it has been closed, or the underlying listener is closed. There is one unusual feature here, which is the close listener event. In all prior examples, events were symbolic names of methods carrying no additional data. The close listener event also carries the port number of the corresponding listener, which is simply ignored in `port-re` using a wildcard pattern. Why the close listener event carries a port number will be clarified momentarily.

The PortExclusivity property is not easily expressed as a regular expression. Another formalism, known as quantified event automata (QEA [4]), is a good match:

```
(define manager-qea
  (qea
   (∀ port)
   (start ready)
   [-> ready `(listen ,port) listening]
   [-> listening `(close-listener ,port) ready]))
```

A QEA is similar to an ordinary finite-state automaton, but it is enriched with quantifiers. By quantifying over a variable, a QEA describes a *family* of automata: one per instantiation of all quantified variables. Intuitively, `manager-qea` constructs a two-state automaton for every possible port number. These automata are created on demand, though, to avoid unnecessary overhead. Each automaton starts in the `ready` state and transitions to the `listening` state when a new TCP listener is created on that port. When the listener is closed, the automaton moves back to the `ready` state. Each listener event must carry a port number so the event can be dispatched to the appropriate automaton.

```
(define (input-stream/c listener/c)
  (object-trace/c
   #:satisfies port-re
   #:include listener/c
   [read-byte (->m byte?) 'use]
   [peek-byte (->m byte?) 'use]
   [close     (->m void?) 'close-stream]))

(define (output-stream/c listener/c)
  (object-trace/c
   #:satisfies port-re
   #:include listener/c
   [write-byte (->m byte? void?) 'use]
   [close      (->m void?)       'close-stream]))

(define (tcp-listener/c manager/c port)
  (object-trace/c
   #:extend manager/c
   [close  (->m void?) `(close-listener ,port)]
   [accept (->m (values (input-stream/c this-contract)
                        (output-stream/c this-contract)))]))

(define tcp-manager/c
  (object-trace/c
   #:satisfies manager-qea
   [listen (->dm ([port (integer-in 0 65535)])
                 [res (tcp-listener/c this-contract port)])
           `(listen ,port)]))
```

Figure 4 The TCP Interface.

Using `object-trace/c`, these logical specifications can be connected to the TCP interface itself; see Figure 4. Two differences from the example in Figure 3 are worth pointing out.

First, `tcp-manager/c` uses the dependent method contract form `->dm` [48] to produce an event that is dependent on the argument given to `listen`. This form permits naming the arguments and result, binding those names for use in the event constructor. Here, the listen event contains the `port` argument.

Second, `tcp-listener/c` uses `#:extend` to contribute events to the parent `manager/c` contract. As shown in Figure 3, `#:include` allows events to flow from "ancestor" to "descendant" object. By contrast, the `#:extend` keyword allows events to flow in the other direction, from "descendant" to "ancestor" object. Specifically, the TCP manager (i.e., the parent) must be aware if a TCP listener (i.e., the child) is closed on a particular port, because then that port becomes available for listening once again according to PortExclusivity. Using `#:extend manager/c` tells the contract to communicate close listener events from the listener to the manager. It turns out that StreamClose requires information to flow in the other direction because input and output streams (i.e., the children) must be closed if the underlying listener (i.e., the parent) is closed. This direction is covered using `#:include listener/c`. In sum, this example demonstrates that `object-trace/c` can accommodate information flow in both directions, even within the same interface, and can mix distinct notations to check all desired properties.

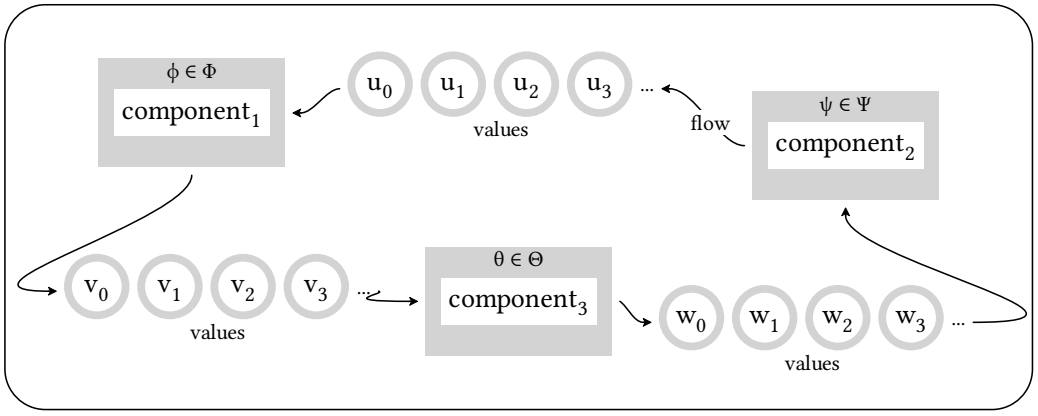

Figure 5 A System with Domain-Specific Contracts.

4 Implementing Domain-Specific Contracts

Implementing DSCs demands two ingredients: a low-level contract system and a mechanism for embedding domain-specific syntax. If a language lacks such a mechanism, a developer can use design patterns to construct embedded languages [41].

Figure 5 graphically summarizes how DSCs work. Each component is combined with a logical formulas (the gray frame). The component's developers choose the most appropriate logic to use, based on the property to be enforced. These logic languages come with translators that turn these specifications into predicates, which then become pieces of trace contracts. In the diagram, the enforcement mechanism comes into play with the sequences of values that components exchange. The contract code checks the sequence of values that a component receives and sends out. Gray borders on values in Figure 5 indicate that values may acquire a *proxy* layer that contains specification-checking code from the component's interface [16, 50]. A proxy interposes on interactions with the underlying object, e.g., a method call, and performs dynamic checks.

This section starts with a brief tutorial of Racket contracts, focusing on trace contracts (Section 4.1). Next, the section introduces essential features of Racket's domain-specific language (DSL) implementation system (Section 4.2) and what features readers should watch out for when implementing DSCs (Section 4.3). Lastly, the section gives some hints concerning the adaptation of this blueprint to languages with different DSL-programming facilities and contract systems (Section 4.4).

4.1 Low-Level Contract Mechanisms

For enforcement, DSCs rely on low-level contract mechanisms for stating and checking various kinds of properties: plain pre-conditions and post-conditions for functions; higher-order contracts for imposing invariants on foreign and behavioral values; and trace contracts for checking properties about sequences of calls.

In an untyped programming language, simple software contracts provide the programmer with the means to check type-like properties; in typed languages, they supplement method signatures not expressible in the type system. In Racket, contracts are also first-class values: they can be named, composed, and attached to values.

Higher-order contracts [16] go beyond plain assertions and describe invariants of behavioral values – such as objects – generating blame information[2] when dynamic[3] checks detect a violation. Here is a vanilla object contract for iterators:

```
(define iterator/c
  (object/c
   [has-next (->m boolean?)]
   [next     (->m any/c)]))
```

This contract specifies the method names along with a contract for the inputs and outputs of each method. When `iterator/c` is attached to an object, it ensures that the object comes with the expected methods and wraps it in a proxy. This wrapper performs checks on the inputs and outputs of the methods according to the stated expectations in method contracts (`->m`). Here, neither method consumes any arguments; both return one value.

An object contract merely enforces the pre-conditions and post-conditions on method arguments and results. It neither states nor checks the HasNext property. To do so requires the trace-contract extension to Racket's higher-order contract system.

A trace contract [37] collects values that flow through certain contract positions and enforces properties of the collected sequence. Hence, trace contracts can check temporal properties such as the HasNext property. Figure 6 shows such a contract.

```
(define iterator/c
  (trace/c ([evts symbol?])
    (object/c
     [has-next (and/c (->m boolean?) (apply/c [evts 'has-next]))]
     [next     (and/c (->m any/c)    (apply/c [evts 'next]))])
    (full (evts) has-next?)))

(define (has-next? s [okay? #false])
  (match s
    [(stream)                    #true]
    [(stream-cons 'has-next s*) (has-next? s* #true)]
    [(stream-cons 'next s*)      (and okay? (has-next? s*
       #false))]))))
```

Figure 6 Checking the HasNext Property.

The `iterator/c` contract is constructed with `trace/c`, which consists of three parts:

1. a declaration of a trace variable (`evts`) and its element type;
2. a contract (here an `object/c` contract); and
3. a predicate clause (`full`).

The declared trace variable names the trace of collected events. Annotations within the object contract push symbols into this trace whenever the corresponding method is called. Concretely, `apply/c` pushes the symbols `'has-next` and `'next` into `evts` when the corresponding method is called. Whenever a symbol is added to `evts`, the trace contract runs the predicate from the third part on the entire trace of events. For the iterator contract, the predicate ensures that the trace does not have two consecutive `'next` symbols.

[2] In a higher-order context, values enter contracts as they flow from one component to another. A contract violation may take place in the receiving component or in some other component, unrelated to the two involved in the contract. Hence, tracking the provenance of values is critical so that a contract violation can be related to a contract attachment [16].

[3] On occasion they can be statically verified [38, 53], but this direction is beyond the scope of this paper.

Importantly, each time a trace contract is attached to a value, it initializes a new trace just for that value. That means, different iterators have distinct traces that are separate from one another. State management is completely left to the trace-contract system and not the programmer. Hence, predicates over traces are plain (testable) functions.

Clearly, the direct use of this low-level contract mechanism "drowns" the essence of the iterator contract. By contrast, with a bit of training, every programmer can comprehend the contract in Figure 1 much more quickly.[4] First, it uses `object-trace/c` which provides a thin layer of syntactic sugar over the repetitive `apply/c` contracts. Second, it uses a one-line regular expression over method names instead of a recursive predicate.

Other features of `object-trace/c` are more complicated to desugar. Trace contracts, as originally implemented, were not expressive enough to support the `#:include` clause from Figure 3. The original implementation restricted contracts such that a predicate clause could only depend on traces from the same `trace/c` form. To support `#:include`, the underlying trace-contract system had to be modified to remove this restriction, allowing predicate clauses to depend on an arbitrary trace.

4.2 Domain-Specific Languages via Macros

Nearly all modern Lisp-like languages [9, 19, 23, 46, 47], and many languages outside the Lisp family [6, 13, 42], support syntactic abstraction via macros. A Lisp-style macro is a programmer-defined transformation from one syntax tree to another. In its most basic form, a macro is just a simple rewrite rule. But some languages, and Racket in particular, take the idea much further. Racket enables language-oriented programming [14] through macros, so programmers can construct rich DSLs and comingle expressions in these DSLs, without ever leaving the host language.

Racket provides one particularly useful tool for constructing DSC implementations: the `syntax-spec` library [2, 3]. Two features of `syntax-spec` make it suitable for creating new DSCs. First, developers can declaratively specify the language grammar, making it straightforward to develop and maintain the Racket-like syntax of DSCs. Second, `syntax-spec` is *binding aware*, meaning it understands the scope of variable declarations. It can thus reliably provide services such as rename refactoring or determine the free variables of a formula.

Figure 7 shows the Backus–Naur form (BNF) representation of the PLTL grammar and the `syntax-spec` definition for the same grammar in Racket. These grammars directly correspond to each other and it is easy to go back and forth. In order to make the `syntax-spec` grammar binding aware, a developer adds *binding specifications* such as the one for the `exists` form. Here, the binding specification states that in $\exists x.\phi$, the variable x is bound in ϕ.

Implementing the static semantics of a DSC is almost as straightforward as declaring its grammar. Take the monitorability criteria of PLTL [5], which says that a well-formed PLTL formula can be turned into a predicate over a trace if it satisfies the judgment on the left side of Figure 8. The equivalent Racket code is on the right side of the figure. Once again, the differences between these two are superficial. The Racket implementation pattern matches on the syntax using the `syntax-parse` system [10]. Each rule in the monitorability judgment corresponds to a branch in the match. In the PLTL pattern case, the function uses the free variables (`fvs`) feature mentioned earlier.[5]

[4] Most programmers are familiar with regular expressions, but other specification languages are less well-understood. For example, LTL is known to pose challenges for developers [21, 22]. Employing such specification languages may necessitate more training on the part of programmers.

[5] A straightforward feature to add to this static semantics is a monitorability search procedure. Some tools, such as MonPoly [5], attempt to rewrite nonmonitorable formulas into monitorable ones if possible. The same can easily be done with DSCs, immediately after the monitorability check fails.

$\phi \in \mathsf{Formula} = p \mid \neg\phi \mid \phi \vee \phi \mid \phi \wedge \phi \mid \exists x.\phi \mid \bullet\,\phi \mid \phi\,\mathsf{S}\,\phi$

```
(syntax-spec
 (nonterminal pltl-formula
  #:allow-extension pltl-macro
  #:binding-space pltl-space
  (neg f:pltl-formula)
  (disj2 f1:pltl-formula f2:pltl-formula)
  (conj2 f1:pltl-formula f2:pltl-formula)
  (exists x:pltl-var f:pltl-formula)
  #:binding (scope (bind x) f)
  (previous f:pltl-formula)
  (since f1:pltl-formula f2:pltl-formula)
  p:pltl-pat))
```

Figure 7 Grammar of PLTL (Simplified).

Finally, if a formula satisfies the static semantics, it can be translated into a predicate. Figure 9 shows a simple translation for PLTL. It translates each formula into a tree of structs, which is then run using the PLTL interpreter provided by the library.

4.3 Features To Observe

While the use of `syntax-spec` greatly facilitates the declaration and translation of DSCs, this very simplicity obscures a number of aspects that come "for free" but may have to be realized separately in alternative implementations. When implemented with `syntax-spec`, domain-specific contracts signal syntax errors at the appropriate level, have direct support from the IDE, and are syntactically extensible.

Static Errors

A `syntax-spec` DSC implementation can automatically synthesize reasonable syntax errors for the new notation. For example, ill-formed PLTL formulas are identified like this:

```
> (define-pltl φ
    (S 'next))
expected more terms in:  (S 'next)
```

In ϕ, the S operator expects another operand, so the error points out an arity mismatch.

Similarly, a `syntax-spec` implementation can issue an informative message when static checking fails. As mentioned in the preceding subsection, a syntactically well-formed PLTL formula may be *invalid* because it cannot be translated into a predicate (as is):

```
> (define-pltl ψ
    (∃ (t) (¬ (• t))))
not monitorable in:  (¬ (• t))
```

Even if a PLTL formula is well-formed and valid, it can still be misused:

```
> (+ ψ 13)
cannot use PLTL formula here:  ψ
```

$$\frac{\rho \vdash \phi \qquad \rho \vdash \psi}{\rho \vdash \phi \vee \psi}$$

$$\frac{\rho_\phi \vdash \phi \qquad \rho_\psi \vdash \psi \qquad \rho_\phi \subseteq \rho_\psi}{\rho_\phi \cup \rho_\psi \vdash \neg\phi \wedge \psi}$$

$$\frac{\rho_\phi \vdash \phi \qquad \rho_\psi \vdash \psi \qquad \rho_\phi \subseteq \rho_\psi}{\rho_\phi \cup \rho_\psi \vdash \neg\phi \,\mathsf{S}\, \psi}$$

$$\frac{\rho_\phi \vdash \phi \qquad \rho_\psi \vdash \psi \qquad \rho_\phi \subseteq \rho_\psi}{\rho_\phi \cup \rho_\psi \vdash \phi \,\mathsf{S}\, \psi}$$

$$\frac{\rho_\phi \vdash \phi \qquad \rho_\psi \vdash \psi}{\rho_\phi \cup \rho_\psi \vdash \phi \wedge \psi} \qquad \frac{\rho \cup \{x\} \vdash \phi}{\rho \vdash \exists x.\phi}$$

$$\frac{\rho \vdash \phi}{\rho \vdash \bullet\phi} \qquad \frac{\rho = \mathrm{FV}(p)}{\rho \vdash p}$$

```
(define (monitorable? stx)
  (syntax-parse stx
    [(disj2 f g)
     (and (equal? (fvs #'f) (fvs #'g))
          (monitorable? #'f)
          (monitorable? #'g))]
    [(conj2 (neg f) g)
     (and (subset? (fvs #'f) (fvs #'g))
          (monitorable? #'f)
          (monitorable? #'g))]
    ── similar cases ──
    [(conj2 f g)
     (and (monitorable? #'f)
          (monitorable? #'g))]
    [(exists (x:id ...) f)
     (monitorable? #'f)]
    ── similar cases ──
    [(neg _) #false]
    [p #true]))
```

Figure 8 Static Semantics for PLTL (Simplified).

```
(define-syntax (translate stx)
  (syntax-parse stx
    [(_ (neg f))             #'(neg-s (translate f))]
    [(_ (disj2 f g))         #'(disj2-s (translate f) (translate g))]
    ── similar cases ──
    [(_ (exists (x ...) f)) #'(exists-s (set 'x ...) (translate f))]
    [(_ x:id)                #'x]
    [(_ p)                   #'(translate-pattern p)]))
```

Figure 9 Translator for PLTL (Simplified).

The `define-pltl` form creates definitions in a separate *binding space*, as required by the one-line `#:binding-space` option in Figure 7. Languages, including domain-specific notations, are often composed of several syntactic categories that are mixed at particular interface points. For example, Java has a syntactic category of expressions and types that are interleaved in a certain way; definitions created in one do not exist in the other. The `syntax-spec` implementation of PLTL creates its own binding space, distinct from the one for expressions, meaning that a reference to a PLTL name from an expression context signals a static error.

User Extensibility

PLTL comes with just two primitive temporal operators. Although derived operators add no expressive power to the logic, they are necessary for writing concise specifications. While the PLTL library could provide direct support for such derived operators, doing so has the serious downside of complicating the static semantics, the translator, and the runtime system, which would have to deal with each kind of operator separately.

Instead, a `syntax-spec` implementation of a DSC can be made syntactically extensible with a single annotation: `#:allow-extension`. This `#:allow-extension` option opens up the `pltl-formula` nonterminal for simple macro extensibility. Using this capability, a user can define additional operators in a straightforward manner:

```
(define-pltl-rule ⊤
  (? (λ _ #true)))

(define-pltl-rule (⧫ ϕ)
  (S ⊤ ϕ))
```

The `syntax-spec`-generated `define-pltl-rule` form defines a syntactic transformation that rewrites all instances of $\top$ and $\blacklozenge\phi$ in a PLTL formula: $\top$ is rewritten to a predicate that always returns `#true`, meaning a machine that succeeds on all traces of collected events; and $\blacklozenge$ is rewritten to a formula that requires nothing to be true until ϕ holds.

These syntactic transformations are seamlessly integrated into PLTL. For example, a user can write a utility library with these abbreviations and export them for use in other modules. In short, user-extensible transformations make the PLTL library flexible to use and simplify its implementation tremendously.

IDE Integration

The `syntax-spec` library facilitates the integration of DSC implementations with Racket IDEs. One such IDE is DrRacket [15]; another one is Racket Mode for Emacs.[6]

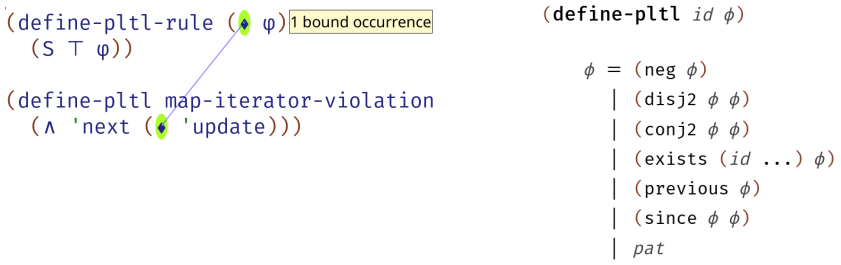

Figure 10 IDE Services for PLTL.

Figure 10 shows two such services. First, when a user hovers over an identifier, arrows are drawn from the binding occurrence of an identifier to every reference (Figure 10, left). Here, the definition of $\blacklozenge$ points to its use in the formula. The IDE has a rich understanding of the binding structure of the DSC, which can be used to support reliable program transformations including rename refactorings. Second, if a DSC comes equipped with documentation, as PLTL does, this documentation can be displayed directly in the IDE. When the cursor is placed inside an identifier with recognized documentation, a box containing a summary of the documentation appears in the upper-right corner of the IDE. For `define-pltl`, that summary is the grammar of primitive PLTL forms (Figure 10, right). This service is available because Racket's documentation language Scribble [18] is binding aware.

[6] This major mode is maintained by Greg Hendershott; see `https://racket-mode.com`.

Compositionality

It is also possible for users to compose contracts that may have been written independently into a single interface contract. For example, the iterator contract from Figure 3 can easily be augmented to additionally check the HasNext property, even though these specifications may have been defined separately:

```
(define (map-iterator*/c map/c)
  (and/c has-next/c (map-iterator/c map/c)))
```

The `and/c` form comes from Racket's contract library and enforces that values satisfy both conjuncts (in order). It may compose *any* kind of contract that compiles to the already-mentioned proxy mechanism in Racket.

Blame Assignments

In the case of Racket and the DSCs in this paper, contracts have a blame-assignment mechanism [16]. That is, once a dynamic contract check discovers a violation, it raises an exception that assigns blame to a particular component. Here is an excerpt from the error message that explains a violation of the HasNext property:

```
> (define m (new map% ——))
> (define c (send m keys))
> (define t (send c iterator))
> (send t next)
next: contract violation
blaming: top level
```

An iterator created from a collection has its `next` method called without a corresponding call to `has-next`. The contract system issues a blame assignment that points to the method that failed and the component that violated the specification – here, the top-level code. This information might be useful for tracking down the source of bugs in large systems [27, 28, 29].

4.4 Ingredients for Adding DSCs to a Programming Language

The DSC architecture is generic and should apply to many programming languages, with varying degrees of ease. It requires two essential ingredients: (1) facilities for creating embedded DSLs for the desired logics, such as macros; and (2) a mechanism for dynamically checking logical formulas, such as contracts. The quality of these ingredients in a language determines how easy it is to instantiate this architecture and how many of the features from the preceding subsection can be realized. For example, a programming language with powerful metaprogramming facilities reduces the notational overhead on programmers; without such facilities, a DSC implementer may have to resort to shallow or deep embedding techniques [20], which may impose an extra burden on developers.

Metaprogramming

A metaprogramming system enables programmers to extend their language with new linguistic constructs and collect them in libraries or frameworks. Ideally, it permits blurring the distinction between built-in constructs and user-defined ones. Importantly, metaprogramming facilities exist *inside* the programming language. Depending on the chosen language, metaprogramming facilities can be used in the small and large: from quick syntactic abbreviations all the way up to full feature-rich special-purpose DSLs. For DSCs, the metaprogramming facilities must be powerful enough to create the *embedded* DSLs necessary for expressing logical specifications.

Different languages have vastly different metaprogramming mechanisms. Some languages provide lightweight syntactic metadata: decorators in Python and annotations in Java. In other languages, such as Ruby, the syntax is sufficiently flexible and the semantics sufficiently dynamic that a DSC notation can be built without any explicit language support. Another major class of metaprogramming facilities are those based on (syntax-tree) *macros*: compile-time rewriting rules. Before code generation, the compiler applies these rules to obtain the program in a core syntax – a process called *macro expansion*. Languages in the Lisp family, such as Clojure [23], are especially well-known for macros, but others including Rust and Scala have adopted them too. Parenthetical syntax is not necessary [17].

Racket is well-suited for defining DSCs as it provides a great deal of support for language-oriented programming [14]. While its advanced macro system essentially makes up a nearly complete compiler API, the implementation of a DSC needs few of these capabilities.

Dynamic Checking

A contract system consists of a notation and a run-time mechanism for dynamically checking a program's behavior. The notation has to provide the means to identify relevant events, e.g., "the first argument to the method call `o.m`," and the predicate that should hold of such events, e.g., "is a positive integer." These statements are usually understandable as ordinary program code – Boolean-valued assertions – and are easily translated into run-time checks. The runtime system issues a descriptive error when any of these checks fail.

Modern contract systems permit programmers to monitor specifications over any kind of value, including higher-order values such as objects, functions, and even the kind of first-class classes found in Python, Racket, and Ruby. The corresponding run-time checks rely on proxies that wrap values flowing through contracts and contain the Boolean-valued run-time checks. Direct support for proxy values is available in a number of languages, e.g., JavaScript [51]. Even if proxies are unavailable, implementing proxies in some dynamic languages does not require explicit support. Ruby, for example, supports objects that can interpose on all `send` method invocations. Such a facility has been used to implemented higher-order contracts [49]. So, while contracts are implemented as a core feature in some languages, such as Eiffel [33, 34], they can often be implemented as a library, especially if proxies are available.

Racket comes with a pioneering higher-order contract system [16]. The contract notation is realized as an embedding, via a rich set of contract combinators; the base contracts are predicates as in any other system. With trace contracts [37], programmers can articulate predicates over traces of values that flow through particular points in a contract. Trace contracts make it particularly straightforward to bridge the gap between the DSC specifications presented here and the low-level contract system itself.

5 Evaluating the Domain-Specific Contracts Approach

An assessment of the DSC idea and its instantiation with trace contracts must address several aspects: (1) whether DSCs can accommodate existing logic notations; (2) what developer-facing features these implementations provide; and (3) how precisely DSCs can report specification violations. The first two points call for identifying and implementing a corpus of logic notations for specifications in the literature (Section 5.1) and for a qualitative assessment of them along several dimensions (Section 5.2). The last point is a matter of implementation quality; an extensive test suite can validate that the blame assignment points to the problematic party for some common example properties from the literature (Section 5.3). In addition, this section relates the DSC idea to prior work (Section 5.4).

5.1 Corpus of Logics

The literature proposes a wide variety of logic notations for specifications that are suitable to check with trace contracts. Here are six common ones:

Past-Time Linear Temporal Logic (PLTL) is a past-time variant of the more commonly used future-time linear temporal logic. See Section 2 for a complete description of PLTL and an example.

Regular Expressions (RE) are a simple formalism equivalent in expressive power to finite state machines [26]; they are a well-known way for specifying parts of the behavior of a software system [45].

Finite State Machines (NFA, DFA) have a finite number of states and transitions between them. A deterministic finite-state machine (DFA) denotes the sequences of events that, when run on the state machine, follow a unique path that ends in an accepting state [43]. A non-deterministic finite-state machine (NFA) denotes the sequences of events that, when run on the state machine, end in an accepting state along *some* path.

Quantified Event Automata (QEA) resemble DFAs but are augmented with extra features [4]. As the name suggests, the machine supports quantification. Conceptually, a QEA represents a family of automata – one for every possible instantiation of quantified variables. Practical implementations of QEA more efficiently compute transitions via a compact representation of this family of automata.

Stream Logic (SL) describes properties by defining stream equations [11]. A stream is a sequence of events that is accessible with a finite lookback. The dynamic checks for SL specifications compute the value for each stream at the current index, making use of the static dependencies of equations to solve them in the correct order. Irrelevant values, i.e., ones that are beyond the finite lookback, are automatically discarded.

All these formalisms have been implemented for use in Racket DSCs.

5.2 Qualitative Assessment

The implementations of these six logic notations have distinct qualities from the perspective of language creators and users. This subsection reports those qualities in terms of four dimensions: binding positions, definitions, static semantics, and macro extensibility. Table 1 summarizes the discussion in a table.

Table 1 Summary Qualitative Assessment of Logic DSLs.

	PLTL	RE	DFA	NFA	QEA	SL
Binding Rules	✓	×	×	×	✓	✓
Definitions	✓	✓	×	×	×	×
Static Semantics	✓	×	×	×	×	✓
Macro Extensible	✓	✓	×	×	×	×

Binding Positions

Some DSLs are variable-free; others come with variable declarations that introduce binding positions and determine the scope of a declaration. Since the `syntax-spec` system comes with a binding-rules mechanism, it allows DSC creators to specify which pieces of a formula are variable references, which are binding positions, and the scope of bindings. By declaring the binding structure, DSC implementations can automatically support IDE services, static-semantics passes, and translations into predicates.

Logic notations without quantification, i.e., RE, DFA, and NFA, do not require binding rules. Specifically, the state-machine notations do not use an up-front declaration of states; if they did, binding rules would be required. By contrast, both PLTL and QEA come with variable quantification, and quantified variables are binders. In SL, equations must reference other equations or primitive event streams. The binding rules for SL guarantee that there are no free variables referencing an undefined stream.

Separate Definitions

For some logic notations, formulas can be defined piecemeal via the binding space mechanism. Developers can build up libraries of reusable formulas that others can then compose into specifications of modules, classes, and other components. For such compositional notations, definition forms are a highly useful mechanism. While the state-machine notations from the literature do not seem compositional, both RE and PLTL greatly benefit from the introduction of definition forms.

Static Semantics

Some specification notations impose criteria that determine whether well-formed formulas are valid. If an implementation can enforce such static-semantics constraints, it is superior to plain frameworks or functional libraries because it informs developers at compile time about basic mistakes, instead of delaying the discovery of specification mistakes until run time. Programmers can thus avoid unexpected run-time errors and dynamic debugging due to invalid specifications.

While Racket's `syntax-spec` library automatically guarantees that logical specifications are well-formed and closed with respect to any binding rules, the static semantics of DSCs must be written as an additional check. Of the investigated notations, PLTL and SL must satisfy such criteria. Section 4 covers the monitorability criteria for PLTL. For SL, the DSL implementation statically checks that the dependency graph of the stream equations has no closed walk with a total weight of zero, where the weights are determined by indices into streams. This check statically generates the dependency graph from the stream equations via local macro expansion, even when references to streams are embedded inside Racket sub-expressions.

Macro Extensibility

When logical formulas are compositional, programmers benefit from a macro-extensible language. The RE and PLTL notations make heavy use of this feature because many useful operators can be derived from a small set of primitive operators. By expanding the surface syntax to a small core language, the implementation can be organized like an ordinary compiler (as in functional languages such as Haskell, ML, or Scheme). Equally important, macro extensibility enables users to create syntactic abstractions when plain functional abstractions do not suffice to hide repeated patterns in formulas.

In summary, the implementation of these specification notations preserve all desirable aspects (e.g., the static checks) and, indeed, go beyond usual implementations, offering users additional affordances. Furthermore, DSCs are embedded into the host, meaning the host's IDEs (DrRacket, Emacs) support DSCs essentially as well as plain Racket programs. When implemented correctly, users do not notice any friction.

5.3 Blame Assignment

One claimed benefit of contracts is that error messages come with blame information identifying the source of the specification violation. Blame assignment in higher-order settings, and even more so for temporal properties, is subtle. In general, blame assignment points to the components that contribute to a violation of a specification.

To understand whether blame assignment from the underlying contract system works well for DSCs, it is necessary to adapt examples from the literature and to test violations on sample code snippets. That is, unit tests should validate that the Racket implementation actually produces blame assignments in accordance with the source of the bug.

Table 2 Sample Properties.

Property	Logic / SLOC	Description
MapIterator	PLTL (7), RE (1)	An iterator constructed from a collection, which is itself constructed from a map, is invalidated once the underlying map is mutated.
HasNext	QEA (6), RE (1)	A call to the `has-next` method must precede every call to the `next` method.
HashCode	QEA (5), SL (7)	An object's `hash-code` must not change so long as it is being used as a key in a map.
ClosedReader	SL (8)	A call to the `read` method of a reader object must not take place after the underlying input stream has been closed.
SetFromMap	SL (6)	Creating a set from a map renders the latter unusable.
RemoveOnce	RE (1)	An iterator's `remove` method can be called only once per invocation of the `next` method.
StreamClose	RE (1)	A stream may be used until it is closed or the underlying TCP listener is closed.
PortExclusivity	QEA (5)	Listeners can be created for a port, so long as there is no active listener already associated with that port.

Table 2 list some sample properties from the literature, which logics they were implemented in, and how many lines it took to write each formula. All explain properties of the Java API that are stated informally but may or may not be checked via the assertion system. Other systems can enforce these properties [30], and so can the Racket realization of DSCs.

The test suite for the Racket implementation contains adaptations for all these properties. The corresponding code come with components that violate the properties. Unit tests ensure that checking these DSC specifications catches all violations and that the relevant blame assignment points to the buggy component.

5.4 Prior Work

Dimoulas et al. [12] present the first and only analysis in the contract-systems literature that explicitly mentions the need for a contract-specific notation. Their analysis explains a contract system as resting on three pillars: (1) a notation for expressing contracts; (2) a set of interposition points in the run-time system that allows inspecting values; and (3) a syntactic

mechanism for attaching contracts to values. Generally speaking, research on contracts has tightly coupled the three, associating one contract notation with specific interposition points and attachment mechanisms. Instead, the DSC architecture proposes that any language with contracts benefits from a *loose coupling* between contract notations on the one hand, and attachment mechanisms and interposition points on the other.

JavaMOP [7], a run-time verification system, is the only existing system with a similarly loose coupling. From a high-level perspective, JavaMOP rests on an aspect-like interposition system, dubbed monitor-oriented programming (MOP) [32]. Since JavaMOP is a run-time verifier, programmers do not formulate method-level or even class-level contracts, but whole-program properties. The JavaMOP framework compiles these properties into monitoring code snippets that are woven into the program at appropriate join points and that send values to a parallel property-checking process.

Unlike other run-time verification systems, JavaMOP permits programmers to choose the property notation best suited to the task and, indeed, allows them to create and plug in their own notation. From this angle, JavaMOP resembles the Racket implementation of the DSC architecture.

However, three differences stand out. First, the DSC proposal is intended to be realizable in any programming language. As detailed in Section 4, an implementation can be realized with minimal effort in languages with macro systems such as Racket, Clojure, Julia, Rust, or Scala. In languages without macro systems, an implementation may require a bit more labor, depending on existing features, but using conventional techniques for embedding domain-specific languages make DSCs feasible, even without significant engineering resources. Second, the end-product of DSCs is more convenient for programmers to use than a toolchain-based solution such as JavaMOP. A library can be installed directly from a language's package manager and used immediately. Finally, DSCs provide additional benefits beyond what JavaMOP delivers, e.g., IDE integration and blame assignment (from the underlying contract system, if available). The remainder of this section provides a detailed comparison.

Logic Plugins

JavaMOP users can develop their own logic plugins to add new, possibly domain-specific, specification languages. These plugins are essentially ordinary compilers from the surface syntax to Java code. Constructing such a compiler requires the use of traditional compiler generator tools, such as a parser generator, and a solid understanding of the semantics and behavior of the target language. As a result, developing a new logic or extending an existing one is challenging and not a lightweight exercise.

In the context of the proposed architecture, DSCs rely on the host language's existing metaprogramming facilities or established DSL implementation patterns. In a language with a macro system, such as Racket, new DSCs with sophisticated features can be created easily with a combination of declarative grammar specifications and recursive functions. And, if the host allows for declarative DSL specifications, these DSCs are maintainable in a straightforward manner.

Linguistic Integration

A byproduct of JavaMOP's extra-linguistic approach is that logical specifications are syntactically isolated from the rest of the program. JavaMOP specifications are typically added as comments to the code or as entirely separate text files. As a consequence, these artifacts end up as second-class citizens within a software project.

By contrast, DSCs make logical specifications an integrated part of the underlying project; they exist *within* the program. As such, all host-language tools continue to work with logical specifications. Notably, DrRacket's existing IDE services seamlessly extend to DSC code.

Trace Management

JavaMOP takes a global perspective on monitoring. System events are captured and stored in a global sequence. This monitoring strategy is central to the run-time verification approach. Since checking globally generated traces requires a slicing technique, JavaMOP's implementation makes slicing independent of the underlying logic to reduce the burden on the developer of a new logic notation [7, 24]. In the end, however, the program-global property approach remains an obstacle to reasoning about code in a compositional manner. Slicing also requires a notion of equality on objects which, if one is not defined already, relies on pointer equality. Depending on pointer equality for objects violates a key principle of object-oriented programming [8].

Contracts, by contrast, often eliminate the need for slicing because the state for a given value is freshly initialized when the value passes through an attachment boundary. Monitoring is local. Thus, the MapIterator property from Section 2 can be attached to a specific object and remains quantifier free; the equivalent formula in JavaMOP requires quantifiers and hence a slicing implementation in the monitoring process. Localized monitoring also unlocks unique advantages such as blame assignment (if the underlying contract system provides it). Slicing is still occasionally useful in contracts. For example, Section 3 shows slicing based on port numbers. A notion of equality is defined for port numbers, so the principles of object-oriented design are maintained.

Run-time Enforcement

As originally published, JavaMOP supported only one run-time enforcement mechanism. The AspectJ [25] weaver would statically inject monitoring code into a system based on the given specification. This requires AspectJ as a compile-time dependency and alters the ordinary build process for a Java project. Now, JavaMOP supports a dynamic enforcement mechanism known as the JavaMOP agent. With this mode, an instrumented JVM supplies the means to record system events during execution. The JavaMOP agent offers some advantages over the static approach, but requires a specialized runtime. Both of these mechanisms are somewhat unique to Java and are not readily available in other languages.

Contracts use a completely different implementation approach. While first-order contracts essentially get away with Boolean-valued assertions, higher-order and trace-contract systems rely on proxy objects to monitor a running program. If the language does not support proxy objects directly, implementing a reasonable approximation is feasible. The key is that proxies enable a simple, local-enforcement mechanism, which is crucial for blame assignment in higher-order settings.

6 A Future for Domain-Specific Contracts

Racket makes it straightforward to instantiate the DSC idea. It comes with an expressive library of contract combinators and a powerful facility for creating domain-specific notations. Leveraging the latter allows the creators of DSCs to implement notations with little effort and translate them to contract expressions. End-users can employ a library that provides DSCs just like any other dependency – critically, while continuing to use, and benefiting from, existing IDEs.

While the Racket implementation is particularly straightforward, several programming languages offer similar combinations of metaprogramming and contract features. For example, Clojure has ported most of Racket's contract system and comes with its own macro system. Scala too has a rich metaprogramming system for embedding DSLs [44] and could be equipped with a contract system based on Java's assertion system.

This paper has discussed the DSC idea only in the context of trace contracts with temporal specification languages. However, the idea of combining contracts with domain-specific specification languages goes far beyond that particular instantiation. For example, effect-handler contracts [36] combined with an authorization logic [1] yields authorization contracts [35] that can enforce security properties. Or, network-aware contracts [52] combined with a DSL for describing the legal moves of a game [12] yields the rule checker for an implementation of an online game. Indeed, there are plenty of other combinations not yet studied and worthy of exploration from the DSC perspective. Contracts and DSLs are useful alone. But together, they are better.
