List of Authors
..... 0:xv–0:xviii

Regular Papers

A Theory of (Linear-Time) Timed Monitors
Mouloud Amara, Giovanni Bernardi, Mohammed Aristide Foughali, and Adrian Francalanza 1:1–1:30

The Algebra of Patterns
David Binder and Lean Ermantraut 2:1–2:28

Pydrofoil: Accelerating Sail-Based Instruction Set Simulators
Carl Friedrich Bolz-Tereick, Luke Panayi, Ferdia McKeogh, Tom Spink, and Martin Berger 3:1–3:31

Ensuring Convergence and Invariants Without Coordination
Dina Borrego, Nuno Preguiça, Elisa Gonzalez Boix, and Carla Ferreira 4:1–4:29

Compositional Bug Detection for Internally Unsafe Libraries: A Logical Approach to Type Unsoundness
Pedro Carrott, Sacha-Élie Ayoun, and Azalea Raad 5:1–5:28

Detecting Functionality-Specific Vulnerabilities via Retrieving Individual Functionality-Equivalent APIs in Open-Source Repositories
Tianyu Chen, Zeyu Wang, Lin Li, Ding Li, Zongyang Li, Xiaoning Chang, Pan Bian, Guangtai Liang, Qianxiang Wang, and Tao Xie 6:1–6:27

Monadic Type-And-Effect Soundness
Francesco Dagnino, Paola Giannini, and Elena Zucca 7:1–7:31

An Effectful Object Calculus
Francesco Dagnino, Paola Giannini, and Elena Zucca 8:1–8:30

Event Race Detection for Node.js Using Delay Injections
Andre Takeshi Endo and Anders Møller 9:1–9:28

Bottom-Up Synthesis of Memory Mutations with Separation Logic
Kasra Ferdowsi and Hila Peleg 10:1–10:32

Contract Usage and Evolution in Android Mobile Applications
David R. Ferreira, Alexandra Mendes, João F. Ferreira, and Carolina Carreira .. 11:1–11:30

39th European Conference on Object-Oriented Programming (ECOOP 2025).
Editors: Jonathan Aldrich and Alexandra Silva
Leibniz International Proceedings in Informatics
LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Automatic Goal Clone Detection in Rocq
Ali Ghanbari 12:1–12:19

FuzzFlesh: Randomised Testing of Decompilers via Control Flow Graph-Based Program Generation
Amber Gorzynski and Alastair F. Donaldson 13:1–13:26

IsaBIL: A Framework for Verifying (In)correctness of Binaries in Isabelle/HOL
Matt Griffin, Brijesh Dongol, and Azalea Raad 14:1–14:30

Spegion: Implicit and Non-Lexical Regions with Sized Allocations
Jack Hughes, Michael Vollmer, and Mark Batty 15:1–15:26

A Lightweight Method for Generating Multi-Tier JIT Compilation Virtual Machine in a Meta-Tracing Compiler Framework
Yusuke Izawa, Hidehiko Masuhara, and Carl Friedrich Bolz-Tereick 16:1–16:29

Contrasting Deadlock-Free Session Processes
Juan C. Jaramillo and Jorge A. Pérez 17:1–17:29

Practical Type-Based Taint Checking and Inference
Nima Karimipour, Kanak Das, Manu Sridharan, and Behnaz Hassanshahi 18:1–18:25

Profile-Guided Field Externalization in an Ahead-Of-Time Compiler
Sebastian Kloibhofer, Lukas Makor[1], Peter Hofer, David Leopoldseder, and Hanspeter Mössenböck 19:1–19:32

Incremental Computing by Differential Execution
Prashant Kumar, André Pacak, and Sebastian Erdweg 20:1–20:24

GSOHC: Global Synchronization Optimization in Heterogeneous Computing
Soumik Kumar Basu and Jyothi Vedurada 21:1–21:30

Quantifying Cache Side-Channel Leakage by Refining Set-Based Abstractions
Jacqueline L. Mitchell and Chao Wang 22:1–22:28

Wastrumentation: Portable WebAssembly Dynamic Analysis with Support for Intercession
Aäron Munsters, Angel Luis Scull Pupo, and Elisa Gonzalez Boix 23:1–23:29

Fair Termination of Asynchronous Binary Sessions
Luca Padovani and Gianluigi Zavattaro 24:1–24:29

Reusing Highly Optimized IR in Dynamic Compilation
Andrej Pečimúth, David Leopoldseder, and Petr Tůma 25:1–25:25

Lightweight Diagramming for Lightweight Formal Methods: A Grounded Language Design
Siddhartha Prasad, Ben Greenman, Tim Nelson, and Shriram Krishnamurthi 26:1–26:29

PoTo: A Hybrid Andersen's Points-To Analysis for Python
Ingkarat Rak-amnouykit, Ana Milanova, Guillaume Baudart, Martin Hirzel, and Julian Dolby 27:1–27:29

Reusing Caches and Invariants for Efficient and Sound Incremental Static Analysis
Mamy Razafintsialonina, David Bühler, Antoine Miné, Valentin Perrelle, and Julien Signoles 28:1–28:29

Declarative Dynamic Object Reclassification
Riccardo Sieve, Eduard Kamburjan, Ferruccio Damiani, and Einar Broch Johnsen 29:1–29:31

In-Memory Object Graph Stores
Aditya Thimmaiah, Zijian Yi, Joseph Kenis, Christopher J Rossbach, and Milos Gligoric 30:1–30:30

Multiparty Asynchronous Session Types: A Mechanised Proof of Subject Reduction
Dawit Tirore, Jesper Bengtson, and Marco Carbone 31:1–31:30

Compositional Static Value Analysis for Higher-Order Numerical Programs
Milla Valnet, Raphaël Monat, and Antoine Miné 32:1–32:29

Mono Types – First-Class Containers for Datalog
Runqing Xu, David Klopp, and Sebastian Erdweg 33:1–33:26

Taming and Dissecting Recursions Through Interprocedural Weak Topological Ordering
Jiawei Yang, Xiao Cheng, Bor-Yuh Evan Chang, Xiapu Luo, and Yulei Sui 34:1–34:31

Chain of Grounded Objectives: Concise Goal-Oriented Prompting for Code Generation
Sangyeop Yeo, Seung-Won Hwang, and Yu-Seung Ma 35:1–35:25

Efficient Neural Network Verification via Order Leading Exploration of Branch-and-Bound Trees
Guanqin Zhang, Kota Fukuda, Zhenya Zhang, H.M.N. Dilum Bandara, Shiping Chen, Jianjun Zhao, and Yulei Sui 36:1–36:29

Experience Papers

RacerF: Lightweight Static Data Race Detection for C Code
Tomáš Dacík and Tomáš Vojnar 37:1–37:19

Type-Safe and Portable Support for Packed Data
Arthur Jamet and Michael Vollmer 38:1–38:19

WebGlitch: A Randomised Testing Tool for the WebGPU API
Matthew K. L. Wong and Alastair F. Donaldson 39:1–39:26

Replication Paper

Scaling Up: Revisiting Mining Android Sandboxes at Scale for Malware Classification
Francisco Handrick Tomaz da Costa, Ismael Medeiros, Leandro Oliveira, João Calássio, Rodrigo Bonifácio, Krishna Narasimhan, Mira Mezini, and Márcio Ribeiro 40:1–40:26

Pearl/Brave New Ideas

Shouting at Memory: Where Did My Write Go?
Vasileios Klimis 41:1–41:26

Contract Systems Need Domain-Specific Notations
Cameron Moy, Ryan Jung, and Matthias Felleisen 42:1–42:24

Preface

Started in 1987, ECOOP is Europe's oldest programming conference, welcoming papers on all practical and theoretical investigations of programming languages, systems, and environments that provide innovative solutions to real problems as well as evaluations of existing solutions. Papers were submitted to one of four categories: *Research* for papers that advance the state of the art in programming; *Replication* for empirical evaluations that reconstruct a published experiment in a different context in order to validate the results of that earlier work; *Experience* for applications of known techniques in practice; and *Pearl/Brave New Idea* for papers that either explain a known idea in an elegant way or unconventional papers introducing ideas that may take some time to substantiate. The chairs thank the Program Committee for their dedication to ensuring a quality program and providing constructive feedback to authors: Aaron Bembenek, Albert Rubio, Carla Ferreira, Daniele Nantes-Sobrinho, Di Wang, Einar Broch Johnsen, Elisa Gonzalez Boix, Elvira Albert, Farzaneh Derakhshan, Federico Olmedo, Jingling Xue, João F. Ferreira, Jules Jacobs, Lingming Zhang, Luis Caires, Max Willsey, Michael Vollmer, Mira Mezini, Niki Vazou, Pascal Weisenburger, Peter Thiemann, Ping Hou, Robbert Krebbers, Sebastian Erdweg, Serena Elisa Ponta, Sophia Drossopoulou, Sung-Shik Jongmans, Tobias Wrigstad, Wenjia Ye, Werner Dietl. We are also grateful for the help from a number of external experts who helped us ensure every paper got a high-confidence review: Adam Barwell, Andreas Lööw, Andrew Lenharth, Ashish Mishra, Ben Titzer, Daniel Ramos, David Naumann, David Richter, Emilio Tuosto, Guillermo Henrique Botelho Guerra, Jérôme Feret, Jesus Correas, Joshua Sunshine, Justin Hsu, Marco Guarnieri, Mike Dodds, Pablo Gordillo, Paulo Torrens, Roberto Giacobazzi, Samir Genaim, Stefan Marr, Yu David Liu.

This year, we continued the review process introduced in 2024, in which all papers were rated on each of the following criteria:

- **Soundness:** How well the paper's contributions are supported by rigorous application of appropriate research methods;
- **Significance:** The extent to which the paper's contributions are novel, original, and important, with respect to the existing body of knowledge;
- **Presentation:** Whether the paper's quality of writing meets the high standards of ECOOP.

After the author response and reviewer discussions, papers were accepted if the PC decided that the paper meets our high bar for Soundness and Presentation, and if at least one reviewer judges the paper to meet the bar for Significance. The goal of this process is to ensure quality of writing and confidence in results, while assuming that if one reviewer finds the paper to be significant then there will be readers who do so as well.

Overall, 102 papers were submitted in the first and second rounds. In the end 42 papers were accepted, in some cases after a round of revisions between the two rounds or a final round of checking for papers that initially received a conditional accept rating. As is common with journals, the ability to resubmit improved versions of a paper allowed the conference to accept a larger percentage of papers overall than in prior editions of ECOOP, while maintaining a high quality thereshold.

LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

We hope that future chairs will continue to experiment with more, and perhaps, different innovations that will enrich the ECOOP community further.

Finally, we would like to thank the local organizers, in particular the ECOOP General Chair, Volker Stolz, and the Local Organization Chair, Violet Ka I Pun, for all the work they did to put together the conference, the AITO executive committee, and the Dagstuhl LIPIcs team. For those who have edited a volume supported by the team led by Michael Wagner will know how responsive and helpful they are, we are extremely grateful for the service they provide, as we recognize this is very valuable for our community and the mission of keeping science open to everyone.

Alexandra Silva
Program Committee Co-chair
Cornell University

Message from the AEC chairs

ECOOP has a long-standing tradition of offering artifact evaluation dating back to 2013. This edition's artifact evaluation exceptionally focused on performing artifact evaluation of accepted papers only, contrary to the ECOOP tradition of evaluating artifacts at the same time as papers are reviewed.

In order to ensure a thorough and efficient artifact evaluation process, we recruited a large and diverse artifact evaluation committee that included a total of 55 artifact reviewers. The artifact submissions were due a few days after papers were accepted at ECOOP. Due to aforementioned change in the artifact evaluation process, we received a total of 21 submissions this year, down from 64 last year. Due to tight calendar constraints of this year's artifact evaluation, and to address potential hardware shortcomings, each artifact has been assigned four reviewers instead of the traditional three. The review phase started with a kick-the-tires review and author response, during which authors had the opportunity to clarify or address technical issues with their submissions. Full reviews have been provided a few weeks later.

We followed ACM's badging policy[1] since 2023. Details about the evaluation process and results can be found in the ECOOP 2025 DARTS proceedings.

The smooth and thorough artifact evaluation process would have not been possible without the members of the committee, who handled the artifact review workload with great dedication. We would like to thank them for their valuable work, feedback to authors and the inspiring discussions! We would also like to thank the ECOOP 2025 program committee chairs Jonathan Aldrich and Alexandra Silva for the pleasant and productive interactions over the coordination of the paper and artifact review processes, and the Dagstuhl Publishing team for their proactive and highly responsive assistance during the preparation of this DARTS volume.

Message from the AITO president

After 21 years, ECOOP returns to Norway, this time hosted by the Western Norway University of Applied Sciences in Bergen. I am delighted to welcome all ECOOP attendees to this vibrant and fascinating city.

Norway holds a special place in the history of ECOOP. One of the early editions of the conference was held here in 1988. More importantly, Norway is the home of Ole-Johan Dahl and Kristen Nygaard, the acknowledged co-inventors of Object-Oriented Programming, who were honored with the “ACM A. M. Turing Award" in 2001 for their groundbreaking contributions.

This year, for the first time, the “ACM SIGPLAN International Conference on Generative Programming: Concepts & Experiences" (GPCE) is co-located with ECOOP. I am confident this will establish a long-standing collaboration between the two conferences and their closely connected communities, which share many researchers and interests.

The ECOOP 2025 organizers, together with the GPCE team, have done an outstanding job putting together a rich and diverse program, featuring seven workshops and a doctoral symposium. Many thanks to the ECOOP General Chair, Volker Stolz; the Local Organization Chair, Violet Ka I Pun; the Program Committee Co-Chairs, Alexandra Silva and Jonathan Aldrich; and all other members of the organizing committee for their dedication and contributions.

I look forward to an exciting week of conferences and workshops, stimulating presentations, fruitful personal interactions, and inspiring keynotes—including the talks by the two 2025 Dahl-Nygaard Prize winners. Enjoy the conference and your time in Bergen!

Davide Ancona
AITO President

Abstract

Runtime Verification (RV) is gaining popularity due to its scalability and ability to analyse block-box systems. *Monitoring* is at the heart of RV; a logical formula ϕ, formalising some property of interest, is typically translated into a monitor that checks whether the system under scrutiny satisfies ϕ during its execution. A logical formula ϕ is violation (resp. satisfaction) *monitorable* iff there exists a monitor for ϕ that is both sound and complete w.r.t. its violation (resp. satisfaction). The *monitorability* problem is thus concerned with determining the largest subset of a logic L that is monitorable. Although this problem has been solved for expressive untimed logics, it remains open for timed logics, where formulae can express both the order of events and the quantity of time separating them. This paper solves the monitorability problem for T^{lin}, a new expressive (linear-time) timed μ-calculus that we propose. First, we show that T^{lin} is strictly more expressive than MTL, the de facto timed extension of LTL. Second, we identify MT^{lin}, the largest monitorable fragment of T^{lin}: we characterise its largest subsets of formulae that are violation monitorable, satisfaction monitorable, and *complete monitorable* (both satisfaction and violation monitorable). To wit, this is the first work that answers the monitorability question for such an expressive timed logic.

2012 ACM Subject Classification Theory of computation → Logic and verification

1 Introduction

Runtime Verification (RV) is a lightweight verification technique [30, 10], where the system at hand is *instrumented* with *monitors* [20, 21]. A monitor M is a software component that corresponds to a logical formula ϕ expressing some property of interest. At runtime, M *incrementally* analyses the execution of the system until it reaches a *verdict* w.r.t. the satisfaction or violation of ϕ [30, 2]. RV can mitigate two major drawbacks of exhaustive, offline techniques such as model checking. First, by trading exhaustiveness for scalability,

RV does not suffer from the state-space explosion problem. Second, provided that actions of interest are visible to monitors, RV is suitable for systems where no model is known beforehand [19], e.g., black-box and self-adaptive systems [33].

Due to the lack of exhaustiveness, the *monitorability* problem becomes a central issue [39, 10, 3]. Intuitively, a formula ϕ is monitorable iff its violation or satisfaction by the system can be detected by a monitor. Consider the following formula, expressed in the (action-based) Linear-time Temporal Logic (LTL) interpreted over infinite executions [38]:

$$\varphi \;=\; G\,(b \Rightarrow F\,c)$$

Formula φ expresses a classical "leads to" property, requiring that "every action b must be followed by an action c in future", with known algorithms to model-check it offline [31, 13, 47]. However, this formula is *not* monitorable, since any satisfaction verdict after a c may be contradicted by a future b not followed by a c (and dually, any violation verdict after a b may be contradicted by a future c). In more technical terms, a formula ϕ is said to be satisfaction (resp. violation) monitorable [2, 19] iff there exists a monitor for ϕ that is both sound and satisfaction (resp. violation) complete (alternative definitions of monitorability are discussed in Section 6). Formula ϕ is said *monitorable* iff it is satisfaction or violation monitorable, and *complete monitorable* if it is both satisfaction and violation monitorable. The *monitorability problem* is thus concerned with determining the largest monitorable subset of a given logic L.

Monitorability has been studied for the modal μ-calculus, also known as the Hennessy-Milner Logic with recursion (μ-HML) [28, 29]. Notably, the *maximally-expressive monitorable subset* of μ-HML, i.e., a subset within which any monitorable formula in μ-HML is expressible, has been identified for both linear-time and branching-time semantics [2, 19]. However, μ-HML is unable to express *timed properties*. Consider φ', a timed version of φ, written in the Metric Temporal Logic MTL [27] (the de facto timed extension of LTL):

$$\varphi' \;=\; G\,(b \Rightarrow F_{[0,5]}\,c)$$

Formula φ' expresses a *bounded-response* property, requiring that every occurrence of b must be followed by an occurrence of c *within 5 time units*. Timed properties are extremely important in real-time systems (see e.g., [35, 17]). Even though the body of research on RV for timed systems is extensive (more in Section 6), there is, to the best of our knowledge, no work that concretely tackles the monitorability problem in the timed setting.

Contributions. Our contribution is twofold. First, we propose T^{lin}, a new timed μ-calculus with a linear-time interpretation[1], and prove that T^{lin} is strictly more expressive than MTL (without past operators, Theorem 3.6). Second, we precisely identify VT^{lin}, ST^{lin} and CT^{lin}, the largest (i.e., maximally-expressive) fragments of T^{lin} that are violation monitorable, satisfaction monitorable and complete monitorable, respectively. Accordingly, $MT^{lin} = VT^{lin} \cup ST^{lin}$ is the largest monitorable fragment of T^{lin} (Theorem 5.43, Theorem 5.45, Theorem 5.44). For practical reasons, we also provide automatic translators (i) from MTL to T^{lin} and (ii) from MT^{lin} to monitors. To the best of our knowledge, this is the first work that solves the monitorability problem for an expressive timed logic, providing a full characterisation of its largest monitorable fragment.

[1] Note that a number of timed μ-calculi exist (see [14] for an overview), yet outside of this paper's scope due to their branching-time semantics.

Outline. The paper is organised as follows. After overviewing the preliminaries in Section 2, we discuss our core contributions in Section 3 through Section 5. Section 3 defines our new logic T^{lin} and proves that it is more expressive than MTL, providing along the way an automatic translation from the latter to the former. Section 4 lays out the theoretical foundations for timed monitors and instrumentation. We then tackle the monitorability problem in Section 5. After setting up the framework (Section 5.1), we provide a compiler from T^{lin} formulae to sound monitors (Section 5.2). We then identify CT^{lin}, VT^{lin} and ST^{lin} (both supersets of CT^{lin}), fragments of complete-, violation- and satisfaction-monitorable formulae in T^{lin}, respectively (Section 5.3, Section 5.4). In Section 5.5, we prove the maximality of CT^{lin}, VT^{lin} and ST^{lin}, and conclude accordingly that $MT^{lin} = VT^{lin} \cup ST^{lin}$ is the largest monitorable fragment of T^{lin}. Section 6 compares our contributions with related work and Section 7 concludes with future work directions.

Full version. An extended version of this paper with all proofs, more examples and further details, is available online (see Full Version above).

2 Preliminaries

In the remainder of this paper, let Σ denote a *non-empty, finite set* of *actions*.

2.1 Timed Labelled Transition Systems

The following definition is inspired from [1].

▶ **Definition 2.1.** *A Timed Labelled Transition System (TLTS) P over Σ is a tuple $\langle S_P, \text{LAB}, \longrightarrow_P \rangle$ where S_P is a set of states, $\text{LAB} = \Sigma \cup \mathbb{R}_{\geq 0} \cup \{\tau\}$ a set of labels, and $\longrightarrow_P \subseteq S_P \times \text{LAB} \times S_P$ the transition relation satisfying:*

1. *Time determinism: for every $p, p', p'' \in S_P$ and $d \in \mathbb{R}_{\geq 0}$, if $(p, d, p') \in \longrightarrow_P$ and $(p, d, p'') \in \longrightarrow_P$ then $p' = p''$,*
2. *Time additivity: for every $p, p'' \in S_P$ and $d_1, d_2 \in \mathbb{R}_{\geq 0}$, $(p, d_1 + d_2, p'') \in \longrightarrow_P$ iff $(p, d_1, p') \in \longrightarrow_P$ and $(p', d_2, p'') \in \longrightarrow_P$ from some $p' \in S_P$,*
3. *Zero delay: for every $p, p' \in S_P$, $(p, 0, p') \in \longrightarrow_P$ iff $p' = p$.*

A transition labelled $\alpha \in \Sigma$ (resp. $\alpha \in \mathbb{R}_{\geq 0}$) is a called an *action* transition (resp. delay transition). A τ transition is a non-observable transition labelled with the special symbol τ. We use a, a_i, b, c and d, d_i to denote, respectively, an element of Σ and $\mathbb{R}_{\geq 0}$. We write $p_1 \xrightarrow{\alpha_1} p_2 \xrightarrow{\alpha_2} p_3 \ldots$ to denote a *sequence of transitions* with $(p_1, \alpha_1, p_2), (p_2, \alpha_2, p_3) \ldots \in \longrightarrow_P$.

Runs. A *run* in the TLTS P is a sequence of labels (in $\text{LAB}^\omega \cup \text{LAB}^* = \text{LAB}^\infty$) corresponding to a sequence of transitions. If there exists an infinite transition sequence $p_1 \xrightarrow{\alpha_1} p_2 \xrightarrow{\alpha_2} p_3 \xrightarrow{\alpha_3} \ldots$, we say that run $\theta = \alpha_1 \alpha_2 \alpha_3 \ldots \in \text{LAB}^\omega$ is *infinite* from $p_1 \in S_P$.

Weak runs. Let $\mathcal{L} = \text{LAB} \setminus \{\tau\}$. To define weak transitions, we write $p \Longrightarrow p'$ instead of $p \, (\xrightarrow{\tau})^* \, p'$ which is the reflexive-transitive closure of the relation $\xrightarrow{\tau}$, and following [49], we write $p \xRightarrow{\alpha} p'$ for $\alpha \in \mathcal{L}$ in the following cases,

(a) $p \xRightarrow{a} p'$ if $p \Longrightarrow \cdot \xrightarrow{a} \cdot \Longrightarrow p'$,

(b) $p \xRightarrow{d} p'$ if there exists $n \geq 0$ s.t. $p \Longrightarrow \cdot \xrightarrow{d_0} \cdot \Longrightarrow \cdot \xrightarrow{d_1} \ldots \xrightarrow{d_n} \cdot \Longrightarrow p'$ where $d = \sum_{i \leq n} d_i$,

with the convention that if the set $d_1, \ldots, d_n$ is empty, then $\sum_{1 \leq i \leq n} d_i = 0$. Following [19], for $\alpha_1, \ldots, \alpha_n \in \mathcal{L}$ and $p, p' \in S_P$, we write sequences of transitions $p \xrightarrow{\alpha_1}\!\!\!\!\rightarrow \ldots \xrightarrow{\alpha_n}\!\!\!\!\rightarrow p'$ as $p \xrightarrow{\theta}\!\!\!\!\rightarrow p'$ where $\theta = \alpha_1 \ldots \alpha_n$. Such θ is called a weak run (in $\mathcal{L}^*$). We say that a weak finite run $\theta' \in \mathcal{L}^*$ *corresponds to* a finite run $\theta \in \text{LAB}^*$ iff removing τ transitions then summing consecutive delays in θ gives θ'. For instance, the weak finite run $5\,a\,3\,b\,2$ corresponds to e.g., finite runs $2\,\tau\,3\,a\,3\,b\,\tau\,2$ and $5\,a\,3\,b\,1\,\tau\,1$. The *empty weak run* is $\epsilon = 0$.

Reachability and inevitability. In TLTS P, a state $p' \in S_P$ is reachable from state $p \in S_P$ along a finite weak run $\theta \in \mathcal{L}^*$ iff $p \xrightarrow{\theta}\!\!\!\!\rightarrow p'$. We say that p' is *inevitably reachable* from p along θ, denoted $p \xrightarrow{\theta}\!\!\!\!\rightarrow_{inev} p'$, if p' is the only reachable state from p along θ, that is:

$$p \xrightarrow{\theta}\!\!\!\!\rightarrow p' \text{ and } \forall p'' \in S_P : p \xrightarrow{\theta}\!\!\!\!\rightarrow p'' \text{ implies } p' = p''$$

Similarly, we write $p \xrightarrow{\theta}\!\!\!\!\!\!\not\rightarrow p'$ if p' is not reachable from p along θ, $p \xrightarrow{\theta}\!\!\!\!\!\!\not\rightarrow$ if there exists a state p' reachable from p along θ, and $p \xrightarrow{\theta}\!\!\!\!\!\!\not\rightarrow$ if there is no reachable state from p along θ.

2.2 Timed Words

As in e.g., [12, 22], we interpret timed logics over infinite timed words.

▶ **Definition 2.2** (Timed words). *A timed word π over Σ is a possibly infinite sequence $(a_1, t_1)(a_2, t_2)...$ of timed events $(a_i, t_i) \in \Sigma \times \mathbb{R}_{\geq 0}$, where t_i are monotonically increasing timestamps, i.e., $\forall i \in \mathbb{N}$: $t_i \leq t_{i+1}$. An empty timed word contains no timed events.*

We denote $T\Sigma^\omega$ and $T\Sigma^*$ the set of infinite (omega) and finite timed words, respectively, and $T\Sigma^\infty$ the set of all timed words ($T\Sigma^\infty = T\Sigma^\omega \cup T\Sigma^*$). We denote by $|\pi|$ the *size* of a timed word $\pi \in T\Sigma^\infty$. The size of a finite timed word $\pi = (a_1, t_1)...(a_n, t_n) \in T\Sigma^*$ equals n. The size of an infinite timed word $\pi \in T\Sigma^\omega$ equals ∞. We use the notation $a_i(\pi)$ (resp. $t_i(\pi)$) for the action (resp. the timestamp) of the timed event at position i of $\pi \in T\Sigma^\infty$, with $i \in \mathbb{N}$ and $i \leq |\pi|$. For a timed event (a_i, t_i), we say that t_i is associated with a_i. The equality between two timed words $\pi, \pi' \in T\Sigma^\infty$ is defined in the usual way. For some $\pi \in T\Sigma^\infty$, we write π^i (resp. ${}^i\pi$), $i \leq |\pi|$, for the suffix of π starting at position i (resp. the prefix of π ending at i). Concatenation is defined through the partial function $Concat : T\Sigma^* \times T\Sigma^\infty \rightharpoonup T\Sigma^\infty$, defined only for couples $(\pi, \pi') \in T\Sigma^* \times T\Sigma^\infty$ such that $\pi' \in T\Sigma^\omega_{\vec{\pi}}$, where $T\Sigma^\omega_{\vec{\pi}}$ is defined as follows, w.r.t. to some finite timed word π: $T\Sigma^\omega_{\vec{\pi}} = \{\pi' \in T\Sigma^\omega \mid t_1(\pi') \geq t_{|\pi|}(\pi)\}$. We use the shorthand notation $\pi.\pi'$ instead of $Concat(\pi, \pi')$. For any timed word $\pi' \in T\Sigma^\infty$, we define the set of its prefixes $Pf(\pi') = \{\pi \in T\Sigma^* \mid \exists \pi'' \in T\Sigma^\omega_{\vec{\pi}} : \pi.\pi'' = \pi'\}$. Dually, we define for any finite timed word $\pi' \in T\Sigma^*$ its infinite *extensions* $Ext(\pi') = \{\pi \in T\Sigma^\omega \mid \pi' \in Pf(\pi)\}$.

Note that a timed word corresponds necessarily to a weak run in $\mathcal{L}^*$, with each timestamp recording the *absolute time* of occurrence of the action associated with it. For example, the finite timed word $(a, 0)(b, 3)(a, 3)(c, 7.2)$ results from the finite weak run $a\,3\,b\,a\,4.2\,c$. We will formalise the function to retrieve a finite weak run from a finite timed word in Section 5.1.

▶ Remark 2.3. Note that, in the timed systems literature, every execution in a TLTS corresponds to an infinite *time divergent* run/timed word (see e.g., [23, 8]), i.e., all runs/timed words diverge in time in the future. We do not make this assumption here since our results up to and including Section 4 do not depend on it. Instead, we formalise, justify and enforce it in Section 5.1 for monitorability purposes.

$$\phi, \psi \quad := \quad a \mid \neg a \mid \phi \wedge \psi \mid \phi \vee \psi \mid \bigcirc_I \phi \mid \phi \, \mathcal{U}_I \, \psi \mid G_I \, \phi$$

Figure 1 MTL syntax.

2.3 Intervals

We now define $\mathcal{I}$, the set of dense-time intervals with natural bounds. Hereafter, we refer to an element of $\mathcal{I}$ simply as "interval".

▶ **Definition 2.4** (Interval syntax). *The set $\mathcal{I}$ is given by the grammar $I \in \mathcal{I} ::= \sqsubset p, q \sqsupset$ where $\sqsubset \in \{[, (\}$, $\sqsupset \in \{],)\}$, $p \in \mathbb{N}$ and $q \in \mathbb{N} \cup \{\infty\}$. As per standard notation, if $q = \infty$ then $\sqsupset =)$. p (resp. q) is the left (resp. right) bound of I, we write accordingly $\mathcal{LB}(I) = p$ (resp. $\mathcal{RB}(I) = q$). I is said left closed if $\sqsubset = [$, right closed if $\sqsupset =]$, and bounded if $\mathcal{RB}(I) \neq \infty$.*

▶ **Definition 2.5** (Interval Semantics). *$[\![I]\!]$, the meaning of an interval $I = \sqsubset p, q \sqsupset \in \mathcal{I}$, is a subset of $\mathbb{R}_{\geq 0}$ defined as follows: $[\![I]\!] = \{x \in \mathbb{R}_{\geq 0} \mid p \prec_l x \prec_r q\}$ where*

- *$\prec_l = \leq$ if $\sqsubset = [$ and $\prec_l = <$ otherwise,*
- *$\prec_r = \leq$ if $\sqsupset =]$ and $\prec_r = <$ otherwise.*

Hereafter, we (i) consider only non-empty intervals, i.e., in the set $\{I \in \mathcal{I} \mid [\![I]\!] \neq \varnothing\}$ and (ii) use I to denote both the syntax and semantics of an interval I.

2.4 Metric Temporal Logic (MTL)

MTL [27] is a timed logic with linear-time semantics; it is the de facto timed extension of LTL. Note that we do not consider past operators.

Syntax and Semantics. The syntax of MTL is given in Figure 1. It includes the timed *Next* operator ($\bigcirc_I$) and the timed *Until* ($\mathcal{U}_I$) operator. As per standard notation, $\top = a \vee \neg a$, $\bot = a \wedge \neg a$, and $F_I \, \phi = \top \, \mathcal{U}_I \, \phi$ (denoting "Eventually ϕ within I"). As in [40], we add the timed *Globally* (G_I) operator to the syntax to guarantee that negations appear only before propositions, without loss of expressivity[2]. The *point-wise* semantics of MTL is given by the truth value of $\pi, i \models \phi$, denoting "$\pi \in T\Sigma^\omega$ satisfies formula ϕ at position i", with the convention that $\pi \models \phi$ iff $\pi, 1 \models \phi$ [6, 36, 45, 32]. Here, we define the semantics of a formula ϕ as the set $\{\pi \mid \pi \models \phi\}$ (Figure 2). In the remainder of this paper, we omit the subscript I of temporal operators if $I = [0, \infty)$. Accordingly, if all operators appearing in a formula ϕ are subscript free, then ϕ is an untimed MTL formula (i.e., $\phi \in$ LTL). For example, $F_{[0,\infty)} \, a$, with $a \in \Sigma$, is simply written as $F \, a$ and is therefore untimed.

▶ **Example 2.6.** Let $b, c \in \Sigma$. $[\![b \, \mathcal{U}_I \, c]\!]$ contains all infinite timed words where b is satisfied in every position from the start, until c becomes satisfied within interval I (relative to the first timestamp in π). In other words, an infinite timed word π is in $[\![b \, \mathcal{U}_I \, c]\!]$ iff $\pi \in [\![b \, \mathcal{U} \, c]\!]$ *and*

[2] That is, any formula expressed within the minimal syntax in e.g., [32] (excluding past operators), allowing negations of formulae and without G_I, can be written in our syntax in Figure 1 using the following standard equalities until negations are pushed to the level of propositions. For timed *Until*: $\neg(\phi \, \mathcal{U}_I \, \psi) = (G_I \, \neg\psi) \vee \neg\psi \, \mathcal{U}_I \, (\neg\psi \wedge \neg\phi)$, and for timed *Next* (see [25]): $\neg \bigcirc_I \phi = \bigvee_{a \in \Sigma} \bigcirc_{[0, \mathcal{LB}(I)\sqsupset} a \vee \bigcirc_I \neg\phi \vee \bigvee_{a \in \Sigma} \bigcirc_{\sqsubset \mathcal{RB}(I), \infty)} a$ where $\sqsupset =)$ if I is left closed and $\sqsupset =]$ otherwise, $\sqsubset = ($ if I is right closed and $\sqsubset = [$ otherwise.

$$
\begin{array}{lcl}
[\![a]\!] & = & \{\pi \mid a_1(\pi) = a\} \\
[\![\neg a]\!] & = & \{\pi \mid a_1(\pi) \neq a\} \\
[\![\phi \wedge \psi]\!] & = & [\![\phi]\!] \cap [\![\psi]\!] \\
[\![\phi \vee \psi]\!] & = & [\![\phi]\!] \cup [\![\psi]\!] \\
[\![\bigcirc_I \phi]\!] & = & \{\pi \mid (t_2(\pi) - t_1(\pi)) \in I \text{ and } \pi^2 \in [\![\phi]\!]\} \\
[\![\phi \,\mathcal{U}_I\, \psi]\!] & = & \{\pi \mid \exists i : (t_i(\pi) - t_1(\pi)) \in I \text{ and } \pi^i \in [\![\psi]\!] \text{ and } \forall 1 \leq j < i : \pi^j \in [\![\phi]\!]\} \\
[\![G_I\, \phi]\!] & = & \{\pi \mid \forall i \geq 1 : (t_i(\pi) - t_1(\pi)) \in I \implies \pi^i \in [\![\phi]\!]\}
\end{array}
$$

Figure 2 MTL semantics.

the first c occurs within I, i.e., at a position i of π satisfying $t_i(\pi) - t_1(\pi) \in I$. For instance, for $I = [2,5]$, $\pi = (b,3)(a,4)(c,7)\ldots$, $\pi' = (b,3)(b,4)(c,7)\ldots$ and $\pi'' = (b,2)(c,3)\ldots$, we have: $\pi \notin [\![b \,\mathcal{U}_I\, c]\!]$, $\pi' \in [\![b \,\mathcal{U}_I\, c]\!]$ and $\pi'' \notin [\![b \,\mathcal{U}_I\, c]\!]$. In particular, $\pi'' \notin [\![b \,\mathcal{U}_I\, c]\!]$ even though $\pi'' \in [\![b \,\mathcal{U}\, c]\!]$, because the first c occurs "too early" with timestamp 3 and $3 - 2 \notin [2,5]$.

3 The logic T^{lin}

We present T^{lin} (Section 3.1), our novel extension of (untimed) modal μ-calculus with linear-time semantics [15] [2, Sect.2] to the dense-time setting, and prove that T^{lin} is strictly more expressive than MTL (Section 3.2).

3.1 T^{lin} Syntax and Semantics

We first introduce a syntactic characterisation of timing constraints which we call *guards*. In the sequel, let $\mathcal{D}$ be an infinite set of variables taking values in $\mathbb{R}_{\geq 0}$, that we call *timestamp variables*, and let $\mathcal{V}$ be the set of valuation functions $v \in \mathcal{D} \to \mathbb{R}_{\geq 0}$.

▶ **Definition 3.1** (Guards). *The set $\mathcal{B}(\mathcal{D})$ of guards over $\mathcal{D}$ is given by the syntax*

$$g \;:=\; x \prec n \;\mid\; (x-y) \prec n \;\mid\; n \prec x \;\mid\; n \prec (x-y) \;\mid\; g \wedge g \;\mid\; \overline{g}$$

where $n \in \mathbb{N}$, $\prec \in \{<, \leq\}$, $x, y \in \mathcal{D}$ and $\overline{g}$ is a compact notation for $\neg g$.

A valuation v *satisfies* a guard g, denoted $v \models g$, iff replacing each variable x by $v(x)$ in g gives an expression that evaluates to true. For example, $v \models (x-y) < 2$ iff $v(x) - v(y) < 2$. We write $v \not\models g$ for $\neg(v \models g)$. If I is an interval, then we write $(x-y) \in I$ as an abbreviation for the guard $\mathcal{LB}(I) \prec_l (x-y) \wedge (x-y) \prec_r \mathcal{RB}(I)$ (where $\prec_l$ and $\prec_r$ are as defined in Definition 2.5), and $(x-y) \notin I$ for $\overline{((x-y) \in I)}$. We write $v[x := m]$, $x \in \mathcal{D}$ and $m \in \mathbb{R}_{\geq 0}$, to denote the valuation that maps x to m and every $y \in \mathcal{D} \setminus \{x\}$ to $v(y)$. We denote by $[x_1 = m_1, \ldots, x_n = m_n]$ the current valuations of some variables of interest $x_1, \ldots, x_n$ when valuation v is understood from the context.

Our T^{lin} consists of a set of *formulae* with linear-time timed semantics. Thus, before defining T^{lin}, we first define TT^{lin}, the set of *terms* that can be used to write a formula ($T^{lin} \subset TT^{lin}$). The set TT^{lin} is generated by the grammar in Figure 3, with $a \in \Sigma$, X an element of a countable set of recursion variables VAR, $x \in \mathcal{D}$, and $g \in \mathcal{B}(\mathcal{D})$. Syntactically $\mathsf{min}(X, \phi)$ and $\mathsf{max}(X, \phi)$ are binders of recursion variable X in ϕ, and $x \,\underline{\mathtt{in}}\, \phi$ binds timestamp variable $x \in \mathcal{D}$ in ϕ. The free recursion (resp. timestamp) variables of a term ϕ are given by the function $fv : TT^{lin} \longrightarrow \mathcal{P}(\text{VAR})$ (resp. $fv_{\text{TIME}} : TT^{lin} \longrightarrow \mathcal{P}(\mathcal{D})$), defined in the expected way. A term in which no variable is free is *closed*.

ϕ	$::=$	tt	*true*	$\mid$	ff	*false*
	$\mid$	X	*variable*	$\mid$	$x \,\underline{\mathtt{in}}\, \phi$	*timestamp*
	$\mid$	$\phi \wedge \psi$	*conjunction*	$\mid$	$\phi \vee \psi$	*disjunction*
	$\mid$	$\langle a \rangle \phi$	*diamond*	$\mid$	$[a]\phi$	*box*
	$\mid$	$\langle g \rangle \phi$	*diamond on time*	$\mid$	$[g]\phi$	*box on time*
	$\mid$	$\mathsf{min}(X, \phi)$	*min. fixpoint*	$\mid$	$\mathsf{max}(X, \phi)$	*max. fixpoint*

Figure 3 Syntax of TT^{lin}.

Compared to the untimed version of linear-time μ-calculi in [15] [2, Sect.2], TT^{lin} provides three new syntactic constructs to handle dense time: $x \,\underline{\mathtt{in}}\, \phi$, $[g]\phi$ and $\langle g \rangle \phi$. These are best discussed when introducing formulae later in this subsection.

$$

\end{array}
$$

Figure 4 Linear time semantics of TT^{lin}.

The semantics of terms over infinite timed words is given in Figure 4, where we have used the auxiliary functions $\langle \cdot a \cdot \rangle(-)$, $[\cdot a \cdot](-)$, $\langle \cdot g \cdot \rangle(v, -)$, $[\cdot g \cdot](v, -) : \mathcal{P}(T\Sigma^\omega) \longrightarrow \mathcal{P}(T\Sigma^\omega)$ defined by the following equalities:

$$
\begin{array}{lll}
\langle \cdot a \cdot \rangle(Z) & = \{\pi \mid a_1(\pi) = a \wedge \pi^2 \in Z\} & [\cdot a \cdot](Z) = \{\pi \mid a_1(\pi) = a \Rightarrow \pi^2 \in Z\} \\
\langle \cdot g \cdot \rangle(v, Z) & = \{\pi \mid v \models g \wedge \pi \in Z\} & [\cdot g \cdot](v, Z) = \{\pi \mid v \models g \Rightarrow \pi \in Z\}
\end{array}
\tag{1}
$$

and where environment ρ is an element of Υ, the set of partial functions $\textsc{Var} \rightharpoonup \mathcal{P}(T\Sigma^\omega)$, and v a valuation in $\mathcal{V}$. The notation $[\![\phi, \rho]\!]_v$, with $fv(\phi) \subseteq dom(\rho)$, denotes the set of timed words that satisfy ϕ w.r.t. the environment ρ and the valuation v.

Properties of the semantics. Let $dom(f)$ denote the domain of definition of a partial function f. For any $\phi \in TT^{lin}$, $v \in \mathcal{V}$, $X \in \textsc{Var}$ and $\rho \in \Upsilon$ s.t. $fv(\phi) \subseteq dom(\rho) \cup \{X\}$ we let

$$
\begin{array}{lcl}
\wr \phi \int_{v,X,\rho} & : & \mathcal{P}(T\Sigma^\omega) \longrightarrow \mathcal{P}(T\Sigma^\omega) \\
\wr \phi \int_{v,X,\rho}(Z) & = & [\![\phi, \rho[X \mapsto Z]]\!]_v
\end{array}
\tag{2}
$$

In other words $\wr \phi \int_{v,X,\rho} = \lambda y. [\![\phi, \rho[X \mapsto y]]\!]_v$.

Since environments are functions from logical variables to complete lattice, we order them in the standard pointwise way to obtain a complete lattice $\langle \textsc{Var} \to \mathcal{P}(T\Sigma^\omega), \leq \rangle$, where infinitary least upper bounds and greatest lower bounds are defined as usual. We prove that the function given in Equation (2) is monotone w.r.t. the pointwise ordering of environments, therefore Knaster-Tarski's fixpoint theorem ensures that the largest and least fixpoints of every function $\wr \phi \int_{v,X,\rho}$ exist, and are the semantics of the terms defined via $\mathsf{min}(X, -)$

and $\mathsf{max}(X, -)$. As we further demonstrate that the semantic function is continuous w.r.t. directed sets over the CPO $\langle \mathcal{P}(T\Sigma^\omega), \subseteq \rangle$, we can reason on terms defined via $\mathsf{min}(X, -)$ (resp. $\mathsf{max}(X, -)$) using Kleene fixpoint theorem and its formal dual. These strong results are crucial to prove a number of statements in this paper, in particular Proposition 3.7.

Formulae. We say that a variable $X \in \textsc{Var}$ is *guarded* in a term ϕ if all occurrences of X in ϕ are in the scope of at least one modality (i.e., $\langle a \rangle -$ or $[a]-$, $a \in \Sigma$). We say that a term ϕ is *guarded* if for all its subterms $\mathsf{min}(X, \psi_1)$ and $\mathsf{max}(Y, \psi_2)$, X is guarded in ψ_1 and Y is guarded in ψ_2. For example, the term $\mathsf{min}(X, \langle a \rangle x \,\underline{\mathtt{in}}\, [x \leq 2] X \vee Y)$ is guarded, and the term $\mathsf{min}(X, \langle a \rangle x \,\underline{\mathtt{in}}\, [x \leq 2] X \vee X)$ is not, because the rightmost occurrence of X is not in the scope of a modality. The term $\mathsf{min}(X, x \,\underline{\mathtt{in}}\, [x < 3] X)$ is not guarded, because neither $x \,\underline{\mathtt{in}}$ nor $[x < 3]$ is a modality. We may now define T^{lin}, the set of formulae in TT^{lin}.

▶ **Definition 3.2.** *The set of formulae T^{lin} is defined as the set of closed and guarded terms in TT^{lin}: $T^{lin} = \{\phi \in TT^{lin} \mid \phi \text{ is guarded and } fv(\phi) = fv_{\mathit{TIME}}(\phi) = \emptyset\}$*

Since elements of T^{lin} are closed, their semantics does not depend on valuations and environments. As a consequence, we simply write $[\![\phi]\!]$ instead of $[\![\phi, \rho]\!]_v$ to denote the semantics of any $\phi \in T^{lin}$ in any environment $\rho \in \Upsilon$ and w.r.t. to any $v \in \mathcal{V}$.

▶ Remark 3.3. Note that we work up to α-conversion of bound timestamp and recursion variables. For clarity, we assume these to be distinct and pick fresh ones when manipulating formulae. We also assume each recursion variable to be bound at most once, e.g., the formula $\mathsf{min}(X, \langle a \rangle X \vee \langle b \rangle X) \vee \mathsf{max}(X, \langle c \rangle X)$ can be expressed as $\mathsf{min}(X, \langle a \rangle X \vee \langle b \rangle X) \vee \mathsf{max}(Y, \langle c \rangle Y)$.

Let us now give two examples of the semantics of a formula $\phi \in T^{lin}$, as to explain concretely the meaning of the new constructs $x \,\underline{\mathtt{in}}\, \phi$, $[g]\phi$ and $\langle g \rangle \phi$, relying on Figure 4. In the remainder of this paper, we write $\langle \Sigma \rangle \phi$ to denote a term $\bigvee_{a \in \Sigma} \langle a \rangle \phi$.

▶ **Example 3.4.** Let $\phi \in T^{lin}$ be the following formula:

$$\phi = x \,\underline{\mathtt{in}}\, [x \leq 5] \langle b \rangle \mathtt{tt}$$

The semantics of this formula equals the set of all infinite timed words π that satisfy the following: either $t_1(\pi) > 5$ or $t_1(\pi) \leq 5$ *and* $a_1(\pi) = b$. That is, ϕ expresses the property: "if the first timestamp is smaller than 5, then the action associated with it must be a b".

▶ **Example 3.5.** Let us discuss a more complex example. The following untimed formula, given in [4, Ex. 4.2], expresses the property "every other action is a b":

$$\phi_{even(b)} = \mathsf{max}(X, \langle \Sigma \rangle \langle b \rangle X)$$

Recalling that an untimed formula is implicitly timed with the interval $[0, \infty)$, $\phi_{even(b)}$ contains all timed words π satisfying the following: at every even position i, $a_i(\pi) = b$. We want a timed version of this formula, i.e., to express $\phi_{even(b),I}$, the generalisation of $\phi_{even(b)}$ to any interval $I \in \mathcal{I}$. More precisely, the semantics of $\phi_{even(b),I}$ must contain every infinite timed word π that satisfies the following: for every even position $i \in \mathbb{N}_{>1}$, i.e., $i \bmod 2 = 0$, if $t_i(\pi) - t_1(\pi)$ is within interval I, then $a_i(\pi)$ must be a b, and $a_i(\pi)$ can be any action otherwise. For this, we use the constructs $x \,\underline{\mathtt{in}}\, -$ and $\langle g \rangle -$ to build up the following formula, where y^a denotes a distinct timestamp variable when ranging over actions in Σ:

$$\phi_{even(b),I} = x_s \,\underline{\mathtt{in}}\, \mathsf{max}(X, \langle \Sigma \rangle (x_e \,\underline{\mathtt{in}}\, \langle x_e - x_s \in I \rangle \langle b \rangle X \vee \bigvee_{a \in \Sigma} y^a \,\underline{\mathtt{in}}\, \langle y^a - x_s \notin I \rangle \langle a \rangle X))$$

Let us explain through evaluating whether some infinite timed word π belongs to the semantics of $\phi_{even(b),I}$. The $x_s \,\underline{\texttt{in}}\, -$ is used outside of the maximal-fixpoint operator, allowing timestamp variable x_s (for x "start") to record the first timestamp in π. Then, each recursion step contains two consecutive actions (as in $\phi_{even(b)}$), but this time with two disjoint recursion "paths" (the terms $x_e \,\underline{\texttt{in}}\langle x_e - x_s \in I\rangle\langle b\rangle X$ and $\bigvee_{a\in\Sigma} y^a \,\underline{\texttt{in}}\langle y^a - x_s \notin I\rangle\langle a\rangle X$). The first path requires the second action to be a b occurring within I, and the second allows the second action to be any action in Σ occurring outside of I. To assess whether an action occurs e.g., in I, the first recursion path uses a timestamp variable x_e (for x "end"), updated with the timestamp of every other action in π, and requires the difference between x_e and x_s to belong to I ($x_e \,\underline{\texttt{in}}\langle x_e - x_s \in I\rangle$). Therefore, the only condition for π to be outside of the semantics of $\phi_{even(b),I}$ is the existence of some even position at which the action is not a b *and* occurs within I. For instance, for $I = [3,5]$ and $\pi = (a,3)(c,4)(a,7)(c,9)\ldots$, $\pi' = (a,3)(b,4)(b,7)(b,8)(c,10)\ldots$ and $\pi'' = (a,2)(b,5)(c,6)(c,7)\ldots$ we have:

- $\pi \in [\![\phi_{even(b),[3,5]}]\!]$ because there is no timed action at an even position that happens within $[3,5]$: at even position 2 we have $4-3 \notin [3,5]$, at the next even position 4 we have $9-3 \notin [3,5]$, and since at this position the right bound of the interval is already exceeded then actions at subsequent even positions will occur outside of I,
- $\pi' \in [\![\phi_{even(b),[3,5]}]\!]$ because the only even position with actions occurring within I is position 4 and we have $a_4(\pi') = b$,
- $\pi'' \notin [\![\phi_{even(b),[3,5]}]\!]$ because at position 4 an action occurs within I ($7-2 \in [3,5]$) and such action is not a b.

In general: $\pi \in [\![\phi_{even(b),I}]\!]$ iff $\forall i \in \mathbb{N}_{>1} : i \bmod 2 = 0 \wedge t_i(\pi) - t_1(\pi) \in I \implies a_i(\pi) = b$, which coincides with the generalisation of $\phi_{even(b)}$ to any interval $I \in \mathcal{I}$. Note that when $I = [0,\infty)$, we obtain exactly the untimed version $\phi_{even(b)}$ using the fact that $x_e - x_s \in [0,\infty)$ is always true and $y^a - x_s \notin [0,\infty)$, for every y^a, is always false.

3.2 T^{lin} is strictly more expressive than MTL

▶ **Theorem 3.6.**

1. $\forall \phi \in MTL\ \exists \psi \in T^{lin} : [\![\phi]\!] = [\![\psi]\!]$,
2. $\exists \psi \in T^{lin}\ \forall \phi \in MTL : [\![\psi]\!] \neq [\![\phi]\!]$.

Proof.

Proving Item 1 of Theorem 3.6. We proceed through proposing the function $\text{TO}\,T^{lin} : MTL \longrightarrow T^{lin}$ that transforms any MTL formula into an equivalent T^{lin} formula (Figure 5).

▶ **Proposition 3.7.** *For every $\phi \in MTL$ we have $[\![\phi]\!] = [\![\text{TO}\,T^{lin}(\phi)]\!]$.*

Proving Item 2 of Theorem 3.6. It suffices to find a formula $\psi \in T^{lin}$ that is not expressible in MTL. As a matter of fact, the formula $\phi_{even,I}$ that we used as an example for T^{lin} (Example 3.5) is not expressible in MTL, as states the following proposition[3]:

▶ **Proposition 3.8.** *For any $I \in \mathcal{I}$, the following formula is not expressible in MTL*

$$\phi_{even(b),I} = x_s \,\underline{\texttt{in}}\, \mathsf{max}(X, \langle\Sigma\rangle(x_e \,\underline{\texttt{in}}\langle x_e - x_s \in I\rangle\langle b\rangle X \vee \bigvee_{a\in\Sigma} y^a \,\underline{\texttt{in}}\langle y^a - x_s \notin I\rangle\langle a\rangle X))$$

[3] We recall that elements of $\mathcal{I}$ cannot be empty.

$$
\begin{array}{lcl}
\textsc{to}\, T^{lin}(a) & = & \langle a \rangle \mathsf{tt} \\
\textsc{to}\, T^{lin}(\neg a) & = & [a] \mathsf{ff} \\
\textsc{to}\, T^{lin}(\phi \wedge \psi) & = & \textsc{to}\, T^{lin}(\phi) \wedge \textsc{to}\, T^{lin}(\psi) \\
\textsc{to}\, T^{lin}(\phi \vee \psi) & = & \textsc{to}\, T^{lin}(\phi) \vee \textsc{to}\, T^{lin}(\psi) \\
\textsc{to}\, T^{lin}(\bigcirc_I \phi) & = & x_s \,\underline{\texttt{in}}\, \langle \Sigma \rangle (x_e \,\underline{\texttt{in}}\, \langle x_e - x_s \in I \rangle \textsc{to}\, T^{lin}(\phi)) \\
\textsc{to}\, T^{lin}(\phi \,\mathcal{U}_I\, \psi) & = & x_s \,\underline{\texttt{in}}\, \mathsf{min}(Y, (x_e \,\underline{\texttt{in}}\, \langle x_e - x_s \in I \rangle \textsc{to}\, T^{lin}(\psi)) \vee \\
 & & \qquad (\textsc{to}\, T^{lin}(\phi) \wedge \langle \Sigma \rangle Y)) \\
\textsc{to}\, T^{lin}(G_I\, \phi) & = & x_s \,\underline{\texttt{in}}\, \mathsf{max}(Y, (x_e \,\underline{\texttt{in}}\, [x_e - x_s \in I] \textsc{to}\, T^{lin}(\phi)) \wedge \langle \Sigma \rangle Y)
\end{array}
$$

Figure 5 From MTL to T^{lin}.

The proof of Proposition 3.8 follows a standard result on the lack of expressivity of temporal logics (even when timed) w.r.t. formulae that involve *counting* such as $\phi_{even,I}$ (see [48, 6]). This concludes the proof of Item 2 of Theorem 3.6, and therefore the proof of Theorem 3.6. ◀

Accordingly, T^{lin} is strictly more expressive than MTL. As we will see in Section 5, $\phi_{even(b),I}$ is monitorable for violations in the general case (and also for satisfactions whenever I is bounded), which means that T^{lin} allows for a larger set of monitorable formulae than MTL.

4 Monitoring a System

In this section, we formally define timed monitors (Section 4.1), as well as the instrumentation operator (Section 4.2). In the sequel, we refer to a timed monitor simply as monitor, and to a system that we want to monitor as a *system under monitoring* (SUM).

4.1 Monitors Syntax and Semantics

$$
\begin{array}{lcl}
M, N & ::= & E \mid a.M \mid g.M \mid M + N \mid \mathsf{rec}\ X.M \mid X \mid \textsc{let}\ x\ \textsc{in}\ M \\
E & ::= & \mathsf{END} \mid \mathsf{NO} \mid \mathsf{YES}
\end{array}
$$

Figure 6 Syntax of m-terms in TMon.

We first define TMon, the set of monitor terms, hereafter abbreviated m-terms (Figure 6, where $x \in \mathcal{D}$, $a \in \Sigma$, $g \in \mathcal{B}(\mathcal{D})$ and $X \in \textsc{Var}$). $\mathsf{YES}, \mathsf{NO}, \mathsf{END}$ are special m-terms called *verdicts*, corresponding respectively to acceptance, rejection and termination (i.e., an inconclusive outcome). By abuse of notation, we write E to denote $L(E)$, the set of m-terms generated by the grammar of Figure 6 starting from the nonterminal symbol E [26].

Notions of guardedness and free variables are defined similarly as for TT^{lin} (Section 3.1). In an m-term, $\mathsf{rec}\ X.M$ (resp. $\textsc{let}\ x\ \textsc{in}\ M$) is a binder of the recursion variable X (resp. timestamp variable x). The free recursion (resp. timestamp) variables of an m-term M are given by the function $mfv : \textsc{TMon} \longrightarrow \mathcal{P}(\textsc{Var})$ (resp. $mfv_{time} : \textsc{TMon} \longrightarrow \mathcal{P}(\mathcal{D})$), defined

in the expected way. A recursion variable X is guarded in an m-term M if every occurrence of X in M is in the scope of at least one modality $(a.)$, and $M \in \text{TMon}$ is guarded if for all its subterms $\mathsf{rec}\ X.N$, X is guarded in N. We may now define the set of monitors Mon.

▶ **Definition 4.1.** *The set of monitors* Mon *is defined as the guarded m-terms in* TMon *closed vis-à-vis recursion variables:* $\text{Mon} = \{M \in \text{TMon} \mid \ M \text{ is guarded and } mfv(M) = \emptyset\}$.

For example, $\mathsf{rec}\ X.(a.\text{let}\ x\ \text{in}\ g.X + Y) \notin \text{Mon}$ because it is not closed w.r.t. recursion variable Y, whereas $\mathsf{rec}\ X.\text{let}\ y\ \text{in}\ (x - y \leq 2).a.X \in \text{Mon}$.

▶ Remark 4.2. Note that, compared to that of formulae (Definition 3.2), Definition 4.1 is more relaxed as monitors are allowed to have free timestamp variables. The practical reason behind this is illustrated later in this subsection (Example 4.6).

▶ Remark 4.3. When manipulating monitors, we assume the same conventions as in Remark 3.3; in particular we assume fresh variables are picked at each recursion step.

The semantics of *all* monitors in Mon is given by the TLTS $\mathbb{M} = \langle S_{\mathbb{M}}, \mathcal{L}, \longrightarrow_{\mathbb{M}} \rangle$. A state $m \in S_{\mathbb{M}}$ is of the form (M, v_c, v_t) where M is a monitor (in Mon), $v_c \in \mathbb{R}_{\geq 0}$ the value of *monitor time* (to record the "global" time) and $v_t \in \mathcal{V}$ a valuation (to update timestamp variables and evaluate guards). The rules of the transition relation $\longrightarrow_{\mathbb{M}} \subseteq S_{\mathbb{M}} \times \mathcal{L} \times \mathbb{M}$ are given by[4] Figure 7, where $a \in \Sigma$ and $d \in \mathbb{R}_{\geq 0}$. The rule mVer states that a verdict state, i.e., a state of the form $(M \in E, -, -)$ can perform a transition with any visible action and reach a state preserving M, i.e., verdicts are *persistent*, a central property of monitors [2]. Rule mTime corresponds to a delay transition. The remaining rules are better explained through examples.

▶ Remark 4.4. In practice, in order to monitor a formula $\phi \in T^{lin}$, we start with a *closed* monitor M (i.e., $M \in \text{Mon}$ *and* $mfv_{time}(M) = \emptyset$) at initial state $m_0 = (M, 0, \mathbf{0})$. As the results in this subsection are more generic and do not rely on these assumptions, the latter will be introduced, justified and enforced in Section 5. Without loss of generality, we still use initial states of the form $(M, 0, \mathbf{0})$ for illustration purposes.

▶ **Example 4.5.** Let $\Sigma = \{b, c\}$, $M = \text{let}\ x\ \text{in}\ ((x > 5).\mathsf{YES} + (x \leq 5).(b.\mathsf{YES} + c.\mathsf{NO}))$, and let $m_0 = (M, 0, \mathbf{0})$ be a state of $\mathbb{M}$ (the TLTS of all monitors, see above). Say M performs, from m_0, the finite run $\theta = 6\,c$. This will give the following (unique) trace: $(M, 0, \mathbf{0}) \xrightarrow{6} (M, 6, \mathbf{0}) \xrightarrow{c} (\mathsf{YES}, 6, [x = 6])$, where, from left to right:

- the delay transition $d = 6$ is allowed by rule mTime,
- the action transition c is allowed by rule mLet. This is because the state $((x > 5).\mathsf{YES} + (x \leq 5).(a.\mathsf{YES} + b.\mathsf{NO}), 6, [x = 6])$ can perform any action in Σ and reach $(\mathsf{YES}, 6, [x = 6])$ following, respectively, rules mSelL, mGuard and MVer (Figure 7).

▶ **Example 4.6.** Let $\Sigma = \{b, c\}$ and the monitor

$$M = \text{let}\ x\ \text{in}\ (\mathsf{rec}\ X.(\text{let}\ y\ \text{in}\ ((y - x \leq 5).(b.X + c.\mathsf{NO}) + (y - x > 5).\mathsf{YES})))$$

and let

$$N = \mathsf{rec}\ X.(\text{let}\ y\ \text{in}\ ((y - x \leq 5).(b.X + c.\mathsf{NO}) + (y - x > 5).\mathsf{YES}))$$

i.e., N is the subterm of M without the binder of timestamp variable x. Intuitively, the syntax of M indicates that it accepts a run (becomes YES) iff every action seen within 5 time units, relative to the global time at which the first action occurs, is a b (otherwise it

[4] We formally prove that these rules are well defined over $S_{\mathbb{M}} \times \mathcal{L} \times S_{\mathbb{M}}$.

$$\textsc{mAct}\ \frac{}{(a.M, v_c, v_t) \xrightarrow{a} (M, v_c, v_t)} \qquad \textsc{mVer}\ \frac{M \in E}{(M, v_c, v_t) \xrightarrow{a} (M, v_c, v_t)}$$

$$\textsc{mLet}\ \frac{(M, v_c, v_t[x := v_c]) \xrightarrow{a} (M', v_c, v_t')}{(\text{LET } x \text{ IN } M, v_c, v_t) \xrightarrow{a} (M', v_c, v_t')} \qquad \textsc{mTime}\ \frac{}{(M, v_c, v_t) \xrightarrow{d} (M, v_c + d, v_t)}$$

$$\textsc{mSelL}\ \frac{(M, v_c, v_t) \xrightarrow{a} (M', v_c, v_t')}{(M + N, v_c, v_t) \xrightarrow{a} (M', v_c, v_t')} \qquad \textsc{mRec}\ \frac{(M[^{\text{rec } X.M}/_X], v_c, v_t) \xrightarrow{a} (M', v_c, v_t')}{(\text{rec } X.M, v_c, v_t) \xrightarrow{a} (M', v_c, v_t')}$$

$$\textsc{mSelR}\ \frac{(N, v_c, v_t) \xrightarrow{a} (N', v_c, v_t')}{(M + N, v_c, v_t) \xrightarrow{a} (N', v_c, v_t')} \qquad \textsc{mGuard}\ \frac{(M, v_c, v_t) \xrightarrow{a} (M', v_c, v_t') \wedge v_t \models g}{(g.M, v_c, v_t) \xrightarrow{a} (M', v_c, v_t')}$$

Figure 7 SOS rules for monitors.

rejects). Let us apply the rules of $\longrightarrow_{\mathbb{M}}$, starting at $(M, 0, \mathbf{0})$, to see whether M accepts the run $\theta = 2\,b\,6\,c\,\ldots$ as it should: $(M, 0, \mathbf{0}) \xrightarrow{2} (M, 2, \mathbf{0}) \xrightarrow{b} (M', 2, [x = 2, y = 2]) \xrightarrow{6} (M', 8, [x = 2, y = 2]) \xrightarrow{c} (\mathsf{YES}, 8, [x = 2, y = 8]) \ldots$ where

$$M' = \text{LET } y \text{ IN } ((y - x \leq 5).(b.N + c.\mathsf{NO}) + (y - x > 5).\mathsf{YES})$$

applying, respectively (from left to right) rule mTime, mLet, mTime and mLet. Notice now that, in M', there is no longer the binder of timestamp variable x, and therefore x is free in M'. This is because LET x IN in M, outside of the recursion, is intended to evaluate constantly to the value of global time corresponding to the first action. This simplification is handy to deal with monitors with both recursion and guards, and justifies the relaxed nature of Definition 4.1, allowing monitors to have free timestamp variables.

Parallel monitors. In practice, a formula is often monitored through composing monitors in parallel [2]. The syntax of m-terms is extended accordingly with two parallel composition operators: $\otimes$ for *parallel conjunction* and $\oplus$ for *parallel disjunction*, adapted from [2] to the (linear-time) timed setting. The extended syntax thereof is given in Figure 8, with $\odot \in \{\otimes, \oplus\}$.

M, N	$::= E$	$\mid a.M$	$\mid g.M$	$\mid M + N$
		$\mid \text{rec } X.M$	$\mid X$	$\mid \text{LET } x \text{ IN } M$
		$\mid$	$M \otimes N$	(par. conj.)
		$\mid$	$M \oplus N$	(par. disj.)
E	$::= \mathsf{VYES}$	$\mid \mathsf{VNO}$	$\mid \mathsf{VEND}$	
VYES	$::= \mathsf{YES}$	$\mid \mathsf{VYES} \oplus M$	$\mid \mathsf{VYES} \otimes \mathsf{VYES}$	
VNO	$::= \mathsf{NO}$	$\mid \mathsf{VNO} \otimes M$	$\mid \mathsf{VNO} \oplus \mathsf{VNO}$	
VEND	$::= \mathsf{END}$	$\mid \mathsf{VEND} \odot \mathsf{VEND}$		

Figure 8 Syntax of TMon (extended with parallel composition).

Accordingly, we extend the set of verdicts by grouping acceptance, rejection and termination verdicts in the set VYES, VNO and VEND respectively. By abuse of notation, we write $E \in \{\mathsf{VYES}, \mathsf{VNO}, \mathsf{VEND}\}$ to denote $L(E)$, the set of m-terms generated by the grammar of Figure 8 starting from the nonterminal symbol E. Each of the latter is defined recursively using the corresponding verdict from a *regular* (i.e., non-parallel) m-term in the expected way. For example, an acceptance verdict VYES is reached in a parallel disjunction of two regular m-terms whenever a YES verdict is reached by one of them. The set of monitors Mon is therefore extended accordingly (by applying Definition 4.1 to TMon, as extended to parallel composition). Thanks to lifting verdict composition rules to the syntax level, the extension of the semantics of monitors in Figure 7 to parallel monitors becomes rather simple; we only need one additional rule, stating that monitors in a composition perform actions together:

$$\textsc{mPar}\ \frac{M \odot N \notin E \quad (M, v_c, v_t) \xrightarrow{a} (M', v_c, v_t') \quad (N, v_c, v_t) \xrightarrow{a} (N', v_c, v_t'')}{(M \odot N, v_c, v_t) \xrightarrow{a} (M' \odot N', v_c, v_t' \overset{v_t}{\sqcup} v_t'')}$$

where

$$v_t' \overset{v_t}{\sqcup} v_t''(x) = \begin{cases} v_t'(x) \text{ if } v_t'(x) \neq v_t(x) \\ v_t''(x) \text{ if } v_t''(x) \neq v_t(x) \\ v_t(x) \text{ otherwise} \end{cases}$$

Recall that bound timestamp variables in M and N are disjoint, and therefore the first two cases are disjoint. $\mathbb{M} = \langle S_{\mathbb{M}}, \mathcal{L}, \longrightarrow_{\mathbb{M}} \rangle$, the TLTS describing the semantics of all monitors in Mon is therefore extended to parallel monitors, with the transition relation $\longrightarrow_{\mathbb{M}}$ defined using the rules in Figure 7 and the rule mPar above.

In the sequel, we use the shorthand notation $N + A.M$ to denote the selection between monitor N and $a.M$ for all actions in $A \subseteq \Sigma$, with the convention $N + A.M = N$ if A is empty. Moreover, we write $\overline{A}$, $A \subseteq \Sigma$, to denote the set $\Sigma \setminus A$ and similarly $\overline{a}$, $a \in \Sigma$ to denote $\Sigma \setminus \{a\}$. Using these compact notations, we can write e.g., for $\Sigma = \{a_1, a_2, a_3, a_4\}$, $a_2.M + \overline{a_2}.\mathsf{NO}$ instead of $a_2.M + a_1.\mathsf{NO} + a_3.\mathsf{NO} + a_4.\mathsf{NO}$.

Verdict persistence. As mentioned earlier, all monitors in Mon are verdict persistent.

▶ **Lemma 4.7** (Verdict presistence). *For all $(M, v_c, v_t), (N, v_c', v_t') \in S_{\mathbb{M}}$ and finite weak run $\theta \in \mathcal{L}^*$, if $M \in E$ then: $(M, v_c, v_t) \xrightarrow{\theta}\!\!\!\!\rightarrow (N, v_c', v_t')$ implies $N = M$.*

Verdict states. Thanks to verdict persistence, once a monitor reaches a *verdict state*, i.e., a state whose first component is a verdict, the information within such state become irrelevant regardless of what the monitor will perform in the future, at the exception of the verdict itself (which will remain unchanged). Therefore, we may denote by yes, no, end any verdict state in $(M, v_c, v_t) \in S_{\mathbb{M}}$ such that $M \in \mathsf{VYES}$, $M \in \mathsf{VNO}$, $M \in \mathsf{VEND}$, respectively. Strictly speaking, yes, no, end may be viewed as equivalent classes grouping states with acceptance, rejection and termination verdicts, respectively. In order to simplify the writing, we abuse notation by defining an equality instead. For all $(M, v_c, v_t), (N, v_c', v_t') \in S_{\mathbb{M}}$:

$$(M, v_c, v_t) = (N, v_c', v_t') = \mathsf{yes} \text{ iff } M \in \mathsf{VYES} \text{ and } N \in \mathsf{VYES}$$

$$(M, v_c, v_t) = (N, v_c', v_t') = \mathsf{no} \text{ iff } M \in \mathsf{VNO} \text{ and } N \in \mathsf{VNO}$$

$$(M, v_c, v_t) = (N, v_c', v_t') = \mathsf{end} \text{ iff } M \in \mathsf{VEND} \text{ and } N \in \mathsf{VEND}$$

For example, we write $m \xrightarrow{\theta}\!\!\!\!\rightarrow \mathsf{yes}$ if there exists a state (N, v_c, v_t) with $N \in \mathsf{VYES}$ reachable from m along θ, and similarly $m \xrightarrow{\theta}\!\!\!\!\rightarrow_{inev} \mathsf{yes}$ if all states (N, v_c, v_t) reachable along θ from m satisfy $N \in \mathsf{VYES}$.

4.2 Instrumentation

The notion of a monitor "performing an action" is in fact misleading, since a monitor is rather a *passive entity* that *follows* an SUM. We need an operator to compose a monitor with an SUM accordingly; this is known as *instrumentation*. We define next the rules of the instrumentation operator $\lhd$, adapted to the timed settings from [2]. Hereafter, recall $\mathbb{M} = \langle S_{\mathbb{M}}, \mathcal{L}, \longrightarrow_{\mathbb{M}} \rangle$ the TLTS describing the behaviour of all monitors, and let $P = \langle S_P, \text{LAB}, \longrightarrow_P \rangle$ be an arbitrary TLTS describing the behaviour of an SUM. That is, we do not assume any particular form of states in S_P or rules in $\longrightarrow_P$, since the SUM can be e.g., a blackbox system.

▶ **Definition 4.8** (Instrumentation). *We define the* monitored system *using the instrumentation operator $\lhd$ as follows: $\mathbb{M} \lhd P = \langle S_{\mathbb{M}} \times S_P, \text{LAB}, \longrightarrow_{\lhd} \rangle$. The transition relation $\longrightarrow_{\lhd}$ is defined in Figure 9, where $m, m' \in S_{\mathbb{M}}$, $p, p' \in S_P$, $\alpha \in \mathcal{L}$ and $a \in \Sigma$. To save notations, we use $m \lhd p$ for $(m, p) \in S_{\mathbb{M}} \times S_P$.*

$$\frac{p \xrightarrow{\alpha}_P p' \quad m \xrightarrow{\alpha}_{\mathbb{M}} m'}{m \lhd p \xrightarrow{\alpha}_{\lhd} m' \lhd p'}\ \textsc{iMon} \qquad \frac{p \xrightarrow{\tau}_P p'}{m \lhd p \xrightarrow{\tau}_{\lhd} m \lhd p'}\ \textsc{iAsy}$$

$$\frac{p \xrightarrow{a}_P p' \quad m \xrightarrow{a}\!\!\!\!\!\!\rightarrow_{\mathbb{M}} \quad m = (N, v_c, v_t)}{m \lhd p \xrightarrow{a}_{\lhd} (\mathsf{END}, v_c, v_t) \lhd p'}\ \textsc{iTer}$$

Figure 9 SOS rules for Instrumentation.

Rule iMon states that the monitor must follow any action or delay transition performed by the SUM, whereas rule iAsy corresponds to the SUM performing a τ transition. Finally, if the SUM may perform an action a and the monitor may not, rule iTer allows the SUM to perform a while forcing the monitor to reach a verdict state end.

▶ Remark 4.9. Note that iTer is defined only for actions and not for time delays. This is because a monitor can always perform time delays (rule mTime, Figure 7) and therefore it can always follow the SUM if it performs a delay.

Preserving the SUM behaviours. We prove, through strong timed bisimulation [1], that the instrumentation operator *preserves* the behaviours of the SUM, i.e., instrumenting any SUM P with any monitor M preserves *exactly* all the behaviours of P. Accordingly, given a finite run $\theta \in \text{LAB}^*$, performed by the SUM, we say that a monitor *consumes* the weak run $\theta' \in \mathcal{L}^*$ corresponding to θ (Section 2.1).

▶ **Example 4.10.** Let us consider the monitor M, starting at state $m_0 = (M, 0, \mathbf{0})$ (Example 4.5), and an SUM performing a finite run $\theta = 2\,\tau\,4\,\tau\,c$ from state p to state p'. We have then $m_0 \lhd p \xrightarrow{\theta} \mathsf{yes} \lhd p'$, which corresponds to M consuming $\theta' = 6\,c$, the weak finite run corresponding to θ. Informally, the monitor M checks the following property at runtime: "if the first consumed action occurs within 5 time units, then such action must be a b".

5 Monitorability of T^{lin}

In this section, we present the monitorability results on T^{lin}. In particular, we characterise its largest violation-, satisfaction- and complete-monitorable fragments.

5.1 Setting the framework

5.1.1 Abstracting Away the Instrumentation Operator

To alleviate notations, we abstract away the instrumentation operator through considering only *reactive* monitors, i.e., monitors that can follow any run from any state of any SUM (i.e., consume any run in $\mathcal{L}^*$). This choice should introduce no loss of generality: in Section 5.2, we show how it is rather straightforward to synthesise a reactive monitor that intuitively "corresponds" to (verifies online) any formula in T^{lin}.

▶ **Definition 5.1** (Monitor Reactivity (extended from [2])). *A monitor $M \in \textsc{Mon}$ is reactive iff* $\forall \theta \in \mathcal{L}^*, v_c \in \mathbb{R}_{\geq 0}, v_t \in \mathcal{V} : (M, v_c, v_t) \xrightarrow{\theta}\!\!\!\!\rightarrow$

Since we are in a linear-time setting, i.e., the set of behaviours of an SUM equals the set of its infinite runs, all behaviours of all SUMs simply collapse into all infinite runs in $\textsc{Lab}^\omega$. We write accordingly $m \xrightarrow{\theta}\!\!\!\!\rightarrow m'$ to denote a reactive monitor consuming weak run θ. This way, we can simply abstract away SUMs and the instrumentation operator, the former replaced with the sum of all infinite runs in $\textsc{Lab}^\omega$ and the latter collapsing into simple consumption of weak runs that is always possible thanks to the reactivity assumption.

5.1.2 Monitor Initial State

Intuitively, in order to assess whether M can monitor ϕ, monitoring should start at state $m_0 = (M, 0, \mathbf{0})$. That is, monitor M is *initialised* at state m_0, at which its time (monitor time) starts. Since monitor time may only increase (through consuming delays), it refers to the relative time since the monitoring of ϕ started. Examples of a monitor M starting at state m_0 have been already discussed within the previous section, e.g., in Example 4.5.

5.1.3 Timed Words, Weak Runs and Time Divergence

First, we make an important, yet natural assumption on infinite timed words, namely *time divergence*. To explain this, let us consider the following infinite timed word: $\pi = (a_1, \frac{1}{2}), (a_2, \frac{3}{4}), (a_3, \frac{7}{8}), (a_4, \frac{15}{16}), \ldots$ One can notice that π corresponds to a weak run with an initial delay of $\frac{1}{2}$, and each subsequent delay equalling half of the previous delay. This results in the timestamps of π increasing but never beyond absolute time 1 (since $\sum_{k=1}^{\infty}(\frac{1}{2^k}) = 1$). The infinite timed word π is *time convergent*, and it is clear to see that there is no "real" system that can produce such timed word; for the simple reason that time always diverges in reality (see e.g., [23, 8][18, Sect.2]). An infinite timed word π is time divergent iff its timestamps are unbounded, formally [23, Sect. 4], [7, Def. 1]:

$$\forall x \in \mathbb{R}, \exists i \in \mathbb{N} : t_i(\pi) > x \tag{3}$$

We restrict ourselves accordingly to the set $T\Sigma^\omega_{div} = \{\pi \in T\Sigma^\omega \mid \pi \text{ satisfies (3) }\}$ henceforth.

Second, as we will see later on, central notions on monitorability, such as monitor soundness and completeness, gravitate around the ability to reach a verdict, w.r.t. whether an infinite timed word $\pi \in T\Sigma^\omega_{div}$ is in the semantics of the monitored formula, based on

consuming a finite prefix of π. We need therefore to define the notion of consuming a finite timed word. Since (i) we already defined the notion of consuming a weak run (Section 4), and (ii) a finite timed word necessarily corresponds to a finite weak run in $\mathcal{L}^*$ (Section 2.2), we simply need to define a function to retrieve the latter from the former.

▶ **Definition 5.2** (From finite timed words to finite weak runs)**.**

$$\textsc{Trn} : T\Sigma^* \longrightarrow \mathcal{L}^*$$

where $\textsc{Trn}(\pi) = d_1 a_1 d_2 a_2 \ldots$ *with* $d_i = t_i - t_{i-1}$ *and* $t_0 = 0$*, and the convention that* $\textsc{Trn}(\pi)$ *gives the empty weak run* ϵ *if* π *is an empty timed word.*

In the remainder of this paper, by abuse of terminology, we often say a monitor "consumes (the finite timed word) π" instead of "consumes (the finite weak run) $\textsc{Trn}(\pi)$"

▶ **Example 5.3.** Consider the finite timed word $\pi = (a, 1.7)(b, 1.7)(b, 5.7)$. The corresponding weak run is obtained using Definition 5.2: $\textsc{Trn}(\pi) = 1.7\, a\, 0\, b\, 4\, b$.

▶ Remark 5.4. Note that time divergence does not pose any particular restriction on finite timed words, i.e., $\{Pf(\pi) \mid \pi \in T\Sigma^\omega_{div}\} = T\Sigma^*$. In words, any finite timed word (in $T\Sigma^*$) can be retrieved as a prefix of a time-divergent infinite timed word, see [8].

5.1.4 Monitor Soundness and Completeness

We now define the central monitor properties of *soundness* and *completeness* extended from [2, Definition 4.1] to our timed setting.

▶ **Definition 5.5** (Monitor Soundness)**.** *A reactive monitor* M *is sound for a formula* $\phi \in T^{lin}$ *if, for every finite timed word* $\pi \in T\Sigma^*$*:*

- $m_0 \overset{\textsc{Trn}(\pi)}{\longrightarrow\!\!\!\!\!\rightarrow}$ yes *implies* $(\forall \pi' \in Ext(\pi) : \pi' \in [\![\phi]\!])$
- $m_0 \overset{\textsc{Trn}(\pi)}{\longrightarrow\!\!\!\!\!\rightarrow}$ no *implies* $(\forall \pi' \in Ext(\pi) : \pi' \notin [\![\phi]\!])$

Sound monitors have the important property of *consistency*.

▶ **Definition 5.6** (Consistent monitors)**.** *A reactive monitor* M *is consistent iff* $\forall \pi \in T\Sigma^*$:

$m_0 \overset{\textsc{Trn}(\pi)}{\longrightarrow\!\!\!\!\!\rightarrow}$ yes *implies* $m_0 \overset{\textsc{Trn}(\pi)}{\not\longrightarrow\!\!\!\!\!\rightarrow}$ no *and* $m_0 \overset{\textsc{Trn}(\pi)}{\longrightarrow\!\!\!\!\!\rightarrow}$ no *implies* $m_0 \overset{\textsc{Trn}(\pi)}{\not\longrightarrow\!\!\!\!\!\rightarrow}$ yes

▶ **Lemma 5.7.** *If* M *is sound for some* $\phi \in T^{lin}$ *then* M *is consistent.*

▶ **Definition 5.8** (Monitor Completenness)**.** *Let* $M \in \textsc{Mon}$ *be a reactive monitor and* $\phi \in T^{lin}$ *a formula.* M *is:*

- *violation complete for* ϕ *iff for all* $\pi \in T\Sigma^\omega_{div}$*,* $\pi \notin [\![\phi]\!]$ *implies* $\exists \pi' \in Pf(\pi) : m_0 \overset{\textsc{Trn}(\pi')}{\longrightarrow\!\!\!\!\!\rightarrow}$ no
- *satisfaction complete for* ϕ *iff for all* $\pi \in T\Sigma^\omega_{div}$*,* $\pi \in [\![\phi]\!]$ *implies* $\exists \pi' \in Pf(\pi) : m_0 \overset{\textsc{Trn}(\pi')}{\longrightarrow\!\!\!\!\!\rightarrow}$ yes
- *complete for* ϕ *if it is both violation and satisfaction complete for* ϕ*.*

Strong completeness. In practice, it is desirable to have *reliable* monitors, i.e., monitors exhibiting a stronger property than violation/satisfaction completeness. Let us explain this through an example.

▶ **Example 5.9.** Let $\Sigma = \{b, c\}$ and consider the monitor

$$M' = \text{LET } x \text{ IN } ((x > 5).\mathsf{YES} + (x \leq 5).(b.\mathsf{YES} + c.\mathsf{NO} + b.\mathsf{END} + c.\mathsf{END}))$$

a slight modification of the monitor M in Example 4.5. M' is reactive, and it is rather easy to see that M' is sound and complete for the following T^{lin} formula:

$$\phi = x \,\underline{\mathtt{in}}[x \leq 5]\langle b\rangle \mathsf{tt}$$

stating that if the first timestamp is smaller than 5, then the action must be a b. For soundness, if verdict state no is reached, then the first timed event the monitor saw was (c, t) with $t \leq 5$, and it is guaranteed that any infinite extension of the finite timed word (c, t) will be outside the semantics of ϕ. (The case where yes is reached is analogous). For violation completeness, any infinite timed word $\pi \notin [\![\phi]\!]$ starts necessarily with a timed event (c, t) with $t \leq 5$, and given any prefix π' of π of the form (c, t), $t \leq 5$, no is reachable from $(M', 0, \mathbf{0})$ along π'. (The reasoning for satisfaction completeness is analogous). In practice, however, M' is not a reliable monitor for ϕ, as it may reach end instead of no after consuming e.g., $(c, 2)$ (and dually, to reach end instead of yes after consuming e.g., $(b, 3)$). We propose a stronger definition of completeness next.

▶ **Definition 5.10** (Strong Completenness)**.** *Let $M \in \text{MON}$ be a reactive monitor and $\phi \in T^{lin}$ a formula. M is:*

- *strongly violation complete for ϕ iff for all $\pi \in T\Sigma^{\omega}_{div}$, $\pi \notin [\![\phi]\!]$ implies $\exists \pi' \in Pf(\pi)$: $m_0 \overset{\text{TRN}(\pi')}{\longrightarrow\!\!\!\!\!\rightarrow}_{inev} \mathsf{no}$*
- *strongly satisfaction complete for ϕ iff for all $\pi \in T\Sigma^{\omega}_{div}$, $\pi \in [\![\phi]\!]$ implies $\exists \pi' \in Pf(\pi)$: $m_0 \overset{\text{TRN}(\pi')}{\longrightarrow\!\!\!\!\!\rightarrow}_{inev} \mathsf{yes}$*

M is strongly complete for ϕ if it is both strongly violation and strongly satisfaction complete for ϕ.

In brief, the key element in the above definition is the inevitability of verdicts. That is, if a strongly satisfaction- (resp. violation-) complete monitor for some $\phi \in T^{lin}$ is given an infinite timed word π that is in (resp. outside of) the semantics of ϕ, then it will inevitably reach verdict yes (resp. no) after consuming a finite prefix of π. Therefore, such monitor has the important feature of reliability in practice as discussed in Example 5.9 above.

▶ **Example 5.11.** In Example 5.9, the monitor M' is neither strongly satisfaction nor strongly violation complete for ϕ.

▶ Remark 5.12. In this paper, the notion of violation- or satisfaction-monitorable formulae will still rely on the existence of a monitor that obeys soundness (Definition 5.5) and the weaker version of completeness (Definition 5.8). Strong (satisfaction/violation) completeness (Definition 5.10) will be a property of *our monitors*, which we synthesise automatically from T^{lin}, for formulae within the satisfaction/violation/complete monitorable fragments.

5.2 Sound monitor synthesis

In this subsection, we define a compiler from T^{lin} to monitors and prove that, for every formula $\phi \in T^{lin}$, our compiler outputs a monitor that is sound for ϕ (Proposition 5.15).

The compiler $(\!|-|\!) : T^{lin} \longrightarrow \text{MON}$ is defined in Figure 10 (note that monitors generated by $(\!|-|\!)$ are necessarily closed since $(\!|-|\!)$ is applied only to formulae, i.e., elements of T^{lin}). The rules of $(\!|-|\!)$ are rather simple and straightforward, operating on the syntax of the formula

$(\!\lvert \mathtt{tt} \rvert\!)$	$=$	YES	$(\!\lvert \mathtt{ff} \rvert\!)$	$=$	NO
$(\!\lvert x \,\underline{\mathtt{in}}\, \phi \rvert\!)$	$=$	LET x IN $(\!\lvert \phi \rvert\!)$	$(\!\lvert X \rvert\!)$	$=$	X
$(\!\lvert [a]\phi \rvert\!)$	$=$	$a.(\!\lvert \phi \rvert\!) + \overline{a}.\mathsf{YES}$	$(\!\lvert \langle a \rangle \phi \rvert\!)$	$=$	$a.(\!\lvert \phi \rvert\!) + \overline{a}.\mathsf{NO}$
$(\!\lvert [g]\phi \rvert\!)$	$=$	$g.(\!\lvert \phi \rvert\!) + \overline{g}.\mathsf{YES}$	$(\!\lvert \langle g \rangle \phi \rvert\!)$	$=$	$g.(\!\lvert \phi \rvert\!) + \overline{g}.\mathsf{NO}$
$(\!\lvert \phi \wedge \psi \rvert\!)$	$=$	$(\!\lvert \phi \rvert\!) \otimes (\!\lvert \psi \rvert\!)$	$(\!\lvert \phi \vee \psi \rvert\!)$	$=$	$(\!\lvert \phi \rvert\!) \oplus (\!\lvert \psi \rvert\!)$
$(\!\lvert \mathsf{max}(X, \phi) \rvert\!)$	$=$	rec $X.(\!\lvert \phi \rvert\!)$	$(\!\lvert \mathsf{min}(X, \phi) \rvert\!)$	$=$	rec $X.(\!\lvert \phi \rvert\!)$

Figure 10 $(\!\lvert - \rvert\!)$ rules from T^{lin} to monitors, defined recursively on subterms of formulae.

provided as an input. For example, if the formula is $[a]\langle b\rangle\mathtt{tt}$, whose semantics is "if the first action is a, then the second must be a b" (Section 3.1), then we want a monitor that consumes the first action, and becomes verdict YES if such action is not a, and monitors that the second action is a b otherwise. We obtain thus the monitor $(\!\lvert [a]\langle b\rangle\mathtt{tt} \rvert\!) = a.(b.\mathsf{YES} + \overline{b}.\mathsf{no}) + \overline{a}.\mathsf{YES}$, which corresponds to the description above (under the rules defined in Section 4.1).

▶ **Example 5.13.** The monitor M in Example 4.5 is compiled from the formula: $x\,\underline{\mathtt{in}}[x \leq 5]\langle b\rangle\mathtt{tt}$ over $\Sigma = \{b, c\}$. More complex examples will follow within the next subsections.

▶ **Lemma 5.14.** *For all $\phi \in T^{lin}$, $(\!\lvert \phi \rvert\!)$ is reactive.*

▶ **Proposition 5.15.** *For all $\phi \in T^{lin}$, $(\!\lvert \phi \rvert\!)$ is sound for ϕ.*

5.3 Complete Monitorable Fragment

In this subsection, we identify CT^{lin}, a subset of T^{lin}, and prove its complete monitorability (Theorem 5.26).

▶ **Definition 5.16** (Complete-monitorable formulae)**.** *A formula $\phi \in T^{lin}$ is complete monitorable iff there exists a reactive monitor M that is sound and complete for it. A fragment $\Gamma \subseteq T^{lin}$ is complete monitrorable iff each $\phi \in \Gamma$ is complete monitorable.*

It has been shown in [2] that the recursion-free fragment of untimed linear-time μ-calculus (μ-HML) is its largest complete-monitorable fragment. We show that this result does not hold in the timed setting, i.e., the maximal set of complete-monitorable formulae in T^{lin} is strictly larger than that of μ-HML. To explain this, let us first prove a handy lemma. Recall that $\mathcal{D}$ is the set of timestamp variables and $\mathcal{V}$ all valuation functions over $\mathcal{D}$ (Section 3.1).

▶ **Lemma 5.17.** *Let $y \in \mathcal{D}$ and $n \in \mathbb{N}$. For all $\pi \in T\Sigma^{\omega}_{div}$, $x \in \mathcal{D} \setminus \{y\}$, $v \in \mathcal{V}$, $g \in \mathcal{B}(\mathcal{D})$:*
1. *$\exists i \in \mathbb{N}_{>0}$ such that $v[x := t_i(\pi)] \not\models (x - y \prec n) \wedge g$,*
2. *$\forall i \in \mathbb{N}_{>0}$: $v[x := t_i(\pi)] \not\models (x - y \prec n) \wedge g$ implies $\forall j \geq i$: $v[x := t_i(\pi)] \not\models (x - y \prec n) \wedge g$.*

Let us depict the consequences of the above lemma through a few examples. To ease the explanation, we sometimes use MTL formulae as a support.

▶ **Example 5.18.** Consider the formula $\phi = F\,b$ (Section 2.4), meaning "action b will be seen in the future" (recall that this is the special case of $F_I\,b$ with $I = [0, \infty)$). Clearly, there is no violation-complete monitor for ϕ, because there is no way for a monitor to say no

based on a finite timed word not containing b (since a b can occur later on). In contrast, ϕ is monitorable for satisfactions: it suffices for the monitor to see a b to say yes. It follows that $\phi' = \text{TO}\,T^{lin}(\phi) = \mathsf{min}(Y, \langle b\rangle \mathtt{tt} \vee \langle\Sigma\rangle Y)$ (recalling that $F\,b$ is syntactic sugar for $\top\,\mathcal{U}_I\,b$, then using the function $\text{TO}\,T^{lin}$, Section 3.2) is satisfaction monitorable, but not violation monitorable. Now, in a (time) *constrained* setting, i.e., whenever we use a bounded interval I (with $\mathcal{RB}(I) \in \mathbb{N}$, Definition 2.4), ϕ becomes both satisfaction and violation monitorable, and therefore complete monitorable. Consider the example $\phi_c = F_I\,b$ with $I = [5, 8]$. Its compilation into T^{lin} gives the following formula:

$$\phi'_c = x_s \,\underline{\mathtt{in}}\, \mathsf{min}(Y, (x_e \,\underline{\mathtt{in}} \langle x_e - x_s \in [5,8]\rangle \langle b\rangle \mathtt{tt}) \vee \langle\Sigma\rangle Y)$$

which means "eventually b will occur within [5,8]". The guard $x_e - x_s \in [5, 8]$ is of the form $x - y \prec n \wedge g$ where $y = x_s$ (constant), $n = 8$ (constant), $x = x_e$, $\prec = \leq$, $g = x_e - x_s \geq 5$, and x_e diverges after a finite number of recursions (because time diverges and Y is guarded by $\langle\Sigma\rangle$). Therefore, by Lemma 5.17, $x_e - x_s \in [5, 8]$ will become false after a finite number of recursions, and will remain false indefinitely afterwards. It follows that the monitor can safely say no when the guard becomes false (which means that the consumed prefix until then did not contain any action b between 5 and 8).

▶ **Example 5.19.** Let us now consider the more complex *leads to* formula $\psi = G\,(b \Rightarrow F\,c)$ stipulating that "whenever an action b occurs, an action c follows in the future". As explained in Section 1, this formula cannot be monitored (neither for satisfactions nor for violations). Now consider the *constrained bounded response* $\psi_c = G_I\,(b \Rightarrow F_{I'}\,c)$ with $I = [1, 3]$ and $I' = [2, 5]$; i.e., in which we constrain both temporal operators with bounded intervals. The compilation of ψ_c into T^{lin} (Figure 5) gives the following formula:

$$\psi'_c = x_s \,\underline{\mathtt{in}}\, \mathsf{max}(Y, (x_e \,\underline{\mathtt{in}} [x_e - x_s \in [1,3]]([b]\mathtt{ff} \vee \zeta)) \wedge (\langle\Sigma\rangle Y))$$

with:

$$\zeta = x'_s \,\underline{\mathtt{in}}\, \mathsf{min}(X, (x'_e \,\underline{\mathtt{in}} \langle x'_e - x'_s \in [2,5]\rangle \langle c\rangle \mathtt{tt}) \vee (\langle\Sigma\rangle X))$$

The constrained bounded response formula ψ'_c is also complete monitorable. Indeed, if no b occurs between 1 and 3, the monitor can safely say yes (when the right bound of $[1, 3]$ is exceeded). Otherwise, for every b occurring between 1 and 3, the monitor checks whether a c occurs between 2 and 5 (relative to the occurrence of such b), and says no if it is not the case. Since $[2, 5]$ is bounded, the monitor can decide as soon as it consumes an action more than 5 time units since the last occurrence of b between 1 and 3.

▶ **Example 5.20.** Let us now consider the formulae given in Example 3.5, not expressible in MTL. The formula

$$\phi_{even(b)} = \mathsf{max}(X, \langle\Sigma\rangle\langle b\rangle X)$$

is violation monitorable (a monitor can say no as soon as it sees an action at an even position different than b), but is not satisfaction monitorable. Now, following the same reasoning as in the previous examples (applying Lemma 5.17), the formula

$$\phi_{even(b),[3,5]} = x_s \,\underline{\mathtt{in}}\, \mathsf{max}(X, \langle\Sigma\rangle(x_e \,\underline{\mathtt{in}} \langle x_e - x_s \in [3,5]\rangle \langle b\rangle X \vee \bigvee_{a\in\Sigma} y^a \,\underline{\mathtt{in}} \langle y^a - x_s \notin I\rangle \langle a\rangle X))$$

is complete monitorable.

Syntactic characterisation. In order to characterise a sufficiently expressive syntax for complete-monitorable formulae, we remark the following. Formulae ϕ'_c (Example 5.18) is equivalent to the following formulae:

$$x_s \,\underline{\mathtt{in}}\, \mathsf{min}(Y, (x_e \,\underline{\mathtt{in}}\langle x_e - x_s \in [5,8]\rangle\langle b\rangle\mathtt{tt}) \vee \bigvee_{a\in\Sigma} y^a \,\underline{\mathtt{in}}\langle y^a - x_s \leq 8\rangle\langle a\rangle Y)$$

because when the monitor time exceeds the right bound of $[5,8]$, then there is no need to check if $\langle b\rangle\mathtt{tt}$ is satisfied, and therefore recursion can be prevented (and the monitor can say no at this stage). Formula ψ'_c in Example 5.19 can be transformed similarly to the following equivalent formula:

$$x_s \,\underline{\mathtt{in}}\, \mathsf{max}(Y, (x_e \,\underline{\mathtt{in}}[x_e - x_s \in [1,3]]([b]\mathtt{ff} \vee \zeta')) \wedge \bigvee_{a\in\Sigma} (y^a \,\underline{\mathtt{in}}[y^a - x_s \leq 3]\langle a\rangle Y))$$

where:

$$\zeta' = x'_s \,\underline{\mathtt{in}}\, \mathsf{min}(X, (x'_e \,\underline{\mathtt{in}}\langle x'_e - x'_s \in [2,5]\rangle\langle c\rangle\mathtt{tt}) \vee \bigvee_{a\in\Sigma} (z^a \,\underline{\mathtt{in}}\langle z^a - x'_s \leq 5\rangle\langle a\rangle X))$$

As for formula $\phi_{even(b),[3,5]}$ in Example 5.20, it can be rewritten similarly as follows:

$$x_s \,\underline{\mathtt{in}}\, \mathsf{max}(X, \langle\Sigma\rangle(x_e \,\underline{\mathtt{in}}\langle x_e - x_s \in [3,5]\rangle\langle b\rangle X \vee \bigvee_{a\in\Sigma} y^a \,\underline{\mathtt{in}}(\langle y^a - x_s < 3\rangle\langle a\rangle X \vee \langle y^a - x_s > 5\rangle\langle a\rangle\mathtt{tt})))$$

since there is no need to recurse after the right bound of $[3,5]$ is exceeded (in such case, the timed word is in the semantics of the formula).

More generally, in a complete-monitorable formula ϕ, every subterm $\mathsf{min}(X,\phi)$ or $\mathsf{max}(X,\psi)$ is *constrained*. That is, in every subterm of ϕ, every occurrence of recursion variable X is preceded by $x \,\underline{\mathtt{in}}\langle g\rangle\langle a\rangle$ or $x \,\underline{\mathtt{in}}[g]\langle a\rangle$ such that g becomes eventually false, and $a \in \Sigma$. To simplify the proofs, we use a straightforward syntactic manipulation in order to require recursion variables to be immediately preceded by $x \,\underline{\mathtt{in}}\langle g\rangle$ or $x \,\underline{\mathtt{in}}[g]$: every $x \,\underline{\mathtt{in}}\langle g\rangle\langle a\rangle$ preceding a recursion variable becomes $x \,\underline{\mathtt{in}}\langle g\rangle\langle a\rangle x' \,\underline{\mathtt{in}}\langle g'\rangle$ where in g' the timestamp variable x is replaced with x'. For example, the formula

$$\zeta' = x'_s \,\underline{\mathtt{in}}\, \mathsf{min}(X, (x'_e \,\underline{\mathtt{in}}\langle x'_e - x'_s \in [2,5]\rangle\langle c\rangle\mathtt{tt}) \vee \bigvee_{a\in\Sigma} (z^a \,\underline{\mathtt{in}}\langle z^a - x'_s \leq 5\rangle\langle a\rangle X))$$

above is semantically equivalent to

$$\zeta'' = x'_s \,\underline{\mathtt{in}}\, \mathsf{min}(X, (x'_e \,\underline{\mathtt{in}}\langle x'_e - x'_s \in [2,5]\rangle\langle c\rangle\mathtt{tt}) \vee \bigvee_{a\in\Sigma} (z^a \,\underline{\mathtt{in}}\langle z^a - x'_s \leq 5\rangle\langle a\rangle y^a \,\underline{\mathtt{in}}\langle y^a - x'_s \leq 5\rangle X))$$

In order to syntactically specify that some guard becomes unsatisfied after a finite number of recursions, we introduce cLVar, an infinite subset of logical variables Var, such that a variable that belongs to cLVar must appear in a particular form within the scope of a fixpoint operator.

▶ **Definition 5.21** (Complete-monitorable fragment). *A formula $\phi \in T^{lin}$ is in the set $CT^{lin} \subset T^{lin}$ of complete-monitorable formulae iff ϕ is generated by the grammar in Figure 11 (with $n \in \mathbb{N}$, $g \in \mathcal{B}(\mathcal{D})$, $x, y \in \mathcal{D}$ and $X \in$ cLVar)* and *for all $\mathsf{min}(X,\psi)$, $\mathsf{max}(X,\psi)$ subterms of ϕ, y is free in ψ[5]. A subterm $\mathsf{max}(X,\phi)$ (resp. $\mathsf{min}(X,\phi)$) of a formula in CT^{lin} is called a constrained max (resp. constrained min).*

$$
\begin{array}{lcllllll}
\phi, \psi & ::= & \mathsf{tt} & \mid \mathsf{ff} & \mid \phi \vee \psi & \mid \phi \wedge \psi & \mid x \,\underline{\mathtt{in}}\, \phi \\

Figure 11 Grammar to generate formulae (closed and guarded terms) of CT^{lin}.

To prove that CT^{lin} is complete monitorable, we show that $(\!|\phi|\!)$ is sound and *strongly* complete for every $\phi \in CT^{lin}$. Strong completeness allows us to both guarantee completeness *and* show that our monitors (synthesised by $(\!|-|\!)$) are reliable for CT^{lin}.

▶ **Proposition 5.22.** *For all $\phi \in CT^{lin}$, $(\!|\phi|\!)$ is sound for ϕ.*

Proof. Since $CT^{lin} \subset T^{lin}$, we conclude by Proposition 5.15. ◀

▶ **Proposition 5.23.** *For all $\phi \in CT^{lin}$, $(\!|\phi|\!)$ is strongly satisfaction complete for ϕ.*

▶ **Proposition 5.24.** *For all $\phi \in CT^{lin}$, $(\!|\phi|\!)$ is strongly violation complete for ϕ.*

▶ **Example 5.25.** Consider the following formula:

$$\phi = x_s \,\underline{\mathtt{in}}\, \mathsf{min}(X, (x \,\underline{\mathtt{in}}\, \langle x - x_s \in (3,7] \rangle \langle b \rangle y \,\underline{\mathtt{in}}\, \langle y - x \in [0,2) \rangle \langle c \rangle \mathsf{tt}) \vee \bigvee_{a \in \Sigma} z^a \,\underline{\mathtt{in}}\, \langle z^a - x_s \leq 7 \rangle \langle a \rangle X)$$

easily expressible in CT^{lin} (see above), which expresses the following property "there exists an occurrence of b within interval $(3,7]$ that is immediately followed by a c within the interval $[0,2)$"; where "immediately followed by" means that there are no other actions occurring in between. In other words, the semantics of ϕ contains all infinite timed words π such that there exists a position i with $a_i(\pi) = b$ *and* $t_i(\pi) - t_1(\pi) \in (3,7]$ *and* $a_{i+1}(\pi) = c$ *and* $t_{i+1}(\pi) - t_i(\pi) \in [0,2)$. The compilation of ϕ into a monitor gives:

$$M = (\!|\phi|\!) = \textsc{let}\ x_s\ \textsc{in}\ \mathsf{rec}\ X.((\textsc{let}\ x\ \textsc{in}\ (((x - x_s \in (3,7]).(b.N + \overline{b}.\mathsf{NO})) +$$
$$(x - x_s \notin (3,7]).\mathsf{NO})) \oplus (\oplus_{a \in \Sigma}\ \textsc{let}\ z^a\ \textsc{in}\ (((z^a - x_s \leq 7).(a.X + \overline{a}.\mathsf{NO})) + (z^a - x_s > 7).\mathsf{NO})))$$

where

$$N = \textsc{let}\ y\ \textsc{in}\ (((y - x \in [0,2)).(c.\mathsf{YES} + \overline{c}.\mathsf{NO})) + (y - x \notin [0,2)).\mathsf{NO})$$

and M is sound and strongly complete for ϕ. For e.g., strong completeness, for any $\pi \in T\Sigma^{\omega}_{div}$ in the semantics of ϕ (resp. not in the semantics of ϕ), the monitor will inevitably reach a verdict state yes (resp. no) after consuming a finite prefix of π. For example, for any infinite timed word $\pi_1.\pi$ with $\pi_1 = (a,1)(b,8)(c,9)$ and $\pi \in T\Sigma^{\omega}_{\vec{\pi_1}}$ (resp. $\pi_2.\pi$ with $\pi_2 = (a,2)(b,6)(c,8)$ and $\pi \in T\Sigma^{\omega}_{\vec{\pi_2}}$) we have $m_0 \xrightarrow{\textsc{Trn}(\pi_1)}{}\!\!\!\!\rightarrow_{inev} \mathsf{yes}$ (resp. $m_0 \xrightarrow{\textsc{Trn}(\pi_2)}{}\!\!\!\!\rightarrow_{inev} \mathsf{no}$).

▶ **Theorem 5.26.** *CT^{lin} is complete monitorable.*

Proof. For every $\phi \in CT^{lin}$, $(\!|\phi|\!)$ is sound (Proposition 5.22), satisfaction complete (implied by Proposition 5.23) and violation complete (implied by Proposition 5.24) for ϕ. It follows that CT^{lin} is complete monitorable (Definition 5.16). ◀

[5] This is to guarantee that, within the scope of $\mathsf{max}(Y, \psi)$ or $\mathsf{min}(X, \psi)$, the valuation of y remains constant and so Lemma 5.17 can be applied.

5.4 Monitorabile Fragment

In this subsection, we identify MT^{lin}, a fragment of T^{lin}, and prove its monitorability (Theorem 5.38).

▶ **Definition 5.27** (Monitorable formulae)**.**

- *A formula $\phi \in T^{lin}$ is* violation *(resp.* satisfaction*)* monitorable *iff there exists a reactive monitor M that is sound and violation (resp. satisfaction) complete for ϕ. A fragment $\Gamma \subseteq T^{lin}$ is violation (resp. satisfaction) monitorable iff each $\phi \in \Gamma$ is violation (resp. satisfaction) monitorable.*
- *A formula $\phi \in T^{lin}$ is* monitorable *iff it is violation* or *satisfaction monitorable. A fragment $\Gamma \subseteq T^{lin}$ is monitorable iff each $\phi \in \Gamma$ is monitorable.*

In order to identify a monitorable fragment, let us first proceed with examples.

▶ **Example 5.28.** Consider the following T^{lin} formula:

$$\phi = \mathsf{max}(Y, ([b]\mathsf{ff} \vee \psi) \wedge (\langle\Sigma\rangle Y))$$

with:

$$\psi = x_s \,\underline{\mathtt{in}}\, \mathsf{min}(X, (x_e \,\underline{\mathtt{in}} \langle x_e - x_s \in I\rangle\langle c\rangle\mathsf{tt}) \vee (\langle\Sigma\rangle X))$$

with $I \in \mathcal{I}$ bounded ($\mathcal{RB}(I) \in \mathbb{N}$). Formula ϕ expresses the important bounded response property (in MTL: $G\,(b \Rightarrow F_I\, c)$, Section 1). Notice how every min subformula of ϕ can be rewritten as a constrained min (Section 5.3), whereas the max subformulae are clearly unconstrained. Formula ϕ is violation monitorable: after every occurrence of b, a monitor can check whether a c will follow within I (relative to such occurrence). Since I is bounded, such check always terminates (by Lemma 5.17), and the monitor can say no if no c occurred. However, this formula is not satisfaction monitorable.

▶ Remark 5.29. Bounded response is not *bounded-memory monitorable* in the general case [35] (it is when I is left-closed at 0, see e.g., [17]). Bounded-memory monitorability is out of this paper's scope and is left for future work (Section 7).

▶ **Example 5.30.** Consider now the following T^{lin} formula:

$$\eta = \mathsf{min}(Y, (\langle b\rangle\zeta \vee \langle\Sigma\rangle Y))$$

with:

$$\zeta = x_s \,\underline{\mathtt{in}}\, \mathsf{max}(X, (x_e \,\underline{\mathtt{in}} [x_e - x_s \in I]\langle c\rangle\mathsf{tt}) \wedge (\langle\Sigma\rangle X))$$

with $I \in \mathcal{I}$ bounded. Notice how every max subformula of η can be rewritten as a constrained max (Section 5.3), whereas the min subformulae are clearly not constrained. Formula η is satisfaction monitorable: if a b occurs, a monitor can safely say yes if every action seen within I after such occurrence is a c (this process terminates, again thanks to Lemma 5.17). This formula is however not violation monitorable: any no verdict may be falsified by a future b after which every action within I is a c.

$$\begin{array}{rcllllll} \phi, \psi & ::= & \mathsf{tt} & \mid \mathsf{ff} & \mid \phi \vee \psi & \mid \phi \wedge \psi & \mid x \,\underline{\mathtt{in}}\, \phi \\ & & \mid \langle a \rangle \phi & \mid [a]\phi & \mid \langle g \rangle \phi & \mid [g]\phi & \\ & & \mid \mathsf{min}(X, \phi) & \mid X & & & \end{array}$$

Figure 12 Grammar to generate formulae (closed and guarded terms) of ST^{lin}.

$$\begin{array}{rcllllll} \phi, \psi & ::= & \mathsf{tt} & \mid \mathsf{ff} & \mid \phi \vee \psi & \mid \phi \wedge \psi & \mid x \,\underline{\mathtt{in}}\, \phi \\ & & \mid \langle a \rangle \phi & \mid [a]\phi & \mid \langle g \rangle \phi & \mid [g]\phi & \\ & & \mid \mathsf{max}(Y, \phi) & \mid Y & & & \end{array}$$

Figure 13 Grammar to generate formulae (closed and guarded terms) of VT^{lin}.

Syntactic characterisation. The intuition is that both violation- and satisfaction-monitorable formulae will share the syntax of CT^{lin} and differ for (unconstrained) minimal and maximal fixpoint operators. To simplify the syntax, we prove that the semantics of constrained min and constrained max coincide. That is, for every constrained formula $\mathsf{min}(X, \phi)$, we have the equality $[\![\mathsf{min}(X, \phi)]\!] = [\![\mathsf{max}(X, \phi)]\!]$ (and dually for constrained max formulae). Accordingly, for violation-monitorable formulae, we do not need constrained min in their syntax (Figure 13). This is because constrained min formulae can be rewritten as constrained max formulae, and a constrained max is a special case of max. For example, in the bounded response property (Example 5.28), and after transforming ψ into a constrained min (Section 5.3), the minimal fixpoint operator can be replaced with the maximal one without changing the semantics. Dually, we do not need constrained max in the syntax of satisfaction-monitorable formula (Figure 12).

▶ **Definition 5.31** (Monitorable fragment). *The set of monitorable formulae $MT^{lin} \subset T^{lin}$ is the union of the set of violation-monitorable formulae (Figure 13) and satisfaction-monitorable formulae (Figure 12), i.e., $MT^{lin} = VT^{lin} \cup ST^{lin}$.*

▶ **Proposition 5.32.** *For all $\phi \in MT^{lin}$, $(\!|\phi|\!)$ is sound for ϕ.*

Proof. Since $MT^{lin} \subset T^{lin}$, we conclude by Proposition 5.15. ◀

▶ **Proposition 5.33.** *For all $\phi \in ST^{lin}$, $(\!|\phi|\!)$ is strongly satisfaction complete for ϕ.*

▶ **Theorem 5.34.** *ST^{lin} is satisfaction monitorable.*

Proof. Direct from Proposition 5.32, Proposition 5.33 and Definition 5.27. ◀

▶ **Proposition 5.35.** *For all $\phi \in VT^{lin}$, $(\!|\phi|\!)$ is strongly violation complete for ϕ.*

▶ **Example 5.36.** The formula $\phi_{even(b)} = \mathsf{max}(X, \langle\Sigma\rangle\langle b\rangle X)$ (Example 3.5) is violation monitorable. Its compilation by $(\!|-|\!)$ gives the monitor

$$M = (\!|\phi_{even(b)}|\!) = \mathsf{rec}\ X.(\oplus_{a \in \Sigma}\ a.(b.X + \overline{b}.\mathsf{NO}) + \overline{a}.\mathsf{NO})$$

and it is rather straightforward to see that M is sound and inevitably reaches verdict no (from m_0) when given any infinite timed word outside of the semantics of $\phi_{even(b)}$. Indeed, for any infinite timed word π, we have $\pi \notin [\![\phi_{even(b)}]\!]$ iff there exists a position $i \in \mathbb{N}_{>1}$, $i \bmod 2 = 0$ such that $a_i(\pi) \neq b$. For any such π and the smallest such i, we have $m_0 \overset{\text{TRN}(^i\pi)}{\longrightarrow\!\!\!\!\!\rightarrow}_{inev} \mathsf{no}$.

5.5 Maximality

▶ **Definition 5.39** (Largest monitorable fragment)**.** *A fragment $\Gamma \subset T^{lin}$ is said:*

- *The largest satisfaction- (resp. violation-, complete-) monitorable fragment of T^{lin} iff (i) Γ is satisfaction (resp. violation, complete) monitorable and (ii) for every satisfaction- (resp. violation-, complete-) monitorable formula $\psi \in T^{lin}$, there exists $\phi \in \Gamma$ such that $[\![\phi]\!] = [\![\psi]\!]$,*
- *The largest monitorable fragment of T^{lin} iff (i) Γ is monitorable and (ii) for every monitorable formula $\psi \in T^{lin}$, there exists $\phi \in \Gamma$ such that $[\![\phi]\!] = [\![\psi]\!]$.*

In order to prove that MT^{lin} is the largest monitorable fragment of T^{lin}, we follow an approach inspired from [2]. First, we prove that for every reactive monitor M, if M is satisfaction (resp. violation) complete for two formulae in T^{lin}, then such formulae are semantically equivalent (Lemma 5.40). Second, we define two functions: $\|-\|$ (Figure 14), that maps any reactive monitor M to a formula in ST^{lin}, and $\langle\langle-\rangle\rangle$ (Figure 15) that maps any reactive monitor M to a formula in VT^{lin}; then prove that any reactive M is sound and satisfaction complete for its image by $\|-\|$ (i.e., $\|M\|$), and sound and violation complete for $\langle\langle M\rangle\rangle$ (Lemma 5.41). We conclude therefore that any formula $\phi \in T^{lin}$ that is satisfaction

(resp. violation) monitorable, through the existence of a monitor M that is satisfaction (resp. violation) complete for ϕ, is necessarily equivalent to $\|M\| \in ST^{lin}$ (resp. $\langle\langle M \rangle\rangle \in VT^{lin}$, Proposition 5.42). Accordingly, ST^{lin} is the largest satisfaction-monitorable fragment of T^{lin}, VT^{lin} the largest violation-monitorable fragment of T^{lin}, and $MT^{lin} = VT^{lin} \cup ST^{lin}$ the largest monitorable fragment of T^{lin} (Theorem 5.43, Theorem 5.44). We also prove that CT^{lin} is the largest complete-monitorable fragment of T^{lin} (Theorem 5.45).

▶ **Lemma 5.40.** *For every reactive monitor M and formulae $\phi, \psi \in T^{lin}$:*

1. *M is sound and satisfaction complete for ϕ and ψ implies $[\![\phi]\!] = [\![\psi]\!]$,*
2. *M is sound and violation complete for ϕ and ψ implies $[\![\phi]\!] = [\![\psi]\!]$.*

▶ **Lemma 5.41.** *For every reactive monitor M, if M is consistent then:*

1. *M is sound and satisfaction complete for $\|M\|$*
2. *M is sound and violation complete for $\langle\langle M \rangle\rangle$*

▶ **Proposition 5.42.** *For every formula $\phi \in T^{lin}$:*

1. *if ϕ is satisfaction monitorable, then there exists $\psi \in ST^{lin}$ such that $[\![\phi]\!] = [\![\psi]\!]$,*
2. *if ϕ is violation monitorable, then there exists $\psi \in VT^{lin}$ such that $[\![\phi]\!] = [\![\psi]\!]$.*

Proof.

Item 1. Assume $\phi \in T^{lin}$ is satisfaction monitorable. By definition, there exists a reactive monitor M that is sound and satisfaction complete for ϕ. By Lemma 5.7, we have M is consistent. Now, by Lemma 5.41 (Item 1), we deduce M is sound and satisfaction complete for $\|M\| \in ST^{lin}$, and finally we conclude $[\![\phi]\!] = [\![\|M\|]\!]$ by Lemma 5.40 (Item 1).

Item 2. Analogous. ◀

▶ **Theorem 5.43.**

1. *ST^{lin} is the largest satisfaction-monitorable fragment of T^{lin},*
2. *VT^{lin} is the largest violation-monitorable fragment of T^{lin}.*

Proof.

Item 1. Direct from Definition 5.39, Theorem 5.34, and Proposition 5.42 (Item 1).

Item 2. Direct from Definition 5.39, Theorem 5.37, and Proposition 5.42 (Item 2). ◀

▶ **Theorem 5.44.** *MT^{lin} is the largest monitorable fragment of T^{lin}.*

Proof. Direct from Definition 5.39, Theorem 5.43 and Definition 5.31. ◀

▶ **Theorem 5.45.** *CT^{lin} is the largest complete-monitorable fragment of T^{lin}.*

▶ Remark 5.46. An important remark here is the fact that MT^{lin} reflects precisely the effect of bounded intervals on monitorability. At a first glance, it may seem that the existence of a bounded interval in the syntax of a formula ϕ is sufficient for ϕ to be monitorable; however, this is generally false. Take for example the MTL formula $\psi = G\,(c \Rightarrow F_{[2,5]}\,(b \wedge F\,c))$. Although $[2, 5]$ is bounded, ψ is not monitorable. For satisfactions, the reasoning is similar to bounded response. For violations, take any infinite timed word π starting with $(c, 1)(b, 4)(b, 8)$ and satisfying $\forall i \in \mathbb{N}_{>3} : a_i(\pi) = b$, then we have $\pi \notin [\![\psi]\!]$. Yet, there is no way for a monitor to say no based on a finite prefix of π. Without a surprise, the compilation of ψ into T^{lin} falls outside of MT^{lin} as it uses both unconstrained min and max subformulae.

6 Related Work

The state of the art on RV of timed properties mainly centres around the study of LTL extensions such as MTL [27] and MITL, the fragment of MTL excluding singular intervals [5]. The use of a declarative logic to describe system behaviour creates a clear delineation between what can be specified and how this can then be verified algorithmically. This is in line with our approach and is more conducive to the study of monitorability. Baldor *et al.* [9] were the first to propose a transition based approach to monitoring of MITL formulae and establish complexity results for their proposed synthesis. Ho *et al.* [24] split unbounded and bounded parts of a dense-time MTL formula to permit a simpler construction for the bounded parts to obtain space-bounded monitors. Neither of these works consider monitorability issues.

The influential work by Bauer *et al.* [12] introduces the idea of an n-valued semantics for a timed version of LTL called TLTL, defined over *trace prefixes* by incorporating inconclusive outcome, typically denoted by "?". This is used as a definition of the expected monitor behaviour when analysing a trace prefix online, which then guides a method of obtaining executable monitors from timed properties. The main drawback of the approach is that monitor synthesis disregards monitorability aspects; it generates monitors for *any* timed property, without information on whether such property is monitorable or not. The recent work on monitoring MITL by Grosen *et al.* [22] also suffers from this drawback as a result of adopting a three-valued semantics. Despite this, they propose new symbolic method of synthesising monitors for MITL properties via a translation into timed Büchi automata. Pinisetty *et al.* [37] consider the monitoring of properties expressed as timed ω-automata. However, they ascribe an n-valued semantics to prefixes of infinite runs as discussed above. The work focuses on how prior knowledge on the system (also expressed as a timed automaton) can be used for sound predictive monitoring.

All of the above works take into account in one sense or another infinite executions; the infinitary nature of traces poses the main complication when considering the monitorability of linear-time properties [2]. Popular work on synthesising monitors for timed LTL properties with finitary semantics, such as that of Thati and Rosu [45] and of Basin *et al.* [11] sidestep any monitorability issues since every formula becomes monitorable. Basin *et al.* consider a first-order version of MTL called MFOTL to describe properties involving data ranging over an infinite domain. Ulus *et al.* [46] describe a monitor algorithm for Timed Regular Expressions based on the union of two-dimensional zones for finite words. Raszyk *et al.* [41] extend this work to an augmented monitoring setup that uses multiple analysis points (i.e., multi-head monitors) that relates to our parallel monitoring setup. Lima *et al.* [32] augment monitoring verdicts of MFOTL with explanations of why the monitored execution led to violations/satisfactions. Roussanaly *et al.* [43] study a decentralised monitor synthesis procedure for timed regular expressions that is similar to our parallel monitors. Note that a number of works study *quantitative monitoring* of STL [34], a version of MITL interpreted over continuous signals, proposing thereby a robustness measure instead of yes/no verdicts. Such works sidestep monitorability problems either through *approximate* measures under infinitary semantics (see e.g., [16]) or more precise measures under finitary semantics [42].

In summary, our approach is complementary to the above efforts. On the one hand, our work is the first that proposes through monitorability results for an expressive timed logic. As shown in Section 3.2, MTL is less expressive than our T^{lin} which both in general and w.r.t. to monitorability; we have shown that there exists monitorable formulae in T^{lin} that are not expressible in MTL (Section 5, Section 5.4). On the other hand, works such as [24] and [22] focus on efficiency of monitoring algorithms rather than monitorability issues.

Studies on monitorability generally consider one of two definitions; the one due to Pnueli and Zaks [39] or that due to Schneider [44]. Aceto *et al.* [4] have shown that the latter definition is strictly stronger and have systematised the various variants in terms of soundness and completeness criteria similar to those we used. In particular, the definition of monitorability assumed in our work is the stronger variant due to Schneider, in part because it allowed us to establish maximality results for our logical fragments; at the time of writing, the methods for establishing maximal monitorable fragments for Pnueli and Zaks monitorability are not well-established.

7 Conclusion

In this paper, we solved the monitorability problem for an expressive timed logic. We proposed T^{lin}, a modal timed μ-calculus with linear-time semantics and proved that it is strictly more expressive than the well-known and popular MTL. Then, we precisely identified the maximal fragments of violation-monitorable, satisfaction-monitorable, complete-monitorable, and monitorable formulae of T^{lin}. To the best of our knowledge, this is the first work that solves the monitorability problem for such expressive timed logic.

A natural direction of future work is to synthesise monitors as timed automata (TA). Such monitors should be simpler than Mon and can be efficiently implemented in TA-based tools. Another direction is the study of bounded-memory monitorability. At least two research axes in this direction are worth investigating. First, the identification of the fragments of bounded-memory monitorable formulae of T^{lin} under the same setting as in this paper (linear time, time-divergent infinite words). Second, analogous to the first axis, the characterisation of the weakest conditions on infinite timed words to enable bounded-memory monitorability for some properties that are not monitorable in bounded memory in the general case.

The Algebra of Patterns

Abstract

Pattern matching is a popular feature in functional, imperative and object-oriented programming languages. Language designers should therefore invest effort in a good design for pattern matching. Most languages choose a *first-match semantics* for pattern matching; that is, clauses are tried in the order in which they appear in the program until the first one matches. As a consequence, the order in which the clauses appear cannot be arbitrarily changed, which results in a less declarative programming model. The declarative alternative to this is an *order-independent semantics* for pattern matching, which is not implemented in most programming languages since it requires more verbose patterns. The reason for this verbosity is that the syntax of patterns is usually not expressive enough to express the *complement* of a pattern. In this paper, we show a principled way to make order-independent pattern matching practical. Our solution consists of two parts: First, we introduce a *boolean algebra of patterns* which can express the complement of a pattern. Second, we introduce *default clauses* to pattern matches. These default clauses capture the essential idea of a fallthrough case without sacrificing the property of order-independence.

1 Introduction

Pattern matching is a programming language feature that combines two operations: Testing whether a value matches a given pattern and, if the test is successful, extracting subexpressions of the value and binding them to variables. A pattern matching expression consists of the *scrutinee* which is analyzed by the pattern match and a list of *clauses*. Each clause consists of a *pattern*, hence the name, and an expression called the *right-hand side*. These elements can all be seen in the following example of the length function, which computes the length of a list:

$$\text{length}(xs) \coloneqq \textbf{case}\ \underbrace{xs}_{\text{scrutinee}}\ \textbf{of}\ \{\ \underbrace{\texttt{Nil} \Rightarrow 0}_{\text{clause}},\ \underbrace{\texttt{Cons}(_, zs)}_{\text{pattern}} \Rightarrow \underbrace{1 + \text{length}(zs)}_{\text{right-hand side}}\ \}$$

Programming with pattern matching is popular. For a long time, only programmers who use functional languages could enjoy this feature, but today pattern matching has arrived in the mainstream of object-oriented and imperative programming languages. For example, Python, Java, Dart, and C# added pattern matching as an extension to the language, and some newer languages such as Rust and Swift, which are not primarily functional languages, supported pattern matching from the beginning.

Pattern matching has become one of the central constructs that is used to structure the control and data flow of a program. How pattern matches are checked and evaluated therefore fundamentally determines how we reason about the meaning of our programs; both informally when we read and write code in our daily lives, and formally in proof assistants, static analyzers and other verification tools. It is therefore important to choose a semantics for pattern matching which makes reasoning as simple as possible. One choice that language designers have to make is whether the clauses are tried in the order in which they appear in the program, or whether the order of the clauses does not matter. The following definition captures this difference:

▶ **Definition 1** (First-Match and Order-Independent Semantics). *A language uses* first-match semantics *if the clauses of a pattern match are tried in the order in which they occur until the first pattern matches the scrutinee. A language uses* order-independent semantics *if any of the matching clauses in a pattern match can be used to non-deterministically reduce a pattern matching expression.*

Overlapping clauses, i.e. two clauses with patterns that can match the same scrutinee, are a problem for order-independent semantics since a pattern-matching expression with overlapping clauses can non-deterministically reduce to two different results. The obvious solution is to enforce that two clauses must never overlap. But if we adopt this solution, then programmers usually have to write much more verbose patterns. For example, instead of the following function which checks whether the argument is the color `Red`

$$\text{isRed}(c) \coloneqq \textbf{case}\ c\ \textbf{of}\ \{\ \texttt{Red} \Rightarrow \texttt{True},\ _ \Rightarrow \texttt{False}\ \},$$

the programmer has to write the following more verbose expression

$$\text{isRed}(c) \coloneqq \textbf{case}\ c\ \textbf{of}\ \{\ \texttt{Red} \Rightarrow \texttt{True},\ \texttt{Green} \Rightarrow \texttt{False},\ \texttt{Blue} \Rightarrow \texttt{False}\ \}.$$

The source of this verbosity is the poor expressiveness of patterns, which usually do not allow to express the *complement* of a pattern without exhaustively enumerating all the alternatives. In this example, we had to explicitly mention both `Blue` and `Green` to express the complement of the pattern `Red`. In languages that support or-patterns we can combine the last two clauses in the single clause $(\texttt{Green} \parallel \texttt{Blue}) \Rightarrow \texttt{False}$, but we still have to mention all constructors explicitly. It is unreasonable to ask programmers to always list all constructors of a data type, and they would rightfully reject a programming language which enforces this. Every proposal to use order-independent pattern matching in a realistic programming language therefore has to address this verbosity problem.

We propose two complementary solutions to the verbosity problem. In our system, the function can be written in the following ways:

$$\text{isRed}(c) \coloneqq \textbf{case}\ c\ \textbf{of}\ \{\ \texttt{Red} \Rightarrow \texttt{True},\ \neg\texttt{Red} \Rightarrow \texttt{False}\ \} \qquad \text{(Negation Pattern)}$$

$$\text{isRed}(c) \coloneqq \textbf{case}\ c\ \textbf{of}\ \{\ \texttt{Red} \Rightarrow \texttt{True},\ \textbf{default} \Rightarrow \texttt{False}\ \} \qquad \text{(Default Clause)}$$

To write the first variant we enrich the syntax of patterns with *negation patterns* which match whenever the negated pattern does not match. The two patterns are no longer overlapping, and at the same time, the pattern matching expression is not more verbose than our first version. Such negation patterns were already proposed under the name of "anti-patterns" [16, 17, 6] and are also mentioned by some other authors [19, 11]; the core contribution of this paper, however, is to consider them in the context of a complete *boolean algebra of patterns* which allows us to apply algebraic reasoning to patterns.

To write the second variant we enrich the syntax of pattern-matching expressions with *default clauses*[1]. A pattern matching expression can contain at most one such default clause (where **default** is a keyword instead of a pattern) which matches whenever none of the normal clauses matches the scrutinee. At first glance, the meaning of a default clause looks identical to the meaning of a clause with a wildcard pattern, but this is only the case for first-match semantics. If we use order-independent semantics, then we see that the meaning of a default clause does not correspond to a clause with a wildcard pattern, but to a clause that is headed by the negation of the disjunction of all other patterns in the pattern matching expression. In the compilation algorithm, however, default clauses are treated natively, so that we don't have to expand a default clause to a large pattern in the case of pattern matches with many clauses.

We are particularly interested in the kind of reasoning which is preserved when we add or remove clauses from a pattern match, or when we add or remove constructors from a data type. We will argue that this is a significant software engineering challenge that most pattern-based languages do not adequately address yet.

1.1 Algebraic Reasoning and Variable Binding

The main contribution of this work is to support a rich catalog of equivalences for patterns. In fact, we strive to treat patterns as a boolean algebra which consists of negation patterns, and-patterns, or-patterns, wildcard-patterns and absurd-patterns, featuring all the expected equivalences. This is challenging from the perspective of variable binding. For instance, we want the law of double negation, i.e. $[\![\neg\neg p]\!] \equiv [\![p]\!]$, to hold, but this entails that we cannot ignore variables that occur inside patterns in a negated context. We will demonstrate that we can achieve the desired equivalences by a variable binding definition that tracks whether variables occur under an even or odd number of negations. A related problem is to have well-defined variable binding in the context of or-patterns $p \parallel p'$, which requires a careful definition of linearity to make sure that the same variables are bound in all cases of an or-pattern. We also describe the conditions under which we can replace a pattern $p_1 \parallel p_2$ by the pattern $p_2 \parallel p_1$; this transformation is not semantic preserving in most systems which implement or-patterns.

1.2 Overview and Contributions

The rest of this article is structured as follows:

- In Section 2 we motivate why the first-match semantics that most programming languages use for pattern matching fails to address several important reasoning and software engineering problems. We show how our contributions can improve upon this status quo.
- In Section 3 we present our first main contribution: the algebra of patterns. We describe the syntax of patterns, the rules for non-deterministically matching a pattern against a value, and the restrictions that characterize the subset of linear and deterministic patterns. We also prove the algebraic properties that characterize the semantic equivalence relation on patterns.

[1] Some programming languages support default clauses with similar semantics to what we propose. Ada, for example, enforces that clauses in a case statement are not overlapping, but allows an optional "other" clause with the same semantics as our default clause. The clauses that Ada allows are however much more restricted, since they only work for enums instead of algebraic data types.

- Section 4 introduces our second contribution, a small term language that contains pattern-matching expressions with default clauses. This section also introduces exemplary typing rules to the untyped patterns of Section 3 and the constructs of our term language; the compilation of patterns described in later sections, however, does not depend on patterns being typed.
- Not all extensions to pattern matching can be compiled to efficient code, but ours can. In Section 5 we show how to compile patterns by translating them to a variant of a disjunctive normal form. We use these normalized patterns in the compilation of pattern-matching expressions to decision trees, which we describe in Section 6.
- We discuss future work in Section 7, related work in Section 8 and conclude in Section 9.

The results in sections Section 3 have been formally verified in the proof assistant Rocq, and are made available as complementary material. Theorems and definitions which have been formalized are marked with the symbol .

2 Motivation

Most programming languages that implement pattern matching use a first-match semantics for which the order of clauses matters. Changing this state of affairs is our main motivation for introducing a more expressive set of algebraic patterns. Let us therefore explain why we think that first-match semantics is not a good default choice for declarative languages.

2.1 First-Match Semantics Weakens Equational Reasoning

Equational reasoning is one of the most important methods functional programmers use to reason about code. Equational reasoning allows us to show that two expressions are equivalent if we can obtain one from the other by a series of rewriting steps. Each rewriting step is justified by some equation between terms, and functions defined by pattern matching are one of the main sources of such equations. Take, for example, the definitions of the functions “id” and “map”:

$$\mathrm{id}(x) \coloneqq x \tag{1}$$
$$\mathrm{map}(f, []) \coloneqq [] \tag{2}$$
$$\mathrm{map}(f, x :: xs) \coloneqq f(x) :: \mathrm{map}(f, xs) \tag{3}$$

We can show that mapping the identity function over a list returns the original list, i.e. that $\mathrm{map}(\mathrm{id}, xs) = xs$ holds, by using the individual clauses of the definition of “map”:

$$\begin{aligned} \mathrm{map}(\mathrm{id}, []) &=_{(2)} [] \\ \mathrm{map}(\mathrm{id}, x :: xs) =_{(3)} \mathrm{id}(x) :: \mathrm{map}(\mathrm{id}, xs) &=_{(1)} x :: \mathrm{map}(\mathrm{id}, xs) =_{(IH)} x :: xs \end{aligned}$$

We have annotated each rewriting step with the equation that justifies it, and in the last step, we have used the induction hypothesis (IH). In this example, we have used the fact that every clause of the pattern match is a valid equation that we can use for rewriting. But this was only valid because the equations in the definition of “map” do not overlap. To see why this is essential, consider the example from the introduction again:

$$\mathrm{isRed}(\texttt{Red}) \coloneqq \texttt{True} \tag{4}$$
$$\mathrm{isRed}(_) \coloneqq \texttt{False} \tag{5}$$

If we are using these clauses as equations we can now show that True is equal to False, using the proof $\texttt{True} =_{(4)} \text{isRed}(\texttt{Red}) =_{(5)} \texttt{False}$. A human is of course very unlikely to make such a silly mistake, but if we cannot guarantee that every clause holds as a valid equality between expressions, then we also limit what automatic tools can do for us.

2.2 First-Match Semantics Complicates Reasoning About Change

Software engineering has been described as the problem of integrating programming over time [27]. This means that we not only have to understand the meaning of a program at a fixed point in time, but we also have to understand how the meaning of a program changes as it is developed and maintained. It should therefore be as simple as possible to reason about how the meaning of a program changes when a programmer adds a clause to a pattern match, removes a clause from a pattern match, adds a constructor to a data type, or removes a constructor from a data type. Let us see why first-match semantics complicates reasoning about these kinds of changes.

If we want to understand the consequences of adding or removing a clause from a pattern match, then we have to consider all clauses occurring both above and below the clause we are changing. Having to reason about the entire context of the clause makes it much harder to spot bugs in code reviews, since it is not uncommon that pattern matching expressions can span multiple pages of code. Order-independent semantics guarantees that it doesn't matter if we add, delete or modify a clause at the beginning, middle or end of a list of clauses.

The other kind of change that frequently occurs is that we add or remove a constructor from an existing data type. Whether we have to adjust existing pattern matches depends on how those have been written. Even if we enforce that clauses in a pattern matching expression must not overlap, we have multiple possibilities to write exhaustive pattern matches. Consider a data type "Group" which consists of administrators, registered users and guests. We want to guarantee that only administrators have write access, but we have two possibilities to write the function:

$\text{hasWriteAccess} : \text{Group} \to \text{Bool}$	$\text{hasWriteAccess} : \text{Group} \to \text{Bool}$
$\text{hasWriteAccess}(\texttt{Admin}) \coloneqq \texttt{True}$	$\text{hasWriteAccess}(\texttt{Admin}) \coloneqq \texttt{True}$
$\text{hasWriteAccess}(\texttt{RegisteredUser} \parallel \texttt{Guest}) \coloneqq \texttt{False}$	$\text{hasWriteAccess}(\neg\texttt{Admin}) \coloneqq \texttt{False}$

On the left side we have pattern matched exhaustively on the complement of `Admin`, whereas on the right side we have used a negation pattern. These two programs behave the same, but we can observe a difference when we add moderators as a fourth type of user. We have to revisit the function on the left, whereas the function on the right continues to compile.

Some programming languages have already started to add support for enforcing these kind of considerations. For example, Rust supports the `#[non_exhaustive]` attribute on type declarations[2]. This attribute restricts pattern matches and ensures that they continue to compile after a new constructor has been added to the type; annotating the Group type with such an attribute would disallow the definition on the left. Dually, OCaml warns against writing "fragile pattern matches". A fragile pattern can hide newly added constructors, which might have unintended consequences. The algebraic patterns presented in this paper provide the necessary tools to program in situations where the programmer wants to enforce either one of these dual restrictions. There is also some empirical evidence that programmers feel uneasy about using wildcard patterns in evolving codebases. For example, the authors

[2] Cp. doc.rust-lang.org/stable/reference/attributes/type_system.html.

of a recent study about the programming practices of functional programmers [21] write: "Participants felt similarly about the use of wildcards in pattern matching, which silently assign pre-existing behavior to new variants of an enumeration. P7 mentioned that, in their main codebase, wildcards are completely disallowed for this reason, even though they make programming more convenient."

2.3 Compositional Pattern Matching and Extensible Data Types

Our main motivation in this paper is to obtain a more declarative programming model for standard nominal data types and ordinary pattern matching. The compilation algorithm that we are presenting, however, also works for polymorphic variants [10]. Polymorphic variants are used in the programming language OCaml, for example, to handle open sets of possible error conditions without having to declare a data type which lists all possible errors. Our algorithm does not presuppose a data type declaration with a fixed set of constructors which is necessary to check for exhaustiveness; we do not discuss exhaustiveness of patterns in the main part of this paper, but outline the necessary modifications to check for it in the extended version [2]. We think that the ideas and the algebraic patterns that we present in this paper are also useful for some proposed solutions of the expression problem. In the compositional programming approach [25, 29, 28], for example, we can create pattern matches whose clauses are distributed among multiple different modules. In that scenario it is especially important to guarantee that the contributing clauses which come from different modules do not overlap in their left-hand side.

3 The Algebra of Patterns

As our first contribution, we introduce an *algebra of patterns*. The syntax of patterns and values is specified in Figure 1. We assume that we have an infinite set CtorNames of constructor names such as `True`, `False` or `Nil`, and a set Variables which contains variables such as x, y or z. Each constructor $\mathcal{C}$ comes with an implicit *arity* n, and we sometimes write $\mathcal{C}^n$ to make this explicit. For example, the constructor `Cons` has arity 2 since it needs to be applied to two arguments. Patterns p consist of variable patterns x, constructor patterns $\mathcal{C}^n(p_1, \ldots, p_n)$, and-patterns $p \,\&\, p$, or-patterns $p \parallel p$, wildcard-patterns _, absurd-patterns #, and negation patterns $\neg p$. Values consist of constructors applied to other values; the two-element list `Cons`(`True`, `Cons`(`False`, `Nil`)) is an example of a value. If a pattern p matches a value v we obtain a substitution σ. Such substitutions are formalized as lists of mappings $x \mapsto v$, and we write $\sigma_1 +\!\!+ \sigma_2$ for the concatenation of two such lists. Not every list of mappings is a proper map since some lists contain multiple mappings for the same variable, but we will later prove that patterns from the subset of linear patterns produce substitutions that map a variable to at most one value. There are two functions that compute the free variables contained in a pattern. The function $\mathrm{FV}^e(p)$ computes the free variables that occur under an *even* number of negations, whereas $\mathrm{FV}^o(p)$ computes the variables under an *odd* number of negations.

Variable, constructor and wildcard patterns are standard, so we do not introduce them explicitly and turn directly to the more interesting absurd-patterns, or-patterns, negation-patterns, and and-patterns.

The absurd-pattern # is the dual of the wildcard-pattern _. Whereas the wildcard-pattern matches any value, the absurd-pattern never matches a value. We include the absurd-pattern in the syntax of patterns since we need a canonical bottom element of the boolean algebra. But there are also more practical reasons to include an absurd pattern. In

\mathrm{FV}^e(_) & := \emptyset & \mathrm{FV}^o(_) & := \emptyset \\
\mathrm{FV}^e(\#) & := \emptyset & \mathrm{FV}^o(\#) & := \emptyset \\
\mathrm{FV}^e(\neg p) & := \mathrm{FV}^o(p) & \mathrm{FV}^o(\neg p) & := \mathrm{FV}^e(p) \\
\mathrm{FV}^e(p_1 \parallel p_2) & := \mathrm{FV}^e(p_1) \cup \mathrm{FV}^e(p_2) & \mathrm{FV}^o(p_1 \parallel p_2) & := \mathrm{FV}^o(p_1) \cup \mathrm{FV}^o(p_2) \\
\mathrm{FV}^e(p_1 \,\&\, p_2) & := \mathrm{FV}^e(p_1) \cup \mathrm{FV}^e(p_2) & \mathrm{FV}^o(p_1 \,\&\, p_2) & := \mathrm{FV}^o(p_1) \cup \mathrm{FV}^o(p_2) \\
\mathrm{FV}^e(\mathcal{C}(p_1, \ldots, p_n)) & := \cup_{i=1}^n \mathrm{FV}^e(p_i) & \mathrm{FV}^o(\mathcal{C}(p_1, \ldots, p_n)) & := \cup_{i=1}^n \mathrm{FV}^o(p_i)
\end{array}
$$

Figure 1 The syntax of values, patterns and substitutions. We track whether variables occur under an even or odd number of negations.

the lazy programming language Haskell, for example, we sometimes have to write a pattern that never matches but forces the evaluation of an argument. This is often achieved by adding a guard clause that evaluates to false, but we can also use an absurd pattern for the same purpose.

An or-pattern $p_1 \parallel p_2$ matches a value if either p_1 or p_2 (or both) matches the value. Or-patterns introduce a complication for the compiler: we have to ensure that if values are bound to variables in p_1 during matching, then p_2 has to bind values of the same type to the same variables. The following example on the left shows how or-patterns without variables can be used to combine multiple clauses into one.

$$
\begin{array}{ll}
\textbf{data}\ \mathrm{Day} \ = \texttt{Mo} \mid \texttt{Tu} \mid \texttt{We} \mid \texttt{Th} \mid \texttt{Fr} \mid \texttt{Sa} \mid \texttt{Su} & \\
\mathrm{isWeekend} : \mathrm{Day} \to \mathrm{Bool} & \mathrm{isWeekend} : \mathrm{Day} \to \mathrm{Bool} \\
\mathrm{isWeekend}(\texttt{Sa} \parallel \texttt{Su}) := \texttt{True} & \mathrm{isWeekend}(\texttt{Sa} \parallel \texttt{Su}) := \texttt{True} \\
\mathrm{isWeekend}(\texttt{Mo} \parallel \texttt{Tu} \parallel \texttt{We} \parallel \texttt{Th} \parallel \texttt{Fr}) := \texttt{False} & \mathrm{isWeekend}(\neg(\texttt{Sa} \parallel \texttt{Su})) := \texttt{False}
\end{array}
$$

We could also have written the second clause of the previous example using a wildcard pattern, but then the two patterns would overlap. We can get rid of the verbose second clause by using a negation pattern, which is illustrated on the right. A negation pattern matches if, and only if, the negated pattern does not match.

The last type of patterns we introduce are and-patterns $p_1 \,\&\, p_2$ which succeed if both p_1 and p_2 match the scrutinee. While or-patterns $p_1 \parallel p_2$ require that p_1 and p_2 bind the same set of variables, and-patterns $p_1 \,\&\, p_2$ require p_1 and p_2 to bind disjoint sets of variables. Many languages already have a special case of and-patterns: An @-pattern $x@p$ (some languages also use the keyword "as") is an and-pattern where the left side must be a variable. If we want to rewrite the previous example to return a string instead of a boolean value, then we could use the following and-patterns:

$$
\begin{array}{l}
\mathrm{isWeekend} : \mathrm{Day} \to \mathrm{String} \\
\mathrm{isWeekend}(x \,\&\, (\texttt{Sa} \parallel \texttt{Su})) := \mathrm{show}(x) \mathbin{+\!\!+} \text{“ is on the weekend”} \\
\mathrm{isWeekend}(x \,\&\, \neg(\texttt{Sa} \parallel \texttt{Su})) := \mathrm{show}(x) \mathbin{+\!\!+} \text{“ is not on the weekend”}
\end{array}
$$

Here we use the show function to print a weekday and ++ for string concatenation. We will use this snippet as a running example in Section 5 and Section 6 to show how patterns are normalized and compiled to efficient code.

3.1 Matching Semantics of Patterns

We will now present the formal rules which specify what happens when we match a pattern against a value; these rules can be found in the upper half of Figure 2. We use two mutually recursive judgments to formalize the semantics of matching: The judgment $p \triangleright v \rightsquigarrow \sigma$ expresses that the pattern p successfully matches the value v and also binds values to variables of the pattern; those mappings are recorded in the substitution σ. The judgment $p \not\triangleright v \rightsquigarrow \sigma$ expresses that the pattern p does *not* match the value v, and also produces a substitution. That the judgment $p \not\triangleright v \rightsquigarrow \sigma$ also produces a substitution might be surprising: How can there be a substitution if the value does not match the pattern? We can think of these as "temporarily deactivated" substitutions which will become available again if we enclose the pattern in an additional negation. In fact, such substitutions are necessary if we want to guarantee that the pattern p is semantically equivalent to $\neg\neg p$ in the case where p contains variables, for example in Equation (5) below.

▶ **Example 2.** These examples show some well-behaved instances of the matching judgments:

$$\mathrm{Cons}(x, xs) \triangleright \mathrm{Cons}(2, \mathrm{Cons}(3, \mathrm{Nil})) \rightsquigarrow [x \mapsto 2, xs \mapsto \mathrm{Cons}(3, \mathrm{Nil})] \tag{1}$$

$$\mathrm{True} \parallel \mathrm{False} \triangleright \mathrm{True} \rightsquigarrow [] \tag{2}$$

$$\mathrm{True} \not\triangleright \mathrm{False} \rightsquigarrow [] \tag{3}$$

$$\neg x \not\triangleright \mathrm{True} \rightsquigarrow [x \mapsto \mathrm{True}] \tag{4}$$

$$\neg\neg x \triangleright \mathrm{True} \rightsquigarrow [x \mapsto \mathrm{True}] \tag{5}$$

Equation (1) illustrates how the rules Var and Ctor can be used to match a constructor pattern against a list while binding components of the list to variables x and xs. Equation (2) shows how the rule Or_1 (together with the rule Ctor) allows to successfully match the left side of an or-pattern against a value. Equation (3) illustrates the rule Ctor_2 and Equation (4) the combination of rules Var and Neg_2. Equation (5) shows why we need two mutually recursive judgments: in order for the pattern $\neg\neg x$ to match against the value True we need to use the rules Neg_1, Neg_2 and Var to ensure that the variable x is bound to the value True.

Using the rules for $p \triangleright v \rightsquigarrow \sigma$ and $p \not\triangleright v \rightsquigarrow \sigma$ we can already prove that they are, in a certain sense, sound and complete:

▶ **Theorem 3** (Matching rules are sound, Agda). *The rules from Figure 2 are sound. There is no pattern p, value v and substitutions σ_1, σ_2 such that both $p \triangleright v \rightsquigarrow \sigma_1$ and $p \not\triangleright v \rightsquigarrow \sigma_2$ hold.*

▶ **Theorem 4** (Matching rules are complete, Agda). *The rules from Figure 2 are complete, i.e. for any pattern p and value v there is some σ such that $p \triangleright v \rightsquigarrow \sigma$ or $p \not\triangleright v \rightsquigarrow \sigma$ holds.*

Since we are interested in algebraic reasoning, we have to say when we consider two patterns to be semantically equivalent. We will define semantic equivalence in Definition 6 using the two judgments introduced above. But first, we have to define when two substitutions (which we formalized as lists of mappings) are semantically equivalent:

Pattern matches: $p \triangleright v \rightsquigarrow \sigma$

$$\frac{}{x \triangleright v \rightsquigarrow [x \mapsto v]}\ \textsc{Var} \qquad \frac{}{_ \triangleright v \rightsquigarrow []}\ \textsc{Wild} \qquad \frac{p \not\triangleright v \rightsquigarrow \sigma}{\neg p \triangleright v \rightsquigarrow \sigma}\ \textsc{Neg}_1$$

$$\frac{p_1 \triangleright v \rightsquigarrow \sigma}{p_1 \parallel p_2 \triangleright v \rightsquigarrow \sigma}\ \textsc{Or}_1 \qquad \frac{p_2 \triangleright v \rightsquigarrow \sigma}{p_1 \parallel p_2 \triangleright v \rightsquigarrow \sigma}\ \textsc{Or}_2 \qquad \frac{p_1 \triangleright v \rightsquigarrow \sigma_1 \qquad p_2 \triangleright v \rightsquigarrow \sigma_2}{p_1 \,\&\, p_2 \triangleright v \rightsquigarrow \sigma_1 +\!\!+ \sigma_2}\ \textsc{And}$$

$$\frac{p_1 \triangleright v_1 \rightsquigarrow \sigma_1 \qquad \dots \qquad p_n \triangleright v_n \rightsquigarrow \sigma_n}{\mathcal{C}^n(p_1, \dots, p_n) \triangleright \mathcal{C}^n(v_1, \dots, v_n) \rightsquigarrow \sigma_1 +\!\!+ \dots +\!\!+ \sigma_n}\ \textsc{Ctor}$$

Pattern doesn't match: $p \not\triangleright v \rightsquigarrow \sigma$

$$\frac{}{\# \not\triangleright v \rightsquigarrow []}\ \textsc{Absurd} \qquad \frac{\exists i : p_i \not\triangleright v_i \rightsquigarrow \sigma}{\mathcal{C}^n(p_1, \dots, p_n) \not\triangleright \mathcal{C}^n(v_1, \dots, v_n) \rightsquigarrow \sigma}\ \textsc{Ctor}_1$$

$$\frac{p \triangleright v \rightsquigarrow \sigma}{\neg p \not\triangleright v \rightsquigarrow \sigma}\ \textsc{Neg}_2 \qquad \frac{\mathcal{C}^n \neq \mathcal{C}'^m}{\mathcal{C}^n(p_1, \dots, p_n) \not\triangleright \mathcal{C}'^m(v_1, \dots, v_m) \rightsquigarrow []}\ \textsc{Ctor}_2$$

$$\frac{p_1 \not\triangleright v \rightsquigarrow \sigma}{p_1 \,\&\, p_2 \not\triangleright v \rightsquigarrow \sigma}\ \textsc{And}_1 \qquad \frac{p_2 \not\triangleright v \rightsquigarrow \sigma}{p_1 \,\&\, p_2 \not\triangleright v \rightsquigarrow \sigma}\ \textsc{And}_2 \qquad \frac{p_1 \not\triangleright v \rightsquigarrow \sigma_1 \qquad p_2 \not\triangleright v \rightsquigarrow \sigma_2}{p_1 \parallel p_2 \not\triangleright v \rightsquigarrow \sigma_1 +\!\!+ \sigma_2}\ \textsc{Or}$$

Pattern is linear: $p\ \mathbf{lin}^+$ and $p\ \mathbf{lin}^-$

$$\frac{}{x\ \mathbf{lin}^\pm}\ \text{L-}\textsc{Var}^\pm \qquad \frac{}{\#\ \mathbf{lin}^\pm}\ \text{L-}\textsc{Absurd}^\pm \qquad \frac{}{_\ \mathbf{lin}^\pm}\ \text{L-}\textsc{Wild}^\pm$$

$$\frac{p_{1,2}\ \mathbf{lin}^+ \quad \mathrm{FV}^e(p_1) = \mathrm{FV}^e(p_2)}{p_1 \parallel p_2\ \mathbf{lin}^+}\ \text{L-}\textsc{Or}^+ \qquad \frac{p_{1,2}\ \mathbf{lin}^- \quad \mathrm{FV}^o(p_1) \cap \mathrm{FV}^o(p_2) = \emptyset}{p_1 \parallel p_2\ \mathbf{lin}^-}\ \text{L-}\textsc{Or}^-$$

$$\frac{p_{1,2}\ \mathbf{lin}^+ \quad \mathrm{FV}^e(p_1) \cap \mathrm{FV}^e(p_2) = \emptyset}{p_1 \,\&\, p_2\ \mathbf{lin}^+}\ \text{L-}\textsc{And}^+ \qquad \frac{p_{1,2}\ \mathbf{lin}^- \quad \mathrm{FV}^o(p_1) = \mathrm{FV}^o(p_2)}{p_1 \,\&\, p_2\ \mathbf{lin}^-}\ \text{L-}\textsc{And}^-$$

$$\frac{p\ \mathbf{lin}^-}{\neg p\ \mathbf{lin}^+}\ \text{L-}\textsc{Neg}^+ \qquad \frac{p\ \mathbf{lin}^+}{\neg p\ \mathbf{lin}^-}\ \text{L-}\textsc{Neg}^-$$

$$\frac{p_i\ \mathbf{lin}^+ \quad \bigcap_{i=1}^n \mathrm{FV}^e(p_i) = \emptyset}{C^n(p_1, \dots, p_n)\ \mathbf{lin}^+}\ \text{L-}\textsc{Ctor}^+ \qquad \frac{p_i\ \mathbf{lin}^- \quad \bigcup_{i=1}^n \mathrm{FV}^o(p_i) = \emptyset}{C^n(p_1, \dots, p_n)\ \mathbf{lin}^-}\ \text{L-}\textsc{Ctor}^-$$

Pattern is deterministic: $p\ \mathbf{det}$

$$\frac{}{x\ \mathbf{det}}\ \text{D-}\textsc{Var} \qquad \frac{}{_\ \mathbf{det}}\ \text{D-}\textsc{Wild} \qquad \frac{p_1\ \mathbf{det}}{\neg p_1\ \mathbf{det}}\ \text{D-}\textsc{Neg} \qquad \frac{}{\#\ \mathbf{det}}\ \text{D-}\textsc{Absurd}$$

$$\frac{p_{1,2}\ \mathbf{det} \quad p_1 \not\perp p_2}{p_1 \parallel p_2\ \mathbf{det}}\ \text{D-}\textsc{Or}_1 \qquad \frac{p_{1,2}\ \mathbf{det} \quad \mathrm{FV}^e(p_1) = \mathrm{FV}^e(p_2) = \emptyset}{p_1 \parallel p_2\ \mathbf{det}}\ \text{D-}\textsc{Or}_2$$

$$\frac{p_{1,2}\ \mathbf{det} \quad \neg p_1 \not\perp \neg p_2}{p_1 \,\&\, p_2\ \mathbf{det}}\ \text{D-}\textsc{And}_1 \qquad \frac{p_{1,2}\ \mathbf{det} \quad \mathrm{FV}^o(p_1) = \mathrm{FV}^o(p_2) = \emptyset}{p_1 \,\&\, p_2\ \mathbf{det}}\ \text{D-}\textsc{And}_2$$

$$\frac{p_1\ \mathbf{det} \cdots p_n\ \mathbf{det}}{C^n(p_1, \dots, p_n)\ \mathbf{det}}\ \text{D-}\textsc{Ctor}$$

Figure 2 Rules for matching patterns against values, and checking for linearity and determinism.

▶ **Definition 5** (Semantic equivalence of substitutions,). *Two substitutions σ and σ' are semantically equivalent if they contain the same mappings:*

$$[\![\,\sigma\,]\!] \equiv [\![\,\sigma'\,]\!] \coloneqq \forall m, m \in \sigma \Leftrightarrow m \in \sigma'$$

We can now state the definition for semantic equivalence of patterns.

▶ **Definition 6** (Semantic equivalence of patterns,). *Two patterns p and q are semantically equivalent if they match the same values with equivalent substitutions, and if they also do not match the same values with equivalent substitutions:*

$$\begin{aligned}[\![\,p\,]\!] \equiv [\![\,q\,]\!] \coloneqq \forall v, \forall \sigma,\ & p \triangleright v \rightsquigarrow \sigma \Rightarrow \exists \sigma', q \triangleright v \rightsquigarrow \sigma' \wedge [\![\,\sigma\,]\!] \equiv [\![\,\sigma'\,]\!] \\ \wedge\ & q \triangleright v \rightsquigarrow \sigma \Rightarrow \exists \sigma', p \triangleright v \rightsquigarrow \sigma' \wedge [\![\,\sigma\,]\!] \equiv [\![\,\sigma'\,]\!] \\ \wedge\ & p \not\triangleright v \rightsquigarrow \sigma \Rightarrow \exists \sigma', q \not\triangleright v \rightsquigarrow \sigma' \wedge [\![\,\sigma\,]\!] \equiv [\![\,\sigma'\,]\!] \\ \wedge\ & q \not\triangleright v \rightsquigarrow \sigma \Rightarrow \exists \sigma', p \not\triangleright v \rightsquigarrow \sigma' \wedge [\![\,\sigma\,]\!] \equiv [\![\,\sigma'\,]\!]\end{aligned}$$

We have to include both judgment forms if we want semantic equivalence to be a congruence relation. To see why this is the case, suppose that we omit the second half of Definition 6. It would then follow that the two patterns $\#$ and $\neg x$ are semantically equivalent since they match against the same set of values (i.e. no values at all). But if we apply a negation-pattern to both patterns, then we can easily show that the resulting patterns are no longer semantically equivalent: $[\![\,\neg\#\,]\!] \equiv [\![\,_\,]\!] \not\equiv [\![\,x\,]\!] \equiv [\![\,\neg\neg x\,]\!]$. But since Definition 6 requires both patterns to agree on the values they match *and* don't match against, it actually defines a congruence relation on patterns:

▶ **Theorem 7** (Congruence,). *If $[\![\,p_1\,]\!] \equiv [\![\,p_1'\,]\!]$ to $[\![\,p_n\,]\!] \equiv [\![\,p_n'\,]\!]$ hold, then we also have $[\![\,\neg p_1\,]\!] \equiv [\![\,\neg p_1'\,]\!]$, $[\![\,p_1 \,\&\, p_2\,]\!] \equiv [\![\,p_1' \,\&\, p_2'\,]\!]$, $[\![\,p_1 \parallel p_2\,]\!] \equiv [\![\,p_1' \parallel p_2'\,]\!]$ and $[\![\,\mathcal{C}(p_1, \ldots, p_n)\,]\!] \equiv [\![\,\mathcal{C}(p_1', \ldots, p_n')\,]\!]$.*

We can use the definition of semantic equivalence to prove that the following algebraic laws hold for patterns:

▶ **Theorem 8** (Algebraic Equivalences of Patterns, I,). *For all patterns p, q, r, the following equivalences hold:*

$$\begin{array}{rcl@{\qquad}rcl@{\qquad}l}
[\![\,p \,\&\, q\,]\!] & \equiv & [\![\,q \,\&\, p\,]\!] & [\![\,p \parallel q\,]\!] & \equiv & [\![\,q \parallel p\,]\!] & \text{Commutativity} \\
[\![\,p \,\&\, (q \,\&\, r)\,]\!] & \equiv & [\![\,(p \,\&\, q) \,\&\, r\,]\!] & [\![\,p \parallel (q \parallel r)\,]\!] & \equiv & [\![\,(p \parallel q) \parallel r\,]\!] & \text{Associativity} \\
[\![\,p \,\&\, _\,]\!] & \equiv & [\![\,p\,]\!] & [\![\,p \parallel \#\,]\!] & \equiv & [\![\,p\,]\!] & \text{Neutral Elements} \\
[\![\,\neg_\,]\!] & \equiv & [\![\,\#\,]\!] & [\![\,\neg\#\,]\!] & \equiv & [\![\,_\,]\!] & \text{Duality} \\
[\![\,\neg(p \parallel q)\,]\!] & \equiv & [\![\,(\neg p) \,\&\, (\neg q)\,]\!] & [\![\,\neg(p \,\&\, q)\,]\!] & \equiv & [\![\,(\neg p) \parallel (\neg q)\,]\!] & \text{De Morgan} \\
\multicolumn{6}{c}{[\![\,\neg\neg p\,]\!] \equiv [\![\,p\,]\!]} & \text{Double Negation}
\end{array}$$

In addition to these boolean laws we can also prove the following equivalences which involve constructor patterns:

▶ **Theorem 9** (Equivalences of Constructor Patterns, I,). *For all patterns p_1 to p_n and p_1' to p_n', the following equivalences hold:*

$$\begin{aligned}[\![\,\mathcal{C}(p_1, \ldots, p_n) \,\&\, \mathcal{C}(p_1', \ldots, p_n')\,]\!] &\equiv [\![\,\mathcal{C}(p_1 \,\&\, p_1', \ldots, p_n \,\&\, p_n')\,]\!] \\ [\![\,\mathcal{C}(p_1, \ldots, p_i \parallel p_i', \ldots, p_n)\,]\!] &\equiv [\![\,\mathcal{C}(p_1, \ldots, p_i, \ldots, p_n) \parallel \mathcal{C}(p_1, \ldots, p_i', \ldots, p_n)\,]\!]\end{aligned}$$

There are still some equivalences that we expect to hold but which are missing from Theorem 8 and Theorem 9. These additional laws, like the distributive law for and- and or-patterns, are not universally valid and require additional restrictions on patterns. We will motivate and introduce these additional constraints in the next subsection.

3.2 Linear Patterns

The first restriction we impose on patterns is *linearity*. The linearity restriction is easy to state if the syntax of patterns does not include and-patterns, or-patterns and negation-patterns: A pattern is linear if every variable occurs at most once. To see why this restriction is necessary consider the nonlinear pattern $\texttt{Cons}(x, x)$, for which we can derive the following judgment:

$$\texttt{Cons}(x, x) \triangleright \texttt{Cons}(2, \texttt{Nil}) \rightsquigarrow [x \mapsto 2, x \mapsto \texttt{Nil}] \tag{6}$$

The problem here is that multiple values are bound to the same variable, i.e. the result of the pattern match is not a proper substitution.

We have a more expressive language of algebraic patterns, and the simple definition of linearity described above is no longer sufficient. To see why this is the case, consider the pattern $(x \,\&\, \texttt{True}) \parallel \texttt{False}$ that is linear according to the simple definition, but which shows the following pathological behavior:

$$(x \,\&\, \texttt{True}) \parallel \texttt{False} \triangleright \texttt{True} \rightsquigarrow [x \mapsto \texttt{True}] \tag{7}$$

$$(x \,\&\, \texttt{True}) \parallel \texttt{False} \triangleright \texttt{False} \rightsquigarrow [] \tag{8}$$

Equations (7) and (8) show that matching against this pattern can produce substitutions that do not have the same domain.

The two examples above tell us what the correct notion of linearity should guarantee: First, if a linear pattern matches against a value, then the resulting substitution should be a proper substitution which contains at most one mapping for a variable. Second, if we use a pattern in a clause we should be able to read off the variables that will be in the domain of the substitution of a successful match.

In order to ensure that these properties hold we have to use two mutually recursive judgments $p\ \mathbf{lin}^+$ and $p\ \mathbf{lin}^-$, whose rules are given in Figure 2. We use $p\ \mathbf{lin}^\pm$ for patterns which satisfy both $p\ \mathbf{lin}^+$ and $p\ \mathbf{lin}^-$. Theorems 10 and 11 show that linear patterns do have the properties described in the previous paragraph.

▶ **Theorem 10** (Linear patterns produce covering substitutions, Agda). *For any pattern p, value v and substitution σ:*

1. *If $p\ \mathbf{lin}^+$ and $p \triangleright v \rightsquigarrow \sigma$, then the domain of σ is equal to $\mathrm{FV}^e(p)$.*
2. *If $p\ \mathbf{lin}^-$ and $p \not\triangleright v \rightsquigarrow \sigma$, then the domain of σ is equal to $\mathrm{FV}^o(p)$.*

▶ **Theorem 11** (Linear patterns produce proper substitutions, Agda). *For any pattern p, value v and substitution σ:*

1. *If $p\ \mathbf{lin}^+$ and $p \triangleright v \rightsquigarrow \sigma$, then σ is a proper substitution.*
2. *If $p\ \mathbf{lin}^-$ and $p \not\triangleright v \rightsquigarrow \sigma$, then σ is a proper substitution.*

A substitution σ is proper if any variable occurs at most once in the domain of σ.

We will now motivate why the rules in Figure 2 have the specific form that they do. Theorem 10 tells us that we should think about the variables in $\mathrm{FV}^e(p)$ as the actual pattern variables which we can use in the right-hand side of a clause, and that we should think of the variables in $\mathrm{FV}^o(p)$ as the "temporarily deactivated" pattern variables "reactivated" by negation.

Let us first look at the restrictions on the variables in $\mathrm{FV}^e(p)$, since those are more intuitive. In the or-pattern $p_1 \parallel p_2$ we require that $\mathrm{FV}^e(p_1)$ is equal to $\mathrm{FV}^e(p_2)$ since we do not know which of the two patterns will match, and we have to ensure that the same variables appear in the substitution. In the and-pattern $p_1 \,\&\, p_2$ we require that $\mathrm{FV}^e(p_1)$ is

disjoint from $\mathrm{FV}^e(p_2)$ since we do not want the same variable to be mapped to two values in the substitution. The reasoning is very similar for constructor patterns $\mathcal{C}(p_1, \ldots, p_i)$ where we require all the $\mathrm{FV}^e(p_i)$ to be disjoint.

Next, let us look at the restrictions on $\mathrm{FV}^o(e)$, i.e. the variables which occur under an odd number of negations. The rules for and-patterns and or-patterns are motivated by duality. We have seen that the De Morgan rules are valid for patterns. We therefore want, for example, that if the pattern $\neg(p_1 \parallel p_2)$ is linear, the pattern $\neg p_1 \mathbin{\&} \neg p_2$ should be linear as well. For this to be true, the restrictions on $\mathrm{FV}^o(p)$ for or-patterns have to mirror the restrictions on $\mathrm{FV}^e(p)$ for and-patterns, and vice-versa. We still have to explain why we require for a constructor pattern $\mathcal{C}(p_1, \ldots, p_n)$ that all $\mathrm{FV}^o(p_i)$ have to be the empty set. The reason for this restriction lies in the following semantic equivalence, which is motivated by its importance for rewriting patterns into a normal form (see Section 5.1) and which we will prove below.

$$[\![\, \neg\mathcal{C}(p_1, \ldots, p_n) \,]\!] \equiv [\![\, \neg\mathcal{C}(_, \ldots, _) \parallel \mathcal{C}(\neg p_1, \ldots, _) \parallel \ldots \parallel \mathcal{C}(_, \ldots, \neg p_n) \,]\!]$$

The pattern on the right consists of several patterns that are joined by or-patterns. The rules for or-patterns require that each disjunct contains the same sets $\mathrm{FV}^e(-)$. But since the first pattern $\neg\mathcal{C}(_, \ldots, _)$ doesn't contain any variables, the other disjuncts must not contain any variables under an even number of negations. And since the subpatterns p_i occur under a negation, we can deduce that the patterns p_i must not contain any variables under an odd number of negations.

Using linearity we can now prove the missing equivalences which were not included in Theorems 8 and 9.

▶ **Theorem 12** (Algebraic equivalences of Patterns, II, 🏴‍☠️). *For all patterns p, q and r, the following equivalences hold if the patterns on both sides are linear (i.e. $\mathbf{lin}^{\pm}$).*

$[\![\, p \mathbin{\&} (q \parallel r) \,]\!] \equiv [\![\, (p \mathbin{\&} q) \parallel (p \mathbin{\&} r) \,]\!]$	$[\![\, p \parallel (q \mathbin{\&} r) \,]\!] \equiv [\![\, (p \parallel q) \mathbin{\&} (p \parallel r) \,]\!]$	Distributivity
$[\![\, p \mathbin{\&} p \,]\!] \equiv [\![\, p \,]\!]$	$[\![\, p \parallel p \,]\!] \equiv [\![\, p \,]\!]$	Idempotence
$[\![\, p \mathbin{\&} \# \,]\!] \equiv [\![\, \# \,]\!]$	$[\![\, p \parallel _ \,]\!] \equiv [\![\, _ \,]\!]$	Zeros

Theorem 8 and Theorem 12 taken together show that patterns form a boolean algebra, with the caveat that the conjunction or disjunction of two linear patterns does not necessarily result in a linear pattern. We can also prove some additional equivalences involving constructor patterns.

▶ **Theorem 13** (Equivalences of Constructor Patterns, II, 🏴‍☠️). *For all patterns p_1 to p_n and p'_1 to p'_n and constructors $\mathcal{C} \neq \mathcal{C}'$, the following equivalences hold if the patterns on both sides are linear (i.e. $\mathbf{lin}^{\pm}$).*

$$\begin{aligned}
[\![\, \mathcal{C}(p_1, \ldots, \#, \ldots, p_n) \,]\!] &\equiv [\![\, \# \,]\!] \\
[\![\, \mathcal{C}(p_1, \ldots, p_n) \mathbin{\&} \mathcal{C}'(p'_1, \ldots, p'_m) \,]\!] &\equiv [\![\, \# \,]\!] \\
[\![\, \mathcal{C}(p_1, \ldots, p_n) \mathbin{\&} \neg\mathcal{C}'(p'_1, \ldots, p'_m) \,]\!] &\equiv [\![\, \mathcal{C}(p_1, \ldots, p_n) \,]\!] \\
[\![\, \neg\mathcal{C}(p_1, \ldots, p_n) \,]\!] &\equiv [\![\, \neg\mathcal{C}(_, \ldots, _) \parallel \mathcal{C}(\neg p_1, \ldots, p_n) \parallel \ldots \parallel \mathcal{C}(p_1, \ldots, \neg p_n) \,]\!]
\end{aligned}$$

The equivalences of Theorem 13 are essential for proving the correctness of the normalization algorithm specified in Section 5.

3.3 Deterministic Patterns

We also have to introduce a notion of deterministic patterns. To see why this is necessary, consider the pathological pattern $\texttt{Pair}(x, _) \parallel \texttt{Pair}(_, x)$. This pattern is linear, but when we match against the value $\texttt{Pair}(2, 4)$ we can either bind the value 2 or the value 4 to the variable x. Deterministic patterns guarantee that when there are multiple derivations which show that a pattern matches against a value, then these alternatives must yield equivalent substitutions[3].

To define deterministic patterns we first have to introduce overlapping and disjoint patterns. In the extended version [2] we give a procedure for deciding whether two patterns in a certain normalized form – which we will introduce in Section 5 – overlap.

▶ **Definition 14** (Overlapping and Disjoint Patterns). *Two patterns p and q are overlapping, written $p \between q$, if there exists a value v and substitutions σ_1 and σ_2 such that $p \triangleright v \rightsquigarrow \sigma_1$ and $q \triangleright v \rightsquigarrow \sigma_2$. Two patterns p and q are disjoint, written $p \not\between q$ if such a value and such substitutions do not exist.*

We write p **det** for patterns which satisfy the determinism restriction specified in Figure 2. Note that there are two rules for or-patterns: The rule D-Or$_1$ says that an or-pattern is deterministic if the subpatterns are disjoint, whereas the rule D-Or$_2$ allows arbitrary deterministic subpatterns as long as they do not contain free variables. As for the linearity restriction, these two rules for or-patterns give rise to corresponding rules for and-patterns via De Morgan duality: Given that the pattern $\neg(p1 \parallel p2)$ is deterministic, we want the semantically equivalent pattern $\neg p_1 \,\&\, \neg p_2$ to be deterministic as well.

▶ **Theorem 15** (Matching for wellformed patterns is deterministic,). *For any pattern p, value v and substitutions σ_1, σ_2:*

1. *If p $\mathbf{lin}^+$, p $\mathbf{det}$ and $p \triangleright v \rightsquigarrow \sigma_1$ and $p \triangleright v \rightsquigarrow \sigma_2$, then $\sigma_1 \equiv \sigma_2$.*
2. *If p $\mathbf{lin}^-$, p $\mathbf{det}$ and $p \not\triangleright v \rightsquigarrow \sigma_1$, and $p \not\triangleright v \rightsquigarrow \sigma_2$, then $\sigma_1 \equiv \sigma_2$.*

This property is also necessary to show that the evaluation of terms is deterministic, since we use the relation $p \triangleright v \rightsquigarrow \sigma$ when we define the evaluation of pattern matches in the next subsection.

4 Terms and Types

In this section we present the second part of our solution: default clauses. We present a small language, specify its operational semantics and introduce the typing rules for patterns and expressions. The language contains only data types and pattern matching and omits higher-order functions, but these could be added in the standard way.

4.1 The Syntax of Expressions

Expressions e consist of variables x, the application of a constructor to arguments $\mathcal{C}(e_1, \ldots, e_n)$ and case expressions. Every case expression consists of a scrutinee, a list of normal clauses c which all have the form $p \Rightarrow e$, and a default clause $\mathbf{default} \Rightarrow e$.

$$\begin{array}{lcll} e & ::= & x \mid \mathcal{C}(e_1, \ldots, e_n) \mid \mathbf{case}\ e\ \mathbf{of}\ \{\ c_1, \ldots, c_n\ ;\ \mathbf{default} \Rightarrow e\ \} & \textit{Expression} \\ c & ::= & p \Rightarrow e & \textit{Clause} \end{array}$$

[3] Most languages which implement or-patterns do not check whether patterns are deterministic and instead evaluate or-patterns left-to-right, but this invalidates algebraic laws such as the commutativity of or-patterns. If we need such left-biased or-patterns $p \parallel^{\leftarrow} q$ then we can easily define them as $p \parallel (\neg p \,\&\, q)$.

Every case expression contains exactly one default clause, but a realistic language would also allow to omit the default clause if all other clauses are exhaustive. As we already mentioned, **default** does not belong to the syntax of patterns, but to the syntax of case expressions. In particular, the meaning of a default clause is not equal to the meaning of a clause $_ \Rightarrow e_d$ which uses a wildcard pattern, but equal to a clause $\neg p_1 \,\&\, \cdots \,\&\, \neg p_n \Rightarrow e_d$, where the p_i are all the patterns from the other clauses of the case expression. For this reason it is not possible to define the meaning of a default clause in isolation, unlike for normal clauses, and a default clause also does not immediately give rise to a valid equation for term rewriting.

4.2 Operational Semantics

We formalize a call-by-value semantics in which the only values v are constructors applied to other values. We use evaluation contexts E and a congruence rule E-Cong to specify evaluation within a subterm, following standard practice [9].

$$E \quad ::= \quad \Box \mid \mathcal{C}(v_1, \ldots, v_n, E, e_1, \ldots, e_m) \mid \mathbf{case}\ E\ \mathbf{of}\ \{\ c_1, \ldots, c_n\ ;\ \mathbf{default} \Rightarrow e\ \}$$

We write $e \to^r e'$ for the single-step reduction of the expression e to e' which does not use the congruence rule, and $e \to e'$ for the single step reduction within an evaluation context. The evaluation of case expressions is governed by the two rules E-Match and E-Default. The rule E-Match allows to reduce a case expression using any of the normal clauses that match the scrutinee; in particular, it is not necessary to try the clauses in the order in which they occur. On the right-hand side of that rule we write $e\,\sigma$ for the result of applying the substitution σ to the expression e. The rule E-Default allows to reduce a case expression to the expression of the default clause if none of the other clauses match against the scrutinee.

Single-step evaluation: $e \to e$

$$\frac{p \triangleright v \rightsquigarrow \sigma}{\mathbf{case}\ v\ \mathbf{of}\ \{c_1, \ldots, c_n, p \Rightarrow e, c_{n+2}, \ldots, c_m\ ;\ \mathbf{default} \Rightarrow e_d\} \to^r e\sigma}\ \text{E-Match}$$

$$\frac{p_1 \not\triangleright v \rightsquigarrow \sigma_1 \quad \cdots \quad p_n \not\triangleright v \rightsquigarrow \sigma_n}{\mathbf{case}\ v\ \mathbf{of}\ \{\ p_1 \Rightarrow e_1, \ldots, p_n \Rightarrow e_n\ ;\ \mathbf{default} \Rightarrow e_d\ \} \to^r e_d}\ \text{E-Default}$$

$$\frac{e \to^r e'}{E[e] \to E[e']}\ \text{E-Cong}$$

Nothing in these rules guarantees that evaluation is deterministic. For example, we can write a case expression with overlapping patterns. If we want evaluation to be deterministic, then we have to check that expressions are wellformed, written as $e\ \checkmark$. For this we have to check that all patterns which occur in case expressions are deterministic, positively linear, and that no two clauses in a case expression have overlapping patterns.

Wellformed expressions: $e\ \checkmark$

$$\frac{}{x\ \checkmark}\ \text{Wf-Var} \qquad \frac{e_1\ \checkmark \cdots e_n\ \checkmark}{\mathcal{C}(e_1, \ldots, e_n)\ \checkmark}\ \text{Wf-Ctor}$$

$$\frac{\{e, e_d, e_1, \ldots, e_n\}\ \checkmark \qquad p_i\ \mathbf{det} \quad p_i\ \mathbf{lin}^+ \quad \text{if } i \neq j \text{ then } p_i \not\between p_j}{\mathbf{case}\ e\ \mathbf{of}\ \{\ p_1 \Rightarrow e_1, \ldots, p_n \Rightarrow e_n\ ;\ \mathbf{default} \Rightarrow e_d\ \}\ \checkmark}\ \text{Wf-Case}$$

The evaluation of wellformed expressions is deterministic. Furthermore, to check whether an expression is wellformed does not depend on any type information.

▶ **Theorem 16** (Evaluation of wellformed expressions is deterministic). *For all expressions e which are wellformed (that is e ✓ holds), evaluation is deterministic: If $e \to e_1$ and $e \to e_2$, then $e_1 = e_2$.*

Multi-step evaluation $\to^*$ is defined as the reflexive-transitive closure of single-step evaluation and allows us to define when two closed expressions are semantically equivalent:

▶ **Definition 17** (Semantic Equivalence of Expressions). *Two closed expressions e and e' are semantically equivalent, written $[\![e]\!] \equiv [\![e']\!]$, if either both of them evaluate to the same value v, i.e. $e \to^* v$ and $e' \to^* v$, or if both expressions diverge.*

▶ **Theorem 18** (Permutation of clauses does not change semantics). *The meaning of a wellformed pattern match does not change when we permute clauses. If $\overline{c'}$ is a permutation of the list of clauses $\overline{c}$, then $[\![\mathbf{case}\ v\ \mathbf{of}\ \{\overline{c}\ ; \mathbf{default} \Rightarrow e_d\}]\!] \equiv [\![\mathbf{case}\ v\ \mathbf{of}\ \{\overline{c'}\ ; \mathbf{default} \Rightarrow e_d\}]\!]$.*

This theorem makes formal what we call pure no-overlap semantics for pattern matching. The next theorem guarantees that we can use algebraic principles when reasoning about patterns in clauses.

▶ **Theorem 19** (Substitution of equivalent patterns preserves semantics). *If $[\![p_1]\!] \equiv [\![p_2]\!]$, then*

$$[\![\mathbf{case}\ v\ \mathbf{of}\ \{p_1 \Rightarrow e, \overline{c}\ ; \mathbf{default} \Rightarrow e_d\}]\!] \equiv [\![\mathbf{case}\ v\ \mathbf{of}\ \{p_2 \Rightarrow e, \overline{c}\ ; \mathbf{default} \Rightarrow e_d\}]\!].$$

4.3 Typing Rules

In this section, we are going to introduce types, typing contexts and (pattern) typing rules. In order to illustrate the typing rules we include three simple data types: the boolean type $\mathbb{B}$ with constructors `True` and `False`, the type of pairs $\tau \otimes \tau$ with the constructor `Pair`, and the type of binary sums $\tau \oplus \tau$ with constructors ι_1 and ι_2.

$$\begin{array}{lcll} \tau & ::= & \mathbb{B} \mid \tau \otimes \tau \mid \tau \oplus \tau & \textit{Types} \\ \Gamma, \Delta & ::= & \cdot \mid \Gamma, x : \tau & \textit{Typing contexts} \end{array}$$

We use the judgment $\Gamma; \Delta \Rightarrow p : \tau$ to express that the pattern p matches against a value of type τ and binds variables whose types are recorded in the context Γ on a successful match, and in context Δ in the case of a non-successful match. In other words, the typing context Γ is used for typing the pattern variables that occur under an even number of negations, and the typing context Δ is used for typing the variables under an odd number of negations. We write $\Gamma_1 +\!\!+ \Gamma_2$ for the naive concatenation of two typing contexts.

Pattern typing: $\Gamma; \Delta \Rightarrow p : \tau$

$$\frac{}{x : \tau; \cdot \Rightarrow x : \tau}\ \text{P-Var} \qquad \frac{}{\cdot; \cdot \Rightarrow _ : \tau}\ \text{P-Wildcard} \qquad \frac{}{\cdot; \cdot \Rightarrow \# : \tau}\ \text{P-Absurd}$$

$$\frac{\Gamma_1; \Delta \Rightarrow p_1 : \tau \quad \Gamma_2; \Delta \Rightarrow p_2 : \tau}{\Gamma_1 +\!\!+ \Gamma_2; \Delta \Rightarrow p_1 \,\&\, p_2 : \tau}\ \text{P-And} \qquad \frac{\Gamma; \Delta_1 \Rightarrow p_1 : \tau \quad \Gamma; \Delta_2 \Rightarrow p_2 : \tau}{\Gamma; \Delta_1 +\!\!+ \Delta_2 \Rightarrow p_1 \parallel p_2 : \tau}\ \text{P-Or}$$

$$\frac{\Gamma; \Delta \Rightarrow p : \tau}{\Delta; \Gamma \Rightarrow \neg p : \tau}\ \text{P-Neg} \qquad \frac{}{\cdot; \cdot \Rightarrow \texttt{True} : \mathbb{B}}\ \text{P-True} \qquad \frac{}{\cdot; \cdot \Rightarrow \texttt{False} : \mathbb{B}}\ \text{P-False}$$

$$\frac{\Gamma; \Delta \Rightarrow p : \tau_1}{\Gamma; \Delta \Rightarrow \iota_1(p) : \tau_1 \oplus \tau_2}\ \text{P-Inl} \qquad \frac{\Gamma; \Delta \Rightarrow p : \tau_2}{\Gamma; \Delta \Rightarrow \iota_2(p) : \tau_1 \oplus \tau_2}\ \text{P-Inr}$$

$$\frac{\Gamma_1; \Delta_1 \Rightarrow p_1 : \tau_1 \qquad \Gamma_2; \Delta_2 \Rightarrow p_2 : \tau_2}{\Gamma_1 +\!\!+ \Gamma_2; \Delta_1 +\!\!+ \Delta_2 \Rightarrow \texttt{Pair}(p_1, p_2) : \tau_1 \otimes \tau_2} \text{ P-Pair}$$

These pattern typing rules do not make sense on their own, but only in conjunction with the rules for linearity. For example, the typing rules allow to derive the typing judgment $x : \tau_1, x : \tau_2; \cdot \Rightarrow \texttt{Pair}(x, x) : \tau_1 \otimes \tau_2$, but the linearity rules disallow this pattern[4]. Lastly, we present the rules for typing expressions:

Expression typing: $\Gamma \vdash e : \tau$

$$\frac{\Gamma \vdash e : \sigma \qquad \Gamma \vdash e_d : \tau \qquad \forall i : \ \Gamma_i; \Delta \Rightarrow p_i : \sigma \text{ and } \Gamma +\!\!+ \Gamma_i \vdash e_i : \tau}{\Gamma \vdash \textbf{case } e \textbf{ of } \{\ p_1 \Rightarrow e_1, \ldots, p_n \Rightarrow e_n\ ; \textbf{ default} \Rightarrow e_d\ \} : \tau} \text{ T-Match}$$

$$\frac{\Gamma(x) = \tau}{\Gamma \vdash x : \tau} \text{ T-Var} \qquad \frac{}{\Gamma \vdash \texttt{True} : \mathbb{B}} \text{ T-True} \qquad \frac{}{\Gamma \vdash \texttt{False} : \mathbb{B}} \text{ T-False}$$

$$\frac{\Gamma \vdash e_1 : \sigma \quad \Gamma \vdash e_2 : \tau}{\Gamma \vdash \texttt{Pair}(e_1, e_2) : \sigma \otimes \tau} \text{ T-Pair} \qquad \frac{\Gamma \vdash e : \sigma}{\Gamma \vdash \iota_1(e) : \sigma \oplus \tau} \text{ T-Inl} \qquad \frac{\Gamma \vdash e : \tau}{\Gamma \vdash \iota_2(e) : \sigma \oplus \tau} \text{ T-Inr}$$

In the rule T-Match we use the pattern typing rule for the pattern in each clause, and add the resulting typing context Γ_i which contains the types of all pattern variables under an even number of negations to the outer typing context Γ in the respective clause.

5 Normalizing Algebraic Patterns

So far, we have considered algebraic patterns in their unrestricted form which is written by the programmer and checked by the compiler. In this section, we consider normal forms for patterns which simplify the compilation algorithm in Section 6. We end up with a normal form that is a variant of disjunctive normal forms, but which takes the use of constructors and variables into account. We describe a normalization procedure which proceeds in three steps: The first step, described in Section 5.1, pushes negation-patterns inward so that they only occur applied to constructors without subpatterns, or to variables. The second step, described in Section 5.2, pushes or-patterns outwards, so that we end up with a disjunctive normal form, that is a disjunction of elementary conjuncts. In the third step, we further simplify these elementary conjuncts; this is described in Section 5.3. The default clause is not affected by the normalization procedure described in this section; the compilation of case expressions to decision trees described in the next section can handle default clauses natively.

5.1 Computing the Negation Normal Form

Consider the pattern $\neg\texttt{Pair}(\texttt{True}, \texttt{False})$ which matches anything except a tuple consisting of the boolean values `True` and `False`. Another way to express the behavior of this pattern is to say that it matches anything which isn't a tuple, or it matches a tuple if either the left element isn't the value `True` or the right element isn't the value `False`. We can therefore also write the pattern as $\neg\texttt{Pair}(_, _) \parallel \texttt{Pair}(\neg\texttt{True}, _) \parallel \texttt{Pair}(_, \neg\texttt{False})$. We can generalize this observation and use it to push all negation-patterns inside, by repeatedly rewriting the pattern using the last equation of Theorem 13. After we have normalized patterns in this way, negation-patterns only occur applied to variables or to constructors where all subpatterns of the constructor are wildcard patterns. We abbreviate these negated constructor patterns $\neg\mathcal{C}^n(_, \ldots, _)$ as $\neg\mathcal{C}^n$.

[4] An implementation might choose to check linearity and typing of patterns simultaneously, but we prefer to present them separately to illustrate that we can also use algebraic patterns in the untyped setting.

▶ **Definition 20** (Negation Normal Forms). *The syntax of negation normal forms is:*

$$N \quad ::= \quad x \mid \neg x \mid \neg \mathcal{C}^n \mid \mathcal{C}^n(N_1, \ldots, N_n) \mid N \,\&\, N \mid N \parallel N \mid _ \mid \#$$

$$\begin{array}{rlrl}
\mathtt{nnf}^-(p_1 \,\&\, p_2) & := \mathtt{nnf}^-(p_1) \parallel \mathtt{nnf}^-(p_2) & \mathtt{nnf}^+(p_1 \,\&\, p_2) & := \mathtt{nnf}^+(p_1) \,\&\, \mathtt{nnf}^+(p_2) \\
\mathtt{nnf}^-(p_1 \parallel p_2) & := \mathtt{nnf}^-(p_1) \,\&\, \mathtt{nnf}^-(p_2) & \mathtt{nnf}^+(p_1 \parallel p_2) & := \mathtt{nnf}^+(p_1) \parallel \mathtt{nnf}^+(p_2) \\
\mathtt{nnf}^-(\neg p) & := \mathtt{nnf}^+(p) & \mathtt{nnf}^+(\neg p) & := \mathtt{nnf}^-(p) \\
\mathtt{nnf}^-(\#) & := _ & \mathtt{nnf}^+(\#) & := \# \\
\mathtt{nnf}^-(_) & := \# & \mathtt{nnf}^+(_) & := _ \\
\mathtt{nnf}^-(x) & := \neg x & \mathtt{nnf}^+(x) & := x
\end{array}$$

$$\begin{array}{ll}
\mathtt{nnf}^-(\mathcal{C}^n(p_1, \ldots, p_n)) & := \neg\mathcal{C}^n \parallel \mathcal{C}^n(\mathtt{nnf}^-(p_1), \ldots, _) \parallel \ldots \parallel \mathcal{C}^n(_, \ldots, \mathtt{nnf}^-(p_n)) \\
\mathtt{nnf}^+(\mathcal{C}^n(p_1, \ldots, p_n)) & := \mathcal{C}^n(\mathtt{nnf}^+(p_1), \ldots, \mathtt{nnf}^+(p_n))
\end{array}$$

The normalization procedure $\mathtt{nnf}(-)$ is split into the two functions $\mathtt{nnf}^-(-)$ and $\mathtt{nnf}^+(-)$ which track if we are currently normalizing a negated or a non-negated pattern. At the top-level, the function $\mathtt{nnf}(-)$ therefore just invokes $\mathtt{nnf}^+(-)$.

▶ **Example 21.** We compute the negation normal form of our running example.

$$\mathtt{nnf}^+(x \,\&\, (\mathtt{Sa} \parallel \mathtt{Su})) = x \,\&\, (\mathtt{Sa} \parallel \mathtt{Su}) \qquad \mathtt{nnf}^+(x \,\&\, \neg(\mathtt{Sa} \parallel \mathtt{Su})) = x \,\&\, (\neg\mathtt{Sa}) \,\&\, (\neg\mathtt{Su})$$

We treat the negation normal forms N as a subset of patterns p, and hence all functions and properties of patterns can also be applied to normal forms. If we translate a pattern into negation normal form then the pattern is still wellformed, can be typed using the same context and type, and has the same semantics as before. This is witnessed by the following lemma.

▶ **Lemma 22** (Negation Normalization Preserves Linearity, Typing and Semantics). *For all patterns p, contexts Γ, Δ and types τ, we have:*

1. *Linearity is preserved: If p $\mathbf{lin}^+$, then $\mathtt{nnf}(p)$ $\mathbf{lin}^+$.*
2. *Typing is preserved: If $\Gamma; \Delta \Rightarrow p : \tau$, then $\Gamma; \Delta \Rightarrow \mathtt{nnf}(p) : \tau$.*
3. *The patterns are semantically equivalent: If p $\mathbf{lin}^\pm$, then $[\![p]\!] \equiv [\![\mathtt{nnf}(p)]\!]$.*

Proof. Available in the appendix of the extended version of this paper [2]. ◀

5.2 Computing the Disjunctive Normal Form

The next step is to bring the negation normal form into a disjunctive normal form. Patterns in disjunctive normal form consist of an outer disjunction of so-called "elementary conjuncts" which do not contain or-patterns. The syntax of the disjunctive normal forms D and elementary conjuncts K is given below. We can normalize a pattern in negation normal form to the disjunctive normal form by the function $\mathtt{dnf}(-)$ which takes a pattern in negation normal form and returns a set of elementary conjuncts. At the top-level we have to wrap the result in a $\parallel \{\ldots\}$ node.

▶ **Definition 23** (Disjunctive Normal Form).

$$\begin{array}{rcll}
D & ::= & \parallel \{K_1, \ldots, K_n\} & \text{Disjunctive Normal Form} \\
K & ::= & x \mid \neg x \mid \neg\mathcal{C}^n \mid \mathcal{C}^n(K_1, \ldots, K_n) \mid K \,\&\, K \mid _ \mid \# & \text{Elementary Conjunct}
\end{array}$$

$$\mathtt{dnf}(x) := \{x\} \quad \mathtt{dnf}(\neg x) := \{\neg x\} \quad \mathtt{dnf}(\neg\mathcal{C}^n) := \{\neg\mathcal{C}^n\} \quad \mathtt{dnf}(_) := \{_\} \quad \mathtt{dnf}(\#) := \{\#\}$$

$$\begin{array}{rcl}
\mathtt{dnf}(\mathcal{C}^n(N_1, \ldots, N_n)) & := & \{\mathcal{C}(k_1, \ldots, k_n) \mid k_1 \in \mathtt{dnf}(N_1), \ldots, k_n \in \mathtt{dnf}(N_n)\} \\
\mathtt{dnf}(N_1 \,\&\, N_2) & := & \{k_1 \,\&\, k_2 \mid k_1 \in \mathtt{dnf}(N_1), k_2 \in \mathtt{dnf}(N_2)\} \\
\mathtt{dnf}(N_1 \parallel N_2) & := & \mathtt{dnf}(N_1) \cup \mathtt{dnf}(N_2)
\end{array}$$

▶ **Example 24.** We compute the disjunctive normal form for our running example.

$$\texttt{dnf}(x \,\&\, (\texttt{Sa} \parallel \texttt{Su})) = \parallel \{x \,\&\, \texttt{Sa}, x \,\&\, \texttt{Su}\} \qquad \texttt{dnf}(x \,\&\, (\neg\texttt{Sa}) \,\&\, (\neg\texttt{Su})) = \parallel \{x \,\&\, (\neg\texttt{Sa}) \,\&\, (\neg\texttt{Su})\}$$

We can embed the disjunctive normal form $\parallel \{K_1, \ldots, K_n\}$ into patterns as $K_1 \parallel \ldots \parallel K_n$. This set of conjuncts is by design never empty ($n > 0$), however, if we do admit this case ($n = 0$) it translates to the absurd-pattern $\#$ and is treated as such in any use case (see Section 6).

5.3 Normalizing Elementary Conjuncts

As a last step, we further simplify the elementary conjuncts of Section 5.2. We write $\overline{D}$ and $\overline{K}$ for these normalized disjunctive normal forms and normalized elementary conjuncts:

▶ **Definition 25** (Normalized Disjunctive Normal Form)**.**

$$\begin{array}{lcl} \overline{D} & ::= & \parallel \{\overline{K}_1, \ldots, \overline{K}_n\} \\ \overline{K} & ::= & \{x_1, \ldots, x_n\} \,\&\, \mathcal{C}(\overline{K}_1, \ldots, \overline{K}_m) \mid \{x_1, \ldots, x_n\} \,\&\, \neg\{\mathcal{C}_1, \ldots, \mathcal{C}_m\} \mid \{x_1, \ldots, x_n\} \,\&\, \# \end{array}$$

These normalized conjuncts follow from the observation that there are essentially only three different kinds of conjuncts: positive, negative and unsatisfiable. Each of these three conjuncts can bind a set of variables $\{x_1, \ldots, x_n\}$. A *positive conjunct* $\{x_1, \ldots, x_n\} \,\&\, \mathcal{C}(\overline{K}_1, \ldots, \overline{K}_m)$ matches against any value headed by the constructor $\mathcal{C}$, and binds that value against all the variables in the set. A *negative conjunct* $\{x_1, \ldots, x_n\} \,\&\, \neg\{\mathcal{C}_1, \ldots, \mathcal{C}_m\}$ matches against any value which is headed by a constructor which is *not* in the list $\{\mathcal{C}_1, \ldots, \mathcal{C}_m\}$. The negative conjunct $\{x\} \& \neg\{\}$ can be used to represent a single pattern variable x, and similarly $\{\} \& \neg\{\}$ can be used to represent a wildcard pattern. An *unsatisfiable conjunct* $\{x_1, \ldots, x_n\} \,\&\, \#$ never matches against a value.

Computing these normalized conjuncts consists in collecting all the variables, as well as all negated and non-negated head constructors of an elementary conjunct. Intuitively, the head constructors are constructors that occur in a pattern without being nested in a subpattern of another constructor. An elementary conjunct is unsatisfiable if two different non-negated constructors appear in the conjunct, or if a head constructor appears both negated and non-negated. An elementary conjunct can be simplified to a negative conjunct if only negated head constructors appear in the original conjunct. Lastly, an elementary conjunct can be simplified to a positive conjunct if neither of the two cases above apply. We write $\texttt{norm}(-)$ for the function which computes these normalized conjuncts; the formal definition of this function is given in the appendix of the extended version of this paper [2]. We also remove negated variables in this step and treat them like absurd patterns; this is, strictly speaking, not semantics preserving, but negated variables cannot be used in the right-hand side of a clause anyway, so this has no effect on the compilation of programs.

▶ **Example 26.** We compute the normalized disjunctive normal form for our running example.

$$\begin{array}{rl} \texttt{norm}(\parallel \{x \,\&\, \texttt{Sa}, x \,\&\, \texttt{Su}\}) & = \parallel \{\{x\} \,\&\, \texttt{Sa}, \{x\} \,\&\, \texttt{Su}\} \\ \texttt{norm}(\parallel \{x \,\&\, (\neg\texttt{Sa}) \,\&\, (\neg\texttt{Su})\}) & = \parallel \{\{x\} \,\&\, \neg\{\texttt{Sa}, \texttt{Su}\}\} \end{array}$$

Like in Section 5.2, we treat the normal forms $\overline{D}$ and $\overline{K}$ as subsets of patterns p. We use patterns in normalized disjunctive normal form in the next section where we define a pattern matching compilation algorithm for nested patterns.

6 Compiling Algebraic Patterns

We have shown that algebraic patterns are more expressive because they explicitly allow us to speak about the complement of a pattern. But programmers won't use them if they have to pay for the gain in expressivity with slower programs. In order to compile programs using these patterns to efficient code we therefore have to use and modify one of the available pattern matching compilation algorithms.

These algorithms can be divided into two general classes: Algorithms which use backtracking [1] and algorithms which compile to decision trees [23]. The algorithms which use backtracking guarantee that the size of the generated code is linear in the size of the input, but the generated code might perform redundant tests. Algorithms which compile to decision trees never examine scrutinees more than once but the generated code might be exponential in the size of the input. Both classes of algorithms are competitive when they are optimized [20, 23], so it is not possible to say which alternative is preferable in general.

In this article we modify and extend the compilation scheme laid out by Maranget [23] which is based on decision trees. His algorithm already includes a treatment of or-patterns, and we will extend it to the normalized patterns that we introduced in Section 5. We introduce the general idea of the compilation to decision trees in Section 6.1, present the central branching step in Section 6.2 in detail and illustrate the algorithm with an example in Section 6.3. We conclude with a statement on the correctness of our extended compilation scheme in Section 6.4.

6.1 General Idea of the Algorithm

The algorithm operates on a generalization of the case expression **case** v **of** $\{\ p_1 \Rightarrow e_1, \ldots, p_n \Rightarrow e_n; \textbf{default} \Rightarrow e\ \}$ that we introduced in Section 4.1. Instead of only one scrutinee v and one pattern p in each clause we now allow a vector $v_1, \ldots, v_n$ of scrutinees and a matrix of clauses with patterns in nDNF (see Section 5.3).

$$\textbf{case } v_1, \ldots, v_n \textbf{ of } \begin{bmatrix} \overline{D}_1^1 & \ldots & \overline{D}_n^1 & \Rightarrow e^1 \\ & \vdots & & \\ \overline{D}_1^m & \ldots & \overline{D}_n^m & \Rightarrow e^m \\ & \textbf{default} & & \Rightarrow e_d \end{bmatrix} \tag{Input}$$

In such multi-column case expressions, the i-th pattern column tests the i-th scrutinee v_i. The main idea of the algorithm is that we take such a multi-column case expression as input and examine all scrutinees – and subscrutinees – one by one, producing a nesting of single-column case expressions with *simple* patterns as output. These simple patterns consist only of constructors applied to variables. We start the compilation by embedding an ordinary case expression into this generalized form on which we call the function *compile*. This function can take one of three steps. It either terminates with a **Default** or **Simple** step, or it examines one of the scrutinees in a **Branch** step.

Default If **default** $\Rightarrow e_d$ is the only clause then we terminate with the expression e_d.

Simple If the first row consists only of variable patterns of the form $\{x_1, \ldots x_k\}$ & $\neg\{\}$ then compilation terminates with the right-hand side of that clause together with appropriate substitutions. This rule also applies if $n = 0$.

Branch If neither of the above steps apply we pick a column i (with $1 \leq i \leq n$) and examine its scrutinee v_i in a single-column case against simple constructor patterns.

All the complexity of the algorithm lies within the **Branch** step, so we will discuss its details in the next subsection.

6.2 The Branching Step

The first step is to choose on which index i we want to perform the case split. This choice does not affect the correctness of the algorithm; selecting a column is a therefore a matter of optimization which other authors [26, 23] have discussed in detail. We only enforce that the selected pattern column must contain outermost constructors. Such a column must necessarily exist if neither the **Default** nor the **Simple** step apply.

Next, we have to gather the constructors against which we can test the scrutinee v_i. We collect these so-called head constructors into a set $\mathcal{H}(\overline{D}_i)$ defined below.

$$\mathcal{H}(\overline{D}_i) := \bigcup_{j=1,\ldots,m} \mathtt{head}(\overline{D}_i^j) \;\; \textit{with} \quad \begin{array}{lcl} \mathtt{head}(\| \{\overline{K}_1, \ldots, \overline{K}_t\}) & := & \bigcup\limits_{l=1,\ldots,t} \mathtt{head}(\overline{K}_l) \\ \mathtt{head}(\{x_1, \ldots, x_s\} \,\&\, \mathcal{C}(\overline{K}_1, \ldots, \overline{K}_t)) & := & \{\mathcal{C}\} \\ \mathtt{head}(\{x_1, \ldots, x_s\} \,\&\, \neg\{\mathcal{C}_1, \ldots, \mathcal{C}_t\}) & := & \{\mathcal{C}_1, \ldots, \mathcal{C}_t\} \\ \mathtt{head}(\{x_1, \ldots, x_s\} \,\&\, \#) & := & \emptyset \end{array}$$

Once we have found these head constructors $\{\mathcal{C}^{n_1}, \ldots, \mathcal{C}^{n_z}\}$ we generate fresh pattern variables x_1^k to $x_{n_k}^k$ for each constructor $\mathcal{C}^{n_k}$ and a simple pattern match. For each clause we have gained information about the scrutinee v_i: Within the right-hand side of a constructor clause, we know that our scrutinee must have conformed to the shape of our constructor. Likewise, if we arrive at the right-hand side of the default clause, we know that our scrutinee must have been different to all the constructors $\{\mathcal{C}^{n_1}, \ldots, \mathcal{C}^{n_z}\}$ before. We use this knowledge by computing clause-specific *subproblems* of our initial Input and we do so via the function $\mathcal{S}$ for constructor clauses and function $\mathcal{D}$ for the default clause.

$$\textbf{case } v_i \textbf{ of } \begin{bmatrix} \mathcal{C}^{n_1}(x_1^1, \ldots, x_{n_1}^1) & \Rightarrow & \mathit{compile}(\mathcal{S}(i, \mathcal{C}^{n_1}(x_1^1, \ldots, x_{n_1}^1), \mathrm{Input})) \\ \vdots & & \vdots \\ \mathcal{C}^{n_z}(x_1^z, \ldots, x_{n_z}^z) & \Rightarrow & \mathit{compile}(\mathcal{S}(i, \mathcal{C}^{n_z}(x_1^z, \ldots, x_{n_z}^z), \mathrm{Input})) \\ \textbf{default} & \Rightarrow & \mathit{compile}(\mathcal{D}(i, \{\mathcal{C}^{n_1}, \ldots, \mathcal{C}^{n_z}\}, \mathrm{Input})) \end{bmatrix} \qquad \text{(Output)}$$

All that is left is to compute these subproblems of *specialization* and *default* which are the arguments of recursive invocations of the compile function.

6.2.1 Computing Specialization

We now show how to compute $\mathcal{S}(i, \mathcal{C}^k(x_1, \ldots, x_k), \mathrm{Input})$ which specializes Input into a constructor-specific subproblem that utilizes *the assumption that the scrutinee v_i has already matched the constructor pattern $\mathcal{C}^k(x_1, \ldots, x_k)$*. We therefore remove the old scrutinee v_i and replace it with the bound variables $x_1, \ldots, x_k$ as new scrutinees.

$$\mathcal{S}(i, \mathcal{C}^k(x_1, \ldots, x_k), \mathrm{Input}) \;=\; \textbf{case } x_1, \ldots, x_k, v_1, \ldots, v_{i-1}, v_{i+1}, \ldots, v_n \textbf{ of } \left[S\right]$$

We now have to build a new clause matrix $\left[S\right]$ that matches against the new list of scrutinees and do so by iterating over the previous clauses. Each clause of the old Input contributes to $\left[S\right]$ only if its i-th pattern could have matched the old scrutinee v_i of shape $\mathcal{C}^k$ by *assumption*. This is, of course, the case for the default clause which we keep unchanged. Otherwise, these i-th patterns are in normalized DNF, and we have to check whether one of its elementary conjuncts could have matched. The following list gives all inclusion rules.

1. Row $\left[\textbf{default} \Rightarrow e_d\right]$ is added to $\left[S\right]$ unchanged.
2. Row $\left[\overline{D}_1^j \;\ldots\; \overline{D}_{i-1}^j \;\; \overline{\mathbf{D}}_\mathbf{i}^\mathbf{j} \;\; \overline{D}_{i+1}^j \;\ldots\; \overline{D}_n^j \;\Rightarrow\; e^j\right]$ only contributes according to $\overline{\mathbf{D}}_\mathbf{i}^\mathbf{j}$:
   a. If $\overline{\mathbf{D}}_\mathbf{i}^\mathbf{j} = \{y_1, \ldots y_s\} \,\&\, \mathcal{C}^k(\overline{K}_1, \ldots, \overline{K}_k)$,
   then add the row $\left[\overline{K}_1 \ldots \overline{K}_k \;\; \overline{D}_1^j \ldots \overline{D}_{i-1}^j \overline{D}_{i+1}^j \ldots \; \overline{D}_n^j \;\Rightarrow e^j[\{y_1, \ldots y_s\} \mapsto v_i]\right]$.
   b. If $\overline{\mathbf{D}}_\mathbf{i}^\mathbf{j} = \{y_1, \ldots y_s\} \,\&\, \neg\{\mathcal{C}_1, \ldots, \mathcal{C}_t\}$ and $\mathcal{C}^k \notin \{\mathcal{C}_1, \ldots, \mathcal{C}_t\}$,
   then add the row $\left[_ \;\ldots\; _ \;\; \overline{D}_1^j \ldots \overline{D}_{i-1}^j \overline{D}_{i+1}^j \ldots \; \overline{D}_n^j \;\Rightarrow e^j[\{y_1, \ldots y_s\} \mapsto v_i]\right]$.
   (Note that we use $_$ simply as a shorthand for the equivalent nDNF $\{\} \,\&\, \neg\{\}$)
   c. If $\overline{\mathbf{D}}_\mathbf{i}^\mathbf{j} = \|\{\overline{K}_1, \ldots, \overline{K}_t\}$, then
   recursively iterate the rows of $\begin{bmatrix} \overline{D}_1^j & \ldots & \overline{D}_{i-1}^j & \overline{\mathbf{K}}_1 & \overline{D}_{i+1}^j & \ldots & \overline{D}_n^j & \Rightarrow & e^j \\ & & & \vdots & & & & & \\ \overline{D}_1^j & \ldots & \overline{D}_{i-1}^j & \overline{\mathbf{K}}_t & \overline{D}_{i+1}^j & \ldots & \overline{D}_n^j & \Rightarrow & e^j \end{bmatrix}$.

We give an example for case 2b which handles negation. Suppose that want to specialize the following case expression into a case expression *subproblem* which assumes that v_1 was matched against $\texttt{Cons}(x, y)$.

$$\mathit{compile}\left(\begin{array}{l}\textbf{case } v_1, v_2 \textbf{ of} \\ \begin{bmatrix} \{\} \,\&\, \neg\{\texttt{Cons}\} & \overline{D}_2^1 & \Rightarrow e^1 \\ \{\} \,\&\, \neg\{\texttt{Nil}\} & \overline{D}_2^2 & \Rightarrow e^2 \\ \textbf{default} & & \Rightarrow e_d \end{bmatrix}\end{array}\right) \quad = \quad \begin{array}{l}\textbf{case } v_1 \textbf{ of} \\ \begin{bmatrix} \texttt{Cons}(x, y) & \Rightarrow \mathit{compile}(\mathit{subproblem}) \\ & \vdots \end{bmatrix}\end{array}$$

The first clause is discarded, because the pattern $\{\} \,\&\, \neg\{\texttt{Cons}\}$ is incompatible with the assumption that v_i matches $\texttt{Cons}$. The second clause using $\{\} \,\&\, \neg\{\texttt{Nil}\}$ is compatible with the assumption. So, how can we transform this clause into a new one testing x, y and v_2? We see that pattern $\{\} \,\&\, \neg\{\texttt{Nil}\}$ does not match on the subvalues x and y of v_1, but for v_2 we still have to match against the pattern $\overline{D}_2^2$. We keep the default clause by rule 1 unchanged.

$$\mathit{subproblem} = \textbf{case } x, y, v_2 \textbf{ of } \begin{bmatrix} _ & _ & \overline{D}_2^2 & \Rightarrow e^2 \\ \textbf{default} & & & \Rightarrow e_d \end{bmatrix}$$

6.2.2 Computing Default

Next we show how to compute $\mathcal{D}(i, \{\mathcal{C}^{n_1}, \ldots, \mathcal{C}^{n_z}\}, \text{Input})$ whose output reflects *the assumption that the scrutinee v_i did not match any of the head constructors $\mathcal{C}^{n_1}$ to $\mathcal{C}^{n_z}$*. This time we have no new scrutinees and only match the leftover list against a new pattern matrix $\left[D\right]$:

$$\mathcal{D}(i, \{\mathcal{C}^{n_1}, \ldots, \mathcal{C}^{n_z}\}, \text{Input}) \;=\; \textbf{case } \; v_1, \ldots, v_{i-1}, v_{i+1}, \ldots, v_n \; \textbf{ of } \; \left[D\right]$$

As before, we build a new matrix $\left[D\right]$ by row-wise iteration over the clauses of the Input. A clause only contributes if its i-th pattern entry allows for a match with scrutinee v_i, knowing that it differs from all the head constructors $C^{n_1}, \ldots, C^{n_z}$.

1. Row $\left[\textbf{default} \Rightarrow e_d\right]$ is added to $\left[D\right]$ unchanged.
2. Row $\left[\overline{D}_1^j \;\ldots\; \overline{D}_{i-1}^j \;\; \overline{\mathbf{D}}_\mathbf{i}^\mathbf{j} \;\; \overline{D}_{i+1}^j \;\ldots\; \overline{D}_n^j \;\Rightarrow\; e^j\right]$, only contributes according to $\overline{\mathbf{D}}_\mathbf{i}^\mathbf{j}$:
   a. If $\overline{\mathbf{D}}_\mathbf{i}^\mathbf{j} = \{y_1, \ldots, y_s\} \,\&\, \neg\{\mathcal{C}_1, \ldots, \mathcal{C}_t\}$,
   then add the row $\left[\overline{D}_1^j \ldots \overline{D}_{i-1}^j \overline{D}_{i+1}^j \ldots \; \overline{D}_n^j \;\Rightarrow e^j[\{y_1, \ldots y_s\} \mapsto v_i]\right]$.
   Note that v_i's constructor differs from all head constructors which include $\{\mathcal{C}_1, \ldots, \mathcal{C}_t\}$

b. If $\overline{\mathbf{D}}^{\mathbf{j}}_{\mathbf{i}} = \|\{\overline{K}_1, \ldots, \overline{K}_t\}$, then

recursively iterate the rows of $\begin{bmatrix} \overline{D}^j_1 & \ldots & \overline{D}^j_{i-1} & \overline{\mathbf{K}}_1 & \overline{D}^j_{i+1} & \ldots & \overline{D}^j_n & \Rightarrow & e^j \\ & & & \vdots & & & & & \\ \overline{D}^j_1 & \ldots & \overline{D}^j_{i-1} & \overline{\mathbf{K}}_t & \overline{D}^j_{i+1} & \ldots & \overline{D}^j_n & \Rightarrow & e^j \end{bmatrix}$.

Let us illustrate rule 2a with the case expression below, where we perform a case split on v_1. We want to construct the default *subproblem* which assumes that v_1 did not match the constructors `Red` or `Green`.

$$\mathit{compile}\left(\begin{array}{l}\textbf{case } v_1, v_2 \textbf{ of} \\ \begin{bmatrix} \{\} \,\&\, \texttt{Red} & \overline{D}^1_2 \Rightarrow e^1 \\ \{\} \,\&\, \neg\{\texttt{Green}\} & \overline{D}^2_2 \Rightarrow e^2 \\ \textbf{default} & \Rightarrow e_d \end{bmatrix}\end{array}\right) = \begin{array}{l}\textbf{case } v_1 \textbf{ of} \\ \begin{bmatrix} \texttt{Red} & \Rightarrow & \ldots \\ \texttt{Green} & \Rightarrow & \ldots \\ \textbf{default} & \Rightarrow & \mathit{compile}(\mathit{subproblem}) \end{bmatrix}\end{array}$$

In *subproblem*, we have no new scrutinees and only need to investigate the remaining scrutinee v_2 $\mathit{subproblem} = \textbf{case } v_2 \textbf{ of } \left[D\right]$. We ask for each clause if it is consistent with v_1 not looking like either `Red` or `Green`. The first clause could not match $\{\} \,\&\, \texttt{Red}$, so we discard it. For the second row, however, the test $\{\} \,\&\, \neg\{\texttt{Green}\}$ does match any v_1 that differs from both `Red` and `Green`, so we keep it. The default clause is also kept unchanged.

$$\mathit{subproblem} = \textbf{case } v_2 \textbf{ of } \begin{bmatrix} \overline{D}^2_2 & \Rightarrow e^2 \\ \textbf{default} & \Rightarrow e_d \end{bmatrix}$$

6.3 Compiling an Example

Let us illustrate the compilation process with a variant of the example introduced in Section 3.

$$\begin{array}{lll} \textbf{case } x \textbf{ of}\{ & y \,\&\, (\texttt{Sa} \parallel \texttt{Su}) & \Rightarrow \text{“Today is weekend!”}, \\ & y \,\&\, \neg(\texttt{Fr} \parallel \texttt{Sa} \parallel \texttt{Su}) & \Rightarrow \text{“Today is ”} +\!\!+ \ \mathrm{show}(y), \\ & \textbf{default} & \Rightarrow \text{“Tomorrow is weekend...”} \quad \} \end{array}$$

First, we rewrite this case expression into the multi-column notation, normalize all patterns (see Section 5), and abbreviate the right-hand sides by $e_1(y)$, $e_2(y)$, and d.

$$\mathit{Input} := \textbf{case } x \textbf{ of } \begin{bmatrix} \|\{\{y\} \,\&\, \texttt{Sa}, \{y\} \,\&\, \texttt{Su}\} & \Rightarrow & e_1(y) \\ \|\{\{y\} \,\&\, \neg\{\texttt{Fr}, \texttt{Sa}, \texttt{Su}\}\} & \Rightarrow & e_2(y) \\ \textbf{default} & \Rightarrow & d \end{bmatrix}$$

We branch on the only available scrutinee x by matching it in a single-column case expression against the head constructors $\{\texttt{Fr}, \texttt{Sa}, \texttt{Su}\}$. We then generate a new case expression with four clauses, one for each constructor. All that is left to do is to compute and compile the clause-specific *subproblems* of specialization and default.

$$\mathit{compile}\,(\mathit{Input}) = \textbf{case } x \textbf{ of } \begin{bmatrix} \texttt{Fr} & \Rightarrow \mathit{compile}\,(\mathcal{S}\,(1, \texttt{Fr}, \mathit{Input})) \\ \texttt{Sa} & \Rightarrow \mathit{compile}\,(\mathcal{S}\,(1, \texttt{Sa}, \mathit{Input})) \\ \texttt{Su} & \Rightarrow \mathit{compile}\,(\mathcal{S}\,(1, \texttt{Su}, \mathit{Input})) \\ \textbf{default} & \Rightarrow \mathit{compile}\,(\mathcal{D}\,(1, \{\texttt{Fr}, \texttt{Sa}, \texttt{Su}\}, \mathit{Input})) \end{bmatrix}$$

Let us consider the subproblem $\mathcal{S}\,(1, \texttt{Sa}, \mathit{Input})$. We know that scrutinee x has matched `Sa`, and we have no left-over scrutinees nor new subscrutinees to consider ($n = 0$), giving $\mathcal{S}\,(1, \texttt{Sa}, \mathit{Input}) = \textbf{case} \quad \textbf{of } \left[S\right]$. We get the new clause matrix $\left[S\right]$ by iterating the old one to see how each row contributes.

- For row $\left[\|\{\{y\}\ \&\ \texttt{Sa}, \{y\}\ \&\ \texttt{Su}\} \ \Rightarrow\ e_1(y)\right]$, by rule (c), iterate $\begin{bmatrix}\{y\}\ \&\ \texttt{Sa} & \Rightarrow & e_1(y)\\ \{y\}\ \&\ \texttt{Su} & \Rightarrow & e_1(y)\end{bmatrix}$.
  - For the first one, by (a) we add the row $\left[\quad \Rightarrow\ e_1(x)\right]$.
  - For the second one, no contribution is made.
- For row $\left[\|\{\{y\}\ \&\ \neg\{\texttt{Fr}, \texttt{Sa}, \texttt{Su}\}\quad \Rightarrow\quad e_2(y)\right]$ no contribution is made.
- For row $\left[\textbf{default}\quad \Rightarrow\quad d\right]$, by (1), we keep it unchanged.

This gives the specialization matrix $\left[S\right] = \begin{bmatrix} & \Rightarrow & e_1(x)\\ \textbf{default} & \Rightarrow & d\end{bmatrix}$.

The other specialization subproblems are computed similarly, and we obtain the following intermediate result.

$$\mathit{compile}\,(\mathit{Input}) = \textbf{case}\ x\ \textbf{of}\ \begin{bmatrix} \texttt{Fr} & \Rightarrow \mathit{compile}\left(\textbf{case}\quad \textbf{of}\left[\textbf{default}\quad \Rightarrow\quad d\right]\right), \\ \texttt{Sa} & \Rightarrow \mathit{compile}\left(\textbf{case}\quad \textbf{of}\begin{bmatrix} & \Rightarrow & e_1(x)\\ \textbf{default} & \Rightarrow & d\end{bmatrix}\right) \\ \texttt{Su} & \Rightarrow \mathit{compile}\left(\textbf{case}\quad \textbf{of}\begin{bmatrix} & \Rightarrow & e_1(x)\\ \textbf{default} & \Rightarrow & d\end{bmatrix}\right) \\ \textbf{default} & \Rightarrow \mathit{compile}\left(\textbf{case}\quad \textbf{of}\begin{bmatrix} & \Rightarrow & e_2(x)\\ \textbf{default} & \Rightarrow & d\end{bmatrix}\right) \end{bmatrix}$$

For each of the subproblems we can apply either **Default** or **Simple** and conclude the computation.

$$\mathit{compile}\,(\mathit{Input}) = \textbf{case}\ x\ \textbf{of}\ \begin{bmatrix} \texttt{Fr} & \Rightarrow d \\ \texttt{Sa} & \Rightarrow e_1(x) \\ \texttt{Su} & \Rightarrow e_1(x) \\ \textbf{default} & \Rightarrow e_2(x) \end{bmatrix}$$

Note how the right-hand expression of the previous default clause d is utilized in a constructor-clause, whereas the right-hand expression of the new default-clause originates from a previously non-default clause.

6.4 Correctness of Compilation

Correctness of compilation states that the *compile* function introduced in Section 6 preserves semantics. Because the compilation algorithm operates on multi-column pattern matches, we extend wellformedness of expressions, the operational semantics and denotations to multi-column pattern matches. We can then state the correctness for the compilation algorithm:

▶ **Theorem 27.** *On a wellformed multi-column pattern match of the normalized shape Input, the compilation algorithm preserves semantics:* $[\![\, \mathit{Input} \,]\!] \equiv [\![\, \mathit{compile}(\mathit{Input}) \,]\!]$.

We provide the proof and the extended definitions in the appendix of the extended version of this paper [2].

7 Future Work

There are two main directions that we plan to investigate in future work.

Allowing Overlapping Patterns

In this article we enforce that no two patterns in a pattern match can overlap in order to guarantee confluence of the system, but [7, 8] showed that this restriction can be relaxed. They allow overlapping patterns under the condition that the right-hand sides of the clauses must become judgmentally equal under a substitution computed from the overlapping patterns. Let us look at an example that is allowed in their system, but not ours:

$$\begin{aligned}\mathrm{or}(x) \coloneqq \textbf{case } x \textbf{ of } \{\ &\texttt{Pair}(\texttt{True}, _) \Rightarrow \texttt{True}, && \texttt{Pair}(_, \texttt{True}) \Rightarrow \texttt{True},\\ &\texttt{Pair}(\texttt{False}, x) \Rightarrow x, && \texttt{Pair}(x, \texttt{False}) \Rightarrow x\ \}\end{aligned}$$

In this example, the first and the last (as well as the second and first, second and third, and the last two) patterns are overlapping. But the definition of this function is still confluent, since if we unify the overlapping patterns $\texttt{Pair}(\mathrm{True}, _)$ and $\texttt{Pair}(x, \mathrm{False})$, and apply the substitution to the right-hand sides True and x, the terms become judgmentally equal. Such overlapping patterns can be useful in a proof assistant, since they yield additional judgmental equalities that can be used to simplify a term during normalization. We think that their approach to allow overlapping patterns and our algebraic patterns can complement each other, and we therefore plan to study their interaction.

Exhaustiveness Checking

In this article, we check whether a set of patterns is overlapping, but we do not check whether a set of patterns is exhaustive. This is in spite of the fact that we are compiling these patterns using decision trees, which is a method that can easily accommodate checking the exhaustiveness of sets of patterns [22]. Checking that a given set of patterns is exhaustive is essential for real programming languages, so we plan to develop and verify an algorithm for this purpose, building on the work of [22, 15, 12]. We sketch a basic outline for such an algorithm in the appendix of the extended version of this paper [2].

8 Related Work

Order-Independent Pattern Matching

As discussed in Section 7, [7] and [8] study the issue of order-independent pattern matching in proof assistants. They want to ensure that every clause in a pattern-matching expression can be used as a judgmental equality for normalizing terms during type checking. Their system lacks advanced patterns such as or-patterns and negation patterns, but they instead relax the non-overlap requirement.

Substructural logics

And-patterns and wildcard patterns are strongly related to the rules of contraction and weakening in the sequent calculus. This relationship between structural rules and certain forms of patterns has been observed by [4], who present a pattern matching calculus for the sequent calculus which includes both and-patterns and wildcard-patterns. This relationship can also be observed in programming languages with substructural type systems, such as Rust, where the expression `match v {x@y => (x, y)}` does not type check if the type of v does not support contraction, i.e. does not implement the `Copy` trait.

Logic Programming and Datalog

The problems with the binding structure of patterns involving negations that we discussed in this paper appears in a similar form for Datalog programs. In this article we are only interested in the binding occurrences of variables in a pattern, i.e. those variables which occur under an even number of negations, and which can be used in the right-hand side of a clause. Occurrences of logic variables in a Datalog program can be distinguished into binding occurrences and bound occurrences, where binding occurrences assign a value to a logic variable and bound occurrences can access the value the variable is bound to. The authors of [18] describe a type system which tracks binding and bound occurences of variables and describe the rules for disjunctions and negations in their Section 4.3. Their rule for negations is:

$$\frac{\Gamma_1 \vdash^{\#\cdot -} a\ \texttt{ok} \dashv \Gamma_2}{\Gamma_1 \vdash^{\#} \texttt{not}\ a\ \texttt{ok} \dashv \Gamma_2}\ \text{A-Not}$$

Here # stands for a polarity, either + or −, which controls which variables in the input context Γ_1 are already bound, and the multiplication with − correspondingly switches this interpretation. This rule therefore operates very similarly to our pattern typing rule P-Neg in Section 4.3 and guarantees that negation is involutive with respect to the typing relation.

Dynamic First Class Patterns

We use "dynamic first class patterns" for systems in which patterns can be computed and passed at runtime. Such systems, whose theory was studied by [14] and [13], can also express our algebraic patterns. The technical report [11] describes an extension of the object-oriented language Newspeak (cf. [3]) by such a system of dynamic pattern matching. They explicitly discuss various *pattern combinators*, i.e. combinators which combine patterns to yield new ones. They discuss disjunction, conjunction and negation pattern combinators which correspond to our or-patterns, and-patterns and negation patterns. In this article, we focus exclusively on statically-known patterns, since these can be analyzed and compiled more easily.

Negation Patterns

Negation patterns also appear in [19], where the author mentions that "Having false- and or-patterns allows us to define the complement of a pattern – for any pattern at a type A, we can define another pattern that matches exactly the values of type A the original does not". [19] presents a translation that eliminates negation patterns, but this translation makes a closed-world assumption about all the available constructors for each data type. For example, he translates the negated pair pattern $\neg\texttt{Pair}(p_1, p_2)$ by the pattern $\texttt{Pair}(\neg p_1, _) \parallel \texttt{Pair}(_, \neg p_2)$, whereas we (in Section 5.1) translate it by the pattern $\neg\texttt{Pair}(_, _) \parallel \texttt{Pair}(\neg p_1, _) \parallel \texttt{Pair}(_, \neg p_2)$. He can omit the first disjunct of the or-pattern because he knows that the pair type only has one constructor. If we extend his translation scheme to the list type, then we would translate the negation of the constructor-pattern Nil to the pattern Cons(_, _), since we know that the list type only has two constructors. Because we encode negative information directly in patterns, we never have to rely on type information during our compilation process. Negation patterns have also been introduced under the name of "anti-patterns" and "anti-pattern matching" by [16, 17, 6]. The formalism they present differs from ours in the following points: They only allow constructor-patterns, variable patterns and negation patterns, which means that they cannot give a recursive

translation for patterns involving negations, since that also requires or-patterns. Their formalism is also more rooted in the theory of term rewriting systems instead of programming languages, and they do not present a compilation algorithm to simple patterns as we do.

Pattern matching compilation algorithms

A simple way to execute pattern matching expressions with nested patterns is to try one clause after another, until the first one matches. This, however, is extremely inefficient if we have multiple clauses which are headed by the same outer constructor. In that case, we are performing the same tests multiple times. As an introduction to this problem, we can still recommend the book by [24, Chapter 5]. There are many algorithms that compile nested pattern matches to efficient code, but most of them fall into one of two categories. Nested pattern matching can be either compiled using backtracking automata [1, 20] or by compiling to decision trees [23]. The main difference between these two approaches is a classical time vs. space trade-off. Compiling to decision trees guarantees that every test is executed at most once, but can potentially increase the size of the generated code; backtracking automata do not increase the size of the code, but may perform some tests multiple times. In Section 6 we present a version of the algorithm by [23] which compiles to decision trees. Recently, Cheng and Parreaux [5] also proved the correctness of a pattern matching compilation algorithm for their very expressive pattern matching syntax; they, however, do not care about order-independence in the same way that we do.

9 Conclusion

Pattern matching is an extremely popular declarative programming construct. We argued that if we want to make pattern matching even more declarative, then the order of the clauses in a program should not matter. But if we require that two patterns must not overlap, and if we want to avoid overly verbose pattern matching expressions, then we have to make the language of patterns and pattern matching more expressive. We introduced two complementary features, a boolean algebra of patterns and default clauses, which together solve the verbosity problem. We have provided the operational and static semantics of these constructs, and have shown that they can be compiled to efficient code.

Data-Availability Statement

The theorems in Section 3 have been formalized and checked in the proof assistant Rocq. These proofs are available as related material.

Abstract

We present *Pydrofoil*, a multi-stage compiler that generates instruction set simulators (ISSs) from processor instruction set architectures (ISAs) expressed in the high-level, verification-oriented ISA specification language Sail. Pydrofoil achieves a $> 230\times$ speedup over the C-based ISS generated by Sail on our benchmarks, thanks to the following insights. (i) An ISS is effectively an interpreter loop, and tracing just-in-time (JIT) compilers have proven effective at accelerating those, albeit mostly for dynamically typed languages. (ii) ISS workloads are highly atypical, dominated by intensive bit manipulation operations. Conventional compiler optimisations for general-purpose programming languages have limited impact for speeding up such workloads. We develop suitable domain-specific optimisations. (iii) Neither tracing JIT compilers, nor ahead-of-time (AOT) compilation alone, even with domain-specific optimisations, suffice for the generation of performant ISSs. Pydrofoil therefore implements a hybrid approach, pairing an AOT compiler with a tracing JIT built on the meta-tracing PyPy framework. AOT and JIT use domain-specific optimisations. Our benchmarks demonstrate that combining AOT and JIT compilers provides significantly greater performance gains than using either compiler alone.

1 Introduction

A processor's functionality is defined by its *instruction set architecture* (ISA), which specifies the machine language interpreted by the hardware. Accurate and comprehensive ISA specifications are essential for processor design, compiler development, and verification.

Instruction set simulators (ISSs), also called functional models, provide software-based representations of processor behaviour. The efficiency of ISS execution directly impacts processor development speed and associated costs. Throughout this paper, unless otherwise noted, ISS refers to full system simulation, encompassing the entire hardware and software stack, not user-mode simulation, which models only the application layer and sends system calls to the host's operating system layer [47, 50].

Traditionally, ISSs were manually implemented, a process that becomes increasingly time-consuming and error-prone as ISA complexity grows. To address this scalability challenge, *architecture definition languages* (ADLs) emerged, allowing for automated ISS generation from formal ISA descriptions [41]. These ADLs aim to streamline the processor development process. Performance overhead associated with generated ISSs is often mitigated through just-in-time (JIT) compilation or partial evaluation. While ISSs are crucial for functional verification, computer architects also require cycle-accurate models and hardware synthesis capabilities. Consequently, many widely used ADLs, such as SystemC [32], extend beyond pure ISA specification to incorporate microarchitectural details, including pipelining information. This integration, while providing comprehensive modelling capabilities, typically uses low-level language constructs, such as C++ classes and macros, which introduce complexity into the specification and verification process.

Sail [6] is an alternative to low-level ADLs and eschews all hardware implementation detail in favour of ISA-only modelling. Sail streamlines ISA specification with high-level language features such as arbitrary-precision arithmetic, pattern matching, and type-based bitwidth-generics. Sail supports formal verification by also compiling to logic, targeting theorem provers like Isabelle/HOL, Lean, and Z3. Notably, Sail has been adopted as the official ISA-specification language for RISC-V [33]. However, the Sail-generated ISS suffers from performance limitations. This leads to our research agenda: *how can a high-level ISA-specification language like Sail be compiled into performant ISSs?* The unique combination of Sail's high-level abstraction and focus on verification challenges the applicability of conventional ISS compilation techniques, including existing JIT-based approaches. Concretely, our paper seeks to answer the following research questions:

- **RQ1.** What are the bottlenecks causing the Sail-generated ISSs to be slow?
- **RQ2.** Can tracing JIT compilation be used to speed up Sail-generated ISSs significantly?
- **RQ3.** How close can we get to the performance of an industrial strength ISS, hand-tuned to RISC-V?

Contributions. To address the research questions, we present *Pydrofoil*, an open-source[1] tracing JIT compiler for Sail, implemented using the RPython/PyPy meta-tracing framework[2]. We developed and evaluated a suite of domain-specific optimisations tailored to the unique characteristics of ISS workloads, which differ from the typical Python applications targeted by PyPy. Our evaluation methodology employs established computer architecture benchmarks, primarily Linux-boot and SPEC workloads, alongside detailed ablation studies to quantify the impact of individual optimisations. In evaluations using the RISC-V Sail model, Pydrofoil exhibited a >230× speedup over the Sail-generated ISS, while exhibiting a 26.7× slowdown compared to handwritten and optimised QEMU. This achievement shows that whilst we make significant improvements over the Sail interpreter, there is still performance to be gained. We discuss methods of achieving this in Section 5.

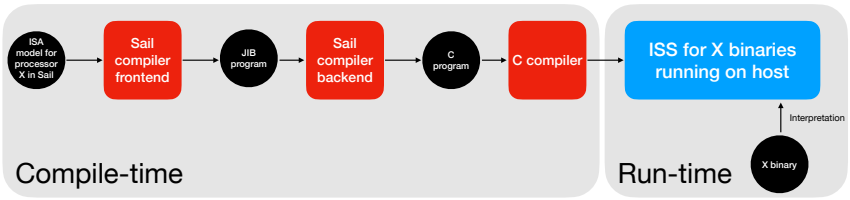

Figure 1 Sail's multi-stage compilation pipeline from Sail to an ISS running as a static binary.

2 Sail and the RISC-V Sail model

2.1 Sail

Sail is a domain-specific language (DSL) within the ML family [27, 40], designed to facilitate processor specification and verification. Sail hybridises first class support for stateful programming with a rich typing system, including algebraic-, singleton-, dependent- and higher-kinded types, as well as domain-specific arbitrary-precision and bitvector types, and a register construct. The compilation pipeline of Sail is depicted in Figure 1. Beyond its primary objective of enabling processor specification and verification through theorem proving, Sail's most noteworthy changes from other ML-family languages are:

- Sail restricts function definitions to first-order, eliminating higher-order functions.
- Sail supports *liquid types* [56, 80].

Liquid types, a form of dependent types, strike a balance between expressive power and decidable type inference. They are useful for addressing the bitwidth parameterisation inherent in modern processor architectures. For instance, the RISC-V ISA supports both 32-bit (RV32) and 64-bit (RV64) variants, where the majority of the ISA specification remains parametric with respect to the bitwidth, represented by a type declaration `xlen`. Traditional ADLs often lack strong typing system support for bitwidth-generic data structures, instead resorting to compile-time meta-programming techniques such as the C preprocessor or C++ templates. Meta-programming simplifies compiler optimisations, but necessitates redundant verification across different bitwidth configurations [12]. We will argue in Section 5 that the current Sail compiler may not fully exploit the optimisation potential afforded by liquid type usage within the RISC-V specification.

This paper primarily focuses on domain-specific compiler design rather than programming language ergonomics. Consequently, a detailed exposition of Sail's language features is beyond the scope of this work. However, it is noteworthy that Sail's capacity to seamlessly support both simulation and logic-based verification contributed to its adoption as the official specification language for RISC-V [33].

2.2 The RISC-V instruction set architecture

RISC-V [8, 75] is an open-source ISA designed to be modular. Unlike proprietary ISAs such as x86, Arm, and MIPS, RISC-V is vendor-neutral. This open nature facilitates academic research and industrial adoption. RISC-V "*is structured as a small base ISA with a variety of optional extensions. The base ISA is simple. [...] The optional extensions form a more powerful ISA for general purpose and high-performance computing.*" [75]. This modularity, combined with the availability of CHERI-RISC-V [78] and its 32-bit and 64-bit variants, results in a significant number of RISC-V ISA configurations, rendering manual ISS

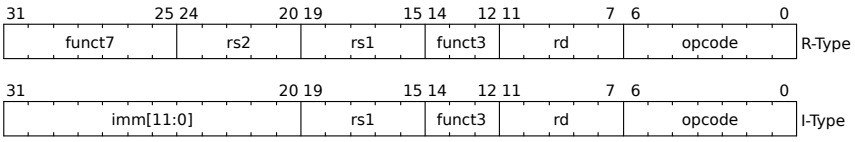

Figure 2 Two of the RISC-V instruction formats [76].

development impractical. Furthermore, the existence of RV32 and RV64 suggests the use of bitwidth-generic data structures, particularly bitvectors. While bitwidth-generics offer flexibility, they introduce compilation complexities and potential performance overhead in ISS implementations, as discussed in subsequent sections.

2.3 The RISC-V model in Sail

We shall now look at a concrete ISA specification in Sail, in order to illustrate how Sail supports the definition of ISA families, using the official RISC-V formal specification [34] as running example.

Abstractly, the toplevel function of the RISC-V Sail model is a big loop, called *fetch-decode-execute loop* in computer architecture. In each round, the loop fetches the next instruction from the external main memory (which an ISS simulates) as a bit pattern, then decodes that pattern into a concrete instruction, and finally calls an `execute` function that executes the decoded instruction. As a simplification, the following pseudo-code serves as a useful mental model:

```
initialise_processor()
pc = 0
while true:
   cmd = memory[pc]
   pc += 4
   match decode(cmd):
      case addi(rd, rs1, imm):
         execute_addi(rd, rs1, imm)
      case xori(rd, rs1, imm):
         execute_xori(rd, rs1, imm)
      ...
      case _:
         ... # Illegal instruction
```

Let us focus our attention on the addition instruction, which, in RISC-V, has the mnemonic `addi rd, rs1, imm`. This instruction adds the 12-bit integer `imm` to the content of a source register `rs1`. The result is stored in the destination register `rd`. Like most ISAs, RISC-V uses instruction formats, which can be seen as rough classifications of instructions that aid decoding bit patterns into instructions. Figure 2 shows the structure of two RISC-V instruction formats. Our example `addi rd, rs1, imm` is an instance of the `ITYPE` format. Like all `ITYPE` instructions,

- `ITYPE` has opcode `0b0010011`, found in bits 0-6.
- The destination register of the instruction is identified in bits 7-11, while the source register is given by bits 15-19.
- The actual function to be computed is in the `funct3` field (bits 12 - 14): `addi` uses `0b000` here, while, e.g., `0b100` identifies `xori`.
- The 12-bit constant to be added to the source register is in bits 20-31.

Let us look at a simplified form of the Sail implementation of `addi`.[3]

```
1  scattered union ast
2
3  val execute : ast -> Retired
4  scattered function execute
5
6  val encdec : ast <-> bits(32)
7  scattered mapping encdec
8
9  union clause ast = ILLEGAL : word
```

First some type declarations: `ast`, short for abstract syntax tree, is the disjoint union type, representing all decoded instructions. In Sail, `ast` is a *scattered* union, which means that the definitions of the variants are allowed to be in different files. This is useful when processor ISAs evolve: we can add new instruction formats in new files *without* needing to modify existing code. The function `execute` (also scattered) specifies the actual semantics of RISC-V instructions, meaning the changes to processor state induced by executing `addi`. The `execute` function takes an `ast` as argument and returns `Retired`, which is an `enum` specifying whether the instruction successfully executed or not (execution can fail, for example due to interrupts). The RISC-V model is imperative: `execute` can and does modify processor state, in particular registers, when invoked. Such processor state is global.

To translate between the encoding of instructions in bits, and their more structured representation as `ast`, the RISC-V model uses the (scattered) mapping `encdec`, short for "encoding-decoding". The keyword `mapping` is for *bidirectional* function definitions [25]. This means `encdec` can either take an `ast` and encode it into a 32-bit bitvector, or take a bitvector and decode it into an `ast`. This reflects, and the typing system enforces, the (almost) one-to-one relationship between ASTs and bitvectors – almost, because not all 32-bit patterns correspond to valid instructions. The model has a fall-through clause `union clause ast = ILLEGAL : word`.

We'll now look at the clauses of `ast`, `encdec` and `execute` for the `ITYPE` format.

```
1  enum iop = {RISCV_ADDI, RISCV_SLTI, RISCV_SLTIU, RISCV_XORI, RISCV_ORI, RISCV_ANDI}
2  ...
3  union clause ast = ITYPE : (bits(12), regidx, regidx, iop)
```

Line 1 enumerates all `ITYPE` instructions and names this type `iop`. Line 3, containing `union clause ast = ITYPE : ...`, defines the variant of the `ast` type that holds `ITYPE` instructions. This clause carries a tuple of information: `(bits(12), regidx, regidx, iop)` The first component holds 12 bits using the type `bits(12)`. This is the constant to be added to the source register. The next two components identify the source and target registers, where `regidx` abbreviates the type `bits(5)`, the type of bitvectors of length 5. (RISC-V has 32 general purpose registers, so 5 bits suffice.) We also need to translate between the 3-bit opcode field in the `ITYPE` instruction format and the enumeration `iop`. This is done by the following bidirectional `mapping`:

```
1  mapping encdec_iop : iop <-> bits(3) = {
2    RISCV_ADDI  <-> 0b000,
3    RISCV_SLTI  <-> 0b010,
4    RISCV_SLTIU <-> 0b011,
5    RISCV_ANDI  <-> 0b111,
6    RISCV_ORI   <-> 0b110,
7    RISCV_XORI  <-> 0b100
8  }
9
10 mapping clause encdec = ITYPE(imm, rs1, rd, op)
11   <-> imm @ rs1 @ encdec_iop(op) @ rd @ 0b0010011
```

[3] See `https://github.com/riscv/sail-riscv/blob/2dfc4ff9f2bed3dcd0a3e8748211c99099e70ab7/model/riscv_insts_base.sail#L159` [55] for full code.

The actual semantics of the `ITYPE` instructions is given by the following `execute` clause:

```
1  function clause execute (ITYPE (imm, rs1, rd, op)) = {
2    let rs1_val = X(rs1);
3    let immext : bits(64) = sign_extend(imm);
4    let result : bits(64) = match op {
5      RISCV_ADDI  => rs1_val + immext,
6      RISCV_SLTI  => zero_extend(bool_to_bits(rs1_val <_s immext)),
7      RISCV_SLTIU => zero_extend(bool_to_bits(rs1_val <_u immext)),
8      RISCV_ANDI  => rs1_val & immext,
9      RISCV_ORI   => rs1_val | immext,
10     RISCV_XORI  => rs1_val ^ immext
11   };
12   X(rd) = result;
13   RETIRE_SUCCESS
14 }
```

The code is beautifully simple and clear. However, the simplicity hides the following complexities:

- The function definition clause in Line 1 pattern matches on the `ast` data type, triggers when the instruction is `ITYPE`, and gives convenient, locally-scoped names to the components `imm`, `rs1`, `rd` and `op`, which were chosen to match the corresponding names in [76].
- Line 2 loads the register value to be added from `rs1`, the source register.
- Line 3 sign-extends the 12 bits value `imm` to the target register bitwidth (32 or 64 bits, depending on the version of RISC-V used). Two things are noteworthy about `sign_extend(imm)` and its use here. First, `sign_extend(imm)` is parameterised with source and target bitwidths, albeit subject to the requirement that the latter not be smaller than the former. This bitwidth parameterisation is visible in the function's type
  $$\texttt{forall 'n 'm, 'm} \geq \texttt{'n. (implicit('m), bits('n))} \rightarrow \texttt{bits('m)}$$
  which has type parameters `'n` and `'m` that range over integers (singleton types). The predicate $\texttt{'m} \geq \texttt{'n}$ is a refinement predicate, evaluated during type checking. We refer to the Sail manual [5] for a detailed explanation of Sail's type syntax. Second, while `sign_extend(imm)` takes two arguments, in Line 3 it is called with only one: the required target bitwidth `'m` is not specified in the call. The keyword `implicit` gives it away: Sail has a restricted form of implicit function parameterisation [37, 43], albeit resolved at compile-time. The resolution of implicit arguments is restricted to the expected output type, here `bits(64)`.
- Line 4 pattern matches on the symbolic name of the exact function to be executed.
- Line 5 triggers if we match `RISCV_ADDI`. In this case, the integer `imm` encoded in the instruction and suitably sign-extended, is added to the content in the source register by $\texttt{rs1_val} + \texttt{immext}$.
- Line 12 writes the result into the destination register `rd`.
- Line 13 returns an indication that the instruction has been successfully executed to the caller.
- Another subtlety is that the register access function $X(\dots)$ is overloaded, and reads from a register when on the right, but writes when on the left of an equality sign.

For this code, Sail offers strong *compile*-time guarantees, for example, we can neither assign bitvectors of different bitwidths, nor access a vector out-of-bounds.

2.4 How does the Sail compiler generate an ISS?

Sail generates a C-based ISS. Unfortunately, this ISS is slow: on a 2024 laptop (AMD Ryzen 7 PRO 7840U, with 32 GB main memory) it executes less than a million RISC-V instructions per second; QEMU simulates a few hundred million instructions in the same time. In this section we identify the root-causes of Sail's poor performance. We start with two possibly unsurprising remarks to set the scene.

```
1  uint64_t imm = ...;
2  ...
3  // let rs1_val = X(rs1);
4  uint64_t rs1_val;
5  rs1_val = rX_bits(rs1);
6  // let immext : xlenbits = sign_extend(imm);
7  uint64_t immext;
8  {
9    i_generic i_generic_64;
10   CREATE(i_generic)(&i_generic_64);
11   CONVERT_OF(i_generic, int64_t)(&i_generic_64, INT64_C(64));
12   bv_generic imm_bv_generic;
13   CREATE(bv_generic)(&imm_bv_generic);
14   CONVERT_OF(bv_generic, fbits)(&imm_bv_generic, imm, UINT64_C(12) , true);
15   bv_generic immext_bv_generic;
16   CREATE(bv_generic)(&immext_bv_generic);
17   sign_extend(&immext_bv_generic, i_generic_64, imm_bv_generic);
18   immext = CONVERT_OF(fbits, bv_generic)(immext_bv_generic, true);
19   KILL(bv_generic)(&immext_bv_generic);
20   KILL(bv_generic)(&imm_bv_generic);
21   KILL(i_generic)(&i_generic_64);
22 }
23 uint64_t result;
24 {
25   __label__ case_8084, finish_match_8083;
26   {
27     if ((RISCV_ADDI != op)) goto case_8084;
28     // rs1_val + immext
29     result = rs1_val + immext;
30     goto finish_match_8083;
31   }
32 case_8084: ;
33   ... // the other cases
34 }
35 {
36   wX_bits(rd, result);
37 }
38 cbz31056 = RETIRE_SUCCESS;
39   goto finish_match_8062;
```

Figure 3 Fragment of the `execute` clause of `ITYPE` instructions after compilation to C by Sail.

- Sail is a high-level language that emphasises precise expression of ISA semantics over concern for simulation speed at every step. High-level languages are harder to generate fast code from than low-level languages.
- Development of optimising compilers is labour intensive and there is a direct correlation between the level of optimisation achievable and developer hours spent. The Sail community chose to spend the scarce developer resources available in a university lab on verification-related parts of the toolchain.

Let us look at concrete code that shows where Sail leaves performance on the table. Figure 3 shows C generated from the `execute` clause of `ITYPE` instructions, discussed above. The code is lightly edited for readability, with Sail code added as comments before the corresponding C code lines. The computation in Line 29 of the result in the `ADDI` case is mapped to an addition on the host machine. Sign extending `imm`, the 12-bit immediate, is done by calling `sign_extend` in Line 17. The arguments of this call are of type `bv_generic`, which is a *heap*-allocated data structure storing bitvectors of arbitrary width. Converting `imm` to `bv_generic`, requires a heap allocation as part of the `CONVERT_OF` macro; `i_generic` is also heap allocated and represents integers of arbitrary size.[4] In Sail, both `bv_generic`

[4] Those types are called `lbits` and `sail_int` in the *actual* C code that Sail generates. We change their names for consistency with Section 3, where we discuss the datatypes in more detail.

and `i_generic` are implemented using the *GNU Multiple Precision Arithmetic library (GMP)* [69] for arbitrary precision arithmetic, operating on signed integers, rational numbers, and floating-point numbers. We summarise the key reasons why the Sail-generated simulator is slow:

- **Bitvectors.** Sail tries to infer the width of the bitvector variables in the program. If they are statically known to fit into an unsigned 64-bit integer, the C backend will map them to the `uint64_t` type. However, many functions in a Sail spec are parametrised with bitwidths, for example `sign_extend`. The bitvectors in these functions are implemented using `bv_generic` and thus ultimately become GMP integers. This has a number of drawbacks: all operations on GMP-based bitvectors require costly heap allocations, because GMP integer types are always heap-allocated.
- **Integers.** Sail's integer type has arbitrary precision. As with bitvectors, Sail tries to infer whether a given integer variables can only have values that fit into a signed 64-bit integer. When that is possible, the C backend will use `int64_t`. However, where it is impossible for Sail to prove that the values fits into `int64_t`, the C backend uses an arbitrary-precision representation from GMP which requires heap allocations on every integer operation.
- **Interpretation overhead.** Finally, Sail generates an interpreter, which has to re-analyse the bits of the program being simulated again and again. Note that actual processors use caches to ameliorate this overhead, e.g., with an instruction cache.

This brings us to our key objective: **how can we improve simulation performance?**

2.5 RPython

Pydrofoil is implemented using the PyPy framework [53]. RPython [3] is PyPy's implementation language. RPython (short for Restricted Python) is a statically typable subset of Python2. The language was developed to aid the implementation of high-performance virtual machines for dynamic languages. To this end, RPython contains a generic meta-tracing just-in-time compilation infrastructure [15] that can be retargeted to different guest languages. Meta-tracing works by tracing through the main interpreter loop (written in the host language – here RPython) of the guest language interpreter [9, 23, 24, 42, 64]. The tracing JIT traces many iterations of the main interpreter loop, effectively unrolling it. This means that one trace contains several guest language instructions, which can then be optimised together. The trace is optimised, compiled to machine code, and then available to execute the corresponding guest language program fragment more efficiently. As ISA models, whether written in Sail or not, are essentially interpreters for an ISA, it seems reasonable to expect that the RPython meta-tracing JIT can speed up the Sail interpreter loop, and compile guest machine instructions to host machine instructions. This has been confirmed in the Pydgin project [39], which implements user-mode ISSs for subsets of Arm v6, MIPS and RISC-V by writing interpreters for them manually in RPython.

3 How is Pydrofoil implemented?

Pydrofoil's approach for better ISS performance is based on the following ideas:

- Better static optimisations of Sail code, in particular optimisations for bitvectors and integers, with the goal of minimising heap allocations.
- Leveraging run-time information with the help of the RPython tracing JIT compiler for further optimisations not available statically.

The first one is, at least in principle, also available to Sail's C backend.

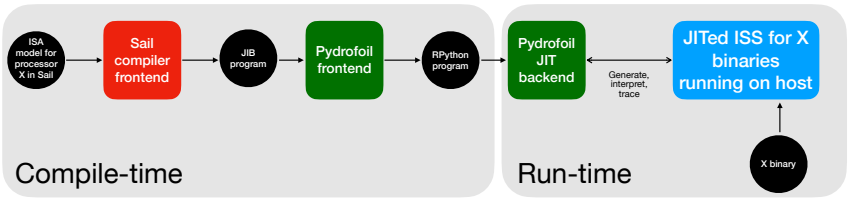

Figure 4 Pydrofoil multi-stage compilation pipeline from Sail to a JITed ISS.

3.1 Pydrofoil architecture

The Sail system emits an ISS in C to be able to use the existing ecosystem of optimising C compilers. In the same way, Pydrofoil reuses the Sail frontend, RPython and the RPython JIT to generate a faster ISS from a Sail model. Pydrofoil's overall architecture is shown in Figure 4.

Pydrofoil's input is JIB, the Sail compiler's textual intermediate representation [7]. When JIB is emitted, all of Sail's type checking has been done, all variables have explicit types and all pattern matching is compiled away into basic blocks and (conditional) gotos. This makes JIB easy for the Pydrofoil ahead-of-time (AOT) compiler to work with. From JIB, Pydrofoil generates its own SSA-based intermediate representation (IR) for Sail functions. These functions are optimised by Pydrofoil's static optimisation passes. Then Pydrofoil generates RPython source code from the optimised IR. The generated code makes use of Pydrofoil's runtime library of support functions that implement Sail datatypes, including problem cases like the aforementioned bitvectors, and arbitrary precision integers. The support library also implements the simulated main memory that the simulated processor interacts with. This resulting RPython code is saved to file, and can be executed with a normal Python2 implementation. This is not performant, but useful for testing. Pydrofoil further translates it into a binary with the existing RPython translation toolchain. During this translation, a tracing JIT compiler can be (optionally) inserted into the resulting binary. The following sections will elaborate on key steps of this process.

3.2 Static Pydrofoil IR optimisations

Once JIB is translated to Pydrofoil's SSA-based IR, we apply a number of standard compiler optimisations: constant folding, dead code elimination, common subexpression elimination, inlining, and scalar replacement of aggregates (using a simple form of partial escape analysis) [14, 62]. All static optimisations are applied until a fixpoint is reached, and further optimisation passes would not alter the IR.

3.2.1 Static Optimisations of bitvector and integer operations

We focus our attention on static optimisations for operations on the bitvector and integer data types, because of their importance for ISSs in general, and Sail in particular. JIB uses two different types for each of these:[5]

[5] In line with the previous section, we renamed two JIB types for consistency: `%bv_generic` is called `%bv` in JIB, whereas `%i_generic` is just called `%i`.

```
1  fn execute(mergez3var) {
2  ...
3    imm : %bv12
4    imm = ...
5    // let rs1_val = X(rs1);
6    rs1_val : %bv64
7    rs1_val = rX_bits(rs1)
8    // let immext : xlenbits = sign_extend(imm);
9    immext : %bv64
10   sail_int_64 : %i_generic
11   sail_int_64 = i64_to_i_generic(64) // cast
12   imm_bv_generic : %bv_generic
13   imm_bv_generic = imm               // cast
14   immext_bv_generic : %bv_generic
15   immext_bv_generic = sign_extend(sail_int_64, imm_bv_generic)
16   immext = immext_bv_generic         // cast
17 ...
```

Figure 5 JIB code for the `execute` clause of `ITYPE` instructions.

- **Bitvectors:** if JIB can infer precise bitwidth, then bitvector types like `%bv64` or `%bv16` of fixed width are used. Otherwise `%bv_generic` is used, a generic bitvector type where the width is not known at runtime (which turns into the `bv_generic`).
- **Integers:** if JIB can infer that an integer can always fit into a 64-bit signed machine integer then `%i64` is used. Otherwise `%i_generic`, a type of arbitrary precision integer, is used.

JIB code frequently casts between the generic and fixed-width variants of the respective representations. Casts do not change the underlying value, but cost a heap allocation when casting to a generic datatype, and heap memory reads when casting in the other direction. Both are expensive. Another reason why the generic forms `%bv_generic` and `%i_generic` are much less efficient at runtime is that the operations (e.g., addition for `%i_generic`) cannot be mapped to directly to host CPU operations, since we do not know their bitwidth. Here is a concrete example. The JIB code in Figure 5, lightly edited for clarity, corresponds to the beginning of `ITYPE`'s `execute` fragment that we already saw in Sail and C in Section 2.3, and Figure 3. Line 8 in Figure 5 shows the `sign_extend` from Sail in comments. JIB Lines 9–16, execute this `sign_extend`: first the immediate value of type `%bv12` is cast to a generic bitvector (Line 13), then sign-extended to 64 bits (Line 15), and finally cast back to `%bv64` (Line 16). This sign extension alone by default requires three heap allocations. The reason why these casts are necessary is that the `sign_extend` function takes a `bv_generic` and an `i_generic` and returns a `bv_generic`.[6]

For all built-in Sail functions and operations that deal with bitvectors and integers, Pydrofoil implements a bundle of variants. They all perform the same computation, but take more specific types as arguments. This enables Pydrofoil to avoid some heap allocations, as we discuss next. To optimise such operations on generic bitvectors and integers, Pydrofoil's static optimiser uses peephole rewrite rules that inspect the IR of a function and rewrite the operations on these types into more efficient forms. In the best case rewrites remove casts between generic and specific bitvector types (as well as machine integers and arbitrary integers) and use specialised operations on the types (when they are available in Pydrofoil's runtime library).

[6] Note that the JIB translation of `sign_extend` takes a bitvector and then an integer as input. We saw in Section 2.3 that the order is reversed in the eponymous Sail function. This is an artefact of Sail's resolution of implicit arguments, and irrelevant for compiler optimisations. It's implemented in the Sail prelude of the RISC-V model by having a small one-operation Sail helper function that has the implicit argument, which calls the JIB `sign_extend` operation with arguments reversed.

Here are Pydrofoil's variants of the `sign_extend` function, together with the rewrite rules that the static optimiser uses:

```
1  # functions
2
3  # nothing is known statically
4  sign_extend:             (%bv_generic, %i_generic) -> %bv_generic
5  # the target width is known to fit into an i64
6  sign_extend_g_i:         (%bv_generic, %i64) -> %bv_generic
7  # the target width is a constant
8  sign_extend_g_c<n>:      (%bv_generic) -> %bv<n>
9  # the argument bitvector has a constant width
10 sign_extend_bv_c<n, m>:  (%bv<n>) -> %bv<m>
11
12 # rewrite rules
13 sign_extend(b, i64_to_i_generic(i))          -> sign_extend_g_i(b, i)
14 sign_extend_g_i(b, c)                       -> sign_extend_g_c<c>(b) [if c <= 64]
15 sign_extend_g_c<c>(cast(b:%bv<n>, %bv_generic)) -> sign_extend_bv_c<n, c>(b, n, c)
```

After applying the rewrite rules to the `sign_extend` call in the example code on Line 15 in Figure 5, it can be replaced by a call to `sign_extend_bv_c`$\langle 12, 64\rangle$. The latter takes a `%bv12` as argument, and returns a `%bv64`. This means we get rid of all three heap allocations. The resulting code is equivalent to the following JIB code and does not contain casts:

```
1  fn execute(mergez3var) {
2  ...
3    imm : %bv12
4    imm = ...
5    // let rs1_val = X(rs1);
6    rs1_val : %bv64
7    rs1_val = rX_bits(rs1)
8    // let immext : xlenbits = sign_extend(imm);
9    immext : %bv64
10   immext = sign_extend_bv_c<12, 64>(imm)
11 ...
```

To be able to narrow the generic integer type `%i_generic` to `%i64`, Pydrofoil also performs a range analysis. If the analysis finds an integer variable where the range fits into a signed 64-bit int, Pydrofoil narrows the type to `%i64`. An example is the RISC-V `mulw` instruction, which multiplies two signed 32-bit bitvectors by converting them to `%i_generic` first. The result of the multiplication of these two integers must fit into an `%i64`, so Pydrofoil narrows the integer types and rewrites the multiplication operation accordingly.

3.2.2 Interaction with inlining

Inlining helps to make bitvector and integer operation rewrites more effective. Many Sail functions are small helper functions that operate on generic bitvectors and integers, passed as arguments. After inlining such small functions into their use contexts, the concrete bitvector widths of the argument can often be inferred from the calling context. Then the bitvector operations in the inlined function are specialised to smaller bitwidths.

Consider another `ITYPE` operation as an example: the `slti` case uses the `operator <_s`, to perform the signed comparison. It is defined as follows in Sail:

```
1  val operator <_s  : forall 'n, 'n > 0. (bits('n), bits('n)) -> bool
2  function operator <_s  (x, y) = signed(x) < signed(y)
```

Here `signed` is a Sail function that takes a bitvector of width n, and returns the corresponding signed integer. This code is compiled to the JIB code in the top part of Figure 6. It implements a signed comparison of bitvectors and operates on generic bitvectors. In the concrete context where the function is called, the bitvector widths are mostly known. For example, its use in the `slti` instruction can be seen in the bottom half of Figure 6.

```
1  val (operator <_s): (%bv_generic, %bv_generic) ->  %bool
2
3  fn (operator <_s)(x, y) {
4    // signed(x) < signed(y)
5    z40 : %i_generic
6    z40 = signed(x)
7    z41 : %i_generic
8    z41 = signed(y)
9    return = lt_int(z40, z41)
10   end;
11 }
```

```
1    jump @neq(RISCV_SLTI, z0) goto 280
2    // RISCV_SLTI  => zero_extend(bool_to_bits(rs1_val <_s immext)),
3    z2 : %bv1
4    z6 : %bool
5    z7 : %bv_generic
6    z7 = rs1_val       // cast
7    z8 : %bv_generic
8    z8 = immext        // cast
9    z6 = (operator <_s)(z7, z8)
10   z2 = bool_to_bits(z6)
11   ...
```

Figure 6 JIB code for `operator <_s` (top half) and its use in the JIB code of the `execute` clause of the `slti` instruction (bottom half).

The arguments to `operator <_s` are cast from `%bv64` to `%bv_generic` (Lines 6 and 8). After inlining the call to `operator <_s`, the calls to `signed` in its body can therefore be optimised to a variant that takes a `%bv64` and returns an `%i64`, which then allows the `lt_int` operation to be replaced by a version that operates on `%i64`. This removes *all* heap allocations from the inlined body of `operator <_s` that replaces the call-site.

3.2.3 Function specialisation

In cases where a function is too large[7] to be inlined, Pydrofoil tries to specialise it to the specific bitvector widths and `%i64` types of its arguments at the function's call-sites. The specialiser will go over all the non-inlinable function calls in the program and check whether any of the arguments are of type `%bv_generic` or `%i_generic` and either constant, or the result of casts from more specific types. For such calls, the target function will be copied into a more specific version. The copied function takes the more specific argument types. The body of the copy is then optimised to take the newly available bitvector widths of its arguments into account. Sometimes, as the result of specialisation, the return type of a function can become more specific, enabling the caller to be optimised further.

3.2.4 When do the static bitvector and integer optimisations fail?

Peephole rewrites for bitvector and integer operations work only within single functions. They can only be applied when the arguments of such operations are cast from more specific types in the same function where the operation happens. Inlining and function specialisation help with peephole rewrites being restricted to single functions. But this is sometimes still insufficient for giving peephole rewrites enough context to do their work. In more complicated cases, particularly if the arguments of bitvector operations are read out of a `union` or a

[7] We use an inlining limit of 25 JIB operations in up to 4 basic blocks at the moment.

```
val mem_read : forall 'n, 0 < 'n <= max_mem_access . (AccessType(ext_access_type),
    physaddr, int('n), bool, bool, bool) -> MemoryOpResult(bits(8 * 'n))

enum word_width = {BYTE, HALF, WORD, DOUBLE}

union clause ast = LOAD : (bits(12), regidx, regidx, bool, word_width, bool, bool)

val extend_value : forall 'n, 0 < 'n <= xlen. (bool, bits('n)) -> xlenbits
function extend_value(is_unsigned, value) = if is_unsigned then zero_extend(value)
    else sign_extend(value)

mapping size_bytes : word_width <-> {1, 2, 4, 8} = {
  BYTE   <-> 1,
  HALF   <-> 2,
  WORD   <-> 4,
  DOUBLE <-> 8,
}

function clause execute (LOAD(imm, rs1, rd, is_unsigned, width, aq, rl)) = {
  let offset : xlenbits = sign_extend(imm);
  let width_bytes = size_bytes(width);
  let addr = X(rs1) + offset;
  // simplified, the real code deals with virtual memory and checks for alignment
  match mem_read(Read(Data), addr, width_bytes, aq, rl, false) {
    Ok(result) => { X(rd) = extend_value(is_unsigned, result); RETIRE_SUCCESS },
    Err(e)     => { handle_mem_exception(vaddr, e); RETIRE_FAIL },
  }
}
```

Figure 7 Sail code for the RISC-V instructions that load from main memory into a register.

`struct`, more powerful static analysis would be needed to be able to optimise the operations to more specific variants. An example is the `LOAD` constructor in the RISC-V Sail model, which implements loading data from simulated main memory into a register. The Sail code can be seen in Figure 7.

The result of calling `mem_read` is a `union` where one of the variants stores a `%bv_generic` at the JIB level. The width of the result of the read from simulated main memory is data-dependent on some bits of the encoded instruction. Therefore it cannot be specialised at compile-time to the `width_bytes` parameter. This also means that the bitwidth of the result is unknown to the static optimisations.

Similarly, it is much harder to track concrete bitvector widths when the values pass through a `union` or are stored into a `struct`. It is conceivable to handle such cases with more powerful intra-procedural static analysis, and taking the information the liquid types into account. We leave this as future work, see Section 5.

3.3 RPython code generation

After Sail functions have been optimised, we generate RPython source code from each. This is straightforward, the only complexity being that the IR control flow graphs use basic blocks with (conditional) jumps between them, and RPython only supports structured control flow. Pydrofoil compiles that to the standard construction of a program counter variable and an infinite loop with one condition for every basic block.[8]

[8] This is an old approach [18], see Harel [30] for a thorough historical discussion. There are better approaches to generating block-structured code out of arbitrary control flow graphs [49, 81] and we plan to switch to one of them.

3.4 Adding a JIT compiler with RPython

To gain efficiency beyond what an interpreter-based simulator can offer, we use RPython's meta-tracing JIT compiler. It traces the execution of the ISS through one loop of the simulated guest program and turns the resulting traces into host machine code. In this way, RPython's tracing JIT acts as a trace-based dynamic binary translator for the simulated instruction set architecture.

RPython's meta-tracing JIT needs a few annotations in the outermost execution loop of the Sail model in question. In particular, the tracing JIT needs to know what the core execution loop is, and which register of the simulated machine stores the program counter. The meta-tracing JIT uses the program counter to detect backwards jumps in the guest program in order to identify loops at the guest program level.

The meta-tracing JIT can further optimise the generic bitvector and integer operations that the static optimisations of Section 3.2 did not improve. Since it traces a concrete execution path of guest machine code, all used bitvector widths are observable by the JIT. The JIT can thus specialise the generic bitvector operations at runtime to the observed widths. This yields performance improvements because the JIT can remove some of the remaining heap allocations of bitvectors and integers using escape analysis [14]. However, it is still preferable to statically remove as many generic bitvector operations as possible, as otherwise the JIT has to continually remove them, every time the ISS is executed.

Consider the following JIT trace, generated for a single RISC-V `addi` instruction (the details of this trace are not important):

```
1  ...
2  i106 = getfield_gc_i(p1, field=s4)
3  ...
4  # c.addi s4. 0x8
5  i144 = getarrayitem_gc_i(ConstPtr(
       ptr142), 26)
6  i146 = int_and(i144, 65535)
7  i148 = int_and(i144, 3)
8  i150 = int_eq(i148, 3)
9  guard_false(i150)
10 i152 = int_eq(i146, 1)
11 guard_false(i152)
12 i154 = uint_rshift(i146, 5)
13 i156 = int_and(i154, 1)
14 i158 = uint_rshift(i146, 6)
15 i160 = int_and(i158, 1)
16 i162 = int_lshift(i156, 1)
17 i163 = int_or(i162, i160)
18 i165 = uint_rshift(i146, 7)
19 i167 = int_and(i165, 15)
20 i169 = uint_rshift(i146, 11)
21 i171 = int_and(i169, 3)
22 i173 = int_lshift(i171, 2)
23 i174 = int_or(i173, i163)
24 i176 = int_lshift(i167, 4)
25 i177 = int_or(i176, i174)
26 i178 = int_is_zero(i177)
27 guard_false(i178)
28 i180 = uint_rshift(i146, 13)
29 i181 = int_is_zero(i180)
30 guard_true(i181)
31 i182 = int_is_zero(i148)
32 guard_false(i182)
33 i184 = int_and(i165, 31)
34 i186 = uint_rshift(i146, 12)
35 i188 = uint_rshift(i146, 2)
36 i190 = int_and(i188, 31)
37 i192 = int_lshift(i186, 5)
38 i193 = int_or(i192, i190)
39 i194 = int_is_zero(i193)
40 guard_false(i194)
41 i195 = int_is_zero(i184)
42 guard_false(i195)
43 i197 = int_eq(i148, 1)
44 guard_true(i197)
45 i199 = int_xor(i193, 32)
46 i201 = int_sub(i199, 32)
47 i203 = int_and(i201, 4095)
48 guard_value(i184, 20)
49 i206 = int_xor(i203, 2048)
50 i208 = int_sub(i206, 2048)
51 i209 = int_add(i106, i208)
52 i211 = int_add(i2, 2)
53 i213 = int_add(i0, 2)
54 setfield_gc(p1, i209, field=s4)
55 i215 = int_eq(i213, 10000)
56 guard_false(i215)
57 # next guest instruction
```

The trace does not contain heap allocations, which is good. However, the trace is long, given that it performs only a single guest addition. The problem is the `getarrayitem_gc_i` instruction at the start, which is the instruction fetch from simulated main memory. A large part of the trace (Lines 6-50) is manipulating the result of that memory read to perform the instruction decoding. This happens despite the program counter register being constant for that point of the trace. In the following section we will look at an optimisation for removing those *instruction-decoding* trace instructions.

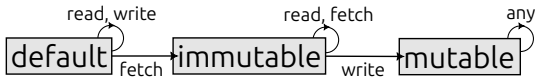

Figure 8 Diagram of the states a 64-bit word of simulated main memory can be in.

3.5 Making the main memory simulation JIT-friendly

One big problem for the JIT compiler is that while it knows the concrete value of the guest program counter, that is not enough for optimising away the decoding of the instruction stored at that program counter.

The reason is the possibility of *self-modifying code*. In practice true self-modifying code is rare, and so we want the JIT to exploit this fact. To do this, we track the status of every part of the simulated main memory. Currently, this tracking happens at the granularity of 8 bytes.[9] Every 64-bit word in simulated main memory can be in one of three states: `status_default`, `status_immutable`, `status_mutable`. All the 64-bit words start out in `status_default` state. If a `status_default` 64-bit word is read or written, its status is unchanged, and the memory read proceeds normally. However, if a `status_default` is read from during instruction fetch, it transitions to `status_immutable`. The JIT will constant-fold reads from `status_immutable` 64-bit words and return the concrete value of the bits stored in the 64-bit word. To behave correctly in the face of self-modifying code, the simulated main memory checks on every write whether a `status_immutable` 64-bit word is being written to.[10] When a `status_immutable` 64-bit word is changed, the generated host machine code is potentially no longer valid, because it was generated under the assumption that `status_immutable` 64-bit words are immutable. Therefore all relevant host machine code is invalidated in such a situation, and the modified 64-bit word is marked as `status_mutable`. `status_mutable` 64-bit words are assumed to potentially contain mutable code, so the JIT will never constant-fold reads from them during host machine code generation. Figure 8 shows a state diagram of the various states every 64-bit word of the simulated main memory can be in, and the transitions it can go through.

After adding this status tracking logic to the simulated main memory, the trace for the `addi` instruction in Section 3.4 gets much simpler. Since the memory read of the instruction bits happens from a `status_immutable` 64-bit word, the bits of the guest instruction are constant. Therefore the trace operations that decode those bits all get constant-folded away. This kind of trace length reduction due to memory status tracking is typical: on average the trace for one guest instruction gets 3–4 times shorter with memory status tracking. The remaining trace looks like this:

```
i35 = getfield_gc_i(p1, field=s4)
...
# c.addi s4, 0x8
i44 = int_add(i35, 8)
i64 = int_add(i0, 2)
setfield_gc(p1, i44, field=s4)
i66 = int_eq(i64, 10000)
guard_false(i66)
```

[9] It is possible that other granularities work better. Pydrofoil could e.g., do this kind of tracking on the granularity of guest pages and take the permission bits from the page tables into account.

[10] This extra check makes all writes to simulated main memory slower, but the trade-off is worth it because instruction fetch is common: there are more instruction fetches than memory writes.

Now the trace looks good! The `addi s4, 0x8` instruction is compiled to a `int_add(..., 8)` instruction, which is its closest equivalent in the RPython trace IR. There are a few extra instructions around to read and write the value of the register field in the `p1` `struct` which contains the simulated machine's state. In addition, there are three instructions that check whether 10,000 instructions have been executed, which would make it time to tick the simulated clock (we discuss the issue of clocks in more details in Section 5).

3.6 Improving the RPython JIT integer optimisations

While developing Pydrofoil, we identified a number of missing trace optimisations for bit manipulation operations in the RPython JIT. This may not be surprising: the RPython JIT was developed for dynamic language implementations where such operations are rare. In contrast, bit manipulation is pervasive in processors, and, as a consequence, in the Pydrofoil traces the JIT needs to optimise. In order to adapt the JIT's optimising passes to such workloads, we have added a number of new integer optimisations. Let us give an example. In processors, individual bits are often used to hold permissions, e.g., whether a specific address range allows non-aligned access. Typically such a permission bit rarely changes, if ever. Nevertheless the permission bit is checked on every access. In hardware such a check is cheap. In software simulation of hardware, checking the bit again and again is expensive. In principle, a JIT can determine during trace-optimisation if a permission bit changes from one instruction to the next. If not, all but the first check can be elided. However JITs targeting high-level languages typically do not track value-constancy *at the bit-level*.

We adapt *Tristate numbers*, used in the Linux kernel by the eBPF verifier to reason about which bits in a variable have constant values [71], to the RPython JIT. An equivalent approach is also used in other compilers such as LLVM, where it is called *Known Bits* [68]. The Tristate number abstraction lets the JIT track values of constant bits of interest in integer and bitvector variables (which map to the same JIT trace IR type) when optimising traces. This enables the removal of permission checks where the JIT can prove that the relevant bits cannot change.

A concrete example for why this is useful are alignment checks. If two load instructions are executed that use the same base register, e.g. like this:

```
ld t0, 0x8(a0)
ld t1, 0x10(a0)
```

Then both loads have to check whether the pointer the value comes from is word-aligned, which means that the lowest bits are zero. The Tristate number analysis lets the JIT conclude that if the first load is aligned, the second one is aligned too, and so the alignment check can be removed from the second load. Here is a sketch[11] of what this looks like in a JIT trace:

```
# ld t0, 0x8(a0) # first load
i1 = getfield_gc_i(p1, field=a0)
i2 = int_add(i1, 8) # add offset to get the actual pointer
i3 = int_and(i2, 7) # alignment check: extract last three bits
i4 = int_is_zero(i3) # check that they are zero
guard_true(i4) # now the JIT knows that i1 and i2 are of the form ???...???000
... # do the actual load from memory

# ld t1, 0x10(a0) # second load
i12 = int_add(i1, 16) # must be of the form ???...???000, because both i1 and 16 are
i13 = int_and(i12, 7) # alignment check for second load: i13 is 0
i14 = int_is_zero(i13) # always 1
guard_true(i14) # can be removed by the JIT's opimizer because i14 is constant 1
... # do the actual load from memory
```

[11] The actual trace is significantly more complicated, due to bounds checks and address translation.

4 Benchmarks

To evaluate the performance of Pydrofoil and quantify the impact of our domain-specific optimisations and JIT compilation, we conducted a comprehensive benchmarking study. Our evaluation, constrained by available resources, aims to be a representative set of industrial ISS workloads, and has four main parts.

- Comparison of Pydrofoil with the Sail-generated ISS, using RISC-V 64.
- Ablations to understand the contribution of each individual domain-specific Pydrofoil optimisation, using RISC-V 64.
- Comparison of Pydrofoil with QEMU and Spike, two handwritten industry-standard ISSs.
- Preliminary benchmarks using Arm v9.4a and CHERIoT ISAs.

We use two classes of benchmark: SPEC CPU and booting Linux (excluding CHERIoT, described below). Both are widely used in computer architecture, and motivated next.

- SPEC, the Standard Performance Evaluation Corporation benchmark [63], is a suite of standardised tests evaluating the performance of computer systems. We focus on the SPEC CPU benchmarks [17], which measure the performance of a system's processor and memory subsystem. We restrict our attention to SPECint, and avoid the floating point arithmetic in SPEC CPU because currently the RISC-V model lacks a Sail implementation of the floating point extensions. Instead, the RISC-V model relies on the C-based Berkeley SoftFloat library [31], and benchmarking floating points would *not* exercise Pydrofoil[12].
- Booting Linux is a critical benchmark due to its prevalence in ISS applications and its challenge for JIT compilers, as the boot process lacks the long-running loops that JITs excel at optimising. Typically, the boot process executes a lot of code that is never seen again, and so this benchmark helps to establish JIT compilation latency.

Each SPEC benchmark was integrated into a complete Linux 6.7.0 boot image, using the initial ramdisk [79] (`initrd`). This approach is necessary because the Sail models do not contain emulated disk devices that could have been used used for storing programs. Unfortunately, due to the limitation of a few hundred MB on `initrd` sizes, we were not able to run `657.xz_s.1`. For the `625.x264` variants we had the same problem but moved input file generation into the Linux image. We mark those SPEC benchmarks with an asterisk (*) when we discuss them in Section 4.3.

Due to the deterministic nature of Sail models, and their lack of access to the host clock, all timing was performed externally on the host system, measuring the simulator's total wall-clock runtime. Therefore, our SPEC benchmark times also include the Linux 6.7.0 boot process until user-mode (about 138 million instructions).

Hardware and software used for benchmarking. All Sail compilation uses the following parameters affecting optimisation: `-dno_cast -O -Oconstant_fold -memo_z3`. Generated C was compiled with `gcc`. For pragmatic reasons, we use three different compute setups (indicating for each benchmark which is used).

- TaiShan server with Kunpeng 920 Arm v8.4 cores, 500 GB main memory, running Ubuntu 18.04.6.
- AMD Ryzen 7 PRO 7840U with 32 GB main memory, running Ubuntu 24.04.6.
- AMD Ryzen 9 7950x3d, with 128GB main memory, running Ubuntu 24.04.1.

[12] A pure Sail implementation of the floating point extensions is in preparation. When it becomes part of the official RISC-V model, it makes sense to revisit our benchmarks.

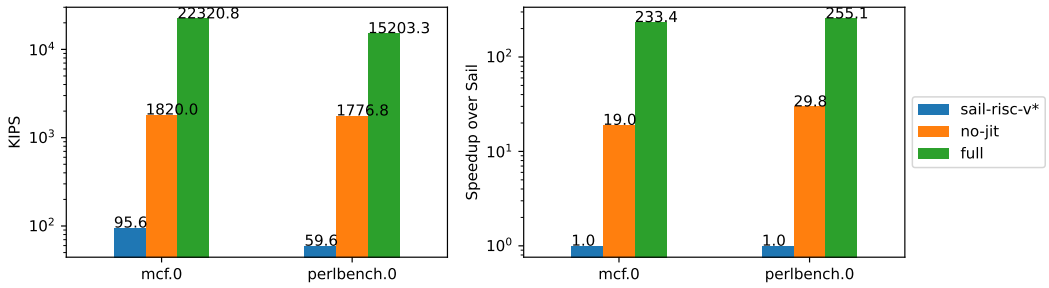

Figure 9 Instructions/second comparison between Sail and Pydrofoil. The left plot shows KIPS (= kilo instructions per second), the right the speedup over Sail. Higher is better.

4.1 Comparing Pydrofoil and Sail performance for the RISC-V model

Pydrofoil's most important goal was generating faster ISSs than Sail itself. This section compares Pydrofoil with Sail. We are resource constrained: the Sail-generated RISC-V ISS is too slow! For example `605.mcf_s.0`, which executes 1.2 trillion instructions, takes roughly six months on the TaiShan server. Therefore, we decided to run the comparison on only two arbitrarily chosen SPEC benchmarks, `605.mcf.0` and `600.perlbench.0`. We stopped the benchmarks for the Sail-generated ISS after 20 billion instructions. Pydrofoil is run to conclusion on the same benchmarks. We compare the instructions per second executed by both systems, extrapolated from the first 20 billion for Sail.

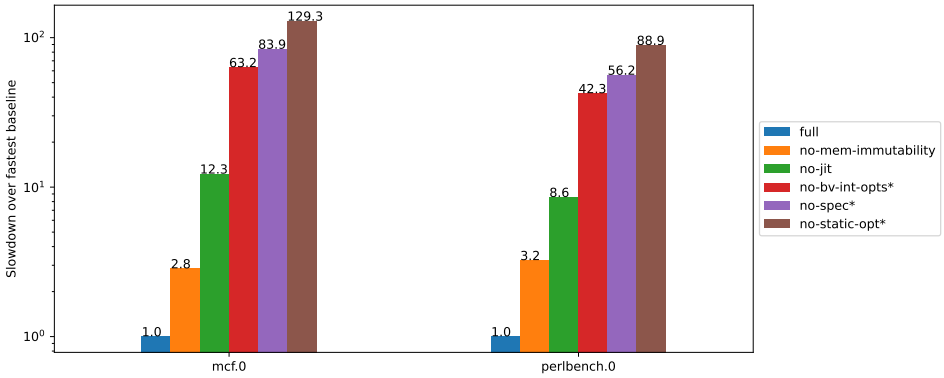
Results. This benchmark uses the TaiShan server. The results of this can be seen in Figure 9. We see that Pydrofoil is 233× and 255× faster than the Sail RISC-V ISS on both benchmarks. Even without the JIT, Pydrofoil is at least 19× faster than Sail.

4.2 Ablations: benchmarking Pydrofoil variants

To quantify the effect of our optimisations, we conduct ablation studies: we systematically disable successively more optimisations and measure the resulting slowdowns. This gives us a quantitative approximation of the relative impact of each optimisation, providing insights into their individual and collective value. We use the following variants.

- `full`: The full Pydrofoil simulator, running the JIT and the AOT with all optimisation enabled.
- `no-mem-immutability`: Disables memory immutability tracking (Section 3.5).
- `no-jit`: Additionally disables the JIT (Section 3.4) and works only as an interpreter at runtime.
- `no-bv-int-opts`: Additionally disables the static optimisations that replace generic bitvector and generic integer operations with more specialise variants operating on 64-bit integers (Section 3.2.1).
- `no-spec`: Additionally disables inlining (Section 3.2.2) and function specialisation (Section 3.2.3).
- `no-static-opt`: Additionally disables all remaining static optimisations (Section 3.2).

Unfortunately, we were unable to run all ablations against the SPEC CPU benchmarks as planned. The problem is that the ablations with many of the optimisations disabled run much too slow to finish in a realistic time frame. For example the aforementioned



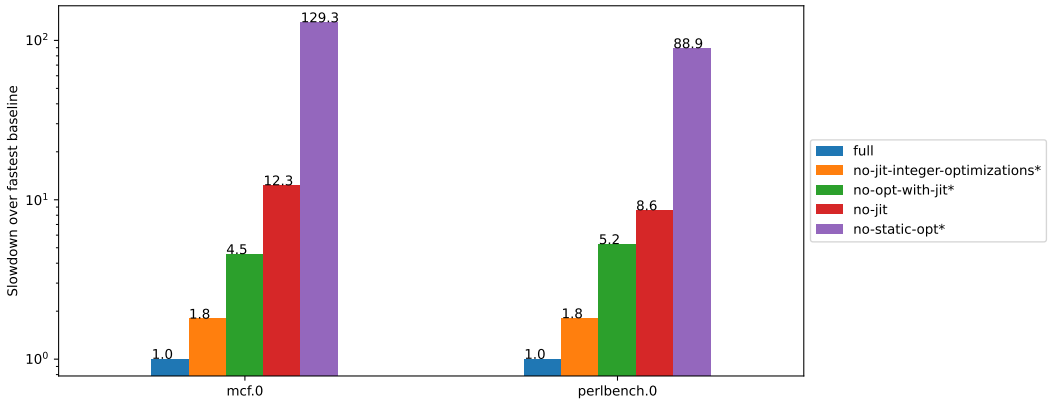
Benchmark Implementation	KIPS mcf.0	KIPS perlbench.0	slowdown mcf.0	slowdown perlbench.0
full	22320.79	15203.28	1.00	1.00
no-mem-immutability	7836.32	4701.09	2.85	3.23
no-jit	1820.04	1776.76	12.26	8.56
no-bv-int-opts*	353.13	359.32	63.21	42.31
no-spec*	266.06	270.47	83.89	56.21
no-static-opt*	172.60	170.92	129.32	88.95

Figure 10 Benchmark results for ablations, as graph and table. The y-axis of the plot is logarithmic. Benchmark results with * are extrapolated from the first 20 billion instructions.

`605.mcf_s.0` takes several months with `no-static-opt`. We deal with this as we did in the previous comparison and run the ablations on the same arbitrarily chosen SPEC benchmarks, `605.mcf.0` and `600.perlbench.0`. We stopped the benchmarks for the slowest ablations after 20 billion instructions. The remaining ablations are run to conclusion on the same benchmarks. We compare the instructions per second executed by both systems, extrapolated from the first 20 billion for the slowest ablations.

Results. This benchmark uses the TaiShan server. The results are shown in Figure 10. We see clearly that the JIT is fundamental for performance, it provides (together with memory immutability tracking) a 12×/8× performance boost. The static bitvector and integer optimisations are the most useful static optimisations. Disabling them slows Pydrofoil down by about a further 5×. Inlining, function specialisation and all other static optimisations are less important. Turning the runtime-switchable integer representation off leads to a further slowdown of more than 2×. We also investigated what is more important: static optimisations or JIT compilation. To that end, we add another ablation, `no-opt-with-jit` It is outside of the sequence of ablations in the previous subsection, because it disables all static optimisations but leaves the JIT-compiler active. The results are in Figure 11. We see that this variant is 4.54×/5.25× slower than `full`. This slowdown is less than `no-jit`, which removes the JIT but keeps the static optimisations. We conclude that the JIT can partly compensate for missing static optimisations (but not vice versa). The JIT does this by performing some, but not all, of the missing static optimisations at runtime.

Unfortunately we were unable to benchmark the additional integer optimisations from Section 3.6: Tristate numbers are now too embedded into the RPython JIT to be easily disabled. To get an upper bound of the effect those optimisations have, we ran an ablation



Benchmark	KIPS		slowdown	
Implementation	mcf.0	perlbench.0	mcf.0	perlbench.0
full	22320.79	15203.28	1.00	1.00
no-jit-integer-optimisations*	12488.84	8454.55	1.79	1.80
no-opt-with-jit*	4912.80	2898.55	4.54	5.25
no-jit	1820.04	1776.76	12.26	8.56
no-static-opt*	172.60	170.92	129.32	88.95

Figure 11 JIT-relevant ablation results. The y-axis of the plot is logarithmic.

`no-jit-integer-optimisations` that disables *all* integer optimisations of the RPython JIT (also in Figure 11). Doing that gives a slowdown of 1.79× and 1.80×. Since the RPython JIT also had integer optimisations before the changes motivated by Pydrofoil (including a range analysis done by the JIT at runtime), we expect the effect of Tristate numbers to be below that number. Therefore it is a less important optimisation compared to any of the Pydrofoil static optimisation and compared to having a JIT in the first place.

4.3 Comparison with QEMU and Spike

To assess the practical performance of Pydrofoil, we benchmark against two established, industrial-strength ISSs. Due to the limited availability of ISS generators capable of compiling Sail specifications, this comparison uses simulators not derived from Sail. We selected QEMU [11] and Spike[13]. QEMU is a widely adopted ISS, implemented in C and incorporating significant manual optimisation. It supports multiple prominent ISAs, including RISC-V, and functions as a core component within various processor simulation frameworks. QEMU utilises a JIT compilation engine that translates guest instructions into host instruction sequences with manually developed, ISA-specific translators. Over two decades of development effort have contributed to QEMU's high simulation performance. While not designed for formal verification, its widespread adoption positions QEMU as a practical performance ceiling for Pydrofoil. Conversely, Spike is manually implemented in C++ specifically for the RISC-V ISA and is widely used within the RISC-V ecosystem. It operates as an interpreter without a JIT compiler, enhancing execution speed through the caching of decoded instructions.

We use SPEC and booting Linux as benchmarks, and RISC-V as ISA.

Geometric mean				26.7×	2.3×

Figure 12 Performance comparison of QEMU, Spike and Pydrofoil on SPEC benchmarks, in seconds. Speedup is the factor by which QEMU, resp. Spike, is faster than Pydrofoil. All benchmark times include booting Linux. Benchmarks marked with * also include the time to generate their input files.

Results. This benchmark uses the AMD Ryzen 9 setup. The results are in Figure 12. We see that QEMU's performance is significantly ahead of Pydrofoil's: QEMU is between 2× and 100× faster than Pydrofoil, with a geometric mean of 26.7× . This is clearly disappointing, it shows that for many cases Pydrofoil is not good enough at removing the overhead of Sail. Section 5 gives concrete suggestions on how to reduce the performance gap with QEMU.

Spike also generally outperforms Pydrofoil. The relative speedup of Spike compared to Pydrofoil ranges from 0.4× (so Pydrofoil is faster) to 96.7×. The geometric mean of the speedup across all benchmarks is 2.3×. Pydrofoil exhibits significantly lower performance relative to Spike on the `625.x264_s.1/2` benchmarks, in particular. The underlying causes of these performance differences, especially the slowdowns observed for Pydrofoil, warrant future investigation.

4.4 Preliminary benchmarks for Pydrofoil-Arm and Pydrofoil-CHERIoT

All benchmarks above use RISC-V. This raises the question how dependent on RISC-V the performance numbers are. This benchmark presents preliminary performance results for two other ISAs, Arm v9.4-a [52] and CHERIoT [1, 2, 19]. For both ISAs, we compared the performance of the Pydrofoil-generated ISS with that of the Sail C backend.

The Arm v9.4-a specification in Sail is obtained by transpilation from Arm's ASL [51] specification, and is *substantially* bigger and more complex than RISC-V. For example the JIB obtained by translation of the Arm model is 20× larger than the corresponding RISC-V. As Arm v9.4-A benchmark, we boot Linux 6.0.7, but only up to the initialisation of the `init` process. This executes 24.6 million instructions.

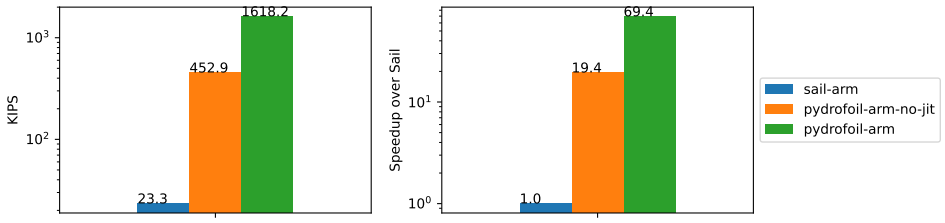

Figure 13 Benchmark results for the Arm ISS, booting Linux. The left plot shows KIPS, the right the speedup over Sail. Higher is better.

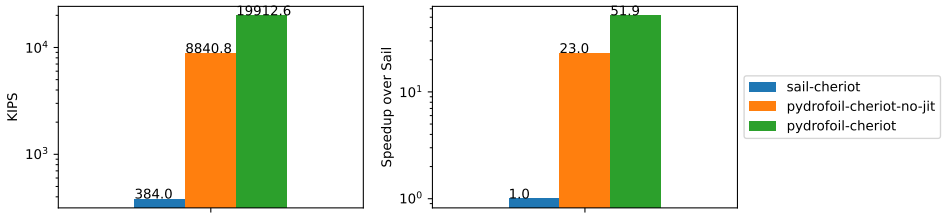

Figure 14 Benchmark results for the CHERIoT ISS, running the allocation-benchmark. The left plot shows KIPS, the right the speedup over Sail. Higher is better.

In contrast to the complex Arm ISA, CHERIoT is a simple 32-bit RISC-V micro-controller without virtual memory and caches, co-designed with a real-time operating system (RTOS), all with a strict focus on security. CHERIoT is a capability machine, based on (a small variant of) CHERI [78]. Capabilities can be seen as a hardware implementation of "fat pointers": conventional integer pointers are replaced by capabilities, which are memory addresses together with permissions constraining capability use. This enables the processor to check every memory access to ensure that it is not out-of-bounds (spatial memory safety). Capabilities can be used to mitigate a wide range of memory safety bugs and vulnerabilities. CHERIoT comes with a Sail specification of its ISA semantics [46], and the ISS that Sail generates is currently the only available ISS for CHERIoT. For CHERIoT we boot its RTOS [45] and then run CHERIoT's "allocation-benchmark"[14]. Booting the RTOS takes 490,000 instructions, while the "allocation-benchmark" takes 274 million.

Results. This benchmark uses the AMD Ryzen 7 setup. The results for Arm are in Figure 13. While Pydrofoil still manages to produce a much faster ISS for Arm than the Sail C backend (by a factor of almost 70×), in terms of instructions per second the performance is significantly worse than that of the RISC-V variant.

The CHERIoT results are in Figure 14. The speedup of Pydrofoil-CHERIoT is about 50×, even lower than that of Arm. This seems to be at least partly caused by Pydrofoil's poor handling of the fact that the CHERIoT-Sail-model uses a Sail `struct` type to store the CHERIoT capability registers (in RISC-V and Arm most registers are bitvectors).

[14] The "allocator-benchmark" can be found in [44]. For each power of 2 from 32 to 131072, the benchmark tries to allocate 1 MB with `malloc`, and then deallocates it using `free`. It also prints (to the emulated character device) the time it took to allocate and deallocate each 1 MB.

4.5 Threats to validity

This study, while providing insights into Pydrofoil's performance, is subject to several threats to validity. The primary limitation stems from the computational intensity of benchmarking ISSs, which operate at significantly lower speeds than the hardware they model. A comprehensive evaluation of Pydrofoil across a broad range of benchmarks requires computational resources and time that exceed our current capacity. Consequently, our findings are based on a subset of representative benchmarks, potentially limiting the scope of our conclusions. Second, the selected benchmarks, while intended to be representative of typical computer architecture workloads, were not specifically designed for ISS evaluation. This misalignment may not fully exercise Pydrofoil's capabilities, potentially under-representing its strengths and weaknesses. We acknowledge the need for benchmarks specifically tailored to evaluate ISS generators. Third, to mitigate limitations in existing tools, we employed certain experimental shortcuts. Notably, we did not perform multiple benchmark runs to assess statistical variation[15]. Finally, our primary focus on the RISC-V ISA introduces a potential limitation to the generalisability of our findings. While we included preliminary evaluations for Arm and CHERIoT, these are subject to methodological constraints. The Arm Sail model, derived from ASL through transpilation, may introduce runtime checks due to ASL's weaker typing, potentially confounding the attribution of performance characteristics. This highlights the challenges of comparing ISSs derived from different specification languages. The CHERIoT evaluation is based on a single, small-scale benchmark, whose results may not generalise well. Nevertheless, we believe that our work demonstrates that ISA specifications in Sail can be compiled into performant ISSs.

4.6 Summary of benchmarking

To address research questions RQ2 and RQ3, we conducted extensive benchmarking, aiming to quantify Pydrofoil's performance. Our ablation studies demonstrate that Pydrofoil's hybrid architecture, combining AOT and JIT compilation with domain-specific optimisations, is a viable approach for accelerating ISSs generated from Sail. Our smaller-scale benchmarks across Arm and CHERIoT ISAs corroborate the trends observed with RISC-V, giving us additional confidence in the robustness of our approach. However, comparisons with QEMU highlight a significant remaining performance gap, indicating substantial room for improvement to match the speed of hand-crafted full-system emulators.

Notably, the considerable resource demands of these benchmarks suggest a need for more efficient and feasible benchmarking strategies.

5 Suggestions for future research

While the present work has demonstrated significant performance gains, achieving a >250× speedup over the Sail-generated ISS, Pydrofoil remains 26.7× slower than QEMU. Spink et al. (2020) [60] report a 2× speedup over QEMU by employing a combination of AOT and partial evaluation techniques, similar in principle to Pydrofoil, albeit compiling from a low-level ADL, which is easier to optimise for than Sail. These discrepancies highlight the potential for further optimisation, and motivate the roadmap presented below, which is intended to bring Pydrofoil to performance parity with QEMU. It might also provide insights for the development of high-performance ISS generators for other high-level ADLs.

[15] Due to the required computational intensity. We hope to fix this in later versions of this work.

Clocks. Simulation of the processor clock is a known inefficiency for ISS acceleration [58]. The RISC-V Sail model ticks its clock every 100 instructions. This number was chosen arbitrarily, and is *not* part of the RISC-V instruction set architecture [76, 77]. Checking whether the next clock tick is reached in every guest instruction is expensive. Moreover, the JIT must generate control flow edges from *all* instruction to the clock logic. QEMU optimises this by only checking for clock ticks at the start of generated basic blocks, and deoptimises whenever a timer event happens elsewhere [48]. It is interesting to investigate if QEMU's approach or the mitigations discussed in [58] improve Pydrofoil performance.

Address translation. Real processors cache the results of address translation in the translation lookaside buffer (TLB), a dedicated hardware cache. Simulation has no TLB, so every memory access must simulate a full page table walk. This is a known problem in ISS research [11, 59]. We believe that a JIT with suitable domain-specific optimisations can lower the cost of simulated page table walks, for example by exploiting the predictability arising from contiguous addresses.

JIT warmup. The time it takes the JIT to generate optimised machine code is called warmup [10], and is the result of a fine balance between the cost and benefits of optimisations. PyPy's tracing mechanism was optimised for general purposed workloads: in PyPy, one Python bytecode produces 6-7 trace operations on average, which the optimiser reduces to about 2. Contrast this with Pydrofoil: tracing one RISC-V guest instruction produces more than 600 trace operations, which are optimised down to about 65 on average. The trade-offs driving the JIT optimisation design in PyPy are likely to be suboptimal for ISS workloads, hence have significant potential for improvement.

Type-erasure. Sail's liquid types can express strong constraints on bitvector widths. Sail's current compilation chain mostly erases them. Consider `size_bytes` from Section 3.2.4 with signature $\texttt{size_bytes} : \texttt{word_width} \leftrightarrow \{1, 2, 4, 8\}$. In other words, any value obtained by calling `size_bytes` is constrained to values $1, 2, 4$ or 8 in the Sail source. This strong constraint is lost in JIB: all the Pydrofoil AOT sees is that `size_bytes` returns `%i64`. If we want to optimise further, the fact that `%i64` stores one of $1, 2, 4, 8$ needs to be re-discovered by static analysis, either at compile-time, or by the JIT at run-time. Such strong constraints are prevalent in ISAs. Given the increasing interest in liquid types in other languages [36, 70], we believe that a better exploitation of the information from liquid types in the compilation toolchain might deliver better optimisations even beyond Sail.

6 Related work

6.1 DSLs used in computer architecture

There are a variety of DSLs that have been created for processor descriptions. Most relevant here are the aforementioned *architecture description languages*. Examples include nML [22], ISDL [28], EXPRESSION [29], SystemC [32], ArchC [54], and GenC [72]. They are often described as being high-level, and are actively used to derive ISSs, especially in commercial tools. Compared to Sail, and with the exception of GenC, they all betray their origins in layers of the processor design stack lower than ISA: they invariably also contain facilities to describe low-level detail, whether pipeline layout, timing constraints, or data-path conflicts. In their context of origin, computer architecture, they are considered higher-level, but only by contrast with RTL languages, such as Verilog and VHDL. Such DSLs are often

based on C/C++, a notable exception being SSL [20], which specifies the ISA semantics of machine instructions in Object-Z (an extension of Z specification language). However, this approach has not gotten much traction. It is only with Arm's ASL [51], Sail's most important predecessor, that a mature, ISA-only DSL emerged.

6.2 ISS acceleration

Evaluating Pydrofoil's performance against existing ISS solutions presents challenges due to the lack of directly comparable systems that utilise Sail. Proprietary tools such as Arm's FastModel [38] and Architecture Envelope Models [4], offer high-performance simulation capabilities. However, their internal architectures, including the extent to which they are automatically generated from Arm's ASL, remain largely undisclosed. Similarly, commercial tools from Synopsys (e.g., ASIP Designer [65], Platform Architect [67], ImperasDV [57,66]), MachineWare [16,26], and Codasip [21] rely on handwritten components or generation from lower-level ADLs like SystemC, nML, or Codal [21]. Many academic ISSs, while valuable, have not seen recent publications or updates to their codebase, making comparison difficult.

Pydgin. Pydgin [39], another meta-tracing and PyPy-based ISS, simulates only user-mode execution. This simplification omits features such as address translation, self-modifying code, and interrupt handling. Furthermore, Pydgin utilises its own Architecture Description Language, which offers a lower level of abstraction compared to Sail. These differences render direct performance comparisons difficult. In addition, due to the lack of recent updates to the Pydgin codebase, Pydgin no longer builds "out of the box". Even after resolving these build issues, we found that the resulting simulator could not correctly load and execute our SPEC benchmarks. For these reasons, we excluded Pydgin from our performance evaluation.

GenSim from the University of Edinburgh. GenSim [60,72–74] provides a retargetable and JIT-accelerated ISS framework. The GenSim toolchain, using the GenC specification language, and Captive dynamic binary translator (DBT) achieve a performance speedup of 2× over QEMU [61]. The performance gains are attributed to: (i) hardware-accelerated guest memory address translation [59]; (ii) partial evaluation [73], a technique related to meta-tracing [13, Chapter 12]; (iii) DBT optimised for ISS workloads [61]; (iv) parallelisation [35]; (v) use of a DSL with performance-focused constructs. We believe most of these techniques are general over the JIT/DBT system and thus applicable to Pydrofoil as an avenue for future work. However, while the hardware-acceleration of guest memory address translation provides substantial performance improvement, the implementation used by Captive is not possible in Pydrofoil. The technique requires arranging host page tables so guest address translations can be performed by the host's memory management unit. This use of hardware translation is faster than the simulation of multiple levels of page table walks in software. Unfortunately, it is only suitable for systems where the address space can be fully managed (Captive hosts the DBT in a bare-metal virtual machine, to gain full and unrestricted access to the host machine's hardware); as a user-mode application Pydrofoil is incapable of that. Additionally, this would harm one of Pydrofoil's features by no longer fully simulating the precise model provided, and instead requiring ahead-of-time knowledge of the guest's memory translation regime and a separate implementation for each host-guest architecture combination. The performance implications of compiling from Sail, compared to lower-level languages, remain a subject of ongoing investigation. A tool was made to translate Sail to GenC, forming a Sail frontend for GenSim, but was unsuccessful. The internal architecture of the GenSim toolchain scales poorly with input model size; the handwritten models are 20,000 lines of

GenC and compile in minutes, but attempts to use Sail translated to GenC resulted in tens of millions of lines and failed to compile even after days. The same issue occurred when developing a tool to translate Sail into Rust; the large volume of code being emitted caused the Rust compiler to use an unsustainable amount of memory. This appears to be a consistent challenge faced when working with high-level, machine-generated Sail specifications.

7 Conclusion

This paper introduces Pydrofoil, a tool designed to enhance the performance of ISSs based on Sail. We identify the primary bottlenecks of the current Sail system in Sections 2 and 3, addressing our first research question (RQ1). We propose a staged compiler architecture that utilises meta-tracing, as detailed in Section 3. Our benchmarks, presented in Section 4, demonstrate that Pydrofoil significantly improves simulation speed compared to Sail. However, in its current iteration, it does not yet reach the performance levels of a hand-tuned system like QEMU, answering RQ2 and RQ3. Future work aimed at closing this gap is outlined in Section 5, serving as a roadmap for achieving performance parity with QEMU.

Abstract

The CAP theorem demonstrates a trade-off between consistency and availability (and, by extension, latency) in systems where network partitions are unavoidable, such as in cloud computing and local-first software. While adopting weak consistency can preserve availability, it may result in inconsistencies that compromise application correctness. Replicated data types provide a principled, coordination-free approach to guarantee convergence but do not consider application invariants. Existing methods for maintaining invariants in replicated systems either rely on coordination – undermining the benefits of weak consistency – or suffer from limited applicability. This paper introduces the No-Op framework, a generic approach for enforcing consistency without coordination while guaranteeing both convergence *and* invariant preservation. The core idea of the No-Op approach is to resolve conflicts among concurrent operations by prioritising one operation over the other according to programmer-defined conflict resolution policies. This prioritisation transforms the less-preferred operation into a no-side-effect operation, ensuring conflict-free execution. We formalise the model underlying the No-Op framework and introduce a replication protocol built upon it, accompanied by a formal proof of correctness for both the framework and the protocol. Furthermore, we demonstrate the framework's applicability by showcasing the design of widely used replicated data types and the preservation of a wide range of application invariants.

1 Introduction

Replication is a key technique in data management systems that enables high availability, fault tolerance, low latency, and scalability. In cloud storage systems [28, 19, 5, 16], data is typically geo-replicated across multiple geographic locations to ensure low latency for clients.

© Dina Borrego, Nuno Preguiça, Elisa Gonzalez Boix, and Carla Ferreira;

Similarly, local-first software [27] allows clients to maintain a local copy of the data, enabling fast execution and continuous operation, even when disconnected. However, achieving these benefits relies on clients accessing a replica without coordinating with others. As a result, replication creates a trade-off between consistency and latency [1].

Weak consistency [45, 2, 34, 10, 43, 27] sacrifices consistency in favour of low latency and offline availability. In these models, operations are first executed locally on a replica (without coordination), with their effects propagating asynchronously to other replicas. This execution model leads to different execution orders across replicas, requiring a mechanism to guarantee that all replicas eventually converge to the same state. Replicated data types (RDTs) [40, 18, 13, 26, 9] offer a principled, coordination-free approach to ensure that, after the execution of the same set of updates, replicas converge to the same state.

However, state convergence alone does not ensure application correctness, as combining the effects of concurrent operations may violate application invariants and lead to an incorrect state. Although synchronising all operations (i.e., employing strong consistency [11, 23]) can preserve invariants, this approach significantly compromises system performance [4].

Much research [15, 30, 7, 21, 31, 25, 18] has focused on reducing coordination by synchronising only operations that might violate invariants, typically identified through static analysis tools. Non-conflicting operations, in contrast, are executed without requiring coordination. An alternative strategy is to move coordination outside the critical execution path, building on escrow and reservation techniques [36, 8, 7, 33, 38, 41]. By reserving the right to execute specific operations in advance, replicas allow operations to be safely executed without synchronisation, provided the necessary rights are locally available. Otherwise, coordination is required to acquire the rights from other replicas, or the operation must abort.

Finally, recent research has focused on maintaining invariants using coordination-free mechanisms [35, 6]. These mechanisms enable asynchronous execution, automatically resolving invariant violations using automatic resolution policies. These approaches build on the principles of RDTs, extending them from ensuring data convergence to preserving invariants: concurrent operations are executed without coordination while guaranteeing that replicas converge to a state where application invariants remain upheld. However, while some solutions, such as Antidote SQL [35], focus solely on referential integrity, others, like IPA [6], address invariant conflicts but rely on RDTs to achieve convergence.

In this paper, we propose a coordination-free consistency framework that addresses both data convergence and invariant preservation in a unified way. Our approach builds on a simple observation: when concurrent operations occur, their effects can be combined to ensure that replicas converge without violating invariants unless the operations conflict with one another. In cases of conflicting operations, it becomes necessary to prioritise the effects of one operation over the other. Our framework conceptually achieves this by transforming the not-preferred operation into an operation with no side effect (or a No-Op).

To validate our claim, we employ two complementary methods. First, we formally define our No-Op approach and provide proof establishing its correctness. Second, we demonstrate its applicability by showing that this simple model can encode popular RDTs and enforce a wide range of invariants, including referential integrity.

We introduce a replication protocol that adopts this framework to maintain consistency in replicated applications. The protocol was implemented in VeriFx [17], a high-level programming language with built-in automated proof capabilities, enabling validation of its correctness through automated proofs on specific data type implementations. These results corroborate the formal proofs provided, confirming the correctness of the No-Op approach.

To summarise, the main contributions of this paper are:

- The No-Op generic framework for enforcing consistency without coordination, achieving both convergence and invariant preservation in a unified way.
- A replication protocol that integrates the No-Op framework.
- Formal proofs of correctness for the proposed framework and replication protocol.
- The applicability of the No-Op framework to the design of popular RDTs and the maintenance of general application invariants.

The remainder of this paper is organised as follows. Section 2 offers an overview of the No-Op approach, followed by Section 3, which introduces its formal model and a formal proof of its correctness. Section 4 details the No-Op replication protocol and provides the corresponding correctness proofs. Section 5 explores the applicability of the proposed solution. Section 6 discusses limitations of the No-Op approach and possible solutions to avoid these limitations. Then, Section 7 discusses related work. Finally, Section 8 concludes the paper.

2 Overview

This section overviews our approach using an album management system as a running example. This application manages a collection of artists and their albums, supporting operations such as adding, removing, and updating artists, as well as adding and removing albums. This example was previously used in [35] and is similar to an example from [16].

The goal of our No-Op approach is to guarantee state convergence and invariant preservation without requiring coordination. Figure 1 and Figure 2 illustrate a convergence and an invariant conflict that could occur when implementing the album management system. Consider that the application's state is modelled as a set of pairs (artist, country) representing artists and their respective countries, along with a set of elements representing albums. Figure 1 shows a convergence conflict. Initially, both replicas are in an equivalent state, each containing one artist (Sam, UK). Replica 1 updates the artist, resulting in a state with one artist (Sam, USA). Replica 2 removes the artist, leaving its state empty. After propagating both updates, the replicas have applied all operations yet reached divergent states. Figure 2 shows how a referential integrity invariant can be violated. The application must ensure that albums are not associated with non-existent artists. Starting again from an initial state where both replicas contain one artist (Sam, UK), replica 1 adds an album, A1, for Sam, updating its state to include the album. Meanwhile, replica 2 removes the artist, leaving its state empty. After propagating both updates, both replicas converge to a state containing the album but not the artist. Therefore, even though the replicas converge after applying all operations, the referential integrity invariant is violated, as the replicas' state contains an album whose associated artist does not exist.

The core idea of the No-Op approach is to avoid by design *conflicting operations*, i.e., operations that violate state convergence or application invariants. When two conflicting operations are executed concurrently, one is converted into a no-side-effect operation (i.e., a No-Op) based on a predefined conflict resolution policy. These policies vary based on the application's intended semantics, and it is the programmer's responsibility to select the most suitable one for the application. The No-Op approach implements conflict resolution using an auxiliary operation called *block*, which encodes the conflict resolution policy defined by the programmer. A *block* is triggered atomically when a conflicting operation is executed and specifies which operations cannot run concurrently due to conflicts. The system then transforms any operation that conflicts with the *block* into a No-Op.

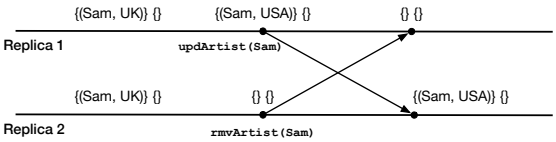

Figure 1 Convergence conflict.

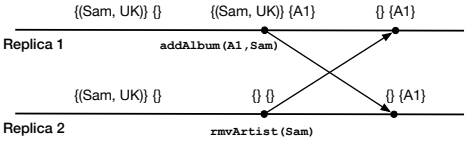

Figure 2 Invariant conflict.

By leveraging conflict resolution policies, the No-Op approach enforces both convergence and invariant preservation in a unified manner. Let us revisit Figure 1 and Figure 2 to see which conflict resolution policies could be applied to solve these conflicts. A conflict resolution policy for solving the convergence conflict in Figure 1 is to prioritise the remove operation by discarding the update operation. This behaviour aligns with the remove-wins policy used in existing remove-wins CRDT sets [40, 9]. Our No-Op approach can encode remove-wins semantics by having remove operations trigger a *block* on updates for the same artist. The *block* on updates will render any concurrent update on the deleted artist a No-Op.

An alternative policy for the convergence conflict is a privilege-based policy suitable for systems where users are assigned privilege levels. Under this policy, both update and remove operations trigger a *block*. An update operation triggers a *block* on all remove operations for the same artist issued by users with lower priority. Similarly, a remove operation triggers a *block* on all update operations for the same artist submitted by users of lower priority. When users share the same privilege level, the policy must specify how to resolve ties. For example, a total order could determine the winning operation among users with equal privilege levels.

Note that an operation only issues a *block* if it can win. For example, under the remove-wins semantics, the update operation never issues a *block* because it never wins against any other operation. In contrast, in a privilege-based policy, both update and remove operations issue a *block*, as either operation can be the winner depending on the user's privilege level.

Similar to convergence conflicts, various conflict resolution policies can be applied to address invariant conflicts. In the case of the referential integrity conflict shown in Figure 2, we can prioritise the operation that adds the album, rendering the remove artist operation ineffective. This behaviour corresponds to an update-wins conflict resolution policy similar to the one used in Antidote SQL [35]. Alternatively, we can prioritise removing the artist by dropping the add album operation, corresponding to remove-wins semantics. These policies are implemented akin to the policies for handling convergence conflicts: the winning operation type issues a *block* on the losing operation type.

2.1 The No-Op Approach by Example

We will now illustrate how the No-Op approach works through a concrete execution trace of the album management system shown in Figure 3.

The execution trace consists of five operations involving two replicas. Replica 1 executes an `addArtist(Sam)` operation, which gets delivered to both replicas. Next, two concurrent `addAlbum` operations are executed and delivered to both replicas. Finally, two concurrent operations follow: `updateArtist` in replica 1 and `rmvArtist` in replica 2.

The No-Op approach stores operations in a graph to determine when a conflict occurs and applies the appropriate conflict resolution policy. This graph forms the core of the No-Op mechanism, representing a partial order of operations that accurately captures concurrency and causality of operations. Figure 3 depicts both replicas' execution graphs for the aforementioned execution trace. Solid circles represent local operations; dashed ones,

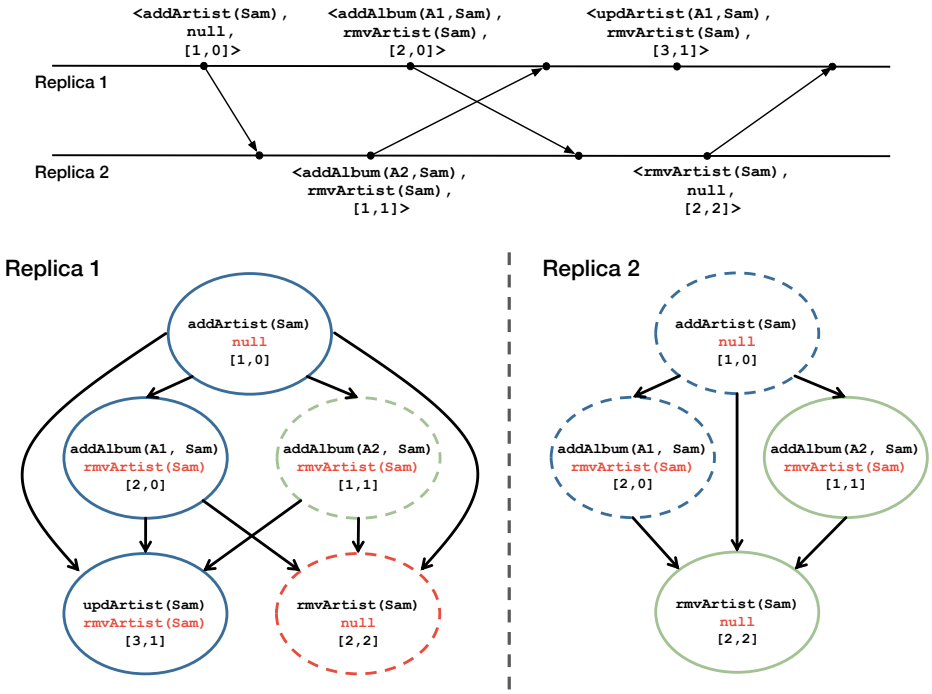

Figure 3 Execution graph for an execution trace of the album management system.

delivered remote operations. Blue, green, and red indicate operations from replica 1, replica 2, and No-Ops, respectively. Each vertex lists the operation call, the *block* operation, and its timestamp. In this example, both referential integrity and convergence conflicts are resolved following the update-wins semantics.

The first node in the operation graph corresponds to the `addArtist(Sam)` operation, which got delivered to both replicas before any subsequent concurrent operations were executed, causally preceding all other operations in the graph. Since the operation was originally executed at replica 1, the node in replica 2 for this operation is dashed. Following this, the two replicas concurrently execute two `addAlbum` operations. Both operations issue a *block* on concurrent `rmvArtist(Sam)` to uphold the referential integrity invariant (according to the update-wins semantics). However, the operations do not conflict, as neither operation blocks the other. Consequently, after propagation, both graphs have two concurrent `addAlbum` operations (one local and one remote), but neither operation is marked as a No-Op.

Lastly, two additional operations are executed concurrently. Replica 1 executes an `updArtist(A1, Sam)` operation, which issues a *block* on concurrent `rmvArtist` on the updated artist, namely `Sam`. Concurrently, replica 2 executes a `rmvArtist(Sam)` operation that does not block any operation. After this operation is propagated to replica 1, the conflict between the *block* on `rmvArtist(Sam)` and the delivered `rmvArtist(Sam)` operation is detected, marking the latter as a No-Op to resolve the conflict. Since the `updArtist` operation has not yet been delivered to replica 2, the graphs currently diverge. Once the `updArtist` operation is delivered to replica 2, the system will also detect the conflict, and the local `rmvArtist(Sam)` operation will be marked as a No-Op.

Note that there are no edges between concurrent operations (e.g., the two concurrent `addAlbum` operations), so there are different possible serialisations of the execution graph. For example, in the graph of replica 2, there are two possible serialisations: i) `addArtist(Sam)`,

`addAlbum(A1, Sam)`, `addAlbum(A2, Sam)`, and `rmvArtist(Sam)`, and ii) `addArtist(Sam)`, `addAlbum(A2, Sam)`, `addAlbum(A1, Sam)`, and `rmvArtist(Sam)`. However, as we prove in Section 3.1, all serialisations are safe and equivalent.

2.2 The No-Op Approach Workflow

We now present the envisioned workflow for developing replicated systems that guarantee state convergence and maintain application invariants using the No-Op approach. This workflow follows a three-step process, which we outline below.

Step 1. Identifying Conflicting Operations. Given the application state and the operations, programmers start by identifying conflicting operations within the system. We assume programmers can leverage existing analysis tools, such as Hamsaz [24] or Ordana [18], to detect conflicts between operations automatically.

Step 2. Defining Conflict Resolution Policies. For each pair of conflicting operations identified by the analysis tool, programmers must define a conflict resolution policy. These policies determine how conflicts are resolved, ensuring consistency while preserving the intended system behaviour. As noted in [37] and illustrated earlier in this section, different concurrency semantics can be applied to solving a conflict, with some being more suitable for specific applications. Our prototype implementation offers a range of conflict resolution policies (e.g., add-wins, remove-wins, last-writer-wins) as shown later in Section 5. These predefined policies enable programmers to adapt them when implementing new data types. Section 4.1.1 shows conflict resolution policy examples.

Step 3. Verification. After defining all conflict resolution policies, we foresee programmers verifying the correctness of the data type or application. In our work, we use VeriFx [17] to validate the correctness of our implementation, though other verification tools could be used. Note that correctness is independent of the conflict resolution semantics, i.e., VeriFx does not validate whether a conflict resolution policy aligns with the programmer's intended semantics. For instance, if a programmer intends to implement an add-wins set but defines a remove-wins policy, the system will enforce the policy as specified without detecting a mismatch. Since we aim to provide flexibility in defining conflict resolution policies, we assume that the programmer correctly specifies policies that align with the application's intended behaviour. To simplify, developers can use or adapt our predefined standard policies covering common concurrency semantics.

3 Model

We now present our model and provide a formal proof of its correctness. The No-Op framework ensures strong convergence and safety, guaranteeing that replicas remain consistent while preserving application invariants without coordination. Strong convergence [39] ensures that correct replicas processing the same set of updates – potentially in different orders – reach equivalent states. Safety ensures that the replicated state consistently upholds the invariants.

We consider a causally consistent database fully replicated across multiple data centres. Replicas may also be stored in mobile devices, which may temporarily be offline. We assume a fail-recover model that preserves durable state and excludes Byzantine faults.

The application state comprises a set of objects, each of which can be accessed and modified at any time through application-defined operations. In turn, the replica state comprises two components: i) the initial application state, and ii) a partial order of operations that tracks concurrency and allows the identification of conflicts as they arise. The current application state of a replica is calculated by applying all operations in partial order to the initial state.

Algorithm 1 Execution model of an update operation under the No-Op approach.

types
$m = \langle op, block \rangle$ ▷ a message is a pair containing operation *op* and the *block* operation
1: **on** operation$_i(op)$
2: $m \leftarrow$ PREPARE$_i(op)$
3: **if** $m \neq \perp$ **then** ▷ m is set to $\perp$ when the operation's precondition is not satisfied
4: bcast$_i(m)$
5: **on** deliver$_i(m, t)$ ▷ we assume causal delivery
6: $c \leftarrow \langle op, block, t \rangle$ ▷ call c contains the operation *op*, the *block* operation, and the timestamp t
7: EFFECT$_i(c)$

An operation consists of a sequence of reads and writes that a replica executes atomically. In line with causal consistency, operations are propagated between replicas using a broadcasting mechanism that guarantees causal delivery. Causally-related operations are ordered according to the "happens-before" relation [29], whilst concurrent operations remain unordered relative to each other. Consequently, the execution order of concurrent operations may differ across replicas, potentially leading to consistency conflicts. These conflicts fall into two categories: i) convergence conflicts, which occur when replicas reach different states by applying concurrent operations in different orders, and ii) invariant conflicts, which arise when concurrent operations violate application-specific invariants.

An operation is *conflicting* if it can cause convergence or invariant conflicts. As such, read-only operations, which do not modify the application state, are non-conflicting.

Algorithm 1 outlines the execution model of the No-Op framework. It draws inspiration from operation-based CRDTs [40] and divides the execution of an update operation into two phases: the prepare phase and the effect phase.

When a user invokes *op* on replica i, the operation$_i$ event on that replica is triggered. This event triggers the prepare phase, executed exclusively on the replica where the operation was invoked. During this phase, the system validates the operation's preconditions. If the preconditions are satisfied, the PREPARE$_i$ returns a message m containing the operation *op* and a *block* operation, codifying the conflict resolution policy to handle conflicts involving the submitted operation. Based on the predefined policy, the *block* specifies which operations cannot be executed concurrently with the operation that issued it. In other words, the *block* encodes the less preferred operations. Consequently, there may be operations where the *block* is null, meaning that it represents the losing operation in the conflict. Conversely, an operation may have a *block* on multiple operations, indicating that it conflicts with and prevails over several others. Then, bcast$_i$ broadcasts the message to all replicas by calling the reliable causal broadcast API (which will add a timestamp to the message).

When a message m with timestamp t is delivered to replica i, the deliver$_i$ event is triggered. The event first creates a tagged call c, associating the message with its timestamp. As the message includes the operation call and the issued *block*, the tagged call is a triple consisting of the operation call, the *block*, and the timestamp. EFFECT$_i$ incorporates the tagged call (or simply call) into the partial order of operations and resolves any resulting local conflicts. A local conflict occurs when the replica detects that the delivered operation has a *block* against a local operation or vice versa. When the conflict is detected, the system transforms the blocked operation into a no-side-effect operation, called a No-Op. This transformation ensures that only the preferred operation (the one that issued the *block*) affects the application state, thus maintaining consistency and enforcing the predefined conflict resolution policy. Conflicts

can also arise with operations that have already been transformed into No-Ops. For instance, if a No-Op has a *block* for a newly received operation, a conflict exists between the two operations, and the system resolves it by transforming the new operation into a No-Op.

3.1 Model Correctness

We now prove that the No-Op framework guarantees strong convergence and safety. To do so, we assume three key prerequisites: i) all replicas receive all updates, ii) updates are delivered in causal order, and ii) a resolution policy is defined for every pair of conflicting operations.

As mentioned before, our model represents the partial order of operations as an execution graph, $G = \langle V, E \rangle$. G is a labelled directed acyclic graph (DAG) where vertices (V) represent tagged operation calls, and the edges (E) denote sequential dependencies between these calls. No-Ops are maintained in a set N, which consists of all the vertices marked as No-Ops. Concurrent operations remain unconnected in the graph, allowing for multiple topological orders. We prove that all topological orders are safe serialisations (Theorem 5) and that replicas receiving the same set of calls will converge to the same state (Theorem 7).

For simplicity, the proofs focus on the effect phase, as the prepare phase only creates the message to be broadcast to all replicas and does not modify the replica state. We assume the prepare phase has been executed, and the *block* has been issued according to the predefined conflict resolution policies. Additionally, the proofs do not distinguish between local and remote replicas, as only EFFECT_i modifies the state.

▶ **Lemma 1.** *Two replicas that observed the same calls have the same execution graph and the same set of No-Ops:*

$$\forall r_1 = \langle G_1, N_1 \rangle,\ r_2 = \langle G_2, N_2 \rangle :$$
$$(G_1 = \langle V_1, E_1 \rangle \land G_2 = \langle V_2, E_2 \rangle \land V_1 = V_2) \implies (E_1 = E_2 \land N_1 = N_2)$$

Proof. The graphs are equivalent iff, upon receiving the same set of calls, they contain the same vertices and edges. When executing the effect phase, the replica adds the call to its execution graph. Consequently, two replicas that observe the same calls will have identical vertices in their execution graphs. We now show that the graphs contain identical edges across replicas. The effect phase computes the edges between sequential calls by comparing each new call c with every other call in the graph. Causal consistency ensures that operations are causally delivered, allowing all replicas to process sequential operations in the same order. As a result, all calls preceding c are consistently compared to c, generating the necessary edges. Thus, all replicas maintain the same edges in their execution graphs. As the vertices and the edges are the same, we can infer that both graphs, G_1 and G_2, are identical.

Lastly, we demonstrate that even when replicas process concurrent calls in different orders, the model marks the same operations as No-Ops. When a tagged call c is added to the graph, the model checks whether c conflicts with its concurrent operations. For each pair of concurrent operations, we distinguish two scenarios. First, if one operation issues a *block* against the other, the blocked operation is marked as a No-Op. Second, if the operations do not conflict, no further action is taken. Since we assume that all operations are eventually delivered, all updates are processed, ensuring all blocks are also processed. Consequently, after processing the same set of operations, all replicas will have identified the same No-Ops. ◀

To demonstrate that all topological orders are safe serialisations, we first define safety based on the definition from [18] adapted to our model.

▶ **Definition 2** (Safe calls). *Two concurrent calls are safe iff applying them in any order preserves the operations' preconditions and invariants. Otherwise, they are unsafe.*

▶ **Definition 3** (Safe operations). *Two operations are safe iff all pairs of concurrent calls to those operations are safe.*

▶ **Definition 4** (Safe serialisation). *A serialisation of correct calls is safe iff every pair of concurrent calls is either safe or includes at least one call that has been marked as a No-Op.*

▶ **Theorem 5.** *All topological orderings of an execution graph G are safe serialisations.*

Proof. By induction on the length of the topological order.

Base Case. No calls occurred, so the topological ordering is empty and trivially safe.

Induction Step. Assume a safe topological order of dimension n derived from an execution graph. When a message is delivered, the effect phase incorporates the new call into the execution graph and calculates the No-Ops according to the issued blocks. We distinguish two cases: either the new call is safe or unsafe.

Case 1. If the new call is safe, indicating no conflicts with any other concurrent call in the execution graph, we can add the call to the graph, ensuring that the resulting topological order(s) are safe serialisations.

Case 2. If the new call is unsafe, the new call invariant conflicts with at least a concurrent operation in the execution graph. Since the call is conflicting, it either appended a *block* during the prepare phase or the conflicting calls did. The blocked operations are then transformed into No-Ops, ensuring that the resulting topological order(s) are safe serialisations. Therefore, assuming the prepare phase was correctly executed, and conflict resolution policies are defined for all conflicts, a *block* must exist for every pair of conflicting operations, ensuring safety.

Starting from an execution graph with a safe topological order of dimension n, our model builds an expanded graph whose topological order of dimension $n+1$ is a safe serialisation. ◀

▶ **Lemma 6.** *Two topological orderings from the same graph G converge to equivalent states.*

Proof. We follow a proof by contradiction. Assume two topological orderings, t_1 and t_2, that result in divergent states. We know that, in both $t1$ and $t2$, all sequential operations appear in the same order. However, concurrent operations may appear in different orders. Given the assumption that the states diverge, there must be at least two concurrent non-commutative calls, c_1 and c_2, appearing in different orders in t_1 and t_2. Let us assume, without loss of generality, that $t_1[c_1] < t_1[c_2]$ and $t_2[c_1] \not< t_2[c_2]$, where $t_i[c_i]$ represents the position of call c_i in the topological ordering t_i. Since c_1 and c_2 are non-commutative, executing them in different orders would lead to divergent outcomes. However, according to the conflict resolution policy, non-commutative operations will issue a *block* in the prepare phase. Therefore, one operation will block the other for all pairs of non-commutative conflicting operations. Consequently, either c_1 or c_2 would become a No-Op. As No-Ops do not affect the application state, it follows that c_1 and c_2 commute, which contradicts our initial assumption that c_1 and c_2 are non-commutative and lead to divergent states. By processing all operations in the graph this way, we ensure that all remaining operations are commutative, guaranteeing that any topological ordering will yield equivalent results. ◀

▶ **Theorem 7.** *Two replicas that observed the same tagged calls converge to equivalent states.*

Proof. Assuming both graphs have observed the same calls, it follows from Lemma 1 that they have the same execution graph. Additionally, by Lemma 6, any topological order within the same graph leads to an equivalent state. Considering the graphs are equal, we can infer that their topological orders are equivalent, thus converging to an equivalent state. ◀

4 No-Op Replication Protocol

We now introduce a coordination-free replication protocol that leverages the No-Op approach to ensure strong convergence and uphold invariants in distributed systems without requiring coordination. The protocol enables replicas to execute operations without synchronisation and handles conflicts as they arise. As explained in Section 2, conflicts are identified and resolved using a *block* operation that encodes a programmer-defined resolution policy. After resolving the conflict, *at most one* of the conflicting operations affects the state.

Algorithm 2 provides an overview of the replication algorithm that implements the model proposed in Section 3. Each replica maintains an execution graph, a No-Op (losing calls) set, and the application's initial state. As in the model, the execution graph is a labelled directed acyclic graph (DAG) in which vertices represent tagged operation calls, and edges denote the sequential dependencies between them. When two concurrent operations conflict – one operation blocks the other – the algorithm designates the blocked operation as a No-Op, ensuring that only the preferred operation affects the application's state.

Since each replica only maintains the initial state, the current state of the application must be calculated based on the operations in the execution graph. The GETSTATE function computes the current state by executing the operations according to the partial order maintained in the graph. The function begins by determining a topological order of the graph. Starting from the initial state, each operation in the topological order is applied, except for No-Op calls, which are ignored and left unexecuted.

The PREPARE function, executed exclusively by the replica where the operation was submitted, verifies whether the operation is enabled in its current state and, if necessary, issues a *block*. The function begins by calculating the replica's local state and evaluating the precondition. If the precondition does not hold, the operation cannot execute, and the function returns $\perp$. Otherwise, it returns a message containing the operation and the corresponding *block*. The *block* is determined based on the operation, the current state, and the predefined conflict resolution policies. In some cases, the application's state does not influence the *block*. However, specific policies may use the state to decide which operations to block (as discussed later in Section 5.2.4).

The EFFECT function operates on all replicas and incorporates the received call into each replica's local operation graph. The function begins by adding the edges between the new call c and all preceding calls in the graph. Since the model assumes causal delivery, no calls occurring after c exist in the graph at this stage. Next, the function checks if the new call conflicts with its concurrent operations. Conflicts are detected using the OPSCONFLICT function, which returns *true* if one operation has a *block* on the other. If a conflict is detected, the algorithm gets the blocked operation through the GETBLOCKEDOP function and adds it to the No-Ops set. Finally, the function adds the call to the set of vertices.

The algorithm allows a replica to validate an operation's precondition while concurrently delivering a remote operation. This is not a problem, as any invalidation of the precondition by the remote operation indicates a conflict, which the system detects and resolves when the effect function integrates the local operation into the graph.

Algorithm 2 The No-Op algorithm main functions.

```
    replica local state
      G = ⟨V, E⟩                                   ▷ execution graph
      N                                            ▷ set of calls marked as No-Ops
      σ_0                                          ▷ initial state
 1: function PREPARE(op)                           ▷ check if an operation can be executed in the current state
 2:     σ ← GETSTATE()                             ▷ calculate the current state based on the execution graph
 3:     if PRE(op, σ) then                         ▷ check if the operation precondition holds in the current state
 4:         b ← GETBLOCK(op, σ)                    ▷ generate the block according to the conflict resolution policy
 5:         return ⟨op, b⟩                         ▷ return the operation and the block if the precondition is satisfied
 6:     else
 7:         return ⊥                               ▷ indicate the operation is not enabled in the current state
 8: function EFFECT(c)                             ▷ integrate call c into the execution graph
 9:     for v ∈ V do                               ▷ determine edges and No-Ops generated by call c
10:         if v ≺ c then                          ▷ call v happens-before call c
11:             E ← E ∪ {⟨v, c⟩}                   ▷ add edge between call v and call c
12:         else if v ∥ c ∧ OPSCONFLICT(v, c) then ▷ operation blocks the concurrent operation
13:             l ← GETBLOCKEDOP(v, c)             ▷ get the blocked operation
14:             N ← N ∪ {l}                        ▷ add the losing call l to the No-Op set
15:     V ← V ∪ {c}                                ▷ add call c to the graph vertices
16: function GETSTATE()                            ▷ calculate the current state
17:     to ← GETTOPOLOGICALORDER()                 ▷ get a topological order from the graph
18:     σ ← σ_0
19:     for c ∈ to do                              ▷ apply all calls according to the topological order
20:         if c ∉ N then                          ▷ No-Ops are ignored and are not executed
21:             σ ← EXECUTE(σ, c)                  ▷ execute call c over state σ
22:     return σ                                   ▷ return the current state
```

4.1 Implementation in VeriFx

We implemented the core of the No-Op replication protocol in VeriFx [17], a programming language for RDTs with automated proof capabilities. VeriFx allows developers to implement RDTs in a high-level language atop functional collections and express correctness properties that are verified automatically. Alongside the algorithm implementation, we developed formal proofs to automatically verify the algorithm's correctness properties when applied to specific data types or application implementations. The implementation considers only the effect phase of Algorithm 2. As in the formal proofs in Section 3.1, we assume the prepare phase was correctly executed according to the programmer-defined conflict resolution policies.

4.1.1 Conflict Resolution Policies Specification

We start by detailing how conflict resolution policies are specified in our VeriFx implementation. These policies are implemented by means of two functions:

- The `blocksEncoding` function verifies whether an operation call is valid. It takes `TaggedOp` type, combining the operation and a corresponding *block*, and defines the *block* value according to the operation type. Since we assume that the prepare phase was correctly executed and VeriFx will generate any possible combination of operation and *block*, we use this function to restrict the set of operations considered in the proofs to those that are correct (i.e., those whose blocks match GETBLOCK in Algorithm 2). Programmers must define this function.

- The `isBlockedBy` function takes two calls and defines the condition under which a given operation instance is blocked by another. It corresponds to the opsConflict in Algorithm 2. Typically, an operation blocks all instances of another operation of a given type. Accordingly, the default implementation of this function returns `true` if a given operation has a *block* that matches the other operation. For some data types (e.g., the LWW Register), an operation may not block all instances of another type. In such cases, the programmer must provide their custom implementation.

The implementation of `blocksEncoding` and `isBlockedBy` depends on the data type semantics. We now illustrate how programmers specify conflict resolution policies through these functions in the context of two concrete data types.

Add-Wins Set. The implementation of `blocksEncoding` for a replicated set defining an add-wins policy is shown below:

```
1  def blocksEncoding(v1: TaggedOp[Time, ID, SetOp[V]]): Boolean =
2    v1.op match {
3      case Add(e) => v1.b == new Rmv(e)
4      case Rmv(_) => v1.b == new NullOp[V]()
5      case _ => false
6    }
```

Given an operation, the `blocksEncoding` function encodes how blocks should have been assigned during the prepare phase. In this case, if the operation is an `Add(e)`, the *block* is equal to `Rmv(e)`. Conversely, if the operation is a `Rmv(_)`, the *block* is null (i.e., the operation does not block any operation) since it represents the losing side of the conflict. In VeriFx, we represent this null value using a special operation called `NullOp`. Accordingly, for the case of `Rmv`, the function returns `true` if the associated *block* is `NullOp`. The last case ensures pattern matching covers all possible scenarios, including `NullOp`. Since `NullOp` does not correspond to an actual operation, there are no operations of this type, and the function returns `false`. This encoding guarantees that only operations with correctly triggered blocks are considered. For example, it ensures that in the proofs we only consider `Add(e)` operations that correctly blocks `Rmv(e)`, and excludes any `Add(e)` that does not block any operation.
In the add-wins set, the *block* matches precisely the operation that should be transformed into a No-Op, i.e., the removes on the same element. Therefore, we can rely on the default implementation of the `isBlockedBy` function.

LWW Register. Listing 1 shows the specification of a register defining a last-writer-wins (LWW) policy. The `blocksEncoding` function defines that an `Assign` operation must block other concurrent `Assign` operations that assign the same value to the register (i.e., `Assign(5)` would only block concurrent `Assign(5)` operations). However, to implement the LWW policy, an `Assign` operation should block all operations lower in the total order for the LWW, regardless of the assigned value. For instance, a *block* on `Assign(5)` must block all concurrent instances of `Assign(e)` operations that are older in the total order, independently of the value of `e`. We specify this requirement in the custom implementation of the `isBlockedBy` function where blocking is defined by operation identifiers (`opID`). As shown in lines 8–10, the operation in the first call (`op1.op`) is considered blocked if both `op1.op` and the *block* of the second call (`op2.b`) are of type `Assign(_)`, regardless of their arguments (denoted by the underscore in pattern matching), and if the identifier of the first call (`op1.opID`) is smaller than that of the second (`op2.opID`). Line 14 ensures exhaustive pattern matching. In the LWW register, it only matches `NullOp`, which is never triggered and thus never evaluated.

Listing 1 Conflict resolution policy specification for a last-writer-wins register.

```
def blocksEncoding(v1: TaggedOp[Time, ID, RegOp[V]]): Boolean =
  v1.op match {
    case Assign(x) => v1.b == new Assign(x)
    case _ => false
  }

override def isBlockedBy(op1: TaggedOp[Time, ID, RegOp[V]],
                         op2: TaggedOp[Time, ID, RegOp[V]]) = {
  op1.op match {
    case Assign(_) => op2.b match {

```

4.1.2 Implementation and Verification of the No-Op Replication Protocol

Our implementation closely follows the formal model, with a few optimisations. In the model, the prepare phase assigns blocks according to conflict resolution policies, and all *block* operations are issued during this phase. In the VeriFx implementation, we assume the prepare phase has been correctly applied. We encode this assumption using the `blocksEncoding` function, which specifies which operations are invalid and should not be considered in the verification process. Additionally, rather than issuing all *block* operations, our implementation only allows one type of concurrent operation to be blocked. Therefore, we need the `isBlockedBy` function to determine whether a specific operation instance is blocked.

To prove the algorithm's correctness, we must guarantee that the implementation upholds the properties of the model proposed in Section 3: strong convergence and safety. In VeriFx, we encoded these properties through two graph-based properties. The first property aligns with the property proven in Lemma 1, demonstrating that applying two concurrent operations in different orders on the same state produces an identical graph and the same No-Ops. We only need to verify this property for concurrent operations, as sequential operations are processed in the same order due to the assumption of causal delivery. The second property encodes the structural characteristics of the graph. It ensures that edges connect all sequential operations and that, for any conflicting pair of concurrent operations, one operation is marked as a No-Op and added to the set of No-Ops. This second property encodes the properties of Theorems 5 and 7.

Listing 2 presents the proofs used to verify the algorithm's correctness. The proofs employ three helper functions present in VeriFx to facilitate the verification process of RDTs:

- The `compatible` function returns true if the two operations denote different operations.
- The `enabledOp` function assesses whether an operation is enabled in the current state. It first checks that the operation has not yet been delivered and that all predecessor operations have already been delivered. This verification is needed because our model assumes causal delivery of operations. Additionally, the function ensures the tagged operation call is correct using the `blocksEncoding` function.
- The `reachable` function defines the states the system can attain. It integrates the structural properties of the graph, ensuring that conflicts between concurrent operations are appropriately resolved and that edges exist between sequential operations.

Listing 2 Proof verifying the algorithm's correctness under concurrent operations, leveraging graph-based properties.

```
proof noOpStrongConverges[Time, ID] {
  forall(s: T[Time, ID], x: TaggedOp[Op, ID, Time],
                         y: TaggedOp[Op, ID, Time]) {
    (s.compatible(x, y) && s.reachable() &&
     s.enabledOp(x) && s.enabledOp(y) &&
     s.execGraph.timeProps.concurrent(x.stamp, y.stamp)) =>:
       s.effect(x).effect(y).equals(s.effect(y).effect(x))
  }
}

proof noOpIsSafe[Time, ID] {
  forall(s: T[Time, ID], x: TaggedOp[Time, ID, Op]) {
    (s.reachable() && s.enabledOp(x)) =>: s.effect(x).reachable()
  }
}
```

The proof `noOpStrongConverges` ensures that starting from a reachable state with two concurrent operations enabled, applying these operations in different orders results in the same graph state. The proof `noOpIsSafe` verifies that integrating an enabled operation into the graph preserves the safety properties encoded in the `reachable` function.

Like our manual proofs (cf. Section 3.1), the VeriFx proofs assume that all possible conflicts have a defined conflict resolution policy. Thus, the analysis may incorrectly indicate that the data type is correct if the resolution policies do not cover all conflicts.

We used the VeriFx implementation of our approach to implement some data types (discussed later in Section 5) and successfully verified their correctness. In this work, data type implementations are used exclusively for verification purposes. However, VeriFx also supports the transpilation of the data types into mainstream languages such as Scala and JavaScript. Thus, if the No-Op algorithm were integrated into a database, developers could design and verify their data types in VeriFx, subsequently transpiling them into a mainstream language for seamless database integration.

4.2 Graph Compaction

Although the algorithm maintains consistency properties, i.e., ensuring convergence and preserving invariants, it is impractical for real-world use due to the linear growth of each replica's state with the number of operations. To make our approach practical and more efficient, we leverage the concept of causal stability [9] to determine when an operation call can be committed and removed from the graph. This optimisation reduces space and prevents the need to reapply the entire operation history for every incoming call. By committing causally stable calls, we ensure that the graph remains compact, improving efficiency while preserving the correctness guarantees of the original algorithm.

An operation is *causally stable* at a replica i when the replica can no longer receive any additional concurrent operations. Once stabilised, the operation can no longer be transformed into a No-Op nor cause other operations to become No-Ops. Therefore, replicas can locally commit causally stable calls without requiring coordination.

The commitStableCalls function, described in Algorithm 3, implements the causal stabilisation of our approach. The function takes a stable timestamp t as its argument and begins by identifying the stable calls in the graph. The getStableCalls function identifies all calls with a timestamp less than or equal to t and returns them as a sequence of operations. This sequence respects the causal ordering defined by the graph. Next, each stable call in the sequence is removed from the graph and applied to the state σ_0. If an operation is a

Algorithm 3 Commiting causally stable calls.

```
1: function commitStableCalls(t)
2:     stableCalls ← getStableCalls(t)          ▷ get the stable calls
3:     for c_s ∈ stableCalls do                 ▷ we assume stableCalls respect causal ordering
4:         V ← V \ {c_s}                        ▷ remove the stable call from the vertices
5:         E ← E \ in(c_s) \ out(c_s)           ▷ remove incoming and outgoing edges
6:         if c_s ∉ N then                      ▷ the stable call is not a No-Op
7:             σ_0 ← execute(σ_0, c_s)          ▷ apply the stable call c_s in the state σ_0
8:         else                                 ▷ the stable call is a No-Op
9:             N ← N \ {o_s}                    ▷ remove the stable call from the set of No-Ops
```

No-Op, it does not affect the stable state, as it has no side effects.

Some applications may benefit from being notified when operations are committed. For example, in an online sales application, a developer may want a purchase to remain in an *accepted pending* state until it is final. Only after the operation is committed (and can no longer be modified) should a notification be sent to the customer, confirming that the purchase has been successfully processed. To support this behaviour, our framework can be extended to let developers register callbacks on operations, which are triggered asynchronously when the operation is committed. Note that the callback notification can be sent as soon as a single replica commits the operation; there's no need to wait for every replica to commit.

4.2.1 Causal Stabilisation and No-Op Operations

During execution, conflicts are resolved by transforming operation calls into no-side-effect operations, known as No-Ops. Since conflicts are handled locally by each replica as they arise, different replicas may detect and resolve them in different orders due to variations in operation arrival. To ensure determinism, the computation of No-Ops must consider all concurrent operations, including those already marked as No-Ops. Consequently, although No-Ops do not modify the application state, they must remain in the graph until causal stabilisation to ensure deterministic conflict resolution and prevent divergence.

To illustrate why No-Op operations must remain in the graph, consider the example in Figure 4, based on the albums management system introduced in Section 2. Initially, the database contains an artist named *Sam*. Now, consider three concurrent operations: `addAlbum(A1, Sam)`, which adds an album *A1* by *Sam*; `rmvArtist(Sam)`, which removes *Sam* from the database; and `updArtist(Sam)`, which updates *Sam*'s information. The operations are executed on replicas 1, 2, and 3, respectively. For simplicity, the figure depicts only two of the three replicas, showing their stable and current state. Replica 1 first executes `addAlbum(A1, Sam)`(denoted as `c1` in the graph), and then it receives the `rmvArtist(Sam)` operation. When the effect phase for `rmvArtist(Sam)` is triggered, replica 1 detects a conflict between the operation and the *block* issued by call `c1`. Consider that the conflict is resolved by removing `c2` from the graph (as the operation would be marked as a No-Op). When `updArtist(Sam)` is delivered to replica 1, it is added to the graph without conflict.

Let us turn our attention to the execution graph in replica 2. Consider that replica 2 executed the `rmvArtist(Sam)` operation, but its effect phase is only triggered after the effect phase of the two remote operations: `addAlbum(A1, Sam)` and `updArtist(Sam)`. First, `addAlbum(A1, Sam)` is processed and added to the graph (denoted as `c1`). Later `updArtist(Sam)` is also added (denoted as `c3`) as the operation does not conflict with `c1`. However, two conflicts arise when the effect phase of `rmvArtist(Sam)` is triggered. The *block*

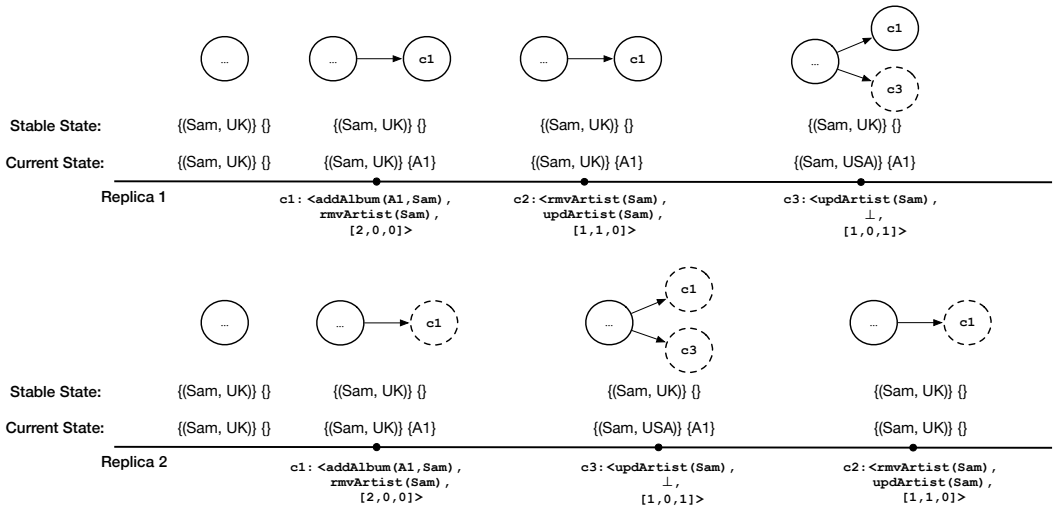

Figure 4 Convergence problems caused by removing No-Op operations from the graph before stabilisation.

on `updArtist(Sam)` issued by call `c3` leads to the removal of call `c2` from the graph. On the other hand, the *block* issued by `addAlbum(A1, Sam)` on `rmvArtist(Sam)` also results in call `c2` being removed from the graph. After executing the same set of operations, the state of the replicas diverges. The problem is that removing operations from the graph when marked as a No-Op before they are causally stable does not guarantee convergence. As such, our algorithm retains unstable No-Op operations in the graph. Maintaining these operations, along with comparing each operation against all its concurrent operations – including those already marked as No-Ops– ensures consistent conflict resolution and prevents divergence.

To optimise metadata storage in the graph, we can replace the operation marked as No-Op with null (i.e., store $\langle \perp, \textit{block}, \text{timestamp} \rangle$). This optimisation is possible because the only information required for a No-Op is the associated *block* operation and the timestamp to detect causal stability. Retaining the operation information is thus unnecessary since a No-Op does not affect the system state.

5 Applicability of the Solution

This section demonstrates how the No-Op framework supports the implementation of CRDTs (Section 5.1), enforces a wide variety of application invariants (Section 5.2), and enables the development of distributed geo-replicated applications such as the RUBiS system (Section 5.3).

The No-Op approach supports a wide range of conflict resolution policies, allowing flexibility in handling concurrent operations. Examples include operation-type-based policies, such as update-wins and delete-wins, where one type of operation takes precedence over the other. Additionally, it supports total-order-based policies, such as the last-writer-wins and first-writer-wins policies, which resolve conflicts based on a total order of operations. Finally, privilege-based policies can resolve conflicts based on criteria, such as user roles, giving precedence to operations initiated by higher-privileged users within the system. Besides these static policies, the framework supports state-dependent policies, where decisions are made based on the system's current state. Ultimately, our mechanism's generality allows programmers to define any policy expressible in terms of blocks.

All policies and mechanisms outlined in this section were implemented and verified using VeriFx. This confirms the correctness of our approach and demonstrates its practicality for

real-world applications.

5.1 CRDTs

Conflict-free Replicated Data Types (CRDTs) [40] are the most well-known class of RDTs. They automatically resolve conflicts by leveraging mathematical properties to ensure convergence by design. These data types can be classified into two categories: those with commutative operations, which naturally avoid conflicts, and those with non-commutative operations, which require conflict resolution policies.

Commutative data types inherently avoid convergence conflicts and do not require conflict resolution policies. Under causal delivery assumptions, if all operations are commutative, they can be applied directly to the state without needing an execution graph. Examples of such data types include the grow-only set [40] and the counter [40]. Since these data types are conflict-free, no operations become No-Ops, making them immediately causally stable and directly applicable to the stable state. In other words, these data types can be implemented as a sequential set and a sequential counter, respectively.

In contrast, non-commutative data types require embedding a conflict resolution policy within the data structure to prioritise specific operations when conflicts arise. These CRDTs leverage conflict resolution policies, making their implementation straightforward with the No-Op framework. For instance, to implement an add-wins set, the conflict resolution policy specifies that add operations take precedence over remove operations on the same element (cf. Section 4.1.1). During the prepare phase of an add operation, the No-Op framework generates a *block* on concurrent removes targeting the same element. As a result, those remove operations are transformed into No-Ops.

Overall, CRDTs typically rely on operation-type-based or total-order-based policies, both supported by the No-Op framework, allowing diverse CRDT implementations. We have implemented in our VeriFx implementation different registers, flags, counters, and sets.

5.2 Invariant Maintenance

This section describes how our model can enforce a wide variety of invariants, ranging from simple invariants on single objects to more complex invariants over multiple objects. To illustrate invariant's examples, we use the albums management system presented in Section 2.

5.2.1 Equality and Inequality of Attributes

Equality and inequality of attributes [4] restrict the values assigned to an attribute. In our running example, an example of attribute equality is defining that the *genre* of an album can only take predefined values, such as *"rock"*, *"pop"*, *"jazz"*, or *"classical"*. This invariant type does not generate conflicts between operations, not requiring any conflict resolution policy to enforce it. Since this invariant does not generate conflicts, it is trivially maintained within our framework without requiring any conflict resolution policy.

5.2.2 Uniqueness

Uniqueness [4, 7, 6] includes all constraints regarding attribute uniqueness and is commonly used to denote primary keys or identifiers. For instance, in our running example, requiring artist identifiers to be unique is a typical uniqueness invariant.

We can classify the identifiers into system-generated identifiers and user-chosen identifiers. In system-generated identifiers, we assume a mechanism that automatically generates them,

ensuring their uniqueness [7, 30]. By generating unique identifiers, the system guarantees that no conflicts related to identifier uniqueness will arise, eliminating the need for a policy to solve uniqueness conflicts. For user-chosen identifiers, two operations conflict if attempting to add distinct objects with the same identifier (insertions with different identifiers do not conflict). When n operations attempt to add different objects with the same identifier, $n-1$ operations need to be converted into No-Ops, allowing only one operation to be successfully executed, thereby preserving the invariant. Therefore, the No-Op approach can resolve these conflicts through a total-order-based policy. Each operation blocks all preceding operations, as determined by a total order (e.g., enforced by Lamport clocks), that attempt to add a different object with the same identifier. As a result, after processing the operations, the No-Op framework converts all but one into No-Ops, ensuring the invariant is preserved.

5.2.3 Referential Integrity

Referential integrity [4, 7, 6] defines dependency relationships between objects, with a parent object representing the referenced entity and a child object referencing the parent. In the context of the running example, a referential integrity constraint could ensure that albums by nonexistent artists cannot exist in the system.

Conflicts arise when an operation inserts or updates an object that references a parent object which has been concurrently deleted. To manage these conflicts without coordination, Antidote SQL [35] introduced two conflict resolution policies: update-wins and delete-wins. Under the update-wins policy, the conflict is resolved by keeping the parent object in the database. In contrast, the delete-wins policy resolves the conflict by removing both the parent object and the concurrently inserted or updated child.

Our model supports the implementation of both policies. In the update-wins policy, insert and update operations on child objects take precedence by blocking the parent deletion, rendering it a No-Op. In the delete-wins policy, the parent deletion takes precedence, blocking insert and update operations on child objects and transforming them into No-Ops.

Furthermore, our model enables the implementation of variations of these policies by simply adjusting how the operations are defined. Consider the update-wins policy. If the operation that deletes the parent object also removes its children, applying the policy would prevent both actions from being executed. As a result, after resolving the conflict, both the parent and its children remain in the database. In contrast, if the operation that deletes the parent first triggers a separate operation to delete its children, the outcome changes. Since deleting the children is an independent operation, it does not conflict with inserting a new child. As a result, the parent remains in the database, while the deleted children do not. This behaviour aligns with the update-wins semantics proposed in Antidote SQL.

5.2.4 Disjunctions

A disjunction invariant requires at least one of several conditions to be true. A violation occurs when all true predicates concurrently transition to false. Therefore, conflicting operations are the operations that transition a predicate from true to false.

Consider an extension to the album management system where each album can contain multiple tracks but must always include at least one. This version introduces two additional operations: adding a track to an album and removing a track from an album. Given this property, operations that remove different tracks conflict, as they may violate the invariant. For example, if an album initially contains two tracks and two operations attempt to remove them concurrently, the album would end up with no tracks, which breaks the invariant.

The disjunction invariant illustrates how issuing blocks based on the system's state can be beneficial. The remove track operation is self-conflicting, which makes it responsible

for triggering blocks. However, traditional policies, such as operation-type or total-order-based, are overly restrictive, limiting execution to at most one operation. Total-order-based policies allow only a single operation to proceed, while operation-based policies prevent all operations from executing, as self-conflicting operations block each other. However, enforcing a disjunction invariant only requires ensuring that at least one predicate remains true.

To address this, we propose a state-based policy where the *block* operation is issued based on the application's current state. This approach preserves the truth value of a predicate by transforming any operation that would transition it to false into a No-Op. By blocking all operations that would make the predicate false, the policy ensures that at least one predicate remains true, thereby maintaining the invariant.

In the example, the *block* operation would guarantee that a specific track could not be removed from an album. In this scenario, the *block* operation would block all operations that transition the predicate "track x is in album y" to false. Consequently, any operation that concurrently attempts to remove track x from album y would conflict with the *block* operation, as it alters the truth value of the blocked predicate. The conflicting remove operation would then become a No-Op.

The specification of such a state-based policy follows a similar approach to the LWW register shown in Section 4.1.1. The specification is provided in Appendix A in [12]. Assuming the application defines the predicate to be blocked and returns the selected predicate to the framework, the framework then issues blocks on all operations that would transition the predicate to false.

Issuing blocks based on the system's state enables the implementation of more fine-grained policies, reducing the number of conflicts. However, it is important to note that some operations may still be unnecessarily undone, depending on how the blocks are assigned. For instance, if the predicate to be blocked is chosen randomly, different operations may block multiple predicates, turning several operations into No-Ops. In contrast, if all operations attempt to block the same predicate, only the operations affecting that specific predicate are undone, minimising the number of No-Ops.

5.2.5 Numerical Invariants

Numerical invariants [4, 7, 6] are usually associated with attributes manipulated by increment or decrement operations, and where there must be some control over the values of the attribute since there is a lower or upper bound. An example of a numerical invariant is guaranteeing that a user's balance does not become negative.

Although the No-Op approach preserves numerical invariants, it can be overly restrictive. Due to the self-conflicting nature of the operations, they block each other and, in some cases, generate more No-Ops than necessary. Consider a counter with a lower bound of 0 and an initial value of 100. Decrements are inherently self-conflicting. Applying the No-Op approach would require decrements to trigger blocks on other decrements. If each decrement blocked another, none of the operations would execute, as the decrements would cancel each other out. Similarly, policies based on a total order would allow only one operation to succeed. For example, if five concurrent decrements of 10 units each were issued, only one decrement would be applied (e.g., the latter following the total order). This behaviour is overly restrictive, as executing all decrements would maintain the invariant and respect the lower bound.

To overcome this limitation, we propose integrating escrow techniques [36, 7, 8] into the model. These techniques enable replicas to pre-allocate permissions for executing future updates, ensuring constraints are maintained. For example, consider a counter $x = 2$ with the invariant $x \geq 0$. In this case, the counter can be decremented by up to two units without violating the invariant. This decrement capacity represents the available rights in the system,

which are distributed among replicas. In a system with three replicas, the rights could be allocated as follows: replica 1 and replica 2 each hold one right, while replica 3 has none. If a decrement operation is submitted to replica 1, it can safely execute as it acquires an available right, preserving the invariant. Conversely, if a decrement operation is submitted to replica 3, it is aborted due to the lack of rights.

If the system supports escrow mechanisms, the necessary rights for an operation would be acquired in advance during the prepare phase, ensuring that the operation can be safely executed across replicas. In other words, escrow techniques eliminate conflicts by converting conflicting operations into non-conflicting ones. As a result, operations that previously required conflict resolution policies can now be executed safely within our framework, as conflicts no longer arise. A bounded counter [8] can, therefore, be implemented as a sequential counter, eliminating the need for an execution graph, much like in commutative CRDTs.

5.2.6 Aggregation Constraints

Aggregation constraints [6] enable the establishment of limits on the size of collections or enumerable attributes. Since the counted objects are in the database, aggregation constraints can be expressed as a disjunction of predicates. For instance, the example provided for the disjunctions – the number of songs in an album must be greater than one – is also an example of an aggregation constraint, as this property restricts the size of a collection of tracks.

Aggregation constraints comprise both lower and upper bounds. In lower bounds, the operations that remove an element from the collection are self-conflicting. Therefore, blocks are triggered whenever an element is removed from the collection. The number of blocked operations depends on the specified limit. For example, if the limit is 1, removing an element from the collection triggers a *block* on operations that remove a specific element. If the limit is 2, removing an element must block the removal of two different elements. Therefore, it triggers blocks on operations that remove one of the two blocked elements.

Conversely, in upper bounds, the conflicting operations are the operations that insert elements into the collection. However, identifying which operations to block is challenging, as it would require preemptively blocking any potential insertion, including block insertion of elements that may not yet exist in the system. Since there is no mechanism to block specific, non-existent elements, the *block* must be generic, restricting all insert operations. This approach can be overly restrictive and shares the same limitations as those faced with numerical invariants. In the future, we plan to explore alternative strategies to reduce the number of blocked operations without relying on escrow techniques.

5.2.7 Linear Resources

Linear resources [7] are applied to partitionable objects/resources to ensure no overlap. For example, a linear resource can be applied to ensure that a seat on a plane is not booked by more than one person. This type of invariant functions similarly to uniqueness, allowing only one operation from a set of concurrent operations to succeed. Consequently, any policy based on a total order is well-suited for maintaining this type of invariant.

5.3 Real-World Example

Ensuring application correctness requires preserving all defined invariants throughout execution and guaranteeing that all replicas converge after applying the same operations. So far, we have demonstrated how the No-Op framework supports the development of CRDTs and enables the creation of data structures that automatically maintain invariants. In this section, we bring these concepts together to illustrate how the No-Op framework can be used

	registerUser(u_2, ...)	unregisterUser(u_2)	update(u_2, ...)	placeBid(a_2, u_2, b_2, ...)	closeAuction(a_2)
registerUser(u_1, ...)	$u_1 = u_2$				
unregisterUser(u_1)	✓	✓			
update(u_1, ...)	✓	$u_1 = u_2$	$u_1 = u_2$		
placeBid(a_1, u_1, b_1, ...)	✓	$u_1 = u_2$	✓	$a_1 = a_2 \wedge b_1 = b_2 \wedge u_1 \neq u_2$	
closeAuction(a_1)	✓	✓	✓	$a_1 = a_2$	✓

Figure 5 Analysis of conflicts for the RUBiS system. Convergence conflicts are shown in yellow, whereas invariant conflicts are shown in red.

for developing a real-world distributed application. To this end, we develop an eBay-like auction system akin to the RUBiS system [14].

RUBiS supports operations such as registering and unregistering users, updating user information, opening and closing auctions, and bidding on open auctions. Additionally, it allows for direct sales, with operations to list items for sale and to purchase items. Based on the supported operations, we define five key invariants for RUBiS:

- System-assigned identifiers must be unique.
- User-chosen nicknames must be unique.
- Item stock cannot be negative.
- Each bid on an open auction must be associated with an existing user.
- There cannot be two bids with the same value for the same auction from two users.

Figure 5 illustrates all considered conflicting operations and their potential conflicts. Read operations are excluded, as they are safe-commutative and do not modify the database. The operations `openAuction`, `sellItem`, and `storeBuyNow` were analysed but are not shown in the figure since they do not conflict with any other operation. In the figure, yellow rectangles represent convergence conflicts, while red rectangles indicate invariant conflicts. Additionally, the relevant attributes responsible for each conflict are specified. For instance, conflicts between two user registration operations occur only when both use the same identifier.

Our RUBiS implementation in VeriFx assumes the system operates with escrow techniques and that its identifier generation mechanism ensures unique identifiers. These mechanisms guarantee that system-assigned identifiers are unique and that the item stock remains non-negative. As a result, there are no conflicting operations concerning these two invariants.

Recall that the No-Op approach relies on programmer-defined conflict resolution policies to handle conflicts between operations. The framework applies these policies at runtime to trigger blocks, which are used to detect and resolve conflicts. In the remainder of this section, we describe the resolution policies chosen for each identified conflict in the RUBiS system.

We opted for the last-writer-wins policy to resolve the uniqueness conflict between two `registerUser` operations. Similarly, we applied this same policy to address the convergence conflict caused by two `updateUser` operations targeting the same user. In both cases, the conflicts stem from self-conflicting operations, and only one operation from a set of concurrent operations must be executed. Consequently, any total-order-based policy is appropriate for resolving these conflicts.

For the same reasons, the uniqueness conflict caused by two users placing bids of the same value can also be resolved using a total-order-based policy. However, in this case, we have defined a policy that prioritises users based on the number of bids they have won. Specifically, the user who has won more auctions takes priority. If both users have won the same number of auctions, the policy resolves the tie using a total order over the operations.

Conflicts between `unregisterUser` and `placeBid` operations, which affect referential integrity, can be resolved using any of the policies described in Section 2. In our VeriFx im-

plementation, we adopted the remove-wins policy. This decision aligns with the application's semantics, favouring the removal of the user and their associated bids over forcing the user to remain in the system, where they could win the auction.

In convergence conflicts between `closeAuction` and `placeBid`, we defined `closeAuction` as the winning operation. Prioritising `closeAuction` ensures the auction closes properly, avoiding inconsistencies such as reopening the auction due to a concurrent bid. If a `placeBid` operation is delivered late due to a failure, it could inadvertently reopen the auction long after it has been closed. By using this policy, we avoid these situations.

Finally, for conflicts involving `updateUser` and `unregisterUser` operations, we selected `updateUser` as the winning operation.

6 Discussion

This section examines the practical implications of the No-Op approach, including its applicability to different applications and the impact of poorly designed conflict resolution policies. Additionally, it explores the trade-off between optimisation and policy determinism.

6.1 When and How to Apply the No-Op Approach

The No-Op approach resolves conflicts by discarding operations, transforming them into no-side-effect operations. Each replica maintains its local view of the system and, using only local knowledge, determines which operations should be transformed into No-Ops to ensure convergence while preserving invariants.

The model may result in operations being discarded after a response has already been sent to the client. For example, consider the referential integrity conflict in Figure 2. Under an update-wins semantics, a client may initially observe an artist as removed but later find that the artist is still present. This occurs because the remove operation is transformed into a No-Op only after the concurrent update operation has been delivered and the conflict resolved. As some operations may be discarded after execution, this mechanism is unsuitable for applications that cannot tolerate such behaviour. Based on this, applications can be classified into two categories:

- **Applications that can handle reversals through compensation mechanisms.** These applications can use the framework alongside compensation mechanisms [20, 44]. When an operation is transformed into a No-Op, the system can trigger a compensation action to maintain consistency.
- **Applications that do not support operation reversals.** These applications require strong consistency and cannot operate under weak consistency models, making coordination the only viable solution.

Many conflict resolution policies prioritise certain operations over others. For example, in the last-writer-wins policy, after applying all updates, the *oldest* update does not affect the system's state, which is similar to transforming it into a No-Op. By explicitly transforming an operation into a No-Op, our approach has the advantage of clearly identifying the operations with no side-effect, making it easier to integrate a recovery or notification mechanism, such as the mentioned compensations.

In some cases, only a specific pair of operations may not support reversals, while all other conflicting pairs do. For example, in the RUBiS scenario, a programmer may believe that their application does not support reversals on `placeBid` and `closeAuction`, meaning neither operation can be transformed into No-Ops. In this case, they may opt for coordination to handle these operations [30]. However, using coordination to prevent the concurrent

execution of operations that cannot be transformed into a No-Op does not preclude applying the No-Op approach to resolve other conflicts within the application. In such scenarios, the No-Op framework can be augmented with strong consistency mechanisms without affecting the rest of the system. For example, coordination could be implemented using locks, ensuring their correctness while allowing the remaining operations in the application to continue following the No-Op framework. This hybrid approach maintains efficiency while addressing specific consistency requirements where necessary.

6.2 Challenges with Poorly Designed Conflict Resolution Policies

Although the No-Op approach is coordination-free, it may sometimes mark operations as No-Ops unnecessarily. This issue can arise for different reasons. Sometimes, the model is overly restrictive for specific invariants, such as numerical invariants (cf. Section 5.2.5). In others, it may stem from the design of the conflict resolution policies implemented by the programmer. This section examines how poorly designed policies can increase the number of No-Ops and explores strategies to identify policy definition improvements.

To illustrate how poorly designed conflict resolution policies can lead to unnecessary No-Ops, let us revisit the example in Figure 4. Consider that the programmer specifies that `addAlbum` wins in conflicts with `rmvArtist`. In turn, `rmvArtist` wins in conflicts with `updArtist`. When `addAlbum`, `rmvArtist`, and `updArtist` are executed concurrently, the algorithm marks both `rmvArtist` and `updArtist` as No-Ops. As a result, fewer concurrent operations can be executed, impacting performance. However, defining `rmvArtist` as the losing operation in both cases solves the conflicts and ensures that only one of the three operations becomes a No-Op. Redefining the conflict resolution policies can thus improve performance without compromising the application's correctness.

Poorly designed conflict resolution policies could, however, lead to more severe issues hindering the overall system progress. For example, operation op_1 marks operation op_2 as a No-Op, operation op_2 marks operation op_3 as a No-Op, and operation op_3, in turn, marks operation op_1 as a No-Op. While this circular dependency does not compromise correctness, it causes all conflicting operations to be marked as No-Ops, hampering progress.

A policy graph provides a systematic way to identify and address those issues. In a policy graph, vertices represent conflicting operations, while edges show how conflicts are resolved. Long path lengths in the graph highlight scenarios where an excessive number of operations are unnecessarily marked as No-Ops. Meanwhile, cycles in the graph indicate circular dependencies. Therefore, programmers should define conflict resolution policies that ensure a cycle-free policy graph while minimising path lengths to reduce inefficiencies. In future work, we plan to explore an automated analysis tool that generates and analyses the policy graph based on programmer-defined conflict resolution policies. This tool will provide feedback, guiding developers to the policies that can be refined to enhance performance.

6.3 Optimisation for Deterministic Resolution

The correctness of our model, described in Algorithms 1 and 2, does not depend on the deterministic nature of conflict resolution policies. The policies only determine how blocks are triggered. If a policy is non-deterministic, two replicas in the same state executing the same operation may generate different blocks. However, since blocks are generated locally during the prepare phase, they are triggered only once per operation, ensuring their assignment remains deterministic. For example, consider a policy that resolves conflicts by randomly selecting an operation to be transformed into a No-Op. In this case, the blocked operation is

chosen randomly during the prepare phase. However, since the prepare phase is executed only by the local replica, the same *block* assignment is propagated to all remote replicas. During the effect phase, each delivered operation is compared against all its concurrent operation calls, including those already marked as No-Ops. As a result, all replicas process blocks uniformly, ensuring No-Ops converge. Therefore, by design, the No-Op approach ensures that replicas processing the same operations produce identical No-Op sets. This is achieved through the block abstraction, which guarantees that conflicts are resolved deterministically regardless of policy non-determinism.

When implementing the model, the creation of blocks could be optimised. Rather than creating the *block* when an operation is submitted (in the prepare phase), it is possible to simply perform the effect of blocks – transform concurrent conflicting operations into No-Ops according to the policy – upon detecting a conflict when an operation is delivered (in the effect phase). This optimisation reduces the amount of metadata that must be broadcast over the network and minimises the data stored in the graph, as blocks are no longer appended to operations.

Note that this optimisation is only applicable to deterministic conflict resolution policies. Since the policy is applied directly during the effect phase, a non-deterministic policy could lead to divergence, as different replicas may resolve conflicts inconsistently. Consider again the policy that resolves conflicts by randomly transforming an operation into a No-Op. In this case, two replicas processing the same conflict could make different decisions, resulting in divergent execution graphs. Another example is state-dependent policies, which issue blocks based on the application's current state.

Optimising the model comes at the cost of imposing stronger assumptions on the conflict resolution policies. While this optimisation reduces metadata overhead and storage costs by eliminating blocks, it requires deterministic conflict resolution to ensure convergence. In contrast, the original model allows for greater flexibility in defining policies, including non-deterministic ones, at the cost of maintaining extra metadata. If the optimised version is adopted, the verification step should verify whether the resolution policies are deterministic.

7 Related Work

Ensuring correctness in applications built on weakly consistent storage is an active research area, with two core challenges: achieving state convergence across replicas and preserving application invariants. Traditional replicated data types (RDTs) [40, 13, 26, 9] provide a principled, coordination-free approach to ensure replicas converge to the same state after executing the same operations. However, these data types are typically hand-crafted for specific use cases. In contrast, our framework offers a unified approach that can be applied consistently to implement different policies. Pure operation-based CRDTs [9] also maintain a graph of operations, encoding conflict resolution in the read operations. Our approach differs fundamentally by resolving conflicts during the write operations. While these approaches for building RDTs guarantee convergence, they do not address invariant maintenance.

The remainder of this section reviews methods for enforcing invariants, classifying them into coordination-based, reservation-based, and coordination-free approaches, and examines their characteristics and trade-offs.

Coordination-based approaches. Coordination-based approaches rely on synchronisation to prevent operations from violating invariants. As described in [4], invariant confluence provides a necessary and sufficient condition for determining whether invariants can be maintained under concurrent operations. This principle identifies the operations requiring coordination: non-$\mathcal{I}$-confluent operations. Several techniques aim to minimise the level

of coordination required. Lucy [46] achieves this by segmenting the state space and restricting transactions within each segment, ensuring each segment becomes $\mathcal{I}$-confluent. Similarly, Blazes [3] identifies locations needing coordination and automatically synthesises application-specific coordination code to reduce synchronisation overhead. Other approaches focus on generating replicated objects that inherently maintain invariants. For instance, Hamsaz [24] and Hampa [32] automatically synthesise replicated objects by coordinating unsafe operations. CISE [21] provides an automated proof rule to verify whether invariants are preserved on replicated databases under a given replication protocol. To ensure invariant safety, CISE coordinates conflicting operations. Quelea [42] determines the weakest consistency model that upholds invariants by statically analysing contracts to assign the most efficient and sound consistency level to each operation. Similarly, Q9 [25] identifies the weakest consistency model needed to prevent invariant violations. Indigo [7] gives programmers more control by allowing them to either coordinate unsafe operations or automatically repair invariants post-facto. It also introduces a multi-level mask reservation mechanism, using fine-grained locking to prevent specific conflicting operations. ECROs [18] reduce synchronisation by reordering conflicting operations, but it still relies on coordination when reordering is impossible. LoRe [22] automatically verifies developer-supplied safety properties for local-first applications, resolving invariant violations due to concurrency by adding coordination logic as needed. Coordination-based approaches optimise synchronisation but remain conservative, since they still rely on coordination to uphold invariants. In contrast, we propose a coordination-free alternative with the No-Op approach, which eliminates the need for synchronisation entirely, offering a novel and efficient solution for maintaining consistency in replicated systems.

Reservation-based approaches. Reservation-based approaches [36, 8, 7, 33, 38, 41] reduce coordination costs by moving synchronisation outside the execution path of operations. By reserving the rights to perform specific operations in advance, replicas can execute operations safely without requiring immediate coordination. However, these mechanisms assume the necessary rights are available at the local replica. Otherwise, coordination is needed to acquire rights from other replicas or operations are aborted. Escrow transactions [36] apply this concept to enforce numerical invariants. The difference between the current value of a numerical variable and its bound determines the number of rights distributed among replicas. The bounded counter CRDT [8] builds on escrow transactions by implementing this mechanism asynchronously to uphold numerical invariants. Partition lock reservation [7] extends these ideas to enforce linear resource constraints. It allows replicas to reserve rights over non-overlapping value intervals, enabling operations within these intervals to execute locally without coordination. However, operations that require values outside the reserved intervals must synchronise with other replicas. Although these mechanisms maximise concurrency for operations that might otherwise violate invariants, they still rely on locks or coordination when local rights are exhausted. In our work, we incorporate escrow techniques specifically for numerical invariants, as the No-Op approach can be overly conservative in such cases. By pre-allocating execution rights, replicas can safely execute concurrent operations without unnecessary No-Ops, ensuring safety. This integration reduces the constraints of the No-Op model for numerical invariants while preserving its coordination-free nature for other invariants.

Coordination-free approaches. Coordination-free approaches maintain invariants by transforming non-$\mathcal{I}$-confluent operations into $\mathcal{I}$-confluent operations. Existing approaches, as well as our approach, do so by introducing conflict resolution mechanisms. IPA [6] resolves conflicts by extending conflicting operations with updates that ensure invariant preservation. It leverages static analysis to identify conflicts and suggests to programmers conflict

resolution policies, enabling them to choose the policy that best suits their application. Compared to IPA, our No-Op approach introduces two key differences. First, while IPA resolves conflicts by adding updates, our approach discards conflicting operations. Second, IPA relies on CRDTs for convergence, whereas our approach natively supports convergence and invariant preservation without additional structures. Antidote SQL [35] enforces referential integrity through resolution policies. However, these policies are limited to referential integrity and cannot be extended to other invariants. In contrast, as shown in Section 5.2, our approach provides broader applicability, enabling the preservation of a wider range of invariants.

8 Conclusion

This paper introduced a coordination-free consistency framework that unifies data convergence and invariant preservation through the novel No-Op approach. Conflicts are resolved by designating one operation in each conflict as a no-side-effect operation. By transforming non-preferred operations into no-side-effect operations, the No-Op approach ensures consistency and safety across all replicas even under concurrent updates, as established by formal proofs. To the best of our knowledge, this is the first unified approach that ensures strong convergence and invariant preservation while eliminating the need for synchronisation.

Our approach allows programmers to define custom conflict resolution policies tailored to the specific semantics of their applications. Additionally, it eliminates the need to design and implement new data structures to support these policies, thereby simplifying the development of highly available distributed systems. We implemented the framework in the VeriFx programming language to demonstrate its practicality, leveraging its automated proof engine to validate each data-type implementation. This implementation confirmed the manual proofs of our approach, bridging the gap between theoretical guarantees of consistency and real-world applicability. Additionally, we showcased its ability to encode popular CRDTs and enforce a wide range of invariants, including referential integrity. Finally, we demonstrate our approach for developing real-world applications, such as the geo-distributed RUBiS system.

While the No-Op approach is coordination-free, it can sometimes unnecessarily transform operations into No-Ops. To address this challenge, we propose to integrate escrow techniques to minimise superfluous No-Ops and leverage policy graphs to identify inefficiencies.

Compositional Bug Detection for Internally Unsafe Libraries

A Logical Approach to Type Unsoundness

Pedro Carrott
Imperial College London, UK

Sacha-Élie Ayoun
Imperial College London, UK

Azalea Raad
Imperial College London, UK

Abstract

Rust is a modern programming language marrying the best of language design by offering fine-grained control over system resources (thus enabling efficient implementations), while simultaneously ensuring memory safety and data-race freedom. However, ensuring type safety in *internally unsafe* libraries remains an important and non-trivial challenge, where unsafe features enable low-level control but can introduce undefined behaviour (UB). Existing works on reasoning about unsafe code either use *verification* techniques to show *correctness* (i.e. safety, useful only when the unsafe code is indeed correct), or use *bug detection* techniques to show *incorrectness* (i.e. unsafety) but fail to do so *automatically* (to avoid developer burden), *compositionally* (to support libraries without a main function), *soundly* (without false positives) and *generally* (rather than applying to specific patterns).

We close this gap by developing RUXt, a *fully automatic*, *compositional* bug detection technique for detecting UB in internally unsafe Rust libraries with a formal *inadequacy* theorem (formalised and proven in Rocq) providing a *no-false-positives guarantee*. RUXt leverages the Rust type system to under-approximate the set of safe values for user-defined types and detect safety violations without requiring manual annotations by the user. By encoding well-typed values in Rust as separation logic assertions, RUXt enables compositional reasoning about types to refute unsound type signatures and detect UB. The inadequacy theorem of RUXt ensures that each UB detected by RUXt in an internally unsafe library is a true safety violation that can be triggered by a *safe* program, i.e. one that solely interacts with the safe API of the library. To this end, when RUXt identifies a UB, it additionally produces a *safe program* witnessing the UB. In addition, we develop a prototype implementation in OCaml that can analyse programs written in a small model of Rust, and apply it to several case studies, showcasing its ability to detect true safety violations.

2012 ACM Subject Classification Theory of computation → Program analysis; Theory of computation → Separation logic; Theory of computation → Programming logic; Theory of computation → Automated reasoning; Theory of computation → Program specifications; Software and its engineering → General programming languages

1 Introduction

Programming languages such as C and C++ provide developers with fine-grained control over system resources, thereby enabling efficient implementations, albeit at the cost of *safety*. By contrast, modern languages prioritise safety through high-level abstractions, compromising on low-level control. A long-standing goal in programming language design has been to bridge this divide and create a language that delivers both safety features and control over system resources. The Rust language [27] is the most significant industrial effort toward achieving this goal to date. Rust enables zero-cost abstractions for common systems programming patterns and operates without relying on a garbage collector. Moreover, Rust offers the safety features of high-level languages, ensuring *memory safety* and *data-race freedom*, thus guaranteeing the absence of *undefined behaviours* (UB).

To do this, Rust uses an ownership-based type system, enforcing a strict discipline that prevents mutation of aliased data. This discipline, *enforced statically* at compile time, ensures the absence of UB in Rust programs. Unfortunately, the Rust type system can be overly conservative at times, making it too restrictive to implement basic low-level data structures such as `Vec`, or synchronisation mechanisms such as `Mutex`. To circumvent this, Rust provides *unsafe* blocks and functions that unlock "unsafe superpowers" to bypass the Rust compiler's safety checks. Using unsafe code, developers can implement, for instance, the aforementioned `Vec` data structure, providing a *safe encapsulation* of the unsafe code. That is, using the safe `Vec` API, developers should not be able to trigger any undefined behaviour.

Effectively, defining such an *internally unsafe* data structure *extends* the Rust type system with a new type whose safety is not monitored by the compiler. That is, while the compiler *enforces* the safety guarantees for safe code, in the case of internally unsafe code it simply *assumes* them to hold, and the onus is on the library developer to ensure their safety.

Ensuring the above, however, is error-prone and far from straightforward, as evidenced by the subtle bugs discovered in the literature [3, 4, 17]. This underlines the need for formal methods and rigorous techniques for reasoning about unsafe code. Indeed, there has been a large body of work on reasoning about unsafe code, falling into one of two main categories (see §7 for a comprehensive discussion): **(i)** *verification* techniques aimed at showing the *correctness* (safety) of unsafe code [10, 1, 7, 23]; or **(ii)** *bug detection* techniques aimed at showing the *incorrectness* (unsafety) of unsafe code [2, 35, 5]. Specifically, the approaches in i are useful when the unsafe code under consideration is correct and they guarantee the absence of *false negatives* (i.e. missed bugs). However, they require extensive annotation efforts from the user, they simply fail when the code is indeed unsafe, and they cannot be used to identify the causes of safety violations. By contrast, the approaches in ii focus on detecting the sources of safety violations.

A bug detection technique (in category ii) should *ideally* (1) be *fully automatic* ("push-button") and require no user input or annotations – this ensures that the technique can be used out of the box, without imposing a learning curve on the user or requiring a background in formal methods; (2) only detect *true positives* (genuine safety violations) without any *false positives* (spurious reports of safety violations); (3) be applicable to a wide range of scenarios rather than specific patterns; and (4) be *compositional* (i.e. support analysing incomplete programs rather than accepting only full programs with a main function) to ensure its scalability and thus wide applicability to large codebases.

Unfortunately, however, no existing bug detection technique meets all above criteria. Specifically, Rudra [2], Kani [35] and TraitInv [5] all suffer from false positives. Moreover, while Rudra and TraitInv are automatic, Kani is *not automatic* and relies on *user-supplied sym-*

bolic tests for checking the desired properties. It only supports first-order, non-compositional properties (i.e. not ownership properties) and cannot reason about type safety. On the other hand, Rudra and TraitInv have limited applicability: Rudra uses linter-like *heuristics* to detect three specific patterns that are *likely* to be safety violations, while TraitInv can only detect violations of simple, first-order properties in the implementations of six standard *traits*, e.g. that a partial equality function is transitive and symmetric.

Our approach: RUXt. Our main contribution bridges this gap: RUXt is a *fully automatic*, *compositional* tool for detecting UB in (internally unsafe) Rust libraries, accompanied by a formal *true-positives* theorem proven in Rocq, guaranteeing that all reported UB are true safety violations.

To do this, we leverage the Rust type system: the type signature of a Rust function *is* indeed a safety specification/annotation provided by the developer (in contrast to type annotations in languages such as C). To this end, we draw inspiration from the semantic model of Rust types as formalised in RustBelt [19]. Specifically, we focus on RUXtBelt, a large fragment of the RustBelt model, enhanced with a clear account of errors necessary for bug detection. As in RustBelt, references in RUXtBelt do not have a different semantics from raw pointers, allowing us to maintain a simple formalism by avoiding special aliasing semantics such as Stacked Borrows [18] or Tree Borrows [37]. As our focus here is bug detection rather than verification, we can safely forgo such semantics, at the cost of missing some safety violations, without compromising on our true-positives result.

As in RustBelt, in RUXtBelt we use *separation logic* [14] and represent well-typed values as resources, enabling *compositional* reasoning about types. This way, given a library that introduces a new type `T`, we can reason about it in isolation and independently of a concrete client by considering only the `T` *type space*, namely the set of all allowed (safe) values in `T`. To ensure type soundness, the `T` type space *disallows* values that lead to UB, and we can find such UB by solving a *reachability* problem: we can explore the `T` type space to show that a set of values modeled by a separation logic assertion are reachable only through *safe* code. Specifically, given a function `fn f(x: U) -> T`, all values reachable by executing `f` *must* belong to the `T` type space, as long as the input belongs to the `U` type space. On the other hand, if we can show that UB is reachable using inputs that *must* belong to the `U` type space, then we have found a safety violation. By iteratively exploring and enlarging our knowledge of the type spaces through symbolically executing functions from the library, we can reliably detect type safety bugs fully automatically.

Our reachability analysis introduces the notion of *type subvariants*, namely a *subset* of the `T` type space, thus *under-approximating* the `T` type space. We obtain this under-approximation by leveraging *incorrectness separation logic* (ISL) [29, 31] to derive reachable values and infer type subvariants. We thus develop RISL (Rust incorrectness separation logic, pronounced *rizzle*), a compositional program logic for detecting UB and show that it is *sound* against our RUXtBelt model. RISL is inspired by ISL and similarly enjoys a *true-positives* theorem, meaning that all type safety bugs found by RISL are indeed true safety violations.

We then develop RUXt as a symbolic execution engine that operates on RISL assertions. RUXt automates the process of deriving RISL triples (and thus detecting UB). We prove that RUXt enjoys a *no-false-positives* guarantee through our *inadequacy theorem*: every UB found is a true type unsoundness in the library. That is, when RUXt detects UB, it guarantees that it is possible to construct a trace of safe calls to the library witnessing the UB. This is a direct consequence of *under-approximating* type spaces.

```rust
struct Even { val: i32 }

fn zero() -> Even {
    Even { val: 0 }
}
unsafe fn succ(x: Even) -> Even {
    Even { val: x.val + 1 }
}
fn next(x: Even) -> Even {
    unsafe { succ(succ(x)) }
}
fn noop(x: Even) -> () {
    if x.val % 2 != 0 {
        unsafe { *(0 as *mut i32) = 1 }
    }
}
```

```c
typedef struct { int val } Even;

Even zero() {
    return (Even){.val = 0};
}
Even succ(Even x) {
    return (Even){.val = x.val + 1};
}
Even next(Even x) {
    return succ(succ(x));
}
void noop(Even x) {
    if (x.val % 2 != 0) {
        *((int *)0) = 1;
    }
}
```

Figure 1 Library for the `Even` type implemented in Rust (left), alongside its C analogue (right).

The underlying theory behind RUXt and the proofs of all our theorems are fully mechanised in Rocq. We also develop a prototype implementation of RUXt in OCaml, and we conduct three small case studies, showing that it can detect subtle safety violations resulting from the interaction of several independently-safe functions of a library.

Outline. The rest of this article is organised as follows. We present an intuitive account of our contributions in §2. In §3 we describe the RUXt algorithm and our prototype implementation in OCaml, and provide an informal argument for why every UB detected by RUXt is indeed a safety violation that can always be triggered. In §4 we present several examples of UB found by RUXt. In §5 we describe our RISL logic for detecting UB. In §6 we present our RUXtBelt model, show that RISL is sound with respect to RUXtBelt and then present our inadequacy theorem *formally* showing that RUXt enjoys a guarantee of no false positives. Finally, we discuss related work and conclude in §7.

2 Overview

We present an intuitive account of our contributions through an example inspired by a case study from RefinedRust [10], as shown in Fig. 1 (left). We define a new type in Rust, `Even`, as an abstraction of even integers, along with a *safe* API for interacting with values of this type. We discuss the specificities and challenges of creating safe abstractions in Rust by showing an analogous C implementation of `Even` and highlighting the differences. Using this illustrative example, we first explain *why* Rust enables the detection of a new class of bugs, thanks to its more expressive type system, and then demonstrate *how* we can leverage Rust types to detect such bugs automatically.

2.1 Type Safety Bugs

We implement the `Even` type as a `struct` encapsulating an `i32` value (a 32-bit integer) in the `val` field. We also implement a library for interacting with `Even` through an API comprising three *safe* functions: (1) `zero` encapsulates 0 as the base value for `Even` and returns it; given an `Even` value, (2) `next` returns a new `Even` value encapsulating the next even integer, and

(3) `noop` writes to an arbitrary pointer if the encapsulated integer is odd. The `zero` and `next` functions encode constructors for well-formed `Even` values: every `Even` value they return encapsulates an integer that is guaranteed to be even. As a result, `noop` effectively performs no operations on safe inputs: the encapsulated integer is never odd by construction. Were this not the case, the function would attempt to write to an arbitrary memory address, resulting in undefined behaviour (UB). Note that `noop` is typed as a *safe* function, even though it is implemented with *unsafe* code; the `unsafe` block is needed as manipulating raw pointers is, in general, unsafe. In this example, however, our usage of unsafe features is safely encapsulated by ensuring that we never perform the unsafe write operation for safe inputs and thus we never observe UB.

The library implementation also includes the `succ` function which we have not yet mentioned. Given an `Even` value as input, `succ` increments the encapsulated integer and returns the result as a value of type `Even`. This behaviour clearly breaks the "evenness" abstraction that we desire for `Even`, and thus `succ` is marked as unsafe. This unsafe function is only used as an auxiliary function in the implementation of `next`, where it is called twice within an unsafe block, ensuring that its usage is safely encapsulated. Although `succ` itself does not contain any unsafe code, it allows odd integers to be encapsulated as `Even` values, breaking the requirements for the safety of `noop`. Therefore, defining `succ` as a safe function invalidates the safety of `noop`, meaning that both functions *cannot co-exist* as safe functions for the library to be *type-safe*.

By maintaining this boundary between safe and unsafe code, one can extend the language with new types that carry rich information besides structural layouts. For instance, `noop` restricts the `val` field of `Even` values to be even, since this is the only way of ensuring `noop` is safe. In C, this kind of information is unattainable as usage of unsafe features is unrestricted and thus safety cannot be expressed programmatically. The C analogue of our Rust library in Fig. 1 (right) exemplifies this: in `noop` the unsafe write is no longer wrapped in an unsafe block. Since we cannot distinguish safe functions from unsafe ones in C, one could assume that all functions are safe by default and apply the same reasoning as in Rust, but we have already shown that `succ` and `noop` cannot be simultaneously safe. Therefore, one must assume that all C functions are unsafe by default, meaning that we cannot leverage the type of `noop` to obtain information about the `Even` type.

Effectively, type signatures in Rust, including the `unsafe` keyword, are *specifications* written by the developer. In particular, safe functions guarantee the *absence* of UB for safe inputs, and we can invalidate such a specification by showing the *presence* of UB for such inputs, hence showing that the library violates safety. Functions such as `noop` and `succ` (if both are declared safe) constitute such a safety violation. Naturally, we refer to these as *type safety bugs*. These bugs are not detectable in C: unlike in Rust, analysis tools can only rely on the structural layout of data and not on the implicit *meaning* that programmers attribute to their programs.

2.2 Finding Real Bugs in Rust Libraries

The state-of-the-art Infer:Pulse analyser [31, 24] classifies memory safety bugs into two categories: (1) **manifest:** a bug that occurs in all calling contexts; and (2) **latent:** a bug that occurs only in specific calling contexts. Infer:Pulse always reports manifest bugs as they are *context-independent*: if a function *always* exhibits UB, then it is not safe to include it in a library. By contrast, a latent bug is only reported if the calling context that triggers it is reachable from a program entry point, e.g. the `main` function. In other words, Infer:Pulse cannot report *context-dependent* bugs as real bugs in libraries, relying on specific codebases to report real bugs that are latent.

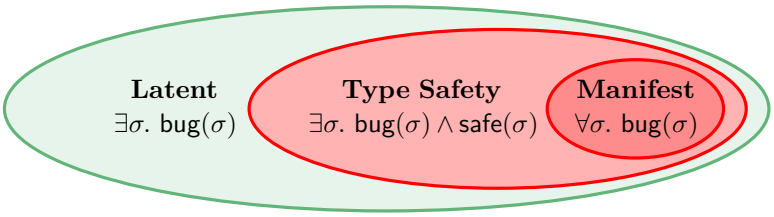

Figure 2 Taxonomy of bug categories. The variable σ represents a calling context, where $\mathsf{bug}(\sigma)$ expresses that UB is observable in σ and $\mathsf{safe}(\sigma)$ expresses that σ is obtained solely from safe code. Every type safety bug is a latent bug. Every manifest bug is a type safety bug: if every context triggers a bug, then the bug occurs in both safe and unsafe contexts. Manifest and type safety bugs are highlighted in red as they are always true bugs, in contrast to latent bugs.

We show that, in Rust, context-dependent bugs can be reported as real bugs as long as we restrict the conditions on calling contexts. In particular, type safety bugs are a class of context-dependent bugs where the calling context is obtained by executing only safe code, *including calls to internally unsafe functions*. For example, by making `succ` safe, we can construct an apparently safe program that encapsulates an odd integer as an `Even` value, resulting in a context where `noop` exhibits UB. Although this type safety bug could be reported as a real bug in the Rust implementation, Infer:Pulse would merely identify it as a latent bug in the C analogue. That is, as type safety is not expressible in C, it is impossible to restrict the calling context as in Rust.

As illustrated in Fig. 2, reasoning about type safety allows us to report more bugs: certain bugs that would be dismissed as latent in C can be reported as type safety bugs in Rust. Indeed, it is possible to detect *strictly more* real bugs than what Infer:Pulse currently reports, since every manifest bug is also a type safety bug. This opens the door to a new realm of analysis techniques for sound bug detection, which is the main contribution of our work.

2.3 Reasoning about Type Safety

Type safety, also known as *type soundness*, is a fundamental property of safe programming languages: well-typed programs (i.e. programs that type-check) will always exhibit well-defined behaviour (no UB). Conversely, one can think of a type safety bug as *type unsoundness*.

The RustBelt project [19] provided a semantic model of Rust types, mechanising and proving the type soundness of the *safe* fragments of Rust (which can be syntactically type-checked). RustBelt further provides a framework for *verifying the type soundness* of internally unsafe libraries (these are not covered by the type soundness proof), provided of course that they are indeed sound. While we focus on *detecting type unsoundness* in internally unsafe libraries, we introduce one of the main ideas behind RustBelt, from which we draw inspiration: *separation logic invariants* [14].

Safe values in RustBelt are interpreted as resources in separation logic, enabling *compositional* reasoning about types. This means that given a library that introduces a new type, we can reason about it in isolation and independently of a concrete client. To ensure type soundness is preserved when introducing a new type, RustBelt relies on user-defined *type invariants* that *over-approximate* the set of allowed values for a given type, which we refer to as *type spaces*. That is, while type spaces define the *exact* set of values inhabiting a given type, type invariants over-approximate types and thus a type invariant is a superset of its associated type space, as illustrated in Fig. 3. Hereafter, we refer to a value in a type space as a *safe value*. Type soundness guarantees that a safe program moves between safe values in

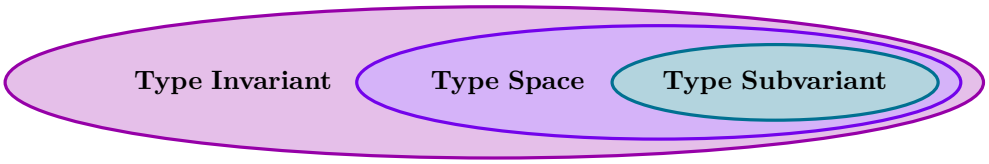

Figure 3 Type spaces represent the *exact* set of safe values of a given type; type invariants *over-approximate* type spaces; type subvariants *under-approximate* type spaces.

type spaces. For example, since the `zero` function is safe, its output must necessarily belong to the `Even` type space. Similarly, given a value in the `Even` type space as input, the `next` function produces another value in the `Even` type space. That is, as both `zero` and `next` are safe functions, every even integer must inhabit the `Even` type space.

2.4 A Logical Approach to Type Unsoundness

We present RUXt, a *compositional*, *fully automated* analysis algorithm and tool for detecting *type safety bugs* in (internally unsafe) Rust libraries. RUXt does not require explicit definitions of type invariants from the user. Instead, it reduces the problem of detecting type unsoundness to a reachability problem. By leveraging type signatures and incorrectness separation logic [31], it automatically infers a set of safely reachable values for each type. The set of reachable values detected by our analysis constitutes an *under-approximation* of the type space, which we call a *type subvariant*. Specifically, we grow type subvariants by iteratively performing under-approximate compositional symbolic execution (à la Infer:Pulse [24] or Gillian [25]) on the library functions. In turn, if the function `f(x: T)` can reach UB from an input `x` that belongs to a subvariant of `T`, then the library must be type-unsound. The relation between type spaces, type invariants and type subvariants is represented pictorially in Fig. 3.

Importantly, RUXt enjoys a guarantee of *no false positives*: every bug found corresponds to a true type unsoundness in the library. That is, when RUXt detects UB, it guarantees that it is possible to construct a trace of syntactically-safe calls to the library witnessing the UB. Furthermore, exploring type spaces is drastically more efficient than exploring the space of all possible *traces*, as we only need to find the safe *values*; that is, while many traces may construct the same safe value, we can mitigate repeated work using each safe value only once as an input to a function execution.

RUXt's symbolic execution engine is based on the set of proof rules that we define for RISL, our incorrectness separation logic for Rust, underpinned by our model of Rust (RUXtBelt), presented in §5. RISL allows us to derive an under-approximate postcondition for each safe function, given initial type subvariants for each of its inputs. In turn, we can use these postconditions to grow the type subvariants for the output types of the functions.

For instance, take the `Even` library defined in Fig. 1 (left). We demonstrate how RUXt can detect type unsoundness by describing the analysis step by step. Remember that the unsoundness arises when the `succ` function is marked as safe.

1. Initially, the subvariant for the `Even` type is empty (no safe values are known).
2. Because `next`, `noop`, and `succ` receive `Even` values as input, we cannot symbolically execute them without first inferring a non-empty subvariant for `Even`. However, `zero` does not require any input, and we can therefore symbolically execute starting from the `emp` assertion, capturing an empty heap (executing `zero` should not need any resources). We can then immediately infer that the output `Even { val: 0 }` must be a safe value, and we thus add it to our subvariant for `Even`.

3. We now have a non-empty subvariant for `Even` and can symbolically execute `next` from this subvariant, learning that the value `Even { val: 2 }` is also safe. Our newly-grown subvariant contains both `Even { val: 0 }` and `Even { val: 2 }`.
4. If we now symbolically execute `succ` from this subvariant, we learn that the values `Even { val: 1 }` and `Even { val: 3 }` are also safe.
5. Finally, if we symbolically execute `noop` from this subvariant, we can detect UB when dereferencing a null-like pointer, as the `Even` type space now includes non-even values.

As soon as we perform the last step and detect the UB, we can report the type unsoundness in the library, with a guarantee that the bug is real and can be triggered by a syntactically-safe program. Specifically, RUXt returns the following program as a *witness* of the UB:

```
fn exhibit_ub() {
    let x = {
        let x = {
            zero()  // witness of Even { val : 0 }
        };
        succ(x)  // witness of Even { val : 1 }
    };
    noop(x);  // witness of UB
}
```

If, however, the `succ` function is correctly marked as unsafe, our analysis does not use it to grow the subvariant for `Even` and never learns that the `Even` type space contains non-even values. In this case, the library is sound, and we do not report any type unsoundness.

Note that, in this case, we would provide a notion of *fuel* to RUXt to prevent it from looping indefinitely, capping its number of iterations. In general, doing so is always sound: in the worst case we fail to detect bugs, but we would never report false positives.

3 RUXt: A Compositional Analysis for Type Safety Refutation

We present our algorithm for compositionally and automatically detecting type unsoundness in internally unsafe Rust libraries. To this end, we introduce the RUXt programming language (§3.1), formally describe type spaces and subvariants (§3.2) and present the RUXt algorithm and discuss our prototype implementation in OCaml (§3.3).

3.1 RUXt Programming Language

Our programming language, λ_{RUXt}, is inspired by those of both RustBelt (λ_{Rust} [19]) and ISL [31]. We consider a heap-manipulating *expression* language in the style of λ_{Rust}, similar to the *command* language in ISL.

$$
\begin{array}{l}
\textsc{Term} \ni t ::= v \mid x \in \textsc{Var} \qquad \textsc{Val} \ni v ::= z \in \mathbb{Z} \mid b \in \mathbb{B} \mid l \in \textsc{Loc} \mid () \\
\textsc{Pure} \ni p ::= t \mid \ominus p \mid p_1 \oplus p_2 \qquad \ominus ::= -_{\mathbb{Z}} \mid \neg_{\mathbb{B}} \qquad \oplus ::= +_{\mathbb{Z}} \mid \leq_{\mathbb{Z}} \\
\textsc{Expr} \ni e ::= p \mid \mathbf{alloc} \mid \mathbf{free}(t) \mid t_1 \leftarrow t_2 \mid {}^*t \mid f(\overline{t}) \mid \\
\qquad\qquad \mathbf{assume}(t) \mid \mathbf{error} \mid e_1 + e_2 \mid \mathbf{let}\ x = e_1\ \mathbf{in}\ e_2
\end{array}
$$

The λ_{RUXt} (program) expressions are defined by the e grammar above and include *pure expressions*, standard heap-manipulating constructs for allocation (**alloc**), deallocation (**free**(t)), storing (heap mutation, $t_1 \leftarrow t_2$) and loading (heap lookup, ${}^*t$), as well as function calls ($f(\overline{t})$, see below), assume expressions (**assume**(t)), explicit error expressions (**error**),

non-deterministic choice ($e_1 + e_2$) and let bindings (**let** $x = e_1$ **in** e_2). Pure expressions (p) have no side effects and comprise *terms* as well as unary/binary operations on terms. A term t is either a *value* or a *program variable* (x) meant to be substituted with concrete values. A value v may be an integer z, a boolean b, a heap location l or the unit value ($()$). Note that as heap-manipulating and assume expressions contain terms instead of pure expressions, unary and binary operations must first be evaluated through a let binding, creating a new variable.

Other standard language constructs such as sequential composition, reference allocation, assert expressions and deterministic conditionals can be encoded using the above:

$$
\begin{aligned}
e_1;\ e_2 &\triangleq \textbf{let}\ _ = e_1\ \textbf{in}\ e_2 \\
\textbf{ref}(t) &\triangleq \textbf{let}\ x = \textbf{alloc}\ \textbf{in}\ x \leftarrow t;\ x \\
\textbf{assert}(t) &\triangleq \textbf{let}\ x = \neg_{\mathbb{B}} t\ \textbf{in}\ \textbf{assume}(t) + (\textbf{assume}(x);\ \textbf{error}) \\
\textbf{if}\ t\ \textbf{then}\ e_1\ \textbf{else}\ e_2 &\triangleq \textbf{let}\ x = \neg_{\mathbb{B}} t\ \textbf{in}\ (\textbf{assume}(t);\ e_1) + (\textbf{assume}(x);\ e_2)
\end{aligned}
$$

Functions and Loops. As λ_{RUXt} supports function calls ($f(\overline{t})$), we omit loop expressions ($e^\star$), since the same behaviour can be obtained with recursive functions. Since λ_{RUXt} is not higher-order, functions must be externally provided as an *implementation context*, γ, mapping function identifiers to their concrete implementations. We write $f(\overline{x})\{e\} \in \gamma$ to denote that γ contains an implementation for f, where e is the f body and $\overline{x}$ are its arguments (i.e. free variables in e). For example, the `Even` library would correspond to an implementation context γ such that $\mathsf{dom}(\gamma) = \{\texttt{zero}, \texttt{succ}, \texttt{next}, \texttt{noop}\}$ and $\texttt{next}(x)\{$ **let** $x = \texttt{succ}(x)$ **in** $\texttt{succ}(x)$ $\} \in \gamma$.

Type signatures. A function implementation is annotated with a type signature, recorded in a *signature context*, Δ. Signature contexts contain type signatures for *safe* functions only, as they are the only ones required to preserve type safety. Therefore, unsafe functions are excluded from signature contexts, even though they still appear in implementation contexts. We write $f(\overline{\tau}) \to \tau \in \Delta$ to denote that Δ contains a signature for f where $\overline{\tau}$ are its input types and τ is its output type. In the case of `Even` with γ described above, we have $\mathsf{dom}(\Delta) = \mathsf{dom}(\gamma) \setminus \{\texttt{succ}\}$ and $\texttt{next}(\texttt{Even}) \to \texttt{Even} \in \Delta$. In essence, excluding `succ` from Δ means that we cannot leverage type information from `succ` to infer anything about `Even`.

3.2 Type Spaces and Subvariants

Recall that we leverage signature contexts to construct type subvariants by inferring safe values of the types in a library. To this end, we introduce the notion of a *summary* and define a type subvariant as a set of summaries. We track the subvariants associated with each library type through a *summary context*.

Summaries. A summary, ς, is of the form $\mathsf{Summary}(\lambda v.\ P \mid e)$, where e is a *safe program* (described below) that *witnesses* value v (i.e. executing e yields v) constrained by the separation logic (SL) *assertion* P. Rather than using *concrete* values, v is a *symbolic* value: it serves as a binder for P, allowing us to represent an infinite number of concrete values in a single assertion. We define assertions as follows:

$$
\begin{aligned}
\textsc{Asrt} \ni P, Q ::= {} & \llcorner \pi \lrcorner \mid \mathsf{True} \mid \mathsf{False} \mid P \wedge Q \mid P \vee Q \mid P \Rightarrow Q \mid \exists\, x.\ P \mid \\
& \mathsf{emp} \mid l \mapsto v \mid l \not\mapsto \mid l \mapsto_? \mid P * Q
\end{aligned}
$$

Our assertion language is standard and includes truth, falsity, conjunction, disjunction, implication and existential quantification. A purely logical proposition[1] π may be lifted to an assertion as $\llcorner \pi \lrcorner$. Our assertions also include standard SL assertions for describing an empty heap (emp), a single-cell heap ($l \mapsto v$, comprising a single location l that holds value v) and composite heaps via the separating conjunction $*$ ($P * Q$, describing a heap that can be decomposed into two parts, one described by P and another by Q). We further include the negative heap assertions from ISL, $l \not\mapsto$, and the unknown heap assertions $l \mapsto_?$, respectively describing a heap comprising a single location l that has been freed or is uninitialised.

For every summary $\mathsf{Summary}(- \mid e)$, e must be a *safe program*: a program e is safe if it is *syntactically* well-typed (i.e. e type-checks) and comprises solely a sequence of calls to the safe functions in the API of the current library. Furthermore, a safe program should require no initial resources to execute safely (i.e. should execute safely starting from emp).

A summary context Σ is a map from types to their subvariants (set of summaries). For example, the `zero` function always returns the value 0 in an empty heap, and thus when the summary context is given by Σ, then $\mathsf{Summary}(\lambda v.\ \llcorner v = 0 \lrcorner \mid \texttt{zero}()) \in \Sigma(\texttt{Even})$. Note that the `Even` type is particularly simple and does not make use of the heap. In §4, we describe a more complex linked-list example where the constraining assertion is not pure.

Summary inference. We infer summaries using compositional symbolic execution [24, 25]: starting with an empty summary context Σ, we iteratively execute *safe* functions from the library to extend Σ. Given a safe function f with return type τ, every output value of f must be a safe value of τ (i.e. in the τ subvariant), and thus we can extend $\Sigma(\tau)$ to include the output value. More concretely, let f be the safe function we consider at the current iteration, where f takes n arguments of types $\tau_1 \cdots \tau_n$ and has output type τ. We then proceed as follows:

1. For each input type τ_i, we pick one summary $\varsigma_i = \mathsf{Summary}(\lambda v_i.\ P_i \mid e_i)$ from $\Sigma(\tau_i)$. At this step we pick a function f only if we have at least one summary for each of its input types, which may not always be the case. The strategy for selecting f is immaterial for soundness of our approach, and thus we omit such details from our formalism. Nevertheless, each library typically has *constructor* functions which do not require an input, or require inputs of other types, for which our analysis would compute subvariants.
2. We combine $v_1 \cdots v_n$ into a list of symbolic values $\overline{v}$ to pass as arguments to f, and define a *precondition* $P \triangleq P_1 * \cdots * P_n$ for f. This yields a *safe context* for executing f: as the input values are safe by construction and f is safe, it *should* execute safely, returning a safe value of type τ. However, recall that this is not always the case when the library is internally unsafe.
3. We sequentially compose witness programs $e_1 \cdots e_n$, followed by a call to f on the associated values, resulting in the program $e \triangleq \textbf{let}\ x_i = e_1\ \textbf{in}\ \ldots \textbf{let}\ x_n = e_n\ \textbf{in}\ f(\overline{x})$. Note that as the function call is syntactically well-typed and every program e_i is a safe program, the composite program e is also safe by construction. Program e will serve as a witness program for the result of executing f on these safe input values, whether it be a safe execution or not.
4. As f may be *internally* unsafe, its execution may reach an error. To distinguish safe executions from unsafe ones, we record *termination (exit) conditions* as follows:

$$\textsc{Exit} \ni \epsilon ::= \mathsf{ok}(v) \mid \mathsf{err} \mid \mathsf{miss}(l)$$

[1] That is, any term definable in Rocq with type Prop, such as equality assertions or other similar relations.

TryRefute$(\gamma, \Delta, \Sigma) \to$ SummCtx + Expr

1: $(f, \overline{\varsigma}, \tau) \leftarrow$ pickCandidate(Δ, Σ)
2: $(\overline{v}, P, \overline{e}) \leftarrow$ constructContext$(\overline{\varsigma})$
3: $e \leftarrow$ constructWitness$(\overline{e}, f)$
4: **for** $[\epsilon : Q] \in$ execute$(\gamma, f(\overline{v}), P)$ **do**
5: **match** ϵ **with**
6: **case** ok(v)
7: $\varsigma \leftarrow$ Summary$(\lambda v.\ Q \mid e)$
8: $\Sigma \leftarrow \Sigma[\tau \mapsto \varsigma, \Sigma(\tau)]$
9: **case** err $\mid$ miss$(-)$
10: **return** e
11: **return** Σ

Summary contexts $\boxed{\gamma, \Delta \vdash \Sigma}$

R-Infer
$$\frac{\gamma, \Delta \vdash \Sigma \quad \text{TryRefute}(\gamma, \Delta, \Sigma) = \Sigma'}{\gamma, \Delta \vdash \Sigma'}$$

Figure 4 The RUXt refutation procedure (left) and rules for inferring well-formed summary contexts (right).

5. We analyse the resulting exit condition ϵ and proceed accordingly.
6. If ϵ is *successful*, denoted by ok(v), the return value v is a *symbolic* value (as the inputs are themselves symbolic) and represents multiple safe values of τ; therefore,
   7. the symbolic execution engine constrains v by returning a postcondition Q, whereby we construct a new summary $\varsigma =$ Summary$(\lambda v.\ Q \mid e)$, where e (constructed as described above) is the safe program that witnesses ς as reachable; and
   8. we extend the subvariant of τ in Σ with ς.

   In the future iterations, we can then use this summary as a safe value for functions that require an input of type τ. Note that we may re-execute previously executed functions with the new input summary Summary$(\lambda v.\ Q \mid e)$: UB may now be reachable from this new summary, even if it was not reachable for prior safe inputs.
9. Otherwise ϵ is *unsuccessful*, given by either **(i)** err: denoting a memory safety error (e.g. performing a double free); or **(ii)** miss(l): denoting an access to a location l for which we do not own sufficient resources (e.g. an out-of-bounds access). We elaborate further on the distinction between these two cases later in §5.
   10. Finally, we report the unsuccessful termination as a type unsoundness (safety violation), returning e as a witness program that triggers the unsoundness.

Note that we can soundly identify an unsuccessful exit as a true bug. Specifically, as we only consider safe functions with safe values (summaries) as input, we solely interact with the safe API of the library. As such, if a safe function does not terminate successfully on safe inputs, then the library API does not encapsulate its usage of unsafe code, resulting in UB and rendering the library type-unsound. In other words, by considering only safe contexts, we can identify latent bugs as type safety bugs thanks to the expressivity of the type system.

3.3 The RUXt Algorithm

We present RUXt, our compositional, fully automatic analysis for detecting safety violations in internally unsafe libraries. The RUXt algorithm comprises a meta-loop that calls the TryRefute procedure (Fig. 4, left) at each iteration. Each execution of TryRefute infers summaries for a safe function and updates Σ to some Σ', as discussed in §3.2, following the rules in Fig. 4 (right). This meta-loop is performed until a type unsoundness is found

or a predefined limit ("fuel") is reached. Although the search is not exhaustive and some bugs may go undetected, we prioritise the guarantee of true positives by only exploring an under-approximation of the possible interactions with the library.

Refutation procedure. The TryRefute procedure is parametrised by the current summary context, Σ, along with an implementation context γ (for function implementations) and a signature context Δ (for function type signatures), returning either the updated summary context or a witness program if a type unsoundness is found. Specifically, lines 1–10 in TryRefute correspond to steps 1–10 on page 10.

The pickCandidate procedure (line 1) selects a safe function f and its associated input summaries and output type (see step 1 on p. 10); that is, $f(\overline{\tau})\to\tau \in \Delta$ and $\forall i.\ \overline{\varsigma}_i \in \Sigma(\overline{\tau}_i)$. We then construct a safe context using constructContext (line 2) and a witness program using constructWitness (line 3), as we described previously (see steps 2 and 3 on p. 10, respectively). Given P, we then call execute (line 4) to symbolically execute the function call $f(\overline{v})$, which returns a *set* of postconditions (due to non-determinism). For each postcondition $[\epsilon : Q]$, we perform a case analysis (lines 5–10) on its exit condition ϵ, as discussed in steps 5–10 on p. 11. Finally, if no type unsoundness is found by the end of the meta-loop, the final summary context is returned (line 11).

Well-formed summary contexts. The judgement $\gamma, \Delta \vdash \Sigma$ (Fig. 4, right) denotes a *well-formed* summary context: every summary in Σ is reachable by interacting solely with the safe functions given in implementation context γ and signature context Δ. The R-Empty rule states that an empty summary context is always well-formed. The R-Infer rule allows a well-formed summary context to be extended: given a well-formed Σ, if TryRefute returns an updated summary context Σ', then Σ' is also well-formed. Since TryRefute maintains the previous summaries and only extends the summary context with new ones that are reachable from a safe function, well-formedness is preserved across iterations.

Soundness. The soundness of RUXt depends on the soundness of its underlying symbolic execution engine. Indeed, the execute procedure must derive a valid under-approximation of the values that are reachable by the program. To ensure this, we develop the RISL program logic (§5) and prove that it is sound with respect to our under-approximate semantics (§6).

The RISL soundness allows us to prove our main result, the *inadequacy theorem* (see Theorem 7): if TryRefute returns a witness program for a library, then the witness is a safe program for which UB is observable. The returned witness thus demonstrates that UB can emerge by interacting solely with the safe API of the library. In other words, we show that any violation reported by RUXt proves the existence of a true safety bug in the library.

Handling references. Until now, we have not discussed how RUXt handles *reference* types. Namely, given a Rust function `fn f(x: &mut T)`, the RUXt algorithm cannot infer anything about type `T` from `f` mutating `x`, since `T` is not the output type. Therefore, rather than perform the analysis directly on `f`, we define a *safe wrapper* `f_wrap` that receives and returns a value of type `T`, and run RUXt on `f_wrap` instead. The wrapper simply calls the original function and returns the mutated input: `fn f_wrap(mut x: T) -> T { f(&mut x); x }`. The intuition for this wrapper function is that any safe mutating operation should always re-establish the safety of its input value, and we can use this information to grow our subvariants. Indeed, since `f_wrap` type-checks, it *must* be safe and therefore our analysis can immediately be applied to the wrapper without further proof. We demonstrate this wrapper transformation through a linked list example in §4.

These wrappers can be constructed fully automatically directly in Rust and then type-checked by the compiler. Moreover, similar wrappers can also be defined for other reference types. For example, a function `fn f(&mut T) -> &mut U` that returns a mutable reference can be wrapped into a function that assigns an arbitrary value to the returned reference: `fn f_wrap(mut x: T, y: U) -> T { *(f(&mut x)) = y; x }`. Again, the intuition is that assigning an arbitrary value to the reference should not break the safety of the input structure. Shared references can be handled similarly by simply checking that *reading* from the reference does not trigger UB on safe inputs. Note that if a function receives or returns several references, we can apply these transformations to each reference separately and analyse each wrapper independently to grow our subvariants.

Even if the wrappers use mutable references in their body, the analysis can still be performed, since references are semantically equivalent to raw pointers in our model (similarly to RustBelt). However, RUXt is thus unable to detect specific classes of bugs related to *aliasing semantics* from stronger semantic models such as Stacked Borrows [18] or Tree Borrows [37]. Nevertheless, our approach remains sound as we are not compromising on our promise of true positives: all bugs reported by RUXt are true safety violations, even if other UBs allowed by Stacked Borrows or Tree Borrows remain undetected.

RUXt prototype implementation. We develop a prototype implementation of RUXt in OCaml. The execute procedure is implemented using the technique of *compositional symbolic execution for incorrectness reasoning* [25], a form of symbolic execution that allows reasoning about fragments of states that correspond to separation logic assertions. A similar technique is implemented in other tools for correctness and/or incorrectness reasoning such as VeriFast [15], Viper [28] or Gillian [26]. The engine was designed to follow the RISL proof rules (see §5), ensuring that, starting from a precondition P and executing a function body e, the engine constructs only postconditions $[\epsilon : Q]$ such that the triple $\vdash [P]\, e\, [\epsilon\colon Q]$ holds.

Furthermore, in the implementation, the analysis is initialised with valid subvariants for the primitive types such as integers and booleans. For instance, the initial subvariant for the `int` type is given by the single summary $\mathsf{Summary}(\lambda v.\ v \in \mathbb{Z} \mid v)$, where v represents all integers, as constrained by the assertion. In §4, we exemplify further the use of such symbolic summaries with a constructor function for the `Even` type that receives an integer as parameter.

Finally, since the algorithm presented in Fig. 4 may loop indefinitely, our implementation receives an initial fuel parameter to limit the number of iterations.

4 Case Studies

To demonstrate the feasibility and applicability of RUXt, we run our prototype implementation on three λ_{RUXt} case studies and show that we can automatically detect type unsoundness in ill-defined libraries. First, we target the unsoundness in our running example `Even` (§2), and next we consider an extension of `Even` with a more general constructor. Finally, we define a `List` library in λ_{RUXt} with a function that causes an unsoundness. Note that as our prototype does not currently construct witness programs, we omit these from the summaries shown in this section.

4.1 Even Integer

We re-implement the functions presented in Fig. 1 within our prototype. Our implementation successfully finds the unsoundness when `succ` is marked as safe, and accurately does not when it is marked as `unsafe`.

Even integer extension. The `Even` example in §2 is simplified and does not fully demonstrate the benefits of using symbolic execution, as all inferred values are concrete. To illustrate the power of symbolic execution, we replace the `zero` constructor with a new function `new` that takes an integer `x` and returns it if `x` is even; otherwise, it increments `x` and returns it.

```
fn new(x: int) -> Even {
  if (x % 2 = 0) { x }
  else { x + 1 }
}
```

Here, `int` is a base case: we know that the *exact* type space (i.e. neither over- nor under-approximate) of a value n of type `int` is "$n \in \mathbb{Z}$". We can use this type space as a subvariant to construct the input context for `new`. We then obtain the following subvariant for `Even` by symbolically executing `new` from that context, obtaining two branches and hence two summaries:

$$\Sigma(\texttt{Even}) = \{\mathsf{Summary}(\lambda n.\ n \in \mathbb{Z} \wedge n\%2 = 0), \mathsf{Summary}(\lambda n.\ n \in \mathbb{Z} \wedge (n-1)\%2 \neq 0)\}$$

This newly obtained subvariant covers exactly the entire type space of `Even`. Using a simple SMT check, we can then prove that the concrete value returned by `zero` is included in this subvariant. This allows us to remove (or never add) the concrete value as a subvariant, thereby reducing path explosion. The same approach could be used for other base cases that are "native" to the language (e.g. the slice or `Box` types), where the type spaces are known exactly and can be formulated as simple separation logic assertions.

4.2 Linked List

We define a simple linked list library, `List`, in λ_{RUXt}. Unlike `Even`, linked lists are real-world data structures that are infamously difficult to implement soundly in Rust. Within `List` we introduce a subtle unsoundness and show that our prototype can detect it automatically. The `List` library contains the following functions:

- `fn new() -> List`: creates a new empty list, a null pointer represented as the value 0;
- `fn push(l: List) -> List`: adds a newly allocated node to the front of (input list) `l`;
- `fn drop(l: List)`: iterates through `l` and frees each node until a null pointer is found;
- `fn cycle(l: List) -> List`: overrides the null pointer terminating `l` with a pointer to its first element, creating a *cycle* in the list.

In a real Rust implementation, `push` and `cycle` would receive a mutable reference to the list. However, as discussed in §3.3 (p. 12), the analysis can only be performed on wrappers. Since our prototype does not yet automate this transformation, we implement `push` and `cycle` as the actual wrappers. For example, we transform the Rust implementation (receiving a mutable reference to the list), `Rust_push`, by wrapping it in our `push` implementation, where `inline_Rust_push(&mut l)` denotes inlining the body of `Rust_push(&mut l)`: `fn push(mut l: List) -> List { inline_Rust_push(&mut l); l }`.

The first three functions (`new`, `push` and `drop`) are standard and exist in the `LinkedList` implementation of Rust standard library. However, the `cycle` function is not standard and indeed introduces unsoundness: dropping a cyclic linked list will lead to a use-after-free error the second time the iteration reaches a node in the cycle[2].

[2] An alternative implementation of `drop` which would check for cycles would not suffer from this issue. However, the current implementation of the `LinkedList` structure in the Rust standard library does not check for cycles when iterating.

RUXt can detect this unsoundness as follows.

1. At first, we can only pick the `new` function: it requires no arguments, while all other functions require an argument of type `List` for which we are yet to infer a subvariant. By executing `new`, we infer that the empty linked list – i.e. a `null` pointer – must be a safe value of type `List`. In other words, thus far we have inferred the type subvariant:

$$\Sigma(\texttt{List}) = \{\mathsf{Summary}(\lambda v.\ \llcorner v = 0 \lrcorner)\}$$

2. Later on, we pick `push` and execute it from our current `List` subvariant, learning a new subvariant for lists of size one:

$$\Sigma(\texttt{List}) = \{\mathsf{Summary}(\lambda v.\ \llcorner v = 0 \lrcorner), \mathsf{Summary}(\lambda l.\ l \mapsto 0)\}$$

3. Subsequently, we pick `cycle` and learn a new subvariant:

$$\Sigma(\texttt{List}) = \{\mathsf{Summary}(\lambda v.\ \llcorner v = 0 \lrcorner), \mathsf{Summary}(\lambda l.\ l \mapsto 0), \mathsf{Summary}(\lambda l.\ l \mapsto l)\}$$

4. Finally, we pick `drop`, and using our last subvariant we detect a use-after-free UB.

4.3 Key Takeaways

These examples highlights several key aspects of the kinds of unsoundness detected by RUXt:

- In Rust, functions such as `cycle` would *require* unsafe code, as safe Rust prevents the kind of aliasing required for a cyclic linked list. Importantly, reasoning about this aliasing is made substantially simpler thanks to separation logic.
- The `cycle` and `succ` functions are not inherently wrong. For instance, in the `List` case, the unsoundness arises from the interaction of `cycle` and `drop`; the library would be sound without either of these functions. Safety is, inherently, an inter-procedural property [16]. In our prototype, we also check that no unsoundness is found if either function is removed from the library, or if either is marked as unsafe.
- We do not need to explore all traces as we build subvariants. As demonstrated with the `zero` and `new` functions of the `Even` library, some subvariants might be removed from our Σ when a strictly larger subvariant is found. We believe that this compositional approach dramatically reduces path explosion issues in comparison to whole-program type-guided approaches such as Crabtree [34], described in more details in §7.

5 The RISL Program Logic

We now present RISL (Rust incorrectness separation logic), our under-approximate logic for deriving reachable states in RUXt. Our proof rules are standard and similar to those of ISL [31], with the caveat that λ_{RUXt} programs are not commands, but rather expressions that reduce to values on successful termination. Unlike ISL, RISL supports function calls and is the first separation logic to reason about missing resources (the miss exit condition).

5.1 Proof Rules

We present the RISL proof rules in Fig. 5. Intuitively, a RISL triple $\Gamma \vdash [P]\ e\ [\epsilon\colon Q]$ is interpreted similarly to ISL: every state in the postcondition Q is reachable by executing program e starting from some state in the precondition P, where ϵ is the exit condition, as described in §3.2 (p. 10). To reason about function *calls*, RISL allows reusing of derived specifications through a *specification context*, Γ, mapping each function to a list of *under-approximate* specifications. More concretely, $\left[(\overline{v})\ P \,\middle|\, \epsilon\colon Q\right] \in \Gamma(f)$ denotes that $[\epsilon : Q]$ is reachable by executing $f(\overline{v})$ starting from P (i.e. $\Gamma \vdash [P]\ f(\overline{v})\ [\epsilon\colon Q]$ holds).

Under-approximate triples $\boxed{\Gamma \vdash [P]\, e\, [\epsilon\colon Q]}$

S-Val
$\Gamma \vdash [\mathsf{emp}]\, v\, [\mathsf{ok}(v)\colon \mathsf{emp}]$

S-Assume
$\Gamma \vdash [\mathsf{emp}]\ \mathbf{assume}(\mathsf{true})\ [\mathsf{ok}\colon \mathsf{emp}]$

S-Error
$\Gamma \vdash [\mathsf{emp}]\ \mathbf{error}\ [\mathsf{err}\colon \mathsf{emp}]$

S-Minus
$$\frac{\Gamma \vdash [\mathsf{emp}]\, p\, [\mathsf{ok}(z)\colon \mathsf{emp}]}{\Gamma \vdash [\mathsf{emp}]\ -_{\mathbb{Z}}\, p\, [\mathsf{ok}(-z)\colon \mathsf{emp}]}$$

S-Add
$$\frac{\Gamma \vdash [\mathsf{emp}]\, p_1\, [\mathsf{ok}(z_1)\colon \mathsf{emp}] \quad \Gamma \vdash [\mathsf{emp}]\, p_2\, [\mathsf{ok}(z_2)\colon \mathsf{emp}]}{\Gamma \vdash [\mathsf{emp}]\, p_1 +_{\mathbb{Z}} p_2\, [\mathsf{ok}(z_1 + z_2)\colon \mathsf{emp}]}$$

S-Not
$$\frac{\Gamma \vdash [\mathsf{emp}]\, p\, [\mathsf{ok}(b)\colon \mathsf{emp}]}{\Gamma \vdash [\mathsf{emp}]\ \neg_{\mathbb{B}} p\, [\mathsf{ok}(\neg b)\colon \mathsf{emp}]}$$

S-Le
$$\frac{\Gamma \vdash [\mathsf{emp}]\, p_1\, [\mathsf{ok}(z_1)\colon \mathsf{emp}] \quad \Gamma \vdash [\mathsf{emp}]\, p_2\, [\mathsf{ok}(z_2)\colon \mathsf{emp}]}{\Gamma \vdash [\mathsf{emp}]\, p_1 \leq_{\mathbb{Z}} p_2\, [\mathsf{ok}(z_1 \leq z_2)\colon \mathsf{emp}]}$$

S-Free
$\Gamma \vdash [l \mapsto v]\ \mathbf{free}(l)\ [\mathsf{ok}\colon l \not\mapsto]$

S-Store
$\Gamma \vdash [l \mapsto v']\, l \leftarrow v\, [\mathsf{ok}\colon l \mapsto v]$

S-Load
$\Gamma \vdash [l \mapsto v]\, {}^{*}l\, [\mathsf{ok}(v)\colon l \mapsto v]$

S-FreeUninit
$\Gamma \vdash [l \mapsto_{?}]\ \mathbf{free}(l)\ [\mathsf{ok}\colon l \not\mapsto]$

S-StoreUninit
$\Gamma \vdash [l \mapsto_{?}]\, l \leftarrow v\, [\mathsf{ok}\colon l \mapsto v]$

S-LoadUninit
$\Gamma \vdash [l \mapsto_{?}]\, {}^{*}l\, [\mathsf{err}\colon l \mapsto_{?}]$

S-FreeFreed
$\Gamma \vdash [l \not\mapsto]\ \mathbf{free}(l)\ [\mathsf{err}\colon l \not\mapsto]$

S-StoreFreed
$\Gamma \vdash [l \not\mapsto]\, l \leftarrow v\, [\mathsf{err}\colon l \not\mapsto]$

S-LoadFreed
$\Gamma \vdash [l \not\mapsto]\, {}^{*}l\, [\mathsf{err}\colon l \not\mapsto]$

S-FreeMiss
$\Gamma \vdash [\mathsf{emp}]\ \mathbf{free}(l)\ [\mathsf{miss}(l)\colon \mathsf{emp}]$

S-StoreMiss
$\Gamma \vdash [\mathsf{emp}]\, l \leftarrow v\, [\mathsf{miss}(l)\colon \mathsf{emp}]$

S-LoadMiss
$\Gamma \vdash [\mathsf{emp}]\, {}^{*}l\, [\mathsf{miss}(l)\colon \mathsf{emp}]$

S-Alloc
$\Gamma \vdash [\mathsf{emp}]\ \mathbf{alloc}\ [\mathsf{ok}(l)\colon l \mapsto_{?}]$

S-Call
$$\frac{[(\overline{v})\ P \mid \epsilon\colon Q] \in \Gamma(f)}{\Gamma \vdash [P]\, f(\overline{v})\, [\epsilon\colon Q]}$$

S-LetCut
$$\frac{\Gamma \vdash [P]\, e_1\, [\epsilon\colon Q] \quad \epsilon \neq \mathsf{ok}(-)}{\Gamma \vdash [P]\ \mathbf{let}\ x = e_1\ \mathbf{in}\ e_2\, [\epsilon\colon Q]}$$

S-Choice
$$\frac{\Gamma \vdash [P]\, e_i\, [\epsilon\colon Q] \quad \exists\, i \in \{1, 2\}}{\Gamma \vdash [P]\, e_1 + e_2\, [\epsilon\colon Q]}$$

S-Let
$$\frac{\Gamma \vdash [P]\, e_1\, [\mathsf{ok}(v)\colon R] \quad \Gamma \vdash [R]\, e_2[v/x]\, [\epsilon\colon Q]}{\Gamma \vdash [P]\ \mathbf{let}\ x = e_1\ \mathbf{in}\ e_2\, [\epsilon\colon Q]}$$

S-Disj
$$\frac{\Gamma \vdash [P_1]\, e\, [\epsilon\colon Q_1] \quad \Gamma \vdash [P_2]\, e\, [\epsilon\colon Q_2]}{\Gamma \vdash [P_1 \vee P_2]\, e\, [\epsilon\colon Q_1 \vee Q_2]}$$

S-Frame
$$\frac{\Gamma \vdash [P]\, e\, [\epsilon\colon Q] \quad \mathsf{frameable}(\epsilon, R)}{\Gamma \vdash [P * R]\, e\, [\epsilon\colon Q * R]}$$

S-Exists
$$\frac{\Gamma \vdash [P]\, e\, [\epsilon\colon Q]}{\Gamma \vdash [\exists\, x.\ P]\, e\, [\epsilon\colon \exists\, x.\ Q]}$$

S-Cons
$$\frac{\Gamma' \subseteq \Gamma \quad \models (P' \Rightarrow P) \quad \Gamma' \vdash [P']\, e\, [\epsilon\colon Q'] \quad \models (Q \Rightarrow Q')}{\Gamma \vdash [P]\, e\, [\epsilon\colon Q]}$$

Figure 5 The RISL proof rules.

Plain values always reduce to the value itself successfully (S-Val). Pure expressions reduce to the result of the underlying operation on the reduction values of its operands (S-Minus, S-Not, S-Add and S-Le). Assume expressions only terminate if the term evaluates to true[3] (S-Assume). Error expressions always terminate erroneously (S-Error).

[3] For readability, when programs reduce to () (unit value), we simply write ok rather than ok(()).

For heap-manipulating expressions, the successful cases (with ok) are analogous to their ISL counterparts (S-Free, S-Store, S-Load and S-Alloc). As in ISL, accessing previously freed locations results in a memory safety issue and thus erroneous termination (S-FreeFreed, S-StoreFreed and S-LoadFreed). As we model uninitialised memory, compared to ISL we further have rules to account for accessing uninitialised memory. Specifically, while freeing and overwriting uninitialised locations terminates successfully (S-FreeUninit and S-StoreUninit), loading from such locations leads to UB (S-LoadUninit). We further introduce new rules to reason about missing resources (via the miss exit condition). For instance, when attempting to free a location l for which we do not own the necessary resources in the precondition, i.e. we have emp rather than $l \mapsto - \vee l \mapsto_?$, then we terminate unsuccessfully due to missing location l, denoted by the $\mathsf{miss}(l)$ exit condition in S-FreeMiss. The S-StoreMiss and S-LoadMiss describe analogous scenarios when storing to or loading from l. This miss exit condition could be surprising to readers familiar with ISL; we discuss it in more details shortly.

Let bindings correspond to sequential composition in ISL. As in ISL, S-LetCut captures the short-circuiting semantics of sequential executions: when the execution of the first expression e_1 terminates unsuccessfully, then the let expression **let** $x = e_1$ **in** e_2 also executes unsuccessfully. The S-Let rule captures the case where executing e_1 terminates successfully with value v, in which case (unlike in ISL) v is propagated to e_2 through variable substitution.

The S-Choice rule states that the states in Q are reachable when executing $e_1 + e_2$ if they are reachable from P when executing *either* branch. As in incorrectness (separation) logic, this is due to the *under-approximate* nature of RISL.

Missing resources. The miss exit condition is a novel aspect of RISL, allowing us to derive triples when the proof context does not carry sufficient resources to execute a program successfully. By contrast, in ISL, missing resources do not lead to a specific exit condition, but rather to a failure to derive a triple.

This is because unlike existing analyses based on ISL, RUXt is designed to reason about the soundness of Rust libraries, where types *capture the resources required for safe execution*. That is, if RUXt computes a subvariant assertion P for a given type `T`, then P *should* contain enough resources to execute the body of any safe function `f(x: T)`. Therefore, if we can derive a triple with a miss exit for the body of a function `f(x: T)` starting from a computed subvariant for `T`, we have shown that the resources associated with `T` are insufficient for the function to execute safely, and thus we can report it as a type safety violation.

Note that additional care is needed to ensure that triples with miss exits do not break the S-Frame rule. Specifically, when applying S-Frame to a triple with $\epsilon = \mathsf{miss}(l)$, we must ensure the framed-on resources R do not invalidate $\mathsf{miss}(l)$ by framing the missing location l. This is captured by the $\mathsf{frameable}(\epsilon, R)$ premise of the S-Frame rule, defined as follows:

$$\mathsf{frameable}(\epsilon, R) \triangleq \forall\, l.\ \epsilon = \mathsf{miss}(l) \Rightarrow \neg\, \mathsf{sat}(R \wedge (\mathsf{True} * (l \mapsto - \vee l \not\mapsto \vee l \mapsto_?)))$$

Note that when $\epsilon \in \{\mathsf{ok}, \mathsf{err}\}$, the $\mathsf{frameable}(\epsilon, R)$ premise is immediately satisfied, ensuring that we can *always* frame on additional resources R in such cases, as in ISL. That is, in these cases our frame rule is identical to that of ISL (which cannot account for missing resources). By contrast, in the case of $\epsilon = \mathsf{miss}(l)$, the right-hand side of the implication above ensures that R does not express ownership of l, i.e. does not contain $l \mapsto -$ or $l \not\mapsto$ or $l \mapsto_?$ (among other resources, as denoted by True).

Function calls. The S-Call rule allows specifications from the Γ context to be directly applied when they match a given function call. Rather than executing $f(\overline{v})$ directly, one can consult the specifications of f in Γ and check if there exists a specification $\left[(\overline{v})\ P \,\middle|\, \epsilon\colon Q\right] \in \Gamma(f)$ for the same input values $\overline{v}$.

Specification contexts $\boxed{\gamma \prec_{\mathsf{S}} \Gamma}$

$$\textsc{S-Empty}\quad \gamma \prec_{\mathsf{S}} \mathsf{empty}(\gamma) \qquad \textsc{S-Extend}\quad \frac{\gamma \prec_{\mathsf{S}} \Gamma \quad f(\overline{x})\{e\} \in \gamma \quad \Gamma \vdash [P]\, e[\overline{v}/\overline{x}]\, [\epsilon\colon Q]}{\gamma \prec_{\mathsf{S}} \Gamma\big[f \mapsto \big[(\overline{v})\ P \,\big|\, \epsilon\colon Q\big],\ \Gamma(f)\big]}$$

Figure 6 Proof rules for well-formed specification contexts.

The S-Cons rule further allows the specification context Γ' to be extended to Γ so long as Γ contains all specifications that Γ' does (i.e. $\Gamma' \subseteq \Gamma \triangleq \forall\ f.\ \Gamma'(f) \subseteq \Gamma(f)$). This ensures that Γ preserves any specification that may have been used to prove the original triple.

Note that RISL rules are only sound provided that the given specification context is consistent with the concrete implementation context under analysis. Therefore, we next show how to construct specification contexts soundly by deriving specifications in RISL.

5.2 Well-Formed Specification Contexts

The rules in Fig. 6 allow one to construct *well-formed* specification contexts. A specification context Γ is well-formed with respect to an implementation context γ, written $\gamma \prec_{\mathsf{S}} \Gamma$, when every specification in $\Gamma(f)$ holds of (can be derived for) the concrete implementation in $\gamma(f)$, for all f in γ. We write $\mathsf{empty}(\gamma)$ to denote an *empty specification context* for γ, i.e. one where $\Gamma(f)$ is an empty list, for all functions f in γ. An empty specification context for γ is vacuously well-formed with respect to γ (S-Empty). When $\gamma \prec_{\mathsf{S}} \Gamma$ holds, we can extend Γ (in a well-formed fashion) with a specification $\big[(\overline{v})\ P \,\big|\, \epsilon\colon Q\big]$ for f in γ, provided that we can prove it in RISL by directly executing the f body with concrete input values $\overline{v}$ (S-Extend).

In other words, by iterating over functions and deriving RISL (under-approximate) specifications for concrete inputs, we can dynamically construct Γ, tailor-made for a specific implementation context γ. This way, we can also reason about (mutually) recursive functions for a bounded number of iterations (i.e. under-approximate them) by first deriving specifications for non-recursive calls, which can then be used to derive specifications for the recursive calls. Moreover, note that the S-Cons rule ensures that derived RISL triples remain valid when extending the specification context, which in turn ensures that RISL is sound under specification context extension.

In the RUXt algorithm, we obtain reachable states by following the RISL proof (Fig. 5) and refinement (Fig. 6) rules. Indeed, every derived postcondition $[\epsilon : Q] \in \mathsf{execute}(\gamma, f(\overline{v}), P)$ on line 3 in Fig. 4 (left) implies that there exists Γ such that $\gamma \prec_{\mathsf{S}} \Gamma$ and $\Gamma \vdash [P]\, f(\overline{v})\, [\epsilon\colon Q]$ hold. As such, the soundness of RUXt follows directly from the soundness of RISL with respect to our under-approximate RUXtBelt semantics, which we describe next in §6.

6 RUXtBelt: The Semantic Model of RUXt

We present RUXtBelt, our under-approximate semantic model underpinning RISL and RUXt. As discussed in §1, RUXtBelt covers a large fragment of RustBelt. Unlike RustBelt, however, in RUXtBelt we explicitly account for memory safety errors (e.g. use after free) as this is required for bug detection. Specifically, while the RustBelt semantics simply gets "stuck" when encountering a memory safety issue, in RUXtBelt we directly identify them as errors using our unsuccessful exit conditions.

In §6.1 we present the RUXtBelt operational semantics. In §6.2 we define the semantic interpretation of RISL triples and prove the RISL proof system sound against the RUXtBelt semantics. Finally in §6.3 we prove that the RUXt algorithm is sound through our inadequacy theorem, stating that every UB detected by RUXt is a true safety violation in the library.

6.1 RUXtBelt Operational Semantics

We present two characterisations of our RUXtBelt semantics. First, we describe our *big-step* semantics that explicitly accounts for unsuccessful termination, but does not distinguish between the two kinds of unsuccessful termination (err or miss). Specifically, in our big-step semantics we assume that we have the *full* heap at all times and do not miss any resources, i.e. that there are no additional resources in the frame. As such, when accessing a location l that is not within the underlying heap, we simply terminate with err (and not miss(l)). We thus refer to this big-step semantics as the RUXtBelt *full semantics*.

We next present the RUXtBelt *instrumented* (big-step) semantics – inspired by JaVerT2.0 [9] and Gillian [26] – that can operate on *partial* heaps and thus distinguishes between unsuccessful termination due to memory safety errors (err) and missing resources (miss). We then establish a semantics preservation lemma (Lemma 1) stating that our instrumented semantics can simply be erased to our big-step semantics, in that if a program e terminates with exit condition ϵ under the instrumented semantics, then (1) either $\epsilon = \mathsf{ok}$ and e also terminates with ok in our big-step semantics; or (2) $\epsilon \neq \mathsf{ok}$ (i.e. it is either err or miss) and e terminates with err in our big-step semantics.

As we show below, our instrumented semantics simplifies the task of proving RISL sound: miss RISL triples directly correspond to miss judgements in our instrumented semantics. As such, we first prove RISL sound against our instrumented semantics, and subsequently show that RUXt is sound against our full semantics through our semantics preservation lemma.

RUXtBelt big-step semantics. We define our RUXtBelt big-step operational semantics in Fig. 7, through judgements of the form $\gamma \vdash \langle h \mid e \rangle \Downarrow \langle h' \mid \epsilon \rangle$, where γ is an implementation context (for function implementations), e is a λ_{RUXt} program (expression), ϵ is an exit condition and h, h' are *program states*. A program state is a heap, $h \in \textsc{Heap} \triangleq \textsc{Loc} \rightharpoonup \textsc{Val} \uplus \{☣, \varnothing\}$, mapping locations to either values in Val or designated values for uninitialised (☣) and freed ($\varnothing$) locations. The $\gamma \vdash \langle h \mid e \rangle \Downarrow \langle h' \mid \epsilon \rangle$ judgement states that h' is reachable with exit condition ϵ by evaluating e starting from h, under the implementation context γ.

We further define partial evaluation functions for terms ($\lfloor \cdot \rfloor_{\mathsf{t}} : \textsc{Term} \rightharpoonup \textsc{Val}$) and pure expressions ($\lfloor \cdot \rfloor_{\mathsf{p}} : \textsc{Pure} \rightharpoonup \textsc{Val}$) as follows:

$$\lfloor v \rfloor_{\mathsf{t}} \triangleq v \qquad \lfloor -_{\mathbb{Z}} p \rfloor_{\mathsf{p}} \triangleq -\lfloor p \rfloor_{\mathsf{p}} \textbf{ if } \lfloor p \rfloor_{\mathsf{p}} \in \mathbb{Z} \qquad \lfloor p_1 +_{\mathbb{Z}} p_2 \rfloor_{\mathsf{p}} \triangleq \lfloor p_1 \rfloor_{\mathsf{p}} + \lfloor p_2 \rfloor_{\mathsf{p}} \textbf{ if } \lfloor p_1 \rfloor_{\mathsf{p}}, \lfloor p_2 \rfloor_{\mathsf{p}} \in \mathbb{Z}$$
$$\lfloor t \rfloor_{\mathsf{p}} \triangleq \lfloor t \rfloor_{\mathsf{t}} \qquad \lfloor \neg_{\mathbb{B}} p \rfloor_{\mathsf{p}} \triangleq \neg \lfloor p \rfloor_{\mathsf{p}} \textbf{ if } \lfloor p \rfloor_{\mathsf{p}} \in \mathbb{B} \qquad \lfloor p_1 \leq_{\mathbb{Z}} p_2 \rfloor_{\mathsf{p}} \triangleq \lfloor p_1 \rfloor_{\mathsf{p}} \leq \lfloor p_2 \rfloor_{\mathsf{p}} \textbf{ if } \lfloor p_1 \rfloor_{\mathsf{p}}, \lfloor p_2 \rfloor_{\mathsf{p}} \in \mathbb{Z}$$

Most of the rules in Fig. 7 are standard. Pure expressions, assume expressions and explicit errors do not interact with the heap and leave it unchanged. Specifically, pure expressions simply reduce to their corresponding value (O-Pure), **assume**(t) is only reducible if t evaluates to true (O-Assume) and **error** terminates unsuccessfully with err (O-Error).

Heap allocation always returns a fresh, uninitialised location (O-Alloc). As in ISL, deallocation updates the value of the freed location to the designated $\varnothing$ value (O-Free). Storing to a heap location l is successful when l is not deallocated but may be potentially uninitialised (O-Store), while loading from l is only successful if l is initialised, in which case it returns the value at l (O-Load). Accessing a previously freed location or loading from an uninitialised location terminates erroneously (O-FreeErr, O-StoreErr and O-LoadErr).

Big-step evaluation $\boxed{\gamma \vdash \langle h \mid e \rangle \Downarrow \langle h' \mid \epsilon \rangle}$

$$\textsc{O-Pure}\ \frac{\lfloor p \rfloor_{\mathsf{p}} = v}{\gamma \vdash \langle h \mid p \rangle \Downarrow \langle h \mid \mathsf{ok}(v) \rangle} \qquad \textsc{O-Assume}\ \frac{\lfloor t \rfloor_{\mathsf{t}} = \mathsf{true}}{\gamma \vdash \langle h \mid \mathbf{assume}(t) \rangle \Downarrow \langle h \mid \mathsf{ok} \rangle} \qquad \textsc{O-Error}\ \frac{}{\gamma \vdash \langle h \mid \mathbf{error} \rangle \Downarrow \langle h \mid \mathsf{err} \rangle}$$

$$\textsc{O-Alloc}\ \frac{l \notin \mathsf{dom}(h)}{\gamma \vdash \langle h \mid \mathbf{alloc} \rangle \Downarrow \langle h[l \mapsto \text{☣}] \mid \mathsf{ok}(l) \rangle} \qquad \textsc{O-Free}\ \frac{\lfloor t \rfloor_{\mathsf{t}} = l \quad h(l) \in \textsc{Val} \uplus \{\text{☣}\}}{\gamma \vdash \langle h \mid \mathbf{free}(t) \rangle \Downarrow \langle h[l \mapsto \varnothing] \mid \mathsf{ok} \rangle}$$

$$\textsc{O-Store}\ \frac{\lfloor t_1 \rfloor_{\mathsf{t}} = l \quad h(l) \in \textsc{Val} \uplus \{\text{☣}\} \quad \lfloor t_2 \rfloor_{\mathsf{t}} = v}{\gamma \vdash \langle h \mid t_1 \leftarrow t_2 \rangle \Downarrow \langle h[l \mapsto v] \mid \mathsf{ok} \rangle} \qquad \textsc{O-Load}\ \frac{\lfloor t \rfloor_{\mathsf{t}} = l \quad h(l) = v}{\gamma \vdash \langle h \mid {}^{*}t \rangle \Downarrow \langle h \mid \mathsf{ok}(v) \rangle}$$

$$\textsc{O-FreeErr}\ \frac{\lfloor t \rfloor_{\mathsf{t}} = l \quad h(l) = \varnothing}{\gamma \vdash \langle h \mid \mathbf{free}(t) \rangle \Downarrow \langle h \mid \mathsf{err} \rangle} \qquad \textsc{O-StoreErr}\ \frac{\lfloor t_1 \rfloor_{\mathsf{t}} = l \quad h(l) = \varnothing}{\gamma \vdash \langle h \mid t_1 \leftarrow t_2 \rangle \Downarrow \langle h \mid \mathsf{err} \rangle} \qquad \textsc{O-LoadErr}\ \frac{\lfloor t \rfloor_{\mathsf{t}} = l \quad h(l) \in \{\varnothing, \text{☣}\}}{\gamma \vdash \langle h \mid {}^{*}t \rangle \Downarrow \langle h \mid \mathsf{err} \rangle}$$

$$\textsc{O-FreeMiss}\ \frac{\lfloor t \rfloor_{\mathsf{t}} = l \quad l \notin \mathsf{dom}(h)}{\gamma \vdash \langle h \mid \mathbf{free}(t) \rangle \Downarrow \langle h \mid \mathsf{err} \rangle} \qquad \textsc{O-StoreMiss}\ \frac{\lfloor t_1 \rfloor_{\mathsf{t}} = l \quad l \notin \mathsf{dom}(h)}{\gamma \vdash \langle h \mid t_1 \leftarrow t_2 \rangle \Downarrow \langle h \mid \mathsf{err} \rangle} \qquad \textsc{O-LoadMiss}\ \frac{\lfloor t \rfloor_{\mathsf{t}} = l \quad l \notin \mathsf{dom}(h)}{\gamma \vdash \langle h \mid {}^{*}t \rangle \Downarrow \langle h \mid \mathsf{err} \rangle}$$

$$\textsc{O-Choice}\ \frac{\gamma \vdash \langle h \mid e_i \rangle \Downarrow \langle h' \mid \epsilon \rangle \quad \exists\, i \in \{1, 2\}}{\gamma \vdash \langle h \mid e_1 + e_2 \rangle \Downarrow \langle h' \mid \epsilon \rangle} \qquad \textsc{O-LetCut}\ \frac{\gamma \vdash \langle h \mid e_1 \rangle \Downarrow \langle h' \mid \epsilon \rangle \quad \epsilon \neq \mathsf{ok}(-)}{\gamma \vdash \langle h \mid \mathbf{let}\ x = e_1\ \mathbf{in}\ e_2 \rangle \Downarrow \langle h' \mid \epsilon \rangle}$$

$$\textsc{O-Let}\ \frac{\gamma \vdash \langle h \mid e_1 \rangle \Downarrow \langle h'' \mid \mathsf{ok}(v) \rangle \quad \gamma \vdash \langle h'' \mid e_2[v/x] \rangle \Downarrow \langle h' \mid \epsilon \rangle}{\gamma \vdash \langle h \mid \mathbf{let}\ x = e_1\ \mathbf{in}\ e_2 \rangle \Downarrow \langle h' \mid \epsilon \rangle}$$

$$\textsc{O-Call}\ \frac{f(\overline{x})\{e\} \in \gamma \quad \gamma \vdash \langle h \mid e[\overline{t}/\overline{x}] \rangle \Downarrow \langle h' \mid \epsilon \rangle}{\gamma \vdash \langle h \mid f(\overline{t}) \rangle \Downarrow \langle h' \mid \epsilon \rangle}$$

Figure 7 The full RUXtBelt semantics; the instrumented RUXtBelt semantics is obtained by replacing err in O-FreeMiss, O-StoreMiss and O-LoadMiss with miss(l).

Moreover, accessing locations that are not part of the (full) heap also terminate erroneously (O-FreeMiss, O-StoreMiss and O-LoadMiss). That is, the full heap must contain all resources required for successful termination or it terminates erroneously.

The remaining judgements closely mimic RISL rules in Fig. 5. Starting from h, non-deterministic choice $e_1 + e_2$ reduces to h' with ϵ if *either* e_1 *or* e_2 does so. A let binding short-circuits if e_1 terminates unsuccessfully (O-LetCut); otherwise, e_1 propagates its value v to e_2 by substituting the binder x (O-Let). A call to f is reduced by substituting its arguments with input terms in its body when f is in the implementation context (O-Call).

Instrumented semantics. We next define our *instrumented* semantics that operates on incomplete heaps and distinguishes err and miss conditions. Our instrumented semantics comprises judgements of the $\gamma \vdash \langle h \mid e \rangle \Downarrow_i \langle h' \mid \epsilon \rangle$ (note the i subscript in $\Downarrow$) and only

differs from the full semantics by yielding a $\mathsf{miss}(l)$ exit in O-FreeMiss, O-StoreMiss and O-LoadMiss. In effect, the full semantics maps every miss termination in the instrumented semantics to an err one, preserving all other outcomes, as we show in the following lemma.

▶ **Lemma 1** (Semantics preservation). *For all γ, h, h', e and ϵ, if $\gamma \vdash \langle h \mid e \rangle \Downarrow_i \langle h' \mid \epsilon \rangle$, then one of the following holds:*

1. $\epsilon = \mathsf{ok}(v)$ *and* $\gamma \vdash \langle h \mid e \rangle \Downarrow \langle h' \mid \mathsf{ok}(v) \rangle$.
2. $\epsilon \neq \mathsf{ok}(-)$ *and* $\gamma \vdash \langle h \mid e \rangle \Downarrow \langle h' \mid \mathsf{err} \rangle$.

As we show below, our instrumented semantics enjoys strong frame preservation properties, namely *frame subtraction* (Lemma 2) and *frame addition* (Lemma 3). The former describes the effects of removing fragments from the underlying heap, while the latter accounts for heap extensions. We write $h_s \# h_F$ to denote that h_s and h_F are *disjoint* (i.e. have disjoint domains) and can thus be composed (combined) through the disjoint union operator $\uplus$.

▶ **Lemma 2** (Frame subtraction). *For all γ, h_s, h_F, h'_s, e and ϵ, if $\gamma \vdash \langle h_s \uplus h_F \mid e \rangle \Downarrow_i \langle h'_s \uplus h_F \mid \epsilon \rangle$ and $h_s \# h_F$ holds, then one of the following holds:*

1. $\gamma \vdash \langle h_s \mid e \rangle \Downarrow_i \langle h'_s \mid \epsilon \rangle$ *and* $h'_s \# h_F$.
2. *There exist h', l such that $\gamma \vdash \langle h_s \mid e \rangle \Downarrow_i \langle h' \mid \mathsf{miss}(l) \rangle$, $h' \# h_F$ and $l \in \mathsf{dom}(h_F)$.*

▶ **Lemma 3** (Frame addition). *For all γ, h, h', e and ϵ, if $\gamma \vdash \langle h \mid e \rangle \Downarrow_i \langle h' \mid \epsilon \rangle$, then for all h_F such that $h' \# h_F$ holds, one of the following holds:*

1. $\gamma \vdash \langle h \uplus h_F \mid e \rangle \Downarrow_i \langle h' \uplus h_F \mid \epsilon \rangle$ *and* $h \# h_F$.
2. *There exists l such that $\epsilon = \mathsf{miss}(l)$ and $l \in \mathsf{dom}(h_F)$.*

Lemma 2 states that removing a fragment from the heap under execution either (1) preserves the behaviour of the program; or (2) terminates unsuccessfully due to a missing location in the frame. Conversely, Lemma 3 states that extending the underlying heap (1) preserves the behaviour of the program unless (2) the program terminates with a miss before adding the frame, and the frame contains the missing location. This is precisely why we need the $\mathsf{frameable}(\epsilon, R)$ requirement in the premise of the S-Frame rule, i.e. to ensure that the extension R does not include missing resources that may change the termination condition.

These lemmas demonstrate how (when dealing with incomplete heaps in our instrumented semantics) extending and shrinking the underlying heap may affect the termination condition with regards to missing resources. By contrast, in our full semantics we assume that the underlying heap is always complete, and thus we need not account for extending or shrinking it. As our instrumented semantics considers partial (incomplete) heaps, it closely captures the *compositional* nature of our RISL proof rules, where in each rule the pre- and post-conditions only describe the (partial) heap fragments needed for executing a given λ_{RUXt} program, and the underlying heap (resources) may always be extended using the S-Frame rule. As such, it is simpler to first show RISL sound against our instrumented semantics, as we show next in §6.2, and then relate it to our full semantics using Lemma 1 for our inadequacy result in §6.3.

6.2 Semantic RISL Triples and Soundness

We next formalise the *semantic interpretation* of RISL triples. Recall that RISL triples (Fig. 5) are given using assertions. As such, we first present the semantics of RISL assertions.

Semantic interpretation $(\!|\cdot|\!) : \textsc{Asrt} \to \textsc{Heap} \to \textsc{Prop}$

$$(\!|\llcorner \pi \lrcorner|\!) \triangleq \lambda\, h.\ h = \emptyset \wedge \pi \qquad (\!|\mathsf{True}|\!) \triangleq \lambda\, _.\ \top \qquad (\!|\mathsf{False}|\!) \triangleq \lambda\, _.\ \bot$$
$$(\!|P \wedge Q|\!) \triangleq \lambda\, h.\ (\!|P|\!)(h) \wedge (\!|Q|\!)(h) \qquad (\!|P \vee Q|\!) \triangleq \lambda\, h.\ (\!|P|\!)(h) \vee (\!|Q|\!)(h)$$
$$(\!|P \Rightarrow Q|\!) \triangleq \lambda\, h.\ (\!|P|\!)(h) \Rightarrow (\!|Q|\!)(h) \qquad (\!|\exists\ x.\ P|\!) \triangleq \lambda\, h.\ \exists\ x.\ (\!|P|\!)(h)$$
$$(\!|l \mapsto v|\!) \triangleq \lambda\, h.\ h = \{l \mapsto v\} \qquad (\!|l \mapsto_? |\!) \triangleq \lambda\, h.\ h = \{l \mapsto \lightning\} \qquad (\!|l \not\mapsto|\!) \triangleq \lambda\, h.\ h = \{l \mapsto \varnothing\}$$
$$(\!|\mathsf{emp}|\!) \triangleq \lambda\, h.\ h = \emptyset \qquad (\!|P * Q|\!) \triangleq \lambda\, h.\ \exists\ h_P, h_Q.\ h = h_P \uplus h_Q \wedge (\!|P|\!)(h_P) \wedge (\!|Q|\!)(h_Q)$$

Figure 8 Assertion semantics.

Assertion semantics. We define the semantics of assertions in Fig. 8 through an interpretation function, $(\!|\cdot|\!)$, that maps assertions to predicates (Prop in Rocq) on heaps (i.e. our program states). Pure assertions require no heap resources and thus assert ownership of an empty heap. Semantics of truth and falsity do not depend on the heap, semantics of conjunction, disjunction, implication and existential quantification are defined inductively and as expected. For separation logic (SL) assertions, emp simply expresses ownership of an empty heap, while $l \mapsto v$ expresses ownership of a singleton heap mapping l to v. Similarly, $l \not\mapsto$ and $l \mapsto_?$ express ownership of a singleton heap mapping l to $\varnothing$ and $\lightning$, respectively. Finally, the separating conjunction requires the heap to be split into two disjoint sub-heaps, each satisfying one sub-assertion. An assertion P is *valid*, written $\models P$, if it holds of *every* heap; P is *satisfiable*, written $\mathsf{sat}(P)$, if it holds of *some* heap:

$$\models P \triangleq \forall\ h.\ (\!|P|\!)(h) \qquad \mathsf{sat}(P) \triangleq \exists\ h.\ (\!|P|\!)(h)$$

Semantic RISL triples. A *semantic* triple (*cf.* *syntactic* RISL triples in Fig. 5), $\gamma \vDash [P]\, e\, [\epsilon\colon Q]$, states that every heap h_q satisfying Q is reachable under ϵ from some heap h_p satisfying P by executing e under implementation context γ:

$$\gamma \vDash [P]\, e\, [\epsilon\colon Q] \triangleq \forall\ h_q.\ (\!|Q|\!)(h_q) \Rightarrow \exists\ h_p.\ (\!|P|\!)(h_p) \wedge \gamma \vdash \langle h_p \mid e \rangle \Downarrow_i \langle h_q \mid \epsilon \rangle$$

Note that while the syntactic RISL triples (Fig. 5) are defined using a *specification* context Γ, semantic triples (above) are given using an *implementation* context γ. To give a semantic meaning to our RISL triples, we thus lift the notion of a semantic triple with γ, to one using Γ, provided that Γ is *well-formed* with respect to γ. Recall that in §5.2 we provided a *logical* notion of this well-formedness, $\gamma \prec_{\mathsf{S}} \Gamma$, that can be derived using the rules in Fig. 6. We analogously define a *semantic* notion of well-formedness as follows. We define the semantics of the refinement relation from §5.2 as follows:

$$\gamma \lessdot_{\mathsf{S}} \Gamma \triangleq \forall f, \overline{v}, P, \epsilon, Q.\ \left[(\overline{v})\ P \mid \epsilon\colon Q\right] \in \Gamma(f) \Rightarrow \exists\ \overline{x}, e.\ f(\overline{x})\{e\} \in \gamma \wedge \gamma \vDash [P]\, e[\overline{v}/\overline{x}]\, [\epsilon\colon Q]$$

This ensures that every specification $\left[(\overline{v})\ P \mid \epsilon\colon Q\right]$ of function f in Γ is the result of directly executing the function body with the given input values.

We next lift the notion of semantic triples (with γ) to *semantic* RISL *triples* (with Γ):

$$\Gamma \vDash [P]\, e\, [\epsilon\colon Q] \triangleq \forall\ \gamma.\ \gamma \lessdot_{\mathsf{S}} \Gamma \Rightarrow \gamma \vDash [P]\, e\, [\epsilon\colon Q]$$

That is, as RISL only relies on derived specifications and not on concrete implementations, a semantic RISL triple with Γ holds when the corresponding semantic triple holds for all implementation contexts γ with respect to which Γ is semantically well-formed.

Soundness of RISL. In Lemma 4 below we prove that (i) every RISL triple that can be derived using the rules in Fig. 5 is a valid semantic RISL triple.; and (ii) every well-formed specification context Γ constructed using the rules in Fig. 6 is semantically well-formed.

▶ **Lemma 4.** *For all Γ, γ, P, Q, e and ϵ:*
1. *if $\Gamma \vdash [P]\, e\, [\epsilon\colon Q]$ is derived using the rules in Fig. 5, then $\Gamma \vDash [P]\, e\, [\epsilon\colon Q]$ holds; and*
2. *if $\gamma \prec_{\mathsf{S}} \Gamma$ is derived using the rules in Fig. 6, then $\gamma \lll_{\mathsf{S}} \Gamma$ holds.*

Finally, we prove that the RISL proof system is sound by showing that every triple derived for a given implementation using the RISL rules in Fig. 5 is a (sound) semantic triple.

▶ **Theorem 5** (RISL soundness). *For all Γ, γ, P, Q, e and ϵ, if $\gamma \prec_{\mathsf{S}} \Gamma$ and $\Gamma \vdash [P]\, e\, [\epsilon\colon Q]$ is derived using the rules in Fig. 5, then $\gamma \vDash [P]\, e\, [\epsilon\colon Q]$ holds.*

Crucially, RUXt relies on this result to justify the soundness of its summary inference. Specifically, every postcondition $[\epsilon : Q] \in \mathsf{execute}(\gamma, f(\overline{v}), P)$ derived by its underlying symbolic execution engine (underpinned by RISL) on line 3 (Fig. 4, left) must ensure that $\gamma \vDash [P]\, f(\overline{v})\, [\epsilon\colon Q]$ holds, which follows immediately from the RISL soundness above (Theorem 5). That is, by implementing the RISL proof system in its underlying symbolic execution engine, the RUXt algorithm thus guarantees that every summary it infers is a sound under-approximation of the reachable states.

6.3 Soundness of RUXt

We next show that RUXt is sound by proving its no-false-positives guarantee: when RUXt detect a UB with a witness program e, then e is indeed a safe program that results in UB, witnessing that the usage of unsafe code is not encapsulated by the safe API of the library. To this end, using the RISL soundness result (Theorem 5), in Theorem 6 below we first show that every summary derived by RUXt yields a sound RISL triple starting from an initial empty heap and terminating successfully. Furthermore, the witness program associated with inferred summary is guaranteed to be a safe program, meaning that the corresponding safe value can be constructed by solely interacting with the safe API of the library. More concretely, given an implementation context γ, a signature context Δ and a summary context Σ, if RUXt derives $\gamma, \Delta \vdash \Sigma$ using the rules in Fig. 4 (right) with $\mathsf{Summary}(\lambda v.\ Q \mid e)$ in Σ, then for every concrete value v (1) e is a safe program; and (2) $\gamma \vDash [\mathsf{emp}]\, e\, [\mathsf{ok}(v)\colon Q]$ holds.

▶ **Theorem 6** (Summary soundness). *For all γ, Δ, Σ, Q, e, if $\gamma, \Delta \vdash \Sigma$ is derived using the rules in Fig. 4 and $\mathsf{Summary}(\lambda v.\ Q \mid e) \in \Sigma$, then e is a safe program and $\gamma \vDash [\mathsf{emp}]\, e\, [\mathsf{ok}(v)\colon Q]$ holds for all v.*

Finally, using the soundness of summary inference in RUXt, we prove our key *inadequacy* theorem: given a well-formed summary context, if the refutation procedure reports a type unsoundness, then the returned witness is a safe program that leads to UB.

▶ **Theorem 7** (Inadequacy). *For all γ, Δ, Σ, e, if $\gamma, \Delta \vdash \Sigma$ is derived using the rules in Fig. 4 and $\mathsf{TryRefute}(\gamma, \Delta, \Sigma)$ returns a witness program e, then e is a safe program and $\gamma \vdash \langle \emptyset \mid e \rangle \Downarrow \langle h \mid \mathsf{err} \rangle$, for some h.*

Note that our inadequacy theorem states that e results in an error in our *full* semantics starting from an empty heap. Although summaries are only shown to be reachable using the *instrumented* semantics (in the conclusion of Theorem 6), our semantics preservation lemma (Lemma 1) allows us to exchange any judgement of the instrumented semantics into

one in our full semantics (by leaving successful judgements unchanged, while transforming unsuccessful ones with miss or err into erroneous ones with err), provided that we operate on the *full* heap. Indeed, the empty heap should suffice for safe programs to execute safely, and thus RUXt can soundly report miss exits as true UB. Concretely, our inadequacy theorem states that *any UB reported by* RUXt *is a true safety violation in the library*, that can be triggered by its returned witness program.

7 Related and Future Work

RUXt exists in a rich ecosystem of tools and techniques for analysing unsafe Rust code, as well as techniques that combine type-guided reasoning with under-approximate reasoning. We discuss these in turn, categorising Rust analysis tools into three categories: compositional verification, whole-program analysis and bug-finding tools.

Compositional type-safety verification for Rust. There are a number of tools that aim to *verify* the type safety of Rust programs. RustBelt [19] is an Iris mechanisation [20, 22] that provides a formal model of Rust's type system and provides a framework for compositionally verifying the type safety of internally unsafe libraries. Later, RefinedRust [10] (based on Lithium [33]), VeriFast for Rust [7] (based on VeriFast [15]) and Gillian-Rust [1] (based on Gillian [8, 26]) are all underpinned by RustBelt and aim to verify the type safety of Rust code, each with their own set of caveats and trade-offs. Verus [23] is a language (embedded in Rust) for writing formally verified code that can be extracted to idiomatic Rust code. However, Verus cannot verify existing unsafe Rust code that has not been written within Verus. While these tools are powerful, they all require a substantial amount of manual effort on the part of users and, as verification tools, are prone to false positives.

Whole-program analysis for Rust. Miri is a Rust interpreter distributed with the Rust compiler. It allows for the concrete execution of Rust programs and can detect many UB such as out-of-bounds memory accesses or more subtle Rust-specific issues, e.g. the violation of aliasing rules [18]. However, Miri is a testing tool, it requires the user to write tests, and can only explore one execution path.

Kani [35] is a whole-program bounded model checker for Rust. It performs symbolic execution, and as such can explore infinitely many execution paths. However, Kani still requires users to write tests and first-order logic assertions, and it is prone to *both* false positives (due to its over-approximate nature) *and* false negatives (as it is bounded). Moreover, Kani is unsound with respect to several Rust-specific features, e.g. the detection of uninitialised memory accesses, or the violation of aliasing rules. Neither Miri nor Kani can detect type unsoundness in Rust programs, as they cannot reason compositionally about library invariants.

Bug-finding tools for Rust. We know of three automatic bug-finders for Rust: Rudra [2], TraitInv [5] and Crabtree [34]. Rudra uses linter-like heuristics to detect three specific unsafe patterns in Rust code that are known to often lead to type unsoundness. It is automatic and was ran on the entirety of the Rust openly-available packages (`crates.io`), finding more than 250 new safety issues. However, its scope is limited to the detection of the three patterns, and it is prone to false positives.

TraitInv automatically synthesises symbolic tests that check certain properties expected to hold for eight core Rust traits (e.g. that `PartialEq` is symmetric and transitive). TraitInv then runs these tests using Kani and reports violations. Unfortunately, TraitInv's approach is

limited to these specific traits, and supporting new traits requires manual effort as it cannot infer new trait invariants. Furthermore, since it relies on Kani, TraitInv is also prone to false positives; it can only be extended to support first-order properties and cannot be used to enforce separation logic (ownership) properties such as that required by the `Copy` trait.

Crabtree is an automatic test synthesiser that uses a type-guided approach to increase coverage of the library under test. It can generate tests that make use of advanced Rust features such as higher-order trait functions; it uses Miri to execute the generated tests and can detect type unsoundness in the library if a test fails. Its type-guided approach is somewhat similar to ours. However, instead of inferring type subvariants, Crabtree notes when it finds a *path* that generates a value of a type not previously seen in the test suite, and uses that information to call functions that have not yet been covered because of the lack of input values for this type. This approach is, unlike ours, not compositional, and still quickly leads to combinatorial (path) explosion.

Type refutation and under-approximation. The recent development of Incorrectness Logic [31] has led to the exploration of reasoning techniques that combine type systems with under-approximation, starting with a theoretical experiment from Ramsay and Walpole [32] who introduced a two-sided type system that allows for refutation of type assignments.

Next, HayStack [38] is an extension of LiquidHaskell [36], a refinement type system for Haskell. HayStack is similar to RUXt, in that it infers subsets of the refinement type spaces that are sufficient to refute the refinement types provided by the user. However, it differs from RUXt in several key aspects. First, HayStack is used to provide explanations for type errors when the user provides a refinement type annotation that cannot be proven by LiquidHaskell. However, as refinement type checking is inherently over-approximate, inability to type-check does not guarantee that the program is incorrect. Furthermore, HayStack can only help finding counter-examples in Haskell programs that have been annotated with refinement types and is therefore not fully automatic. Finally, LiquidHaskell refinement types are first-order and cannot express separation logic (ownership) properties.

Finally, Qian et al. [30] propose a semantic type refuter that can find type unsoundness in a simple functional language. However, their approach requires knowledge of the *semantic typing of all existing types*, which must be defined using first-order logic. As such, they cannot find type unsoundness in internally-unsafe libraries, where type invariants must be inferred from the code itself and must be expressed using separation logic.

Symbolic execution for bug-finding. There is an extensive literature on symbolic execution for bug-finding, which can be split into two categories: dynamic and static symbolic execution. None of these techniques have been applied to Rust, or leverage the main novelty in our approach: the use of type-guided reasoning to refute the type safety of a program.

Dynamic first-order symbolic execution (or concolic execution) has been used to automatically detect bugs and generate tests using tools such as KLEE [6], DART [12, 11, 13], and more [39, 21]. However, our prototype implementation is based on static compositional symbolic execution, which, in the context of bug-finding, is implemented in Infer:Pulse [24] and Gillian [26, 25]. However, as explained in §2, these tools are only able to soundly detect *manifest* bugs, while our approach can detect a larger class of bugs, namely *type unsafety*.

Future Work. In the future, we will extend and build on our work here in several ways. First, we will extend our λ_{RUXt} language and RUXtBelt formalisation to include support for relevant Rust features such as polymorphism and higher-order functions. Second, we

will extend RUXt accordingly to include support for these features, and further ensure that UB reports are accompanied by witness programs. Finally, we will perform a large-scale evaluation of RUXt by applying it to real Rust codebases.

Abstract

Functionality-specific vulnerabilities, which mainly occur in Application Programming Interfaces (APIs) with specific functionalities, are crucial for software developers to detect and avoid. When detecting individual functionality-specific vulnerabilities, the existing two categories of approaches are ineffective because they consider only the API bodies and are unable to handle diverse implementations of functionality-equivalent APIs. To effectively detect functionality-specific vulnerabilities, we propose APISS, the first approach to utilize API doc strings and signatures instead of API bodies. APISS first retrieves functionality-equivalent APIs for APIs with existing vulnerabilities and then migrates Proof-of-Concepts (PoCs) of the existing vulnerabilities for newly detected vulnerable APIs. To retrieve functionality-equivalent APIs, we leverage a Large Language Model for API embedding to improve the accuracy and address the effectiveness and scalability issues suffered by the existing approaches. To migrate PoCs of the existing vulnerabilities for newly detected vulnerable APIs, we design a semi-automatic schema to substantially reduce manual costs. We conduct a comprehensive evaluation to empirically compare APISS with four state-of-the-art approaches of detecting vulnerabilities and two state-of-the-art approaches of retrieving functionality-equivalent APIs. The evaluation subjects include 180 widely used Java repositories using 10 existing vulnerabilities, along with their PoCs. The results show that APISS effectively retrieves functionality-equivalent APIs, achieving a Top-1 Accuracy of 0.81 while the best of the baselines under comparison achieves only 0.55. APISS is highly efficient: the manual costs are within 10 minutes per vulnerability and the end-to-end runtime overhead of testing one candidate API is less than 2 hours. APISS detects 179 new vulnerabilities and receives 60 new CVE IDs, bringing high value to security practice.

1 Introduction

Application Programming Interfaces (APIs) in open source software are critical and widely used in software development [40], while the usage of APIs also increases the burden on developers to avoid security vulnerabilities among the APIs. Functionality-specific vulnerabilities, as one common type of API vulnerabilities, are defined as those that mainly occur in APIs with specific functionalities. For example, `Path Traversal` vulnerabilities (i.e., unauthorized access to a restricted directory) likely occur in an `unzip` API if it forgets to check whether the paths in its inputs (an uploaded zip file) are permitted. These vulnerabilities are often caused by lacking crucial operations during implementation, such as input validation, so similar vulnerabilities might occur among individual APIs with equivalent/similar functionalities (referred to as functionality-equivalent APIs).

However, the existing approaches, which fall into two categories, are ineffective in detecting functionality-specific vulnerabilities, as these approaches consider only the API bodies. First, some approaches [43, 26] aim to detect recurring vulnerabilities, which come from reused code base or shared code logic. However, these approaches find only vulnerabilities that have both similar functionalities and similar implementations with existing ones, thus suffering from high false negatives when encountering functionality-equivalent APIs with diverse implementations. Second, some other approaches [41, 52, 39, 8, 38, 37, 42, 31, 17, 7] aim to detect vulnerabilities other than recurring ones, typically via deep learning, which learns code features of vulnerable APIs/methods of existing vulnerabilities. However, these approaches are ineffective because the APIs affected by these vulnerabilities have diverse implementations without a common pattern. Additionally, these approaches cannot provide Proof-of-Concepts (PoCs) for the detected vulnerabilities, leading to high manual costs in vulnerability validation.

To effectively detect functionality-specific vulnerabilities, we propose APISS, the first approach that utilizes API doc strings and signatures (instead of focusing on API bodies), consisting of two steps: retrieving functionality-equivalent APIs for existing vulnerabilities and then migrating PoCs of the existing vulnerabilities to exploit new vulnerabilities. Our rationale comes from our observation of functionality-equivalent APIs: these APIs have similar doc strings and signatures because an API's input/output format (i.e., the API name, parameters, and output type included in its signature) is determined by this API's functionality and the doc string is used to explain each component of this API's signature. Thus, the doc strings and signatures of APIs with existing vulnerabilities can be utilized to retrieve functionality-equivalent APIs with potential functionality-specific vulnerabilities.

There are two main challenges in the two steps of APISS, respectively. First, the main challenge of retrieving functionality-equivalent APIs is the effectiveness and scalability issues. The effectiveness issue of existing approaches [29, 11, 6, 47] is caused by their overemphasis on the similarities of API bodies, not being able to handle diverse implementations of functionality-equivalent APIs. The scalability issue of these existing approaches comes from their training/fine-tuning on specific datasets, e.g., mapping a Java API to a C# API [29, 11, 6] or a Swift one [47]. Second, the main challenge of migrating the PoCs of existing vulnerabilities is the high manual costs. Migrating the PoCs requires building the environment and API dependencies of the project repository that includes a newly-detected

vulnerable API. Given that newly-detected vulnerable APIs come from different repositories and have different context dependencies, environment/dependency building incurs high manual costs.

To address the preceding two challenges, we design two respective techniques based on our observations on functionality-equivalent APIs and PoCs of functionality-specific vulnerabilities. First, we leverage a Large Language Model (LLM) for API embedding to address the effectiveness and scalability issues due to the enormous achievements of LLMs. For each pair of APIs, we combine the embedding distances of each component (doc string, signature, body) between them to determine whether they are functionality-equivalent. Our observation is the similarities among API doc strings and signatures of functionality-equivalent APIs. Second, we design a semi-automatic schema to migrate the PoC of existing vulnerabilities, thus substantially reducing manual costs. Our observation is that a vulnerability PoC consists of two parts: input construction (constructing a specific object) and API invocation (invoking the target API) where the former remains the same during migration and the latter often accounts for one or two lines of PoCs and can be semi-automatically migrated by the algorithm of parameter mapping [45].

We evaluate APISS on 180 widely used Java repositories using 10 existing vulnerabilities along with their PoCs. Additionally, we compare APISS's effectiveness with four state-of-the-art approaches of detecting vulnerabilities and two state-of-the-art approaches of retrieving functionality-equivalent APIs. Our evaluation results show that APISS is effective in detecting new vulnerabilities as the best of the baselines under comparison can detect only 58% of the vulnerabilities detected by APISS. Additionally, APISS effectively retrieves functionality-equivalent APIs, achieving a Top-1 Accuracy of 0.81 while the best of the baselines under comparison achieves only 0.55. APISS is highly efficient: its manual costs are within 10 minutes per vulnerability and the end-to-end runtime overhead of analyzing one candidate API is less than 2 hours. APISS has detected 170 new vulnerabilities and received 60 new CVE IDs, bringing high value to security practice.

In summary, this paper makes the following main contributions:

- To the best of our knowledge, we are the first to utilize API doc strings and signatures instead of focusing on API bodies to retrieve functionality-equivalent APIs and then detect functionality-specific vulnerabilities.
- We propose an effective technique of API mapping to retrieve functionality-equivalent APIs mainly based on the embedding distance of API doc strings and signatures, and achieve a Top-1 Accuracy of 0.81 while the best of the baselines under comparison achieves only 0.55.
- We design a semi-automatic schema to reduce the manual costs of migrating the PoC of existing vulnerabilities within 10 minutes per vulnerability.
- We implement a prototype of APISS and show its high value to security practice by detecting 179 new vulnerabilities and receiving 60 new CVE IDs.

2 Preliminaries

In this section, we provide definitions for three key concepts to improve accessibility for a broader audience.

CVE (Common Vulnerabilities and Exposures): It is maintained by the MITRE Corporation. CVEs are used to identify, define, and catalog publicly disclosed cybersecurity vulnerabilities. Once a vulnerability is discovered, developers can request a unique CVE ID from MITRE. Once assigned, this ID enables consistent reference to the vulnerability across databases and platforms. CVEs are widely used by security practitioners to monitor relevant vulnerabilities and track vulnerability patches and affected packages.

CWE (Common Weakness Enumeration): It is also maintained by MITRE. CWE provides a classification system for types of software vulnerabilities. As of now, there are 943 unique CWE types, offering a standardized framework for understanding software vulnerabilities.

PoC (Proof-of-Concept): A PoC is a minimal, verifiable demonstration that confirms the existence and exploitability of a specific security vulnerability. In our paper, we define a PoC as **a single unit test case that demonstrates such exploitability**. Due to the potential security risks, PoCs are often withheld by practitioners to prevent attackers from exploiting vulnerabilities before affected users can apply necessary fixes.

3 Motivation

In this section, we use a motivating example to introduce functionality-specific vulnerabilities and functionality-equivalent APIs. We further leverage this example to demonstrate why existing approaches fail to identify these vulnerabilities. Then we explain our observations on functionality-equivalent APIs and our insights of APISS.

3.1 A Motivating Example

Listing 1 and Listing 2 show a motivating example of two functionality-equivalent APIs with similar functionality-specific vulnerabilities, CVE-2023-27603[1] and CVE-2023-33484[2]. Specifically, CVE-2023-27603 is an existing Scala vulnerability whose PoC is available while CVE-2023-33484 is a Java vulnerability newly detected by APISS based on the former vulnerability.

Functionality-Specific Vulnerabilities. Functionality-specific vulnerabilities are defined as vulnerabilities that mainly occur in APIs with specific functionalities. These vulnerabilities are often caused by a lack of crucial operations during implementation, such as input validation. Listing 1 is the patch of an example functionality-specific vulnerability, CVE-2023-27603, which affects the `fileToUnzip` API in a widely used third-party repository, `Apache Linkis`. This vulnerability corresponds to a representative type of functionality-specific vulnerability, CWE-22 (i.e., improper limitation of a pathname to a restricted directory). Lines 16-21 in Listing 1 of this patch explain how this vulnerability is exploited and fixed. Specifically, the vulnerable API `fileToUnzip` forgets to check whether the file paths (`filePath` in Line 16) in the input zip file (`zipFilePath`) contain improper relative paths, e.g., "`..`", which has the risk of unzipping into a restricted directory (in Line 23).

Functionality-Equivalent APIs. Functionality-equivalent APIs refer to a collection of APIs that provide equivalent/similar functionalities, such as "unzip a zip file" or "parse a JSON file". Take Listing 1 and Listing 2 as examples. These two APIs, which come from two repositories (`Apache Linkis` and `Light4J`), respectively, perform the same functionality: unzipping an input zip file to a specific path.

Based on the preceding definitions, functionality-equivalent APIs often share similar or even the same functionality-specific vulnerabilities. For example, the `unzip` API in Listing 2 is also vulnerable to a path traversal vulnerability, CVE-2023-33484, and is fixed by invoking the `validateZipOut` method before unzipping. However, the implementations of these APIs might diverge substantially. For example, `fileToUnzip`'s source code spans only 27 lines while that of `unzip` spans 46 lines.

[2] `https://github.com/networknt/light-4j/issues/1760`

3.2 Limitations of Existing Approaches

Recurring-Vulnerability Detection Approaches. Some existing approaches [43, 26, 36] are designed to detect recurring vulnerabilities, which come from reused code or shared code logic. For example, MVP [43] utilizes hash values based on the code property graphs of known vulnerable APIs to match similar APIs in open-source repositories. However, these approaches rely heavily on matching the preceding implementation-based features. This reliance may produce high false negatives in detecting functionality-specific vulnerabilities while the affected APIs have diverse implementations.

Deep-Learning Approaches. Some other approaches [41, 52, 39, 8, 38, 37, 42] learn code features extracted from vulnerable APIs/methods including existing vulnerabilities. For example, Devign [52] uses a Graph Neural Network (GNN) to learn the code property graphs (e.g., control/data-flow graphs) of vulnerable APIs. These approaches can effectively detect vulnerabilities caused by incorrect implementation, such as use-after-free, because the source code of their affected APIs has specific patterns, e.g., a pointer operation after a `free` API invocation. However, these approaches are ineffective in detecting functionality-specific vulnerabilities because their affected APIs have diverse implementations without a common pattern. Additionally, these existing approaches also face limitations in generating PoCs for the detected vulnerabilities. A recent study [46] shows that deep-learning models, including LLMs, struggle to generate inputs to cover a specific code branch, let alone generate inputs to exploit a specific vulnerability.

3.3 Observation of Functionality-Equivalent APIs

Considering that an API's source code comprises not only its implementation (i.e., its body) but also a doc string and a signature, we explore the similarities and disparities among these elements in the APIs affected by existing functionality-specific vulnerabilities.

For example, in Listing 1 and Listing 2, we present a pair of functionality-equivalent APIs. Notably, while both APIs share comparable doc strings and signatures, their bodies diverge. Specifically, Line 7 in Listing 1 and Line 8 in Listing 2 represent their signatures. These signatures directly point out their intended functionality of `unzip` and include similar input parameters, such as the zip file's path/name and the destination directory for extraction. Moreover, their doc strings (Lines 1-6 in Listing 1 and Lines 1-7 in Listing 2) explain the purpose of these parameters, thus helping us classify them as functionality-equivalent APIs. However, in terms of their bodies (Lines 8-32 in Listing 1 and Lines 9-19 in Listing 2), there are noticeable disparities, e.g., their differing lengths (27 lines in the former and 46 lines in the latter).

3.4 Our Insight

Our observation reveals that functionality-equivalent APIs often share similarities in their doc strings and signatures, and disparities in their implementations (bodies). Based on this observation, in this paper, we propose to utilize API doc strings and signatures to retrieve functionality-equivalent APIs, thus contributing to detecting functionality-specific vulnerabilities.

A main characteristic of doc strings and signatures is that they are closer to natural language than code. Doc strings are written in natural language and serve the purpose of explaining API functionalities and the purpose of each parameter. Signatures are part of the API source code, primarily consisting of API names and parameters without structured information, e.g., control/data-flow dependencies.

Listing 1 The Vulnerability Patch of CVE-2023-27603 (an Existing Scala Vulnerability).[3]

```
/**
 * @param zipFilePath
 *   Path of the zip file to be extracted
 * @param unzipDir
 *   Path of the destination directory
 */
def fileToUnzip(zipFilePath: String, unzipDir: String): Unit = {
    val zipIn = new ZipInputStream(new FileInputStream(zipFilePath))
    Utils.tryFinally {
    val destDir = new File(unzipDir)
    if (!destDir.exists()) {
        destDir.mkdir()
    }
    var entry = zipIn.getNextEntry
    while (entry != null) {
-       val filePath = destDir.getPath + File.separator + entry.
    getName
+       var entryName = entry.getName
+       if (entryName.contains(".." + File.separator)) {
         throw new IOException("Zip entry contains illegal characters:
              " + entryName)
+       }
+       val filePath = destDir.getPath + File.separator + entryName
         if (!entry.isDirectory) {
           extractFile(zipIn, filePath)
         } else {
           val dir = new File(filePath)
           dir.mkdir
         }
         zipIn.closeEntry()
         entry = zipIn.getNextEntry
       }
    }(IOUtils.closeQuietly(zipIn))
}
```

Considering the preceding characteristic of doc strings and signatures, we propose to leverage a Large Language Model (LLM) to retrieve functionality-equivalent APIs due to an LLM's significant advancements in natural language and code comprehension. Our proposed approach involves separately embedding each combination of elements (doc string, signature, and body) of a given API as its embedding features. For each API pair, we compute the distances between their respective embedding features and average them as their weighted distances. Notably, our empirical results in Section 5.4 indicate that the embedding features with API bodies have a negligible contribution.

Advantages Over Existing API Mapping Approaches. Our proposed approach has two main advantages when compared to existing work [29, 11, 6, 50, 47], which models the task of retrieving functionality-equivalent APIs as an API mapping task. First, existing

[3] https://github.com/apache/linkis/pull/4279/commits/b3a16c4f1d4ab66d412b0d55bd8c0c35b48775b5

Listing 2 The Vulnerability Patch of CVE-2023-33484 (a Newly-Detected Java Vulnerability).[4]

```
/**
 * Unzips the specified zip file to the specified destination
     directory.
 * Replaces any files in the destination, if they already exist.
 * @param zipFilename the name of the zip file to extract
 * @param destDirname the directory to unzip to
 * @throws IOException IOException
 */
public static void unzip(String zipFilename, String destDirname) {
... //17 lines
    final Path destFile = Paths.get(destDir.toString(), file.toString
        ());

+   // validate unzip cross file
+   validateZipOutputFile(zipFilename, new File(destDirname,file.
    toString()), new File(destDirname));

    if(logger.isDebugEnabled()) logger.debug("Extracting file %s to %
        s", file, destFile);
    Files.copy(file, destFile, StandardCopyOption.REPLACE_EXISTING);
    return FileVisitResult.CONTINUE;
... //19 lines
}
```

approaches are less effective. Similar to vulnerability-detection approaches, existing API mapping approaches also overemphasize API bodies without being able to handle diverse implementations of functionality-equivalent APIs. Second, existing approaches are less generalizable because they are trained/fine-tuned on specific datasets, e.g., mapping first-party APIs in Java libraries to C# ones [29, 11, 6, 50] or Swift ones [47].

4 Approach

In this section, we propose APISS, the first approach to detect functionality-specific vulnerabilities via retrieving functionality-equivalent APIs. Unlike existing deep-learning and recurring-vulnerability detection approaches, APISS utilizes API doc strings and signatures to retrieve functionality-equivalent APIs and subsequently detect and exploit new functionality-specific vulnerabilities.

The workflow of APISS is illustrated in Figure 1. The input of APISS consists of two parts, an existing vulnerability (a.k.a., source vulnerability), including its affected API and its Proof-of-Concept (PoC), and a series of candidate APIs on which APISS intends to detect functionality-specific vulnerabilities if any exist. The output of APISS is a series of new vulnerabilities, each including an affected API and its corresponding PoC.

As shown in Figure 1, APISS contains two steps. First, APISS retrieves functionality-equivalent APIs among these candidate APIs by leveraging the embedding of each combination of API elements (doc string, signature, and body). Second, for each retrieved functionality-

[4] https://github.com/networknt/light-4j/pull/1768/commits/dff1dcb7f87622f86c953c9a7e639077d694a291

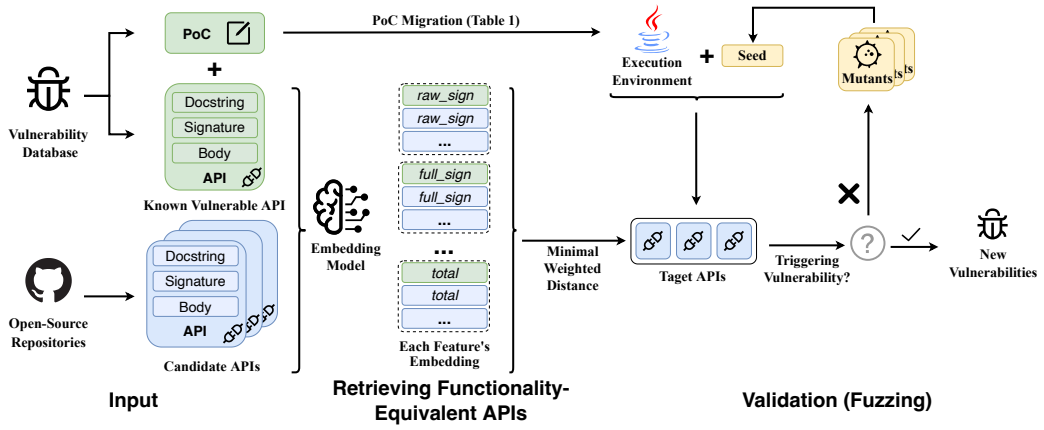

Figure 1 High-level framework of APISS.

equivalent API, APISS migrates the PoC of the source vulnerabilities. Additionally, for functionality-equivalent APIs corresponding to specific vulnerability types, APISS employs a fuzzing engine to conduct fuzzing based on the migrated PoC.

4.1 Retrieving Functionality-Equivalent APIs

Retrieving functionality-equivalent APIs is the basis of APISS as these APIs are more susceptible to vulnerabilities (similar to the given existing vulnerability) than other existing APIs.

Given that the source code of an API comprises three elements (its doc string, signature, and body), our key insight for retrieving functionality-equivalent APIs is to combine the embedding distances of these API elements. Specifically, we mainly focus on the embedding distances corresponding to API doc strings and signatures due to their similarities among functionality-equivalent APIs (as shown in Section 3.3). Considering the significant advancements achieved by Large Language Models (LLMs), we propose to leverage an LLM to embed various combinations of these three elements, termed as API features. To further investigate the contribution of each element, we also consider bodies when selecting features. In Section 5.4, we show that features including API bodies make only marginal contributions.

Specifically, we consider the following eight features:

- *raw_sign*: the raw signature, e.g., `public static void unzip (String zipFilename, String destDirname)` in Listing 2
- *full_sign*: the full signature (including the package and class names), e.g., `com.networknt.utility.NioUtils.unzip (String zipFilename, String destDirname)` in Listing 2
- *doc*: the doc string, e.g., Lines 1-7 in Listing 2
- *body*: the body, e.g., Lines 9-19 in Listing 2
- *raw_sb*: the combination of *raw_sign* and *body*
- *raw_ds*: the combination of *raw_sign* and *doc*
- *full_ds*: the combination of *full_sign* and *doc*
- *total*: the combination of *full_sign*, *doc*, and *body*

Pseudocode. Algorithm 1 presents the pseudocode of APISS' module of retrieving functionality-equivalent APIs. The algorithm takes as input a source API of an existing vulnerability ($srcAPI$), a set of candidate APIs ($candidateAPIs$), the weight of each feature ($\mathcal{W}_i$), and the desired number of functionality-equivalent APIs (N). This algorithm outputs N functionality-equivalent APIs associated with $srcAPI$.

Algorithm 1 Retrieving Functionality-Equivalent APIs.

input : $srcAPI$, a source API (of an existing vulnerability)
input : $candidateAPIs$, candidate APIs
input : $\mathcal{W}_i$, the weight of each feature
input : N, target number of functionality-equivalent APIs
output : $equivAPIs$, $srcAPI$'s functionality-equivalent APIs

```
// Obtain one code line's minimal depth in AST
1 Function getEmbeddings (API) :
2     features ← [raw_sign, full_sign, doc, body, raw_sb, raw_ds, full_ds, total];
3     for i ∈ features do
          // Each feature's normalized embedding
4         E_i(API) ← LLM(API_i).last_hidden_states[−1];
5         Ê_i(API) = E_i(API) / ||E_i(API)||;
6     E(API) ← [Ê_1, ..., Ê_F];
7     return E(API)
// Searching the top N closest APIs
8 E(src) ← getEmbeddings(srcAPI);
9 for dst ∈ candidateAPIs do
10    E(dst) ← getEmbeddings(dst);
11    D(src, dst) ← Σ_{i∈features} W_i * ||E_i(src) − E_i(dst)||_2;
12 equivAPIs ← argmin_{dst}[N]{D(src, dst)};
13 return equivAPIs;
```

In Lines 1–7, we compute each feature's embedding of a given API. In Line 4, we compute the raw embedding of each API feature, $\mathcal{E}_i(API)$. Then in Line 5, we normalize each embedding vector, denoted as $\hat{\mathcal{E}}_i(API)$. Our rationale for normalization is to ensure that the distances of each feature are within the same ranges.

In Lines 8–13, we compare the API embeddings of $srcAPI$ with those of $candidateAPIs$. In Lines 8–10, we generate the embeddings of both the $srcAPI$ and each candidate API using the `getEmbeddings` method. Then in Line 10, we define the distance of each pair of API embeddings as the weighted distance of each feature. Here, the distance of each feature is defined as the L2 norm [27, 12] of their embeddings' subtraction, $||\mathcal{E}_i(src) - \mathcal{E}_i(dst)||_2$.

Weight Optimization. The performance of Algorithm 1 depends on the selection of feature weights ($\mathcal{W}_i$). To determine the optimal set of values, we employ a global optimization technique. Specifically, we utilize the Basin-hopping algorithm [24], which has been widely applied in high-dimensional search problems [33, 48]. The optimization is performed on a dataset comprising Java and C# APIs (as shown in Table 6), and the resulting weights are subsequently used in the vulnerability detection process.

Acceleration by Vector Database. To enhance retrieval efficiency and mitigate the runtime costs of Algorithm 1, we utilize a vector database [20, 14]. Algorithm 1 requires calculating $|srcAPIs|$ * $|candidateAPIs|$ pairs of distances for all $|srcAPIs|$ as the distance between the src API and each dst API is computed in Lines 9-11. On the contrary, a vector database substantially reduces the runtime cost to $|srcAPIs| + |candidateAPIs|$ by storing

and retrieving the embeddings of $candidateAPIs$ while querying each $srcAPI$. During implementation, we choose Faiss[5] as our vector database and modify the selection criteria equivalently in Lines 11-12:

$$\begin{aligned} \textbf{Define: } \hat{\mathcal{E}}(API) = &< Weight_1 * \hat{\mathcal{E}}_1, \ldots, Weight_F * \hat{\mathcal{E}}_F > \\ &\underset{dst \in APIs}{argmin} \sum_{i \in Features} Weight_i * ||\hat{\mathcal{E}}_i(src) - \hat{\mathcal{E}}_i(dst)||_2 \\ &\Leftrightarrow \underset{dst}{argmin} \, ||\hat{\mathcal{E}}(src) - \hat{\mathcal{E}}(dst)||_2 \end{aligned} \tag{1}$$

where $\mathcal{E}_i(API)$ is the i-th feature embedding of API, $\hat{\mathcal{E}}_i(API)$ is the normalized embedding, and $\hat{\mathcal{E}}(API)$ is the concatenated embeddings of all API's features. Thus, we store only $\hat{\mathcal{E}}(dst)$ of all candidate APIs in our vector database.

4.2 Migrating PoCs of Existing Vulnerabilities

In this step, we migrate the PoC for each retrieved functionality-equivalent API from that of its source API. Our goal is to reduce the substantial human labor of manually constructing PoCs. Specifically, the input for this step includes a PoC from a source API and one of its functionality-equivalent APIs, while the output is an executable PoC for this functionality-equivalent API.

Our Observation. Our solution leverages our observation that a functionality-specific vulnerability's PoC generally consists of two parts: input construction and API invocation. Input construction, i.e., creating specific objects or data structures, remains consistent across functionality-equivalent APIs. For example, in the PoCs of CVE-2023-27603 and CVE-2023-33484 (Listing 3), the construction of a zip file containing a malicious file is identical (Lines 12–30 in both PoCs). This zip file attempts to access a restricted path using the relative address "../../a/b/c/poc.txt". On the contrary, API invocation, i.e., the actual invocation of the targeted API, varies minimally and comprises a smaller code portion of the PoC. Lines 7–8 demonstrate that the "unzip" method is called in the former CVE and "NioUtils.unzip" is called in the latter, both aiming to unzip the malicious zip file. Notably, the parameters for these invocations, including the path of the zip file and the targeted extraction path, remain identical/similar across different APIs.

Migration Procedure. The preceding observation highlights the feasibility of adapting PoCs between functionality-equivalent APIs with minimal adjustment. Thus, we design a semi-automatic schema to migrate the PoC of existing vulnerabilities with two steps. First, for each type of vulnerability, we collect a representative affected API with its PoC, and manually create a heuristic-based template for PoC migration. The details are listed in Table 1. Second, for the API invocation part, we migrate the usage of each source API into the destination API based on a simple parameter-matching algorithm [45]. As for those cases where automatic migration fails, we manually migrate them. Specifically, we look up the documents in their corresponding repositories or directly consult with search engines.

[5] `https://faiss.ai/index.html`

Listing 3 The PoC of CVE-2023-27603 and CVE-2023-33484.

```
//API invocation
public static void main(String[] args) throws IOException {
    zip();
    String zipFilename = "./testData/unzip/poc.zip";
    String destDirname = "./testData/unzip";
    //The core lines of both PoCs
    unzip(zipFilename, destDirname)(fs) // CVE-2023-27603
    NioUtils.unzip(zipFilename, destDirname);  // CVE-2023-33484
}

// Input construction
public static void zip() {
    ZipOutputStream zos = null;
    try {
        zos = new ZipOutputStream(new FileOutputStream( "./testData/
            unzip/poc.zip"));
        String srcFile = "../../a/b/c/poc.txt";
        String destFile = "./testData/unzip/poc.txt";
        zos.putNextEntry(new ZipEntry(srcFile));
        FileInputStream in = new FileInputStream(destFile);
        int len;
        byte[] buf = new byte[1024];
        while ((len = in.read(buf)) != -1) {
            zos.write(buf, 0, len);
        }
        zos.closeEntry();
        in.close();
    } catch (Exception e) {
        throw new RuntimeException("zip␣error␣from␣ZipUtils", e);
    } ...//9 Lines
}
```

API Fuzzing. We employ API fuzzing to further exploit functionality-specific vulnerabilities in functionality-equivalent APIs whose source APIs are associated with specific vulnerability types. Our rationale is that identical inputs may not trigger the same or similar vulnerabilities in different APIs if their functionalities diverge slightly. Thus, APISS employs a fuzzer to generate more inputs to exploit potential vulnerabilities. We focus our fuzzing efforts on APIs whose inputs are amenable to mutation, as some constructed inputs cannot be effectively fuzzed. The vulnerabilities whose affected APIs require fuzzing are detailed in the "Need Fuzzing" column of Table 1.

5 Evaluation

Our evaluation answers the following three research questions about APISS:

- **RQ1**: How effective is APISS in detecting real-world vulnerabilities when compared with baseline approaches?
- **RQ2**: How effective is APISS' API mapping module when compared with baseline approaches?
- **RQ3**: What are the manual/runtime costs of APISS?

Table 1 Heuristics of PoC Migration for Various Types of Vulnerabilities.

CWE Type	Characteristics of PoC	Fuzzing
CWE-121	Reuse the deep-nested JSON file in the "load" API	✓
CWE-22	Reuse the malicious zip file in the "unzip" API	✗
CWE-400/835	Reuse the test case with a vulnerable method sequence	✓
CWE-200	Reuse the malicious file in the "download" API	✗
CWE-502/611	Reuse the vulnerable JSON/XML files in the "parse" API	✓
CWE-94	Reuse the injected code in the execution API	✗
CWE-358	Reuse the initialization API of `collections` with various sizes	✓
CWE-434	Reuse the malicious file in the "upload" API	✗
CWE-275/79	Reuse the malicious XSS request in the "content_editing" API	✗
CWE-122/917	Reuse the malicious string expression in the "parse" API	✗

5.1 Background Information of Our Manual Efforts

Considering that the reliability of our detected vulnerabilities and the costs of our manual efforts highly depend on the expertise of our engineers, we explain the background of our manual efforts here. Evaluating APISS involves 10 software engineers, each with at least two years of Java development and one year of vulnerability-related tasks, e.g., vulnerability mining and fuzzing. Specifically, our engineers come from one of the major IT companies. This company has more than 20,000 engineers and more than 100 papers in top-tier conferences and journals on software engineering and security. The entire process of manually verifying existing vulnerabilities and their PoCs takes about 30 human-hours, and the entire process of detecting, validating, and reporting new vulnerabilities takes about 50 human-hours.

5.2 Dataset Collection

To evaluate APISS, we collect our dataset with two components: the affected APIs and PoCs of existing vulnerabilities, and a set of candidate APIs.

Vulnerability and PoC Collection. We collect source vulnerabilities from a Java vulnerability dataset used by VulFixMiner [51], MiDas [30], and CompVPD [10], including 1,359 vulnerabilities from 127 Java repositories. For each vulnerability in this dataset, we search for its related issue from the commit message in its patch, and the reference links in its vulnerability reports in NVD[6]. Then, for each issue with an executable PoC, we manually validate this PoC. For each type of functionality vulnerability, we choose the earliest PoC as the template one for migration (as shown in Table 2).

Candidate-API Collection. We extract 42,612 candidate APIs from 180 randomly sampled Java repositories on GitHub. Specifically, we adopt tree-sitter[7], a widely-used parser, to extract the elements of each API, including doc string, signatures, and bodies.

CWE-122/917	1	1	0	0	2	33	0.06
Total	60	18	87	14	179	263	0.40

5.3 RQ1: How effective is APISS in detecting real-world vulnerabilities when compared with baseline approaches?

This research question aims to show the effectiveness of APISS in terms of detecting new vulnerabilities in real-world settings. Then, we take the vulnerabilities detected by APISS as ground truths to investigate the effectiveness of baselines (i.e., how many of them can be detected by our baselines).

Baselines. We compare APISS with three state-of-the-art deep-learning models: GGNN [23] (used by Devign [52], Funded [38], and ReVeal [8]), GCN [21] (used by IVDetect [22]), and RGCN [9] (used by Vu1SPG [49]). Although these models are originally trained on C/C++ vulnerability datasets, we retrain them on the preceding Java vulnerability dataset to ensure a fair comparison in detecting Java vulnerabilities. We also compare APISS with another state-of-the-art recurring-vulnerability detection approach, MVP [43]. We exclude AHPH [26] and ReurScan [36] as they are specialized for detecting specific recurring vulnerabilities (non-functionality ones).

Table 4 Vulnerabilities Detected by APISS with CVE IDs.

CVE ID	CWE Type	Repository	CVE ID	CWE Type	Repository
CVE-2023-33484	CWE-22	light-4j	CVE-2023-36067	CWE-121	groovy-json

CVE-2023-34620	CWE-121	hjson	CVE-2023-51075	CWE-835	hutool-core
CVE-2023-34623	CWE-121	jtidy	CVE-2023-51080	CWE-835	hutool-core
CVE-2023-34624	CWE-121	htmlcleaner	CVE-2023-51084	CWE-835	hyavijava

New Vulnerabilities Detected by APISS. At the time of writing, APISS has detected 179 new vulnerabilities. As shown in Table 3, 60 have received new Common Vulnerabilities & Exposures Identifiers (CVE IDs), 18 have been confirmed by developers without CVE IDs, 87 are currently under review, and 14 have been reported by others. Vulnerabilities with CVE IDs are listed in Table 4. Among the 60 vulnerabilities with new CVE IDs, 15 are classified as high-risk and 3 as critical based on the CVSS Base Score [35]. This result highlights APISS' effectiveness in detecting new vulnerabilities, bringing high value to security practice.

Difference Among Various Vulnerability Types. Table 3 shows that the majority of vulnerabilities detected by APISS belong to CWE-121 (Stack-based Buffer Overflow) and CWE-400/835 (Uncontrolled Resource Consumption/Infinite Loop). According to our manual investigation of the PoCs of these vulnerabilities, they are triggered by unexpected JSON inputs, especially those that are deeply nested. For example, Listing 5 shows the PoC of CVE-2023-34610, a new vulnerability (belonging to CWE-121) detected by APISS. Its input is constructed in Lines 3-22 and has the following format: "$[[\ldots[\ 0\ ]]\ldots]$" (9999 and 9999).

APISS' False Positives. Table 3 also shows the false-positive numbers of each type of vulnerabilities. APISS incorrectly identifies 263 false-positive vulnerable APIs, achieving a high precision score of 0.40. It is mainly because we discard functionality-equivalent APIS for which APISS fails to generate its PoC.

Listing 4 An Example False-Positve Vulnerability.

```
import org.junit.Test;
import cn.hutool.core.net.*;
import java.util.List;
public class Ipv4UtilFuzzerList {
    // oom
    @Test
    public void listFuzzerTest() {
        try {
            List<String> result = Ipv4Util.list("213.3.13.2/2/",
                false);
        } catch (Exception e) {
        }
    }
}

-------------------------------------------------
Error messages:
java.lang.OutOfMemoryError: Java heap space
        at cn.hutool.core.net.Ipv4Util.list(Ipv4Util.java:141)
```

An Example of a False-Positive Vulnerability. Listing 4 presents an example of a false-positive vulnerability. The issue arises due to the use of a subnet mask of `/2`, which results in an excessively large capacity (i.e., 1,073,741,822) when initializing an ArrayList. The maintainer has acknowledged that a validation check could be added to Ipv4Util to handle such illogical inputs and prevent errors.

However, the maintainer does not classify this case as a vulnerability, stating that "A subnet mask is typically used to divide an IP address range into smaller networks, so a `/2` subnet is too large for any practical use, particularly for a public IP address such as `213.3.13.2`."

It is worth noting that false positives count for a small portion because most of them are crash-like vulnerabilities, which can be automatically verified. Such false positives rejected by repository maintainers account for a small fraction (i.e., less than 20%). Given the overall end-to-end effort (80 human-hours, as detailed in Section 5.1) and the effectiveness of our approach (identifying 179 new vulnerabilities and 60 new CVE IDs), the occurrence of such false positives remains within an acceptable range.

Comparison With Baselines. Table 5 illustrates the proportion of vulnerabilities detected by APISS and also detected by existing baselines. Overall, our baseline approaches can detect at most 58% of these vulnerabilities while MVP can detect 41% of them (corresponding to their recall values). Additionally, these baseline approaches encounter substantial false positives. MVP achieves a precision score of only 0.41 while the precision scores of existing deep-learning approaches (GCN, RGCN, and GGNN) are 0.02, 0.04, and 0.03, respectively. Such false positives will lead to a substantial manual costs when these identified vulnerabilities are validated. This result indicates that APISS is more effective in detecting functionality-specific vulnerabilities when compared with baselines. The main reason for their ineffectiveness is

[8] `https://nvd.nist.gov/vuln/detail/CVE-2023-34610`

Listing 5 The PoC of CVE-2023-34610.[8]

```
public class PoC {
    //Input Construction
    public final static int TOO_DEEP_NESTING = 9999;
    public final static String TOO_DEEP_DOC = _nestedDoc(
        TOO_DEEP_NESTING, "[␣", "]␣", "0");

    public static String _nestedDoc(int nesting, String open, String
        close, String content) {
        StringBuilder sb = new StringBuilder(nesting * (open.length()
            + close.length()));
        for (int i = 0; i < nesting; ++i) {
            sb.append(open);
            if ((i & 31) == 0) {
                sb.append("\n");
            }
        }
        sb.append("\n").append(content).append("\n");
        for (int i = 0; i < nesting; ++i) {
            sb.append(close);
            if ((i & 31) == 0) {
                sb.append("\n");
            }
        }
        return sb.toString();
    }
    //API invocation
    public static void main(String[] args) {
        String jsonString = TOO_DEEP_DOC;
        JsonReader.jsonToJava(jsonString);
    }
}
```

their overemphasis on API bodies disregarding the various implementations of functionality-equivalent APIs. On the contrary, APISS utilizes the similarities among API doc strings and signatures, thus successfully detecting these vulnerabilities.

5.4 RQ2: How effective is APISS' API mapping module when compared with baseline approaches?

This research question evaluates the effectiveness of APISS' API mapping module. In the evaluation, we choose two representative LLMs as the embedding model in APISS, ChatGPT (text-embedding-ada-002) [1] and CodeLLaMa (with 7B parameters) [34]. For each embedding model, we evaluate the effectiveness of each LLM with five feature combinations (configurations): `All Features` (using the optimal feature weights determined by Basin-hopping), `Signature+Doc String`, `Signature Only`, `Doc String Only`, and `Body Only`.

To quantitatively investigate the contribution of each embedding feature, we conduct Shapley Additive exPlanations (SHAPs) [3, 32], a game-theoretic technique to interpret the outputs of machine learning models. SHAP values help us understand how each feature contributes to APISS' effectiveness, thus providing evidence of focusing on doc strings and signatures instead of bodies.

Table 5 Proportions of Vulnerabilities Detected by Baselines.

CWE Type	MVP				GCN			
	TP	FP	Precision	Recall	TP	FP	Precision	Recall
CWE-121	52	50	0.51	0.53	18	874	0.02	0.18

Total	104	2,492	0.04	0.58	65	2,079	0.03	0.36

Baselines. We select two state-of-the-art API mapping approaches as our baselines, Api2Api [29] and SAR [6]. Both approaches employ a seeding step that is critical to their performance. For fair comparison, we evaluate all three seeding strategies (used in their paper): Random Seeds, k-Fold Seeds ($k = 1, 2, 3, 4$), and Signature-Based Seeds. For each strategy, we choose the optimal seed number that maximizes accuracy, based on the highest reported results in their paper [6].

Dataset. We use the same dataset, Java2CSharp [18], as our baselines. This dataset maps Java First-Party APIs to functionality-equivalent C# First-Party APIs. It includes 1570 Java APIs, 2457 C# APIs, and 860 pairs of functionality-equivalent APIs.

Given that the API source code in Java2CSharp is not available and the SAR repository[9] does not provide complete details of API bodies and doc strings, we recollect all First-Party Java and C# APIs from *jdk8u40*[10] and *.NET 4.8. for Windows January 2020 Update*[11].

[9] `https://github.com/bdqnghi/SAR_API_mapping`
[10] `https://hg.openjdk.org/jdk8u/jdk8u40/jdk/file/c7bbaa04eaa8/src`
[11] `https://referencesource.microsoft.com/DotNet48ZDP2.zip`

Table 6 The Effectiveness of API Mapping.

Baselines	Configuration	Top-1	Top-5
Api2Api	Random Seeds	0.19	0.24
	1-Fold Seeds	0.24	0.35
	2-Fold Seeds	0.34	0.35
	3-Fold Seeds	0.37	0.51
	4-Fold Seeds	0.43	0.64
	Signature-based Seeds	0.35	0.41
SAR	Random Seeds	0.44	0.50
	1-Fold Seeds	0.36	0.39
	2-Fold Seeds	0.45	0.50
	3-Fold Seeds	0.54	0.66
	4-Fold Seeds	0.59	0.77
	Signature-based Seeds	0.54	0.75
APISS-CodeLLaMa	All Features	**0.69**	**0.78**
	Signature+Doc String	**0.69**	**0.78**
	Signature Only	0.65	0.70
	Doc String Only	0.02	0.03
	Body Only	0.19	0.31
APISS-ChatGPT	All Features	**0.81**	**0.84**
	Signature+Doc String	0.74	0.78
	Signature Only	**0.81**	**0.84**
	Doc String Only	0.34	0.44
	Body Only	0.40	0.58

For each configuration of baselines (Api2Api and SAR), we choose the optimal seed number that maximizes accuracy.

Metrics. To keep the same setting with our baselines, we use Top-k Accuracy ($k = 1, 5$) as our evaluation metric. Top-k Accuracy measures the accuracy of API mappings by assessing whether the functionality-equivalent C# API for a given Java API appears within the top k positions of the predicted API list.

Results of Top-k Accuracy. Table 6 shows the Top-k Accuracy results of APISS and baselines. APISS substantially improves the API mapping accuracy with an increase of 22% in Top-1 Accuracy ($0.81 - 0.59$) and an increase of 7% in Top-5 Accuracy ($0.84 - 0.77$). This improvement is attributed to APISS' use of LLMs, which effectively comprehend API functionalities.

We also observe that comparing the embeddings of only signatures achieves higher accuracy than our baselines, while comparing the embeddings of only doc strings or bodies achieves relatively lower accuracy. This result indicates that API signatures are the most critical feature for API mapping than doc strings or bodies.

Explanation of Each Feature's Contribution. The contribution of each feature in APISS' embedding models, ChatGPT and CodeLLaMa, are depicted in Figure 2 and Figure 3. Each feature's contribution percentage is noted within brackets, and the scatter points represent the feature's contribution on each input API.

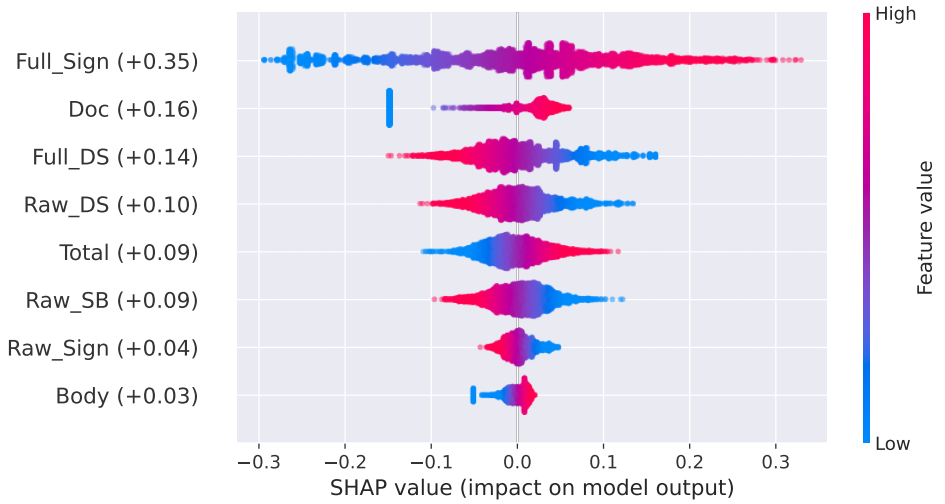

Figure 2 Each Feature's Contribution to API Mapping (Using ChatGPT's Embedding Model).

Both figures reveal that the three most important features are *full_sign*, *doc*, and *Full_DS*. These results highlight that both API doc strings and signatures (and their combination) mainly contribute to API mapping, while the API body has a negligible contribution (3% and 2%). Thus, the preceding results effectively support our proposal of utilizing API doc strings and signatures (instead of bodies) in API mapping.

Additionally, we notice two main differences from these figures. First, documentation strings show high value in smaller models in API mapping. For example, the most important feature for ChatGPT is *full_sign* (API signatures) while that of CodeLLaMa is *full_ds*, the combination of API doc strings and signatures. Second, features that include full signatures, which include package and class names (e.g., `com.networknt.utility.NioUtils`), are more effective than those with raw signatures. This result suggests that this contextual information enhances LLM's effectiveness in understanding API functionalities.

5.5 RQ3: What are the manual/runtime costs of APISS?

In this research question, we evaluate the manual and runtime costs of APISS. For manual costs, we detail the steps in the process where engineers detect new vulnerabilities, specifying their average time consumption. As for the runtime costs, we measure the end-to-end time costs of APISS on two main processes: (1) retrieving functionality-equivalent APIs, and (2) migrating PoCs and exploiting new vulnerabilities.

We perform all the evaluations on the system of Ubuntu 20.04. We use one Intel(R) Xeon(R) Gold 6248R@3.00GHz CPU, which contains 64 cores and 512GB memory. We use 1 Tesla A100 PCIe GPU with 40GB memory for API embedding.

Background Information of Our Manual Efforts. The end-to-end effectiveness of APISS highly depends on the expertise of our software engineers. Our evaluation, in which we have detected 179 new vulnerabilities, includes five software engineers. Each engineer has at least two years of experience in Java development and one year in fuzzing. The entire process of their manual costs takes approximately 50 man-days.

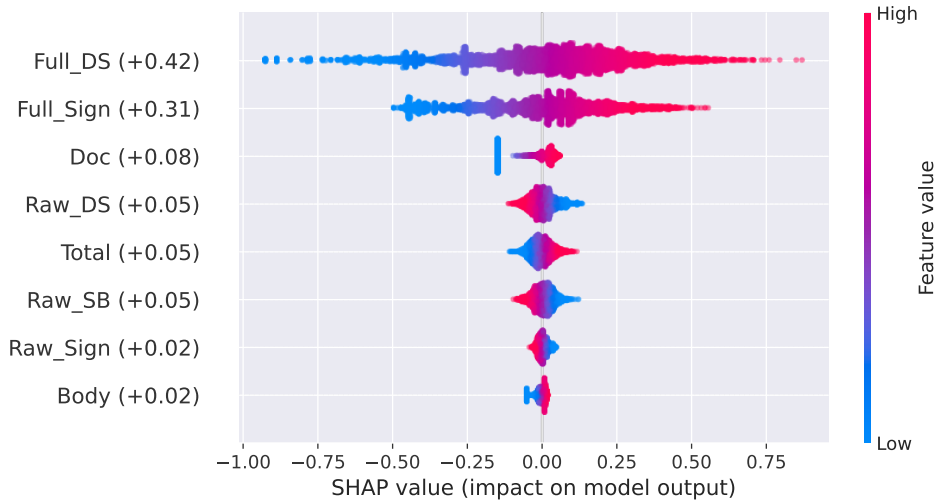

Figure 3 Each Feature's Contribution to API Mapping (Using CodeLLaMa for Embedding).

The Manual Costs of APISS. Figure 4 depicts the detailed workflow of how our engineers are involved in detecting new functionality-specific vulnerabilities. In this flowchart, steps requiring human intervention are highlighted in yellow. Adjacent to each step, we provide a breakdown of the average time costs.

The process of retrieving functionality-equivalent APIs, including extracting and validating the PoCs of existing vulnerabilities, requires approximately four hours per PoC. Our engineers read the vulnerability issue (if exists) and its URL links, and test the PoC within the affected software repository (on its vulnerable version). As shown in Section 5.3, a single validated PoC leads to the detection of an average of 17.9 new vulnerabilities, so the manual costs of four hours are affordable. Additionally, existing vulnerability databases, e.g., Snyk[12] and VeraCode[13], have already collected a large number of PoCs although they do not open-source these PoCs to avoid potential risks.

The procedure of migrating PoCs and exploiting new vulnerabilities involves three steps requiring human intervention. First, our engineers identify the usage for each functionality-equivalent API that cannot be directly invoked by our parameter-matching algorithm [45]. This task applies to 20% of APIs, with each requiring 3-5 minutes to address. Second, for each API triggered by a potential vulnerability, our engineers verify whether the API inputs are legal. This step is necessary for 19.6% of APIs, also taking 3-5 minutes per API. Third, once a vulnerability is confirmed, reporting each one takes approximately 15 minutes. We exclude the manual costs of this step as the vulnerability is already detected and exploited. Therefore, the manual costs of migrating a PoC to a new vulnerability is within 10 minutes.

The Runtime Costs of APISS. The runtime costs of APISS are shown in Table 7. For API mapping, APISS demonstrates high efficiency, with each step of embedding and retrieving taking less than one second. In the fuzzing process, we limit the maximum duration to two hours, determined based on the similarities between migrated inputs and potential vulnerability-triggering inputs. Consequently, the end-to-end fuzzing costs a total of 296 hours and successfully detects 144 vulnerabilities. These results confirm that the runtime costs of APISS are practical for real-world applications.

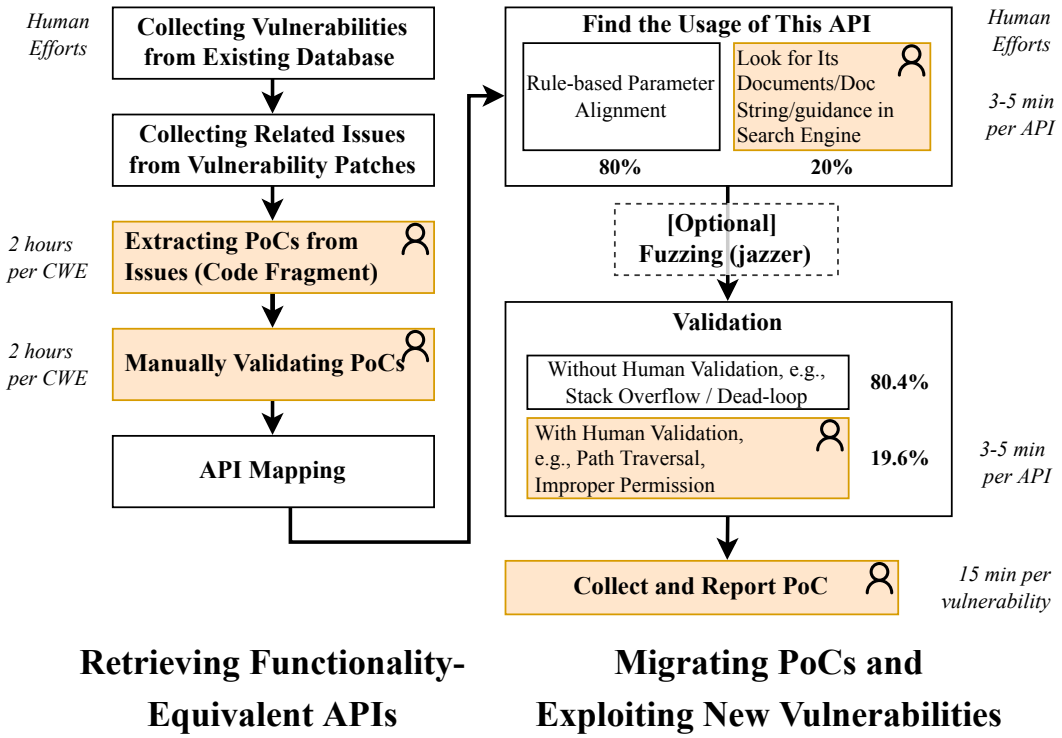

Figure 4 The Details of Human-Involved Procedure. White Boxes are Automatic Steps While Orange Boxes are Human-Involved Steps.

6 Discussion

Detecting Functionality-Specific Vulnerabilities of Other Programming Languages. We primarily focus on Java vulnerabilities due to the widespread usage of Java third-party libraries in software development [40]. APISS is designed with a high degree of generalization ability and is not restricted to Java vulnerabilities. For instance, APISS detects a new Java vulnerability (Listing 2) based on a Scala one (Listing 1). In Section 5.4, we also show that APISS can effectively retrieve functionality-equivalent APIs among various programming languages, e.g., Java and C#, without extra fine-tuning or training. Thus, APISS can be easily adapted to detect other programming languages' functionality-specific vulnerabilities.

Detecting Non-Functionality-Specific Vulnerabilities. Non-functionality-specific vulnerabilities also count for a large portion of vulnerabilities in third-party libraries. For example, among the Top 5 vulnerability types in 2023[14], CWE-787 (Out-of-bounds Write) and CWE-416 (Use-After-Write) are two representative non-functionality-specific ones because they do not occur in specific functionalities and remain widespread, especially in C/C++ repositories. Thus, the likelihood of being affected by these vulnerabilities is quite similar between functionality-equivalent APIs and the rest APIs. Now that APISS mainly focuses on retrieving candidate APIs based on their functionalities, we consider detecting such vulnerabilities as future work as they belong to different scopes of approaches.

[14] https://cwe.mitre.org/top25/archive/2023/2023_stubborn_weaknesses.html

Table 7 Hyper-Parameters and Runtime Costs of APISS.

API Mapping	CodeLLaMa	ChatGPT
Embedding Length	4,096 (default)	1,536 (default)
Embedding	465ms (per API)	554 ms (per API)
Initialize DB	0.4ms (per API)	0.1 ms (per API)
Retrieving	391ms (per API)	423 ms (per API)
Fuzzing Runtime	2 hours (per API)	296 hours (Total)

7 Threats to Validity

A major threat to external validity comes from the training dataset for evaluating existing deep-learning approaches. Existing deep-learning approaches [52, 8] are trained on two datasets including only C/C++ repositories while the vulnerabilities detected by APISS are mainly Java ones. To mitigate this threat, we choose a widely-used Java vulnerability dataset [51, 30, 10], which is general enough by including 1,359 Java vulnerabilities from 127 Java repositories. Thus, our reproduced models of existing deep-learning approaches reflect their effectiveness in detecting Java vulnerabilities. Additionally, the vulnerabilities in this dataset are before 2022 while those detected by APISS are later in 2023, so the potential risks of look-ahead bias [2] also do not exist.

The threats to internal validity are instrumentation effects that can bias our results. To reduce these threats, we manually inspect the intermediate results such as the functionality-equivalent APIs retrieved by APISS for dozens of sampled vulnerability patches, such as those in Listing 1 and Listing 2.

8 Related Work

8.1 Vulnerability Detection Approaches

Recurring-Vulnerability Detection Approaches. These approaches [43, 26, 36] are designed to detect recurring vulnerabilities, which come from reused code or shared code logic. For example, MVP [43] utilizes hash values based on the code property graphs of known vulnerable APIs to match similar APIs in open-source repositories.

However, these approaches rely heavily on matching the preceding implementation-based features. These approaches may produce high false negatives in detecting functionality-specific vulnerabilities as they rely heavily on matching the preceding implementation-based features while the affected APIs have diverse implementations. On the contrary, APISS considers functionality equivalence, a less strict constraint than implementation equivalence, to detect more vulnerabilities.

Deep-Learning Approaches. These approaches [41, 52, 39, 8, 38, 37, 42] determine whether a given method contains a potential vulnerability by learning code features of vulnerable APIs/methods of existing vulnerabilities. Devign [52] is a representative deep-learning approach. It uses Code Property Graphs (e.g., control/data-flow graphs) to represent the given method and designs a specialized Graph Neural Network (GNN) to determine whether this method is vulnerable.

These approaches can effectively detect vulnerabilities caused by incorrect implementation, such as use-after-free, because the source code of their affected APIs has specific patterns, e.g., a pointer operation after a `free` API invocation. However, deep-learning approaches are ineffective in detecting functionality-specific vulnerabilities because their affected APIs have diverse implementations without a common pattern, and they also face limitations in generating PoCs for detected vulnerabilities. On the contrary, APISS specifies the targeted vulnerabilities as functionality-specific ones, whose PoCs can be migrated from existing vulnerabilities.

8.2 API Mapping Approaches

API Mapping maps a library API to another functionality-equivalent one. Existing work [29, 11, 6, 50, 47] mainly focuses on translating an API of a specific programming language to another one. For example, SAR [6] translates first-party Java APIs to C# ones. Specifically, it learns the vector representation of both Java and C# APIs and trains a mapping model by adversarial learning. However, there are two main limitations when adopting existing API mapping approaches to retrieve functionality-equivalent APIs. First, for each pair of programming languages, these approaches need to train a specific model to translate an API between them, resulting in the scalability problem. Second, similar to existing vulnerability detection approaches, they also overemphasize the importance of API bodies. As shown in Section 5.4, API bodies hardly contribute to the effectiveness of API mapping. Thus, we design our API mapping module in APISS to address the preceding limitations.

8.3 API Fuzzing

API fuzzing [16, 4, 15, 44, 13, 19, 28, 5], as a special category of fuzzing approaches [53, 5, 25], is widely used to exploit API vulnerabilities. RULF [19] is a representative approach that fuzzes API vulnerabilities in Rust standard libraries. These approaches mainly use template-based or synthesized API sequences and randomly generated API inputs. Additionally, these approaches need to be executed for a long period to cover the input space as possible, thus resulting in low efficiency/effectiveness. On the contrary, APISS migrates the PoCs and inputs of existing vulnerabilities, so it can detect and trigger new functionality-specific vulnerabilities with higher probability within a short period.

9 Conclusion

In this paper, we have presented the first approach to utilize API doc strings and signatures instead of focusing on API bodies to retrieve functionality-equivalent APIs and then detect functionality-specific vulnerabilities. We have conducted a comprehensive evaluation to demonstrate APISS' effectiveness in retrieving functionality-equivalent APIs, achieving a Top-1 Accuracy of 0.81 while the best of the baselines under comparison achieves only 0.55. We have designed a semi-automatic schema to reduce the manual costs of migrating the PoC of existing vulnerabilities. We have demonstrated APISS' efficiency, costing less than 10 minutes of human labor per vulnerability, and the end-to-end runtime overhead of analyzing one candidate API is less than 2 hours. We have demonstrated APISS' high value to security practice by detecting 179 new vulnerabilities and receiving 60 new CVE IDs.

Abstract

We introduce the abstract notions of *monadic operational semantics*, a small-step semantics where computational effects are modularly modeled by a monad, and *type-and-effect system*, including *effect types* whose interpretation lifts well-typedness to its monadic version. In this meta-theory, as usual in the non-monadic case, we can express progress and subject reduction, and provide a proof, given once and for all, that they imply soundness. The approach is illustrated on a lambda calculus with generic effects, equipped with an expressive type-and-effect system We provide proofs of progress and subject reduction, parametric on the interpretation of effect types. In this way, we obtain as instances many significant examples, such as checking exceptions, preventing/limiting non-determinism, constraining order/fairness of outputs. We also provide an extension with constructs to raise and handle computational effects, which can be instantiated to model different policies.

2012 ACM Subject Classification Theory of computation → Operational semantics; Theory of computation → Type structures

Keywords and phrases Effects, monads, type soundness

1 Introduction

It would be hard to overstate the impact on foundations of programming languages of, on one hand, the idea that computational effects can be modeled by monads [30, 31], and, on the other hand, the technique based on progress and subject reduction to prove the soundness of a type system with respect to a small-step operational semantics [47].

Moggi's seminal work [30, 31] recognized monads as the suitable structure to modularly describe the denotational semantics of effectful languages. The key idea was the distinction between *pure* (effect-free) and *monadic* (effectful) expressions, also called *computations*, the latter getting semantics in a monad. Haskell has firstly[1] shown that such an approach can be fruitfully adopted in a mainstream language, through a monad type constructor allowing to encapsulate effectful code. However, the structure of a monad[2] does not include operations for *raising* effects, which need to be defined ad-hoc in instances. *Algebraic and generic effects* [33, 34, 35], instead, explicitly consider operations to raise effects, interpreted by additional structure on the monad. Such an approach, combined with handlers [37, 38, 4, 40], has been exploited in fully-fledged programming languages, e.g., in Scala and OCaml 5.

[1] Many other languages have then supported a monad pattern, e.g., Scheme, Python, Racket, Scala, F#.
[2] In Haskell, methods of the `Monad` typeclass.

To provide guarantees on, besides the result, the computational effects possibly raised by a computation, type systems are generalized to *type-and-effect systems*. A great many of these have been designed for specific calculi, modelling effects by relying on auxiliary structures, e.g., memory in imperative calculi, and providing ad-hoc soundness proofs; Katsumata [25] has provided a unified view of such systems, however based on denotational semantics. In this paper, instead, we provide an *operational meta-theory of monadic type-and-effect soundness*, analogous to the one mentioned above for usual type soundness based on small-step semantics, progress and subject reduction [47]. To this end, we provide abstract notions of small-step monadic semantics, type-and-effect system, and soundness, as detailed below.[3]

Operational semantics. We design a language semantics which is *monadic*, since effects are, as customary, expressed by a monad, and simultaneously *small-step*, since we define sequences of reduction steps. To this end, we start from a reduction from language expressions to monadic expressions (in a given monad) required to be deterministic, and extend such a relation to a *total* function, so to be able to combine steps by Kleisli composition, similarly to the approach in [17]. In this way, reduction sequences are always infinite, so termination is conventionally represented by monadic elements called *results*, which always reduce to themselves without raising any effect. On top of the reduction, we define the *finitary* semantics of an expression, which is either the monadic result reached in many steps, if any, or divergence. This semantics does not describe the computational effects raised by infinite computations. Hence, we define an *infinitary* semantics, obtained, as customary, as the supremum of a chain of approximants, provided that the monad has the necessary structure.

Type-and-effect system. As done in [7, 6] for standard type systems, we abstractly model a *type-and-effect system* as a family of predicates over expressions, indexed by types and *effect types*, statically approximating the computational effects that may be raised during evaluation. Effect types are required to form an ordered monoid, as typically assumed in effect systems [32, 29] and proposed as algebraic structure by [25]. The relation between an effect type and the allowed computational effects is specified by a family of *predicate liftings* [21]. In this way the transformation from a predicate to a monadic one associated to a given effect type is independent from the predicate and its universe.

Soundness. We provide abstract definitions of monadic progress and monadic subject reduction, and a proof, given once and for all, that they imply soundness. The latter means that, if a monadic element is the result of a well-typed expression, then it should be well-typed, that is, satisfy the lifting through the effect type of well-typedness of values.

We illustrate the approach on Λ_Σ, a lambda calculus with generic effects, equipped with an expressive type-and-effect system. We provide proofs of progress and subject reduction parametrically on the interpretation of effect types. In this way, we obtain as instances many significant examples, such as checking exceptions, preventing/limiting non-determinism, constraining order/fairness of outputs on different locations. We also provide an extension with constructs to handle effects, which can be instantiated as well to model different policies.

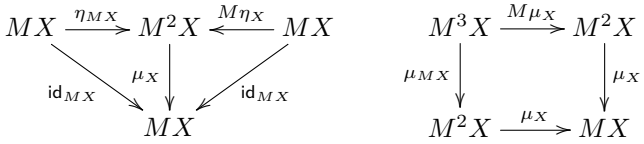
[3] The term "effect" is used in literature both as synonym of computational effect, and in the context of type-and-effect systems, as a static approximation of the former. We will use "effect" when there is no ambiguity, otherwise "computational effect" and "effect type", respectively.

Outline. Section 2 reports the background on monads. Section 3 introduces monadic operational semantics, exemplified through Λ_Σ in Section 4, where we also design a type-and-effect system, discussing its soundness. The approach is formalized by the abstract framework in Section 5; the proof technique introduced there is applied in Section 6 to Λ_Σ. Finally, in Section 7 we enhance the example by handlers, and in Section 8 we discuss related and future work, and summarize the contributions. Omitted proofs can be found in the extended version [9].

2 Preliminaries on monads

Monads [13, 43] are a fundamental notion in category theory, enabling an abstract and unified study of algebraic structures. Since Moggi's seminal papers [30, 31], they have also become a major tool in computer science, especially for describing the semantics of computational effects, and integrating them in programming languages in a structured and principled way. In this section, we recall basic notions about monads, and provide some examples. We will focus on monads on the category of sets and functions, denoted by $\mathcal{Set}$, referring the reader to standard textbooks [41] for a detailed introduction in full generality.

A *monad* $\mathbb{M} = \langle M, \eta, \mu \rangle$ (on $\mathcal{Set}$) consists of a functor $M \colon \mathcal{Set} \to \mathcal{Set}$ and two natural transformations $\eta : \mathsf{Id} \Rightarrow M$ and $\mu : M^2 \Rightarrow M$ such that, for every set X, the following diagrams commute:



The functor M specifies, for every set X, a set MX of monadic elements built over X, in a way that is compatible with functions. The map η_X, named *unit*, embeds elements of X into monadic elements in MX, and the map μ_X, named *multiplication*, flattens monadic elements built on top of other monadic elements into plain monadic elements.

From these data, one can derive an operation on functions of type $X \to MY$, dubbed *Kleisli extension*, which is crucial for modelling computational effects using monads. For all sets X, Y, we have a function $(-)^\dagger \colon (X \to MY) \to (MX \to MY)$, defined by $f^\dagger = \mu_Y \circ Mf$, that is, first we lift f through M to apply it to monadic elements and then we flatten the result using μ_Y. It is easy to see that the operation $(-)^\dagger$ satisfies the following equations for all $f \colon X \to MY$ and $g \colon Y \to MZ$:

$$\eta_X^\dagger = \mathsf{id}_{MX} \qquad f^\dagger \circ \eta_X = f \qquad g^\dagger \circ f^\dagger = (g^\dagger \circ f)^\dagger$$

Actually, a monad can be equivalently specified in the form of a *Kleisli triple* $\langle M, \eta, (-)^\dagger \rangle$ [28], where M is a mapping on sets, η is a family of functions $\eta_X \colon X \to MX$, for every set X, and $(-)^\dagger$ is a family of functions $(-)^\dagger \colon (X \to MY) \to (MX \to MY)$, for all sets X, Y, satisfying the three equations above. In particular we have $\mu_X = \mathsf{id}^\dagger_{MX}$.

Functions of type $X \to MY$ are called *Kleisli functions* and play a special role: they can be regarded as "effectful functions" from X to Y, raising effects described by the monad $\mathbb{M}$. Indeed, from the Kleisli extension, we can define a composition on Kleisli functions, known as Kleisli composition: given $f \colon X \to MY$ and $g \colon Y \to MZ$ we set

$$g * f = g^\dagger \circ f = \mu_Z \circ Mg \circ f$$

Intuitively, $g * f$ applies f followed by g, sequentially composing the effects they may raise. It is immediate to see that Kleisli composition is associative and η_X is the identity Kleisli function on the set X, that is, η_X is the function raising no effects.

We introduce some useful notation, corresponding to standard operations of monadic types in languages, where such types are assigned to expressions with effects. Given $\alpha \in MX$, $f\colon X \to MY$ and $g\colon X \to Y$, we set

$$\begin{array}{ll} - \gg\!= -\colon MX \to (X \to MY) \to MY & \alpha \gg\!= f = f^\dagger(\alpha) \\ \mathsf{map}\colon (X \to Y) \to MX \to MY & \mathsf{map}\, g\, \alpha = Mg(\alpha) \end{array}$$

The operator $\gg\!=$ is also called bind. As its definition shows, it can be seen as an alternative description of the Kleisli extension, where the parameters are taken in inverse order. This view corresponds, intuitively, to the sequential composition of two expressions with effects, where the latter depends on a parameter *bound* to the result of the former. The operator map describes the effect of the functor M on functions. That is, the lifting of function g through M is applied to a monadic value α. Note that bind and map are interdefinable:

$$\alpha \gg\!= f = \mu_Y(\mathsf{map}\, f\, \alpha) \qquad\qquad \mathsf{map}\, g\, \alpha = \alpha \gg\!= (\eta_Y \circ g)$$

Furthermore, we can express Kleisli composition using bind: $(g * f)(x) = f(x) \gg\!= g$.

In the following examples we characterize the monads by defining bind rather than multiplication μ since this is often more insightful, and customary in programming languages.

▶ **Example 1** (Exceptions)**.** Let us fix a set Exc. The monad $\mathbb{E}_{\mathsf{Exc}} = \langle E_{\mathsf{Exc}}, \eta^{\mathbb{E}_{\mathsf{Exc}}}, \mu^{\mathbb{E}_{\mathsf{Exc}}} \rangle$ is given by $E_{\mathsf{Exc}}X = \mathsf{Exc} + X$, and

$$\eta^{\mathbb{E}_{\mathsf{Exc}}}(x) = \iota_2(x) \qquad\qquad \alpha \gg\!= f = \begin{cases} f(x) \text{ if } \alpha = \iota_1(x) \\ \alpha \text{ otherwise } (\alpha = \iota_2(\mathsf{e}) \text{ for some } \mathsf{e} \in \mathsf{Exc}) \end{cases}$$

where $+$ denotes disjoint union (coproduct) and ι_1, ι_2 the left and right injections, respectively. We will omit the reference to the set Exc when it is clear from the context.

▶ **Example 2** (Classical Non-Determinism)**.** The monad $\mathbb{P} = \langle P, \eta^{\mathbb{P}}, \mu^{\mathbb{P}} \rangle$ is given by $PX = \wp(X)$, that is, PX is the set of all subsets of X, and

$$\eta^{\mathbb{P}}(x) = \{x\} \qquad\qquad \alpha \gg\!= f = \bigcup_{x \in \alpha} f(x)$$

A variant of this monad is the list monad $\mathbb{L} = \langle L, \eta^{\mathbb{L}}, \mu^{\mathbb{L}} \rangle$, where the set LX of (possibly infinite) lists over X is coinductively defined by the following rules: $\epsilon \in L(X)$ and, if $x \in X$ and $l \in L(X)$, then $x\colon l \in L(X)$. We use the notation $[x_1, \ldots, x_n]$ to denote the finite list $x_1\colon \ldots\colon x_n\colon \epsilon$. Then, the unit is given by $\eta^{\mathbb{L}}_X(x) = [x]$ and the monadic bind is corecursively defined by the following clauses: $\epsilon \gg\!= f = \epsilon$ and $(x\colon l) \gg\!= f = f(x)(l \gg\!= f)$, where juxtaposition denotes the concatenation of possibly infinite lists.

▶ **Example 3** (Probabilistic Non-Determinism)**.** Denote by DX the set of probability subdistributions α over X with countable support, i.e., $\alpha\colon X \to [0..1]$ with $\sum_{x \in X} \alpha(x) \leq 1$ and $\mathsf{supp}(\alpha) = \{x \in X \mid \alpha(x) \neq 0\}$ countable set. We write $r \cdot \alpha$ for the pointwise multiplication of a subdistribution α with a number $r \in [0, 1]$. The monad $\mathbb{D} = \langle D, \eta^{\mathbb{D}}, \mu^{\mathbb{D}} \rangle$ is given by

$$\eta^{\mathbb{D}}(x) = y \mapsto \begin{cases} 1 & y = x \\ 0 & \text{otherwise} \end{cases} \qquad\qquad \alpha \gg\!= f = \sum_{x \in X} \alpha(x) \cdot f(x)$$

▶ **Example 4** (Output/Writer). Let $\langle \mathsf{Out}, \cdot, \varepsilon \rangle$ be a monoid, e.g., the monoid of strings over a fixed alphabet. The monad $\mathbb{O} = \langle O, \eta^{\mathbb{O}}, \mu^{\mathbb{O}} \rangle$ is given by $OX = \mathsf{Out} \times X$ and

$$\eta^{\mathbb{O}}(x) = \langle \varepsilon, x \rangle \qquad \langle o, x \rangle \gg\!= f = \langle o \cdot \pi_1(f(x)), \pi_2(f(x)) \rangle$$

Combining this monad with the exception monad of Example 1, we obtain the pointed output monad, whose underlying functor is given by $O'X = \mathsf{Out} \times (X + \{\bot\})$.

▶ **Example 5** (Global State). Let S be a set of states. The monad $\mathbb{S} = \langle S, \eta^{\mathbb{S}}, \mu^{\mathbb{S}} \rangle$ is given by $SX = \mathsf{S} \to \mathsf{S} \times X$ and

$$\eta^{\mathbb{S}}(x) = s \mapsto \langle s, x \rangle \qquad \alpha \gg\!= f = s \mapsto f(\pi_2(\alpha(s)))(\pi_1(\alpha(s)))$$

We can combine this monad with the exception monad of Example 1 obtaining $\mathbb{S}_{\mathsf{Exc}} = \langle S_{\mathsf{Exc}}, \eta^{\mathbb{S}_{\mathsf{Exc}}}, \mu^{\mathbb{S}_{\mathsf{Exc}}} \rangle$ where $S_{\mathsf{Exc}} = \mathsf{S} \to (\mathsf{S} \times X) + \mathsf{Exc}$ and $\eta^{\mathbb{S}_{\mathsf{Exc}}}_X(x) = s \mapsto \eta^{\mathbb{E}_{\mathsf{Exc}}}_{\mathsf{S} \times X}(\langle s, x \rangle)$ and $\alpha \gg\!= f = s \mapsto (\alpha(s)) \gg\!=_{\mathbb{E}_{\mathsf{Exc}}} (x \mapsto f(x)(s))$. This combination yields a monad thanks to the fact that $\mathbb{S}$ determines a monad transformer [27, 22].

3 Monadic operational semantics

In this section we abstractly describe a framework for (deterministic) monadic operational semantics, adapting from [16, 17].

▶ **Definition 6.** *Let $\mathcal{L}$ be a triple $\langle \mathsf{Exp}, \mathsf{Val}, \mathsf{ret} \rangle$, called a* language*, with* Exp *the set of* expressions*,* Val *the set of* values*, and* $\mathsf{ret} \colon \mathsf{Val} \to \mathsf{Exp}$ *an injective function. A* monadic operational semantics *for $\mathcal{L}$ consists of:*

- *a monad $\mathbb{M} = \langle M, \eta, \mu \rangle$*
- *a relation $\to \subseteq \mathsf{Exp} \times M\mathsf{Exp}$, called* monadic (one-step) reduction*, such that*
  - *$\to$ is a partial function and*
  - *for all $v \in \mathsf{Val}$, $\mathsf{ret}(v) \not\to$.*

The set Exp contains expressions that can be executed, while Val contains values produced by the computation. The inclusion ret identifies the expressions representing successful termination with a given value. The elements of $M\mathsf{Exp}$, called *monadic expressions*, are the counterpart of expressions in the monad $\mathbb{M}$. The relation $\to$ models single computation steps, which transform expressions into monadic ones, thus possibly raising computational effects. Finally, the first requirement on $\to$ ensures that it is deterministic, while the latter one that expressions representing values cannot be reduced.

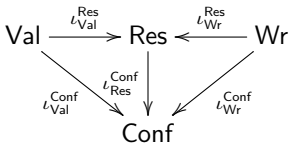
Assume a monadic operational semantics $\langle \mathbb{M}, \to \rangle$ for a language $\langle \mathsf{Exp}, \mathsf{Val}, \mathsf{ret} \rangle$. In standard (small-step) operational semantics, starting from the one-step reduction we can model computations as (either finite of infinite) sequences of reduction steps. In particular, finite computations are obtained by the reflexive and transitive closure $\to^\star$ of the one-step reduction. Starting from the *monadic* one-step reduction, which is a relation from a set to a different one, there is no transitive closure in the usual sense.

In the solution proposed in [16], the monadic reduction can be an arbitrary relation; however, this requires a relational extension of the monad [3]. On the other hand, given a relation $\to \subseteq \mathsf{Exp} \times M\mathsf{Exp}$ which is a *total* function, we can define, by iterating Kleisli composition, a relation $\to^\star \subseteq \mathsf{Exp} \times M\mathsf{Exp}$ which plays the role of transitive closure, as in [17].

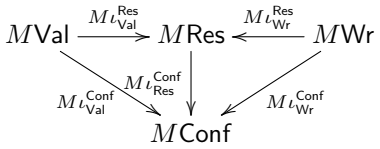
Our aim here is to define $\to^\star$ taking the second approach, which does not require relational extensions. Unfortunately, the monadic reduction, exactly as the standard one, is by its own nature a partial function, where some expressions, representing terminated computations,

cannot be reduced. Notably, those representing successful termination with a value, and others, intuitively corresponding to stuck computations. To obtain a total function, we extend the monadic reduction to *configurations* (expressions, values, or a special result wrong). In particular, expressions representing terminating computations reduce to (the monadic embedding of) a value, and wrong, respectively. In this way, we can define the transitive closure by Kleisli composition, as formally detailed below.

Set $\mathsf{Res} = \mathsf{Val} + \mathsf{Wr}$, where $\mathsf{Wr} = \{\mathsf{wrong}\}$, that is, a result r is either a value, modelling successful termination, or wrong, modelling a stuck computation. Then, we consider the set $\mathsf{Conf} = \mathsf{Exp} + \mathsf{Res}$ of *configurations*, ranged over by c. We have the following commutative diagram of coproduct injections:



As customary, with a slight abuse of notation, we identify elements with their images along such injections. We use E, V, R and C to range over monadic expressions, monadic values, monadic results and monadic configurations, respectively, that is, elements of $M\mathsf{Exp}$, $M\mathsf{Val}$, $M\mathsf{Res}$ and $M\mathsf{Conf}$. Since monads on $\mathcal{S}et$ preserve injections [1], by applying M to the diagram above we get another diagram of injections:



In the following, we use some shortcuts for the application of such injections: notably, we write $\hat{\mathrm{E}}$ for $M\iota^{\mathsf{Conf}}_{\mathsf{Exp}}(\mathrm{E})$, $\hat{\mathrm{R}}$ for $M\iota^{\mathsf{Conf}}_{\mathsf{Res}}(\mathrm{R})$ and $\hat{\mathrm{V}}$ for $M\iota^{\mathsf{Res}}_{\mathsf{Val}}(\mathrm{V})$.

We can now extend the monadic reduction $\to$ to configurations, getting the relation $\xrightarrow[\mathsf{step}]{} \subseteq \mathsf{Conf} \times M\mathsf{Conf}$ shown in Figure 1. As said above, reduction is extended to expressions

$$(\textsc{exp})\ \frac{e \to \mathrm{E}}{e \xrightarrow[\mathsf{step}]{} \hat{\mathrm{E}}} \qquad (\textsc{ret})\ \frac{}{\mathsf{ret}(v) \xrightarrow[\mathsf{step}]{} \eta_{\mathsf{Conf}}(v)}$$

$$(\textsc{wrong})\ \frac{e \not\to \quad e \neq \mathsf{ret}(v) \text{ for all } v \in \mathsf{Val}}{e \xrightarrow[\mathsf{step}]{} \eta_{\mathsf{Conf}}(\mathsf{wrong})} \qquad (\textsc{res})\ \frac{}{r \xrightarrow[\mathsf{step}]{} \eta_{\mathsf{Conf}}(r)}$$

Figure 1 Monadic (one-step) reduction on configurations.

which represent terminated computations, which reduce to the monadic embedding of the corresponding value or wrong, respectively; moreover, it is extended to results (either values or wrong) as well, which conventionally reduce to their monadic embedding.

It is immediate to see that $\xrightarrow[\mathsf{step}]{}$ is (the graph of) a total function from Conf to $M\mathsf{Conf}$, which we simply write step. Clearly step is a Kleisli function for $\mathbb{M}$, hence we can define the "monadic reflexive and transitive closure" $\xrightarrow[\mathsf{step}]{}^{\star} \subseteq \mathsf{Conf} \times M\mathsf{Conf}$ of $\xrightarrow[\mathsf{step}]{}$ as follows:

$$(\textsc{refl})\ \frac{}{c \xrightarrow[\mathsf{step}]{}^{\star} \eta_{\mathsf{Conf}}(c)} \qquad (\textsc{step})\ \frac{c \xrightarrow[\mathsf{step}]{}^{\star} \mathrm{C}}{c \xrightarrow[\mathsf{step}]{}^{\star} \mathrm{C} \gg\!= \mathsf{step}}$$

These rules are analogous to those defining the reflexive and transitive closure of a standard one-step relation. In (REFL) a configuration reduces, rather than to itself, to its monadic counterpart. In rule (STEP), $\xrightarrow{\mathsf{step}}{}^{\star}$ is combined with $\xrightarrow{\mathsf{step}}$, rather than by standard composition, through the $\gg=$ operator. That is, a computation is extended by one step through a monadic binding of the previously computed monadic configuration C to the step function.

Equivalently, we can define the Kleisli n-th iteration step^n of the step function by setting $\mathsf{step}^0 = \eta_{\mathsf{Conf}}$ and $\mathsf{step}^{n+1} = \mathsf{step} * \mathsf{step}^n$. Then, the following holds:

▶ **Proposition 7.** *$c \xrightarrow{\mathsf{step}}{}^{\star} \mathrm{C}$ if and only if $\mathsf{step}^n(c) = \mathrm{C}$ for some $n \in \mathbb{N}$.*

In a similar way, we can define a small-step reduction on monadic configurations. Recall that the Kleisli extension of step gives the function $\mathsf{step}^{\dagger} \colon M\mathsf{Conf} \to M\mathsf{Conf}$.

▶ **Definition 8.** *The* small-step reduction induced by $\xrightarrow{\mathsf{step}}$ *is the relation $\Rightarrow$ on $M\mathsf{Conf}$ defined by: $\mathrm{C} \Rightarrow \mathrm{C}'$ iff $\mathsf{step}^{\dagger}(\mathrm{C}) = \mathrm{C}'$.*

Then, since $\Rightarrow$ is a relation on $M\mathsf{Conf}$, we can consider its (standard) reflexive and transitive closure $\Rightarrow^{\star} \subseteq M\mathsf{Conf} \times M\mathsf{Conf}$, which describes computations on monadic configurations.

▶ **Proposition 9.** *$\mathrm{C} \Rightarrow^{\star} \mathrm{C}'$ if and only if $\mathrm{C} \gg= \mathsf{step}^n = \mathrm{C}'$ for some $n \in \mathbb{N}$.*

Combining Propositions 7 and 9, we get the following corollary which relates $\xrightarrow{\mathsf{step}}{}^{\star}$ and $\Rightarrow^{\star}$.

▶ **Corollary 10.** *The following are equivalent:*

1. $c \xrightarrow{\mathsf{step}}{}^{\star} \mathrm{C}$
2. $\eta_{\mathsf{Conf}}(c) \Rightarrow^{\star} \mathrm{C}$
3. $c \xrightarrow{\mathsf{step}}{}^{\star} \mathrm{C}' \Rightarrow^{\star} \mathrm{C}$, *for some* $\mathrm{C}' \in M\mathsf{Exp}$

To use the above machinery for describing the semantics of expressions, we essentially follow the approach in [17], with minor adjustments to fit our context.

First of all note that, being defined on top of a total function, $\Rightarrow^{\star}$ has no normal forms. However, monadic results should intuitively correspond to termination. Formally, this is a consequence of the proposition below, stating that a monadic configuration which is a result only reduces to itself; hence, when a monadic result is reached, its reduction continues with an infinite sequence of trivial reduction steps, which can be seen as a representation of termination. Hence, the outcome of a (terminating) computation is a monadic result.

▶ **Proposition 11.** *$\hat{\mathrm{R}} \Rightarrow \mathrm{C}$ if and only if $\mathrm{C} = \hat{\mathrm{R}}$.*

Thanks to the above proposition, we can prove the following, stating that the monadic result of a computation, if any, is unique.

▶ **Proposition 12.** *If $c \xrightarrow{\mathsf{step}}{}^{\star} \hat{\mathrm{R}}_1$ and $c \xrightarrow{\mathsf{step}}{}^{\star} \hat{\mathrm{R}}_2$, then $\mathrm{R}_1 = \mathrm{R}_2$.*

Hence, we can define a function $[\![-]\!]_{\star} \colon \mathsf{Exp} \to M\mathsf{Res} + \{\infty\}$ describing the semantics of expressions as follows:

$$[\![e]\!]_{\star} = \begin{cases} \mathrm{R} & \text{if } e \xrightarrow{\mathsf{step}}{}^{\star} \hat{\mathrm{R}} \\ \infty & \text{otherwise} \end{cases}$$

This is called *finitary semantics*, as it describes only monadic results that can be reached in finitely many steps. In other words, all diverging computations are identified and no information on computational effects they may produce is available. Even worse, when the monad supports some form of non-determinism, we may have computations that terminate in some cases and diverge in others, but the finitary semantics considers them as diverging, as they never reach a result after finitely many steps.

To overcome this limitation, again following [17], we introduce an *infinitary semantics*, which is able to provide more information on diverging computations. To achieve this, we need to assume more structure on the monad $\mathbb{M}$. Recall that, given a partially ordered set $\langle P, \sqsubseteq \rangle$, an ω-chain is an increasing sequence $(x_n)_{n\in\mathbb{N}}$ of points in P. We say that $\langle P, \sqsubseteq \rangle$ is an ω-CPO if it has a least element $\bot$ and every ω-chain in $\langle P, \sqsubseteq \rangle$ has a supremum $\bigsqcup_{n\in\mathbb{N}} x_n$. A function $f\colon \langle P, \sqsubseteq \rangle \to \langle P', \sqsubseteq' \rangle$ between ω-CPO is said to be ω-continuous if it preserves the least element, and suprema of ω-chains. Note that an ω-continuous function is necessarily monotone. Then, we have the following definition:

▶ **Definition 13.** *An ω-CPO-ordered monad $\mathbb{M} = \langle M, \sqsubseteq, \eta, \mu \rangle$ is a monad $\langle M, \eta, \mu \rangle$ together with a partial order $\sqsubseteq_X$ on MX, for every set X, such that*

1. *for every set X, the poset $\langle MX, \sqsubseteq_X \rangle$ is an ω-CPO and*
2. *for all sets X, Y, the Kleisli extension $(-)^\dagger\colon (X \to MY) \to (MX \to MY)$ is ω-continuous with respect to the pointwise extension of $\sqsubseteq_Y$ to function spaces $X \to MY$ and $MX \to MY$.*

▶ **Example 14.** The powerset and list monads of Example 2 are ω-CPO-ordered with the subset and prefix ordering, respectively. The subdistribution monad of Example 3 is ω-CPO-ordered with the pointwise ordering on subdistributions. The other monads of Section 2 can also be turned into ω-CPO-ordered monads, but require adjustements, typically a combination with the exception monad. For instance, in Example 4, the output monad is not ω-CPO-ordered in general, but its pointed version is ω-CPO-ordered when the underlying monoid is an ω-CPO and the multiplication is ω-continuous in the second argument.

From now on, we assume the monad $\mathbb{M}$ to have an ω-CPO-ordered structure. Our goal is to define a function $[\![-]\!]_\infty\colon \mathsf{Exp} \to M\mathsf{Res}$ modelling the infinitary semantics of expressions. To this end, we first define a function $\mathsf{res}\colon M\mathsf{Conf} \to M\mathsf{Res}$ extracting monadic results from monadic configurations. Let $\mathsf{res}_0\colon \mathsf{Conf} \to M\mathsf{Res}$ be the function given by

$$\mathsf{res}_0(c) = \begin{cases} \bot_{\mathsf{Res}} & c = e \\ \eta_{\mathsf{Res}}(r) & c = r \end{cases}$$

and set $\mathsf{res} = \mathsf{res}_0^\dagger$. The key point is that the total relation $\Rightarrow$ on monadic configurations is compatible with the order $\sqsubseteq_{\mathsf{Res}}$ under the application of res, as the following proposition shows.

▶ **Proposition 15.** *If $c \Rightarrow c'$ then $\mathsf{res}(c) \sqsubseteq_{\mathsf{Res}} \mathsf{res}(c')$.*

For every $e \in \mathsf{Exp}$ and $n \in \mathbb{N}$, we define $[\![e]\!]_n = \mathsf{res}(\mathsf{step}^n(e))$. From Propositions 7 and 9, we easily derive $\mathsf{step}^n(e) \Rightarrow \mathsf{step}^{n+1}(e)$, and, by Proposition 15, $[\![e]\!]_n \sqsubseteq_{\mathsf{Res}} [\![e]\!]_{n+1}$. Hence, the sequence $([\![e]\!]_n)_{n\in\mathbb{N}}$ is an ω-chain in $\langle M\mathsf{Res}, \sqsubseteq_{\mathsf{Res}} \rangle$ and so we define the infinitary semantics as

$$[\![e]\!]_\infty = \bigsqcup_{n\in\mathbb{N}} [\![e]\!]_n$$

Intuitively, $[\![e]\!]_n$ is the portion of the result that is reached after n reduction steps. Hence, the actual result is obtained as the supremum of all such approximations and it may be never reached, thus describing also the observable behaviour of possibly diverging computations.

We conclude this section by stating that infinitary and finitary semantics agree on terminating computations.

▶ **Proposition 16.** *If $[\![e]\!]_\star = r$, then $[\![e]\!]_\infty = r$.*

4 Example: a lambda calculus with generic effects

The aim of this section is twofold:

- to ilustrate the monadic operational semantics in Section 3 through a simple example
- to equip such example with a type-and-effect system, and to discuss how to express and prove type soundness with respect to finitary/infinitary semantics

To this end, we introduce Λ_Σ, a call-by-value λ-calculus with *generic effects*. Here Σ is a family of sets $\{\Sigma_k\}_{k\in\mathbb{N}}$ of k-ary operations raising effects. We choose generic rather than algebraic effects, thus avoiding explicit continuations, to have a style more convenient for a programmer [40], and a more significant monadic reduction.[4]

The syntax is shown in Figure 2. We use $\overline{v}$ as metavariable for sequences $v_1, \ldots, v_n$, and analogously for other sequences. We assume variables x, y, f, ..., using the last for variables

$$\begin{array}{lcll} v & ::= & x \mid \mathtt{rec}\, f.\lambda x.e \mid \ldots & \text{value} \\ e & ::= & v\, v' \mid op(\overline{v}) \mid \mathtt{return}\ v \mid \mathtt{do}\ x = e_1\,;\ e_2 \mid \ldots & \text{expression} \end{array}$$

Figure 2 Λ_Σ: fine-grain syntax.

denoting functions. We adopt, as customary, the fine-grain approach [26], where *values* are effect-free, whereas *expressions*, also called *computations*, may raise effects. Dots stand for additional, unspecified, constructs, such as operators of primitive types, conditional, etc.

To illustrate type soundness with respect to the infinitary semantics as well, the calculus includes recursive functions; notably, $\mathtt{rec}\, f.\lambda x.e$ is a function with parameter x and body e which can recursively call itself through the variable f. Standard lambda expressions can be recovered as those where f does not occur free in e, that is, when the function is non-recursive, and we will use the abbreviation $\lambda x.e$ for such expressions.

In this section, Exp and Val denote the sets of closed expressions and values of Λ_Σ, respectively. In the following, we define a monadic (one-step) reduction for the language, parametric on a monad $\mathbb{M} = \langle M, \eta, \mu\rangle$, being a relation $\rightarrow$ on $\mathsf{Exp} \times M\mathsf{Exp}$. As in Section 3, we use V and E to range over $M\mathsf{Val}$ and $M\mathsf{Exp}$, respectively.

This relation is modularly defined on top of a "pure" reduction $\rightarrow_p$ on $\mathsf{Exp} \times \mathsf{Exp}$. In our example, such relation only reduces function calls into the corresponding bodies, as shown in Figure 3; other rules should be added to deal with additional language constructs, as we will do for handlers in Section 7. `Do` expressions are, then, normal forms for the pure reduction, and will be handled by the rules of the monadic reduction.

$$(\textsc{app})\ \frac{}{v\, v' \rightarrow_p e[v/f][v'/x]}\ v = \mathtt{rec}\, f.\lambda x.e$$

Figure 3 Pure reduction.

Rules defining the monadic reduction are given in Figure 4. As mentioned, they are parametric on the underlying monad; more in detail, they depend on the following ingredients:

- The function $\eta_{\mathsf{Exp}}\colon \mathsf{Exp} \rightarrow M\mathsf{Exp}$ embedding language expressions into their counterpart in the monad, written simply η in this section.
- The function $\mathsf{map}\colon (\mathsf{Exp} \rightarrow \mathsf{Exp}) \rightarrow M\mathsf{Exp} \rightarrow M\mathsf{Exp}$ lifting functions from expressions to expressions to their counterpart in the monad.

[4] In the case of algebraic effects there would be no monadic reduction inside a context, as in rule (DO).

Moreover we assume, for each operation op with arity k, a partial function $\mathsf{run}_{op}{:}\mathsf{Val}^k \rightharpoonup M\mathsf{Val}$, returning a monadic value expressing the effects raised by a call of the operation. The function could be undefined, for instance when arguments do not have the expected types.

$$(\textsc{pure})\ \frac{e \to_p e'}{e \to \eta(e')} \qquad (\textsc{effect})\ \frac{}{op(\overline{v}) \to \mathsf{map}\,(\mathtt{return}\ [\,])\,\mathsf{run}_{op}(\overline{v})}$$

$$(\textsc{ret})\ \frac{}{\mathtt{do}\ x = \mathtt{return}\ v;\ e \to \eta(e[v/x])} \qquad (\textsc{do})\ \frac{e_1 \to \mathrm{E}}{\mathtt{do}\ x = e_1;\ e_2 \to \mathsf{map}\,(\mathtt{do}\ x = [\,];\ e_2)\,\mathrm{E}}$$

Figure 4 Monadic (one-step) reduction.

Rule (PURE) propagates a pure step, embedding its result in the monad. In rule (EFFECT), the effect is actually raised. To this end, we apply the function of type $M\mathsf{Val} \to M\mathsf{Exp}$ obtained by lifting, through map, the context `return` [ ] to the monadic value obtained from the call. Here we identify the context `return` [ ], which is an expression with a hole, with the function $v \mapsto \mathtt{return}\ [v]$ of type $\mathsf{Val} \to \mathsf{Exp}$. In rule (RET), when the first subterm of a `do` expression returns a value, the expression is reduced to the monadic embedding of the second subterm, after replacing the variable with the value. Rule (DO), instead, propagates the reduction of the first subterm. To take into account raised effects, we apply the function of type $M\mathsf{Exp} \to M\mathsf{Exp}$ obtained by lifting, through map, the context $\mathtt{do}\ x = [\,];\ e_2$ to the monadic expression obtained from e_1. Analogously to above, we identify the context $\mathtt{do}\ x = [\,];\ e_2$ with the function $e \mapsto \mathtt{do}\ x = [e];\ e_2$ of type $\mathsf{Exp} \to \mathsf{Exp}$.

The following property is needed to have an instance of the framework in Section 3.

▶ **Proposition 17** (Determinism). *If $e \to E_1$ and $e \to E_2$ then $E_1 = E_2$.*

We show now some examples of expressions and their monadic operational semantics. We assume the calculus to be extended with standard constructs, such `unit`, 0, `succ`, `true` and `false` constructors, `pred` selector, `iszero` test, and conditional. We write $e; e'$ for $\mathtt{do}\ x = e;\ e'$ when x does not occur free in e', and sometimes, to save space, n for $\mathtt{succ}^n\,0$.

▶ **Example 18.** Set, as underlying monad, the monad of exceptions introduced in Example 1, where $EX = X + \mathsf{Exc}$. For each $\mathsf{e} \in \mathsf{Exc}$, we assume an operation $\mathtt{raise}\langle \mathsf{e} \rangle$, with

$$\mathsf{run}_{\mathtt{raise}\langle \mathsf{e} \rangle} : \mathbf{1} \to M\mathsf{Val} \qquad \mathsf{run}_{\mathtt{raise}\langle \mathsf{e} \rangle} = \iota_2(\mathsf{e})$$

The function $\mathsf{predfun} = \lambda x.\mathtt{if}\ \mathtt{iszero}\ x\ \mathtt{then}\ \mathtt{raise}\langle \mathsf{PredZero} \rangle\ \mathtt{else}\ \mathtt{return}\ \mathtt{pred}\,x$ raises the exception PredZero when the argument is 0. The following are examples of small-step reduction sequences on monadic configurations[5]:

$$\begin{array}{lcl}
\mathsf{predfun}\,\mathtt{succ}\,0 & \Rightarrow & \mathtt{if}\ \mathtt{iszero}\ \mathtt{succ}\,0\ \mathtt{then}\ \mathtt{raise}\langle \mathsf{PredZero} \rangle\ \mathtt{else}\ \mathtt{return}\ 0 \\
& \Rightarrow & \mathtt{if}\ \mathtt{false}\ \mathtt{then}\ \mathtt{raise}\langle \mathsf{PredZero} \rangle\ \mathtt{else}\ \mathtt{return}\ 0 \\
& \Rightarrow & \mathtt{return}\ 0 \\
& \Rightarrow & 0 \\
\mathsf{predfun}\,0 & \Rightarrow & \mathtt{if}\ \mathtt{iszero}\ 0\ \mathtt{then}\ \mathtt{raise}\langle \mathsf{PredZero} \rangle\ \mathtt{else}\ \mathtt{return}\ 0 \\
& \Rightarrow & \mathtt{if}\ \mathtt{true}\ \mathtt{then}\ \mathtt{raise}\langle \mathsf{PredZero} \rangle\ \mathtt{else}\ \mathtt{return}\ 0 \\
& \Rightarrow & \mathtt{raise}\langle \mathsf{PredZero} \rangle \\
& \Rightarrow & \mathsf{PredZero}
\end{array}$$

[5] Where we omit the injections from monadic expressions and values.

In the first reduction sequence, all steps are derived by rules (PURE) in Figure 4 and (EXP) in Figure 1, except for the last one, which is derived by rule (RET) in Figure 1. Analogously in the second reduction sequence, where the last step is derived by rule (EFFECT) in Figure 4 and (EXP) in Figure 1. Note that, here and in the following examples, after reaching a monadic result the sequence of steps continues with an infinite sequence of steps, in the case above $0 \Rightarrow 0$ and $\mathsf{PredZero} \Rightarrow \mathsf{PredZero}$ steps.

▶ **Example 19.** Set, as underlying monad, the monad of non-determinism of Example 2, in the variant of the possibly infinite lists. We assume a constant operation `choose`, with

$$\mathsf{run}_{\mathtt{choose}} \colon \mathbf{1} \to M\mathsf{Val} \qquad \mathsf{run}_{\mathtt{choose}} = [\mathtt{true}, \mathtt{false}]$$

Then, $e = \mathtt{do}\ y = \mathtt{choose};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{return}\ 0\ \mathtt{else}\ \mathtt{return}\ \mathtt{succ}\,0$ reduces as follows.[6]

$$\begin{array}{rcl}
[\,e\,] & \Rightarrow & [\,\mathtt{do}\ y = \mathtt{true};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{return}\ 0\ \mathtt{else}\ \mathtt{return}\ \mathtt{succ}\,0, \\
& & \ \mathtt{do}\ y = \mathtt{false};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{return}\ 0\ \mathtt{else}\ \mathtt{return}\ \mathtt{succ}\,0\,] \\
& \Rightarrow & [\,\mathtt{if}\ \mathtt{t}\ \mathtt{then}\ \mathtt{ret}\ 0\ \mathtt{else}\ \mathtt{ret}\ 1, \mathtt{if}\ \mathtt{f}\ \mathtt{then}\ \mathtt{ret}\ 0\ \mathtt{else}\ \mathtt{ret}\ 1\,] \\
& \Rightarrow & [\,\mathtt{return}\ 0, \mathtt{return}\ \mathtt{succ}\,0\,] \\
& \Rightarrow & [\,0, \mathtt{succ}\,0\,]
\end{array}$$

Given $\mathsf{chfun}^{\uparrow} = \mathtt{rec}\, f.\lambda x.\mathtt{do}\ y = \mathtt{choose};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{return}\ x\ \mathtt{else}\ f\,\mathtt{succ}\,x$, the expression $\mathsf{chfun}^{\uparrow}\,0$ reduces as follows:

$$\begin{array}{rcl}
[\,\mathsf{chfun}^{\uparrow}\,0\,] & \Rightarrow & [\,\mathtt{do}\ y = \mathtt{choose};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{return}\ 0\ \mathtt{else}\ \mathsf{chfun}^{\uparrow}\,\mathtt{succ}\,0\,] \\
& \Rightarrow & [\,\mathtt{do}\ y = \mathtt{true};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{return}\ 0\ \mathtt{else}\ \mathtt{return}\ \mathsf{chfun}^{\uparrow}\,\mathtt{succ}\,0, \\
& & \ \mathtt{do}\ y = \mathtt{false};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{return}\ 0\ \mathtt{else}\ \mathsf{chfun}^{\uparrow}\,\mathtt{succ}\,0\,] \\
& \Rightarrow & [\,\mathtt{if}\ \mathtt{t}\ \mathtt{then}\ \mathtt{ret}\ 0\ \mathtt{else}\ \mathtt{ret}\ 1, \mathtt{if}\ \mathtt{f}\ \mathtt{then}\ \mathtt{ret}\ 0\ \mathtt{else}\ \mathsf{chfun}^{\uparrow}\ 1\,] \\
& \Rightarrow & [\,\mathtt{return}\ 0, \mathsf{chfun}^{\uparrow}\,\mathtt{succ}\,0\,] \\
& \Rightarrow & [\,0, \mathsf{chfun}^{\uparrow}\,\mathtt{succ}\,0\,] \\
& \Rightarrow & [\,0, \mathtt{do}\ y = \mathtt{choose};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{ret}\ \mathtt{succ}\,0\ \mathtt{else}\ \mathsf{chfun}^{\uparrow}\,\mathtt{s}\,\mathtt{s}\,0\,] \\
& \Rightarrow^{\star} & [\,0, \mathtt{succ}\,0, \mathsf{chfun}^{\uparrow}\,\mathtt{succ}\,\mathtt{succ}\,0\,] \\
& \cdots &
\end{array}$$

Note that the second reduction is non-terminating, in the sense that a monadic result (a list of values) is never reached. Hence, with the finitary semantics, we get $[\![\mathsf{chfun}^{\uparrow}\,0]\!]_{\star} = \infty$. With the infinitary semantics, instead, we get the following ω-chain:

$$[\ ], \ldots, [\,0\,], \ldots, [\,0, \mathtt{succ}\,0\,], \ldots, [\,0, \mathtt{succ}\,0, \ldots, \mathtt{succ}^n\,0\,], \ldots,$$

whose supremum is, as expected, the infinite list of the (values representing the) natural numbers. On the other end, given the function

$$\mathsf{chfun}^{\downarrow} = \mathtt{rec}\, f.\lambda x.\mathtt{if}\ \mathtt{iszero}\ x\ \mathtt{then}\ \mathtt{ret}\ x\ \mathtt{else}\ \mathtt{do}\ y = \mathtt{choose};\ \mathtt{if}\ y\ \mathtt{then}\ \mathtt{ret}\ x\ \mathtt{else}\ f\,\mathtt{pred}\,x$$

we get $[\![\mathsf{chfun}^{\downarrow}\,\mathtt{succ}^n\,0]\!]_{\star} = [\![\mathsf{chfun}^{\downarrow}\,\mathtt{succ}^n\,0]\!]_{\infty} = [\,\mathtt{succ}^n\,0, \ldots, 0\,]$.

▶ **Example 20.** Set, as underlying monad, the monad of probabilistic non-determinism of Example 3. We consider a discrete uniform distribution over a set of two elements and use the same function `choose`, now returning the list consisting of the values `true` and `false` with probability $\frac{1}{2}$, that we denote by $[\,\frac{1}{2} : \mathtt{true}, \frac{1}{2} : \mathtt{false}\,]$.

[6] We use `t`, `f`, `ret`, and `s`, for `true`, `false`, `return`, and `succ`, to save space.

Then, $[\,1 : e\,]$ and $[\,1 : \mathsf{chfun}^{\uparrow}\,0\,]$ reduce analogously to the previous example:

$$[\,1 : e\,] \Rightarrow^{\star} [\,\frac{1}{2} : 0, \frac{1}{2} : \mathtt{succ}\,0\,]$$

$$[\,[\,1 : \mathsf{chfun}^{\uparrow}\,0\,]\,] \Rightarrow^{\star} [\,\frac{1}{2} : 0, \frac{1}{4} : \mathtt{succ}\,0, \frac{1}{8} : \mathtt{succ}^2\,0, \frac{1}{16} : \mathtt{succ}^3\,0\,] \Rightarrow \ldots$$

Again, the second reduction is non-terminating, hence, with the finitary semantics, we get ∞, whereas, with the infinitary semantics, we get an ω-chain whose supremum is the infinite list where each (value representing the) number n has probability $\frac{1}{2^{n+1}}$.

▶ **Example 21.** Set, as underlying monad, the output monad of Example 4, in its pointed version. As a simple concrete choice, we take as elements of Out sequences of pairs $\langle \ell, \mathtt{succ}^n\,0\rangle$ where ℓ ranges over a fixed set Loc of *output locations* modeling, e.g., file names or output channels. We assume, for each ℓ, an operation $\mathtt{write}\langle\ell\rangle\colon \mathtt{Nat} \to \mathtt{Unit}$, with

$$\mathsf{run}_{\mathtt{write}\langle\ell\rangle}\colon \mathsf{Val} \to M\mathsf{Val} \qquad \mathsf{run}_{\mathtt{write}\langle\ell\rangle}(v) = \begin{cases} \langle\langle \ell, v\rangle, \mathtt{unit}\rangle & \text{if } v = \mathtt{succ}^n\,0 \\ \text{undefined} & \text{otherwise} \end{cases}$$

Given two distinct output locations ℓ, ℓ', and the functions

$$\mathsf{wfun}^{\uparrow} = \mathtt{rec}\,f.\lambda x.\mathtt{write}\langle\ell\rangle(x)\mathtt{;write}\langle\ell'\rangle(x)\mathtt{;}f\,\mathtt{succ}\,x$$
$$\mathsf{wfun}^{\downarrow} = \mathtt{rec}\,f.\lambda x.\mathtt{write}\langle\ell\rangle(x)\mathtt{;write}\langle\ell'\rangle(x)\mathtt{;if\ iszero}\ x\ \mathtt{then\ unit\ else}\ f\,\mathtt{pred}\,x$$

we get, as in the previous examples, the following semantics:

$$[\![\mathsf{wfun}^{\uparrow}\,0]\!]_{\star} = \infty$$
$$[\![\mathsf{wfun}^{\uparrow}\,0]\!]_{\infty} = \langle\langle \ell, 0\rangle \cdot \langle \ell', 0\rangle \cdot \langle \ell, \mathtt{succ}\,0\rangle \cdot \langle \ell', \mathtt{succ}\,0\rangle \cdot \ldots, \bot\rangle$$
$$[\![\mathsf{wfun}^{\downarrow}\,\mathtt{s}^n\,0]\!]_{\star} = [\![\mathsf{wfun}^{\downarrow}\,\mathtt{s}^n\,0]\!]_{\infty} = \langle\langle \ell, \mathtt{s}^n\,0\rangle \cdot \langle \ell', \mathtt{s}^n\,0\rangle \cdot \ldots \cdot \langle \ell, 0\rangle \cdot \langle \ell', 0\rangle, \mathtt{unit}\rangle$$

In the first two cases the reduction does not terminate, so no value is returned. With the finitary semantics also no effect is produced, whereas with the infinitary semantics the effect is the infinite sequence of outputs.

In order to equip the calculus (Figure 2) with a type-and-effect system, we need the ingredients shown in Figure 5. Besides types, which are functional types and additional unspecified

$$\begin{array}{lcll} T & ::= & \ldots \mid T \to_E T' & \text{type} \\ \Gamma & ::= & \overline{x : T} & \text{context} \end{array}$$

Figure 5 Types and contexts.

types, we consider *effect types* (*effects* when there is no ambiguity), ranged over by E, meant to be static approximations of the computational effects raised by an expression. As formally detailed below, effects are sets of (possibly infinite) sequences of operations. In this way, they are expressive enough to approximate computational effects in many different monads, as we will describe in Section 6, and we abstract away from details of a syntactic representation, which of course would be needed in a real language. Functional types are annotated with an effect, approximating the computational effects of calling the function. Finally, we assume operations to be typed; formally, for each op, we write $op\colon T_1 \ldots T_n \to T$.

Set Σ^{∞} the set of either finite or infinite sequences of operations. We use α, β to range over elements of Σ^{∞}, denote by ϵ the empty sequence, by $op{:}\alpha$ the sequence consisting of op followed by α, and by $\cdot$ sequence concatenation, coinductively defined by:

$$\epsilon\cdot\beta = \beta \qquad (op{:}\alpha)\cdot\beta = op{:}(\alpha\cdot\beta)$$

As customary, we write op for the sequence $op{:}\epsilon$.

An *effect* is a non-empty subset of Σ^∞. We denote by $\cdot$ composition of effects, defined by:

$$E{\cdot}E' = \{\alpha{\cdot}\beta \mid \alpha \in E, \beta \in E'\}$$

Absence of effects is modeled by the set $\{\epsilon\}$; the empty effect, if allowed, could be assigned to non-terminating computations which never call operations; however, since $E{\cdot}\emptyset = \emptyset$, effects assigned to a previous terminating computation would be lost.

The type-and-effect system is shown in Figure 6. The subtyping judgment has shape

$$\text{(SUB-FUN)}\ \frac{T_1' \le T_1 \quad T_2 \le T_2'}{T_1 \to_E T_2 \le T_1' \to_{E'} T_2'}\ E \subseteq E' \qquad \text{(SUB-REFL)}\ \frac{}{T \le T}$$

$$\text{(SUB-TRANS)}\ \frac{T \le T' \quad T' \le T''}{T \le T''} \qquad \text{(SUB-TE)}\ \frac{T \le T' \quad E \subseteq E'}{T!E \le T'!E'}$$

$$\text{(T-VAR)}\ \frac{}{\Gamma \vdash x : T}\ \Gamma(x) = T \qquad \text{(T-ABS)}\ \frac{\Gamma, f : T \to_E T', x : T \vdash e : T''!E'}{\Gamma \vdash \mathtt{rec}\, f.\lambda x.e : T \to_E T'}\ T''!E' \le T'!E$$

$$\text{(T-APP)}\ \frac{\Gamma \vdash v_1 : T_1 \to_E T \quad \Gamma \vdash v_2 : T_2}{\Gamma \vdash v_1\, v_2 : T!E}\ T_2 \le T_1 \qquad \text{(T-OP)}\ \frac{\Gamma \vdash v_i : T_i' \ \ \forall i \in 1..n}{\Gamma \vdash op(\overline{v}) : T!\{op\}}\ \begin{array}{l}\overline{v} = v_1, \ldots, v_n \\ op{:}\, T_1 \ldots T_n \to T \\ T_i' \le T_i\ \forall i \in 1..n\end{array}$$

$$\text{(T-RET)}\ \frac{\Gamma \vdash v : T}{\Gamma \vdash \mathtt{return}\ v : T!\{\epsilon\}} \qquad \text{(T-DO)}\ \frac{\Gamma \vdash e_1 : T_1!E_1 \quad \Gamma, x : T_2 \vdash e_2 : T!E_2}{\Gamma \vdash \mathtt{do}\ x = e_1\,;\ e_2 : T!E_1{\cdot}E_2}\ T_1 \le T_2$$

Figure 6 Type-and-effect system.

$T \le T'$. In (SUB-FUN) inclusion of effect types is propagated to functional types. Moreover subtyping is, as expected, covariant/contravariant on the result/parameter of functions. The other rules are standard.

The typing judgment for values has shape $\Gamma \vdash v : T$, since they have no effects. The judgment for expressions, instead, has shape $\Gamma \vdash e : T!E$.

Rule (T-VAR) is standard. In rule (T-ABS), a (possibly recursive) function gets a functional type, consisting of parameter/result types and effect, if the body, in a context where parameter and function are added with their types, gets a subtype and a subeffect of the result type and effect of the function. In rule (T-APP), an application gets the result type and the effect of the applied function, provided that the argument type is subtype of the expected one. In rule (T-OP), calling an operation raises the corresponding singleton effect, provided that the argument types are subtypes of the expected ones. In rule (T-RET), an expression representing a value has the trivial effect, and, in (T-DO), a sequential composition of two computations has the composition of the two effects.

▶ **Example 22.** We show some typing judgments which can be derived for the previous examples. We assume primitive types `Nat` and `Bool`, an empty type `Bot` subtype of any type, the singleton type `Unit` for the constant `unit`, and the obvious typing rule for conditional which takes the union of the effects of the two branches. Finally, we denote by α^n and α^ω a finite and infinite concatenation of αs, respectively.

1. In Example 18, with, for each $\mathsf{e} \in \mathsf{Exc}$, $\mathtt{raise}\langle \mathsf{e} \rangle{:}\, \mathbf{1} \to \mathtt{Bot}$,

$$\emptyset \vdash \mathsf{predfun} : \mathtt{Nat} \to_{\{\epsilon, \mathtt{raise}\langle \mathsf{PredZero} \rangle\}} \mathtt{Nat}$$

$$\emptyset \vdash \mathsf{predfun}\, v : \mathtt{Nat}!\{\epsilon, \mathtt{raise}\langle \mathsf{PredZero} \rangle\}\mathtt{if}\emptyset \vdash \mathtt{v} : \mathtt{Nat}$$

Note a significant feature of our type effects: differently from, e.g., Java checked exceptions, we can distinguish code which *may* raise an exception, as expressed by the effect $\{\epsilon, \texttt{raise}\langle\mathsf{PredZero}\rangle\}$, from code which *necessarily* raises an exception, as expressed by the effect $\{\texttt{raise}\langle\mathsf{PredZero}\rangle\}$, which is assigned, e.g., to the function $\lambda x.\texttt{raise}\langle\mathsf{PredZero}\rangle$. More in general, our type effects can *force* computational effects to be raised.

2. In Example 19, with $\texttt{choose}\colon \to \texttt{Bool}$,

$$\emptyset \vdash \mathsf{chfun}^{\uparrow} : \texttt{Nat} \to_{\{\texttt{choose}^n \mid n \geq 1\}} \texttt{Nat}$$
$$\emptyset \vdash \mathsf{chfun}^{\downarrow} : \texttt{Nat} \to_{\{\texttt{choose}^n \mid n \geq 0\}} \texttt{Nat}$$

Again, the effect of the first function forces non-determinism, differently from that of the second one. Apart from that, the two effects are very similar, even though calls of the first and second function always diverge and terminate, respectively. Indeed, as usual, effect types only provide a static approximation of the computational effects.

3. In Example 21, with, for each output location ℓ, $\texttt{write}\langle\ell\rangle\colon \texttt{Nat} \to \texttt{Unit}$,

$$\emptyset \vdash \mathsf{wfun}^{\uparrow} : \texttt{Nat} \to_{\{(\texttt{write}\langle\ell\rangle \cdot \texttt{write}\langle\ell'\rangle)^{\omega}\}} \texttt{Unit}$$
$$\emptyset \vdash \mathsf{wfun}^{\downarrow} : \texttt{Nat} \to_{\{(\texttt{write}\langle\ell\rangle \cdot \texttt{write}\langle\ell'\rangle)^{n} \mid n \geq 0\}} \texttt{Unit}$$

Here the difference between the effects of the two functions is even more significant: in the former, the sequence of two write calls is necessarily done infinitely many times, in the latter it can be done any arbitrary, yet finite, positive number of times. Moreover, in this case effects also provide an information on the the order among different write calls; for instance, here a $\texttt{write}\langle\ell\rangle$ call should be always followed by a $\texttt{write}\langle\ell'\rangle$ call.

We discuss now how to express and prove type soundness. Recall that the monadic operational semantics defined in Section 3 constructs, on top of the one-step reduction:

- a finitary semantics $[\![-]\!]_{\star}\colon \mathsf{Exp} \to M\mathsf{Res} + \{\infty\}$
- an infinitary semantics $[\![-]\!]_{\infty}\colon \mathsf{Exp} \to M\mathsf{Res}$

where $\mathsf{Res} = \mathsf{Val} + \mathsf{Wr}$, with the latter modelling a stuck computation. Hence, we expect a sound type-and-effect system to guarantee, first of all, that

(1) the (monadic) result of a well-typed expression is never wrong

analogously to what we expect for a standard type system. In the standard case, we also expect the result, if any, to be in agreement with the expression type. Here, since the expression has an effect as well, approximating the computational effects raised by its execution, we expect that

(2) the monadic result, if any, is in agreement with the expression type and effect

In finitary semantics, (2) imposes nothing on diverging expressions, since they have no monadic result, whereas, in infinitary semantics, (2) is significant for diverging expressions as well.

To formally express (2), we need to derive, from the well-typedness predicates (one for each type and effect), analogous predicates on monadic results. In the following section, this is achieved through a *predicate lifting* [21] λ, that is, a way to lift, for every set X, predicates over X to predicates over MX. Intuitively, λ adds requirements on the computational effects,expressed by an effect type, that is, lifting provides an *interpretation of effect types*.

5 Monadic type-and-effect soundness

The standard technique for proving type soundness with respect to a small-step operational semantics is as a consequence, by a simple inductive argument, of progress and subject reduction properties [47]. In this section, we introduce an analogous technique for monadic

operational semantics. Notably, we express progress and subject reduction for the monadic one-step reduction, and prove that they imply soundness. We develop our technique for *type-and-effect systems* [45, 32, 46, 29, 25], that is, formal systems providing an (over)approximation not only of the result of a computation, but also of its computational effects.

Following [7, 6], a type system can be abstractly seen as a family of predicates over expressions and values indexed by types. In a type-and-effect system, predicates over expressions will be indexed not only by types but also by *effect types*, describing the computational effects that expressions can produce during their evaluation, as defined below.

▶ **Definition 23.** *A* type-and-effect system $\Theta = \langle \mathsf{Ty}, \mathcal{E}, \mathsf{WT}^{\mathsf{E}}, \mathsf{WT}^{\mathsf{V}} \rangle$ *for a language* $\mathcal{L} = \langle \mathsf{Exp}, \mathsf{Val}, \mathsf{ret} \rangle$ *consists of the following data:*

- *a set* Ty *of* types
- *an ordered monoid* $\mathcal{E} = \langle \mathsf{Eff}, \preceq, \cdot, 1 \rangle$ *of* effect types
- *for every* $\tau \in \mathsf{Ty}$ *and* $\varepsilon \in \mathsf{Eff}$*, predicates* $\mathsf{WT}^{\mathsf{V}}_{\tau} \subseteq \mathsf{Val}$ *and* $\mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon} \subseteq \mathsf{Exp}$ *such that*
  - $\varepsilon \preceq \varepsilon'$ *implies* $\mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon} \subseteq \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon'}$ *and*
  - $\mathsf{ret}(v) \in \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$ *iff* $v \in \mathsf{WT}^{\mathsf{V}}_{\tau}$ *and* $1 \preceq \varepsilon$

The ordered monoid is a typical structure for effect systems [32, 29, 25]: 1 represents the absence of computational effects, $\varepsilon_1 \cdot \varepsilon_2$ represents the composition of computational effects described by ε_1 and ε_2, and $\varepsilon_1 \preceq \varepsilon_2$ states that the effect type ε_1 is more specific than ε_2.

The two families WT^{V} and WT^{E} are, for each index, predicates over values and expressions, respectively: $\mathsf{WT}^{\mathsf{V}}_{\tau}$ is the set of values of type τ, and $\mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$ is the set of expressions of type τ which may raise effects described by ε. The first requirement, that is, monotonicity with respect to the order, states that the latter actually models if $\varepsilon_1 \preceq \varepsilon_2$, then ε_1 is really more specific than ε_2. The second requirement states that an expression which is the embedding of a value has the same type, and an effect type which is not forcing any effect.[7]

Consider now an operational semantics $\langle \mathbb{M}, \rightarrow \rangle$, with $\mathbb{M} = \langle M, \mu, \eta \rangle$, and focus, e.g., on reduction from expressions to monadic expressions. To express type preservation, we should define, for each τ and ε, the monadic counterpart of $\mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$, being a predicate on $M\mathsf{Exp}$. The key idea is to obtain such predicate by applying a *predicate lifting* [21], that is, a way to lift, for every set X, predicates over X to predicates over MX, adding requirements on the computational effects modeled by the monad. In our case, for each effect type ε, the predicate lifting modularly models the meaning of ε, that is, the computational effects approximated by ε, independently from the set X and the predicate A, as formally detailed below.

For a set X, we denote by $\mathcal{P}(X)$ the poset of all subsets (a.k.a. predicates) on X, ordered by subset inclusion. For a function $f\colon X \to Y$, we have a monotone function $\mathcal{P}_f\colon \mathcal{P}(Y) \to \mathcal{P}(X)$, given by the inverse image: for $A \subseteq Y$, $\mathcal{P}_f(A) = \{x \in X \mid f(x) \in A\}$. That is, $\mathcal{P}_f$ is a predicate transformer, giving, for each predicate A on Y, the weakest condition elements of X should satisfy to be mapped by f in elements satisfying A. These data determine a functor $\mathcal{P}\colon \mathcal{S}et^{\mathrm{op}} \to \mathcal{P}os$, where $\mathcal{P}os$ denotes the category of posets and monotone functions.

▶ **Definition 24** (Interpretation of effect types)**.** *Let* $\mathbb{M} = \langle M, \mu, \eta \rangle$ *be a monad, and* $\mathcal{E} = \langle \mathsf{Eff}, \preceq, \cdot, 1 \rangle$ *an ordered monoid of effect types. Then, an* interpretation *of* $\mathcal{E}$ *in* $\mathbb{M}$ *consists of a family* λ *of monotone functions* $\lambda^{\varepsilon}_X\colon \mathcal{P}(X) \to \mathcal{P}(MX)$*, for every* $\varepsilon \in \mathsf{Eff}$ *and set* X*, such that*

1. $\lambda^{\varepsilon}_X(\mathcal{P}_f(A)) = \mathcal{P}_{Mf}(\lambda^{\varepsilon}_Y(A))$*, for every* $A \subseteq Y$ *and function* $f\colon X \to Y$
2. $\varepsilon \preceq \varepsilon'$ *implies* $\lambda^{\varepsilon}_X(A) \subseteq \lambda^{\varepsilon'}_X(A)$*, for every* $A \subseteq X$*,*
3. $A \subseteq \mathcal{P}_{\eta X}(\lambda^{1}_X(A))$*, for every* $A \subseteq X$*,*
4. $\lambda^{\varepsilon}_{MX}(\lambda^{\varepsilon'}_X(A)) \subseteq \mathcal{P}_{\mu X}(\lambda^{\varepsilon \cdot \varepsilon'}_X(A))$*, for every* $A \subseteq X$*.*

[7] For instance, in Example 22(1), we have $\{\epsilon\} \preceq \{\epsilon, \mathtt{raise}\langle \mathsf{PredZero} \rangle\}$, whereas $\{\epsilon\} \not\preceq \{\mathtt{raise}\langle \mathsf{PredZero} \rangle\}$.

The family $\lambda = (\lambda^{\varepsilon})_{\varepsilon \in \mathsf{Eff}}$ is a family of predicate liftings for the monad $\mathbb{M}$, indexed by effect types. For a subset $A \subseteq X$, the subset $\lambda^{\varepsilon}_X(A) \subseteq MX$ contains monadic elements which agree with A and whose computational effects are described by ε.

Item 1 states that λ^{ε}_X is natural in X, that is, for every $\varepsilon \in \mathsf{Eff}$, we have a natural transformation $\lambda^{\varepsilon} : \mathcal{P} \Rightarrow \mathcal{P} \circ M^{\mathrm{op}}$.[8] The naturality on X ensures that the semantics of each effect type is independent from the specific set X, thus depending only on the functor M.

Item 2 states that λ^{ε}_X is monotone with respect to the order on effects, that is, computational effects described by ε are also described by ε'.

Item 3 states that monadic elements in the image of η_X contain computational effects described by 1, that is, no computational effect.

Finally, in Item 4 we consider elements of M^2X whose computational effects are described by lifting predicates to MX through ε', and then by lifting through ε. By flattening such elements through $\mu_X \colon M^2X \to MX$ we obtain elements whose computational effects are described by the composition $\varepsilon \cdot \varepsilon'$.

▶ Remark 25. The monad $\mathbb{M}$ with an interpretation λ determine a structure on the functor $\mathcal{P}$, which can be described as a graded/parametric monad [14] on $\mathcal{P}$ in an appropriate 2-category (see e.g., [10]). Equivalently, λ determines a graded/parametric monad above $\mathbb{M}$ [25, Def. 2.6] along the fibration obtained from $\mathcal{P}$ by the Grothendieck construction [18].

▶ **Example 26.** Consider the exception monad $\mathbb{E}_{\mathsf{Exc}}$ of Example 1 and the ordered monoid $\langle \wp(\mathsf{Exc} + \{\mathsf{none}\}), \subseteq, \cdot, \{\mathsf{none}\}\rangle$ where $\mathsf{E}_1 \cdot \mathsf{E}_2 = (\mathsf{E}_1 \setminus \{\mathsf{none}\}) \cup \mathsf{E}_2$, if $\mathsf{none} \in \mathsf{E}_1$, and $\mathsf{E}_1 \cdot \mathsf{E}_2 = \mathsf{E}_1$, otherwise. For every $\mathsf{E} \in \wp(\mathsf{Exc} + \{\mathsf{none}\})$, set X, and $A \subseteq X$, the assigment

$$\lambda^{\mathsf{E}}_X(A) = \begin{cases} A + (\mathsf{E} \setminus \{\mathsf{none}\}) & \text{if } \mathsf{none} \in \mathsf{E} \\ \mathsf{E} & \text{otherwise} \end{cases}$$

determines an interpretation of effect types into $\mathbb{E}_{\mathsf{Exc}}$. Intuitively, the interpretation of E requires exceptions possibly raised to be in E, and, if it is allowed that no exception be raised ($\mathsf{none} \in \mathsf{E}$), requires the predicate A to be satisfied.

▶ **Example 27.** Consider the powerset monad $\mathbb{P}$ of Example 2.

1. Taking the ordered monoid $\langle \{0,1\}, \leq, \vee, 0\rangle$, for every set X and $A \subseteq X$, the following assignments determine two interpretations of effect types into $\mathbb{P}$:

$$\forall^1_X(A) = \{B \in PX \mid B \subseteq A\},$$
$$\exists^1_X(A) = \{B \in PX \mid B = \emptyset \text{ or } B \cap A \neq \emptyset\} \textit{and}$$
$$\forall^0_X(A) = \exists^0_X(A) = \{B \in PX \mid B \subseteq A \text{ and } \sharp B \leq 1\}$$

   where $\sharp B$ is the cardinality of B. Intuitively, in both cases, the interpretation of 0 disallows non-determinism, while the interpretation of 1 requires the predicate A to be always satisfied, according to $\forall$, and satisfied in at least one case, according to $\exists$.
2. Taking instead the ordered monoid $\langle \mathbb{N} \cup \{\infty\}, \leq, \cdot, 1\rangle$, we can give a finer version of $\forall$:

$$\forall^n_X(A) = \{B \in PX \mid B \subseteq A \text{ and } \sharp B \leq n\}$$
$$\forall^\infty_X(A) = \{B \in PX \mid B \subseteq A\}$$

   In this way, we can quantify the level of non-determinism in terms of the maximum number of possible outcomes.

[8] Here $M^{\mathrm{op}} \colon \mathcal{S}et^{\mathrm{op}} \to \mathcal{S}et^{\mathrm{op}}$ denotes the functor defined exactly as M but on the opposite category.

Similar interpretations can be defined for the list and subdistribution monads of Example 3.

▶ **Example 28.** Consider the output monad $\mathbb{O}$ of Example 4 for the monoid $\langle A^\infty, \cdot, \epsilon\rangle$ of possibly infinite words over A and the ordered monoid $\langle \mathbb{N}\cup\{\infty\}, \leq, +, 0\rangle$ of effect types. For a word $\sigma \in A^\infty$, we write $|\sigma|$ for its length, which is an element of $\mathbb{N}\cup\{\infty\}$. For every $n \in \mathbb{N}\cup\{\infty\}$, set X and $A \subseteq X$, the assignment $\lambda^n_X(A) = \{\langle\sigma, x\rangle \in OX \mid x \in A, |\sigma| \leq n\}$ determines an interpretation of effect types into $\mathbb{O}$. Intuitively, such interpretation imposes an upper bound (or none) to the length of the outputs.

▶ **Example 29.** Let $\mathcal{E}$ be an ordered monoid of effect types and λ an interpretation of $\mathcal{E}$ into a monad $\mathbb{M}$. Let $\mathcal{E}'$ be another ordered monoid. To give an interpretation of $\mathcal{E}'$ into $\mathbb{M}$, it suffices to give a *lax monoid homomorphism* $f\colon \mathcal{E}' \to \mathcal{E}$, that is, a monotone function $f\colon \langle \mathsf{Eff}', \preceq'\rangle \to \langle \mathsf{Eff}, \preceq\rangle$ such that $1 \preceq f(1')$ and $f(\varepsilon'_1)\cdot f(\varepsilon'_2) \preceq f(\varepsilon'_1\cdot\varepsilon'_2)$. Then, we can define an interpretation ρ of $\mathcal{E}'$ into $\mathbb{M}$ by setting $\rho^{\varepsilon'} = \lambda^{f(\varepsilon')}$ for all $\varepsilon' \in \mathsf{Eff}'$.

Let us fix a monadic operational semantics $\langle \mathbb{M}, \to\rangle$ for a language $\mathcal{L} = \langle \mathsf{Exp}, \mathsf{Val}, \mathsf{ret}\rangle$, a type-and-effect system $\Theta = \langle \mathsf{Ty}, \mathcal{E}, \mathsf{WT}^{\mathsf{E}}, \mathsf{WT}^{\mathsf{V}}\rangle$ for $\mathcal{L}$, and an interpretation λ of $\mathcal{E}$ into $\mathbb{M}$.

Then, we can formally state monadic progress and monadic subject reduction.

▶ **Definition 30** (Monadic Progress). *The type-and-effect system Θ has* monadic progress *if $e \in \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$ implies either $e = \mathsf{ret}(v)$ for some $v \in \mathsf{Val}$, or $e \to \mathrm{E}$ for some $\mathrm{E} \in M\mathsf{Exp}$.*

▶ **Definition 31** (Monadic Subject Reduction). *The type-and-effect system Θ has* monadic subject reduction *if $e \in \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$ and $e \to \mathrm{E}$ imply $\mathrm{E} \in \lambda^{\varepsilon_1}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon_2})$ for some $\varepsilon_1\cdot\varepsilon_2 \preceq \varepsilon$.*

Monadic progress is standard: a well-typed expression either represents a value or can reduce. Monadic subject reduction, instead, takes into account effects: if an expression of type τ and effect ε reduces to a monadic expression E, then E "has type τ and effect ε" as well, meaning that: ε can be decomposed as $\varepsilon_1\cdot\varepsilon_2$ and E contains computational effects described by ε_1 and expressions of type τ and effect ε_2. In other words, the type τ is preserved and the effect ε is an upper bound of the computational effects produced by the current reduction step, described by ε_1, composed with those produced by future reductions, described by ε_2.

Our next step is expressing type-and-effect soundness. In standard small-step semantics, soundness means that, starting from a well-typed expression, if termination, that is, an expression which cannot be reduced, is reached, then such expression should be a well-typed value. In our monadic operational semantics, termination is conventionally represented by monadic results. Hence, an analogous statement is that, starting from a well-typed expression, if termination, that is, a monadic result, is reached, then this should be a well-typed result, meaning that is satisfies the lifting through the effect type of well-typedness of values.

Again slightly abusing the notation, we will consider predicates $\mathsf{WT}^{\mathsf{V}}_\tau$ on values also as predicates on results. Note that in particular $\mathsf{wrong} \notin \mathsf{WT}^{\mathsf{V}}_\tau$ for all $\tau \in \mathsf{Ty}$.

▶ **Definition 32** (Finitary type-and-effect soundness). *The type-and-effect system Θ is* finitarily sound *if $e \in \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$ and $[\![e]\!]_\star = R$ imply $R \in \lambda^{\varepsilon}_{\mathsf{Res}}(\mathsf{WT}^{\mathsf{V}}_\tau)$.*

This notion of soundness is very general: whenever an expression of type τ and effect ε evaluates to a monadic result, this belongs to the interpretation of ε applied to (the image of) values of type τ. Hence, the nature of the soundness property heavily depends on the interpretation λ of effect types. For instance, considering the interpretations for the powerset monad of Example 27, $\forall$ and $\exists$ induce induce a notion of must-soundness, and may-soundness, respectively: the former ensures that the evaluation of a well-typed expression never reaches wrong, while the latter only that it either diverges or reaches at least a well-typed value.

More specifically, it is not guaranteed that the monadic result is actually a monadic value. Formally, viewing $M\mathsf{Val}$ as a subset of $M\mathsf{Res}$, the inclusion $\lambda^{\varepsilon}_{\mathsf{Res}}(\mathsf{WT}^{\mathsf{V}}_{\tau}) \subseteq M\mathsf{Val}$ does not hold in general, as happens for instance with the $\exists$ interpretation. However, we can recover this property when the interpretation λ enjoys an additional condition, as detailed below.

Given $f\colon X \to Y$, the mapping $\mathcal{P}_f\colon \mathcal{P}(Y) \to \mathcal{P}(X)$ has a left adjoint $\mathcal{P}^f\colon \mathcal{P}(X) \to \mathcal{P}(Y)$, that is, a monotone function such that, for every $A \subseteq X$ and $B \subseteq Y$, $\mathcal{P}^f(A) \subseteq B$ if and only if $A \subseteq \mathcal{P}_f(B)$. The function $\mathcal{P}^f$ is the direct image along f, that is, for $A \subseteq X$, $\mathcal{P}^f(A) = \{f(x) \mid x \in A\}$. Then, the following is an easy observation.

▶ **Proposition 33.** *If λ satisfies*
5. $\lambda^{\varepsilon}_{Y}(\mathcal{P}^f(A)) \subseteq \mathcal{P}^{Mf}(\lambda^{\varepsilon}_{X}(A))$ *for $f\colon X \to Y$ and $A \subseteq X$*
then $\lambda^{\varepsilon}_{\mathsf{Res}}(\mathsf{WT}^{\mathsf{V}}_{\tau}) \subseteq M\mathsf{Val}$.

Proof. Recall that we are implicitly using an inclusion $\iota^{\mathsf{Res}}_{\mathsf{Val}}\colon \mathsf{Val} \to \mathsf{Res}$. Making it explicit, the thesis becomes $\lambda^{\varepsilon}_{\mathsf{Res}}(\mathcal{P}^{\iota^{\mathsf{Res}}_{\mathsf{Val}}}(\mathsf{WT}^{\mathsf{V}}_{\tau})) \subseteq \mathcal{P}^{\iota^{\mathsf{Res}}_{\mathsf{Val}}}(M\mathsf{Val})$. This follows from $\lambda^{\varepsilon}_{\mathsf{Res}}(\mathcal{P}^{\iota^{\mathsf{Res}}_{\mathsf{Val}}}(\mathsf{WT}^{\mathsf{V}}_{\tau})) \subseteq \mathcal{P}^{M\iota^{\mathsf{Res}}_{\mathsf{Val}}}(\lambda^{\varepsilon}_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_{\tau})) \subseteq \mathcal{P}^{M\iota^{\mathsf{Res}}_{\mathsf{Val}}}(M\mathsf{Val})$. ◀

Note that the inclusion in Item 5 is actually an equality, since the converse always holds thanks to Item 1 of Definition 24, as $\mathcal{P}^f$ is the left adjoint of $\mathcal{P}_f$. This ensures that a monadic result $\mathrm{R} \in \lambda^{\varepsilon}_{\mathsf{Res}}(\mathsf{WT}^{\mathsf{V}}_{\tau})$ contains only values of type τ, hence, in particular, cannot contain wrong. In fact, the $\exists$ interpretation of Example 27 does not satisfy Item 5 of Proposition 33.

From now on, we assume that Θ has monadic progress and monadic subject reduction, and our goal is to prove that they imply type-and-effect soundness.

We first extend the type-and-effect system to configurations, defining $\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon} \subseteq \mathsf{Conf}$ as

$$\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon} = \begin{cases} \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon} + \mathsf{WT}^{\mathsf{V}}_{\tau} & \text{if } 1 \preceq \varepsilon \\ \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon} & \text{otherwise} \end{cases}$$

Note that wrong is never a well-typed configuration, while configurations which are values of type τ are well-typed with type τ and effect ε only when ε is larger than 1, that is, the type effect does not force raising effects.

Then, we should extend monadic progress and monadic subject reduction to the reduction relation $\xrightarrow[\mathsf{step}]{}$. However, since it is a total function, it trivially enjoys progress, hence, we only have to deal with subject reduction. In the proof, we also use monadic progress of the monadic reduction $\to$ on expressions to ensure that wrong, which is ill-typed, is not produced.

▶ **Lemma 34.** *If $c \in \mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon}$ and $c \xrightarrow[\mathsf{step}]{} \mathrm{C}$, then $\mathrm{C} \in \lambda^{\varepsilon_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\varepsilon_2})$ with $\varepsilon_1 \cdot \varepsilon_2 \preceq \varepsilon$.*

Proof. We split cases on the shape of c.

- $c = e$. From $e \in \mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon}$ we derive $e \in \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$. By monadic progress, either $e = \mathsf{ret}(v)$ or $e \to \mathrm{E}$. In the former case, $\mathrm{C} = \eta_{\mathsf{Conf}}(v)$ and, by Definition 23, $1 \preceq \varepsilon$ and $v \in \mathsf{WT}^{\mathsf{V}}_{\tau}$. Hence, the thesis follows by Definition 24(3), taking $\varepsilon_1 = 1$ and $\varepsilon_2 = \varepsilon$. In the latter case, $\mathrm{C} = \hat{\mathrm{E}} = M\iota^{\mathsf{Conf}}_{\mathsf{Exp}}(\mathrm{E})$ and, by monadic subject reduction, $\mathrm{E} \in \lambda^{\varepsilon_1}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon_2})$, with $\varepsilon_1 \cdot \varepsilon_2 \preceq \varepsilon$. From $\mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon_2} = \mathcal{P}_{\iota^{\mathsf{Conf}}_{\mathsf{Exp}}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon_2})$, by Definition 24(1),

  $$\mathrm{E} \in \lambda^{\varepsilon_1}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon_2}) = \lambda^{\varepsilon_1}_{\mathsf{Exp}}(\mathcal{P}_{\iota^{\mathsf{Conf}}_{\mathsf{Exp}}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon_2})) = \mathcal{P}_{M\iota^{\mathsf{Conf}}_{\mathsf{Exp}}}(\lambda^{\varepsilon_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon_2}))$$

  which implies that $\hat{\mathrm{E}} = M\iota^{\mathsf{Conf}}_{\mathsf{Exp}}(\mathrm{E}) \in \lambda^{\varepsilon_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon_2})$, as needed.
- $c = r$. Since $r \in \mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon}$, we have $r \neq \mathsf{wrong}$, hence $r = v$ and this implies that $v \in \mathsf{WT}^{\mathsf{V}}_{\tau}$ and $1 \preceq \varepsilon$. By definition of $\xrightarrow[\mathsf{step}]{}$, we also know that $\mathrm{C} = \eta_{\mathsf{Conf}}(v)$, hence, the thesis follows from Definition 24(3) taking $\varepsilon_1 = 1$ and $\varepsilon_2 = \varepsilon$. ◀

Then, we obtain the following result, showing a form of soundness for the multistep reduction on configurations.

▶ **Theorem 35.** *If* $c \in \mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon}$ *and* $c \xrightarrow{\mathsf{step}}{}^{\star} \mathrm{C}$*, then* $\mathrm{C} \in \lambda^{\varepsilon_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon_2})$ *with* $\varepsilon_1 \cdot \varepsilon_2 \preceq \varepsilon$*.*

Proof. By induction on rules defining $\xrightarrow{\mathsf{step}}{}^{\star}$.

(REFL). We have $\mathrm{C} = \eta_{\mathsf{Conf}}(c)$. By Definition 24(3), $c \in \mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon} \subseteq \mathcal{P}_{\eta_{\mathsf{Conf}}}(\lambda^{1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon}))$, which implies $\mathrm{C} = \eta_{\mathsf{Conf}}(c) \in \lambda^{1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon})$. This proves the thesis since $1 \cdot \varepsilon \preceq \varepsilon$.

(STEP). We know that $c \xrightarrow{\mathsf{step}}{}^{\star} \mathrm{C}_1$ and $\mathrm{C} = \mathrm{C}_1 \gg\!= \mathsf{step}$. By induction hypothesis, $\mathrm{C}_1 \in \lambda^{\varepsilon_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon_2})$ with $\varepsilon_1 \cdot \varepsilon_2 \preceq \varepsilon$. By Lemma 34, we derive $\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon_2} \subseteq \mathcal{P}_{\mathsf{step}}(\lambda^{\varepsilon'_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon'_2}))$ with $\varepsilon'_1 \cdot \varepsilon'_2 \preceq \varepsilon_2$. Then, using Items 1 and 4 of Definition 24, we have

$$\begin{aligned}
\mathrm{C}_1 \in \lambda^{\varepsilon_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon_2}) &\subseteq \lambda^{\varepsilon_1}_{\mathsf{Conf}}(\mathcal{P}_{\mathsf{step}}(\lambda^{\varepsilon'_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon'_2}))) = \mathcal{P}_{M\mathsf{step}}(\lambda^{\varepsilon_1}_{M\mathsf{Conf}}(\lambda^{\varepsilon'_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon'_2})))\\
&\subseteq \mathcal{P}_{M\mathsf{step}}(\mathcal{P}_{\mu_{\mathsf{Conf}}}(\lambda^{\varepsilon_1\cdot\varepsilon'_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon'_2}))) = \mathcal{P}_{\mu_{\mathsf{Conf}}\circ M\mathsf{step}}(\lambda^{\varepsilon_1\cdot\varepsilon'_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon'_2}))\\
&= \mathcal{P}_{(\mathsf{step})^{\dagger}}(\lambda^{\varepsilon_1\cdot\varepsilon'_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon'_2}))
\end{aligned}$$

This implies that $\mathrm{C} = (\mathsf{step})^{\dagger}(\mathrm{C}_1) \in \lambda^{\varepsilon_1\cdot\varepsilon'_1}_{\mathsf{Conf}}(\mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon'_2})$, hence the thesis follows observing that $(\varepsilon_1 \cdot \varepsilon'_1) \cdot \varepsilon'_2 \preceq \varepsilon_1 \cdot \varepsilon_2 \preceq \varepsilon$. ◀

▶ **Theorem 36** (Finitary type-and-effect soundness)**.** *If* $e \in \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$ *and* $[\![e]\!]_{\star} = R$ *then* $R \in \lambda^{\varepsilon}(\mathsf{WT}^{\mathsf{V}}_{\tau})$*.*

Theorem 36 states that monadic progress and monadic subject reduction imply soundness with respect to the finitary semantics. To state an analogous result for infinitary semantics, the interpretation of effect types has to take into account the additional structure of the monad.

▶ **Definition 37.** *Let* $\mathbb{M} = \langle M, \sqsubseteq, \mu, \eta \rangle$ *be an* ω*-CPO-ordered monad. An interpretation* λ *of* $\mathcal{E}$ *in* $\mathbb{M}$ *is* ω-CPO-ordered *if, for every effect type* $\varepsilon \in \mathsf{Eff}$*, set* X*, and* $A \subseteq X$*, we have*

1. $\bot_X \in \lambda^{\varepsilon}_X(A)$ *and*
2. *for every* ω*-chain* $(\alpha_n)_{n\in\mathbb{N}}$ *in* MX*,* $\alpha_n \in \lambda^{\varepsilon}_X(A)$ *for all* $n \in \mathbb{N}$ *implies* $\bigsqcup_{n\in\mathbb{N}} \alpha_n \in \lambda^{\varepsilon}_X(A)$*.*

For example, the interpretations in Example 27 are ω-CPO-ordered and also that in Example 28 can be turned into an ω-CPO-ordered one if applied to the pointed output monad. Finally, the construction of Example 29 applies to ω-CPO-ordered interpretations as well.

From now on, we assume that the monad $\mathbb{M}$ has an ω-CPO-ordered structure and the interpretation λ of effect types is ω-CPO-ordered as well.

▶ **Definition 38** (Infinitary type-and-effect soundness)**.** *The type-and-effect system* Θ *is* infinitarily sound *if* $e \in \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$ *implies* $[\![e]\!]_{\infty} \in \lambda^{\varepsilon}_{\mathsf{Res}}(\mathsf{WT}^{\mathsf{V}}_{\tau})$*.*

Infinitary soundness states that the limit behaviour of an expression of type τ and effect type ε is a monadic result belonging to the interpretation of ε applied to values of type τ. Observations in Proposition 33 applies to infinitary soundness as well.

In order to prove that monadic progress and monadic subject reduction imply infinitary soundness, we first need a simple property of the function $\mathsf{res} = \mathsf{res}^{\dagger}_0$, introduced at page 8, which is at the basis of the definition of the infinitary semantics.

▶ **Lemma 39.** *If* $\mathrm{C} \in \mathsf{WT}^{\mathsf{C}}_{\tau,\varepsilon}$ *then* $\mathsf{res}_0(c) \in \lambda^{\varepsilon}_{\mathsf{Res}}(\mathsf{WT}^{\mathsf{V}}_{\tau})$*.*

▶ **Theorem 40** (Infinitary type-and-effect soundness)**.** *If* $e \in \mathsf{WT}^{\mathsf{E}}_{\tau,\varepsilon}$ *then* $[\![e]\!]_{\infty} \in \lambda^{\varepsilon}_{\mathsf{Res}}(\mathsf{WT}^{\mathsf{V}}_{\tau})$*.*

6 Example of soundness proof

We show an instance of the technique introduced in the previous section, by proving monadic progress (Theorem 42) and monadic subject reduction (Theorem 45), hence, type-and-effect soundness, for our example. Recall that monadic reduction in Section 4 is parametric on a monad $\mathbb{M}$, and, for each operation op with arity k, a partial function $\mathsf{run}_{op}{:}\mathsf{Val}^k \rightharpoonup M\mathsf{Val}$.

The type-and-effect system defined in Section 4 is an example of Definition 23, where, omitting empty environments and environments in judgments for simplicity:

- Ty is the set of types T as in Figure 5
- $\mathcal{E} = \langle \mathsf{Eff}, \subseteq, \cdot, \{\epsilon\}\rangle$ where Eff is the set of non-empty subsets of Σ^∞
- $\mathsf{WT}^{\mathsf{E}}_{T,E}(e)$ iff $\vdash e : T'!E'$ for some T', E' such that $T'!E' \leq T!E$.
- $\mathsf{WT}^{\mathsf{V}}_{T}(v)$ iff $\vdash v : T'$ for some T' such that $T' \leq T$

In order to prove progress and subject reduction properties, we need a last parameter, that is, an interpretation λ of effect types. Since the proof is parametric on the computational effects raised by operations, these two parameters should agree, as described below.

for each $op\colon T_1 \dots T_n \to T$, and $\overline{v}$ such that $\vdash \overline{v} : \overline{T}'$ and $\overline{T}' \leq \overline{T}$

(RUN) $\quad \mathsf{run}_{op}(\overline{v}) \in \lambda^{\{op\}}_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_{T})$

▶ **Example 41.** We describe interpretations of the effect types suitable for the examples in Section 4. Such interpretations are defined by first mapping[9] the effect types into one of the ordered monoids in Section 5, and then taking the interpretation of the latter into the monad; in this way, as described in Example 29, we get an interpretation of the original effect types. In other words, for an instantiation of the calculus on specific monad and operations, sets of possibly infinite sequences could be reduced to simpler effect types, as exemplified below.

1. In Example 18, we reduce effect types to sets whose elements are either exceptions or none:

$$[\![\epsilon]\!] = \{\mathsf{none}\} \qquad [\![\mathtt{raise}\langle \mathsf{e}\rangle{:}\alpha]\!] = \{\mathsf{e}\} \qquad [\![E]\!] = \bigcup_{\alpha\in E} [\![\alpha]\!]$$

That is, effect types are mapped into those of Example 26, so that, if $[\![E]\!] = \mathsf{E}$, then

$$\lambda^{E}_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_{T}) = \begin{cases} \mathsf{WT}^{\mathsf{V}}_{T} + \mathsf{E} \text{ if } \epsilon \in E \\ \mathsf{E} \text{ otherwise} \end{cases}$$

In this way, monadic values[10] (either values or exceptions) are well-typed if they are either exceptions in E, or, if it is allowed that no exception be raised ($\mathsf{none} \in \mathsf{E}$), well-typed values. Note that an expression such as, e.g., $\mathtt{raise}\langle \mathsf{e}\rangle\mathtt{;raise}\langle \mathsf{e}'\rangle$, gets the effect (reducing to) $\{\mathsf{e}\}$, highlighting the fact that $\mathtt{raise}\langle \mathsf{e}'\rangle$ cannot be reached.

2. In Example 19, the simplest interpretation is to reduce effect types to either 0 or 1:

$[\![\epsilon]\!] = 0$
$[\![\mathtt{choose}{:}\alpha]\!] = 1$
$[\![E]\!] = 1$ if $[\![\alpha]\!] = 1$ for some $\alpha \in E, 0$ otherwise

[9] In all the examples it is easy to see that the mapping is a lax monoid homomorphism.
[10] We explain how the lifting works on values; of course the same applies to expressions and configurations.

That is, effect types are mapped into those of Example 27(1), so that, if $[\![E]\!] = 0$, then

$$\lambda^E_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \lambda^0_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \{\mathsf{V} \in P\mathsf{Val} \mid \mathsf{V} \subseteq \mathsf{WT}^{\mathsf{V}}_T \text{ and } \sharp\mathsf{V} \leq 1\}$$

If, instead, $[\![E]\!] = 1$, then we can choose

$$\text{either } \lambda^E_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \forall^1_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \{\mathsf{V} \in P\mathsf{Val} \mid \mathsf{V} \subseteq \mathsf{WT}^{\mathsf{V}}_T\}$$
$$\text{or } \lambda^E_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \exists^1_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \{\mathsf{V} \in P\mathsf{Val} \mid \mathsf{V} = \emptyset \text{ or } \mathsf{V} \cap \mathsf{WT}^{\mathsf{V}}_T \neq \emptyset\}$$

In this way, monadic values (sets of values, representing possibile results of a computation) are well-typed with a type effect (reducing to) 0 if they have at most one element, and this element, if any, is well-typed; in other words, the computation is deterministic. On the other hand, they are well-typed with a type effect (reducing to) 1 if all the values in the set are well-typed, or there is at least one well-typed value, respectively.

3. A finer interpretation for Example 19 is to reduce effect types to the ordered monoid $\langle \mathbb{N} \cup \{\infty\}, \leq, \cdot, 1\rangle$ of Example 27(2), thus controlling the level of non-determinism:

$$[\![\mathtt{choose}^n]\!] = 2^n \text{ for } n \in \mathbb{N}, [\![\mathtt{choose}^\omega]\!] = \infty$$
$$[\![E]\!] = \sup\{[\![\alpha]\!] \mid \alpha \in E\}$$

Indeed, each call can be seen as a node in a binary tree of choices. In this way, if $[\![E]\!] = k \in \mathbb{N} \cup \{\infty\}$, then monadic values (sets of values, representing possibile results of a computation) are well-typed with E if there are at most 2^k values, hence possible results, in the set and these are all well typed.

4. In Example 21, a possible interpretation of a sequence of $\mathtt{write}\langle\ell\rangle$ is its length:

$$[\![\mathtt{write}\langle\ell\rangle^{\mathtt{n}}]\!] = \mathtt{n} \text{ for } \mathtt{n} \in \mathbb{N} \cup \{\infty\}$$
$$[\![E]\!] = \sup\{[\![\alpha]\!] \mid \alpha \in E\}$$

That is, effect types are mapped into $\mathbb{N} \cup \{\infty\}$ as done in Example 28, so that, if $[\![E]\!] = n$, then $\lambda^E_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \lambda^n_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \{\langle\sigma, v\rangle \in O\mathsf{Val} \mid v \in \mathsf{WT}^{\mathsf{V}}_T \text{ and } \mid \sigma \mid \leq n\}$. In this way, an upper bound (or none) is imposed on the length of the produced outputs.

5. A finer interpretation for Example 21 is obtained by taking effect types as they are, and $\lambda^E_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_T) = \{\langle\sigma, v\rangle \in O\mathsf{Val} \mid v \in \mathsf{WT}^{\mathsf{V}}_T, \mathsf{extract}(\sigma) \in E\}$ where, if $\sigma = \langle\ell_1, n_1\rangle \ldots \langle\ell_k, n_k\rangle$, then $\mathsf{extract}(\sigma) = \mathtt{write}\langle\ell_1\rangle \ldots \mathtt{write}\langle\ell_{\mathtt{k}}\rangle$.In this way, effect types can express properties about the order, or the fairness, in which write operations to different output locations can be performed. Similar sophisticated properties can be expressed in cases where different operations can be performed, e.g., reading and updating in the global state monad.

We state now monadic progress and monadic subject reduction for the type-and-effect system in Section 4; as shown in Section 5, they imply monadic soundness. We report only the proof of monadic subject reduction; other proofs and lemmas they depend on are given in [9].

▶ **Theorem 42** (Monadic Progress). *If $e \in \mathsf{WT}^{\mathsf{E}}_{T,E}$ then either $e = \mathtt{return}\ v$ or $e \to_E$.*

The proof of monadic subject reduction uses the standard substitution lemma, and subject reduction for the pure relation $\to_p$ defined in Figure 3. Both properties do not involve any monadic ingredient, and are proved by standard techniques.

▶ **Lemma 43** (Substitution). *If $\Gamma, \overline{x} : \overline{T} \vdash e : T!E$ and $\overline{T'} \leq \overline{T}$, then $\vdash \overline{v} : \overline{T'}$ implies $\Gamma \vdash e[\overline{v}/\overline{x}] : T'!E'$ with $T'!E' \leq T!E$.*

▶ **Lemma 44** (Subject Reduction). *If $\vdash e : T!E$ and $e \to_p e'$ then $\vdash e' : T'!E'$ with $T'!E' \leq T!E$.*

▶ **Theorem 45** (Monadic Subject Reduction). *If* $e \in \mathsf{WT}^{\mathsf{E}}_{T,E}$ *and* $e \to \mathrm{E}$ *then* $\mathrm{E} \in \lambda^{E_1}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T,E_2})$ *for some* E_1 *and* E_2 *such that* $E_1 \cdot E_2 \subseteq E$.

Proof. From $e \in \mathsf{WT}^{\mathsf{E}}_{T,E}$ we get $\vdash e : T'!E'$ and $T'!E' \leq T!E$. By induction on the reduction rules of Figure 4.

(pure) In this case $e \to_p e'$ and $\mathrm{E} = \eta(e')$. From $\vdash e : T'!E'$ and Lemma 44 we get $\vdash e' : T_1!E_1$ and $T_1!E_1 \leq T'!E'$ and, by transitivity of $\leq$, $e' \in \mathsf{WT}^{\mathsf{E}}_{T,E}$. From Definition 24(3) we derive $\eta(e') \in \lambda^{\{\epsilon\}}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T,E})$ with $\{\epsilon\} \cdot E \subseteq E$.

(effect) In this case $e = op(\overline{v})$ and $\mathrm{E} = \mathsf{map}\,(\mathtt{return}\ [\ ])\,\mathrm{V}$, with $\mathrm{V} = \mathsf{run}_{op}(\overline{v})$. From rule (T-OP), $op\colon T_1 \dots T_n \to T'$ and $\vdash \overline{v} : \overline{T}'$ and $\overline{T}' \leq \overline{T}$ and $E' = \{op\}$. Hence, by rule (RUN), $\mathrm{V} \in \lambda^{\{op\}}_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_{T'})$. Let $f\colon \mathsf{Val} \to \mathsf{Exp}$ be defined by $f(v) = \mathtt{return}\ v$, then $\mathrm{E} = \mathsf{map}\,(\mathtt{return}\ [\ ])\,\mathrm{V} = Mf(\mathrm{V})$. From Definition 24(1) and $\mathsf{WT}^{\mathsf{V}}_{T'} = \mathcal{P}_f(\mathsf{WT}^{\mathsf{E}}_{T',\{\epsilon\}})$

$$\mathrm{V} \in \lambda^{\{op\}}_{\mathsf{Val}}(\mathsf{WT}^{\mathsf{V}}_{T'}) = \lambda^{\{op\}}_{\mathsf{Val}}(\mathcal{P}_f(\mathsf{WT}^{\mathsf{E}}_{T',\{\epsilon\}}) = \mathcal{P}_{Mf}(\lambda^{\{op\}}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T',\{\epsilon\}}))$$

This implies $\mathrm{E} = Mf(v) \in \lambda^{\{op\}}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T',\{\epsilon\}})$. Since $T' \leq T$, $\mathsf{WT}^{\mathsf{E}}_{T',\{\epsilon\}} \subseteq \mathsf{WT}^{\mathsf{E}}_{T,\{\epsilon\}}$, hence by monotonicity of $\lambda^{\{op\}}_{\mathsf{Exp}}$, we get $\mathrm{E} \in \lambda^{\{op\}}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T,\{\epsilon\}})$, with $\{op\}\cdot\{\epsilon\} = \{op\} \subseteq E$.

(ret) In this case $e = \mathtt{do}\ x = \mathtt{return}\ v\mathtt{;}\ e'$ and $\mathrm{E} = \eta(e'[v/x])$. From rules (T-DO) and (T-RET), $\vdash v : T_1$ and $x : T_1' \vdash e' : T'!E'$, with $T_1 \leq T_1'$. By Lemma 43, we get $\vdash e'[v/x] : T''!E''$ with $T''!E'' \leq T'!E'$. Hence, $T''!E'' \leq T!E$ and so $e'[v/x] \in \mathsf{WT}^{\mathsf{E}}_{T,E}$. Finally, from Definition 24(3), $\eta(e'[v/x]) \in \lambda^{\{\epsilon\}}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T,E})$ with $\{\epsilon\}\cdot E = E$.

(do) In this case $e = \mathtt{do}\ x = e_1\mathtt{;}\ e_2$ and $\mathrm{E} = \mathsf{map}\,(\mathtt{do}\ x = [\ ]\mathtt{;}\ e_2)\,\mathrm{E}_1$ and $e_1 \to \mathrm{E}_1$. From rule (T-DO), $\vdash e_1 : T_1!E_1$ and $x : T_1' \vdash e_2 : T'!E_2$ with $E' = E_1 \cdot E_2$ and $T_1 \leq T_1'$. Hence, from $e_1 \in \mathsf{WT}^{\mathsf{E}}_{T_1,E_1}$, by induction hypothesis we get that $\mathrm{E}_1 \in \lambda^{E_1'}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T_1,E_2'})$ with $E_1' \cdot E_2' \subseteq E_1$. Let $f\colon \mathsf{Exp} \to \mathsf{Exp}$ be defined by $f(\hat{e}) = \mathtt{do}\ x = \hat{e}\mathtt{;}\ e_2$, hence $\mathrm{E} = Mf(\mathrm{E}_1)$. By rule (T-DO), we know that $\hat{e} \in \mathsf{WT}^{\mathsf{E}}_{T_1,\hat{E}}$ implies $f(\hat{e}) \in \mathsf{WT}^{\mathsf{E}}_{T',\hat{E}\cdot E_2} \subseteq \mathsf{WT}^{\mathsf{E}}_{T,\hat{E}\cdot E_2}$, that is, $\mathsf{WT}^{\mathsf{E}}_{T_1,\hat{E}} \subseteq \mathcal{P}_f(\mathsf{WT}^{\mathsf{E}}_{T,\hat{E}\cdot E_2})$. From Definition 24(1) and monotonicity of $\lambda^{E_1'}_{\mathsf{Exp}}$ we get

$$\mathrm{E}_1 \in \lambda^{E_1'}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T_1,E_2'}) \subseteq \lambda^{E_1'}_{\mathsf{Exp}}(\mathcal{P}_f(\mathsf{WT}^{\mathsf{E}}_{T,E_2'\cdot E_2})) = \mathcal{P}_{Mf}(\lambda^{E_1'}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T,E_2'\cdot E_2}))$$

that is, $\mathrm{E} = Mf(\mathrm{E}_1) \in \lambda^{E_1'}_{\mathsf{Exp}}(\mathsf{WT}^{\mathsf{E}}_{T,E_2'\cdot E_2})$, and we get the thesis since $E_1'\cdot E_2'\cdot E_2 \subseteq E_1 \cdot E_2 \subseteq E'$. ◀

The results hold for the core calculus in Figure 2, for an arbitrary family Σ of operations. The calculus, the type system and the proofs can be modularly extended by just considering cases for additional constructs, as we will do in Section 7 for handlers. Extending the subtyping relation, instead, requires some care to preserve the needed properties.[11]

7 Handlers

We extend Λ_Σ with *handlers*, showing how our framework can deal with more sophisticated language features and, at the same time, how proofs can be modularly extended. In particular, it is important to illustrate that monadic semantics can incorporate handlers. Constructs and terminology are inspired by those for algebraic effects, see, e.g., [40]; however, the approach is different since our calculus, being based on generic effects, has no explicit continuations.

[11] For instance, adding $\mathtt{Bot} \leq T$ for all T as in Example 18 is sound since $\mathtt{Bot}$ is an empty type.

$$
\begin{array}{lcll}
e & ::= & \ldots \mid \texttt{handle}\ e\ \texttt{with}\ h & \text{expression with handler} \\
h & ::= & \overline{c}, x \mapsto e & \text{handler} \\
c & ::= & op(\overline{x}) \mapsto_{\mu} e & \text{clause} \\
\mu & ::= & \texttt{c} \mid \texttt{s} & \text{mode}
\end{array}
$$

Figure 7 Syntax of handlers.

The syntax is reported in Figure 7. A handler specifies a *final expression*, and a sequence of *clauses*, assumed to be a map, that is, there can be at most one clause for an operation. Such a clause, if any, handles a call of the operation by executing the clause expression. After that, the final expression is either executed or not depending on the *mode*, either `c` or `s`, for "continue" and "stop", respectively. As illustrated in the following examples, a `c`-clause replaces an effect with an alternative behaviour in a continuous manner, whereas in `s`-clauses handling the computational effect interrupts the normal flow of execution.

$$h = \overline{c}, x \mapsto e'$$

$$\text{(WITH-DO)}\ \frac{}{\texttt{handle do}\ y = e_1\texttt{;}\ e_2\ \texttt{with}\ h \to_p \texttt{handle}\ e_1\ \texttt{with}\ \overline{c}, y \mapsto (\texttt{handle}\ e_2\ \texttt{with}\ h)}$$

$$\text{(WITH-RET)}\ \frac{}{\texttt{handle return}\ v\ \texttt{with}\ h \to_p \texttt{do}\ x = \texttt{return}\ v\texttt{;}\ e'}$$

$$\text{(WITH-CONTINUE)}\ \frac{}{\texttt{handle}\ op(\overline{v})\ \texttt{with}\ h \to_p \texttt{do}\ x = e[\overline{v}/\overline{x}]\texttt{;}\ e'}\ op(\overline{x}) \mapsto_{\texttt{c}} e \in \overline{c}$$

$$\text{(WITH-STOP)}\ \frac{}{\texttt{handle}\ op(\overline{v})\ \texttt{with}\ h \to_p e[\overline{v}/\overline{x}]}\ op(\overline{x}) \mapsto_{\texttt{s}} e \in \overline{c}$$

$$\text{(WITH-FWD)}\ \frac{}{\texttt{handle}\ op(\overline{v})\ \texttt{with}\ h \to_p \texttt{do}\ x = op(\overline{v})\texttt{;}\ e'}\ op \notin \overline{c}$$

$$\text{(WITH-CTX)}\ \frac{e \to_p e'}{\texttt{handle}\ e\ \texttt{with}\ h \to_p \texttt{handle}\ e'\ \texttt{with}\ h}$$

Figure 8 Pure reduction with handlers.

The pure reduction extended with handlers is shown in Figure 8. The behaviour of an expression with handler depends on the shape of the handled expression.

In case of a `do` composition of two subexpressions, the `do` is eliminated by reducing to the first subexpression with as final expression the second one; clauses are propagated to both the subexpressions. In case of a `return`, the handler is eliminated by reducing to the `do` composition of the handled expression and the final expression.

In case of an operation call, the behaviour depends on whether a matching clause is found or not. If it is found, then the clause expression is executed, after replacing parameters by arguments, as shown in rules (WITH-CONTINUE) and (WITH-STOP). In a `c`-clause, the final expression is executed as well. If there is no matching clause, instead, the handler is eliminated, by reducing to the `do` composition of the operation call and the final expression. The outcome is that the operation call is forwarded to be possibly handled by an outer level. gFinally, the contextual rule is as expected.

To extend the type-and-effect system, we rely on *filter functions* associated to handlers, which describe how they transform effects, by essentially replacing operations matching some clause with the effect of the clause expression.

To this end, first we define a *(handler) filter* H to be the information about transforming effects which can be extracted from a handler, as shown in the top section of Figure 9. Then, given a filter H, we define the associated function $\widehat{\mathcal{F}}_H\colon \mathsf{Eff} \to \mathsf{Eff}$. This function, as shown in the bottom section of Figure 9, is obtained on top of the function $\mathcal{F}_H\colon \Sigma^\infty \to \mathsf{Eff}^\infty$ which transforms a single possibly infinite sequence of operations into a possibly infinite sequence of effects. The latter is transformed into a unique effect by taking the possibly infinite concatenation of its elements, denoted $\bullet^\infty\colon \mathsf{Eff}^\infty \to \mathsf{Eff}$. Finally, the function is extended to effects (sets of sequences) in the obvious way.

$$\begin{array}{lcll} H & ::= & \overline{C}, E & \text{filter} \\ C & ::= & op \mapsto_\mu E & \text{clause filter} \end{array}$$

$H = op_1 \mapsto_{\mu_1} E_1 \dots op_n \mapsto_{\mu_n} E_n, E$

$\mathcal{F}_H\colon \Sigma^\infty \to \mathsf{Eff}^\infty$ coinductively defined by:

$\mathcal{F}_H(\epsilon) = E$

$\mathcal{F}_H(op_i{:}\alpha) = E_i{:}\mathcal{F}_H(\alpha) \qquad i \in 1..n, \mu_i = \mathsf{c}$

$\mathcal{F}_H(op_i{:}\alpha) = E_i \qquad i \in 1..n, \mu_i = \mathsf{s}$

$\mathcal{F}_H(op{:}\alpha) = \{op\}{:}\mathcal{F}_H(\alpha) \qquad op \neq op_i \text{ for all } i \in 1..n$

$\widehat{\mathcal{F}}_H\colon \mathsf{Eff} \to \mathsf{Eff}$

$\widehat{\mathcal{F}}_H(E) = \bigcup_{\alpha \in E} \{\bullet^\infty \mathcal{F}_H(\alpha)\}$

Figure 9 Filters.

$$\text{(T-WITH)}\ \frac{\Gamma \vdash e : T!E \quad \Gamma;\, T' \vdash h : T''!H}{\Gamma \vdash \texttt{handle}\ e\ \texttt{with}\ h : T''!\mathcal{F}_H(E)}\ T \leq T'$$

$$\text{(T-HANDLER)}\ \frac{\Gamma, x : T \vdash e' : T'!E' \quad \Gamma;\, T'' \vdash c_i : C_i}{\Gamma;\, T \vdash c_1 \dots c_n, x \mapsto e' : T''!C_1 \dots C_n, E'}\ T' \leq T''$$

$$\text{(T-CONTINUE)}\ \frac{\Gamma, \overline{x}{:}\overline{T} \vdash e : T''!E'}{\Gamma;\, T' \vdash op(\overline{x}) \mapsto_{\mathsf{c}} e : op \mapsto_{\mathsf{c}} E'}\ \begin{array}{l} op{:}\,\overline{T} \to T \\ T'' \leq T \end{array}$$

$$\text{(T-STOP)}\ \frac{\Gamma, \overline{x}{:}\overline{T} \vdash e : T''!E'}{\Gamma;\, T' \vdash op(\overline{x}) \mapsto_{\mathsf{s}} e : op \mapsto_{\mathsf{s}} E'}\ \begin{array}{l} op{:}\,\overline{T} \to T \\ T'' \leq T' \end{array}$$

Figure 10 Typing rules for handlers.

In Figure 10 we show the typing rules for expressions with handlers. In rule (T-WITH), in order to typecheck an expression with handler, first we get the type and effect of the handled expression. The type is used to typecheck the handler, as (subtype of the) type of the parameter of the final expression, see rule (T-HANDLER). Typechecking the handler we get a type, being that of the final expression, which will be the type of the whole expression. Moreover, we extract from the handler a filter, which is used to transform the effect E of the handled expression, getting the resulting effect of the whole expression. In detail, as formally described in Figure 9, the filter transforms any sequence of operations in E by replacing the first operation matching some clause, if any, with the effect of the clause expression; then, the remaining sequence is disregarded if the clause is s, otherwise filtered in turn. If the sequence to be filtered is finite, and no matching s-clause is found, then the final effect is appended in the end.

In rule (T-HANDLER), as said above, the type on the left of the judgment is used as type of the parameter of the final expression, whose type will be returned by the handler. This type is also needed to typecheck s-clauses, see below. The filter extracted from the handler consists in a clause filter for each clause, and the effect of the final expression.

For each clause, the extracted filter consists of the operation name, mode, and effect of the expression, as shown in rules (T-CONTINUE) and (T-STOP). A c-clause is meant to provide alternative code to be executed before the final expression, hence the type of the clause expression should be (a subtype of) the return type of the operation. In a s-clause, instead, the result of the clause expression becomes that of the whole expression with handler, hence the type of the former should be (a subtype of) the latter.

▶ **Example 46.** We show handlers for some of the previous examples. A handler of shape $\overline{c}, x \mapsto \texttt{return}\ x$ is abbreviated by $\overline{c}$.

1. Set $h = \texttt{raise}\langle\mathsf{PredZero}\rangle() \mapsto_{\mathsf{s}} \texttt{return}\ 0$. Then

$$\begin{array}{lcl} \texttt{handle}\ \mathsf{predfun}\,0\ \texttt{with}\ h & \Rightarrow^{\star} & \texttt{handle}\ \texttt{raise}\langle\mathsf{PredZero}\rangle\ \texttt{with}\ h \\ & \Rightarrow & \texttt{return}\ 0 \\ & \Rightarrow & 0 \end{array}$$

   As shown in Example 22(1), we get the judgment $\emptyset \vdash \mathsf{predfun}\,0 : \texttt{Nat}!\{\epsilon, \texttt{raise}\langle\mathsf{PredZero}\rangle\}$. On the other hand, with the handler we get

$$\emptyset \vdash \texttt{handle}\ \mathsf{predfun}\,0\ \texttt{with}\ h : \texttt{Nat}!\{\epsilon\}$$

   since $\widehat{\mathcal{F}}_H(\{\epsilon, \texttt{raise}\langle\mathsf{PredZero}\rangle\}) = \{\epsilon\}$ where $H = \texttt{raise}\langle\mathsf{PredZero}\rangle \mapsto_{\mathsf{s}} \{\epsilon\}, \{\epsilon\}$ is the filter extracted from h. As the reader could expect, an s-clause is appropriate in this case. With a c-clause, see rule (T-CONTINUE), the type of the clause expression should be (a subtype of) the return type of the operation, which is `Bot`. Since no value has type `Bot`, no value could be returned, as already noted in [35].[12]

2. Assuming the function even: `Nat` $\to$ `Bool` checking the parity of a number, set

$$h_1 = \texttt{write}\langle\ell'\rangle(x) \mapsto_{\mathsf{c}} \texttt{write}\langle\ell\rangle(x)$$
$$h_2 = \texttt{write}\langle\ell'\rangle(x) \mapsto_{\mathsf{c}} \texttt{if}\ \mathsf{even}(x)\ \texttt{then return}\ x\ \texttt{else write}\langle\ell\rangle(x)$$

   Then

$$[\![\texttt{handle}\ \mathsf{wfun}^{\uparrow}\,0\ \texttt{with}\ h_1]\!]_{\infty} = \langle\langle\ell,0\rangle\cdot\langle\ell,0\rangle\cdot\langle\ell,1\rangle\cdot\langle\ell,1\rangle\cdot\ldots\cdot\langle\ell,n\rangle\cdot\langle\ell,n\rangle\cdot\ldots,\bot\rangle$$
$$[\![\texttt{handle}\ \mathsf{wfun}^{\uparrow}\,0\ \texttt{with}\ h_2]\!]_{\infty} = \langle\langle\ell,0\rangle\cdot\langle\ell,1\rangle\cdot\langle\ell,1\rangle\cdot\ldots\langle\ell,2k\rangle\cdot\langle\ell,2k{+}1\rangle\cdot\langle\ell,2k{+}1\rangle\cdot\ldots,\bot\rangle$$
$$[\![\texttt{handle}\ \mathsf{wfun}^{\downarrow}\,n\ \texttt{with}\ h_1]\!]_{\star} = \langle\langle\ell,n\rangle\cdot\langle\ell,n\rangle\cdot\ldots\cdot\langle\ell,0\rangle\cdot\langle\ell,0\rangle,\texttt{unit}\rangle$$
$$[\![\texttt{handle}\ \mathsf{wfun}^{\downarrow}\,2k\ \texttt{with}\ h_2]\!]_{\star} = \langle\langle\ell,2k\rangle\cdot\langle\ell,2k{-}1\rangle\cdot\langle\ell,2k{-}1\rangle\ldots\cdot\langle\ell,1\rangle\cdot\langle\ell,1\rangle\cdot\langle\ell,0\rangle,\texttt{unit}\rangle$$

   In this case, a c-clause is appropriate, since the aim is to continuously handle the $\texttt{write}\langle\ell'\rangle$ operation. By the typing judgments shown in Example 22(3), we get

$$\emptyset \vdash \mathsf{wfun}^{\uparrow}\,0 : \texttt{Unit}!\{(\texttt{write}\langle\ell\rangle\cdot\texttt{write}\langle\ell'\rangle)^{\omega}\}$$
$$\emptyset \vdash \mathsf{wfun}^{\downarrow} : \texttt{Unit}!\{(\texttt{write}\langle\ell\rangle\cdot\texttt{write}\langle\ell'\rangle)^{\mathtt{n}} \mid \mathtt{n} \geq 1\}$$

[12] Hence, the clause expression could only be another raise or a diverging expression.

On the other hand, with the handler we get, with $\alpha ::= \epsilon \mid \texttt{write}\langle\ell\rangle$

$$\emptyset \vdash \texttt{handle wfun}^{\uparrow}\, 0 \texttt{ with } h_1 : \texttt{Unit!}\{(\texttt{write}\langle\ell\rangle \cdot \texttt{write}\langle\ell\rangle)^{\omega}\}$$
$$\emptyset \vdash \texttt{handle wfun}^{\uparrow}\, 0 \texttt{ with } h_2 : \texttt{Unit!}\{\alpha \cdot \texttt{write}\langle\ell\rangle)^{\omega}\}$$
$$\emptyset \vdash \texttt{wfun}^{\downarrow}\, n : \texttt{Unit!}\{\alpha \cdot \texttt{write}\langle\ell'\rangle)^{\texttt{n}} \mid \texttt{n} \geq \texttt{1}\}$$

As already noted, effect types only provide a static approximation of the computational effects; notably, in the last two judgments, the effect type contains other sequences besides the two which can be actually performed, depending on the argument.

Soundness for handlers. The results of Section 6 can be extended to handlers. For monadic subject reduction we only need to show subject reduction for the newly introduced rules, since they are pure. The proofs of the results are in the extended version [9].

▶ **Lemma 47** (Monadic Progress for handlers). *Set e of shape* `handle _ with _`.
If $\vdash e : T!E$ then $e \to \mathrm{E}$ for some $\mathrm{E} \in M\mathsf{Exp}$.

▶ **Lemma 48** (Subject Reduction for handlers). *Set e of shape* `handle _ with _`.
If $\vdash e : T!E$ and $e \to_p e'$, then $\vdash e' : T'!E'$ such that $T'!E' \leq T!E$.

8 Related work and conclusion

Monadic semantics. The idea that monads can model computational effects in programming languages goes back to the pioneering Moggi's work [30, 31]. He showed that one can use (strong) monads to organise the denotational semantics of effectful languages, interpreting impure expressions as functions (actually arrows of an arbitrary category) returning monadic values, which can be sequenced by Kleisli composition. However, the structure of a monad does not include any operation for actually raising computational effects, which thus need to be defined ad-hoc in specific instances. Moreover, monads are difficult to combine, requiring non trivial notions like monad transformers [27, 22].

To overcome these difficulties and make the model closer to the syntax, Plotkin and Power [33, 34, 35] introduced algebraic effects which, instead, explicitly consider operations to raise computational effects. These can be interpreted by additional structure on the monad and, moreover, when equipped with an equational theory, they actually determine a monad, which provides a syntactic model for the language. Thus, one reduces the problem of combining monads to the much easier problem of combining theories [20], greatly increasing modularity.

An alternative, essentially equivalent, way of interpreting algebraic operations is by means of runners, a.k.a. comodels [39, 36, 44, 2]. Roughly, runners describe how operations are executed by the system, that is, how they transform the environment where they are run. This essentially amounts to giving an interpretation of operations in the state monad. More general runners, where the system is modelled in a more expressive way, are considered by [2], where the state monad is combined with errors and system primitive operations.

On the operational side, algebraic effects are typically treated as uninterpreted operations, that is, the evaluation process just builds a tree of operation calls [23, 42, 48, 40]. Monadic operational semantics for λ-calculi with algebraic effects are also considered, mainly in the form of a monadic definitional interpreter (see, e.g., [27, 12, 15, 11, 8]). That is, they directly define a function from expressions to monadic values, which essentially corresponds to our infinitary semantics. Small-step approaches are also considered by [16, 17]. The former tackles a different problem, that is, studying monadic rewriting systems, which require the

use of sophisticated relational techniques, and thus restricts the class of available monads. We can avoid these difficulties since we focus on deterministic rewriting, which can be addressed using just sets and functions. The latter, instead, studies a specific calculus where, as already noticed, the way sequences of steps are constructed is very close to ours; however, they do not need to introduce wrong in configurations, as type errors are prevented syntactically.

Type-and-effect systems. Type-and-effect systems, or simply effect systems [45, 32, 46, 29, 25], are the most popular way of statically controlling computational effects. Many have been designed for specific notions of computational effect and implemented in mainstream programming languages, the most well-known being the mechanism of Java checked exceptions. Katsumata [25] recognized that effect systems share a common algebraic structure, notably they form an ordered monoid, and gave them denotational semantics through parametric monads, using a structure equivalent to our notion of interpretation (see Remark 25).

Effect handlers. Plotkin and Pretnar [37, 38] introduced effect handlers as a generalisation of exception handling mechanisms. They are an extremely powerful programming abstraction, allowing to describe the semantics of algebraic operations in the language itself, thus enabling the simulation of several effectful programs, such as stream redirection or cooperative concurrency [38, 24, 4, 40]. When a call to an algebraic operation is caught, the alternative code can resume the original computation using a form of continuation-passing style. Other forms of handlers have been considered, notably, shallow handlers [24, 19], where only the first call to an operation is handled. Our handlers are inspired by those for algebraic effects, see, e.g., [40]; however, the approach is different since our calculus has no explicit continuations.

Summary. In the research on foundations of programming languages, it is a routine task to describe execution through a small-step reduction, and prove progress and subject reduction for the type system. Can this be smoothly combined with the long-established approach where computational effects are modularly modeled by a monad, so to enjoy all the advantages of separation of concerns? The answer provided in this paper is yes. Notably, we provide a meta-theory defining abstract notions of monadic small-step semantics and type-and-effect system, and prove that type-and-effect soundness is implied by progress and subject reduction properties, with an inductive argument similar to the standard one.

This overall achievement relies on two key specific contributions. On one hand, we provide a canonical way to construct, on top of a monadic reduction, a small-step operational semantics where computations, even though always represented by infinite sequences, can be distinguished as either non-terminating, or successfully terminating, or stuck. On the other hand, we provide a formal model of the "meaning" of effect types, independent in principle from the underlying language and type system.

Discussion and future work. The way we define the "transitive closure" of a monadic reduction, which is a relation from a set to a different one, is similar, as said, to that proposed by [17]. Notably, such reduction is assumed to be deterministic, since starting from an arbitrary relation would require a relational extension of the monad [3]. Confluence as well would require strong assumptions on the monad, notably some form of commutativity, ruling out most of the relevant examples. Moreover, the aim here is to prove soundness for programming languages, which typically adopt a deterministic evaluation strategy. Differently from [17], we provide a language independent definition; moreover, whereas they consider an intrinsically total reduction, in this paper, as mentioned above, we address the additional problem to characterize stuck computations, as needed to express soundness.

In our framework, non-termination is always possibile, rather than be considered as an effect. This is essentially a choice we made, possibly influenced by the fact that in standard soundness we have three possible outcomes: non-termination, termination with a value, and stuck. The coinductive Delay monad [5] could be an alternative approach to define the infinitary semantics, assuming a way to be combined with the monad modeling computational effects, that is, a distributive law. The relationship between these two approaches, as far as we know, is not clear, and is an interesting direction to be investigated.

Our definition of ω-CPO-ordered monad is given for monads on $\mathcal{S}et$. A challenging and relevant problem is to consider a category different from $\mathcal{S}et$; our feeling is that the notion could be generalized by considering a monad $\mathbb{M}$ on a category $\mathcal{C}$ such that the Kleisli category $\mathcal{C}^{\mathbb{M}}$ is CPO-enriched.

In this paper, where the focus is different, we did not study decidability of the type-and-effect system; we did not even provide a syntactic representation of effects, which are considered semantic entities, notably possibly infinite sets of possibly infinite sequences. Of course decidability is a very important issue to be investigated; the first step should then be to choose a finite representation, e.g., by means of a system of guarded equations.

We illustrated our approach by a lambda-calculus with generic effects. Clearly, it would be important to investigate how other calculi can be formalized as to take advantage of the meta-theory. Notably, we plan to apply the approach to an object-oriented calculus.

Finally, here we considered non-standard handlers, as our calculus is based on generic effects and so it does not use explicit continuations. Hence, it would be nice to investigate the precise relationship between them and handlers for algebraic effects used in the literature.

An Effectful Object Calculus

Abstract

We show how to smoothly incorporate in the object-oriented paradigm constructs to raise, compose, and handle effects in an arbitrary monad. The underlying pure calculus is meant to be a representative of the last generation of OO languages, and the effectful extension is manageable enough for ordinary programmers; notably, constructs to raise effects are just special methods. We equip the calculus with an expressive type-and-effect system, which, again by relying on standard features such as inheritance and generic types, allows a simple form of effect polymorphism. The soundness of the type-and-effect system is expressed and proved by a recently introduced technique, where the semantics is formalized by a one-step reduction relation from language expressions into monadic ones, so that it is enough to prove progress and subject reduction properties on this relation.

1 Introduction

Every modern programming language needs to support a wide range of computational effects, such as exceptions, input/output, interaction with a memory and classical or probabilistic non-determinism. Several approaches have been proposed for designing language constructs dealing with different computational effects in a uniform and principled way. The monad pattern [31, 32, 46] and algebraic effects and handlers [34, 35, 36, 38, 39, 6, 41] stand out for their impact on real world programming, and are now incorporated into many mainstream languages such as Haskell, OCaml 5 and Scala. However, this area of research focuses on the functional paradigm. The aim of this paper, instead, is to show that constructs to raise, compose, and handle effects can be smoothly incorporated into object-oriented languages; in fact, the specific features of the paradigm help in allowing a simple effectful extension.

To illustrate the effectful extension, we choose a pure object calculus designed for the purpose, rather than Featherweight Java (FJ)[1] [21], for more than twenty years the paradigmatic calculus for Java-like languages. As FJ, our calculus only includes distinctive ingredients, such as nominal types, inheritance, and objects, and no imperative features. However, following the current trend in OO languages, and inspired by recent work [49, 43, 50], object values are, rather than class instances with fields, *object literals*, extending a sequence

[1] In its version with generic types.

of nominal types with additional methods. In other words, we select, as subset of Java features, interfaces with default methods and anonymous classes, rather than classes with fields and constructors. This choice leads to generality, in the sense that the language design encompasses both Java-like and functional calculi. More precisely, FJ can be easily encoded by representing fields as constant methods, and, at the same time, as in seminal object calculi [1], the simply-typed lambda calculus can be seen as a language subset, since functions are a special case of stateless objects.

The effectful extension builds on generic effects [36] and handlers [38], carefully adapted to be more familiar to OO programmers. Constructs for raising effects are just method calls of a special kind, called *magic*.[2] They are made available through predefined interfaces, and do not specify an implementation, like abstract ones. However, rather than being deferred to subtypes, their implementation is provided "by the system". For instance, throwing an exception is a magic call `Exception.throw()`. This fits naturally in the OO paradigm, where computations happen in the context of a program. Again to be familiar, the construct to handle effects is a generalized try-block with catch clauses. A raised effect (a magic call) is caught by a clause when the receiver's type is (a subtype of) that specified in the clause, as for Java exceptions, generalized to arbitrary magic calls. To this end, besides those interrupting the normal flow of execution, we allow catch clauses replacing an effect with an alternative behaviour in a continuous manner. Altogether, the construct provides a good compromise between simplicity and expressivity: notably, it does not explicitly handle continuations, as in handlers of algebraic effects [38, 39, 24, 19], yet expressing a variety of handling mechanisms.

We endow our calculus with a type-and-effect system where effect types[3] again generalize sets of exceptions, as in `throws` clauses, to sets of *call-effects*, of shape $T.\mathsf{m}[\overline{T}]$, approximating the computational effects of a call of m in type T, with types $\overline{T}$ instantiating the type variables of the method. This approach, inspired by [15], provides more expressivity than the effect systems for algebraic effects [5, 6, 41], which only track the *names* of operations raising effects, without any type information. Moreover, T can be a type variable X, expressing a call-effect not yet specified, which will become, when X is instantiated to a specific type, the effect type declared there for the method. This allows a rather sophisticated approximation of effects, encompassing a simple form of *effect polymorphism* [26, 20, 29, 7, 9, 8].

Last but not least, the soundness of the type-and-effect system is expressed and proved by a newly introduced approach [12], building on a recent line of research on *monadic operational semantics* for effectful languages [17, 18]. That is, the semantics is formalized by a one-step reduction from language expressions into monadic ones, parameterized by a monad modeling the capabilities provided by the system. In this way, we can uniformly deal with a wide range of effects, by just providing an interpretation of magic methods in the monad. Then, applying a technique from [12], to ensure type-and-effect soundness it is enough to prove progress and subject reduction on the monadic one-step reduction. Accordingly with its shape, subject reduction roughly means that reducing an expression to a monadic one preserves its type-and-effect; hence, to express and prove this property, we need *monadic typing judgments*, which can be derived by *lifting* the non-monadic ones.

We describe the language in Section 2, and its semantics in Section 3. The type-and-effect system is illustrated in Section 4, and its soundness is shown in Section 5. Section 6 discusses related work and Section 7 summarizes our contribution and outlines future work. Auxiliary definitions and omitted proofs can be found in the extended version [11].

---

[2] This terminology is taken from [50], and also informally used in Java reflection and Python.

[3] The term "effect" is used in literature both as synonym of computational effect, and in the context of type-and-effect systems, as a static approximation of the former. We will use "effect" when there is no ambiguity, otherwise "computational effect" and "effect type", respectively.

2 Language

To have a smoother presentation, we first provide the syntax, discuss the key features, and show some examples, for the effect-free subset of the language; then we illustrate the constructs to raise, compose, and handle computational effects.

Effect-free language. As anticipated, in our calculus objects are not created by invoking constructors, but directly obtained by extending a sequence of nominal types with additional methods. In this way, the notions of class (more in general, nominal type) and object almost coincide. The only difference is that nominal types are top-level entities in a program, possibly generic (declaring type variables), and abstract (including non-implemented methods). On the other hand, objects can be seen as anonymous types declared on-the-fly in the code.

Syntax and types are given in Figure 1. We assume *type names* N, *method names* m, *type variables* X, Y, and *variables* x, y. The metavariable $\overline{td}$ stands for a sequence $td_1 \dots td_n$, and analogously for other overlined metavariables. An empty sequence will be denoted by ϵ.

P	::=	$\overline{td}$	program
td	::=	$\mathsf{N}[\overline{Y} \lhd \overline{T}] \lhd \overline{N}\{\overline{md}\}$	(nominal) type declaration
md	::=	$\mathsf{m} : \mathsf{abs}\, MT \mid \mathsf{m} : \mathsf{def}\, MT\, \langle x\, \overline{x}, e\rangle$	method declaration
e	::=	$x \mid \overline{N}\{\overline{md}\} \mid e.\mathsf{m}[\overline{T}](\overline{e})$	expression: variable, object, method call
T, U	::=	$X \mid \overline{N}\{s\}$	type
N	::=	$\mathsf{N}[\overline{T}]$	nominal type
s	::=	$\overline{\mathsf{m}} : \overline{\mathsf{k}}\ \overline{MT}$	signature (structural type)
k	::=	$\mathsf{abs} \mid \mathsf{def}$	(method) kind
MT	::=	$[\overline{X} \lhd \overline{U}]\overline{T} \to T$	method type

Figure 1 Effect-free syntax and types.

A program P is a sequence of declarations of *(nominal) types*[4]. This sequence is assumed to be a map, that is, type names are distinct. Hence, we can safely use the notations $P(\mathsf{N})$ and $\mathsf{dom}(P)$, as we will do for other (sequences representing) maps.

A type declaration $\mathsf{N}[\overline{Y} \lhd \overline{T}] \lhd \overline{N}\{\overline{md}\}$ introduces a generic nominal type $\mathsf{N}[\overline{Y} \lhd \overline{T}]$, inheriting from all those in $\overline{N}$. We assume that the notation $\overline{Y} \lhd \overline{T}$ represents a map from type variables to types (their bounds), that is, type variables are distinct and the two sequences have the same length; moreover, $\overline{N}$ represents a set, that is, order and repetitions are immaterial, and $\overline{md}$ represents a map, that is, method names are distinct. Analogous assumptions hold in an object $\overline{N}\{\overline{md}\}$ and a method type $[\overline{X} \lhd \overline{U}]\overline{T} \to T$.

Method declarations can be either abstract (abs), that is, only specifying a method type, or defined (def), providing the (variables to be used as) parameters and the method body. The programmer can choose an arbitrary variable x for the first parameter in defined methods to denote the current object, rather than a fixed name as, e.g., this in Java.

In the calculus, we adopt a uniform syntax for abstract and defined methods, to simplify the technical treatment; a more realistic language would likely use a different concrete syntax, for instance declaring parameters together with their types.

▶ Remark 1. Lambda-expressions can be encoded in the calculus, similarly to what is done in Java; that is, the object $\{\mathsf{apply} : \mathsf{def}\ T \to U\ \langle _\, x, e\rangle\}$ can be abbreviated $\lambda x{:}T.e$. Note that, in this way, encoded functions are possibly recursive and higher-order.

[4] We adopt this terminology to avoid more connoted terms such as class, interface, trait.

Types are either type variables X or *object types*, of shape $\overline{N}\{s\}$. Nominal types are (instantiations of) those declared in the program. Object types are a form of intersection types, present also in Scala 3, denoting, without introducing a name, a type which is a subtype of all types in $\overline{N}$, additionally providing methods in the signature s. Nominal types can be seen as special object types. We assume that a signature s represents a map from method names to method kinds and types, that is, method names are distinct and the three sequences have the same length. Hence, we can safely use the notations $s(\mathsf{m})$ and $\mathsf{dom}(s)$.

Note that type annotations written by the programmer are allowed to be arbitrary types, rather than only nominal. In this respect, our calculus offers more generality than Java.

In the following, we will write $\overline{N}$ for $\overline{N}\{\}$; note that such a syntactic form can be seen both as an object and the corresponding object type. Moreover, we will write Object for $\{\}$, which, as a type, is the top of the subtyping relation.

Examples. In the code examples, we will use a number of other obvious conventions and abbreviations, such as omitting square brackets around an empty sequence in type/method declarations and method calls, and writing the pair of sequences $\overline{X} \triangleleft \overline{T}$ as a sequence of pairs, omitting bounds which are Object. Finally, in both code and formalism, we will often use the wildcard _ to indicate that some variable or meta-variable does not matter.

▶ **Example 2.** As an example of a program, we show the classic encoding of booleans and natural numbers in the object-oriented paradigm, through an inheritance hierarchy, using the visitor pattern for defining functions over them.

```
Bool {
  if: abs [X Y◁ThenElse[X]] Y -> X
  not: def -> Bool <b, b.if[Bool ThenElse[Bool]](
    ThenElse[Bool]{
      then: def -> Bool <_, False>
      else: def -> Bool <_, True>
    }
  )
}

True ◁ Bool { if: def [X Y◁ThenElse[X]] Y -> X <_ te, te.then()> }
False ◁ Bool { if: def [X Y◁ThenElse[X]] Y -> X <_ te, te.else()> }

ThenElse[X] {
  then: abs -> X
  else: abs -> X
}
```

Let us focus first on the method `if`, which takes a parameter of (a subtype of) `ThenElse[X]`, expected to provide two alternative results of type `X`. The method, abstract in `Bool`, is implemented in `True` and `False` by selecting the `then` and `else` alternative provided by the argument, respectively. As said above, we use the wildcard as variable for the current object, since it does not occur in the body.

The type `ThenElse[X]` declares methods `then` and `else` to be implemented in its subtypes. To illustrate the language features, we define `not` in `Bool` by invoking `if` on the current object with, as argument, an object which implements `ThenElse[Bool]`. Clearly `not` could declared abstract in `Bool` and defined in the obvious way in the two subtypes.

Turning now to naturals, a similar encoding through an inheritance hierarchy could be:

```
Nat {
  succ: def -> Nat <n, Succ{pred: def -> Nat <_, n>}
  match: abs [X] NatMatch[X] -> X
}
```

```
Zero ◁ Nat { match: def [X] NatMatch[X] -> X <_ nm, nm.zero()> }
Succ ◁ Nat {
  pred: abs -> Nat
  match: def [X] NatMatch[X] -> X <n nm, nm.succ(n.pred())>
}

NatMatch[X] { zero: abs -> X   succ: abs Nat -> X }
```

Since in the calculus data are uniformly implemented by stateless objects, numbers greater than 0 are encoded as objects which extend `Succ` by implementing the predecessor method; that is, if $\texttt{Nat}_n$ is the object encoding number n, then $n+1$ is encoded by $\texttt{Nat}_n\texttt{.succ()}$, which evaluates to $\texttt{Succ\{pred: def -> Nat <_, Nat}_n\texttt{>\}}$.

The type `NatMatch[X]` declares methods `zero` and `succ` to be implemented in subtypes, offering a programming schema for definitions given by arithmetic induction. For instance:

```
Even ◁ NatMatch[Bool] {
  zero: def -> Bool <_,True>
  succ: def Nat -> Bool <even n, n.match(even).not()>
}
```

A different encoding of natural numbers could be provided with no inheritance hierarchy:

```
Nat {
  match: def [X] NatMatch[X] -> X <_ nm, nm.zero()>
  succ: def -> Nat
    <n, Nat{match: def [X] NatMatch[X] -> X <_ nm, nm.succ(n)>}}
}
```

In this version, 0 is encoded by `Nat`, and, if $\texttt{Nat}_n$ is the object encoding number n, then $n+1$ is encoded by $\texttt{Nat.succ(Nat}_n\texttt{)}$, which evaluates to

$$\texttt{Nat\{ match: def [X] NatMatch[X] -> X <_ nm, nm.succ(Nat}_n\texttt{)>\} \}}$$

Effectful language. In Figure 2 we extend the language by adding constructs to raise, compose, and handle effects. As customary, we adopt a fine-grain syntax [27], where *values*

P	::=	$\overline{td}$	program
td	::=	$\mathsf{N}[\overline{Y} \triangleleft \overline{T}] \triangleleft \overline{N}\{\overline{md}\}$	type declaration
md	::=	$\mathsf{m} : \mathsf{abs}\, MT \mid \mathsf{m} : \mathsf{def}\, MT\, \langle x\, \overline{x}, e\rangle \mid \mathsf{m} : \mathsf{mgc}\, MT$	method declaration
v	::=	$x \mid \overline{N}\{\overline{md}\}$	value
e	::=	$v.\mathsf{m}[\overline{T}](\overline{v}) \mid \texttt{return}\ v \mid \texttt{do}\ x = e_1\texttt{;}\ e_2 \mid \texttt{try}\ e\ \texttt{with}\ h$	expression
h	::=	$\overline{c}, \langle x, e\rangle$	handler
c	::=	$N.\mathsf{m} : [\overline{X}]\langle x\, \overline{x}, e\rangle_\mu$	(catch) clause
μ	::=	$\mathsf{c} \mid \mathsf{s}$	mode
k	::=	$\mathsf{abs} \mid \mathsf{def} \mid \mathsf{mgc}$	(method) kind

Figure 2 Fine-grain syntax for the effectful language.

are effect-free, whereas expressions may raise effects, and are also called *computations*. Methods can be, besides abstract and defined, *magic* (abbreviated mgc). Magic methods are made available to the programmer in the type declarations composing the program, and do not specify an implementation, like abstract methods. However, rather than being deferred to subtypes, their implementation is provided "by the system". We add the standard operators `return` for embedding values into computations, and `do` for composing computations

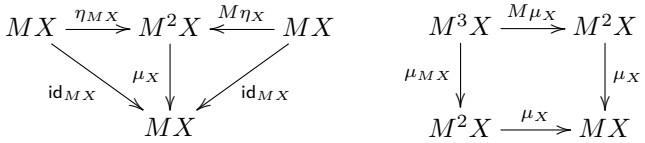
sequentially passing the result of the former to the latter. Finally, we provide a try-block enclosing a computation with a *handler*, consisting of a sequence of *(catch) clauses*, and a *final expression*, parametric on a variable. A clause specifies a type and method name, expected to identify a magic method declaration; the clause may catch calls of such method, by executing the *clause expression* instead, parametric on type variables and variables, analogously to a method body. After that, the final expression is either executed or not depending on the *mode*, either c or s, for "continue" and "stop", respectively, of the clause. As illustrated in the following examples, a c-clause replaces an effect with an alternative behaviour in a continuous manner, whereas in s-clauses handling the computational effect interrupts the normal flow of execution.

3 Monadic Operational Semantics

In this section, following the approach in [12], we define a *monadic operational semantics* for the language, parametric on an underlying monad.

Monads. First of all we recall basic notions about monads, referring to standard textbooks [42] for a detailed presentation.

A *monad* $\mathbb{M} = \langle M, \eta, \mu \rangle$ (on $\mathcal{Set}$) consists of a functor $M : \mathcal{Set} \to \mathcal{Set}$ and two natural transformations $\eta : \mathsf{Id} \Rightarrow M$ and $\mu : M^2 \Rightarrow M$ such that, for every set X, the following diagrams commute:



The functor M specifies, for every set X, a set MX of monadic elements built over X, in a way compatible with functions. The map η_X, named *unit*, embeds elements of X into monadic elements in MX, and the map μ_X, named *multiplication*, flattens monadic elements built on top of other monadic elements into plain monadic elements.

Functions of type $X \to MY$ are called *Kleisli functions* and play a special role: they can be seen as "effectful functions" from X to Y, raising effects described by the monad $\mathbb{M}$. Given a Kleisli function, by *Kleisli extension* we can define:

$$f^\dagger : MX \to MY \quad f^\dagger = \mu_Y \circ Mf$$

that is, first we lift f through M to apply it to monadic elements and then we flatten the result using μ_Y. Moreover, given $\alpha \in MX$, $f : X \to MY$ and $g : X \to Y$, we set

$$\begin{array}{ll} - \gg\!= - : MX \to (X \to MY) \to MY & \alpha \gg\!= f = f^\dagger(\alpha) \\ \mathsf{map} : (X \to Y) \to MX \to MY & \mathsf{map}\, g\, \alpha = Mg(\alpha) \end{array}$$

The operator $\gg\!=$ is also called bind. As its definition shows, it can be seen as an alternative description of the Kleisli extension, where the parameters are taken in inverse order. This view corresponds, intuitively, to the sequential composition of two expressions with effects, where the latter depends on a parameter *bound* to the result of the former. The operator map describes the effect of the functor M on functions. That is, the lifting of function g through M is applied to a monadic value α.

$$\text{(INVK)}\ \frac{}{v.\mathsf{m}[\overline{T}](\overline{v}) \to_p e[\overline{T}/\overline{X}][v/x][\overline{v}/\overline{x}]}\ \mathsf{lookup}(v,\mathsf{m}) = \langle \overline{X}, x, \overline{x}, e\rangle$$

$h = \overline{c}, \langle x, e'\rangle$

$$\text{(TRY-RET)}\ \frac{}{\texttt{try return } v \texttt{ with } h \to_p \texttt{do } x = \texttt{return } v\texttt{; } e'}$$

$$\text{(TRY-DO)}\ \frac{}{\texttt{try do } y = e_1\texttt{; } e_2 \texttt{ with } h \to_p \texttt{try } e_1 \texttt{ with } \overline{c}, \langle y, \texttt{try } e_2 \texttt{ with } h\rangle}$$

$$\text{(CATCH-CONTINUE)}\ \frac{}{\begin{array}{l}\texttt{try } v.\mathsf{m}[\overline{T}](\overline{v}) \texttt{ with } h \to_p \\ \qquad \texttt{do } x = e[\overline{T}/\overline{X}][v/x][\overline{v}/\overline{x}]\texttt{; } e'\end{array}}\ \begin{array}{l}\mathsf{lookup}(v,\mathsf{m}) = \langle \mathsf{mgc}, _\rangle \\ \mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), \overline{c}) = [\overline{X}]\langle x\,\overline{x}, e\rangle_{\mathsf{c}}\end{array}$$

$$\text{(CATCH-STOP)}\ \frac{}{\texttt{try } v.\mathsf{m}[\overline{T}](\overline{v}) \texttt{ with } h \to_p e[\overline{T}/\overline{X}][v/x][\overline{v}/\overline{x}]}\ \begin{array}{l}\mathsf{lookup}(v,\mathsf{m}) = \langle \mathsf{mgc}, _\rangle \\ \mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), \overline{c}) = [\overline{X}]\langle x\,\overline{x}, e\rangle_{\mathsf{s}}\end{array}$$

$$\text{(FWD)}\ \frac{}{\texttt{try } v.\mathsf{m}[\overline{T}](\overline{v}) \texttt{ with } h \to_p \texttt{do } x = v.\mathsf{m}[\overline{T}](\overline{v})\texttt{; } e'}\ \begin{array}{l}\mathsf{lookup}(v,\mathsf{m}) = \langle \mathsf{mgc}, _\rangle \\ \mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), \overline{c}) \text{ undefined}\end{array}$$

$$\text{(TRY-CTX)}\ \frac{e_1 \to_p e_2}{\texttt{try } e_1 \texttt{ with } h \to_p \texttt{try } e_2 \texttt{ with } h}$$

Figure 3 Pure reduction.

Monadic reduction. Let Val and Exp be the sets of closed values and expressions, respectively. In the following, we define a monadic (one-step) reduction for the language, being a relation $\to$ on $\mathsf{Exp} \times M\mathsf{Exp}$, parametric on a monad $\mathbb{M} = \langle M, \eta, \mu\rangle$. More in detail, its definition depends on the following ingredients:

- The function $\eta_{\mathsf{Exp}} : \mathsf{Exp} \to M\mathsf{Exp}$ embedding language expressions into their counterpart in the monad, written simply η in the following.
- The function $\mathsf{map} : (\mathsf{Exp} \to \mathsf{Exp}) \to M\mathsf{Exp} \to M\mathsf{Exp}$ lifting functions from expressions to expressions to their counterpart in the monad.

Moreover we assume:

- For every magic method m declared in N, a partial function $\mathsf{run}_{\mathsf{N},\mathsf{m}} : \mathsf{Val} \times \mathsf{Val}^\star \rightharpoonup M\mathsf{Val}$, returning a monadic value expressing the effects raised by a call. The function could be undefined, for instance, when arguments do not have the expected types.

The monadic reduction is modularly defined on top of a "pure" reduction $\to_p$ on $\mathsf{Exp} \times \mathsf{Exp}$, which transforms calls of non-magic methods into the corresponding bodies, as usual, and try-blocks into either magic calls or `do` expressions, by distributing and possibly applying catch clauses; magic calls and `do` expressions are, then, normal forms for the pure reduction.

Rules defining the pure reduction are given in Figure 3. The abbreviation h for $\overline{c}, \langle x, e'\rangle$ is intended to be used in all the rules below. The lookup function models method look-up, searching for the method declaration corresponding to a call, with two different successful outcomes: either a defined method, and the result are its type variables, variables, and body, or a magic method, necessarily in a type declaration, and the result is an mgc tag, and the type name. The cmatch function is defined, on a pair consisting of a magic call and a sequence of clauses, when there is a (first) clause catching the call; in this case, the corresponding clause expression is returned. The formal definitions are given in Figure 4.

Rule (INVK) is the standard rule for method invocation. That is, method look-up finds a defined method, and the call reduces to the method's body where type variables and variables are replaced by actual types and arguments. The other rules model the behaviour of a computation enclosed in a try-block.

$$\mathsf{lookup}(\overline{N}\{\overline{md}\}, \mathsf{m}) = \begin{cases} [\overline{X}]\langle x\,\overline{x}, e\rangle & \text{if } \overline{md}(\mathsf{m}) = \mathsf{m} : \mathsf{def}\ [\overline{X} \triangleleft _]_ \to _\,\langle x\,\overline{x}, e\rangle \\ \mathsf{lookup}(\overline{N}, \mathsf{m}) & \text{otherwise} \end{cases}$$

$$\mathsf{lookup}(N_1 \dots N_n, \mathsf{m}) = \begin{cases} \mathsf{lookup}(N_i, \mathsf{m}) & \text{if } \mathsf{lookup}(N_i, \mathsf{m}) \text{ defined for a unique } i \in 1..n \\ \text{undefined} & \text{otherwise} \end{cases}$$

$$\mathsf{lookup}(\mathsf{N}[\overline{T}], \mathsf{m}) = \begin{cases} [\overline{X}]\langle x\,\overline{x}, e[\overline{T}/\overline{Y}]\rangle & \text{if } \overline{md}(\mathsf{m}) = \mathsf{m} : \mathsf{def}\ [\overline{X} \triangleleft _]_ \to _\,\langle x\,\overline{x}, e\rangle \\ \langle \mathsf{mgc}, \mathsf{N}\rangle & \text{if } \overline{md}(\mathsf{m}) = \mathsf{m} : \mathsf{mgc}\ [_ \triangleleft _]_ \to _ \\ \mathsf{lookup}(\overline{N}[\overline{T}/\overline{Y}], \mathsf{m}) & \text{otherwise} \end{cases}$$

$$\text{where } P(\mathsf{N}) = \mathsf{N}[\overline{Y} \triangleleft _] \triangleleft \overline{N}\{\overline{md}\}$$

$$\mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), c) = \begin{cases} [\overline{X}]\langle x\,\overline{x}, e\rangle_\mu & \text{if } c = N.\mathsf{m} : [\overline{X}]\langle x\,\overline{x}, e\rangle_\mu \text{ and } v\ \mathsf{instof}\ N \\ \text{undefined} & \text{otherwise} \end{cases}$$

$$\mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), c\,\overline{c}) = \begin{cases} \mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), \overline{c}) & \text{if } \mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), c) \text{ undefined} \\ \mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), c) & \text{otherwise} \end{cases}$$

$$\mathsf{cmatch}(v.\mathsf{m}[\overline{T}](\overline{v}), \epsilon) = \text{undefined}$$

Figure 4 Method look-up and matching.

When the enclosed computation has no effects, rule (TRY-RET), the try-block is reduced to the sequential composition of this computation with the final expression. In case of a `do` composition of two computations, the `do` is eliminated by reducing it to a try-block enclosing the first computation, with as final expression another try-block enclosing the second one; clauses are propagated to both.

When the computation calls a magic method, the behaviour depends on whether a matching clause is found. If it is found, then the clause expression is executed, after replacing parameters by arguments, see rules (CATCH-CONTINUE) and (CATCH-STOP). In a `c`-clause, the final expression is then executed. If no matching clause is found, then in rule (FWD) the try-block is reduced to the sequential composition of the magic call with the final expression.

Finally, rule (TRY-CTX) is the standard contextual rule. Note that, as already mentioned, in the pure reduction there are no rules for magic calls and `do` expressions. Indeed, the pure reduction only handles expressions when they are enclosed in a try-block, so that effects which would be raised by magic calls can be possibly caught.

The lookup function is defined in Figure 4. When a method is invoked on an object receiver, it is first searched among the method declarations in the object itself (first clause). Objects cannot declare magic methods, since they are made available to the programmer through predefined interfaces, as illustrated by examples later. If not found, then look-up is propagated to the parent types. In this case, there should be exactly one parent type where method look-up is successful. In a nominal type, analogously, the method is first searched among those defined in the corresponding declaration. If a defined method is found, then the type parameters of the declaration are replaced by the corresponding type arguments in the nominal type. If a magic method is found, necessarily in a type declaration, then the result is an mgc tag, and the type name. If the method is not found, then look-up is propagated to the parents, again replacing type parameters with the corresponding type arguments.

The cmatch function is defined in Figure 4 as well. We write v instof N meaning that the dynamic type of v, which can be extracted from v by just erasing method bodies, defined in the obvious way, is a subtype of N. Note that the extraction of the dynamic type and the subtyping check, being part of the runtime semantics, are purely syntactic. Notably, the extracted type could violate constraints on conflicting methods and overriding (which will be

$$\text{(PURE)}\ \frac{e \to_p e'}{e \to \eta(e')} \qquad \text{(MGC)}\ \frac{}{v.\mathsf{m}[\overline{T}](\overline{v}) \to \mathsf{map}\,(\texttt{return}\ [\,])\,\mathsf{run}_{\mathsf{N},\mathsf{m}}(v,\overline{v})}\ \mathsf{lookup}(v,\mathsf{m}) = \langle \mathsf{mgc}, \mathsf{N}\rangle$$

$$\text{(RET)}\ \frac{}{\texttt{do}\ x = \texttt{return}\ v;\ e \to \eta(e[v/x])} \qquad \text{(DO)}\ \frac{e_1 \to \mathrm{E}}{\texttt{do}\ x = e_1;\ e_2 \to \mathsf{map}\,(\texttt{do}\ x = [\,];\ e_2)\,\mathrm{E}}$$

Figure 5 Monadic (one-step) reduction.

checked by the type system) or even be ill-formed. If a (first) matching clause is found, then such clause provides an alternative body with its type parameters and parameters, which are instantiated with the corresponding arguments in the magic call. This resembles very much what happens for the call of a defined method, except that look-up is performed in the catch clauses, following the syntactic order.

In Figure 5 we give the rules for the monadic reduction. An expression is reduced to a monadic expression either by propagating a pure step, embedding its result in the monad, as shown in rule (PURE), or by interpreting in the monad magic calls and `do` expressions, as shown in the following rules.

In rule (MGC), method look-up finds a magic method in a type declaration named N, and the call reduces to the corresponding monadic expression. In other words, the effect is actually raised. To this end, we apply the function of type $M\mathsf{Val} \to M\mathsf{Exp}$ obtained by lifting, through map, the context $\texttt{return}\ [\,]$ to the monadic value obtained from the call. Here we identify the context $\texttt{return}\ [\,]$, which is an expression with a hole, with the function $v \mapsto \texttt{return}\ [v]$ of type $\mathsf{Val} \to \mathsf{Exp}$.

Rules (RET) and (DO) are the monadic version of the standard ones for these constructs. More in detail, given a `do` expression, when the first subterm does not raise effects, just returning a value, the expression can be reduced to the monadic embedding of the second subterm, after replacing the variable with the returned value, as shown in rule (RET). Rule (DO), instead, propagates the reduction of the first subterm, taking into account possibly raised effects. To this end, we apply the function of type $M\mathsf{Exp} \to M\mathsf{Exp}$ obtained by lifting, through map, the context $\texttt{do}\ x = [\,];\ e_2$, to the monadic expression obtained from e_1. Analogously to above, we identify the context $\texttt{do}\ x = [\,];\ e_2$, which is an expression with a hole, with the function $e \mapsto \texttt{do}\ x = [e];\ e_2$ of type $\mathsf{Exp} \to \mathsf{Exp}$.

Monadic small-step reduction and semantics. Following the approach in [12], we can define, on top of the monadic one-step reduction $\to$ on $\mathsf{Exp} \times M\mathsf{Exp}$:

- a small-step reduction on *monadic configurations*
- a *finitary semantics* of expressions
- assuming an appropriate structure on the monad, an *infinitary semantics* of expressions.

To apply the construction in [12], the monadic one-step reduction is required to be deterministic, and this is the case indeed.

▶ **Proposition 3** (Determinism). *If $e \to E_1$ and $e \to E_2$ then $E_1 = E_2$.*

We outline the construction, referring to [12] for technical details and proofs.

First of all, we set $\mathsf{Conf} = \mathsf{Exp} + \mathsf{Res}$, where $\mathsf{Res} = \mathsf{Val} + \mathsf{Wr}$, $\mathsf{Wr} = \{\mathsf{wrong}\}$. That is, a *configuration* c is either an expression or a result r, which, in turn, is either a value, modelling successful termination, or wrong, modelling a stuck computation. Then, we extend the monadic reduction $\to$ to configurations, getting the relation $\xrightarrow[\mathsf{step}]{} \subseteq \mathsf{Conf} \times M\mathsf{Conf}$ shown in Figure 6. Expressions which represent terminated computations reduce to the monadic embedding of the corresponding value or wrong, respectively; moreover, results (either values or wrong) conventionally reduce to their monadic embedding.

$$(\text{EXP})\ \frac{e \to \mathrm{E}}{e \xrightarrow[\mathsf{step}]{} \mathrm{E}} \qquad (\text{RET})\ \frac{}{\texttt{return}\ v \xrightarrow[\mathsf{step}]{} \eta_{\mathsf{Conf}}(v)}$$

$$(\text{WRONG})\ \frac{e \not\to \quad e \neq \texttt{return}\ v \text{ for all } v \in \mathsf{Val}}{e \xrightarrow[\mathsf{step}]{} \eta_{\mathsf{Conf}}(\mathsf{wrong})} \qquad (\text{RES})\ \frac{}{r \xrightarrow[\mathsf{step}]{} \eta_{\mathsf{Conf}}(r)}$$

Figure 6 Monadic (one-step) reduction on configurations.

Now, we can define a relation $\Rightarrow$ on $M\mathsf{Conf}$ as follows:

$\mathrm{C} \Rightarrow \mathrm{C}'$ iff $\mathsf{step}^\dagger(\mathrm{C}) = \mathrm{C}'$.

In this way, computations on monadic configurations are described, as usual in small-step style, by sequences of $\Rightarrow$ steps.

Then, the finitary semantics is the function $[\![-]\!]_\star : \mathsf{Exp} \to M\mathsf{Res} + \{\infty\}$ defined as follows[5]:

$$[\![e]\!]_\star = \begin{cases} \mathrm{R} & \text{if } \eta_{\mathsf{Conf}}(e) \Rightarrow^\star \mathrm{R} \\ \infty & \text{otherwise} \end{cases}$$

where $\Rightarrow^\star$ is the reflexive and transitive closure of $\Rightarrow$. This semantics describes only monadic results that can be reached in finitely many steps. In other words, all diverging computations are identified and no information on computational effects they may produce is available.

To overcome this limitation, we introduce an *infinitary semantics*. As formally detailed in [12], we assume, for each set X, a partial order on MX with a least element $\bot_X$ and suprema $\bigsqcup$ of ω-chains. Let $\mathsf{res}_0 : \mathsf{Conf} \to M\mathsf{Res}$ be the function given by

$$\mathsf{res}_0(c) = \begin{cases} \bot_{\mathsf{Res}} & c = e \\ \eta_{\mathsf{Res}}(r) & c = r \end{cases}$$

For every $e \in \mathsf{Exp}$ and $n \in \mathbb{N}$, we define $[\![e]\!]_n = \mathsf{res}_0{}^\dagger(\mathrm{C})$ iff $\eta_{\mathsf{Conf}}(e) \Rightarrow^n \mathrm{C}$. Note that $[\![e]\!]_n$ is well-defined for all $n \in \mathbb{N}$ since $\Rightarrow$ is (the graph of) a total function and so is its n-th iteration. The sequence $([\![e]\!]_n)_{n\in\mathbb{N}}$ turns out to be an ω-chain, so we define the infinitary semantics as

$$[\![e]\!]_\infty = \bigsqcup_{n\in\mathbb{N}} [\![e]\!]_n$$

Intuitively, $[\![e]\!]_n$ is the portion of the result that is reached after n reduction steps. Hence, the actual result is obtained as the supremum of all such approximations, thus describing also the observable behaviour of possibly diverging computations.

Examples. We show now examples of type declarations providing the user interface to raise effects in an underlying monad, together with some reductions and semantics. Booleans, natural numbers, conditional, and checking that a number is even, are encoded as shown in Example 2, except that, for brevity, we assume that `not` in `True` directly returns `False`. We recall the (inductive) definition of $\texttt{Nat}_n$, the object encoding the natural number n:

$\texttt{Nat}_0 = \texttt{Zero}$ $\qquad$ $\texttt{Nat}_{n+1} = \texttt{Succ\{pred: def -> Nat <_, Nat}_n\texttt{>\}}$

Finally, a handler of shape $\overline{c}, \langle x, \texttt{return}\ x\rangle$ is abbreviated by $\overline{c}$.

[5] Here and in rule (EXP) we omit the injection into monadic configurations.

▶ **Example 4** (Exceptions)**.** Let us fix a set Exc. The monad $\mathbb{E}_{\mathsf{Exc}} = \langle E_{\mathsf{Exc}}, \eta^{\mathbb{E}_{\mathsf{Exc}}}, \mu^{\mathbb{E}_{\mathsf{Exc}}} \rangle$ is given by $E_{\mathsf{Exc}}X = X + \mathsf{Exc}$, and

$$\eta^{\mathbb{E}_{\mathsf{Exc}}}(x) = x \qquad \alpha \gg\!= f = \begin{cases} f(x) & \text{if } \alpha = x \in X \\ \alpha & \text{otherwise } (\alpha = \mathsf{e} \in \mathsf{Exc}) \end{cases}$$

where $+$ denotes disjoint union (coproduct) and, for simplicity, we omit the injections.

We define a nominal type `Exception` of the (objects representing) exceptions. More formally, we assume that, for each v such that v instof `Exception`, that is, the dynamic type of v is a subtype of `Exception`, there is an associated exception in Exc, denoted $\mathsf{exc}(v)$. As a minimal example, we define, besides `Exception`, a subtype `MyException`, and assume[6] $\mathsf{exc}(\texttt{Exception}) = \mathsf{E}$, and $\mathsf{exc}(\texttt{MyException}) = \mathsf{MyE}$, with E, MyE elements of Exc.

```
Exception { throw : mgc[X] -> X }

MyException◁Exception { throw : mgc[X] -> X }
```

Both types declare a magic method `throw` that can be called to raise the exception corresponding to the receiver object. Note that the method `throw` declares a type variable as result type, since it could be called in an arbitrary context. We have:

- $\mathsf{run}_{\texttt{Exception},\texttt{throw}} : \mathsf{Val} \times \mathsf{Val}^\star \rightharpoonup M\mathsf{Val}$ only defined on $\langle v, \epsilon \rangle$ with v instof `Exception`
  $\mathsf{run}_{\texttt{Exception},\texttt{throw}}(v, \epsilon) = \mathsf{exc}(v)$
- $\mathsf{run}_{\texttt{MyException},\texttt{throw}} : \mathsf{Val} \times \mathsf{Val}^\star \rightharpoonup M\mathsf{Val}$ only defined on $\langle v, \epsilon \rangle$ with v instof `MyException`
  $\mathsf{run}_{\texttt{MyException},\texttt{throw}}(v, \epsilon) = \mathsf{exc}(v)$

The `throw` magic method in `MyException` has the same behaviour of that in the parent type; however, redefining the method will be significant in the type-and-effect system (Section 4), to precisely track the possibly raised exceptions.

The type `My` below defines a method that, depending on whether its argument (a natural number) is either even or odd, returns a natural or calls the method `throw` of `MyException`.

```
My {
  m : def Nat -> Nat<x y, y.match(Even).if[Nat ThenElse[Nat]](MyTE)}>
}

MyTE = ThenElse[Nat]{
    then : def [Nat] ->Nat <_, return One>
    else : def [Nat] ->Nat <_, Exception.throw[Nat]()>
}

One = Nat₁ = Succ{pred : def -> Nat <_,Zero>}
```

In the following reductions, we use the abbreviations `MyTE` and `One` above and write `if` for `if`[`Nat ThenElse`[`Nat`]].

Consider the expression:

$$e_1 = \texttt{try}\,\texttt{My.m}(\texttt{One})\,\texttt{with}\,c_1 \text{ where } c_1 = \texttt{Exception.throw} : [X]\langle x, \texttt{return One}\rangle_{\mathsf{s}}$$

[6] In this simple example exc only depends on the exception type; generally, it could depend on a specific instance, for instance if exceptions provide error messages or other information.

We have the following small-step reduction sequences on monadic configurations[7]:

$$
\begin{array}{rcl}
e_1 & \Rightarrow & \texttt{try}\,\texttt{One.match(Even).if(MyTE)}\,\texttt{with}\,c_1 \\
& \Rightarrow & \texttt{try}\,\texttt{Even.succ(One.pred()).if(MyTE)}\,\texttt{with}\,c_1 \\
& \Rightarrow & \texttt{try}\,\texttt{One.pred().match(Even).not().if(MyTE)}\,\texttt{with}\,c_1 \\
& \Rightarrow & \texttt{try}\,\texttt{Zero.match(Even).not().if(MyTE)}\,\texttt{with}\,c_1 \\
& \Rightarrow & \texttt{try}\,\texttt{Even.zero().not().if(MyTE)}\,\texttt{with}\,c_1 \\
& \Rightarrow & \texttt{try}\,\texttt{True.not().if(MyTE)}\,\texttt{with}\,c_1 \\
& \Rightarrow & \texttt{try}\,\texttt{False.if(MyTE)}\,\texttt{with}\,c_1 \\
& \Rightarrow & \texttt{try}\,\texttt{Exception.throw[Nat]()}\,\texttt{with}\,c_1 \\
& \Rightarrow & \texttt{return One} \Rightarrow \texttt{One}
\end{array}
$$

where all steps are derived by rules (PURE) in Figure 5 and (EXP) in Figure 6, except the last one, which is derived by rule (RET) in Figure 6.

Considering now:

$$e_2 = \texttt{try}\,\texttt{My.m(One)}\,\texttt{with}\,c_2 \text{ where } c_2 = \texttt{MyException.throw} : [X]\langle x\,, \texttt{return One}\rangle$$

we have

$$
\begin{array}{rcl}
e_2 & \Rightarrow^\star & \texttt{try}\,\texttt{False.if(MyTE)}\,\texttt{with}\,c_2 \text{ first 8 steps as for } e_1 \\
& \Rightarrow & \texttt{do}\ x = \texttt{Exception.throw()}\texttt{; return Zero} \\
& \Rightarrow & \mathsf{E} \text{ since} \\
& & \texttt{do}\ x = \texttt{Exception.throw()}\texttt{; return Zero} \to \mathsf{E} \text{ by rule (DO)}
\end{array}
$$

As the reader may have noted, the s-clause models the expected behaviour of exceptions, which, even when caught, interrupt the normal flow of execution. In the following example we show a different interface, still using the exception monad, paired with c-clauses, which replace an effect with an alternative behaviour in a continuous manner.

▶ **Example 5** (Failure).[8] Consider the exception monad with $\mathsf{Fail} \in \mathsf{Exc}$, and the following type declarations, with $\mathsf{run}_{\texttt{Failure,fail}}$ returning Fail.

```
Failure[X]{ fail : mgc -> X }

String{ ...  toNat: def -> Nat < ... > }

Test {
 sumAsNat: def String String -> Nat
   <_ s1 s2,do n1=s1.toNat();do n2=s2.toNat();do n=n1.sum(n2);return n>
}
```

Method `toNat`, whose implementation is omitted, is expected to return the natural number represented by a string, if any; otherwise, Fail is raised, through the magic call `Failure[Nat].fail()`. We assume a method `sum` in `Nat` returning the sum of two numbers.

The expression `Test.sumAsNat(s1,s2)` clearly raises Fail if one of the two strings does not represent a natural number. However, we can catch such effect returning a default value:

```
try Test.sumAsNat(s1,s2) with Failure[Nat].fail : <_ , return Zero>c
```

[7] We omit the injections from monadic expressions and values.
[8] This example is a minimal version of one in [9].

In this way, we always get a result; in particular, if `s1` does not represent a natural number, and `s2` represents the natural number `n`, we get `n`, as expected. Instead, with a `s`-clause, we would get `Zero`, without performing the sum. An example of reduction sequence is below.[9]

$e = \texttt{try Test.sumAsNat("1","a") with } c \text{ where } c = \texttt{Failure[Nat].fail} : \langle _ , \texttt{return Zero} \rangle_{\texttt{c}}$

$$
\begin{array}{rcl}
e & \Rightarrow & \texttt{try do n1="1".toNat();do n2="a".toNat();do n=n1.sum(n2);ret n with } c \\
& \Rightarrow & \texttt{try "1".toNat() with } c, \langle \texttt{n1} , \texttt{try do n2="a".toNat();do n=n1.sum(n2);ret n with } c \rangle \\
& \Rightarrow^{\star} & \texttt{try ret One with } c, \langle \texttt{n1} , \texttt{try do n2="a".toNat();do n=n1.sum(n2);ret n with } c \rangle \\
& \Rightarrow & \texttt{do n1 = return One; try do n2 = "a".toNat(); return n1.sum(n2) with } c \\
& \Rightarrow & \texttt{try do n2="a".toNat();do n=One.sum(n2);ret n with } c \\
& \Rightarrow & \texttt{try "a".toNat() with } c, \langle \texttt{n2} , \texttt{try do n=One.sum(n2);ret n with } c \rangle \\
& \Rightarrow^{\star} & \texttt{try Failure[Nat].fail with } c, \langle \texttt{n2} , \texttt{try do n=One.sum(n2);ret n with } c \rangle (*) \\
& \Rightarrow & \texttt{do n2 = return Zero; try do n=One.sum(n2);ret n with } c \\
& \Rightarrow & \texttt{try do n=One.sum(Zero);ret n with } c \\
& \Rightarrow & \texttt{try One.sum(Zero) with } c, \langle \texttt{n} , \texttt{ret n} \rangle \\
& \Rightarrow^{\star} & \texttt{try return One with } c, \langle \texttt{n} , \texttt{ret n} \rangle \\
& \Rightarrow & \texttt{do n = return One; return n} \\
& \Rightarrow & \texttt{return One} \Rightarrow \texttt{One}
\end{array}
$$

If the catch `c`-clause were a `s`-clause, then the expression at line $(*)$ would reduce to `return Zero` and therefore the reduction would produce `Zero`.

It is worthwhile to compare the interfaces:

```
Exception { throw : mgc[X] -> X }

Failure[X]{ fail : mgc String -> X }
```

`Exception` offers a generic method `throw`, so that a magic call `Exception.throw()` can occur in any context. On the other hand, `Failure` is a parametric type, so that a magic call `Failure[T].fail()` can only occur where a `T` is expected.

▶ **Example 6** (Non-determinism). The monad $\mathbb{L} = \langle L, \eta^{\mathbb{L}}, \mu^{\mathbb{L}} \rangle$ is given by LX the set of (possibly infinite) lists over X, coinductively defined by the following rules: $\epsilon \in L(X)$ and, if $x \in X$ and $l \in L(X)$, then $x : l \in L(X)$. We use the notation $[x_1, \ldots, x_n]$ to denote the finite list $x_1 : \ldots : x_n : \epsilon$. Then, the unit is $\eta^{\mathbb{L}}_X(x) = [x]$, and the bind is corecursively defined as follows: $\epsilon \gg\!= f = \epsilon$ and $(x : l) \gg\!= f = f(x)(l \gg\!= f)$, where juxtaposition denotes the concatenation of possibly infinite lists. We define the nominal type `Chooser` declaring the magic method `choose`, with $\mathsf{run}_{\texttt{Chooser,choose}}$ returning the list (monadic value) consisting of the values `True` and `False` and we use the abbreviations `MyTE1` and $\texttt{MyTE}^y$ defined below.

```
Chooser { choose : mgc -> Bool }

My {
  m1 : def -> Nat  <_, do z = Chooser.choose();
                        z.if[Nat ThenElse[Nat]](MyTE1)>
  m2 : def Nat -> Nat <_ y, do z = Chooser.choose();
                              z.if[Nat ThenElse[Nat]](MyTE^y)>
}

MyTE1 = ThenElse[Nat]{
  then : def [Nat] -> Nat <_, return One>
  else : def [Nat] -> Nat <_, return Zero>
}
```

[9] We use `ret` for `return` to save space.

```
MyTE^y = ThenElse[Nat]{
  then : def [Nat] ->Nat <_, return y>
  else : def [Nat] ->Nat <_, My.m2(y.succ())>
}

Two = Nat_2 = Succ{ pred: def ->Nat <_,Succ{pred: def ->Nat <_,Zero>}> }
```

We have the following small-step reduction sequences:

$$
\begin{array}{lll}
[\,\texttt{My.m1()}\,] & \Rightarrow & [\,\texttt{do z=Chooser.choose();z.if(MyTE1)}\,] \\
& \Rightarrow & [\,\texttt{do z=ret True;z.if(MyTE1)}, \texttt{do z=ret False;z.if(MyTE1)}\,] \\
& \Rightarrow & [\,\texttt{True.if(MyTE1)}, \texttt{False.if(MyTE1)}\,] \\
& \Rightarrow & [\,\texttt{ret One}, \texttt{ret Zero}\,] \\
& \Rightarrow & [\,\texttt{One}, \texttt{Zero}\,] \\
[\,\texttt{My.m2(Zero)}\,] & \Rightarrow & [\,\texttt{do z=Chooser.choose();z.if(MyTE}^{\texttt{y}}\texttt{)}\,] \\
& \Rightarrow & [\,\texttt{do z=ret True;z.if(MyTE}^{\texttt{y}}\texttt{)}\,,\ \texttt{do z=ret False;z.if(MyTE}^{\texttt{y}}\texttt{)}\,] \\
& \Rightarrow & [\,\texttt{True.if(MyTE}^{\texttt{y}}\texttt{)}\,,\ \texttt{False.if(MyTE}^{\texttt{y}}\texttt{)}\,] \\
& \Rightarrow & [\,\texttt{ret Zero}\,,\ \texttt{My.m2(Zero.succ())}\,] \\
& \Rightarrow & [\,\texttt{Zero}\,,\ \texttt{My.m2(One)}\,] \\
& \Rightarrow & [\,\texttt{Zero}\,,\ \texttt{do z=Chooser.choose();z.if(MyTE}^{\texttt{y}}\texttt{)}\,] \\
& \Rightarrow & [\,\texttt{Zero}\,,\ \texttt{do z=ret True;z.if(MyTE}^{\texttt{y}}\texttt{)}\,,\ \texttt{do z=ret False;z.if(MyTE}^{\texttt{y}}\texttt{)}\,] \\
& \Rightarrow & [\,\texttt{Zero}\,,\ \texttt{True.if(MyTE}^{\texttt{y}}\texttt{)}\,,\ \texttt{False.if(MyTE}^{\texttt{y}}\texttt{)}\,] \\
& \Rightarrow & [\,\texttt{Zero}\,,\ \texttt{ret One}\,,\ \texttt{My.m2(One.succ())}\,] \\
& \Rightarrow & [\,\texttt{Zero}\,,\ \texttt{One}\,,\ \texttt{My.m2(Two)}\,] \\
& \Rightarrow^{\star} & [\,\texttt{Zero}\,,\ \texttt{One}\,,\ \texttt{Two}\,,\ \texttt{My.m2(Two.succ())}\,] \\
& \dots &
\end{array}
$$

Note that the second reduction is non-terminating, in the sense that a monadic result (a list of values) is never reached. Hence, with the finitary semantics, we get $[\![[\,\texttt{My.m2(Zero)}\,]]\!]_{\star} = \infty$. With the infinitary semantics, instead, we get the following ω-chain:

$$\texttt{[]}, \dots, \texttt{[Zero]}, \dots, \texttt{[Zero, One]}, \dots, \texttt{[Zero, One, Two]}, \dots, \texttt{[Nat}_0\texttt{, ..., Nat}_n\texttt{]}, \dots,$$

whose supremum is the infinite list of the (objects representing the) natural numbers.

▶ **Example 7.** Denote by DX the set of probability subdistributions α over X with countable support, i.e., $\alpha : X \to [0..1]$ with $\sum_{x\in X} \alpha(x) \leq 1$ and $\texttt{supp}(\alpha) = \{x \in X \mid \alpha(x) \neq 0\}$ countable set. We write $r \cdot \alpha$ for the pointwise multiplication of a subdistribution α with a number $r \in [0, 1]$. The monad $\mathbb{D} = \langle D, \eta^{\mathbb{D}}, \mu^{\mathbb{D}}\rangle$ is given by

$$\eta^{\mathbb{D}}(x) = y \mapsto \begin{cases} 1 & y = x \\ 0 & \text{otherwise} \end{cases} \qquad \alpha \gg\!= f = \textstyle\sum_{x\in X} \alpha(x) \cdot f(x)$$

We use the same nominal type `Chooser` with the magic method `choose`, now returning the distribution consisting of the values `True` and `False` with probability $\frac{1}{2}$, that we denote by $[\,\frac{1}{2} : \texttt{return True}, \frac{1}{2} : \texttt{return False}\,]$.

The expressions $[\,1 : \texttt{My.m1()}\,]$ and $[\,1 : \texttt{My.m2(Zero)}\,]$ can be reduced analogously to the previous example:

$[\,1 : \texttt{My.m1()}\,] \Rightarrow^{\star} [\,\frac{1}{2} : \texttt{One}, \frac{1}{2} : \texttt{Zero}\,]$
$[\,1 : \texttt{My.m2(Zero)}\,] \Rightarrow^{\star} [\,\frac{1}{2} : \texttt{Zero}, \frac{1}{4} : \texttt{One}, \frac{1}{8} : \texttt{Two}, \frac{1}{16} : \texttt{My.m2(Two.succ())}\,]\ \dots$

Again, the second reduction is non-terminating, hence, with the finitary semantics, we get $[\![[\,1 : \texttt{My.m2(Zero)}\,]]\!]_{\star} = \infty$. With the infinitary semantics we get the following ω-chain:

$$\texttt{[]}, \dots, [\tfrac{1}{2}\texttt{:Zero]}, \dots, [\tfrac{1}{2}\texttt{:Zero, }\tfrac{1}{4}\texttt{:One]}, \dots, [\tfrac{1}{2}\texttt{:Nat}_0\texttt{, ..., }\tfrac{1}{2^{n+1}}\texttt{:Nat}_n\texttt{]}, \dots,$$

whose supremum is the infinite list where each (object representing the) number n has probability $\frac{1}{2^{n+1}}$.

4 Type-and-effect System

In order to equip the language with a type-and-effect system, first of all we extend the syntax and the signatures, as shown in Figure 7. In method declarations, method types are replaced by *method type-and-effects*, where an *effect* component is added; we maintain the same meta-variable for simplicity. They are considered equal up-to α-renaming. That is, $[\overline{X} \triangleleft \overline{U}]\overline{T} \to T!E = ([\overline{Y} \triangleleft \overline{U'}]\overline{T'} \to T'!E')[\overline{X}/\overline{Y}]$.

MT	::=	$[\overline{X} \triangleleft \overline{U}]\overline{T} \to T!E$	method type-and-effect
md	::=	$\mathsf{m} : \mathsf{def}\ MT\ \langle x\,\overline{x}, e\rangle \mid \mathsf{m} : \mathsf{abs}\ MT \mid \mathsf{m} : \mathsf{mgc}\ MT$	method declaration
E	::=	$\bullet \mid \top \mid E \vee E' \mid T.\mathsf{m}[\overline{T}]$	effect
s	::=	$\overline{\mathsf{m}} : \overline{\mathsf{k}}\ \overline{MT}$	signature
k	::=	$\mathsf{abs} \mid \mathsf{def} \mid \mathsf{mgc}$	(method) kind

Figure 7 Adding effects.

Effects are the empty effect, the top effect, union of effects, and *call-effects*. For magic methods, this component is assumed to have a canonical form, hence can be omitted in the concrete syntax. Notably, for a method $\mathsf{m} : \mathsf{mgc}\,[\overline{X} \triangleleft _]_ \to _$ in the declaration of the nominal type $\mathsf{N}[\overline{Y} \triangleleft _]$, the effect is $\mathsf{N}[\overline{Y}].\mathsf{m}[\overline{X}]$. In signatures, the information associated to method names is analogously extended; moreover, the additional kind mgc is considered.

Φ	::=	$\overline{X} \leq \overline{T}$	type environment
Γ	::=	$\overline{x} : \overline{T}$	environment

Figure 8 Syntax of (type) environments.

Type environments and environments, defined in Figure 8, are assumed to be maps, from type variables to types (their bounds), and from variables to types, respectively. Hence (type) variables are distinct, and the two sequences have the same length.

Before the formal details, we illustrate the most distinctive feature of our type system.

Variable call-effects and simplification. As shown in Figure 7, except for $\top$, effects are essentially (representations of) sets of call-effects, with $\bullet$ the empty set and $\vee$ the union. Sets of "atomic" effects are a rather natural idea, generalizing what happens, e.g., in Java `throws` clauses. What is interesting here is the nature of such atomic effects, and the role of $\top$. A call-effect $T.\mathsf{m}[\overline{T}]$ is a static approximation of the computational effects of a call to m with receiver of type T and type arguments $\overline{T}$. More precisely, we only allow call-effects which are:

magic $T.\mathsf{m}[\overline{T}]$ with T object type (that is, not of shape X), and m magic in T. As expected, this means that this magic method could be possibly invoked, raising the corresponding computational effect; for instance, as will be shown in Example 8, a call-effect `Exception.throw` denotes that an exception could be possibly thrown.

variable $X.\mathsf{m}[\overline{T}]$. This call-effect can be assigned to code parametric on the type variable X; the meaning is that, for each instantiation of X with an object type T, this becomes, through a non-trivial process called *simplification*, the effect of m in T. In other words, $X.\mathsf{m}[\overline{T}]$ is a parametric effect, which can be made concrete in the types which replace X.

In addition to sets of call-effects, we include the *top* effect, which plays the role of default for (typically abstract) methods which do not pose constraints on the effects in implementations. In a sense, this generalizes the meaning of a `throws Exception` clause in Java.

We illustrate now the above features on an example, notably showing how (simplification of) variable call-effects allows a very precise approximation.

▶ **Example 8.** Consider again the encoding of booleans in Example 2 (Section 2), where we added effect annotations.

```
Bool { if : abs [X Y◁ThenElse[X]] Y -> X ! Y.then ∨ Y.else }

True ◁ Bool {
  if : def [X Y◁ThenElse[X]] Y -> X ! Y.then <_ te, return te.then()>
}

False ◁ Bool {
  if : def [X Y◁ThenElse[X]] Y -> X ! Y.else <_ te, return te.else()>
}

ThenElse[X] {
  then: abs -> X ! ⊤
  else: abs -> X ! ⊤
}
```

The abstract method if in `Bool` has, as parameter type, the type variable `Y`, expected to be instantiated with subtypes of `ThenElse[X]`, hence providing methods `then` and `else`. As effect, the method declares the union of two variable call-effects, `Y.then` ∨ `Y.else`. This means that the computational effects of this method can only be those propagated from calling either `then` or `else` on the argument. Subtypes `True` and `False` specializes the effect of `if` as expected, since they select the `then` and the `else` alternative provided by the argument, respectively.

In the type `ThenElse[X]` the methods `then` and `else` are abstract, and their implementation in subtypes is allowed to raise arbitrary effects, as denoted by ⊤. This makes sense, since we would like to instantiate `ThenElse[X]` on types implementing these methods in arbitrary ways.

For instance, consider the following code, where `b` is an expression of type `Bool`, and `Exception`, `MyTE` are the type and object introduced in Example 4, where the latter has been annotated with effects, and `MyTEType` is the corresponding object type.

```
b.if[Nat, MyTEType](MyTE)

MyTE = ThenElse[Nat]{
  then: def  -> Nat ! • <_, return Zero>
  else: def  -> Nat ! MyException.throw[Nat] <_, MyException.throw()>
}

MyTEType =
ThenElse[Nat]{
  then: def -> Nat ! •,
  else: def -> Nat ! MyException.throw[Nat]
}
```

The argument passed to `if` is an object implementing `then` by returning `Zero`, hence declaring no effects, whereas `else` calls a magic method, and declares the corresponding effect.

The effect computed for the call is, as intuitively expected, `MyException.throw[Nat]`. This happens thanks to effect simplification, which will be formally specified in Figure 10. Indeed, looking for method `if` in the receiver's type `Bool` gives the effect `X.then` ∨ `X.else`, which is instantiated to the argument type, giving `MyTEType.then` ∨ `MyTEType.else`. This effect would be highly inaccurate. However, `MyTEType.then` and `MyTEType.else` are simplified to the effects of the corresponding methods, that is, • and `MyException.throw[Nat]`, respectively.

In conclusion, our type-and-effect system supports a form of effect polymorphism which does not need additional ingredients, such as, e.g., explicit effect variables. Indeed, the effect of a method can be parametric on those of methods called on type variables in the context (variable call-effects): for instance, the effect of `if` is parametric on `Y.then` and `Y.else`. This

only relies on existing language features, notably on the OO paradigm. The key point is that a method is identified by, besides its name, the type where it is declared. Hence, to be parametric on the effect of a method, it is enough to be parametric on the type where it is declared, and this is for free since we have type variables. In other words, whereas effect variables stand for arbitrary effects, variable call-effects stand for effects declared by a method, and standard instantiation is complemented here by a non-trivial step of simplification.

Key formal definitions. The typing rules for values and expressions are given in Figure 9. The typing judgment for values has the shape $\Phi;\Gamma \vdash v : T$, since values have no effects; the one for expressions, instead, has the shape $\Phi;\Gamma \vdash e : T!E$.

$$\text{(T-VAR)}\ \frac{}{\Phi;\Gamma \vdash x : T}\ \Gamma(x) = T \qquad \text{(T-OBJ)}\ \frac{\Phi;\Gamma;\overline{N}\{s\} \vdash \overline{md}\diamond}{\Phi;\Gamma \vdash \overline{N}\{\overline{md}\} : \overline{N}\{s\}}\ \begin{array}{l}\Phi \vdash \overline{md} \rightsquigarrow s\\ \Phi \vdash \overline{N}\{s\} \rightsquigarrow s'\\ \mathsf{NoMgc}(s)\\ \mathsf{NoAbs}(s')\end{array}$$

$$\text{(T-INVK)}\ \frac{\Phi;\Gamma \vdash v_0 : T_0 \qquad \Phi;\Gamma \vdash v_i : T_i'\ \forall i \in 1..n}{\Phi;\Gamma \vdash v_0.\mathsf{m}[\overline{T}](v_1,\ldots,v_n) : T[\overline{T}/\overline{X}]!E'}\ \begin{array}{l}\mathsf{mtype}_\Phi(T_0,\mathsf{m})=_\ [\overline{X} \lhd \overline{U}]\,T_1 \ldots T_n \to T!E\\ \Phi \vdash \overline{T} \le \overline{U}[\overline{T}/\overline{X}]\\ \Phi \vdash T_i' \le T_i[\overline{T}/\overline{X}]\ \forall i \in 1..n\\ \Phi \vdash E[\overline{T}/\overline{X}] \Downarrow E'\end{array}$$

$$\text{(T-RET)}\ \frac{\Phi;\Gamma \vdash v : T}{\Phi;\Gamma \vdash \texttt{return}\ v : T!\bullet} \qquad \text{(T-DO)}\ \frac{\Phi;\Gamma \vdash e : T!E \qquad \Phi;\Gamma, x : T \vdash e' : T'!E'}{\Phi;\Gamma \vdash \texttt{do}\ x = e;\ e' : T'!E \vee E'}$$

$$\text{(T-TRY)}\ \frac{\Phi;\Gamma \vdash e : T!E \qquad \Phi;\Gamma;T \vdash h : T'!H}{\Phi;\Gamma \vdash \texttt{try}\ e\ \texttt{with}\ h : T'!\mathcal{F}_H(E)}$$

$$\text{(T-HANDLER)}\ \frac{\Phi;\Gamma, x : T \vdash e' : T'!E' \qquad \Phi;\Gamma;T'' \vdash c_i \Rightarrow C_i\ \forall i \in 1..n}{\Phi;\Gamma;T \vdash c_1 \ldots c_n, \langle x, e'\rangle : T''!C_1 \ldots C_n, E'}\ \Phi \vdash T' \le T''$$

$$\text{(T-CONTINUE)}\ \frac{\Phi;\Gamma, x : N_x, \overline{x}{:}\overline{T} \vdash e : T''!E}{\Phi;\Gamma;\ T' \vdash N_x.\mathsf{m} : [\overline{X}]\langle x\,\overline{x}, e\rangle_{\mathsf{c}} \Rightarrow T_x.\mathsf{m} : [\overline{X}]\langle E\rangle}\ \begin{array}{l}\mathsf{mtype}_\Phi(N_x,\mathsf{m})=\mathsf{mgc}\,[\overline{X} \lhd \overline{U}]\overline{T} \to T!_\\ \Phi \vdash T'' \le T\end{array}$$

$$\text{(T-STOP)}\ \frac{\Phi;\Gamma, x : N_x, \overline{x}{:}\overline{T} \vdash e : T''!E}{\Phi;\Gamma;\ T' \vdash N_x.\mathsf{m} : [\overline{X}]\langle x\,\overline{x}, e\rangle_{\mathsf{s}} \Rightarrow T_x.\mathsf{m} : [\overline{X}]\langle E\rangle}\ \begin{array}{l}\mathsf{mtype}_\Phi(N_x,\mathsf{m})=\mathsf{mgc}\,[\overline{X} \lhd \overline{U}]\overline{T} \to _!_\\ \Phi \vdash T'' \le T'\end{array}$$

Figure 9 Typing rules for values and expressions.

They rely on the following auxiliary notations:

1. $\Phi \vdash E \Downarrow E'$ meaning that the effect E can be simplified to E'
2. $\mathcal{F}_h$ the *filter function* associated to the handler h
3. $\Phi \vdash T \rightsquigarrow s$ meaning that we can safely extract a signature s from a type; the notation $\mathsf{mtype}_\Phi(T,\mathsf{m})=\mathsf{k}\,MT$ is an abbreviation for $\Phi \vdash T \rightsquigarrow s$ and $s(\mathsf{m}) = \mathsf{k}\,MT$
4. $\Phi \vdash T \le T'$ the subtyping relation

We illustrate the typing rules and notations (1) and (2), whereas the formal definitions of (3) and (4), which are almost standard, are given in the extended version [11]. The reader should only know that (3) models extracting the structural type information; in this phase, constraints about no conflicting method definitions and safe overriding are checked. Then, typing rules model another phase where code (method bodies) is typechecked against this type information.[10]

[10] Differently from other type systems for Java-like languages [21], here the two phases cannot be sequenced, since we still need signature extraction for the types introduced "on the fly" by objects.

$$(\text{EMPTY})\ \frac{}{\Phi \vdash \bullet \Downarrow \bullet} \qquad (\text{TOP})\ \frac{}{\Phi \vdash \top \Downarrow \top} \qquad (\text{VAR})\ \frac{}{\Phi \vdash X.\mathsf{m}[\overline{T}] \Downarrow X.\mathsf{m}[\overline{T}]}\ X \in \mathsf{dom}(\Phi)$$

$$(\text{MGC})\ \frac{}{\Phi \vdash T.\mathsf{m}[\overline{T}] \Downarrow T.\mathsf{m}[\overline{T}]}\ \mathsf{mtype}_\Phi(T, \mathsf{m}) = \mathsf{mgc}\,[\overline{X} \triangleleft _]_ \to _!E$$

$$(\text{SIMPLIFY-NON-MGC})\ \frac{\Phi \vdash E[\overline{T}/\overline{X}] \Downarrow E' \quad \mathsf{mtype}_\Phi(T, \mathsf{m}) = \mathsf{k}\,[\overline{X} \triangleleft _]_ \to _!E \quad \mathsf{k} \neq \mathsf{mgc}}{\Phi \vdash T.\mathsf{m}[\overline{T}] \Downarrow E'}$$

$$(\text{SIMPLIFY-UNION})\ \frac{\Phi \vdash E_i \Downarrow E'_i \ \ i \in 1..2}{\Phi \vdash E_1 \vee E_2 \Downarrow E'_1 \vee E'_2}$$

Figure 10 Simplification of effects.

Rule (T-VAR) is straightforward. An object is well-typed, rule (T-OBJ), if a signature can be safely extracted from its type. This essentially means that there are no conflicts among the parent types, and they are safely overriden by the method declarations in the object (first and second side conditions). Moreover, an object cannot declare magic methods (third side condition), and should provide an implementation for all its (either inherited or declared) methods (last side condition). Finally, in the premise, (bodies of) declared methods should be well-typed with respect to an enclosing type which is the object type.

In rule (T-INVK), the type-and-effect of the invoked method is found in the (signature extracted from) the receiver's type, as expressed by the first side condition. In the second side condition, the type annotations in the call should (recursively) satisfy the bounds for the corresponding type variables, and, in the third side condition, the argument types should be subtypes of the corresponding parameter types where type variables have been replaced by the corresponding type annotations. The type assigned to the call is the return type of the method, with the same replacement. The method effect is instantiated by replacing the type variables with the type annotations. However, the effect assigned to the call is obtained by a further *simplification step* (last side condition).

The formal definition of simplification is given in Figure 10, where $\Phi \vdash E \Downarrow E'$ means that the (not necessarily simplified) effect E is simplified to E', which only contains call-effects which are either magic or variable, as described before.

We assume that effect annotations are written by the programmer (or preliminarily reduced) in a simplified shape. Non-simplified effects can, however, appear during typechecking, when a method declared with an effect E which is generic, that is, depending on the method's type variables $\overline{X}$, is invoked with actual type arguments[11] Indeed, in this case, instantiating the type variables, in some variable call-effect $X.\mathsf{m}[\overline{T}]$ in E, X can become an object type providing a (non-magic) method m, allowing to simplify to the corresponding effect of m in the object type. This allows us to give a more refined approximations of the effects raised at runtime, as illustrated by Example 8 above, where the non-simplified effect `MyTEType.then` $\vee$ `MyTEType.else` is simplified to $\bullet \vee$ `MyException.throw[Nat]`. To ensure decidability of typechecking, an issue we do not deal with in this paper, termination of effect simplification should be enforced by some standard technique, essentially by forbidding (mutual) recursion in effect annotations.

[11] This happens in rule (T-INVK) in Figure 9.

$$
\begin{array}{lcll}
h & ::= & \overline{c}, \langle x, e\rangle & \text{handler} \\
H & ::= & \overline{C}, E & \text{filter} \\
c & ::= & N.\mathsf{m} : [\overline{X}]\langle x\,\overline{x}, e\rangle_{\mu} & \text{catch clause} \\
C & ::= & N.\mathsf{m} : [\overline{X}]\langle E\rangle & \text{clause filter}
\end{array}
$$

$\mathcal{F}_H$ defined by:
$\mathcal{F}_H(E) = \mathcal{F}_{\overline{C}}(E) \vee E'$ if $H = \overline{C}, E'$

$\mathcal{F}_{\overline{C}}$ defined by:

$$\mathcal{F}_{\overline{C}}(\bullet) = \bullet \qquad \mathcal{F}_{\overline{C}}(\top) = \top \qquad \mathcal{F}_{\overline{C}}(E_1 \vee E_2) = \mathcal{F}_{\overline{C}}(E_1) \vee \mathcal{F}_{\overline{C}}(E_2)$$

$$E = T.\mathsf{m}[\overline{T}] \qquad \mathcal{F}_{C\overline{C}}(E) = \begin{cases} \mathcal{F}_C(E) & \text{if } \mathcal{F}_C(E) \text{ defined} \\ \mathcal{F}_{\overline{C}}(E) & \text{otherwise} \end{cases} \qquad \mathcal{F}_{\epsilon}(E) = E$$

$$C = N.\mathsf{m} : [\overline{X}]\langle E\rangle \qquad \mathcal{F}_C(T.\mathsf{m}[\overline{T}]) = \begin{cases} E[\overline{T}/\overline{X}] & \text{if } \Phi \vdash T \leq N \\ \text{undefined} & \text{otherwise} \end{cases}$$

Figure 11 Filters.

In rule (T-RET), a computation which is the embedding of a value has no effects, and, in (T-DO), a sequential composition of two computations has the union of the two effects.

Typing rules for try-blocks rely on *filter functions* associated to handlers, which describe how they transform effects, by essentially replacing calls of magic methods matching some clause with the effect of the clause expression, as formally defined in Figure 11. Filter functions allow to typecheck try-blocks in a very precise way, since effects of the expression in a clause are only added if the clause could be possibly applied. This generalizes to arbitrary effects what happens for Java catch clauses; however, in Java this is part of the analysis of unreachable code, whereas here it is a feature of the type system. Filters are not a novelty of this type-and-effect system, since they were firstly used in [12] for a functional calculus; however, it is worthwhile to describe them in detail since they are a new feature, and the general idea is applied here to rather different effects, leading to another formal definition.

As shown in Figure 11, filters are the type information which can be extracted from a handler, consisting of a sequence of clause filters and a final effect. The filter function $\mathcal{F}_H$ associated to H transforms an effect by first applying the sequence of clause filters, and then adding the final effect. The transformation applying a sequence of clause filters is defined inductively. The significant case is a call-effect, which is either transformed by a (first) matching clause filter, or remains unaffected. A clause filter matches a call-effect with the same method name and a subtype of the nominal type; the call-effect is replaced by the effect of the clause filter, where type variables have been substituted by the types in the call-effect.

In rule (T-TRY), in order to typecheck a try-block, first we get the type and effect of the enclosed expression. This type is then used to typecheck the handler, as type of the parameter of the final expression, see rule (T-HANDLER). By typechecking the handler we get a type, being a supertype of the final expression, which will be the type of the whole expression. Moreover, we extract from the handler a filter, which is used to transform the effect of the enclosed expression, getting the resulting effect of the whole expression.

In rule (T-HANDLER), as said above, the type on the left of the judgment is used as type of the parameter of the final expression, required to be a subtype of that of the handler. This latter type is also needed to typecheck s-clauses, see below. The filter extracted from the handler consists in a clause filter for each clause, and the effect of the final expression.

The filter extracted from a clause keeps the first three components (nominal type, method name, and type variables), and adds the effect obtained typechecking the clause expression, as shown in rules (T-CONTINUE) and (T-STOP). A c-clause is meant to provide alternative code

$$\text{(T-METHS)}\ \frac{\Phi;\Gamma;\ T \vdash md_i \diamond\ \forall i \in 1..n}{\Phi;\Gamma;\ T \vdash md_1 \dots md_n \diamond}$$

$$\text{(T-METH)}\ \frac{\Phi, \overline{X} \lhd \overline{U};\Gamma, x : T_x, \overline{x}{:}\overline{T} \vdash e : T'!E'}{\Phi;\Gamma;\ T_x \vdash \mathsf{m} : \mathsf{def}\ [\overline{X} \lhd \overline{U}]\overline{T} \to T!E\ \langle x\,\overline{x}, e\rangle \diamond}\ \Phi, \overline{X} \lhd \overline{U} \vdash T'!E' \leq T!E$$

$$\text{(T-PROG)}\ \frac{\vdash td_i \diamond\ \forall i \in 1..n}{\vdash td_1 \dots td_n \diamond}$$

$$\text{(T-NTYPE)}\ \frac{\overline{Y} \lhd \overline{T};\emptyset;\mathsf{N}[\overline{Y}] \vdash \mathsf{GetDef}(\overline{md}) \diamond}{\vdash \mathsf{N}[\overline{Y} \lhd \overline{T}] \lhd \overline{N}\{\overline{md}\} \diamond}\ \vdash \mathsf{N}[\overline{Y} \lhd \overline{T}] \lhd \overline{N}\{\overline{md}\} \rightsquigarrow _$$

Figure 12 Typing rules for method and type declarations.

to be executed before the final expression, hence the type of the clause expression should be (a subtype of) the return type of the operation. In a s-clause, instead, the result of the clause expression becomes that of the whole expression with handler, hence the type of the former should be (a subtype of) the latter.

Referring to Example 4, note that catching an exception with a c-clause would be ill-typed. Indeed, the type of the clause expression should be (a subtype of) the return type of `throw`, which is a type variable X. Since no value has type X, no value could be returned[12], as already noted in [36].

In Figure 12 we show the typing rules for method and type declarations, which are mainly straightforward. The typing judgment for method definitions has shape $\Phi;\Gamma;\ T \vdash \overline{md}\diamond$. In rule (T-METH), a method definition is well-typed if the body is well-typed with respect to a type environment enriched by the type variables with their bounds, and an environment enriched by the variable denoting the current object with the enclosing type, and parameters with the corresponding parameter types. The type-and-effect of the body should be a sub-type-and-effect of that declared for the method. The typing judgment for type declarations has shape $\vdash \overline{td}\diamond$. In rule (T-NTYPE), a type declaration, assumed to have passed the extraction phase (side condition), is well-typed if its defined method declarations, denoted by $\mathsf{GetDef}(\overline{md})$, are well-typed with respect to the type environment consisting of the type variables with their bounds, the empty environment, and the declared type as enclosing type. Here the environment is empty since these method declarations are top-level, whereas in those inside objects, handled in rule (T-OBJ), there can be variables declared at an outer level.

5 Type-and-effect Soundness

In this section, we express and prove soundness of our type-and-effect system, by applying definitions and results in [12]. We focus on explaining the concepts, referring to [12] for detailed formal definitions and proofs.

Informal introduction. In Section 3 we defined, on top of the monadic one-step reduction:

- a finitary semantics $[\![-]\!]_\star : \mathsf{Exp} \to M\mathsf{Res} + \{\infty\}$
- an infinitary semantics $[\![-]\!]_\infty : \mathsf{Exp} \to M\mathsf{Res}$

In standard soundness we expect the result, if any, to be in agreement with the expression type. Here, since the expression has also an effect, approximating the computational effects raised by its execution, we expect the monadic result, if any, to be in agreement with the expression type and effect.

[12] Hence, the clause expression could only be another `throw` or a diverging expression.

Let us write $\vdash e : T!E$ for $\emptyset;\emptyset \vdash e : T!E$, and analogously for $\vdash v : T$, and other ground judgments. Moreover, $\vdash r : T$ only holds if $r = v$ and $\vdash v : T$ holds. Note that the result wrong is never well-typed, that is, $\vdash \mathsf{wrong} : T$ does not hold for any type T.

To formally express the above soundness requirement, we need analogous typing judgments[13] $\vdash_E \mathrm{R} : T$, one for each type and effect, on monadic results. Assuming to have such judgments, we can express the soundness results as follows.

▶ **Theorem 9** (Finitary type-and-effect soundness). *$\vdash e : T!E$ and $[\![e]\!]_\star = r$ imply $\vdash_E r : T$.*

▶ **Theorem 10** (Infinitary type-and-effect soundness). *$\vdash e : T!E$ implies $\vdash_E [\![e]\!]_\infty : T$.*

Note that finitary soundness is vacuous when the finitary semantics of an expression is ∞. On the other hand, the infinitary semantics is always a monadic result.

Before explaining how the monadic typing judgments can be derived from the non-monadic ones, we show some examples.

▶ **Example 11.** Consider the exception monad as in Example 4. We have $E\mathsf{Res} = \mathsf{Res} + \mathsf{Exc}$, that is, monadic results are either values, or wrong, or exceptions. We expect the typing judgment $\vdash_E \mathrm{R} : T$ to be defined as follows:

$$\text{(T-VAL)}\ \frac{\vdash v : T}{\vdash_E v : T} \qquad \text{(T-EXC)}\ \frac{}{\vdash_E \mathsf{e} : T}\ \mathsf{e} \in [\![E]\!]$$

That is, a monadic result is well-typed with a given type-and-effect if it is either a well-typed value with the type, or an exception belonging to (the set denoted by) the effect. Note that wrong is ill-typed. The set of exceptions $[\![E]\!]$ represented by E is defined by:

$$[\![\bullet]\!] = \emptyset \qquad [\![\top]\!] = \mathsf{Exc} \qquad [\![E \vee E']\!] = [\![E]\!] \cup [\![E']\!]$$
$$[\![\mathsf{N}.\texttt{throw}]\!] = \{\mathsf{e} \mid \mathsf{e} = \mathsf{exc}(v), v\ \mathsf{instof}\ \mathsf{N}\}$$

That is, call-effects of the `throw` method in N denote the set of the exceptions (represented by objects) of subtypes of N, and the other operators have the obvious set-theoretic meaning.

▶ **Example 12.** Consider the monad of non-determinism as in Example 6. We have $L\mathsf{Res}$ the set of (possibly infinite) lists of results (values or wrong). We show two different ways to define the typing judgment for monadic results, denoted $\vdash^{\mathsf{q}}_E \mathrm{R} : T$ for $\mathsf{q} ::= \forall \mid \exists$.

$$\text{(T-NO-RES)}\ \frac{}{\vdash^{\mathsf{q}}_E \epsilon : T} \qquad \text{(T-DET)}\ \frac{\vdash v : T}{\vdash^{\mathsf{q}}_E [v] : T}\ [\![E]\!] = 0$$
$$\text{(T-}\forall\text{)}\ \frac{\vdash r : T\ \forall r \in \mathrm{R}}{\vdash^{\forall}_E \mathrm{R} : T}\ [\![E]\!] = 1 \qquad \text{(T-}\exists\text{)}\ \frac{\vdash r : T}{\vdash^{\exists}_E \mathrm{R} : T}\ [\![E]\!] = 1\ r \in \mathrm{R}$$

where $[\![E]\!]$ is 1 if non-determinism is allowed, 0 otherwise, as defined below:

$$[\![\bullet]\!] = 0 \qquad [\![\top]\!] = 1 \qquad [\![E \vee E']\!] = [\![E]\!] \vee [\![E']\!]$$
$$[\![\texttt{Chooser.choose}[\ ]]\!] = 1$$

That is, monadic results (representing possible results of a computation) are well-typed with a type effect (denoting) 0 if they have at most one element, and this element, if any, is well-typed; in other words, the computation is deterministic. On the other hand, they are well-typed with a type effect (denoting) 1 if all the results in the list are well-typed

[13] The effect is written under the turnstile to emphasize that this typing judgment is obtained by lifting the non-monadic one, as will be described in the following.

values, or there is either no result, or at least one well-typed value, respectively. The two interpretations express "must" and "may" soundness of a non-deterministic computation: with $\forall$, we require every possible result to be well-typed, whereas, with $\exists$, it is enough to have a well-typed result, and the others could be even wrong.

Interpretation of effect types. Monadic typing judgments can be derived from non-monadic ones by providing an *interpretation of effect types* into the considered monad.

Let us denote by Eff the set of effects, assumed to be simplified (Figure 10), ground, and well-formed, considered modulo the equivalence induced by the subtyping preorder[14]. As customary, we write E for the element of Eff it represents, i.e., its equivalence class. Then, it is easy to see that Eff is the carrier of an ordered monoid $\mathcal{E}$, where the unit is $\bullet$, the multiplication, which turns out to be idempotent and commutative, is $\vee$, and the order is $\leq$.

For a set X, we denote by $\mathcal{P}(X)$ the poset of all subsets (a.k.a. predicates or properties) on X, ordered by subset inclusion. For a function $f : X \to Y$, we have a monotone function $\mathcal{P}_f : \mathcal{P}(Y) \to \mathcal{P}(X)$, given by the inverse image: for $A \subseteq Y$, $\mathcal{P}_f(A) = \{x \in X \mid f(x) \in A\}$.

▶ **Definition 13** (Interpretation of effect types). *Let $\mathbb{M} = \langle M, \mu, \eta\rangle$ be a monad. Then, an* interpretation *of $\mathcal{E}$ in $\mathbb{M}$ consists of a family λ of monotone functions $\lambda^E_X : \mathcal{P}(X) \to \mathcal{P}(MX)$, for every $E \in \mathsf{Eff}$ and set X, such that*

1. *$\lambda^E_X(\mathcal{P}_f(A)) = \mathcal{P}_{Mf}(\lambda^E_Y(A))$, for every $A \subseteq Y$ and function $f : X \to Y$*
2. *$E \leq E'$ implies $\lambda^E_X(A) \subseteq \lambda^{E'}_X(A)$, for every $A \subseteq X$*
3. *$A \subseteq \mathcal{P}_{\eta_X}(\lambda^\bullet_X(A))$, for every $A \subseteq X$*
4. *$\lambda^E_{MX}(\lambda^{E'}_X(A)) \subseteq \mathcal{P}_{\mu_X}(\lambda^{E\vee E'}_X(A))$, for every $A \subseteq X$.*

The family $\lambda = (\lambda^E)_{E\in\mathsf{Eff}}$ is a family of predicate liftings [22] for the monad $\mathbb{M}$, indexed by effect types. That is, for each effect type E, λ^E transforms predicates on X into predicates on MX, and can be regarded as the semantics of the effect type E.

Item 1 states that λ^E_X is natural in X. This ensures that the semantics of each effect type is independent from the specific set X. Item 2 states that λ^E_X is monotone with respect to the order on effects, that is, computational effects described by E are also described by E'. Item 3 states that monadic elements in the image of η_X contain computational effects described by $\bullet$, that is, no computational effect. Finally, in Item 4 we consider elements of M^2X whose computational effects are described by lifting predicates to MX through E', and then by lifting through E. By flattening such elements through $\mu_X : M^2X \to MX$ we obtain elements whose computational effects are described by the composition $E \vee E'$.

In the proof of soundness for our calculus, we only need Item 3 and Item 1, instantiated as will be detailed in Lemma 16. Item 2 and Item 4 are only required in the general framework in [12] to derive soundness from progress and subject reduction.

We show now how the previous examples can be obtained through an appropriate interpretation of effect types.

In Example 11, we can take $\lambda^E_X(A) = A + [\![E]\!]$. That is, the interpretation of an effect type E transforms a predicate A on X into a predicate on MX which holds either on elements which satisfy the original predicate, or exceptions in the set denoted by E.

In Example 12, we can take the following two interpretations $\forall$ and $\exists$:

if $[\![E]\!] = 1$, then

[14] That is, we consider effects as sets of call-effects, plus the top effect. For the formal definition of well-formedness and subtyping, which are standard, see [11].

$\forall^E_X(A) = \{B \in PX \mid B \subseteq A\}$ and
$\exists^E_X(A) = \{B \in PX \mid B = \emptyset \text{ or } B \cap A \neq \emptyset\}$

if $[\![E]\!] = 1$, then $\forall^0_X(A) = \exists^0_X(A) = \{B \in PX \mid B \subseteq A \text{ and } \sharp B \leq 1\}$

That is, in both cases, the interpretation of 0 forbids non-determinism, while the interpretation of 1 requires the predicate A to be always satisfied, according to $\forall$, and satisfied in at least one case, according to $\exists$.

Proof of type-and-effect soundness. Thanks to a general result proved in [12], to prove Theorem 9 and Theorem 10 we can use a technique similar to that widely used to prove soundness of a type system with respect to a small-step semantics, that is, it is enough to prove the progress and subject reduction properties, stated below. For the infinitary soundness, the interpretation of effect types has to respect the additional structure of the monad, that is, the least monadic element should be always well-typed, and the monadic typing judgment should be closed with respect to suprema of ω-chains. We refer to [12] for the formal definition of such requirement, which trivially holds in our case.

Let us denote by $\vdash_{\hat{E}} \mathrm{V} : T$ and $\vdash_{\hat{E}} \mathrm{E} : T!E$ the typing judgments on monadic values and expressions obtained by lifting the non-monadic ones through $\hat{E}$.

▶ **Theorem 14** (Monadic Progress). *$\vdash e : T!E$ implies either $e = \mathtt{return}\ v$ for some $v \in \mathsf{Val}$, or $e \to \mathrm{E}$ for some $\mathrm{E} \in M\mathsf{Exp}$.*

▶ **Theorem 15** (Monadic Subject Reduction). *$\vdash e : T!E$ and $e \to \mathrm{E}$ imply $\vdash_{\hat{E}} \mathrm{E} : T!E'$ for some $T', \hat{E}, E'$ such that $T'!\hat{E} \vee E' \leq T!E$.*

Monadic progress is standard: a well-typed expression either is (the embedding of) a value or can reduce. For monadic subject reduction, if a well-typed expression reduces to a monadic one, then the monadic expression has a more specific type, and the expression effect is an upper bound of the computational effects produced by the current reduction step, described by $\hat{E}$, composed with those produced by future reductions, described by E'.

Remarkably enough, the proofs of monadic progress and subject reduction can be driven by the usual rule-based reasoning, without any need to know about Definition 13, thanks to Lemma 16 below. Recall that the interpretation of effects *lifts* predicates to monadic predicates, in our case typing judgments to monadic typing judgments. Lemma 16 shows that it is even possible to lift, in a sense, the type system itself. That is, we can derive a typing rule for each operator on monadic elements used in the semantics. The proofs in the following only rely on such monadic type system.

▶ **Lemma 16.** *The following rules can be derived.*

$$(\text{T-UNIT})\ \frac{\vdash e : T!E}{\vdash_\bullet \eta(e) : T!E} \qquad (\text{T-RET-LIFT})\ \frac{\vdash_{\hat{E}} \mathrm{V} : T}{\vdash_{\hat{E}} \mathsf{map}\,(\mathtt{return}\ [\,])\ \mathrm{V} : T!\bullet}$$

$$(\text{T-DO-LIFT})\ \frac{\vdash_{\hat{E}} \mathrm{E} : T!E \qquad \emptyset; x : T \vdash e' : T'!E'}{\vdash_{\hat{E}} \mathsf{map}\,(\mathtt{do}\ x = [\,];\ e')\mathrm{E} : T'!E \vee E'}$$

Proof. By instantiating Definition 13(3) with $X = \mathsf{Exp}$ and $A = \{e \mid \vdash e : T!E\}$, we get $A \subseteq \{e \mid \vdash_\bullet \eta(e) : T!E\}$, that is, $\vdash e : T!E$ implies $\vdash_\bullet \eta(e) : T!E$, as expressed by rule (T-UNIT).

We show how to derive (T-RET-LIFT), (T-DO-LIFT) can be derived analogously. Since, by rule (T-RET), $\vdash v : T$ implies $\vdash \mathtt{return}\ v : T!\bullet$, by the monotonicity of $\lambda^{\hat{E}}$ we have that, set $Pre = \{v \mid \vdash v : T\}$, $Cons = \{v \mid \vdash \mathtt{return}\ v : T!\bullet\}$, $\lambda^{\hat{E}}_{\mathsf{Val}}(Pre) \subseteq \lambda^{\hat{E}}_{\mathsf{Val}}(Cons)$. Since $\lambda^{\hat{E}}_{\mathsf{Val}}(Pre) = \{\mathrm{V} \mid$

$\vdash_{\hat{E}} \mathrm{V} : T\}$, and, by Definition 13(1), instantiated with function (context) $\texttt{return}\ [\,] : \mathsf{Val} \to \mathsf{Exp}$ and $A = \{e \mid \vdash e{:}T!\bullet\}$, $\lambda^{\hat{E}}_{\mathsf{Val}}(\mathit{Cons}) = \{\mathrm{V} \mid \vdash_{\hat{E}} \mathsf{map}\,(\texttt{return}\ [\,])\ \mathrm{V} : T!\bullet\}$, we get that $\vdash_{\hat{E}} \mathrm{V} : T$ implies $\vdash_{\hat{E}} \mathsf{map}\,(\texttt{return}\ [\,])\ \mathrm{V} : T!\bullet$, as expressed by rule (T-RET-LIFT). ◀

Lemma 16 derives a typing rule for each monadic operator used in the semantics. In addition, the semantics uses monadic constants, which are the results of some $\mathsf{run}_{\mathsf{N},\mathsf{m}}$ function, depending on (the magic methods declared in) the specific program. Hence, like standard constants, we have to assume that these are well-typed. To this end, we require a typing rule for such constants, as given below. Essentially, since the (canonical) effect of a magic method m declared in N should be an approximation of the computational effects raised by a call, formalized by the monadic value obtained as result of $\mathsf{run}_{\mathsf{N},\mathsf{m}}$, then such monadic value should be well-typed with respect to the type-and-effect of the method.

$$\text{(T-RUN)}\ \frac{\vdash v_0 : T_0 \qquad \vdash \overline{v} : \overline{T'}}{\vdash_{\mathsf{N}[\overline{T_Y}].\mathsf{m}[\overline{T_X}]} \mathsf{run}_{\mathsf{N},\mathsf{m}}(\overline{v}) : T[\overline{T_Y}/\overline{Y}][\overline{T_X}/\overline{X}]}\ \begin{array}{l}\mathsf{mtype}(\mathsf{N}[\overline{Y} \lhd \overline{U_Y}] \lhd _\{_\}, \mathsf{m}){=}\mathsf{mgc}\ MT\\ MT = [\overline{X} \lhd \overline{U_X}]\overline{T} \to T!\mathsf{N}[\overline{Y}].\mathsf{m}[\overline{X}]\\ T_0 \le \mathsf{N}[\overline{T_Y}]\\ \overline{T_Y} \le \overline{U_Y}[\overline{T_Y}/\overline{Y}]\\ \overline{T'} \le \overline{T}[\overline{T_Y}/\overline{Y}][\overline{T_X}/\overline{X}]\\ \overline{T_X} \le \overline{U_X}[\overline{T_Y}/\overline{Y}][\overline{T_X}/\overline{X}]\end{array}$$

More in detail, given a magic method m declared in N (first and second side conditions, where the effect is the canonical one), the result of a $\mathsf{run}_{\mathsf{N},\mathsf{m}}$ function is well-typed if the first argument has a subtype of one obtained by instantiating the type variables in N, and each other argument has a subtype of that obtained by instantiating the type variables in N and those in m with the corresponding parameter type. The type and the effect of the result are obtained by an analogous instantiation of variables of the return type-and-effect.

We provide below the proof of monadic subject reduction (Theorem 15), noteworthy since it relies on the monadic typing rules, that is, those derived in Lemma 16 and rule (T-RUN). The proofs of monadic progress and subject reduction for the pure relation (Lemma 17) can be found in [11], together with the standard inversion and substitution lemmas.

▶ **Lemma 17** (Subject Reduction). *If* $\vdash e{:}T!E$ *and* $e \to_p e'$, *then* $\vdash e'{:}T'!E'$ *and* $T'!E' \le T!E$.

Proof of Theorem 15. Assuming $\vdash e{:}T!E$ and $e \to \mathrm{E}$, we have to prove that $\vdash_{\hat{E}} \mathrm{E} : T!E'$ for some $T', \hat{E}, E'$ such that $T'!\hat{E} \vee E' \le T!E$. By induction on the reduction rules of Figure 5.

(pure) E is $\eta(e')$ and $e \to_p e'$. From $\vdash e{:}T!E$ and Lemma 17 we get $\vdash e'{:}T'!E'$ with $T'!E' \le T!E$. From Lemma 16 by rule (T-UNIT) we derive $\vdash_{\bullet} \eta(e') : T'!E'$, and $T'!\bullet \vee E \le T!E$.

(mgc) e is $v_0.\mathsf{m}[\overline{T_X}](\overline{v})$ and $\mathrm{E} = \mathsf{map}\,(\texttt{return}\ [\,])\,\mathsf{run}_{\mathsf{N},\mathsf{m}}(v, \overline{v})$ and $\mathsf{lookup}(v_0, \mathsf{m}) = \langle \mathsf{mgc}, \mathsf{N}\rangle$. By inversion we get $\vdash v_0{:}T_0$ and $\vdash \overline{v}{:}\overline{T}$, and, from the definition of lookup, $\mathsf{mkind}(T_0, \mathsf{m}) = \mathsf{mgc}$. Hence, again by inversion,

- $\mathsf{mtype}(td, \mathsf{m}){=}\mathsf{mgc}\,[\overline{X} \lhd \overline{U_X}]\overline{T''} \to T''!\mathsf{N}[\overline{Y}].\mathsf{m}[\overline{X}]$ for some $td = \mathsf{N}[\overline{Y} \lhd \overline{U_Y}] \lhd _\{_\}$
- there is $\overline{T_Y}$ such that $T_0 \le \mathsf{N}[\overline{T_Y}]$ and $\overline{T_Y} \le U_Y[\overline{T_Y}/\overline{Y}]$
- $\overline{T_X} \le \overline{U_X}[\overline{T_Y}/\overline{Y}][\overline{T_X}/\overline{X}]$ and $\overline{T'} \le \overline{T''}[\overline{T_Y}/\overline{Y}][\overline{T_X}/\overline{X}]$ and $T = T''[\overline{T_Y}/\overline{Y}][\overline{T_X}/\overline{X}]$ and $E = \mathsf{N}[\overline{T_Y}].\mathsf{m}[\overline{T_X}]$.

Since the premises of rule (T-RUN) are satisfied, we get $\vdash_{E} \mathsf{run}_{\mathsf{N},\mathsf{m}}(v, \overline{v}) : T$. From Lemma 16 by rule (T-RET-LIFT) we get $\vdash_{E} \mathsf{map}\,(\texttt{return}\ [\,])\ \mathsf{run}_{\mathsf{N},\mathsf{m}}(v, \overline{v}) : T!\bullet$, and $T!E \vee \bullet \le T!E$.

(ret) e is $\texttt{do}\ x = \texttt{return}\ v;\ e'$ and $\mathrm{E} = \eta(e'[v/x])$. By inversion $\vdash v{:}T_1$ and $\emptyset; x{:}T_1 \vdash e'{:}T!E$. Therefore, by substitution, we get $\vdash e'[v/x]{:}T!E$. From Lemma 16 by (T-UNIT) we derive $\vdash_{\bullet} \eta(e'[v/x]) : T!E$, and $T!\bullet \vee E \le T!E$.

(do) $e = \mathsf{do}\ x = e_1\,;\ e_2$ and $\mathrm{E} = \mathsf{map}\,(\mathsf{do}\ x = [\ ]\,;\ e_2)\,\mathrm{E}_1$ and $e_1 \to \mathrm{E}_1$. By inversion $E' = E_1 \vee E_2$ and $\vdash e_1 : T_1 ! E_1$ and $\emptyset; x : T_1 \vdash e_2 : T ! E_2$. By induction hypothesis $\vdash_{\hat{E}_1} \mathrm{E}_1 : T_1' ! E_1'$ for some $\hat{E}_1$ and E_1' with $T_1' ! \hat{E}_1 \vee E_1' \leq T_1 ! E_1$. From Lemma 16 by rule (T-DO-LIFT) we get $\vdash_{\hat{E}_1} \mathsf{map}\,(\mathsf{do}\ x = [\ ]\,;\ e')\mathrm{E} : T ! E_1' \vee E_2 \mathrm{U}$. Therefore, we get the thesis noting that $T ! \hat{E}_1 \vee E_1' \vee E_2 \leq T ! E_1 \vee E_2 \leq T ! E$. ◀

6 Related Work

Design of the pure language. As mentioned, the pure calculus we choose as basis for the effectful extension is inspired by recent work [49, 43, 50] proposing an object-oriented paradigm based on interfaces with default methods and anonymous classes, rather than class instances with fields. In particular, classless objects were also adopted in *interface-based programming* [49], enabling multiple inheritance by decoupling state and behaviour. Then, in *λ-based object-oriented programming* [43], objects are classless and stateless, but limited to be lambdas implementing a single abstract method. In the Fearless language [50], as in our calculus, this approach is generalized to arbitrary Java anonymous classes with no fields.

Design of the effectful language. In our effectful language, constructs to raise effects, similarly to generic effects [36], are just method calls of a special kind, called *magic*. As mentioned, this terminology is taken from Fearless [50], and also informally used in Java reflection and Python. Concerning constructs for handling effects, handlers of algebraic effects [38, 39, 24, 19] are an extremely powerful programming abstraction, describing the semantics of algebraic operations in the language itself, thus enabling the simulation of several effectful programs, such as stream redirection or cooperative concurrency [39, 24, 6, 41]. The code executed when a call is caught can resume the original computation, using a form of continuation-passing style. Differently from exception handling, all occurrences of an operation within the scope of a handler are handled. Other forms of handlers have been considered, e.g., shallow handlers [24, 19], where only the first call is handled. The handling mechanism in our language is meant to provide a good compromise between simplicity and expressivity: notably, it does not explicitly handle continuations, as in handlers of algebraic effects, hence we cannot resume the original computation more than once; yet we can express a variety of handling mechanisms.

Type-and-effect system. Type-and-effect systems, or simply effect systems [47, 33, 48, 30, 25], are a popular way of statically controlling computational effects. Many of them have been designed for specific notions of computational effect and also implemented in mainstream programming languages, the most well-known being the mechanism of Java exceptions. Katsumata [25] recognized that effect systems share a common algebraic structure, notably they form an ordered monoid, and gave them denotational semantics through parametric monads, using a structure equivalent to our notion of interpretation.

Our effects are essentially sets, like in formal models of Java exceptions [3], tracking which magic calls an expression is allowed to do. Differently from effect systems for algebraic effects [5, 6, 41], also implemented in Eff [4], and inspired by [15], we enrich the effects with type information, not using just the name of magic methods. By using this type information, which is polymorphic, we also allow effects to depend on the effect of other methods, smoothly enabling a form of effect polymorphism. Effect systems supporting effect polymorphism have been widely studied for algebraic effects [26, 20, 29, 7, 9, 8], especially in the form of row polymorphism. A precise comparison with these systems is left for future work.

Semantics for effectful languages. Algebraic effects are typically treated as uninterpreted operations, that is, the evaluation process just builds a tree of operation calls [23, 44, 41]. Monadic operational semantics for λ-calculi with algebraic effects are also considered, mainly in the form of a monadic definitional interpreter (see, e.g., [28, 14, 16, 13, 10]). That is, they directly define a function from expressions to monadic values, which essentially corresponds to our infinitary semantics. Small-step approaches are also considered by [17, 18].

An alternative way of interpreting algebraic operations is by means of runners, a.k.a. comodels [40, 37, 45, 2]. Roughly, runners describe how operations are executed by the system, that is, how they transform the environment where they are run. This essentially amounts to giving an interpretation of operations in the state monad. More general runners, where the system is modelled in a more expressive way, are considered by [2], where the state monad is combined with errors and system primitive operations.

The motivation to have methods interpreted in a monad, rather than implemented in code, is the same nicely illustrated for runners by [2]. They observe that some kinds of effects, such as input/output, even though represented in the language as algebraic operations (as in Eff) or a monad (as in Haskell), are handled by an operating system functionality. Hence, semantics lacks modularity, which can be recovered by introducing runners. The same modularity is achieved in our calculus by providing the interpretations of magic methods as an independent ingredient of the semantics, which can be regarded as the operational counterpart of (effectful) runners. Differently from runners of [2], our magic methods can be interpreted in an arbitrary monad. Moreover, our interpretation is a parameter of the operational semantics, while runners of [2] are described in the language itself through a mechanism similar to effect handlers, with a limited use of continuations.

7 Conclusion

This paper provides a positive answer to the question:

> *Is it possible to smoothly incorporate in the object-oriented paradigm constructs to raise, compose, and handle effects in an arbitrary monad?*

In particular, we consider a pure OO paradigm based on interfaces with default methods and anonymous classes, exemplified by a higher-order calculus subsuming both FJ and λ-calculus. The effectful extension is designed to be familiar for OO programmers, with magic methods to raise effects, and an expressive, yet simple, handling mechanism. Effect types are designed to be familiar, being sets of call-effects generalizing exception names; the key novel feature is that type effects containing type variables can be refined in concrete calls, through a non-trivial process called *simplification*. The semantics and the soundness proof are given by a novel approach [12], providing a significant application for a language with a complex type system (both nominal and structural types, subtyping and generic types). Instantiating such an approach, we derive from the type system a *monadic type system*, allowing to carry the proof of subject reduction by the usual rule-based reasoning.

The integration of effectful features turned out to be, in fact, even smoother than in the functional case, fitting naturally in the OO paradigm, where computations happen in the context of a given program (class table in Java). That is, magic methods are, from the point of view of the programmer, as other methods offered by the environment (system, libraries), with the only difference that their calls can be handled. Another advantage is that, since methods "belong to a type", atomic effects (call-effects in our paper) naturally include a type, rather than being just operation names as in previous literature handling the functional case. Thus, effect polymorphism is obtained for free from the fact that types can be type variables, without any need of ad-hoc effect variables.

Concerning the specific calculus, we could have likely used FJ (with generic types) as well. However we have, besides nominal, structural and intersection types, hence a paradigm partly object-based, as in seminal object calculi [1], rather than class-based. This leads to more flexibility, hence the tracking of effects is more flexible as well (can be done on an object's basis). In particular, FJ is not higher-order, meaning that functions are not first-class values as customary in functional languages. Formally, in the translation of λ-calculus shown in Remark 1, any arbitrary function is encoded by an object literal; without object literals, only a finite collection of functions could be encoded, each one by a class, in a program.

This is a foundational paper, hence we focus on the introduction of design features, formalisation, and results through a toy language. Of course, any step towards an implementation and/or the application to a realistic language would be an important contribution, as it would be to mechanize some proofs. Other directions for future work are outlined below.

We plan to analyze better the handling mechanism proposed in the paper, and its relation with other approaches. The type-and-effect system we design is, as said above, novel and expressive; however, it is very simple in the sense that effect types are essentially sets. Hence, it is not adequate to approximate computational effects where the order matters, such as, e.g., sequences of write operations. A type-and-effect system with a non-commutative operator on effects is shown in [12]; however, effects there are purely semantics, and a syntactic representation should be investigated in order to apply the approach to real languages.

Finally, the interpretation of magic methods could return monadic expressions, rather than values. This would enable a more interactive behaviour with the system; for instance, the semantics of a magic method, instead of returning an unrecoverable error, could return a call to the method `throw` of an exception, which then could be handled by the program.

Event Race Detection for Node.js Using Delay Injections

Andre Takeshi Endo
Federal University of São Carlos, Brazil

Anders Møller
Aarhus University, Denmark

Abstract

Node.js is a widely used platform for building JavaScript server-side web applications, desktop applications, and software engineering tools. Its asynchronous execution model is essential for performance, but also gives rise to event races, which cause many subtle bugs that can be hard to detect and reproduce. Current solutions to expose such races are based on modifications of the source code of the Node.js system or on guided executions using complex happens-before modeling.

This paper presents a simpler and more effective approach called NACD that works by dynamically instrumenting core asynchronous operations in the Node.js runtime system to inject delays and thereby reveal event race bugs. It consists of a small, robust runtime instrumentation module implemented in JavaScript that is configured by a flexible JSON model of the essential parts of the Node.js API. Experimental results show that NACD can reproduce event race bugs with higher probability and fewer runs than state-of-the-art tools.

1 Introduction

Node.js[1] is an asynchronous, event-driven JavaScript runtime designed for building scalable network applications. Its single-threaded, non-blocking I/O architecture makes it well suited for server-side web applications, microservices, desktop applications, and command-line tools. Node.js comes with a lean core API that offers access to file systems, networking, cryptography, timers, and processes, and is supported by a vast ecosystem of open-source libraries and frameworks available via the npm[2] package manager.

The single-threaded asynchronous execution model of Node.js brings new challenges regarding concurrency [18]. To avoid blocking the main thread, Node.js delegates I/O or high processing tasks to worker threads that run in the background. These tasks are initiated through asynchronous calls, and their results are processed through JavaScript callbacks acting as event handlers. The single-threaded model makes a Node.js application immune to traditional data races. However, the timing of worker threads and event handlers is non-deterministic, which makes Node.js applications prone to so-called event races.

Event races may cause system crashes, data corruption, application hangs, and security vulnerabilities. Detecting whether a program is susceptible to such harmful event races is often challenging. Approaches like NodeAV [6], NRace [7] and NodeRT [30] adopt a predictive strategy in which a happens-before model is built and used to predict event races from individual executions. Not all event races are harmful, so predictive approaches also employ mechanisms to filter out harmless races. Still, a key limitation of these predictive techniques is that they often produce many false positives.

Another group of approaches employ dynamic exploration or fuzzing of interleavings to produce executions that expose harmful event races. Node.fz [9] is based on a modification of the internal parts of Node.js written in C/C++ code to shuffle the task and event queues and thereby fuzz the scheduling of worker threads and event handlers. This approach is limited to reordering entries that are present in the scheduler queues, and it is difficult to maintain as Node.js evolves.[3] Differently, NodeRacer [11] works on the JavaScript side. It first observes a sample run, builds a happens-before graph, and then uses it in subsequent runs to explore different callback interleavings by instrumenting the application code to selectively postpone event handler executions. Although NodeRacer has shown to be effective in many cases, by design it only explores interleavings of the events seen in the sample run. As shown in Section 2, this prevents detection of certain event race errors.

We need an approach that (1) generates witnesses in the form of crashes or test failures whenever potential event race errors are reported (unlike NodeAV, NRace, and NodeRT), (2) does not require modifications of the Node.js source code (unlike Node.fz), and (3) is not limited to reordering of scheduler queues (unlike Node.fz) or event handler callbacks (unlike NodeRacer). This paper presents an event race detection technique named NACD[4] that satisfies these requirements. It is inspired by Node.fz and NodeRacer, but with some key differences that enhance maintainability and efficacy. The key idea is to fuzz the scheduling of event handlers by dynamically injecting random delays around both before and after the asynchronous functions in the built-in Node.js modules. This is achieved purely using JavaScript code, without modifications of the Node.js source code, and it avoids the complications of implementing happens-before computation and the overhead of program code instrumentation. By introducing delays rather than merely attempting to reorder events, more bugs can be found.

In summary, this paper makes the following main contributions:

1. We describe the design of NACD: a novel approach to event race detection for Node.js applications. It consists of a JavaScript component that dynamically instruments the Node.js module loading mechanism and is configured using a JSON model of the asynchronous operations in the Node.js API.
2. We present an experimental evaluation based on benchmarks from prior work, demonstrating that the approach has a high bug reproduction ratio and tends to find bugs with fewer runs compared to Node.fz and NodeRacer.

The remainder of the paper is organized as follows. Section 2 gives a motivating example. Section 3 describes the proposed approach, while Section 4 shows the main implementation details. Section 5 presents an experimental evaluation we conducted and the results obtained. Section 6 discusses the main limitations. The related work is presented in Section 7, and Section 8 makes the concluding remarks.

[3] The Node.fz implementation was based on Node.js v0.12.7, which is 32,720 commits from the latest version at the time of writing.

[4] Node.js Asynchronous Callback Delayer.

```
1   const fse = require('fs-extra');
2
3   it('should delete without a callback', (done) => { /*c1*/
4     const filePath = TEST_DIR + 'file.txt';
5     createFileSync(filePath, 'some text');
6
7     const existsChecker = setInterval(() => { /*c2*/
8       fse.pathExists(filePath, (itDoes) => { /*c3*/
9         if (!itDoes) {
10          clearInterval(existsChecker);
11          done();
12        }
13      });
14    }, 25);
15    fse.remove(file);
16  });
```

Figure 1 Motivating example.

2 Motivating Example

Figure 1 contains JavaScript code that is subjected to a race condition; this motivating example is based on a previously unknown race condition detected by NACD in the widely used Node.js package called fs-extra.[5] The code defines a test case for function `fse.remove` that receives the file path as argument and removes the file asynchronously. The test, here named `c1` (lines 3–16), intends to check if the removal is successful. Argument `done` is a function that signals to the test runner when the test is completed.[6] The test starts in lines 4–5 creating a text file that will be removed afterwards. In line 7, a timer is started[7] and its callback `c2` (lines 7–14) is called every 25 milliseconds. Line 15 executes the function under test that will remove the created file asynchronously. To test this operation, callback `c2` checks in line 8 if the file still exists, using an asynchronous call to `pathExists` with callback `c3`. Within `c3`, if the file does not exist (line 9), the timer is stopped (line 10) and the test ends successfully by calling function `done` in line 11.

Due to an existing race condition, this test is flaky as it may pass or fail non-deterministically [20]. This issue was reported and a pull request fixing it was accepted and merged.[8] Figure 2 illustrates the callback ordering, using directed edges to indicate happens-before relations between callbacks (nodes). The first row represents trivial executions (i.e., passing test runs) in which `c2` is enqueued only once by the timer, and `c3` stops the timer before `c2` is scheduled again. The race occurs if function `fse.pathExists` (line 8) takes long enough for the timer (line 7) to enqueue a new instance of its callback, referred to as `c2'`. The nodes and edges in the second row represent event handlers that only exist in this situation. When `c2'` is scheduled to run, it calls function `fse.pathExists` again, provoking a second instance of its callback, referred to as `c3'`. Both instances of `c3` are eventually invoked, and function `done` is called twice, which makes the test runner report a test failure even though the file has been removed.

The package `fs-extra` provides extra features for file system manipulation in Node.js. It uses other packages like `graceful-fs`, but ultimately those features depend on the Node.js built-in module `fs`. This scenario is predominant in Node.js applications, where application

[5] `https://www.npmjs.com/package/fs-extra`
[6] This mechanism is defined by testing frameworks like Mocha and Jest to test asynchronous code.
[7] `setInterval` is a Node.js function that starts a timer whose associated callback is called repeatedly after a number of milliseconds. It can be stopped by calling function `clearInterval`.
[8] `https://github.com/jprichardson/node-fs-extra/pull/736`

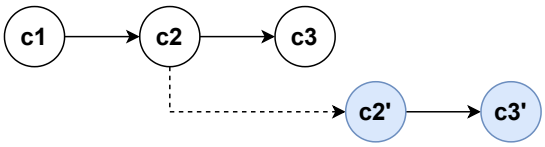

Figure 2 Callback order for motivating example.

code may use numerous third-party packages, but the asynchronous behavior comes from the built-in modules of Node.js. Notice in the example that, while `fs` is not used directly, several of its functions are called. An ordinary run of this test indirectly calls seven different `fs` functions with asynchronous behavior. In particular, package `fs-extra`'s function `fse.pathExists` is a promise-supported wrapper that uses built-in function `fs.access`.

Current versions of state-of-the-art tools cannot uncover the race bug illustrated in the example. Approaches based on happens-before relations (e.g., NodeRacer, NodeRT) rely on a logging phase to collect a trace and build happens-before relations. As previously discussed, an ordinary run will trace data to build happens-before relations similarly to the first row in Figure 2. If there is no potential interleaving between the callbacks, these approaches will fail to flag or explore this event race. Node.fz, which applies a different strategy, is also not capable of revealing this event race because it is not compatible with the Node.js version used by the project and cannot introduce sufficiently long delays [11].

3 Approach

Our approach to uncover event races, such as the one described in the previous section, is based on the observation that the asynchronous behavior originates from the core API provided by the Node.js built-in modules. By dynamically instrumenting those functions, we can introduce delays that will help to explore different callback interleavings and, as a consequence, increase the likelihood of exposing race bugs. Although centered on Node.js, the proposed approach is sufficiently general to be adapted to any software runtime that follows a single-threaded asynchronous model.

Figure 3 gives an overview of the proposed approach. A Node.js application consists of application code together with library code in the form of npm packages. Both application code and library code interact with Node.js built-in modules in order to access features related to networking, file system, cryptography, compression, etc. The key idea behind NACD is to inject delays in the asynchronous core API of the built-in modules, so that different interleavings of callbacks are explored, independently of the application and library code. For instance, delaying the callback of built-in function `fs.access` would be enough for `c2'` to be scheduled and provoke the event race in Figures 1-2. This requires no manipulation of application or library code, and explores callback interleavings within both levels.

To obtain a clean and extensible implementation of NACD, we first design a model of the API, describing its asynchronous behavior. As the Node.js built-in modules provide different API styles to perform asynchronous tasks, the model is based on a number of code patterns that are described in Section 3.1. Using this model, a runtime system instruments the API to inject delays that foster the execution of different callback scheduling. The runtime system and delay injection mechanisms are presented in Section 3.2.

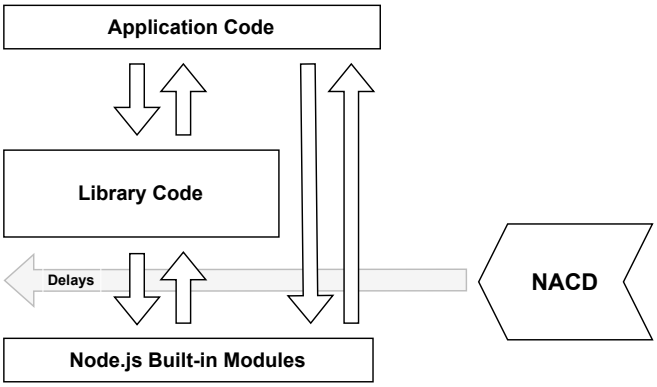

Figure 3 Overview of the proposed approach.

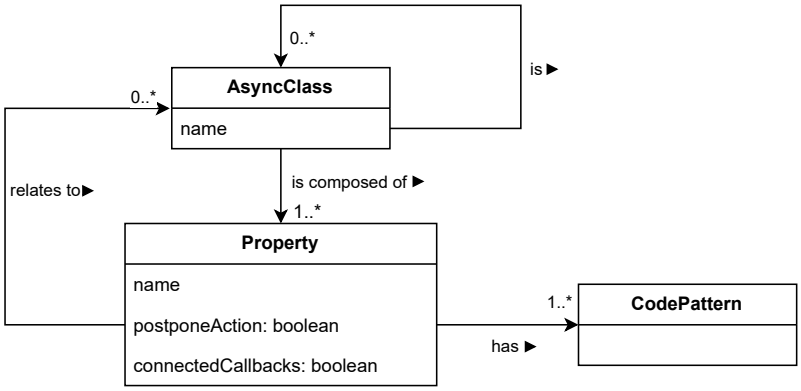

Figure 4 Model representation.

3.1 Modeling Node.js Asynchronous API

To perform the modeling of Node.js asynchronous API required to implement NACD, we have carefully studied the built-in modules and how they use asynchrony. Figure 4 shows how the proposed model is structured. It consists of a collection of *async classes*, each describing a module (e.g., `zlib`) or a class in the Node.js standard library (e.g., `zlib.ZlibTransformInterface`). Each async class has a name and is composed of *properties*. An async class can also inherit properties from other async classes, specified using the relationship `is`. For instance, several objects from the core API are event emitters, so we have an async class `EventEmitter` and several other classes inheriting from it.

The properties of an async class describe its functions and other objects. Each property may involve different forms of asynchronous behavior; we group these different styles in code patterns. Additionally, each property can be flagged as `postponeAction` or as `connectedCallbacks`, the meaning of which is explained below. Properties can also be related to other async classes; for example, a function may return an object with asynchronous behavior specified by another async class. Representative examples are presented in the following.

Next, we describe the asynchronous code patterns found in Node.js built-in modules. The identified code patterns are presented as follows together with illustrative example code.

Simple callback (CB). This pattern represents the most common case in which a function is associated with an asynchronous task and receives a callback as one of its arguments, which is scheduled to run in the future as a reaction to the task. Figure 5a shows an example where function `readFile` of the `fs` module is used to read the contents of a file and callback `c4` is called when the file contents are ready.

```
18 const fs = require('fs')
19 ...
20 fs.readFile('file.txt', (err, data) => { /*c4*/
21   ...
22 })
```

(a) Example code.

```
23 {
24   "moduleName": "fs",
25   "properties": [
26     {
27       "name": "readFile",
28       "type": [ "CB" ],
29       "postponeAction": true
30     },
31     ...
32   ]
33 }
```

(b) Model snippet.

Figure 5 Simple callback pattern.

Figure 5b shows how this code pattern is represented in the model. Using a JSON object for built-in module `fs` (line 24), it has an array of properties (starting in line 25). Function `readFile` (line 27) is identified with type `CB` (line 28), and the `postponeAction` is set to true, which instructs NACD to inject delays not only when `c4` is about to be executed but also before the file read action itself, thereby enabling exploration of alternative schedules that involve external actions.

Returned object (RO). This represents the case in which a function returns an object that is an instance of an async class. We refer to such objects as *async objects*. In Figure 6a, function `createGzip` of `zlib` returns an object (i.e., `gzip`) that supports compression using gzip (line 36). Object `gzip` is known within the API to have asynchronous behavior, as is later used to register callbacks for asynchronous events (lines 38–39).

Figure 6b shows how this code pattern is modeled. A JSON object for `createGzip` (line 44) with type `RO` (line 45) is defined as a property of `zlib` (line 41). Particularly, this code pattern requires attribute `returnedObject` (line 47). This attribute points to a different class (e.g., `zlib.ZlibTransformInterface` in lines 53–57) which has its own async behavior specified (omitted here). Consequently, the functions called in lines 38–39 of Figure 6a are identified by the model of `zlib.ZlibTransformInterface`.

Object creation (OC). This code pattern is similar to the previous case; here a class is employed to instantiate an async object. In Figure 7a, class `Agent` of built-in module `http` is used to instantiate an async object named `agent` (line 60).

```
34 const zlib = require('zlib')
35 ...
36 const gzip = zlib.createGzip()
37 ...
38 gzip.on('data', () => { ... })
39 gzip.on('end', () => { ... })
```

(a) Example code.

```
40 {
41   "moduleName": "zlib",
42   "properties": [
43     {
44       "name": "createGzip",
45       "type": [ "RO" ],
46       "postponeAction": false,
47       "returnedObject": "zlib.ZlibTransformInterface"
48     },
49     ...
50   ]
51 },
52 ...

(b) Model snippet.

Figure 6 Returned object pattern.

Figure 7b shows how this code pattern is modeled. A JSON object for `Agent` (line 67) with type `OC` (line 68) is defined as a property of `http` (line 64). Similarly to the previous code pattern, attribute `returnedObject` (line 70) has a reference for a different async class (`http.Agent` in lines 76–79).

Object property (`OP`). In this case, an async class has a property that is an async object itself. In Figure 8a, object `childProcess` is returned to represent a new process created using function `spawn` of built-in module `child_process` (line 82). This object has property `stdout` which is an async object itself for the standard output of the process (line 84).

Figure 8b shows how this code pattern is modeled. A JSON object for `child_process.ChildProcess` (line 98) is defined as the `returnedObject` attribute of function `spawn` (line 91). Among the properties of `child_process.ChildProcess`, `stdout` (line 101) is defined with type `OP`, requiring attribute `AsyncObjectProperty` that links to a different async class (i.e., `stream.ReadStream`).

Callback object (`CO`). In this case, the argument of a callback is an async object. In Figure 9a, function `createServer` of built-in module `net` is called to create a server, passing a callback for new connections (line 110). The argument of this callback, namely `socket`, is an async object itself.

Figure 9b shows how this code pattern is modeled. Using a JSON object for built-in module `net` (line 115), `createServer` (line 118) is defined with type `CO` (line 119). This code pattern requires attribute `callbackObjects` (line 121) with an array of async classes related to the arguments of its callback. In this example, the argument of `createServer`'s callback is a socket, represented in the model by async class `net.Socket` (lines 127–130).

```
58 const http = require('http')
59 ...
60 const agent = new http.Agent()
61 ...
62 agent.on('free', () => { ... })
```

(a) Example code.

65   "properties": [
66     {
67         "name": "Agent",
68         "type": [ "OC" ],
69         "postponeAction": false,
70         "returnedObject": "http.Agent"
71     },
72     ...
73   ]
74 },
75 ...
76 {
77   "moduleName": "http.Agent",
78   "is": [ "EventEmitter" ]
79 }
```

(b) Model snippet.

Figure 7 Object creation pattern.

Returned promise (RP). Some built-in modules support the use of JavaScript promises.[9] A promise is standard JavaScript built-in object that provides an abstraction for the result of an asynchronous computation [3]. Its eventual completion or failure is referred to as the promise being resolved or rejected, respectively. In either case, we say that the promise is settled.

In Figure 10a, function `resolve` is loaded from the promise API of built-in module `dns` (line 131). This function triggers a task to resolve a hostname, `'example.org'`, and returns a promise, which is asynchronously settled with an array of resource records. The result of this function is processed using `promise.then` in lines 134–135, while the function may be also used in the context of the JavaScript async-await style in line 140.

Figure 10b shows how this code pattern is modeled. The promise API is defined as an object property (line 149) of built-in module `dns` (line 144). Within `dns.Promises` (lines 155–164), function `resolve` (line 159) is identified with type `RP` (line 160).

NACD injects delays only into the promises returned by the core API of Node.js built-in modules. No special treatment is necessary for promise chains; delaying the settlement of the first promise in a chain automatically also affects the remaining promises in the chain.

Combining code patterns. Code patterns may be combined to represent the async behavior of more complex API functions. Figure 11 shows an example with an HTTP GET request. (To avoid redundancy from previously explanations, we omit the model code in the examples presented here.) In line 167, function `get` of built-in module `http` is used to request a JSON file from a web site. Making an HTTP request is an asynchronous operation, and a callback is also passed as the last argument. As mentioned before, this represents the code pattern

[9] `https://developer.mozilla.org/docs/Web/JavaScript/Reference/Global_Objects/Promise`

```
80 const { spawn } = require('child_process')
81 ...
82 const childProcess = spawn('ls', ['-l', '/usr'])
83 ...
84 childProcess.stdout.on('data', (data) => { ... })
```

(a) Example code.

```
85 {
86   "moduleName": "child_process",
87   "properties": [
88     {
89       "name": "spawn",
90       "type": [ "RO" ],
91       "returnedObject": "child_process.ChildProcess"
92     },
93     ...
94   ]
95 },
96 ...
97 {
98   "moduleName": "child_process.ChildProcess",
99   "properties": [
100    {
101      "name": "stdout",
102      "type": [ "OP" ],
103      "AsyncObjectProperty": "stream.ReadStream"
104    },
105    ...
106  ]
107 }
```

(b) Model snippet.

Figure 8 Object property pattern.

simple callback. This callback receives as an argument an async object `res`, which has its own asynchronous behavior (lines 168–169); this characterizes the code pattern *callback object*. Finally, function `http.get` returns object `clientRequest` (line 167), which also has asynchronous behavior (line 172), corresponding to code pattern *returned object*. Notice that for function `http.get` and other functions in the built-in modules, two or more code patterns may be present. The proposed model represents those cases with an array that identifies all patterns in attribute `type`, as well as other pattern-specific attributes.

Connected callbacks. I/O operations and CPU-intensive tasks in Node.js applications are treated outside JavaScript code and concurrently by the workers. Therefore, an order among their callbacks cannot be established [11, 6]. Nevertheless, this does not hold with event emitter objects from the core API. The event-driven architecture of Node.js is implemented by special objects called *event emitters*.[10] With such objects, callbacks can be associated with a named event; once an event is emitted, its associated callbacks are scheduled to run.

Figure 12 shows an example of such a case. First, a readable stream object (that is, an event emitter) is created for some JSON file (line 175). Then, callbacks `cbData`, `cbEnd`, and `cbClose` are registered for events `'data'`, `'end'`, and `'close'`, respectively. The readable stream emits several `'data'` events for each chunk of data read from the file, emits `'end'` when there is no more data to consume, and finally emits `'close'` when the underlying file

```
const net = require('net')
...
net.createServer(function (socket) {
    socket.on('data', (data) => { ... })
    socket.on('error', () => { ... })
})
```

(a) Example code.

```
{
  "moduleName": "net",
  "properties": [
    {
      "name": "createServer",
      "type": [ "CO" ],
      "postponeAction": false,
      "callbackObjects": [ "net.Socket" ]
    },
    ...
  ]
}
...
{
  "moduleName": "net.Socket",
  ...
}
```

(b) Model snippet.

Figure 9 Callback object pattern.

descriptor is closed. So, callbacks `cbData`, `cbEnd`, and `cbClose` are asynchronous and related to I/O operations, but are ordered in the context of the event emitter object. We call them *connected callbacks*. This case is indicated in the model using the `connectedCallbacks` flag.

A key observation here is that for event emitters from the core API, the order in which its *connected* callbacks are scheduled by Node.js needs to be preserved when inserting the delays. So, we specify such cases in our model, and NACD's instrumentation provides the needed information for the delays being injected while respecting such order. To do so, we use a mechanism based on queues, described in Section 3.2.

Streams. All streams in the Node.js core API are also event emitters. As such, they can draw asynchronous behavior through their event emitters. However, streams may also propagate asynchrony by other means, as illustrated in Figure 13. A readable stream from an XML file is instantiated (line 195) and, using the `pipe` method, a writable stream `parser` (line 196) provided by a third-party library is attached. The callbacks in lines 197–198 are from `parser`, but are also asynchronous since they react based on the readable stream. To handle such cases, NACD injects delays in modeled functions of the stream objects so that different callback interleavings may be explored even in the presence of streams. In this example, the model represents the readable stream's `_read` function that fetches data from the underlying resource.

3.2 Runtime System

Using the model of the asynchronous behavior of the Node.js API, the NACD runtime system installs hooks in the asynchronous operations that we intend to delay. Such hooks, named `onRun`, are invoked right before an asynchronous operation is about to run; at this moment,

```
const { resolve } = require('dns').promises
...
// example 1
resolve('example.org')
    .then((records) => { ... })

// example 2
async function () {
    ...
    const records = await resolve('example.org')
    ...
};
```

(a) Example code.

```
{
  "moduleName": "dns",
  "properties": [
    {
      "name": "promises",
      "type": [ "OP" ],
      "AsyncObjectProperty": "dns.Promises"
    },
    ...
  ]
},
...
{
  "moduleName": "dns.Promises",
  "properties": [
    {
      "name": "resolve",
      "type": [ "RP" ]
    },
    ...
  ]
}
```

(b) Model snippet.

Figure 10 Returned promise pattern.

NACD may decide to inject a delay. This step occurs at runtime and on-demand, as NACD intercepts the Node.js application's accesses to the core API. The implementation details are presented in Section 4.

The model specified in Section 3.1 defines which functions and objects are tracked, providing the needed information to install `onRun` hooks. Algorithm 1 illustrates what those hooks look like. As discussed, function `onRun` is invoked for each asynchronous operation NACD tracks. The first argument `op` is an object with all the needed information to run the asynchronous operation; in most cases, `op` refers to a callback, but may also refer to a promise (see pattern *returned promise*). The second argument `connected` is a Boolean value that specifies whether or not `op` is a connected callback. If `connected` is true, then the third argument `objectID` comes with an integer that uniquely identifies the object with which `op` may have other connected callbacks. During the instrumentation, NACD uses the model's information to identify connected callbacks, and it keeps track of instantiation of async objects so that unique IDs (`objectID`) are correctly assigned. In line 200, NACD checks if `op` is connected and invokes either `decideSimpleDelay` or `decideConnectedDelay`. These two cases are explained as follows.

```
165 const http = require('http')
166
167 const clientRequest = http.get('http://some.site/file.json', (res) => {
168    res.on('data', (chunk) => { ... })
169    res.on('end', () => { ... })
170 })
171
172 clientRequest.on('close', () => { ... })
```

Figure 11 Example of combining different code patterns.

```
173 const fs = require('fs')
174
175 const readStream = fs.createReadStream('some_file.json')
176 let rawData = ''
177 let pkg
178
179 readStream.on('data', function cbData(chunk) {
180    rawData += chunk
181 })
182
183 readStream.on('end', function cbEnd() {
184    pkg = JSON.parse(rawData)
185 })
186
187 readStream.on('close', function cbClose() {
188    useObject(pkg)
189 })
```

Figure 12 Example of connected callbacks.

Simple delays. This is the simple case where the delay NACD applies does not depend on any other operation. Algorithm 2 describes how NACD decides whether or not to delay an asynchronous operation `op`. Function `decideSimpleDelay` is called when an asynchronous operation `op` is about to run. First, function `makeChoice` makes random choices and returns a Boolean variable (`delay`) and an integer (`timeout`) (line 206). If `delay` is true (line 207), `op` is delayed for `timeout` miliseconds (line 208); otherwise, `op` is run immediately (line 210). We discuss how the random choices of function `makeChoice` are implemented in Section 4.

In NACD, this delay mechanism is applied in three different operations:

1. Callback: The async callback is completely independent; as such, any delay injected in it should not interfere with the execution, apart from delaying it.
2. Registration: In some cases we modeled, it is possible to delay the registration (start) of an asynchronous task. For instance, when deleting a file, NACD delays when this operation is actually run, not its callback. This may reveal race conditions outside of Node.js. These cases are marked with `postponeAction` in the model.
3. Promise: In this case, the returned promise has its fullfilment delayed. So, we simulate the case where the asynchronous task takes a longer time to complete.

Connected callbacks. We now describe how to inject delays while preserving the order of connected callbacks. In Algorithm 3, function `decideConnectedDelay` is invoked with callback `cb` and `objectID` that uniquely identifies the object with which `cb` has other connected callbacks. As this function is called before `cb` occurs, NACD labels it as not scheduled (line 213), retrieves a queue, or creates one if does not exist, identified by `objectID` (line 214). The retrieved queue is referred to as `q`. Then, it pushes `cb` to the end of this queue (line 215), and calls function `scheduleFirstOf` passing queue `q` as argument (line 216).

```
190 const fs = require('fs')
191 const expat = require('node-expat')
192
193 const parser = new expat.Parser('UTF-8')
194
195 fs.createReadStream('some.xml')
196   .pipe(parser)
197     .on('startElement', (name, attrs) => { ... })
198     .on('endElement', (name) => { ... })
```

Figure 13 Piping streams.

Algorithm 1 Function `onRun`.

```
199 Function onRun(op, connected, objectID)
200     if ¬ connected then
201         decideSimpleDelay(op)
202     else
203         decideConnectedDelay(op, objectID)
204     end
```

Function `scheduleFirstOf` is defined in lines 218–231. Initially, line 219 starts a loop that repeats while queue `q` is not empty. Within the loop, it peeks the first element `cb` of the queue, without removing it (line 220). If `cb` is not scheduled yet (line 221), NACD starts the scheduling and delay injection process. First, `cb` is labelled as scheduled so that this occurs only once (line 222). Similarly to function `decideSimpleDelay`, NACD decides to delay or not callback `cb` (lines 223–228). The difference here is that line 229 is run right after `cb` is actually run (delayed or not). So, `cb` is dropped from the queue (line 229), and the next callback (if exists) is processed in the next iteration of the queue loop (line 219). The idea is to push callbacks that share the same `objectID` to the same queue, while scheduling the first element to run and removing it when it is actually run. For instance, if NACD decides to delay the execution of a callback `c1`, the call to `scheduleFirstOf` will be waiting in line 225. Meanwhile, function `decideConnectedDelay` may be invoked again for a connected callback `c2`, which is then pushed to the same queue (line 215), followed by another call to `scheduleFirstOf` (line 216). At this point, NACD sees that the first element in the queue (i.e., `c1`) has already been scheduled but not yet executed, taking no action (false branch in line 221). When the waiting period in line 225 ends and `c1` is actually executed, `c1` is removed from the queue (line 229). Since `c2` remains in the queue, another loop iteration (line 219) occurs to process `c2`. This mechanism ensures that the queue preserves the callback ordering originally defined by the Node.js runtime, while NACD's function `scheduleFirstOf` delays callbacks, one at a time, without disrupting the queue order.

4 Implementation

NACD is implemented as a Node.js Command Line Interface (CLI) tool, with its main modules comprising approximately 1.3 KLoC written in JavaScript. The tool takes an entry script as input, which runs a Node.js application with potential event races. Entry scripts may be automated tests for the Node.js application being analyzed. We have successfully used NACD with automated tests created with well-known testing frameworks, such as Mocha, Jest, Jasmine, and Karma.

Algorithm 2 Function `decideSimpleDelay`.

```
205 Function decideSimpleDelay(op)
206 |  {delay, timeout} ← makeChoice()
207 |  if delay then
208 |  |  runAfterDelay(op, timeout)
209 |  else
210 |  |  runImmediately(op)
211 |  end
```

Algorithm 3 Function `decideConnectedDelay`.

```
212 Function decideConnectedDelay(cb, objectID)
213 |  cb.scheduled ← false
214 |  q ← getQueue(objectID)
215 |  q.enqueue(cb)
216 |  scheduleFirstOf(q)
217
218 Function scheduleFirstOf(q)
219 |  while q.isNotEmpty() do
220 |  |  cb ← q.peekFirst()
221 |  |  if ¬ cb.scheduled then
222 |  |  |  cb.scheduled ← true
223 |  |  |  {delay, timeout} ← makeChoice()
224 |  |  |  if delay then
225 |  |  |  |  runAfterDelay(cb, timeout)
226 |  |  |  else
227 |  |  |  |  runImmediately(cb)
228 |  |  |  end
229 |  |  |  q.removeFirst()
230 |  |  end
231 |  end
```

As mentioned in Section 3.1, the model of the Node.js Asynchronous API is stored in JSON files. To identify the core API that triggers asynchronous operations, we manually inspected the Node.js documentation,[11] source code,[12] and type definitions.[13] This research was conducted based on Node.js v.10. To avoid bias, the benchmarks in Section 5 were not used for this task. At the time of writing, the NACD's model includes 19 JSON files with around 2.2 KLoC, representing 46 async classes and 424 properties.

The runtime system of NACD modifies the Node.js module system to intercept module imports made by the application under test. When a module is imported, NACD checks its internal model and, if the module is one of interest, it injects specific hooks for the async classes and properties (the `onRun` hook shown in Section 3.2). To realize this functionality,

[11] `https://nodejs.org/api`
[12] `https://github.com/nodejs/node`
[13] `https://definitelytyped.org`

we leverage JavaScript's built-in Proxy[14] and Reflect[15] APIs. This design avoids the need for the fine-grained instrumentation techniques used in tools like NodeRacer, NodeRT, and NRace. Function `makeChoice` of Section 3.2 introduces a 50/50 probability of injecting a random delay between 0 and 500 miliseconds. NACD only instruments calls to the Node.js core API; it requires no modeling of third-party packages.

5 Evaluation

The evaluation of the proposed approach is based on the following research questions:

- **RQ1** To what extent is NACD capable of reproducing race bugs in Node.js applications?
- **RQ2** How many runs does NACD take to reveal a race bug?
- **RQ3** What is the overhead imposed by NACD?

These questions intend to analyze different aspects of NACD in comparison with similar state-of-the-art tools available for race detection in Node.js applications. **RQ1** aims to assess fault detection capabilities by analyzing how often the tools can reproduce known race bugs. In **RQ2**, we focus on how many runs each tool would take to first reveal a race bug. Finally, **RQ3** targets the runtime overhead observed when executing the race detection tools.

5.1 Experimental Setting

To answer **RQ1**, we made an experimental comparison of NACD with state-of-the-art tools Node.fz [9] and NodeRacer [11]. To do so, we reused the experimental package with 24 benchmarks provided by NodeRacer [11]. Each benchmark is a specific version of an open source Node.js application with a race bug, and an automated test that passes in ordinary runs (by using vanilla Node.js) and fails when the race bug is explored. Node.fz and NodeRacer were run with their default settings [9, 11]. As in [9, 11], we measured how many times a tool reveals the bug in 100 runs, i.e., bug reproduction ratio. The three tools make random decisions, so this step was repeated 30 times and median values with median absolute deviation (MAD) were calculated for the bug reproduction ratio of each tool, per benchmark. Using the same setup for **RQ2**, we measured the number of runs until the test first fails. It is desirable for a tool to reveal a bug with the fewest number of runs possible. In **RQ3**, we collected runtime data for the tools across 100 runs using GNU Time. We refer to the wall clock runtime (the "real" output of GNU Time) as *elapsed time*, and the actual CPU time consumed during execution without delays (the sum of "user" and "sys" outputs from GNU Time) as *CPU time*. To compute the overhead for these two metrics, we use benchmark data gathered from runs with vanilla Node.js as baseline. Analyzing overhead costs alone may fail to take the bug detection capabilities of each tool into account. For this reason, we also compute the overhead divided by the bug reproduction ratio collected for RQ1.

The development, tests, and experiments were conducted on a machine with an Intel i7-1260P (16 cores), 32GB of RAM, running Ubuntu 22.04. The NACD implementation and the experimental package are available at:

`https://github.com/andreendo/nacd`

[15] `https://developer.mozilla.org/docs/Web/JavaScript/Reference/Global_Objects/Reflect`

5.2 Analysis of Results

RQ1 – Bug Reproduction. Table 1 summarizes the comparison of NACD with Node.fz and NodeRacer. The first four columns characterize the benchmark: its ID, the project name, the GitHub issue ID that describes the race bug, and the number of lines of JavaScript code (LoC[16]). The next three columns show the results for each tool, each cell contains the median value (and its MAD between parentheses) of the bug reproduction ratio, i.e., how many times the tool is capable of revealing the bug in 100 runs. Overall, the three tools presented small variations in the results, as their MADs were at most 4% for Node.fz, 6% for NodeRacer, and 5% for NACD.

Node.fz was capable of running in only 8 benchmarks. This is because Node.fz was built on top of an early version of Node.js, so benchmarks adopting newer features are not compatible. For the 8 benchmarks, Node.fz's bug reproduction ratios were smaller than NodeRacer and NACD.

NodeRacer and NACD were compatible with all benchmarks. Benchmark #24 is a special case, as it has no race bug. Nevertheless, NodeRacer sometimes schedules the event handlers in a way that is impossible in ordinary executions, causing test failure to be mistakenly reported (i.e., false alarms) in 75% of the runs. We included the benchmark in the RQ1 experiments to show that NACD is not subjected to the same issue, as the test passed in all runs (ratio 0%). For the following discussion, the analyses are based on the 23 remaining benchmarks.

NACD had better bug reproduction ratio in 18 benchmarks (78%), in which it increased the ratio by on average +36% relative to NodeRacer. The improvements varied from +6% for Benchmark #3 to up to +79% in Benchmark #19. Proportionally, the greatest improvements occurred for Benchmarks #21 and #22. In both cases, NodeRacer would take 100 runs to expose the bug, while around 3 runs would be enough for NACD.

On the other hand, NodeRacer had a better performance in 5 benchmarks (22%), in which NACD had decreased the ratio by on average −28% when comparing to NodeRacer. The major difference was for Benchmark #11. NACD had a median bug reproduction ratio of 0% (though it had a ratio 1% in two of the 30 repetitions). This means that NACD could not reveal this race bug consistently. This occurred due to a file stream that is piped to another transform stream, a corner case for NACD (we discuss this limitation in Section 6). Yet, it is possible to extend NACD with a model of the library involved in the async behavior. With this extension, NACD is able to reproduce the bug consistently, in 100% of the runs. For the remaining 4 benchmarks, we manually inspected the code, logs and supporting artifacts generated by both tools, but found no discernible pattern. This may be explained by the fact that NACD and NodeRacer employ strategies that are fundamentally different, along with the random elements in their designs. Those factors introduce sufficient variation even in the same computing environment, as reflected in the MADs shown in Table 1.

Table 1 partially reproduces the bug reproduction experiments in [11], concerning Benchmarks #1–#11. For Node.fz, the results are essentially equal for 4 benchmarks (#2, #4, #6, #10), slightly better for #1 (from 8% to 11%), and slightly worse for #3 (from 26% to 15%) and #7 (from 1% to 0%). As for NodeRacer, the results are essentially equal for 2 benchmarks (#2, #6), slightly worse in 6 cases (with decreases varying from −2% to −6%), and better for Benchmarks #3 (+1%), #9 (+16%), and #10 (+19%). Overall, the ratios are similar with minor variations, though we recognize that the tool designs and the computing environment do have an impact.

[16] Data collected with the cloc tool.

[1]The issue IDs have links to the corresponding GitHub pages.

[2]Node.fz did not run with benchmarks marked with '-', as it is based on an outdated version of Node.js.

‡This bug was reported in a repeated issue, but is a different case (flaky test).

*This benchmark has no issue, reported as a false alarm in [11].

Response to RQ1: NACD is capable of uncovering race bugs without false alarms, being on average more effective than state-of-the-art tools Node.fz and NodeRacer. Particularly, NACD had the best bug reproduction ratio in 78% of the benchmarks, with improvements from 6% to up to 79%.

RQ2 – Number of runs until first failure. We also analyze the number of runs required for the race bug to first manifest (i.e., the test fails). This provides insight on how quickly each tool can uncover potential race bugs. Table 2 summarizes these results for each benchmark. Under each tool (columns 2–4), each cell shows the median number of runs until the first failure (and its MAD between parentheses). Similar to RQ1, Node.fz had results inferior to those of the others, and failed to reveal the bugs in Benchmarks #2, #4, and #10. NACD and NodeRacer had similar performance in 7 cases, where a single run was typically sufficient to uncover the bug. NACD had the best results in 12 cases, whereas NodeRacer outperformed it in 4 cases (#9, #11, #12, and #16). In Benchmarks #11, #12, and #16, NodeRacer also had a higher bug reproduction ratio, while NACD had a better ratio for Benchmark #9.

Table 2 Runs required for the bug to first manifest.

[1]Node.fz did not run with benchmarks marked with '-'.

**The bug was not revealed in 100 runs.

Observe in Table 2 that a higher median value is associated with greater variation (MAD). This suggests that results tend to vary more when the tool requires more runs to initially detect a bug. Also, notice that the bug reproduction ratio (Table 1) appears to be negatively correlated with the number of runs. For instance, ratios exceeding 50% are associated with fewer than 2 runs. On the other hand, lower ratios (close to 1%) require more than 40 runs to reveal the bug for the first time.

By aggregating the results of the 23 benchmarks, across all runs in applicable benchmarks, NACD revealed the bug within the first 25 runs in 95.7% of cases, compared to 87.3% for NodeRacer and 48.3% for Node.fz. Figure 14 shows the aggregated number of runs taken to uncover the bug, with the data limited to the first 25 runs for clarity. For each tool, it brings the boxplot, its distribution using violin plot, and the mean represented by a blue X. On average, Node.fz took 13.1 runs (median 7), its mean is out of the interquartile range due to outliers greater than 25. Next, NodeRacer needed fewer runs, 7.8 on average (median 2). It also had outliers to went up to 100 runs, making the furthest mean from the interquartile range. This wide range is due to NodeRacer having more benchmarks with values exceeding 3 than NACD, specifically the high values in Benchmarks #19–#23 (Table 2). NACD outperformed the previous tools, as it took on average 2.5 runs (median 1) to uncover

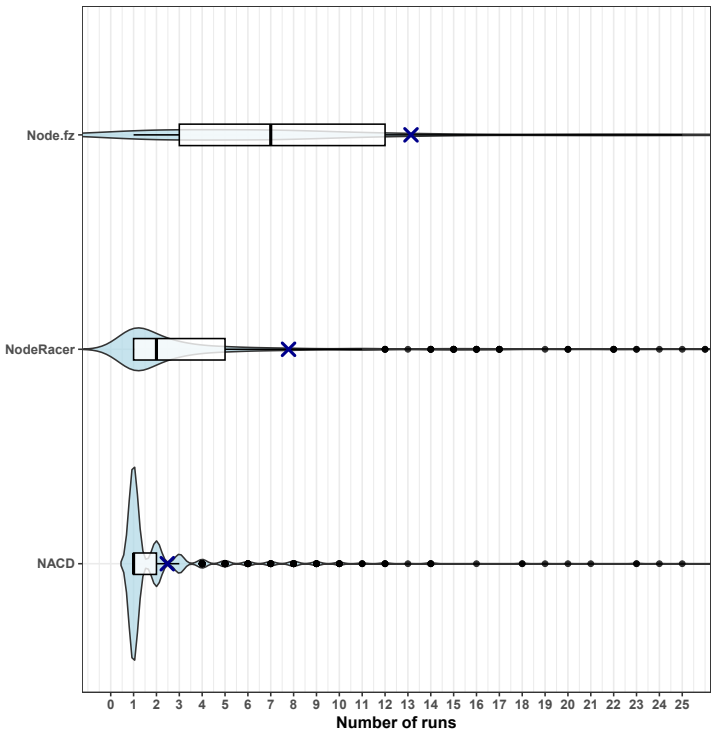

Figure 14 Runs required for the bug to first manifest.

the race bug. Its mean is the one closest to the interquartile range, since most data is concentrated on range 1–2, and only one outlier is above 25 (in one run for Benchmark #11, NACD took 61 runs).

Response to RQ2: To trigger the first failure, NACD performed as well as or better in 82.6% of the benchmarks, while NodeRacer achieved similar or better results in 47.8%. When considering the aggregated results across all 23 benchmarks, NACD can provoke the first failure faster than other state-of-the-art tools, taking an average of 2.5 runs.

RQ3 – Overhead. Using vanilla Node.js as a reference, the elapsed time for 100 runs across all benchmarks was on average 121.1 seconds, ranging from 64.9s in Benchmark #8 to 452.8s in Benchmark #13. For CPU time, the average was 29.8 seconds, ranging from 13.7s in Benchmark #4 to 51.7s in Benchmark #13. Table 3 summarizes the overhead-related results.

By aggregating the results of the applicable benchmarks, Figure 15 shows the overhead introduced by the tools with respect to executions with vanilla Node.js. As for the *elapsed time* observed in Figure 15a and listed in columns 2–4 of Table 3, Node.fz imposes the smallest overhead (median: 1.0x), followed by NodeRacer (median: 2.6x), and NACD (median: 3.7x). One reason for NACD's higher elapsed time is that it explores more opportunities to inject delays. Additionally, some benchmarks manifest race bugs through timeouts and hangs (observed in higher overhead of Benchmarks #2, #6, #7, #11, and #21), so NACD's high bug reproduction ratio (observed in RQ1) has a negative impact on this metric.

Concerning *CPU time* shown in Figure 15b and listed in columns 5–7 of Table 3, NACD generates the least overhead (median: 2.0x), followed by NodeRacer (median: 2.3x) and Node.fz (median: 3.2x). Surprisingly, Node.fz consumed more CPU time, as half of its

Table 3 Overhead results.

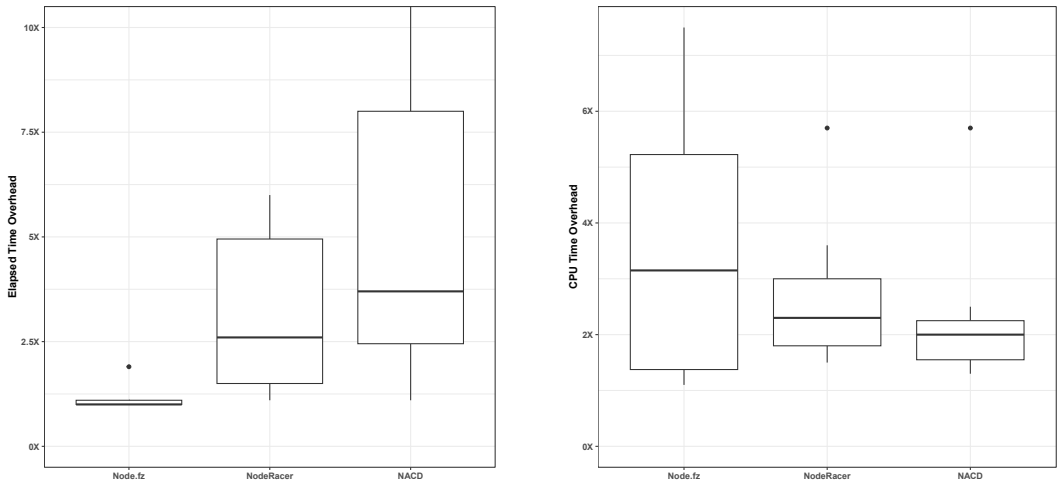
**It is not calculated since the bug reproduction ratio is 0.

benchmarks exhibited overheads exceeding 4.5x (Benchmark #10), moving the median upward. We surmise that since Node.fz is based on an outdated version of Node.js, it lacks optimizations introduced in newer releases, which affects certain benchmarks. Since NACD employs lightweight instrumentation and does not perform happens-before computations, it achieves lower CPU time overhead than NodeRacer in 19 out of the 23 benchmarks (82.6%). For the remaining 17.4%, NodeRacer was marginally better in Benchmarks #3, #9, and #13, while NACD exhibited a significant overhead of 37.1x in Benchmark #11, a limitation further discussed in Section 6.

By aggregating the results of the applicable benchmarks, Figure 16 illustrates the overhead related to the bug reproduction ratio. This provides a clearer perspective to the cost-effectiveness relation by examining the overhead through the lens of the tools' bug reproduction capabilities. As for the *elapsed time per bug reproduction ratio* shown in Figure 16a and listed in columns 8–10 of Table 3, NACD exhibits the smallest overhead (median: 0.05x), followed by NodeRacer (median: 0.08x), and Node.fz (median: 0.15x). Although there is a reasonable overlap in the interquartile ranges of the 3 tools, the NACD's range is below 0.25x



(a) Elapsed time. **(b)** CPU time.

Figure 15 Overhead introduced by the tools (measured relative to vanilla Node.js).

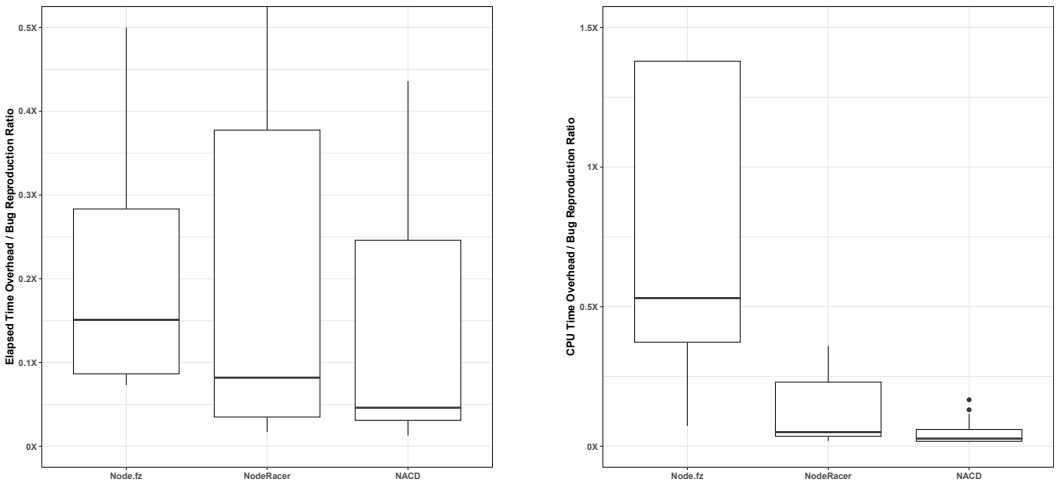
and its median is the lowest among the tools. In addition, NACD achieves the lowest overhead in 16 out of 23 benchmarks. Among the 7 benchmarks in which NodeRacer outperformed (#2, #6, #10, #11, #12, #15, and #16), it also had a higher bug reproduction ratio than NACD in 5 of them. In Benchmarks #2 and #15, NodeRacer exhibited lower overhead in terms of elapsed time (see columns 2–4 in Table 3).

Concerning *CPU time per bug reproduction ratio* presented in Figure 16b and listed in columns 11–13 of Table 3, NACD again has the lowest overhead (median: 0.03x), followed by NodeRacer (median: 0.05x) and Node.fz (median: 0.53x). Among the tools, NACD also exhibits the least data dispersion, as point out by its smallest interquartile range. Furthermore, NACD achieves the lowest overhead in 18 out of 23 benchmarks. Among the 5 benchmarks where NodeRacer performed better (#3, #10, #11, #12, #16), it also achieved the higher bug reproduction ratio in 4 of them. The improved performance in Benchmark #3 is due to NodeRacer's lower CPU time overhead (1.8x) compared to NACD's (2.0x) (see columns 5–7 in Table 3).

Response to RQ3: Node.fz and NodeRacer exhibit lower elapsed time overhead compared to NACD, while NACD consumes lower CPU time in most benchmarks. When considering overhead in relation to bug detection, NACD presents significantly better performance in terms of both elapsed time and CPU time for most benchmarks.

5.3 Threats to Validity

We here discuss threats to the validity of the experimental results. The implementation may be subjected to potential flaws, so we took several steps to minimize this threat. NACD was implemented with a logging feature so that all actions performed are logged for post-mortem analyses. Using this feature, we tested various examples across different functions within the Node.js core modules. Additionally, NACD comes with a suite of automated tests to verify the behavior of its classes.



(a) Elapsed time.

(b) CPU time.

Figure 16 Overhead in relation to bug reproduction ratio.

Node.fz and NodeRacer allow parameter adjustments that may alter their behavior. We adopted their default configuration, without any parameter fine-tuning. We believe this is a fair approach as most practitioners will likely use the out-of-the-box tools, and fine-tuning requires some expertise. Nevertheless, different configurations may yield varying results. For example, Node.fz could be parameterized to achieve better results under certain hypothetical circumstances. However, this is a challenging task, as it must be performed for each benchmark, and Node.fz has over 10 parameters that control complex operations within the Node.js runtime. All tools are subjected to randomness and may impact the results. This risk is mitigated by repeating the data collection for each pair tool-benchmark 30 times.

The benchmarks used in our experiments may not be fully representative, and results may not generalize in different contexts. We utilized the benchmarks provided by the NodeRacer study, which include race bugs from previous studies of Davis et al. [9] and Wang et al. [27], as well as additional bugs extracted from open source projects. All benchmarks are based on real-world Node.js projects, with corresponding issues documenting the race conditions.

We anticipate that the computing environment in which the experiments are run may also have some impact. To assist in replicating the results in future research, we have provided an experimental package, along with a detailed description of environment (e.g., computer configurations, software versions, and a Docker file).

6 Discussion

Evolution of Node.js core API. Node.js is an active distributed development project facilitated by the OpenJS foundation. As such, the platform has been actively evolved and the core API is subjected to modifications. As NACD relies on a model of the core API, the model itself needs to be updated to keep track of advances in the Node.js platform. Currently, this task can be performed manually by updating the NACD JSON model of the API. While inspecting the documentation, we simultaneously identified code patterns and developed the proposed approach. As a result, we do not have an accurate estimate of the effort spent building the current model. However, we predict that, once all code patterns are known, modeling each relevant function would take approximately 1–2 minutes. For this task, it

would be worthwhile exploring automation. A principled way could involve dynamic analysis to inspect the objects returned by the core API. We also anticipate that LLMs with access to up-to-date documentation may assist in this task.

Timers and scheduling functions. Node.js has several functions to define timers and schedule future tasks (e.g., `setTimeout`, `setImmediate`, `setInterval`, `process.nextTick`). These functions introduce asynchronous behavior and may involve complex happens-before relations [11, 30, 7], but we intentionally left them out of NACD to avoid this complexity. While event races may occur exclusively among them, most are in some way related to some I/O operation [27]. In the benchmarks, we did not miss any event race due to this design decision.

No observation phase. NACD starts to explore callback interleavings in the first run, as it does not require an observation phase like NodeRacer. This feature avoids false positives due to non-deterministic test setup (as in Benchmark #24), since NACD will inject delays only based on the current execution without querying happens-before relations built in a previous run. The absence of an observation phase also makes NACD more useful for executions that are hard to reproduce, such as a performance test that triggers multiple requests.

Limitation to handle pipe streams. As noted in Section 5, NACD was unable to consistently reproduce the event race in Benchmark #11. The race originates from the following context: there is a stream that reads data from a compressed (zip) file. This stream is piped into a transform stream, provided by the `unzip2` package, which splits the data and emits specific events for each XML file within the zip file. Each XML file is then parsed using the event emitter API of the `node-expat` package, where the event race occurs.

NACD can inject delays into the execution of the zip file stream, as the benchmark code uses the API provided by Node.js built-in module `fs`. Under normal circumstances, these delays help explore subsequent callback intervealings, even when the stream is piped to other streams. However, in this case, the `unzip2` transform stream emits an event only after all data chunks for an XML file have been read. This behavior prevents the injected delays from propagating to subsequent streams. In other words, the code being tested cancels the injected delays beyond that point, which afterwards effectively behave just like vanilla Node.js. A potential solution is to include the involved third-party packages in NACD's model. With this approach, we were able to reproduce the race bug consistently.

Asynchronous behavior out of the core API. In the Node.js and npm ecosystem, there are packages that work as wrappers for code in C/C++ or other programming languages. Asynchronous behavior may come from such a third-party code, and not from the Node.js built-in modules. In such situations, NACD would not know about it and no delay would be injected. While we did not observe this case in the benchmarks, this may occur in practice. To handle it, the developer would need to extend NACD's model by including information about the functions and classes that have asynchronous behavior in such packages.

7 Related Work

Race detection in JavaScript applications. The particularities of the single-threaded asynchronous model of JavaScript applications have been widely investigated to enhance programming tools and environments [29, 16, 17, 24, 3, 4, 5, 19, 26]. Specifically, the literature on race detection for JavaScript applications can be categorized into two main groups: client-side and server-side.

Race detection in client-side applications has been extensively explored. Tools like WebRacer [21] and EventRacer [22] leverage the WebKit browser framework to collect dynamic information and apply predictive techniques based on happens-before (HB) relations to detect event races. Both tools implement filtering mechanisms to minimize the detection of harmless races. To better identify harmful races, WAVE [13] and R4 [14] employ mechanisms to obtain observable manifestations, known as witness runs, that characterize such races. Similarly, RClassify [28], InitRacer [2], and AjaxRacer [1] aim to generate witness runs but rely on JavaScript code instrumentation instead of browser modifications.

In general, race detectors for client-side JavaScript applications need to simulate user actions, handle browser-specific API and integrated technologies like HTML and CSS, and adopt oracle mechanisms to flag harmful races. In contrast, NACD is designed for server-side applications in Node.js and does not adopt HB relations; yet, it aims for a witness run typically in the form of a failed test. Notably, many of those tools assume that the application under test lacks an automated test suite. However, with the widespread use of end-to-end (E2E) web testing in industry [15], we surmise that an approach with a design similar to NACD could be developed to detect race bugs also in client-side JavaScript applications.

In contrast to client-side tools, race detectors for server-side JavaScript start with an existing test or script that runs the application with potential event races. This is a plausible requirement since test suites are common in Node.js application development.

Given a test, some approaches rely on predictive strategies that, in general, observe the test execution as a reference run, reason about it using HB relations and heuristics, and report likely event races [6, 7, 30]. NodeAV [6] is the first initiative and targets violations on event groups that are supposed to be processed together but are not due to a race, i.e., atomicity violations. To obtain an execution trace, NodeAV initially instruments the application using Node.js experimental API Async Hooks along with the dynamic analysis framework Jalangi [23] to track reads and writes of memory locations and files. Using the trace, it establishes HB relations and the violation detection occurs by inferring atomicity intentions.

Differently from NodeAV, NRace [7] does not focus on a specific type of event race. Its detection method is based on conflicting operations that access memory or files and relies on optimizations to construct the HB graph faster than previous work. Nevertheless, its design is similar to NodeAV as it also adopts the Async Hooks API and Jalangi. NRace also applies some pattern-based heuristics to detect potential benign races and prune them.

NodeRT [30] advances the HB graph construction and race detection in order to reduce the overhead with respect to NRace. To do so, it simplifies the existing HB relation rules, and a partial HB-graph is built while the trace collection is performed. It also uses the Async Hooks API, but the instrumentation is performed using NodeProf [25].[17] The tool implements some matching rules that identify and remove race candidates that are false positives.

Although efforts have been made to reduce false positives, these predictive detectors still flag a substantial number of harmless races [30]. This is undesirable in practice because it often demands considerable developer effort to debug the code. Even worse, there is a high likelihood that the flagged issue is a harmless event race, leading to wasted resources. These tools primarily focus on the detection at the application code level, which leaves potential races that occur within library code or in its interaction with application code as an area for further investigation.

[17] NodeProf is a dynamic analysis framework for Node.js, built on top of GraalVM. Empirical results give evidence that NodeProf is faster than Jalangi [25].

NACD follows another approach to server-side race detection that instead performs dynamic exploration or fuzzing of callback interleavings [9, 11]. This kind of tools can be computationally expensive when many iterations are needed to uncover a race bug. On the other hand, by design, these techniques avoid false positives and provide actionable information in the form of witness executions of failed tests.

Node.fz [9] seeks to perturb the execution of an application by fuzzing the internal event scheduling mechanism of Node.js. Based on modifications in certain internal components of Node.js, Node.fz shuffles the queues related to the event loop, worker pool tasks, and done operations. By doing so, it intends to explore alternative schedules, amplify the non-determinism in Node.js, and expose event race bugs. A drawback of Node.fz is that it functions with a one-thread worker pool, which may limit the exploration of interleavings when the actual execution involves several workers. While NACD also avoids the use of HB relations, similar to Node.fz, it manipulates the execution using the knowledge of the asynchronous APIs provided by built-in modules. Unlike Node.fz, this is performed entirely through JavaScript code, without changing Node.js internals. This design choice improves the maintainability concerning the evolving Node.js ecosystem.

NodeRacer [11] operates in three distinct phases. In the observation phase, NodeRacer instruments all functions at the application code level, gathers asynchronous information using Async Hooks, and produces a log file. In the next phase, an HB-graph is created by applying happens-before relation rules while processing the log file. Finally, in the guided execution phase, reruns are executed using a dynamic HB-graph to decide whether to postpone the scheduled callbacks. If the HB-graph indicates that a callback may interleave with others, NodeRacer randomly decides whether to postpone the callback. As previously discussed, NACD can explore more callback interleavings since it does not rely on a previously observed run to postpone callbacks (see Section 2), and injects delays at the Node.js API level.

Other related work. As illustrated by the motivating example in Section 2, event races sometimes manifest as flaky tests. Several techniques have been developed specifically to detect concurrency-related flaky tests [10, 8]. Ganji et al. [12] propose code coverage criteria that are specific for asynchronous operations in JavaScript programs. Arteca et al. [5] have introduced an approach to generate automated tests for JavaScript code with asynchronous callbacks. It may be interesting to combine such techniques with event race detection tools like NACD.

8 Conclusion

In this paper, we have introduced NACD, an approach and tool to explore potential callback interleavings in Node.js applications. The main innovation of NACD comes from understanding that most of the asynchronous behavior in Node.js programs originates from the Node.js built-in modules. This leads to a simple and extensible design, consisting of a model of the asynchronous behavior present in the Node.js modules, combined with a JavaScript runtime system that injects random delays when the asynchronous functions and objects of those modules are used by applications and libraries. Experimental results using 24 benchmarks from prior work show that NACD is capable of uncovering race bugs more effectively than existing state-of-the-art tools.

One direction for future work is to improve the delay injection mechanism to make more informed decisions using contextual information (like code patterns, API used, run state) and history of previous runs; this has potential to reduce the need for more runs. As race

bugs in JavaScript and Node.js applications can be complex bugs, more research could be conducted to provide support for visualization, execution replay, pinpointing root causes, and proposing fixes. Such research may help to shed some light on the bug detection variations observed across different tools. It may also be interesting to conduct larger-scale studies to investigate how tools like NACD can support the diagnosis of open issues related to event race bugs. Finally, we anticipate that the ideas in the design of NACD can be applied not only to other JavaScript runtimes like Deno and Bun, but also to other software platforms that employ similar single-threaded event-driven architectures, such as, Flutter for Dart or FastAPI for Python.

Bottom-Up Synthesis of Memory Mutations with Separation Logic

Kasra Ferdowsi

Abstract

Programming-by-Example (PBE) is the paradigm of program synthesis specified via input-output pairs. It is commonly used because examples are easy to provide and collect from the environment. A popular optimization for enumerative synthesis with examples is Observational Equivalence (OE), which groups programs into equivalence classes according to their evaluation on example inputs. Current formulations of OE, however, are severely limited by the assumption that the synthesizer's target language contains only *pure* components with no side-effects, either enforcing this in their target language, or ignoring it, leading to an incorrect enumeration. This limits their ability to use realistic component sets.

We address this limitation by borrowing from Separation Logic, which can compositionally reason about heap mutations. We reformulate PBE using a restricted Separation Logic: Concrete Heap Separation Logic (CHSL), transforming the search for programs into a proof search in CHSL. This lets us perform bottom-up enumerative synthesis without the need for expert-provided annotations or domain-specific inferences, but with three key advantages: we (i) preserve *correctness* in the presence of memory-mutating operations, (ii) *compact* the search space by representing many concrete programs as one under CHSL, and (iii) perform a provably correct OE-reduction.

We present SOBEQ (*Side-effects in OBservational EQuivalence*), a bottom-up enumerative algorithm that, given a PBE task, searches for its CHSL derivation. The SOBEQ algorithm is proved correct with no purity assumptions: we show it is guaranteed to lose no solutions. We also evaluate our implementation of SOBEQ on benchmarks from the literature and online sources, and show that it produces high-quality results quickly.

1 Introduction

Program Synthesis is the task of automatically generating a program that satisfies a given specification. A popular specification modality for synthesizing general-purpose programs is input-output examples, where a solution is defined as a program that, evaluated on each provided input, produces the provided output. This is commonly referred to as

Figure 1 (a) Classical OE bank of programs with their observed evaluation results used to enumerate pure programs. Size 2 contains `arr.sort()` that sorts in-place, making compositions with it incorrect. (b) AST of the target program, divided into the variable states in which each subexpression is evaluated.

Programming-by-Example (PBE) [23, 16, 7, 21, 26]. PBE is notable because, unlike logic-based specifications [49, 56, 29], it does not require specialized knowledge to use, and values for it can be collected from a programming environment. It has been used to develop synthesizers for both end-users [23, 60] and programmers [17, 16, 12].

Consider a synthesis specification for a JavaScript program where, given an array of integers `arr` of length `n`, we want to return the sum of the smallest and largest elements of the array. We might specify this problem with the example:

$$\{\texttt{arr} \mapsto [10, 100, 90, -1, 2], \texttt{n} \mapsto 5\} \to 99$$

If we assume the value in `arr` is disposable, e.g., the program may sort it in place, the following is a solution that we would like to synthesize:

```
arr.sort()[0] + arr[n-1]
```

To solve this synthesis task, we can select a set of *components* (operations, library functions, etc.) and search the space of all programs constructed from those components. There are many ways to search, including constructing a representation of the space that can be traversed [15, 39, 23] and encoding the problem for a solver [56, 30]. Such approaches place heavy constraints on which components can be included. But the simplest form of search is to enumerate the space of programs [13, 19, 25, 52] by applying the components, then test resulting programs. Because the space of programs is astronomical, this approach is prohibitively slow when implemented naively. Moreover, most mechanisms to prune the space are domain-specific and restricted by the manual effort for handling each component individually.

Bottom-up Enumeration. One technique that does not require any domain-specific effort is *bottom-up enumeration* with an *Observational Equivalence* (OE) reduction [59, 2]. OE uses components to combine smaller programs into increasingly larger ones. To prune its search space, it maintains a bank of programs that are representatives of the *equivalence classes* of observationally equivalent programs, i.e., programs that, on the given inputs, evaluate to the same outputs.

New programs are obtained by applying components from the component set to smaller sub-expressions already in the bank. For example, in Fig. 1(a) applying `+` to the representative of equivalence classes ⟨5⟩ and ⟨10⟩ will yield the program `n + arr[0]`, which will be banked as the representative of equivalence class ⟨15⟩. The bank lets the enumeration memoize the

evaluation results of each program, and use them when evaluating larger programs, rather than re-evaluating each full program from scratch. The space is pruned by keeping only one program per equivalence class. Despite discarding many programs, this ensures no solution that existed in the un-reduced space is lost. Previous works use variations of this technique in synthesizers for C [59], Python [17, 16], JavaScript [45], Java [22], Selenium [36], and OCaml [2, 40].

Enumeration with heap mutations. The standard assumption of OE is that all components are *pure* and cause no side-effects [40, 17, 60, 59, 2, 36], and any mutations of the state in the target program are performed outside the synthesis task. Other synthesizers make assumptions on the intermediate states [16, 47], reducing the problem to synthesis of pure programs.

This is because OE has a fundamental limitation when handling mutating programs. Notice that JavaScript's `sort()` works in-place. In the example above, the call to `arr[n-1]` evaluates to a different value if evaluated before `arr.sort()` versus after it. A classical OE enumerator that performs its OE-reduction based on variable values in the inputs would consider `arr[n-1]` to be in the equivalence class $\langle 2 \rangle$. However, unlike its equivalent in languages like Python, `arr.sort()` also returns a self-reference, allowing the result to be composed into larger expressions, as in our target program. If the enumeration itself does not account for this, it will use the wrong memoized value computed using the unsorted value of `arr` in its candidates, yielding a result that does not actually satisfy the specifications. Moreover, the enumeration may see another program whose value is *really* $\langle 2 \rangle$, discard `arr[n-1]`, and never find this solution.

In other words, the classical bottom-up enumeration with OE described above is incorrect with memory mutations. This was also a problem in previous work: some synthesizers ignore the issue, leading to an incorrect enumeration [22, 45]. Peleg et al. [45], for example, allow JavaScript's in-place `sort()`, breaking their own purity assumption.

The key question addressed by this work, then, is how to correctly enumerate mutating programs without losing solutions while maintaining enough pruning to make the process tractable.

The Problem with Mutations. Classical OE considers only one memory state, the state both before and after evaluation of any expression. A composition with memory mutations, however, must consider a potentially different *after-state*. Fig. 1(b) shows this: sub-programs after a mutation are evaluated in a modified *before-state*, the after-state of the mutation. Since composition by the synthesizer simulates evaluation, composition with a mutating expression requires that the synthesizer to be aware of modified before-states. The synthesizer will need to generate complex expressions, e.g., `arr[n-1]` in Fig. 1(b), in a modified state.

Naively, we could store alongside each program not only its evaluation results, as in classical OE, but also its before- and after-state. While this would correct the equivalence relation and ensure programs are not erroneously discarded, the enumeration would still need to enumerate programs over and over: the program `n-1` that yields the result 4 would be enumerated both when `arr` is in its initial state and its modified state, and, as we do not know what the sequence of mutations in the target program will be (if any), in many other states as well. This is not only costly, as it creates many copies of the program in different equivalence classes, it is unnecessarily wasteful, since `n-1` is independent of the value of `arr`. We need an alternative equivalence reduction that both composes *valid* evaluation sequences, and constructs a *compact* program space.

Our approach. We introduce SOBEQ (*Side-effects in OBservational EQuivalence*), to our knowledge the first bottom-up proof-directed synthesis technique. SOBEQ is a bottom-up enumerative algorithm for expressions proven correct in the presence of mutating components.

A key insight of SOBEQ is that mutating operations only mutate a small portion of the state. If the variable state, usually considered as a variable valuation or a stack, is considered as a heap, then *Separation Logic*'s [51, 44] concept of *local reasoning* can be used to reason about programs in the synthesizer's space. The *Frame Rule* gives us the tools for a *compositional* application of operations, in much the same way that bottom-up synthesis already does for pure programs. Thanks to the Frame Rule, a compact representation of programs suffices, rather than considering the full variable valuation every time.

We define Concrete Heap Separation Logic (CHSL), a representation of the operational semantics of the language in the style of Separation Logic. For example, in CHSL we describe the mutating program `n++` evaluated on the example's input as the triple $\{\texttt{n} \mapsto 5\}\texttt{n++}\{\texttt{n} \mapsto 6; 5\}$ where the precondition $\texttt{n} \mapsto 5$ describes `n`'s initial value, and the postcondition $\texttt{n} \mapsto 6; 5$ describes its value after mutation and its result. Instead of searching for a program, SOBEQ searches for a CHSL derivation from inputs to outputs. Separation Logic has been used in program synthesis before [49, 29], including where information from the environment can be leveraged as a SL specification [20]. But previous work performed the proof search *deductively*, applying manually-crafted inference rules. The concrete heaps of CHSL allow SOBEQ to instead search the proof space bottom-up, composing larger programs from smaller ones, and relying only on program evaluation, like a classical OE search does. CHSL gives SOBEQ two key advantages over classical bottom-up synthesis.

Correct composition via logic. First, SOBEQ's bank stores CHSL triples rather than programs. To build larger programs, SOBEQ also applies each component to smaller triples in the bank, but unlike simple programs, triples can only be combined according to the rules of the logic. This means programs always compose in a way that forms a valid evaluation, and there is no risk of evaluating a program in the wrong state. Moreover, OE can be determined by simply ignoring the program and comparing the specifications surrounding each triple: two programs with the same pre- and postcondition are guaranteed to behave the same, and will also compose the same. This maintains SOBEQ's *correctness* in the presence of mutations.

Local reasoning. Second, thanks to the Frame Rule, CHSL can reason about the local effects of programs: triples do not need to store parts of the state that the program does not touch. For instance, $\{\texttt{n} \mapsto 5\}\texttt{n++}\{\texttt{n} \mapsto 6; 5\}$ does not specify anything about `arr`, because `n++` will behave the same way in all concrete states where the value of `n` is 5. This representation is *compact*, with each triple describing the behavior in many, potentially infinitely many, concrete states. This makes it much easier for SOBEQ to find programs that use variables after a mutation occurs, like our example, compared to the naive solution of enumerating using the full before- and after-states. This local reasoning also allows us to prioritize more general programs: ones that provide the same result and the same mutations for more concrete states. Discarding the less general programs lets us compact the space even further.

Our implementation. We implemented SOBEQ as a synthesizer for JavaScript programs that can create non-pure expressions, including sequences of expressions. We evaluated our synthesizer on 63 benchmarks curated from the literature, from STACKOVERFLOW and from competitive programming website LEETCODE. Compared to state of the art synthesis

$\texttt{arr} \mapsto [-1,2,10,90,100] * \texttt{n} \mapsto 5$:	$\{\texttt{arr} \mapsto [-1,2,10,90,100] * \texttt{n} \mapsto 5; 100\}$ `arr[n-1]`	⋯

Figure 2 The precondition bank used to enumerate the program in Fig. 1(b). Each program is additionally labeled with its postcondition comprising an assertion and its result.

of general mutations, SObEq returns more concise and higher quality solutions, with less overfitting and without performing spurious operations, on both tasks that require and do not require mutations. Importantly, SObEq is both deterministic, meaning it will more reliably integrate with a larger tool, and proved correct, meaning that it will never discard all solutions to a task while exploring the space.

Contributions. The main contributions of this paper are as follows:

- A formulation of the PBE problem with memory mutations as the search for a derivation in a restricted Separation Logic, CHSL.
- The SObEq algorithm, a bottom-up enumerative algorithm that searches for a derivation with a proven-correct OE-reduction.
- An implementation of SObEq in a JavaScript synthesizer, and an evaluation on 63 benchmarks curated from the literature, StackOverflow and LeetCode, which shows that SObEq outperforms state of the art on a variety of synthesis tasks with and without mutations, and highlights the class of tasks for which a naive approach would fail.

2 Overview

In this section, we present SObEq through the example introduced in Sec. 1. First, we present SObEq's notation for mutating programs, which is compact compared to the real space of programs. Next, we show how this helps us enumerate programs correctly. Finally, we show how ordering programs by generality helps us prune the space even further.

2.1 Mutating programs

We begin with a reminder of programs and their construction in Observational Equivalence [2, 59], then show how we modify them to correctly reason about side-effects.

Classical OE-reduction and the program bank. Bottom-up enumeration with an OE-reduction uses a component set $\mathcal{C}$ comprising functions, operators, variables, and literals, to search for a program specified by a vector of input-output examples, $\vec{\mathcal{E}}$, where each example is of the form $\iota \to \omega$. For each program we compute its equivalence class's label. In classical

OE, we use its evaluation result, $[\![p]\!](\iota)$, for each ι in $\vec{\mathcal{E}}$. In our example, the expression `arr` has the *observed behavior* $[10, 100, 90, -1, 2]$ on the provided input, so its equivalence class is $\langle[10, 100, 90, -1, 2]\rangle$.

To enumerate the space of programs, we use a *bank* to store representatives of equivalence classes, as seen in Fig. 1(a). For each function or operator $f \in \mathcal{C}$ with arity k, we collect all k-tuples of programs already in the bank and use them as arguments to apply f. This is usually done with some notion of iterations, e.g., as in Fig. 1(a), by increasing number of AST nodes. When enumerating programs of AST size 5, then, the enumerator considers the component array dereference (`[]`), which has an arity of 2. Among pairs of programs collected from the bank with a total size of 4 will be the program `arr`, representative of the equivalence class $\langle[10, 100, 90, -1, 2]\rangle$, and the program `n - 1`, representative of $\langle 4\rangle$. Applying array dereference yields `arr[n - 1]` with the observed behavior $\langle 2\rangle$. Crucially, we do not have to evaluate the full program `arr[n - 1]` to get this value: we can use observed values $[10, 100, 90, -1, 2]$ and 4 and only compute the final step.

When the enumeration finds a program from an equivalence class with no representative in the bank – i.e., no program in the bank has the same label – it is added to the bank to be used when constructing larger programs. This is the case with `arr[n - 1]`, which is added to the bank at size 5. Alternatively, if a representative of the equivalence class already exists in the bank, we discard the new program. If a program's observed values are equal to the provided outputs, the program is a solution. Since we only use discovered equivalence classes (i.e., programs) to construct larger programs, the effect of OE's pruning compounds.

The problems with side-effects. We quickly run into issues when $\mathcal{C}$ contains functions or operators that can cause side-effects. The next step in solving our example is to enumerate `arr.sort()[0] + arr[n - 1]`. But, as we are about to see, using the classical approach this program will not be evaluated correctly, and it may even be pruned away.

We already saw how the subprogram p_1 = `arr[n - 1]` was enumerated and labeled $\langle 2\rangle$, and p_2 = `arr.sort()[0]` will be enumerated similarly: at size 4, it will be composed from `arr.sort()` (size 2) and `0` (size 1), and added to the bank as a representative of $\langle -1\rangle$.

The first source of trouble is that OE is a dynamic programming algorithm: when constructing the larger p_2 `+` p_1, the enumerator uses the memoized observed values to compute: $\langle -1 + 2\rangle = \langle 1\rangle$. However, since p_2 modifies `arr`, p_2 `+` p_1 *actually* evaluates to 99 on the input ι. Worse, this erroneous value means the synthesizer will consider p_2 `+` p_1, our solution, equivalent to p_1 `+` p_2 so it may be discarded. While a seemingly simple solution is to just evaluate the program in full each time, ensuring labels are correct, this is not only expensive, depending on the operation, but more importantly, insufficient. If the synthesizer sees the constant value 2, e.g., by enumerating `1 + 1`, this would cause the larger – and seemingly equivalent – `arr[n - 1]` to be discarded. OE hinges on the enumeration only discarding a program when it already has a suitable replacement, but `arr[n - 1]` evaluated *after* `arr.sort()` would still have no equivalent program in the bank.

Rethinking the program representation. Our problem was not distinguishing between the *same* program when evaluated using *different* values of `arr`. We also saw in Sec. 1 the need for distinction between programs that return the same value, but their *effect* on variables is different, e.g., `n` and `n++` when evaluated using the same value of `n`.

We replace programs with triples in Concrete Heap Separation Logic (CHSL): the precondition records the variables before its evaluation, and the postcondition comprises an assertion recording the variables after evaluation and the result of the evaluation, like so:

$$\{\texttt{arr} \mapsto [10, 100, 90, -1, 2]\}\texttt{arr.sort()}\{\texttt{arr} \mapsto [-1, 2, 10, 90, 100]; [-1, 2, 10, 90, 100]\}$$

From here on, we name the original array value arr_{orig} and its sorted value arr_{sort}, and use them in our examples and figures for brevity. In this representation, we can tell apart these two triples:

$$\{\texttt{arr} \mapsto arr_{orig}\}\texttt{arr}\{\texttt{arr} \mapsto arr_{orig}; arr_{orig}\} \qquad \{\texttt{arr} \mapsto arr_{sort}\}\texttt{arr}\{\texttt{arr} \mapsto arr_{sort}; arr_{sort}\}$$

where the first is `arr` evaluated on the original array, returning the original array value, and the second is evaluated on a state where the array has been sorted, returning the sorted value. We use the second triple to construct larger programs evaluated after `sort()`.

Notice that since all values are concrete, CHSL does not need domain- or library-specific inference rules to connect the pre- and postcondition of the triple, but can rely entirely on evaluation.

Local reasoning. These pre- and postconditions do not encode fully-concrete states, they leave `n` unconstrained. This makes our representation of the space more compact: the triple $\{\texttt{arr} \mapsto arr_{orig}\}\texttt{arr.sort()}\{\texttt{arr} \mapsto arr_{sort}; arr_{sort}\}$ takes advantage of the fact that only constraining `arr` is sufficient to reason about the behavior of this program. We only need to constrain the *footprint* of the program.

CHSL includes the notion of the separating conjunction $*$ to indicate separate parts of the heap (or, in our case, variable store) that can be reasoned about locally. Thanks to aliasing restrictions of the synthesizer's target language detailed in Sec. 3.1, any two variables can be separated with $*$. E.g., the assertion $\texttt{arr} \mapsto arr_{orig} * \texttt{n} \mapsto 5$ describes the concrete initial state. Once we replace the programs in our bank with CHSL triples, we can now further borrow from Separation Logic when considering evaluation sequences.

2.2 Enumeration and heaps

A bottom-up enumeration composes larger programs from smaller ones by selecting a sequence of arguments to apply functions or operators f to. In a classical enumeration, our bank contains programs, so if we wish to apply `+` to two programs in it, this is only a matter of creating the new program p_1 `+` p_2. When executing p_1 `+` p_2 on some variable valuation, the runtime first evaluates p_1, then p_2, then their addition. The classical OE enumeration duplicates this by summing the evaluation result banked for p_1 to that banked for p_2. Without mutations, this is correct for all orderings of arguments to `+` as all the programs evaluate from the initial state and to the initial state, so their results can always be memoized in the bank.

Now that our bank comprises CHSL triples, however, the enumeration needs to apply f to triples, not programs. Here, we have to be more careful. Let us consider two programs in our space, `arr[0]` and `arr.sort()[0]` enumerated with classical OE in Fig. 1(a). In our new bank, they are now the triples:

$$tr_1 = \{\texttt{arr} \mapsto arr_{orig}\}\texttt{arr[0]}\{\texttt{arr} \mapsto arr_{orig}; 10\}$$
$$tr_2 = \{\texttt{arr} \mapsto arr_{orig}\}\texttt{arr.sort()[0]}\{\texttt{arr} \mapsto arr_{sort}; -1\}$$

First, we consider what applying `+` to a pair of triples means: applying it to (tr_1, tr_2) as arguments means trying to create `arr[0] + arr.sort()[0]`, or applying `+` to the program components of the triples. However, unlike the mutation-free case, not every pair of triples with those two programs can create this application. We expect a sequence of arguments to a component to describe a real evaluation of those arguments.

This is akin to creating a valid composition or sequence in Separation Logic, the postcondition of each argument must be equal to the precondition of the next one in the sequence; this means all mutations are accounted for. For (tr_1, tr_2), this is not a problem: $\texttt{arr} \mapsto arr_{orig}$ is

the after-state of tr_1 and the before-state of tr_2, which means that their sequence mutates the state from the precondition of tr_1 to the postcondition of tr_2, and they can be used in the application of any component, e.g., `+`, with the values memoized in the triple, so we add the two precomputed results $10 + -1$, and get:

$\{\texttt{arr} \mapsto arr_{orig}\}\texttt{arr[0] + arr.sort()[0]}\{\texttt{arr} \mapsto arr_{sort}; 9\}$

However, we cannot compose (tr_2, tr_1) in the same way: `arr.sort()` mutated the state, changing the value of `arr` to arr_{sort}, so tr_1, whose memoized result was computed where `arr` is arr_{orig}, cannot follow it. Requiring arguments to a component to form a valid sequence ensures that only valid executions are enumerated by the synthesizer. The enumerator will not try to compose (tr_2, tr_1) under any binary operator, but can – and will – select (tr_1, tr_2) as arguments to `+`. Once a new program is composed, the enumerator invokes the language interpreter to evaluate the composition from the values of its arguments, yielding a triple containing the result and compound effect of the arguments and operation. We denote this invocation the Eval inference rule.

If we partition our bank of programs by the program's precondition, as in Fig. 2, then the enumerator can always create correct sequences of arguments by construction, using a triple's postcondition to fetch all suitable next arguments according to their precondition.

Discovering more preconditions. Let us consider the last subprogram of our target program: `arr[n - 1]`. It is going to be added with `arr.sort()[0]`, which means that for that composition to be allowed, it must match the state after `arr` is sorted. Specifically, we consider the first argument of the array dereference, which will be needed to enumerate it:

$tr_3 = \{\texttt{arr} \mapsto arr_{sort}\}\texttt{arr}\{\texttt{arr} \mapsto arr_{sort}; arr_{sort}\}$

Importantly, this triple will never be enumerated if the enumerator only considers triples starting at a precondition describing the initial state, but without it we will never find the target program.

We have to ensure, therefore, that we also enumerate programs that have other preconditions. tr_3 is a necessary building block for such programs.

To this end, whenever a new assertion is discovered by the enumerator, e.g., when a mutating component is evaluated, creating a never-before-seen assertion in the postcondition, as enumerating $\{\texttt{arr} \mapsto arr_{orig}\}\texttt{arr.sort()}\{\texttt{arr} \mapsto arr_{sort}; arr_{sort}\}$ does, we get ready to enumerate programs that *begin* in this new assertion: we create tr_3, which any program starting at $\texttt{arr} \mapsto arr_{sort}$ will need to incorporate, and add it to the bank, which also adds $\texttt{arr} \mapsto arr_{sort}$ to the bank as a precondition. The next time the enumerator selects arguments to an operator, tr_3 will be available. This lets the enumerator create programs that begin at $\texttt{arr} \mapsto arr_{sort}$.

Programs with different footprints. Now that we have tr_3, the first argument to the array dereference, let us consider the second:

$\{\texttt{n} \mapsto 5\}\texttt{n - 1}\{\texttt{n} \mapsto 5; 4\}$

We enumerate this program at the initial value of `n`, i.e., without the need for its precondition to be discovered. However, when the enumerator tries to compose it with tr_3 into a sequence of arguments to `[]`, it runs into a problem: the two triples do not make a valid sequence. The assertion in the postcondition of the first argument, $\texttt{arr} \mapsto arr_{sort}$, is different than the precondition of the following argument, $\texttt{n} \mapsto 5$.

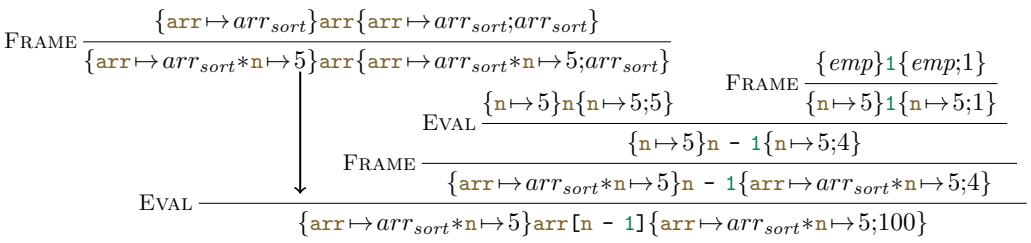

Figure 3 Using Frame and Eval to enumerate `arr[n - 1]`. Recall arr_{sort} denotes the constant value $[-1, 2, 10, 90, 100]$ for brevity.

However, we clearly see that these two assertions deal with separate parts of the heap, and do not interfere with each other. This is where we draw on Separation Logic's powerful tool: the Frame rule. Since these are separate parts of the heap, we can use the separating conjunction to create a unified heap in the pre- and postcondition of both triples. The more constrained triples are now composable, so the enumerator can apply array dereference and Eval, yielding:

$$\{\texttt{arr} \mapsto arr_{sort} * \texttt{n} \mapsto 5\}\texttt{arr[n - 1]}\{\texttt{arr} \mapsto arr_{sort} * \texttt{n} \mapsto 5; 100\}$$

The full derivation is shown in Fig. 3. Then similarly, the same extension – now adding $\texttt{n} \mapsto 5$ to tr_2 and nothing to the second argument – is applied to allow the enumerator to compose the target program. This is an important strength of our technique: the same triple for `n - 1` can compose with any value for `arr` – we will only enumerate it once!

We notice that in this case, this will discover a new assertion not as a postcondition as we did when `sort()` mutated `arr` but as a precondition. Once the program is added to the bank, the enumerator will continue to enumerate more programs with this new assertion as their precondition.

2.3 Equivalence and mutation

So far, we showed how the enumerator composes programs, but we did not show how the OE-reduction works. Now that we have a new representation of programs, we can re-define how each triple is observed and labeled, so that the label vector suits our needs.

In classical OE, the observed value for each example is the program's evaluation result, but this is now insufficient: while in the precondition $\texttt{arr} \mapsto [10, 100, 90, -1, 2]$ the program `arr[1]` evaluates to 100, if we discard all the following programs that evaluate to 100 we will also discard the `arr[n - 1]` that is evaluated on a sorted array. Likewise, `n` and `n++` with the same precondition are distinct in that they return the same value given the same precondition, but have a different effect on the state.

Generally, we can see that we can label a triple with its pre- and postcondition, including the result. Once those are identical, any programs that form a valid triple with them would be *interchangeable*, i.e., can be swapped for each other with no change to a larger evaluation. In Fig. 2, the precondition component is expressed by the precondition the triple is stored under in the bank, while the postcondition appears above each program.

Generality of equivalence classes. The equivalence class labels above define an *equivalence relation* for OE. However, in this setting, we can do even better: there are cases where we want to discard programs even though one is not equivalent to the other. Let us consider two triples:

$$tr_4 = \{\texttt{n} \mapsto 5\}\texttt{n - n}\{\texttt{n} \mapsto 5; 0\} \qquad tr_5 = \{emp\}\texttt{0}\{emp; 0\}$$

where *emp* is the unconstrained heap.

Both triples have the same evaluation result (0), and the same effect (no effect), but different assertions at the pre- and postconditions. But they are not completely different: if we select a *frame axiom* $R = \texttt{n} \mapsto 5$, we can bridge their difference: $\{emp * R\}\texttt{0}\{emp * R; 0\}$ is equivalent to tr_4. Under this condition, we say that tr_5 is more general than tr_4: it describes a program that behaves the same over more concrete states. If we let the more general equivalence class *subsume* less general ones, we further compact our representation of the space while remainting correct. While we cannot tractably apply this additional reduction to the entire space, we can at least discard less general programs once more general ones exist in the bank.

Temporary values and variables. This tactic cannot stand on its own: naively employing it means $tr_6 = \{emp\}\texttt{5}\{emp; 5\}$ subsumes $tr_7 = \{\texttt{n} \mapsto 5\}\texttt{n}\{\texttt{n} \mapsto 5; 5\}$ in the same way. However, in Fig. 2 similar subsumptions do not happen: $\{emp\}\texttt{-1}\{emp; -1\}$ does not subsume $\{\texttt{arr} \mapsto arr_{sort}\}\texttt{arr[0]}\{\texttt{arr} \mapsto arr_{sort}; -1\}$ and $\{\texttt{arr} \mapsto arr_{orig} * \texttt{n} \mapsto 5\}\texttt{arr[n - (1+1)]}\{\texttt{arr} \mapsto arr_{orig} * \texttt{n} \mapsto 5; -1\}$, which are still in the bank. Why?

We notice that if these subsumptions are allowed, the programs will no longer be interchangeable, and some will break entirely. Consider the application of `++`: while $\{\texttt{n} \mapsto 5\}\texttt{n++}\{\texttt{n} \mapsto 6; 5\}$ uses tr_7 as its argument, `5++` using tr_6 does not compile. Likewise, replacing `arr` within `arr.sort()` with the array literal with `arr`'s value would produce a different mutation of the heap, indicting they should be separate programs. The difference, which must be encoded into our representation, is what is *reachable* from state variables, and if so, from *where*.

Our evaluation result therefore comprises two components: the *value* returned by evaluation, and the *location* of that value. tr_3, then, returns $arr_{sort}@arr$, and tr_7 returns $5@n$. This ensures the interchangeability within `++` or `sort`: the new program will not only compile, it will affect the same variable.

What, then, should be the location of a temporary variable, i.e., a variable that is not reachable from the stack? We must consider the location's purpose: to separate programs enough to preserve interchangeability when the heap is mutated. Two temporary values, on the other hand, are (inherently) interchangeable, so we do not want to over-separate them which would inflate the number of equivalence classes in the bank. We therefore give all temporary values the *same* location: $\bot$. This way, tr_4 and tr_5 both return $0@\bot$, preserving the subsumption, and tr_6 returns $5@\bot$ which separates it from tr_7.

Fig. 2 omits this for simplicity, but does still separate $\{emp\}\texttt{-1}\{emp; -1\}$ with result $-1@\bot$ from $\{\texttt{arr} \mapsto arr_{sort}\}\texttt{arr[0]}\{\texttt{arr} \mapsto arr_{sort}; -1\}$ with result $-1@arr[0]$ and from $\{\texttt{arr} \mapsto arr_{orig} * \texttt{n} \mapsto 5\}\texttt{arr[n-(1+1)]}\{\texttt{arr} \mapsto arr_{orig} * \texttt{n} \mapsto 5; -1\}$ with result $-1@arr[3]$.

Defining the Solution. We are almost finished: like classical OE, we continue iteratively enumerating programs into the bank until a solution is found. Our final step is to reconsider the definition of a solution to a synthesis specification.

Input variables	Identifiers $x \in \mathcal{V}$
Literal values	$v \in \mathcal{K}$
Assertion	$a \in \mathcal{A} ::= emp \mid x \mapsto v * \mathcal{A}$
Assertions	$\vec{a}, \vec{P}, \vec{Q} \in \mathcal{A} \times \cdots \times \mathcal{A}$
Location	$l \in \mathcal{M} ::= \bot \mid x \mid x[n]$, n is an integer literal
Result	$r \in \mathcal{R} ::= v@l$
Results	$\vec{r} \in \mathcal{R} \times \cdots \times \mathcal{R}$
Postcondition	$\{\vec{Q}; \vec{r}\}$

$$\frac{\{\vec{P_1}\}p_1\{\vec{P_2};\vec{r_1}\} \;\; \{\vec{P_2}\}p_2\{\vec{P_3};\vec{r_2}\} \;\; \cdots \;\; \{\vec{P_k}\}p_k\{\vec{P}_{k+1};\vec{r_k}\} \quad c \in \mathcal{C}, arity(c) = k \quad \forall i.(c(r_1^i, \ldots, r_k^i), P_{k+1}^i) \to (r^i, Q^i)}{\{\vec{P_1}\}c(p_1, \ldots, p_k)\{\vec{Q};\vec{r}\}} \textsc{Eval}$$

$$\frac{\{\vec{P}\}p\{\vec{Q};\vec{r}\}}{\{\vec{P} * \vec{R}\}p\{\vec{Q} * \vec{R};\vec{r}\}} \textsc{Frame}$$

Figure 4 CHSL syntax and inference rules.

When enumerating a program in a non-mutating space with an OE-reduction using the examples' inputs, a solution is a program that is labeled by (i.e., that evaluates to) the provided outputs. In SOBEQ this is insufficient: the enumerator can find a triple returning the correct value in *some* precondition. To be correct when evaluated on the concrete example inputs, we require that a solution's precondition describe the concrete initial state ι. In our example, `arr` $\mapsto arr_{orig} *$ `n` $\mapsto 5$ trivially describes ι – it is equal to it – but so does `n` $\mapsto 5$.

Thus, to be a solution, a triple must: 1) return the values of the example outputs, and 2) have a precondition that describes ι.

SOBEQ is, to our knowledge, the first proof-directed synthesis algorithm that works bottom-up. It is also the first bottom-up enumerative synthesizer for general mutating components with a correctness guarantee: if a solution exists in the space spanned by $\mathcal{C}$, SOBEQ will find an equivalent solution.

3 Enumerative Synthesis and Heap Mutations

In this section we define the basic elements with which we construct SOBEQ: programs and their evaluation, and the synthesis task.

3.1 Concrete Heap Separation Logic

In this section, we introduce Concrete Heap Separation Logic (CHSL), a notation for operational semantics in the style of Separation Logic. Its syntax and two inference rules are showin in Fig. 4.

The heap. In CHSL, we use a heap notation to reason about the concrete values assigned to variables from the input. We can reason locally about each individual variable because SOBEQ's target language does not allow assignments, and so as long as nothing is aliased at the input – we can enforce this when generating the synthesis task – each variable is separate from all others and can be separated from them with a separating conjunction, $*$.

CHSL assertions. CHSL reasons about concrete values assigned to variables. As such, a CHSL assertion comprises heaplets of the form $x \mapsto v$ where v is a concrete value.

This also means we can trivially transform a state (partial function) σ into an assertion describing an identical heap s.t. $x_1 \mapsto \sigma(x_1) * \cdots * x_n \mapsto \sigma(x_n)$ for all $x_i \in \text{dom}(\sigma)$. We use the function interchangeably with its assertion equivalent, i.e., σ as a shorthand for the assertion above.

For a vector of states $\vec{\sigma}$, corresponding to the vector of examples $\vec{\mathcal{E}}$, CHSL likewise uses a vector of assertions. We therefore also define a vector separating conjunction s.t. $\vec{P} * \vec{R} = \langle P_i * R_i \rangle_i$.

Values with location. In the presence of mutations, we must also consider that some values are reachable from our heap. As shown in Sec. 2, this is important for components that modify their arguments (e.g. `arr.sort()`), especially components that return a self-reference and are therefore composable, as in `arr.sort().reverse()`, where both `sort` and `reverse` mutate `arr`.

To support this, a result $r \in \mathcal{R}$ comprises two components: a *value* and that value's *location*, $l \in \mathcal{M}$ that can be a variable, a variable at a *concrete* index, or $\perp$. We use $\perp$ to indicate a value not reachable from any variable, i.e., a temporary value. We decompose the result as $r = v@l$. As with variable values, the values in results are concrete.

Triples. A triple in CHSL comprises a precondition $\vec{P} \in \mathcal{A}^k$ (where $|\vec{\mathcal{E}}| = k$), the program p, and a postcondition. Our postconditions have two components: i) an assertion $\vec{Q} \in \mathcal{A}^k$, and ii) the evaluation results of p on $\vec{P}$. Vectors of assertions and results form a conjunction: $\{\vec{P}\}p\{\vec{Q}; \vec{r}\}$ means all triples $\{P^1\}p\{Q^1; r^1\}, \{P^2\}p\{Q^2; r^2\}, \ldots, \{P^k\}p\{Q^k; r^k\}$ hold.

We call the subset of each assertion Q whose values are different from P the *effect* of the program on P. For example, in the triple $\{\texttt{x} \mapsto 1 * \texttt{y} \mapsto 2\}\texttt{x++ + y}\{\texttt{x} \mapsto 2 * \texttt{y} \mapsto 2; 3\}$ the effect is $\texttt{x} \mapsto 2$.

We consider $\{\vec{P}\}p\{\vec{Q}; \vec{r}\}$ to be a *valid* triple if it accurately tracks the evaluation of p on $\vec{P}$. In other words, assuming a (deterministic) small-step operational semantics for programs the behavior of which is defined by the interpreter of the language: $\rightarrow : (\mathbb{P}, \mathcal{A}) \rightarrow (\mathcal{R}, \mathcal{A})$, we say $\{\vec{P}\}p\{\vec{Q}; \vec{r}\}$ is valid if $\forall 1 \leq i \leq k.(p, P^i) \rightarrow (r^i, Q^i)$.

Because SObEq will be *enumerating* triples, it is crucial that it can construct valid triples.

The Eval rule. When constructing a new triple, the Eval rule denotes the use of the interpreter to ensure the resulting triple is valid. Because an evaluation of an AST node will first evaluate its children in sequence, then use the results to evaluate the node's operation, Eval requires a sequence of triples. As in the classical Hoare Logic Sequence rule, Eval requires matching midconditions. However, since we often want to form a sequence from triples where $Q_i \neq P_{i+1}$, we use the Frame rule to find a larger composed heap where the midconditions do match.

The Frame rule. Generally, all triples in the space contain only their footprint in their pre- and postcondition. As the example in Fig. 3 shows, in this compact representation midconditions may not match. We recall that the frame rule allows us to reason about a larger heap by equally extending the pre- and postcondition with an additional assertion called the *frame axiom*.

Fortunately, in CHSL, frame axioms are very easy to find. To prepare a pair of arguments for Eval, then, one of two things is true: either for every i, $Q_1^i \cup P_2^i$ is still a partial function (i.e., if the same variable appears in both, it maps to the same value) and R_1^i, R_2^i are found by their difference, or the two triples cannot form a valid sequence.

Combining Eval and Frame. When the SObEq enumeration will apply a function or operator f to k child triples, this will combine the two rules. Since not all valid sequences of possible arguments to f have matching midconditions, we apply the Frame rule to the entire sequence:

given a set of $k = \mathit{arity}(f)$ triples $tr_i = \{\vec{P_i}\}p_i\{\vec{Q_i}; \vec{r_i}\}$, Eval is applicable if there exist k frame axioms $\vec{R}_1, \ldots, \vec{R}_k$ where $\vec{Q}_1 * \vec{R}_1 = \vec{P}_2 * \vec{R}_2, \vec{Q}_2 * \vec{R}_2 = \vec{P}_3 * \vec{R}_3, \ldots, \vec{Q}_{k-1} * \vec{R}_{k-1} = \vec{P}_k * \vec{R}_k$. Some of these $\vec{R}_i$ may be $\vec{emp}$. Now that the midconditions of the triples match, Eval can be applied, yielding a triple that evaluates from the new shared precondition $\vec{P}_1 * \vec{R}_1$, and computing the result and precondition for $f(p_1, \ldots, p_k)$.

3.2 Problem definition

Since SObEq uses CHSL triples to solve a PBE problem, we must re-state the PBE problem for CHSL. In this section we define what it means for a CHSL triple to represent our target program, define a translation from a PBE task, and explain how additional specifications, constraining the program's effects on the state, can also be supported.

The Programming by Example (PBE) task is usually defined as follows: given a vector of input-output examples $\vec{\mathcal{E}} = \langle \iota_i \to \omega_i \rangle_i$, find a program p over a component set $\mathcal{C}$ where for every input ι_i, evaluating p on ι_i, denoted $[\![p]\!](\iota_i)$, is equal to the provided output ω_i. We first want to translate this into a goal of the shape $\{P\}_\{Q; r\}$.

Examples in CHSL. We denote the vector of input states $\vec{I} = \langle \iota_i \mid \iota_i \to \omega_i \rangle_i$. The direct translation of $\vec{\mathcal{E}}$ to CHSL, then, is $\{\vec{P}\}_\{_; \langle \omega_i @ _ \rangle_i\}$, where $\exists \vec{R}.\vec{P} * \vec{R} = \vec{I}$. In other words, the precondition needs to *describe* the initial states (it is a footprint, so it may not describe all input variables), any postcondition will satisfy our specification, and the correct values can be at any location.

Constraining effect. Users may want to constrain specific mutations as well as the value. We let the user pair with each example any constraints on the effect, e.g., the value of `n` must be 9, or `arr` must end in its initial value $[10, 100, 90, -1, 2]$. To do this, we let the user provide an *effect constraint* $q : \mathcal{V} \to \mathcal{K}$, constraining the target value for any variable, where if $x \notin \mathrm{dom}(q)$, x is unconstrained.

The SObEq task. A PBE user does not need to know about CHSL. Much like the original $\vec{\mathcal{E}}$, they provide a vector $\vec{\Phi}$ where each $\varphi \in \vec{\Phi}$ is a pair of example and effect constraint: $\varphi = (\iota \to \omega, q)$. If they are unconcerned with effects, this is identical to providing $\vec{\mathcal{E}}$.

We then turn $\vec{\Phi}$ into a synthesis goal in CHSL:

▶ **Definition 1** (SObEq synthesis goal). *Given a specification $\vec{\Phi}$, our goal $\mathcal{G}_{\vec{\Phi}}$ is:*

$$\mathcal{G}_{\vec{\Phi}} = \{\vec{P}\}_\{\langle q_i * _ \rangle_i; \langle \omega_i @ _ \rangle_i\}, \textit{ where } \exists \vec{R}.\vec{P} * \vec{R} = \vec{I}$$

The SObEq task is to find a triple $\{\vec{\sigma}\}p\{\vec{\sigma}'; \vec{r}\}$ that matches $\mathcal{G}_{\vec{\Phi}}$.

3.3 The program space

Now that we have SObEq's specifications, we define the space in which it performs the search. We consider the component set $\mathcal{C}$ as a union of three sets: $\mathcal{V} \cup \mathit{lits} \cup \mathcal{F}$, where $x \in \mathcal{V}$ are the variables in $\vec{I}$, $l \in \mathit{lits}$ are literals in the component set, and $f \in \mathcal{F}$ are the functions and operators that can be applied to subprograms ($\mathit{arity}(f) > 0$). The full program space of a synthesizer with a component set $\mathcal{C}$ is then every program using the components in $\mathcal{C}$. We denote this program set $(\!|\mathcal{C}|\!)$. This set is infinite and highly redundant, e.g., contains both `x + 1` and `1 + x + 0`, and in our mutating domain, both `arr.sort()` and `arr.sort().sort()`.

Classical Observational Equivalence. In a problem domain with no side-effects, observational equivalence unifies programs with the same evaluation results on the example inputs. This is expressed in the equivalence relation $\equiv_{\vec{\mathcal{E}}}$ that deems two programs p_1, p_2 (observationally) equivalent if $\forall \iota \to \omega \in \vec{\mathcal{E}}.[\![p_1]\!](\iota) = [\![p_2]\!](\iota)$. The OE-reduced space $(\!|\mathcal{C}|\!)^{OE}$ is then defined using $\equiv_{\vec{\mathcal{E}}}$. This idea was first suggested by Udupa et al. [59] and Albarghouthi et al. [2] and is in wide use today.

A classical bottom-up enumeration (CBE), keeps a bank of programs, and the vector of observed results is used to label the program's equivalence class. Only one program with each vector is added to the bank, meaning any observationally equivalent programs are discarded.

A program space with mutations. In the presence of mutations, the space of possible programs no longer comprises only programs evaluated in the initial states $\vec{I}$. As we saw in Sec. 2, composition in this space requires subprograms that are evaluated in a modified state.

The full program space when $\mathcal{F}$ includes mutations is constructed inductively, building larger valid triples from smaller ones via applications of Eval, and the Frame rule when necessary. We denote the possible values for each $x \in \mathcal{V}$ as $\mathcal{K}_x$. We define the full space of programs $(\!|\mathcal{C}|\!)$:

▶ **Definition 2** (Full program space). *We define the full program space* $(\!|\mathcal{C}|\!)$ *as* $\bigcup_{i\geq 0}(\!|\mathcal{C}|\!)_{(i)}$ *where* $(\!|\mathcal{C}|\!)_{(i)}$ *is defined inductively as follows:*

$$(\!|\mathcal{C}|\!)_{(0)} = \{\{e\vec{m}p\}l\{e\vec{m}p; \overrightarrow{v@\bot}\} | l \in lits, v \in \mathcal{K} \text{ is the value of } l\} \cup$$
$$\{\{\vec{\sigma}\}x\{\vec{\sigma}; \langle v_i @ x\rangle_i\} | x \in \mathcal{V}, \vec{\sigma} = \langle x \mapsto v_i\rangle_i, \vec{v} = \mathcal{K}_x \times \cdots \times \mathcal{K}_x\}$$
$$(\!|\mathcal{C}|\!)_{(n)} = (\!|\mathcal{C}|\!)_{(n-1)} \cup \big\{\{\vec{P}\}f(p_1,\ldots,p_k)\{\vec{Q};\vec{r}\} | f \in \mathcal{F}, arity(f) = k, \{\vec{\sigma}_i\}p_i\{\vec{\sigma}'_i; r_i\} \in (\!|\mathcal{C}|\!)_{(n-1)},$$
$$\exists \vec{R}_1,\ldots,\vec{R}_k.\textsc{Eval} \text{ of } f \text{ on } \{\vec{\sigma}_i * \vec{R}_i\}p_i\{\vec{\sigma}'_i * \vec{R}_i; \vec{r}_i\} \text{ is } \{\vec{P}\}f(p_1,\ldots,p_k)\{\vec{Q};\vec{r}\}\big\}$$

Finally, given $(\!|\mathcal{C}|\!)$, we can define the OE-reduced space that SObEq will enumerate.

3.4 SObEq: observational equivalence with side effects

As we showed in Sec. 2, classical OE's $\equiv_{\vec{\mathcal{E}}}$ is no longer useful for the program space in Def. 2. We need our equivalence relation to encompass every aspect of the goal φ (Def. 1).

The generalized formalization of OE [45] defined two properties for equivalence, *interchangeability*: two equivalent programs can be used interchangeably within a larger program, and *consistency*: two equivalent programs will either both satisfy or both not satisfy the specification.

To satisfy consistency we must include everything that participates in Def. 1. The *value* returned by the expression, and the postcondition, which includes any constrained effect. We also need the state on which the program will be evaluated to check whether it describes $\vec{I}$.

As we saw in Sec. 2, to satisfy interchangeability we need the *location* of the value as well: while the literal $[2,3,1]$ and a variable `x` whose valuation is $[2,3,1]$ return the same value, they are not interchangeable under a larger program like `?.sort()`, where they would lead to different postconditions. Moreover, to be able to swap a program in, its postcondition must be the same.

Combined, then, our equivalence relation simply compares the triple excluding the program:

▶ **Definition 3** (SObEq equivalence relation). *The equivalence relation for* $\vec{\Phi} = \langle(\iota_i \to \omega_i, q_i)\rangle_i$ *is*

$$\{\vec{\sigma}_1\}p_1\{\vec{\sigma}'_1;\vec{r}_1\} \equiv_{\vec{\Phi}} \{\vec{\sigma}_2\}p_2\{\vec{\sigma}'_2;\vec{r}_2\} \iff \vec{\sigma}_1 = \vec{\sigma}_2 \wedge \vec{\sigma}'_1 = \vec{\sigma}'_2 \wedge \vec{r}_1 = \vec{r}_2$$

Or in other words, equivalence does not look at the program, only at its specifications.

Subsumption of triples. Finally, we consider the generality ordering of triples and (implicitly) of their equivalence classes, which will let us find more general programs.

In Sec. 2, we considered the two triples $tr_4 = \{\texttt{n} \mapsto 5\}\texttt{n - n}\{\texttt{n} \mapsto 5; 0@\bot\}$ and $tr_5 = \{emp\}\texttt{0}\{emp; 0@\bot\}$. While tr_4 and tr_5 are not observationally equivalent under Def. 3, as $emp \neq \texttt{n} \mapsto 5$, tr_5 is *more general* than tr_4: it produces the same result ($0@\bot$) and the same effect ($\emptyset$) from more concrete states. If tr_5 can absorb tr_4, we can arrive at a more compact representation of the space. To this end, we formally define this generality: the partial order of programs that differ by only a more general pre- and postcondition.

▶ **Definition 4** (Generality ordering of triples). *Given a specification $\vec{\Phi}$, we define*

$$\{\vec{P}_1\}p_1\{\vec{Q}_1; \vec{r}_1\} \sqsubseteq_{\vec{\Phi}} \{\vec{P}_2\}p_2\{\vec{Q}_2; \vec{r}_2\} \iff \exists \vec{R}.\{\vec{P}_1\}p_1\{\vec{Q}_1; \vec{r}_1\} \equiv_{\vec{\Phi}} \{\vec{P}_2 * \vec{R}\}p_2\{\vec{Q}_2 * \vec{R}; \vec{r}_2\}$$

I.e., the more general way to achieve the same result and effect is considered larger.

While $\sqsubseteq_{\vec{\Phi}}$ is clearly not an equivalence relation (the existence of a frame axiom is not symmetrical) so it cannot be used to partition the space into classes, we notice that replacing a triple with one that is larger according to $\sqsubseteq_{\vec{\Phi}}$ does preserve the two properties of an OE-relation, *interchangeability* and *consistency*, in one direction. Originally [45], *interchangeability* states that swapping two equivalent programs within a larger program will yield an equivalent larger program, and *consistency* states that two equivalent programs either both satisfy a given specification φ or neither does. Under $\sqsubseteq$, however, a slightly weaker – but still useful – version holds.

Interchangeability under $\sqsubseteq_{\vec{\Phi}}$ means that given $f \in \mathcal{F}, arity(f) = k$, k triples $tr_j = \{\vec{P}_j\}p_j\{\vec{Q}_j; \vec{r}_j\}$, $1 \leq j \leq k$, and k assertions $\vec{R}_j$ s.t. Eval can be applied on f and $\{\vec{P}_j * \vec{R}_j\}p_j\{\vec{Q}_j * \vec{R}_j; \vec{r}_j\}$ to infer $\{\vec{P}\}f(p_1, \ldots, p_k)\{\vec{Q}; \vec{r}\}$, and a triple $tr'_i = \{\vec{P}'_i\}p'_i\{\vec{Q}'_i; \vec{r'}_i\}$ s.t. $tr_i \sqsubseteq_{\vec{\Phi}} tr'_i$ for some $1 \leq i \leq k$, then:

1. There exists $\vec{R'}_i$ s.t. Eval can still be applied on f when replacing $\{\vec{P}_i * \vec{R}_i\}p_i\{\vec{Q}_i * \vec{R}_i; \vec{r}_i\}$ with $\{\vec{P'}_i * \vec{R}'_i\}p'_i\{\vec{Q'}_i * \vec{R}'_i; \vec{r'}_i\}$ to infer $\{\vec{P'}\}f(p_1, \ldots, p'_i, \ldots, p_k)\{\vec{Q'}; \vec{r'}\}$, and
2. $\{\vec{P}\}f(p_1, \ldots, p_k)\{\vec{Q}; \vec{r}\} \sqsubseteq_{\vec{\Phi}} \{\vec{P'}\}f(p_1, \ldots, p'_i, \ldots, p_k)\{\vec{Q'}; \vec{r'}\}$

Consistency under $\sqsubseteq_{\vec{\Phi}}$ means that for goal $\mathcal{G}$, if $\{\vec{P}_1\}p_1\{\vec{Q}_1; \vec{r}_1\} \sqsubseteq_{\vec{\Phi}} \{\vec{P}_2\}p_2\{\vec{Q}_2; \vec{r}_2\}$, then if there exists $\vec{R}_1$ s.t. $\{\vec{P}_1 * \vec{R}_1\}p_1\{\vec{Q}_1 * \vec{R}_1; \vec{r}_1\}$ matches $\mathcal{G}$, then there exists $\vec{R}_2$ s.t. $\{\vec{P}_2 * \vec{R}_2\}p_2\{\vec{Q}_2 * \vec{R}_2; \vec{r}_2\}$ matches $\mathcal{G}$. It's important to notice that the $\Leftrightarrow$ of the equivalence version of *consistency* is now $\Rightarrow$: if $\{\vec{P}_1\}p_1\{\vec{Q}_1; \vec{r}_1\}$ is a solution, so is $\{\vec{P}_2\}p_2\{\vec{Q}_2; \vec{r}_2\}$, but since $\{\vec{P}_2\}p_2\{\vec{Q}_2; \vec{r}_2\}$ is more general $\vec{P}_2$ might describe $\vec{I}$ even if $\vec{P}_1$ did not.

▶ **Lemma 5.** Interchangeability *and* consistency *are preserved under* $\sqsubseteq$.

The proof of Lemma 5 is found in the extended version of the paper.

With the program space $(\!|\mathcal{C}|\!)$ and the SObEq equivalence relation and generality ordering, we are ready to search for a program, i.e., to construct the OE-reduced space via enumeration.

4 The SObEq Enumeration

In this section, we describe the construction of the OE-reduced space. We first describe the structure of the space, then the enumeration, and finally how the enumeration can find equivalence classes that, by virtue of their generality, subsume other equivalence classes.

Classical Bottom-Up Enumeration. A bottom-up enumeration consists of applying each $f \in \mathcal{F}$ to k-tuples of child programs from the bank of previously seen programs, where $\mathit{arity}(f) = k$. Each newly enumerated $f(p_1, \ldots, p_k)$ is evaluated, and if an equivalence class labeled by its observed values is not yet represented in the bank, it is added to the bank. Enumeration is done according to some ordering, e.g., height, number of AST nodes, or probability score [7]. This is usually facilitated by the structure of the bank to allow for easier retrieval of relevant child-programs.

The precondition bank. In our setting, we want to bank discovered triples according to their precondition: a bank section $\vec{a}$ contains all discovered programs whose precondition is $\vec{a}$.

There are two reasons for this: first, when composing a k-tuple of arguments to f, finding a sequence Eval is enabled for can be done constructively, without considering all possible k-tuples. For a sequence of length $k-1$ with postcondition assertion $\vec{Q}_{k-1}$, we can preemptively rule out assertion vectors $\vec{a}$ with different values assigned to a variable appearing in both $\vec{Q}_{k-1}$ and $\vec{a}$, and will never form a valid sequence. In Algorithm 1 we call this construction CollectChildren.

Second, and even more importantly, this lets us track what assertions have been discovered by the enumeration. If the enumeration produces a triple $\{\vec{a}\}p\{\vec{a}';\vec{r}\}$ where $\vec{a}$ or $\vec{a}'$ have not yet been seen by the enumeration, then a new bank will be initialized for $\vec{a}$ (or $\vec{a}'$, resp.).

Initializing a new bank. A new assertion $\vec{a}$ can be discovered by the enumeration in one of two ways, as a pre- or a postcondition. For example, the derivation in Fig. 3 combines $\{\mathtt{n} \mapsto 5\}\mathtt{n\ -\ 1}\{\mathtt{n} \mapsto 5; 4\}$ with $\{\mathtt{arr} \mapsto \mathit{arr}_{\mathit{sort}}\}\mathtt{arr}\{\mathtt{arr} \mapsto \mathit{arr}_{\mathit{sort}}; \mathit{arr}_{\mathit{sort}}\}$ into $\{\mathtt{arr} \mapsto \mathit{arr}_{\mathit{sort}} * \mathtt{n} \mapsto 5\}\mathtt{arr[n-1]}\{\mathtt{arr} \mapsto \mathit{arr}_{\mathit{sort}} * \mathtt{n} \mapsto 5; 100\}$. Both the compound pre- and postcondition might be new for the enumeration, in which case they do not have a section in the bank.

If $\vec{a}$ is discovered as a precondition, we naturally add a section of the bank to bank the newly enumerated program. If $\vec{a}$ was discovered as a postcondition, then it may be a result of an effect, which means some of its atomic heaplets may not be in the bank yet. In this case, we create a section for $\vec{a}$ in the bank, but also add its atomic heaplets to the bank if they are new: we construct $\{a_x\}x\{a_x; r_x\}$ where $a_x = \langle x \mapsto a_i(x)\rangle_i$ and $r_x = \langle a_i(x)\rangle_i$ for each x in $\vec{a}$, and add it to the bank if a_x is not yet in the bank. In Algorithm 1, this is collectively denoted as InitBank($\vec{a}$).

At the beginning of the enumeration, the bank is trivially initialized with the empty assertion $\vec{emp}$ for literals and with $\langle x \mapsto \iota_i(x)\rangle_i$ for each variable $x \in \mathcal{V}$.

Enumerating terms. The main enumeration is not very different from the CBE enumeration: the enumerator selects $f \in \mathcal{F}$ with $\mathit{arity}(f) = k$, and composes as arguments for it all k-tuples of triples $\{\vec{P}_i\}p_i\{\vec{Q}_i;\vec{r}_i\}$ that Eval can be applied to from triples already in the bank.

The application of Eval then constructs a new triple $\{\vec{P}\}f(p_1, \ldots, p_k)\{\vec{Q};\vec{r}\}$ that can then be *observed*: we use its pre- and postcondition assertions and its results as the label for its equivalence class. This label is searched for in the bank for precondition $\vec{P}$. If the bank for $\vec{P}$ has an equivalent program, $\{\vec{P}\}f(p_1, \ldots, p_k)\{\vec{Q};\vec{r}\}$ is discarded, and if no equivalent program was previously seen, $\{\vec{P}\}f(p_1, \ldots, p_k)\{\vec{Q};\vec{r}\}$ is added to the bank for $\vec{P}$.

We also have at our disposal $\sqsubseteq_{\vec{\Phi}}$ (Def. 4), which means we reduce the space even further.

Algorithm 1 The SObEq enumeration.

Input : Set of specifications $\vec{\Phi} = \langle(\iota_i \to \omega_i, q_i)\rangle_i$, variables $\mathcal{V}$ specified in example inputs
Output : Program p composed of components $\mathcal{C}$ s.t. p that satisfies $\vec{\Phi}$
Globals: Precondition bank *bank*, mapping from assertion to an OE bank

```
1  initialAsserts := {emp} ∪ {⟨x ↦ ι_i(x)⟩_i | x ∈ V}
2  foreach ā ∈ initialAsserts do InitBank(ā);
3  repeat // until timeout
4      foreach f ∈ F, arity(f) = k do
5          foreach {σ̄_1 * R̄_1}p_1{σ̄'_1 * R̄_1; r̄_1} ··· {σ̄_k * R̄_k}p_k{σ̄'_k * R̄_k; r̄_k} ∈
             CollectChildren(bank, k) do
6              {σ̄}p{Q̄; r̄} := Eval (f, {σ̄_1 * R̄_1}p_1{σ̄'_1 * R̄_1; r̄_1} ··· {σ̄_k * R̄_k}p_k{σ̄'_k * R̄_k; r̄_k})
7              if ∃R̄.{σ̄ * R̄}p{Q̄ * R̄; r̄} matches G_Φ̄ then return p;
8              if ∀ā ∈ keys(bank).∃R̄.(ā * R̄ = σ̄ ∧ R̄ ⊆ Q̄) ⇒ (ā, Q̄ \ R̄, r̄) ∉ bank(ā) then
9                  if σ̄ ∉ keys(bank) then InitBank(σ̄);
10                 bank(σ̄) += {σ̄}p{Q̄; r̄}
11             end
12             if Q̄ ∉ keys(bank) then InitBank(Q̄);
13         end
14     end
15 until timeout;
```

Using more general triples. We want to use the $\sqsubseteq_{\vec{\Phi}}$ relation to let more general triples subsume less general ones in the course of enumeration, even when they are not strictly equivalent. However, this can happen in one of two cases: (i) the less general triple being enumerated after the more general triple is in the bank, and (ii) a more general triple being enumerated later.

Handling (i) is simple enough: when enumerating $\{\vec{\sigma}\}p\{\vec{\sigma}';\vec{r}\}$, even if there is no representative for the equivalence class of $\{\vec{\sigma}\}p\{\vec{\sigma}';\vec{r}\}$, the enumerator checks whether some $\{\vec{\sigma}_2\}p_2\{\vec{\sigma}'_2;\vec{r_2}\}$ s.t. $\{\vec{\sigma}\}p\{\vec{\sigma}';\vec{r}\} \sqsubseteq_{\vec{\Phi}} \{\vec{\sigma}_2\}p_2\{\vec{\sigma}'_2;\vec{r_2}\}$ already exists in the bank, and if it does, discards $\{\vec{\sigma}\}p\{\vec{\sigma}';\vec{r}\}$. This is efficiently done by changing the assertions to more general ones and searching the bank.

Handling (ii), however, is a larger feat. *In theory*, once we enumerate the more generic triple $\{\vec{\sigma}\}p\{\vec{\sigma}';\vec{r}\}$, we can replace all less-general triples $\{\vec{\sigma}_2\}p_2\{\vec{\sigma}'_2;\vec{r_2}\}$ with $\{\vec{\sigma}\}p\{\vec{\sigma}';\vec{r}\}$, propagating this change to any compositions that use p_2. This would be prohibitively costly on its own before the implications of Lemma 5: this replacement can weaken the pre- and postconditions of compositions, changing their place in the bank. This cascade might even weaken the precondition a triple that did not satisfy $\vec{\Phi}$ enough to describe $\vec{I}$ and become a solution. As such, we elect to only incorporate (i) into SObEq.

4.1 The enumeration algorithm

We can now compose the complete SObEq enumeration, seen in Algorithm 1.

Lines 1–2 of the algorithm initialize the enumeration by calling InitBank, described above, to create the basic programs for $\vec{emp}$ and for each of the variables' initial values.

Line 4 selects the next component for application; components with an arity of 0 are handled exclusively by InitBank. Next, on line 5 CollectChildren constructs all k-tuples of children that Eval is enabled for. Since it is a part of the construction process, CollectChildren returns each k triples already updated with the frame axioms $\vec{R}_1, \ldots, \vec{R}_k$ to a unified composed heap.

Line 6 then applies Eval to construct the new triple. If the new triple is a solution to the task, it will be returned by line 7. If not, line 8 checks whether an equivalent or subsuming program already exists in the bank via its equivalence class label: if some existing key in the bank can be made equivalent to the current program via a frame axiom. For example, the program $\{\mathtt{n} \mapsto 5\}n - n\{\mathtt{n} \mapsto 5; 0@\bot\}$ will be enumerated, and will then be tested twice: for $R = emp$, $(\mathtt{n} \mapsto 5, \mathtt{n} \mapsto 5, 0@\bot)$ will be searched for in the bank, and also for $R = n \mapsto 5$, $(emp, emp, 0@\bot)$ will be searched and found (for the program `0`), so $\{\mathtt{n} \mapsto 5\}n - n\{\mathtt{n} \mapsto 5; 0@\bot\}$ is discarded. A precondition $\vec{a}$ in the bank is deemed relevant if there exists a frame axiom $\vec{R}$ s.t. $\vec{R}$ both matches $\vec{a}$ to $\vec{\sigma}$ and all values in $\vec{R}$ are unchanged in $\vec{Q}$ (i.e., $\vec{R}$ truly is a frame). Every $\vec{a}$ in the bank lookup uses the relevant equivalence class label, with $\vec{a}$ as its precondition and subtracting the frame axiom from its postcondition assertion. If no triple is found, the new triple is added to the bank. If either the pre- or postcondition assertion do not exist in the bank, InitBank is called for them to generate triples for their variables.

SObEq as a base enumerator. Many synthesizers [16, 45, 36, 5] use a base OE enumeration of expressions to synthesize additional language constructs, e.g., conditionals, higher-order functions, and assignments. These techniques are parameterizable in their base enumerator, and so could leverage SObEq to expand their target language.

Correctness of SObEq. We show that Algorithm 1 is *correct*: that if a solution p exists in the unreduced space, SObEq's enumeration will find a solution observationally equivalent to p or more general than p.

▶ **Theorem 6** (Correctness of SObEq). *If a valid solution $\{\vec{\sigma}\}p\{\vec{\sigma}'; \vec{r}\}$ to goal $\mathcal{G}_{\vec{\Phi}}$ exists in $(\!|\mathcal{C}|\!)$, then there exists $\{\vec{\sigma}''\}p'\{\vec{\sigma}'''; \vec{r}'\}$ that matches $\mathcal{G}_{\vec{\Phi}}$ in the SObEq-reduced space, and it is reachable by SObEq's enumeration.*

In the extended version of the paper we prove Theorem 6 in two steps: first we define the (unreduced) space reachable via enumeration and show that any solution will still be in that space, then we apply the reduction of $\equiv_{\vec{\Phi}}$ to the space, defining the *SObEq-reduced program space* $(\!|\mathcal{C}|\!)^S$, and prove that any solution will have an observationally equivalent or more general under $\sqsubseteq_{\vec{\Phi}}$ solution in $(\!|\mathcal{C}|\!)^S$.

5 Implementation

We implemented a SObEq synthesizer for JavaScript programs in 3,700 lines of Scala code. The set of functions and operators $\mathcal{F}$ contains 54 components for integers, strings, arrays, and sets, including nine mutating operations: postfix increment for integers, the array functions `sort`, `reverse`, `splice`, `push`, `pop`, `shift`, and the set functions `add` and `delete`. JavaScript strings are immutable, so $\mathcal{F}$ includes no mutating components for strings. $\mathcal{F}$ also includes a sequence operator for any two expressions. We allow a task to provide additional string constants for *lits*, common in benchmarks from the literature [4, 7] or interaction models [17, 16].

Preserving immutability. Effect constraints in $\vec{\Phi}$ can specify that a variable has not changed in the postcondition of the solution. But effect constraints cannot distinguish between, e.g., `x` and `--(++x)` because we only reason about the pre- and postcondition, not the path between them. This is generally desirable as it marks `--(++x)` as redundant, but this will only happen when applying `--`. The user may want `x` to *always* be immutable.

This can be enforced by the enumeration. We add to our task specifications the ability to mark a variable as `immut`. Once the user specifies `x` as immutable, there is no reason to construct `++x` at all: a triple $\{\vec{\sigma}\}p\{\vec{\sigma}';\vec{r}\}$ where $\langle\sigma_i(x)\rangle_i \neq \langle\sigma'_i(x)\rangle_i$ is discarded immediately, and $\vec{\sigma}'$ is not initialized in the bank, since any programs with the precondition $\vec{\sigma}'$ assume a mutation of `x`.

Goals without an output. Under CHSL it is possible to express a goal that has no specified output, only a specified effect. This is desirable when, e.g., specifying that a value is inserted into a list, but what the insertion returns is irrelevant. If a benchmark has no specified outputs, i.e., $\vec{\Phi} = \langle(\iota_i, q_i)\rangle_i$, we create the synthesis goal $\mathcal{G}_{\vec{\Phi}} = \{\vec{P}\}_\{\langle q_i * _\rangle_i;_\}$. The lack of an output does not change anything in how programs are enumerated and the goal is matched in the same way.

6 Experimental Evaluation

We evaluate SOBEQ on our implementation. All our experiments used a server with Intel Xeon Gold 6338 2 GHz[1] and 128GB of RAM, with the JVM maximum heap size set to 110 GB.

Research Questions. We aim to answer the following research questions:

RQ1 How does SOBEQ compare to the state-of-the-art in syntax-guided synthesis of heap mutations?

RQ2 What is the overhead of SOBEQ compared to a classical OE enumeration?

RQ3 How effective is SOBEQ at pruning the space of programs?

RQ4 How does SOBEQ compare to enumerating with concrete states?

6.1 Benchmarks and baselines

We evaluated SOBEQ on a set of 63 benchmarks, curated from previous synthesizers [52, 7, 16, 22], programming exercises on LEETCODE.COM, and questions on STACKOVERFLOW.COM. We discarded benchmarks that use types other than strings, arrays and sets, i.e., that would be inherently unsupported by our implementation. As SOBEQ supports a straight-line sequence of expressions, we also discarded benchmarks from Shi et al. [52] and Ferdowsifard et al. [16] if their solution used assignments to intermediate variables, loops, or conditionals.

We split the benchmarks into two sets: ▷ ***May* Mutate**: 45 benchmarks that have a non-mutating solution in $\mathcal{C}$. ▷ ***Must* Mutate**: 18 benchmarks that require mutation: benchmarks with a non-empty effect constraint or cannot be solved without mutation in $\mathcal{C}$. Of these, five are benchmarks from *May* with a constrained effect, ruling out non-mutating solutions. For RQ2, we also create ▷ ***Pure***: a version of *May* where all variables are marked as `immut`.

On average, *May* benchmarks have 2.8 examples (min 1, max 4) and 1.4 variables (min 1, max 3). *Must* benchmarks have 2.7 examples (min 1, max 5), 2.3 variables (min 1, max 4), and 1.2 variables specified in the effect (min 0, max 2). Five *Must* benchmarks have no specified outputs. More information about our benchmarks is provided in the extended version of the paper.

[1] This processor has 32 cores/64 threads, but our implementation is single-threaded.

Selecting a baseline. We considered several synthesizers as baselines for SOBEQ, ruling out synthesizers built for a single example [22], synthesizers that mutate by assigning synthesized pure expressions [16, 17, 59], and tools hinging on Java's rich type system [15, 61]. FRANGEL [52] is the current state of the art in synthesis of general programs with heap mutations: it is specified with input-output examples, it has the same ability as SOBEQ to declare a variable as immutable, and its stochastic search carries no additional requirements for specification other than the ability to evaluate – just as SOBEQ does. This makes it the most suitable baseline.

FrAngel as a baseline. FRANGEL targets Java collection implementations, which have many more methods than their JavaScript counterparts. This means FRANGEL and SOBEQ can yield solutions that are entirely incomparable. To ensure an apples-to-apples comparison, we created new Java classes that mimic JavaScript types in Java, recreating the same $\mathcal{C}$ used by SOBEQ's implementation. We then defined our benchmark set over these types.

In addition, in order to force FRANGEL to create a straight-line sequence of expression statements as SOBEQ does, we also removed from its enumeration loops, conditionals, and assignments. Notice that removing choices from its random sampling only improves FRANGEL's odds of finding a solution; before this additional change, FRANGEL's run times were considerably worse.

FRANGEL also has the option to set inputs as immutable, which let us encode `immut` variables, and an option to set a target value for an input, which we used for encoding effect constraints in the benchmark. This means FRANGEL can run on every benchmark in SOBEQ's suite.

Selecting timeouts. We consider two timeouts for our runs. First, we set our timeout at 60 minutes, extending the original 30 minute timeout used to evaluate FRANGEL. However, since we aim SOBEQ to be used in interactive systems, and by other OE-based systems as the base enumerator, we also consider results at an *interactive timeout* or a timeout needed for the synthesizer to run in a user-facing tool and not create a *disruptive interruption* [43]. Building on recent interactive synthesizers, we choose 7 seconds as our interactive timeout.

6.2 RQ1: Comparison to FrAngel

We compare SOBEQ to state of the art FRANGEL, using an equivalent component set as detailed in Sec. 6.1. FRANGEL's algorithm is stochastic, so we ran FRANGEL five times on each of the 63 benchmarks. We consider a benchmark *solved* if the synthesizer returns a solution that is correct on all examples. While some benchmarks from the literature contained a gold standard solution, we only used those as part of the analysis of result quality. We compare the quality of SOBEQ's solutions to FRANGEL on three counts: the size of the solution, is it *overfitted*, and does it contain *spurious operations*. These are shown in Fig. 5. In addition, we compare the run times of the two tools at both an interactive 7s and a one-hour timeout.

Size of the solution. While the size of solutions is not, in itself, a good proxy for quality, it is telling in combination with overfitting and spurious operations. SOBEQ postprocessed solutions had an average of 6.2 AST nodes at an interactive timeout and 6.9 at a 1-hour timeout (max 14, 25, resp.) where *Must* benchmarks were generally smaller – 5.7 nodes at the interactive timeout and 6.1 in an hour – compared to *May* benchmarks – 6.4 and 7.1 nodes.

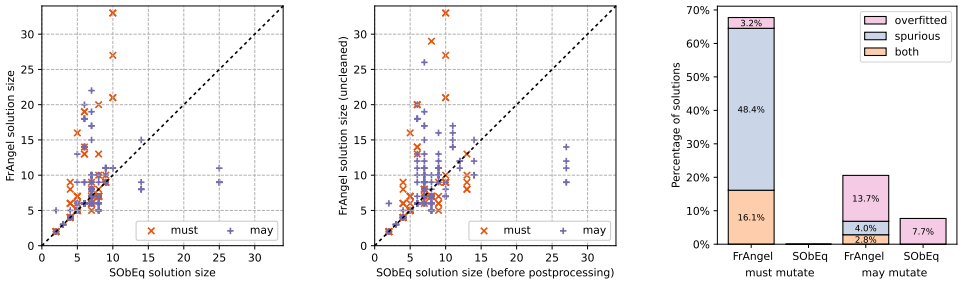

Figure 5 RQ1: Comparing SObEq's solutions to FrAngel's on size (left, center) and quality (right). Solution sizes are per-benchmark: each SObEq solution has up to five corresponding FrAngel values. Above the line means SObEq is smaller. We consider both the final results (left) and solutions before postprocessing/cleaning steps (center). Solution quality (right) indicates the percentage of solutions with overfitted or spurious operations, determined by manual inspection (lower is better).

The left and center of Fig. 5 show the AST size for each SObEq solution compared to each of FrAngel's solutions for the same benchmark. Overall, FrAngel's solutions are much larger than SObEq's. There are two benchmarks where SObEq's solution is considerably larger than FrAngel's: *Is All Positive?* (originally from FrAngel), both SObEq's and FrAngel's solutions were overfitted. In *Get first name from name with comma* (originally from Probe [7]), FrAngel returned two overfitted solutions similar to SObEq's, both appearing closer to the diagonal line, and three times found a solution closer to the gold standard solution, which is shorter, though never the gold standard solution itself. (The two identical solutions and three identical solutions overlap in Fig. 5.) An interesting trend in SObEq's solutions was that the enumeration order favored extracting postfix increment to a sequence. E.g., instead of `buffer[idx++]++, idx` SObEq returns the larger but functionally identical `buffer[idx]++, idx++, idx`.

Overfitted solutions. We define overfitted solutions as solutions that do not generalize beyond the provided examples. This was determined by manual inspection of both SObEq and FrAngel solutions, and with reference to task descriptions and gold standard solutions, if they exist.

Two SObEq solutions were overfitted, and one additional benchmark was close to a gold standard solution for the task, but since all its inputs were of length 4, it replaced `str.length` in the gold standard solution with `4`. Altogether, 3 of SObEq's 54 solutions were overfitted (6%). Of 279 FrAngel solutions (up to five per benchmark, which sometimes differ) 47 were overfitted (17%). As the right of Fig. 5 shows, both tools were more prone to overfitting in *May* benchmarks.

We bring several examples of FrAngel's overfitted solutions here.

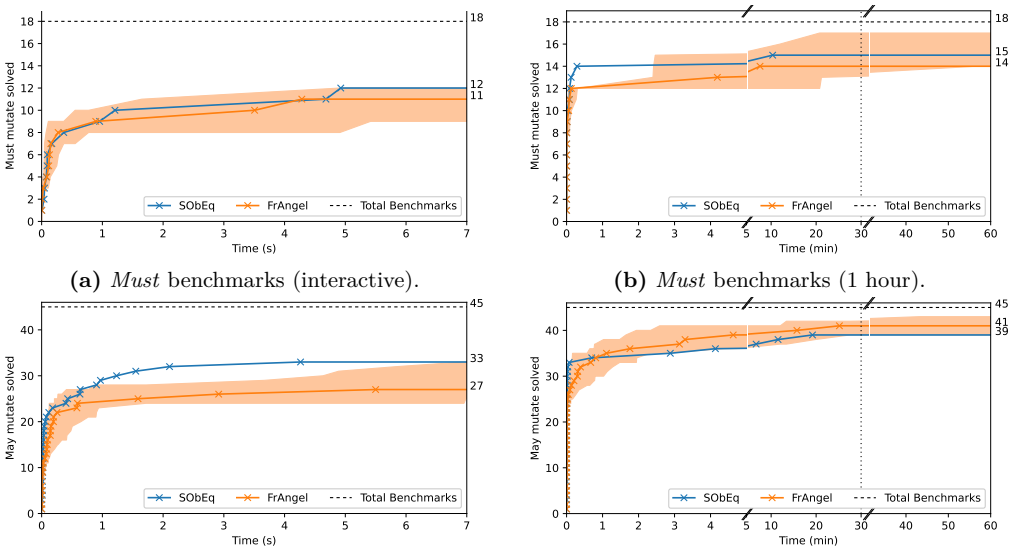
For example in the *Max and Min* benchmark, a simplified version of the example in Sec. 1, all four solutions (one run timed out) are overfitted and *different*. Two of them are:

```
return arr.join(arr.join(Str("").replaceAll(Str(""), Str("␣"))
  .concat(arr.join(Str("")).indexOf(arr.slice(Int(0), Int(1)).join(Str(""));
```

where the result number (max plus min) is generated by `indexOf`, and

```
arr.reverse();
return arr.join(arr.sort().join(Str("")).replaceAll(Str(""), Str("␣")).replace(
  arr.join(arr.join(Str("")).replaceAll(Str(""), Str("␣")), Str("␣")
).length();
```

where it is generated by the length of a string.



(a) *Must* benchmarks (interactive). **(b)** *Must* benchmarks (1 hour).

(c) *May* benchmarks (interactive). **(d)** *May* benchmarks (1 hour).

Figure 6 RQ1: The number of benchmarks SObEq and FrAngel solve over time. FrAngel is stochastic: median run for each benchmark shown by line with best and worst runs as range.

We also consider FrAngel's results on the three benchmarks that SObEq overfitted on: For the *Is All Positive?* benchmark mentioned above for its large solutions, both SObEq and FrAngel overfit to the examples in two different ways. FrAngel overfit all give solutions, returning `true` only for arrays where the smallest element is 1, and SObEq looked for a `'-'` in an overfitted location in the printed array. For *get from name with comma*, four of five FrAngel solutions were *not* overfit. The fifth is:

```
return _arg_0.split(Str(",")).sort().slice(Int(1).subtract(_arg_1),_arg_1).join(Str(""));
```

where the input string is split into words but then sorted before extracting the `1-_arg_1`th word. This happens to be true because all example inputs have a decreasing lexicographic ordering of the words. In *Negative Index Of*, where SObEq string lengths to `4`, three of FrAngel's solutions are not overfitted, but two rely on string `<` comparisons to between variables and constants.

Spurious operations. We define spurious operations as terms in the AST that do not contribute to reaching the target values: e.g., sorting an already-sorted list, mutating a temporary value that is then discarded, etc. Of the 279 FrAngel solutions, 37 had spurious operations (13%). We bring a few examples of these here.

One of the solutions FrAngel found for the *buffer-add* benchmark was:

```
arr.splice(beg++, 1, toadd).reverse();
return end + 1;
```

Here, `splice` removes a sub-array from `arr`, replaces it with `toadd`, and returns it. The solution then calls `reverse()` on this temporary value, which is immediately discarded.

Likewise, in three of the five solutions to *rotate queue*:

```
mod.equals(inp.push(inp.shift()));
```

where input variable `mod` is compared to the result of the target program (shifting the first element out of the array and pushing it back in at the end).

For *set add-delete*, which asks for an in-place mutation of a the set `seen`, one solution is:

```
seen.delete(s2).compareTo(seen.add(s1).has(null));
```

where both `has` and `compareTo` are useless, computing a result that is not returned.

And, of course, this problem is not disparate from overfitting; the only successful run of FrAngel for *fill fibonacci window* found this solution:

```
out.reverse().spliceReplace(
  Int(1),
  out.concat(out).length().subtract(
    Str("␣").concat(out.join(Str(""))).lastIndexOf((new IntArray(Int(1))).join(Str("")))
) ).shift();
```

where `reverse().spliceReplace(1,_)` is a consistent, if odd, way to remove the first element and add something after the second element by swapping the elements and then replacing the (now) second one. The second argument to `splice`, which is expected to compute the next fibonacci element, overfits to the examples, and `shift`ing on the discarded return value of `splice` is spurious.

SObEq, in contrast, had no spurious operations. Some are avoided thanks to OE: FrAngel can draw programs that perform round trip operations like reversing multiple times (3 of 5 solutions to the example from Sec. 1 do this) or sort a sorted list. Enumerating with OE discards these, as they return the heap to a state it was already at and return the same value.

Other spurious operations are avoided because of the implicit bias of a bottom-up search toward small programs: the program `inp.push(inp.shift())` already satisfies the input, so a bottom-up search would not try to compose it into a larger program adding on spurious operations. Likewise, the enumeration would try to compose `arr.splice(beg++, 1, toadd)` to `end + 1` before trying it with the larger `arr.splice(beg++, 1, toadd).reverse()`.

Runtimes. We compared SObEq's runtimes to FrAngel's best, worst and median performance on each benchmark in Fig. 6. In an interactive timeout, SObEq outperforms FrAngel for the majority of the 7 seconds. At the 7s limit, SObEq solves 45 benchmarks, 7 benchmarks more than FrAngel's median run, whereas FrAngel solves between 34 and 45 benchmarks. We also notice the main disadvantage of FrAngel, which is the variance introduced by the stochastic algorithm: a difference of 30% between its best and worst cases. At the 1-hour timeout, SObEq solves 54 benchmarks, compared to FrAngel's 53–60 (median 55).

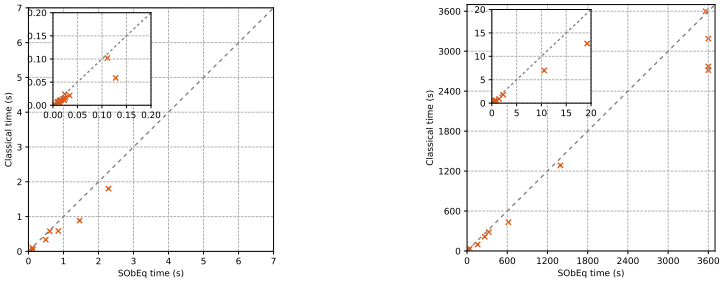
Fig. 6 separates benchmarks into sets to ensure performance is not at the expense of one set of benchmarks over the other, important for a general-purpose synthesizer. At an interactive timeout, SObEq performs on *Must* benchmarks as well as FrAngel's best run, both solving 12 of 18 benchmarks, and solves one more than FrAngel's median run of 11. For *May* benchmarks, SObEq solves 33 of 45, while FrAngel solves between 25 and 33 (median 27). After an hour, SObEq outperforms FrAngel's median run for *Must* benchmarks, solving 15 benchmarks to FrAngel's 14 and is within FrAngel's range for both benchmark sets.

To answer RQ1, **SObEq returns higher quality solutions than FrAngel at comparable runtimes, without the nondeterministic variance in both time and expected solution.**

6.3 RQ2: Overhead of SObEq

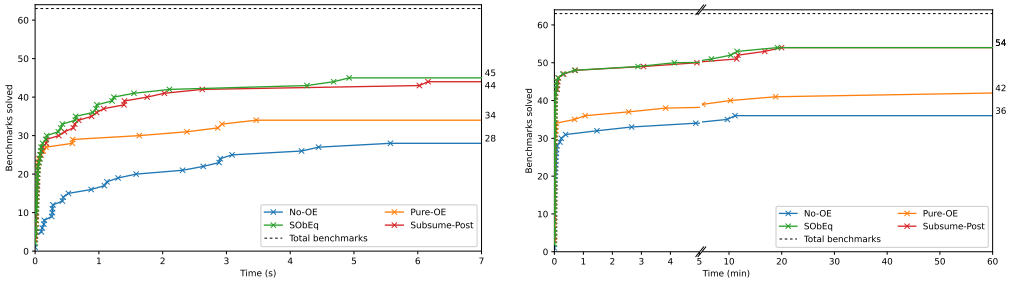
A more general algorithm inevitably carries an overhead on a (now) special case compared to specialized algorithms for that case. This is often because of additional work by an algorithm making fewer assumptions, but in OE this can also take the form of a more refined equivalence relation, which unifies fewer programs creating a bigger space to explore. We wish to measure this overhead in order to quantify the cost of the changes made to support mutations in SObEq.

If $\mathcal{C}$ has no mutating components, SObEq would not discover assertions outside the initial preconditions and their compositions. Such a search space is directly comparable to a classical bottom-up enumeration (CBE). This lets us measure the cost of the more



(a) Interactive timeout. **(b)** 1-hour timeout.

Figure 7 RQ2: Comparison with CBE: time to termination for each *Pure* benchmark with SObEq compared to a classical bottom-up enumeration. Points at (timeout,timeout) not shown.



(a) Interactive timeout. **(b)** 1-hour timeout.

Figure 8 RQ3: Run times of disabling different pruning mechanisms within SObEq: any OE, OE outside the initial state, and discarding programs according to $\sqsubseteq$.

fine-grained equivalence classes caused by using results, not just values, in equivalence class labels, and the additional overhead of creating a compound heap for sub-programs using different variables.

To measure the overhead, we restricted our $\mathcal{C}$ to only non-mutating components, and compared its performance on *Pure* benchmarks to an enumerator that uses only the initial *concrete* state and uses the classical value-based equivalence relation for an OE-reduction. This is equivalent classical OE with a height-based enumeration. By removing the mutating components for this evaluation, we avoid the correctness issues in classical OE, while controlling for performance differences caused by having different grammars.

In this restricted context CBE outperforms SObEq for most benchmarks (time comparison shown in Fig. 7). In an interactive timeout, CBE solved the benchmarks an average of 1.52 times faster (median 1.5). CBE was also able to solve one additional benchmark, *Max and Min*, within the 7s timeout whereas SObEq took 10.5s, and it is therefore not shown in Fig. 7. The biggest difference, where CBE was 2x faster or more (up to a maximum of 2.16 times faster), were all in benchmarks with runtimes of under 130ms for both enumerators.

In the full hour, CBE solved the benchmarks an average of 1.48 times faster (median 1.5), and finished with a two-benchmark lead: there are three benchmarks CBE solved that SObEq did not, and one benchmark that SObEq solved and CBE did not.

For RQ2, **we find that the overhead of SObEq's more fine-grained equivalence classes and creating compound heaps is not negligible compared to CBE.**

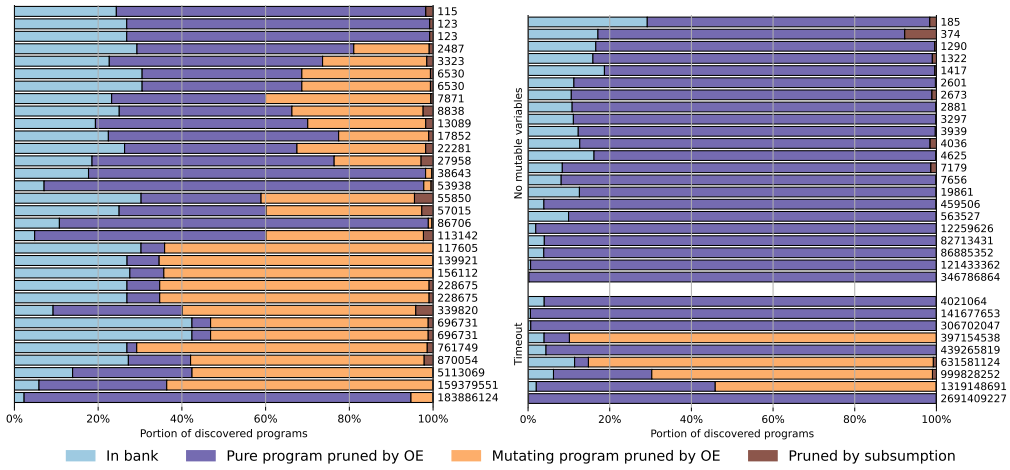


Figure 9 Handling of programs seen in the space of each benchmark (percentages plotted, no. programs in text). Benchmarks where mutation cannot occur and timeouts plotted separately.

6.4 RQ3: SObEq's effectiveness in pruning

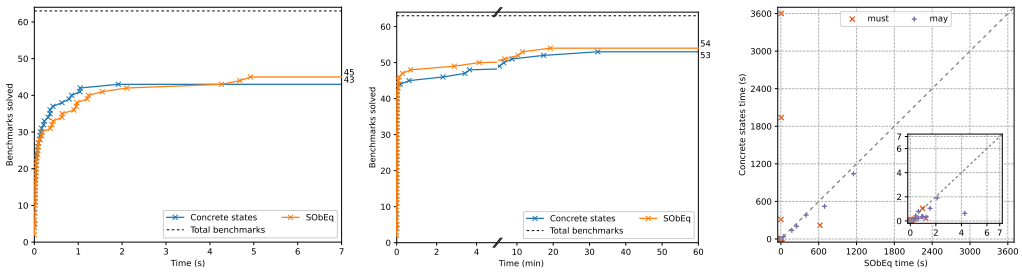
To test SObEq's effectiveness at pruning its space we compare SObEq to two ablation enumerations: 1. *No-OE*: an enumeration that discards no programs, i.e, enumerates $(\!|\mathcal{C}|\!)^{reach}$. 2. *Pure-OE*: an enumeration that only performs OE on pure programs, i.e., fully enumerates the space outside preconditions that cover the initial state. Additionally, to measure the effect of subsumption, we also add 3. *Subsume-Post*: an enumeration with the SObEq OE-reduction, but no subsumption during enumeration, only as postprocessing of results. The results are shown in Fig. 8.

It is, of course, unsurprising that *No-OE* performs poorly: with no reduction of the space, few programs are feasible, and this version solves only 28 benchmarks within 7s, diverging completely after 10 minutes. *Pure-OE* is an interesting case: testing whether it should prune a program required computing its effect, an expensive operation that leads *Pure-OE* to be considerably slower. At the 1-hour limit, *Subsume-Post* does as well as SObEq. However, it lags a little behind SObEq for most of its run, having solved one fewer benchmark at 7s.

In summary, **both the application of OE to the entire space and the application of subsumption help SObEq's performance, particularly in an interactive timeout.**

We also looked at what happens to the discovered programs across runs of SObEq, shown in Fig. 9, specifically to gauge how many programs are discarded and how many are subsumed by a more general program that already exists in the bank. We separate out runs that time out and benchmarks where all input variables are strings, i.e., no mutation is *possible*. In the latter, the number of mutating programs pruned is trivially 0, but subsumption still takes place.

On (weighted) average, only 3% of programs seen by SObEq are added to the bank (med 14%, min 0.1%, max 42% of the programs). 66% on average are pure programs pruned by equivalence (med 72%, min 2%, max 99.98%), and another 30% are mutating programs pruned by equivalence (med 1.5%, min 0%, max 90%). Finally, an average 0.2% of the programs are pruned by subsumption (med 0.4%, min 0.00002%, max 8%). **While the ratios vary, each of the pruning methods in SObEq is significant for some of the benchmarks.**



(a) Interactive timeout. **(b)** 1-hour timeout. **(c)** Per-benchmark comparison.

Figure 10 RQ4: Comparing an enumeration with preconditions to an enumeration with concrete states. Points at (timeout,timeout) not shown in (c).

6.5 RQ4: Enumerating with preconditions vs. concrete states

Finally, we examine the effect of the *local reasoning* in SObEq's enumeration. Composing partial heaps takes effort, but how costly is it, and does it allow more benchmarks to be solved? To test this, we created a version of SObEq where instead of footprints, preconditions are always *full* concrete states. We compare this to SObEq's enumeration in Fig. 10.

For most benchmarks, both enumerations perform similarly with concrete states slightly faster. We expected to see this as an effect of the overhead of composition, but it is also caused by pure programs being banked in one main state, which changes the enumeration order favorably for *May* benchmarks. If we consider only *Must* benchmarks, SObEq overtakes the concrete state enumeration after 1.5s and stays ahead for the entire 1-hour run.

Three benchmarks are noteworthy in this experiment. The concrete state enumeration times out on our overview example (benchmark *Max and Min with n*) while SObEq solves it in under 5s. Two more, *partition k largest* and *get range loopy while*, SObEq solves in 90ms and 4.6s, resp., and enumerating with concrete states takes 5min and 32min, resp. All three share the need to use multiple variables *after* one is mutated, which means subprograms already enumerated with the unmutated variable do not make a valid sequence and need to be re-enumerated.

To conclude, **SObEq's local reasoning is faster for benchmarks that need to mutate, and is not significantly slower for other benchmarks.**

7 Related work

Syntax- and Component-Guided Synthesis. Syntax-Guided Synthesis (SyGuS) [3] is a form of the synthesis problem providing a specification along with a grammar defining its program space. It can also describe a form of synthesis where programs are constructed by syntax rules. The latter is essentially identical to Component-Based Synthesis, where the synthesizer is provided with a list of functions and operations spanning the program space. Both of these formulations are tackled by many synthesis strategies: enumerative [35, 52, 7, 14, 25, 22, 28, 54, 9, 62, 34], SMT [30, 6, 50, 1] and SAT [56, 58] based, by traversing constructed representations of the space such as VSAs [31, 33, 63], version spaces [53] and Petri-nets [15, 24].

Proof-directed synthesizers. A specific form of enumerative synthesis is one that attempts to find a proof for a proof goal, where the proof dictates a program. This idea is not new [57], and some deductive type-driven synthesizers describe their search as a proof

search [24, 42]. Other works' goals are more expressive than types: refinement types [48], relational specifications [32], select/update operators [41], Separation Logic, and even natural language [10]. Importantly, proof searches are overwhelmingly *deductive*, searching the proof space top-down. To our knowledge, SObEq is the first synthesis proof search that enumerates the proof space bottom-up.

Synthesis with Separation Logic. Separation Logic proofs are a popular vehicle for proof-directed synthesis. They have been successfully used for parallelizing non-parallel code [8], but are most often used to synthesize heap-manipulating programs. SuSLik [49] performs a deductive search with inferences about the heap to generate programs performing pointer operations. Cypress [29] extends this with the ability to synthesize recursive auxiliaries, RoboSuSLik [11] extends it with read-only borrows, and RusSOL [20] applies it to Rust programs, leveraging Rust's type system to simplify the required specification from formal assertions to functional annotations of Rust functions. All of these accept assertions as their specification, hinge on manually-crafted inference rules, and employ solvers. SObEq, in contrast, works on input-output examples and relies only the generic Eval rule in conjunction with an interpreter.

Observational equivalence. Observational Equivalence [59, 2] is a popular way to reduce the size of the space when enumerating bottom-up. Originally OE works on examples, but RESL [45] generalized it to other specifications on programs as well; this generalization also introduced the notions of *interchangeability* and *consistency* that SObEq's correctness relies on. SyMetric [18] relaxes OE to observational similarity by choosing representatives via clustering instead of equivalence, then repairing the resulting program. While this compacts the space like SObEq's subsumption, correctness of SyMetric's solutions hinges on the success of its repair step.

Many of the synthesizers that use OE only synthesize pure programs [46, 7, 45, 2, 60, 40] (we include [45] in this list, despite its misuse of JavaScript's `Array.sort`), others employ synthesis with OE to produce pure expressions that are then used in assignments or other larger mutating expressions [37, 38, 59, 17, 16], creating a top-level program with memory mutations.

Arborist [36] and Lens [47] relax the purity assumption in interesting ways. Arborist tackles the specific problem of dependent loops (e.g., *fold*) where the composition of smaller programs discovers new inputs and changes the equivalence classes. Arborist uses finite tree automata to unify programs without discarding them, which allows it to iteratively break up equivalence classes. Arborist finds a solution if its iterative refinement terminates. Lens take advantage of its target domain (straight line assembly code) to treat operations as having no arguments, making sequences the only composition. In this representation, OE values are full register valuations, and synthesis of state-mutating programs reduces to the OE enumeration used for pure programs. Both hinge on the ability to represent equivalence classes *without* discarding any programs using, implementing OE without a bank, which is only tractable under very strict assumptions on the set of components and on values.

Synthesis with heap mutations. The problem of synthesizing mutating snippets has been worked around in many ways. SL proof-directed approaches assume a limited target language of mutations available to the proof. Sketch[56], Transit [59], SnipPy [17], Simpl [55] and Cozy [37, 38] assume expressions are pure, then use them in specific mutating contexts validated by other means (e.g., SMT). SyPet [15] and EdSynth [61] rely on types for getting programs, and only then evaluate them. Likewise, FrAngel [52] draws random programs, then evaluates them.

LooPy's [16] problem statement bounds the intermediate mutations, and is to enumerate independent paths between these states. Similarly Lens [47] reduces all registers to 3-bit and constructs the full space of intermediate states. Cobalt [41] also separates pure expressions from mutations using provided API annotations. Toshokan [27] encodes the specifications for mutating methods as two versions of the function, one for changes to the state and the other the for result, akin to the two parts of SObEq's postcondition.

CodeHint [22] is, in some ways, the closest to our approach: it defines expressions as equivalent if they have the same value and side effects in the *current state*, or, in our terminology, an equivalence relation on both before- and after-states. How current states are used in enumeration is not defined in the paper, but their implementation uses programs enumerated on the initial state to populate their bank for new after-states, replicating the problem discussed in Sec. 2.1. Moreover, CodeHint's focus is its interactivity, and its interaction is designed around a single example, with any additional information only filtering an initial list of programs, not informing the OE enumeration. This is why we ruled it out as a baseline in Sec. 6.1.

SObEq sheds assumptions that expressions are pure and that intermediate states are known in advance. Moreover, SObEq has the formal guarantee in Theorem 6, unlike the two most general existing solutions: FrAngel, which randomly draws programs, and CodeHint, which performs OE only on its first example and mutated states in an unprincipled manner.

Other side effects like file or database writes have been a challenge in program synthesis. RbSyn [25] addresses database writes via a type-guided top-down enumeration from a syntax including *effect holes* that can be filled with annotated mutating methods; expressions not within effect holes have a purity assumption, limiting how effects are composed, unlike SObEq that can use mutating operations anywhere. CodeHint allows users to enable effects on the file system in their enumeration, even though they cannot be undone like memory mutations are.

Abstract

Contracts and assertions are effective methods to enhance software quality by enforcing preconditions, postconditions, and invariants. Previous research has demonstrated the value of contracts in traditional software development. However, the adoption and impact of contracts in the context of mobile app development, particularly of Android apps, remain unexplored.

To address this, we present the first large-scale empirical study on the use of contracts in Android apps, written in Java or Kotlin. We consider contract elements divided into five categories: conditional runtime exceptions, APIs, annotations, assertions, and other. We analyzed 2,390 Android apps from the F-Droid repository and processed 52,977 KLOC to determine 1) how and to what extent contracts are used, 2) which language features are used to denote contracts, 3) how contract usage evolves from the first to the last version, and 4) whether contracts are used safely in the context of program evolution and inheritance. Our findings include: 1) although most apps do not specify contracts, annotation-based approaches are the most popular; 2) apps that use contracts continue to use them in later versions, but the number of methods increases at a higher rate than the number of contracts; and 3) there are potentially unsafe specification changes when apps evolve and in subtyping relationships, which indicates a lack of specification stability. Finally, we present a qualitative study that gathers challenges faced by practitioners when using contracts and that validates our recommendations.

1 Introduction

Building reliable mobile applications is a growing concern, as they are increasingly used in critical domains such as health, finance, and government. There are now more mobile phones than people in the world[1] with more than 2 million apps available in the App Store and Google Play [37]. Additionally, data from 2024 shows that Android is the most used platform (47%), followed by Windows (26%), and then iOS (18%) [35]. Therefore, faults in mobile apps, and particularly in Android apps, can impact a very large number of users. In addition, with an increasing number of apps in critical areas such as health and finance, faults can have a huge negative impact. It is thus important to use software reliability techniques when developing mobile applications.

One of these techniques is Design by Contract (DbC) [26], under which software systems are seen as components that interact amongst themselves based on precisely defined specifications of client-supplier obligations (*contracts*). Suppliers expect that certain conditions are met by the client before using the component (*preconditions*), maintain certain properties from entry to exit (*invariants)*, and guarantee that certain properties are met upon exit (*postconditions*). These contracts are written as *assertions* in the code. Currently, there are assertion capabilities in most programming languages, but assertions are not universally used.

Current efforts in academia and industry show that DbC [27] is an active topic of interest to the software industry, with companies such as Amazon Web Services and Consensys investing largely in the development of tools such as Dafny [25]. Additionally, the creation of tools like Verus [23] for correctness verification in Rust, further underline its importance. Such tools use DbC in the specifications used for formal verification.

DbC can help identify failures [4], improve code understanding [16], and improve testing efforts [36]. This has led to a number of empirical studies on the use of contracts in a variety of contexts [10, 33, 15, 9, 22, 21, 12, 13]. However, *there are no previous studies on the presence and usage of contracts in Android applications nor any study that includes the Kotlin language*.

We present the first large-scale empirical study of contract usage in Android mobile apps written in Java or Kotlin. Our goal is to understand 1) how and to what extent contracts are used, 2) which language features are used to denote contracts, 3) how contract usage evolves from the first to the last version, and 4) whether contracts are used safely in the context of program evolution and inheritance. Information on how practitioners use contracts can help create and improve tools and libraries by researchers and tool builders [33]. Also, empirical evidence about the benefits of contracts can encourage their adoption by practitioners and the establishment of DbC as a software design standard [36].

In summary, the contributions of this paper are:

- The first large-scale empirical study about contract usage and evolution in Android apps, resulting in a list of findings and recommendations for practitioners, researchers, and tool builders. No previous studies consider Kotlin.

[1] `https://www.weforum.org/agenda/2023/04/charted-there-are-more-phones-than-people-in-the-world/` (last accessed on 01 April 2025)

- A list of language features, tools, and libraries to represent contracts in Android applications.
- A dataset of 1,767 Java and 623 Kotlin Android apps, together with scripts that can be used to build large-scale datasets of Android apps.
- An updated and extended version of Dietrich et al.'s tool [13], which can now analyze Kotlin code and can be used to investigate additional Android-specific contracts.
- A user study that validates our recommendations and contributes with further suggestions from practitioners for increasing contract usage.

Even though we update and extend Dietrich et al.'s tool [13], our work *is not* a replication of their study. Our study differs from theirs by focusing on Android apps and not on Java apps only. Due to the focus on Android, our study considers Kotlin in addition to Java, as since 2019, Kotlin is the preferred language for Android app developers[2]. Further, Kotlin is now used by over 60% of Android professional developers[3].

As mentioned above, similar studies to ours have been conducted for different ecosystems, because investigating how developers use contracts can inform future developments that make DbC more effective in practice, thus increasing software reliability.

Data & Artifact Availability. To support our study, an artifact was developed to automatically collect contracts from Android applications and to produce the necessary empirical data. The artifact is written in Python and Java, and includes an extension of the tool proposed by Dietrich et al. [13]. All the code and datasets are publicly available: `https://github.com/sr-lab/contracts-android`

2 Contracts in Android Applications

Our notion of contract follows from the theory of *design by contract* [26], where preconditions, postconditions, and invariants are used to document (and specify) state changes that might occur in a program. Pre and postconditions are associated with individual methods and constrain their input and output values. On the other hand, invariants are associated with classes and properties and constrain all the public methods in a given class. Preconditions represent the expectations of the contract, and postconditions represent its guarantees. Invariants represent the conditions that the contract maintains.

Contrary to the Eiffel language, conceived by Bertrand Meyer in 1985, neither Java nor Kotlin provide a native and standardized approach for contract specification [10]. Still, developers can take advantage of language features and libraries to specify preconditions, postconditions, and class invariants in both languages. For example, they can use constructs provided by the programming language, such as the Java `assert` keyword introduced in Java 1.4; they can use conditional runtime exceptions such as Java `IllegalArgumentException`; they can use annotations such as the AndroidX annotations `@NonNull` and `@Nullable`; and they can use specialized libraries such as Google Guava's Preconditions API.[4]

To facilitate the comparison with previous studies, we group these constructs into the five categories proposed by Dietrich et al. [13]: conditional runtime exceptions (CREs), APIs, annotations, assertions, and other. The main difference is that, since we focus on Android

[4] `https://guava.dev/releases/snapshot-jre/api/docs/com/google/common/base/Preconditions.html` (last accessed on 01 April 2025)

Table 1 Contract elements considered in this study.

category	examples

CREs (74 constructs)	`IllegalArgumentException`
	`EmptyStackException`
	`SecurityException`
	`UnsupportedOperationException`
	`AccessControlException`
	`IndexOutOfBoundsException`
	`NullPointerException`

APIs (31 constructs)	`org.apache.commons.lang.Validate.*`
	`org.apache.commons.lang3.Validate.*`
	`com.google.common.base.Preconditions.*`
	`org.springframework.util.Assert.*`

Assertions (6 constructs)	`assert` (Java) `assert` (Kotlin) `check(), checkNotNull()` (Kotlin) `require(), requireNotNull()` (Kotlin)

Annotations (136 constructs)	`org.jetbrains.annotations.*`
	`org.intellij.lang.annotations.*`
	`edu.umd.cs.findbugs.annotations.*`
	`android.annotation.*`
	`androidx.annotation.*`
	`javax.annotation.*` (JSR305)

Other (1 construct)	`@ExperimentalContracts` (Kotlin)

applications, we include contract elements that are specifically used by Android developers (e.g., Android annotations and specific Android runtime exceptions). To search for relevant contract elements, we used two main additional sources: the Android API Reference[5] and the Kotlin Standard Lib API[6]. Table 1 summarizes the classification and provides some examples; we consider a total of 248 constructs. Below, we briefly describe each category. More details are included in the Supplementary Material [17].

2.1 CREs

An exception can be used to signal, at runtime, a contract violation. Bloch [6] suggests the use of runtime exceptions to indicate programming errors, as the great majority indicates precondition violations. However, it is important to note that the exception itself does not represent a contract; it needs to be associated with a previous check (e.g., an exception thrown inside an *if-else block*) to be considered so. Java and Kotlin offer many exceptions that can be used for this purpose, such as the *IllegalArgumentException*. The *android.util* package offers additional exceptions that we are also interested in analyzing, such as the case of the *AndroidRuntimeException*. Additionally, we are interested in a particular exception, the *UnsupportedOperationException*, which, according to the Java documentation, is thrown to indicate that the requested operation is not supported. As Dietrich et al. argue, this is the strongest possible precondition and can not be satisfied by any client [13].

The following code shows an example of a precondition. An *IllegalArgumentException* is thrown when the contract *shoppingCart.isEmpty()* is violated. The method *proceed-*

[5] `https://developer.android.com/reference` (last accessed on 01 April 2025)
[6] `https://kotlinlang.org/api/core/kotlin-stdlib` (last accessed on 01 April 2025)

WithCheckout can only perform its task when the *shoppingCart* has at least one item.

```
1      public void proceedWithCheckout(List<Item> shoppingCart)  {
2          if (shoppingCart.isEmpty()) {
3            throw new IllegalArgumentException();
4          }
5          ...
6      }
```

We consider a total of 74 CREs (while Dietrich et al. [13] consider six). We show some examples in Table 1 but, due to lack of space, the full list is in the Supplementary Material [17].

2.2 APIs

APIs consist of wrappers around conditional exceptions and other basic constructs. This contributes to a simpler and explicit representation of contracts. We are interested in the four APIs listed in Table 1. For example, the *Apache Commons* offers the *Validate*[7] class that, according to the official documentation, "assists in validating arguments", suggesting a precondition usage. The methods provided by the *Validate* class are simply wrapping exceptions that we have already considered in the CREs. The same libraries do not offer any equal approach to specify postconditions, which suggests a preference from tool builders towards preconditions. Nevertheless, and against the guidelines, practitioners can still use any of those API's methods to check postconditions.

In the following example, that makes use of an API, a precondition *items list is not empty* is declared. In other words, the method *addToShoppingCart* guarantees that if the client fulfills its obligation to provide a non-empty list of items, it will be able to perform its job correctly.

```
1      import org.apache.commons.lang3.Validate
2
3      fun addToShoppingCart(items: List<Item>): List<Item>  {
4          Validate.notEmpty(items)
5          shoppingCart.addAll(items)
6          return shoppingCart
7      }
```

2.3 Assertions

Assertions were introduced in Java 1.4 and are specified through the *assert* reserved keyword. It helps practitioners verify conditions that must be true during runtime. JVM throws an *AssertionError* if the condition is false. However, JVM disables assertion validation by default, requiring it to be explicitly enabled. This means that practitioners may assume that contracts specified through assertions will be validated at runtime when in fact the assertions are disabled. This leads to an incorrect, and potentially dangerous, assumption. Having that in mind, assertions can still easily be used to check preconditions and postconditions.

In the following example, the contract associated with the *addToShoppingCart* method defines two preconditions – the list of items to add to the shopping cart must have a size of

[7] `https://commons.apache.org/proper/commons-lang/apidocs/org/apache/commons/lang3/Validate.html` (last accessed on 01 April 2025)

greater than zero and *smaller or equal to ten* – and a postcondition – the items added to the shopping cart *will be present in the shopping cart list*.

```
1      public List<Item> addToShoppingCart(List<Item> items){
2        assert !items.isEmpty();
3        assert items.size() <= 10;
4        shoppingCartItems.addAll(items);
5        assert shoppingCartItems.containsAll(items);
6        return shoppingCartItems;
7      }
```

Kotlin also has its own *assert*. However, contrary to the Java version, *assert* in Kotlin is a function and not a reserved word. This means that any class can define a method with the name *assert*, which makes it harder for an automated analysis tool to distinguish between Kotlin's assert or a developer's custom method. Additionally, contrary to Java, Kotlin always executes the assert expression and only uses the *-ea* JVM flag to decide whether to throw the exception. Kotlin also offers other methods: *check()*, *checkNotNull()*, *require()*, and *requireNotNull()*. Although these throw an *IllegalArgumentException* or an *IllegalStateException* instead of an *AssertionError*, we added them to the assertions category because of their syntactic similarities.

The following code uses Kotlin's methods to specify the same pre and postconditions as in the previous Java example.

```
1      fun addToShoppingCart(items: List<Item>): List<Item> {
2          assert(items.isNotEmpty())
3          require(items.size <= 10)
4          shoppingCartItems.addAll(items)
5          check(shoppingCartItems.containsAll(items))
6          return shoppingCartItems
7      }
```

2.4 Annotations

Annotations are metadata added to the program providing information that can be used at compile time or runtime to perform further actions. Java provides many annotations through the *java.lang* package. Table 1 lists the annotation packages we are particularly interested in studying. No previous studies consider the *android.annotation* and the *androidx.annotation*.

The annotation-based approach is particularly interesting for two reasons. First, many annotations can be associated with the method's arguments (preconditions), the method's return values (postconditions), or the class properties (invariants). Second, since annotations are usually added to the method's signature or to the class property, there is a greater separation between the contract specification and the service's implementation. This means that annotations, like in the Eiffel's approach, do not increase the complexity of the method's implementation, contrary to what happens with CREs, APIs, and assertion-based approaches.

The code shown below uses annotations from the *javax.validation.constraints.** packages to specify contracts. The method states that it can only *return a list with a minimum size of 1* (postcondition), if the *item identifier is not null* and the *quantity is greater or equal to one* (preconditions). Also, the class property *items* is associated with a class invariant that states that the *shopping cart can only contain ten items at maximum*. This example shows that adding contracts through annotations does not require adding extra checks to

the implementation, contributing to cleaner code.

```
1      import javax.validation.constraints.*
2      class ShoppingCart {
3          @Size(max=10)
4          private val items: List<Item> = mutableListOf()
5
6          @Size(min=1) fun addItem(@NotNull itemUUID: String, @Min(1)
               quantity: Int): List<Item> {
7              ...
8          }
9      }
```

2.5 Other

We consider Kotlin Contracts[8], an experimental feature introduced in Kotlin 1.3 that allows developers to state a method's behavior to the compiler explicitly. As the following example shows, they also provide useful information to the compiler: the call to *split* in line 4 causes no error, because the contract specified in line 10 guarantees that *birthdate* is not null.

```
1  @ExperimentalContracts
2  fun sendBirthdayMessage(birthdate: String?) {
3   birthdateIsValid(birthdate)
4   val birthdaySplit = birthdate.split("/")
5    ...
6  }
7
8  @ExperimentalContracts
9  fun birthdateIsValid(birthdate: String?) {
10  contract{returns() implies (birthdate != null)}
11  if (birthdate == null) {
12   throw IllegalArgumentException()
13  } ... }
```

3 Related Work

This section presents related work on the usage of contracts, assertions, and annotations by practitioners.

3.1 DbC and Contract Usage

It is widely supported that DbC contributes to improving software reliability [28, 39, 19]. The advantages commonly mentioned are that DbC (i) improves code understanding [16, 29, 39, 34], (ii) helps identify bugs earlier and diagnose failures [39, 4, 9, 13, 33], and (iii) contributes to better tests [39, 4, 33, 3, 36]. Some studies demonstrated that DbC requires fewer project person-to-hour resources [8, 36], but could not confirm an impact on quality. Moreover, DbC contributes to less time spent on writing tests [36]. Blom et al. [7] suggest that DbC results in fewer errors and decreases development time. In another study, Zhou et al. [42] show that DbC increased reliability in software components. In a study on C# projects using Code Contracts, Schiller et al. [33] found a high percentage of contracts related to

[8] `https://github.com/Kotlin/KEEP/blob/master/proposals/kotlin-contracts.md` (last accessed on 01 April 2025)

null checking and suggest the importance of creating design patterns alongside tools and libraries. Estler et al. [15] analyzed 21 Eiffel, C#, and Java projects known to be equipped with contracts. Most contracts are null checks, with preconditions being typically larger than postconditions. The authors concluded that the average number of clauses per specification is stable over time and that the method's implementation changes more frequently than its specification. However, they warned that strengthening contracts may be more frequent than weakening, indicating some unsafe evolution of contracts. Lastly, Dietrich et al. [13] investigated 176 popular Java projects in the Maven repository and found that the majority of programs do not use contracts significantly. They found that CREs are the most commonly used category, followed by asserts. The dominance of preconditions over postconditions in contracts is consistent with other studies [10, 33]. They found that projects that use contracts maintain or even expand their usage over time. Similarly to Estler et al. [15], the authors reported some unsafe evolution of contracts, which can happen when a method strengthens its preconditions or weakens its postconditions. They also found many violations of the Liskov Substitution Principle (LSP), with prevalence in the annotations. The LSP states that objects of a superclass should be replaceable with objects of a subclass without altering the correctness of the program. According to this principle, a sub-type can only weaken preconditions or strengthen postconditions and class-invariants from its parent [1]. A sub-type should behave in a way that does not violate the expectations set by its super-type. This ensures that any code that works with the super-type can work with the sub-type without requiring modifications or encountering unexpected behavior. The authors caution that their dataset mainly includes libraries, which may explain the low usage of annotations. This study is the one most related to the work presented here, as it also studies contracts in Java. However, our study differs from Dietrich et al.'s [13] in that, not only we consider more constructs, we also focus on Android apps and we study both Java and Kotlin.

3.2 Assertion Usage

Kudrjavets et al. [22] studied two Microsoft Corporation components, written mainly in C and C++, and found that increased assert density led to a decrease in fault density, and that using asserts was more effective for fault detection than some static analysis tools. Kochhar and Lo [21] studied a dataset of 185 Apache Java projects available on GitHub and found that adding asserts contributes to fewer defects, especially when many developers are involved. This agrees with reports from Kudrjavets et al. [22] but it is not supported by Counsell et al. [12], who analyzed two industrial Java systems and found no evidence that asserts were related to the number of defects. Kochhar and Lo [21] also concluded that developers with more ownership and experience use asserts more often, which shows that more advanced programmers see it as a valuable practice. In line with other previously mentioned studies for contracts [33, 15], most uses are related to null-checking.

3.3 Annotation Usage

There is a general understanding that the use of annotations among practitioners is growing [40, 18]. Yu et al. [40] conducted a study on 1,094 GitHub open-source projects and found a median value of 1.707 annotations per project, with some developers overusing them. The authors argue the need for better training and tools to help derive better annotations. Other authors made a similar claim for contracts [33]. Additionally, developers with higher ownership use annotations more often, which agrees with the findings by Kochhar and Lo [21] related to assertion usage. Grazia and Pradel [18] investigated the evolution of type

annotations, some of which can act as contracts, in 9,655 Python projects. The authors reported that although type annotations usage is increasing, less than 10% of potential elements are being annotated. This contradicts the (general) annotations overuse reported by Yu et al. [40]. More importantly, the study found that once added, 90.1% of type annotations are never updated. This indicates that specifications are more stable than implementations, which is desirable. A similar finding was reported by Estler et al. [15] related to the stability of contracts while the program evolves. Also relevant is that most type annotations were associated with parameter and return types, rather than with variable types. Finally, the authors found that adding type annotations increased the number of detected type errors. This motivates the general use of these features to improve software reliability.

4 Study Design

In this section, we present the design of our study, including the research questions, how the dataset of Android apps is created, the classification used for contracts, and the methodologies used to study contract usage and evolution.

4.1 Research Questions

In this study, we aim to answer the following research questions:

- **RQ1**. [**Contract Usage**] How and to what extent are contracts used in Android applications?
- **RQ2**. [**First-To-Last Version Evolution**] How does contract usage evolve in an application from the first to the last version?
- **RQ3**. [**Safety**] Are contracts used safely in the context of program evolution and inheritance?

4.2 Dataset

The dataset used is composed of real-world apps obtained from F-droid,[9] an alternative app store listing over 4,000 free and open-source projects. The fact that it has a large number of open-source apps on a wide range of domains, makes F-Droid a good option. Moreover, F-Droid is normally used in research studies on Android apps [11, 41]. Apart from native Android apps written in Java or Kotlin, F-Droid's catalog also contains projects that use hybrid frameworks (e.g., React Native) that we exclude from our dataset.

We started by downloading the *F-Droid index*, which is a list of URLs for each project available in the catalog. Next, this list is *filtered* based on the following criteria: **1)** The application source code is hosted in GitHub; **2)** The application source code is either Java or Kotlin; **3)** The GitHub project is not archived; **4)** The GitHub project has had a commit since 2018. These inclusion criteria ensure that the project's source code is easily accessible (through GitHub), is written mainly in Java or Kotlin (the languages we are interested in studying), while also guaranteeing that the project is active and relevant. We retrieve *two versions* for each of the filtered projects, which is a required step for the *First-to-Last Version* evolution study. We do this by storing a list of the URLs pointing to two GitHub versions: we first try to retrieve the oldest and the most recent *release*; if there are not enough releases, we try to retrieve the oldest and the most recent *tag*; finally, if there are not enough tags, we

[9] `https://f-droid.org` (last accessed on 01 April 2025)

Table 2 Dataset metrics.

metric	Java	Kotlin	Both
projects	1,767	623	2,390
compilation units	208,479	129,490	337,969
classes	305,749	265,410	571,159
methods (all)	2,113,620	632,416	2,746,036
constructors (all)	208,949	100,534	309,483
methods (public, protected, internal)	1,801,171	506,647	2,307,818
constructors (public, protected, internal)	187,789	99,221	287,010
KLOC including comments	40,635	12,341	52,977

just keep the most recent commit of the repository. If there are no releases nor tags, we only consider one version (excluding it from the *First-to-Last Version* evolution study). Although our script resolved most of the versioning schemes found, some projects required manual handling to determine which version was the first and the last. Throughout the paper we refer to the most recent version as *last* or *second* version. Finally, we clone all the projects contained in the versions list. *Every file that is neither a Java nor a Kotlin file is removed* from the dataset, which helps to decrease its size.

4.2.1 Dataset metrics

From the initial list of 4,070 projects in the F-Droid index retrieved on May 21, 2023, we got 3,215 hosted in GitHub, 3,141 non-duplicated URLs, and 2,390 projects after filtering by the inclusion criteria. Out of these, 1,767 are Java applications and 623 are Kotlin applications. For 1,802 applications we were able to retrieve two versions to be used in the *first-to-last version evolution* study. This means that for 588 applications it was only possible to retrieve one version (these are applications for which there are no GitHub releases nor tags). While these applications are still evaluated in the context of the *usage* and *LSP* studies, they are not considered for the *first-to-last version evolution* study.

Table 2 presents additional metrics about the dataset size. As the table shows, the dataset is imbalanced, with more Java apps. The dataset includes 208,479 Java and 129,490 Kotlin compilation units and, therefore, Java represents 61.7% of the overall number of compilation units. This imbalance requires caution when trying to read this work's results from the perspective of comparing Java against Kotlin's use of contracts. Furthermore, the dataset includes 571,159 classes, 2,746,036 methods, and 309,483 constructors. We did not consider *private* methods, because those are not used directly by a client, and a contract is a bond between a supplier and a client. In total, we analyzed 2,594,828 *public*, *protected*, and *internal* methods and constructors.

In terms of diversity, the dataset includes apps from various domains, such as gaming, communication, multimedia, security, health, and productivity.

4.3 Data Collection and Analysis

Here, we describe the analysis tool and the studies conducted to answer our research questions: the usage study, the *first-to-last version* evolution study, and the Liskov Substitution Principle study.

4.3.1 Analysis Tool

Our analysis tool is an extension of the tool created by Dietrich et al. [13], which was used in their study on the usage of contracts in Java apps. We extended the tool to support Kotlin and more constructs focused on Android apps. Additionally, the framework suffered considerable refactoring and organization to ease its comprehension and maintainability. The main effort was to add support for Kotlin. The original tool used the JavaParser[10] library to perform AST analysis of Java code. Since this library is not able to parse Kotlin source code, we integrated JetBrains's Kotlin compiler[11] to perform this task. This required us to implement new versions of the tool's extractors and visitors classes using the methods provided by the new library to be able to identify contract patterns in Kotlin. We also updated the JavaParser library to support newer Java versions.

The tool is divided into three parts: 1) *usage*, which extracts the list of contracts present in each program and produces statistics about their use; 2) *inheritance*, which identifies contracts in overridden methods and validates whether they violate the Liskov Substitution Principle; and 3) *first-to-last version evolution*, which analyses how identified contracts evolve in later versions of the application. The following sections describe how each component contributes to answering our research questions.

4.3.2 Usage Study

The usage study is divided in two main steps: 1) identifying contract occurrences and 2) producing statistics about those results. Our tool uses the JavaParser and JetBrains's Kotlin compiler libraries to perform AST analysis. This analysis is done against a set of extractors to identify occurrences of our defined constructs. Each category requires different approaches for their identification:

- *CREs*. During the AST analysis, we look for the pattern:

  ```
  if (<condition>) { throw new <exception> (<args>) }
  ```

  When this pattern is found, we check whether the exception belongs to the list of CREs considered (see Section 2). In line with Java's good practices, we assume that CREs are used with preconditions.
- *APIs*. Firstly, we check whether the file contains an import declaration to any API package considered. If any is found, all call expressions in that file are analyzed to determine if they are invoking any of the methods provided by the API. As stated before, we assume the analyzed APIs to be associated with preconditions.
- *Assertions*. Identifying Java asserts is straightforward since the JavaParser provides a visitor method for this particular statement. The complexity lies in identifying Kotlin asserts, which is not a reserved keyword. To handle this challenge, when analyzing a file, we first search for any method declaration and any import statement that has a name equal to one of the following expressions: *assert*, *require*, *requireNotNull*, *check*, and *checkNotNull*. Next, we identify whether the class invokes any method with one of those names. Suppose a class contains a method declaration or import statement, as well as an invocation using the name of one of these expressions. In that case, we consider it an ambiguous situation, and therefore, we do not consider it an assert instance. If the class

[10] `https://javaparser.org` (last accessed on 01 April 2025)
[11] `https://github.com/JetBrains/kotlin` (last accessed on 01 April 2025)

invokes one of those methods but does not declare/import any method with that same name, we consider it an assert. We do not classify assertions either as preconditions or postconditions.

- *Annotations*. We check if the source code file contains an import statement to one of the packages listed in Table 1. If that is the case, we check every annotation in that file to see if it matches any of those provided by the imported package. We also identify the artifact to which the annotation is associated as follows: 1) annotations associated with a method's parameters are preconditions; 2) annotations associated with a method are postconditions; and 3) annotations associated with a field are class invariants.
- *Others*. This category only includes the investigation of the experimental *Kotlin Contracts*. To identify occurrences of this construct, we look for the pattern `contract {returns (<condition>) implies (<condition>)}`.

Our tool creates a *JSON* file for program version that stores the identified contracts, including 1) the file path, 2) the associated condition, 3) the method or property name, 4) the type of artifact (method or property), 5) the line number, and 6) the contract type. In the second step of the *usage* study, all the *JSON* files are analyzed to produce statistics about the identified contracts, including the frequency of each category (API, annotation, assertion, etc.), class (preconditions, postconditions, and class invariants), and construct (java assert, Guava API, *androidx* annotations, etc.). For each category, we also compute the Gini coefficient and the list of programs with more contracts.

4.3.3 First-to-Last Version Evolution

We focus on the initial and final GitHub versions of each project as these represent critical moments in the development: the initial introduction of the DbC constructs and the culmination of the development process. This allows us to check if there were any significant changes in the use of contracts.

After identifying a contract in the first version of the app, we check whether, in the later version, the contract still exists, was modified, or removed. We also report cases when a contract is added to an artifact (method or parameter) in the later version of the app (but was not present in the first version). These provide insights into how contracts evolve in an app and whether this evolution poses risks to the client.

As already mentioned, a contract establishes rights and obligations between clients and suppliers. Therefore, when a contract is altered, both parts should be informed and updated accordingly. This is particularly crucial when a *precondition is strengthened* or when a *postcondition is weakened*. In the first case, if the precondition is strengthened and the client does not know it, it can fail to cover its new obligations, and, therefore, the supplier is not bound to keep its part of the contract. In the latter case, if the postcondition is weakened, the client may still be making assumptions that the supplier does not ensure anymore. An example is shown in Listing 1, where the annotation *@NonNull* was added to the *toolbar* parameter in the last version. This is the case of a *precondition strengthening*: in the first version, the method accepted a null *toolbar*, but now it requires it to be not null. Therefore, if the client is not updated, it will fail to cover its new obligation.

Similarly to Dietrich et al. [13], we create *diff records* from the contracts present in the two versions of a program's method and then classify them according to the *evolution patterns* listed in Table 3.

4.3.4 Liskov Substitution Principle Study

When a method is overridden in a subclass, that class can specify new contracts added to the ones inherited from the superclass method. In this case, proper handling of contracts should

Listing 1 Example of a precondition strengthened using the annotation `@NonNull`, taken from the project Retro Music Player, a music player for Android (in class ToolbarContentTintHelper).

```
    public static void setToolbarContentColorBasedOnToolbarColor(
        @NonNull Context context,
-       Toolbar toolbar,
+       @NonNull Toolbar toolbar,
        @Nullable Menu menu,
        int toolbarColor,
        final @ColorInt int menuWidgetColor
```

Table 3 Classification of the diff records produced during the evolution and LSP study.

Classification	Description	Risk
PreconditionsStrengthened	A precondition was added to a method or a clause to an existing precondition with the '&' or '&&' operators.	Potential risk
PreconditionsWeakened	A precondition was removed from a method, or a clause was added to an existing precondition with the '|' or '||' operators.	No risk.
PostconditionsStrengthened	A postcondition was added to a method or a clause to an existing postcondition with the '&' or '&&' operators.	No risk.
PostconditionsWeakened	A postcondition was removed from a method, or a clause was added to an existing postcondition with the '|' or '||' operators.	Potential risk.
MinorChange	Contract elements are the same, but in different order; or removal of a Nullable postcondition, which is not considered as a significant weakening [13].	No risk.

follow the Liskov Substitution Principle (LSP), which states that the subclass method must accept all input that is valid to the superclass method and meet all guarantees made by the superclass method. In other words, a subclass method can only *weaken preconditions* and *strengthen postconditions*.

To detect those occurrences, we list all methods in each program-version pair associated with their respective class. We also identify the class' parents. Then, similarly to the *first-to-last version* evolution study, diff records are created between the subclass and the superclass methods. These records are classified based on the evolution patterns outlined in Table 3, following the categories and descriptions proposed by Dietrich et al. [13].

5 Results

In this section, we present the results of our empirical study, as well as the main findings. As mentioned earlier, the dataset contains an imbalanced distribution of compilation units, with 61.7% written in Java and 38.3% in Kotlin. This imbalance should be considered when interpreting the findings, particularly in the context of comparing contract usage between Java and Kotlin.

5.1 RQ1: Contract Usage

Table 4 shows the number of contracts found per category, considering all versions (columns 2 and 3) and considering only the latest version of each app (columns 4 and 5). The table also identifies the number of apps containing at least one contract for that category (columns 6 and 7). The most obvious conclusion is that, in both languages, annotation-based contracts are the most popular category. More specifically, considering both languages in the last version, annotations represent 85.2% of the contracts found, followed by CRE with 11.1%, and then assertions with 2.9%. The results show similar tendencies between Java and Kotlin, and the only difference is that while Java's second most popular category is CREs, in Kotlin, it is assertions. This relatively high percentage of the assertion category in Kotlin is explained by our inclusion of the four language's standard library methods listed in Section 2, where *require()* alone counts 901 total occurrences.

Finding 1: Most contracts are annotation-based, accounting for 86.21% in Java and 79.29% in Kotlin of the total number of contracts found.

This distribution in categories' popularity significantly differs from the findings of Dietrich et al. [13], who reported that the most common category was CREs and found surprisingly low use of annotations. This may be explained by the fact that, while our dataset is formed mostly by user-focused Android applications, Dietrich et al.'s dataset was mainly Java libraries. In Table 6, we can also see that most annotations found belong to the *androidx.annotation.** package that the authors did not consider since it is Android-specific. Nevertheless, the high number of annotation-based contracts found is in line with literature that supports its increasing popularity [40, 18].

From Table 4, we also verify that the usage of *APIs* is low in both languages, and it is even more residual in Kotlin applications, where only nine instances were found in the latest versions. Skepticism around adding third-party dependencies to projects, which may lead to maintainability and support issues in the future, may explain this finding [5, 38].

Table 4 Number of contracts found in the dataset by category.

	contracts (all ver.)		contracts (2nd ver.)		applications	
Category	Java	Kotlin	Java	Kotlin	Java	Kotlin
API	1,813	10	1,125	9	24	4
annotation	194,448	26,849	115,861	17,490	1,227	547
assertion	3,525	3,868	2,217	2,370	325	234
CRE	26,076	3,374	15,195	2,187	787	288
other	–	1	–	1	–	1

Table 5 Gini coefficient by category.

Category	**Java**	**Kotlin**
assertion	0.70	0.71
API	0.80	0.37
annotation	0.87	0.76
CRE	0.77	0.67
others	–	1.00

Finding 2: The use of APIs to specify contracts is rare.

Table 6 shows the frequency of each construct. We highlight that the high number of annotations found is leveraged mostly by the *androidx.annotation.** package. In APIs, the *Guava* library constitutes most of the usage. We were not expecting to see any usage of *Spring Framework Asserts* since this library was designed to be used in the *Spring* framework, but we still found one occurrence. At the same time, we found no occurrences of the now deprecated *FindBugs* annotations. Additionally, we identified a single occurrence of *Kotlin Contracts*, which may depict the practitioner's distrust of using a feature still in an experimental phase.

We now consider Table 5, which presents each category's computed *Gini coefficient*. The *Gini coefficient* measures the inequality among the values of a frequency distribution. In other words, a *Gini coefficient* of 0 indicates perfect equality, where all apps have the same number of contracts. In contrast, a *Gini coefficient* of 1 means that a single program has all the contracts. We observe that all coefficients in the table are high, except for Kotlin's API usage. This means that although some apps use contracts intensively, the majority does not use them significantly. This aligns with the results found by Dietrich et al. [13]. This conclusion can also be seen in Table 7, where the five projects that use more contracts per category are listed. The table shows the number of contract elements used and the application's category. We find that a small group of projects own a large percentage of the overall use in each category. It is clearly visible from the *assertion* and *CRE* categories that the numbers quickly decrease through the first to the fifth application showing the unbalanced usage between applications. F-Droid does not provide statistics, such as downloads, but the categories shown provide an indication of their purpose (with over half of these applications belonging to the category *Internet*).

Finding 3: Although there are some applications that use contracts intensively, the majority do not use them significantly.

Lastly, Table 8 presents the frequency of each contract type. Once again, we have distinct results for Java and Kotlin. In Java, we found 64.80% of the *classified* instances in the

Table 6 Number of contracts found in the dataset by construct and category.

		contracts (all ver.)		contracts (2nd ver.)

JetBrainsNotNull (612)	AndroidXUiThread (347)

last versions to be preconditions, 22.87% postconditions, and only 12.32% class invariants. These results align with other studies on contracts [10, 33, 13] that show a clear preference towards preconditions. However, results for Kotlin are different: considering last versions, we found 38.81% to be postconditions, 31.64% class invariants, and 29.55% preconditions. This suggests that Kotlin developers tend to favor postconditions, while preconditions come at the last position. According to the classification described in Section 4.3.2, only annotations are classified as postconditions or class invariants. This means that in Kotlin, there is a higher number of annotations associated with methods' return values and class properties than with the methods' parameters.

Finding 4: Java and Kotlin practitioners display different tendencies when it comes to the contract type. In Java, there is a preference towards preconditions, while in Kotlin, postconditions are the most frequent type.

Although we can not provide a reason for this finding with certainty, analysing the most frequent constructs for pre and postconditions in both languages can give us some hints.

Tables 9 and 10 show the top 10 most frequent constructs per type in the last versions of Java and Kotlin apps, respectively. Comparing the two tables reveals distinct behavior patterns: for Kotlin, none of the top ten constructs relates to null-checking; however, for Java's instances reported in Table 9, 84.48% of preconditions and 73.05% of postconditions are associated with null-checking. In this number, we are not considering potential *IllegalArgumentException* and *IllegalStateException* that could be associated with null-checking since this would require analyzing the condition in the *if-statement*. This suggests a lack of expressiveness in the contracts specified by Java practitioners, with most being associated with null-checking, consistent with prior studies [33, 15].

This contrast in null-checking contracts between Java and Kotlin is easily explained by the languages' different takes on nullability. In Kotlin, regular types are non-nullable

Table 10 The top 10 most frequent constructs per type in the last versions of Kotlin applications.

Preconditions	Postconditions
AndroidXStringRes (1,162)	AndroidSuppressLint (2,289)
IllegalStateException (772)	AndroidXVisibleForTesting (1,663)
IllegalArgumentException (748)	AndroidXRequiresApi (738)
AndroidXColorInt (532)	AndroidXWorkerThread (638)
AndroidXDrawableRes (435)	AndroidXMainThread (442)
AndroidXAttrRes (255)	AndroidXCallSuper (323)
AndroidXColorRes (199)	AndroidXColorInt (244)
AndroidXIdRes (187)	AndroidTargetApi (205)
ProviderMismatchException (177)	AndroidXUiThread (196)
UnsupportedOperationException (116)	AndroidXAnyThread (184)

Table 11 Contract elements by type in both versions.

		contracts (1st vers.)		contracts (2nd vers.)	
Type	category	Java	Kotlin	Java	Kotlin
cond. runtime exc.	CRE	10,678	1,161	14,887	2,071
unsupp. op. exc.	CRE	203	26	308	116
java assert	assertion	1,308	–	2,217	–
kotlin assert	assertion	–	1,498	–	2,370
guava precond.	API	677	1	1,121	9
commons validate	API	11	0	3	0
spring assert	API	0	0	1	0
JSR303, JSR349	annotation	0	0	0	0
JSR305	annotation	2,062	7	2,133	13
findbugs	annotation	0	0	0	0
jetbrains	annotation	714	40	1,596	98
android	annotation	4,990	2,290	7,013	3,414
androidx	annotation	70,821	7,022	105,119	13,965
kotlin contracts	others	–	0	–	1

by default; therefore, in most cases, practitioners do not have the need for constructs like *AndroidXNonNull* or *JSR305NonNull*. On the other hand, it is interesting to observe that relaxing this constraint to allow nullable types is not a common practice since we found no meaningful use of constraints like *AndroidXNullable* and similar in Kotlin.

Finding 5: In Java applications, at least 80.85% of preconditions, 63.84% of postconditions, and 62.73% of class invariants are related to null-checking. In the case of Kotlin, we found only about 3.18% of preconditions, 7.17% of postconditions, and 0.66% of class invariants to be performing null-checking.

5.2 RQ2: First-to-Last Version Evolution

Table 11 presents the number of contracts in both versions by category. The *Type* column presents all types that are supported. In general, for most cases, the number of contracts in each category increased from the first to the last version. The only category where the number decreased was the *Apache's Commons Validate* for Java.

We computed some metrics to understand how the increase in the program's size relates to the number of contracts (see Table 12). These include the average and median values

Table 12 Average and median number of methods, contracts, and their ratio for the two versions.

	1st version		2nd version	
Metric	Median	Average	Median	Average
methods count	288	925.175	334	1039.360
contracts count	8	72.567	7	86.807
contract-to-method ratio	0.038	0.072	0.030	0.064

for the number of methods, the number of contracts, and the ratio between both (for both versions). The table shows that there is an average increase of about 114.185 methods per program. This is expected since the program's size tends to increase from the first to the second version. However, a more interesting insight comes from the contracts count. Although the average number of contracts per program increased, its median value decreased. This means that the dataset includes outliers with a significant rise in contract usage that considerably affected the average value. To confirm this data, we computed the ratio between the number of contracts and the number of methods for each version of a program. Then, we computed the difference between the second and the first version's ratio for each program. The average of these differences is -0.0077, and the median is -0.0012. Although the values are very small, we conclude that the number of methods increases significantly more than the number of contracts.

Finding 6: Apps that use contracts continue to use them in later versions. Moreover, the total and average numbers of contracts increase, but its median decreases by a small factor. Also, the number of methods increases at a higher rate than the number of contracts.

Similarly to our study, Dietrich et al. [13] also found that the median value of the ratio does not change much. Still, while we observed a decline between the two versions (from 0.038 to 0.030), they reported an increase (from 0.021 to 0.023). This means that although both studies show general stability related to contracts usage, contrary to their study, we were not able to find a positive correlation between the increase in the number of methods and in the number of contracts.

5.3 RQ3: Safety

To address whether practitioners tend to misuse contracts in either program evolution or inheritance contexts, we build *diff records* to be classified according to *evolution patterns*. Some of these *evolution patterns* are associated with a potential risk that may lead to client breaks, namely when *preconditions are strengthened* or *postconditions are weakened*. This process was described in more detail in Sections 4.3.3 and 4.3.4. It is important to note that the analysis tool cannot precisely capture all contract changes due to the variety of constructs we are analyzing and the complexity of their semantics. This can potentially lead to under-reporting. Another factor that may contribute to under-reporting is file path changes between versions, which may lead to no evolution patterns being detected. Even so, Table 13 still provides valuable insights into the safety of contract usage and evolution. The table shows the frequency of each *evolution pattern* in the context of *program evolution* (third column). We see that many contracts remain unchanged and that most changes are not critical. However, most of the changes that occur can lead to potential breaks, with *precondition strengthening* being over three and a half times more prevalent than *postcondition weakening*.

Listing 2 Example of a postcondition weakened using a Jetbrains annotation, taken from the project mGerrit, a Gerrit client for Android (in class SyncProcessor).

```
1 -   @NotNull
2     public Intent getIntent() { return intent; }
```

Table 13 Contract evolution in the context of program evolution and inheritance.

Contract Evolution	Critical	Evolution (#)	Inheritance (#)
unchanged	no	28,723	207
minor change	no	61	5
preconditions weakened	no	688	5
postconditions strengthened	no	1,035	76
preconditions strengthened	yes	1,963	284
postconditions weakened	yes	552	1
unclassified	?	858	159

An example of a precondition strengthening using an annotation and taken from our dataset was already shown in Listing 1. The code is from the class `ToolbarContentTintHelper` in project Retro Music Player,[12] a music player for Android. Adding `@NonNull` to the toolbar parameter strengthens the precondition by explicitly requiring callers to pass a non-null `Toolbar` instance, potentially breaking clients that previously relied on more permissive behavior. Listing 2 shows an example of a postcondition weakening. The code is taken from class `SyncProcessor` in project mGerrit,[13] a Gerrit client for Android. The postcondition is weakened because the `@NotNull` annotation promises a non-null `Intent`, but if `intent` is ever null, this contract is violated – potentially leading to runtime errors like NullPointerException in callers that rely on the non-null guarantee.

Finding 7: There are instances of unsafe contract changes while the program evolves, particularly cases of preconditions strengthening.

Finally, Table 13 also presents the results found for *evolution patterns* in the context of *inheritance* (fourth column). We observe that the *precondition strengthening* pattern makes up almost 50% of classified instances. We also note that from the classified instances, most parts are related to contract changes which means a lack of stability in specifications. Both in the *evolution* and the *inheritance* study, we found lower occurrences of *postcondition weakening* when compared to the other classifications. Also, compared to the reports from Dietrich et al.'s study [13], our results indicate a greater ratio of *precondition strengthening* per preconditions found.

Finding 8: There are instances of unsafe contract changes in an overriding context that violate the Liskov Substitution Principle, particularly cases of preconditions strengthening.

6 Discussion

In this section, we answer the research questions listed in Section 4.1, we discuss the practical implications of our findings, and we outline threats to the validity of our work.

6.1 Answers to Research Questions

Based on our findings, we answer the research questions posed in Section 4.1 as follows:

RQ1 [Contract Usage]. *How and to what extent are contracts used in Android applications?* Contracts are concentrated in a small number of apps. When applications use contracts, annotation-based approaches are the most frequent, with the *androidx.annotation* package being the most popular. The use of APIs to specify contracts is rare. While in Java, 64.80% of the classified instances are preconditions, Kotlin programs display a more equally distributed selection with 22.87% postconditions at the top. We also found that more than 60% of the classified contracts in Java are related to null-checking, while in Kotlin that number is smaller than 8%.

RQ2 [First-to-Last Version Evolution]. *How does contract usage evolve in an application from the first to the last version?* Applications that use contracts continue to use them in later versions. When comparing the number of contracts in both versions, the average number of contracts increases. This is caused by some outliers that increase its usage substantially, driving up the average. In fact, the median value decreases. Furthermore, the contract-to-method ratio decreases between versions – an average decrease of -0.0077 and a median decrease of -0.0012. Although by a residual factor, we observed that the number of contracts declines as programs grow.

RQ3 [Safety]. *Are contracts used safely in the context of program evolution and inheritance?* Contract changes are frequent and can lead to potential breaks, with *preconditions strengthening* being the most classified pattern. These results show a potentially unsafe use of contracts that may lead to client breaks and violate the Liskov Substitution Principle.

6.2 Practical Implications & Recommendations

Our findings lead to the following practical implications and recommendations.

Recommendation 1. Due to the fragmentation of technologies and approaches to specifying contracts, both Java and Kotlin standard libraries should be equipped with constructs to specify contracts and with proper official documentation.

Recommendation 2. It would be desirable to have libraries that standardize contract specifications in Java and Kotlin. Our results suggest that these libraries should be built around annotation-based contracts, given its popularity among practitioners. An annotation-based approach, where specifications are added to the program as metadata, is similar to Eiffel's approach, where the assertions do not obfuscate the method's implementation. This recommendation also applies to tool builders: given that the current use of APIs in Android development appears to be relatively low, analysis tools for Android that leverage contracts should prioritize annotations.

Recommendation 3. New tools to aid practitioners writing contracts would be valuable. For example, the integration into IDEs of contract suggestion features supported by tools for invariant inference, such as Daikon [14], could help increase practitioners' use of contracts. Another contribution could be IDE and continuous integration plugins to detect contract violations in the context of program evolution and inheritance.

Recommendation 4. Our findings show that Kotlin's default non-nullable types reduce the need to explicitly write some contracts, highlighting the significance of language design features that enable safety by default. These findings are relevant for the design of programming languages and can serve as motivation for practitioners when selecting programming languages for new projects.

6.3 User Study

To evaluate the recommendations we derived from our findings, and to gather challenges faced by practitioners when using contracts, we conducted a qualitative survey study with 16 practitioners. In particular, we are interested in answering the following research questions (SRQs):

- **SRQ1**. [**Challenges**] What are the main challenges that users face when using contracts?
- **SRQ2**. [**Recommendations**] What do users recommend to increase contracts' adoption?

6.3.1 Methodology

To answer our RQs, we designed a qualitative survey study.

6.3.1.1 Recruitment

To improve the external validity, we allowed the participation of all kinds of software developers, but we recorded their experience with Android development. We recruited participants through Discord, LinkedIn, and our network (e.g., past students and colleagues). We also used snowball sampling by asking our contacts to distribute the study to their professional network. Our survey was implemented on Qualtrics and shared online. To prevent bots, all participants had to complete a reCAPTCHA challenge[14]. Per our inclusion criteria, participants were required to be at least 18 years old, in the United States, fluent in English, and possess some programming experience to ensure familiarity with basic software development concepts. All participants that we were able to recruit and who met the eligibility criteria were included in the final sample. Before deploying the study, we piloted it with five participants, iterating the survey between participants.

6.3.1.2 Survey Description

We begin our survey by showing participants the consent form. If they agree, we show the first section of our study, where we ask participants about their programming background and years of programming experience. Then, to ensure all participants are aware of the concept of DbC, we provide a short description and an example (see Figure 1). Participants are then asked about their confidence in understanding the definition of a contract, followed by questions regarding their frequency of contract use.

[14] reCAPTCHA is a security service provided by Google that protects websites from fraud and abuse by distinguishing human users from automated software.

Design by Contract is a technique in which software systems are seen as components that interact amongst themselves based on precisely defined specifications of client-supplier obligations (contracts).
Contracts are specifications of an agreement between the client and the supplier of a component, where the supplier expects that certain conditions are met by the client before using the component (preconditions), maintains certain properties from entry to the component to exit (invariants), and guarantees that certain properties are met upon exit (postconditions). These contracts can be written as assertions directly into the code.
For example, a way of enforcing a precondition in Java using exceptions might be:

```
public void proceedWithCheckout ( List < Item> shoppingCart ) {
if ( shoppingCart.isEmpty () ) {
throw new IllegalArgumentException () ;
}
...
}
```

Other examples include annotations such as `@NonNull` , which can be used to express preconditions. In Java and Kotlin, the assert keyword can be used to enforce the validity of a condition (for example, an invariant). APIs such as `org.apache.commons.lang.Validate.*` or `com.google.common.base.Preconditions.*` are also used to denote contracts. Finally, Kotlin offers features such as `@ExperimentalContracts` that allow the developer to state a method's behavior to the compiler explicitly.

Figure 1 Explanation shown to participants about DbC.

Here, the survey is split into two parts. For those who never use contracts, a follow-up section asks for the reasons for not using contracts. Participants who use contracts are asked to describe their reasons for using contracts and any challenges they have encountered. This is followed by the recommendations section. It begins by asking participants to suggest ways to improve the adoption of contracts. Following this, participants are presented with the following recommendations to improve contracts, obtained from the findings of our empirical study:

- Extend Java and Kotlin standard libraries with specialized constructs to specify contracts and with proper official documentation.
- Have libraries that standardize contract specifications in Java and Kotlin.
- Integrate into IDEs contract suggestion features supported by tools that automatically generate assertions and contracts.
- IDE and continuous integration plugins to automatically detect contract violations.

Participants were asked to rank these recommendations in terms of importance. Finally, the survey concludes with a demographic section.

The recommendations presented to participants in the user study were derived from our empirical findings but reformulated in a more concise and direct way. Presenting the recommendations exactly as shown in Section 6.2, which includes both context and the recommendation itself, was deemed too verbose for the user study.

6.3.1.3 Ethical Considerations

The study was approved by the IRB of Carnegie Mellon University. The participants did not receive payment upon survey completion. All participants were shown a consent form before filling in the survey. We did not collect any personally identifiable data.

6.3.1.4 Demographics

We recruited two participants for the initial pilot and three more for the follow-up pilot. For the finished survey, we recruited 23 participants. Of those 23, seven were ineligible or did not pass our screening questions (e.g., by not having programming experience). The remaining 16 participants sample is composed of individuals aged between 18 and 44 years, with most (nine participants) in the 25-34 age bracket. Gender representation includes male, female, non-binary/third gender, and one participant preferring not to disclose their gender. Educational backgrounds are high, with most participants holding graduate or

professional degrees and a smaller portion possessing bachelor's degrees. The sample is primarily White or Caucasian, with one Asian participant and one preferring not to disclose their race. Programming experience among the participants is diverse, with Python being the most commonly used language, followed by Java, JavaScript, C++, Rust, TypeScript, Go, C, Kotlin, and Dafny. All participants had some programming experience, with five participants having 1–3 years, three with 4–6 years, another five with 7–10 years, and finally, two with over 10 years of experience. Only one had less than one year of experience. Regarding experience with Android development, about half of the participants, 9 out of 16, had no years of experience. A subset had some experience, with one participant having between 1–3 years and another 7–10 years. The remaining five participants had less than one year of experience with Android software development.

6.3.1.5 Analysis

We used descriptive statistics to analyze the survey data from the closed-answer questions. For the qualitative responses, we developed three distinct codebooks tailored to different aspects of the dataset: 1) the reasons behind participants' use or non-use of contracts, 2) the challenges encountered while using contracts, and 3) the recommendations offered by participants to enhance the adoption of contracts. We used emergent coding techniques to develop the codebooks. We followed an iterative process to code the qualitative data. One of the researchers began by creating the first versions of the three codebooks. After this, two researchers independently double-coded all the answers, refined the codebook, recoded the answers again, and finally met to discuss any disagreements and reach a consensus.

6.3.2 Results

Among our survey participants, all, except one, reported using contracts in their programming practices, citing various reasons that underscore the multifaceted benefits of this approach. The participant who said they did not use contracts attributed their decision to the informal nature of their programming work, mainly prototyping and scripting. A significant majority, 11, highlighted the role of contracts in enhancing code quality and reliability. They mention that they use contracts to assert postconditions, verify preconditions, detect bugs, and identify edge-case bugs. This ensures that the code behaves as expected across compile-time and runtime scenarios. Four participants mentioned the importance of contracts as a documentation tool for improving code clarity. Three responses said that they used contracts in software design to manage expectations for software behavior. Lastly, two participants pointed out the operational benefits of contracts in enhancing the development process. They mentioned how contracts facilitate "sanity checks" (Participant 10) and ensure compliance with requirements.

6.3.2.1 SRQ1: Challenges

This subsection addresses SRQ1 and explores users' main challenges when using contracts in software development.

Participants provided diverse answers when questioned about their challenges when using contracts. In Table 14, we describe the codes and their respective frequency in participants' answers. The most cited obstacle was *Maintenance and Flexibility*, mentioned by three participants. This code highlights the sometimes complicated tasks of maintaining and updating contracts in complex projects. Participant 12 mentioned, "*if the implementation changes, we need to update the contract, and so, it can become complex to know which contracts*

Table 14 Codebook for participants' challenges when using contracts.

#	Code	Description
3	Maintenance and Flexibility	Problem with maintenance of contracts when implementations change, and the perceived lack of flexibility with contracts.
2	Specification and Expressiveness	Challenges in defining specifications and on the balance between contract expressiveness and automatic verification capabilities.
2	Cognitive Overload and Integration	Increased cognitive load due to managing both code and contracts, and integrating contracts into existing codebases.
2	Loop Invariants and Abstraction Levels	Specific challenges in formulating loop invariants and choosing the appropriate level of abstraction.
2	Enforcement Challenges	Challenges related to effectively enforcing contracts within the development process.
1	Security Concerns	Potential security risks.
1	Learning Curve and Documentation	Initial learning curve, difficulty in understanding contract libraries and navigating the documentation.

need to be updated". Challenges like *Specification and Expressiveness, Cognitive Overload, Loop Invariants*, and *Enforcement* were each present in the answers of two participants. And, finally, *Security Risks* and *Learning Curve and Documentation* were mentioned as challenges by one participant each.

6.3.2.2 SRQ2: Recommendations

This subsection addresses SRQ2 and users' recommendations to improve the adoption and usage of contracts in software development.

As mentioned before, we showed participants four recommendations obtained from our empirical study. Overall, participants seem to value all recommendations previously identified, as most classify them as "Very Important" and "Somewhat Important". The recommendation that participants seem to value the most is "IDE and continuous integration plugins to automatically detect contract violations" with 14 saying it is "Very Important" for them and two "Somewhat Important". This recommendation is closely followed by the one that suggests integrating contracts into IDEs ("Integrate into IDEs contract suggestion features supported by tools that automatically generate assertions and contracts") with 11 saying it is "Very Important" for them, and five "Somewhat Important." The remaining suggestions are to extend standard libraries with specialized constructs to specify contracts and with proper official documentation; these were also valued by participants, but one participant showed some uncertainty and indicated they were "Not sure" and classified it as "Not Important at All". Our results suggest that participants view the recommendations identified in our empirical work as valuable and support our insights.

Before asking participants to rank the previously identified recommendations, we asked them to suggest ways to improve the adoption of DbC. The codebook with the frequency of each code can be seen in Table 15. Participants' answers were diverse and seemed to also validate our results. The most frequent code in participants' suggestions is *Tool Support and Integration*: in total, seven participants suggested developing tools and IDE integrations that assist in creating, verifying, and managing contracts. This code validates our findings as it is similar to the recommendations that we derived from our empirical study. The second most frequent codes were the ones related to providing educational materials, templates, user-friendly interfaces, and robust error handling for users. The codes *Educational Resources and Training, Error Handling and Debugging Support, and User Interface and Templates*

Table 15 Codebook for participants' suggestions, including the frequency and description of each code.

#	Code	Description
7	Tool Support and Integration	Developing tools and IDE integrations that assist in creating, verifying, and managing contracts.
3	Educational Resources and Training	Providing more educational materials, examples, and training on DbC principles and benefits.
3	Error Handling and Debugging Support	Ensuring error recovery mechanisms and developing tools to simplify debugging processes related to contract violations.
2	Standards and Guidelines	Establishing standards or guidelines for how contracts should be defined, including preconditions and postconditions.
2	Incremental Adoption Strategies	Encouraging incremental adoption of DbC to make it easier for developers to integrate into their workflows.
2	User Interface and Templates	Providing user interfaces and templates to facilitate the writing of contracts and automatic code generation/repair.
2	NLP and AI	Utilizing NLP and AI for contract code suggestions.
2	Specification / Code Repair	Providing the ability to repair code based on changes to specifications (contracts) or update specifications based on code changes.
1	Programming Language Support	Enhancing programming language features to support contracts more effectively.
1	Automatic Verification and Testing	Improving automatic verification of contracts with less human effort and generating tests from contracts.
1	Real-Time Feedback and Metrics	Integrating real-time feedback and metrics within IDEs to provide indicators of code quality and contract coverage..

were each found three times in participants' answers. These recommendations suggest that participants need resources that support them in the practical implementation of contracts. Participant 9 directly says that they think that a way to improve the adoption of contracts is to "*always make sure there is a way to recover from the exceptions thrown whenever the assert (Python) statement is used.*" *Standards and Guidelines, Incremental Adoption Strategies, Natural Language Processing and AI, and Specification / Code Repair* were each mentioned twice. Particularly, *Natural Language Processing and AI* in similar ways by two participants, with Participant 7 saying "*I think AI contract code suggestions would reduce the barrier to entry and cost of writing the code.*" Finally, *Programming Language Support, Automatic Verification and Testing, and Real-Time Feedback and Metrics* were mentioned once, reinforcing that participants desire more automatic implementations of contracts and more feedback from their application.

Overall, our results suggest a clear direction – developers seem to desire improved tool support and integration of DbC in the development process. Our results highlight the need for future work on contracts and validate the findings of our empirical study.

6.4 Threats to Validity

Internal Validity. The accuracy of our results depends on the quality and correctness of the artifact, and there may exist bugs in the code. To mitigate this, we extensively tested the tool. In addition, all code and datasets used are publicly available for other researchers and potential users to check the validity of the results. Regarding the user study, one potential threat is the Hawthorne effect, where participants may alter their behaviour because they are aware they are being observed. To mitigate this risk, we ensured that participation was confidential and that responses could not be linked to individuals.

External Validity. The projects that we selected might not be an accurate representation of other, more popular, Android app stores. We mitigated this by using F-Droid, a collection of open-source applications commonly used in other research studies. We also mitigated this risk by analysing *all* the projects that satisfy the inclusion criteria, leading to a substantial dataset (51 MLoC) with applications of different types. Regarding the user study, one potential threat arises from the fact that about half of the participants lacked prior experience with Android development. As a result, the findings may not fully generalize.

Conclusion Validity. We might have missed language constructs that could be used to specify contracts. To mitigate this, we followed an established taxonomy [13] that we adapted and extended by systematically searching forums and the official Android documentation. The full list of constructs is available in the Supplementary Material [17]. Also, all our code is easily open to extension. Another risk comes from our dataset being imbalanced (with more Java than Kotlin applications). We mitigate this by explicitly discussing this imbalance when presenting results that might be affected by it.

7 Conclusions

Empirical evidence about contract usage can help the software engineering community create or improve existing libraries and tools to increase DbC adoption. This also helps to understand DbC's current practices better, helping practitioners discover and decide between different approaches. Researchers can also use our contributions to conduct additional studies.

Future work includes large-scale studies with practitioners to understand the challenges faced when specifying contracts, the use of annotations to improve Android analysis tools [24, 32, 30, 31], and the development of tools that can help increase the adoption of DbC [20, 43, 2].

Automatic Goal Clone Detection in Rocq

Ali Ghanbari
Auburn University, Al, USA

Abstract

Proof engineering in Rocq is a labor-intensive process, and as proof developments grow in size, redundancy and maintainability become challenges. One such redundancy is *goal cloning*, *i.e.*, proving α-equivalent goals multiple times, leading to wasted effort and bloated proof scripts. In this paper, we introduce clone-finder, a novel technique for detecting goal clones in Rocq proofs. By leveraging the formal notion of α-equivalence for Gallina terms, clone-finder systematically identifies duplicated proof goals across large Rocq codebases. We evaluate clone-finder on 40 real-world Rocq projects from the CoqGym dataset. Our results reveal that each project contains an average of 27.73 instances of goal clone. We observed that the clones can be categorized as either *exact goal duplication*, *generalization*, or *α-equivalent goals with different proofs*, each signifying varying levels duplicate effort. Our findings highlight significant untapped potential for proof reuse in Rocq-based formal verification projects, paving the way for future improvements in automated proof engineering.

1 Introduction

Rocq [20][1] is a popular interactive theorem prover based on type theory. Rocq has proved to be a viable tool for constructing certified software, as demonstrated by projects like CompCert [27], Iris [22], ConCert [2], and Fiat Cryptography [13].

Proof engineering [33] in Rocq is a labor-intensive task [6, 15, 14]. As proof developments grow in size, redundancy and maintainability become major challenges. An important, yet relatively overlooked, issue in proof engineering research is *goal cloning* – proving of α-equivalent goals more than once. Such a duplication of effort not only results in waste of manpower, but also inflates proof scripts, increases maintenance costs, and reduces opportunities for reuse. While Rocq offers mechanisms for structuring proofs, avoiding redundancy remains a challenge. Large-scale verification projects, such as seL4 [26] and Verisoft [1], have highlighted the necessity of tools that support automated detection of redundant proof efforts [6]. While there is tool support for code clone detection [18, 40] in Isabelle/HOL [30], to the best of our knowledge, detection of redundant proof efforts in Rocq proofs is not explored yet.

The problem that we set out to solve is as follows. *Given a set of Rocq proofs, find the set of α-equivalent goals making up the proofs.* "Goal" is a Rocq terminology for proof obligation; each proof comprises sub-proofs for a set of goals that are written as Gallina [20]

[1] The Coq development community recently renamed the system to The Rocq Prover. In this paper, we use Coq and Rocq interchangeably.

terms. We want to automatically identify *goal clones*, *i.e.*, α-equivalent goals. Such goals, and their corresponding sub-proofs, can be factored out as independent lemmas and reused, instead of proving them from scratch each time they are observed. To solve this, we introduce clone-finder, a novel technique that leverages the formal definition of α-equivalence of Gallina terms to systematically identify duplicated proof goals across large Rocq codebases. This enables proof engineers to refactor their developments by extracting common subproofs as reusable lemmas, thereby reducing redundant proof effort and improving maintainability. Although the problem statement is simple, and the notion of α-equivalence of Gallina terms has a solid foundation in the well-established field of type theory, finding α-equivalent Gallina terms in practice is not trivial. This is mainly because the variables mean different things in different contexts and any comparison must first universally quantify the terms with the free variables defined in the context before performing α-equivalence check (see §3 for more details on the proposed approach).

Our prototype Python implementation of clone-finder interacts with Rocq through Coq-LSP [9] and its Python interface, CoqPyt [7]. We evaluate clone-finder on 40 real-world Rocq projects from the CoqGym dataset [42]. Our benchmark contains a diverse set of Rocq projects, representative of the real-world Rocq projects: the project are of different sizes, ranging from 53 to 29,260 lines of code, and they are from various domains – from set theory to distributed system verification to geometry (see §5.1 for more details on benchmark preparation process). We ran clone-finder on our benchmark of Rocq projects, while measuring the number of goal clones that it detects as well as its runtime overhead. We observed that in 20 out of 40 projects, clone-finder detected at least one goal clone. On average clone-finder finds 27.73 instances of goal clones per project. Manual review of the reported clones revealed three common patterns of goal cloning: (1) exact goal duplication with identical or near-identical proofs, *e.g.*, structurally identical proofs with different variable names; (2) α-equivalent goals with generalized proofs, where one proof subsumes the other; and (3) α-equivalent goals with entirely different proofs. Each of these instances signifies extra spent proof effort that could be saved and repurposed for other tasks by factoring out the duplicated goals as independent lemmas. These findings suggest significant untapped potential for proof reuse in Rocq-based formal verification projects.

Another observation that we make is that clone-finder is a light-weight system: over 94.71% of its running time is from using Coq-LSP through CoqPyt. An average 45.31 seconds of run time, for a fresh run, and support for incremental analysis, which could significantly reduce the run time, make clone-finder a practical tool for daily proof engineering. Mitigating the overhead of interfacing Coq-LSP is a matter of investing engineering effort so that CoqPyt does not reload common dependencies of the proof scripts within a workspace every time we load a script from that workspace. Another possibility is to implement clone-finder directly as a Rocq plugin using Rocq plugin library and Coq-Elpi [8]. We save these as a future extension of this work.

Beyond detecting proof redundancy, our work contributes an open-source enhancement to CoqPyt, which enables analyzing real-world Rocq projects with it. We will make both clone-finder and our enhancement publicly available to foster further research in automated proof engineering. To summarize, this paper makes the following contributions.

- **Technique:** a simple technique, named clone-finder, based on the theoretically elegant notion of α-equivalence is proposed for detecting goal clones in Rocq scripts. This technique can be used alongside lemma extraction tool-set [32, 35] to rewrite clones as independent lemmas to increase reuse and mitigate waste of proof efforts. Additionally, the support for incremental analysis would allow using clone-finder in a background thread in a Rocq IDE to detect clones as the proof engineer writes the proofs.

- **Evaluation:** We evaluate clone-finder using a set of real-world Rocq projects. We report that real-world Rocq projects are likely to contain large numbers of clones with either (1) identical; (2) generalized; or (3) entirely different pairs of proofs. These clones indicate waste of manpower in proof engineering that could potentially be repurposed for use in other aspects of system specification and verification.
- **Open-Source Contribution:** While implementing clone-finder, which interacts with the Python interface for Coq-LSP, named CoqPyt, we realized that CoqPyt does not allow passing physical-to-logical path mapping, which is essential in working with real-world Rocq projects. We have added this feature to the framework and will make a pull request about it. We have also made clone-finder publicly available [17]. This source code contains a Python-based parser for Gallina that can be used in future research projects.

The remainder of this paper is organized as follows. We provide background on Rocq and code clone detection in §2. In §3 we present the clone-finder approach in detail, and in §4 we discuss the implementation of our prototype. We present our experimental evaluation in §5, followed by an analysis of threats to validity in §6. We review related work in §7 and conclude the paper, while sketching future research directions, in §8.

2 Background

In this section, we briefly introduce Rocq, Gallina, Calculus of Inductive Constructions, and code clone detection. We also provide references for further reading on these topics.

2.1 Rocq, Gallina, and Calculus of Inductive Constructions

Rocq [20], formerly known as Coq, is an interactive theorem prover. At its core, lies a specification language, named Gallina [20]. Gallina is an elegant functional programming language that was originally built upon the calculus of inductive constructions with definitions [4, 31, 39]. This calculus still constitutes a substantial subset of Gallina today. Proofs in Rocq are usually written in a tactic language, named Ltac [12, 20], which is a domain-specific language for building Gallina terms in a type-driven fashion that serve as proofs. The type of these terms are also Gallina terms, that serve as theorem statements and goals.

Rocq is a state-based interactive proof assistant. Theorem proving in Rocq starts with the theorem itself as the initial goal. The proof engineer repeatedly applies Ltac tactics to decompose the goal into a list of subgoals. The proof is complete when there are no sub-goals left. At each step, Rocq displays the local definitions as available hypotheses that can be used in theorem proving. A successful Rocq proof implicitly amounts to creating a proof tree whose root is the original theorem and whose nodes are the goals. Figure 1 shows a simple example. All goals share the same global context, but have exclusive local contexts, *e.g.*, hypotheses a, b : nat in Figure 1. The edges of the proof tree are annotated with tactics. The proof for a goal in the proof tree can be obtained by conducting a depth-first search [10] on the node corresponding to the goal and accumulating the tactics that are visited along the way.

2.2 Code Clone Detection

Code clone detection is an active area of research in software engineering aimed at identifying duplicated code snippets within software systems [28, 36, 29, 41]. Code duplication is widespread in software development. It is sometimes introduced deliberately to accelerate prototyping, reuse existing functionality, or meet tight deadlines, and other times it arises inadvertently. However, excessive cloning can degrade code quality, increase maintenance overhead, and propagate defects across multiple locations in the codebase [23, 24].

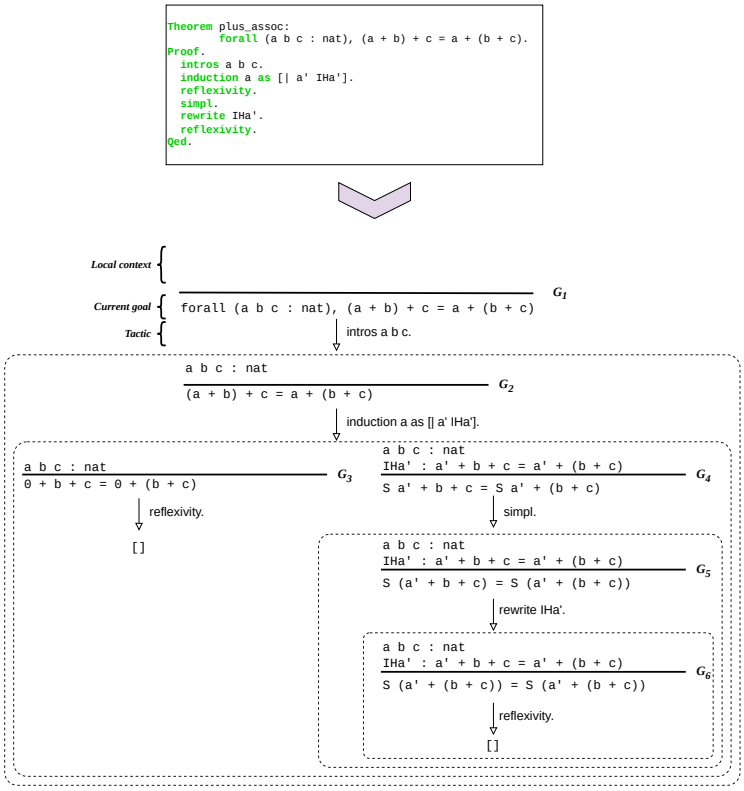

Figure 1 A simple Rocq theorem and its proof in Ltac. The proof process starts with the theorem statement as the current goal. Each valid Ltac command transforms the state of the proof assistant, prompting it to generate zero or more new goals. This amounts to creating a proof tree, where nodes corresponds to goals and the edges are labeled with the Ltac command that generated the child nodes. A depth-first search on each node of the tree to accumulate the tactics at the edges constitute the sub-proof for the goal at each node. This figure also illustrates how Algorithm 1 constructs proof trees by executing proofs line by line, while tracking the goals that are created and eliminated as a result of running each tactic.

Code clones refer to code snippets that exhibit similarity based on a defined metric. The literature categorizes code clones into four primary types [36, 29]: (1) exact clones; (2) renamed clones; (3) near-miss clones; and (4) semantic clones.

While the code clone detection technique introduced in this paper falls under the categories of type 1 and type 2 clones (our technique finds α-equivalent goals in a project), the type of code that we study in this paper are fundamentally different from that of studied in the literature. We are finding clones in functional programs, rather than imperative programs, so the existing techniques for code clone detection [28, 29, 41] could not be used directly.

3 The clone-finder Approach

At the highest level, clone-finder takes, as input, the base path for a Rocq project, Rocq options, and the minimum proof size threshold, and outputs a list of clones with proofs at least as large as the provided threshold. The proof size is defined in terms of lines of Ltac code. The operations of clone-finder can be summarized as (1) constructing proof trees

$$
\begin{array}{rcl}
t & ::= & s \mid x \mid t_1\ t_2 \mid \texttt{forall}\ (x : t_1),\ t_2 \\
& & \mid \texttt{fun}\ (x : t_1)\ \Rightarrow\ t_2 \mid \texttt{let}\ x : t_1 \coloneqq t_2\ \texttt{in}\ t_3 \\
& & \mid \texttt{fix}\ y\ (x : t_1) : t_2 \coloneqq t_3 \\
& & \mid \texttt{match}\ t_1\ \texttt{return}\ t_2\ \texttt{with}\ \ [\mid x_1\ \ldots\ x_n\ \Rightarrow t_3]^*\ \texttt{end}
\end{array}
$$

$$
\begin{array}{rrcl}
\text{(terms)} & t, t_1, t_2, t_3 & \in & \mathbb{T} \\
\text{(sorts)} & s & \in & \{\texttt{Set}, \texttt{Type}\} \\
\text{(variables)} & x, y, x_1, \ldots, x_n & \in & \mathbb{V}
\end{array}
$$

Figure 2 Abstract syntax of a core subset of Gallina terms.

(described in Algorithm 1); (2) flattening, deduplicating, and generalization of the proof trees to construct the list of pairs of goals and their corresponding proofs (described in Algorithms 2 and 3); (3) finding pairs of α-equivalent generalized goals and reporting the output (described in Algorithm 4). We now describe each of these steps in more details.

The enabling tool of clone-finder are the notions of free variables and α-equivalence. To define these notions more precisely, we use a core subset of Gallina subsumed by the calculus of inductive constructions with definitions. Figure 2 shows this subset of Gallina. Note that while inductive type definitions are part of the syntax of the calculus of inductive constructions with definitions, we have not included them in our core language, because this is how Rocq operates: after an inductive type definition is type checked, the type name, its constructors, as well as induction principles and recursor, are added as constants into the global type environment and type definition themselves do not appear in goals. The following definitions define notions of free variables, substitution, and α-equivalence. Readers familiar with these standard notions may skip the following three definitions.

▶ **Definition 1** (Free Variables). *The set of free variables of a Gallina term t, denoted $FV(t)$, is defined recursively as follows.*

- $FV(s) = \emptyset$, *for all sorts* s,
- $FV(x) = \{x\}$, *for all* $x \in \mathbb{V}$,
- $FV(t_1\ t_2) = FV(t_1) \cup FV(t_2)$ *for all* $t_1, t_2 \in \mathbb{T}$,
- $FV(\texttt{forall}\ (x : t_1),\ t_2) = FV(t_1) \cup (FV(t_2) - \{x\})$, *for* $x \in \mathbb{V}$ *and* $t_1, t_2 \in \mathbb{T}$,
- $FV(\texttt{fun}\ (x : t_1)\ \Rightarrow\ t_2) = FV(t_1) \cup (FV(t_2) - \{x\})$, *for* $x \in \mathbb{V}$ *and* $t_1, t_2 \in \mathbb{T}$,
- $FV(\texttt{let}\ x : t_1 \coloneqq t_2\ \texttt{in}\ t_3) = FV(t_1) \cup FV(t_2) \cup (FV(t_3) - \{x\})$, *for* $x \in \mathbb{V}$ *and* $t_1, t_2, t_3 \in \mathbb{T}$,
- $FV(\texttt{fix}\ y\ (x : t_1) : t_2 \coloneqq t_3) = FV(t_1) \cup FV(t_2) \cup (FV(t_3) - \{x, y\})$,
- $FV(\texttt{match}\ t_1\ \texttt{return}\ t_2\ \texttt{with}\ |C_1| \ldots |C_k\ \texttt{end}) = FV(t_1) \cup FV(t_2) \cup FV_C(C_1) \cup \cdots \cup FV_C(C_k)$, *for* $k \geq 0$,

where s is a sort, $x, y \in \mathbb{V}$, and $t_1, t_2, t_3 \in \mathbb{T}$. The helper function FV_C is defined to be $FV_C(x_1\ \ldots\ x_n\ \Rightarrow t_3) = FV(t_3) - \{x_1, \ldots, x_n\}$, wherein $n \geq 1$ and $x_1, \ldots, x_n \in \mathbb{V}$.

All the non-free variables occurring in a Gallina term are referred to as *bound variables*. Two Gallina terms are said to be α-equivalent, if we can systematically rename bound variables in one term to make it syntactically equal to another. To define this notion precisely, we first need to define variable replacement, which is used for variable renaming in the α-equivalence check.

▶ **Definition 2** (Substitution). *Given a variable x and a term u, $t^{x\to u}$ denotes the substitution of x with u in t, and is defined as follows.*

- $s^{x\to u} = s$, *for all sorts* s,
- $x_0^{x\to u} = u$, *if* $x_0 = x$,
- $x_0^{x\to u} = x_0$, *for all* $x_0 \in \mathbb{V}$ *such that* $x_0 \neq x$,
- $(t_1\ t_2)^{x\to u} = t_1^{x\to u}\ t_2^{x\to u}$, *for all* $t_1, t_2 \in \mathbb{T}$,
- $(\texttt{forall}\ (x_0 : t_1),\ t_2)^{x\to u} = \texttt{forall}\ (x_0 : t_1^{x\to u}),\ t_2^{x\to u}$, *for all* $x_0 \in \mathbb{V}$ *and* $t_1, t_2 \in \mathbb{T}$ *such that* $x_0 \neq x$ *and* $x_0 \notin FV(u)$,
- $(\texttt{forall}\ (x_0 : t_1),\ t_2)^{x\to u} = \texttt{forall}\ (x_0 : t_1^{x\to u}),\ t_2$, *if* $x_0 \notin FV(u)$,
- $(\texttt{fun}\ (x_0 : t_1)\ \Rightarrow\ t_2)^{x\to u} = \texttt{fun}\ (x_0 : t_1^{x\to u})\ \Rightarrow\ t_2^{x\to u}$, *for all* $x_0 \in \mathbb{V}$ *and* $t_1, t_2 \in \mathbb{T}$ *such that* $x_0 \neq x$ *and* $x_0 \notin FV(u)$,
- $(\texttt{fun}\ (x_0 : t_1)\ \Rightarrow\ t_2)^{x\to u} = \texttt{fun}\ (x_0 : t_1^{x\to u})\ \Rightarrow\ t_2$, *for all* $t_1, t_2 \in \mathbb{T}$ *such that* $x_0 \in FV(u)$,
- $(\texttt{let}\ x_0 : t_1 \coloneqq t_2\ \texttt{in}\ t_3)^{x\to u} = \texttt{let}\ x_0 : t_1^{x\to u} \coloneqq t_2^{x\to u}\ \texttt{in}\ t_3^{x\to u}$, *for all* $x_0 \in \mathbb{V}$ *and* $t_1, t_2, t_3 \in \mathbb{T}$ *such that* $x_0 \neq x$ *and* $x_0 \notin FV(u)$,
- $(\texttt{let}\ x_0 : t_1 \coloneqq t_2\ \texttt{in}\ t_3)^{x\to u} = \texttt{let}\ x_0 : t_1^{x\to u} \coloneqq t_2^{x\to u}\ \texttt{in}\ t_3$, *for all* $t_1, t_2, t_3 \in \mathbb{T}$ *such that* $x_0 \in FV(u)$,
- $(\texttt{fix}\ y\ (x_0 : t_1) : t_2 \coloneqq t_3)^{x\to u} = \texttt{fix}\ y\ (x_0 : t_1^{x\to u}) : t_2^{x\to u} \coloneqq t_3^{x\to u}$, *for all* $y, x_0 \in \mathbb{V}$ *and* $t_1, t_2, t_3 \in \mathbb{T}$ *such that* $y \neq x$, $x_0 \neq x$, $x_0 \notin FV(u)$, *and* $y \notin FV(u)$,
- $(\texttt{fix}\ y\ (x_0 : t_1) : t_2 \coloneqq t_3)^{x\to u} = \texttt{fix}\ y\ (x_0 : t_1^{x\to u}) : t_2^{x\to u} \coloneqq t_3$, *for all* $t_1, t_2, t_3 \in \mathbb{T}$ *such that* $x_0 \in FV(u)$ *or* $y \in FV(u)$,
- $(\texttt{match}\ t_1\ \texttt{return}\ t_2\ \texttt{with}\ |C_1| \ldots |C_k\ \texttt{end})^{x\to u} = \texttt{match}\ t_1^{x\to u}\ \texttt{return}\ t_2^{x\to u}\ \texttt{with}\ |C_1^{x\to u}| \ldots |C_k^{x\to u}\ \texttt{end}$, *where* $C_i^{x\to u}$ *is defined as* $(x_1\ \ldots\ x_n\ \Rightarrow t_3)^{x\to u} = (x_1\ \ldots\ x_n\ \Rightarrow t_3^{x\to u})$, *if* $x \notin \{x_1, ..., x_n\}$ *and* $\{x_1, ..., x_n\} \cap FV(u) = \emptyset$, *and* $(x_1\ \ldots\ x_n\ \Rightarrow t_3)^{x\to u} = x_1\ \ldots\ x_n\ \Rightarrow t_3$ *if* $\{x_1, ..., x_n\} \cap FV(u) \neq \emptyset$.

We now define the notion of α-equivalence as follows.

▶ **Definition 3** (α-equivalence). *The following axiom and rules of inference prove judgments of the form $t_1 =_\alpha t_2$, where t_1 and t_2 are Gallina terms.*

- ***(Renaming-Forall)**:* $(\texttt{forall}\ (x : t_1),\ t_2) =_\alpha (\texttt{forall}\ (y : t_1'),\ t_2')$, *if* $t_1 =_\alpha t_1'$, $y \notin FV(t_2)$, y *is not bound in* t_2, *and* $t_2^{x\to y} =_\alpha t_2'$,
- ***(Renaming-Fun)**:* $(\texttt{fun}\ (x : t_1)\ \Rightarrow\ t_2) =_\alpha (\texttt{fun}\ (y : t_1')\ \Rightarrow\ t_2')$, *if* $t_1 =_\alpha t_1'$, $y \notin FV(t_2)$, y *is not bound in* t_2, *and* $t_2^{x\to y} =_\alpha t_2'$,
- ***(Renaming-Let)**:* $(\texttt{let}\ x : t_1 \coloneqq t_2\ \texttt{in}\ t_3) =_\alpha (\texttt{let}\ y : t_1' \coloneqq t_2'\ \texttt{in}\ t_3')$, *if* $t_1 =_\alpha t_1'$, $t_2 =_\alpha t_2'$, $y \notin FV(t_3)$, y *is not bound in* t_3, *and* $t_3^{x\to y} =_\alpha t_3'$,
- ***(Renaming-Fix)**:* $(\texttt{fix}\ y\ (x : t_1) : t_2 \coloneqq t_3) =_\alpha \texttt{fix}\ y'\ (x' : t_1') : t_2' \coloneqq t_3'$, *if* $t_1 =_\alpha t_1'$, $t_2 =_\alpha t_2'$, $y' \notin FV(t_3)$, y' *is not bound in* t_3, $x' \notin FV(t_3)$, x' *is not bound in* t_3, *and* $t_3^{y\to y'\ x\to x'} =_\alpha t_3'$,
- ***(Renaming-Match)**:* $(\texttt{match}\ t_1\ \texttt{return}\ t_2\ \texttt{with}\ |\ C_1\ |\ \ldots\ |\ C_k\ \texttt{end})$ $=_\alpha (\texttt{match}\ t_1'\ \texttt{return}\ t_2'\ \texttt{with}\ |\ C_1'\ |\ \ldots\ |\ C_k'\ \texttt{end})$, *if* $t_1 =_\alpha t_1'$, $t_2 =_\alpha t_2'$, *and for all* $1 \leq i \leq k$, *we have* $C_i \equiv_\alpha C_i'$, *where* $\equiv_\alpha$ *is defined as:* $(x_1\ \ldots\ x_n\ \Rightarrow t_3) \equiv_\alpha (x_1'\ \ldots\ x_n'\ \Rightarrow t_3')$ *if* $x_1'\ \ldots\ x_n' \notin FV(t_3)$, *variables* $x_1'\ \ldots\ x_n'$ *are not bound in* t_3, *and* $t_3^{x_1\to x_1'\ \ldots\ x_n\to x_n'} =_\alpha t_3'$.

- ***(Compatibility-2)**: If* $t_1 =_\alpha t_2$, *then* $(\texttt{match}\ t_1\ \texttt{return}\ t\ \texttt{with}\ |\ C_1\ |\ \ldots\ |\ C_k\ \texttt{end}) =_\alpha (\texttt{match}\ t_2\ \texttt{return}\ t\ \texttt{with}\ |\ C_1\ |\ \ldots\ |\ C_k\ \texttt{end})$ *and* $(\texttt{match}\ t\ \texttt{return}\ t_1\ \texttt{with}\ |\ C_1\ |\ \ldots\ |\ C_k\ \texttt{end}) =_\alpha (\texttt{match}\ t\ \texttt{return}\ t_2\ \texttt{with}\ |\ C_1\ |\ \ldots\ |\ C_k\ \texttt{end})$, *for all term* t *and match clauses* C_1, ..., C_k.

Algorithm 1 Constructing proof trees from Rocq proofs.

Require: List of Rocq source files, coq_files, and `coqc` flags, stored in variable "flags"
Ensure: Returning a mapping from ⟨File, Theorem⟩ to ProofTree

```
tree_map ← ∅
for all file ∈ coq_files do                          ▷ Construct a proof tree for each theorem in each file
    pf ← connect_to_coq_lsp(file, flags)             ▷ Connect to Coq-LSP: an iterable proof file object is returned
    for all step ∈ pf do                             ▷ Sweep the current file step-by-step
        step.execute()
        if step.in_proof() then                      ▷ Have stepped into the proof of a theorem?
            thm ← step.get_theorem()
            tree ← ProofTree()                       ▷ Initialize a new proof tree
            tree_map[⟨file, thm⟩] ← tree             ▷ Store the proof tree
            prev ← ∅                                 ▷ Track goals at the last step
            while not step.can_close() do            ▷ Iterate through the proof steps until no more goals remain
                step.execute()
                curr ← ∅                             ▷ Store current proof state
                for all g ∈ pf.goals() do
                    ctx ← g.get_hypotheses()         ▷ Extract local and in-file context (hypotheses)
                    goal ← g.get_type()              ▷ Extract the goal type (i.e., goal statement)
                    curr ← curr ∪ {⟨ctx, goal⟩}      ▷ Store current goals
                end for
                if prev ≠ ∅ then
                    gone ← {t ∈ prev | t ∉ curr}     ▷ Goals that disappeared
                    new ← {t ∈ curr | t ∉ prev}      ▷ Newly introduced goals
                    for all t ∈ gone do
                        ctx ← t[0]
                        goal ← t[1]
                        children ← {c[1] | c ∈ new}  ▷ Children are new goals
                        tac ← step.get_tactic()      ▷ Get the applied tactic
                        tree.AddNode(goal, ctx, children, tac)
                                                     ▷ Add node to proof tree and connect it to its children
                    end for
                end if
                prev ← curr                          ▷ Update tracking state
            end while
        end if
    end for
    close(pf)                                        ▷ Close the proof file and the Coq-LSP connection
end for
return tree_map                                      ▷ Return the constructed proof tree map
```

- ***(Compatibility-3)***: *If* $t_1 =_\alpha t_2$, *then* $(\texttt{let}\ x : t_1 := t\ \texttt{in}\ u) =_\alpha (\texttt{let}\ x : t_2 := t\ \texttt{in}\ u)$, $(\texttt{let}\ x : t := t_1\ \texttt{in}\ u) =_\alpha (\texttt{let}\ x : t := t_2\ \texttt{in}\ u)$, $(\texttt{fix}\ y(x : t_1) : t \Rightarrow u) =_\alpha (\texttt{fix}\ y(x : t_2) : t \Rightarrow u)$, *and* $(\texttt{fix}\ y(x : t) : t_1 \Rightarrow u) =_\alpha (\texttt{fix}\ y(x : t) : t_2 \Rightarrow u)$, *for all terms* t *and* u,

- ***(Compatibility-5)***: *If* $t_1 =_\alpha t_2$, *then* $(\texttt{let}\ x : t := u\ \texttt{in}\ t_1) =_\alpha (\texttt{let}\ z : t := u\ \texttt{in}\ t_2)$, $(\texttt{fix}\ y(x : t) : u \Rightarrow t_1) =_\alpha (\texttt{fix}\ z(x : t) : u \Rightarrow t_2)$, *and* $(\texttt{fix}\ y(x : t) : u \Rightarrow t_1) =_\alpha (\texttt{fix}\ y(z : t) : u \Rightarrow t_2)$, *and* $(\texttt{match}\ t\ \texttt{return}\ u\ \texttt{with} \mid C_1 \mid \ldots \mid (x_1\ \ldots\ x\ \ldots\ x_n) \Rightarrow t_1\ \ldots \mid C_k\ \texttt{end}) =_\alpha (\texttt{match}\ t\ \texttt{return}\ u\ \texttt{with} \mid C_1 \mid \ldots \mid (x_1\ \ldots\ z\ \ldots\ x_n) \Rightarrow t_2\ \ldots \mid C_k\ \texttt{end})$, *for all terms* t *and* u, *and variable* z,
- ***(Reflexivity)***: $t =_\alpha t$, *for all term* t,
- ***(Symmetry)***: *If* $t_1 =_\alpha t_2$ *then* $t_2 =_\alpha t_1$,
- ***(Transitivity)***: *If* $t_1 =_\alpha t_2$ *and* $t_2 =_\alpha t_3$ *then* $t_1 =_\alpha t_3$.

Renaming rules are the foundations of α*-equivalence. Compatibility rules have the effect of extending* α*-equivalence from subterms to bigger terms. Reflexivity, symmetry, and transitivity make* α*-equivalence an equivalence relation. If we can derive* $t_1 =_\alpha t_2$, *we say that the terms* t_1 *and* t_2 *are* α*-equivalent.*

Armed with these definitions, we are now in a position to define our algorithms making up clone-finder. The first step is to extract goals and construct proof trees, which is described in Algorithm 1. This step is performed to find the proof corresponding to each goal in a Rocq project. clone-finder invokes this algorithm by first finding all the `.v` files in the target

Algorithm 2 Flatten and remove redundant goals.

Require: pt_map, a mapping from ⟨File, Theorem⟩ to ProofTree, *i.e.*, Algorithm 1's output
Ensure: List of goals and their generalizations, where redundant goals have been removed

```
1: g_list ← []                                              ▷ Initialize list for storing goals
2: for all (f, t, pt) ∈ pt_map do                           ▷ Iterate over proof tree map
3:     for all g ∈ pt.GetNodes() do                         ▷ Extract goals from proof tree
4:         ctx ← g.GetContext()
5:         g_gen ← Generalize(ctx, g)
6:         p ← g.GetProof()
7:         g_list.append(⟨g, g_gen, p, f, t⟩)
8:     end for
9: end for
10: red_g ← {}                                              ▷ Initialize set for redundant goals
11: for i = 0 to |g_list| − 1 do                            ▷ Iterate through goals list
12:     for j = 0 to |g_list| − 1 do                        ▷ Compare each goal with others
13:         if i ≠ j and prodBody(g_list[i][1], g_list[j][1]) then   ▷ Check if one goal is part of another
14:             red_g.add(g_list[j][1])
15:         end if
16:     end for
17: end for
18: g_list ← [g ∈ g_list | g[1] ∉ red_g]                    ▷ Remove redundant goals
19: return g_list
```

Rocq project directory. This list, together with `coqc` flags are passed to the algorithm. In summary, this algorithm runs each Rocq script in the given project step by step to construct proof trees using a tree data structure. Proof tree construction is done as follows. After executing a tactic, the current goal disappears, and a set of new goals might be created, these goals are regarded as the children of the current goal in the proof tree. We can identify the edges of the tree by tracking how goals are created during the proof execution. For example, if the list of goals changes from $[A, B]$ to $[C, D, B]$, we know that node A has two children C and D. Algorithm 1 creates nodes that point to the children node with the help of a dictionary-based data structure that maps current goal to the child goals and other information about the current goals such as the tactic that transforms it to the child goals and the context right before the execution of the tactic. Figure 1 provides a simple example of a Rocq proof and its corresponding proof tree.

More precisely, Algorithm 1 constructs a mapping of Rocq scripts to their corresponding proof trees, capturing the hierarchical structure of goals and tactics used to prove them. It iterates over each Rocq source file (line 2), establishing a connection to Coq-LSP to analyze proof steps (lines 3 and 4). When a proof of a theorem is encountered (line 6), the algorithm initializes a proof tree data structure and adds it to the resulting map, mapping file name and the the current theorem name pairs to the newly created proof tree (lines 7-9). This proof tree object, gets populated as follows. The algorithm iterates through proof steps until the proof is complete (line 11). At each step, it extracts the current goals and the local, and in-file, contexts (lines 13–18), detects goals that have disappeared or emerged (lines 20–21), and records the proof structure by adding nodes to the proof tree (lines 22–29). Finally, after processing all steps, the proof file is closed (line 35), and the mapping of file names and theorem names to proof trees is returned (line 31).

The next step in clone-finder's pipeline is to flatten the proof trees by turning the proof tree map generated by Algorithm 1 into a list of tuples of a goal, its generalization (*i.e.*, universal quantification of its free variables), its proof, its containing file name, and its containing theorem name. At this step, clone-finder also deduplicates the goals by removing the tuples whose generalization is a body of another tuple's generalization. Algorithm 2 formalizes this process. This algorithm processes a proof tree map by flattening its structure and eliminating redundant goals. First, it initializes an empty list g_list (line 1) to store extracted goals and their associated information. Then, it iterates through the proof tree

Algorithm 3 Generalization of a Goal.

Require: ctx: A map from variables to terms
Require: goal: The goal to be generalized
Ensure: A generalized goal with universally quantified variables
1: fvs ← $\{v \in FV(\text{goal}) \mid v \in \text{ctx}\}$ ▷ Find free variables bound in the context
2: rev_top_order ← reverse(topo_sort(ctx, fvs)) ▷ Sort dependencies in reverse topological order
3: **for** each $v \in$ rev_top_order **do**
4: goal ← "`forall` ("v" : "ctx[v]", "goal")" ▷ Prepend universal quantifiers
5: **end for**
6: **return** goal

map (pt_map) and extracts goals from each proof tree (lines 2–3). The method GetNodes of proof tree, returns the set of nodes, *i.e.*, the goals, in the proof tree. For each goal, it retrieves its context, generalizes it, and pairs it with its proof, file, and theorem name before appending this information to g_list (lines 4–7). The method GetProof, receives a node, *i.e.*, a goal, as input, conducts a depth-first search rooted at that node, while accumulating the tactics along each edge that it visits. The list of tactics ultimately returned by the method constitutes the proof for that goal. Another function used by the algorithm is the Generalize function, which is calculated according to Algorithm 3 and will be described shortly. Next, a set red_g is initialized (line 10) to keep track of redundant goals. The algorithm then performs a pairwise comparison of the goals (lines 11–13), marking a goal as redundant if its generalized form appears as a subterm within another goal using the function prodBody (line 13). The definition below, provides a more formal description of the prodBody function.

▶ **Definition 4** (prodBody Function). *Given Gallina terms t and t', prodBody(t, t') returns true if t is a product type, aka, universally quantified term, with body t'', i.e., $t =$ `forall` $(x : t_0)$, t'' for some term t_0, such that either $t' = t''$ or prodBody(t'', t') is true.*

Finally, the redundant goals are removed from g_list (line 18), ensuring that only distinct, non-nested goals remain.

The Generalize function transforms a given goal into a universally quantified form by identifying and universally quantifying all free variables in the goal that are present in the context (ctx). Algorithm 3 defines this function. This function first collects the relevant free variables (fvs) and determines their dependency order using topo_sort (Line 2), ensuring that variables are introduced in a correct dependency-aware sequence. The topological sorting in reverse order ensures that if variable v1 depends on v2, then v2 is quantified before v1, preventing type dependency issues. The function then iterates through the reverse of this topological order (Line 2) and prepends universal quantifiers (`forall`) to the goal in the correct order, making sure all dependent variables appear before their use. This process ensures that dependently typed terms remain well-formed while abstracting away unnecessary local dependencies.

The function topo_sort constructs a topological ordering [10] of variables in ctx that are also present in fvs. It first builds a directed acyclic graph wherein nodes are variables and edges represent dependency relationships between the variables. More precisely, assume that we have $v_1 : t_1$ and $v_2 : t_2$ in local context, where t_1 is a Gallina term such that $v_2 \in FV(t_1)$. Intuitively, this means that v_1 needs v_2 in order for it to be defined, because its type uses v_2, so we create a directed edge from the node corresponding to v_1 to that of v_2 to denote this dependency. The function then conducts a topological sorting on this graph by conducting a depth-first search on each node. The output of topo_sort function is a list of variables that if reversed will present the variables in a valid dependency order. So, if v_1 depends on v_2 in the graph, we will universally quantify v_2 before v_1, thereby creating a well-formed dependently typed term.

Algorithm 4 Reporting clones.

Require: goals_list: List of deduplicated and generalized goals, *i.e.*, Algorithm 2's output
Ensure: List of alpha equivalent goals
1: output $\leftarrow \emptyset$
2: **for** $i = 0$ to $|\text{goals_list}| - 1$ **do**
3: **for** $j = i + 1$ to $|\text{goals_list}| - 1$ **do**
4: **if** goals_list$[i][1]$ $=_\alpha$ goals_list$[j][1]$ **then**
5: output.append(goals_list$[i]$ $\cdot$ goals_list$[j]$)
6: ▷ Concatenate goals_list[i] and goals_list[j] to generate output pairs
7: **end if**
8: **end for**
9: **end for**
10: **return** output

The last step in clone-finder's pipeline involves finding pairs of generalized goals that are α-equivalent. This process is formalized in Algorithm 4. The algorithm simply picks pairs of tuples from the output of Algorithm 2 and checks if the compartments corresponding to the generalized goals are α-equivalent. If so, the tuples, that contain various information, such as the containing theorem name, file name, and proofs, are concatenated to form the output of clone-finder.

4 Implementation

We have implemented clone-finder in 4,969 lines of Python code. As we have given high-level explanation in §3, clone-finder interacts with Coq-LSP to open the Rocq files in a project and execute them step by step, extracting goals, as well as local context entries. In this implementation of clone-finder, for the sake of efficiency, we only consider local contexts, which could introduce unsoundness and false positives. We have implemented a Gallina parser to parse the goals and find α-equivalent goals, as outlined in §3. Currently, clone-finder offers a command-line interface though which it receives target project's base directory, Rocq command-line options, *i.e.*, `-R/-Q` for mapping physical paths to logical paths, and the minimum size of the proofs. clone-finder interfaces Coq-LSP through a recent Python framework, named CoqPyt [7]. We observed that CoqPy does not allow passing `-R/-Q` options to Coq-LSP, which is essential for running real-world projects that we have studied in this paper. Therefore, we extended the API provided by the framework so that they receive `-R/-Q` options and pass them to Coq-LSP. We shall publish this open-source contribution.

Minimum size of proofs parameter of clone-finder dictates the tool to ignore clones with proofs under a certain number of lines of Ltac code. This parameter defaults to 5, *i.e.*, only clones with proofs equal to 5 lines of Ltac commands or more will be reported. In §5, we study clone-finder's performance with this default value. Studying clone-finder with different parameter sizes is the subject of a future extension of this work. We would also like to emphasize that clone-finder could be implemented using Coq-Elpi [8]. Our Python implementation of Gallina parser calls for disabling the notations that might have been used in the proof scripts. Specifically, in all our experiments, we invoked clone-finder by first prepending each proof script with the directive `Set Printing All` to disable the notations. This is essential for our parser to work. Despite this limitation, we opted for using Python and directly parsing Gallina expressions, as we believe that this approach would make this infrastructure available for a wider research community and foster research in automated theorem proving.

5 Experiments

In this section, we report our experimental results for running clone-finder on a number of real-world Rocq projects. All our experiments are conducted on a Dell workstation with a 48-core Intel Xeon Gold CPU @ 2.3 GHz and 512 GB of RAM, running Ubuntu 22.04.5 LTS.

5.1 Benchmark Projects

Our benchmark suite consists of real-world Rocq projects from the CoqGym dataset [42], which is a widely used dataset in the literature [42, 38, 37, 16, 15, 14]. CoqGym comprises 135 Rocq projects obtained from GitHub. We observed that the projects were compatible with 5 different versions of Rocq. Older projects were compatible with Coq version 8.5, 8.9.0, or 8.12.0. 46 projects were compatible with version 8.16.0, and 36 projects with version 8.20.0, *i.e.*, the latest version of Rocq as of conducting our experiments. Coq 8.16.0 is the first version of Rocq that includes Coq-LSP, so we had to use version 8.16.0 or newer. We chose Coq 8.16.0, because it was compatible with most number of projects. Unfortunately, the older version of Coq-LSP, shipped with Coq 8.16.0, occasionally crashed with a "segmentation fault" error, when we used it through CoqPyt, so we ended up with 40 working Rocq projects.

Columns "Project Name" and "Project Size" of Table 1 list all the projects in our benchmark and their sizes. We have reported the project sizes both in terms of number of `.v` files in the project (column "#Files") and total lines of code (column "LoC"). Our benchmark contains a diverse set of Rocq projects, representative of the real-world Rocq projects. The projects are of varying sizes from 53 to 29,260 lines of code, and they are from various domains: from set theory to distributed system verification to geometry.

5.2 Results

We ran clone-finder on each of our benchmark projects. The last four columns of Table 1 report our experimental results in terms of number clones, *i.e.*, the number of α-equivalent goal pairs with minimum proof size of 5 lines of Ltac code, as well as the time, in seconds. We make three time measurements: (1) under the column "Build," we report the time for running Rocq on all the project files to build and generate ".vo" files; (2) under the column "clone-finder Total," we report the end-to-end time for running clone-finder, including the time Rocq needs to load and type-check the files; and (2) under the column "Analysis," we report the time clone-finder needs to parse the goals, generalize and deduplicate them, and find α-equivalent ones. Studying clones with different proof sizes is left as a future work.

In 20 out of 40 projects, clone-finder finds at least one clone. The average number of goal clones per project is 27.73 (with median being 0.5). Larger projects tend to have more instances of redundancy in them. By inspecting the clones and their proofs, we observed 3 major types of proofs: (1) identical or near identical proofs, where the proofs are almost the same, except the variable names have changed; (2) generalized proofs, where one proof proves a more general form of the goal; (3) entirely different proofs, where new proofs have been invented in each case the goal is observed.

Figure 3 shows an example of a pair of α-equivalent goals and their identical proofs. We do not have information about how the authors have written these proofs. Specifically, we are not sure whether the author have copied and pasted the proofs or they have rewritten the proofs in each case. Either way, we believe that this kind of redundancy is the least expensive one, as no new theorem or a generalization thereof needs to be created.

Table 1 Benchmark of Rocq projects and the result of applying clone-finder on each project.

Figure 4 shows an example of the second type of redundancy, wherein one goal is in fact a generalization of the other. In the first case, the local variable `eH` is bound to a specific value of type `U`, while in the second case, the author proves the same theorem for all values of type `U`. In such cases, it would be possible to factor out the more general goal as an independent lemma, which could also be useful for future developments of the system.

```
(*Goal 1:*) step_star (init ?x) ?x0 ?x1 /\ In ?x2 (messages ?x1)
(*Proof 1:*)
    split_all.
    eassumption.
    subv s1.
    apply in_app_iff.
    right.
    apply in_eq.

(*Goal 2:*) step_star (init ?x) ?x0 ?x1 /\ In ?x2 (messages ?x1)
(*Proof 2:*)
    split_all.
    eassumption.
    subv s1.
    apply in_app_iff.
    right.
    apply in_eq.
```

Figure 3 Duplicate proofs example: Example of two goals from Rocq project Chapar where α-equivalent goals show up in two different theorems `KVSAlg1CauseObl.algrec_step` and `KVSAlg1CauseObl.cause_rec` and identical proofs have been used.

Lastly, Figure 5 shows an example of the third kind of redundancy, *i.e.*, entirely different proofs have been proposed for α-equivalent goals. This could have educational value, *e.g.*, proving same goals in different ways, or the authors have proved these goals at different times, or different people have proved the goals, and a refactoring opportunity was missed.

Another observation that we can make from Table 1 concerns the time measurements. We observe that, on average, it takes 1,833.345 seconds for clone-finder to analyze a Rocq project in our benchmark to find clones. We further observed that 94.71% of this end-to-end time is from using CoqPyt/Coq-LSP to execute the Rocq files step by step, as the average time required to find clones after type checking the files is only 45.31 seconds (with median being 2.091 seconds). This means that, compared to normal build (normal build time is reported under "Build" column in Table 1), on average, there is a 122.4X increase in run time. This significant overhead is because CoqPyt loads Rocq script files individually, rather than loading the entire project as a batch, which calls for loading and checking all the dependencies of the script file each time we load Rocq script. We are still investigating if this issue can be resolved by only modifying CoqPyt so that its `ProofFile` class can accept a Rocq project to load, and cache the common dependencies between the files in the project and avoid loading and checking them from scratch, or if a modification to Coq-LSP is also needed. Another way to mitigate this overhead would be through incorporating clone-finder as a Rocq plugin that directly retrieves the AST for goals and contexts from Rocq platform itself. We save these engineering enhancements as a future extension of this work. The current version of clone-finder tool stores partial results in file and avoids invoking Coq-LSP whenever the cached results are already available.

6 Threats to Validity

Like all empirical studies, our findings are subject to threats to validity. In this section we discuss some of these threats and how we mitigate them.

We had to limit our experiments to the set of Rocq projects that were compatible with Coq 8.16.0, which slashed the size of our benchmark by 86 projects. Additionally, the Coq-LSP version shipped with Coq 8.16.0 occasionally crashed, leading to a reduced set of 40 working Rocq projects out of the 46 projects compatible with Coq 8.16.0. Despite these cuts in the size of the benchmark, the Rocq projects are of varying sizes and domains, giving us some level of confidence about their representativeness. Nevertheless, this reduction could introduce bias by excluding certain types of projects or proofs from the analysis, potentially affecting the representativeness of the results. To mitigate this threat, we will make clone-finder open-source so that research community can study it on larger available Rocq dataset.

```
(*Goal 1:*) In U H eH -> Setsubgroup U H Gr
(*Proof 1:*)
    intro H'.
    apply T_1_6_2 with (witness := witness); auto with sets.
    red in |- *; intros a b H'0 H'1; try assumption.
    lapply (h2 a (inv b)); [ intro H'5; lapply H'5; [ intro H'6; generalize H'6; clear H'5 | clear H'5 ] | idtac ];
    auto with sets.
    rewrite <- (inv_involution' b); auto with sets.
    red in |- *; intros a H'0; try assumption.
    rewrite <- (G2b' (inv a)).
    apply h2; auto with sets.
    rewrite <- (G3b' witness); auto with sets.

(*Goal 2:*) forall x : U, In U H x -> Setsubgroup U H Gr
(*Proof 2:*)
    intros witness inH.
    apply T_1_6_2 with (witness := witness); trivial.
    red in |- *.
    intros a H'.
    cut (exists n : nat, inv a = phi a n).
    intro H'0; elim H'0; intros n E; rewrite E; clear H'0.
    apply positive_powers; trivial.
    cut (inv a = phi a m).
    intro H'0; rewrite H'0.
    exists m; trivial.
    symmetry in |- *.
    apply powers_repeat with (n := r); trivial.
    apply H_included_in_G; auto.
```

Figure 4 More general proof reinvented: Example of two goals from Rocq project GroupTheory where α-equivalent goals show up in two different theorems `T_1_6_3` and `T_1_6_4`. The second proof is a more general form of the first one, and the proofs seem to be reinvented for each goal.

clone-finder looks for α-equivalent goals in Rocq projects. In other words, in this paper, we only consider syntactic clones. Our results are not generalizable to the other major type of clones. Specifically, the projects in our benchmark could contain semantic clones, *e.g.*, closely related goals that can be generalized into a single more general goal, or even universally quantified goal pairs with non-dependent quantified variables that are different only in the order of their quantified variables. We save this interesting topic for a future work (see §8).

The basic idea behind Algorithm 1 is inspired from [42]. Similar algorithm has been used in other works as well [32, 35]. This style of constructing proof trees has the drawback of reporting inaccurate results when facing with compound tactics, tactics that resolves more than one goal, and focus-shifting tactics. Some authors [35] have explicitly mentioned that such commands would break the algorithm, while others [42] have desugared or otherwise filtered out the proofs containing such tactics. In this work, we opted for not filtering out proofs, as in our application, missing a few clone cases or reporting inaccurate proof boundaries for a goal is not harmful.

Last but not least, the primary metrics used to evaluate clone-finder are the number of clones detected and the time taken for analysis. While these metrics provide significant insights into the performance of the proposed technique, they may not fully capture the practical significance or impact of the detected clones. Additional metrics, such as the effort required to refactor or eliminate the clones will be studied in a future work.

7 Related Work

The works by Ghanouchi [18] and Vinan and Hupel [40] that introduce two approaches for clone detection in Isabelle/HOL theories are closest to clone-finder. Ghanouchi [18] applies fuzzy token matching to detect clones in Isabelle/HOL theory files. This technique extends previous token-based approaches by considering near-miss clones through similarity-based token matching. Vinan and Hupel [40], on the other hand, adapt the ConQAT framework, a well-known clone detection tool, to detect proof clones in Isabelle/HOL theories. This technique extracts structured information from Isabelle document markup and performs syntactic clone detection using ConQAT's text-based similarity analysis. Unlike these two techniques, clone-finder is not intended to find clones in proof scripts themselves. Instead,

```
(*Goal 1:*) orthogonal (vec H O) (vec H C)
(*Proof 1:*)
    apply ortho_sym.
    rewrite H11.
    VReplace (vec H A) (mult_PP (-1) (vec A H)).
    rewrite H12.
    VReplace (mult_PP k (mult_PP (-1) (mult_PP k' (vec A B)))) (mult_PP (- (k * k')) (vec A B)).
    auto with geo.

(*Goal 2:*) orthogonal (vec H O) (vec H A)
(*Proof 2:*)
    apply ortho_sym.
    replace (vec H A) with (mult_PP (- k) (vec A B)).
    auto with geo.
    VReplace (vec H A) (mult_PP (-1) (vec A H)).
    rewrite H8; Ringvec.
```

Figure 5 Reinvented proofs example: Example of two goals from Rocq project HighschoolGeometry where α-equivalent goals show up in two different theorems `intersection_cercle_droite` and `intersection2_cercle_droite`, different proofs seem to be reinvented.

it is designed to detect goals that could be addressed once and for all. In other words clone-finder leverages notions of α-equivalence of goals, and proof irrelevance [4], to detect redundant proof efforts. One major benefit of clone-finder's clone detection approach, driven by α-equivalence notion, is that it can be sound and complete, but the aforementioned similarity-based heuristics may result in false positives/negatives.

Goal clone detection aligns with *proof reuse* in proof engineering. "Large-scale proof development may involve redundant efforts that can be time-consuming. Proof reuse addresses this by repurposing existing proofs as much as possible, minimizing the amount of redundant work that proof engineers must do" [33]. Existing proof reuse techniques mainly focus on proof generalization [11, 19, 5, 3, 34, 21]. To the best of our knowledge, clone-finder is the first technique on the topic of goal clone detection that realizes proof reuse by identifying α-equivalent goals that can be extracted as independent lemmas and reused. As such lemma extraction tools for Rocq, *e.g.*, company-coq [32] and CoqPIE [35], can be used alongside clone-finder.

Finding α-equivalent goals in Rocq proofs is directly related to the software engineering problem Type 1, *i.e.*, exact clones, and Type 2, rename clones, clone detection. There is a rich body of knowledge developed for clone detection for various procedural programming languages [28, 36, 29, 41] and even Java bytecode [25, 43]. Being language dependent, none of these techniques can be directly applied to goal clone detection. Additionally, functional programming defines α-equivalence, which is a theoretically sound notion of syntactic clones, *i.e.*, Type 1 and Type 2 combined, that can be leveraged in the context of functional programming, in general, and Rocq, in particular, without resorting to potentially inaccurate heuristics proposed in the past.

8 Conclusion and Future Work

We design, implement, and evaluate a technique and a tool, named clone-finder, for detecting goal clones, *i.e.*, instances of α-equivalent goals that are proved multiple times within a Rocq project. Our evaluation of clone-finder on 40 real-world Rocq projects reveals that half of the projects (20 out of 40) contained at least one goal clone. The detected redundancies fell into three primary categories: (1) exact goal duplication with identical or near-identical proofs, *e.g.*, structurally identical proofs with different variable names; (2) α-equivalent goals with generalized proofs, where one proof subsumes the other; and (3) α-equivalent goals with entirely different proofs. These findings highlight a significant opportunity for improving proof maintainability and reusability in large-scale Rocq developments.

Performance analysis of clone-finder provided empirical evidence that it is a lightweight system, with an average runtime of 45.31 seconds per project, making it a practical tool for daily proof engineering tasks. Additionally, in the process of implementing clone-finder, we contributed an enhancement to CoqPyt, allowing for handling of physical-to-logical path mappings in Rocq projects.

Our results suggest that redundancy in proof engineering is a widespread issue and that automation could help mitigate wasted effort. Moving forward, we envision extending clone-finder to detect semantic clones with the help of large language models, integrating it directly as a Rocq plugin for improved efficiency, and exploring automated lemma extraction to further reduce redundant proof efforts. We are also planning to incorporate an η-equivalence detection mechanism in clone-finder.

FuzzFlesh: Randomised Testing of Decompilers via Control Flow Graph-Based Program Generation

Amber Gorzynski

Alastair F. Donaldson
Imperial College London, UK

Abstract

Decompilation is the process of translating compiled code into high-level code. Control flow recovery is a challenging part of the process. "Misdecompilations" can occur, whereby the decompiled code does not accurately represent the semantics of the compiled code, despite it being syntactically valid. This is problematic because it can mislead users who are trying to reason about the program.

We present CFG-based program generation: a novel approach to randomised testing that aims to improve the control flow recovery of decompilers. CFG-based program generation involves randomly generating control flow graphs (CFGs) and paths through each graph. Inspired by prior work in the domain of GPU computing, (CFG, path) pairs are "fleshed" into test programs. Each program is decompiled and recompiled. The test oracle verifies whether the actual runtime path through the graph matches the expected path. Any difference in the execution paths after recompilation indicates a possible misdecompilation. A key benefit of this approach is that it is largely independent of the source and target languages in question because it is focused on control flow. The approach is therefore applicable to numerous decompilation settings. The trade-off resulting from the focus on control flow is that misdecompilation bugs that do not relate to control flow (e.g. bugs that involve specific arithmetic operations) are out of scope.

We have implemented this approach in FuzzFlesh, an open-source randomised testing tool. FuzzFlesh can be easily configured to target a variety of low-level languages and decompiler toolchains because most of the CFG and path generation process is language-independent. At present, FuzzFlesh supports testing decompilation of Java bytecode, .NET assembly and x86 machine code. In addition to program generation, FuzzFlesh also includes an automated test-case reducer that operates on the CFG rather than the low-level program, which means that it can be applied to any of the target languages.

We present a large experimental campaign applying FuzzFlesh to a variety of decompilers, leading to the discovery of 12 previously-unknown bugs across two language formats, six of which have been fixed. We present experiments comparing our generic FuzzFlesh tool to two state-of-the-art decompiler testing tools targeted at specific languages. As expected, the coverage our generic FuzzFlesh tool achieves on a given decompiler is lower than the coverage achieved by a tool specifically designed for the input format of that decompiler. However, due to its focus on control flow, FuzzFlesh is able to cover sections of control flow recovery code that the targeted tools cannot reach, and identify control flow related bugs that the targeted tools miss.

1 Introduction

In this work we present a new randomised testing approach for automatically finding *misdecompilation* bugs in decompilers.

Decompilers aim to reconstruct source code corresponding to compiled code. This can be useful for detecting security vulnerabilities in binaries [1, 17, 54, 28, 60, 48], source code recovery [18], or to enable program analysis in cases where the source code is unavailable [45, 55, 52, 20, 24].

Decompilation is a difficult process because (a) some information is lost during compilation and (b) restoring high-level code structure is technically difficult, particularly when the code has been heavily altered through compiler optimisations. Control flow recovery is especially challenging because there are often multiple valid ways to structure a given control flow graph (CFG) using high-level constructs (such as `while` or `if/else`) and the process of deciding which structure to use can be a source of errors. In addition, attempts by the decompiler to make the output code more readable (for example by eliminating as many `goto` statements as possible) rely on complex algorithms [6, 65, 25, 4].

In this paper, we define *misdecompilation* as any semantic deviation between the original low-level code and its decompiled counterpart. Misdecompilations mislead analysts, wasting their time. They are more serious than decompiler crashes or failures to decompile because there is no indication to the user that the output is incorrect. The consequences of misdecompilations can be severe: misunderstandings arising from a misdecompilation could cause a security analyst to overlook a vulnerability or mis-classify a piece of malware. For example, Votipka et al. [59] find that malware engineers prefer working with decompiled code for readability, but must switch to (harder-to-read) disassembly when they suspect a misdecompilation has occurred. Source code recovery can also be complicated by the presence of misdecompilation bugs [18].

In recognition of the importance of reliable decompilers, recent work has used randomised testing to search for decompiler bugs in a proactive manner [41, 71, 43]. However, these only target one language format each and do not focus specifically on control flow.

We build on Klimis et al. [34] to develop a novel decompiler fuzzing approach called CFG-based program generation. It has two key features:

CFG-based program generation targets control flow recovery. The approach aims to thoroughly test the control flow recovery components of decompilers. Beyond control flow, our programs are designed to use limited low-level language features, so that the only source of complexity is the control flow. This restriction to a limited set of features is important, because in practice each decompiler has an informal "scope", which is the set of programs it *should* be able to decompile. Programs that make intricate use of specialised low-level language features risk being outside of the scope of a decompiler, which may not support the reconstruction of these features. These programs are not useful as test cases because (a) they will not be recompilable, and therefore cannot detect misdecompilation bugs, and (b) will not be interesting as crash- or failure-inducing test cases to developers, who generally focus on in-scope supported language features. Prior work has devoted considerable attention to addressing the problem of recompilability, for example through post-processing the decompiled output [41, 71]. By producing programs that are syntactically simple, our approach sidesteps this problem.

The trade-off associated with our restriction to the control flow-related parts of low-level languages is that the programs generated by our approach are unlikely to trigger bugs related to detailed language-specific features (such as bugs in the handling of arithmetic operations).

CFG-based program generation is easily retargeted to various low-level languages. All mainstream programming languages have some notion of control flow. CFGs generated by our approach can therefore be "fleshed" into many different target languages, without the

need to provide full grammars to the tool or perform extensive language-specific engineering. We are not aware of any other decompiler testing techniques that can be easily retargeted to work with distinct low-level languages. Prior decompiler testing tools have been highly customised for particular languages, requiring a great deal of expertise to build and typically using existing specialised program generators for the target language [43]. Our approach drastically reduces this manual effort with respect to the testing of control flow recovery.

In more detail, CFG-based program generation involves randomly generating CFGs according to graph generation algorithms. Random paths through each CFG are also generated; these represent the expected runtime execution path. Each (CFG, path) pair is "fleshed" into a program that (a) guarantees that a particular path through the program should be traversed, and (b) checks that this path really *is* followed when the program executes. This check forms the test oracle: each program contains a self-checking assertion that fails if there is any difference between the actual and expected path.

We have implemented this approach in FuzzFlesh, a new open source decompiler testing tool. Figure 1 illustrates how we use FuzzFlesh to test decompilers. First, we **generate** a CFG and path, which we **flesh** into a low-level program (for example a Java bytecode class). We use the decompiler under test to **decompile** the program. We then **recompile** the program. Finally, we **execute** the recompiled program and assert that the actual runtime path matches the expected path. Any differences indicate a possible misdecompilation.

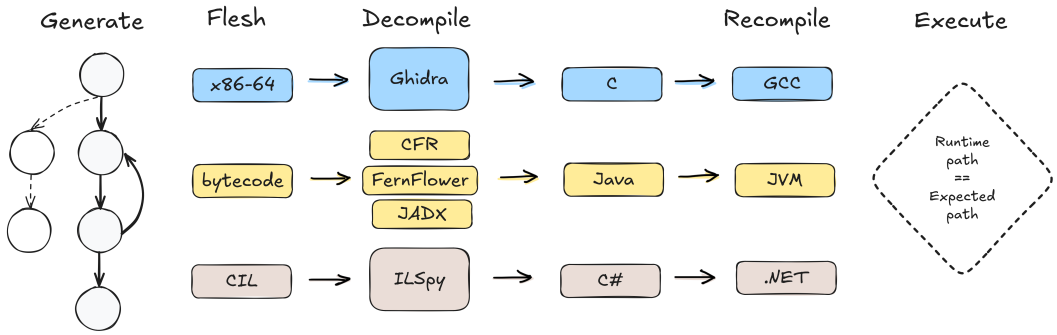

Figure 1 Workflow of CFG-based program generation as implemented by FuzzFlesh.

FuzzFlesh also features a test case reducer that operates on the CFG and path to automatically reduce bug-triggering programs to a manageable size. The reduction process retains the "expected vs. actual path" test oracle, which assists in pinpointing the source of the misdecompilation.

Most of the program generation and reduction toolchain required can be implemented in a language-independent way, which means that it can be easily extended to multiple languages. Based on our experience implementing support for four languages, we estimate that implementing an additional language would only take approximately 8 hours for an experienced programmer (see Section 6.1). This is in contrast to other program generators used by decompiler testing tools, which require extensive language-specific engineering to produce test cases. For example, JavaFuzzer [66] and Csmith [68] are used by other tools and can only produce Java and C programs respectively. Such custom program generation tools require a large amount of effort to produce for each language. FuzzFlesh is therefore particularly useful for quickly testing a range of decompiler toolchains across different languages.

Currently, FuzzFlesh supports the generation of low-level programs in three different formats: Java bytecode, x86-64 machine code, and .NET assembly. We have used FuzzFlesh to test three Java decompilers (CFR, FernFlower, JADX), one binary decompiler (Ghidra), and one C# decompiler (ILSpy). We compare the performance of FuzzFlesh to a binary decompiler testing tool (DecFuzzer) and a Java decompiler testing tool (JD-Tester).

Our evaluation aims to answer the following research questions about CFG-based program generation, in the context of the FuzzFlesh tool:

RQ1 How effective is FuzzFlesh at identifying decompiler bugs?

RQ2 How does the efficacy of FuzzFlesh vary across languages and decompiler toolchains?

RQ3 How thoroughly is FuzzFlesh able to test the control flow recovery components of decompilers in comparison to other decompiler testing approaches?

RQ4 To what extent can FuzzFlesh identify bugs that are different from those identified by other decompiler testing approaches?

Our results show that FuzzFlesh is effective: it has found 12 previously-unknown bugs in four decompilers across two languages, of which eight have been confirmed (with six already fixed) in response to our bug reports. Ten of the bugs are directly related to control flow recovery. Six of the total bugs are misdecompilations, while the remaining six are refusals to decompile, whereby the decompiler refuses to produce a program in the target language due to an internal failure.[1] FuzzFlesh achieves reasonable code coverage of decompilers despite the limited syntax and language features used within its programs. As expected, due to its focus on control flow, the coverage FuzzFlesh achieves on any particular decompiler is lower than that achieved by language-specific decompiler testing tools. Nevertheless, FuzzFlesh is able to cover code that other tools cannot reach. In particular, FuzzFlesh identifies bugs within control flow recovery code that is not covered by other tools.

In summary, our main contributions are:

- A novel program generation technique that specifically targets control flow recovery in decompilers by generating CFG data structures. The programs are designed to be syntactically simple and therefore easily recompilable.
- An implementation of this technique, FuzzFlesh, which comprises: a CFG and path generating component, three different program "fleshing" modules that target x86, Java bytecode, and .NET assembly, a program reducer that operates on the CFG and path data structures, and a test harness for automating the decompiler testing workflow.
- A large-scale testing campaign that identified 12 bugs by applying FuzzFlesh to five decompilers covering three distinct (low, high) language pairs: CFR, FernFlower, JADX, Ghidra, and ILSpy.
- An evaluation of FuzzFlesh featuring a comparison to two other recent decompiler testing approaches, DecFuzzer and JD-Tester, showing that FuzzFlesh offers complementary bug-finding abilities.

Availability. FuzzFlesh is open-source and available on GitHub [21]. An artifact is also published along with this paper [22]. This includes a copy of FuzzFlesh and all scripts and instructions required to reproduce our results.

[1] See Section 2.2 for further detail on decompiler problem categorisation.

2 Background

In this section we explain the necessary prerequisites for understanding the CFG-based program generation approach. Further related work is described in Section 7.

2.1 Decompilation

Decompilers are available for many languages [5, 30, 50, 29]. In general, decompilers are "best effort": they may detect and reject low-level programs that are overly complex. Even when decompilation is attempted, decompilers typically cannot produce code that is syntactically identical to the original source code [16, 64]. Nevertheless, in order to be useful, decompilers must be free from serious errors. In particular, when a decompiler *does* deem a given low-level program in scope for decompilation, the high-level program that the decompiler emits *must* respect the semantics of the low-level program.

Decompilation involves several phases that reverse the compilation process. Implementations vary, but the general approach is as follows [13]. First, the executable binary is lifted to an intermediate representation (IR) using a process similar to disassembly. Next, the CFG, variables, and types are recovered from the IR. Further phases of recovery may take place, notably control flow structure recovery that recovers high-level syntactic control flow structures from the CFG (e.g. `if/else`, `for`, `while` and `do-while` in C-like languages). Other optimisations such as dead code elimination and variable renaming may be performed. Finally, code generation outputs a decompiled program in the source code language.

All phases of decompilation are challenging because information is irretrievably lost during compilation, including variable names (unless debug information has been inserted by the compiler), types, and high-level programming abstractions. Control flow structure recovery is particularly important and has been much researched. Early structuring algorithms attempt to match node configurations against a codified set of high-level schema [6]. However, this technique struggles when it encounters unexpected configurations. As a fallback, a decompiler may handle such cases by using `goto` statements. However, the use of `goto` can lead to code that is difficult to read, and many high-level languages (notably Java) do not feature an unrestricted `goto` statement or similar. Alternative structuring algorithms can be used to attempt to eliminate [65, 25] or minimise [4] the need for `goto` statements, but correctly implementing these algorithms is technically challenging. Control flow recovery becomes difficult when the program's control flow graph features *irreducible* structures [2] – cycles in the graph that have multiple entry points – but the target language does not support arbitrary `goto` statements, because irreducible control flow does not map naturally to structured programming language constructs.

2.2 Decompiler bug categories

Two categories of decompiler problems are unequivocally bugs:

- **Decompiler crash:** The decompiler fails to produce a program in the target language, and crashes, hangs, or otherwise fails ungracefully.
- **Misdecompilation:** The decompiler produces a program in the target language that can be successfully recompiled, but it is semantically inconsistent with the original program.

Two other categories of problems are sometimes, but not always, indicative of bugs:

- **Refusal to decompile:** The decompiler refuses to produce a program in the target language, failing gracefully with an error message. This may be indicative of a bug in the decompiler, but alternatively may be because the input program does not fall within the scope of programs the decompiler aims to handle.

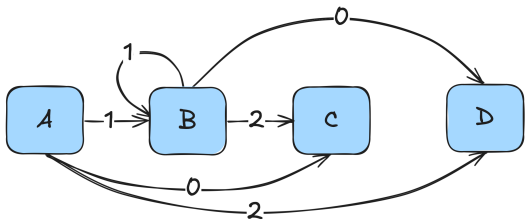

Figure 2 Example CFG generated by FuzzFlesh with directions `[0]` and expected output `[A,C]`.

- **Recompilation failure:** The decompiler produces a program in the target language that cannot be successfully recompiled, due to syntax or typing problems. Whether such problems constitute decompiler bugs depends on whether the decompiler has been designed to produce code that is expected to be directly recompilable.

Our approach aims to find misdecompilation bugs, which are of prime interest because they may mislead users. As a by-product, our approach has the potential to find decompiler crash bugs, which may be frustrating for users but are less serious than misdecompilations. It can also find "refusal to decompile" issues that may be useful to decompiler developers in understanding and assessing the limits of their tools.

While some works address the detection of recompilation failures [71], this is not our focus because many decompilers do not aim to produce code that is directly recompilable. A distinction exists between *semantically correct* and *recompilable* code: the decompiler output may be semantically correct in that it is an accurate representation of the original code, but it may need significant formatting adjustments in order to recompile without errors. For example, Ghidra [50] sometimes excludes function declarations or necessary `#include` statements. This does not pose a problem for the typical user who visually analyses the decompiled output. We therefore do not include this category of failure because it conflates bugs and expected limitations of the decompiler.[2]

3 CFG-based Program Generation and the FuzzFlesh Tool

We now describe our CFG-based program generation approach in detail and explain how we have put it into practice in the FuzzFlesh tool.

We start with an overview of how the approach works using an example graph that was able to identify a misdecompilation bug in CFR [5], a tool that decompiles Java bytecode into Java source code. We then provide further details of each component of the approach.

CFG-based program generation involves randomly generating CFG skeleton data structures and then "fleshing" them into programs in a target low-level language. Figure 2 shows an example CFG that might be generated. Each node represents a basic block in the low-level program that will ultimately be generated, and each edge represents a jump in the control flow between two nodes. The outgoing edges of a node are numbered with consecutive integers starting from 0. A CFG has a single entry point, in this case node A.

A path through the CFG is also randomly chosen, and a corresponding sequence of edge labels is determined; we call this sequence the *directions* that must be taken for the path to be followed. For example, suppose the path $[A, C]$ through the CFG of Figure 2 was chosen. The directions sequence [0] would force this path to be taken.

[2] We do automatically apply minor fixes to programs to support recompilability, which are discussed in Section 4. We do not report these issues as bugs.

```
test_program() {
    int[] directions = {0};
    int[] actual_output;

    int dir_index = 0;
    int out_index = 0;

block_A:
  actual_output[out_index++] = 0;
  switch(directions[dir_index++]) {
    case 0: goto block_C;
    case 1: goto block_B;
    case 2: goto block_D;
  }
```

```
block_B:
  actual_output[out_index++] = 1;
  switch(directions[dir_index++]) {
    case 0: goto block_D;
    case 1: goto block_B;
    case 2 : goto block_C;
  }

block_C:
  actual_output[out_index++] = 2;
  return;

block_D:
  actual_output[out_index++] = 3;
  return;
}
```

Figure 3 Example pseudocode corresponding to the CFG in Figure 2.

From a (CFG, path) pair, (G, p), a concrete low-level program and program input are synthesised, where the program input is the sequence of directions associated with p. The program is designed to (a) consume the directions and follow the corresponding control flow path, and (b) output the sequence of nodes that is traversed during execution. Therefore, on execution, the program should output the path p.

The synthesised low-level program is then decompiled and recompiled, and executed on the input, and a check is performed to confirm that the program output does indeed indicate that the required path was followed. If not, a misdecompilation has occurred and can be investigated.[3] The comparison of the expected and actual path forms the test oracle, which is self-contained within every test case.

Returning to the example of Figure 2, Figure 3 shows C-like pseudocode illustrating how the graph can be fleshed into a program. The actual output is recorded at each node in the `actual_output` array. The `directions` array is read from every time that a conditional jump is encountered. The target language of the flesher depends on the toolchain under test.

When configured to target Java, our FuzzFlesh tool generates a textual Java bytecode program for this example, which is converted to a `class` file using the Jasmin assembler [47]. FuzzFlesh uses CFR to decompile the program, uses `javac` to recompile it, and executes it on the input [0], which should force the path $[A, C]$ to be followed. The actual output indicated that the path $[A, B, C]$ had been followed: the bytecode program had been misdecompiled. We have reported this issue to the CFR developers.

An attractive feature of CFG-based program generation is that it is easy to retarget for various low-level languages. For example, the graph- and path-generation parts of our FuzzFlesh implementation are entirely language-independent. The only language-specific work that is required is the straightforward logic to flesh a (CFG, path) pair into a low-level program. The tool is thereby able to test a range of decompilers for various languages.

In practice, FuzzFlesh generates larger and more complex CFGs than the one shown in Figure 2. Once a potential bug is identified, FuzzFlesh reduces the program to a manageable size by performing a series of operations on the CFG data structure and then re-fleshing it into a (smaller) program.

[3] Is is theoretically possible that the problem could actually be a compiler bug introduced during the recompilation process, but this has not occurred in practice in our experience.

We now provide further detail on how we have realised each component of CFG-based program generation in FuzzFlesh. Section 3.1 and Section 3.2 set out the CFG and path generation approaches. Section 3.3 describes how these CFGs and paths are fleshed into programs. Section 3.4 explains the test oracle used to identify potential misdecompilations. Finally, Section 3.5 describes the CFG-based program reducer.

3.1 Graph generation

The aim of the graph generator is to create a CFG that can be used as the basis for a program. It generates graphs using a set of user-configurable input parameters including a random seed. Each graph is randomly generated from scratch; there is no initial corpus of graphs. The output is a directed graph data structure that contains nodes and directed edges. The generated graphs must be a valid basis for programs, which is achieved by ensuring that they meet a set of conditions. First, there must exist a single entry point to the graph; second, there must exist at least one path from the entry node to an *exit node*: a node with no successors. All target languages (x86-64, Java bytecode, and .NET assembly) allow irreducible control flow (see Section 2.1), which means we do not impose further restrictions on the shape of the graphs, although other target languages that do not support arbitrary control flow (such as WebAssembly) would require additional checks. This issue is discussed further in Section 4.2. Disconnected graphs are valid programs, providing there is only one entry point in the graph. The disconnected region can be considered "dead" code that the decompiler may eliminate.

The graph generator in FuzzFlesh grows a graph of a parameterised target size using a breadth-first algorithm adapted from Krapivsky and Redner [35]. Starting with the root, the generation algorithm adds a random number of successors nodes. It continues to add a random number of successor nodes to each existing node until the target graph size is reached. This constructs a wide tree graph that contains a path from the entry node to at least one exit node, but does not have any jumps beyond immediate child nodes. To enhance the graph shape, we add edges to a randomly chosen number of nodes in the graph. A proportion of these additional edges jump backwards to a direct ancestor of the current node, which introduce cycles into the CFG so that important program constructs such as loops are represented. Finally, additional exit nodes are optionally added to a randomly selected sample of nodes in the graph. This reduces the likelihood that a path will become stuck in a part of the graph that has no naturally-occurring exit nodes due to the back edge annotations.

We also implemented an alternative graph-generation algorithm adapted from Erdős and Rényi [19]. This graph generator creates a set of nodes according to a graph size parameter and randomly connects them via directed edges. A single node is randomly selected as the root node. In addition, exit nodes are randomly added. In practice we found that this method generates graphs with many disconnected components and short paths, and we found it to be ineffective at triggering bugs in practice, so do not discuss it further.

FuzzFlesh has been designed in a modular fashion so that other graph generation approaches would be straightforward to integrate. For example, one could mine existing programs for interesting control flow graphs and using these as the basis for fuzzing; this is an area for future work.

This stage of the toolchain is entirely language-independent.

3.2 Path generation

The FuzzFlesh path generator performs a random traversal of each generated CFG. It records the sequence of nodes visited on the path, and the sequence of directions that will force this path to be followed. Multiple paths can be generated for each graph, and they can be configured by a maximum length input parameter. Once this length is reached, the path generation algorithm identifies the shortest path to an exit node and adds this to the path. FuzzFlesh does not attempt to cover all paths through the CFG. Instead, a user-configurable number of paths through each CFG are selected at random.

This stage of the toolchain is also language-independent: paths are a data structure containing the path and the directions array.

3.3 Program fleshing

At this stage, FuzzFlesh becomes language-specific. The inputs to the flesher component are a graph data structure and a path. The output is a program in a particular low-level language, ready to be decompiled. By construction, the output program will write the IDs of each node visited at runtime to an actual output array. The contents of this output array can be compared with the expected output from the path to provide the test oracle.

Program fleshing involves traversing the CFG and fleshing each node based on its characteristics. As described in Section 3.1, the CFG is constructed as an abstract graph (i.e. not in a low-level language format) and fleshing provides a direct mapping between CFG nodes and appropriate low-level language operations. First, the start of the program is fleshed with the necessary code to begin the program, including the declaration of the function and data structures for the directions and output arrays. Next, the flesher traverses the CFG and fleshes each node with code that records the node ID in the output array so that the actual path taken through the program at runtime is recorded. In addition, the flesher checks the number of children that each node has and fleshes it with an appropriate basic control instruction such as `goto`, `if/else`, or `switch`. Exit nodes with no children contain a return instruction. We do not include more complex language features in order to ensure that the resulting program is simple enough to be decompiled and subsequently recompiled.

During the fleshing stage, the directions array corresponding to the expected path can be configured to be statically unknown or known. This provides respectively less or more information about the program to the decompiler under test.

If the directions are statically unknown, then the directions array is passed to the test case function at runtime as a parameter from the wrapper program. In this case, the test case is fleshed to accept the directions array and read directions from it, but these directions are not known at decompile-time. This creates a program in which every node in the graph is potentially dynamically reachable at runtime, given suitable inputs.

Alternatively, the directions array can be hard-coded into the function during the fleshing step. In this case, the directions are known to the decompiler.

These approaches may result in different decompilation heuristics. The overall impact on the decompiler is unclear: providing more information to the decompiler by hard-coding the directions could make the program easier to decompile. However, as discussed in Section 4.1, in some cases we generate programs in a high-level language such as C and use a compiler to generate the low-level program (rather than directly generating the low-level program). In this setting, statically-known directions can be used to perform optimisations at compile-time. The resulting optimised binary may have a more complicated and less easily recoverable

structure. Alternatively, compiler optimisations may have greatly simplified the program, which could result in more straightforward decompilation. To maximise diversity during testing, we generate the low-level programs using a range of compiler optimisation levels.

3.4 Test oracle evaluation

Each program generated by FuzzFlesh contains a built-in self-checking test oracle in the form of the expected output. A test harness performs the testing process and evaluates the test oracle to determine whether the test has failed. The testing process for decompilers is as follows:

1. **Decompile:** We use the decompiler under test to decompile the program to a target source code. At this stage, the decompiler may crash or fail and throw an exception if it encounters code that it is unable to process.
2. **Recompile:** If the decompilation was able to produce a source program, we recompile the resulting program.
3. **Execute:** Finally, we execute the de- and recompiled program. If the actual output recorded by the program at runtime differs from the expected output, then a misdecompilation bug is flagged for investigation.

3.5 Test case reduction

Once a possible bug is found, FuzzFlesh reduces the bug-triggering test case to a manageable size in order to pinpoint the source of the error. We have designed a custom automated test case reducer to make the simplification and triage of bug-triggering test cases easier. Most of the reduction is done at the language-independent graph and path level, which means that it can be reused across multiple languages. The reducer performs the following types of operation on a (CFG, path) pair:

- Merge nodes: Two nodes n_1 and n_2 are merged together into a single node n' so that the total number of nodes in the graph is reduced by one. Any inwards edge to n_1 or n_2 becomes an inward edge to n', and similarly for any outwards edge. If either of the nodes was on the path, then the path and associated directions are also updated. Node merge operations must ensure that at least one exit node is retained so that the program does not become non-terminating.
- Remove edges: Edges are removed from the graph. If an edge is on the path, then the path and directions are also updated.

After each operation, the (CFG, path) pair are re-fleshed into a program. If compiling, decompiling, and recompiling still trigger the same bug, then the program is saved and reduced further. Otherwise, the updated program is discarded and a different reduction operation is attempted.

4 Decompilers under test

We test three Java decompilers: CFR [5], FernFlower [30], and JADX [32], the popular binary decompiler Ghidra [50], and the C# decompiler ILSpy [29]. We selected these decompilers because they are relatively well established and currently maintained, and they have been reviewed in previous studies [41, 43, 71]. Although it is considered in prior work we did not include the decompiler RetDec because it describes itself as in “limited maintenance mode” and only has one commit in the past six months [3]. We also do not consider the angr decompiler [57] because we found that extensive engineering effort is required to allow outputs from angr to be recompiled.

Table 1 summarises the key characteristics of these decompilers, which we now discuss in more detail.

Table 1 Decompilers under test.

Name	Input	Target	CFG recovery
CFR	Java bytecode	Java	Pattern-matching
FernFlower	Java bytecode	Java	Tarjan's algorithm
JADX	Java bytecode	Java	Pattern-matching
Ghidra	Binary	C	Tarjan's algorithm
ILSpy	.NET assembly	C#	Pattern-matching

4.1 Binary decompilers

Ghidra [50] is an open-source reverse engineering tool that allows users to perform a range of analyses on compiled code. We specifically test the decompiler configuration that decompiles x86-64 machine code to C. Rather than directly generating machine code, FuzzFlesh instead fleshes graphs into C programs, which are then compiled to machine code using gcc with a randomly chosen optimisation level. Ghidra disassembles and decompiles these programs to C code. It uses Tarjan's algorithm for identifying strongly connected graph components [58] for control flow recovery. The output programs can typically be re-compiled and executed. Some minimal adjustments are occasionally required. For example, Ghidra output often includes a function call to `__stack_chk_fail()` to indicate that there may be an issue with the decompilation process, but it does not define this function and so the program fails to recompile. This adjustment is easily automatable: we simply insert a line into the decompiled program: `void __stack_chk_fail(){ return; }`, which allows the program to recompile and execute without errors or warnings. Based on our experience, Ghidra tends to insert such calls frequently even within programs that it otherwise appears to have decompiled correctly, which indicates a degree of over-caution. In the case that the `__stack_chk_fail()` call relates to a genuine problem with the decompiled code, our test oracle should identify the decompilation as incorrect since the program output will be altered.

4.2 Java decompilers

FernFlower [30], CFR [5], and JADX [32] are open-source decompilers that decompile Java bytecode class files to Java source code. CFR and JADX use pattern-matching control flow recovery algorithms that are supplemented by heuristics (for example in the handling of switch statements). FernFlower uses some pattern-matching for code generation but, similarly to Ghidra, also makes use of Tarjan's algorithm (see Section 4.1). It was the first Java decompiler that specifically aimed to be able to deobfuscate code, and it includes modules specifically for restructuring control flow that is not representable in Java.

FuzzFlesh generates test programs in textual Java bytecode, which are converted to binary Java class files using Jasmin [47]. We generate Java bytecode rather than Java because it allows more expressive control flow. Specifically, Java does not allow irreducible control flow [23, Section 2.2.6] (see Section 2.1). However, Java bytecode *does* allow irreducible control flow; the bytecode instruction set [51] includes an unrestricted `goto` command that can be used to transfer control to anywhere in the program. This difference in restrictions allows compilers that generate bytecode to perform optimisations that introduce irreducible control flow.

It is possible that some Java bytecode programs do not have a corresponding representation in Java due to differences in restrictions between the languages. In this case, it is expected that a bytecode decompiler will gracefully refuse to decompile the program. Nevertheless, since decompilers can be used for security purposes to inspect potentially malicious class files, it is desirable for bytecode decompilers to be as capable as possible in decompiling atypical bytecode. At a minimum, the decompiler should provide an informative error message stating which part of the bytecode it was unable to process.

4.3 C# decompilers

ILSpy [29] is an open source .NET decompiler that decompiles programs expressed in the .NET intermediate representation, Common Intermediate Language (CIL) to C#. Unlike the Java decompilers, it does not have to convert irreducible control flow to a reducible graph because C# supports irreducible control flow via a `goto` statement. FuzzFlesh has two modes for targeting CIL: one in which CIL code is generated directly, and another where C# programs are generated, and then compiled into CIL using the .NET C# compiler csc.

C# programs are typically compiled to CIL, which is then JIT-compiled using the .NET runtime on Windows and Linux or the mono runtime on Mac OS. The intermediate CIL programs are not usually optimised ahead of runtime, and there are no options to do so in .NET or mono. ILSpy decompiles these programs and returns a corresponding C# program.

ILSpy does not apply algorithms to remove or reduce `goto` statements. This means that the decompiler output is often very long and consists mainly of `goto`s rather than other control flow structures.

5 Evaluation: Bugs found

In this section we answer research questions **RQ1** and **RQ2** set out in Section 1 and recapped below. In Section 6 we further evaluate FuzzFlesh in comparison to other decompiler testing tools to answer the remaining research questions.

RQ1 How effective is FuzzFlesh at identifying decompiler bugs? (Section 5.1)

RQ2 How does the efficacy of FuzzFlesh vary across languages and decompiler toolchains? (Section 5.2)

5.1 RQ1: Effectiveness of FuzzFlesh for bug-finding

We tested five decompilers, which are described in detail in Section 4 and summarised in Table 1. FuzzFlesh identified 12 bugs in total, comprising six misdecompilation bugs and six decompiler failures. Details of these bugs are provided in Table 2. The bugs were found across a total of four decompilers, which target two different low- to high-level language pairs. At the time of writing, eight bugs have been confirmed and six fixed by developers. We label each bug as “M” to denote a misdecompilation, or “R” to denote a refusal to decompile that we deemed to be likely to be in-scope for the decompiler in question, in line with our definitions of bug types in Section 2.

Most bugs are related to control flow restructuring. The bugs can be grouped into themes: cycle bugs, switch bugs, and Java-specific irreducible control flow bugs.

5.1.1 Cycles

At a low level, all program cycles are implemented via branch instructions. The control flow recovery algorithm must translate these to high-level looping constructs, potentially resorting to the use of `goto` statements if these are supported by the target high-level language. As

Table 2 List of decompilation bugs found (GitHub issues are hyperlinked to the bug ID) Type M = misdecompilation, Type R = refusal to decompile.

ID	Decompiler	Type	Description	Fixed
G1	Ghidra	M	Missing jump table entry	✓
G2	Ghidra	M	Incorrect counter increment	✓
G3	Ghidra	M	Counter array incorrectly sized	
G4	Ghidra	M	Locals instead of array	
G5	Ghidra	R	Incorrect switch decompilation	✓
C1	CFR	M	Missing switch case	
C2	CFR	R	Nested switch	✓
C3	CFR	R	Irreducible control flow cannot be restructured	✓
F1	FernFlower	M	Incorrect infinite loop	
F2	FernFlower	R	Irreducible control flow cannot be restructured	
J1	JADX	R	Code restructure failure	✓
J2	JADX	R	Unreachable block	

discussed in Section 2, some decompilers use advanced recovery algorithms that aim to minimise or completely avoid the use of `goto`, but can be hard to implement correctly. FuzzFlesh found several bugs related to incorrect decompilation of cycles.

As an example, Figure 4 shows a CFG and path that generated by FuzzFlesh that triggered a bug in FernFlower after being fleshed into Java bytecode; this is issue F1 in Table 2. The path is shown by solid edges, while other off-path edges are shown by dotted lines. Figure 5 shows the CFG and path corresponding to the Java program that was emitted by FernFlower. The decompiler output contains an infinite loop: FernFlower attempted to form the code into a `while` structure but did not correctly determine how the termination should occur.

Other cycle-related bugs included misdecompilations of loop-control variables by Ghidra.

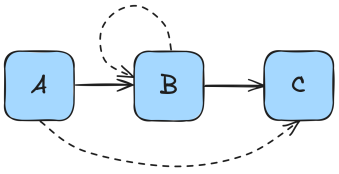

Figure 4 CFG and path of original program.

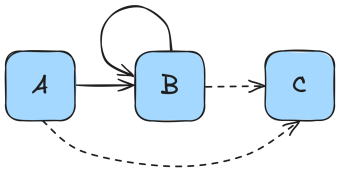

Figure 5 CFG and path of program decompiled by FernFlower containing an infinite loop.

5.1.2 Switch statements

Three bugs were related to the decompilation of switch statements. Figures 6a and 6b show an example of a switch misdecompilation by Ghidra. The original program contains a jump table with five distinct instruction addresses (lines 3–7 of Figure 6a). However, the decompiled code only contains four switch cases (lines 3–6 of Figure 6b): there should be another case for the value 0. The problem was caused by an issue in the algorithm that reconstructs loops, which did not correctly handle the existence of a self-edge. This has been fixed by the Ghidra developers in response to our bug report [36].

```
switchD_001000b9::switchdataD_0010018c

0010018c d4 fe ff ff     uint     FFFFFED4h
00100190 98 ff ff ff     uint     FFFFFF98h
00100194 db ff ff ff     uint     FFFFFFDBh
00100198 51 ff ff ff     uint     FFFFFE51h
0010019c 76 ff ff ff     uint     FFFFFE76h
```

(a) Original jump table.

```
void test(int* p_1, int* p_2) {
switch(p_2[local_2]){
    case 1: goto block_D; ...
    case 2: goto block_E; ...
    case 3: goto block_I; ...
    case 4: goto block_F; ...
}
```

(b) Decompiled switch statement.

Figure 6 Illustration of a bug in Ghidra related to switch statements (issue G1 of Table 2). The jump table contains five entries, but only four of these are captured by switch cases in the decompiled code.

5.1.3 Java-specific irreducible control flow

As discussed in Section 4.2, Java bytecode allows irreducible control flow while Java does not. This means that decompilers must structure any irreducible control flow to produce valid Java. Irreducible control flow can be converted to reducible control flow using several techniques [8]. We found a number of bugs relating to this conversion process. These bugs are particularly interesting because they are unlikely to be found by program generation approaches that do not specifically aim to create unusual control flow structures.

An example of an irreducible CFG produced by FuzzFlesh is shown in Figure 7. This formed the basis for a program that caused a decompiler failure in FernFlower, which we reported in issue F2. Feedback in the discussion thread for the issue indicates that FernFlower should be able to handle simple cases of irreducible control flow such as this one. Indeed, the removal of any edge, node or statement from the CFG resulted in a program that FernFlower was able to decompile, even those still containing irreducible control flow.

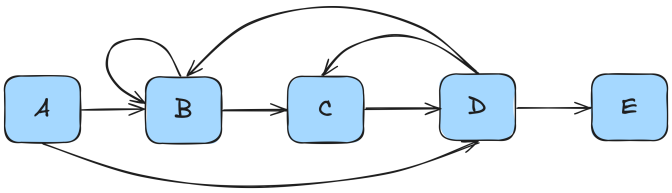

Figure 7 CFG that triggered a decompiler failure bug in FernFlower (issue F2 of Table 2).

5.2 RQ2: Efficacy of FuzzFlesh across languages and decompiler toolchains

FuzzFlesh found bugs in binary and Java decompilers but was not successful at finding bugs in C# decompilers. This is likely to be because CIL is fairly high level (unlike machine code), C# allows unrestricted control flow (unlike Java), and ILSpy does not appear to attempt to minimise the number of `goto` statements in the output code.

FuzzFlesh is not able to test decompilers whose output requires extensive engineering effort to recompile, for example angr [57].

6 Evaluation: Comparison to other approaches

In this section we answer research questions **RQ3** and **RQ4** set out in Section 1 and recapped below by evaluating the efficacy of FuzzFlesh and its ability to exercise the control flow recovery components of decompilers in comparison to other decompiler testing approaches.

RQ3 How thoroughly is FuzzFlesh able to test the control flow recovery components of decompilers in comparison to other decompiler testing approaches? (Section 6.2)

RQ4 To what extent can FuzzFlesh identify bugs that are different from those identified by other decompiler testing approaches? (Section 6.3)

6.1 Overview of decompiler testing approaches

We compare FuzzFlesh to two other tools[4] that aim to test decompilers:

- **DecFuzzer** [41], a binary decompiler fuzzer that targets open-source decompilers Ghidra and RetDec and commercial decompilers IDA-Pro and JEB3. It uses Csmith to generate an initial corpus of programs for de- and recompilation. Only a subset of the Csmith grammar is used to improve the likelihood of recompilability. Mutations are applied to any programs that successfully recompile, designed to yield programs that are equivalent modulo inputs [37]. Comparing results between original and mutated programs then provides a metamorphic test oracle [11].
- **JD-Tester** [43], a Java decompiler fuzzer that targets three Java decompilers: CFR, FernFlower, and JADX. JD-Tester uses two existing Java program generators: JavaFuzzer and Hephaestus. Each program is compiled to a class file, decompiled by the decompiler under test, and recompiled. The output of the original and recompiled program are compared to find decompilation bugs.

Table 3 Overview of decompiler testing tools.

Tool	Generator	Decompilation scenarios			Control flow bugs
		bin to C	class to Java	CIL to C#	
FuzzFlesh	FuzzFlesh	✓	✓	✓	✓
DecFuzzer	Csmith	✓			
JD-Tester	JavaFuzzer / Hephaestus		✓		✓

Table 3 summarises the characteristics of each testing approach, and highlights two key features of FuzzFlesh. First, FuzzFlesh covers multiple (low-level, high-level) language pairs, while the other tools only cover a single language pair. We are not aware of any decompiler testing tool that is able to target multiple languages. This is because of the simple nature of program generation in FuzzFlesh. For example, FuzzFlesh devotes only 86 lines of code to Java-specific program generation, while JavaFuzzer consists of 3,412 lines and Csmith contains around 40,000 lines of code.[5] This feature means that it is easy to add an additional language pair to FuzzFlesh. Most of the program generation logic is language-independent, which means it does not need to be repeated for each new language.

[4] A recent paper evaluates binary decompilers using Dsmith [7], a fuzzer based on Csmith. The artifact was released in September 2024; due to time constraints we have not included it in our evaluation.

[5] Lines of code were measured using the cloc tool.

Second, Fuzzflesh targets control flow recovery. DecFuzzer and JD-Tester programs do contain complex control flow, however DecFuzzer is not able to find any control-flow related bugs. A detailed comparison of the nature of bugs found by each tool is given in Section 6.3.

6.2 RQ3: Comparison of thoroughness of control flow recovery testing

Code coverage measures the proportion of the decompiler source code that is executed ("covered") during testing. This provides a high-level indication of the extent to which a testing tool is exercising the decompiler. However, coverage is limited as an evaluation metric because (a) it does not provide any information on the relative importance of different lines, and (b) it is possible to execute code that contains a bug without actually triggering the bug. We therefore also include a comparison of actual bugs in Section 6.3.

Table 4 summarises the aggregate line coverage of each decompiler by FuzzFlesh, JD-Tester and DecFuzzer. The coverage is calculated by running each tool in fuzzing mode 8 hours on a 16-core 128GB RAM machine running Ubuntu 22.04. The "path known" and "path unknown" configurations of FuzzFlesh refer to whether the directions array that guides the path through the CFG are hard-coded into the program or passed at runtime respectively (see Section 3.3). The "JavaFuzzer" and "Hephaestus" configurations of JD-tester refer to the underlying Java program generator used (see Section 6.1). We report bytecode instruction coverage for Java and line coverage for C throughout; branch coverage follows a similar pattern but is lower for all tools (not reported here but available in the accompanying artifact).

We summarise our main findings, before giving more specific detail on the experimental setup and results for binary decompilers and Java decompilers in Sections 6.2.1 and 6.2.2, respectively.

Overall, coverage of each decompiler is highest for the language-specific testing tools JD-Tester and DecFuzzer. This is expected because they are far more syntactically expressive than the FuzzFlesh programs. Nevertheless, despite its limited syntax, FuzzFlesh achieves reasonable overall coverage of up to 36% of Ghidra, 31% of CFR, 42% of FernFlower, and 37% of JADX. The different FuzzFlesh generation modes generally achieve similar levels of overall coverage, as do the different program generators used by JD-Tester.

As part of these experiments we also computed coverage data at checkpoints of 2 and 4 hours of each 8 hour fuzzing run, and found that coverage had already plateaued after 2 hours for all tools.

Table 4 Instruction coverage comparison for an 8 hour fuzzing run (%).

Decompiler	Testing tool				
	FuzzFlesh path known	FuzzFlesh path unknown	DecFuzzer	JD-Tester JavaFuzzer	JD-tester Hephaestus
Ghidra	36	31	39	–	–
CFR	31	30	–	53	42
FernFlower	42	41	–	55	48
JADX	37	36	–	50	44

6.2.1 Binary decompiler coverage

Ghidra is implemented in a combination of Java and C++. We restrict our coverage comparison to the decompiler component, which is implemented entirely in C++. We use gcov and gcovr to analyse coverage.

DecFuzzer generates programs using Csmith. These are compiled to binaries, decompiled using Ghidra, and recompiled. Successfully recompiled programs are used as seeds for equivalence modulo inputs testing. DecFuzzer aims to improve the likelihood of successful recompilation by restricting Csmith to produce only one function (besides `main()`), limiting the complexity of expressions, and excluding arrays, structs, unions, pointers and various other language features. The restricted Csmith command in full is:

```
csmith -no-arrays -no-structs -no-unions -no-safe-math -no-pointers
-no-longlong -max-funcs 1 -max-expr-complexity 5
```

As discussed further in Section 6.3.2, despite these restrictions DecFuzzer's use of Csmith does not lead to programs that can be successfully recompiled after decompilation by recent versions of Ghidra.

In addition to overall coverage, we compare the unique coverage of each testing tool. Table 5 shows that FuzzFlesh is able to cover around 12,700 lines within Ghidra that DecFuzzer programs are not able to cover. In particular, FuzzFlesh covers parts of the control flow restructuring algorithms (within `block.cc`) that DecFuzzer does not cover.

Table 5 Unique line coverage comparison for the binary decompiler Ghidra.

	Lines covered by				
Decompiler	FuzzFlesh only	DecFuzzer only	Both	Neither	Total lines
Ghidra	12,700	6,300	12,800	39,800	71,600

6.2.2 Java decompiler coverage

We use the Jacoco code coverage tool to measure coverage of the bytecode-to-Java decompilers, which are implemented in Java. Fuzzing mode involves program generation, compilation, decompilation, recompilation, and test oracle evaluation. Neither of these tools requires an initial seed corpus for test generation. We then gather the programs that were generated by each testing tool and decompile them using versions of CFR, FernFlower, and JADX that are instrumented with Jacoco. The motivation for separating the coverage measurement from the previous step is that coverage instrumentation can slow program execution, which could lead to underestimating the coverage achieved in a given time budget.

In addition to overall coverage, we also analyse the unique coverage of each tool. Although JD-Tester achieves higher overall coverage, FuzzFlesh is able to cover some parts of each decompiler's code that are not covered by JD-tester. Table 6 shows the number of instructions that are covered by only FuzzFlesh or only JD-Tester. The instructions covered by FuzzFlesh that are not covered by JD-Tester mainly relate to control-flow recovery. For example, FuzzFlesh covers instructions in the following classes that are not covered by JD-Tester (non-exhaustive list):

- CFR: SwitchReplacer, LoopIdentifier, JumpsIntoDoRewriter, and JoinBlocks
- FernFlower: IrreducibleCFGDeobfuscator, ControlFlowGraph, SwitchStatement, JumpInstruction, and DomHelper (which calculates node dominance),
- JADX: BlockSplitter, BlockProcessor, FixMultiEntryLoops, SwitchInsn, and LoopRegionVisitor

Table 6 Unique bytecode instruction coverage comparison for Java decompilers.

Decompiler	Instructions covered by				Total instructions
	FuzzFlesh only	JD-Tester only	Both	Neither	
CFR	800	35,300	51,000	79,000	166,100
FernFlower	4,700	15,900	34,900	38,300	93,800
JADX	1,300	17,100	43,400	60,400	122,200

6.3 RQ4: The kinds of bugs found by FuzzFlesh vs. other approaches

While code coverage provides a useful overview of the potential capabilities of decompiler testing tools, it is only a proxy for the ideal fuzzer performance measurement: the potential number of "useful" bugs that can be found [33]. In this section we evaluate the bug-finding ability of FuzzFlesh in comparison to DecFuzzer and JD-Tester.

6.3.1 Bugs in all decompilers

FuzzFlesh is the only decompiler testing tool that we are aware of that is able to find bugs in decompilers that target different language-pairs. In this respect it has a higher bug-finding potential than other tools, since it can be easily extended to other languages in the future, while DecFuzzer and JD-Tester both rely on language-specific program generators.

6.3.2 Bugs in binary decompilers

Problems with recompilability within DecFuzzer mean that we cannot perform a head-to-head comparison of bug-finding ability. No DecFuzzer programs are recompilable using the latest Ghidra plugin, which means that they are not able to identify misdecompilations. DecFuzzer runs on Radare2, which is a reverse-engineering framework that uses a Ghidra plugin for decompilation. However, multiple compiler errors occur when trying to recompile the decompiled programs within DecFuzzer's workflow. The errors include trivial issues such as "unknown type name uint" but also more complex issues such as the incorrect number of arguments to functions. Modifying DecFuzzer to support recompilability would likely require a significant amount of engineering work to address the latest Ghidra output format. This illustrates the difficulty of ensuring recompilability. We contacted the authors of DecFuzzer, and they shared with us the commit used for Radare2 and their best estimate of the versions of the Ghidra plugin, r2ghidra, and other tools that were used, however some of the original artifacts from the paper (such as the contemporary binaries) are no longer available. It has therefore not been possible to reconstruct a working version of the tool to perform a direct bug-finding comparison due to incompatibilities between the historic Ghidra versions and current binaries. The simple syntax used by FuzzFlesh means that we are less likely to encounter this type of recompilation issues in the future, because we expect that future versions of all tools will continue to support basic syntax.

Considering the original bugs reported to have been found by DecFuzzer [41] and the actual bugs found by FuzzFlesh: FuzzFlesh mostly identifies control flow related bugs, while DecFuzzer mainly identified bugs relating to type recovery and optimisations, and was not able to find any bugs within the control flow recovery module of Ghidra or any other binary decompiler. FuzzFlesh found a total of 6 bugs in Ghidra, at least three of which are confirmed by developers to be directly related to control flow recovery. While the sample size is small, this indicates that FuzzFlesh is likely to be capable of finding control flow related bugs that DecFuzzer would not identify.

6.3.3 Bugs in Java decompilers

JD-Tester is able to find control flow related bugs. This is because (a) the programs generated by JD-Tester include control flow structures, and (b) decompiling bytecode to Java is easier than decompiling machine code (for example because instructions and data are separate). This means that more programs are recompilable than in the case of binary decompiler testing, which enables the detection of control flow misdecompilations. However, some of the bugs identified by FuzzFlesh are unlikely to be discoverable by JD-Tester due to the complex control flow employed. To compare the tools directly, we evaluate whether JD-Tester is able to find the control flow related bugs that FuzzFlesh identified in Java decompilers. We restrict the comparison to bugs that have been fixed.

To do this, we rely on the notion of "correcting commit" used in an empirical study of compiler testing techniques [9]: the commit in which a bug is fixed (so that the bug manifests before the commit but not after). This is essential because otherwise, especially in the case of misdecompilation bugs, it is not possible to directly identify which underlying bug is triggered by a bug-inducing test program. Our evaluation works as follows:

- We identify correcting commits associated with two CFR bugs and one JADX bug.
- We run JD-Tester on a preceding commit (i.e. one for which we know that the bug is present) for 2 hours and identify any failing test cases. These are potential bug-triggering programs that could identify the bug.
- We run the failing test cases on the correcting commit. If any test now passes, then we infer that its original failure was caused by the bug. Such a test identifies the bug.

We found that none of the JD-Tester programs that failed on the preceding commit passed on the correcting commit, indicating that none of the potential bug-triggering test programs produced by JD-Tester were caused by these specific bugs. Although the time budget is limited, in contrast FuzzFlesh was able to identify these bugs almost immediately. These results suggest that JD-Tester is not able to identify some bugs that are found by FuzzFlesh. This evaluation is based on a very small sample size of the two correcting commits (recall that we focus here only on bugs that have been fixed), however the coverage analysis provides supporting evidence that JD-Tester may not be able to trigger bugs in some parts of the decompiler code. While neither of the FernFlower bugs have been fixed, one relates to irreducible control flow restructuring. This would certainly not be detectable by JD-Tester because its programs do not contain irreducible control flow. Similarly, the Jadx bug would not be detectable by JD-Tester because it related to irreducible control flow restructuring.

To summarise, in prior work JD-Tester has been shown to perform well at finding a range of bugs in Java decompilers, including some control flow bugs [41]. However, FuzzFlesh was able to identify some previously-unknown and potentially significant bugs that JD-Tester appears unable to find.

7 Related Work

Decompiler testing. Historically, the main evaluation metrics used to assess decompilers were focused on readability, for example code compactness and complexity (measured by cyclic complexity and the number of `goto`s in a decompiled program). In recent years there has been an increasing focus on correctness within decompiler research [41].

As discussed in Section 6, as far as we are aware FuzzFlesh is the first random program generator that is specifically targeted at decompilers. JD-Tester [43] uses a differential testing approach with the pre-existing program generator JavaFuzzer [66]. It finds 62 bugs in three

Java decompilers: CFR, FernFlower, and JADX. A vast majority of the bugs reported in this study are decompilation failures and crashes, most of which have not been fixed by developers. This highlights the importance of focusing on misdecompilations that are more likely to present a serious problem to users.

DecFuzzer [41] evaluates leading commercial and open-source decompilers using the existing program generator Csmith [68] to generate a corpus of programs. It uses equivalence modulo inputs testing [37] to compare the performance of four binary decompilers (Ghidra [50], RetDec [3], IDA-Pro [27] and Jeb3 [53]). They find 13 bugs, however they report that this required "extensive manual effort" from expert security analysts.

We recently became aware of D-Helix [71], which proposes a general framework for decompiler testing that is intended to assist developers with decompilation tasks, and identifies 25 bugs across binary decompilers Ghidra and angr. D-Helix detects semantic discrepancies between the binary input and the decompiled output by performing symbolic execution on both the original binary and a recompiled decompiled output. It also includes a debugging tool that helps to pinpoint the source of the discrepancy. In future work it would be interesting to compare FuzzFlesh experimentally with D-Helix.

Compiler testing. We have used techniques from the wider compiler fuzzing domain. In recent years there has been a surge of interest in randomised compiler testing techniques, for languages such as C [68, 42, 37], Java / Java bytecode [12, 69, 62], various GPU programming languages [38, 14, 15], Rust [56, 61], Verilog [26], as well as techniques for testing machine learning compilers [39, 40, 44], and techniques that use large language models for randomised compiler testing [67].

Our approach is directly inspired work on testing compilers for SPIR-V, a low level language for GPU programming [34], in which skeleton control flow graphs generated by the Alloy tool [31] are fleshed into executable SPIR-V programs. Our approach is somewhat related to a compiler testing method called *skeletal program enumeration* where the control flow structure of an existing program is used as the basis for generating a large set of programs that populate this structure with different uses of program variables [70]. Other program generation approaches include creating full programs from scratch [68, 42] and mutating existing full programs [37, 15, 49, 38]. A comprehensive review of current state-of-the-art compiler testing approaches is given by Chen et al. [10]. Recently, Large Language Models (LLMs) have been used to generate programs in a range of languages based on user prompts [63]. However, these programs are only designed to detect crash bugs due to the difficulty of ensuring that LLM-generated programs are free from undefined behaviour (UB). We are not aware of any other program generator targeting miscompilations or misdecompilations that is designed to be easily extensible to other languages.

Strategies for constructing test oracles include differential testing [46, 38, 68, 42], where the output of similar compilation systems are compared, and metamorphic testing [11, 37, 49, 38, 15], which specifies how changes in the input source code should affect the output code produced by the compiler.

8 Conclusion and future work

CFG-based program generation is a novel decompiler testing approach that we have used to identify 12 bugs across four decompilers covering two languages. Our implementation, FuzzFlesh, demonstrates the feasibility of sharing a language-independent random CFG and path generator across several different languages with a small amount of incremental programming time.

Areas for further work include alternative CFG and path generation algorithms. For example, mining a corpus of graph structures from real-world programs and mutating them. This would ensure that realistic control flow structures are included in test cases. In addition, more sophisticated path generation algorithms could be created to ensure that each generated CFG is well-explored. For example, repeating path cycles to ensure that loop-like behaviour is included in the test programs.

CFG-based program generation also has the potential to be applied to find bugs in general-purpose compilers. The self-checking nature of the test cases mean that only a single compiler is required, and the ease of adding new languages mean that the approach could be used for newly established compiler toolchains. It is most likely to be useful for testing the control flow optimisation passes of compilers. However, our current implementation is unlikely to produce programs that will detect bugs in mainstream compilers without further work. Decompiler control flow recovery is challenging because it involves imposing structure onto spaghetti code: the more bizarre the control flow, the more challenging decompilation is. Compiling complex control flow has different challenges: it is permissible for a compiler to produce spaghetti code as output, and if the control flow of the source program is too complex then it is possible that the compiler will not attempt to optimise it. Therefore, further work in this area could explore graph generation approaches that may be more likely to find bugs in compilers. For example, graphs could be generated in a way that will be sufficiently complex to thoroughly exercise control flow optimisation compiler passes, but not so complex that compilers will not attempt to perform optimisation.

Abstract

This paper presents IsaBIL, a binary analysis framework in Isabelle/HOL that is based on the widely used Binary Analysis Platform (BAP). Specifically, in IsaBIL, we formalise BAP's intermediate language, called BIL and integrate it with Hoare logic (to enable proofs of *correctness*) as well as incorrectness logic (to enable proofs of *incorrectness*). IsaBIL inherits the full flexibility of BAP, allowing us to verify binaries for a wide range of languages (C, C++, Rust), toolchains (LLVM, Ghidra) and target architectures (x86, RISC-V), and can also be used when the source code for a binary is unavailable.

To make verification tractable, we develop a number of big-step rules that combine BIL's existing small-step rules at different levels of abstraction to support reuse. We develop high-level reasoning rules for RISC-V instructions (our main target architecture) to further optimise verification. Additionally, we develop Isabelle proof tactics that exploit common patterns in C binaries for RISC-V to discharge large numbers of proof goals (often in the 100s) automatically. IsaBIL includes an Isabelle/ML based parser for BIL programs, allowing one to *automatically* generate the associated Isabelle/HOL program locale from a BAP output. Taken together, IsaBIL provides a highly flexible proof environment for program binaries. As examples, we prove correctness of key examples from the Joint Strike Fighter coding standards and the MITRE database.

1 Introduction

Analysing binary code is highly challenging and is essential for decompilation and verification when one does not have access to the source code (e.g., proprietary code). It is also a key tool for finding security vulnerabilities and exploits and is often the only way to (dis)prove properties about programs [46]. Many tools for binary analysis such as angr [52], LIEF [49] and Manticore [36] lift machine code to higher-level, human-readable representations. These tools have been developed for different goals covering different languages (Rust, C++), hardware architectures (e.g., x86, RISC-V), types of binaries (ELF, smart contracts) and security analysis (malware analysis, reverse engineering).

The *Binary Analysis Platform* (BAP) [8] provides a generic approach to binary analysis. BAP natively supports several languages (C, Python and Rust) and hardware architectures (x86, Arm, RISC-V, MIPS) and additionally can be integrated with toolchains such as LLVM and Ghidra to analyse programs on less common architectures such as Atmel AVR [2]. BAP is well-supported and widely used with an active user community. The platform can analyse binaries derived from a particular source language such as C/C++ and Rust, as well as closed-source functions. BAP provides a disassembler that lifts binaries into a unified intermediate language called *BIL (Binary Instruction Language)*, thus enabling architecture-agnostic analysis. While BAP also provides a set of static analysis tools, they do not provide mechanisms for formal verification, e.g., logics for (dis)proving correctness of programs. Recent works have covered subsets of BAP (called AIR) in UCLID5 [10] and use an extended semantics to enable reasoning about an information flow hyper-property known as *trace-property observational determinism* [10].

We present IsaBIL, a verification framework for low-level binaries encoded using the Isabelle/HOL theorem prover. IsaBIL provides a *deep embedding* of BIL programs into Isabelle/HOL, providing a *direct interface* between BAP and Isabelle/HOL without using any additional tools. We leverage the fact that BAP can generate BIL programs as abstract data types, providing a convenient hook for IsaBIL's ML-based parser.[1] Since BAP can lift binaries into BIL both with and without the source code being available, so can IsaBIL. Moreover, IsaBIL allows the generated BIL program to be connected to *any* operational semantics. We build on the semantics described by [8] (see § 3) to enable bit-precise analysis. Our approach generates an Isabelle *locale* [27], which provides an extensible interface that can be instantiated to different scenarios (see Figure 2). We demonstrate this by both proving (using Hoare logic [23]) and disproving (using Incorrectness logic [42]) properties for a number of key examples (see Table 1).

Table 1 IsaBIL examples and their sizes.

Test	Size (LoC)			
	C	**RISC-V**	**BIL**	**Isabelle**
AV Rule 17	13	34	80	94
AV Rule 19	10	16	36	64
AV Rule 20	18	52	118	393
AV Rule 21	16	45	105	210
AV Rule 23	11	35	81	90
AV Rule 24	15	40	107	74
AV Rule 25	24	99	233	578
DF (good)	27	19	44	366
DF (bad)	27	19	43	171
read_data (bad)	74	131	296	474
sec_recv (bad)	38	122	272	752
Total	**273**	**612**	**1415**	**3266**

Scalability. Our approach is *compositional* in that we can analyse and (dis)prove properties about a *code fragment*, say a function f, *in isolation* and then *reuse* these properties (without reproving them) in bigger contexts where f is used. To show this, we use our technique to detect (using incorrectness logic) a *double-free vulnerability* in the cURL library (used primarily for transferring data over the internet). As we demonstrate in § 7, although this

[1] Note that this is a significant advancement over the encoding by Griffin and Dongol [19], which used an external Python tool to translate BAP outputs to Isabelle/HOL.

Listing 1 Double Free (Bad).

```
void bad() {
    int *p = malloc(42);
    if (MyTrue) {
        free(p);
        // ...
    }
    free(p);
}
```

Listing 2 Double Free (Good).

```
void good() {
    int *p = malloc(42);
    if (MyTrue) {
        free(p);
        return;
    }
    free(p);
}
```

vulnerability is "hidden" in an internal function (not exposed in a header file) and is not visible to client applications, it is accessible by a call chain (comprising four separate functions) that can be triggered from an external function, i.e. it is accessible from within a client application and thus this vulnerability can be easily exploited. Indeed, this vulnerability has been previously documented as CVE-2016-8619.

Contributions. Our main contributions are as follows. **(1)** We develop IsaBIL, a flexible, semi-automated tool for verifying binaries (lifted to BIL) within the Isabelle/HOL theorem prover. Our mechanisation is complete with respect to the BIL language and semantics. During the mechanisation, we uncovered and fixed several inconsistencies in the official BAP documentation (see §3). **(2)** We developed IsaBIL as a highly flexible and extensible system (see Figure 2) using Isabelle *locales* [3, 27]. We incorporate logics for (in)correctness, thus obtain methods for both proving and disproving properties. To the best of our knowledge, this is the first application of Incorrectness logic [42] in the analysis of low-level binaries. **(3)** We extend IsaBIL with a number of automation techniques, including reusable high-level big-step theorems, proof tactics that automatically discharge large numbers of proof goals, and architecture-specific proof optimisations. We also include a native parser for BIL_{ADT} programs, written in Isabelle/ML, to *automatically* transpile BAP outputs to an Isabelle/HOL locale suitable for verification. **(4)** We apply our methods to a number of examples (see Table 1), including key tests from the Joint Strike Fighter (JSF) C++ Coding Standards [32]. **(5)** We show the scalability of IsaBIL by detecting a double-free vulnerability in a large example (253 assembly LoC) in the cURL library.

2 Motivation and Workflow

In this section, we motivate our work and provide an overview of our overall approach using two running examples. We give the C program and their equivalent BIL in §2.1. We present our workflow and an overview of the Isabelle/HOL mechanisation in §2.2.

2.1 Two C programs and their BIL representations

We motivate our analysis using two variations of a double-free vulnerability (listed as CWE-415 in the MITRE database[2]). A double-free error occurs when a program calls `free` twice with the same argument. This may cause two later calls to `malloc` to return the same pointer, potentially giving an attacker control over the data written to memory.

The occurrence of the double-free vulnerability is straightforward to see in Listing 1, but of course, in a real program, the vulnerability may be much more difficult to identify. Listing 2 presents an alternative program that contains two occurrences of `free(p)` with no intervening `malloc`. However, Listing 2 does not contain a double-free vulnerability since the true branch returns from the method call before the second `free(p)` is executed.

14 call @free with return 16
15
16 call X1 with noreturn
```

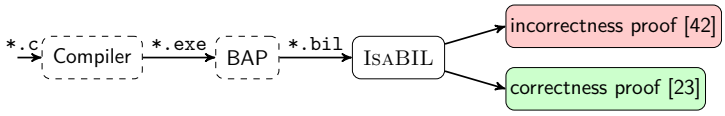

Figure 1 Translation of C source programs to an Isabelle/HOL proof.

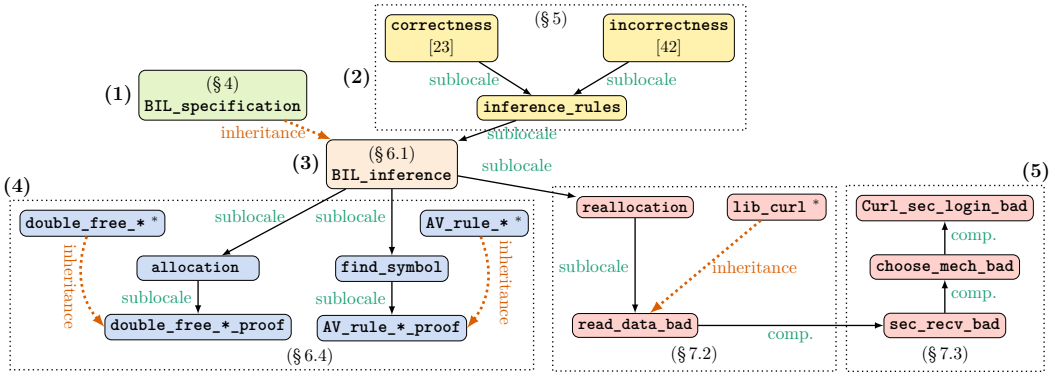

Figure 2 Structure of IsaBIL locales: theories indicated by * are auto-generated from a given `*.bil` file following the translation in Figure 1.

The focus of our work is to analyse such programs *without* relying on any high-level language semantics. Instead, we aim to develop a technique for reasoning about programs (e.g., those in Listings 1 and 2) at a lower level of abstraction by first compiling the programs then, lifting the resulting binaries to an intermediate representation (BIL). Although such analysis contains more detail, the analysis reflects the behaviour of the *actual* executable, thus is more accurate (e.g., does not require any additional compiler correctness assumptions).

2.2 Workflow and Mechanisation

Our overall workflow is given in Figure 1, where the dashed steps represent existing work. The first step to proving properties about our example program is to use BAP to generate a BIL representation of a binary executable (see Figure 1). For our example program in Listings 1 and 2, the BIL equivalent (expressed in BIR format) are given in Listings 3 and 4, respectively. BIR (Binary Intermediate Representation) is a structured refinement of BIL that significantly enhances human readability by presenting sequences of BIL as a

single instruction. Take for example the BIR instruction `call @free with return 18` on line 16 in Listings 3 and 4. This represents two BIL statements, a jump to the address of the symbol "free", and the assignment of the return value 18 to the return pointer. Note that IsaBIL takes as input BAP's *abstract data type* format (see § 4), which we refer to as BIL_{ADT}, as opposed to the human-readable forms shown in Listings 3 and 4. This makes the BIL instructions simpler to parse when generating the corresponding Isabelle/HOL object (discussed in more detail below).

Extensions to Isabelle/HOL's logic [15, 5, 26, 18] often make use of Isabelle/HOL's *locale* system [27, 3], which provides convenient modules for building parametric theories. Locales are aimed at supporting the use of local assumptions and definitions for collections of similar theories, defined in terms of fixed variables and definitions. We refer to the fixed variables as parameters which must satisfy the local assumptions. For a locale $\mathcal{L}$, we give its definition as $\mathcal{L} = (p_1, p_2, \dots)$ where p_1, p_2 are the parameters of the locale. Each parameter may be any type derived from a set or a relation. From these variables, assumptions and definitions we can derive general theorems within the context of a locale. These theorems can be exported to the current proof context by *instantiation*, in which we provide values to one or all of the parameters and verify the fixed assumptions of these parameters. This effectively gives us the general theorems contained within each locale for free for a specific instantiation. Locales can be extended through *inheritance* or *interpretation*, enabling reusability and specialisation by introducing and refining a locale's parameters. Inheritance operates hierarchically, directly propagating the context of a parent locale to a child locale. This transfer includes general theorems, assumptions, definitions and fixed variables. Interpretation is compositional, associating a locale or definition with another locale. During interpretation, the assumptions of the parent locale must be satisfied as part of the mapping process. A locale that interprets another locale is referred to as a sublocale, denoted $\mathcal{L} \subseteq \mathcal{L}'$, where locale $\mathcal{L}'$ is the parent of $\mathcal{L}$. For IsaBIL, they provide a uniform system for representing both the program, and the underlying reasoning framework.

The overall structure of the IsaBIL development is given in Figure 2, and comprises four main parts (which highlight our four main contributions). Overall, we have: **(1)** a locale (see § 4), representing a complete formalisation of the BIL specification from § 3, **(2)** a set of locales (see § 5) that encode Hoare Logic (to verify correctness) and Incorrectness Logic (as developed by O'Hearn), **(3)** a locale (see § 6.1) that combines formalisation of the BIL specification with (in)correctness logics, **(4)** a set of locales (see § 6.4) that apply the resulting verification framework to prove correctness of a number of examples from the literature and **(5)** a set of locales (see § 7.2 and 7.3) that demonstrate scalability of the approach. In particular, § 7.2 demonstrates the use of subroutines to enable one to focus on key functions of interest, even when starting with large BIL files (> 100k LoC). Then § 7.3 describes how verified subroutines can be used as subcomponents to prove (in)correctness of a larger system.

Our framework is highly flexible and extensible. For instance, the **`BIL_inference`** locale combines the **`BIL_specification`** and **`inference_rules`** locales. In case one wishes to change the specification (for a different operational semantics), or use a different set of inference rules (to perform a type of analysis), one can simply change the specification and/or inference rule locales. Similarly, a locale can be extended with additional semantic features: our proofs extend the **`BIL_inference`** locale with an **`allocation`** locale (that models memory allocation) and a **`find_symbol`** locale (that tracks a symbol table) to enable reasoning about different program features.

Our encoding of BIL (§ 4) is the *first* full mechanisation of BIL in Isabelle/HOL. This mechanisation is a standalone contribution and can be used by others outside of our reasoning framework. Our encoding uncovers some inconsistencies in the official specification, which are addressed by the mechanisation (see § 3). Moreover, given that BIL is an intermediate language for many different architectures, future versions could be further optimised to a particular architecture. As an example, we present optimisations for RISC-V (see § 6.2.3), which is the architecture that we focus on.

To maximise flexibility, we provide an encoding of the inference rules parameterised by an operational semantics, i.e., an *instance* of the correctness and incorrectness rules can be generated for *any* operational semantics. This instance automatically inherits all of the rules of Hoare and Incorrectness logic that we prove generically in the `correctness` and `incorrectness` locales (§ 5).

The BIL semantics from § 4 and the inference rules from § 5 are combined to form a new locale, `BIL_inference`, which provides facilities to verify BIL programs. Then, as discussed above, to verify particular types of examples, we extend the locales with models of allocation and symbols to verify particular sets of examples. These proofs represent the *first* proofs of both correctness and incorrectness for BIL programs in Isabelle/HOL. As we shall see in § 3, the BIL semantics is highly detailed, with the reductions related to even single load command potentially splitting into a large number of *small-step* transitions. This has the potential to increase the verification complexity making the proofs of even small programs intractable. To address this, we use BIL's big-step semantics (§ 6.1) and introduce a number of high-level lemmas that allow one to discharge such proofs generically. These lemmas are reusable across all of the examples that we verify.

Our proofs cover key examples from the JSF coding standards [32] and the CWE database[2]. This task is greatly simplified using IsaBIL's parser, written in Isabelle/ML [50], that *automatically generates* a locale corresponding to a BIL program written in BIL_{ADT} format. Note that Isabelle isolates Isabelle/ML programming, and hence our parser cannot interfere with soundness of Isabelle's core logic engine. The generated locale is then combined with `BIL_inference` to provide a context in which (in)correctness proofs can be carried out.

3 BIL Syntax and Semantics

Before proceeding with the presentation of our proofs, it is essential to acquire a basic understanding of BIL. This section serves as a succinct introduction to BIL, emphasizing its type system, memory model and operational semantics. We encourage interested readers to explore the BIL manual [8].

3.1 Syntax

The basic syntax of BIL programs is given in Figure 3.

Statements. A BIL statement may assign an expression e to a variable var, transfer control to a given address e, interrupt the CPU with a given interrupt num, be an instruction with unknown semantics, a while loop, or an if-then-else conditional (with an optional else clause). Note that each BIL statement (including a compound statement) corresponds to a single machine instruction, thus side effects such as setting a status register must be captured in the statement definition (see § 3.4).

Statements, where str denotes a string (of type $string$) and $i \in \mathbb{Z}$

$$\begin{aligned} stmt \ni s ::= {} & var := e \mid \textbf{jmp}\ e \mid \textbf{cpuexn}(i) \mid \textbf{special}(str) \mid \textbf{while}\ (e)\ seq \\ & \mid \textbf{if}\ (e)\ seq \mid \textbf{if}\ (e)\ seq_1\ \textbf{else}\ seq_2 \\ bil \ni seq ::= {} & stmt^* \end{aligned}$$

Expressions, where id denotes a variable name literal (of type $string$)

$$\begin{aligned} exp \ni e ::= {} & v \mid var \mid e_1[e_2, ed] : sz \mid e_1\ \textbf{with}\ [e_2, ed] : sz \leftarrow e_3 \mid e_1\ bop\ e_2 \mid uop\ e \\ & \mid cast : sz[e] \mid \textbf{let}\ var = e_1\ \textbf{in}\ e_2 \mid \textbf{ite}\ e_1\ e_2\ e_3 \mid e_1\ @\ e_2 \mid \textbf{extract}: sz_1 : sz_2[e] \\ bop ::= {} & aop \mid lop \qquad var ::= id : type \qquad endian \ni ed ::= \textbf{el} \mid \textbf{be} \\ cast ::= {} & \textbf{low} \mid \textbf{high} \mid \textbf{signed} \mid \textbf{unsigned} \end{aligned}$$

Types and Values, where $sz, nat \in \mathbb{N}$

$$\begin{aligned} type \ni t ::= {} & \textbf{imm}\langle sz\rangle \mid \textbf{mem}\langle sz_{addr},\ sz_{val}\rangle \qquad\qquad word \ni w ::= nat :: sz \\ value \ni v ::= {} & w \mid v[w \leftarrow v',\ sz_{val}] \mid \textbf{unknown}[str] : t \end{aligned}$$

Figure 3 BIL syntax and types.

Expressions. Memory loads and stores are represented at the expression level as $e_1[e_2, ed] : sz$ for loads, and e_1 **with** $[e_2, ed] : sz \leftarrow e_3$ for stores. In these expressions, the evaluation of e_1 represents the target storage being accessed, while the evaluation of e_2 specifies the address. Since a memory operation can span multiple addresses, both the endianess (ed) and the size (sz) of the operation are provided. For stores, the evaluated value of e_3 is written to memory at the given address. Binary operations now differentiate arithmetic (aop) and logical (lop) operations. Expressions in BIL also include casts, let bindings, if-then-else expressions, concatenations and extractions. The extraction operation, denoted as $\textbf{extract}: sz_1 : sz_2[e]$, first evaluates the expression e to a word w and then extracts a slice from w using BIL's existing extraction mechanism. Specifically, $\textbf{ext}\ w \backsim \textbf{hi} : sz_1 \backsim \textbf{lo} : sz_2$ represents the bits of w from bit sz_1 to bit sz_2. Thus, for example, $\textbf{ext}\ 01001011 \backsim \textbf{hi} : 5 \backsim \textbf{lo} : 2$ is 0010. Expressions are side-effect free and are evaluated wrt a state $\Delta : var \to val$ mapping variables to values.

Types and Values. The highly expressible nature of BIL is due to its type system, which defines two distinct types for its values, the irreducible subset of a BIL expression. These types are $\textbf{imm}\langle sz\rangle$ (describing an *immediate type* of size sz) and $\textbf{mem}\langle sz_{addr},\ sz_{val}\rangle$ (describing a *storage type* with address size sz_{addr} and value size sz_{val}). A value can be bound to one of the three possibilities. **(1)** A machine word (w). **(2)** An abstract storage ($v[w \leftarrow v',\ sz_{val}]$), which allows us to define a memory as a chain of mappings, where $[w \leftarrow v', sz_{val}]$ defines a single mapping from an address (w) to a value (v') of size sz_{val}. Here, v could either be the root of the chain (in which case it is $\textbf{unknown}[str] : t$) or another storage. Technically, v could also be a word, but we disallow this by introducing a typing context (see below). Similarly, v' could be a storage according to the grammar, but this possibility is also eliminated by the typing context. When v or v' is an unknown value, we require that type of v is **mem** and the type of v' is **imm**. **(3)** An "unknown" value ($\textbf{unknown}[str] : t$), which is obtained from the evaluation of a BIL expression holding some string information str of some type t.

The type of a value can be obtained using the function `type`, which is define as follows:

$$\begin{aligned} \texttt{type}(nat :: sz) &= \textbf{imm}\langle sz\rangle \\ \texttt{type}(v[(nat :: sz_{addr}) \leftarrow v',\ sz_{val}]) &= \textbf{mem}\langle sz_{addr},\ sz_{val}\rangle \\ \texttt{type}(\textbf{unknown}[str] : t) &= t \end{aligned}$$

In [21] we show the lifted BIL equivalent of a RISC-V program using the syntax presented in this section.

3.2 Typing Rules and Typing Context

BIL's type system facilitates the need for typing rules to ensure type correctness. At the lowest level, the rules ensure that types are correctly defined with the predicate t **is ok**. The type of variables must be tracked during symbolic execution to ensure that they do not change and only values of the correct type can be assigned. This is achieved via a *typing context*, defined as $\Gamma ::= var^*$, where type correctness of Γ is expressed by overloading the predicate Γ **is ok**. The rules for t **is ok** and Γ **is ok** are given below:

$$\frac{sz > 0}{\textbf{imm}\langle sz\rangle \textbf{ is ok}}\ (\textsc{twf_imm}) \qquad \frac{sz_{addr} > 0 \qquad sz_{val} > 0}{\textbf{mem}\langle sz_{addr},\ sz_{val}\rangle \textbf{ is ok}}\ (\textsc{twf_mem}) \qquad \frac{}{[] \textbf{ is ok}}\ (\textsc{tg_nil})$$

$$\frac{str \notin dom(\Gamma) \qquad t \textbf{ is ok} \qquad \Gamma \textbf{ is ok}}{(str : t) \# \Gamma \textbf{ is ok}}\ (\textsc{tg_cons})$$

These are extended to expressions, then to the level of statements (see [8] for details). As part of our formalisation, we discover a missing typing rule for empty sequences, which would otherwise be needed to ensure the sequencing rules are type correct. We have created a pull request in the BAP repositories for this issue (see `https://github.com/BinaryAnalysisPlatform/bap/pull/1588`), which has now been merged.

3.3 Expression Semantics

Expression evaluation requires the repeated application of small-step semantics rules until the expression is reduced to a value. An expression step in BIL is formally expressed with the $\Delta \vdash e \rightsquigarrow e'$, where multiple steps can be reduced using the reflexive transitive closure $\Delta \vdash e \rightsquigarrow^* e'$. Recall that loads and stores occur at the expression level, and are sensitive to endian orderings. We provide the load rules here, and refer the interested reader to the BIL manual [8] for further details.

A store instruction (semantics not shown) targets a single unit of addressable memory, typically 8-bits in size. When a storage operation exceeds this size, it is converted into a sequence of 8-bit stores, organised in big-endian order. The reduction rules for load operations is given in Figure 4. First, all sub-expressions of a memory object are reduced to values using the rules LOAD_STEP_ADDR and LOAD_STEP_MEM. Then, the resulting object is recursively deconstructed using the LOAD_WORD_EL and LOAD_WORD_BE rules, depending on the endian. This process continues until one of LOAD_BYTE, LOAD_UN_MEM or LOAD_UN_ADDR is used. LOAD_BYTE reduces the expression to the value, v', when the memory object is a storage of an immediate (known) value, w. LOAD_UN_MEM and LOAD_UN_ADDR both reduce the expression to an unknown value when the memory or address being loaded is unknown, respectively.

▶ **Example 1.** Consider the instruction, `X10 := mem[X8-0x18, el]:u64`, from line 12 in Listing 3, which performs a little-endian load of a 64-bit word from address `X8-0x18` in the variable `mem`. We first reduce the address expression, `X8-0x18`, to a value using LOAD_STEP_ADDR, next we apply LOAD_STEP_MEM to read the value stored in `mem`. Next,

$$\frac{(var, v) \in \Delta}{\Delta \vdash var \rightsquigarrow v}\ (\textsc{var_in})$$

$$\frac{\Delta \vdash e_2 \rightsquigarrow e_2'}{\Delta \vdash e_1[e_2, ed] : sz \rightsquigarrow e_1[e_2', ed] : sz}\ (\textsc{load_step_addr})$$

$$\frac{\Delta \vdash e_1 \rightsquigarrow e_1'}{\Delta \vdash e_1[v_2, ed] : sz \rightsquigarrow e_1'[v_2, ed] : sz}\ (\textsc{load_step_mem})$$

$$\frac{}{\Delta \vdash v[w \leftarrow v',\ sz][w, ed] : sz \rightsquigarrow v'}\ (\textsc{load_byte})$$

$$\frac{w_1 \neq w_2}{\Delta \vdash v[w_1 \leftarrow v',\ sz][w_2, ed] : sz \rightsquigarrow v[w_2, ed] : sz}\ (\textsc{load_byte_from_next})$$

$$\frac{}{\Delta \vdash (\mathbf{unknown}[str] : t)[v, ed] : sz \rightsquigarrow \mathbf{unknown}[str] : \mathbf{imm}\langle sz\rangle}\ (\textsc{load_un_mem})$$

$$\frac{}{\Delta \vdash v[w_1 \leftarrow v',\ sz'][\mathbf{unknown}[str] : t, ed] : sz \rightsquigarrow \mathbf{unknown}[str] : \mathbf{imm}\langle sz\rangle}\ (\textsc{load_un_addr})$$

$$\frac{sz > sz_{mem} \qquad \mathtt{succ}(w) = w' \qquad \mathtt{type}(v) = \mathbf{mem}\langle sz_{addr},\ sz_{mem}\rangle}{\Delta \vdash v[w, \mathbf{be}] : sz \rightsquigarrow v[w, \mathbf{be}] : sz_{mem} \mathbin{@} v[w', \mathbf{be}] : (sz - sz_{mem})}\ (\textsc{load_word_be})$$

$$\frac{sz > sz_{mem} \qquad \mathtt{succ}(w) = w' \qquad \mathtt{type}(v) = \mathbf{mem}\langle sz_{addr},\ sz_{mem}\rangle}{\Delta \vdash v[w, \mathbf{el}] : sz \rightsquigarrow v[w', \mathbf{el}] : (sz - sz_{mem}) \mathbin{@} v[w, \mathbf{el}] : sz_{mem}}\ (\textsc{load_word_el})$$

Figure 4 Reduction rules for Load.

we look up the value of `mem` in Δ in VAR_IN, which reduces `mem` to the corresponding storage. Next, we apply LOAD_WORD_EL to break down the 64-bit load into 8 separate loads in little-endian format. Each of the 8 byte-sized loads are individually read from memory using LOAD_BYTE and LOAD_BYTE_FROM_NEXT. Finally, we apply BIL's concatenation rule (not shown) to join each byte into a single 64-bit word.

IsaBIL Extensions. The previous sections present a summary of BIL's semantics from the BIL manual [8] with some minor corrections. In this section, we present extensions to BIL's big-step expression evaluation semantics. The reduction of expressions, e.g., in load and store instructions, results in a significant proof burden. To make verification tractable, IsaBIL defines additional big-step expression evaluation rules which are derived from a combination of BIL's existing small-step and big-step expression semantics. For example, the load expression in Example 1 requires the repeated application of over 150 small-step rules. Splitting the 64-bit read into individual reads in Example 1 (from LOAD_WORD_EL onwards) and the concatenation of the result can be combined into a single big-step rule. We first provide some syntactic sugar for a storage whose size is a multiple of 8.

The definition uses the function $\mathtt{succ}(w)$, which retrieves the successor of the word w such that $\mathtt{succ}(w) ::= w + 1$. Furthermore, we use $\mathtt{storage}_{en}\ (v, w, v', N)$ to refer to a contiguous storage of the value v' of size $N \in \{8i \mid i \in \mathbb{N}\}$ (i.e., N is a multiple of 8) at address w on the storage v:

$$\mathtt{storage}_{\mathbf{el}}\ (v, w, v', N) \doteq \begin{cases} \mathtt{storage}_{\mathbf{el}} \begin{pmatrix} v[w \leftarrow \mathbf{ext}\ v' \backsim \mathbf{hi} : 7 \backsim \mathbf{lo} : 0,\ 8], \\ \mathtt{succ}(w), \mathbf{ext}\ v' \backsim \mathbf{hi} : N - 1 \backsim \mathbf{lo} : 8, N - 8 \end{pmatrix} & \textbf{if } \boldsymbol{N > 8} \\ v[w \leftarrow v',\ 8] & \textbf{otherwise} \end{cases}$$

$$\mathtt{storage}_{\mathbf{be}}\ (v, w, v', N) \doteq \begin{cases} \mathtt{storage}_{\mathbf{be}} \begin{pmatrix} v[w \leftarrow \mathbf{ext}\ v' \backsim \mathbf{hi} : N - 1 \backsim \mathbf{lo} : N - 8,\ 8], \\ \mathtt{succ}(w), \mathbf{ext}\ v' \backsim \mathbf{hi} : N - 9 \backsim \mathbf{lo} : 0, N - 8 \end{pmatrix} & \textbf{if } \boldsymbol{N > 8} \\ v[w \leftarrow v',\ 8] & \textbf{otherwise} \end{cases}$$

For example, suppose B_1 and B_2 are two 8-bit words. We have:

$$\mathtt{storage}_{\mathbf{el}}\ (v, w, B_1B_2, 16) = v[w \leftarrow B_2, 8][\mathtt{succ}(w) \leftarrow B_1, 8]$$
$$\mathtt{storage}_{\mathbf{be}}\ (v, w, B_1B_2, 16) = v[w \leftarrow B_1, 8][\mathtt{succ}(w) \leftarrow B_2, 8]$$

We give a subset of these rules for little endian 64-bit load and store operations below.

$$\frac{}{\Delta \vdash \texttt{storage}_{\mathbf{el}}\,(v, w_2, w_1, 64)\,[w_2, 64] : \mathbf{el} \rightsquigarrow^* w_1}\ (\textsc{refl_load_el_word64})$$

$$\frac{}{\Delta \vdash v\ \mathbf{with}\ [w_2, \mathbf{el}] : 64 \leftarrow w_1 \rightsquigarrow^* \texttt{storage}_{\mathbf{el}}\,(v, w_2, w_1, 64)}\ (\textsc{refl_store_el_word64})$$

▶ **Example 2.** Consider the load from Example 1. The first few steps proceed as before. However, instead of applying LOAD_WORD_EL, we can directly apply REFL_LOAD_EL_WORD64 to obtain the corresponding value $\Delta \vdash (\texttt{storage}_{\mathbf{el}}\,(v, w, v', 64))[w, el] : u64 \rightsquigarrow^* v'$.

All big-step rules from this section, such as REFL_LOAD_EL_WORD64 have been verified in Isabelle wrt to the small step semantics.

3.4 Statement semantics

In this section, we describe the operational semantics for evaluating statements. We also provide a correction to the sequencing rule from the manual [4]. Although each statement induces local control flow, in BIL, they are assumed to execute to completion in a single step.

The semantics of a statement is defined by $(\Delta,\ pc) \vdash seq \rightsquigarrow (\Delta',\ pc')$, which executes the *bil* statement *seq* from the variable store Δ to generate a new variable store Δ' and program counter pc'. The MOVE statement (see below) modifies Δ by generating a new variable binding, and JMP (not shown) affects program counter.

Example rules for MOVE (aka assignment) and IF_TRUE (for branching on a true guard are given below). In the move rule, the given expression e is evaluated to a value using the big-step semantics, and the value for the given variable var is updated in the variable state. In the IF_TRUE rule, the guard is evaluated (to *true*) then the statement seq_1 is executed. The sequencing rules describe execution of a list of statements to completion. The sequencing rules in manual [4] do not provide a means to reduce multiple statements in a single transition[3].

$$\frac{\Delta \vdash e \rightsquigarrow^* v}{(\Delta,\ pc) \vdash var := e \rightsquigarrow (\Delta(var \mapsto v),\ pc)}\ (\textsc{move})$$

$$\frac{\Delta \vdash e \rightsquigarrow^* true \qquad (\Delta, pc) \vdash seq_1 \rightsquigarrow (\Delta', pc')}{(\Delta,\ pc) \vdash \mathbf{if}\ (e)\ seq_1\ \mathbf{else}\ seq_2 \rightsquigarrow (\Delta',\ pc')}\ (\textsc{if_true})$$

$$\frac{(\Delta_1,\ pc_1) \vdash s_1 \rightsquigarrow (\Delta_2,\ pc_2) \qquad (\Delta, pc_2) \vdash s_2 \ldots s_n \rightsquigarrow (\Delta_3, pc_3)}{(\Delta_1, pc_1) \vdash s_1 s_2 \ldots s_n \rightsquigarrow (\Delta_3, pc_3)}\ (\textsc{seq_rec})$$

$$\frac{}{(\Delta, pc) \vdash \varepsilon \rightsquigarrow (\Delta, pc)}\ (\textsc{seq_nil})$$

▶ **Example 3.** Consider the load expression from Example 1, which appears on the right-hand side of the assignment statement given below:

$$(\Delta, (12 :: 64) + (1 :: 64)) \vdash \{\texttt{X10 := mem[X8-0x18, el]:u64}\} \rightsquigarrow (\Delta(X10 \mapsto v'), (13 :: 64))$$

To apply the statement semantics, we start by deconstructing it using SEQ_REC, which results in two sub-steps. For the first, we apply MOVE and the steps in Example 1 to reduce the expression `mem[X8-0x18,el]:u64` to a value, v'. Since the original sequence only contained a single statement, our recursive sequence (i.e., the second premise of SEQ_REC) is empty, which can be trivially reduced using SEQ_NIL.

[3] We have created a Git pull request in the BAP repositories for this issue (`https://github.com/BinaryAnalysisPlatform/bil/pull/12`.

3.5 BIL Step Relation

A machine instruction in BIL is represented by a named tuple, $insn = (\!|\ \mathbf{addr},\ \mathbf{size},\ \mathbf{code}\ |\!)$ (implemented later as an Isabelle `record`). Here **addr**, refers to the instruction's address in memory; **size**, the size of the instruction; and **code**, the semantics of the program represented by BIL statements. Instructions operate over the BIL machine state, (Δ, pc, mem), where Δ is the variable store, pc is the program counter and mem is a variable that denotes the memory. To decode the current instruction from a machine state, we assume an uninterpreted $\mapsto$ function, referred to as the *decode predicate*, which maps a machine state, (Δ, pc, mem), to the corresponding instruction, $(\!|\ \mathbf{addr},\ \mathbf{size},\ \mathbf{code}\ |\!)$. The BIL step relation $(\Delta, pc, mem) \rightsquigarrow (\Delta', pc', mem')$ defines the execution of a single BIL statement:

$$\frac{(\Delta, pc, mem) \mapsto (\!|\ \mathbf{addr} = pc, \mathbf{size} = z, \mathbf{code} = bil\ |\!) \qquad (\Delta, pc + z) \vdash bil \rightsquigarrow (\Delta', pc')}{(\Delta, pc, mem) \rightsquigarrow (\Delta', pc', mem)}\ (\textsc{step_prog})$$

▶ **Example 4.** Consider the move statement from Example 3, which resides at the program address 12 and being of one-byte size. This is expressed as the BIL instruction below:

$$(\!|\ \mathbf{addr} = 12 :: 64, \mathbf{size} = 1 :: 64, \mathbf{code} = \{\texttt{X10 := mem[X8-0x18, el]:u64}\}\ |\!)$$

The instruction is obtained by decoding $(\mapsto)$ a machine state of the form $(\Delta, 12 :: 64, mem)$ where $X8, mem \in \texttt{dom}(\Delta)$. By using decode we can structure a step proof for the machine state as follows:

$$(\Delta, 12 :: 64, mem) \rightsquigarrow (\Delta(X10 \mapsto v'), 13 :: 64, mem)$$

By applying the STEP_PROG rule for programs, we are left with a reduction $(\Delta, (12 :: 64) + (1 :: 64)) \vdash \{\texttt{X10 := mem[X8-0x18, el]:u64}\} \rightsquigarrow (\Delta(X10 \mapsto v'), (13 :: 64))$, which we derived in Example 3.

4 Mechanisation

In this section, we describe the IsaBIL mechanisation, which utilises extensible *locales* to maximize reusability. In § 4.1, we describe the generic `BIL_specification` locale that formalises BIL's syntax and semantics, and in § 4.2 we describe the IsaBIL translation tool that automatically generates locales from BIL programs.

4.1 The `BIL_specification` Locale

IsaBIL's `BIL_specification` locale (see Figure 2) provides a complete mechanisation of BIL's syntax and semantics[4]. We encode BIL's operational rules (§ 3.5) as Isabelle's built-in *inductive predicates*, which allow one to formalise the structure of the syntax from Figure 3.

The `BIL_specification` $= (\mapsto)$ locale provides a single parameter: the *decode* predicate $(\mapsto)$, which will be uniquely instantiated for each binary that we wish to verify.

We provide rules for both *introduction* (which are used to introduce compound statements such as **if-then-else** to the proof goal) as well as *elimination* (which are used to eliminate compound statements from the proof assumptions) directly within the `BIL_specification` locale. For example, introduction and elimination rules for the STEP_PROG rule in § 3.5 which formalises a single step of the program are given below:

[4] As outlined in § 3 and provided in full in [21].

```
lemma step_progI[intro]:
assumes ‹(Δ, pc, mem) ↦
            ⦇addr = pc, size = sz, code =
     seq⦈›
    and ‹(Δ, pc + sz) ⊢ seq ⇝ (Δ', pc')›
  shows ‹(Δ, pc, mem) ⇝ (Δ', pc', mem)›
proof ...
```

```
lemma step_progE[elim]:
assumes ‹(Δ, pc, mem) ⇝ (Δ', pc', mem)›
    and ‹(Δ, pc, mem) ↦
           ⦇addr = pc, size = sz, code =
     seq⦈›
obtains ‹(Δ, pc + sz) ⊢ seq ⇝ (Δ', pc')›
proof ...
```

We prove introduction and elimination lemmas in this way for all of the rules in the official BIL specification [6] with respect to our changes (§ 3). In total, the `BIL_specification` locale consists of over 500 lemmas and rules.

4.2 The Program Locale

Recall that our workflow (Figure 1) proceeds by *Step 1*: compiling the given program; *Step 2*: feeding the resulting assembly into BAP to generate the corresponding BIL_{ADT}; and *Step 3*: using IsaBIL to automatically generate an Isabelle/HOL locale for the given BIL_{ADT} input. Note that if a binary is distributed without source code, then Step 1 could be skipped and the given assembly could be fed directly into BAP to generate the BIL_{ADT}.

The locale for a program prog is generated using IsaBIL's translation tool, which is written in Isabelle/ML and is invoked using the custom Isabelle/HOL commands `BIL` or `BIL_file` for inline or external BIL in BIL_{ADT} format, respectively. Both commands take as an input, a name for the locale and either a BIL string (for `BIL`) or a filename (for `BIL_file`). Within this locale, we automatically generate a decode predicate, $\mapsto_{\text{prog}}$, that maps each machine state (Δ, pc, mem) to an instruction.

Note that, internally, Isabelle maintains the BIL_{ADT} format, however, we choose to represent it using `class` locales [50, 3, 41] to maintain human-readable syntax. For instance, without these syntax classes, expressing a direct jump to the fixed program address 3076 would require writing `RAX := Val(Imm(Word(3076,64)))`. By instantiating the word syntax (*nat* :: *sz*, see Figure 3), we can simplify the expression to the syntax `RAX := (3076 :: 64)`.

In addition to $\mapsto_{\text{prog}}$, a program's locale defines *Step 1*: an *address set*, `addr_set` : $\mathbb{P}(word)$ (defining the set of addresses that have corresponding instructions) and *Step 2*: a *symbol table*, `sym_table` : $string \rightarrow word$ (mapping the binary's symbols, e.g. main, memcpy, free, as string literals to raw addresses).

Both `addr_set` and `sym_table` capture additional information about a binary that can be used later in a proof. For example, the `addr_set` is useful for determining whether the program counter points to a valid address and is particularly important for validating the correctness of indirect jumps. Many binary proofs verify that execution from some entry point, such as the `main` function, is either correct or incorrect with respect to some property. Symbols typically represent entry points to functions and although the address of an entrypoint may differ between binaries, the symbol will remain constant. Hence, referring to positions within the binary using symbol names, stored in the `sym_table` rather than program addresses, is often more convenient. Further details regarding the extraction of the `addr_set` and `sym_table` from a binary can be found in § 6.3.

▶ **Example 5.** Consider the `Binary_A` program below, written in BIL_{ADT}, which corresponds to the BIL instruction `X8 := X2 + 32`. We assume the program has been compiled for RISC-V; for readability, BIL_{ADT} provides the original assembly at Example 5. The program locale corresponding to Example 5 starts on Example 5, which fixes the corresponding decode predicate.

```
BIL ‹
105dc: <test>
105dc: addi s0, sp, 32
(Move(Var("X8",Imm(64)),PLUS(Var("X2",Imm(64)),Int(32,64))))
› defining Binary_A

locale Binary_A
    fixes decode :: ‹(var ⇒ val option) × word × var ⇒ insn ⇒ bool›
    assumes decode_105dc: ‹(Δ, 0x105dc :: 64, mem) ↦prog
                ⦇ addr = 0x105dc :: 64, size = 4, bil = [X8 := X2 + (32 ::
     64)] ⦈›
begin
definition addr_set :: ‹word set› where ‹addr_set = {(0x105dc :: 64)}›
definition sym_table :: ‹str ⇀ word› where ‹sym_table = ["test" ↦ (0x105dc
    :: 64)]›
end
```

Externally linked binaries. Binaries often include links to external code, typically in the form of function calls. Accurately modeling these external calls is crucial for understanding the behavior of the original binary. IsaBIL provides two methods for handling externally linked code, depending on the availability of that external code. If the external binary is available, an Isabelle/HOL locale can be generated for the external binary, which is then combined with the existing binary locale through inheritance. If the external binary is not available, we can make assumptions about its behavior and define an approximate implementation using locale assumptions. We give an example for both cases in [21].

5 (In)correctness

In this section, we present the IsaBIL encoding of Hoare and Incorrectness logic (see Figure 2). Our locale-based encoding combines both into a single proof system **`inference_rules`** locale, where we verify the AGREEMENT and DENIAL lemmas (see [42]).

Hoare and O'Hearn triples define (in)correctness of a command c over a pre-state σ satisfying the predicate P, resulting in a post-state τ satisfying the predicate Q. In the locale, we assume the existence of a big-step transition relation $(c, \sigma) \Rightarrow \tau$ defining the execution of c from state σ to termination, resulting in state τ. Thus, we have the well-known under- and over-approximating rules:

$$\text{(HOARE)}\ \frac{\forall \sigma, \tau.\ ((c,\sigma) \Rightarrow \tau) \implies (P(\sigma) \implies Q(\tau))}{\{P\}c\{Q\}} \qquad \text{(OHEARN)}\ \frac{\forall \tau.\ Q(\tau) \implies \exists \sigma.\ P(\sigma) \wedge ((c,\sigma) \Rightarrow \tau)}{[P]\,c\,[Q]}$$

Note that our definition of correctness follows partial correctness, meaning termination is not guaranteed. We encode Hoare and Incorrectness triples as locales **`correctness`** $= (\Rightarrow)$ and **`incorrectness`** $= (\Rightarrow)$, respectively, both of which are parameterised by $\Rightarrow$. Within the **`correctness`** locale, we verify standard Hoare logic rules, e.g.,

$$\text{(POST__CONJ__CORR)}\ \frac{\{P\}c\{Q_1\} \quad \{P\}c\{Q_2\}}{\{P\}c\{Q_1 \wedge Q_2\}} \qquad \text{(PRE__DISJ__CORR)}\ \frac{\{P_1\}c\{Q\} \quad \{P_2\}c\{Q\}}{\{P_1 \vee P_2\}c\{Q\}} \qquad \text{(STRENGTHEN__WEAKEN__CORR)}\ \frac{P' \implies P \quad \{P\}c\{Q\} \quad Q \implies Q'}{\{P'\}c\{Q'\}}$$

Similarly, within the **`incorrectness`** locale, we verify rules for Incorrectness logic, e.g.,

$$\text{(POST__DISJ__INCORR)}\ \frac{[P]\,c\,[Q_1] \quad [P]\,c\,[Q_2]}{[P]\,c\,[Q_1 \vee Q_2]} \qquad \text{(PRE__DISJ__INCORR)}\ \frac{[P_1]\,c\,[Q] \quad [P_2]\,c\,[Q]}{[P_1 \vee P_2]\,c\,[Q]} \qquad \text{(STRENGTHEN__WEAKEN__INCORR)}\ \frac{P \implies P' \quad [P]\,c\,[Q] \quad Q' \implies Q}{[P']\,c\,[Q']}$$

We then combine these to form a locale **inference_rules** $= (\Rightarrow)$, again parameterised by $\Rightarrow$. Within this combined locale, we are able to prove the AGREEMENT and DENIAL rules [42]:

$$\text{(AGREEMENT)}\quad \frac{[U]\,c\,[U'] \qquad U \implies O \qquad \{O\}c\{O'\}}{U' \implies O'} \qquad \text{(DENIAL)}\quad \frac{[U]\,c\,[U'] \qquad U \implies O \qquad \neg(U' \implies O')}{\neg(\{O\}c\{O'\})}$$

For proofs of incorrectness, it is typically not enough to simply state that if $[P]\,c\,[Q]$ holds for an error state Q then the program c is incorrect. A program cannot be incorrect if there is no valid state that satisfies Q and as such, we must ensure that Q is *non-trivial*, i.e., $\exists\sigma.\ Q(\sigma)$. Proving that Q is non-trivial can be difficult, as Q is often an over-approximation of the actual set of post-states (defined by some predicate Q') reachable from P. Therefore, proofs of incorrectness usually take the form $\exists Q'.\ [P]\,c\,[Q'] \wedge (\forall\sigma.\ Q'(\sigma) \implies Q(\sigma)) \wedge (\exists\sigma.\ Q'(\sigma))$. Note that this does not necessarily imply that $[P]\,c\,[Q] \wedge (\exists\sigma.\ Q(\sigma))$ since the implication is in the wrong direction to apply the STRENGTHEN_WEAKEN_INCORR rule.

6 Automation and Examples

In this section, we bring together the **BIL_specification** and the **inference_rules** locales to create a new locale, **BIL_inference** (see § 6.1), providing a proof environment for BIL programs. This in turn enables us to develop a large number of highly reusable proof automation procedures for verifying both correctness and incorrectness of BIL programs (see § 6.2). The final major component of IsaBIL automation is the BIL_{ADT} parser that automatically generates Isabelle/HOL locales for BIL programs (§ 6.3), providing a smooth and seamless pipeline from BAP to Isabelle/HOL proofs. We offer an overview of IsaBIL, discussing correctness and incorrectness proofs for a handful of examples.

6.1 The BIL_inference locale

BIL_inference interfaces with the **BIL_specification** and **inference_rules** locales (see Figure 2) and is later extended with instances of state models (e.g., **allocation** and **find_symbol**) to enable verification of generated BIL programs. Therefore, it is one of IsaBIL's most complex components.

Our first task is to define a big-step relation, $\xRightarrow[BIL]{}$, required by **inference_rules**, using the BIL step relation, $(\Delta, pc, mem) \rightsquigarrow (\Delta', pc', mem')$, defined in § 3.5. One option for defining $\xRightarrow[BIL]{}$ is to simply take the transitive closure of $\rightsquigarrow$. However, this would mean that the pre/postconditions that we define in our example would be predicates over the full variable store Δ, which is heavy-handed.

An alternative (which is the approach we take) is to define another transition relation $\xrightarrow[BIL]{}$ that abstracts $\rightsquigarrow$, and define $\xRightarrow[BIL]{}$ as the transitive closure of $\xrightarrow[BIL]{}$. As we shall see, this vastly increases the flexibility of our approach, which becomes **(1)** extensible, since $\xrightarrow[BIL]{}$ can be used to cover additional program features such as memory allocation (see § 6.4.1), and **(2)** more efficient since the components of Δ that are not needed for the proof can be ignored.Thus, assuming $\mathcal{C} = (\Delta, pc, mem)$, we have:

$$\text{(PROGRAM_BIG_STEP)}\quad \frac{\mathcal{C} = (_, pc, _) \qquad pc \in \texttt{addr_set} \qquad \mathcal{C} \rightsquigarrow \mathcal{C}' \qquad (\mathcal{C}, \sigma) \xrightarrow[BIL]{} \sigma' \qquad (\mathcal{C}', \sigma') \xRightarrow[BIL]{} \tau}{(\mathcal{C}, \sigma) \xRightarrow[BIL]{} \tau}(\mapsto)$$

$$\text{(PROGRAM_BIG_STEP_LAST)}\quad \frac{\mathcal{C} = (_, pc, _) \qquad \mathcal{C}' = (_, pc', _) \qquad pc \in \texttt{addr_set} \qquad pc' \notin \texttt{addr_set} \qquad \mathcal{C} \rightsquigarrow \mathcal{C}' \qquad (\mathcal{C}, \sigma) \xrightarrow[BIL]{} \tau}{(\mathcal{C}, \sigma) \xRightarrow[BIL]{} \tau}(\mapsto)$$

Here, we assume `addr_set` is the set of addresses that contain program instructions (see § 4.2), which will be later instantiated by a program's locale. A program may take a step as long as the current program counter corresponds to a program instruction. Note that the precise state model (i.e., type of σ, σ' and τ) that one uses in PROGRAM_BIG_STEP and PROGRAM_BIG_STEP_LAST will depend on the verification task at hand. If required, one could also take $\sigma = \Delta$ allowing the proofs to inspect the full variable state (at a low level of abstraction).

Overall, we obtain a locale **`BIL_inference`** $= (\mapsto, \xrightarrow[BIL]{}, \texttt{addr_set})$. This locale extends the **`BIL_specification`** (from § 4) from which we inherit the decode predicate, $\mapsto$. Then, we use $\xrightarrow[BIL]{}$ and `addr_set` to define $\Longrightarrow_{BIL}$ as above. This allows us to interpret the **`inference_rules`** as sublocale, instantiating the parameter $\Rightarrow$ to $\Longrightarrow_{BIL}$.

Within **`BIL_inference`**, we can prove several rules of Hoare and Incorrectness logic in terms of the BIL semantics. These proofs are trivial at this level, but are nevertheless critical for proof automation since they can be used by all of our examples [21].

Stuckness and Undefined Behaviour. A BIL program is considered stuck if it reaches a state where no transition rules apply. Programs that become stuck are deemed correct, as they do not terminate.

The most common cause of stuckness in BIL is an attempt to decode an instruction at an address that does not exist within the program (see § 3.5). This typically occurs when a jump targets a non-existent address, resulting in a post-state with no valid instruction to execute. However, the big step semantics treat this as valid program termination rather than an explicit error. If the prover wishes to ensure that the program terminates with an expected PC they may assert its value in an (in)correctness triple's post-state Q.

Stuckness may also arise due to type errors, such as assigning a variable a value of an incompatible type. These types of stuckness are prevented by ensuring BIL statements are type correct, which can be achieved using IsaBIL's automated type checker (see [21]). In our proofs, we verify type correctness when necessary to prevent stuckness. More details, along with an example, can be found in the BIL manual [6].

Many traditional sources of stuckness in program semantics, such as dereferencing invalid memory or reading from uninitialized registers, result in undefined behaviour (UB) for BIL. In BIL, UB is represented using the **unknown**[str] : t value. For example, if an uninitialized register is used:

```
1     mv a6, a5      # UB if a5 was never initialized
```

Since the value of `a5` (a 64 bit register) is unspecified, **unknown**[*str*] : **imm**⟨64⟩ will be set to `a6`. Evaluating BIL semantics that contain unknown values (such as `a6` + 5) will propagate further unknowns unless avoided by control flow structures such as if-then-else. However, this does not necessarily lead to stuckness, except in cases where the target of a dynamic jump is unknown (i.e. **jmp unknown**[*str*] : **imm**⟨64⟩). In such cases, the program cannot take a step as it does not know which program address to jump to. In (in)correctness logic, unknowns that do not lead to stuckness may still prevent the discharge of the post-state (Q). Unknown values in BIL can be resolved by explicitly specifying constraints on the program and pre-state as required.

6.2 Proof Automation

Instruction set architectures (ISAs), despite their large scale, are inherently finite, and compilers employ common patterns for optimization. Additionally, developers leverage reusable components such as *functions* and *gadgets* to perform common tasks. Consequently,

binaries often exhibit a significant degree of repetition. Once identified, this repetition can be verified without the need for human input. IsaBIL exploits this repetition to alleviate the burden associated with proof construction and verification. In this section, we outline the proof automation techniques employed by IsaBIL.

6.2.1 Eisbach

IsaBIL heavily leverages Eisbach [33], an Isabelle tactic framework for proof automation, to discharge proof goals automatically. We create Eisbach methods for symbolic execution (`sexc`) and type checking (`typec`) which utilise IsaBIL's *introduction* and *elimination* rules to solve both big- and small-step BIL statements, expressions and variables as well as proving type correctness. These methods employ a best-effort approach. If a case that cannot be solved automatically occurs, the methods will backtrack to a safe state and the partially completed proof context will be handed back to the human prover, whereby corrections or manual inputs can be made before resuming the automation (see [21] for details).

6.2.2 Human Readability

In assembly languages, registers are typically assigned specific names and types. However, in BIL, registers are represented as generic *variables* of type *var*. These variables are parameterised with names and types. For example, the RISC-V registers `R0-31` are represented by the variables ("R0-31" : **imm**⟨64⟩). While this representation offers flexibility, it can be verbose. It is common knowledge for RISC-V developers that R0-31 are registers capable of storing 64-bit words. To enhance program readability, we define the set of registers for `riscv64` [55] as the 64bit registers R0-31 : **imm**⟨64⟩. Additionally, we introduce syntax abbreviations for the 64-bit x86 architecture.

6.2.3 Architecture-Specific Proof Optimisations (for RISC-V)

Whilst IsaBIL provides sufficient granularity to handle many architectures out of the box, the speed and efficiency of proofs can be improved by tailoring optimizations to specific hardware architectures. This section describes the proof optimizations undertaken for RISC-V.

Instructions. Modern architectures comprise of large instruction sets. Proofs of programs can be optimised by verifying high-level lemmas corresponding to program steps of the most commonly used instructions directly in the `BIL_inference` locale. For example, IsaBIL provides step rules for the 32-bit (4-byte) RISC-V instructions `auipc`, `jalr` and `ld`.

$$\texttt{auipc}\ rd,\ imm = (\!|\ \mathbf{addr} = pc, \mathbf{size} = 4 :: 64, \mathbf{code} = \{rd := pc + imm\}\ |\!)$$

The `auipc` (Add Upper Immediate to Program Counter) instruction facilitates the computation of an absolute address. It achieves this by adding the immediate value *imm* to *pc*, storing the result in the destination register *rd*. `auipc` is commonly used to create jump targets, such as those for external functions.

$$\texttt{jalr}\ rd,\ rs1,\ \mathit{offset} = (\!|\ \mathbf{addr} = pc, \mathbf{size} = 4 :: 64, \mathbf{code} = \{rd := pc + 4;\ \mathbf{jmp}\ rs1 + \mathit{offset}\}\ |\!)$$

The `jalr` (Jump And Link Register) instruction performs an unconditional jump. It sets *pc* to the address stored in the source register $rs1$ with an optional immediate value *offset*. The address of the subsequent instruction is then stored in the destination register *rd*. This instruction is used for function calls, where it is important to preserve the return address.

$$\texttt{ld}\ rd,\ \mathit{offset}(rs1) = (\!|\ \mathbf{addr} = pc, \mathbf{size} = 4 :: 64, \mathbf{code} = \{rd := mem[rs1 + \mathit{offset}, \mathbf{el}] : 64\}\ |\!)$$

```
00000000000104a0 <malloc@plt>:
   104a0: 00002e17            auipc  t3,0x2
   104a4: b78e3e03            ld     t3,-1160(t3) # 12018 <malloc@GLIBC_2
    .27>
   104a8: 000e0367            jalr   t1,t3

   104b0: 00002e17            auipc  t3,0x2
   104b4: b70e3e03            ld     t3,-1168(t3) # 12020 <free@GLIBC_2
    .27>
   104b8: 000e0367            jalr   t1,t3
   104bc: 00000013            nop
```

Figure 5 PLT stubs for free and malloc.

The `ld` (Load Double) instruction is used to load a 64-bit word, referred to as a double word, from memory. First, `ld` computes an address by adding the contents of the source register $rs1$ to the immediate *offset*. The value at this address in memory is then stored in the destination register rd. `ld` is the primary means of retrieving data of this size from memory.

Representing the instructions `auipc`, `jalr` and `ld` as the high-level program step lemmas (given below) allows the prover to otherwise skip the lengthy reduction for a program step. The rules for these instructions are provided below:

$$\frac{(\Delta, pc, mem) \mapsto \texttt{auipc}\ rd,\ imm}{(\Delta, pc, mem) \rightsquigarrow (\Delta(rd \mapsto pc + imm), pc + 4), mem)}\ (\text{AUIPC_LEMMA})$$

$$\frac{(\Delta, pc, mem) \mapsto \texttt{jalr}\ rd,\ rs1,\ offset \quad (rs1, addr) \in \Delta}{(\Delta, pc, mem) \rightsquigarrow (\Delta(rd \mapsto pc + 4), addr + offset, mem)}\ (\text{JALR_LEMMA})$$

$$\frac{(\Delta, pc, mem) \mapsto \texttt{ld}\ rd,\ offset(rs1) \quad (mem, v) \in \Delta \quad (rs1, addr) \in \Delta \quad \Delta \vdash v[addr + offset, \mathbf{el}] : 64 \rightsquigarrow^* w}{(\Delta, pc, mem) \rightsquigarrow (\Delta(rd \mapsto w), pc + 4), mem)}\ (\text{LD_LEMMA})$$

Further semantics for `addi`, `sd` and `ret` RISC-V instructions are provided in [21].

Execution. We also prove high-level big-step semantics rules for common gadgets in binary executables. For example, the *procedure linkage table* (PLT) acts as an intermediary between the current program and shared libraries, including C's standard library. The PLT facilitates indirect calls to external functions, whose locations are unknown until runtime when they are resolved by the dynamic loader. In the dump of the RISC-V binary for Listing 1 given in § 6.2.3, we can observe the presence of stubs within the PLT, representing entries for each external call. Specifically, in § 6.2.3, the stubs correspond to the functions `free` and `malloc` that are called by the program.

By leveraging the consistent pattern observed in PLT entries, we can construct universal big-step rules for PLT stubs, as demonstrated below.

$$\frac{\begin{array}{c}(\Delta_1, pc, mem) \mapsto \texttt{auipc}\ t3,\ 0x2 \qquad (\Delta_2, pc + 4, mem) \mapsto \texttt{ld}\ t3,\ offset(t3) \\ (\Delta_3, pc + 8, mem) \mapsto \texttt{jalr}\ t1,\ t3,\ 0 \qquad \{pc, pc + 4, pc + 8\} \subseteq \texttt{addr_set} \\ \Delta_2 = \Delta_1(t3 \mapsto pc + 0x2) \qquad \Delta_3 = \Delta_2(t3 \mapsto w) \qquad \Delta_4 = \Delta_3(t1 \mapsto pc + 12) \\ ((\Delta_1, pc, mem), \sigma_1) \xrightarrow[BIL]{} \sigma_2 \qquad ((\Delta_2, pc + 4, mem), \sigma_2) \xrightarrow[BIL]{} \sigma_3 \qquad ((\Delta_3, pc + 8, mem), \sigma_3) \xrightarrow[BIL]{} \sigma_4 \\ ((\Delta_4, w, mem), \sigma_4) \xRightarrow[BIL]{} \tau \qquad (mem, v) \in \Delta_1 \qquad \Delta \vdash v[pc + \texttt{0x2} + offset, \mathbf{el}] : 64 \rightsquigarrow^* w\end{array}}{((\Delta_1, pc, mem), \sigma_1) \xRightarrow[BIL]{} \tau}\ (\text{PLT_STUB_LEMMA})$$

Now, if we encounter a PLT stub in a proof at a lower level, we can discharge the proof obligation efficiently using PLT_STUB_LEMMA. This lemma significantly reduces the proof effort required. Without PLT_STUB_LEMMA, one must apply over 150 rules to achieve the same result. Furthermore, by applying this approach to stack allocations and deallocations, we eliminate the need for approximately 50 rules in the case of allocation and 250 rules in the case of deallocation. Further details on this are provided in [21].

6.3 BIL to IsaBIL transpiler

A key component of our IsaBIL framework is a verified BIL parser that transpiles BIL_{ADT} programs into an Isabelle/HOL locale to enable verification.

Parsing occurs in two distinct phases. The first phase involves the translation of BIL_{ADT} into BIL_{ML}, a format suitable for manipulation within Isabelle/ML. This intermediate step enables analysis tasks in Isabelle/ML, such as calculating the size of instructions. The second phase involves translating BIL_{ML} into an Isabelle/HOL representation, which is the starting point for verification. Parsing can be invoked directly on a BIL_{ADT} string with `BIL` or alternately on a file containing BIL_{ADT} with `BIL_file`. An overview of the parsing process is given in Figure 6.

During the first phase, the parser iterates over the instructions in a BIL_{ADT} input. It captures and stores all program addresses in `addr_set`. Moreover, the parser associates symbols with a program address in `sym_table`. Since the syntax of BIL_{ADT} resembles a tree structure, it is intuitive to convert it into an Abstract Syntax Tree (AST) using a lexer. This AST is processed by a Recursive Descent Parser (RDP), which traverses each node in the tree depth-first, matching the node's value to a corresponding parsing function. For example, if the parser encounters a `Var` node, it will attempt to parse the first child as a `string` and the second child as a BIL type. This process transforms the input into BIL_{ML}, a structured data type closely resembling BIL_{ADT} which can be manipulated within Isabelle/ML.

The second phase defines a locale within the current proof context with a fixed decode predicate. For each BIL_{ML} instruction, an assumption is added to the locale, stating how a program with any variable state and memory, but with the instructions program address, decodes to an Isabelle/HOL representation of said instruction. To obtain the Isabelle/HOL representation, an RDP translator recursively converts each BIL_{ML} instruction to Isabelle/HOL terms defined in the **`BIL_specification`** locale (see § 4).

The first phase of the parser harnesses Isabelle/HOL's *code generation*, where specifications for both the lexer and parser were defined within Isabelle/HOL and subsequently translated into ML. BIL_{ML} for example, is a direct ML representation of the BIL specification from the IsaBIL framework. Using *code reflection*, we import the generated ML code back into Isabelle/HOL as a plugin. Consequently, the lexer and parser are formally verified under the Isabelle/HOL framework. In contrast, the second phase employs non-code-generated ML. This decision stems from its necessity to interface with Isabelle/HOL's core ML library, which cannot be achieved via code-generated ML. To bridge this gap, we introduce a minimal layer of unverified ML code that lifts the BIL representation obtained from the verified parser into Isabelle/HOL's proof system. Below, as an example, we present a snippet of the translation code responsible for converting BIL_{ML}'s binary operations to IsaBIL's binary operations:

```
mk_exp (AstParser.BinOp (e1,bop,e2)) = @{term "BinOp"} $ mk_exp e1 $
    mk_bop bop $ mk_exp e2
```

Note that Isabelle isolates Isabelle/ML programming, and hence our parser cannot interfere with the soundness of Isabelle's core logic engine.

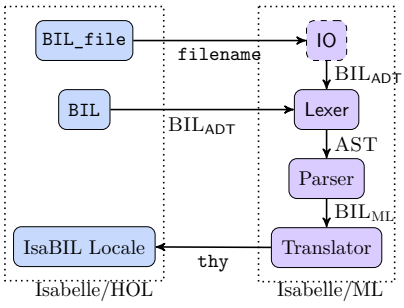

Figure 6 Overview of the BIL parser, entry-points via the `BIL` or `BIL_file` commands.

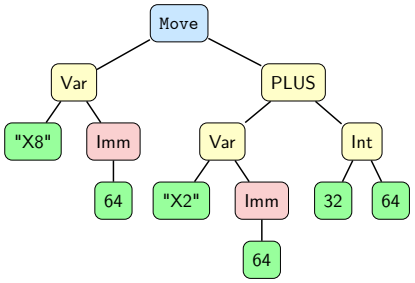

Figure 7 AST representation of the BIL_{ADT} statement `Move(Var("X8", Imm(64)), PLUS(Var("X2", Imm(64)), Int(32, 64)))`.

Table 2 Overview of theories and lemma for each of IsaBIL's components.

Component	Lemmas
Correctness	13
Incorrectness	3
Inference Rules	2
BIL Specification (including syntax)	594
BIL Inference	13
RISC-V optimisations	74
Alloc Model	6
Find Symbol	0
Double Free (total for both examples)	77
AV Rules (total for all seven examples)	187

Table 3 AV rules with description.

AVR	Description (the following shall not be used)
17	The error indicator errno
19	`<locale.h>` and the setlocale function[5]
20	The `setjmp` macro and the `longjmp` functions
21	The signal handling facilities of `<signal.h>`
23	The library functions `atof`, `atoi` and `atol` from library `<stdlib.h>`
24	The library functions `abort`, `exit`, `getenv` and system from library `<stdlib.h>`
25	The time handling functions of library `<time.h>`

6.4 Example Proofs

The majority of the development consists of general tactics and lemmas which can be reused across multiple developments. We give the number of lemmas for each component in Table 2.

All of the sublocales and inherited locales can reuse the proofs of the higher-level (more abstract) locales. Thus, for instance, the 594 lemmas of the **`BIL_specification`** locale are applicable to **`BIL_inference`** and all of the examples, which improves re-usability. The RISC-V optimisations help improve performance and are reusable across all examples. The theories for **`double_free_*`** and **`find_symbol`** are general and apply to all corresponding examples. Finally, each example comprises a step lemma for each line of code. Using the earlier optimisations, solving them is trivial and only requires running the automated tactics.

To motivate IsaBIL, we employ a combination of correctness and incorrectness proofs, focusing on illustrative examples frequently referenced in BAP literature [8]. These examples represent patterns commonly found within much larger programs/libraries.

6.4.1 Double Free

We detail the (in)correctness proofs for CWE-415: Double Free outlined in §2. To classify this vulnerability, we require a memory allocation model, which is not part of the BIL semantics (§3). Memory allocation in C is reflected as a PLT stub in the binary. In particular, we are only required to track the pointer (memory address) that is allocated (and later freed). To this end, we develop a locale, **`allocation`**, that extends the BIL semantics (see Figure 2) with an abstract allocation model inspired by earlier works [34, 31].

$$\frac{\texttt{is_alloc}(\mathcal{C}) \quad w = \texttt{next_ptr}(\omega_{\mathcal{A}}) \quad sz = \texttt{get_sz}(\mathcal{C}) \quad \omega'_{\mathcal{A}} = \omega_{\mathcal{A}}.[\texttt{alloc}(w, sz)]}{(\mathcal{C}, \omega_{\mathcal{A}}) \underset{\mathcal{A}}{\longrightarrow} \omega'_{\mathcal{A}}}\ (\text{ALLOC}) \qquad \frac{\texttt{is_free}(\mathcal{C}) \quad w = \texttt{get_ptr}(\mathcal{C}) \quad \omega'_{\mathcal{A}} = \omega_{\mathcal{A}}.[\texttt{free}(w)]}{(\mathcal{C}, \omega_{\mathcal{A}}) \underset{\mathcal{A}}{\longrightarrow} \omega'_{\mathcal{A}}}\ (\text{FREE}) \qquad \frac{\neg\texttt{is_free}(\mathcal{C}) \quad \neg\texttt{is_alloc}(\mathcal{C})}{(\mathcal{C}, \omega_{\mathcal{A}}) \underset{\mathcal{A}}{\longrightarrow} \omega_{\mathcal{A}}}\ (\text{SKIP})$$

Figure 8 Allocation semantics.

The `allocation` locale. We define `allocation` by instantiating the small-step transition relation $\underset{BIL}{\longrightarrow}$ of `BIL_specification` (see §6.1). We start by defining two memory operations:

$$memop ::= \texttt{alloc}(w, sz) \mid \texttt{free}(w)$$

where w is the memory being allocated or freed and sz is the size. Additionally, we assume an abstract allocation function `next_ptr` : $memop^* \rightarrow word$ that serves the purpose of selecting suitable memory addresses for allocation and retrieves the next address from the allocator based on the given history (sequence) of allocations and deallocations. For each allocation, we use `next_ptr` to obtain the next available memory address. Consequently, in the state of `allocation`, we must track the sequence of *memop* operations, which is provided to `next_ptr` as an input whenever an allocation occurs. For the Double Free example, no other variables need to be tracked, hence we simply assume the state to be this sequence, which we denote $\omega_{\mathcal{A}} : memop^*$.

Recall that by using the $\mapsto$ predicate (§ 3.5), the BIL instruction corresponding to $\mathcal{C} = (\Delta, pc, mem)$ can be uniquely identified. We use predicates `is_free` : $prog \rightarrow bool$ and `is_alloc` : $prog \rightarrow bool$, which hold when the next instruction to be executed in the given $\mathcal{C} \in prog$ corresponds to a free and allocation instruction, respectively. We assume that an instruction that frees memory cannot simultaneously perform an allocation and vice versa, i.e., $\neg\texttt{is_free}(\mathcal{C}) \vee \neg\texttt{is_alloc}(\mathcal{C})$. When the instruction for $\mathcal{C}$ is an allocation, we utilise the function `get_sz` : $prog \rightarrow sz$ to obtain the size allocated and when the instruction for $\mathcal{C}$ is a deallocation, we utilise the function `get_ptr` : $prog \rightarrow word$ to obtain the address that is freed. The size and location can be determined using the $\mapsto$ function on the given $\mathcal{C}$. Thus, we define a small-step transition relation, $\underset{\mathcal{A}}{\longrightarrow}$, over allocations in Figure 8.

We encode this *allocation model* as the locale `allocation`, fixing the functions `next_ptr`, `is_free`, `is_alloc`, `get_sz` and `get_ptr`. This locale is derived as an *interpretation* of the locale `BIL_inference` retaining the decode predicate $\mapsto$ and address set `addr_set` as abstract, but overriding $\underset{BIL}{\longrightarrow} = \underset{\mathcal{A}}{\longrightarrow}$. Thus, we have the signature `allocation` = ($\mapsto$, `addr_set`, `next_ptr`, `is_free`, `is_alloc`, `get_sz`, `get_ptr`), where parameters `next_ptr`, `is_free`, `is_alloc`, `get_sz` and `get_ptr` are used to derive $\underset{\mathcal{A}}{\longrightarrow}$ within the locale.

The `double_free_bad` and `double_free_good` locales. These locales correspond to the double free program and are *auto-generated* from the corresponding BIL programs (shown in Listings 3 and 4). This step is trivial when using IsaBIL's `BIL_file` command, which we have developed using Isabelle/ML. In particular, we invoke the Isabelle/HOL commands:

```
BIL_file ‹double-free-bad.bil.adt›  defining double_free_bad
BIL_file ‹double-free-good.bil.adt› defining double_free_good
```

where `double-free-bad.bil.adt` is a file containing the BIL for Listing 1 in BIL_{ADT} format and `double_free_bad` is the name of the locale to be generated. The good version is similar.

The `double_free_*_proof` locales. We combine the locales generated from the BIL programs with our allocator locale (**`allocation`**) to produce new locales **`double_free_bad_proof`** and **`double_free_good_proof`**. Recall from § 4.2 that for each locale generated from a BIL_{ADT} program, we have access to a symbol table `sym_table` mapping strings (i.e., external function calls) to the program address at which the symbol appears. Note that when a BIL program calls a function, it typically stores the return address, then jumps to the function. The symbol corresponding to the program counter after the jump contains the name of the external function, which is stored in the symbol table. In RISC-V convention, the first argument of a function call is stored in the register `X10`. To allocate memory, function `malloc` is called with the size as the first argument whereas to deallocate a pointer, function `free` is called with the pointer as the first argument. Therefore, we can obtain the size allocated by a call to `malloc` and pointer freed by a call to `free` by retrieving the value stored in register `X10`.

We therefore instantiate the predicates `is_free`, `is_alloc`, `get_sz` and `get_ptr` from the **`allocation`** locale as follows:

$$\texttt{is_free}((_, pc, _)) = (pc = \texttt{sym_table}(\text{“}\texttt{free}\text{”})) \qquad \texttt{get_ptr}((\Delta, _, _)) = \Delta(\texttt{X10})$$
$$\texttt{is_alloc}((_, pc, _)) = (pc = \texttt{sym_table}(\text{“}\texttt{malloc}\text{”})) \qquad \texttt{get_sz}((\Delta, _, _)) = \Delta(\texttt{X10})$$

The exact implementation of `next_free` occurs at a lower level of abstraction, and depends on the allocation model. At this level, we provide the main requirement axiomatically, i.e., we require

$$w = \texttt{next_ptr}(\omega_{\mathcal{A}}) \implies (\forall i.\ \omega_{\mathcal{A}}(i) = \texttt{alloc}(w, sz) \implies \exists j.\ j > i \wedge \omega_{\mathcal{A}}(i) = \texttt{free}(w))$$

This presents us with all the components necessary to prove (in)correctness of our examples. The following predicate captures the double-free over the memory state defined above:

$$\texttt{double_free_vuln} = \lambda\omega_{\mathcal{A}}.\ \exists i, j, w.\ i < j \wedge \omega_{\mathcal{A}}[i] = \texttt{free}(w) \wedge \omega_{\mathcal{A}}[j] = \texttt{free}(w) \wedge (\forall k.\ i < k < j \implies \omega_{\mathcal{A}}[k] \neq \texttt{alloc}(w, sz))$$

Note that the predicate captures *only* the double-free vulnerability and does not formalise other pointer misuse vulnerabilities, e.g., use-after-free or free-before-alloc.

▶ **Theorem 6.** *Let $\mathcal{C}_{bad}$ and $\mathcal{C}_{good}$ be the programs corresponding to* ***`double_free_bad`*** *and* ***`double_free_good`****, respectively. Both of the following hold*

1. $\exists Q.\ [\neg\texttt{double_free_vuln}]\ \mathcal{C}_{bad}\ [Q] \wedge (\forall \sigma.\ Q(\sigma) \Longrightarrow \texttt{double_free_vuln}(\sigma)) \wedge (\exists \sigma.\ Q(\sigma))$
2. $\{\neg\texttt{double_free_vuln}\}\ \mathcal{C}_{good}\ \{\neg\texttt{double_free_vuln}\}$

Note that in $\mathcal{C}_{bad}$, the memory error does not lead to early termination via the allocation semantics in Figure 8. The program continues executing as normal, but generates a history that can be shown to contain a double-free vulnerability at termination.

6.4.2 AV rules

In a similar manner, we prove incorrectness of the AV rules from Table 3. Details of these proofs are provided in [21].

7 Case Study: Double-Free Vulnerability in cURL (CVE-2016-8619)

cURL is an open-source library primarily used for transferring data over the internet using various protocols, including TLS. It has a large user base, supporting multiple operating systems and architectures (including RISC-V), and thus ensuring the security of cURL is critically important.

```
1  static __attribute__ ((noinline)) CURLcode read_data(struct connectdata *conn,
2                                                       curl_socket_t fd,
3                                                       struct krb5buffer *buf)
4  {
5    int len;
6    void* tmp = NULL;
7    CURLcode result;
8
9    result = socket_read(fd, &len, sizeof(len)); // result = 0 iff socket_read successful
10   if(result)
11     return result;
12
13   len = ntohl(len);
14   tmp = realloc(buf->data, len);
15
16   if (len) {
17     len = ntohl(len);
18     tmp = realloc(buf->data, len);
19   }
20
21   if(tmp == NULL)
22     return CURLE_OUT_OF_MEMORY;
23
24   buf->data = tmp;
25   result = socket_read(fd, buf->data, len);
26   if(result)
27     return result;
28   buf->size = conn->mech->decode(conn->app_data, buf->data, len,
29                                  conn->data_prot, conn);
30   buf->index = 0;
31   return CURLE_OK;
32 }
```

Figure 9 The `read_data` function of the cURL library in `security.c`. The snippet highlighted in red shows the vulnerable code in version 7.50.3, and that in green shows the corrected vulnerability in version 7.51.0.

Unfortunately, however, cURL has been known to contain vulnerabilities. Consider the function `read_data` in Figure 9, which underpins the Kerberos authentication protocol in cURL (prior to version 7.51.0), where § 7 reads the length of an incoming data packet from a socket. If this succeeds, `socket_read` will return a 0, causing the if statement on § 7 to fall through. Then, on § 7 the call to `ntohl` converts the data length (`len`) from network byte order (big-endian) to host byte order (big- or little-endian). Note that this method does not sanitise its input. Next, `realloc` on § 7 resizes the `data` buffer in `krb5buffer`, and returns either a new pointer to the resized memory, or `NULL` if an error occurs. The rest of the method then reads and decodes the remaining data from the socket.

The caller is responsible for managing the `krb5buffer` pointer by allocating it before and freeing it after calling `read_data`. Here we assume `malloc` is called directly before `read_data` and free is called directly after, as follows: `malloc(buf, sz); read_data(conn, fd, buf); free(buf);`

If receiving data from the socket on § 7 yields a length of 0 (`len` = 0), the call to `realloc` with `len` = 0 results in *zero reallocation*, leading to *undefined behaviour*[6]. Most implementations of `realloc` will return NULL and free the pointer following a *zero reallocation*. As such, since the `krb5buffer` buffer is already freed before `realloc` returns and the caller is expected to free it after the function returns, this will lead to a *double-free vulnerability*, identified by the vulnerability enumeration CVE-2016-8619.

[6] `https://www.open-std.org/jtc1/sc22/wg14/www/docs/n2464.pdf`

$$\frac{\texttt{is_realloc}(\mathcal{C}) \quad w = \texttt{get_ptr}(\mathcal{C}) \quad sz = \texttt{get_sz}(\mathcal{C}) \quad \omega'_{\mathcal{A}} = \omega_{\mathcal{A}}.[\texttt{alloc}(w, sz)]}{(\mathcal{C}, \omega_{\mathcal{A}}) \xrightarrow[\mathcal{R}]{} \omega'_{\mathcal{A}}} \text{(REALLOC)}$$

$$\frac{\texttt{is_realloc}(\mathcal{C}) \quad w = \texttt{get_ptr}(\mathcal{C}) \quad sz = \texttt{get_sz}(\mathcal{C}) \quad sz = 0 \quad \omega'_{\mathcal{A}} = \omega_{\mathcal{A}}.[\texttt{free}(w)]}{(\mathcal{C}, \omega_{\mathcal{A}}) \xrightarrow[\mathcal{R}]{} \omega'_{\mathcal{A}}} \text{(ZERO_REALLOC)}$$

$$\frac{\neg\texttt{is_free}(\mathcal{C}) \quad \neg\texttt{is_alloc}(\mathcal{C}) \quad \neg\texttt{is_realloc}(\mathcal{C})}{(\mathcal{C}, \omega_{\mathcal{A}}) \xrightarrow[\mathcal{R}]{} \omega_{\mathcal{A}}} \text{(SKIP)}$$

Figure 10 Reallocation semantics.

This vulnerability is resolved in version 7.51.0 of cURL by preempting the zero-allocation that leads to it: as highlighted in green in Figure 9, placing a guard around the call to `realloc`[7] ensures that it is not called with a zero length. As such, if `len` $= 0$, then the call to `realloc` is skipped, `TMP` remains `NULL` and returns 0. This ensures consistent behaviour across all C implementations.

7.1 Scalability of the Parser

We cross compile cURL 7.50.3 for RISC-V on Linux using the GNU RISC-V compiler with the default options. We modify the source code for `read_data` by adding the `noinline` attribute, which ensures the function is not inlined. Note that `noinline` is not a requirement for verification, but facilitates compositional reasoning (see § 7.3).

Using the generated BIL directly creates a scalability challenge. The assembly corresponding to version 7.50.3 contains *63,592 RISC-V instructions*, which equates to *127,023 LoC in BIL* with *63,592 BIL instructions*. Naively generating the corresponding IsaBIL locales (see § 6.3) takes approximately 14 minutes, which is impractical for verification. Of this, the lexer takes 4s, the parser takes 2s and the translator takes approximately 13 minutes. The wait time in the translator arises from instantiating the Isabelle/HOL locale in the proof context, an operation which cannot be avoided.

To address this, we extend the `BIL_file` command with a *new option*, `with_subroutines`, to focus only on the subroutines of interest (and their dependencies). For example, to generate the IsaBIL locale for `read_data` in version 7.50.3, we use the following command:

```
BIL_file <libcurl.7.50.3.bil.adt> defining read_data_7_50_3
  with_subroutines read_data and ...
```

where "..." contains functions that `read_data` calls (e.g., `ntohl`). Running `BIL_file` now takes only 6s, with 131 instructions to verify. We next show how we detect this vulnerability in version 7.50.3 using an incorrectness proof.

7.2 Incorrectness of the `read_data` Subroutine

`read_data` contains a double-free vulnerability. However, unlike our prior example (§ 6.4.1), the vulnerability arises from a reallocation of memory. Thus, we first describe the construction of a **`reallocation`** locale, which reuses components from the **`allocation`** locale. Then, we prove the incorrectness of the `read_data` function in version 7.50.3.

The `reallocation` locale. We define **`reallocation`** by instantiating the small-step transition relation $\xrightarrow[BIL]{}$ of **`BIL_specification`** (see § 6.1). Whilst we do not extend **`allocation`** from § 6.4.1 directly, as it already defines small step semantics ($\xrightarrow[\mathcal{A}]{}$) that are incompatible

[7] https://github.com/curl/curl/commit/3d6460edeee21d7d790ec570d0887bed1f4366dd

with reallocation, we can borrow: (1) the definition of *memop*, (2) our abstract allocator `next_ptr`, (3) our memory trace $\omega_{\mathcal{A}}$, (4) the getter for the size `get_sz`, (5) the getter for the pointer to free `get_ptr`, (6) the predicate that denotes a program is freeing memory `is_free` and (7) the predicate that denotes a program is allocating memory `is_alloc`. These concepts are explained in detail in § 6.4.1.

We use the predicate `is_realloc` to determine whether the next instruction to be executed in the given $\mathcal{C}$ corresponds to a `realloc` instruction. We assume that an instruction that frees or allocates memory cannot simultaneously perform an reallocation and vice versa, i.e., $\neg\texttt{is_free}(\mathcal{C}) \vee \neg\texttt{is_alloc}(\mathcal{C}) \vee \neg\texttt{is_realloc}(\mathcal{C})$.

When a program reallocates memory it has two parameters, a pointer to the memory to be resized, and the new size of that memory. We utilise the existing functions `get_sz` to obtain the size reallocated and `get_ptr` to obtain the address that is reallocated. The size and location can be determined using the $\mapsto$ function on the given $\mathcal{C}$. The size and location are then used to add an $\texttt{alloc}(w, sz)$ to the $\omega_{\mathcal{A}}$. However, if the size of a reallocation is 0, this represents a zero-reallocation, and hence a $\texttt{free}(w)$ is added to the $\omega_{\mathcal{A}}$. This results in a small-step transition relation, $\underset{\mathcal{R}}{\longrightarrow}$, over reallocations as given in Figure 10. Note that we retain the ALLOC and FREE rules from Figure 8, and adapt the SKIP to encompass is reallocations. Finally, we obtain the signature

$$\texttt{reallocation} = (\mapsto, \texttt{addr_set}, \texttt{next_ptr}, \texttt{is_free}, \texttt{is_alloc}, \texttt{is_realloc}, \texttt{get_sz}, \texttt{get_ptr})$$

where the parameters `next_ptr`, `is_free`, `is_realloc`, `is_alloc`, `get_sz` and `get_ptr` are used to derive $\underset{\mathcal{R}}{\longrightarrow}$ within the locale.

The `read_data` proof locale. We combine the locale generated for cURL binaries to produce a new locale `read_data_7_50_3_proof`. Reallocations are handled by calls to a PLT stub for `realloc` so we can proceed in the same way as `malloc`/`free`. In § 6.4.1, we discussed how the first argument of a subroutine call is stored in the register `X10`. Reallocations take two arguments: (1) a pointer to memory, and (2) a size. The second argument (2) is stored in the return register (`X11`), thus we instantiate the parameters of **`reallocation`** as follows for both locales:

$$\texttt{is_realloc}(_, pc, _) = (pc = \texttt{sym_table}(\text{“}\texttt{realloc}\text{”}))$$

$$\texttt{get_sz}(\Delta, pc, _) = \begin{cases} \Delta(\texttt{X11}) & \textbf{if } pc = \texttt{sym_table}(\text{“}\texttt{realloc}\text{”}) \\ \Delta(\texttt{X10}) & \textbf{otherwise} \end{cases}$$

The remaining definitions of `get_ptr`, `is_free` and `is_alloc` match **`allocation`** (see §6.4.1).

▶ **Theorem 7.** *Let $RD_{7.50.3}$ be the program corresponding to* **`read_data_7_50_3`**. *Then*

$$\exists Q.\ [\neg\texttt{double_free_vuln}]\ RD_{7.50.3}\ [Q] \wedge (\forall \sigma.\ Q(\sigma) \implies \texttt{double_free_vuln}(\sigma)) \wedge (\exists \sigma.\ Q(\sigma)).$$

7.3 Compositionality

The proof in Figure 9 covers the `read_data` subroutine in the cURL library. However, this subroutine is an *internal* function (i.e. not defined in a header file), making the vulnerability difficult to exploit directly in practice. Nevertheless, as shown in the call graph in Figure 11, there is a path from an *external* function (defined in a header file), namely `Curl_sec_login`,

Figure 11 A partial call graph in cURL demonstrating a path from an external function (highlighted), `Curl_sec_login`, to the internal function `read_data`.

to `read_data`. That is, a call to `Curl_sec_login` includes a call to `choose_mech`, which in turn includes a call to `sec_recv`, which itself calls `read_data`. As such, the vulnerability in `read_data` *could potentially* be exploited by a call to `Curl_sec_login`.

Note that this may not always be the case, as freeing the data buffer pointer is left up to the caller, not the callee, and thus further incorrect behaviour to by caller (in this case a function above `read_data` in the call graph) could rectify this vulnerability by forgetting to call free, or perhaps reallocating the pointer again before freeing it. Thus, we should aim to establish that each of these methods are (in)correct formally.

We do this in a *compositional* fashion through *proof reuse*: we reuse the (in)correctness specifications we prove at lower levels of the call graph in higher levels. For instance, when proving that `sec_recv` is (in)correct, we reuse the specification of `read_data` in Theorem 7 as a lemma. Indeed, this is precisely why we used the `noinline` attribute when compiling `read_data`: this allows us to reuse its specification; otherwise each call to `read_data` would be inlined, preventing us from proof reuse.

In Theorem 8 below, we prove incorrectness specifications for the $SR_{7.50.3}$, $CM_{7.50.3}$ and $CSL_{7.50.3}$ functions, showing that each of these functions do indeed exhibit a double-free vulnerability. Our proof is compositional in that the proof for each function reuses the specification of the function below it, as discussed above (e.g. the proof of $SR_{7.50.3}$ reuses the incorrectness specification of `read_data` in Theorem 7 as a lemma).

▶ **Theorem 8.** *Let* $C \in \{SR_{7.50.3}, CM_{7.50.3}, CSL_{7.50.3}\}$*, be a program corresponding to the 7.50.3 versions of* `sec_recv`*,* `choose_mech` *and* `Curl_sec_login`*. Then:*

$$\exists Q.\ [\neg\texttt{double_free_vuln}]\ C\ [Q] \wedge (\forall \sigma.\ Q(\sigma) \implies \texttt{double_free_vuln}(\sigma)) \wedge (\exists \sigma.\ Q(\sigma)).$$

Theorem 8 demonstrates a scalable proof for the incorrectness specifications of the functions in Figure 11. We can apply similar techniques to verify their corresponding correctness specifications for version 7.51.0; we have elided these proofs as they are similar.

8 Conclusions and Related Work

Program analysis in the absence of source code techniques typically focus on a combination of hardware (e.g., x86, ARM), intermediary representations, e.g., LLVM-IR, high-level language models (e.g., C/C++). Our work adds to the growing literature on low-level verification using Hoare logic, and is the first to also apply incorrectness logic to verify the absence and presence of bugs in binaries. While many works in the literature focus on particular architectures, e.g., RISC-V, x86 or ARM, our work is on the generic BAP platform, and hence inherits its generality. BAP is a production ready system with 1000s of users but lack a verification component that IsaBIL provides. We have developed a complete formalisation of BIL, and developed the first (in)correctness logics for BIL. Our formalisation of the BIL specification uncovered bugs in that specification, which have been reported to the developers and corrected. We provide automation to enable better proof scalability, and demonstrate compositional proofs.

The importance of binary-level analysis has meant that there is increasing work on theorem provers being applied to verify program binaries.

Verified machine code. Closest to our work is the PICINÆ framework [22], which lifts BIL to Coq for verifying properties like termination and functional correctness. Unlike IsaBIL, its lifter is unverified and adds an extra step via a custom intermediate representation (IR) with unclear semantics. The work is preliminary, focusing on small examples like memset and string comparisons.

Early machine-code verification includes Myreen et al.[37, 38], who used Hoare logic on high-level Arm models. Similarly, Jensen et al. [25] developed separation logic for verifying low-level x86 code via abstractions, with the framework being encoded in Coq. Later work on *decompilation into logic* [39, 40] targets x86, ARM, and PowerPC by translating binaries into tail-recursive functions in HOL4 [24], avoiding conventional lifters like BAP. Verification is done via Hoare triples over these functions, shifting trust to mechanised ISA models [13, 30, 16, 17]. However, these models were not originally designed for decompilation and may not reflect modern ISAs.

The Islaris framework [44] builds on Sail-based Armv8-A and RISC-V semantics [47, 48, 1], using higher-order separation logic in Coq with automatic Sail-to-Coq translation. Unlike Islaris, which focuses on reasoning directly over ISA models, our approach targets lifted assembly to enable a unifying, architecture-agnostic proof layer. Our automation (§ 6) is reusable across architectures supported by BAP. MiniSail [54] encodes a subset of Sail in proof assistants like Isabelle/HOL, enabling reasoning over lifted Sail models similar to IsaBIL. While useful for verifying Sail's type soundness, it lacks IsaBIL's automation and higher-level reasoning capabilities.

Verified compilation. Notable compilation correctness efforts include CakeML [28] and CompCert [7], targeting ML and C, respectively. Sewell et al.[45] verify seL4 C code down to gcc-generated binaries. Bedrock [11] uses an intermediate representation and strongest postcondition reasoning in Coq for C macros, unlike IsaBIL, which allows verification of binaries that may not be generated by a compiler. Overall, these approaches verify functional correctness at the source level, requiring compiler models and assumptions about architecture and optimisation levels. Moreoever, they are unsuitable when source code is unavailable, whereas IsaBIL, via BAP, operates directly on binaries.

Verified lifting. Verbeek et al [51] have formalised and integrated a subset of the x86-64 instruction set (i.e., the 64-bit subset of x86) within Isabelle/HOL and used it to verify so called *sanity properties* (e.g., the integrity of a return address) for a large codebase. However, the focus of this verification is correctness of the lifting, as opposed to properties about the program itself (e.g., termination, functionality). IsaBIL employs type verification, however, this method only verifies that the lifted BIL is correct according to its specification, and not the specification of the assembly it was lifted from. Lam and Coughlin [29] developed a verified BAP lifter for ARMv8. BAP is already accompanied by an extensive set of validation tools that uses trace files to verify the lifter's accuracy [8], that are checked "per instruction". We consider formal verification of BAP lifters to be future work.

Verified instrumentation. Armor [56] presents a checker for memory safety and control flow integrity of Arm binaries, which instruments a check before particular operations, then uses HOL to prove that the modified binary is correct. Similarly, RockSalt [35] is a

[8] `https://github.com/BinaryAnalysisPlatform/bap-veri`

Coq-based checker for a subset of x86 that is used to verify software-based fault isolation implementations. RockSalt is designed to check specific sandbox policies, e.g., that the code will only read/write data from specified contiguous segments in memory. Unlike IsaBIL, which has the full flexibility of Hoare and O'Hearn's logics for proving (in)correctness, both Armor and RockSalt focus on a subset of properties.

Security analysis. An overview of security properties, exploits and tools for binary analysis has been given by Shoshitaishvili et al [46]. Above, we have focussed mainly on safety, though also describe how BAP can be extended to reason about transient execution vulnerabilities (e.g., as exploited by Spectre and Meltdown) [53, 10, 19]. Cheang et al [10] cover model checking (using UCLID5), while Wang et al [53] develop a taint tracking tool based on BAP to check correctness of Spectre mitigations. Griffin and Dongol [19] consider proofs of speculative execution over BAP outputs, but only cover a subset of the BIL language called AIR. They apply Hoare-style proofs to verify a hyperproperty [12] known as TPOD [10] directly over AIR without any of the modularity offered by IsaBIL. Nevertheless, it would be interesting to extend our work to cover proofs of (in)correctness of speculative execution [9, 14].

(Incorrectness) separation logic. In IsaBIL we do not currently have support for separation logic (SL) or its incorrectness analogue, ISL [43]. While the absence of (I)SL support does not impede the scalability of our approach, it is an interesting direction of future work to pursue. Doing so, however, is non-trivial as the memory representation in BIL is incompatible with that of (I)SL. As described in § 3.1, memory in BIL is represented as a "history" of updates (mutations) that must be "replayed" to ascertain its contents. For instance, the BIL memory $[x \leftarrow 1][y \leftarrow 2][x \leftarrow 3]$ describes *any* memory obtainable after applying (replaying) the listed updates in order, namely by first updating location x to hold 1, then updating y to 2 and finally re-updating x to 3. While this confers the existence and the final values of locations x and y, it has no bearing on the existence or the values of other memory locations.

Representing the memory in BIL as described above is a design choice we *inherited* from BIL, and it is not immediately conducive to "separation" as in (I)SL. As such, to add support for (I)SL in BIL we would have to fundamentally change the memory representation in BIL, an undertaking which is far from trivial. While we believe this a worthy direction of work in the future, doing so is beyond the scope of our work here.

Abstract

Region based memory management is a powerful tool designed with the goal of ensuring memory safety statically. The region calculus of Tofte and Talpin is a well known example of a region based system, which uses regions to manage memory in a stack-like fashion. However, the region calculus is lexically scoped and requires explicit annotation of memory regions, which can be cumbersome for the programmer. Other systems have addressed non-lexical regions, but these approaches typically require the use of a substructural type system to track the lifetimes of regions. We present Spegion, a language with implicit non-lexical regions, which provides these same memory safety guarantees for programs that go beyond using memory allocation in a stack-like manner. We are able to achieve this with a concise syntax, and without the use of substructural types, relying instead on an effect system to enforce constraints on region allocation and deallocation. These regions may be divided into sub-regions, i.e., **Sp**littable r**Egion**s, allowing fine grained control over memory allocation. Furthermore, Spegion permits *sized* allocations, where each value has an associated size which is used to ensure that regions are not over-allocated into. We present a type system for Spegion and prove it is type safe with respect to a small-step operational semantics.

1 Introduction

Writing error-free code is hard. Writing error-free systems code is even harder. Possibly the most common source of bugs in systems programming code is the traditional approach of manual memory management. Use-after-free bugs, where a program attempts to access memory that has been deallocated, are pervasive in C code, and can lead to undefined behaviour, crashes, and security vulnerabilities. Nevertheless, manual memory management is still widely used in systems code as it provides the programmer with fine-grained control over memory usage. A vast swathe of research has been dedicated to the problem of memory safety in systems programming languages. One approach is to use a garbage collector to automatically manage memory. However, garbage collectors can introduce unpredictable pauses in the execution of a program, which is unacceptable in systems programming where performance is critical. Another approach is to ensure memory safety statically using a type system, one of the most well-studied verification tools in computer science.

The region calculus of Tofte and Talpin [29] is a type system designed for ensuring memory safety in ML [27] through the use of memory *regions*. Memory is divided into regions which are allocated in a stack-like manner, using the language's **letregion** construct. This allows deallocation to be done in a single operation by popping the topmost region from the stack:

letregion ρ **in** e

The memory region ρ is created and pushed onto the region stack. After the evaluation of **letregion**, ρ is popped from the stack, deallocating any memory allocated during the evaluation of e. Region based memory management has since been applied to languages other than ML, such as Java [6,9] and Prolog [21]. However, these region calculi are lexically scoped, restricting the programmer from expressing more complex memory usage patterns that may arise in code. Lexically-scoped regions are tied to the static structure of the program and are deallocated in a stack-like manner. This limits flexibility in memory management, as regions cannot be split or partially deallocated. Consider the following C program, for example: Here

```
struct task {int n; struct task* next;};

struct task* build_tasks () {
    struct task* t      = malloc(sizeof(struct task));
    t->next             = malloc(sizeof(struct task));
    t->next->next       = malloc(sizeof(struct task));
    t->next->next->n    = 1;
    t->next->next->next = NULL;
    return t;
  }

int main () {
  struct task* t_head = build_tasks();
  struct task* t_last = t_head->next->next;
  free(t_head->next);
  free(t_head);
  return t_last->n;
}
```

Figure 1 Non-lexically-scoped memory use.

we have a linked list of tasks, where each task has a pointer to the next task. The function `build_tasks` allocates three tasks and links them together. The main function then frees the first two tasks, leaving the third task dangling. Traditional region calculi are unable to express this pattern as the regions are allocated and de-allocated non-lexically.

There has been prior work exploring the safe use of non-lexically scoped regions, though this work has often focused on inferring region annotations for functional programs, or involved the use of substructural types (requiring that code is written to use memory linearly or avoid aliasing, for example), or imposed constraints on the runtime of programs like requiring reference counting. This research is covered in detail in Section 6.2.

We present an approach to non-lexically scoped region which allows for the same memory safety guarantees as prior systems, without the need for linear or substructural types and with a concise syntax. We refer to these as *implicit* regions, as they are not first-class values in the language's syntax and are not tied to the lexical structure of the program. Our system, named Spegion, removes the need for first class regions in the language's source syntax (with the exception of polymorphic constructs). Instead, when allocating a piece of data, the programmer needs only to provide an existing value in the region they wish to allocate the new value into. For example,

let $x =$ **newrgn in**
  v **at** x
  freergn x;

The **newrgn** construct returns a null pointer for a new region, which is then used to allocate v into that region. The type system then ensures that the region associated with x is live when v is allocated into it. Eliminating first-class regions from the syntax provides natural compatibility with C-like languages, where regions are not first-class values. Spegion sidesteps the need to retrofit complex region syntax onto C by using a special syntactic form for allocation (v **at** x) to determine which region to allocate a value into. Moreover, implicit regions eliminate the need for substructural type constraints, a common source of complexity in region type systems and a feature which C does not support.

Our non-lexical approach to regions in Spegion also permits the splitting of regions into sub-regions, allowing unused memory to be reclaimed without deallocating the entire region. This allows the typing of patterns which are difficult to express, even in C.

Furthermore, our system introduces the notion of *sized* regions. Each value in our language has an associated size, which is an abstract representation of the amount of memory that the value occupies. We use this information to ensure that regions are not over-allocated into, as each region has an associated maximum size constraint. These constraints are provided explicitly by the programmer as annotations on region creation and allocation sites, giving them fine-grained control over memory usage in their program. In the previous example, we allocated v into the region associated with x. This allocation carries the implicit constraint that the region of x must be of an arbitrary size. A more fine-grained allocation is possible using size annotations:

let $x =$ **newrgn** [10] **in**
  v [5] **at** x

Here, 10 is a size representing 10 abstract units of memory. The region associated with x has a size of 5 and we can only allocate into this region if the total size of allocations into the region does not exceed 10. In the above code, we allocate 5 units of memory into the region. as indicated by the size annotation on the allocation site. Contrarily, the following code would be invalid:

let $x =$ **newrgn** [10] **in**
  v [10] **at** x;
  v [5] **at** x

Since the sum of allocations (15) is greater than the region's bound size. This program is thus rejected by the type checker.

Spegion's size annotations are abstract units of memory, but the principle can be applied to concrete memory sizes. In performance critical applications, such as embedded systems, where the programmer has clear static constraints on the size of data structures, the programmer can use these size annotations to ensure that the program does not exceed the available memory.

Size annotations are an optional feature of Spegion, as unannotated regions and allocations default to being of unbounded size. These size constraints on allocations can be enforced using an effect system, and present an opportunity for further research into type-level reasoning about memory usage.

1.1 Contributions

This paper makes the following contributions:

- We introduce Spegion, a novel core calculus and formal semantics for a language featuring implicit, non-lexical regions with explicit size constraints. Unlike traditional region calculi which are lexically scoped and require first-class region syntax, Spegion removes first-class regions from the source language syntax (except for polymorphic constructs), enabling natural compatibility with C-like languages.
- We develop a type system that leverages effects to ensure safe allocation into implicit regions, eliminating the need for substructural or linear types commonly required in prior non-lexical region systems such as Cyclone. This approach supports flexible memory management patterns including region splitting and partial deallocation, which are difficult to express in lexically scoped systems.
- We extend the concept of region-based memory management by introducing sized regions, where each region and allocation carries an abstract size annotation. This allows static enforcement of memory usage bounds via an effect system, providing fine-grained control over memory consumption and enabling static reasoning about memory usage in performance-critical applications.
- We provide a formal proof of type safety for Spegion, building on and adapting the syntactic proof techniques from Helsen and Thiemann's work on the region calculus.
- We demonstrate the expressiveness and practical applicability of Spegion through a series of illustrative examples, including a sketch of an extension combining refinement types with region sizes to further enhance static guarantees about memory usage.

1.2 Overview

The rest of the paper is structured as follows. Section 2 introduces the syntax and typing rules of Spegion. In Section 3 we present the dynamic semantics of the language as reduction rules. In Section 4 we present the type safety properties of the language in the form of progress and preservation theorems. Section 5 explores the potential applications of Spegion in several domains, including a sketch of how refinement types can be combined with our system to provide powerful static guarantees about memory usage. We also discuss the application of our system in the context of memory safety in C-like languages. Section 6 discusses related work, and Section 7 concludes.

2 Static Semantics

We define a core calculus for Spegion, drawing from the region calculus of [29] and the presentation by [17]. The syntax of types is given by:

$$\begin{aligned} \tau &::= \quad \alpha \mid \text{Int} \mid \text{Unit} \mid \text{Bool} \mid \text{Ref}\ \tau \mid \mu \xrightarrow{\varphi} \mu \mid \forall\{\alpha, \rho, \epsilon\}.\mu \xrightarrow{\varphi} \mu \\ \mu &::= \quad (\tau, \rho) \end{aligned} \tag{types}$$

Types τ are either type variables α, integers, units, booleans, references to other types, function types, or polymorphic types. A program expression in our calculus is assigned a "type-with-place", i.e., a pair of a type and a region, denoted by μ.

Function types are written as $\mu_1 \xrightarrow{\varphi} \mu_2$. Above the function arrow is an *arrow effect*, i.e. the latent effect that happens on application of the function, as in [29]. Polymorphic functions are typed by type schemes $\forall\{\alpha, \rho, \epsilon\}.\mu$ which bind type α, region ρ, and effect ϵ variables. We refer to these as kind-annotated type variables, however, in the syntax of our calculus we typically omit the kind annotations for brevity.

Kinds are given by the grammar:

$$\kappa ::= \quad \text{Type} \mid \kappa \to \kappa \mid \text{Region} \mid \text{Effect} \mid \text{Size} \qquad \text{(kinds)}$$

That is a kind is either a type, a function kind, a region, an effect, or a size. Kinding rules for types are given in Figure 2. These rules are mostly straightforward and ensure that type, regions, effects, and sizes are well-structured.

$$\frac{\text{Type} = K(\alpha)}{K \vdash \alpha : \text{Type}}\ \kappa\text{-VAR} \qquad \frac{K, \alpha : \text{Type}, \rho : \text{Region}, \epsilon : \text{Effect} \vdash \tau : \text{Type}}{K \vdash \forall\{\alpha, \rho, \epsilon\}.\tau : \text{Type}}\ \kappa\text{-FORALL} \qquad \frac{\text{Region} = K(\rho)}{K \vdash \rho : \text{Region}}\ \kappa\text{-REG}$$

$$\frac{}{K \vdash (\to) : \text{Type} \to \text{Effect} \to \text{Type} \to \text{Type}}\ \kappa\text{-}\to \qquad \frac{K \vdash \kappa_1 : \text{Type} \qquad K \vdash \tau : \text{Type}}{K \vdash (\kappa_1 \to \kappa_2)\ \tau : \kappa_2}\ \kappa\text{-APP}_1$$

$$\frac{K \vdash \kappa_1 : \text{Effect} \qquad K \vdash \varphi : \text{Effect}}{K \vdash (\kappa_1 \to \kappa_2)\ \varphi : \kappa_2}\ \kappa\text{-APP}_2 \qquad \frac{}{K \vdash \text{Int} : \text{Type}}\ \kappa\text{-INT} \qquad \frac{}{K \vdash \text{Unit} : \text{Type}}\ \kappa\text{-UNIT}$$

$$\frac{K \vdash \tau : \text{Type}}{K \vdash \text{Ref}\ \tau : \text{Type}}\ \kappa\text{-REF} \qquad \frac{}{K \vdash \text{Bool} : \text{Type}}\ \kappa\text{-BOOL} \qquad \frac{}{K \vdash s : \text{Size}}\ \kappa\text{-SIZE}$$

$$\frac{K \vdash \kappa_1 : \text{Size} \qquad K \vdash \kappa_2 : \text{Size}}{K \vdash \kappa_1\ op\ \kappa_2 : \text{Size}}\ \kappa\text{-OP} \qquad \frac{K \vdash \tau : \text{Type} \qquad K \vdash \rho : \text{Region}}{K \vdash (\tau, \rho) : \text{Type}}\ \kappa\text{-TyWithPlace}$$

$$\frac{}{K \vdash_\kappa \{\bot\} : \text{Effect}}\ \kappa\text{-BOT} \qquad \frac{K \vdash \varphi_1 : \text{Effect} \quad K \vdash \varphi_2 : \text{Effect}}{K \vdash \varphi_1 \times \varphi_2 : \text{Effect}}\ \kappa\text{-}\times \qquad \frac{K \vdash \varphi_1 : \text{Effect} \quad K \vdash \varphi_2 : \text{Effect}}{K \vdash \varphi_1 \sqcup \varphi_2 : \text{Effect}}\ \kappa\text{-}\sqcup$$

$$\frac{K \vdash s : \text{Size} \qquad K \vdash \rho : \text{Region}}{K \vdash \{\textbf{alloc}\ s\ \rho\} : \text{Effect}}\ \kappa\text{-ALLOC} \qquad \frac{K \vdash \rho : \text{Region} \qquad K \vdash s : \text{Size}}{K \vdash \{\textbf{fresh}\ \rho\ s\} : \text{Effect}}\ \kappa\text{-FRESH}$$

$$\frac{K \vdash \rho : \text{Region} \qquad K \vdash s : \text{Size} \qquad K \vdash \rho' : \text{Region}}{K \vdash \{\textbf{split}\ \rho\ s\ \rho'\} : \text{Effect}}\ \kappa\text{-SPLIT}$$

$$\frac{K \vdash \rho : \text{Region}}{K \vdash \{\textbf{free}\ \rho\} : \text{Effect}}\ \kappa\text{-FREE} \qquad \frac{\text{Effect} = K(\epsilon)}{K \vdash \{\epsilon\} : \text{Effect}}\ \kappa\text{-}\epsilon \qquad \frac{K \vdash \epsilon : \text{Effect} \qquad K \vdash \varphi : \text{Effect}}{K \vdash \{\textbf{rec}\ \epsilon\ \varphi\} : \text{Effect}}\ \kappa\text{-REC}$$

Figure 2 Kinding rules in Spegion.

2.1 Effects and Sizes

An effect φ describes the sequence of actions that are performed on a region when an expression is evaluated. Many expressions in the calculus convey some effect, which form part of the expression's typing judgement. The following grammar defines these actions:

$$\begin{aligned}\varphi ::= \quad & \varphi \times \varphi \mid \{\bot\} \mid \{\textbf{fresh } \rho\ s\} \mid \{\textbf{free } \rho\} \mid \{\textbf{split } \rho\ s\ \rho'\} \mid \{\textbf{alloc } s\ \rho\} \mid \varphi \sqcup \varphi \\ \mid \quad & \{\epsilon\} \mid \{\textbf{rec } \epsilon\ \varphi\}\end{aligned} \tag{effects}$$

Effects are composed using the $\times$ operator, which describes the sequential composition of two effects. This operator also ensures constraints on memory usage are respected when two effects are composed. The $\{\bot\}$ effect describes an empty effect, i.e., no actions are performed, and is used in the typing of expressions which are pure computations. The creation of a fresh region is denoted by $\{\textbf{fresh } \rho\ s\}$, where ρ is a fresh region name and s is the region's *size*.

A size is an abstract unit of memory. For simplicity, we consider sizes to be natural numbers, extended with a special size ω which represents an unknown size. Sizes thus comprise an extended natural numbers preordered semiring $(\overline{\mathbb{N}}, +, \cdot, \dot{-}, 0, 1, \sqsubseteq)$ where $\overline{\mathbb{N}} = \mathbb{N} \cup \{\omega\}$, such that $\forall n \in \overline{\mathbb{N}}. n + \omega = \omega = \omega + n = \omega$. The preorder $\sqsubseteq$ is the standard preorder on $\mathbb{N}$ with ω as the greatest element. The semiring is also equipped with a truncated subtraction (or *monus*) operation $\dot{-}$, given by Definition 2.1:

▶ **Definition 2.1** (Monus ($\dot{-}$)). For any two numbers $n, n' \in \overline{\mathbb{N}}$, $\dot{-}$ is defined:

$$n \dot{-} n' = \begin{cases} n - n' & n, n' \sqsubset \omega \wedge n \sqsupseteq n', \\ 0 & n, n' \sqsubset \omega \wedge n \sqsubset n' \\ n & n' = 0 \\ 0 & n \sqsubset n' \wedge n' = \omega, \\ \omega & \text{if } n = \omega \end{cases}$$

The typing rules do not make use of subtraction, however, it is required during evaluation.

The effect $\{\textbf{free } \rho\}$ describes the freeing of a region ρ, which deallocates all memory in the region. The creation of sub-regions is denoted by $\{\textbf{split } \rho\ s\ \rho'\}$, where ρ' is a fresh region name for a sub-region of ρ with size s. Allocation of a value into a region is described by $\{\textbf{alloc } s\ \rho\}$, where s is the size of the value being allocated, and ρ is the region it is being allocated into. If statements introduce branching into our calculus, with the different cases potentially having different effects. This is captured by the $\{\varphi_1 \sqcup \varphi_2\}$ effect, where φ_1 denotes the effect of the true branch and φ_2 the effect of the false branch. Recursion is described in effects through the $\{\epsilon\}$ and $\{\textbf{rec } \epsilon\ \varphi\}$ effects. The former denotes the usage of a recursive function definition, while the latter captures the latent effect of this function upon application. We explain further when we discuss the typing rules for recursive functions.

2.2 Syntax and Typing

The term syntax of our calculus comprises the λ-calculus, with the addition of references, sequential composition, polymorphic recursion, as well as constructs for region manipulation. These include expressions for creating, freeing, and splitting regions, as well as primitives for allocating data into regions and copying data between regions. The full syntax is given by the following grammar, which divides constructs between values v and expressions e:

$$\begin{aligned} v ::= \quad & n \mid \text{true} \mid \text{false} \mid \Lambda\{\alpha, \rho, \epsilon\}.\lambda x.e \mid \lambda x.e \mid () \mid l_\rho \\ e ::= \quad & x \mid l_\rho \mid v\ [s]\ \textbf{at}\ e \mid e\ e \mid \textbf{ref}\ e \mid\ !e \mid e := e \mid e;\ e \mid \textbf{if}\ e\ \textbf{then}\ e\ \textbf{else}\ e \\ \mid \quad & \textbf{let}\ x = e\ \textbf{in}\ e \mid e\ @\ \mu \mid \textbf{let}\ f = \textbf{fix}(f, (\Lambda\{\alpha, \rho, \epsilon\}.\lambda x.e_1)\ [s]\ \textbf{at}\ e_2)\ \textbf{in}\ e_3 \\ \mid \quad & \textbf{newrgn}\ [s] \mid \textbf{freergn}\ e \mid \textbf{split}\ [s]\ e \mid \textbf{copy}\ e\ \textbf{into}\ e \end{aligned} \tag{terms}$$

The syntax of values v includes integers n, booleans true and false, polymorphic functions $\Lambda\{\alpha, \rho, \epsilon\}.\lambda x.e$, functions $\lambda x.e$, unit $()$, and locations l_ρ. Expressions e include variables x, locations l_ρ, value allocations $v\ [s]\ \textbf{at}\ e$, function application $e\ e$, reference creation $\textbf{ref}\ e$,

$$\frac{}{K \mid \Gamma \mid \Sigma \vdash c : \mathrm{Int}}\ \textsc{t-int} \qquad \frac{}{K \mid \Gamma \mid \Sigma \vdash () : \mathrm{Unit}}\ \textsc{t-unit}$$

$$\frac{}{K \mid \Gamma \mid \Sigma \vdash \mathrm{true} : \mathrm{Bool}}\ \textsc{t-true} \qquad \frac{}{K \mid \Gamma \mid \Sigma \vdash \mathrm{false} : \mathrm{Bool}}\ \textsc{t-false}$$

$$\frac{\tau = \Sigma(l_\rho) \qquad K \vdash \tau : \mathrm{Type}}{K \mid \Gamma \mid \Sigma \vdash l_\rho : \tau}\ \textsc{t-loc} \qquad \frac{K \vdash \mu_1 : \mathrm{Type} \quad K \mid \Gamma, x : \mu_1 \mid \Sigma \vdash e : \mu_2 \mid \varphi}{K \mid \Gamma \mid \Sigma \vdash \lambda x.e : \mu_1 \xrightarrow{\varphi} \mu_2}\ \textsc{t-}\lambda$$

$$\frac{K, \alpha : \mathrm{Type}, \rho : \mathrm{Region}, \epsilon : \mathrm{Effect} \mid \Gamma, x : \mu_1 \mid \Sigma \vdash e : \mu_2 \mid \varphi}{K \mid \Gamma \mid \Sigma \vdash \Lambda\{\alpha, \rho, \epsilon\}.\lambda x.e : \forall\{\alpha : \mathrm{Type}, \rho : \mathrm{Region}, \epsilon : \mathrm{Effect}\}.\mu_1 \xrightarrow{\varphi} \mu_2}\ \textsc{t-}\Lambda$$

Figure 3 Value typing rules in Spegion.

dereferencing $!e$, assignment $e := e$, sequential composition $e;\ e$, conditionals **if** e **then** e **else** e, let-binding **let** $x = e$ **in** e, type applications $e\ @\ \mu$, and recursive function definitions **let** $f =$ **fix**$(f, (\Lambda\{\alpha, \rho, \epsilon\}.\lambda x.e_1)\ [s]$ **at** $e_2)$ **in** e_3. Region manipulation constructs include creating a new region **newrgn** $[s]$, freeing a region **freergn** e, splitting a sub-region from another region **split** $[s]\ e$, and copying data between regions **copy** e **into** e.

Expressions are typed by the judgement:

$$K \mid \Gamma \mid \Sigma \vdash e : (\tau, \rho) \mid \varphi$$

assigning an expression e the type τ in region ρ with effect φ. A context of kind-annotated type variables K provides a mapping from type variables to kinds, given by:

$$K ::= \quad \emptyset \mid K, \alpha : \mathrm{Type} \mid K, \rho : \mathrm{Region} \mid K, \epsilon : \mathrm{Effect} \qquad \text{(kinding contexts)}$$

That is, a context may be empty $\emptyset$, extended with a type variable $\alpha : \mathrm{Type}$, a region variable $\rho : \mathrm{Region}$, or an effect variable $\epsilon : \mathrm{Effect}$. Free variable contexts Γ are given by:

$$\Gamma ::= \quad \emptyset \mid \Gamma, x : \mu \qquad \text{(free variable contexts)}$$

A store typing context Σ is a mapping from locations to types, defined:

$$\Sigma ::= \quad \emptyset \mid \Sigma, l_\rho : \tau \qquad \text{(store typing)}$$

That is l_ρ is a location in region ρ with type τ. Figure 4 provides typing rules for the expressions. Values, which are non-computational objects, are typed by a separate judgement

$$K \mid \Gamma \mid \Sigma \vdash v : \tau$$

This judgement is similar to that of expressions but does not include an effect. Figure 3 gives the typing rules for values, relating terms to types.

The rules for integers (T-INT), unit (T-UNIT), and bools (T-TRUE, T-FALSE) are standard. For (T-λ), the type of the argument x is added to the variable context Γ and the expression e is typed. The type of the function is then a function type from the type of the argument to the type of the body. The effect of the function is the latent effect of the body. A location l_ρ is typed by (T-LOC), where the location's type τ is looked up in the store typing Σ. Finally, polymorphic functions are typed by (T-Λ), which also adds the kind-annotated type, region, and effect variables to the kind variable context K.

$$\text{T-USE-VAL}\ \frac{K \mid \Gamma \mid \Sigma \vdash l_\rho : \tau}{K \mid \Gamma \mid \Sigma \vdash l_\rho : (\tau, \rho) \mid \{\bot\}} \qquad \frac{K \mid \Gamma \mid \Sigma \vdash e : (\tau', \rho) \mid \varphi \qquad K \mid \Gamma \mid \Sigma \vdash v : \tau \qquad K \vdash s : \text{Size}}{K \mid \Gamma \mid \Sigma \vdash v\ [s]\ \textbf{at}\ e : (\tau, \rho) \mid \varphi \times \{\textbf{alloc}\ s\ \rho\}}\ \text{T-VAL}$$

$$\frac{s \sqsupseteq 1 \qquad K, \rho : \text{Region} \vdash s : \text{Size}}{K \mid \Gamma \mid \Sigma \vdash \textbf{newrgn}\ [s] : (\text{Unit}, \rho) \mid \{\textbf{fresh}\ \rho\ s\} \times \{\textbf{alloc}\ 1\ \rho\}}\ \text{T-NEWRGN}$$

$$\frac{K \mid \Gamma \mid \Sigma \vdash e : (\tau, \rho) \mid \varphi}{K \mid \Gamma \mid \Sigma \vdash \textbf{freergn}\ e : (\text{Unit}, \rho_{\text{glob}}) \mid \varphi \times \{\textbf{free}\ \rho\}}\ \text{T-FREERGN}$$

Figure 4 Expression typing rules in Spegion.

In the typing of expressions, the rule for variables (T-VAR) is straightforward, if the variable is present in the free variable context Γ with type μ then $x : \mu$. The rule for locations (T-USE-VAL) is also straightforward, if the location l_ρ is present in the store typing Σ with type τ then $l_\rho : (\tau, \rho)$.

Creating a new region is handled by the (T-NEWRGN) rule. The **newrgn** construct allocates a new region of size s and has type (Unit, ρ) where ρ is the freshly allocated region. This behaviour is captured in the rule's effect $\{\textbf{fresh}\ \rho\ s\}$, which binds a fresh region name ρ to the size s. Evaluating this expression returns a unit value, which acts as a pointer into the region, allowing this region to be referenced in the subsequent program. This eliminates the need for syntactic region variables in all non-polymorphic code. The allocation of this null value is described in the second part of the effect $\{\textbf{alloc}\ 1\ \rho\}$, i.e., allocate a value of size 1 into ρ (since a value cannot be 0-sized). Thus, we have the additional constraint $s \sqsupseteq 1$ ensuring regions must be able to allocate at least 1 unit of memory.

The rule for freeing a region (T-FREERGN) deletes the region ρ associated with the expression e, freeing its associated memory locations. This yields an effect comprised of the effect of typing e (φ) followed by the effect $\{\textbf{free}\ \rho\}$. Evaluating a **freergn** expression returns a pointer to value of type Unit in the global region ρ_{glob} which is always available.

A sub-region may be split from a region using the (T-SPLIT) rule. As with **freergn**, the region to be split is associated with the sub-expression e. The programmer-defined size s determines the size of the new sub-region, represented by the effect $\{\textbf{split}\ \rho\ s\ \rho'\}$. As in (T-NEWRGN), a null pointer into the new region is created (thus the rule also has an **alloc** effect), and the overall expression has the type (Unit, ρ'), where ρ' is the fresh sub-region.

Copying data between regions is handled by the (T-COPY) rule. The behaviour of **copy** can also be simulated in terms of (T-ASSIGN) and (T-VAL). However, we include the **copy** construct as a useful primitive. The expression **copy** e_1 **into** e_2 copies the location obtained from evaluating e_1 from its region ρ into the region ρ' associated with e_2. The effect of this operation is the composition of the effects obtained from typing e_1 and e_2, followed by the effect $\{\textbf{alloc}\ 1\ \rho'\}$. Locations have a size of 1, thus this effect conveys the creation of a new location in ρ' pointing to location value.

Allocating a value into a region is handled by the T-VAL rule. A programmer is required to annotate the allocation of a value with a size, which is used in the effect $\{\textbf{alloc}\ s\ \rho\}$. Unlike [29], where the region is explicitly passed as an argument to the allocation primitive, our rule allocates the value into the region associated with the sub-expression e. For example, consider the following trivial program:

$$\textbf{let}\ x = \textbf{newrgn}\ [3]\ \textbf{in}\ ()\ [2]\ \textbf{at}\ x$$

which creates a new region of size 3 and allocates a unit value of size 2 into it. This program has the type (Int, ρ) with the effect:

$$\{\textbf{fresh}\ \rho\ 3\} \times \{\textbf{alloc}\ 1\ \rho\} \times \{\textbf{alloc}\ 2\ \rho\}$$

conveying the creation and allocation into a region without ever giving it an explicit name in the program. This allows our calculus to model region-based memory management in languages where these first-class regions are not present in the source language.

Typing rules for let-binding (T-LET), creating a reference (T-REF), dereferencing (T-DEREF), assigning to a reference (T-ASSIGN), and sequential composition (T-SEQ) thus handle the sequencing of the effects of their sub-expressions, but are otherwise straightforward. Similarly, application (T-APP) sequences the effects of the sub-expressions, followed by the function type's latent effect. If statements (T-IF) are typed using a join effect $\{\varphi_1 \sqcup \varphi_2\}$, which is the effect of the true branch φ_1 and the false branch φ_2 combined.

Recursive function definitions are typed by the (T-FIX) rule. The body of the definition is typed with an effect variable in place of the functions actual latent effect. In the rule's third premise, this variable is then substituted for the recursive effect $\{\textbf{rec}\ \epsilon\ \varphi\}$ yielding φ'. In the typing of e_3, f is then bound with the same function type as before but with this new latent effect φ'. This recursive effect conveys that the the effect φ may be repeated an unbounded number of times. This is akin to the notion of "Kleene star effects" [23, 24] and iterable sequential effects [15].

A consequence of recursion is that regions which appear freely in e_1 must be capable of allocating an unbounded amount of memory. This constraint is enforced at the point where the recursive variable effect is composed with another effect in the typing of the function body (via $\times$), since the presence of a ϵ in φ indicates that the function recurses. We provide the definition of valid effect composition in detail in Section 2.3.

Recursive variable usage thus requires that the variable's type scheme be instantiated via the (T-TYAPP) rule, which instantiates the type scheme and region at the type and region provided by the programmer. This is the only rule in the syntax where a region name is required, which can be obtained using a primitive operator regionOf(e).

2.3 Effect Composition

The typing rules above define the individual effects of expressions. However, taken alone an effect does not provide a complete picture of the memory usage of a program. For example, the effect of an allocation is the $\{\textbf{alloc}\ s\ \rho\}$ effect preceded by the effect of the expression which identifies the region being allocated into. However, at the point of typing this allocation, there is no way of knowing if the allocation described by this effect is valid – this can only be known when the effect is composed with the effect which describes the creation of ρ. We describe below the behaviour of the $\times$ operator, which composes two effects. Effects in our calculus are sequential, thus the effect $\varphi \times \varphi'$ describes the effect of φ followed by the effect of φ'. Figure 5 provides the rules for valid effect compositions.

In the ($\times$-$\bot$) and ($\times$-FRESH) rules, composing an effect with $\{\bot\}$ or $\{\textbf{fresh}\ \rho\ s\}$ is always valid. In the latter case we thus assume that SPEGION always has the ability to allocate new regions. An effect which frees a region $\{\textbf{free}\ \rho\}$ is valid only if the region is not already freed in the preceding effect ($\times$-FREE).

Effects which handle allocation must consider three cases. The first ($\times$-FRESHALLOC) is when the entire lifetime of the region up until the point of the current allocation is described in the preceding effects. In this case, the size of the new allocation effect s' must not exceed the current total size of allocations in the ρ. This is enforced by the constraint $\exists s''.s'' + s' + \text{sumAllocs}(\rho, \varphi) \sqsubseteq s$, i.e., there exists some leftover space s'' after adding the size of the new allocation s' to the total size of allocations in ρ. Definition 2.2 defines the function calculating this total size, mapping a region and effect to a size.

▶ **Definition 2.2** (Total Size of Allocations)**.**

$$\text{sumAllocs}(\rho, \varphi) = \begin{cases} s + \text{sumAllocs}(\rho, \varphi') & \varphi = \varphi' \times \{\textbf{alloc}\ s\ \rho\} \\ s + \text{sumAllocs}(\rho, \varphi') & \varphi = \varphi' \times \{\textbf{split}\ \rho\ s\ \rho'\} \wedge \\ s + s' & \varphi = \varphi' \times \varphi'' \wedge \\ & s\ = \text{sumAllocs}(\rho, \varphi') \wedge \\ & s' = \text{sumAllocs}(\rho, \varphi'') \\ \max(s, s') & \varphi = \varphi' \sqcup \varphi'' \wedge \\ & s\ = \text{sumAllocs}(\rho, \varphi') \wedge \\ & s' = \text{sumAllocs}(\rho, \varphi'') \\ 0 & \text{otherwise} \end{cases}$$

$$\frac{}{\varphi \times \{\bot\}}\ \times\text{-}\bot \qquad \frac{}{\varphi \times \{\mathbf{fresh}\ \rho\ s\}}\ \times\text{-Fresh} \qquad \frac{\{\mathbf{free}\ \rho\} \notin \varphi}{\varphi \times \{\mathbf{free}\ \rho\}}\ \times\text{-Free}$$

$$\times\text{-FreshAlloc}\ \frac{\exists s''.s' + s'' + \mathrm{sumAllocs}(\rho, \varphi) \sqsubseteq s}{\{\mathbf{fresh}\ \rho\ s\} \times \varphi \times \{\mathbf{alloc}\ s'\ \rho\}} \qquad \times\text{-Alloc}\ \frac{\{\mathbf{free}\ \rho\} \notin \varphi \qquad \{\mathbf{fresh}\ \rho\ s'\} \notin \varphi}{\varphi \times \{\mathbf{alloc}\ s\ \rho\}}$$

$$\times\text{-SplitAlloc}\ \frac{\exists s''.s' + s'' + \mathrm{sumAllocs}(\rho, \varphi) \sqsubseteq s}{\{\mathbf{split}\ \rho\ s\ \rho'\} \times \varphi \times \{\mathbf{alloc}\ s'\ \rho\}} \qquad \times\text{-FreshSplit}\ \frac{\exists s''.s' + s'' + \mathrm{sumAllocs}(\rho, \varphi) \sqsubseteq s}{\{\mathbf{fresh}\ \rho\ s\} \times \varphi \times \{\mathbf{split}\ \rho\ s'\ \rho'\}}$$

$$\times\text{-Split}\ \frac{\{\mathbf{free}\ \rho\} \notin \varphi}{\varphi \times \{\mathbf{split}\ \rho\ s\ \rho'\}} \qquad \times\text{-SplitSplit}\ \frac{\exists s''.s' + s'' + \mathrm{sumAllocs}(\rho, \varphi) \sqsubseteq s}{\{\mathbf{split}\ \rho\ s\ \rho'\} \times \varphi \times \{\mathbf{split}\ \rho'\ s'\ \rho''\}} \qquad \times\text{-}\sqcup\ \frac{\varphi_1 \times \varphi_2 \qquad \varphi_1 \times \varphi_3}{\varphi_1 \times (\varphi_2 \sqcup \varphi_3)}$$

$$\times\text{-VarR}\ \frac{\forall(\rho \times s) \in \mathrm{freeAllocs}(\varphi).s \sqsupseteq \omega}{\varphi \times \{\epsilon\}} \qquad \times\text{-VarL}\ \frac{\forall(\rho \times s) \in \mathrm{freeAllocs}(\varphi).s \sqsupseteq \omega}{\{\epsilon\} \times \varphi} \qquad \times\text{-Rec}\ \frac{\times[\epsilon \mapsto \{\bot\}]\varphi'}{\varphi \times \{\mathbf{rec}\ \epsilon\ \varphi'\}}$$

Figure 5 Effect composition rules in Spegion ($\times$).

A similar case applies when allocating into a sub-region where the entire lifetime of the region is described in the preceding effects ($\times$-SplitAlloc).

The second case for allocation ($\times$-Alloc) is when the region is not created in the preceding effect, i.e. $\varphi \times \{\mathbf{alloc}\ s\ \rho\}$ where $\{\mathbf{fresh}\ s'\ \rho\} \notin \varphi$. This situation arises when combining two effects in the typing of a sub-term of the expression where the region is created. In this case, the current total size of allocations in ρ is unknown, thus the permissibility of the current allocation effect is unknown. Thus, the allocation is simply accepted as valid with the knowledge that $\varphi \times \{\mathbf{alloc}\ s\ \rho\}$ will eventually be composed with some effect describing the preceding lifetime of ρ, at which point it will be validated by the previous case.

The rules for composing split effects $\{\mathbf{split}\ \rho\ s\ \rho'\}$ behave in a similar manner as allocation ($\times$-FreshSplit), ($\times$-SplitSplit), and ($\times$-Split). The first two rules handle the cases where the entire lifetime of the region is described in the preceding effects, whilst the last rule handles the case where this information is not available.

Composing a join effect $\varphi_2 \sqcup \varphi_3$ with another effect φ_1 is straightforward ($\times$-$\sqcup$). Since both branches of the program must be well-typed, the effect φ_1 is simply composed with both effects. If this is valid then so the composition of the join: $\varphi_1 \times \{\varphi_2 \sqcup \varphi_3\}$.

Effect variables ϵ occur as part of an effect when a recursive function definition is typed. Composition of these effects are handled by the ($\times$-VarR) and ($\times$-VarL) rules. A constraint of recursive function definitions is that regions which occur freely of the function body must be created with an unbounded size ω since it is not possible to know statically how many times the function will recurse. Regions which are created inside the function body itself may be given any size. The addition of a lightweight refinement types would allow us to express and type programs which allocate recursively into a free region under some constraints. We consider this idea in more depth in Section 5.2.

The free regions of the effects $\varphi \times \{\epsilon\}$ and $\{\epsilon\} \times \varphi$ are collected by the function freeAllocs, given by Definition 2.3. This function maps an effect to the set of allocations (and splits) of free regions which occur in the effect. A region is free if there is no $\{\mathbf{fresh}\ s\ \rho\}$ effect in φ.

This set takes the form of pairs of regions and sizes, where $\bot$ is used to indicate that the region was freed inside φ. Since regions of unbounded size are represented by size ω, the only sized allocations that are permitted must also be those of ω. This is enforced by the constraint $\forall(\rho \times s) \in \text{freeAllocs}(\varphi).s \sqsupseteq \omega$.

▶ **Definition 2.3** (Free Region Allocations of an Effect)**.** Given an effect φ, the allocations of regions which are free in φ is given by:

$$\text{freeAllocs}(\varphi) = \begin{cases} \{(\rho \times s)\} & \varphi = \{\textbf{alloc}\ s\ \rho\} \\ \{(\rho \times s)\} \cup \text{freeAllocs}(\varphi') & \varphi = \varphi' \times \{\textbf{alloc}\ s\ \rho\} \wedge \\ & \{\textbf{fresh}\ \rho\ s'\} \notin \varphi' \\ \{(\rho \times s)\} & \varphi = \{\textbf{split}\ \rho\ s\ \rho'\} \\ \{(\rho \times s)\} \cup \text{freeAllocs}(\varphi') & \varphi = \varphi' \times \{\textbf{split}\ \rho\ s\ \rho'\} \wedge \\ & \{\textbf{fresh}\ \rho\ s'\} \notin \varphi' \\ \{(\rho \times 0)\} & \varphi = \{\textbf{free}\ \rho\} \\ \{(\rho \times 0)\} \cup \text{freeAllocs}(\varphi') & \varphi = \varphi' \times \{\textbf{free}\ \rho\} \wedge \\ & \{\textbf{fresh}\ \rho\ s\} \notin \varphi' \\ \text{freeAllocs}(\varphi') & \varphi = \{\textbf{rec}\ \epsilon\ \varphi'\} \\ \text{freeAllocs}(\varphi') \cup \text{freeAllocs}(\varphi'') & \varphi = \varphi' \times \varphi'' \\ \text{freeAllocs}(\varphi') \cup \text{freeAllocs}(\varphi'') & \varphi = \varphi' \sqcup \varphi'' \\ \emptyset & \text{otherwise} \end{cases}$$

Finally, the usage of a recursive function definition is handled via the $\{\textbf{rec}\ \epsilon\ \varphi''\}$ effect. This rule ($\times$-Rec) is straightforward, since the burden of ensuring that free regions in φ'' are unbounded is placed on the ($\times$-VarR) and ($\times$-VarL) rules. The latent effect of the recursive function definition φ'' is simply composed with the preceding effect φ. Effect variables in φ'' are substituted for $\{\bot\}$ since there is no need to recheck the validity of $\{\epsilon\}$ effects.

Effect combination is a partial function, since the combination of some effects is not valid. For example, the combination of two effects which free the same region is invalid. In this case, the function $\times$ is undefined. Undefined compositions are rejected during typing.

We conclude this section with an example of a Spegion program and its typing:

```
let x = newrgn [5] in
in
   (λz.newrgn [5];
      newrgn [5]) [1] at x
```

which defines a function that creates two fresh regions, and is typed as:

$$((\text{Unit}, \rho')\ \xrightarrow{\{\textbf{fresh}\ \rho_1\ 5\} \times \{\textbf{fresh}\ \rho_2\ 5\}}\ (\text{Unit}, \rho_2), \rho) \mid \{\textbf{alloc}\ 1\ \rho\}$$

3 Dynamic Semantics

The relation $\langle e \mid \sigma \rangle \to \langle e' \mid \sigma' \rangle$ means that e reduces to e' in a single step. Unlike the calculus of [17], our reduction rules include an explicit store to enable the use of references. This store is dual layered, with an outer store σ mapping region names ρ to pairs of inner stores $\sigma_\rho^{in\cdot}$, and maximum sizes s:

$$\sigma ::= \quad \emptyset \mid \rho \mapsto (\sigma_\rho^{in\cdot}, s) \qquad \text{(outer store)}$$

This maximum size which is specified by the programmer as an annotation when the store is allocated initially via a **newrgn** expression. Inner stores thus map locations to values:

$$\sigma_\rho^{in\cdot} ::= \quad \emptyset \mid l \mapsto v \qquad \text{(inner store)}$$

Using our store typing context Σ which maps locations to types, we define the following judgement for well-typed stores:

$$K \mid \Gamma \mid \Sigma \vdash \sigma$$

This judgement asserts that all values in the store are coherent with the store typing, and that the total size allocated for each region does not exceed the region's specified maximum size. Figure 6 gives the typing rules for stores.

$$\frac{}{K \mid \Gamma \mid \Sigma \vdash \emptyset}\ \textsc{st-outer-empty} \qquad \frac{\text{currentSize}(\sigma(\rho)) \sqsubseteq s \qquad K \mid \Gamma \mid \Sigma \vdash \sigma \qquad K \mid \Gamma \mid \Sigma \vdash \sigma_\rho^{in\cdot}}{K \mid \Gamma \mid \Sigma \vdash \sigma, \rho \mapsto (\sigma_\rho^{in\cdot}, s)}\ \textsc{st-outer-region}$$

Figure 6 Typing rules of σ.

From these rules a store is well-typed if it is empty (ST-OUTER-EMPTY) or (ST-OUTER-REGION) if each of its inner stores are well-typed, and the total size of values allocated in a region does not exceed the region's maximum size s.

The currentSize function is given by Definition 3.1, mapping inner stores to the total size of values allocated in that inner store, the dynamic counterpart to Definition 2.2 in Section 2:

▶ **Definition 3.1** (Current Size).

$$\text{currentSize}(\sigma_\rho^{in\cdot}) = \begin{cases} \text{currentSize}(\emptyset, s) & = 0 \\ \text{currentSize}((\sigma_\rho^{in\cdot\prime}, l_\rho \mapsto v), s) & = \text{sizeOf}(v) \\ & \quad + \text{currentSize}(\sigma_\rho^{in\cdot\prime}, s) \end{cases}$$

The function sizeOf(v) maps values v to sizes, given by Definition 3.2:

▶ **Definition 3.2** (Value Size). Given a value v, sizeOf(v) is defined:

$$\text{sizeOf}(v) = \begin{cases} 1 + |\text{freeLocs}(e)| & v = (\lambda x.e) \\ 1 + |\text{freeLocs}(e)| & v = (\Lambda\{\alpha, \rho, \epsilon\}.\lambda x.e) \\ 1 & \text{otherwise} \end{cases}$$

where freeLocs(e) returns a list of locations in an expression e.

A separate judgement types the inner store:

$$K \mid \Gamma \mid \Sigma \vdash \sigma_\rho^{in\cdot}$$

asserting that all values in the inner store are coherent with the store typing. The typing rules for inner stores are straightforward and are given in Figure 7.

$$\frac{}{K \mid \Gamma \mid \Sigma \vdash \emptyset}\ \textsc{st-inner-empty} \qquad \frac{\tau = \Sigma(l_\rho) \qquad K \mid \Gamma \mid \Sigma \vdash \sigma_\rho^{in\cdot} \qquad K \mid \Gamma \mid \Sigma \vdash v : \tau}{K \mid \Gamma \mid \Sigma \vdash \sigma_\rho^{in\cdot}, l_\rho \mapsto v}\ \textsc{st-inner-loc}$$

Figure 7 Typing rules of $\sigma_\rho^{in\cdot}$.

$$\textsc{e-newrgn}\ \frac{\rho = \text{freshRegion}() \qquad l_\rho = \text{freshLoc}(\rho)}{\langle \textbf{newrgn}\ [s] \mid \sigma \rangle \longrightarrow \langle l_\rho \mid \sigma, \rho \mapsto (l_\rho \mapsto (), s) \rangle}$$

$$\frac{}{\langle \textbf{freergn}\ l_\rho \mid \sigma \rangle \longrightarrow \langle l^1_{\rho_{\text{glob}}} \mid \sigma \setminus \rho \rangle}\ \textsc{e-freergnL}$$

$$\frac{\rho' = \text{freshRegion}() \qquad (\sigma^{in.}_\rho, s_a) = \sigma(\rho) \qquad l_{\rho'} = \text{freshLoc}(\rho')}{\langle \textbf{split}\ [s]\ l_\rho \mid \sigma \rangle \longrightarrow \langle l'_\rho \mid [\rho \mapsto (\sigma^{in.}_\rho, s_a \dot{-} s)]\sigma, \rho' \mapsto (l_{\rho'} \mapsto (), s) \rangle}\ \textsc{e-splitL}$$

$$\frac{\begin{array}{c}(\sigma^{in.}_\rho, s_a) = \sigma(\rho) \qquad (\sigma^{in.}_{\rho'}, s'_a) = \sigma(\rho') \\ v = \sigma^{in.}_\rho(l_\rho) \qquad l'_{\rho'} = \text{freshLoc}(\rho')\end{array}}{\langle \textbf{copy}\ l_\rho\ \textbf{into}\ l_{\rho'} \mid \sigma \rangle \longrightarrow \langle l'_{\rho'} \mid [\rho' \mapsto ((\sigma^{in.}_{\rho'}, l'_{\rho'} \mapsto l_\rho), s'_a)]\sigma \rangle}\ \textsc{e-copyL}$$

$$\frac{\begin{array}{c}(\sigma^{in.}_\rho, s_a) = \sigma(\rho) \qquad s_v = \text{sizeOf}(v) \\ s_v \sqsubseteq s \qquad l'_\rho = \text{freshLoc}(\rho)\end{array}}{\langle v\ [s]\ \textbf{at}\ l_\rho \mid \sigma \rangle \longrightarrow \langle l'_\rho \mid [\rho \mapsto ((\sigma^{in.}_\rho, l'_\rho \mapsto v), s_a)]\sigma \rangle}\ \textsc{e-valL}$$

$$\frac{(\sigma^{in.}_\rho, s_a) = \sigma(\rho) \qquad (\lambda x.e) = \sigma^\rho_{in.}(l_\rho)}{\langle l_\rho\ l'_{\rho'} \mid \sigma \rangle \longrightarrow \langle [x \mapsto l'_{\rho'}]e \mid \sigma \rangle}\ \textsc{e-appL}$$

$$\frac{}{\langle \textbf{let}\ x : \mu = l_\rho\ \textbf{in}\ e_2 \mid \sigma \rangle \longrightarrow \langle [x \mapsto l_\rho]e_2 \mid \sigma \rangle}\ \textsc{e-letL}$$

$$\textsc{e-ifFalse}\ \frac{\sigma^{in.}_\rho = \sigma(\rho) \qquad \text{false} = \sigma^{in.}_\rho(l_\rho)}{\langle \textbf{if}\ l_\rho\ \textbf{then}\ e_2\ \textbf{else}\ e_3 \mid \sigma \rangle \longrightarrow \langle e_3 \mid \sigma \rangle} \qquad \textsc{e-ifTrue}\ \frac{\sigma^{in.}_\rho = \sigma(\rho) \qquad \text{true} = \sigma^{in.}_\rho(l_\rho)}{\langle \textbf{if}\ l_\rho\ \textbf{then}\ e_2\ \textbf{else}\ e_3 \mid \sigma \rangle \longrightarrow \langle e_2 \mid \sigma \rangle}$$

$$\frac{(\sigma^{in.}_\rho, s_a) = \sigma(\rho) \qquad l'_\rho = \text{freshLoc}(\rho)}{\langle \textbf{ref}\ l_\rho \mid \sigma \rangle \longrightarrow \langle l'_\rho \mid [\rho \mapsto ((\sigma^{in.}_\rho, l'_\rho \mapsto l_\rho), s_a)]\sigma \rangle}\ \textsc{e-refL}$$

$$\frac{(\sigma^{in.}_\rho, s_a) = \sigma(\rho) \qquad l'_\rho = \sigma^\rho_{in.}(l_\rho)}{\langle !l_\rho \mid \sigma \rangle \longrightarrow \langle l'_\rho \mid \sigma \rangle}\ \textsc{e-derefL}$$

$$\textsc{e-assignL}\ \frac{(\sigma^{in.}_\rho, s_a) = \sigma(\rho)}{\langle l_\rho := l_{\rho'} \mid \sigma \rangle \longrightarrow \langle l^1_{\rho_{\text{glob}}} \mid [\rho \mapsto ((\sigma^{in.}_\rho, l_\rho \mapsto l_{\rho'}), s_a)]\sigma \rangle} \qquad \textsc{e-seqNext}\ \frac{}{\langle l_\rho; e_2 \mid \sigma \rangle \longrightarrow \langle e_2 \mid \sigma \rangle}$$

$$\textsc{e-tyApp}\ \frac{}{\langle e\ @\ (\tau, \rho') \mid \sigma \rangle \longrightarrow \langle e \mid \sigma \rangle} \qquad \textsc{e-fixL}\ \frac{\sigma^{in.}_\rho = \sigma(\rho) \qquad \Lambda\{\alpha, \rho, \epsilon\}.\lambda x.e_1 = \sigma^{in.}_\rho(l_\rho)}{\langle \textbf{let}\ f = (f, l_\rho)\ \textbf{in}\ e_3 \mid \sigma \rangle \longrightarrow \langle [x \mapsto l_\rho]e_3 \mid \sigma \rangle}$$

Figure 8 Evaluation rules of Spegion.

Figure 8 gives the reduction rules for Spegion. For brevity, we omit congruence rules which are standard. The complete set of rules can be found in the appendix.

The (E-NEWRGN) rule allocates a new region in the store, with the specified size s, and allocates and steps to a new location that points to a unit value in the fresh region. The (E-FREERGNL) rule simply frees the region ρ from the store and steps to a pointer to the unit value in the global region $l^1_{\rho_{\text{glob}}}$.

Splitting a sub-region off from another region is handled by the (E-SPLITL) rule. The rule makes use of the size semiring's truncated subtraction operation, given by Definition 2.1, to calculate the new reduced maximum size of the parent region ρ. As in (E-NEWRGN), the rule then allocates a new region ρ', then allocates and steps to a location in ρ' pointing to a unit value to act as a pointer to the region.

The (E-COPYL) rule copies a location from one region to another. A fresh location $l'_{\rho'}$ is allocated in the region being copied to (ρ') pointing to the location being copied from ρ (l_ρ).

The reduction rule for allocation (E-VALL) compares the programmer annotated size against the actual size of the value being allocated (calculated via 3.2). If the annotated size is greater than or equal to the actual size, the value is allocated into the region at a fresh location l'_ρ in the store. Type safety guarantees that ρ has enough space to allocate a value of the annotated size. If the annotated size is less than the actual size, the program gets stuck. Type safety also ensures that such a situation should never arise.

The reduction rules for application (E-APPL), let binding (E-LETL), if statements (E-IFFALSE), (E-IFTRUE), referencing (E-REFL), dereferencing (E-DEREFL), assignment (E-ASSIGNL), and sequential composition (E-SEQNEXT) are standard.

Type application (E-BIGAPP) is handled by the rule of the same name, which is a no-op, since it is a purely static construct. Recursive functions are handled by the (E-FIXL) rule, which substitutes the location l_ρ, where the recursive function $\Lambda\{\alpha, \rho, \epsilon\}.\lambda x.e_1$ is stored, for the variable f in e_3.

4 Properties of the Type System

Type safety is guaranteed by Theorems 1 and 2. Theorem 1 states the property of *progress*, i.e, a well-typed closed term is either a value, or can be further reduced. Theorem 2 states the property of type *preservation* (or *subject reduction*), which states that if a term is well-typed and can take a step of evaluation, then the resulting term is also well-typed. The proofs are based on the syntactic type soundness proofs of Helsen and Thiemann [17], and can be found in the extended version of this paper.

▶ **Theorem 1** (Progress). *If*

$$K \mid \Gamma \mid \Sigma \vdash e : (\tau, \rho) \mid \varphi$$

and

$$K \mid \Gamma \mid \Sigma \vdash \sigma$$

then either

i *e is a value or*
ii *e has the form (x) (a variable), with $x \in fv(e)$ or*
iii *there exists an e' such that $\langle e \mid \sigma \rangle \longrightarrow \langle e' \mid \sigma' \rangle$*

▶ **Theorem 2** (Preservation). *If*

$$K \mid \Gamma \mid \Sigma \vdash e : \mu \mid \varphi$$
$$K \mid \Gamma \mid \Sigma \vdash \sigma$$
$$\langle e \mid \sigma \rangle \longrightarrow \langle e' \mid \sigma' \rangle$$

for some Σ' such that

$$\Sigma' \supseteq \Sigma$$

we have that

$$K \mid \Gamma \mid \Sigma' \vdash e' : \mu \mid \varphi'$$
$$K \mid \Gamma \mid \Sigma' \vdash \sigma'$$

where

$$K \vdash \varphi' \sqsubseteq \varphi : \mathit{Effect}$$

From our assumption of store typing correctness, we assert that e is a sub-derivation of some larger derivation e″ for which correctness with regard to region size holds, i.e., given

$$K \mid \Gamma \mid \Sigma \vdash \sigma$$

we have that:

$$\forall \rho \in \sigma . \forall l_\rho \in \sigma^{in \cdot}_\rho . l_\rho \in dom(\Sigma) \wedge sizeOf(\Sigma(l_\rho)) \sqsupseteq sizeOf(\sigma^{in \cdot}_\rho(l_\rho))$$

Finally, we assume the existence of a global region parametrising the calculus which cannot be freed, as well as a location inside this global region of type Unit:

$$\forall \Sigma . l^1_{\rho_{glob}} : \mathit{Unit} \in \Sigma$$

Preservation states that if an expression e is well-typed and has effect φ, and a reduction step can be made, then the resulting expression e' is also well-typed with an updated store typing Σ' and an effect φ' such that $\varphi' \sqsubseteq \varphi$.

$$\frac{K \vdash \varphi_1 \equiv \varphi_2 : \text{Effect}}{K \vdash \varphi_1 \sqsubseteq \varphi_2 : \text{Effect}}\ \text{SB-}\equiv$$

$$\frac{K \vdash \varphi : \text{Effect}}{K \vdash \{\bot\} \sqsubseteq \varphi}\ \text{SB-}\bot$$

$$\frac{K \vdash \varphi_1 \sqsubseteq \varphi_3 : \text{Effect} \qquad K \vdash \varphi_2 \sqsubseteq \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \times \varphi_2 \sqsubseteq \varphi_3 : \text{Effect}}\ \text{SB-}\times_{above}$$

$$\frac{K \vdash \varphi_1 \sqsubseteq \varphi_2 : \text{Effect} \qquad K \vdash \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \sqsubseteq \varphi_2 \times \varphi_3 : \text{Effect}}\ \text{SB-}\times^1_{below}$$

$$\frac{K \vdash \varphi_2 : \text{Effect} \qquad K \vdash \varphi_1 \sqsubseteq \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \sqsubseteq \varphi_2 \times \varphi_3 : \text{Effect}}\ \text{SB-}\times^2_{below}$$

$$\frac{K \vdash \varphi_1 \sqsubseteq \varphi_3 : \text{Effect} \qquad K \vdash \varphi_2 \sqsubseteq \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \sqcup \varphi_2 \sqsubseteq \varphi_3 : \text{Effect}}\ \text{SB-}\sqcup_{above}$$

$$\frac{K \vdash \varphi_1 \sqsubseteq \varphi_2 : \text{Effect} \qquad K \vdash \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \sqsubseteq \varphi_2 \sqcup \varphi_3 : \text{Effect}}\ \text{SB-}\sqcup^1_{below}$$

$$\frac{K \vdash \varphi_2 : \text{Effect} \qquad K \vdash \varphi_1 \sqsubseteq \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \sqsubseteq \varphi_2 \sqcup \varphi_3 : \text{Effect}}\ \text{SB-}\sqcup^2_{below}$$

Figure 9 Subsumption rules for Spegion ($\sqsubseteq$).

The relation $\sqsubseteq$ defines effect *subsumption*. Effect subsumption is used to relate the effects of intermediate terms as a program is evaluated, since evaluation does not preserve syntactic effects. For example, an allocation expression has an effect which contains an allocation effect $\{\mathbf{alloc}\ s\ \rho\}$. However, the reduction step for allocation expressions produces a location, and locations are typed with an empty effect $\{\bot\}$. To the programmer, these intermediate effects are not of interest – the effect of importance is the overall effect of the program. In preservation, however, we ensure that the intermediate effects are related to this overall effect via the subsumption judgement:

$$K \vdash \varphi_1 \sqsubseteq \varphi_2 : \text{Effect}$$

These rules are given in Figure 9. These rules are standard, however, note that we include

$$\frac{K \vdash \varphi : \text{Effect}}{K \vdash \varphi \equiv \varphi : \text{Effect}}\ \equiv\text{-REFL} \qquad \frac{K \vdash \varphi_1 : \text{Effect} \quad K \vdash \varphi_2 : \text{Effect} \quad K \vdash \varphi_1 \equiv \varphi_2 : \text{Effect}}{K \vdash \varphi_2 \equiv \varphi_1 : \text{Effect}}\ \equiv\text{-SYM}$$

$$\frac{K \vdash \varphi_1 \equiv \varphi_2 : \text{Effect} \quad K \vdash \varphi_2 \equiv \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \equiv \varphi_3 : \text{Effect}}\ \equiv\text{-TR}$$

$$\frac{K \vdash \varphi_1 \equiv \varphi_1' : \text{Effect} \quad K \vdash \varphi_2 \equiv \varphi_2' : \text{Effect}}{K \vdash \varphi_1 \times \varphi_2 \equiv \varphi_1' \times \varphi_2' : \text{Effect}}\ \equiv\text{-}\times\text{-CONG}$$

$$\frac{K \vdash \varphi_1 : \text{Effect} \quad K \vdash \varphi_2 : \text{Effect} \quad K \vdash \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \times (\varphi_2 \times \varphi_3) \equiv (\varphi_1 \times \varphi_2) \times \varphi_3 : \text{Effect}}\ \equiv\text{-}\times\text{-ASSOC}$$

$$\frac{K \vdash \varphi_1 : \text{Effect} \quad K \vdash \varphi_2 : \text{Effect} \quad K \vdash \varphi_3 : \text{Effect}}{K \vdash \varphi_1 \sqcup (\varphi_2 \sqcup \varphi_3) \equiv (\varphi_1 \sqcup \varphi_2) \sqcup \varphi_3 : \text{Effect}}\ \equiv\text{-}\sqcup\text{-ASSOC}$$

$$\frac{K \vdash \varphi_1 \equiv \varphi_1' : \text{Effect} \quad K \vdash \varphi_2 \equiv \varphi_2' : \text{Effect}}{K \vdash \varphi_1 \sqcup \varphi_2 \equiv \varphi_1' \sqcup \varphi_2' : \text{Effect}}\ \equiv\text{-}\sqcup\text{-CONG}$$

Figure 10 Effect equality rules for Spegion ($\equiv$).

kinding of effects and we include rules for the join operator $\sqcup$. The (SB-$\equiv$) rule requires a judgement of effect equivalence:

$$K \vdash \varphi_1 \equiv \varphi_2 : \text{Effect}$$

which is given by the rules in Figure 10. Again, these rules are completely standard.

5 Applications

5.1 System Code Examples

Various systems programming idioms are expressible in the language. Below, we present examples first in C and then in Spegion. In each case, the translation is shallow: region-size annotations required by our language can be inferred from the C program. In one example, our language exceeds what can be expressed in C. In all cases, the type system statically recognises memory safety errors.

Use After Free. In the C code below, a struct with two members is allocated, written to, freed, and then erroneously read from. This is *use after free*, a failure of memory safety.

```
struct mine {int a; int b;};

int free_help(int* p) { free(p); }

int main () {
  struct mine *mp = malloc(sizeof(struct mine));
  mp->a = 0;
  mp->b = 1;
  int *bp = &(mp->b);
  free_help(mp);
  return *bp;    // uaf
}
```

The translation of this code to our language is direct: the size of the new region is taken from the call to `malloc` in the C code.

let $r =$ **newrgn** $[2]$ **in**
let $(x, y) = (\mathbf{ref}\ 0, \mathbf{ref}\ 0)\ [2]$ **at** r **in**
let $x := 0\ [1]$ **at** ρ_{glob} **in**
let $y := 1\ [1]$ **at** ρ_{glob} **in**
let $bp = y$ **in**
freergn r;
let $b = !bp$

This program does not pass the static semantics because on the last line, the type effects record that region r was previously freed, and in typing the final line, the T-REF rule requires the region of bp to be live.

Recursion. Below, a function allocates, calls itself recursively, and then frees its prior allocation. There is no memory safety error: despite being nested by the recursion, all of the allocations are matched by frees.

```
int alloc_rec_free (int n) {
  if (n) {
    int *p = malloc(sizeof(int));
    int  v = alloc_rec_free (n - 1);
    free(p);
    return v;
  } else
    return 0;
}

int main () {
  return alloc_rec_free(10);
}
```

The translation uses the **fix** constructor. Again the translation is shallow: none of the additional annotations in our language require any analysis to concoct. Indeed the function's type scheme is empty because it conveys no change to the live regions to its context.

let arf $=$ **fix**(arf, $(\Lambda\emptyset.\lambda n.$
  if $(n == 0\ [1]$ **at** $\rho_{\text{glob}})$ **then**
    let $r =$ **newrgn** $[1]$ **in**

$$
\begin{array}{l}
\quad\quad \textbf{let } p = \textbf{ref } 0\ [1]\ \textbf{at } r\ \textbf{in} \\
\quad\quad \textbf{let } v = (\mathrm{arf}\ @\ \emptyset)\ (n-1\ [1]\ \textbf{at } \rho_{\mathrm{glob}})\ \textbf{in} \\
\quad\quad \textbf{freergn } p; \\
\quad\quad v \\
\quad \textbf{else} \\
\quad\quad 0\ [1]\ \textbf{at } \rho_{\mathrm{glob}} \\
)\ [1]\ \textbf{at } \rho_{\mathrm{glob}})\ \textbf{in} \\
(\mathrm{arf}\ @\ \emptyset)\ (10\ [1]\ \textbf{at } \rho_{\mathrm{glob}})
\end{array}
$$

The static semantics accepts this program and it is memory safe.

Modelling Loops. Loops can be translated to recursive functions. The C code below is analogous to the code above but it uses a loop. The loop body allocates, it records the value of the index and then frees the prior allocation.

```
int main () {
  int v;
  for (int n = 10; n > 0; n--) {
    int *p = malloc(sizeof(int));
    v = n;
    free(p);
  }
  return v;
}
```

The loop is translated into a recursive function whose argument serves as the loop index.

$$
\begin{array}{l}
\textbf{let } \mathrm{loop} = \textbf{fix}(\mathrm{loop}, (\Lambda\emptyset.\lambda n. \\
\quad \textbf{if } (n > 0\ [1]\ \textbf{at } \rho_{\mathrm{glob}})\ \textbf{then} \\
\quad\quad \textbf{let } r = \textbf{newrgn } [1]\ \textbf{in} \\
\quad\quad \textbf{let } p = \textbf{ref } (0\ [1]\ \textbf{at } \rho_{\mathrm{glob}})\ [1]\ \textbf{at } r\ \textbf{in} \\
\quad\quad \textbf{let } v := n\ \textbf{in} \\
\quad\quad \textbf{freergn } r; \\
\quad\quad (\mathrm{loop}\ @\ \emptyset)\ (n-1\ [1]\ \textbf{at } \rho_{\mathrm{glob}}) \\
\quad \textbf{else } () \\
)\ [1]\ \textbf{at } \rho_{\mathrm{glob}})\ \textbf{in} \\
(\mathrm{loop}\ @\ \emptyset)\ (10\ [1]\ \textbf{at } \rho_{\mathrm{glob}}); \\
v
\end{array}
$$

Pointer Arithmetic and Finite Buffers. The C code below produces and consumes packets, serialising them in a buffer. Spegion tracks pointer arithmetic and will catch patterns of use that exhaust the size of the buffer.

```
struct packet {int len; int payload[];};

struct packet * produce (struct packet *p, int data) {
  p->len = sizeof(int);  p->payload[0] = data;
  return p->payload + p->len;
}
```

```
struct packet * consume (struct packet *p, int* sum) {
  *sum += p->payload[0];
  return p->payload + p->len;
}

int main () {
  int sum = 0;
  void *buf = malloc(1000);
  struct packet *pp = buf, *cp = buf;
  pp = produce(pp, 1);  pp = produce(pp, 2);
  cp = consume(cp, &sum);  cp = consume(cp, &sum);
  return sum;
}
```

`main` function translates into the following Spegion. Statically, the loads and stores of calls to produce and consume are checked against the bounds of the region of buf. The return pointers type check, even if they escape the region of buf, matching idiomatic use of pointer arithmetic in C.

let r1 = **newrgn in**
let sum = **ref** (0 **at** r1) **in**
let buf = **newrgn** [1000] **in**
let init = **ref** (initPacket [1] **at** buf) **in**
let (pp, cp) =!init **in**
let pp = produce(pp, 1) **in**
let pp = produce(pp, 2) **in**
let cp = consume(cp, sum) **in**
let cp = consume(cp, sum) **in**
!sum

Non-Lexically-Scoped Lifetimes. The C code of Figure 1 allocates a linked list of three tasks in list order, takes a reference to the last task, and then frees the first two tasks. Spegion can represent and statically type programs like this. The translation is direct:

let re = **newrgn** [1] **in**
let end = 0 [1] **at** re **in**

let r_0 = **newrgn** [2] **in**
let t_0 = (0 [1] **at** ρ_{glob}, end) [2] **at** r_0 **in**
let $(n_0, \text{next}_0) = t_0$ **in**

let r_1 = **newrgn** [2] **in**
let t_1 = (0 [1] **at** ρ_{glob}, end) [2] **at** r_1 **in**
let $(n_1, \text{next}_1) = t_1$ **in**
let $\text{next}_0 = t_1$ **in**

let r_2 = **newrgn** [2] **in**
let t_2 = (0 [1] **at** ρ_{glob}, end) [2] **at** r_2 **in**
let $(n_2, \text{next}_2) = t_2$ **in**
let $\text{next}_1 = t_2$ **in**

let $n_2 = 1$ [1] **at** ρ_{glob} **in**

freergn t_0;

freergn t_1;

let $(n, _) = !t_2$ **in**

n

Splitting. Our language represents idioms that C cannot represent, in particular *splitting*. In this idiom, the programmer creates a region. Subsequently they split the region into a part that is freed, and a part that is kept and used.

C cannot represent this idiom, but the C code below demonstrates the idea. The `alloc2` function mirrors the initial allocation, but to match the limitations of C it is implemented with an indirection and two allocations matching the subsequent split. The first part of the allocation made by `alloc2` is freed, and the second part is used.

```
struct indirect {int* p1; int* p2;};

struct indirect * alloc2 () {
  struct indirect *p = malloc(sizeof(struct indirect));
  p->p1 = malloc(sizeof(int));
  p->p2 = malloc(sizeof(int));
  return p;
}

int main () {
  struct indirect *pr = alloc2();
  *(pr->p2) = 1;
  free(pr->p1);
  return *(pr->p2);
}
```

Our language can represent this programming idiom. The region r is created in one call to **newrgn**, and then split into two parts. These parts can be used as a pair, but they can also be independently freed.

let $r =$ **newrgn** [2] **in**

let $r_1 =$ **split** [1] **in**

let $v_1 = (0$ [1] **at** $\rho_{\text{glob}})$ [1] **at** r_1 **in**

let $v_2 = (0$ [1] **at** $\rho_{\text{glob}})$ [1] **at** r **in**

let $(p_1, p_2) = (v_1, v_2)$ [2] **at** ρ_{glob} **in**

let $p_2 := 1$ [1] **at** ρ_{glob}**in**

freergn p_1;

$!p_2$

5.2 Refinement Types

Refinement types give the programmer the ability to use *predicates* in the type as a means of restricting the values described by the type [11, 22]. For example, the type:

$n : \text{Int} \to \text{Int}\ [n' \mid n' \leq n]$

describes a function from integers to integers which returns a value that must be less than or equal to the input. This is a simple example of a refinement type, but they can be used to encode many forms of specification.

A natural extension of our work would be to incorporate refinement types into our type system, allowing the programmer to reason about region sizes in the types of their programs. In this section we sketch out a simple refinement system based on the approach of Jhala and Vazou [18] that could be used in tandem with SPEGION's region sizes and sized allocations. We define a new sort of *predicates* which can be used in the type system to restrict the values described by a type. This section is mostly a sketch of the ideas, and we leave the full development of the system to future work. We begin with the syntax of predicates:

$$p := \quad x \mid n \mid \text{true} \mid \text{false} \mid p + p \mid p \cdot p \mid \neg p \mid \textbf{if } p \textbf{ then } p \textbf{ else } p \mid f(\overline{p}) \qquad \text{(predicates)}$$

Predicates are drawn from quantifier-free fragment of linear arithmetic and uninterpreted functions [3]. That is, a predicate p may be a variable x, a natural number constant n, boolean constants true and false, the sum or product of two predicates, the negation of a predicate, a conditional, or the application of an uninterpreted function f to a list of predicates. For this section, we extend SPEGION with type annotations and a new list datatype:

$$\text{List } (\tau, \rho) = \text{Nil} : \text{List } (\tau, \rho) \mid \text{Cons} : (\tau, \rho) \xrightarrow{\{\bot\}} \text{List } (\tau, \rho) \xrightarrow{\{\bot\}} \text{List } (\tau, \rho)$$

That is, a list is a value which is either empty or a pair of a value of type (τ, ρ) and a reference to another list. For simplicity the payload of the list must be stored in the same region as the list itself. One could envision a more complex type where the payload and indeed the tail of the list could be stored in separate regions. With the above type we can construct a function which takes an integer n and creates a list in a region of arbitrary size that has length n:

```
let r = newrgn
  in
  let buildList = fix(buildList, Λ{α, ρ, ϵ}λn.
    if n == 0
      then
        Nil at r
      else
        Cons (n, buildList @(Int, regionOf(r)) n − 1)) at r
in ...
```

With refinement types we could constrain this function to only return lists where the size of the list is less than or equal to the size of the region:

```
let r = newrgn [5]
in
  let buildList : ((n : Int, regionOf(r)) -φ-> (List (Int, regionOf(r))) [1 + (2 · n) < 5]) =
    fix(buildList, Λ{α, ρ, ϵ}λn.
      if n == 0
        then
          Nil [1] at r
        else
          Cons (n at [1], buildList @(Int, regionOf(r)) n − 1)) [1] at r
  in ...
```

where $\varphi = \{\textbf{alloc } 1 \text{ regionOf}(r)\} \sqcup (\{\epsilon\} \times \{\textbf{alloc } 1 \text{ regionOf}(r)\})$. Note we remove superfluous $\{\bot\}$ effects from the type annotation for brevity. Thus if we try to apply buildList to the integer 10, this application will fail as the size of the list produced is greater than the

size of the region associated with r. This is just a taste of what the interaction between refinement types and region sizes can offer. We believe that adding refinements to Spegion is a natural extension of the language, with few changes required to the core calculus.

6 Related Work

Key areas of related work for this research relate to the Rust programming language, and effect and region types in programming language design.

6.1 Rust

Rust is a popular systems programming language that aims to statically enforce memory safety, and it has also been the subject of significant academic research. Notable formal work includes Rust Belt [19] and Oxide [31]. The key concepts involved in Rust's approach to enforcing memory safety are *ownership* and *lifetimes*, with the latter corresponding to regions. As a key component of enforcing safety guarantees, Rust often limits or prohibits the introduction of *aliases* of pointers to mutable data, giving it a similar flavour to the substructural type system approaches detailed later in this section. This is, in part, because Rust is also concerned with preventing data races in concurrent code.

The type system might be extended to the concurrent context by reconciling the sequence of effects with the orderings imposed by a declarative concurrency semantics, like those of sequential consistency, ARMv8, or C++, but this is left to future work. Even in sequential code, however, there are difficulties involved in aliasing pointers and (for example) building cyclic data structures.

The following program is rejected by the Rust compiler:

```
fn main() {
    let mut a: i32 = 10;
    let b: &i32 = &a;

    {
        let c: &mut i32 = &mut a;
        *c = 20;
    }
    // use a,b ...
}
```

The compiler will point out `a` being borrowed multiple times (immutably by `b` and mutably by `c`). This program can be represented in our calculus with no issue, as our approach allows arbitray aliasing of mutable references. In general, Rust's expressive type system supports many patterns of memory usage, and we believe there is potential in combining ideas from Rust and from our effect-based approach.

6.2 Effect Types and Region Calculi

There is extensive prior work on using effects and regions in programming language design. Starting in the 1980s, Lucassen and Gifford, among others, explored the development of polymorphic effect type systems [14, 20]. They made use of a *kind* system consisting of types, which describe what sort of value an expression may evaluate to; effects, which describe what side effects may be performed when evaluating an expression; and regions, which describe groups of values in memory that are related. Building upon the idea of associating types with regions, Tofte and Talpin introduced the region calculus and region-based memory management [28, 29], which provided a structured way to control memory in higher order programs by associating types with parameters to statically track their lifetimes.

Region-based memory management formed the basis of ML-Kit, a compiler for Standard ML that used *region inference* to infer region annotations of source programs and statically determine memory usage [4, 25]. Rather than requiring programmers to manually annotate their programs with region/lifetime parameters, the compiler determines them automatically. Subsequent work investigated improving region inference, as it was prone to potentially producing programs that leak memory or unnecessarily extend the lifetime of objects [1, 26]. ML-Kit was augmented with a runtime garbage collector in order to collect memory left around inside regions which had become garbage but had not yet been de-allocated because it lived inside a still-alive region [16].

Existing papers have proven type safety theorems for variations of the region calculus. Helsen and Thiemann give an elegant syntactic proof of type safety for a region calculus with polymorphic types and recursive let-bindings, which was a primary source for the formalism in this paper [17]. They represent region de-allocation by introducing a special "dead" region identifier, and when a region goes out of scope they substitute this special identifier for the now-dead reagion. This also means they do not need to have a phase distinction between handles and region identifiers. However, they do not have a store in their operational semantics, which leads to a straightforward proof but unfortunately does not allow for mutable data. Subsequent work extended this approach with an explicit store, but had to remove polymorphic types [7]. Prior work also investigated proof of soundness for a fragment of the region calculus via a translation into a target language [2].

One of the major issues with using region-based memory management as proposed in the original region calculus is that the lexical scoping of regions means they are required to follow a stack or last-in-first-out (LIFO) ordering. This was observed by Aiken et al., demonstrating that extending the traditional region calculus by removing the LIFO restriction dramatically reduces memory usage (sometimes asymptotically) in functional programs [1]. Like our approach, they de-couple allocation and de-allocation, though their approach is for functional programs without mutable memory. They are also focused on region annotation inference in order to statically determine memory lifetimes of ML programs, and so they do not consider bounding or splitting regions and cannot track fine-grained effect details like an allocation consuming a specific amount of memory in a region.

Relatedly, Boudol presented a monomorphic variant of the region calculus that permitted early de-allocation [5]. A type system tracks both negative de-allocation effects and positive effects such as reads and writes, ensuring that the positive effects on a region cannot occur after the negative effect.

Further work explored adding explicit region allocation and de-allocation to a C-like language, where the safety of region de-allocation relied on keeping track of a dynamic *reference count* for objects in the heap [12, 13].

A prominent line of research that addressed the problem of LIFO lifetimes of regions is the use of *substructural types* in region type systems [10]. The Cyclone programming language, and related work on the calcluls of capabilities, allowed for type-safe manual memory management using a combination of type system features including substuctural types, allowing for both LIFO regions as well as first-class dynamic regions and unique pointers [8, 10]. This style of type system requires that programmers thread resources linearly through programs and avoid creating aliases. In contrast, a primary goal of our system is to avoid imposing this requirement of linearity in programs, and allowing for the aliasing of pointers that occurs in idiomatic imperative code.

Region types have also been used in programming language design for reasons beyond memory management. For example, in Gibbon, region types are used in combination with an effect type system to type programs that create and manipulate serialised data, where each region contains a serialised data structure [30].

7 Conclusion

We have proposed a type system for region-based memory management that allows implicit regions with non-lexical scoping and explicit size constraints. We have proven type safety for this system, and shown several directions in which this system can be extended. Based on this type system, we are currently developing an implementation of Spegion in the form of both an interpreter for Spegion as well as a static analysis tool targeting the C language.

Abstract

Meta-compiler frameworks, such as RPython and Graal/Truffle, generate high-performance virtual machines (VMs) from interpreter definitions. Although they generate VMs with high-quality just-in-time (JIT) compilers, they still lack an important feature that dedicated VMs (i.e., VMs that are developed for specific languages) have, namely *multi-tier compilation*. Multi-tier compilation uses light-weight compilers at early stages and highly optimizing compilers at later stages in order to balance between compilation overheads and code quality.

We propose a novel approach to enabling multi-tier compilation in the VMs generated by a meta-compiler framework. Instead of extending the JIT compiler backend of the framework, our approach drives an existing (heavyweight) compiler backend in the framework to quickly generate unoptimized native code by merely embedding directives and compile-time operations into interpreter definitions.

As a validation of the approach, we developed 2SOM, a Simple Object Machine with a two-tier JIT compiler based on RPython. 2SOM first applies the tier-1 threaded code generator that is generated by our proposed technique, then, to the loops that exceed a threshold, applies the tier-2 tracing JIT compiler that is generated by the original RPython framework. Our performance evaluation that runs a program with a realistic workload showed that 2SOM improved, when compared against an RPython-based VM, warm-up performance by 15%, with merely a 5% reduction in peak performance.

1 Introduction

A *meta-compiler framework* [7, 38] is a system that generates high-performance virtual machines (VMs) from interpreter definitions. Traditionally, VMs were manually implemented by VM developers from scratch, including interpreters, just-in-time (JIT) compilers, and garbage collectors. However, by using a meta-compiler framework, it is possible to generate a VM of comparable quality to traditional VMs simply by defining the interpreter. Currently, there are two frameworks in this domain: RPython [6] and Graal/Truffle [39]. These frameworks have demonstrated their practical effectiveness by generating high-performance VMs such as PyPy [36], Pycket [33], TruffleSqueak [31], and TruffleRuby [38].

Given the importance of multi-tier JIT compilation VMs, efforts have been made with Graal/Truffle to enable a meta-compiler framework to perform multi-tier JIT compilation [35]. The multi-tier JIT compilation VM has multiple execution tiers using different compilation methods or optimization levels to balance code quality and compilation time [1]. In Graal/Truffle's methodology, a single JIT backend is used, and first-tier and second-tier compilations are achieved by gradually enabling or disabling optimizations. However, it has not yet achieved the incorporation of tiers with fundamentally different compilation methods, as has been done in traditional VMs.

Furthermore, as with traditional VMs, enabling a meta-compiler framework to generate a multi-tier JIT compilation VM requires a significant development effort. In traditional VMs, developing a multi-tier JIT compilation VM is more complex than simply implementing multiple compilers. At the least, a VM developer develops multiple compilers with different compilation behaviors – a compiler for rapid compilation speed but generating code with moderate quality, and a compiler for generating quality code – plus a profiler to gather runtime information for switching between different compilers, and a mechanism to transition between code generated by different compilers. Therefore, a framework developer needs to implement these components at the level of a meta-compiler framework.

To address the implementation cost, we propose a novel methodology that enables a meta-compiler framework to generate a multi-tier JIT compilation VM without requiring the development of new JIT compilation backends. Our methodology treats interpreter definitions not only as semantic specifications of the source language but also as specifications of compilation strategies of the meta-compiler. Under our methodology, a VM developer provides interpreter definitions for each compilation tier. Then, RPython can automatically generate the necessary components for multi-tier JIT compilation.

Specifically, the proposed methodology:

(Multiple compilers:) generates a lightweight compiler for rapid code generation during the warm-up phase of a source program, and a heavyweight compiler for optimizing the hot spots of a source program,

(Profiling mechanism:) generates profiling code fragments that dynamically identify hot spots and trigger tier transitions, and

(Transition mechanism:) switches between code generated by different compilers.

To validate our methodology, we implemented a two-level Simple Object Machine, which we call 2SOM for short, on top of the RPython framework. 2SOM is an extended version of PySOM [27] that is an implementation of Simple Object Machine [19] by RPython. 2SOM has two JIT compilers:

(Tier-1:) A threaded code generator, which quickly generates subroutine-threaded code for frequently invoked methods. The threaded code generator is generated by using the RPython's mechanism based on the seminal ideas of Izawa et al. [25] along with several techniques proposed in this paper to make it practical.

(Tier-2:) A tracing JIT compiler, which is generated by RPython [6, 16, 17] and compiles traces with aggressive optimizations to frequently executed loops in the threaded code.

Our approach effectively enables multi-tier JIT compilation for meta-compiler frameworks. Although this paper demonstrates an application to SOM, the proposed approach should also be applicable to other RPython-based language implementations.

To evaluate the effectiveness of the proposed approach, we analyzed the performance of 2SOM with respect to (1) improvement of the warm-up performance for a realistic workload, (2) degradation of peak performance, and (3) quality of the threaded code generator. Our evaluation demonstrates that (1) two-level compilation runs about 15% faster than tracing JIT-only compilation, (2) the degradation is up to about 5% compared to tracing JIT-only compilation, and (3) our contribution improves the code quality of about 10% compared to interpreter execution.

This paper makes the following contributions:

- A novel approach for creating a multi-tier JIT compilation VM using the RPython framework by extending interpreter definitions.
- The optimization of meta-compiler–based threaded code generation [25], addressing practical issues and proposing solutions for integration with meta-tracing JIT compiler frameworks.
- The implementation of 2SOM, the first VM with two JIT compilers – a threaded code generator and a tracing compiler – generated entirely from interpreter definitions.
- A methodology for synthesizing large-scale application programs to evaluate the warm-up performance of the JIT-compiler-based VMs.
- The improvement of warm-up execution speed in 2SOM for synthesized application programs.

The remainder of this paper is organized as follows. Section 2 introduces the techniques underlying our proposal, including JIT and multi-tier JIT compilation, meta-compilation, meta-tracing compilation, and meta-compiler–based threaded code generation. Section 3 discusses the challenges of realizing a multi-tier JIT compilation VM within a meta-compiler framework. Section 4 presents the architecture and technical details of 2SOM. Section 5 identifies practical problems in meta-compiler-based threaded code generation and proposes solutions. Section 6 evaluates 2SOM's performance and discusses the results. Section 7 sets the results into the context of related work, and Section 8 concludes the paper.

2 Background

In this section, we demonstrate the overview and implementation challenges in a multi-tier JIT compiler. Subsequently, we present an overview of the meta-compiler framework. Finally, we introduce meta-compiler–based threaded code generation, a promising technique for lightweight compilation. Finally, we provide an overview of the Simple Object Machine that we used to implement our proposal.

2.1 JIT and Multi-Tier JIT Compilation

In general, most VMs have interpreters as their first execution tier. This is because the interpreter is easy to implement and can perform profiling tasks such as type information collection. For many languages, a VM developer can likely develop a lightweight JIT compiler with moderate effort. A lightweight JIT compiler generates code quickly, but the performance of the generated code is moderate. To achieve the desired performance, heavyweight JIT compilers are implemented. The code that they generate is highly optimized but compilation consumes markedly more time than lightweight JIT compilation.

Most traditional VMs such as Java and JavaScript VMs [32, 26, 13, 18, 34] use multi-tier JIT compilation [1]. A multi-tier JIT compilation VM involves a hierarchy of JIT compilers, each offering different optimization tiers. As the optimization tiers grow in number, compilation time also increases, and the resulting code achieves higher performance. Most multi-tier JIT compilation VMs include at least two lightweight and heavyweight compilers.

Multi-tier JIT compilation dynamically profiles the runtime information of a source program to select the most appropriate compiler for compilation and execution. Additionally, it transitions execution to higher optimization levels when beneficial, thereby enhancing the overall JIT performance.

The early execution phase, evaluated by *warm-up performance*, and the computationally intensive phase, evaluated by *peak performance*, are crucial for improving the VM's overall performance. The lightweight compiler is typically used to accelerate warm-up, whereas the heavyweight compiler focuses on maximizing peak performance. Below, we discuss the relationship between VM execution, warm-up performance, peak performance, and multi-tier JIT compilation in detail.

2.1.1 Warm-up and Peak Performance in Multi-Tier JIT Compilation

Warm-up performance refers to the efficiency during the phase required for a VM to transition from its initial execution. This phase typically involves interpretation or lightweight compilation to a state where the optimized machine code generated by the JIT compiler is actively used. This transition is critical for interactive or short-lived applications, for which execution speed during the early stages of program execution exerts a significant impact on user experience. For long-running server applications, however, warm-up performance is less critical than peak performance.

Peak performance, conversely, represents the maximum level of processing power and resource utilization that a VM can achieve under optimal conditions. This phase is usually reached after the warm-up phase, when the VM is executing fully optimized code. This is particularly important for long-running applications, such as server processes, for which sustained high performance is essential. The C2 compiler in HotSpot JVM [32] is designed to maximize peak performance by leveraging the profiling data gathered during the warm-up phase to generate highly optimized machine code. However, achieving peak performance comes with trade-offs including the overhead of profiling, the complexity of code transitions, and potential inefficiencies caused by suboptimal profiling parameters or compilation strategies.

In the case of HotSpot JVM, the C1 compiler [26] generates moderately optimized code quickly, allowing the application to execute at a reasonable speed while gathering profiling information. This profiling data is then used by the C2 compiler [32] to produce highly optimized code, improving performance over time. However, the extra overhead introduced by tiered compilation, such when as profiling and transitioning between different levels of compiled code, can undermine warm-up performance if not carefully managed.

Multi-tier JIT compilation technique ensures that frequently executed code is greatly optimized and achieves faster peak performance. On the other hand, the code parts that are not frequently executed benefit from quicker compilation, leading to the improvement of warm-up performance. Correspondingly, overall execution performance is improved by tailoring the level of optimization to the usage frequency of each part of the code.

2.2 Meta-Compilation

While interpreters are easy to implement, understand, and extend, implementing a JIT compiler is an error-prone task and requires engineering work-hours summing, at times, to dozens of years.

Meta-compilation reduces the amount of work in implementing an individual JIT compiler by making the JIT compiler reusable and language-independent. A meta-compiler compiles the source program together with the interpreter that runs it. By using both the source code and the interpreter for compilation, meta-compilers can produce highly optimized code that is equivalent to state-of-the-art JIT compilers.

In general, a meta-compiler compiles a source program together with an interpreter that executes the source program. The process involves the following steps:

1. **Hot Spot Identification**: identifying hot spots by executing the interpreter,
2. **Behavior Extraction**: extracting the selected hot spot's behavior, and
3. **Native Code Translation**: translating this behavior into native code.

The current meta-compilation system differs from the method of extracting the hot spot's behavior. The meta-tracing JIT compilation system in RPython [6] traces the interpreter as it executes the hot spot, whereas the self-optimizing interpreter in Graal/Truffle [39] applies partial evaluation to it.

Next, we introduce RPython, which we use as the basis of our proposal.

2.2.1 RPython: A Meta-Tracing Compiler Framework

While traditional JIT compilers compile a frequently executed method as their compilation unit, tracing JIT compilers [2, 16, 3] compile the execution path of a source program called *trace*. Typically, tracing JIT compilers compile a loop in a source program.

The RPython framework [36, 6] uses tracing JIT compilation for its meta-compilation technique. A meta-tracing JIT compiler doesn't trace a source program directly but instead traces the executing interpreter. The RPython framework provides annotations to indicate which part of the interpreter can be a compilation target. For instance, to find a loop in a source program, an annotation is inserted where the back edge of the loop occurs in the interpreter. The meta-tracing compiler starts to trace there when a profiling counter on a back edge exceeds a threshold. Then, tracing continues until it reaches the inserted annotation again. The resulting trace is compiled into machine code, and the subsequent executions of the compiled source program are run in the generated machine code.

To further improve performance, VM developers can use annotations to convey more information to the meta-tracing JIT compiler. For instance, VM developers can specify that certain variables in the interpreter implementation should be constant, allowing for more aggressive optimizations. In addition, by specifying a function as side-effect–free, the meta-tracing JIT compiler can replace the function call with a resulting constant if all of the passed arguments are constant. If not, when the meta-tracing JIT compiler sees the same operation on the same arguments again later, it reuses the result from the previous operation's result. In addition, if inlining a particular function defined in an interpreter would make the performance worse, the developers can avoid inlining that function by specifying an annotation to leave a call instruction on it.

2.3 Meta-Compiler–Based Threaded Code Generation

Threaded code [4, 12, 9, 10] is a form of machine code generated from a bytecode-based source program and its interpreter. Among various types of threading (which include direct threading [4] and indirect threading [9, 10], and subroutine threading [9, 10]) compiles a sequence of bytecode instructions into corresponding call instructions to their respective handlers. Threaded code generation is a lightweight compilation technique, simplifying the process and eliminating the overhead of bytecode fetching and dispatching [14].

Meta-compiler–based threaded code generation [25] is a compilation technique for lightweight compilation that generates subroutine-threaded code using a meta-tracing JIT compiler. Unlike other threaded code generators that develop a compiler from scratch, this approach leverages the interpreter definitions used in the compilation of the meta-tracing JIT compiler. Specifically, it makes use of the annotation mechanisms provided by the RPython framework. For instance, annotations are added to prevent inlining within all handler functions in the interpreter definitions, allowing call instructions to bytecode handlers to be aligned sequentially in the resulting trace. Additionally, while tracing JIT compilers trace only one side of a branch; this technique introduces mechanisms to trace all possible paths in the source program in one shot to compile the entire method. In this way, a new lightweight compilation technique is achieved without creating an entirely new compilation pipeline within the meta-tracing compiler.

The workflow for threaded code generation is illustrated in Figure 2. First, the threaded code generator traces `strange_add` by executing its bytecode, as shown in Listing 2. During this process, it records call instructions to the corresponding handler functions in the trace. When it encounters a branch instruction, such as `JUMP_IF L1`, it first traces the false branch. Upon reaching `RET`, a dummy instruction, `cut_here(return)`, is temporarily added to the trace. The technique then returns to trace the true branch, stopping at `RET` again. The resulting trace, shown in Listing 3, includes only calls to handlers, along with guards, labels, and pseudo instructions such as `cut_here`.

Next, the technique splits the trace into two parts, `Trace A` and `Trace B`, replacing the dummy instructions with actual RPython intermediate representations (e.g., `finish()`). The split traces are shown in Listing 4. Finally, it stitches `Trace B` back into `Trace A` at the guard point, `guard_false(i2)`. This stitched trace is then compiled into the final assembly code, as displayed in Listing 5.

Meta-compiler–based threaded code generation demonstrates promise as a foundation for multi-tier JIT compilation in a meta-compiler framework, because it simplifies the integration of a lightweight JIT compiler within the RPython framework. However, meta-compiler–based threaded code generation was limited to *offline* code generation, and the generated code was not optimized sufficiently. This paper, therefore, proposes optimizations to enable practical code generation (discussed in Section 5).

2.4 Simple Object Machine

Simple Object Machine (SOM) is a dynamically typed language similar to Smalltalk. It is designed as a subset of Smalltalk for the purpose of teaching and researching the implementation of a VM [19]. SOM supports class inheritance, closures, and non-local returns. The SOM family comprises many VM implementations written in C/C++, Rust, Java, Python, and Smalltalk.

Our proposed two-level SOM is based on PySOM. PySOM is a SOM VM that has AST and bytecode interpreters written in RPython. We are going to adopt the bytecode interpreter to implement 2SOM.

Listing (1) Example SOM program.

```
C = (
  calc: n = (
    | x |
    # for ...
    1 to: n do: [ |i|
      x :=
        "Addition: call strange_add"
        x + strange_add: i m: n.
    ] )

  "Newly added method"
  strange_add: n m: m = (
    [ n % 42 == 0 ]
      ifTrue:  [ ^ (m - 42) ]
      ifFalse: [ ^ (n + m) ] )

  "Entry point of this program"
  run = (
    calc: 10000.
  ) )
```

3 Problem

While multi-tier JIT is used to improve performance in widely used VMs, implementing a multi-tier JIT compilation VM is harder than implementing a single-tier JIT compilation VM. The multi-tier option requires at least the following components of VM developers:

(Multiple compiler implementations:) Both lightweight and heavyweight compilers are required, each generating code at different optimization levels, balancing code generation time and execution efficiency.

(Profiling mechanism:) A profiling mechanism is necessary to dynamically determine which compiler to invoke. The profiler measures the execution frequency of methods or loops in an interpreter or in code generated by a lightweight compiler. Profiling data are collected to trigger higher optimization levels for frequently executed code.

(Transition mechanism from code to code generated by different compilers:) A mechanism is required to transition between code generated from different compilers, enabling seamless transitions between different compilation tiers.

Due to these complexities, it is not trivial to generate a multi-tier JIT compilation VM using a meta-compiler framework. Thus, a naïve approach may unnecessarily increase the implementation costs. The primary problem lies in the absence of a mechanism for integrating multiple compilers into such frameworks. One potential approach is to separately implement both lightweight and heavyweight compilers within the framework, coupled with a profiler to trigger transitions and manage the control flow between code from different compilers. While this approach appears feasible, it incurs significant implementation costs comparable to those already associated with traditional VMs featuring multi-tier JIT compilation.

4 Two-Level Compilation by Integrating Meta-Compiler–Based Threaded Code Generation

To address the problems outlined in Section 3, we propose a novel methodology for generating a multi-tier JIT compilation VM with minimal implementation costs. This methodology leverages the RPython framework to generate a multi-tier JIT compiler VM directly from interpreter definitions, reducing the need to implement several necessary components for multi-tier JIT compilation from scratch. As a proof of concept, we generate 2SOM, a two-level multi-tier JIT compiler VM for Simple Object Machine [19], using RPython. We will begin by showing the architecture and behavior of 2SOM in Section 4.1 and then describe how we realize it in Section 4.2.

4.1 Architecture and Behavior of 2SOM

The architecture of 2SOM, illustrated in Figure 3, uses a single meta-tracing JIT compiler for multi-tier JIT compilation to simplify the implementation of multiple compilers. In this architecture, the interpreter controls whether lightweight or heavyweight compilation is applied. The interpreter for lightweight compilation, which is called the *lightweight interpreter* here, generates threaded code [25] in collaboration with the meta-tracing JIT compiler to improve warm-up performance. Conversely, the interpreter for heavyweight compilation (the *heavyweight interpreter*) generates trace-based, highly optimized code for peak performance. To manage runtime integration, 2SOM incorporates a profiler and switcher. The profiler identifies hot spots in code compiled by a lightweight JIT compiler, and the switcher transitions execution to heavyweight compilation when necessary, ensuring

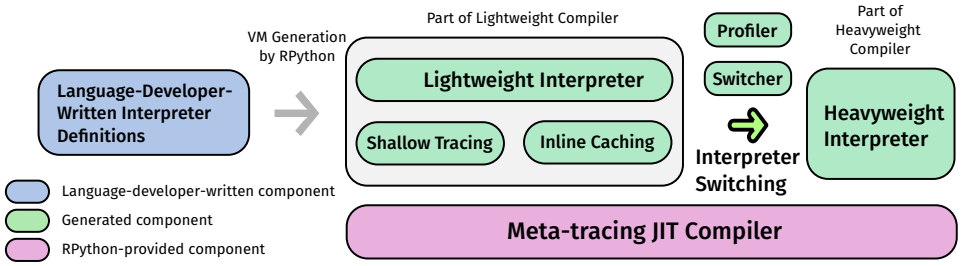

Figure 3 Architecture of 2SOM.

i2 = getarrayitem(p0, 2) # get x
# inlining strange_add
i3 = int_mod(i0, 42)     # n % 42
guard_false(i3)          # n % 42 == 0
i4 = int_add(i1, i0)     # ^(n + m)
# inlining finished
i5 = int_add(i2, i4)     # x + strange..
i6 = int_add(i1, 1)      # incr i
i6 = int_le(i6, i0)
guard_true(i6)
setarrayitem(p0, 1, i6) # set to x
setarrayitem(p0, 2, i5) # set to i
jump(loop)
```

Figure 5 Obtained traces from 2SOM when executing the program shown in Figure 1.

efficient optimization and seamless control flow. The profiler and switcher are implemented as interpreter definitions for the sake of reducing the need to develop complex components from scratch.

Next, we illustrate how 2SOM's multi-tier JIT compilation works, using the program shown in Figure 5 and the traces presented in Figure 5. An overview of 2SOM's execution flow is provided in Figure 4.

As depicted in Figure 4, the execution of 2SOM begins in the lightweight interpreter with the `run` function, which serves as the program's entry point. This function calls `calc:` with an argument of 10,000. The lightweight interpreter then processes the `calc:` function, starting with `initialization: x`. Subsequently, the `initialization` function is compiled into a subroutine-threaded code by the lightweight compiler. Subroutine-threaded code replaces bytecode instructions with direct calls to operation handlers, ensuring efficient execution with minimal overhead compared to heavyweight compilation. The trace obtained from this process is shown in Listing 6.

After initialization, the `calc` function enters a loop that iterates from 1 to `n`. Within this loop, the result of `strange_add: i m: n` is repeatedly added to `x`. The `strange_add: i m: n` function is initially compiled by the lightweight compiler. This loop involves frequent backward jumps, which are monitored by an embedded profiler in the code compiled by the lightweight interpreter, as depicted by Figure 4. Once the frequency of these backward jumps surpass a predefined threshold, the profiler identifies the loop as a "hot" spot suitable for more aggressive optimization.

At this stage, the interpreter switcher transfers control from the lightweight interpreter to the heavyweight interpreter. The interpreter switcher recovers the frame used by the lightweight interpreter and passes it to the heavyweight interpreter for continued execution. The heavyweight interpreter performs trace-based compilation, applying advanced techniques such as loop unrolling and inlining. The tracing JIT compiler then compiles the entire loop, inlining and optimizing the `strange_add` function. Hence, the remainder of the loop executes using highly optimized machine code generated by the heavyweight compilation tier, thereby improving efficiency while maintaining correctness. The corresponding trace is presented in Listing 7.

4.2 Technical Details

In this section, we describe the technical details of realizing 2SOM. We describe how each of the three elements essential for realizing two-level JIT compilation in 2SOM is achieved, specifically using interpreter definitions and the RPython framework.

4.2.1 Multiple Compiler Implementations

To enable multi-tier JIT compilation without the complexity of implementing multiple distinct compilers, we introduce meta-compiler–based threaded code generation [25] into RPython. Consequently, RPython can generate both generator and compiler from the two interpreter definitions with different specifications of compiler strategies. In this setup, the meta-compiler-based threaded code generation works as a lightweight compiler, while the tracing JIT compiler serves as the heavyweight compiler.

Using this technique minimizes the development and maintenance overhead associated with creating and supporting multiple compilers. Additionally, VM developers can leverage the interpreter annotations and hints provided by RPython to further customize the compilation process, tailoring optimization levels to the unique requirements of their language.

To illustrate this technique, we provide examples of implementing a heavyweight compiler, which will be followed later by a lightweight compiler example.

For the heavyweight compiler, we use the original interpreter definition originally provided by the RPython framework. In this interpreter, a `jitdriver` is created to configure the constant variables (greens) and varying variables (reds) in the dispatching loop. Also, hints are used to guide the JIT compiler in optimizing frequently executed code paths. The hint

Listing 8 Lightweight interpreter for threaded code generation.

```
# greens: names of constant
# reds: varying variables (reds)
threadeddriver = JitDriver(
  greens=['bytecodes','pc'],
  reds=['frame'],
  threaded_code_gen=True)

def threaded_interpret(frame):
  # entry point of lightweight compilation
  threadedriver.can_enter_jit(frame=frame,
   bytecodes=frame.bytecodes, pc=frame.pc)

  while True:
    # indicate dispatch loop to
    # the meta-tracing compiler
    threadedriver.jit_merge_point(
      frame=frame,
      bytecodes=frame.bytecodes,
      pc=frame.pc)

    opcode = frame.bytecodes[frame.pc]
    if opcode == ADD:
      handler_add(frame)
    elif opcode == SUB:
      handler_sub(frame)
    # ... other handlers ...
    frame.pc += 1

@enable_threaded_code
def handler_add(frame):
  w_y = frame.pop()
  w_x = frame.pop()
  frame.push(w_x.add(w_y))

# ... other handler functions ...
```

Listing 9 Heavyweight interpreter for tracing compilation.

```
tracingdriver = JitDriver(
  greens=['bytecodes','pc'], reds=['frame'])

def tracing_interpret(frame):
  while True:
    # indicate dispatch loop to
    # meta-tracing compiler
    tracingdriver.jit_merge_point(
      frame=frame,
      bytecodes=frame.bytecodes,
      pc=frame.pc)
    opcode = frame.bytecodes[frame.pc]

    # handle back-ward jump
    if opcode == JUMP_BACKWARD:
      # entry point of heavyweight
      # compilation
      tracingdriver.can_enter_jit(
        frame=frame,
        bytecodes=frame.bytecodes,
        pc=frame.pc)

    elif bytecode == ADD:
      handler_add(frame)
    elif bytecode == SUB:
      handler_sub(frame)
    # ... other handlers ...
    frame.pc += 1

def handler_add(frame):
  w_y = frame.pop()
  w_x = frame.pop()
  frame.push(w_x.add(w_y))

# ... other handler functions ...
```

`jit_merge_point` tells the meta-tracing JIT compiler the part of interpreter-dispatching loop, and the `can_enter_jit` informs an entry point of the JIT compilation to the meta-tracing JIT compiler.

The heavyweight interpreter is defined as displayed by Listing 9. The interpreter guides the meta-tracing JIT compiler to perform heavyweight compilation. To indicate the place of the dispatching loop, the `jit_merge_point` hint is placed just after `while True: ...` To compile the loop of a source program, `can_enter_jit` hint is placed at the handler for `JUMP_BACKWARD`, which corresponds to the back-edge jump in a source program.

For the lightweight compiler, we define an interpreter that enables the meta-tracing JIT compiler to perform meta-compiler-based threaded code generation. The major differences from the heavyweight interpreter are that all handlers are annotated with `enable_threaded_code` and the placement of `can_enter_jit`. The `enable_threaded_code` annotation serves as an instruction to retain calls to handlers in the trace. Moreover, to compile the method body, `can_enter_jit` is placed at the very beginning of the method call–that is, just before the interpreter is invoked and enters the dispatching loop.

The lightweight interpreter is defined as shown in Listing 8. The handlers `handler_add` and `handler_sub` are decorated with the annotation `enable_threaded_code`, and the placement of `can_enter_jit` is moved to just before the entry of the dispatching loop.

Listing 10 Embedded profiler in the interpreter

```
HOT_THRESHOLD = 1000

def threaded_interpret(frame):
  while True:
    opcode = frame.bytecodes[frame.pc]

    # backward jump should be
    # compiled by heavyweight compiler
    if opcode == JUMP_BACKWARD:
      # increment the counting value
      count = frame.counts.get(frame.pc,0)+1
      frame.counts[frame.pc] = count

      if count == HOT_THRESHOLD:
        # Trigger heavyweight compilation
        raise ContinueInTier2(frame)

    # ... Execute other opcodes ...
    frame.pc += 1
```

Listing 11 Interpreter switcher that dispatches from lightweight to heavyweight interpreters

```
def interpet_switcher(bytecode):
  frame = Frame(bytecode)
  while True:
    try:
      # Start interpretation first
      # in lightweight interpreter
      w_x = threaded_interpret(frame)
    except ContinueInTier2 as e:
      # Catch thrown ContinueTier2
      # from a generated threaded code,
      # and Continue to execute in
      # heavyweight interpreter
      w_x = tracing_interpret(e.frame)
    return w_x
```

4.2.2 Profiling Mechanism

Integrating different compilers requires a mechanism to decide when to trigger heavyweight compilation during executing code generated by a lightweight JIT compiler. We achieve this by generating code fragments that can profile runtime information in the code compiled by a lightweight JIT compiler. These generated profilers are responsible for monitoring the execution frequency of code spots and triggering recompilation at higher optimization levels when necessary.

The profiler works using a simple frequency counter that increments each time a particular code spot, such as a method or loop, is executed. When the counter exceeds a predefined threshold, the profiler determines that the code spot is "hot" and would benefit from additional optimization. At this point, the profiler triggers the heavyweight tracing JIT compilation for that spot.

Under our methodology, this profiling mechanism provides a flexible method to manage multiple compilers generated by RPython. VM developers can adjust the thresholds and profiling strategies to suit the dynamic behavior of their language in their interpreter definitions.

The example definition of the profiler is depicted in Listing 10. This profiler monitors the execution of specific opcodes. In this definition, backward jumps – typically indicating loops – are identified as key candidates for heavyweight compilation. When a backward jump opcode (`JUMP_BACKWARD`) is encountered, the profiler increases a counter tied to the program counter (`frame.pc`) stored in the `frame.counts` dictionary, which tracks execution frequencies for each opcode.

If this counter exceeds the predefined `HOT_THRESHOLD` (set to 1000 in this case), the profiler marks the code spot as "hot" and suitable for further optimization. At this point, the profiler triggers heavyweight compilation by using a global jump. Because RPython does not provide global jumping, we use an exception mechanism instead. This exception, called `ContinueTier2`, halts the lightweight interpreter and switches control to the heavyweight interpreter. To make the transition work correctly, the exception contains an execution context. The exception is used in the transition mechanism described in Section 4.2.3.

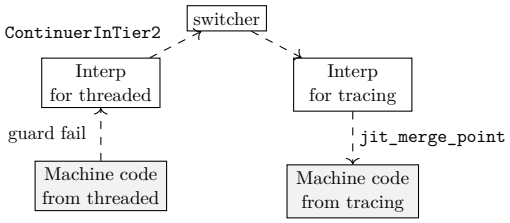

Figure 6 Overview of interpreter switching technique.

4.2.3 Transition Mechanism Between Generated Code

Finally, we need a mechanism to effect transitions from code generated by a lightweight JIT compiler to that generated by a heavyweight JIT compiler. This is achieved through the *interpreter switching* technique, which redirects the execution in code compiled by the lightweight compiler to the code compiled by the heavyweight compiler.

We overview the technique in Figure 6. When the profiler, the function of which is explained in Section 4.2.2, detects a hot spot suitable for tracing JIT compilation, a guard fail occurs. Then, a global jump from code generated by a lightweight JIT compiler to the lightweight interpreter happens. Next, the lightweight interpreter throws an exception to move to the interpreter switcher. The switcher catches it and resumes the execution context. Next, it launches the heavyweight interpreter with the resumed execution context. If the running program is already compiled by the heavyweight compiler, the control goes to the compiled machine code via `jit_merge_point`. Otherwise, the program is interpreted and will be compiled via `can_enter_jit` in the heavyweight interpreter.

The interpreter switcher is implemented as described in Listing 11. The `interpret_switcher` function handles this transition. It starts with the lightweight interpreter and, upon catching a `ContinueTier2` exception thrown from `threaded_interpret`, passes the execution context (`e.frame`) to the heavyweight interpreter `tracing_interpret`. Both interpreters return a result, `w_x`, to the caller, ensuring consistent execution flow.

Together with the profiling and interpreter switching technique explained in sections 4.2.2 and 4.2.3, we can maintain correctness while optimizing performance. By leveraging the interpreter for managing transitions, the framework provides a basis for multi-tier JIT compilation.

However, this mechanism can introduce significant runtime overhead because the control bypasses the interpreter when it goes to other code. We evaluate the overhead by measuring the peak performance of 2SOM's two-level compilation in section 6.

5 Improving Meta-Compiler–Based Threaded Code Generation

In 2SOM, we use meta-compiler–based threaded code generation [25] for lightweight compilation. However, its integration with a meta-tracing JIT compiler in 2SOM has exposed problems, as the earlier implementation [25] focused solely on code generation. Therefore, we analyzed the technical problems that arise when introducing meta-compiler–based threaded code generation to the meta-tracing compiler framework and introduced a new technique and optimization to enhance its efficiency and compatibility within the meta-tracing JIT compiler.

Listing 12 Example of SOM program that has a side effect.

```
"Compute the sum of arr"
strange_sum_arr: arr index: i
  sum: n = (
  [ i <= arr length ]
    ifTrue: [
     sum_array: arr
      index: (i + 1)
      sum: (n + (arr at: i)).
    ]
    ifFalse: [
     "Clear all the elements"
     arr clear. ^ n  ] )

"Entry point"
run = (
  | arr |
  "Create an array where"
  "all elements are 1"
  arr :=
    Array new: 30 putAll: 1.
  strage_sum_arr: arr
    index: 1 sum: 0. )
```

Listing 13 Simplified bytecode from Listing 12.

```
strange_sum_arr:
 DUP0 # arr
      # arr length
 CALL(length, frame)
 DUP2 # i
 LE   # i <= arr length
 JUMP_IF_FALSE L1
 DUP1 # i
 CONST 1
 ADD  # i + 1
 DUP1 # arr
 CALL(at, frame)
      # arr at: i
 DUP2 # n
 ADD  # n + (arr at: i)
 JUMP strange_sum_arr
L1:
 DUP0 # arr
 CALL(clear, frame)
 DUP2 # n
 RET
```

Listing 14 Handler function that interprets `CALL` instruction.

```
def threaded_interpret(frame):
  ...
  while True:
    ...
    if opcode == CALL:
      handler_CALL(frame)
```

```
    # ... XXX ...

@dont_look_inside
def handler_CALL(frame):
  method = frame.bytecodes[frame.pc+1]
  newframe = crate_frame(frame, method)
  w_x = threaded_interpret(newframe)
  frame.push(w_x)
```

5.1 Runtime Problem of the Meta-Compiler-Based Threaded Code Generation

Meta-compiler–based threaded code generation exhibits unsatisfactory runtime execution and performance. In particular, the following technical problems occur when we use it in 2SOM.

1. If the definition of the lightweight interpreter has side effects, tracing the lightweight interpreter leads to an incorrect state due to tracing both conditional branches in a row.
2. Function calls always become indirect in the compiled code.

The first problem occurs because meta-compiler–based threaded code generation and tracing JIT compilation use different compilation scopes (method-based for the threaded code generation and trace-based for tracing compilation) but rely on the same compilation engine. For example, when performing threaded code generation, as described in the previous section, branches in the code are linearized into a single sequence during tracing. This means that even branches that would not be executed during actual program runs are included in the trace. If these unnecessary branches are executed during tracing, it can lead to an invalid runtime state.

Consider a simple `if-then-else` statement where the `then` branch is always taken during execution. During threaded code generation, both branches are traced at compilation time as described in Section 2. Although the meta-tracing JIT compiler executes the source

program with the interpreter at compilation, tracing the `else` branch can modify variables or states, causing inconsistencies. For example, the program in Listing 12[1] computes the sum of an array: the `then` clause (receiver of `ifTrue`) adds each value to `n`, while the `else` clause (receiver of `ifFalse`) returns `n`. However, executing the `clear` function in the `else` clause, which sets the array to zeros, corrupts the runtime state if na"ively traced by the meta-compiler–based threaded code generation.

The second problem arises because the meta-tracing JIT compiler could not identify the target of a handler function wrapped in a call instruction during tracing, when the handler represented a method invocation. In general, calling a dynamically bound method takes longer time than calling a statically bound method. This is because a system needs to look up a correct method by using the runtime class of a callee method. The same kind of problem occurs in threaded code generation.

For example, consider a handler function `handler_CALL` that dynamically dispatches a method call as illustrated in Listing 14. During tracing, the meta-tracing JIT compiler encounters the call instruction for `handler_CALL` but cannot identify the callee method compiled at tracing. Without knowing whether the target method is compiled, the compiler cannot optimize the method call, which leads to worse performance.

In meta-compiler–based threaded code generation, this could result in repeated interpretation or inefficient indirect calls, even if the invoked method is a commonly used one that would benefit from inlining or specialized optimizations. This lack of optimization is particularly problematic for workloads with frequent method invocations, as it leads to missed performance improvements.

5.2 Our Solutions

In this section, we show the solutions, namely, shallow tracing and direct calls by inline caching to the first and second problems.

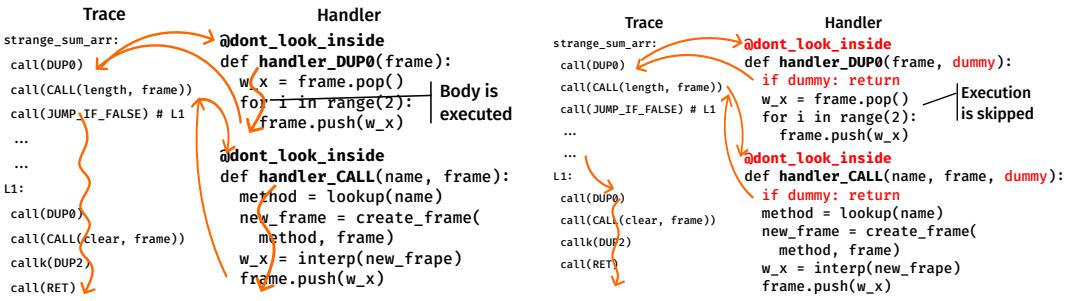
5.2.1 Shallow Tracing

For the first problem, we propose the *shallow tracing* technique. Shallow tracing prevents side effects during tracing by introducing lightweight annotations within the interpreter. These annotations guide the tracing process to leave only call instructions to handler functions, while the actual execution of these handlers is avoided. In contrast, during the interpretation and execution of generated machine code, the annotations have no effect, ensuring seamless runtime execution.

The fundamental reason for needing shallow tracing lies in the fact that, while the `dont_look_inside` annotation retains the call instruction to the handler function, it still executes the function's body, using the interpreter's state. This is not a problem in standard tracing compilation. However, in method-based threaded code generation, both branches of a conditional are traced. If side effects occur during the tracing of one branch, they propagate to the tracing of the other branch, corrupting the interpreter's state.

Shallow tracing suppresses the execution of the body that would otherwise occur under `dont_look_inside`. This technique relies on the following two key annotations and the dummy flag mechanism:

[1] Its simplified bytecode appears in Listing 13.



(a) Flow of tracing before applying shallow tracing. The left-hand side and right-hand side show the trace and the handler functions, respectively.

(b) Flow of tracing after applying shallow tracing. The left-hand side and right-hand side show the trace and the handler functions, respectively.

Figure 7 The problem with naïvely integrating meta-compiler-based threaded code generation with a meta-tracing JIT compiler (left-hand side), and our solution to it (right-hand-side). In each side, orange lines are the flow of tracing. In naïve integration, the body of the handler function is executed during tracing, which can lead to side effects that corrupt the interpreter's state. To resolve this, we introduce shallow tracing, a technique that prevents the execution of the handler function's body during tracing, thereby avoiding such side effects.

- `we_are_jitted`: Checks whether the execution is currently within a traced and compiled context, and
- `dont_look_inside`: Ensures that only call instructions to annotated functions are traced without inlining their bodies of annotated functions, and
- `dummy` flag mechanism: the dummy flag is inserted into every handler. It is turned into `True` inside the then branch conditioned with `we_are_jitted`. When this flag is on, the dummy return is triggered. When this trace is compiled and executed, the dummy flag is turned into `False`, allowing the handler's body to execute correctly.

Its overall execution flows are compared in Figure 7: the left-hand side illustrates the trace without shallow tracing, while the right-hand side shows the execution flow with shallow tracing applied. Shallow tracing introduces a *dummy flag* and a *dummy return* for each handler (except for control-flow–related handlers like `JUMP_IF_FALSE`). Also, the implementation in an interpreter and the resulting trace are shown in Listings 15 and 16, respectively.

5.2.1.1 Optimizing Shallow Tracing

Manually implementing the code in Listing 15 is complex and time-consuming for VM developers. Naïve insertion of a dummy flag into handlers also risks performance overhead. To address this, we automate the interpreter generation at VM generation time, while optimizing shallow-tracing code by eliminating redundant `dummy` flag checks.

We introduce a new annotation, `enable_threaded_code`, to automate this process. Annotated handlers are automatically marked with `dont_look_inside` and a dummy flag, and their call sites are wrapped with `we_are_jitted`, leveraging the RPython VM generation process [36]. Developers only need to annotate each handler function, as shown in Listing 17, and the annotated interpreter is transformed into the structure in Listing 18.

To mitigate the dummy flag overhead, we apply a two-step optimization. First, for each annotated handler, we generate both a stub handler (with a dummy check) and a real handler (without the check) under the same name. Second, during shallow tracing, only stub handlers

Listing 15 Naïve version of an interpreter that supports shallow tracing.

```
def threaded_interpret(frame):
  while True:
    opcode = frame.bytecodes[frame.pc]
    if opcode == ADD:
      # returns true while tracing and
      # executing machine code
      if we_are_jitted():
        # set 'dummy' True
        # to avoid side-effects
        handler_add(frame, dummy=True)
      else:
        # set 'dummy' False
        # execute body
        handler_add(frame, dummy=False)

    elif opcode == SUB:
      if we_are_jitted():
        handler_sub(frame, dummy=True)
      else:
        handler_sub(frame, dummy=False)
    # ... other handlers ...
    frame.pc += 1

# leaves only handler call but
# executes the body
@dont_look_inside
def handler_add(frame, dummy):
  # immediately return when dummy
  # is true to avoid side-effects
  if dummy: return
  w_y, w_x = frame.pop(), frame.pop()
  frame.push(w_x.add(w_y))

@dont_look_inside
def handler_sub(frame, dummy):
  if dummy: return
  # ... subtract two elements in
  # frame.stack ...
```

Listing 16 Naïve version of a generated trace by shallow tracing.

```
label(strange_sum_arr)
call(handler_DUP, p0, True)
call(handler_CALL, "length", p0, True)

label(L1)
call(handler_DUP0, p0, True)
call(handler_CALL, "clear", p0, True)
finish()
```

are traced to build the instruction-to-handler mapping; after tracing, they are replaced with real handlers at compile time. Listings 19 and 20 show the traces before and after this optimization.

5.2.2 Direct Calls with Inline Caching

Inline caching [11] is a well-known runtime optimization technique used to accelerate method dispatch in object-oriented programming languages such as Smalltalk-80, SELF, and Java. It optimizes method calls by caching method lookups directly at the call site, avoiding redundant type resolution when the same types are repeatedly encountered. If the cached type matches the runtime type of the receiver, a fast path is taken; otherwise, the system falls back to a slow path for dynamic method resolution [20].

In the absence of inline caching in meta-compiler–based threaded code generation, method calls to compiled code are executed as indirect calls. Such calls bypass `jit_merge_point`, which can lead to significant performance degradation when methods are invoked repeatedly. Direct calls with inline caching alleviate this by converting indirect calls into direct calls, thereby improving execution speed. Figure 8 provides an overview of this transformation at runtime, revealing the transition from indirect to direct calls enabled by inline caching.

To integrate inline caching efficiently, we leverage the annotation mechanism of the RPython framework instead of implementing it from scratch. Inline caching is realized by instrumenting the interpreter with runtime type collection, validation, and direct call conversion. During interpretation, runtime type information – such as the receiver's type and the associated method – is collected. This collected type information is then validated at runtime, enabling the conversion of indirect calls into direct calls.

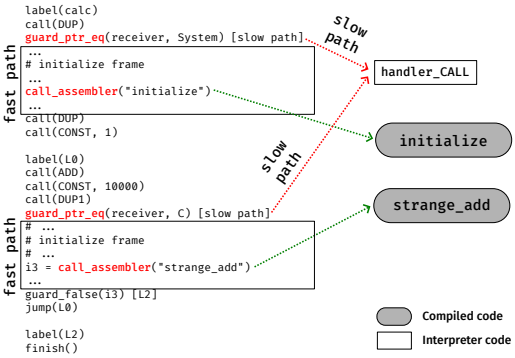

Figure 8 Overview of direct calls with inline caching.

Listing 21 Interpreter definition instrumented for inline caching

```
def threaded_interpret(frame):
  while True:
    jit_merge_point(..)
    ...
    if opcode == CALL:
      # check whether the runtime type of
      # this method equals to the
      # recorded runtime type
      method = frame.stack[frame.pc]
      if check_type(method, frame.pc):
        # if it matches, calling the
        # method with call_assembler
        call_assembler(interp(frame))
      else:
        # otherwise, call handler_CALL
        handler_CALL(frame)

def handler_CALL(frame):
  method = pop(stack)
  if not we_are_jitted():
     # during interpreting (not jitted),
     # record runtime method types at pc
     record_type(pc, method.type)
  r = threaded_interpret(frame)
  frame.push(r)
```

At runtime, our inline caching implementation works as follows:

- Fast Path: If the runtime type matches the cached type, the system directly calls the compiled method using the `call_assembler` instruction.
- Slow Path: If the type validation fails, the system falls back to the `handler_CALL` function, which dynamically resolves the method and records type information for future optimizations.

The implementation uses the RPython annotation mechanism. Two annotations were originally developed:

- `record_type`: records the runtime type of a method during interpretation.
- `check_type`: validates the runtime type against the cached type.
- `call_assembler`: performs the direct call to the compiled method.

Listing 21 illustrates how these annotations are used in the interpreter:

Based on the implementation, the compilation with direct calls with inline caching works as follows:

1. During interpretation, the `handler_CALL` function records the runtime type of the receiver using the `record_type` annotation.
2. During tracing, the `CALL` handler, `check_type` validates the runtime type of the receiver. If the validation succeeds, the `call_assembler` instruction is invoked to perform a direct call to the compiled method.
3. During compilation, `check_type` is transformed into a guard instruction that ensures the receiver type matches the recorded type. Similarly, `call_assembler` is converted directly into an assembler call instruction in the resulting trace.

6 Evaluation

In this section, we address the three questions introduced at the beginning of this paper by evaluating the performance of the two-level compilation implemented in 2SOM. We begin by describing the benchmarking programs and the execution environment used in the evaluation. Each research question is then addressed by analyzing both the warmup performance and peak performance of two-level compilation and meta-compiler–based threaded code generation using 2SOM. Since the measurement methods differ for each case, they are described in separate sections of their own.

6.1 Methodology

Throughout this evaluation, we basically use the SOM benchmarks [28], an extended version of the Are We Fast Yet benchmark [30], which includes programs such as PageRank and graph search algorithms.

To answer Q1 and Q2 in particular, we should analyze the performance of two-level JIT using real-world large-scale programs. However, SOM benchmark suite does not have such programs. Thus, we synthesize a program that has workloads similar to real-world large-scale programs.

First, we examined the relationship when methods in the DaCapo benchmark [5] were sorted in descending order based on the number of method calls. Using the least squares method to analyze this relationship, we found that the R^2 value exceeded 0.98, indicating a high correlation. Therefore, we aimed to approximate the ranking correlation between DaCapo's method call counts and the method order using the SOM benchmark suite.

We generated 20 variants of *synthesized benchmark program* using the following procedure: (1) place each program SOM's benchmark suite in order, (2) manually tune the number of internal iterations for each program so that the correlation between DaCapo's method call counts and method ranks is as close as possible. (3) Finally, from the program created in steps (1) and (2), generate the remaining 19 variants by randomly shuffling the program execution order.The details are described and discussed in Appendix A of the extended version [24].

In Q1, we measure the elapsed time obtained from the first iteration of each program and repeat this measurement 2,000 times. We calculate their medians, averages, and variances.

We evaluate the warm-up and peak performances against six execution modes:

- Interpreter-only execution: execution using 2SOM's interpreter without any form of compilation.
- Threaded code generation: meta-compiler–based threaded code generation implemented in 2SOM, offering a lightweight approach to improving execution efficiency.
- Tracing JIT: execution utilizing RPython's meta-tracing compiler.
- Tracing JIT with high threshold: A variation of the tracing compilation where the compilation threshold is increased by a factor of three. This configuration is designed to investigate the fundamental differences between a higher-threshold tracing and two-level JIT compilations.
- Two-level JIT: A combined strategy that combines both threaded code generation and tracing compilation, leveraging the strengths of both techniques for improved execution performance.
- TrufleSOM: execution using TruffleSOM, which is another SOM built with the Truffle framework [39], to compare the performance of 2SOM with a different language implementation. Note that multi-tier JIT compilation [35] is enabled.

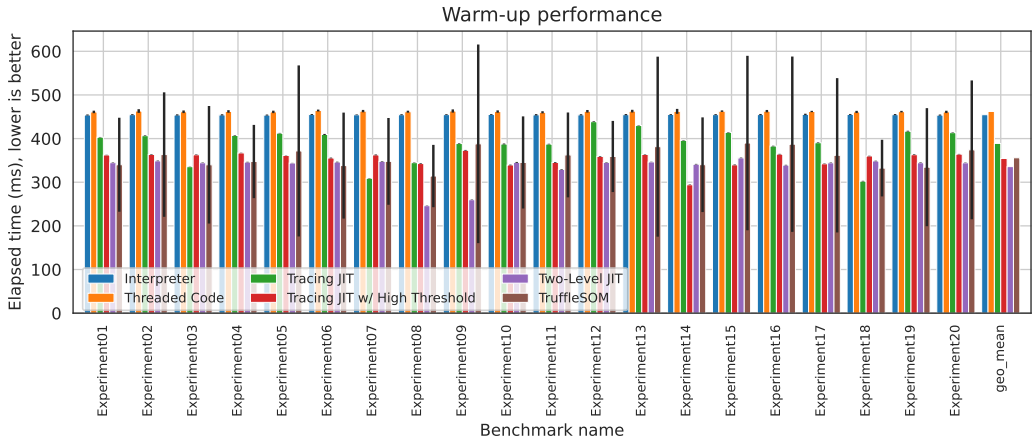

Figure 9 Warm-up performance (execution time of the first iteration).

In Q2, we evaluate the peak performance of 2SOM. We use the synthesized programs used in Q1 in addition to the SOM microbenchmark programs. Each program is executed 2,000 times, and the average elapsed times are calculated based on the last half of the iterations to omit the effect of JIT compilation. We compare the following execution models: tracing JIT, tracing JIT with a higher threshold, and two-level JIT.

In Q3 (performance of threaded code), we assess the improvements introduced by meta-compiler–based threaded code generation by utilizing the SOM microbenchmarks. Specifically, we measure the peak performance of these benchmarks to evaluate the effectiveness of meta-compiler–based threaded code generation enhancements.

The 2SOM codebase is available at Zenodo [21]. To build 2SOM, we use GCC version 14.2.1 and our customized PyPy, which is available at Zenodo [22]. For measuring time, we use `monotonic_clock` by our RPython extension [23]. For TruffleSOM, we use revision e9d8032 of the repository hosted on GitHub[2], along with GraalVM Community Edition version 23.0.2.

All evaluations are conducted on a system running Ubuntu 22.04.1 LTS, equipped with a quad-core Intel Core i7-6700 CPU and 32 GB of RAM. To ensure reliable and consistent measurements, we use ReBench [29], a benchmarking framework designed to manage the evaluation process and minimize measurement noise.

6.2 Q1: Does Two-Level Compilation Improve Warm-Up Performance?

In this section, we answer Q1 by evaluating the warm-up performance of two-level JIT in 2SOM. The results of these measurements are presented in Figure 9, which shows the elapsed times with error bars displaying their variances.

As shown in Figure 9, two-level compilation demonstrated the best warm-up performance; it executed approximately 15% faster than tracing JIT alone. Furthermore, even when compared to tracing compilation with a threshold increased by a factor of three and TruffleSOM, two-level compilation outperformed by approximately 5%.

[2] `https://github.com/SOM-st/TruffleSOM`

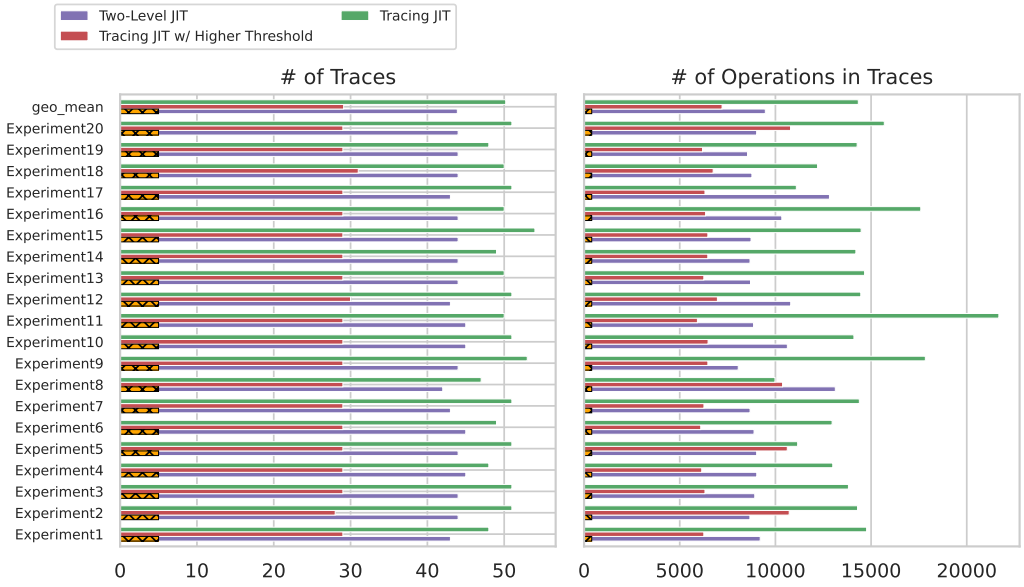

Figure 10 Number of operations and traces in the following strategies: two-level JIT, tracing JIT with high threshold, and tracing JIT in the evaluation of warm-up performance. The orange stitched bar inside the two-level JIT shows the number of operations and traces generated from the threaded code generation.

To statistically validate whether there were differences in the data for each pair – two-level and tracing JITs, as well as two-level JIT and tracing JIT with a high threshold – we conducted the Wilcoxon signed-rank test. The results revealed that for the two-level and tracing JITs pair, $p = 0.0314\%$, and for the two-level JIT and tracing JIT with a higher threshold pair, $p = 2.151\%$. In both cases, the null hypothesis was rejected.

These findings indicate that two-level JIT improves warm-up performance compared to RPython's single-tier compilation. Furthermore, they suggest that two-level JIT enhances warm-up performance more effectively than optimizing compilation strategies by limiting the compilation target scope, such as adjusting thresholds to reduce compilation time.

In addition, we break down the traces generated from these strategies: two-level JIT, tracing JIT with high threshold, and tracing JIT. The results are shown in Figure 10.

The first breakdown (the left-hand side of Figure 10: number of traces) shows that two-level JIT generates fewer traces than tracing JIT but more than tracing JIT with a high threshold.

The second breakdown (the right-hand side of Figure 10: number of operations in traces) shows that two-level JIT generates fewer operations in traces than tracing JIT but slightly more than tracing JIT with a high threshold. In addition, the ratio of traces generated from threaded code overall number of traces are approximately 10%. These results stem from the characteristic of the lightweight compiler that it generates compact traces during early execution phases.

These results demonstrate the ability of the two-level JIT to balance warm-up speed and trace generation; lightweight compilation using threaded code can improve early performance. Therefore, two-level JIT effectively works interpreter execution, threaded code generation, and tracing together.

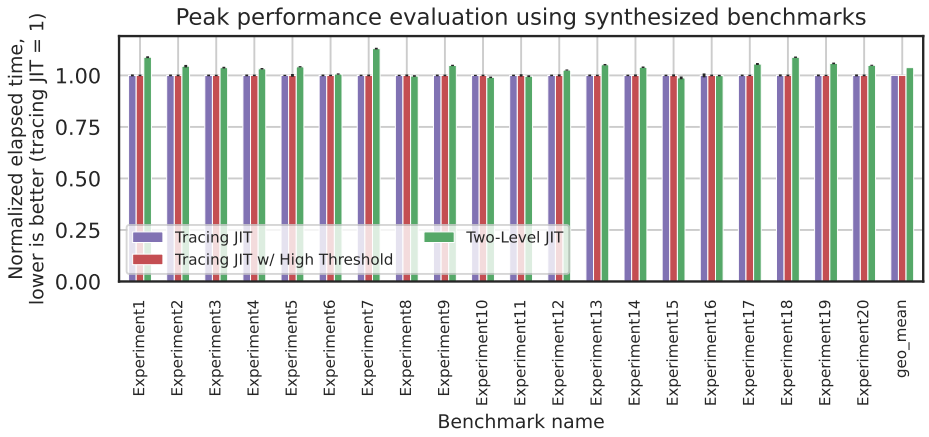

Figure 11 Peak performance results: Normalized elapsed time (lower is better) across synthesized programs for different JIT compilation strategies: (1) Tracing JIT, (2) Tracing JIT with a high threshold, and (3) Two-Level JIT. Results are normalized to the baseline Tracing JIT.

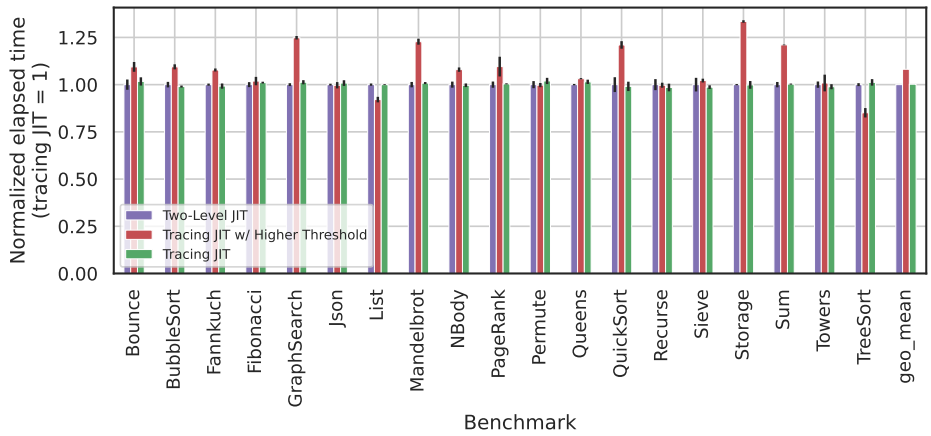

Figure 12 Peak performance results: Normalized elapsed time (lower is better) for SOM benchmarks, comparing three JIT compilation strategies: (1) Two-Level JIT, (2) Tracing JIT with a higher threshold, and (3) Tracing JIT. The results are normalized to the baseline Tracing JIT.

6.3 Q2: How Good is the Peak Performance of Two-Level Compilation?

In this section, we answer Q2 by describing the peak performance of two-level JIT in 2SOM. We measure the peak performance of synthesized programs and the SOM microbenchmark programs, and these results are shown in Figures 11 and 12.

As shown in Figure 11, the peak performance of two-level JIT is slower than approximately 3% against tracing JIT, and approximately 5% slower than tracing JIT with high threshold. In addition, as shown in Figure 12, the peak performance of two-level JIT is slower than approximately 7% against tracing compilation and approximately 10% slower than tracing JIT with high threshold.

This result indicates that introducing the meta-compiler–based threaded code generation to a meta-tracing JIT compiler does not significantly reduce the peak performance of meta-tracing JIT compilation. In particular, the introduction of interpreter switching does not result in a significant performance degradation in peak performance.

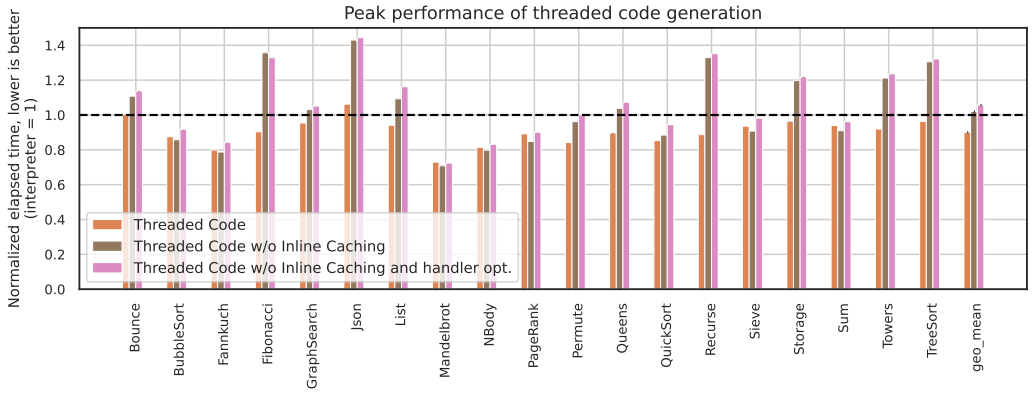

Figure 13 Comparison of peak performance for threaded code generation under different optimization configurations: (1) all optimizations enabled, (2) without inline caching, and (3) without both inline caching and shallow tracing handler optimization. Each data is normalized to interpreter-only execution.

6.4 Q3: How Much is the Improvement of Threaded Code Generation?

In this section, we answer Q3 by describing the peak performance of the meta-compiler–based threaded code generation. To evaluate the impact of the optimizations implemented in threaded code generation, we measured its peak performance. Specifically, we compare three configurations: one with all optimization options enabled, one with only the direct calls with inline caching optimization disabled, and another with both direct calls with inline caching and shallow tracing handler optimization disabled. This comparison allowed us to assess the performance improvements contributed by each optimization individually. The result is shown in Figure 13.

As shown in Figure 13, the fully optimized configuration (Threaded Code, orange-colored bar) consistently achieves the best performance across all benchmarks, running about 10% faster than the interpreter. Disabling direct calls with inline caching (brown-colored bar) degrades performance by about 10% on average, highlighting its importance in optimizing frequent function calls and dynamic dispatch. Disabling both direct calls with inline caching and shallow tracing handler optimization (pink-colored bar) further degrades performance by about 5%, highlighting their complementary impact on efficiency. Overall, the results underscore the need for these optimizations to achieve optimal runtime performance.

This result shows that our implemented optimization improves the performance of the meta-compiler–based threaded code generation. In particular, direct calls with inline caching significantly improve the performance in function call-intensive programs such as Fibonacci, Json, Recurse, Storage, Towers, and TreeSort. However, further optimization is needed to improve the warm-up performance more. For example, we believe that inline caching implemented this time can be optimized more efficiently by using polymorphic inline caching.

6.5 Threats to Validity

Since this evaluation was conducted on a subset of Smalltalk, the results may differ when it is performed on a larger language implementation such as PyPy and RSqueak [15].

7 Related Work

There exist several approaches to building a lightweight compiler in a meta-compiler framework. Copy-and-patch compilation [40] is a meta-compilation technique that performs template-based compilation. The template is generated from a bytecode instruction or an AST node of a high-level language by the MetaVar compiler. Although they build a new meta-compiler to generate a new baseline compiler, our approach is built on an existing meta-tracing compiler. In addition, although they use a parameterized binary code for generating a template, we use an interpreter definition with annotations to compile a source program.

There are also other methodologies for realizing a multi-tier JIT compilation VM using a meta-compiler framework. Graal/Truffle [38] has introduced a first-tier execution in addition to the second-tier execution that performs heavyweight compilation [35]. The approach is straightforward: they control the level of optimization in their meta-compilation system to enable multi-tier execution. While their methodology requires major modifications to the meta-compiler, our methodology is adding multiple tiers with different compilation methods in RPython.

Furthermore, other meta-circular VMs provide multi-tier JIT compilation, such as Jikes RVM [1] and Maxine VM [37]. These two VMs have lightweight and heavyweight compilers. In particular, they have original code generators for lightweight compilation: Jikes RVM's lightweight compiler translates Java bytecode into native code by simulating Java's operand stack. Maxine VM's lightweight compiler translates Java functions into native code using templates. In contrast, our lightweight compilation reuses the compiler of heavyweight compilation. To control the code quality and compilation time, we slightly modify the definition of an interpreter provided to the meta-tracing compiler.

8 Conclusion and Future Work

This paper introduces a lightweight methodology that enables a meta-compiler framework to generate a multi-tier JIT compilation VM. By treating interpreter definitions as specifications not only for language semantics but also for compilation strategies, we enable RPython to generate key components for multi-tier JIT compilation: multiple compilers, a profiler, and a transition mechanism.

To demonstrate our approach, we created a two-tier JIT compilation version of the Simple Object Machine called 2SOM. 2SOM incorporates two JIT compilers: a tier-1 threaded code generator and a tier-2 tracing JIT compiler. This integration was achieved by addressing practical challenges in combining meta-compiler-based threaded code generation [25] with RPython.

Our evaluation shows that the proposed methodology significantly improves performance. Warm-up performance was improved by approximately 15%, while peak performance degradation was limited to approximately 5% compared to tracing JIT-only systems. Furthermore, enhancements to the threaded code generator improved execution speed by 10% compared to interpreter-based execution. These results demonstrated the potential of our methodology to simplify the development of multi-tier JIT compilers in other RPython-based language implementations.

Despite its advantages, our approach has certain limitations. First, it cannot add a tier that requires different low-level code generation and optimization mechanisms (e.g., register allocation or instruction-level scheduling) because it does not change the processes of RPython after generated traces. Second, it cannot add a tier that requires manipulating intermediate

code. This limitation arises because the approach relies on running the interpreter to obtain traces of the intermediate code (RPython traces). The design does not assume modifications to these traces.

Future work is not only to solve these limitations, but also to apply our method to larger language systems than 2SOM and validate the effectiveness of multi-tier JIT compilation VMs using more realistic data.

One potential application is PyPy. Although we have conducted experiments using synthesized programs to evaluate the effectiveness of multi-tier JIT compilation VMs. However, we think that using a larger benchmark set would enable more detailed analysis. To achieve this in PyPy, two specific challenges must be addressed: a) How to reduce the effort required to annotate PyPy's interpreter, which consists of approximately 200,000 lines of code. b) How to handle cases where handlers in the PyPy interpreter may throw exceptions, given that our current tier-1 compiler does not support tracing handlers that can raise RPython-level exceptions. c) How to develop a lightweight compiler that can generate higher-quality code than threaded code generation, enabling the multi-tier JIT compilation VM to be effective for a broader range of workloads.

For challenge a), it will be necessary to allow at least two interpreters to be generated from a single interpreter. One idea is to improve PyPy's translation flow, which generates VMs, to automate the generation of interpreters.

For challenge b), we believe that adopting the *zero-cost exception mechanism* [8] introduced in Python 3.11–now being integrated into PyPy–will allow us to trace handlers in the PyPy interpreter. Unlike earlier versions of Python where try statements compiled to `SETUP_FINALLY` (incurring overhead even without exceptions), Python 3.11 uses `NOP` instructions for the non-exception path. This change should let our threaded code generation avoid triggering RPython-level exceptions and work smoothly in PyPy with this mechanism enabled.

For challenge c), we believe that a solution can be achieved through further refinement of meta-compiler–based threaded code generation. In general, interpreters implement the behavior of handler functions by calling various helper functions within those handlers. The current threaded code generator only leaves call instructions to the handler functions in the trace, but more efficient lightweight compilation could be achieved by inlining non-critical helper functions and leaving only those helper functions that are time-consuming to compile as call instructions.

Abstract

Deadlock freedom is a crucial property for message-passing programs. Over the years, several different type systems for concurrent processes that ensure deadlock freedom have been proposed; this diversity raises the question of how they compare. We address this question, considering two type systems not covered in prior work: Kokke *et al.*'s HCP, a type system based on a linear logic with *hypersequents*, and Padovani's *priority-based* type system for asynchronous processes, dubbed P. Their distinctive features make formal comparisons relevant and challenging. Our findings are two-fold: (1) the hypersequent setting does not drastically change the class of deadlock-free processes induced by linear logic, and (2) we relate the classes of deadlock-free processes induced by HCP and P. We prove that our results hold under both synchronous and asynchronous communication. Our results provide new insights into the essential mechanisms involved in statically avoiding deadlocks in concurrency.

1 Introduction

The *deadlock freedom* property (DF, in the following) is a crucial guarantee for message-passing programs. Informally, DF ensures that processes "never get stuck" – an essential requirement in concurrent and distributed software systems, where even a single component that becomes permanently blocked while waiting for a message can compromise reliability. As illustration, consider a toy concurrent program in the language of Gay and Vasconcelos [14]:

$$\langle \mathsf{let}\,(x_1, z) = \mathsf{receive}\,x_1\ \mathsf{in}\ \mathsf{send}\ \mathtt{42}\,y_1\rangle \parallel \langle \mathsf{let}\,(y_2, k) = \mathsf{receive}\,y_2\ \mathsf{in}\ \mathsf{send}\ \text{`}\mathtt{hello}\text{'}\,x_2\rangle$$

We have two concurrent threads, each running an expression with two actions in sequence. This program is evaluated under a context that binds together x_1 and x_2 and declares them as endpoints of the same linear channel (same for y_1 and y_2); we omit it for readability. Given a linear channel x, "$\mathsf{send}\ \mathtt{v}\,x$" sends value $\mathtt{v}$ along x and returns the continuation of x, whereas "$\mathsf{receive}\,x$" returns a pair with the continuation of x and a received value. The threads are thus engaged in separate but intertwined protocols (one along x_i, the other along y_i). Each thread should receive on a channel and then send a value on the other. However, the output matching the input in one thread is blocked in the other – the program is stuck. The key challenge in enforcing DF is thus performing the non-local analysis needed to avoid *circular dependencies* between threads, which are often less apparent than in this program.

An expressive model for concurrent processes, the π-calculus offers a convenient basis for developing analysis techniques for message-passing programs in different paradigms [32]. Several type systems that enforce (forms of) DF have been proposed over the years (see, e.g., [21, 11, 5, 27, 7, 34, 1]). They avoid circular dependencies in processes using different insights, which raises the question of how they compare. In this paper, we rigorously compare some representative type systems for DF to better understand their underlying mechanisms.

A key motivation for studying type systems for concurrent processes is their suitability for developing advanced analysis techniques at an appropriate level of abstraction – these typed frameworks have been directly incorporated into languages such as Scala [33], OCaml [28, 17], and Rust [24]. Also, concurrent processes offer an adequate representation level for verifying liveness properties in real Go programs [25, 26]. Moreover, type systems for the π-calculus are the basis for static analyzers (such as Kobayashi's TyPiCal [20]) and can be ported to enforce DF for higher-order concurrent programs [29]. Type systems based on the Curry-Howard correspondence between session types and linear logic ("propositions-as-sessions" [3, 37]) enforce DF; they entail topological invariants on processes, key to ensure deadlock and memory leak freedom in concurrent programs [18]. Further understanding the essential mechanisms that enforce DF in logic-based session types is a central topic in our work.

Prior work by Dardha and Pérez [9] contrasts type systems for DF by relating the classes of processes they induce. They compare a *priority-based* type system by Kobayashi [21] and a type system derived from "propositions-as-sessions". Writing $\mathbb{K}$ and $\mathbb{L}$ to denote the respective classes of processes, a result in [9] is that $\mathbb{L} \subsetneq \mathbb{K}$: there exist deadlock-free processes that cannot be typed by logic-based type systems. The class $\mathbb{K} \setminus \mathbb{L}$ includes, for instance, process networks organized in circular topologies (e.g., the dinning philosophers). It also includes process P_0 below, in which two processes interact along independent protocols (*sessions*):

$$P_0 \triangleq (\nu\, x_1x_2)(\nu\, y_1y_2)(x_1(z).\overline{y_1}\langle \texttt{42}\rangle.\mathbf{0} \mid \overline{x_2}\langle \texttt{hello}\rangle.y_2(k).\mathbf{0})$$

Above, "$(\nu\, x_1x_2)$" declares a new session with linear endpoints x_1 and x_2, and "$x(y).Q$" (resp. "$\overline{x}\langle v\rangle.Q$") denotes an input (resp. output of value v) along x with continuation Q. P_0 is the deadlock-free variant of the program given above, now neatly specified as a process. In $\mathbb{L}$, processes can share at most one session in parallel, whereas processes in P_0 share two: the session "x_1x_2" for exchanging "`hello`" and the session "y_1y_2" for exchanging "`42`". In [9], both compared classes rely on a reduction semantics; accordingly, DF concerns the absence of stable states with *pending reduction steps* on linear names/channels.

Here we extend the work in [9] by considering type systems not studied there: (i) Kokke *et al.*'s HCP [23] and (ii) Padovani's priority-based type system [27], here dubbed P. Their distinctive features make formal comparisons relevant and challenging, as we discuss next.

Derived from "propositions-as-sessions", HCP is based on a presentation of classical linear logic (CLL) with *hypersequents*. HCP has been studied in several works, which have deepened into its theory and applications [22, 12, 31]. In HCP, the semantics of processes is given by a Labeled Transition System (LTS), rather than by a reduction semantics. This unlocks the use of well-established analysis techniques, notably observational equivalences, to reason about typed processes. The (typed) LTS for HCP includes the usual rules for observing actions and synchronizations, here dubbed *regular transitions*, but also rules that allow for *delayed actions* (i.e., observable actions due to prefixes not at top-level) and *self-synchronizations* (i.e., internal actions that do not require the interaction of two parallel processes). Remarkably, the bisimilarity induced by the LTS coincides, in a fully-abstract way, with a *denotational equivalence* over processes – this gives a strong justification for the design of the LTS. Typing ensures *progress*: well-typed processes not equivalent to $\mathbf{0}$ always have a transition step.

An intriguing observation is that there are HCP processes that are stuck in a reduction-based setting but have synchronizations under HCP's LTS. We discuss two interesting examples, using "$x().Q$" and "$\overline{x}\langle\rangle.Q$" to denote empty inputs and outputs, respectively:

- Process $P_1 \triangleq (\nu\, xx')\overline{x'}\langle\rangle.x().\mathbf{0}$ is self-synchronizing: it does not have any reductions, whereas $P_1 \xrightarrow{\tau} \mathbf{0}$, as in HCP synchronizations do not need a parallel context to be enabled.
- Process $P_2 \triangleq (\nu\, xx')(\nu\, yy')(\overline{y}\langle\rangle.x().\mathbf{0} \mid \overline{x'}\langle\rangle.y'().\mathbf{0})$ is arguably the paradigmatic example of a deadlock, with two independent sessions unable to reduce. In HCP, thanks to delayed actions, we have both $P_2 \xrightarrow{\tau} (\nu\, yy')(\overline{y}\langle\rangle.\mathbf{0} \mid y'().\mathbf{0})$ and $P_2 \xrightarrow{\tau} (\nu\, xx')(\overline{x}\langle\rangle.\mathbf{0} \mid x'().\mathbf{0})$.

This observation shows that comparisons such as [9] should accommodate other semantics for processes, beyond reductions, which entail other definitions of DF and induce new deadlock-free processes (such as P_1 and P_2). This begs a first question:

(Q1) What is the status of delayed actions and self-synchronizations, as typable in HCP, with respect to DF? Do they induce a distinct class of deadlock-free processes?

Considering Padovani's P means addressing the case of processes with *asynchronous communication*, widely used in real programs. In the π-calculus, asynchronous communication is obtained by defining outputs as non-blocking actions; only inputs can block the execution of a process [2, 16]. Asynchrony and DF are then closely related: because an asynchronous setting involves the least amount of blocking operations, it offers the most elementary scenario for investigating DF [35]. Now, the comparisons in [9] are limited to synchronous processes; we then observe that they should be extended to address asynchronous communication, too. Let us write $\mathbb{H}$ and $\mathbb{P}$ to denote the class of processes induced by HCP and P, respectively, and $\mathbb{C}$ to denote the class of processes induced by CP (a fragment of HCP without hypersequents and with a restricted form of parallel composition). We consider the second question:

(Q2) What is the status of $\mathbb{H}$ and $\mathbb{C}$ with respect to asynchronous processes in $\mathbb{P}$?

Interestingly, our two questions are intertwined: HCP and P are related due to asynchrony. Our insight is that delayed actions in HCP already implement an asynchronous semantics. To see this, consider the process $P_3 \triangleq (\nu\, xx')(\nu\, yy')(\overline{y}\langle\rangle.\overline{x}\langle\rangle.\mathbf{0} \mid x'().y'().\mathbf{0})$, which is not stuck: the output on y is not really blocking, as delayed actions allow to anticipate the output (and synchronization) on x. In other words, P_3 is morally the same as $(\nu\, xx')(\nu\, yy')(\overline{y}\langle\rangle.\mathbf{0} \mid \overline{x}\langle\rangle.\mathbf{0} \mid x'().y'().\mathbf{0})$. We thus conclude that the (typed) operational semantics for HCP admits many synchronous-looking processes (such as P_3) that actually behave in an asynchronous way; this naturally invites the question of how $\mathbb{H}$ relates to $\mathbb{P}$.

Contributions and Outline. This paper offers conceptual and technical contributions. From a conceptual view, we reflect upon the significance of formally comparing different type systems for concurrency, while uniformly presenting various notions in the literature. On the technical side, we address **(Q1)** and **(Q2)**, thus extending and complementing [9]. A key discovery is identifying *commuting conversions* and *disentanglement* as key notions for characterizing deadlock-free processes in HCP – as we will see, these notions define sound *process optimizations* that respect causality and increase parallelism. As our results hold also in an asynchronous setting, not treated in prior work, our findings are most related to abstractions and mechanisms used in practical concurrent programming. More in detail:

§ 2 We introduce SP, a session π-calculus that we use as baseline for comparisons, as well as CP and HCP, the type systems resulting from the Curry-Howard correspondence with CLL and CLL with hypersequents, respectively.

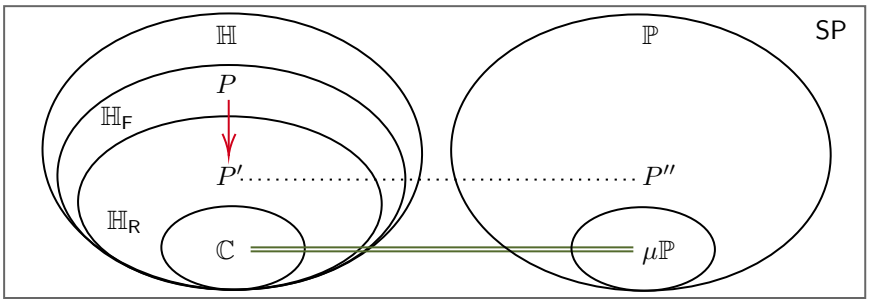

Figure 1 Overview of main results. Above, $\mathbb{H}_\mathsf{F}$, $\mathbb{H}_\mathsf{R}$, $\mathbb{P}$, $\mathbb{C}$, and $\mu\mathbb{P}$ stand for classes of deadlock-free SP processes. The red arrow represents optimizations (commuting conversions and disentanglement) that relate $\mathbb{H}_\mathsf{F}$ and $\mathbb{H}_\mathsf{R}$. The green lines denote the correspondence $\mathbb{C} = \mu\mathbb{P}$. The dotted line means that P' and P'' are the representatives of P in $\mathbb{H}_\mathsf{R}$ and $\mathbb{P}$, up to an encoding.

§ 3 We define $\mathbb{C}$ and $\mathbb{H}$: the classes of deadlock-free SP processes induced by CP and HCP, respectively. We identify two relevant sub-classes of $\mathbb{H}$:
$\mathbb{H}_\mathsf{F}$**:** Processes that use the Full LTS.
$\mathbb{H}_\mathsf{R}$**:** Processes that *only* use Regular transitions (no delayed actions/self-synchronizations).
In our main result (Corollary 53), we prove that for every process $P \in \mathbb{H}_\mathsf{F}$, there exists an observationally equivalent process $P' \in \mathbb{H}_\mathsf{R}$. Enabled by process optimizations induced via commuting conversions and disentanglement, this result shows that delayed actions and self-synchronizations are *inessential* when it comes to DF, addressing **(Q1)**.

§ 4 To address **(Q2)**, we define $\mathbb{P}$: the class of deadlock free SP processes induced by P, and its sub-class $\mu\mathbb{P}$ ("micro $\mathbb{P}$"), which is inspired by CP. We prove that $\mathbb{C} = \mu\mathbb{P}$ (Corollary 74), thus casting Dardha and Pérez's key finding into the asynchronous setting. Our main results are: Theorem 76, which precisely relates the classes $\mathbb{H}$, $\mathbb{H}_\mathsf{F}$, $\mathbb{H}_\mathsf{R}$, and $\mathbb{P}$; and Corollary 77, which strengthens Corollary 53 by considering DF in $\mathbb{P}$. Moreover, we introduce SP^a, an asynchronous variant of SP, and its corresponding classes of processes. We show how to transfer Theorem 76 and Corollary 77 from SP to SP^a (Corollary 88).

Figure 1 offers a graphical description of the classes of processes and some of our main results (Corollaries 53 and 74 and Theorem 76). For simplicity, the figure does not depict several encodings needed to bridge syntactic differences between the various classes of processes / type systems under consideration; Figure 12 (Page 26) presents a detailed version. In § 5 we collect some closing remarks. The extended version of the paper [19] contains omitted proofs.

2 Session Processes and Their Type Systems

We present SP, our reference language of session processes. As observed by Dardha and Pérez [9], this is a convenient framework for formal comparisons, because typing in SP ensures communication safety but not DF. We also present CP and HCP, the two typed languages based on "propositions-as-sessions", and recall useful associated results.

2.1 Session Processes (SP)

SP is a core session-typed π-calculus, based on the language defined by Vasconcelos [36]. We assume a base set of *variables*, ranged over by $x, y, \ldots$, which denote *channels* (or *names*): they can be seen as *endpoints* on which interaction takes place. Processes interact to exchange values $v, v', \ldots$; for simplicity, values correspond to variables, i.e., $v ::= x$. We write $\widetilde{x}$ to denote a finite sequence of variables. The syntax of *processes* is as follows:

$$P \quad ::= \quad \mathbf{0} \mid \overline{x}\langle v\rangle.P \mid x(y).P \mid P_1 \mid P_2 \mid (\nu\, xy)P \mid \overline{x}\langle\,\rangle.P \mid x().P$$

$$(\nu\, xy)(\overline{x}\langle v\rangle.P \mid y(z).Q \mid S) \longrightarrow (\nu\, xy)(P \mid Q\{^{v}/_{z}\} \mid S) \qquad \text{R-Com}$$

$$(\nu\, xy)(\overline{x}\langle\,\rangle.P \mid y().Q) \longrightarrow P \mid Q \qquad \text{R-EmptyCom}$$

$$\text{R-Par}\ \frac{P \longrightarrow P'}{P \mid Q \longrightarrow P' \mid Q} \qquad \text{R-Res}\ \frac{P \longrightarrow P'}{(\nu\, xy)P \longrightarrow (\nu\, xy)P'} \qquad \text{R-Struct}\ \frac{P \equiv P' \quad P' \longrightarrow Q' \quad Q' \equiv Q}{P \longrightarrow Q}$$

$$P \mid Q \equiv Q \mid P \qquad P \mid \mathbf{0} \equiv P$$

$$P \mid (Q \mid R) \equiv (P \mid Q) \mid R \qquad (\nu\, xy)P \equiv (\nu\, yx)P$$

$$(\nu\, xy)P \mid Q \equiv (\nu\, xy)(P \mid Q) \ \text{ if } x, y \notin \mathtt{fv}(Q) \qquad (\nu\, xy)(\nu\, wz)P \equiv (\nu\, wz)(\nu\, xy)P$$

Figure 2 SP: Reduction semantics (top) and structural congruence (bottom).

Process $\mathbf{0}$ denotes inaction. Process $\overline{x}\langle v\rangle.P$ sends v along x and continues as P. Process $x(y).P$ receives v along x and continues as $P\{^{v}/_{y}\}$, i.e., the process resulting from the capture-avoiding substitution of y by v in P. Process $P_1 \mid P_2$ denotes the parallel execution of P_1 and P_2. Process $(\nu\, xy)P$ declares x and y as *co-variables*, restricting their scope to P. That is, restriction declares co-variables as dual ends of a channel. Finally, $\overline{x}\langle\,\rangle.P$ and $x().P$ denote empty output and input (close and wait), which represent the closing of session x.

As usual, $x(y).P$ binds y in P and $(\nu\, xy)P$ binds x, y in P. The sets of free and bound variables of P, denoted $\mathtt{fv}(P)$ and $\mathtt{bv}(P)$, are defined accordingly. The semantics of processes is given using a reduction relation, defined next.

▶ **Definition 1** (SP: Reduction)**.** Reduction *for* SP*, denoted* $\longrightarrow$*, is defined by the rules in Figure 2 (top). It relies on* structural congruence*, denoted* $\equiv$*, the smallest congruence on processes that satisfies the axioms in Figure 2 (bottom).*

We now define session types, which express protocols associated to channels:

▶ **Definition 2** (SP: Session Types and Typing Environments)**.** *The syntax of session types and typing environments is inductively defined as follows:*

$$T, S \ ::= \ ?S.T \mid\ !S.T \mid \mathsf{end}_? \mid \mathsf{end}_! \qquad \Gamma \ ::= \ \emptyset \mid \Gamma, x : T$$

The type $!S.T$ (resp. $?S.T$) is assigned to a channel able to send (resp. receive) a value of type S and to continue as T. For convenience, we have two different types for channels with terminated protocols, denoted $\mathsf{end}_?$ and $\mathsf{end}_!$. Duality on types ensures that the endpoints of a channel agree on the protocol they describe:

▶ **Definition 3** (SP: Duality)**.** *The dual of* S*, denoted* $\overline{S}$*, is defined as follows:*

$$?S.T \triangleq\ !S.\overline{T} \qquad \overline{!S.T} \triangleq ?S.\overline{T} \qquad \overline{\mathsf{end}_?} \triangleq \mathsf{end}_! \qquad \overline{\mathsf{end}_!} \triangleq \mathsf{end}_?$$

▶ **Definition 4** (SP: Typing Judgment and Typing Rules)**.** *The judgment* $\Gamma \vdash_{\mathrm{S}} P$ *describes a well-typed process under the typing environment* Γ*. The typing rules for* SP *are shown in Figure 3. We shall write* $P \in \mathsf{SP}$ *if* $\Gamma \vdash_{\mathrm{S}} P$*, for some* Γ*.*

We now state the properties of well-typed SP processes, whose proofs follow [36]:

$$\textsc{Inact}\ \frac{}{\cdot \vdash_{\mathrm{S}} \mathbf{0}} \qquad \textsc{EInput}\ \frac{\Gamma \vdash_{\mathrm{S}} P}{\Gamma, x : \mathsf{end}_? \vdash_{\mathrm{S}} x().P} \qquad \textsc{EOutput}\ \frac{\Gamma \vdash_{\mathrm{S}} P}{\Gamma, x : \mathsf{end}_! \vdash_{\mathrm{S}} \overline{x}\langle\rangle.P} \qquad \textsc{Par}\ \frac{\Gamma_1 \vdash_{\mathrm{S}} P \qquad \Gamma_2 \vdash_{\mathrm{S}} Q}{\Gamma_1, \Gamma_2 \vdash_{\mathrm{S}} P \mid Q}$$

$$\textsc{Res}\ \frac{\Gamma, x : T, y : \overline{T} \vdash_{\mathrm{S}} P}{\Gamma \vdash_{\mathrm{S}} (\nu\, xy)P} \qquad \textsc{Out}\ \frac{\Gamma, x : U \vdash_{\mathrm{S}} P}{\Gamma, x : !T.U, v : T \vdash_{\mathrm{S}} \overline{x}\langle v\rangle.P} \qquad \textsc{In}\ \frac{\Gamma, y : T, x : U \vdash_{\mathrm{S}} P}{\Gamma, x : ?T.U \vdash_{\mathrm{S}} x(y).P}$$

Figure 3 SP: Typing Rules for Processes.

▶ **Theorem 5** (SP: Preservation [36]). *Suppose* $\Gamma \vdash_{\mathrm{S}} P$. *If* $P \equiv Q$ *then* $\Gamma \vdash_{\mathrm{S}} Q$. *Also, if* $P \longrightarrow Q$ *then* $\Gamma \vdash_{\mathrm{S}} Q$.

We will be interested in *well-formed processes*, defined using two auxiliary notions. First, we say that P is *prefixed at* x, written $\mathtt{Pr}(P) = x$, if P has one of the following forms: $x().P'$, $\overline{x}\langle\rangle.P$, $x(z).P'$, or $\overline{x}\langle v\rangle.P'$. Second, we say a process $(\nu\, xy)(P \mid Q)$ is a *redex* if: (1) $P = x().P'$ and $Q = \overline{y}\langle\rangle.Q'$, or (2) $P = x(z).P'$ and $Q = \overline{y}\langle v\rangle.Q'$. We may now define:

▶ **Definition 6** (SP: Well-formedness). *A process is well-formed if for each of its structural congruent processes of the form* $(\nu\, x_1y_1)\dots(\nu\, x_ny_n)(P_1 \mid \cdots \mid P_m)$ *where* $\mathtt{Pr}(P_i) = x_k$ *and* $\mathtt{Pr}(P_j) = y_k$, *then* $(\nu\, x_ky_k)(P_i \mid P_j)$ *is a redex.*

▶ **Theorem 7** (Safety [36]). *Typable processes are well-formed.*

As a consequence of Theorems 5 and 7 we obtain the main guarantee of SP: *typable processes only reduce to well-formed processes.*

▶ **Corollary 8** ([36]). *If* $\Gamma \vdash_{\mathrm{S}} P$ *and* $P \longrightarrow^* Q$, *then* Q *is well-formed.*

Even though typability ensures well-formedness, which excludes error processes such as $(\nu\, xy)(\overline{x}\langle v\rangle.P \mid y().Q)$ and $(\nu\, xy)(x().P \mid y().Q)$, typability in SP also admits well-typed process that exhibit unwanted behaviors, in particular deadlocks. Before illustrating this fact, we give the first definition of deadlock freedom that we will encounter, which follows [9]. We write $(\nu\, \widetilde{xy})Q$ to stand for $(\nu\, x_1y_1)\cdots(\nu\, x_ny_n)Q$, for some $n \geq 0$.

▶ **Definition 9** (SP: Deadlock Freedom). *A process* $P \in \mathsf{SP}$ *is deadlock free, written* $\mathcal{D}_{\mathbf{S}}(P)$, *if the following condition holds: whenever* $P \longrightarrow^* P'$ *and one of the following holds:* (1) $P' \equiv (\nu\, \widetilde{xy})(\overline{x_i}\langle v\rangle.Q_1 \mid Q_2)$, (2) $P' \equiv (\nu\, \widetilde{xy})(x_i(z).Q_1 \mid Q_2)$, (3) $P' \equiv (\nu\, \widetilde{xy})(x_i().Q_1 \mid Q_2)$, *or* (4) $P' \equiv (\nu\, \widetilde{xy})(\overline{x_i}\langle\rangle.Q_1 \mid Q_2)$ *(with* $x_i \in \widetilde{x}$ *in all cases), then* $P' \longrightarrow R$, *for some* R.

Hence, $\mathcal{D}_{\mathbf{S}}(P)$ is read as "P is deadlock-free in SP". Later on, we will encounter analogous notations for HCP and P; they will be denoted $\mathcal{D}_{\mathbf{H}}(P)$ and $\mathcal{D}_{\mathbf{P}}(P)$, respectively.

▶ **Example 10** (SP: A Typable but Deadlocked Process). Consider the process P_{10} defined as

$$P_{10} \triangleq (\nu\, x_1y_1)(\nu\, x_2y_2)(\nu\, v_1k_1)(\nu\, v_2k_2)(x_1(z_1).x_2(z_2).C_1 \mid \overline{y_2}\langle v_2\rangle.\overline{y_1}\langle v_1\rangle.C_2)$$

where $C_1 \triangleq x_1().x_2().z_1().z_2().\mathbf{0}$ and $C_2 \triangleq \overline{y_1}\langle\rangle.\overline{y_2}\langle\rangle.\overline{k_1}\langle\rangle.\overline{k_2}\langle\rangle.\mathbf{0}$. Similar to P_2 (§ 1), the structure of actions in process P_{10} induces a circular dependency that prevents synchronizations: we have that $\neg\mathcal{D}_{\mathbf{S}}(P_{10})$ and yet P_{10} is well-typed with the empty environment.

$$\text{C-}\mathbf{1}\ \frac{}{x[\,].\mathbf{0} \vdash_{\mathsf{C}} x : \mathbf{1}} \qquad \text{C-}\bot\ \frac{P \vdash_{\mathsf{C}} \Gamma}{x().P \vdash_{\mathsf{C}} \Gamma, x : \bot} \qquad \text{C-Mix}_0\ \frac{}{\mathbf{0} \vdash_{\mathsf{C}} \cdot} \qquad \text{C-}\otimes\ \frac{P \vdash_{\mathsf{C}} \Gamma, y : A \qquad Q \vdash_{\mathsf{C}} \Delta, x : B}{x[y].(P \mid Q) \vdash_{\mathsf{C}} \Gamma, \Delta, x : A \otimes B}$$

$$\text{C-}\parr\ \frac{P \vdash_{\mathsf{C}} \Gamma, y : A, x : B}{x(y).P \vdash_{\mathsf{C}} \Gamma, x : A \parr B} \qquad \text{C-Cut}\ \frac{P \vdash_{\mathsf{C}} \Gamma, x : A \qquad Q \vdash_{\mathsf{C}} \Delta, y : A^{\bot}}{(\nu xy)(P \mid Q) \vdash_{\mathsf{C}} \Gamma, \Delta} \qquad \text{C-Id}\ \frac{}{[x \leftrightarrow y] \vdash_{\mathsf{C}} x : A, y : A^{\bot}}$$

Figure 4 CP: Typing rules for processes.

2.2 CP and HCP

The languages CP and HCP use the same syntax. Here we consider HCP as presented by Kokke *et al.* [23] (other variants have been studied in, e.g., [13]). Assuming an infinite set of *names* $(x, y, z, \dots)$, the set of *processes* $(P, Q, \dots)$ in CP and HCP is defined as follows:

$$P, Q ::= \mathbf{0} \mid (\nu xy)P \mid P \mid Q \mid [x \leftrightarrow y] \mid x[y].P \mid x(y).P \mid x[\,].P \mid x().P$$

Most constructs are similar to those in SP; differences are the forwarder process $[x \leftrightarrow y]$, which equates x and y, and process $x[y].P$, which denotes the output of the private name y along x, with continuation P. Also, the empty output is now denoted $x[\,].P$. In $x[y].P$ and $x(y).P$, the name y is bound in P. We write $P\{x/y\}$ to denote the capture-avoiding substitution of y for x in P. We write $\mathsf{fn}(P)$ to denote the free names of P. We use π to range over prefixes: $x[y], x(y), x(), x[\,]$.

The types assigned to names correspond to formulas of classical linear logic (CLL):

$$A, B ::= \mathbf{1} \mid \bot \mid A \otimes B \mid A \parr B$$

The assignment $x : A$ says that x follows the input/output interactions described by A. Assignments $x : A \otimes B$ and $x : A \parr B$ are read as sending and receiving an object of type A along x, with continuation B, respectively. There is a duality in the interpretation of the following pairs: $\otimes$ and $\parr$; $\mathbf{1}$ and $\bot$. Formally, the dual type of A, denoted $A^{\bot}$, is defined as

$$\mathbf{1}^{\bot} \triangleq \bot \qquad \bot^{\bot} \triangleq \mathbf{1} \qquad (A \otimes B)^{\bot} \triangleq A^{\bot} \parr B^{\bot} \qquad (A \parr B)^{\bot} \triangleq A^{\bot} \otimes B^{\bot}$$

Let Γ, Δ range over *environments*, unordered collections of assignments. Given an environment $\Delta = x_1 : A_1, \dots, x_n : A_n$, its domain, written $dom(\Delta)$, is the set $\{x_1, \dots, x_n\}$.

▶ **Definition 11** (CP). *Typing judgements for* CP *are of the form* $P \vdash_{\mathsf{C}} \Gamma$*, with typing rules as given in Figure 4. We shall write* $P \in$ CP *if* $P \vdash_{\mathsf{C}} \Gamma$*, for some* Γ*.*

Observe how typing in CP induces a specific shape for output processes: $x[y].(P \mid Q)$. This is not the case in HCP, where processes are described by *hyperenvironments*, unordered collections of environments: $\mathcal{H}, \mathcal{G} ::= \Gamma_1 \parallel \cdots \parallel \Gamma_n$.

▶ **Definition 12** (HCP). *Typing judgements for* HCP *are of the form* $P \vdash_{\mathsf{H}} \mathcal{G}$*, with typing rules as given in Figure 5. We shall write* $P \in$ HCP *if* $P \vdash_{\mathsf{H}} \mathcal{G}$*, for some* $\mathcal{G}$*.*

CP and HCP differ in process composition, which is key to exclude the circular dependencies that lead to deadlocks: it is realized by Rule C-Cut in CP and Rule H-Cut in HCP. The former requires two premises describing processes that share exactly one session; typing

$$\text{H-Mix}_2\ \frac{P \vdash_{\text{H}} \mathcal{H} \quad Q \vdash_{\text{H}} \mathcal{G}}{P \mid Q \vdash_{\text{H}} \mathcal{H} \parallel \mathcal{G}} \qquad \text{H-Mix}_0\ \frac{}{\mathbf{0} \vdash_{\text{H}} \cdot} \qquad \text{H-ID}\ \frac{}{[x \leftrightarrow y] \vdash_{\text{H}} x : A, y : A^{\perp}} \qquad \text{H-}\bot\ \frac{P \vdash_{\text{H}} \mathcal{H} \parallel \Delta}{x().P \vdash_{\text{H}} \mathcal{H} \parallel \Delta, x : \bot} \qquad \text{H-}\mathbf{1}\ \frac{P \vdash_{\text{H}} \mathcal{H}}{x[].P \vdash_{\text{H}} \mathcal{H} \parallel x : \mathbf{1}}$$

$$\text{H-}\otimes\ \frac{P \vdash_{\text{H}} \mathcal{H} \parallel \Delta, y : A \parallel \Gamma, x : B}{x[y].P \vdash_{\text{H}} \mathcal{H} \parallel \Delta, \Gamma, x : A \otimes B} \qquad \text{H-}\parr\ \frac{P \vdash_{\text{H}} \mathcal{G} \parallel \Delta, y : B, x : A}{x(y).P \vdash_{\text{H}} \mathcal{G} \parallel \Delta, x : A \parr B} \qquad \text{H-Cut}\ \frac{P \vdash_{\text{H}} \mathcal{H} \parallel \Delta, x : A \parallel \Gamma, y : A^{\perp}}{(\nu\, xy)P \vdash_{\text{H}} \mathcal{H} \parallel \Delta, \Gamma}$$

Figure 5 HCP: Typing rules for processes.

involves both composition and restriction and induces tree-like process topologies. The latter involves one premise only, which describes a process in which the separation between x and y is made explicit by "$\parallel$" at the level of hyperenvironments; typing involves restriction only.

Every P typable in CP is also typable in HCP, but the converse does not hold. We have:

▶ **Lemma 13** (Relation Between CP and HCP [23]). *If* $P \vdash_{\text{C}} \Gamma$ *then* $P \vdash_{\text{H}} \Gamma$.

▶ **Example 14** (The converse of Lemma 13 does not hold). To illustrate a process typable in HCP but not in CP, consider $P_{14} \triangleq (\nu\, x_1y_1)(\nu\, x_2y_2)(\nu\, v_1k_1)(\nu\, v_2k_2)(P'_{14} \mid P''_{14})$, where:

$$P'_{14} \triangleq x_1(z_1).x_2(z_2).x_1().x_2().z_1().z_2().\mathbf{0}$$
$$P''_{14} \triangleq y_1[v'_1].([v'_1 \leftrightarrow v_1] \mid y_2[v'_2].([v'_2 \leftrightarrow v_2] \mid C)) \qquad C \triangleq y_1[].\mathbf{0} \mid y_2[].\mathbf{0} \mid k_1[].\mathbf{0} \mid k_2[].\mathbf{0}$$

We have $P_{14} \vdash_{\text{H}} \cdot$. First, $P'_{14} \vdash_{\text{H}} x_1 : \bot \parr \bot, x_2 : \bot \parr \bot$ follows from several applications of Rules H-$\bot$ and H-$\parr$. To type P''_{14}, we first obtain $C \vdash_{\text{H}} y_1 : \mathbf{1} \parallel y_2 : \mathbf{1} \parallel k_1 : \mathbf{1} \parallel k_2 : \mathbf{1}$, crucially using Rule H-Mix$_2$ several times to compose the four independent processes. Because $[v'_2 \leftrightarrow v_2] \vdash_{\text{H}} v'_2 : \mathbf{1}, v_2 : \bot$, by Rules H-Mix$_2$ and H-$\otimes$ we have: $y_2[v'_2].([v'_2 \leftrightarrow v_2] \mid C) \vdash_{\text{H}} y_1 : \mathbf{1} \parallel y_2 : \mathbf{1} \otimes \mathbf{1}, v_2 : \bot \parallel k_1 : \mathbf{1} \parallel k_2 : \mathbf{1}$. We proceed similarly to type the output on y_1 and complete the typing of P''_{14}. Finally, to compose P'_{14} and P''_{14} we apply H-Mix$_2$ and H-Cut.

Now, C cannot be typed in CP: there is no rule similar to Rule H-Mix$_2$, which can compose independent processes. Hence, P_{14} is not typable in CP.

In general, the composition of two processes that share more than one session cannot be typed in CP. Now consider Q_{14}:

$$Q_{14} \triangleq (\nu\, v_2k_2)((\nu\, v_1k_1)((\nu\, x_2y_2)((\nu\, x_1y_1)(P'_{14} \mid y_1[v'_1].([v'_1 \leftrightarrow v_1] \mid y_1[].\mathbf{0}) \mid y_2[v'_2].([v'_2 \leftrightarrow v_2] \mid y_2[].\mathbf{0})) \mid k_1[].\mathbf{0}) \mid k_2[].\mathbf{0})$$

Observe how Q_{14} modifies P_{14} by keeping P'_{14} unchanged and dividing the two outputs in P''_{14} into threads that can be composed separately using Rule C-Cut. We have $Q_{14} \vdash_{\text{C}} \cdot$.

Given a $P \vdash_{\text{H}} \mathcal{G}$, with $\mathcal{G} = \Gamma_1 \parallel \cdots \parallel \Gamma_n$, we are interested in partitioning the free names in P according to the environments $\Gamma_1, \ldots, \Gamma_n$. These *name partitions* describe which names are used by each parallel component of P; they are defined considering all the different hyperenvironments under which P is typable.

▶ **Definition 15** (HCP: Name Partitions). *Given* $\mathcal{G} = \Gamma_1 \parallel \cdots \parallel \Gamma_n$, *we define* $\mathsf{Part}(\mathcal{G}) = \{dom(\Gamma_1), \ldots, dom(\Gamma_n)\}$. *Given* P, *its* name partitions *are* $\mathsf{np}(P) = \{\mathsf{Part}(\mathcal{G}) \mid P \vdash_{\text{H}} \mathcal{G}\}$.

$x *_P y$ *holds whenever there is a* $G \in \mathsf{np}(P)$ *such that* x *and* y *belong to different proper subsets of* G. *Also,* $x \circledast_P y$ *holds whenever* x *and* y *belong to the same proper subset of* G.

▶ **Example 16.** Consider the process $P_{16} \triangleq x().(z[].\mathbf{0} \mid y[].\mathbf{0})$: it can be typed under the hyperenvironments $\mathcal{G} \triangleq x : \bot, z : \mathbf{1} \parallel y : \mathbf{1}$ and $\mathcal{H} \triangleq z : \mathbf{1} \parallel x : \bot, y : \mathbf{1}$. Given this, $\mathsf{np}(P_{16}) = \{\{\{x, z\}, \{y\}\}, \{\{z\}, \{x, y\}\}\}$, and we have, e.g., $y *_{P_{16}} z$ and $x \circledast_{P_{16}} y$.

$$\frac{}{[x \leftrightarrow y] \xrightarrow{[x \leftrightarrow y]} \mathbf{0}}\ [x \leftrightarrow y] \qquad \frac{}{[x \leftrightarrow y] \xrightarrow{[y \leftrightarrow x]} \mathbf{0}}\ [x \leftrightarrow y] \qquad \frac{\pi \in \{x[y], x(y), x(), x[]\}}{\pi.P \xrightarrow{\pi} P}\ \pi$$

$$\frac{P \xrightarrow{l} P' \quad \mathsf{bn}(l) \cap \mathsf{fn}(Q) = \emptyset}{P \mid Q \xrightarrow{l} P' \mid Q}\ \text{PAR}_1 \qquad \frac{Q \xrightarrow{l} Q' \quad \mathsf{bn}(l) \cap \mathsf{fn}(P) = \emptyset}{P \mid Q \xrightarrow{l} P \mid Q'}\ \text{PAR}_2 \qquad \frac{P \xrightarrow{[y \leftrightarrow z]} P'}{(\nu\, xy)P \xrightarrow{\tau} P'\{x/z\}}\ \textsc{AxCut}$$

$$\frac{P \xrightarrow{x[] \mid y()} P'}{(\nu\, xy)P \xrightarrow{\tau} P'}\ \bot\mathbf{1} \qquad \frac{P =_\alpha Q \quad Q \xrightarrow{l} R}{P \xrightarrow{l} R}\ =_\alpha \qquad \frac{P \xrightarrow{l} P' \quad x, y \notin \mathsf{cn}(l) \quad x *_{P'} y}{(\nu\, xy)P \xrightarrow{l} (\nu\, xy)P'}\ \textsc{Res}$$

$$\frac{P \xrightarrow{x[x'] \mid y(y')} P'}{(\nu\, xy)P \xrightarrow{\tau} (\nu\, xy)(\nu\, x'y')P'}\ \otimes\!\!\!\!\otimes \qquad \frac{P \xrightarrow{l} P' \quad Q \xrightarrow{l'} Q' \quad \mathsf{bn}(l) \cap \mathsf{bn}(l') = \emptyset}{P \mid Q \xrightarrow{l \mid l'} P' \mid Q'}\ \text{SYN}$$

$$\frac{P \xrightarrow{l} P' \quad x \notin \mathsf{cn}(l)}{x[].P \xrightarrow{l} x[].P'}\ \pi_1 \qquad \frac{P \xrightarrow{l} P' \quad \mathsf{fn}(P') \neq \emptyset}{x().P \xrightarrow{l} x().P'}\ \pi_2 \qquad \frac{P \xrightarrow{l} P' \quad x, x' \notin \mathsf{cn}(l) \quad x *_{P'} x'}{x[x'].P \xrightarrow{l} x[x'].P'}\ \otimes$$

$$\frac{P \xrightarrow{l} P' \quad x, x' \notin \mathsf{cn}(l) \quad x \circledast_{P'} x'}{x(x').P \xrightarrow{l} x(x').P'}\ \parr \qquad \frac{\pi.P \xrightarrow{l} \pi.P' \quad \mathsf{fn}(\pi) *_{\pi.P} \mathsf{fn}(l)}{\pi.P \xrightarrow{\pi \mid l} P'}\ \mid \pi$$

Figure 6 The LTS for HCP (Definition 17) includes rules for actions and communication (top) and for delayed actions and self-synchronizations (bottom).

The semantics of HCP is given in terms of a Labeled Transition System (LTS):

▶ **Definition 17** (HCP: LTS). *The binary relation on* HCP *processes* $\xrightarrow{l}$ *is defined by the rules in Figure 6, with action labels defined as follows:*

$$l, l' ::= [x \leftrightarrow y] \mid x[y] \mid x(y) \mid x() \mid x[] \mid l \mid l \mid \tau$$

In the following, $\mathsf{fn}(l)$, $\mathsf{bn}(l)$, *and* $\mathsf{cn}(l)$ *denote the free, bound, and channel names of* l, *respectively. They are defined as follows:* $\mathsf{fn}([x \leftrightarrow y]) \triangleq \{x, y\}$, $\mathsf{fn}(\tau) = \mathsf{bn}(\tau) \triangleq \emptyset$, $\mathsf{fn}(x[y]) = \mathsf{fn}(x(y)) = \mathsf{fn}(x()) = \mathsf{fn}(x()) \triangleq x$, *and* $\mathsf{bn}(x[y]) = \mathsf{bn}(x(y)) \triangleq \{y\}$. *Also,* $\mathsf{fn}(l_1 \mid l_2) \triangleq \mathsf{fn}(l_1) \cup \mathsf{fn}(l_2)$, *and* $\mathsf{bn}(l_1 \mid l_2) \triangleq \mathsf{bn}(l_1) \cup \mathsf{bn}(l_2)$. *Moreover,* $\mathsf{cn}(l) \triangleq \mathsf{fn}(l) \cup \mathsf{bn}(l)$.

The rules in Figure 6 are inspired by proof-theoretical transformations on HCP's proof derivations [23]; they can be divided into two classes. The rules above the line are usual formulations for actions, structural rules, and communication. Actions can appear in parallel in a label, and compatible actions in parallel induce a τ-transition. The five rules below the line formalize *delayed actions* and *self-synchronizations*. Intuitively, the first four rules allow to observe an action l in a delayed style; such an action must be independent from the prefix at the top-level (on x). The last rule, $\mid \pi$, implements self-synchronization for a process $\pi.P$: the (top-level) prefix π is considered in parallel with a (delayed) action l emanating from P.

▶ **Example 18.** To illustrate the LTS of HCP, recall the processes P_1 and P_2 from § 1. In HCP, they are denoted as: $P_{18} \triangleq (\nu\, xx')(x[].x'().\mathbf{0})$ and $Q_{18} \triangleq (\nu\, xx')(\nu\, yy')(y[].x().\mathbf{0} \mid x'[].y'().\mathbf{0})$. Consider the following type derivation, parametric on w, z:

$$\Pi_{w,z} = \frac{\dfrac{\mathbf{0} \vdash_{\text{H}}}{w().\mathbf{0} \vdash_{\text{H}} w : \bot}\ \text{H-}\bot}{z[].w().\mathbf{0} \vdash_{\text{H}} w : \bot \parallel z : \mathbf{1}}\ \text{H-}\mathbf{1}$$

Thus, P_{18} is typed as $\Pi_{x',x}$ followed by an application of Rule H-Cut. Also, Q_{18} is typed by $\Pi_{x,y}$ and $\Pi_{y',x'}$ followed by an application of Rules H-Mix$_2$ and H-Cut. Because Rule C-**1** only types empty outputs followed by $\mathbf{0}$, neither P_{18} nor Q_{18} are typable in CP.

By Rules $\mid \pi$ and $\bot\mathbf{1}$ in Figure 6, $P_{18} \xrightarrow{\tau} \mathbf{0}$. Similarly, $y[].x().\mathbf{0} \mid x'[].y'().\mathbf{0} \xrightarrow{x() \mid x'[]} y[].\mathbf{0} \mid y'().\mathbf{0}$ by Rules π, π_1 and SYN. Finally, by Rule $\bot\mathbf{1}$, $Q_{18} \xrightarrow{\tau} (\nu\, yy')(y[].\mathbf{0} \mid y'().\mathbf{0})$.

We now recall some useful notions and results from [23].

▶ **Definition 19** (HCP: Weak LTS and Bisimilarity [23]). *$\stackrel{l}{\Rightarrow}$ is the smallest relation such that:* (1) *$P \stackrel{\tau}{\Rightarrow} P$ for all P;* (2) *and if $P \stackrel{\tau}{\Rightarrow} P'$, $P' \xrightarrow{l} Q'$, and $Q' \stackrel{\tau}{\Rightarrow} Q$, then $P \stackrel{l}{\Rightarrow} Q$.*

A symmetric relation $\mathcal{R}$ is a bisimulation if $P\ \mathcal{R}\ Q$ implies that if $P \stackrel{l}{\Rightarrow} P'$ then $Q \stackrel{l}{\Rightarrow} Q'$ for some Q' such that $P'\ \mathcal{R}\ Q'$. Bisimilarity is the largest relation $\approx_{\mathtt{H}}$ that is a bisimulation.

Well-typed processes satisfy readiness, defined as follows:

▶ **Theorem 20** (HCP: Readiness [23]). *Let $P \vdash_{\mathtt{H}} \Gamma_1 \parallel \cdots \parallel \Gamma_n$. For every $i \in [1,n]$, there exist $x \in dom(\Gamma_i)$, l_x, and P' such that $P \stackrel{l_x}{\Longrightarrow} P'$.*

In HCP, transitions associated to sessions in different partitions can be fired in parallel:

▶ **Lemma 21** ([23]). *If $P \vdash_{\mathtt{H}} \mathcal{G} \parallel \Gamma, x : A \parallel \Delta, y : B$, $P \stackrel{l_x}{\Longrightarrow} P'$, and $P \stackrel{l_y}{\Longrightarrow} P''$, then there exists Q s.t. $P \stackrel{l_x \mid l_y}{\Longrightarrow} Q$ (up to α-renaming).*

▶ **Definition 22** (HCP: Structural Congruence). *Let $\equiv_{\mathtt{H}}$ be the smallest congruence relation generated by the axioms:*

$$P \mid Q \equiv_{\mathtt{H}} Q \mid P \qquad P \mid \mathbf{0} \equiv_{\mathtt{H}} P$$
$$P \mid (Q \mid R) \equiv_{\mathtt{H}} (P \mid Q) \mid R \qquad (\nu\, xy)P \equiv_{\mathtt{H}} (\nu\, yx)P$$
$$(\nu\, xy)P \mid Q \equiv_{\mathtt{H}} (\nu\, xy)(P \mid Q) \quad \text{if } x, y \notin \mathsf{fn}(Q) \qquad (\nu\, xy)(\nu\, wz)P \equiv_{\mathtt{H}} (\nu\, wz)(\nu\, xy)P$$

Because of Readiness (Theorem 20), HCP also satisfies *progress*:

▶ **Corollary 23** (HCP: Progress [23]). *If $P \in$ HCP and $P \not\equiv_{\mathtt{H}} \mathbf{0}$, then $P \xrightarrow{l} P'$ for some l, P'.*

In order to relate with reduction-based semantics (in SP), we define the following:

▶ **Definition 24** (HCP: Reduction). *We write $\rightarrow^*$ for the reflexive, transitive closure of $\xrightarrow{\tau}$.*

▶ **Lemma 25.** *Let $P \in$ HCP s.t. $P \vdash_{\mathtt{H}} \cdot$, then exists P' s.t. $P \rightarrow^* P' \equiv_{\mathtt{H}} \mathbf{0}$.*

Proof sketch. We prove it in two steps: (1) We prove that if $P \not\equiv_{\mathtt{H}} \mathbf{0}$, then there exists P' s.t. $P \xrightarrow{\tau} P'$, and $P' \vdash_{\mathtt{H}} \cdot$. This ensures the existence of a τ-transition in every step. (2) We then prove that $\mathbf{0}$ can be reached in finitely many steps. See [19] for details. ◀

Inspired by Lemma 25 we have the following definition of deadlock freedom for HCP.

▶ **Definition 26** (HCP: Deadlock Freedom). *Let $P \in$ HCP. We say that P is deadlock free, written $\mathcal{D}_{\mathbf{H}}(P)$, iff there exists P' s.t. $P \rightarrow^* P' \equiv_{\mathtt{H}} \mathbf{0}$.*

HCP has a *denotational semantics* that interprets well-typed processes as sets of possible interactions on their free names. Given a process P, its set of denotations is written $\|P\|$. Denotational equivalence, noted $\doteq$, is the typed relation defined as: $P \doteq Q$ iff $\|P\| = \|Q\|$. We shall rely on denotational equivalence; its exact formulation, given in [19], is interesting but not crucial for following our results. We notice that $\equiv_{\mathtt{H}}$ is sound wrt $\doteq$ and that our results are reflected by bisimilarity, as ensured by the following result:

▶ **Theorem 27** (HCP: Full Abstraction [23]). *For well-typed processes: $\approx_{\mathtt{H}} = \doteq$.*

3 The Role of Delayed Actions and Self-Synchronizations in DF

We have seen that SP defines a flexible typing discipline that admits deadlocked and deadlock-free processes. Also, we saw the way in which CP and HCP enforce DF by typing, and that the latter's LTS allows for delayed actions and self-synchronizations. By defining two classes of SP processes, $\mathbb{C}$ and $\mathbb{H}$, which capture typability as in CP and HCP, respectively (Definition 34), we study whether delayed actions and self-synchronizations influence DF.

We proceed as follows. As we have seen, $\mathcal{D}_{\mathbf{H}}(P)$ means that P is deadlock free by considering all sources of behavior, including delayed actions and self-synchronizations; we shall also define $\mathcal{D}^{\mathsf{R}}_{\mathbf{H}}(P)$ to mean that P is deadlock free by considering *regular transitions only*. Our main result is Corollary 53, which ensures: (1) delayed actions and self-synchronizations are *inessential* when it comes to DF, and (2) given an encoding $[\![\cdot]\!] : \mathsf{SP} \to \mathsf{HCP}$, for a process $P \in \mathsf{SP}$ such that $\mathcal{D}_{\mathbf{H}}([\![P]\!])$, there is a P' that *simulates* P, and $\mathcal{D}^{\mathsf{R}}_{\mathbf{H}}([\![P']\!])$.

3.1 From SP to HCP

We start by translating processes in SP into processes in HCP:

▶ **Definition 28.** *Let $P \in \mathsf{SP}$. The encoding $[\![\cdot]\!] : \mathsf{SP} \to \mathsf{HCP}$ is a homomorphism except for the case of free output, defined as $[\![\overline{x}\langle v\rangle.P]\!] \triangleq x[y].([y \leftrightarrow v] \mid [\![P]\!])$. For types, we define:*

$$[\![\mathsf{end}_?]\!] \triangleq \bot \qquad [\![\mathsf{end}_!]\!] \triangleq \mathbf{1} \qquad [\![?T.S]\!] \triangleq [\![T]\!] \parr [\![S]\!] \qquad [\![!T.S]\!] \triangleq [\![T]\!]^{\bot} \otimes [\![S]\!]$$

For typing environments, we define: $[\![\emptyset]\!] \triangleq \emptyset$ and $[\![\Gamma, x : T]\!] \triangleq [\![\Gamma]\!], x : [\![T]\!]$.

Regular Transitions do not depend on self-synchronizations or delayed actions:

▶ **Definition 29** (HCP: Regular Transitions)**.** *A derivation T for $P \xrightarrow{l} Q$ is denoted $T : P \xrightarrow{l} Q$. We define $\mathsf{RT}(T)$ iff T is derived only using rules above the horizontal line in Figure 6.*

▶ **Example 30.** Recall the processes P_{18} and Q_{18} from Example 18, which use self-synchronizations and delayed actions, respectively: we have that $T_1 : P_{18} \xrightarrow{\tau} \mathbf{0}$, and $T_2 : Q_{18} \xrightarrow{\tau} (\nu\, yy')(y[\,].\mathbf{0} \mid y'().\mathbf{0})$. Therefore, $\neg\mathsf{RT}(T_1)$ and $\neg\mathsf{RT}(T_2)$.

The encoding of free output induces transitions involving the forwarder process, not present in the source SP process. We handle the substitutions induced by forwarders in Rule AxCut (Figure 6) as follows:

▶ **Definition 31** (HCP: Ready-for-Substitution)**.** *Let $P \in \mathsf{HCP}$. We say that $P = (\nu\, xy)P'$ is ready for substitution of z for x, written $\mathsf{RS}_{z,x}(P)$, if there exists $z \in \mathsf{fn}(P)$ and P' s.t. $P \xrightarrow{[y \leftrightarrow z]} P'$, and $(\nu\, xy)P \xrightarrow{\tau} P'\{x/z\}$. Otherwise, we write $\neg\mathsf{RS}(P)$.*

We may now define transitions for processes that are ready for a substitution.

▶ **Definition 32** (HCP: Eager-to-Rename)**.** *The relation $\xrightarrow[\mathtt{ER}]{l}$ on HCP processes is defined as:*

$$(P \xrightarrow{l} Q) \wedge \mathsf{RS}_{x,z}(Q) \Rightarrow P \xrightarrow[\mathtt{ER}]{l} Q\{x/z\} \qquad \textit{and} \qquad (P \xrightarrow{l} Q) \wedge \neg\mathsf{RS}(Q) \Rightarrow P \xrightarrow[\mathtt{ER}]{l} Q$$

Intuitively, $\xrightarrow[\mathtt{ER}]{l}$ executes outputs and forwarders in one single step. When $[\![P]\!]$ only relies on regular transitions we have the following operational correspondence result.

▶ **Theorem 33** ($[\![\cdot]\!]$: Operational Correspondence). *Let* $P \in \mathbb{H}$.
1. *If* $T : [\![P]\!] \xrightarrow[\text{ER}]{\tau} R$ *and* $\mathsf{RT}(T)$, *then* $P \longrightarrow Q$ *s.t.* $[\![Q]\!] \equiv_{\text{H}} R$.
2. *If* $P \longrightarrow Q$, *then* $[\![P]\!] \xrightarrow[\text{ER}]{\tau} R$ *s.t.* $R \equiv_{\text{H}} [\![Q]\!]$.

Proof sketch. Part (1) is proven by case analysis in $\xrightarrow{\tau}$, and (2) is proven by induction in the derivation of $\longrightarrow$. See [19] for details. ◀

Following Dardha and Pérez [9], we now define $\mathbb{C}$ and $\mathbb{H}$ as the classes of SP processes that are also typable in CP and HCP, respectively:

▶ **Definition 34** (Classes $\mathbb{C}$ and $\mathbb{H}$). *The classes* $\mathbb{C}$ *and* $\mathbb{H}$ *of* SP *processes are defined as:*

$$\mathbb{C} \triangleq \{P \in \mathsf{SP} \mid \Gamma \vdash_{\text{S}} P \wedge [\![P]\!] \vdash_{\text{C}} [\![\Gamma]\!]\}$$
$$\mathbb{H} \triangleq \{P \in \mathsf{SP} \mid \Gamma \vdash_{\text{S}} P \wedge \Gamma = \Gamma_1, \ldots, \Gamma_n \wedge [\![P]\!] \vdash_{\text{H}} [\![\Gamma_1]\!] \parallel \cdots \parallel [\![\Gamma_n]\!]\}$$

Hence, in writing "$P \in \mathbb{H}$" we are not referring to an HCP process directly, but rather to a SP process P (in the sense of § 2.1) that is related (up to $[\![\cdot]\!]$) to some (typable) HCP process. This is how SP offers a unifying framework for comparing different type systems. As a direct consequence of Lemma 13 and Example 14 we have that $\mathbb{C} \subsetneq \mathbb{H}$.

3.2 A Refined Account of $\mathbb{H}$, Based on Deadlock Freedom

As explained in the previous section, HCP enjoys liveness properties corresponding to the LTS. If we focus only on τ-transitions (cf. Definition 24) we obtain the following results.

We extend Definition 29 (regular transitions) to sequences of transitions, as follows:

▶ **Definition 35** (HCP: Regular Sequence of Transitions). *Assume* $P_1, \ldots, P_n$ *in* HCP *and transitions* $T_i : P_i \xrightarrow{l_i} P_{i+1}$. *We say that a transition sequence* $\rho : P \xrightarrow{l_1} \cdots \xrightarrow{l_n} P_n$ *transitions regularly iff* $\mathsf{RT}(T_i)$ *for all* $i = 1, \ldots, n$. *We write* $\mathsf{RT}(\rho)$.

We are interested in processes whose transitions are regular, thus we refine deadlock freedom in HCP (Definition 26) as follows:

▶ **Definition 36** (HCP: Deadlock Freedom based on Regular Transitions). *Let* $P \in \mathsf{HCP}$. *We say that* P *is deadlock free without delayed actions and self-synchronizations, written* $\mathcal{D}^{\text{R}}_{\mathbf{H}}(P)$, *iff* $\mathcal{D}_{\mathbf{H}}(P)$, $\rho : P \to^* P' \equiv_{\text{H}} \mathbf{0}$, *and* $\mathsf{RT}(\rho)$.

In turn, Definitions 26 and 36 allow us to refine the definition of $\mathbb{H}$ (Definition 34):

▶ **Definition 37** (HCP: Sub-classes of $\mathbb{H}$). *We define the following classes of DF processes:*

$$\mathbb{H}_{\text{F}} \triangleq \{P \in \mathbb{H} \mid \mathcal{D}_{\mathbf{H}}([\![P]\!])\} \qquad \mathbb{H}_{\text{R}} \triangleq \{P \in \mathbb{H} \mid \mathcal{D}^{\text{R}}_{\mathbf{H}}([\![P]\!])\}$$

By Definitions 34 and 37 we have $\mathbb{H}_{\text{R}} \subsetneq \mathbb{H}_{\text{F}} \subsetneq \mathbb{H}$.

▶ **Example 38.** Consider the SP processes:

$$P_{38} \triangleq (\nu\, wz)(\overline{w}\langle\rangle.(\nu\, xy)(\overline{x}\langle\rangle.\mathbf{0} \mid y().z().\mathbf{0})) \quad Q_{38} \triangleq (\nu\, wz)(\overline{w}\langle\rangle.\mathbf{0} \mid (\nu\, xy)(\overline{x}\langle\rangle.\mathbf{0} \mid z().y().\mathbf{0}))$$

We have $P_{38} \in \mathbb{H}_{\text{F}} \setminus \mathbb{H}_{\text{R}}$ and $Q_{38} \in \mathbb{H}_{\text{R}}$. Although $\neg\mathcal{D}_{\mathbf{S}}(P_{38})$, the HCP process $[\![P_{38}]\!]$ has a τ-transition due to a delayed action, and therefore $\mathcal{D}_{\mathbf{H}}([\![P_{38}]\!])$.

▶ **Theorem 39.** *If* $P \in \mathbb{H}_{\text{R}}$, *then* $\mathcal{D}_{\mathbf{S}}(P)$.

Proof. It follows from Theorem 33 and Definitions 9 and 37. ◀

$$
\begin{array}{cc}
x().x'().P \simeq_{cc} x'().x().P & x().x'(y').P \simeq_{cc} x'(y').x().P \\
x(y).x'(y').P \simeq_{cc} x'(y').x(y).P & x().x'[y'].P \simeq_{cc} x'[y'].x().P \\
x[y].x'(y').P \simeq_{cc} x'(y').x[y].P & x[\,].x'(y').P \simeq_{cc} x'(y').x[\,].P \\
x[y].x'[y'].P \simeq_{cc} x'[y'].x[y].P & x[\,].x'[y'].P \simeq_{cc} x'[y'].x[\,].P \\
x[\,].x'[\,].P \simeq_{cc} x'[\,].x[\,].P & x[\,].x'().P \simeq_{cc} x'().x[\,].P \\
(\nu\, xy)(x'().P) \simeq_{cc} x'().(\nu\, xy)(P) & (\nu\, xy)(x'[\,].P) \simeq_{cc} x'[\,].(\nu\, xy)(P) \\
(\nu\, xy)(x'(y').P) \simeq_{cc} x'(y').(\nu\, xy)(P) & (\nu\, xy)(x'[y'].P) \simeq_{cc} x'[y'].(\nu\, xy)(P)
\end{array}
$$

Figure 7 HCP: Commuting Conversions (Definition 40).

From $\mathbb{H}_{\mathsf{F}}$ to $\mathbb{H}_{\mathsf{R}}$ via process optimizations. We now embark to show how to transform processes in $\mathbb{H}_{\mathsf{F}}$ (where self-synchronizations and delayed actions are used) into processes in $\mathbb{H}_{\mathsf{R}}$ (where they are not). Intuitively, we would like to transform, e.g.,

$$(\nu\, wz)(\overline{w}\langle\,\rangle.(\nu\, xy)(\overline{x}\langle\,\rangle.\mathbf{0} \mid y().z().\mathbf{0})) \quad \text{into} \quad (\nu\, wz)(\overline{w}\langle\,\rangle.\mathbf{0} \mid (\nu\, xy)(\overline{x}\langle\,\rangle.\mathbf{0} \mid z().y().\mathbf{0}))$$

The transformation from $\mathbb{H}_{\mathsf{F}}$ to $\mathbb{H}_{\mathsf{R}}$ is formalized by Theorem 47. To achieve it, we leverage two existing ingredients. The *first ingredient* is the notion of *commuting conversions*: sound transformations on processes that involve actions from independent sessions (cf. [10, 30]).

▶ **Definition 40** (HCP: Commuting Conversions)**.** *We define $\simeq_{cc}$ as the smallest congruence on* HCP *processes induced by the equalities in Figure 7.*

The transformations induced by $\simeq_{cc}$ have a proof-theoretical origin, and so they are type-preserving, which ensures that they do not alter the causality relations on processes. We can show that that $\simeq_{cc}$ is sound wrt $\approx_{\mathtt{H}}$, i.e., if $P \simeq_{cc} Q$ then $P \approx_{\mathtt{H}} Q$.

▶ **Example 41.** Recall processes P'_{14}, P''_{14}, and P_{14} from Example 14. We illustrate the optimizations on processes induced by commuting conversions by combining P''_{14} and the process $Q_{41} \triangleq x_2(z_2).x_1(z_1).x_1().x_2().z_1().z_2().\mathbf{0}$, as follows:

$$P_{41} \triangleq (\nu\, x_1y_1)(\nu\, x_2y_2)(\nu\, v_1k_1)(\nu\, v_2k_2)(Q_{41} \mid P''_{14})$$

Note that a τ-transition along the sessions x_1y_1 or x_2y_2 in P_{41} would depend on a delayed action. Now, we can use a commuting conversion to swap the order of the inputs, effectively anticipating the input on x_1: $Q_{41} \simeq_{cc} x_1(z_1).x_2(z_2).x_1().x_2().z_1().z_2().\mathbf{0} = P'_{14}$; therefore, $P_{41} \simeq_{cc} P_{14}$. Clearly, there is a transition sequence $\rho : P_{14} \to^* \equiv_{\mathtt{H}} \mathbf{0}$ s.t. $\mathsf{RT}(\rho)$.

The *second ingredient* is *disentanglement*, which also induces optimizations on processes:

▶ **Definition 42** (HCP: Disentanglement [22])**.** *Disentanglement is described by the smallest relation $\rightsquigarrow$ on (typed) processes closed under the rules in Figure 8. We write $\rightsquigarrow^*$ for the reflexive and transitive closure of $\rightsquigarrow$.*

Each of the process transformations in Figure 8 is justified by an operation on derivations; this way, e.g., for the second rule we have:

$$\dfrac{\dfrac{P \vdash_{\mathtt{H}} \mathcal{G} \parallel \Gamma \qquad Q \vdash_{\mathtt{H}} \mathcal{H}}{P \mid Q \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma}\,\mathsf{H}\text{-}\textsc{Mix}_2}{x().(P \mid Q) \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma, x : \bot}\,\mathsf{H}\text{-}\bot \quad \rightsquigarrow \quad \dfrac{\dfrac{P \vdash_{\mathtt{H}} \mathcal{G} \parallel \Gamma}{x().P \vdash_{\mathtt{H}} \mathcal{G} \parallel \Gamma, x : \bot}\,\mathsf{H}\text{-}\bot \qquad Q \vdash_{\mathtt{H}} \mathcal{H}}{x().P \mid Q \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma, x : \bot}\,\mathsf{H}\text{-}\textsc{Mix}_2$$

$$
\begin{array}{lcl}
x[\,].P \vdash_{\mathtt{H}} \mathcal{G} \parallel x : \mathbf{1} & \rightsquigarrow & x[\,].\mathbf{0} \mid P \vdash_{\mathtt{H}} \mathcal{G} \parallel x : \mathbf{1} \\
x().(P \mid Q) \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma, x : \bot & \rightsquigarrow & x().P \mid Q \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma, x : \bot \\
(\nu xy)(P \mid Q) \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma \parallel \Delta & \rightsquigarrow & (\nu\, xy)P \mid Q \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma \parallel \Delta \\
x[y].(P \mid Q) \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma, \Delta, x : A \otimes B & \rightsquigarrow & x[y].P \mid Q \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma, \Delta, x : A \otimes B \\
x(y).(P \mid Q) \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma, \Delta, x : A \parr B & \rightsquigarrow & x(y).P \mid Q \vdash_{\mathtt{H}} \mathcal{G} \parallel \mathcal{H} \parallel \Gamma, \Delta, x : A \otimes B
\end{array}
$$

Figure 8 HCP: Disentanglement (Definition 42). See [19] for details.

This way, disentanglement proceeds by the repeated application of the rules from Figure 8 to the derivation of $P \vdash_{\mathtt{H}} \Gamma_1 \parallel \cdots \parallel \Gamma_n$, which aims at moving downwards the instances of Rule H-Mix$_2$ (cf. Figure 5). If H-Mix$_2$ gets stuck in either H-Cut or H-$\otimes$, then it becomes an instance of C-Cut or C-$\otimes$, respectively (cf. Figure 4).

Disentanglement increases the parallelism in processes. This way, e.g., for P_{14} and Q_{14} (Example 14) we have: $P_{14} \rightsquigarrow^* Q_{14}$. Also, note that Rule H-**1** types $x[\,].P \vdash_{\mathtt{H}} \Gamma \parallel x : \mathbf{1}$, induces a discrepancy: at the process level, the rule places the empty output in sequential composition with P, whereas at the level of typing $x : \mathbf{1}$ is placed in its own partition, enforcing independence from all names in $\mathsf{fn}(P)$. Disentanglement solves this discrepancy. Consider, e.g., process $P_{18} = (\nu\, xx')(x[\,].x'().\mathbf{0})$: we have $P_{18} \rightsquigarrow^* (\nu\, xx')(x[\,].\mathbf{0} \mid x'().\mathbf{0})$.

▶ **Lemma 43** (Disentanglement [23])**.** *If there exists a derivation d of $P \vdash_{\mathtt{H}} \Gamma_1 \parallel \cdots \parallel \Gamma_n$, then there exist derivations $d_1, \ldots, d_n$ of $P_1 \vdash_{\mathtt{C}} \Gamma_1, \ldots, P_n \vdash_{\mathtt{C}} \Gamma_n$ in* CP*, and*

$$
P \vdash_{\mathtt{H}} \Gamma_1 \parallel \cdots \parallel \Gamma_n \quad \rightsquigarrow^* \quad \dfrac{P_1 \vdash_{\mathtt{C}} \Gamma_1 \;\cdots\; P_n \vdash_{\mathtt{C}} \Gamma_n}{P_1 \mid \cdots \mid P_n \vdash_{\mathtt{H}} \Gamma_1 \parallel \cdots \parallel \Gamma_n}\ \textit{H-Mix}_2
$$

where we use the double line to indicate multiple uses of the same rule.

The following result ensures that process observations are invariant under disentanglement. Moreover, since instances of H-Cut are turned into instances of C-Cut, disentangled processes do not feature occurrences of restriction between sessions in sequential composition.

▶ **Lemma 44.** *Suppose $P \in$ HCP. If $P \rightsquigarrow^* P'$ then $P \approx_{\mathtt{H}} P'$.*

Proof. We prove that if $P \rightsquigarrow^* P'$ then $P \triangleq P'$ by induction on the length k of $\rightsquigarrow^*$. For the base case ($k = 1$) we proceed by a case analysis in the last rule applied in the type derivation of $P \vdash_{\mathtt{H}} \mathcal{G}$. The fact that $P \approx_{\mathtt{H}} P'$ follows from Theorem 27. ◀

Given a process P, the rules for disentanglement can be applied in any order; we therefore define a set of disentangled processes:

▶ **Definition 45** (HCP: Disentangled Processes)**.** *Given $P \in$ HCP, the set $\textsc{Dist}(P)$ is defined as follows:*

$$
\textsc{Dist}(P) \triangleq \left\{ P' \in \mathsf{HCP} \;\middle|\; \begin{array}{c} P \rightsquigarrow^* P', \\ P' = P_1 \mid \cdots \mid P_n \vdash_{\mathtt{H}} \Gamma_1 \parallel \cdots \parallel \Gamma_n, \quad P_1 \vdash_{\mathtt{C}} \Gamma_1, \;\cdots\; , P_n \vdash_{\mathtt{C}} \Gamma_n \end{array} \right\}
$$

From Lemma 44 we have that all disentangled processes are observationally equivalent:

▶ **Lemma 46.** *Let $P \in$ HCP. If $Q, R \in \textsc{Dist}(P)$, then $Q \approx_{\mathtt{H}} R$.*

Proof. From Lemma 44, $P \approx_{\mathtt{H}} P'$ for all $P' \in \textsc{Dist}(P)$. By Definition 19, $\approx_{\mathtt{H}}$ is transitive. Hence, for all $Q, R \in \textsc{Dist}(P)$, $Q \approx_{\mathtt{H}} R$. ◀

We use disentanglement to prove that if $\mathcal{D}_{\mathbf{H}}(P)$ then there is a P' s.t. $\mathcal{D}^{\mathsf{R}}_{\mathbf{H}}(P')$, with $P \approx_{\mathtt{H}} P'$.

The following main result establishes that the notions of $\mathcal{D}_{\mathbf{H}}(\cdot)$ (Definition 26) and $\mathcal{D}^{\mathsf{R}}_{\mathbf{H}}(\cdot)$ (Definition 36) are equivalent, up to commuting conversions and disentanglement.

▶ **Theorem 47.** *For all processes $P \in \mathsf{HCP}$ s.t. $\mathcal{D}_{\mathbf{H}}(P)$, then there exist $P', Q \in \mathsf{HCP}$ s.t.:* (1) $P' \in \textit{Dist}(P)$, (2) $P' \simeq_{cc} Q$, (3) $P \approx_{\mathtt{H}} Q$, (4) $\mathcal{D}^{\mathsf{R}}_{\mathbf{H}}(Q)$.

Proof sketch. Parts (1)-(3) follow from Definitions 40 and 45 and Lemma 44. For part (4) we show that self-synchronizations and delayed actions are eliminated by means of disentanglement and commuting conversions, respectively. See [19] for details. ◀

Theorem 47 concerns HCP processes. To lift this result to SP, we need some results.

▶ **Lemma 48.** *Let $P \in \mathbb{H}$. There exists $P' \in \mathbb{H}$ s.t.:* (1) $[\![P]\!] \rightsquigarrow^* [\![P']\!]$. (2) $[\![P]\!] \simeq^*_{cc} [\![P']\!]$.

Proof. The items follow by induction on the length of $\rightsquigarrow^*$ and $\simeq^*_{cc}$, respectively. For (1) in the base cases we proceed by a case analysis in the last rule applied in the type derivation of $[\![P]\!] \vdash_{\mathtt{H}} [\![\Gamma]\!]$; it shows the structure of $[\![P]\!]$ and by Definition 28 we obtain the structure of P. The proof finishes by applying a single step of $\rightsquigarrow$ to the type derivation of $[\![P]\!] \vdash_{\mathtt{H}} [\![\Gamma]\!]$ and replicating it to the derivation of $\Gamma \vdash_{\mathtt{S}} P$. The proof of (2) proceeds similarly. ◀

Lemma 48 ensures that the following definition is sound:

▶ **Definition 49** (Lifting Commuting Conversions and Disentanglement to SP). *Let $P, P' \in \mathbb{H}$. We write $P \rightsquigarrow^* P'$ and $P \simeq^*_{cc} P'$, whenever $[\![P]\!] \rightsquigarrow^* [\![P']\!]$ and $[\![P]\!] \simeq^*_{cc} [\![P']\!]$ hold, respectively.*

Having disentanglement in SP, we aim to prove that the resulting disentangled process *simulates* the original process. To define simulation in SP, we need the following notion:

▶ **Definition 50** (SP: Labelled Reduction Semantics). *Let $P \in \mathsf{SP}$, then $P \overset{\tau:xy}{\Longrightarrow} Q$ whenever:* (1) $P \equiv (\nu\, xy)(\overline{x}\langle v\rangle.P' \mid y(z).Q' \mid R) \longrightarrow (\nu\, xy)(P' \mid Q'\{^v/_z\} \mid R) \equiv Q$, *or* (2) $P \equiv (\nu\, xy)(x().P' \mid \overline{y}\langle\rangle.Q' \mid R) \longrightarrow (\nu\, xy)(P' \mid Q' \mid R) \equiv Q$.

▶ **Definition 51** (SP: Simulation). *A binary relation $\mathbb{S}$ in SP is a (typed) simulation if whenever $(P, Q) \in \mathbb{S}$ then $\Gamma \vdash_{\mathtt{S}} P$, $\Gamma \vdash_{\mathtt{S}} Q$ and $P \overset{\tau:xy}{\Longrightarrow} P'$ implies $Q \overset{\tau:xy}{\Longrightarrow} Q'$ for some Q' s.t. $(P', Q') \in \mathbb{S}$. We write $P \lesssim Q$ whenever $(P, Q) \in \mathbb{S}$ for a (typed) simulation $\mathbb{S}$.*

In the LTS semantics of HCP, the processes P and Q from Theorem 47 are bisimilar; however, in a reduction semantics, any transitions of P that use delayed actions or self-synchronization would be considered as deadlocks, and then Q would only simulate P. Formally:

▶ **Theorem 52.** *The relation $\mathbb{S} = \{(P, R) \mid P \in \mathbb{H}, \text{and } P \rightsquigarrow R\}$ is a simulation.*

Proof sketch. By induction in the structure of P, with a case analysis in $\rightsquigarrow$. See [19] for details. ◀

Finally, Corollary 53, given below, brings Theorem 47 to SP: it shows that even though in HCP both $\mathcal{D}_{\mathbf{H}}(\cdot)$ and $\mathcal{D}^{\mathsf{R}}_{\mathbf{H}}(\cdot)$ are equivalent, in SP those notions are related via a simulation.

▶ **Corollary 53.** *Given $P \in \mathbb{H}_{\mathsf{F}}$, then there exist $Q \in \mathbb{H}$ and $P' \in \mathbb{H}_{\mathsf{R}}$ s.t.:* (1) $[\![Q]\!] \in \textit{Dist}([\![P]\!])$, (2) $[\![Q]\!] \simeq^*_{cc} [\![P']\!]$, (3) $P \lesssim P'$, (4) $[\![P]\!] \approx_{\mathtt{H}} [\![P']\!]$.

Proof. It follows by Lemma 48 and Theorems 47 and 52. ◀

Table 1 Inventory of type systems, classes of processes, and encodings considered in the paper. Shaded cells concern elements used in the case of asynchronous processes (§ 4).

SP^a	Definition 78	$\mathbb{C}^\mathsf{a}$, $\mathbb{H}^\mathsf{a}$	Definition 86		

▶ **Example 54** (Corollary 53, At Work)**.** Consider the process P_{54} and its encoding into HCP:

$$P_{54} \triangleq (\nu\, wz)(\overline{w}\langle\rangle.(\nu\, xy)(\overline{x}\langle\rangle.\mathbf{0} \mid (\nu\, ku)(k().\mathbf{0} \mid y().z().\overline{u}\langle\rangle.\mathbf{0})))$$
$$[\![P_{54}]\!] \triangleq (\nu\, wz)(w[].(\nu\, xy)(x[].\mathbf{0} \mid (\nu\, ku)(k().\mathbf{0} \mid y().z().u[].\mathbf{0})))$$

Note that $\neg\mathcal{D}_\mathbf{S}(P_{54})$ but $[\![P_{54}]\!]$ has two τ-transitions:

$$[\![P_{54}]\!] \xrightarrow{\tau} (\nu\, xy)(x[].\mathbf{0} \mid (\nu\, ku)(k().\mathbf{0} \mid y().u[].\mathbf{0})) \to^* \equiv_\mathtt{H} \mathbf{0} \tag{1}$$
$$[\![P_{54}]\!] \xrightarrow{\tau} (\nu\, wz)(w[].(\nu\, ku)(k().\mathbf{0} \mid z().u[].\mathbf{0})) \to^* \equiv_\mathtt{H} \mathbf{0} \tag{2}$$

where the transition in (1) is due to a delayed action on z and a self-synchronization along the session wz, and the transition in (2) is due to a delayed τ-transition along the session xy. Hence, $\mathcal{D}_\mathbf{H}([\![P_{54}]\!])$. Via disentanglement we obtain:

$$[\![P_{54}]\!] \rightsquigarrow (\nu\, wz)(w[].\mathbf{0} \mid (\nu\, xy)(x[].\mathbf{0} \mid (\nu\, ku)(k().\mathbf{0} \mid y().z().u[].\mathbf{0}))) \triangleq R'$$

In R', neither a delayed action nor a self-synchronization are needed, thus $\mathcal{D}^\mathsf{R}_\mathbf{H}(R')$. We could also give priority to the τ-transition along wz; however, because the input on z is not at the top-level, a synchronization on wz still requires a delayed action. This shows the need for commuting conversions. Indeed, by using $\simeq_{cc}$ we obtain:

$$R' \simeq_{cc} (\nu\, wz)(w[].\mathbf{0} \mid (\nu\, xy)(x[].\mathbf{0} \mid (\nu\, ku)(k().\mathbf{0} \mid z().y().u[].\mathbf{0}))) \triangleq R$$

We have that $\mathcal{D}^\mathsf{R}_\mathbf{H}(R)$. Moreover, there is a process P' in SP s.t. $[\![P']\!] = R$:

$$P' \triangleq (\nu\, wz)(\overline{w}\langle\rangle.\mathbf{0} \mid (\nu\, xy)(\overline{x}\langle\rangle.\mathbf{0} \mid (\nu\, ku)(k().\mathbf{0} \mid z().y().\overline{u}\langle\rangle.\mathbf{0})))$$

Notice that $P_{54} \lesssim P'$ follows trivially since $\mathcal{D}_\mathbf{S}(P')$.

4 The Case of Asynchronous Processes

Up to here we have addressed **(Q1)** by considering the relation between $\mathbb{H}_\mathsf{F}$ and $\mathbb{H}_\mathsf{R}$ in HCP. We now turn our attention to **(Q2)** and consider the interplay of DF and *asynchronous processes* as typable by Padovani's type system for asynchronous processes, here dubbed P [27].

We proceed as follows. In § 4.1 we recall Padovani's type system and introduce $\mathbb{P}$, the class of SP processes induced by P, and its sub-class $\mu\mathbb{P}$, derived from the type system μP. In § 4.2, we show that $\mu\mathbb{P} = \mathbb{C}$ (Corollary 74). In § 4.3, we establish a key result: the precise relations between $\mathbb{H}$, $\mathbb{H}_\mathsf{F}$, $\mathbb{H}_\mathsf{R}$, and $\mathbb{P}$ (Theorem 76). Also, we revisit Corollary 53 from the standpoint of P: we prove that the process $P' \in \mathbb{H}_\mathsf{R}$ (obtained via commuting conversions and disentanglement) is also in $\mathbb{P}$ (Corollary 77). In § 4.4 we present SP^a, an asynchronous version of SP, and show how to extend our results for SP to SP^a (Corollary 88).

Table 1 summarizes all technical ingredients, including those introduced in this section.

4.1 The Type System P

We summarize the linear fragment of the type system P by Padovani [27], which streamlines Kobayashi's type system for deadlock freedom [21]. We assume sets of channels $a, b, \ldots$ and variables $x, y, \ldots$; then, names $u, v, \ldots$ are either channels or variables. We find it convenient to use processes with polyadic communication:

$$P ::= u!\langle x_1, \ldots, x_n\rangle \mid u?(x_1, \ldots, x_n).P \mid P \mid Q \mid (\nu\, a)P \mid \mathbf{0}$$

Two salient features are the output $u!\langle x_1, \ldots, x_n\rangle$, which does not have a continuation, and "$(\nu\, a)P$", the standard restriction construct of the π-calculus. Notions of free and bound names are as usual: in the process $u?(x_1, \ldots, x_n).P$, $x_1, \ldots, x_n$ are bound in P; in $(\nu\, a)P$, a is bound in P. We write $\mathsf{fn}(P)$ and $\mathsf{bn}(P)$ for the free and bound names of P, respectively.

The reduction semantics is closed under a structural congruence, denoted $\equiv_{\mathsf{P}}$, which is standardly defined by the following axioms: (i) $P \mid Q \equiv_{\mathsf{P}} Q \mid P$, (ii) $P \mid \mathbf{0} \equiv_{\mathsf{P}} P$, (iii) $P \mid (Q \mid R) \equiv_{\mathsf{P}} (P \mid Q) \mid R$, (iv) $(\nu\, x)P \mid Q \equiv_{\mathsf{P}} (\nu\, x)(P \mid Q)$ (if $x \notin \mathsf{fn}(Q)$), and (v) $(\nu\, x)(\nu\, y) \equiv_{\mathsf{P}} (\nu\, y)(\nu\, x)P$.

Reduction is then defined as

$$a!\langle v_1, \ldots, v_n\rangle \mid a?(x_1, \ldots, x_n).P \longrightarrow_{\mathsf{P}} P\{v_1, \ldots, v_n/x_1, \ldots, x_n\}$$

▶ **Example 55.** Differently from SP, channels in Padovani's framework are used exactly once. Structured communications can of course be still expressed, using continuations. Consider the process $P_{55} \triangleq (\nu\, x)(Q_{55} \mid R_{55})$ with

$$Q_{55} \triangleq (\nu\, a)(\nu\, c)(x!\langle a, c\rangle \mid c!\langle a\rangle) \qquad R_{55} \triangleq x?(z_1, w).w?(z_2).((\nu\, r)z_1!\langle r\rangle \mid z_2?(w).\mathbf{0})$$

Q_{55} sends the two endpoints of a channel: the first is sent along x (together with a continuation channel c), and the other is sent along c. Channel a occurs in both outputs, but these occurrences actually denote different endpoints; this difference will be justified by typing (cf. Example 59). R_{55} receives these endpoints to implement a local exchange of name r along a.

Padovani's type system ensures the *absence of pending communications* in a process with respect to a channel. To formalize this notion, we rely on reduction contexts, defined as $\mathcal{C} ::= [\circ] \mid (\mathcal{C} \mid P) \mid (\nu\, x)\mathcal{C}$. We may now define the following auxiliary predicates:

$$\mathsf{out}(a, P) \;\Leftrightarrow\; P \equiv_{\mathsf{P}} \mathcal{C}[a!\langle e\rangle] \;\wedge\; a \notin \mathsf{bn}(C) \qquad \mathsf{in}(a, P) \;\Leftrightarrow\; P \equiv_{\mathsf{P}} \mathcal{C}[a?(x).Q] \;\wedge\; a \notin \mathsf{bn}(C)$$
$$\mathsf{sync}(a, P) \;\Leftrightarrow\; (\mathsf{in}(a, P) \wedge\; \mathsf{out}(a, P))$$

Intuitively, predicate $\mathsf{in}(a, P)$ holds if a is free in P and there is a subprocess of P that can perform a linear input on a. Predicate $\mathsf{out}(a, P)$ holds if a is free in P and a subprocess of P is waiting to send a value v. Predicate $\mathsf{sync}(a, P)$ denotes a pending input/output on a for which a synchronization on a is immediately available. This way, to formalize a pending input/output for which a synchronization on a is not immediately possible, we define:

$$\mathsf{wait}(a, P) \;\Leftrightarrow\; (\mathsf{in}(a, P) \;\vee\; \mathsf{out}(a, P)) \;\wedge\; \neg\mathsf{sync}(a, P)$$

Thus, ensuring no pending communications in P means ensuring $\neg\mathsf{wait}(a, P)$ for every a.

▶ **Example 56** (Predicates at work)**.** Consider the process $P_{56} \triangleq a?(x).b!\langle v_1\rangle \mid b?(y).a!\langle v_2\rangle$, which has a circular dependency. We have: (1) $\mathsf{out}(a, P_{56})$ and $\mathsf{out}(b, P_{56})$. (2) $\mathsf{in}(a, P_{56})$ and $\mathsf{in}(b, P_{56})$. (3) $\neg\mathsf{sync}(a, P_{56})$ and $\neg\mathsf{sync}(b, P_{56})$. (4) $\mathsf{wait}(a, P_{56})$ and $\mathsf{wait}(b, P_{56})$.

Type System. To ensure absence of pending communications, P relies on *priorities*. Let $p, q, \ldots$ denote subsets of $\{?, !\}$ (*polarities*). Types for channels are defined as follows:

$$t ::= p[t_1, \ldots, t_m]^n$$

where $n \in \mathbb{Z}$ is the priority of a channel, which indicates urgency for its use: the lower the number, the higher the urgency. We write $\#$ for $\{?, !\}$. This way, $\#$ and $\emptyset$ are even polarities.

▶ **Example 57** (Priorities)**.** To illustrate types and priorities, recall again the process $P_{56} = a?(x).b!\langle v_1\rangle \mid b?(y).a!\langle v_2\rangle$. As we have seen, we have $\mathsf{wait}(a, P_{56})$ and $\mathsf{wait}(b, P_{56})$.

Let us assume that x, y, v_1, v_2 are all typed with some type t. By inspecting the left thread of P_{56}, we infer that a and b must be typed as $?[t]^m$ and $![t]^n$, respectively, for some m, n. Then, by inspecting the right thread, we infer that a and b must then be typed with $![t]^m$ and $?[t]^n$, respectively. This way, their types in the composed process are $\#[t]^m$ (for a) and $\#[t]^n$ (for b). Looking again at the left thread, as the input along a is blocking the output along b, we must have $m < n$; in the right thread we have the exact opposite situation, thus $n < m$. These unsolvable inequalities reveal the circular dependency between a and b, which will make P_{56} not typable in the type system P.

We now summarize how typing excludes pending communications. Type environments $\Gamma, \Gamma', \ldots$ are finite maps from channels to types. We write $dom(\Gamma)$ for the domain of Γ. We write Γ, Γ' for the union of Γ and Γ' when $dom(\Gamma) \cap dom(\Gamma') = \emptyset$. We write $+$ to denote a partial composition operator on types defined as: $p[s_1, \ldots, s_m]^n + q[s_1, \ldots, s_m]^n = (p \cup q)[s_1, \ldots, s_m]^n$ if $p \cap q = \emptyset$, and undefined otherwise. For type environments we have: $\Gamma + \Gamma' \triangleq \Gamma, \Gamma'$ if $dom(\Gamma) \cap dom(\Gamma') = \emptyset$, and $(\Gamma, u : t) + (\Gamma', u : s) \triangleq (\Gamma + \Gamma'), u : t + s$. Let $\mathbb{Z}_\top = \mathbb{Z} \cup \{\top\}$, where $n < \top$ for every $n \in \mathbb{Z}$. The functions $|\cdot|$, from types to $\mathbb{Z}_\top$, and $\$^h$ from types to types are defined as follows:

$$|t| \triangleq \begin{cases} n & \text{if } t = p[s]^n \text{and } p \neq \emptyset \\ \top & \text{otherwise} \end{cases} \qquad \$^h t \triangleq \begin{cases} p[s]^{n+h} & \text{if } t = p[s]^n \text{and } p \neq \emptyset \\ t & \text{otherwise} \end{cases}$$

Intuitively, the function $\$^h$ allows us to shift priorities. We say that a type t is *unlimited*, written $\mathsf{un}(t)$, iff $|t| = \top$. We write $\mathsf{un}(\Gamma)$ iff all the types in the range of Γ are unlimited. We are now ready to give the typing rules, considering only processes with biadic communication, for simplicity. The rules for monadic communication are as expected.

▶ **Definition 58** (P)**.** *The typing rules for processes use judgements of the form* $\Gamma \vdash_{\mathrm{P}} P$ *and* $\Gamma \vdash_{\mathrm{P}} \widetilde{e} : \widetilde{t}$ *and are presented in Figure 9. We shall write* $P \in \mathsf{P}$ *if* $\Gamma \vdash_{\mathrm{P}} P$*, for some* Γ*.*

Rule T-In is used to type inputs $u?(x_1, x_2).P$, where u has type $?[t_1, t_2]^n$. The condition $n < |\Gamma|$ ensures that u has been assigned the highest urgency; accordingly, the types of x and y are shifted by n. Rule T-Out, used to type outputs on channels of type $![t_1, t_2]^n$, follows a similar principle: the types of x and y are shifted by n, since they must have lower urgency than u. Rule T-New is used for restricting new channels with full ($\#$) or empty ($\emptyset$) polarity.

▶ **Example 59.** Recall processes Q_{55} and R_{55} from Example 55. Consider types $s' = \$^1![\emptyset[]^4]^2$ and $s = \$^2?[\emptyset[]^4]^1$. Note that $s' + s = \#[\emptyset[]^4]^3$. Process Q_{55} is typed as follows:

$$\dfrac{\dfrac{\dfrac{\dfrac{a : s', c : \$^1?[s]^1 \vdash_{\mathrm{P}} a : s', c : \$^1?[s]^1}{a : s', c : \$^1?[s]^1, x :![s', \$^1?[s]^1]^1 \vdash_{\mathrm{P}} x!\langle a, c\rangle}\ \text{T-Out} \quad \dfrac{a : s \vdash_{\mathrm{P}} a : s}{a : s, c :![s]^2 \vdash_{\mathrm{P}} c!\langle a\rangle}\ \text{T-Out}}{a : \#[\emptyset[]^4]^3, x :![s', \$^1?[s]^1]^1, c : \#[s]^2 \vdash_{\mathrm{P}} x!\langle a, c\rangle \mid c!\langle a\rangle}\ \text{T-Par}}{a : \#[\emptyset[]^4]^3, x :![s', \$^1?[s]^1]^1 \vdash_{\mathrm{P}} (\nu\, c)(x!\langle a, c\rangle \mid c!\langle a\rangle)}\ \text{T-New}}{x :![s', \$^1?[s]^1]^1 \vdash_{\mathrm{P}} (\nu\, a)(\nu\, c)(x!\langle a, c\rangle \mid c!\langle a\rangle)}\ \text{T-New}$$

$$\text{T-Idle}\ \frac{\mathsf{un}(\Gamma)}{\Gamma \vdash_{\mathrm{P}} \mathbf{0}} \qquad \text{T-Par}\ \frac{\Gamma_1 \vdash_{\mathrm{P}} P_1 \quad \Gamma_2 \vdash_{\mathrm{P}} P_2}{\Gamma_1 + \Gamma_2 \vdash_{\mathrm{P}} P_1 \mid P_2} \qquad \text{T-out}\ \frac{\Gamma, e_1 : \$^n t_1, e_2 : \$^n t_2 \vdash_{\mathrm{P}} e_1 : \$^n t_1, e_2 : \$^n t_2 \quad \mathsf{un}(\Gamma)}{\Gamma + u :![t_1,t_2]^n \vdash_{\mathrm{P}} u!\langle e_1, e_2\rangle}$$

$$\text{T-In}\ \frac{\Gamma, x : \$^n t_1, y : \$^n t_2 \vdash_{\mathrm{P}} P \qquad n < |\Gamma|}{\Gamma + u :?[t_1,t_2]^n \vdash_{\mathrm{P}} u?(x,y).P} \qquad \text{T-New}\ \frac{\Gamma, a : p[t]^n \vdash_{\mathrm{P}} P \qquad p \text{ even}}{\Gamma \vdash_{\mathrm{P}} (\nu\, a)P}$$

Figure 9 P: Typing rules for asynchronous processes.

$$\text{M-Idle}\ \frac{\mathsf{un}(\Gamma)}{\Gamma \vdash^{\mu}_{\mathrm{P}} \mathbf{0}} \qquad \text{M-Out}\ \frac{\Gamma, e_1 : \$^n t_1, e_2 : \$^n t_2 \vdash^{\mu}_{\mathrm{P}} e_1 : \$^n t_1, e_2 : \$^n t_2 \quad \mathsf{un}(\Gamma)}{\Gamma + u :![t_1,t_2]^n \vdash^{\mu}_{\mathrm{P}} u!\langle e_1, e_2\rangle}$$

$$\text{M-In}\ \frac{\Gamma, x : \$^n t_1, y : \$^n t_2 \vdash^{\mu}_{\mathrm{P}} P \qquad n < |\Gamma|}{\Gamma + u :?[t_1,t_2]^n \vdash^{\mu}_{\mathrm{P}} u?(x,y).P}$$

$$\text{M-New-Par}\ \frac{\Gamma_1, a : p[t]^n \vdash^{\mu}_{\mathrm{P}} P \qquad \Gamma_2, a : q[t]^n \vdash^{\mu}_{\mathrm{P}} Q \qquad dom(\Gamma_1) \cap dom(\Gamma_2) = \emptyset,\ p \cup q \text{ even}}{\Gamma_1 + \Gamma_2 \vdash^{\mu}_{\mathrm{P}} (\nu\, a)(P \mid Q)}$$

Figure 10 μP: Modified typing rules for asynchronous processes.

Similarly we can check that $x :?[s', \$^1?[s]^1]^1 \vdash_{\mathrm{P}} R_{55}$. Note that x is typed with opposite polarities in Q_{55} and R_{55}; thus by applying Rules T-Par and T-New we obtain $\vdash_{\mathrm{P}} P_{55}$.

We may now characterize deadlock freedom. Let us write $\longrightarrow^*_{\mathrm{P}}$ to denote the reflexive, transitive closure of $\longrightarrow_{\mathrm{P}}$. Also, write $P \not\longrightarrow_{\mathrm{P}}$ if there is no Q such that $P \longrightarrow_{\mathrm{P}} Q$. We have:

▶ **Definition 60** (P: Deadlock Freedom [27]). *We say that $P \in \mathsf{P}$ is deadlock free, written $\mathcal{D}_{\mathbf{P}}(P)$, if for every Q such that $P \longrightarrow^*_{\mathrm{P}} (\nu\, \tilde{a})Q \not\longrightarrow_{\mathrm{P}}$ we have $\neg\mathsf{wait}(a, Q)$ for every a.*

We have that processes typed in the empty environment are deadlock free:

▶ **Theorem 61** (P: Deadlock Freedom [27]). *If $\vdash_{\mathrm{P}} P$, then $\mathcal{D}_{\mathbf{P}}(P)$.*

4.2 Relating $\mathbb{P}$ and $\mathbb{C}$

We now consider μP ("micro P"), which is a fragment of P that is similar to CP. We also define the encoding $\{\!|\cdot|\!\}^f : \mathsf{SP} \to \mathsf{P}$, and $\mathbb{P}$ and $\mu\mathbb{P}$ the classes of SP processes that are captured by P and μP, respectively. These are all ingredients for our results in § 4.3.

▶ **Definition 62** (μP). *The typing rules for processes are presented in Figure 10. A judgement $\Gamma \vdash^{\mu}_{\mathrm{P}} P$ denotes that P is well typed in Γ. We shall write $P \in \mu\mathsf{P}$ if $\Gamma \vdash^{\mu}_{\mathrm{P}} P$, for some Γ.*

μP results from P by replacing Rules T-Par and T-New in Figure 9 with Rule M-New-Par, which combines restriction and parallel just as Rule C-Cut in Figure 4.

▶ **Lemma 63.** *If $\Gamma \vdash^{\mu}_{\mathrm{P}} P$ then $\Gamma \vdash_{\mathrm{P}} P$.*

Proof sketch. By induction on the type derivation, with a case analysis in the last rule applied. See [19] for details. ◀

▶ **Corollary 64.** *If* $\vdash^{\mu}_{\mathsf{P}} P$, *then* $\mathcal{D}_{\mathbf{P}}(P)$.

Proof. It follows by Lemma 63 and Theorem 61. ◀

We now define an encoding from SP to P, following a continuation-passing style (cf. [8]). Let f be a function from names to names. We use the following conventions: f_x stands for $f(x)$, and $f, \{x \mapsto c\}$ stands for the function f' s.t. $f'(x) = c$ and $f'(y) = f(y)$ if $x \neq y$.

▶ **Definition 65.** *The (partial) encoding* $\{\![\,\cdot\,]\!\}^f : \mathsf{SP} \to \mathsf{P}$ *is parameterized by a function, ranging over* f, g, *from names to names, and is defined for processes as follows:*

$$
\begin{aligned}
\{\![\overline{x}\langle v\rangle.P]\!\}^f &\triangleq (\nu\, m)(f_x!\langle f_v, m\rangle \mid m?(k).(\nu\, c)(k!\langle c\rangle \mid \{\![P]\!\}^{f,\{x\mapsto c\}})) \\
\{\![x(z).P]\!\}^f &\triangleq f_x?(z,m).(\nu\, a)(m!\langle a\rangle \mid a?(c).\{\![P]\!\}^{f,\{x\mapsto c\}}) \\
\{\![\overline{x}\langle\,\rangle.\mathbf{0}]\!\}^f &\triangleq (\nu\, r) f_x!\langle r\rangle \\
\{\![x().P]\!\}^f &\triangleq f_x?(r).\{\![P]\!\}^f \qquad \textit{(with } r \notin \mathtt{fv}(P) \cup \mathtt{bv}(P)\textit{)} \\
\{\![(\nu\, xy)P]\!\}^f &\triangleq (\nu\, d)\{\![P]\!\}^{f,\{x,y\mapsto d\}}
\end{aligned}
$$

and as a homomorphism for $P \mid Q$ *and* $\mathbf{0}$. *The encoding of session types is as follows:*

$$
\begin{aligned}
\{\![\mathsf{end}_?]\!\} &\triangleq ?[\emptyset[]]^n & \{\![!S.T]\!\} &\triangleq ?[\{\![T]\!\}, ![![\{\![S]\!\}]^i]^j]^n \\
\{\![\mathsf{end}_!]\!\} &\triangleq ![\emptyset[]]^n & \{\![?S.T]\!\} &\triangleq ![\{\![T]\!\}, ![![\{\![\overline{S}]\!\}]^i]^j]^n
\end{aligned}
$$

Typing environments are encoded inductively as $\{\![\emptyset]\!\}^f \triangleq \emptyset$ *and* $\{\![\Gamma, x : T]\!\}^f \triangleq \{\![\Gamma]\!\}^f, f_x : \{\![T]\!\}$. *The values of* i, j *and* n *are calculated when checking in* $\mu\mathsf{P}$ *the typablity of* $\{\![\Gamma]\!\}^f \vdash^{\mu}_{\mathsf{P}} \{\![P]\!\}^f$.

Intuitively, the encoding of processes in Definition 65 collapses the two endpoints of a session into a single name in P. The encoding of $\overline{x}\langle v\rangle.P$ mimics both the sequential structure of a session and synchronous communication. $\{\![\overline{x}\langle v\rangle.P]\!\}^f$ sends the (renamed) value f_v and a new channel m along which an input $m?(k).$ blocks the continuation $\{\![P]\!\}^{f,\{x\mapsto c\}}$, and receives the channel along which the the continuation c of the session x will be sent. Dually, $\{\![x(z).P]\!\}^f$ receives the intended value and the channel m, which sends the channel a, along which the continuation of the session x will be received. Finally, the encoding is partial because $\{\![\overline{x}\langle\,\rangle.P]\!\}^f$ is only defined when $P = \mathbf{0}$: this allows us to characterize the session processes captured in CP, where the empty output has no continuation (see Definition 11).

▶ **Example 66.** Consider the process $P_{66} \triangleq (\nu\, xy)(\overline{x}\langle v\rangle.R \mid y(z).Q)$ in SP. We show $\{\![P_{66}]\!\}^f$ and illustrate its reductions. Let us assume P_{66} is well-typed. Because of linearity of x and y, they only appear in the left and right subprocess, respectively. Let $f = \{x, y \mapsto d\}$ and $g_1 = \{x \mapsto c\}$,$g_2 = \{y \mapsto c'\}$, then we have:

$$
\begin{aligned}
\{\![P_{66}]\!\}^{\emptyset} &= (\nu\, d)(\{\![\overline{x}\langle v\rangle.R]\!\}^f \mid \{\![y(z).Q]\!\}^f) \\
&= (\nu\, d)((\nu\, m)(d!\langle v, m\rangle \mid m?(k).(\nu\, c)(k!\langle c\rangle \mid \{\![R]\!\}^{g_1})) \\
&\qquad\qquad \mid d?(z,m').(\nu\, a)(m'!\langle a\rangle \mid a?(c').\{\![Q]\!\}^{g_2})) \\
&\longrightarrow_{\mathsf{P}} (\nu\, m)(m?(k).(\nu\, c)(k!\langle c\rangle \mid \{\![R]\!\}^{g_1}) \mid (\nu\, a)(m!\langle a\rangle \mid a?(c').\{\![Q]\!\}^{g_2}\{v/z\})) \\
&\longrightarrow_{\mathsf{P}} (\nu\, a)((\nu\, c)(a!\langle c\rangle \mid \{\![R]\!\}^{g_1}) \mid a?(c').\{\![Q]\!\}^{g_2}\{v/z\}) \\
&\longrightarrow_{\mathsf{P}} (\nu\, c)(\{\![R]\!\}^{g_1} \mid \{\![Q]\!\}^{g_2}\{v/z, c/c'\})
\end{aligned}
$$

Our main result concerns the classes of processes associated to P and $\mu\mathsf{P}$, which we define by mirroring the definition of $\mathbb{C}$ and $\mathbb{H}$ (Definition 34):

▶ **Definition 67** ($\mathbb{P}$ and $\mu\mathbb{P}$). *The classes of processes $\mathbb{P}$ and $\mu\mathbb{P}$ are defined as follows:*

$$\mathbb{P} \triangleq \{P \in \mathsf{SP} \mid \Gamma \vdash_{\mathsf{S}} P \wedge \{\!|\Gamma|\!\}^f \vdash_{\mathsf{P}} \{\!|P|\!\}^f\} \qquad \mu\mathbb{P} \triangleq \{P \in \mathsf{SP} \mid \Gamma \vdash_{\mathsf{S}} P \wedge \{\!|\Gamma|\!\}^f \vdash^{\mu}_{\mathsf{P}} \{\!|P|\!\}^f\}$$

The following result establishes an operational correspondence between a process and its encoding, what will allows us to capture deadlock free session processes via the encoding.

▶ **Theorem 68** (Operational Correspondence for $\{\!|\cdot|\!\}^f$). *Let $P \in \mu\mathbb{P}$. We have:*

1. **a.** *If $P \equiv (\nu\,\widetilde{xy})(\overline{x}\langle\rangle.Q_1 \mid y().Q_2 \mid S)$, then $\exists Q \in \mathsf{P}$ such that $\{\!|P|\!\}^f \longrightarrow_{\mathsf{P}} Q$ and $Q \equiv_{\mathsf{P}} \{\!|(\nu\,\widetilde{xy})(Q_1 \mid Q_2 \mid S)|\!\}^f$.*
   b. *If $P \equiv (\nu\,\widetilde{xy})(\overline{x}\langle v\rangle.Q_1 \mid y(z).Q_2 \mid S)$, then $\exists Q \in \mathsf{P}$ such that $\{\!|P|\!\}^f \longrightarrow^3_{\mathsf{P}} Q$ and $Q \equiv_{\mathsf{P}} \{\!|(\nu\,\widetilde{xy})(Q_1 \mid Q_2\{v/z\} \mid S)|\!\}^f$.*
2. *If $\{\!|P|\!\}^f \longrightarrow_{\mathsf{P}} R$, then either:*
   a. *$\exists P' \in \mathsf{SP}$ such that $P \longrightarrow P'$ and $R \equiv_{\mathsf{P}} \{\!|P'|\!\}^f$, or*
   b. *$\exists Q \in \mathsf{P}$, and $P' \in \mathsf{SP}$ such that $R \longrightarrow^2_{\mathsf{P}} Q$, $P \longrightarrow P'$ and $Q \equiv_{\mathsf{P}} \{\!|P'|\!\}^f$.*

Proof. By assumption, $P \in \mu\mathbb{P}$ and so we have that $\Gamma \vdash_{\mathsf{S}} P$, for some Γ, and $\{\!|\Gamma|\!\}^f \vdash^{\mu}_{\mathsf{P}} \{\!|P|\!\}^f$ is defined. Moreover, by Corollary 8 P is well-formed. We consider each item separately. Item 1(b) follows by Definition 65 and the rest of the analysis proceeds as in Example 66; Item 1(a) is similar. Item (2): If $\{\!|P|\!\}^f \longrightarrow_{\mathsf{P}} R$, then $\{\!|P|\!\}^f \equiv_{\mathsf{P}} (\nu\,\tilde{a})(d!\langle\tilde{v}\rangle \mid d?(\tilde{x}).K \mid S)$. By typability of P and Definition 65 one of the two possibilities apply:

- **i** $P \equiv (\nu\,\widetilde{xy})(\overline{x}\langle\rangle.\mathbf{0} \mid y().K' \mid S')$, $\{\!|S'|\!\}^f = S$, $\{\!|K'|\!\}^f = K$ and $f = f', \{x, y \mapsto d\}$,
- **ii** $P \equiv (\nu\,\widetilde{xy})(\overline{x}\langle v\rangle.S_1 \mid y(z).K' \mid S_2)$ and $f = f', \{x, y \mapsto d\}$

In case (i) $\{\!|P|\!\}^f \equiv_{\mathsf{P}} (\nu\,\tilde{a})((\nu\,r)d!\langle r\rangle \mid d?(r').K \mid S) \longrightarrow_{\mathsf{P}} (\nu\,\tilde{a})(K \mid S)$ and $P \equiv (\nu\,\widetilde{xy})(\overline{x}\langle\rangle.\mathbf{0} \mid y().K' \mid S') \longrightarrow (\nu\,\widetilde{xy'})(K' \mid S'')$, which verifies case (2a). In case (ii) we proceed as in Example 66, which verifies case (2b). ◀

As a consequence of Theorem 68 we have the following result, which shows the relation between deadlock-free processes in $\mu\mathbb{P}$.

▶ **Corollary 69.** *Let $P \in \mu\mathbb{P}$. $\mathcal{D}_{\mathbf{S}}(P)$ iff $\mathcal{D}_{\mathbf{P}}(\{\!|P|\!\}^f)$.*

Proof. For each direction we prove its contrapositive. We discuss only the right-to-left direction; the analysis for the left-to-right direction is similar. By Definition 60, there exist R and a s.t. $\{\!|P|\!\}^f \longrightarrow^*_{\mathsf{P}} (\nu\,\tilde{a})R \not\longrightarrow_{\mathsf{P}}$ and $\mathsf{wait}(a, R)$. If $\mathsf{wait}(a, R)$ holds because $\mathsf{in}(a, R)$ then $R \equiv_{\mathsf{P}} (\nu\,\tilde{a})(a?(x).Q \mid S)$. By Theorem 68 and Definition 65 there exists $P' \equiv (\nu\,\widetilde{xy})(z(w).Q' \mid S')$ s.t. $P \longrightarrow^* P'$ and $R \equiv_{\mathsf{P}} \{\!|P'|\!\}^f$. Note that $P' \not\longrightarrow$, since otherwise by Theorem 68(1), $(\nu\,\tilde{a})R \longrightarrow_{\mathsf{P}} R''$ for some process R'', contradicting our assumption, thus $\neg\mathcal{D}_{\mathbf{S}}(P)$. The case when $\mathsf{wait}(a, R)$ holds because $\mathsf{out}(a, R)$ proceeds similarly. ◀

Corollary 69 allows us to detect DF session processes via the encoding.

4.3 Comparing $\mathbb{H}$ and $\mathbb{P}$

From § 3 we infer that a process $P \in \mathbb{H}$, typed as $[\![P]\!] \vdash_{\mathtt{H}} \Gamma_1 \parallel \cdots \parallel \Gamma_n$, can be decomposed into processes $P_1 \vdash_{\mathtt{C}} \Gamma_1, \ldots, P_n \vdash_{\mathtt{C}} \Gamma_n$. Moreover, by Lemma 48 (disentanglement in SP) we infer that processes $P_1, \ldots, P_n$ have a pre-image in SP, therefore $\forall i \in [1, n].\, P_i \in \mathbb{C} \subsetneq \mathbb{H}$.

As an important preliminary step, we first prove that $\mathbb{C} = \mu\mathbb{P}$ (Corollary 74). We split the proof in two separate inclusions. The following lemma is useful to prove that $\mathbb{C} \subseteq \mu\mathbb{P}$.

▶ **Lemma 70.** *Let Γ and P be an environment and a process in P, resp. The following hold:*
1. *If $\Gamma \vdash_{\mathsf{P}} P$, then $\$^n\Gamma \vdash_{\mathsf{P}} P$.*
2. *If $\Gamma \vdash^{\mu}_{\mathsf{P}} P$, then $\$^n\Gamma \vdash^{\mu}_{\mathsf{P}} P$.*
3. *Let $P \in \mathsf{P}$. If $\Gamma \vdash^{\mu}_{\mathsf{P}} P$ and $\mathsf{un}(T)$, then $\Gamma, x : T \vdash^{\mu}_{\mathsf{P}} P$, with x fresh wrt P.*
4. *Let $\Gamma_1, \ldots, \Gamma_n$ be typing environments in SP, then $\{\!|\Gamma_1, \cdots, \Gamma_n|\!\}^f = \{\!|\Gamma_1|\!\}^f + \cdots + \{\!|\Gamma_n|\!\}^f$, for some renaming function f.*
5. *Let T be a session type. Then $\{\!|T|\!\}^f + \$^m\{\!|\overline{T}|\!\}^f = p[T']^n$, for some $m \geq 0$, $n \in \mathbb{Z}$, T' a type in P, and p even.*

Proof. (1) Proven in [27]. (2) Follows from Lemma 63 and item 1. (3) Follows by induction on the type derivation. (Figure 10). (4) Follows immediately by linearity of names in Γ_i, for $i \in [1, n]$. (5) Follows by induction on the structure of T. ◀

▶ **Theorem 71.** $\mathbb{C} \subseteq \mu\mathbb{P}$.

Proof sketch. By induction on the type derivation $\Gamma \vdash_{\mathsf{S}} P$ with a case analysis in the last rule applied. See [19] for details. ◀

To prove the other direction we need the following result.

▶ **Lemma 72.** *Let S and T be session types. We have:* (1) $\{\!|S|\!\}^f + \{\!|T|\!\}^f$ *is defined iff* $T = \overline{S}$. (2) $[\![\overline{S}]\!] = ([\![S]\!])^{\perp}$.

Proof. Item (1) follows by Definition 65 and def. of $+$. Item (2) follows immediately by induction in the structure of S and Definition 28. ◀

▶ **Theorem 73.** $\mu\mathbb{P} \subseteq \mathbb{C}$.

Proof sketch. By induction on the type derivation $\Gamma \vdash_{\mathsf{S}} P$ with a case analysis in the last rule applied. See [19] for details. ◀

▶ **Corollary 74.** $\mathbb{C} = \mu\mathbb{P}$.

Proof. It follows by Theorems 71 and 73. ◀

Main Results. We may now return to considering $\mathbb{H}$. Note that $\mathbb{H} \setminus \mathbb{P} \neq \emptyset$: to see this, consider, e.g., the self-synchronizing process $P_1 \in \mathbb{H}_{\mathsf{F}}$ from Example 18. Using Corollary 74 and disentanglement (Definition 42) we show that given a process $P \in \mathbb{H}_{\mathsf{F}}$, we can find a deadlock-free process $P' \in \mathbb{P}$. Formally, we have:

▶ **Theorem 75.** *Given $P \in \mathbb{H}_{\mathsf{F}}$, $\exists P' \in \mathbb{H}_{\mathsf{R}}$ s.t. $P' \in \mathbb{P}$, $[\![P]\!] \approx_{\mathtt{H}} [\![P']\!]$, and $\mathcal{D}_{\mathbf{P}}(\{\!|P'|\!\}^f)$.*

Proof. By Corollary 53, $[\![P]\!] \rightsquigarrow^* \simeq^*_{cc} [\![P']\!] = P_1 \mid \cdots \mid P_n$, and by Lemma 48 $\forall i \in [1, n]$, there exists $P'_i \in \mathbb{C}$ s.t. $[\![P'_i]\!] = P_i$. From Corollary 74 and Lemma 63 we infer $\{\!|P'_i|\!\}^f \in \mathbb{P}$, $\forall i \in [1, n]$. Moreover, by repeatedly applying Rule T-Par we have that $P' \in \mathbb{P}$. Finally, $\mathcal{D}_{\mathbf{P}}(\{\!|P'|\!\}^f)$ follows from Theorem 39 and Corollary 69. ◀

The following result relates $\mathbb{H}$, its subclasses $\mathbb{H}_{\mathsf{F}}$ and $\mathbb{H}_{\mathsf{R}}$, and $\mathbb{P}$.

▶ **Theorem 76.** *The following hold:* (1) $\mathbb{P} \setminus \mathbb{H} \neq \emptyset$. (2) $\mathbb{H}_{\mathsf{F}} \setminus \mathbb{P} \neq \emptyset$. (3) $\mathbb{P} \cap \mathbb{H}_{\mathsf{R}} \neq \emptyset$.

Proof sketch. We give witnesses for each statement; see [19] for details. ◀

Finally, from Theorem 75 we have the following result, which complements Corollary 53: given $P \in \mathbb{H}_{\mathsf{F}}$, there exists a bisimilar process $P' \in \mathbb{H}_{\mathsf{R}} \cap \mathbb{P}$ via disentanglement. Note that this result applies in particular to processes in $\mathbb{H}_{\mathsf{F}} \setminus \mathbb{P}$.

▶ **Corollary 77.** *Given $P \in \mathbb{H}_{\mathsf{F}}$, there exists $P' \in \mathbb{H}_{\mathsf{R}}$ s.t.* (1) $P \lesssim P'$, (2) $[\![P]\!] \approx_{\mathtt{H}} [\![P']\!]$, *and* (2) $\mathcal{D}_{\mathbf{P}}(\{\!|P'|\!\}^f)$.

$$\text{A-Out}\ \frac{}{v : T, c : S, x : !T.S \vdash^{a}_{S} \overline{x}\langle v, c\rangle} \qquad \text{A-In}\ \frac{\Gamma, y : T, w : S \vdash^{a}_{S} P}{\Gamma, x : ?T.S \vdash^{a}_{S} x(y, w).P} \qquad \text{A-Inact}\ \frac{}{\cdot \vdash^{a}_{S} \mathbf{0}}$$

$$\text{A-EInput}\ \frac{\Gamma \vdash^{a}_{S} P}{\Gamma, x : \mathsf{end}_? \vdash^{a}_{S} x().P} \qquad \text{A-EOutput}\ \frac{}{x : \mathsf{end}_! \vdash^{a}_{S} \overline{x}\langle\rangle} \qquad \text{A-Res}\ \frac{\Gamma, x : T, y : \overline{T} \vdash^{a}_{S} P}{\Gamma \vdash^{a}_{S} (\nu\, xy)P} \qquad \text{A-Par}\ \frac{\Gamma_1 \vdash^{a}_{S} P \qquad \Gamma_2 \vdash^{a}_{S} Q}{\Gamma_1, \Gamma_2 \vdash^{a}_{S} P \mid Q}$$

Figure 11 SP^{a}: Typing Rules for Processes.

4.4 Asynchronous Session Processes

Up to here, we have considered asynchronous communication somewhat indirectly: we have examined the type system for asynchronous processes P, defined its associated classes $\mathbb{P}$ and $\mu\mathbb{P}$, and related them to $\mathbb{C}$ and $\mathbb{H}_{\mathsf{F}}$. To treat asynchronous communication directly, here we consider SP^{a}, an asynchronous variant of SP, and discuss how to transfer our results from §§ 3 and 4.3 from SP to SP^{a} by leveraging an encoding $\langle\!\langle \cdot \rangle\!\rangle : \mathsf{SP}^{a} \to \mathsf{SP}$.

SP^{a}: Asynchronous SP. We define SP^{a} as a variant of SP with asynchronous communication. Considerations about variables, endpoints, and values are as for SP (cf. § 2.1). The syntax of processes is largely as before; only constructs for output and input are modified:

$$P \quad ::= \quad \mathbf{0} \mid x().P \mid \overline{x}\langle\rangle \mid \overline{x}\langle v, c\rangle \mid x(y, w).P \mid P_1 \mid P_2 \mid (\nu\, xy)P$$

Process $\overline{x}\langle v, c\rangle$ sends names v and c along x: the former is a message and the latter is a continuation. Because it has no continuation, this process may be seen as an "output particle" that carries a message. Accordingly, process $x(y, w).P$ receives two values v and c along x and continues as $P\{v/y, c/w\}$, i.e., the process resulting from the capture-avoiding substitution of y by v, and w by c in P. The construct for empty output is also modified. In both $z(x, y).P$ and $(\nu\, xy)P$ x, y are bound in P.

▶ **Definition 78** (SP^{a}). *The typing rules for processes are presented in Figure 11. A judgement $\Gamma \vdash^{a}_{S} P$ denotes that P is well typed in Γ. We shall write $P \in \mathsf{SP}^{a}$ if $\Gamma \vdash^{a}_{S} P$, for some Γ.*

Most typing rules are self-explanatory. Rule A-EOutput types an empty output without continuation. Rule A-Out types the output particle $\overline{x}\langle v, c\rangle$ where $x : !T.S$. Since the output has no continuation, the session name c typed as S serves a a continuation name for x. Dually, Rule A-In types x as $?T.S$ provided that y and w are typed as T and S in P, respectively, thus, w serves as a continuation for x in P.

The reduction semantics for SP^{a} is defined as follows:

$$(\nu\, xy)(\overline{x}\langle v, c\rangle \mid y(z, w).Q \mid S) \longrightarrow (Q\{v/z, c/w\} \mid S) \qquad \text{A-Com}$$

$$(\nu\, xy)(\overline{x}\langle\rangle \mid y().Q \mid S) \longrightarrow Q \mid S \qquad \text{A-EmptyCom}$$

Structural rules and the congruence $\equiv$ are defined as in Figure 2. A labeled reduction semantics $P \xrightarrow{\tau : xy} Q$ for SP^{a} follows easily from Definition 50.

▶ **Example 79.** Consider the process P_{10} from Example 10, which is typable and deadlocked in SP. The following process can be seen as the analogue of P_{10} but in the asynchronous setting of SP^{a}. We define P_{79} as $(\nu\, x_1y_1)(\nu\, x_2y_2)(\nu\, v_1k_1)(\nu\, v_2k_2)P'$, where

$$\begin{aligned} P' \triangleq\ & x_1(z_1,w_1).x_2(z_2,w_2).w_1().w_2().z_1().z_2().\mathbf{0} \\ & \mid (\nu\, c_2c_2')(\overline{y_2}\langle v_2,c_2\rangle \mid \overline{c_2'}\langle\rangle) \mid (\nu\, c_1c_1')(\overline{y_1}\langle v_1,c_1\rangle \mid \overline{c_1'}\langle\rangle) \mid \overline{k_1}\langle\rangle \mid \overline{k_2}\langle\rangle \end{aligned}$$

Note how c_1 and c_2 serve as a continuation for y_1 and y_2, respectively. There exist processes Q_1, Q_2 such that $P_{79} \xrightarrow{\tau:x_1y_1} Q_1 \xrightarrow{\tau:x_2y_2} Q_2 \longrightarrow^* \equiv\ \mathbf{0}$.

We define DF for SP^{a} by adapting Definition 9:

▶ **Definition 80** (SP^{a}: Deadlock Freedom). *A process $P \in \mathsf{SP}^{\mathsf{a}}$ is deadlock free, written $\mathcal{D}_{\mathbf{A}}(P)$, if the following holds: whenever $P \longrightarrow^* P'$ and one of the following holds:* (1) $P' \equiv (\nu\, \tilde{x}\tilde{y})(\overline{x_i}\langle v,c\rangle \mid Q_2)$, (2) $P' \equiv (\nu\, \tilde{x}\tilde{y})(x_i(y).Q_1 \mid Q_2)$, (3) $P' \equiv (\nu\, \tilde{x}\tilde{y})(x_i().Q_1 \mid Q_2)$, *or* (4) $P' \equiv (\nu\, \tilde{x}\tilde{y})(\overline{x_i}\langle\rangle \mid Q_2)$ *(with $x_i \in \tilde{x}$ in all cases) then there exists R such that $P' \longrightarrow R$.*

▶ **Example 81** (Comparing DF in SP and SP^{a}). As just illustrated by means of processes P_{10} (from Example 10) and P_{79}, moving to an asynchronous setting may solve certain deadlocks: we have $\neg\mathcal{D}_{\mathbf{S}}(P_{10})$ and $\mathcal{D}_{\mathbf{A}}(P_{79})$.

On the other hand, moving to an asynchronous setting alone does not resolve the problem. Consider the process $Q_{81} \triangleq (\nu\, x_2y_2)(y_2().\mathbf{0} \mid (\nu\, x_1y_1)(y_1().(\overline{x_2}\langle\rangle \mid \overline{x_1}\langle\rangle)))$. Clearly, Q_{81} is typable in SP^{a}. Also, let Q_{81}^* be the SP variant of Q_{81} with $\mathbf{0}$ as continuation for outputs, i.e., $Q_{81}^* \triangleq (\nu\, x_2y_2)(y_2().\mathbf{0} \mid (\nu\, x_1y_1)(y_1().(\overline{x_2}\langle\rangle.\mathbf{0} \mid \overline{x_1}\langle\rangle.\mathbf{0})))$. We have that Q_{81}^* is typable in SP and that $\neg\mathcal{D}_{\mathbf{S}}(Q_{81}^*)$ and $\neg\mathcal{D}_{\mathbf{A}}(Q_{81})$.

Our goal is to transfer our technical results for SP to the asynchronous setting of SP^{a}. To this end, we define the following encoding:

▶ **Definition 82.** *We define the encoding $\langle\!\langle\, \cdot\, \rangle\!\rangle$ from SP^{a} to SP as follows:*

$$\begin{aligned} \langle\!\langle \overline{x}\langle v,c\rangle \rangle\!\rangle &\triangleq \overline{x}\langle v\rangle.\overline{x}\langle c\rangle.\overline{x}\langle\rangle.\mathbf{0} & \langle\!\langle \mathsf{end}_? \rangle\!\rangle &\triangleq \mathsf{end}_? \\ \langle\!\langle x(y,w).P \rangle\!\rangle &\triangleq x(y).x(w).x().\langle\!\langle P \rangle\!\rangle & \langle\!\langle \mathsf{end}_! \rangle\!\rangle &\triangleq \mathsf{end}_! \\ \langle\!\langle x().P \rangle\!\rangle &\triangleq x().\langle\!\langle P \rangle\!\rangle & \langle\!\langle !T.S \rangle\!\rangle &\triangleq !T.!S.\mathsf{end}_! \\ \langle\!\langle \overline{x}\langle\rangle \rangle\!\rangle &\triangleq \overline{x}\langle\rangle.\mathbf{0} & \langle\!\langle ?T.S \rangle\!\rangle &\triangleq ?T.?S.\mathsf{end}_? \end{aligned}$$

and as an homomorphism for $\mathbf{0}$, $P \mid Q$, and $(\nu\, xy)P$.

▶ **Example 83** ($\langle\!\langle\, \cdot\, \rangle\!\rangle$, At Work). Consider again the process P_{79}. We have seen that $\mathcal{D}_{\mathbf{A}}(P_{79})$. We now check that $\langle\!\langle\, \cdot\, \rangle\!\rangle$ does not add deadlocks by verifying that $\mathcal{D}_{\mathbf{S}}(\langle\!\langle P_{79} \rangle\!\rangle)$:

$$\begin{aligned} \langle\!\langle P_{79} \rangle\!\rangle \triangleq\ & (\nu\, x_1y_1)(\nu\, x_2y_2)(\nu\, v_1k_1)(\nu\, v_2k_2)\langle\!\langle P' \rangle\!\rangle \\ \langle\!\langle P' \rangle\!\rangle \triangleq\ & x_1(z_1).x_1(w_1).x_1().x_2(z_2).x_2(w_2).x_2().w_1().w_2().z_1().z_2().\mathbf{0} \\ & \mid (\nu\, c_2c_2')(\overline{y_2}\langle v_2\rangle.\overline{y_2}\langle c_2\rangle.\overline{y_2}\langle\rangle.\mathbf{0} \mid \overline{c_2'}\langle\rangle.\mathbf{0}) \\ & \mid (\nu\, c_1c_1')(\overline{y_1}\langle v_1\rangle.\overline{y_1}\langle c_1\rangle.\overline{y_1}\langle\rangle.\mathbf{0} \mid \overline{c_1'}\langle\rangle.\mathbf{0}) \mid \overline{k_1}\langle\rangle.\mathbf{0} \mid \overline{k_2}\langle\rangle.\mathbf{0} \end{aligned}$$

One can show that there exist Q_1, Q_2 such that $\langle\!\langle P_{79} \rangle\!\rangle \xrightarrow{\tau:x_1y_1}{}^{3} \equiv Q_1 \xrightarrow{\tau:x_2y_2}{}^{3} \equiv Q_2 \longrightarrow^* \equiv \mathbf{0}$.

By a similar analysis to the one for Theorem 68, we have the following result:

▶ **Theorem 84** ($\langle\!\langle \cdot \rangle\!\rangle$: Operational Correspondence). *Let $P \in \mathsf{SP}^{\mathfrak{a}}$. The following holds:*

1. *if $P \equiv (\nu\, xy)(x(w,z).P \mid \overline{y}\langle v_1, v_2\rangle \mid R)$, then $\exists Q \in \mathsf{SP}$ s.t. $\langle\!\langle P \rangle\!\rangle \longrightarrow^3 Q$ and $Q = \langle\!\langle P\{v_1/w, v_2/z\} \mid R \rangle\!\rangle$.*
2. *If $P \equiv (\nu\, xy)(x().P \mid \overline{y}\langle\rangle.\mathbf{0} \mid R)$, then $\exists Q \in \mathsf{SP}$ s.t. $\langle\!\langle P \rangle\!\rangle \longrightarrow Q$ and $Q = \langle\!\langle P \mid R \rangle\!\rangle$.*
3. *If $\langle\!\langle P \rangle\!\rangle \longrightarrow Q'$, then either: (i) there exists $Q \in \mathsf{SP}$ s.t. $Q' \longrightarrow^2 Q$, $P \longrightarrow P'$ and $\langle\!\langle P' \rangle\!\rangle = Q$, or (ii) $P \longrightarrow P'$ and $\langle\!\langle P' \rangle\!\rangle = Q'$.*

Using Theorem 84 and Definitions 9 and 80 we formalize our claim from Example 83: $\langle\!\langle \cdot \rangle\!\rangle$ does not add deadlocks.

▶ **Theorem 85** (Correspondence DF). *For all $P \in \mathsf{SP}^{\mathfrak{a}}$, $\mathcal{D}_{\mathbf{A}}(P)$ iff $\mathcal{D}_{\mathbf{S}}(\langle\!\langle P \rangle\!\rangle)$.*

Proof sketch. For each direction we prove its contrapositive and proceed by contradiction. See [19] for details. ◀

Using the encoding $\langle\!\langle \cdot \rangle\!\rangle$, and inspired by Theorems 84 and 85, we can define the following classes of asynchronous processes by relying on their synchronous counterparts:

▶ **Definition 86.** *The classes of asynchronous processes are defined as follows:*

$$\mathbb{C}^{\mathfrak{a}} \triangleq \{P \in \mathsf{SP}^{\mathfrak{a}} \mid \langle\!\langle P \rangle\!\rangle \in \mathbb{C}\} \quad \mathbb{P}^{\mathfrak{a}} \triangleq \{P \in \mathsf{SP}^{\mathfrak{a}} \mid \langle\!\langle P \rangle\!\rangle \in \mathbb{P}\} \quad \mu\mathbb{P}^{\mathfrak{a}} \triangleq \{P \in \mathsf{SP}^{\mathfrak{a}} \mid \langle\!\langle P \rangle\!\rangle \in \mu\mathbb{P}\}$$
$$\mathbb{H}^{\mathfrak{a}} \triangleq \{P \in \mathsf{SP}^{\mathfrak{a}} \mid \langle\!\langle P \rangle\!\rangle \in \mathbb{H}\} \quad \mathbb{H}^{\mathfrak{a}}_{\mathsf{F}} \triangleq \{P \in \mathsf{SP}^{\mathfrak{a}} \mid \langle\!\langle P \rangle\!\rangle \in \mathbb{H}_{\mathsf{F}}\} \quad \mathbb{H}^{\mathfrak{a}}_{\mathsf{R}} \triangleq \{P \in \mathsf{SP}^{\mathfrak{a}} \mid \langle\!\langle P \rangle\!\rangle \in \mathbb{H}_{\mathsf{R}}\}$$

Each asynchronous class is contained (up to $\langle\!\langle \cdot \rangle\!\rangle$) in its corresponding synchronous class:

▶ **Lemma 87.** *Let $P \in \mathsf{SP}^{\mathfrak{a}}$. The following hold:* (1) *If $P \in \mathbb{C}^{\mathfrak{a}}$, then $\langle\!\langle P \rangle\!\rangle \in \mathbb{C}$.* (2) *If $P \in \mathbb{H}^{\mathfrak{a}}$, then $\langle\!\langle P \rangle\!\rangle \in \mathbb{H}$.* (3) *If $P \in \mathbb{P}^{\mathfrak{a}}$, then $\langle\!\langle P \rangle\!\rangle \in \mathbb{P}$.* (4) *If $P \in \mu\mathbb{P}^{\mathfrak{a}}$, then $\langle\!\langle P \rangle\!\rangle \in \mu\mathbb{P}$.* (5) *If $P \in \mathbb{H}^{\mathfrak{a}}_{\mathsf{F}}$, then $\langle\!\langle P \rangle\!\rangle \in \mathbb{H}_{\mathsf{F}}$.* (6) *If $P \in \mathbb{H}^{\mathfrak{a}}_{\mathsf{R}}$, then $\langle\!\langle P \rangle\!\rangle \in \mathbb{H}_{\mathsf{R}}$.*

Proof. It follows straightforwardly from Definition 86. ◀

Thus, we can transfer our main results (Corollaries 53, 74, and 77) to $\mathsf{SP}^{\mathfrak{a}}$ via $\langle\!\langle \cdot \rangle\!\rangle$. For instance, Corollary 53 is transferred to $\mathsf{SP}^{\mathfrak{a}}$ as follows, using Lemma 87, and Theorem 84:

▶ **Corollary 88.** *Given $P \in \mathbb{H}^{\mathfrak{a}}_{\mathsf{F}}$, there exist $Q \in \mathbb{H}$ and $P' \in \mathbb{H}^{\mathfrak{a}}_{\mathsf{R}}$ s.t.:* (1) $[\![Q]\!] \in \textsc{Dist}([\![\langle\!\langle P \rangle\!\rangle]\!])$, (2) $[\![Q]\!] \simeq^*_{cc} [\![\langle\!\langle P' \rangle\!\rangle]\!]$, (3) $\langle\!\langle P \rangle\!\rangle \lesssim \langle\!\langle P' \rangle\!\rangle$, (4) $[\![\langle\!\langle P \rangle\!\rangle]\!] \approx_{\mathtt{H}} [\![\langle\!\langle P' \rangle\!\rangle]\!]$.

5 Closing Remarks

Enforcing DF is a relevant issue for message-passing programs, and type systems for concurrent processes offer a convenient setting to develop analysis techniques that detect insidious circular dependencies in programs. Because there exist different type systems that enforce DF, it is natural to wonder how they compare.

We have studied this question in the general and expressive setting of the π-calculus. Our approach aims at establishing the key strengths and limitations of three representative type systems: SP, the reference language for session-typed processes; HCP, the session-typed language based on "propositions-as-sessions" and hypersequents; and P, the priority-based type system for asynchronous processes. Figure 12 gives an overview of our main technical results, refining Figure 1. We briefly discuss their broader significance. Our work can be seen as covering three dimensions of comparison: type systems (SP, HCP, P), process semantics (reduction semantics and LTS), and several definitions of DF (cf. Definitions 9, 26, 36, 60, and 80). Clearly, each type system connects these dimensions in its own way via meta-theoretical results (e.g., type preservation). From this perspective, considering a type

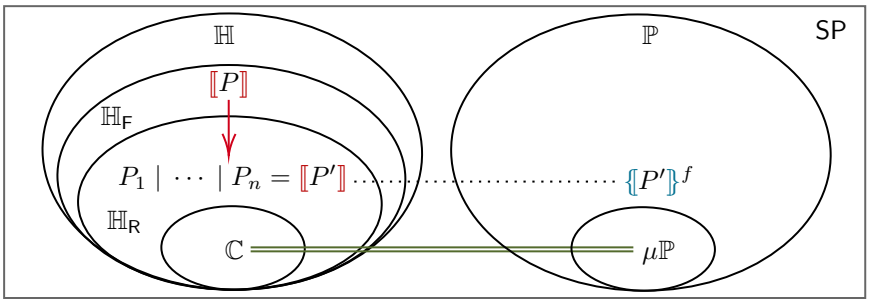

Figure 12 Overview of main results (detailed version). The inclusions between the classes of processes follow from Theorem 76. The red arrow stands for the relation $\rightsquigarrow^* \simeq^*_{cc}$ (disentanglement and commuting conversions) from Corollary 53, where $P_1, \ldots, P_n \in \mathbb{C}$. This arrow, together with $\{\!|P'|\!\}^f \in \mathbb{P}$, represent Corollary 77. The green lines represent Corollary 74 ($\mathbb{C} = \mu\mathbb{P}$).

system such as HCP, which comes with an LTS for typed processes with very distinctive features (delayed actions and self-synchronizations), brings significant value to our results. In contrast, the work of Dardha and Pérez [9] (the most closely related work) considers different type systems for synchronous processes but only under a reduction semantics, which influences the definition(s) of DF to be considered.

Our key discovery is identifying the role that commuting conversions and disentanglement have in the class of deadlock-free processes induced by HCP (Corollary 53). Although studying the practical ramifications of our results goes beyond the scope of this paper, two observations are relevant. First, our results pave the way for developing extensions of the static analyzer TyPiCal [20] that support the mechanized analysis of (session) processes with asynchronous communication. Second, commuting conversions are already important in practical developments, such as execution strategies in *abstract machines* for session-typed programs [4] and definitions of *session subtyping* [6, 15] that enable flexible programming interfaces. An in-depth exploration of these latent connections between our results and tools for the analysis of message-passing programs is left for future work.

It is worth stressing that HCP's LTS enjoys strong logical and denotational justifications; by identifying disentanglement and commuting conversions as key notions for DF, we provide new insights into HCP and its LTS. This way, our work sheds new light into the foundations of HCP, its positioning within the line of work on "propositions-as-sessions", and its expressive power. For instance, it is surprising that processes that share more than one session are typable in HCP, in the sense of Example 14. While Kokke *et al.* [23, 22] have studied disentanglement as a tool to relate HCP and CP, here we uncover its connection with DF. Also, their work on HCP$^-$ (HCP with a reduction semantics but without delayed actions and self-synchronizations) is complementary to our findings. In this sense, our work also offers good motivations for the use of LTSs with regular transitions as the semantics for logic-based session processes (which usually rely on reduction semantics).

It is remarkable that HCP and P are not just two type systems relevant for a formal comparison, but that they are actually connected thanks to asynchrony (an important aspect not covered in Dardha and Pérez's work); the connection is made precise by Theorem 76 and Corollary 77. Here again delayed actions in HCP result to be insightful for an enhanced understanding of logic-based session types. In this line, we observe that De Young *et al.* [10] study asynchrony under "propositions-as-sessions", and in particular explain the role of commuting conversions, which in an asynchronous setting act as as structural congruences (cf. Definition 40). In the synchronous case, they correspond to behavioral equivalences [30].

An interesting point concerns the exact relation between our class $\mathbb{C}$ (Definition 34) and the class $\mathbb{L}$ in Dardha and Pérez's work. There is a key difference between the two: while they consider CP with a typing rule for independent parallel composition (cf. Rule H-MIX$_2$ in Figure 5), we only have Rule C-MIX$_0$ in Figure 4. The reason is technical: it is known that having both MIX$_0$ and MIX$_2$ induces the conflation of the units $\mathbf{1}$ and $\bot$, which conflicts with the distinction made by HCP's denotational semantics (see [19] for details). (In [9], the conflated type is denoted "$\bullet$", and there are no process constructs for session closing.) For the sake of consistency with the denotational semantics, we opted to not include this rule. Therefore, there are processes that are not in our class $\mathbb{C}$ but are in Dardha and Pérez's $\mathbb{L}$.

Having discovered the relation between DF and commuting conversions and disentanglement, an interesting item for future work is revisiting the process transformations proposed by Dardha and Pérez [9] using disentanglement. To focus on the fundamental issues of DF enforcement, we have not covered processes with recursion/sharing; we also plan to consider typed languages with constructs for shared servers and clients.

Abstract

Many important security properties can be formulated in terms of flows of tainted data, and improved taint analysis tools to prevent such flows are of critical need. Most existing taint analyses use whole-program static analysis, leading to scalability challenges. Type-based checking is a promising alternative, as it enables modular and incremental checking for fast performance. However, type-based approaches have not been widely adopted in practice, due to challenges with false positives and annotating existing codebases. In this paper, we present a new approach to type-based checking of taint properties that addresses these challenges, based on two key techniques. First, we present a new type-based tainting checker with significantly reduced false positives, via more practical handling of third-party libraries and other language constructs. Second, we present a novel technique to automatically infer tainting type qualifiers for existing code. Our technique supports inference of generic type argument annotations, crucial for tainting properties. We implemented our techniques in a tool TaintTyper and evaluated it on real-world benchmarks. TaintTyper exceeds the recall of a state-of-the-art whole-program taint analyzer, with comparable precision, and 2.93X–22.9X faster checking time. Further, TaintTyper infers annotations comparable to those written by hand, suitable for insertion into source code. TaintTyper is a promising new approach to efficient and practical taint checking.

1 Introduction

Software security is of critical importance to society, as security vulnerabilities can have severe financial and safety impacts. Many security vulnerabilities can be described as an undesirable flow of *tainted* data. For example, program inputs possibly controlled by an attacker are tainted, and should not flow to sensitive program operations without proper sanitization. *Static taint analysis* aims to automatically discover these dangerous data flows, and many approaches to static taint analysis have been proposed [13, 44, 11, 27, 24, 4, 21, 45, 34, 46, 26].

We desire a static taint analysis with the following properties:

- *high precision*, i.e., few false positive reports;
- *high recall*, i.e., few missed vulnerabilities;
- *fast running times*, enabling checking during continuous integration (CI) or even on local builds; and
- *applicability* to existing code bases.

Previous approaches do not satisfy all of these properties. Most existing tools perform whole-program analysis, using inter-procedural alias and dataflow analysis to discover tainted flows. Such approaches are applicable to extant code and can have high precision and recall, but they are difficult to scale to large programs, which can have millions of lines of code [13, 44]. Such analyses can take hours to complete, making them insuitable for CI deployment or local developer runs. Incremental analysis techniques can speed re-analyzing code after small changes [13, 15, 42], but they may miss issues [41] or still consume excessive resources [42].

An alternative approach is type-based checking using type qualifiers [23], as embodied in pluggable type checkers [36, 19]. A type-based approach performs *modular* checking for tainted flows, combining intra-procedural analysis with annotations at method boundaries to capture inter-procedural flows. The Checker Framework [36, 19] includes a type-based tainting checker [2]. Such approaches can have high recall, and they have fast running times, as the use of annotations *completely obviates* the need for inter-procedural analysis. They are also naturally incremental due to modularity, yielding an automatic and significant speedup (nearly 10X in our initial measurements) for small code changes with modern build systems [6]. However, extant type-based approaches lack both precision and applicability. For precision, the previous checker [2] treats third-party libraries and various language constructs too conservatively, leading to excessive false positives. For applicability, running a type-based approach on extant code requires adding annotations, a significant up-front effort that limits adoption.

In this paper, we present a new approach to type-based checking for taint properties that achieves all of our desired properties: high precision and recall, fast running times, and applicability. In contrast to the extant approach [2], we design our checker to prioritize usability and flexibility over full soundness. We handle un-annotated library methods as *polymorphic* by default [27], i.e., only returning tainted data when it is passed in, dramatically reducing the need to annotate such methods. We also introduce more practical handling of a variety of language constructs to reduce false positives. While these techniques can in theory introduce unsoundness, our extensive evaluation showed that the impact on analysis recall was minimal.

We also present a novel technique to automatically infer tainting type qualifiers, achieving applicability to existing code. Our technique extends a recent search-based approach for inferring nullability annotations [30] with several important new features. We develop a novel algorithm for inferring type annotations on generic type arguments, crucial for tainting; this problem was left open in recent work [30, 31]. Our algorithm can also infer polymorphic method annotations when generic types are not present. We introduce an optimized handling of local variable annotations to further improve inference performance.

We implemented our technique in a tool TaintTyper and evaluated it on a range of benchmarks. TaintTyper was able to infer annotations comparable to human-written annotations and suitable for insertion into source code. Further, once inference was completed, TaintTyper had higher recall than a state-of-the-art taint analyzer on real-world benchmarks, with comparable precision, and 2.93X–22.9X faster checking time. Hence, the

evaluation showed that TaintTyper achieved the precision, recall, speed, and applicability goals outlined above. An ablation experiment showed that our new checker and inference features were crucial for TaintTyper's effectiveness.

This paper makes the following key contributions:

- We present a new, more practical type-based tainting checker, with improved handling of third-party libraries and other language constructs.
- We describe a novel inference technique for tainting types. Crucially, the technique handles generic type arguments, and includes an important new optimization to reduce inference time.
- We present a detailed experimental evaluation showing our approach makes type-based taint checking much more practical for real-world projects, significantly improving over the state-of-the-art.

The implementation of TaintTyper is available at `https://github.com/ucr-riple/TaintTyper`.

2 Background

In this section, we provide background on typical approaches to taint analysis (Sec. 2.1) and the type-based approach (Sec. 2.2), comparing them and motivating our techniques.

2.1 Taint Analysis

Taint analysis aims to discover *information flow vulnerabilities* in code [18], an undesirable flow of information from some designated *source* of values to a designated *sink* operation. Our attacker model assumes that the attacker controls inputs originating from untrusted sources and seeks to reach sensitive sinks. In this context, sources include typical mechanisms that receive data from external origins, such as reading from the network, accessing files, or handling user input. Conversely, sinks are operations that have security-critical effects, such as writing to a file, sending data over the network, or executing system or database commands. E.g., for an SQL injection attack, the source is an input from a potential attacker and the sink is a database query, while for a cross-site scripting (XSS) attack, the sink renders output to a web page. Information flow may be *direct*, solely involving data dependencies, or *indirect*, potentially involving control dependence. As with most practical static taint analyses, we consider only direct information flow in this work.

The most common approach to static taint analysis is to perform an inter-procedural (whole-program) dataflow analysis to discover source-to-sink data flows [13, 44, 11, 27, 24, 4, 21, 45, 34, 46, 26]. For languages like Java, inter-procedural analysis requires computing a call graph, typically using whole-program pointer analysis [40]. Tracking of tainted data flows also requires handling of pointer aliasing, to account for flows through object fields and data structures like lists. Precise reasoning about call graphs and pointer aliasing is the key scalability bottleneck for whole-program taint analysis. For example, a recent approach [25] required over 3 hours and 153GB of RAM to precisely analyze the full Java standard library, and real-world programs may grow much larger. Approaches to make such analyses incremental have been proposed [13, 15, 42], which could speed up re-analysis of a code base after a small change. But, such approaches can miss issues [41] or still require significant time or memory [42].

Tainting rules capturing which source-sink flows may be vulnerable are typically provided as input to a taint analysis tool. Such rules may also capture information about *validator* and *sanitizer* operations, whose use may make a source-sink flow safe. Discovering tainting

rules is itself non-trivial and has been a subject of much research [38, 17, 20, 33]. In this work, we focus on the core analysis problems and assume tainting rules have been provided; any improvements in taint rule discovery could be easily combined with our approach.

2.2 Type-Based Taint Analysis

2.2.1 Basics

Type-based taint analysis is built on the ideas of pluggable type systems [36, 19]. A pluggable type system defines a set of *type qualifiers* that refine the built-in types of a language, further restricting the kind of value an expression may evaluate to. We write type qualifiers by prefixing with an `@` character, using Java annotation syntax. For tainting, the main qualifiers are `@Tainted`, for expressions that *may* be influenced by (data-dependent on) a source, and `@Untainted`, for expressions that *must not* be influenced by a source. Tainting rules are provided in the form of `@Tainted` qualifiers on source operations and `@Untainted` qualifiers on sink operations.

A pluggable type system must also define a subtyping relationship $\leq$ between qualifiers. For tainting, we have `@Untainted` $T \leq$ `@Tainted` T for any base type T; `@Untainted` values may safely flow to (possibly) `@Tainted` locations, but not vice-versa. Enforcing this property requires checking for subtype compatibility at all pseudo-assignments in the program, including assignments to variables / fields, parameter passing, and returns. To reduce the number of explicit annotations required, pluggable type systems interpret unqualified types as having a default qualifier. For tainting, the default qualifier is `@Tainted`. The following example illustrates this checking:

```
1 class Ex {
2   @Tainted String f1; @Untainted String f2;
3   void m1(@Untainted String s) {
4     f1 = s; // no error: @Untainted assigned to @Tainted
5   }
6   void m2(@Tainted String t) {
7     m1(t); // error: @Tainted passed to @Untainted
8     f2 = t; // error: @Tainted assigned to @Untainted
9   }
10 }
```

In the code, `@Tainted String f1` could have been written as just `String f1` due to defaulting. Local variables are not subject to defaulting: their types are inferred using flow-sensitive dataflow analysis [36, 19], which also enables handling of taint validators. By default, the Checker Framework's Tainting Checker [2] treats all code, including unannotated third-party libraries, with the same defaulting rules. So, since `@Tainted` is the default qualifier, any value returned by a third-party method is assumed to be tainted. This approach leads to too many false positives in practice; Sec. 4.1 describes our more practical handling of such code.

2.2.2 Method calls

Pluggable type systems must also check that method overriding respects the subtyping rules for the type qualifiers. Return types must be covariant in overriding methods, and parameter types must be contravariant. Consider the following (erroneous) example:

```
1 class Super {
2   @Untainted String foo() { return "hi"; }
3 }
4 class Sub extends Super {
```

```
5   // invalid override!
6   @Tainted String foo() { return source(); }
7 }
```

`Sub.foo()` cannot be allowed to return a `@Tainted String`, since code written to handle `Super` objects may expect `foo()` to return an `@Untainted String`. Without this checking, the following vulnerable code would pass the checker:

```
1 void process(Super s) { sink(s.foo()); }
2 process(new Sub());
```

Given this method override checking, method calls can be handled in the pluggable types approach *without computing a call graph*. At a call c to a method with declared target `P.m`, the checker needs only to check that the parameters passed and return value use at c are consistent with the type of `P.m` itself. If at runtime, an overriding method `Q.m` is invoked at c, override checking ensures that the tainting behavior of `Q.m` is consistent with `P.m`, so no vulnerability is possible. This ability to check calls without a call graph yields a huge scalability benefit for the pluggable types approach.

2.2.3 Data structures / polymorphism

Pluggable type systems use parametric polymorphism to support storing differing types of data in different instances of a data structure. Consider the following example:

```
1 List<@Tainted String> taintedStrs = new ArrayList<>();
2 List<@Untainted String> untaintedStrs = new ArrayList<>();
3 taintedStrs.add(source()); untaintedStrs.add("safe");
4 sink(taintedStrs.get(0)); // error reported
5 sink(untaintedStrs.get(0)); // no error reported
```

Here we have two `ArrayList` instances, one holding possibly-tainted strings and the other holding untainted strings. The taintedness of list contents is captured by adding a taint qualifier to the generic type argument, e.g., `List<@Tainted String>`. With these type declarations, the pluggable type checker reports an error at the first `sink` call while also proving that the second `sink` call is safe.

To achieve similar precision, a whole-program static analysis must use *context sensitivity*: each call to the relevant `ArrayList` methods must be analyzed separately, and `ArrayList`'s internal state must be represented with a context-sensitive heap abstraction [40]. Context sensitivity significantly increases the running time of such analyses. The pluggable types approach uses qualified type arguments to achieve similar precision with much less cost.

`@PolyTaint` annotations can be used for polymorphic methods that do not already use type variables. Consider, e.g., the `parentPath` function in Fig. 1. Here, the return value of a call to `parentPath` should only be considered `@Tainted` if the parameter for that call is `@Tainted`; the `@PolyTaint` annotations capture this property. Again, a standard whole-program analysis can achieve this precision with context sensitivity, but at greater cost to scalability.

It is possible that different objects of a non-generic class vary in terms of whether tainted data is stored in their fields. Such cases can be handled in whole-program analysis using field sensitivity, which models each field of each (abstract) object separately. Typically, no such modeling is used in the pluggable types approach, outside of generic types. We have found that this rarely leads to false positives; qualified generic type arguments and `@PolyTaint` nearly always suffice for good precision in practice.

```
1 Map<String, +@Untainted String> paths = ...;
2 +@PolyTaint String parentPath(+@PolyTaint String path) {
3   return path.substring(0, path.lastIndexOf("/"));
4 }
5 void exec(String name) {
6   String path = paths.get(name);
7   String parent = parentPath(path);
8   sink(Paths.get(parent).toAbsolutePath().toFile());
9 }
10 void sink(@Untainted String t) { ... }
```

Figure 1 Motivating example for inference. Green text indicates where annotations are inserted by TaintTyper.

2.2.4 Benefits

A typechecking approach to tainting scales well since the checking is fully modular: each method can be checked in isolation given only the type signatures of fields it accesses and methods it invokes. Checking is also incremental: after a change, only the code that needs to be re-compiled needs to be re-checked. Beyond improved scalability, a type-based approach to taint checking has various other advantages [36, 19]. Qualifiers serve as machine-checked documentation of tainting properties and invariants, and can also aid in safely performing refactorings. And, errors from the type-based approach can be more understandable, since they only require reasoning about local code and the types of related functions, not an inter-procedural trace. Because our analysis is type-based, it operates over type annotations rather than runtime behavior, meaning the attacker's knowledge of the program's internals does not fundamentally affect the analysis. We assume the attacker cannot modify the program's source code.

Currently, adopting type-based taint checking imposes a significant burden on programmers, as they must manually annotate their own code and any relevant third-party code. Our checking and inference techniques significantly reduce this burden, making the type-based approach more practical.

3 Motivating Example and Approach

Example. Fig. 1 gives a motivating example for our approach. (Disregard the green inferred annotations for the moment.) The `sink` method (line 10) requires an `@Untainted` argument. Assuming the values in the `paths` map cannot be tainted, the `sink` call at line 8 is safe. We shall show how the enhanced checker and inference of TaintTyper can automatically annotate and validate this example.

The first challenge is the use of library methods like `Paths.get`, `toAbsolutePath`, and `toFile` on line 8. Without manual annotation, the previous type-based approach [2] treats these calls as returning a `@Tainted` value by default. Our approach treats most unannotated methods as polymorphic [27]: it assumes they only return `@Tainted` data when a parameter is `@Tainted`. Therefore, by default, TaintTyper determines that the expression passed to `sink` can only be `@Tainted` if the `parent` variable is `@Tainted`, a correct handling for this example.

The `parent` variable is assigned the result of calling `parentPath(path)` (line 7), where `path` is a value in the `paths` map (line 6). As noted above, the values in the `paths` map are not tainted, which is captured by giving `paths` the type `Map<String,@Untainted String>` (line 1); this type makes the `path` variable `@Untainted` at line 6. The `parentPath` function

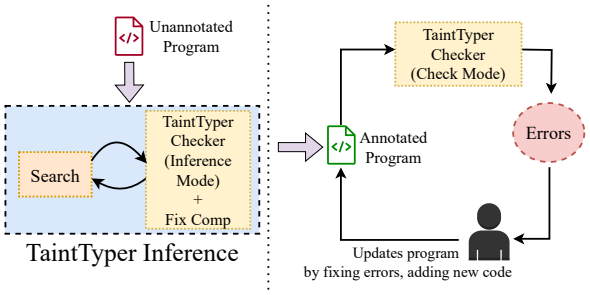

Figure 2 High-level architecture of TaintTyper.

can only return `@Tainted` data if its argument is `@Tainted`, captured with `@PolyTaint` annotations (line 2). With these annotations, the TaintTyper checker reports no warning for this code, as desired.

The example shows that to be effective, TaintTyper must support inferring annotations on generic type arguments and `@PolyTaint` annotations. The generic type argument support is required to eliminate the error, and `@PolyTaint` properly captures the behavior of the `parentPath` method.[1] The inference technique of Sec. 5 can successfully infer the necessary green annotations in Fig. 1.

Our approach. Fig. 2 shows the high-level architecture of TaintTyper. Given an unannotated program, TaintTyper first performs inference to create an annotated version of the program. The inference improves on a recent search-based technique [30] that repeatedly runs a checker to determine the best set of annotations to insert. Here, the checker is our new type-based taint checker, combined with a new fix computation algorithm to enable inference of type argument annotations and `@PolyTaint`. The inference step only needs to run once. Afterward, developers need only run the TaintTyper checker. They can fix the errors initially reported by the checker and also write new code (with annotations) that will be verified by the checker. Since the checker is type based, it runs much faster than a whole-program static analysis, enabling quick turnaround times, less CI resource usage, and even checking on local builds.

4 Practical Type-Based Checking

This section details the new features in TaintTyper's type checker that reduce false positives in real-world code, making the checker practical. We discuss handling of unannotated code, and then new handling of other language constructs.

4.1 Unannotated Code

TaintTyper specially handles interactions with unannotated, unchecked code, typically written by a third-party. Given the prevalence of third-party libraries lacking taint annotations in modern Java programs, such interactions occur commonly. By default, the Checker Framework's Tainting Checker [2] uses `@Tainted` annotation for all code, whether from source or from libraries. So, all unannotated library methods are assumed to have a `@Tainted` return type, yielding too many false positives to be usable.

[1] For this code excerpt, the parameter and return of `parentPath` could be marked `@Untainted`, but this would unnecessarily force all other callers of `parentPath` to pass in `@Untainted` data.

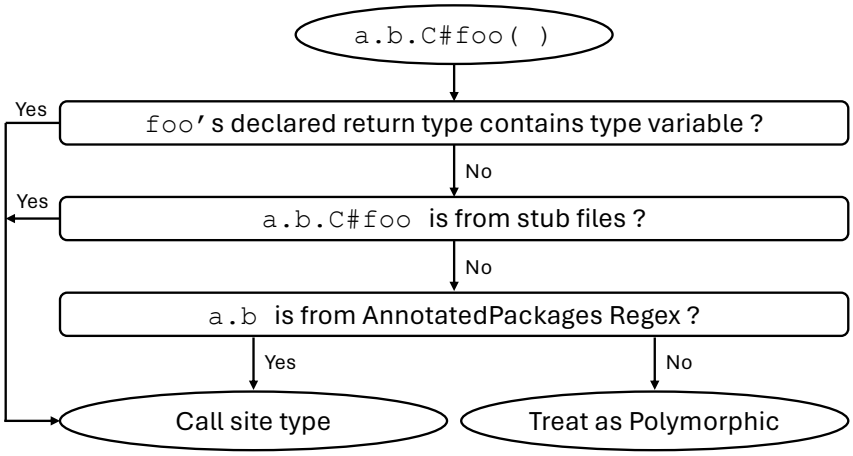

Figure 3 Logic for determining the return type qualifier for a method call, accounting for unannotated code.

TaintTyper adopts a *polymorphic by default* handling of calls to unannotated methods, extending a technique from previous work [27]. This approach treats the return type and all parameter types (including the receiver type) of an unannotated method as if they were annotated as `@PolyTaint` (see Sec. 2.2.3). For calls to such methods, the return value will be treated as `@Tainted` only if at least one of the actual parameters at the call is `@Tainted`. Consider this expression from line 8 from Fig. 1:

```
Paths.get(parent).toAbsolutePath().toFile();
```

The invoked `toFile` method is unannotated, so with our polymorphic treatment, its return value will only be treated as `@Tainted` if the result of the `toAbsolutePath` call is `@Tainted`. Since `toAbsolutePath` is also unannotated, the process recurses, and the taintedness depends on the result of the `Paths.get(parent)` call. Finally, since `Paths.get` is also unannotated, TaintTyper concludes the taintedness of the whole expression depends on whether *parent* is tainted, as desired for this example.

An overview of the logic for determining the return type qualifier for a method call, and when to apply polymorphic defaulting, is given in Fig. 3 (the logic for parameter types is similar). The flowchart handles a call to some method `a.b.C#foo`, where `a.b` is the package containing class `C`. If `foo`'s declared return type contains a generic type variable, we use the standard type checking rule for the call site, even if `foo` is in unannotated code. This exception is important since the return type is at least partially determined by type arguments from the call site. E.g., line 6 of Fig. 1 invokes `Map.get`, whose return type is the type variable `V` for map values. Though `Map.get` is unannotated, TaintTyper applies standard checking, to preserve information from the type argument `@Untainted String` given for this particular `Map` at line 1.

TaintTyper also always uses the standard call site type if `foo`'s type been specified in a stub file [3], as such files allow for externally providing types for library routines like sources and sinks. Otherwise, to determine whether code should be treated as annotated, TaintTyper takes as input an *AnnotatedPackages* regular expression (borrowing from the NullAway nullness checker [12]) which specifies which Java packages should be treated as annotated code. Note that this setting does not distinguish between first-party and third-party code, providing flexibility. E.g., when adopting TaintTyper, source packages

can be set as annotated gradually, initially leaving other source packages as unannotated and unchecked. Only if the `a.b` package is not part of the annotated packages, the polymorphic handling for unannotated code is applied.

The polymorphic-by-default handling of unannotated code is not sound for all cases. For example, if an unannotated method is itself a tainted source, then its return value should be treated as tainted, independent of the argument taintedness. Similar issues arise for unannotated sink methods. As discussed in Sec. 2.1, we view discovery of source and sink methods as a separate problem from the core checking and inference issues we address here. A method may also return tainted data even with untainted arguments, if a setter method of the receiver is invoked earlier with tainted data. When discovered, such cases can be addressed via stub file models [3]. In practice, our evaluation (Sec. 7) showed that this technique did not lead to false negatives in comparison to two state-of-the-art tools on real-world benchmarks, and that it dramatically increased practicality compared to [2].

4.2 Other Constructs

TaintTyper computes a default `@Untainted` type for a variety of language constructs that are treated as `@Tainted` by the previous checker [2]. Enum constants, class literals, lambda expressions, and fields of annotations are always treated as `@Untainted`. A static final field is treated as `@Untainted` if its initializer expression is `@Untainted`. An array initializer expression (e.g., `new String[] {x,y}`) has `@Untainted` contents by default if all the initial array values are `@Untainted`. Similarly, a cast expression is `@Untainted` if the casted expression is `@Untainted`. In some cases, like static final fields, an explicit `@Untainted` annotation could be written, but our defaulting reduces the annotation burden. Note that other cases like lambda expressions cannot be directly annotated, and can only be handled with a warning suppression without our approach.

`java.util.Collection` data structures are widely used in Java programs, making special-case handling useful. A `Collection` is often constructed directly from another `Collection` or array, e.g., `new ArrayList<>(otherList)`. In such cases, if the other `Collection` holds `@Untainted` elements, TaintTyper always treats the new `Collection` as having `@Untainted` elements. The version of [2] we compared with did not handle these cases correctly due to type inference limitations.[2]

The `Collection.toArray(T[])` method, which converts a `Collection` to a `T[]` array, is also frequently used. With the baseline checker, even for a `Collection` of `@Untainted` values, the array contents type of a `toArray` call is `@Tainted` unless the `toArray` argument is explicitly annotated (e.g., `c.toArray(new @Untainted String[0])`). TaintTyper does not require this annotation and treats the result of `toArray` as having `@Untainted` contents if the `Collection` contents are `@Untainted`.

5 Inference

In this section we detail how TaintTyper performs inference. TaintTyper extends a previous search-based inference technique with support for generic types, `@PolyTaint` annotations, and unannotated code. It also introduces a new optimization that significantly improves inference performance.

[2] The inference limitations have been addressed in more recent versions, but we found that these versions introduced new bugs, so we did not update the version that we compared to.

5.1 Baseline Algorithm

Our inference extends the search-based inference approach of Karimipour et al. [30]. The approach aims to infer annotations that minimize the final number of errors reported by a checker, which in [30] was the nullness checker NullAway [12]. By minimizing the final number of errors, this approach infers annotations that *maximize* the amount of code that fully passes the checker. A recent study showed this search-based approach to work better than alternate approaches in practice [28].

The search performs *black-box inference*, in which the effectiveness of annotations in reducing errors is measured by running the checker itself and observing its output. This technique computes a set of annotations that fix some reported checker errors. Then, the checker is re-applied to see if these annotations cause new errors. Consider this example:

```
1 void m1() { m2(source()); m2(source()); }
2 void m2(String t) { sink(t); }
```

Initially, TaintTyper reports an error at line 2, since `t` is `@Tainted` by default and passed to a sink. A local fix for this error is to annotate `t` as `@Untainted`. But, with this fix, TaintTyper reports two new errors on line 1 (since `source`'s return is `@Tainted`), increasing the total number of errors. So, the fix is rejected by the search. The previous work describes optimizations to speed the search process, by evaluating independent annotations simultaneously [30]; we evaluate the effectiveness of these optimizations for taint inference in Sec. 7.2.3.

The previous work only described how to fix errors reported by NullAway. For tainting, computing annotations for fixes is significantly more complex due to the need to support generic types and `@PolyTaint`. Recent work on pluggable type inference left open inference for generic types due to the challenges involved [30, 31]. In Sec. 5.2, we describe our novel technique for computing annotations to fix tainting errors, supporting generic type arguments and `@PolyTaint`.

5.2 Computing Fixes

For our tainting checker, there are two main causes of reported errors: type incompatibility at a (pseudo-)assignment, and incorrect method overriding (see Sec. 2.2). For both cases, fixing the error requires *adjusting the type* of relevant variables or expressions. E.g., for the example of Sec. 5.1, the initial fix was to change the type of parameter `t` to `@Untainted String`. Alg. 1 gives our new technique to compute the annotations to achieve a desired type adjustment. The main procedure FindAnnots takes as arguments an expression e and a desired type for the fix T_f. It either returns a set of annotations that modify e's type to be T_f, or $\perp$ to indicate it has failed to find such a set. FindAnnots relies on various other procedures, some of which we elide for brevity but describe in text. We also only show handling of key representative language constructs for simplicity. We first explain the basic cases for Alg. 1, and then present our novel handling of generic type arguments and `@PolyTaint` annotations.

5.2.1 Basics

For a variable v (which could be a local, parameter, or field), line 3 uses a routine UpdateType (not shown) to update v's declared type directly. UpdateType may fail and return $\perp$; e.g., TaintTyper does not attempt to convert a raw type like `List` to a generic type like `List<@Untainted String>`, as this change is out of scope for our work (other tools can

Algorithm 1 Pseudocode for finding annotations for a fix.

```
1: procedure FindAnnots(e, T_f)
2:     if e is a variable v then
3:         return UpdateType(v, T_f)
4:     else if e is a binary expression e_1 op e_2 then
5:         return FindAnnots(e_1, T_f) ⊎ FindAnnots(e_2, T_f)
6:     else if e is a call e_1.m(e_2, ..., e_n) then
7:         G ← GenericsAnnots(e, T_f)
8:         if G ≠ ⊥ return G
9:         P ← PolyTaintAnnots(e, T_f)
10:        if P ≠ ⊥ return P
11:        m ← InvokedMethod(e)
12:        if TreatAsPolyTainted(m) then
13:            return ⊎_{i∈PTArgs(m)} MakeUntainted(e_i)
14:        else
15:            return UpdateType(ReturnType(m), T_f)
16:        end if
17:    end if
18: end procedure
19: procedure MakeUntainted(e)
20:    T' ← @Untainted TypeOf(e)
21:    return FindAnnots(e, T')
22: end procedure
23: procedure GenericsAnnots(e, T_f)
24:    m ← InvokedMethod(e)
25:    S ← FindTypeSubst(ReturnType(m), T_f)
26:    if S = ⊥ return ⊥
27:    e_r ← ReceiverArg(e)
28:    T' ← ApplySubst(S, ReceiverType(m), TypeOf(e_r))
29:    return FindAnnots(e_r, T')
30: end procedure
```

be applied for such cases [43]). For binary operators with sub-expressions e_1 and e_2, we recursively compute fixes for e_1 and e_2 and then combine them using a special $\uplus$ operator (line 5). $\uplus$ propagates the failure value $\bot$ – it is defined as follows:

$$A \uplus B = \begin{cases} \bot & A = \bot \vee B = \bot, \\ A \cup B & \text{otherwise.} \end{cases}$$

Method calls, handled at lines 6–16, require the most complex handling. We first attempt to handle the call by inferring annotations on generic type arguments (line 7). If that fails, we attempt inference of `@PolyTaint` annotations (line 9). We will explain the generics and `@PolyTaint` cases further shortly. If both generics and `@PolyTaint` inference fail (by returning $\bot$), we fall back to a more direct handling, depending on the method being invoked.

Line 12 checks if the invoked method m should be treated as having `@PolyTaint` annotations. This check returns true if either m has declared `@PolyTaint` annotations or if m is unannotated and our default polymorphic handling applies (see Sec. 4.1). In such cases, to make the call's type untainted, *all* `@PolyTaint` parameters must be made untainted, reflected in line 13 (PTArgs(m) returns the `@PolyTaint` argument positions for m). MakeUntainted (lines 19–22) updates the type of expression e with a top-level `@Untainted` annotation and then recursively calls FindAnnots. Any failure to make an argument untainted is propagated using $\uplus$. Finally, for calls to annotated methods, our base handling is to update the declared return type of the invoked method (line 15).

5.2.2 Generics

For calls to methods involving generic types, our approach aims to find fixes that annotate type arguments instead of directly updating the invoked method's return type. To see why, consider the call `paths.get(name)` on line 6 in Fig. 1. This call invokes `Map.get`, whose return type is generic type variable `V`. Say that FindAnnots aims to make the result of the call `@Untainted`. The baseline technique for method calls (line 15 in Alg. 1) would change `get`'s return type to `@Untainted V`, a valid fix. But, this change would force *all* calls to `Map.get` to return untainted values, preventing *any* `Map` from holding possibly-tainted values, which is impractical.

Instead, our technique tries to find a fix that leverages generic type arguments, as shown in the GenericsAnnots routine of Alg. 1. First (line 25), we call FindTypeSubst (not shown) to find a *substitution* for the type variables in the return type of m that yields the desired type T_f. For the above example, GenericsAnnots is called with $e =$ `paths.get(name)` and $T_f =$ `@Untainted String`. Since `get`'s return type is type variable `V`, line 25 successfully finds a substitution $S =$ `V` $\mapsto$ `@Untainted String` that yields T_f. FindTypeSubst may fail to find a substitution, in which case it returns $\bot$ (line 26). FindTypeSubst works by recursing through type structures, mapping type variables to the desired type arguments; we elide details as they are straightforward.

When we successfully find a substitution S, we then *apply* S to the declared receiver type of the method, and recursively try to find corresponding annotations for the receiver argument of the call (lines 27–29). If S does not cover all type variables in the receiver type, we reuse the generic type arguments from the receiver argument at the call site. For our `paths.get` example, the declared type of the `Map.get` receiver is `Map<K,V>`, but our substitution `V` $\mapsto$ `@Untainted String` does not cover `K`. So, we reuse the `String` type argument for `K` from line 1 of Fig. 1, yielding a recursive call FindAnnots(`paths`, `Map<String,@Untainted String>`) at line 29.

The recursive nature of FindAnnots successfully handles much more complex uses of generic types, e.g.:

```
1 void foo(Map<Integer, +@Untainted String> t) {
2   sink(t.values().iterator().next());
3 }
```

FindAnnots aims to make the return type for the `next` call `@Untainted String`, but it is not immediately evident which generic type argument must be annotated to achieve this. In our algorithm, the generics logic proceeds by recursively trying to make the `iterator` call return `Iterator<@Untainted String>`. This in turn leads to trying to make the `values` call return `Collection<@Untainted String>`, which finally leads to successfully adjusting the type of `t` to `Map<Integer, @Untainted String>`. TaintTyper can also annotate generic type arguments in `extends` clauses of class declarations, and generic methods (where the type variable is scoped to the method instead of the class) are also handled fully.

5.2.3 `@PolyTaint` inference

As noted in Sec. 2.2, `@PolyTaint` can be useful when a method is generic in its tainting behavior but was not declared using generic type variables. Due to the lack of type variables, inference of `@PolyTaint` annotations must *discover* relevant data flow from parameters to return values, which may occur through callee methods. E.g., for the `parentPath` method in Fig. 1, the taintedness of the `path` argument influences the return taintedness via a call to `path.substring`.

Algorithm 2 Pseudocode for inferring polymorphic annotations.

```
1: procedure PolyTaintAnnots(e, T_f)
2:     m ← InvokedMethod(e)
3:     Result ← ∅
4:     F_return ← FindAnnotForReturnStatements(m, T_f)
5:     Worklist ← F_return
6:     Processed ← ∅
7:     while Worklist ≠ ∅ do
8:         F_element ← Worklist.pop()
9:         if F_element is not on a local variable then
10:            Result ← Result ∪ {F_element}
11:            continue
12:        end if
13:        if F_element ∈ Processed then
14:            continue
15:        end if
16:        Processed ← Processed ∪ {F_element}
17:        F_assign ← FindAnnotForAssignments(m, F_element, T_f)
18:        Worklist ← Worklist ∪ F_assign
19:    end while
20:    F_Parameters ← {F | F ∈ Result ∧ F is on parameter of m}
21:    F_NonParameters ← Result \ F_Parameters
22:    if F_Parameters = ∅ then
23:        return MakeUntainted(m)
24:    else
25:        PolyMethodFix ← MakePolyTainted(m, F_Parameters) ∪ F_NonParameters
26:        F_args ← ∅
27:        for arg ∈ PolyMethodFix.args do
28:            F_args ← F_args ∪ FindAnnots(arg, UpdatedTarget(T_f))
29:        end for
30:    end if
31:    return F_args ⊎ PolyMethodFix
32: end procedure
```

The PolyTaintAnnots procedure for inferring `@PolyTaint` annotations (called at line 9 in Alg. 1) is conceptually simple: it works by inserting `@PolyTaint` annotations, observing where such annotations lead to type checking errors, and then recursively inserting more annotations to fix those errors. However, we found that a straightforward implementation based on this strategy was too inefficient, so we introduced two improvements. First, a naïve approach to discovering new type errors is to re-run the full type checker, but leads to many expensive checker runs; instead, we implemented our own limited analysis of data flows relevant to `@PolyTaint` to discover new errors. Second, we bounded the depth of the search into callee methods, giving up and returning $\perp$ if inference required searching further (we found depth five to work best in our experiments).

Alg. 2 gives a simplified view of the PolyTaintAnnots procedure. The algorithm starts by invoking FindAnnotForReturnStatements (not shown), which scans the method body for returned expressions and uses FindAnnots to discover the annotations needed to align each expression's type with T_f. If any of the computed annotations targets a local variable v, PolyTaintAnnots uses FindAnnotForAssignments (not shown) to scan for expressions assigned to v and compute necessary annotations for those expressions (again via FindAnnots). This process iterates using a worklist until all locals are handled. Upon

completing the iterations, if there exists an annotation on a method parameter, the method is identified as polymorphic, and the necessary annotations are computed. The method indirectly invokes FindAnnots from Alg. 1 through calls to FindAnnotForReturnStatements and FindAnnotForAssignments, which may recursively invoke PolyTaintAnnots. A separate depth bound ensures termination, and the algorithm returns $\perp$ if the bound is reached or if any call to FindAnnots returns $\perp$. When a method is determined to be polymorphic, the algorithm calculates the required annotations for its arguments and combines these with the annotations derived for the return type.

5.2.4 Example

We now discuss the overall process of applying inference to our motivating example in Fig. 1. Since the error in the unannotated code is reported at line 8, initially FindAnnots is invoked to try to make the `toFile()` call passed to `sink` have type `@Untainted String`. As discussed in Sec. 4.1, this expression includes nested calls to unannotated code, handled by line 13 in Alg. 1. Eventually, this leads to annotating `parent` as `@Untainted`. This annotation causes a new checker error at line 7, leading inference to use FindAnnots to make the `parentPath(path)` call `@Untainted`. Here, our `@PolyTaint` inference succeeds for `parentPath`, leading to the annotations on line 2. The search then makes `path` `@Untainted`, causing a type error at line 6. Here, FindAnnots makes the `paths.get` call `@Untainted` by updating the generic type of the `paths` field, discussed in detail in Sec. 5.2.2 above. With this change, no new errors are reported, completing inference.

5.2.5 Local Variable Optimization

Our initial inference implementation took an excessive amount of time, nearly 24 hours for larger benchmarks. Most inference time is spent running the checker to detect the impact of annotations on warnings. For tainting, we found that many such checker runs were for annotations on local variables, e.g., the runs for `parent` and `path` in Fig. 1 (discussed above). As an optimization, we enhanced our fix computation to *internally* determine the impact of local variable annotations rather than using the checker. This reasoning requires finding assignments to the relevant locals, and then recursively invoking FindAnnots to make the type of each assignment's right-hand side match the local's new type, similar to the logic shown in Alg. 2 for inferring `@PolyTaint`. With this optimization, two checker calls (for `parent` and `path`) are eliminated in inference for Fig. 1. In Sec. 7.2 we show this optimization has a very significant impact on inference performance.

6 Implementation

TaintTyper includes both type-based taint checking and inference (see Fig. 2). TaintTyper's checker (see Sec. 4) was built using the Checker Framework [36, 19], version 3.42.0. Use of the Checker Framework equips the TaintTyper checker with robust support for flow-sensitive local type inference, checking of generic types, and qualifier polymorphism. For our prototype, we modeled a number of source and sink methods involved in the most common Java vulnerabilities [7]. Our sinks include common methods that write to a file, send data over the network, or execute sensitive system or database commands. We modeled sources that read from the network, the file system, or user input. We also modeled a few relevant well-known sanitizer methods [8]. As noted in Sec. 2, creating more complete databases of sources, sinks, and sanitizers is still a research problem, and TaintTyper can easily benefit from further advances in that area.

TaintTyper's inference implementation uses a modified version of the NullAwayAnnotator tool [30]. Inside the TaintTyper checker, we implemented Alg. 1 to find annotations that can fix an error, and added support for serializing this information in the checker output. Our inference implementation reads in this serialized output to use during its search. The search is similar to that of [30], enhanced with our local variable optimization (Sec. 5.2.5). The search is depth bounded [30], and we used a bound of 15 in our experiments.

7 Evaluation

Here we present an experimental evaluation showing the high effectiveness of TaintTyper in practice.

7.1 Experimental setup and research questions

From previous work we found three benchmark suites will all tainting violations labeled, serving as a ground truth. They are:

- **Securibench Micro** [32], which provides 122 servlets exhibiting potential information-flow vulnerabilities, with the source code annotated with benign or problematic flows.
- **JInfoFlow** [24], a self-contained benchmark of 12 information-flow violations featuring reflection-intensive, event-driven code without dependencies on external libraries.
- **Injection Experiments** [39], comprising 8 Java programs with information-flow violations reported by their tool. While the original tool is no longer available, the dataset remains accessible. In the metadata, the authors label the reports from their tool as true or false positives.

Although these three benchmarks capture various interesting cases, they consist either of toy examples [32, 24] or projects that have not been maintained for years [39]. Consequently, we use them solely as one validation of the impact of the techniques of Sec. 4 on TaintTyper's recall.

For a more realistic evaluation, we examine a suite of actively-developed open-source Java programs used in recent work [10, 14]. We selected only projects for which there were some reported tainting errors. We also strove to include a variety of project sizes and types, ensuring the benchmark reflects real-world scenarios; our suite includes a web framework, content management system, security framework, forum software, and library management system. Due to the lack of a ground truth on these benchmarks, we made considerable manual efforts to ensure the accuracy of our results. This included carefully comparing results against previous static analyzers and manually annotating the code for comparison (further details below). In the end, we prioritized benchmarks that were the most representative and important, ultimately selecting seven projects for our evaluation, as listed in Table 1. We used all benchmarks from [10] for which there were reported tainting errors except for webgoat and opencms, which were not included due to complex build system configurations that TaintTyper cannot yet handle. One such complexity arises when the code relies on generated code, such as when using Project Lombok [1]. If a generated getter method is inferred to return untainted, it must first be delomboked and explicitly annotated. However, when the code is compiled, the generated code is overwritten, causing the loss of information needed to propagate the untainted annotation from the getter to the corresponding field. This is not a fundamental limitation of our approach but rather an implementation challenge that could be addressed with additional engineering effort.

Table 1 Benchmark sizes and inferred annotation counts.

Project	KLoC	Inferred Annotations	
		Total	per kLoC
esapi-java-legacy	18.3	265	14.4
pybbs	9.7	105	10.8
alfresco-core	13.4	81	6.0
alfresco-remote-api	85.8	213	2.5
cxf	47.5	296	6.2
struts	49.3	313	6.3
commons-configuration	20.2	261	12.9

We used CodeQL [4] v2.15.1 and P/Taint [24, 5] as baseline tools for our evaluation. CodeQL is a production-quality security analysis tool, widely used and freely available. P/Taint uses state-of-the-art whole-program analysis techniques, also employed in recent work [13]. We configured both tools to detect issues involving the sources and sinks modeled for TaintTyper (Sec. 6). We considered a variety of other tools for our experiments but found them unsuitable. FlowDroid [11] is a well-known taint analyzer for Android, but it does not support analysis of Java server programs. And, the taint analyses in SonarQube [9], RAPID [21], and CompTaint [13] are not freely available.

Given these benchmarks and tools, we studied seven research questions:

RQ1 Does TaintTyper find the known errors in existing labeled benchmarks?

RQ2 After inference, how do TaintTyper's reported errors compare to those reported by state-of-the-art tools (in terms of precision and recall)?

RQ3 After inference, how does TaintTyper's checking time compare with state-of-the-art tools on real-world benchmarks?

RQ4 Does TaintTyper's inference run in a reasonable amount of time, and are our optimizations effective?

RQ5 Does TaintTyper require a reasonable number of annotations?

RQ6 How do the annotations inferred by TaintTyper compare to manually-written annotations?

RQ7 How is TaintTyper's effectiveness impacted if we disable checker improvements, generic type argument inference, and `@PolyTaint` inference?

We address RQ1–RQ4 in Sec. 7.2. Then, Sec. 7.3 addresses RQ5 and RQ6, and Sec. 7.4 answers RQ7. All experiments were conducted in a Google Cloud instance with an AMD EPYC Milan 3rd Generation 2.45GHz CPU with 32vcpu (16 cores) and 128GB memory.

7.2 Inference effectiveness

7.2.1 Soundness on labeled benchmarks

To evaluate the soundness of TaintTyper, the three labeled benchmark suites were used. For these experiments, we customized the source and sink specifications used by TaintTyper to match what was expected by each benchmark suite.

We first ran TaintTyper's checker without inference, and confirmed that it did not miss *any* labeled vulnerabilities in the benchmarks. We then applied our inference to annotate the benchmarks automatically and re-check them again, to check how the inferred annotations impacted recall.

Table 2 Without inference, TaintTyper reports all the labeled true-positive issues across these three benchmarks. With inferred annotatations, it misses one issue in Securibench Micro, detects all issues in JInfoFlow, and misses 15 issues in Injection Experiments.

SecuriBench Micro		JInfoFlow-bench		Injection Experiments	
Total	136(137)	Total	12	Total	730(745)
aliasing	12	JInfoFlow/basic	2	Snake&Ladder	40
arrays	9	JInfoFlow/ctx	5	MediaPlayer	0
basic	61	JInfoFlow/event	5	EmergencySNRest	0(3)
collections	14			FarmTycoon	5
datastructures	5			Abagail	0
factories	3			JExcelAPI	3(4)
inter	16			Colossus	682(693)
pred	5

sanitizers	3(4)				
session	3				
strong updates	1				

Table 3 Precision and recall results across our benchmark suite.

Project	TP	CodeQL		TaintTyper	
		Precision	Recall	Precision	Recall
esapi-java-legacy	18	0.90	0.50	0.95	1.00
pybbs	9	1.00	0.89	1.00	1.00
alfresco-core	2	1.00	0.50	1.00	1.00
alfresco-remote-api	21	0.82	0.43	0.70	1.00
cxf	9	1.00	0.11	0.75	1.00
struts	23	0.39	0.39	0.50	1.00
commons-configuration	11	1.00	0.73	0.69	1.00

For Securibench Micro, the metadata indicated 136 labeled vulnerabilities. However, manual inspection revealed 137 in total, with one unlabeled issue in *Basic26.java* and one missing label in *Basic31.java*. Securibench Micro also makes extensive use of raw types, which appear rarely in modern Java code and are not yet fully handled by TaintTyper; we inserted (unannotated) generic type arguments for these cases. With these fixes, after inference, TaintTyper only missed one true issue out of 137; this was due to an interaction between our polymorphic-by-default library handling and side effects, as discussed in Sec. 4.1.

In inference-annotated JInfoFlow-bench, TaintTyper successfully identifies all 12 labeled vulnerabilities. The Injection Experiments consist of eight Java programs, one of which could not be compiled. We annotated the remaining seven programs (collectively comprising 754 labeled issues) using TaintTyper inference. Eight of the labeled issues occur in files not part of the available benchmark codebase, and one occurs in test code. Upon manually inspecting the inferred annotations and the reported errors from TaintTyper, we found that it discovered 730 of the remaining 745 issues, with the missed issues again due to side-effecting third-party library calls. The number of missed issues across these benchmarks is small, and as shall be shown in Sec. 7.2.2, we saw *no* missed issues for TaintTyper when compared to a production-quality tool on real-world benchmarks. Table 2 summarizes our findings across these benchmarks.

RQ1: TaintTyper's checker identifies all known issues in the labeled benchmarks, and inference reduces recall only slightly.

Table 4 Analysis runtime and inference runtime results across our benchmark suite.

Project	Analysis Runtime			Inference Runtime			
	TaintTyper	CodeQL	P/Taint	ALL	LOC	CORE	NONE

commons-configuration	25s	114s	209m	105m	168m	299m	432m

7.2.2 Reported errors

Table 3 compares the precision and recall of TaintTyper and CodeQL for our benchmarks, addressing RQ2. For TaintTyper, the errors are computed after inference has run, so the code includes inferred annotations. Computing recall requires knowing the ground truth of all real issues in these benchmarks, which is infeasible to collect. To estimate recall, we use the union of all true positive issues reported by TaintTyper, CodeQL, and P/Taint as our ground truth. (We treat a report as a true positive if the corresponding dataflow is deemed feasible by manual inspection.) This may over-estimate the true recall of all tools, but it provides a good basis for comparing the tools. The "TP" column gives the number of true positive issues for each benchmark.

Comparing error reports between the tools was non-trivial due to their different reporting approaches. For TaintTyper, an error is typically reported as a code location where a `@Tainted` value is being written into an `@Untainted` location. CodeQL reports an error as a data flow trace from a source to a sink, and P/Taint reports an error as a source/sink pair without a trace. Comparing these errors required manually matching each true-positive TaintTyper error to a step in some CodeQL trace, or to some data flow for a P/Taint source/sink pair, and vice versa. CodeQL sometimes treats a formal parameter as a tainted source, without any explicit call passing in tainted data. In these cases, TaintTyper annotates the parameter as `@Untainted`, capturing the fact that tainted data should not be passed in, but does not report an error. We count such cases as equivalent to reporting the error; TaintTyper could easily report errors for such cases if desired.

We exclude the precision and recall of P/Taint from Table 3 as both were very low on our benchmarks. P/Taint found a total of six true positive issues across the benchmarks (all of which were also found by some other tool), and it reported 50 false positives. We carefully checked our P/Taint configuration and confirmed it found expected issues in smaller benchmarks like Securibench Micro [32]. We also consulted with the tool authors, who acknowledged that P/Taint may not handle these benchmarks well (e.g., due to missing framework support). Still, triaging P/Taint results was very useful, to gain further confidence in our ground truth.

TaintTyper finds all true positive issues discovered by CodeQL and P/Taint, leading to a recall of 1 on all benchmarks in Table 3. TaintTyper also finds additional true positives missed by CodeQL, reflected in CodeQL's lower recall numbers. TaintTyper has lower precision than CodeQL on three benchmarks; we suspect this is due to heuristics in CodeQL that are missing in TaintTyper. Still, TaintTyper matches or exceeds CodeQL's precision on the other four benchmarks.

Table 5 Number of annotations inserted manually and by TaintTyper inference, and final error counts with various features disabled; C for checker improvements, G for generics inference, and P for `@PolyTaint` inference.

Project	Manual Annotation Count			Inferred Annotation Count			Error Count			
	Total	TypeArg	PolyTaint	Total	TypeArg	PolyTaint	C off	G off	P off	All Active
esapi-java-legacy	278	20	34	265	13	34	49	16	13	13
pybbs	95	27	4	105	46	4	21	16	2	2
alfresco-core	81	38	0	81	36	0	12	5	2	2
alfresco-remote-api	110	12	10	213	22	7	66	42	27	24
cxf	380	62	37	296	51	42	73	37	20	11
struts	347	50	5	313	47	7	116	54	44	37
commons-configuration	239	10	25	261	12	23	33	17	11	11

RQ2: On our benchmarks, TaintTyper has outstanding recall, with comparable precision to CodeQL.

7.2.3 Performance

Table 4 gives analysis runtimes for TaintTyper, CodeQL, and P/Taint checking. The speedups of TaintTyper's checker over CodeQL are quite significant, ranging from 2.93X–22.9X. And, we see orders-of-magnitude speedups compared to P/Taint, which could not analyze the struts benchmark within a 48-hour time limit. Given that TaintTyper's checking is modular and incremental, we expect even larger speedups over the whole-program analysis approach for larger benchmarks. As a sanity check of the benefits of incremental checking, we manually re-ran TaintTyper checking for five randomly-chosen source files for alfresco-remote-api and struts (the two largest benchmarks), and observed further speedups of 8.7X and 10.9X respectively.

RQ3: TaintTyper's checker runs much faster than the baseline tools, with further incremental speedups.

Table 4 shows inference performance with all optimizations enabled in the ALL column. Fully-optimized inference always ran in less than 6 hours, suitable for an overnight run and acceptable since it only needs to run once (see Fig. 2). The LOC, CORE, and NONE columns respectively show running times with our new local variable optimization only (Sec. 5.2.5), the core optimizations of [30] only (see Sec. 5.1), and no optimizations. The core optimizations of [30] seem to have a lesser impact for tainting inference than they did for nullability; excluding struts (which did not terminate in 48 hours with optimizations disabled), we see a maximum speedup of 2.23X, compared to 17.8X reported in [30]. Our local variables optimization on its own yields speedups of 1.47X–2.78X, sometimes larger than the core optimizations. Fortunately, the techniques are complementary, together yielding the best speedups of 2.75X–5.52X.

RQ4: TaintTyper has acceptable inference performance, aided significantly by our new optimization.

7.3 Assessing annotations

Table 1 shows the number of annotations inferred by TaintTyper for our benchmarks and the corresponding annotation density, addressing RQ4. The number of inferred annotations per KLoC is relatively low, ranging from 2.5-14.4. In comparison, Banerjee et al. [12] reported an average of 13 annotations per KLoC for NullAway, ranging up to 46 annotations, and that checker has been widely adopted.

RQ5: The annotation requirements of TaintTyper are low enough to enable adoption, given the importance of preventing tainting vulnerabilities.

Table 5 compares the number of annotations inferred by TaintTyper to the number of annotations inserted in a separate manual process. Two co-authors added manual annotations, each checking the other's work and coming to consensus for any disagreement. We completed this process, adding 1,530 manual annotations. We limited the manual changes to inserting annotations, prohibiting code changes. This limitation is contrived: a developer would most likely fix bugs and refactor code alongside adding annotations. We chose this methodology to fairly compare with TaintTyper inference, which only inserts annotations.

Table 5 shows that the number of inserted annotations does tend to differ between the two approaches. We inspected the discrepancies in detail, and found that in all cases, TaintTyper's inserted annotations were reasonable; which annotations were "better" was a subjective question. In cases where TaintTyper inserted fewer annotations, one pattern was where a manually-written annotation captured some desired invariant, but TaintTyper eschewed the annotation since it increased the final error count. A second pattern were cases where during manual annotation, an opportunity to use `@PolyTaint` was missed, but TaintTyper made use of `@PolyTaint` to avoid several other `@Untainted` annotations.

For cases where TaintTyper inserted more annotations, a common explanation was again reducing error count; TaintTyper would insert many extra annotations to reduce the final error count by one, but this was not deemed to be worthwhile during manual annotation. In such cases, arguably a better fix would be to restructure the code so fewer annotations would be needed. We could easily add a setting to TaintTyper to limit the number of annotations it inserts to fix a single warning to avoid such cases. In an extended version of the paper [29], we give detailed examples illustrating the above scenarios.

RQ6: TaintTyper's inserted annotations were always acceptable for insertion into source code, and sometimes improved on our manual annotations.

7.4 Ablation

Finally, to answer RQ6, we performed an ablation study to see how many errors are reported by TaintTyper when disabling the checker features of Sec. 4, generics inference (Sec. 5.2.2), and `@PolyTaint` inference (Sec. 5.2.3) individually. The results are shown in Table 5. We see large increases in reported errors with our new checker features disabled (3X-10.5X more errors), and similar impacts with generics support disabled (1.2X-8X more errors), showing the criticality of these features for precision. Further, without the new checker features, 85 of the additional errors were false positives that could not be removed with annotations (see Sec. 4.2); such cases require a warning suppression, causing developer frustration.

Inference of `@PolyTaint` has a less significant impact on final error counts. However, `@PolyTaint` inference is still critical for generating annotations close to what would be manually written, as shown in Table 5. Manual annotations included a total of 115 `@PolyTaint` annotations across our benchmarks, and with inference of such annotations disabled, none of these would be found by TaintTyper. Similarly, Table 5 shows that generic type annotations are used commonly, and hence TaintTyper's support for inferring these annotations is important.

RQ7: Our new checker features, generic type support, and `@PolyTaint` support were all critical to TaintTyper's effectiveness.

7.5 Threats to Validity

Our benchmark choices are a threat to external validity. We described our methodology for choosing benchmarks in Sec. 7.1. While we strove to choose diverse benchmarks, it is possible that TaintTyper will be less effective on a different set of programs. Our choice of tools for comparison (CodeQL and P/Taint) is another threat to external validity; other whole-program static analyzers may perform differently. See Sec. 7.1 for our process in choosing these tools. Paper co-authors performing the manual annotation of benchmarks is a threat to internal validity. We strove to add these annotations disregarding the workings of TaintTyper's inference. Other developers may manually annotate code in different ways, but a user study evaluating the degree of such differences is out of scope for this work. Implementation bugs in TaintTyper may also impact internal validity; but, we have done significant checking of correctness using manual inspection and a suite of regression tests.

8 Related Work

There is a broad literature on taint analysis; here we discuss the most closely related work. In Sec. 2 we contrasted type-based techniques with whole-program approaches [13, 44, 11, 27, 24, 4, 21, 45, 34, 46, 26], and we compared with CodeQL [4] and P/Taint [24] in our evaluation. Recent work by Banerjee et al. [13] describes an approach to incremental taint analysis but does not evaluate its performance. Szabo [42] presents an initial exploration of incrementalizing CodeQL analyses. While their incremental running times were promising, the additional memory usage of their technique was prohibitive. Type-based taint analysis is naturally incremental and does not suffer from these engineering challenges.

The most closely related whole-program approach is that of Huang et al. [27], which partially inspired our work. Their work is also formulated in terms of type-based taint analysis and type inference. Their type system does not support generic types: instead, they apply polymorphic types to fields to achieve a form of field sensitivity. It is unclear how to expose such field polymorphism in terms of standard pluggable types. Their work does not present a technique to persist types into source code to enable checking without inference and is specific to Android applications so we did not include this tool in our evaluations. TaintTyper performs inference for standard Java pluggable types, including generic types, enabling a straightforward integration with standard development workflows. The inference of [27] runs faster than ours since it operates over a single constraint encoding. However, our inference works with an existing checker without requiring a constraint encoding, which simplifies making improvements to the checker like those of Sec. 4.

There are many other approaches to enforcing information flow properties with types. The well-known Jif system [35] and many subsequent works support sophisticated properties like multiple principals. Such features are not necessary to capture the vulnerabilities targeted

by typical taint analyses and this work. Ernst et al. [22] target verification of Android apps, also using pluggable types. Their system aims for soundness for a security-critical military context, leading to an annotation burden of 60 annotations per KLoC, much higher than ours. TaintTyper eschews strict soundness to reduce the annotation burden for usability. We believe TaintTyper's inference technique could be adapted to systems like [22] in the future.

Regarding alternate inference approaches, standard type inference [37, Chapter 22] tries to discover a complete typing for a program in a given type system. Such techniques do not directly apply to our scenario, as a typical program will not be verifiable in our taint type system solely through adding annotations, due to true or false positives; we aim to find a good set of annotations for such untypable programs. Kellogg et al. [31] present a general inference technique for any pluggable type system built on the Checker Framework. However, their technique does not infer polymorphic or generic type annotations, and it may generate many more annotations than what would be written by developer.

Checker Framework Inference [16] uses constraint-based approach to infer types, with applications to domains like a type system for measurement units [47]. We chose a "black box" inference approach [30] for this work since it enabled re-using a checker implementation without reimplementing its logic in a constraint language. The approach of [47] does not support inference of polymorphic method annotations like `@PolyTaint`, and the paper does not discuss in detail its level of support for inferring annotations on generic type arguments.

9 Conclusions

We have presented TaintTyper, a novel approach to type-based taint checking and inference for Java. TaintTyper includes a novel checker that makes the core tainting type system more practical to use, and a novel inference algorithm capable of handling generic types and polymorphic annotations. Our evaluation showed that TaintTyper provided significant scalability advantages over a standard approach, with improved recall and comparable precision, and inferred annotations suitable for direct inclusion in source code. Hence, TaintTyper is a significant step toward practical and widescale type-based taint checking for Java.

Abstract

Field externalization is a technique to reduce the footprint of objects by removing fields that most frequently contain zero or null. While researchers have developed ways to bring this optimization into the Java world, these have been limited to research compilers or virtual machines for embedded systems. In this work, we present a novel field externalization technique that uses information from static analysis and profiling to determine externalizable fields. During compilation, we remove those fields and define *companion classes*. These are used in case of non-default-value writes to the externalized fields. Our approach also correctly handles synchronization to prevent issues in multithreaded environments. We integrated our approach into the modern Java ahead-of-time compiler GraalVM Native Image. We conducted an evaluation on a diverse set of benchmarks that includes standard and microservice-based benchmarks. For standard benchmarks, our approach reduces the total allocated bytes by 2.76% and the maximum resident set size (max-RSS) by 2.55%. For microservice benchmarks, we achieved a reduction of 6.88% for normalized allocated bytes and 2.45% for max-RSS. We computed these improvements via the geometric mean. The median reductions are 1.46% (alloc. bytes) and 0.22% (max-RSS) in standard benchmarks, as well as 3.63% (alloc. bytes) and 0.20% (max-RSS) in microservice benchmarks.

1 Introduction

Optimizing a program for speed, efficiency, and safety is a crucial goal of most compilers. In modern languages, such optimizations frequently concern objects and similar structured types. Java is a language that enables object-oriented programming at a high abstraction

(a) `Order` class with an ID, an array of (unspecified) items, shipping costs, and a discount code. The example assumes that `shippingCosts` and `discountCode` are rarely needed and thus externalizable.

(b) Externalized version of `Order` including its generated companion class that holds the externalized fields. The original class is augmented with a new `_ref` field that references the companion object if allocated. In later parts of the paper we detail improvements that allow us to eliminate this field.

Figure 1 Original and externalized representation of an `Order` class that is used as a continuous example to explain various aspects of our field externalization implementation.

level without sacrificing performance. As manifold as the usage scenarios of objects are in Java, as varied are the optimizations that compilers can apply. Optimizations on objects tend to fall into two categories: Reducing the memory footprint of objects and improving the efficiency of accesses to the objects' properties and methods. Object allocations are made more efficient by directly allocating into thread-local allocation buffers [32] or are eliminated altogether via escape analysis [14, 67]. Escape analysis typically also removes field accesses via scalar replacement, thus improving performance. Dynamic dispatch on methods is also a frequent target for optimizations. Compilers try to devirtualize calls [31], inline them [1, 36], or use inline caches [13, 15, 27, 28, 36, 82] to optimize for the most common cases. Other optimizations aim to shrink the object header [33, 74], a prefix in every object that references, among other things, type information and the virtual method table. While compilers also try to minimize the memory consumption of objects, the range of techniques [12, 72] applicable in this area has been more limited so far.

When analyzing heap dumps of Java applications, we noticed that certain fields of objects often just hold their default values. Other researchers have pointed out similar findings [4, 11, 23, 62]. This shows potential for optimization, as such objects occupy more memory than necessary. Especially in cloud and serverless computing, reducing the memory footprint of applications is important. Thus, we propose a novel form of *field externalization* – a technique for removing such fields, thereby reducing the memory footprint of objects and thus the overall memory consumption of an application.

The `Order` class shown in Figure 1a is used as a running example throughout this paper. In this example, an order consists of an ID, an array of order items (the implementation of which is irrelevant for this example), the shipping costs, and a discount code. We assume that the first two fields are non-zero and non-null in most objects. However, both `shippingCosts` and `discountCode` are not; they are mostly zero or null (the default values for these fields) and only hold relevant values in a small number of objects.

Via field externalization, we can optimize the layout of the `Order` class by removing fields that hold default values in most cases. This results in the layout presented on the left-hand side of Figure 1b. However, as optimizations have to ensure that also corner cases are handled correctly, we must be able to handle `shippingCosts` and `discountCode` if they are ever set to a non-default value. Therefore, we create a new class, the so-called *companion type* `Order$Companion`, that stores the *externalized fields*, i.e., the fields that were removed from the original `Order` class. Additionally, we introduce a pointer in the original class – we call this the *companion reference field*. Initially, this pointer is null. If a non-default value is assigned to an externalized field, an instance of the companion type – the *companion object* –

is allocated to store the field value. This companion object is assigned to the companion reference field. Hence, writing a non-default value to an externalized field introduces some overhead. However, as allocating the companion object should only be necessary in a few cases, these costs are outweighed by the reduced overall footprint of the other objects.

Various researchers have developed approaches to integrate field externalization into compilers [4, 11, 23, 62]. Notably, most are based on just-in-time (JIT) compilers [4, 11, 23], compilers for embedded systems [11, 23, 62], or research compilers [4, 62]. These approaches have shown promising results in combating memory consumption in Java programs. However, we could not find any contemporary approach that enables field externalization in a production-grade compiler without compromising language or run-time features such as multithreading.

Therefore, we propose a novel approach for field externalization in the state-of-the-art ahead-of-time (AOT) compiler framework GraalVM Native Image [78, 79]. It works by first gathering profiling information for a target program in an offline profiling run. Then, we combine the profiling information with information from Native Image's points-to analysis [7, 24, 25, 26, 39, 40, 60, 61, 66, 68, 71, 80] to identify and subsequently externalize fields that most often hold their default value. Furthermore, we developed a synchronization mechanism for accesses to externalized fields that adheres to the Java Memory Model [43].

Our approach targets web and microservice applications hosted in the cloud. Providers of Function-as-a-Service infrastructures (AWS Lambda [3], Google Cloud Functions [21], etc.) typically not only base their pricing on CPU usage but also on the amount of memory that is consumed by the application [84, 19, 18]. Hence, reducing memory usage can save costs.

With this work, we make the following contributions:

1. A profiling approach that utilizes both static analysis as well as field-level profiling to identify fields for optimization.
2. A novel AOT profile-guided field externalization approach that removes fields from objects ahead of time. Our approach is integrated into a state-of-the-art AOT compiler and supports multithreaded access to externalized fields.
3. Novel techniques to reduce the overhead and increase the applicability of field externalization by reusing existing fields as *masked companion references*, supporting *class hierarchies*, and generating *companion factory methods*.
4. An evaluation of our approach on standard and microservice benchmarks measuring memory footprint, run-time performance, and image size. The evaluation demonstrates that our approach can reduce the maximum RSS and the allocated bytes in individual benchmarks, showcasing its viability to reduce the footprint of cloud applications.

The paper is structured as follows: Section 2 describes GraalVM and GraalVM Native Image. In Section 3, we summarize our profiling methodology and its implementation. We explain our field externalization approach, notable improvements, and the integration into Native Image in Section 4. Section 5 presents the results of applying our approach to a large set of benchmarks. We explain our evaluation methodology and discuss the results in detail. In Section 6, we list the limitations of our approach. In Section 7, we compare our techniques to related work.

2 Background

We integrated our approach into GraalVM Native Image [49, 78, 79] based on GraalVM 23.1 with Java version 21: We use its profile-guided optimization feature [5, 9, 53, 64, 78] to first collect information about field values in a profiling run on an instrumented executable and subsequently externalize rarely written fields based on this profiling information during the compilation of the final executable.

2.1 GraalVM

GraalVM is a high-performance, polyglot virtual machine [49, 82] designed to run programs written in a wide range of languages. It can handle traditional Java-bytecode languages, such as Java, Kotlin, and Scala, as well as languages like JavaScript [50], Ruby [52], Python [48], and even C/C++[57]. The GraalVM compiler is a state-of-the-art JIT compiler within GraalVM [16, 38, 67]. It uses a graph-based intermediate representation (the Graal IR) [16, 17] and performs optimizations such as inlining, constant folding, loop unrolling, and escape analysis [37, 82]. When used as a JIT compiler in a regular Java Virtual Machine (JVM), GraalVM collects run-time information to guide its optimizations. For instance, it identifies hot methods, frequently taken branches, and targets of virtual calls. By exploiting this data, the compiler can further optimize the application according to the observed workload. However, relying on run-time profiling data means that optimizations only take full effect once the application has been running long enough to gather representative insights. This can lead to slower startup times.

2.2 GraalVM Native Image

To provide fast startup times and reduced resource usage, GraalVM offers Native Image [78, 79], an AOT compiler that compiles a Java application ahead of time into a self-contained native binary (the so-called *image*). This binary bundles the application code, all necessary libraries, and a lightweight runtime called *SubstrateVM*, which provides essential services such as threading and garbage collection, into a single executable [46]. Once compiled, no standard JVM is needed at run time, and the startup performance can be improved by up to two orders of magnitude compared to the Java HotSpot VM [79], which can be critical for short-lived processes, serverless functions, or microservices. A key concept in GraalVM Native Image is the closed-world assumption [79]. Under this assumption, all classes, methods, and fields that may possibly be accessed at run time must be known at compile time. This contrasts with the traditional JVM, where classes can be dynamically loaded at run time. The closed-world assumption allows GraalVM Native Image to perform powerful whole-program static analyses.

2.2.1 Points-to Analysis

One important step performed by GraalVM Native Image during static analysis is the points-to analysis [7, 24, 25, 26, 39, 40, 60, 61, 66, 68, 71, 80]. This analysis determines which objects, fields, and methods can be reached from the program's entry point. The points-to analysis in GraalVM Native Image is context-insensitive, flow-insensitive for fields, but flow-sensitive for local variables (since the input language is in SSA form) [79]. It is type-based and uses saturation to prune the inter-procedural pointer assignment graph while the analysis is running. This makes the analysis as scalable as a rapid type analysis, while preserving most of the precision of the points-to analysis [80]. By understanding which objects point to which other objects (and thus which fields and methods are relevant), Native Image can identify what parts of the code are actually needed. Points-to analysis builds a global, static view of the application's data flow. The analysis can reveal, for example, that a certain type's fields are never written to or that certain methods are never invoked. Since Native Image has all code available at compile time, it utilizes this analysis to optimize the final binary.

2.2.2 Image Heap

In the context of GraalVM Native Image, the *image heap* refers to a specialized, pre-initialized memory region that is embedded into the native executable [79]. During the Native Image compilation process, GraalVM analyzes the application to determine which objects that are needed at run time can already be created at compile time and stored in the image heap. For example, `java.lang.Class` objects that represent the type descriptors of objects in Java are stored there. Furthermore, class initializers can often be already executed at compile time. Since many objects are already present in the image heap, the native executable doesn't need to perform extensive object allocation and initialization at startup. This leads to significantly reduced startup times compared to traditional JVM applications that rely on JIT compilation and need to allocate all objects at run time [79].

2.2.3 Profile-Guided Optimization

Unlike a JIT compiler, which relies on program behavior observed at run time, an AOT compiler has no direct knowledge of how code executes under real workloads. Without further input, it must rely solely on static heuristics to guide optimizations, which can limit the potential improvements. Profile-guided optimization (PGO) addresses this limitation [5, 9, 53, 64, 78]. PGO is a technique in which the AOT compiler is supplied with run-time execution data collected from a representative workload. This approach mirrors how a JIT compiler uses run-time profiling, but shifts the process to compile time via a two-stage compilation workflow:

1. **Instrumentation and Profiling Phase:**
   First, an instrumented version of the application is generated by Native Image. This instrumented binary contains additional logic to record information about the program as it runs. When executed with a suitable workload that reflects real usage scenarios, the instrumented binary collects detailed run-time data, including call frequencies, branch probabilities, and type occurrences. At the end of this run, the collected profiling information is stored in a file.
2. **Optimized Compilation Phase:**
   In the second stage, the profiling data is fed back into Native Image to produce a new, optimized binary. Equipped with the recorded execution patterns, the AOT compiler can apply more informed optimizations, such as refining method inlining decisions and optimizing frequently executed hot paths.

This two-phase compilation adds complexity and overhead to the build process. However, once the optimized binary is produced, it can be deployed and run without incurring any additional overhead.

PGO enables AOT compilers to tailor optimizations to specific workloads. When the workload employed during the instrumentation phase closely resembles the production environment, the resulting binary is finely tuned for that particular scenario. In essence, PGO provides workload-specific optimizations comparable to those offered by JIT compilers, but in a context where all code is precompiled to native form. This technique is also utilized in related work [10, 22, 35, 41, 73, 81, 83].

It is important to distinguish PGO from machine-learning-based optimization techniques [59], which typically utilize a larger and more diverse set of inputs to optimize a broader range of applications. The objective of machine learning is to train models that can reliably predict optimization opportunities in *new programs* based on extensive training datasets. In contrast to that, PGO aims to optimize a program for a *specific workload*.

Developing a generalized version of the program that performs efficiently across different workloads is an explicit non-goal of PGO. Thus, our evaluation is conducted accordingly. We employ the same workload for both profiling and measurement phases, although the profiling workload is smaller in size compared to that used for measurements.

3 Field Profiling

To enable field externalization, we collect two kinds of information: information that is gathered statically during the compilation of the instrumented program (e.g., information on objects in the image heap) as well as information that is gathered dynamically during the execution of the instrumented program.

The information that is computed at compile time is only available very late in the compilation process, e.g., after the compilation of all methods or when computing the layout of all types. Field externalization, however, has to be initiated early to adapt the corresponding types and field accesses. Therefore, we want to communicate such information from the first compilation (for the instrumented binary) to the subsequent, optimizing compilation. We do this by storing compile-time profiling information in the compiled binary itself. When executing the instrumented binary, we collect the run-time profiling information and merge it with the static profiling information stored in the binary. This combined profiling information is then stored in the profiling file and subsequently used for optimizations in the final compilation of the program.

3.1 Information Needed for Field Externalization

As it is expensive to write a non-default value to an externalized field, we need to make sure to only externalize fields where such writes happen rarely compared to the number of allocated objects of that type. Therefore, we need to know how many objects of a certain type are allocated. For each field, we also need to know in how many objects the respective field ever holds a non-default value. Furthermore, we need information about the size of a type, so that we can calculate how many bytes we need to remove from a type to achieve an actual size reduction (taking alignment into account). The points-to analysis (cf. Section 2.2.1) of GraalVM Native Image is able to detect fields that are unused; they will be removed automatically. We don't want to hinder that optimization and thus have to detect and prevent externalization of such fields. Finally, as we cannot safely externalize fields that are accessed in an unsafe context (via `sun.misc.Unsafe`) or in a VM-internal context, we also have to store information about incompatible accesses per field.

3.2 Metrics

We present our collected metrics in Table 1. The *level* indicates whether the metric is collected per type or per field. Details of the individual metrics are discussed below.

Allocations. To accurately track the number of allocations per type, we consider both compile-time information and run-time information. As explained in Section 2.2.2, Native Image already allocates objects at compile time and stores them in the *image heap*. Thus, we count those instances before they are written into the final binary. We track the objects allocated at run time during garbage collection, i.e., for each object allocation, we increment the counter for the respective type.

Table 1 Overview of all metrics we collect. The *level* describes the granularity at which the tracking is performed. The *time* indicates whether a metric is tracked at run time (RT) and/or at compile time (CT).

Metric	Level	Time	Description
allocations	Type	RT+CT	The number of allocations of a type.
size	Type	CT	The exact and unaligned size of the instances of a type. Used to calculate how many bytes need to be externalized to achieve a reduction of the instance size for that type.
non-default value count	Field	RT+CT	The number of objects of a type that hold a non-default value for a specific field at any point during the execution of the program.
access kind	Field	CT	Indicates whether the field is eligible, unused, or accessed via reflection, in an unsafe context, or in a VM-internal context.

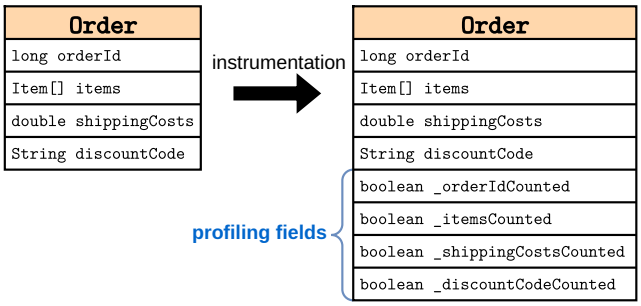

Figure 2 Instrumentation of the `Order` class from Figure 1 to track the *non-default value counts*. A profiling field is added for each original field.

Size. The size of a type is computed late in the compilation process, whereas field externalization requires this information early in the compilation process. Hence, when compiling the instrumented program, we store the types sizes in the profiling data.

Non-default value count. We track this metric at field level. For each field, the metric represents the number of objects that – at any point during the execution of the program – held a non-default value in this specific field. For example, if a non-default value is written ten times to the same field for a single object, the *non-default value count* is only increased by 1. This metric is important for the selection of externalized fields, as only fields that have a low non-default value count – compared to the number of objects allocated of that type – are good candidates for field externalization. We do not count the total number of writes to a field, as a single non-default-value write is enough to cancel out the achieved memory reduction for a single object due to the required companion object. Similar to the *allocations* metric, we also consider the objects in the image heap for this metric.

To identify first-time non-default-value writes for each field/object combination, we instrument all types in the profiling run. For each field, we generate an additional boolean field that indicates whether a non-default value has already been written for that field/object combination, as can be seen in Figure 2. To correctly track the *non-default value count*, we have to instrument all field writes. The instrumentation of field accesses is depicted in Figure 3. First, we check whether the value written to the field is a non-default value, i.e., in the example, we check whether `x` is not `null`. In that case, we verify that the field has not yet been written for this object. If so, we set the profiling field to `true` and increment the counter associated with the *non-default value count* metric for that field.

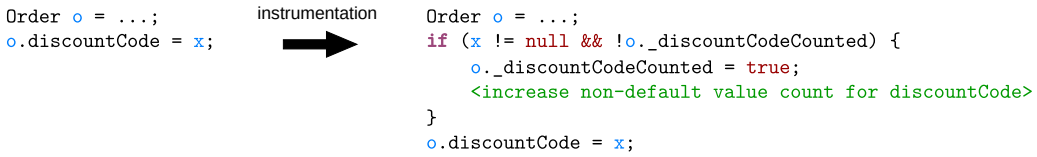

Figure 3 Instrumentation of a write to the `discountCode` field from the example in Figure 1.

Access kind. Native Image performs extensive static analysis, including points-to-analysis (cf. Section 2.2.1), and marks all unsafe, reflection, or JNI accesses that it can detect at build time. Users can provide configuration files to make additional components available for these kinds of accesses. Therefore, we are able to identify where and how fields are accessed. However, again, this information is only fully available late in the compilation process, and thus, similar to the size metric, we store that information in the profiling data when compiling the instrumented program. The access kind denotes one of three cases: *Unused*, when the field is unused and thus deleted by Native Image, *incompatible*, when the field is accessed using reflection, in an unsafe context or in a VM-internal context, or *eligible*, for fields that do not fall into any of the other categories. Only *eligible* fields are considered relevant for field externalization.

4 Field Externalization

The goal of field externalization is to reduce the memory footprint of an application by reducing the size of objects. To do so, we use heuristics based on the profiling information described before to identify fields where the default value dominates within types and to determine whether removing them from a type is beneficial. If we remove fields, we have to adapt their accesses within the compiled code: In case we ever write a non-default value, a companion object has to be allocated that consequently stores this field value. Subsequent accesses to externalized fields of the object then have to access this companion object. To actually benefit from field externalization, we need to minimize the number of required companion objects by tuning the heuristics accordingly.

4.1 Externalization Heuristic

Early in the compilation of a program, we load the profiling information generated during the instrumented run. For every type, we query the profiling data for its fields and use the metrics described in Section 3.2 to determine whether externalization is beneficial. Notably, we disallow externalization of types for which we do not have profiling data or for which the profiling reports no allocations. First, we determine a set F of all externalizable fields of a type as follows:

1. We only externalize fields where the *access kind* shows *eligible* accesses, i.e., we don't support externalization of *unused* or *incompatible* fields.
2. We determine the fraction of *non-default values* in all allocations, i.e., the percentage of instances where the field at some point held a non-default value. We compare this with a configurable threshold and mark the field for externalization if its non-default value fraction does not exceed this threshold:

$$\frac{\text{non-default value count}}{\text{allocations}} \leq \text{externalization threshold}$$

Based on experiments, we use 5% as a default value for this threshold because it yielded the overall best results in our benchmark set.

While this approach yields all externalizable fields of a type, we still need to determine whether externalization of those fields actually shrinks the objects of this type. Consider the `Order` class from the initial example in Figure 1. Figure 4a depicts the initial memory layout of an object of this class: The object header typically takes up 8 bytes. *Compressed object pointers* [45, 79] reduce the size of reference fields to 4 bytes. As the figure shows, this results in an overall size of 32 bytes. Native Image aligns objects at 8-byte boundaries [79]; with a size of 32 bytes this requirement is already met. The requirement for externalization is to reduce the size to at least the next smaller alignment boundary (24 bytes). Otherwise, the reduction in the type size is canceled out by the alignment. In the example, this means that we have to reduce the overall size by 8 bytes. We have to take into account that our externalization approach injects a new reference field (4 bytes) into the type that points to a companion object if this is needed. Therefore, the required reduction in the example increases to 12 bytes.

Figure 4b shows the result of externalizing the `shippingCosts`, an 8-byte `double` field. Unfortunately, if we consider the 4 bytes of the injected `_ref` field, the object size is only reduced to 28 bytes and alignment brings this up again to 32 bytes. The situation is different when externalizing both `shippingCosts` and `discountCode`, as shown in Figure 4c: The overall reduction (including the injected field) is now 8 bytes, which reduces the object size to 24 bytes – again at an 8-byte-alignment boundary.

Profiling information gives us the size t_size of each type before alignment (cf. Section 3.2). Assuming the injected field size to be ref_size, and an alignment of 8 bytes, the minimal required amount of bytes that must be externalized is calculated as follows:

$$\text{min. externalization bytes} = ref_size + \begin{cases} 8, & \text{if } t_size \bmod 8 = 0 \\ t_size \bmod 8, & \text{otherwise} \end{cases}$$

Then, we use the following formula to determine whether externalization is beneficial for the set of theoretically externalizable fields F that we derived in the prior step:

$$\sum_{f \in F} sizeof(f) \geq \text{min. externalization bytes}$$

If the result is to externalize the fields F, we subsequently delete them from the type. For each type with externalized fields, we create a corresponding *companion type*, a synthetic class that only contains the externalized fields of the class. Subsequently, we inject the `_ref` field – also called *companion reference field* – that may reference a companion object if needed into the type with externalized fields.

4.2 Rewiring Accesses to Externalized Fields

Externalizing fields into companion classes is only the first step in the externalization process. Next, we have to adapt all accesses to externalized fields, as shown in Figure 5. Values of externalized fields are now stored in the corresponding fields of the companion object. This object, however, should only be allocated if we write a non-default (non-zero/non-null) value to an externalized field. Therefore, regardless of the access kind, we have to make a case distinction on whether a companion object exists. For each object, we store this information in an additional header bit, which we call the *companion allocated (CA)* bit. If the bit is unset, no companion object exists and the fields never held anything other than the default value. This is the ideal case and our heuristics mentioned in Section 4.1 are tuned to ensure that this is the most frequent case. Hence, we have to adapt the field accesses in such a

object structure	size (bytes)
object header	8
long orderId	8
Item[] items	4
double shippingCosts	8
String discountCode	4
before alignment	**32**
after alignment	**32**
req. externalization	**12**

(a) Layout of an `Order` object from Figure 1 assuming an 8 byte object header, *compressed object pointers* [45, 79], and 8 byte alignment [79].

object structure	size (bytes)
object header	8
long orderId	8
Item[] items	4
double shippingCosts	0
String discountCode	4
Order$Companion _ref	4
before alignment	**28**
after alignment	**32**
size reduction	**0**

(b) Layout of an `Order` object where `discountCode` has been externalized but overall object size remains the same due to the required addition of a `_ref` field.

object structure	size (bytes)
object header	8
long orderId	8
Item[] items	4
double shippingCosts	0
String discountCode	0
Order$Companion _ref	4
before alignment	**24**
after alignment	**24**
size reduction	**8**

(c) Layout of an `Order` object where `discountCode` and `shippingCosts` have been externalized, resulting in a reduction of the object size by 8 bytes.

Figure 4 Memory layout of the `Order` class from Figure 1 before and after externalization.

way that this case is still efficient. If the bit is set, it indicates that an object already has a companion object. This should be the outlier case which we want to avoid as much as possible, as the companion object consumes additional memory.

Read Accesses. Figure 5a shows a read access to the `discountCode` field of the `Order` class. Figure 5c depicts the adaption of the read access when the field is externalized. At every access to an externalized field, we have to introduce a header bit check (CA bit) that tells us whether the object already has a companion object. If the bit is unset, the read is trivial as this tells us that the field still holds its default value. This is the fast path and should be the default case. Thus, we can simply yield the default value as a result of the read access. If the bit is set, the companion object must exist and we have to load it from the `_ref` field to get the actual field value.

Write Accesses. For write accesses, as shown in Figure 5b, we need to do more work, as each write may require the allocation of a companion object. Figure 5d depicts the adaption of write accesses to an externalized field of the `Order` class. Again, the CA bit tells us whether the object already references a companion object. If a companion object exists, we write the new value to the corresponding companion object field. If the bit has not been set, we have to check the value that is written. If we again want to write the default value (null or zero) to this field and the companion object does not exist yet, we can simply skip the write as the field is guaranteed to still hold the default value. This is the optimal case and should be the most frequent path. However, if we write a non-default value, we have to allocate a new companion object and write the value to the field in the companion object. Additionally, we have to store the companion object in the original object and set the CA bit to communicate this change to future accesses. This is the slow path. After the companion object has been allocated, all the benefits that we achieved for this particular object by reducing its size are voided. Thus, our heuristics should minimize the frequency of this case.

```
Order o = ...;
var x = o.discountCode;
```

(a) Read access to `discountCode` before field externalization.

```
Order o = ...;
o.discountCode = y;
```

(b) Write access to `discountCode` before field externalization.

```
Order o = ...;
var x;
// check whether companion exists
if (<ca_bit_set>(o))
  x = o._ref.discountCode;
else
  x = null; // use default value
```

(c) Read access to `discountCode` after field externalization. Since the field no longer exists within the original type, we either yield the default value or have to get the field value from the companion object depending on the result of the CA bit check.

```
Order o = ...;
if (<ca_bit_set>(o)) { // check whether companion exists
  o._ref.discountCode = y;
} else if (y != null) { // default value check
  var _cmp = new Order$Companion(); // allocate companion
  _cmp.discountCode = y; // write companion field
  o._ref = _cmp; // store companion in original object
  <set_ca_bit>(o); // mark existence of a companion
} // no write if we write the default value
```

(d) Write access to `discountCode` after field externalization. Depending on whether the CA bit is set, we may have to allocate a companion object if the value to write is not the default value.

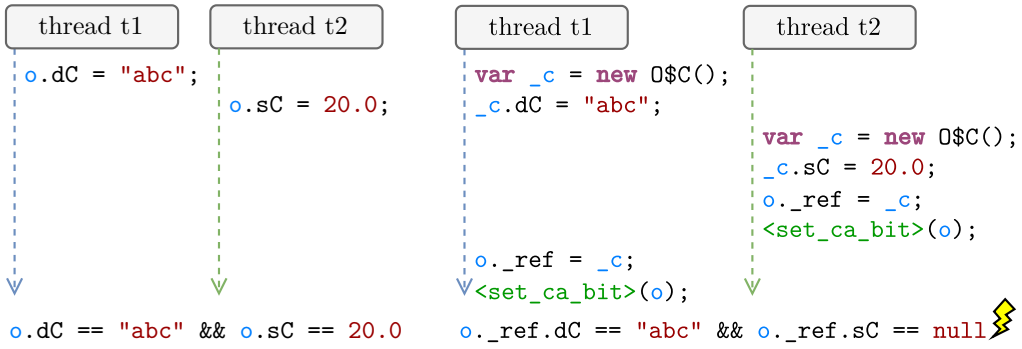
Figure 5 Accesses to fields of the `Order` class before and after field externalization.

4.2.1 Adhering to the Java Memory Model

The adaptations necessary to handle accesses to externalized fields are trivial in principle. However, it gets more complicated when we consider their effects in the context of the Java Memory Model, which defines the language semantics in multithreaded environments [43]. Particularly, the writing process is affected, as a write to an externalized field may now consist of multiple instructions, which may interfere with each other if executed on the same object in different threads. Figure 6a shows the behavior of two write accesses to fields of the same object in multiple threads without externalization. After the writes have been completed, both values are eventually [2] visible in the object. Figure 6b shows what could happen when writing to externalized fields: Here, we assume that the target object does not have a companion object yet – the CA bit is unset – and both threads want to write non-default values to two independent fields, forcing allocation of a companion object. *Thread t1* first allocates a companion object and stores a value to the first field. Then, *thread t2* resumes, also allocates a companion object and stores a value to the second field. In the example, *t2* immediately stores the companion object in the original object and sets the CA bit. When *t1* resumes, it also stores its companion object in the original object and thus overwrites the `_ref` field. This results in a *lost update* as the value written in thread `t2` is lost. In fact, the order of the writes does not even matter: the allocation of two different companion objects for the same original object is a problem in terms of the memory model. Therefore, we need to introduce a synchronization mechanism for externalized field writes.

As read accesses can simply rely on the CA bit to determine whether a companion object exists, they require no modification. If another thread writes a non-default value to the same field at the same time and thus allocates a companion object, this would result in a race condition in the case of a non-synchronized access even without field externalization. With field externalization, a race condition may occur at the header bit access. However, results of this race condition are always within the set of possible results of the original race condition.

[2] Omitting the fact that non-volatile writes within threads may not be visible to other threads immediately [43] – the overall problem still remains.



(a) Write access to `Order` fields from multiple threads before field externalization.

(b) Write accesses to `Order` fields from multiple threads after field externalization if the companion object was not created before. As two threads may simultaneously allocate companion objects and store them in the original object, the result is a lost update as the companion object from thread `t2` is overwritten by the one from thread `t1`.

Figure 6 Write access in multiple threads to fields of the `Order` class before and after field externalization. For brevity, we abbreviate the fields `discountCode` and `shippingCosts` with `dC` and `sC`, and the companion class `Order$Companion` with `O$C`.

Figure 7 describes the synchronization process we introduce to correctly mimic field write semantics in our `Order` example. The dashed green path denotes the fast path and thus the most frequent one. The initial steps remain the same: We check whether a companion object exists (via the CA bit). If so, we write the value into the companion object. Otherwise, we check whether the write concerns the default value. If that is the case, the write can be omitted. The process differs when we write a non-default value and thus require a companion object. First, we allocate the companion object (**A**) and assign the field value (**B**). Note that this can be performed by multiple threads at the same time per object. Next, however, we use an additional header bit – the *companion-in-creation (CC)* bit – that indicates whether some other thread currently allocates the companion. We use a *compare-and-set (CAS)* instruction [29] (**C**) that atomically tries to set the CC bit if and only if it has not been set. A CAS is a three-operand instruction that takes an *expected value* (the object header where the CC bit is zero), a *destination operand* (the address of the object header) and a *source operand* (the object header with the CC bit set). Then, it performs the following steps atomically: First, it compares the *expected value* with the value in the *destination operand*. If the values match (the object header does not have the CC bit set), it writes the value in the *source operand* to the *destination operand* (sets the CC bit) and returns the *expected value*. If the values are different, it returns the value in the *destination operand* (the actual object header). Subsequently, we can use the return value of the instruction to determine whether the current thread could set the CC bit. Therefore, the CAS can only ever succeed for a single thread per object. We call this thread the *CC thread*. The CC thread subsequently enters a *protected region*, where it can safely assign the companion object it previously created (**D**) and also set the CA bit (**E**) to signal that a companion object is available now. Any other thread that tried to CAS the CC bit at the same time has to wait until the CC thread has completed the assignment of the companion. We introduce a *spin lock* [30, 65] (**F**) that loops until the CA bit is set. Note that this branch is entered very infrequently, namely only if two threads try to allocate a companion object for the same object at the same time. Once the thread leaves the spin lock, it can safely assume that a companion object exists and can thus access it and perform its field write (**G**).

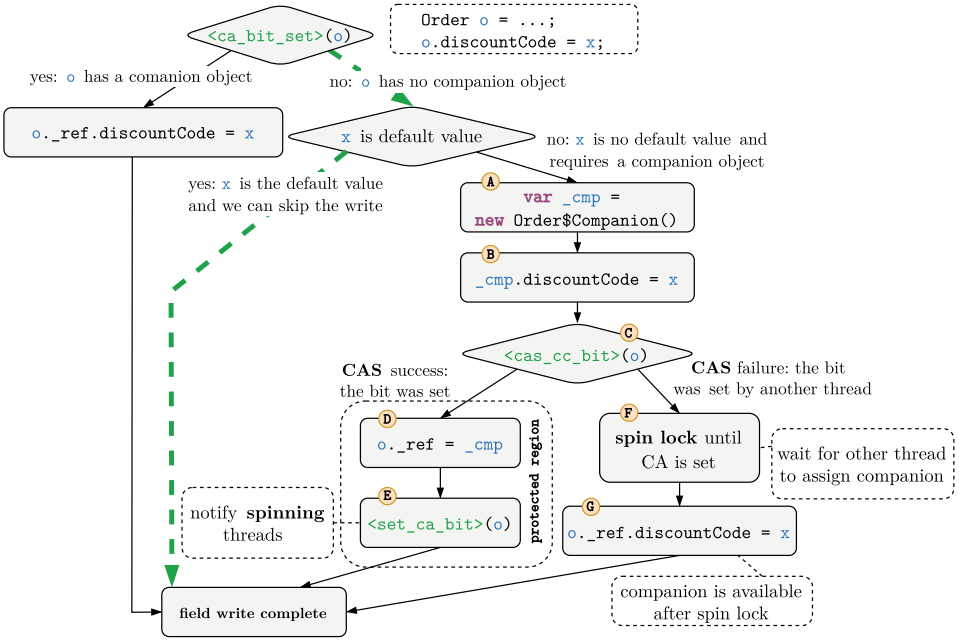


Figure 7 Write accesses to externalized fields including a synchronization mechanism that uses 2 header bits (*CA*, *CC*) to ensure that for a specific object only one thread can assign the companion object. The dashed (green) path is the (most frequent) fast path.

4.3 Compile-Time Externalization

As explained in Section 2.2.2, objects that can be created at compile time, but are needed at run time, are already allocated during compilation and are stored in the image heap. Our externalization process, however, only affects the objects that are created at run time – objects allocated at compile time still adhere to their original layout. To ensure that the objects in the image heap are compatible with the types after externalization, we introduce special handling for all compile-time-allocated objects that have externalized fields. When writing those objects into the image heap, we check whether they contain a non-default value for an externalized field. If so, we allocate a companion object and copy the values of the externalized fields to the companion object. Finally, we link the companion object with the original object (now reduced to its non-externalized fields and the companion reference) and also store the companion object in the image heap. Thus, the object representation in the image heap is compatible with the types after externalization.

4.4 Field Externalization and Class Inheritance

Consider the case when a class `A` has some fields that can be externalized. Suppose that a subclass `B` of `A` also has externalizable fields, making it eligible for externalization according to our heuristic. With our current approach, B would require two companion reference fields (for `A$Companion` and for `B$Companion`), and thus 4 header bits (two bits per reference field). Hence, field externalization does not scale efficiently with class hierarchies. Furthermore, the number of object header bits that can be used for field externalization is limited, hence, preventing us from using more than 2 object header bits. However, as externalizing fields of classes that already have externalized superclasses is beneficial (as it can further shrink the object size), we want to support it as well.

4.4.1 Companion Inheritance

We present the solution to externalizing fields of class hierarchies based on the example in Figure 8. The example shows three classes `A`, `B`, and `C`, where `A` is the superclass of `B` and `B` is the superclass of `C`. In the example, two fields of class `C` can be externalized. However, the superclass `A` also has externalized fields. To solve this problem in an efficient manner, we propose that the companion type that is created for `C` (`C$Companion`) is defined as a subclass of the companion type of the (closest) externalized superclass (here `A$Companion`). Thereby, the problems mentioned above are solved, as at most one companion object is needed for an object. The `C$Companion` instance now contains both: the fields externalized in `C`, as well as the fields externalized in `A`. Therefore, only a single companion reference field and 2 object header bits are needed.

However, this approach introduces an additional challenge: We can no longer determine at compile time which companion object should be allocated when writing to an externalized field. For example, if a method has a parameter of type `A` and subsequently writes a non-default value to the `a1` field, we would either have to allocate an `A$Companion` object or a `C$Companion` object depending on the actual object. Thus, the allocated companion object now depends on the *dynamic type* of an object. We solve this by introducing a run-time type check on the object, but this introduces overhead in terms of performance and code size.

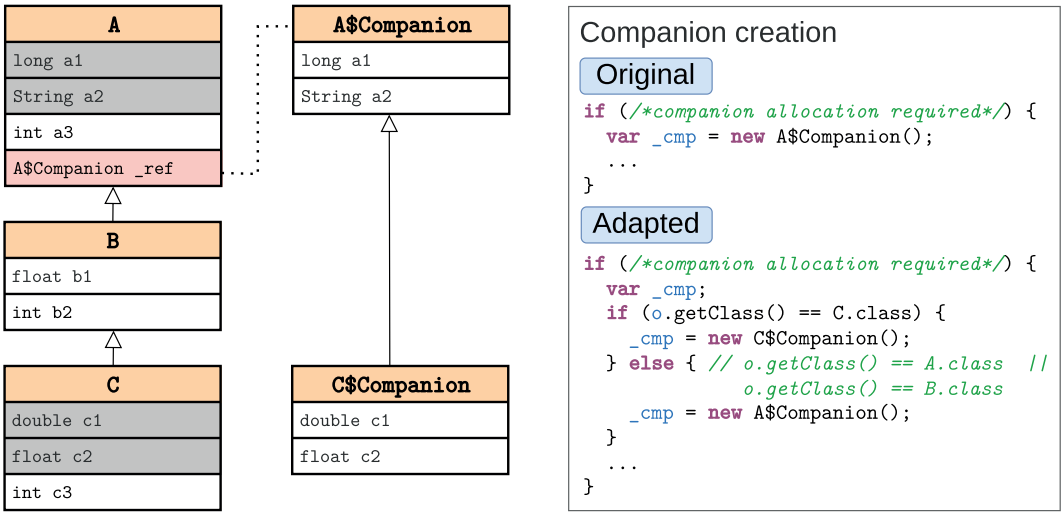

Figure 8 Companion hierarchy for a class hierarchy with multiple types with externalized fields. The necessary adaptations to the companion creation process are illustrated on the right-hand side.

4.4.2 Companion Factory Methods

The companion creation code gets more complicated the more classes of a class hierarchy are externalized. As we need to adapt every write to an externalized field, directly inserting all type checks and allocations of the right companion object within the class hierarchy leads to code bloat. Therefore, we utilize what we call *companion factory methods*. A *companion factory method* is a generated method that receives a type with externalized fields as a parameter and returns a new instance of the matching companion type. Hence, for each root of an externalization hierarchy one companion factory method is generated. That method contains the if-else-if ladder for all externalized subtypes of the externalized root type and returns a companion object of the respective type.

```
...
if (/*companion allocation required*/) {
  var _cmp = createCompanionA(o.getClass());
  ...
}
...
```

```
static A$Companion createCompanionA(Class c) {
  if (c == C.class){
    return new C$Companion();
  } else { // c == A.class || c == B.class
    return new A$Companion();
  }
}
```

Figure 9 Creation of a companion object using a *companion factory method*.

Figure 9 shows an example of a companion factory method and its usage. The *companion factory method* `createCompanionA` is used to create the correct companion object based on the class passed as a parameter. During compilation, we insert a call to this method when writing a non-default value to an externalized field, as shown on the left-hand side of Figure 9. Through these factory methods we can reduce the code bloat. We prevent inlining of these methods to not mitigate their effect but also inform the compiler of their effects to not prevent other optimizations such as partial escape analysis [67].

4.5 Masked Companion References

Our field externalization approach requires adding a reference to a companion object to enable us to handle the cases when non-default values are written to externalized fields. Therefore, externalization also needs to amortize the cost of that additional field, as explained in Section 4.1. Consequently, this limits the applicability of our approach and thus our optimization potential.

To tackle that issue we propose an optimization of field externalization, which we call *masked companion references*. A *masked companion reference* is a non-externalized *reference* field of a type that we reuse as the companion reference field. As long as no companion object is needed, this field is used just like a normal field and stores its normal value. In Figure 10, we again show the `Order` example from the previous sections with the two externalized fields `shippingCosts` and `discountCode`. The remaining `items` field is used as the *masked companion reference*, indicated by the dashed line and light red background. As shown in the first part of the image, the `items` field holds a reference to an ordinary item array, because no companion object is required yet. When a non-default value is written to an externalized field, a companion object is allocated (as explained in Section 4.2) and the reference to the companion object is stored in the `items` field. However, before writing the companion reference, the old value stored in the `items` field needs to be evacuated in order to preserve its value. Therefore, when using *masked companion references*, the companion object contains not only the externalized fields but also the *masked companion reference* field. In the example of Figure 10, when a non-default value is written to the externalized field `shippingCosts` (shown at the right-hand side of the figure), a companion object is allocated and the value that should be stored in `shippingCosts` is stored there. Then, the value stored in `o.items` is evacuated and stored in the companion, and finally, the reference to the companion object is stored in the `items` field (the masked companion reference field) of the `Order` object. By applying this optimization, we do not need to introduce an additional companion reference field that increases the size of all `Order` objects just to hold the reference to an – ideally – rarely needed companion object. If a type does not contain a suitable reference field, we can still fall back to the original approach.

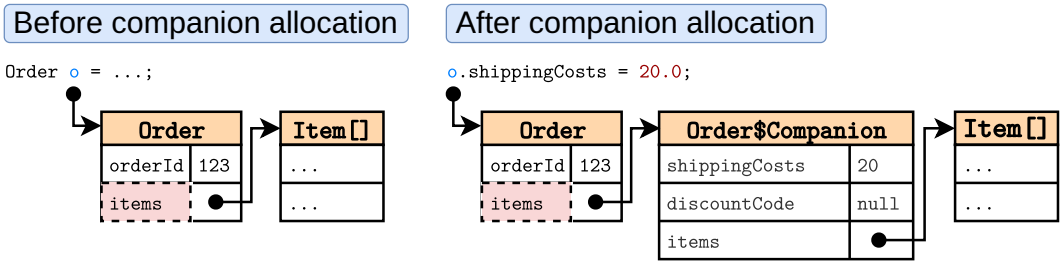

Figure 10 As long as no companion object is need for an object with externalized fields, the *masked companion reference* field (`items`) holds its normal value. When a companion object is needed, the value of the `items` field is evacuated into the companion object and the reference to the companion object is stored in the `items` field.

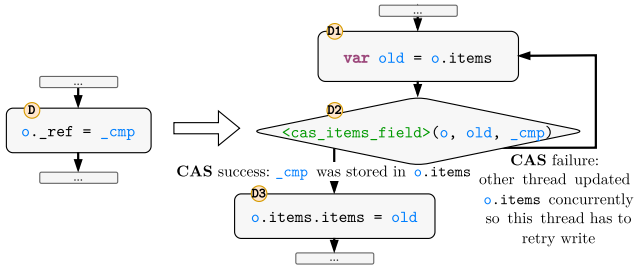

Figure 11 Changes necessary to the process shown in Figure 7 at step **D** for externalized field writes with masked companion references.

4.5.1 Field Access Adaptations for Masked Companion Reference Fields

To accommodate masked companion reference fields we also have to slightly change the field access pattern introduced in Section 4.2.1. First, both field writes and reads now have to access the corresponding masked companion reference to load a companion object if required – the check for its existence is still done via the CA bit. Figure 11 shows the change necessary for writing to an externalized field, as explained in Figure 7. We now no longer have a dedicated companion reference field that points to a companion object. Thus we have to consider both cases: another thread writing a new `Item[]` instance to `Order.items`, and another thread writing a non-default value to an externalized field and thus assigning a newly allocated companion object to the masked companion reference field. Therefore, we have to ensure that both cases are properly synchronized. As step **D** of Figure 7 is in the protected region, we can at least be sure that no other thread concurrently tries to write a companion object. However, regular writes to the masked companion reference field are not guarded by the CC bit. Therefore, we have to make sure to check for concurrent writes when storing the newly allocated companion object. We first load the original value from the companion reference field `items` (**D1**). Then, we use a CAS instruction (**D2**) to atomically check, whether the `old` value in `o.items` has changed. If not, the CAS instruction stores the companion object (`_cmp`) in the `items` field. The result of the CAS tells us, whether the companion object was stored. If the value did change between reading the field and the CAS (and the companion object was not stored), we repeat steps **D1** and **D2** until they succeed. While this is an expensive process, we expect it to be very infrequent. After the CAS, we still have to store the old value of the masked companion reference (`old`) in the corresponding companion object field (`o.items.items` in **D3**).

Writing to a Masked Companion Reference Field

Since the masked companion reference field is a regular field within the original object, we have to adapt accesses to it. When writing to the field, we have to check whether it already references a companion object. The necessary steps are outlined in Figure 12. Once again, the – ideally most frequent – fast path is highlighted with dashed (green) lines. In step **A**, we load the value of the masked companion reference field `o.items`. The CA and the CC bits tell us whether the loaded value might already be a companion object (**B**). If one of the bits is set, we specifically check whether the CA bit is set (**C**). If not, we know that the CC bit is set and that another thread is currently assigning the companion object to this object. Hence, we *spin lock* until this process is complete (**D**). If the CA bit was set or after the spin lock, we know that a companion object must exist and thus assign the value to the corresponding `items` field *within* the companion object (**E**). Note that we cannot use the value read before from the masked companion reference field (`old`), as this value may not have been a companion object at that point. Therefore, we re-read the companion object and assign the actual value (`x`) to its field (**E**).

If step **B** showed that no bit was set, we try to directly store the value in the masked companion reference field (**F**). As this may again interfere with similar accesses in other threads, we use an atomic CAS instruction. This CAS compares the previous value in the masked companion reference field (`old`) with the value currently stored in the field. If this comparison succeeds, it stores the desired value `x` in the masked companion reference field. In this case, we are done with the field write. If the CAS did not succeed, we have to perform a similar procedure as in **B**, as some other thread has changed the value of the field. We cannot know whether the field still holds a *regular* value or a freshly allocated companion object and thus have to check the header bits again (**G**). If any bit was set, we make sure to wait until the CA bit is set (which ensures that the other thread successfully wrote the companion) and only then write the value to the companion object. If no bit was set, we know that the other thread writing the same field wrote another regular value (i.e., some other `Item[]` array) to the field. We consider this a race condition (*racy write*) and can thus skip updating the field.

Reading from a Masked Companion Reference Field

In contrast to read accesses to externalized fields, reading from a masked companion reference field also requires some synchronization, as another thread may concurrently assign a companion object to the same field. We discuss the necessary steps in this process based on Figure 13 – the dashed green path is the fast path. First, we load the current value of the masked companion reference field (`o.items`). Then, similar to the writing process, we check for either the CA or the CC bit, as either tells us that the previously loaded value might be a companion object. If any bit is set, we specifically check the CA bit (**C**) and then either first wait for it to be set or immediately access the corresponding field within the – now safely available – companion object (`o.items.items` in **D**). If no bit was set, we know that the loaded value from step **A** cannot be a companion object and thus, we simply use this value as a result of the field read (**E**).

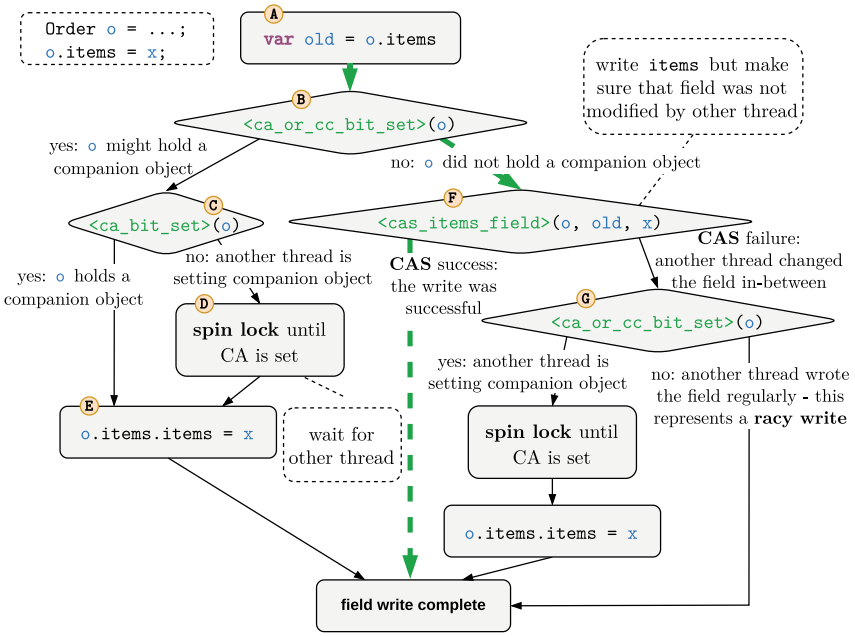

Figure 12 Write access adaptations to masked companion reference fields that take into account multithreaded accesses. As a masked companion reference field can be used both for regular writes and for storing the companion object, synchronization is more expensive than for regular externalized field writes.

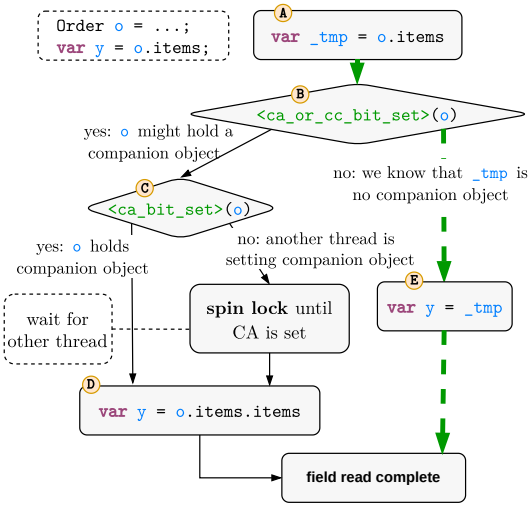

Figure 13 Read access adaptations to masked companion reference fields that take into account multithreaded accesses.

5 Evaluation

We conducted our evaluation on a comprehensive, mixed benchmark corpus. This corpus blends classical benchmark suites (*DaCapo 9.12-MR1-bach* [6], *Scala-DaCapo 0.1.0* [63], *Renaissance 0.9.0* [54]) with additional benchmark suites designed for Native Image performance assessment, all built atop leading Java microservice frameworks – namely Spring [75], Quarkus [56], and Micronaut [58]. These benchmarks encompass both single- and multi-threaded applications. Note that we excluded standard benchmarks that are not supported by the version of Native Image on which our approach is based. Furthermore, our experiments revealed an infrequent bug within GraalVM Native Image related to inlining that distorted our measurements for the *scala-dacapo factorie* benchmark. This bug was reported but has not been fixed yet. Thus, we exclude the benchmark from both analysis and evaluation. Each framework-based benchmark suite includes a concise "helloworld" scenario based on its respective launcher or "getting started" material, thus showcasing the fundamental functionalities of the framework. In addition, every suite contains a second, more complex benchmark with varying workload parameters (tiny, small, medium, etc.). Specifically, the Spring suite employs a tailored version of the Spring Boot PetClinic Sample Application [76]. Quarkus incorporates a microservice benchmark originating from the Apache Tika Quickstart [55]. Micronaut, in turn, provides a second benchmark known as *ShopCart*, a web shopping application. Contemporary works on Native Image also use these microservice benchmarks in their evaluation [7, 8, 34, 42, 80].

Benchmark Methodology

We compared the standard version of GraalVM Native Image to our modified version of Native Image, which automatically externalizes rarely used fields. Both configurations involved an initial profiling run for PGO, followed by the actual measurement run for each benchmark. In standard benchmarks, profiling runs a single iteration, while measurement runs multiple iterations with warm-up. Microservice benchmarks use varying workloads in measurement to assess latency, peak performance, and response time, but only peak-performance is used for profiling. We executed each configuration 8 times – each execution involved a new profiling run to get new profiling data. The experimental platform was an Intel I7-4790K @ 4.4 GHz with 20 G of main memory. Hyper-threading, frequency scaling, and network access were disabled to mitigate fluctuations. All benchmarks were performed using Java 21.

5.1 Benchmark Results

We present the results of the evaluation of our approach on standard benchmarks in Figure 14. Figure 15 contains the results on microservice benchmarks. All numbers – unless otherwise noted – represent the geometric mean (GM) of the corresponding metric across all conducted measurement runs. First, we compare the number of overall allocated bytes compared to the baseline (*relative allocated bytes*). It is important to note that the microservice benchmarks are *throughput* benchmarks, i.e., they are executed for a fixed duration and we measure how many *requests* they manage to process (as they all concern web frameworks). The number of requests furthermore represents the performance metric for these benchmarks (compared to the benchmark *time* metric in standard benchmarks). Hence, the allocated bytes in a benchmark execution also depend on the number of processed requests. Thus, we normalize the *relative allocated bytes* by the number of processed requests. This is represented by the *allocated bytes/request* metric (row 2 in Figure 15). In addition to the allocated bytes, we also compare the execution times/throughput as well as the maximum resident set size (RSS) of each benchmark.

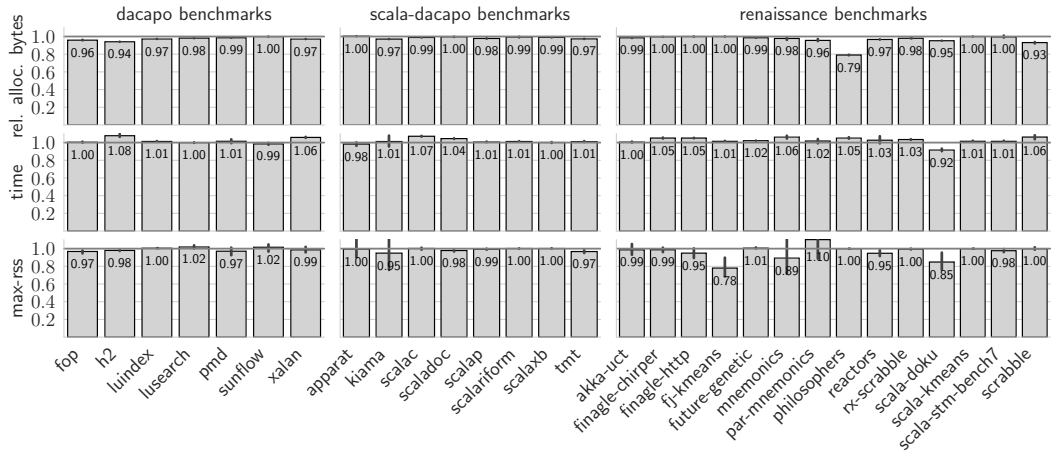

Figure 14 Evaluation of total memory allocation (*relative allocated bytes*), benchmark run time (*time*), and the max-RSS (*max-rss*) on standard benchmarks relative to results on Native Image without our approach.

Allocated Bytes

Because our focus lies on reducing allocated memory, we monitor the total allocated bytes for each benchmark by summing the sizes of newly allocated objects. This metric is also used in related work to evaluate the effectiveness of field externalization [4]. The total allocated bytes are our most stable metric (Figure 14). For this metric, almost all standard benchmarks show reductions, namely 2.72% for *dacapo* (2.74% median reduction), 1.30% for *scala-dacapo* (1.09% median reduction), and 3.60% for *renaissance* (1.41% median reduction). The *renaissance* benchmarks *philosophers* and *scrabble* benefit the most from our approach. In both benchmarks, objects with externalized fields appear frequently and contribute significantly to the overall allocated bytes. At the same time, they do not show many companion objects.

In the microservice benchmarks, the allocated bytes per request show a minor regression in the *tiny* workload of *quarkus tika* (Figure 15). This regression stems from a performance degradation (6.52%) that outweighs the improvement in allocated bytes.

The noticeable differences in the results in the *spring petclinic* benchmarks (Figure 15), where we see large improvements for *huge* and *large* (35.15% and 20.53%, respectively), but only minor improvements for the three smaller workloads, can be explained by the single type `java.util.concurrent.locks.AbstractQueuedSynchronizer$ConditionObject` that shows large fluctuations in its allocations. In the baseline, millions of objects of that type are allocated in each run for all workload sizes. With our approach, we still see millions of allocations for this type in the smaller workloads but only around 22000 allocations in *huge*, thus explaining the significant improvement here. In the *large* workload, the allocation count fluctuates between the baseline values and the 22000 objects, hence the large error.

RSS

Although we use the resident set size to estimate memory consumption, we observed high RSS fluctuations in many benchmarks, as shown in Figure 14 and Figure 15. This is because this metric is highly dependent on the garbage collection behavior in a benchmark. Thus, minor variations in the run-time behavior can lead to different RSS values even for the same

application. Our evaluation shows a max-RSS reduction of 2.55% on standard benchmarks (0.22% median reduction) and a reduction of 2.45% on microservice benchmarks (0.20% median reduction).

Most notable are the results in the *renaissance fj-kmeans* and *scala-doku* benchmarks (21.97% and 15.13% reductions, respectively) – despite a considerable error, their results are consistently below the baseline. Other *renaissance* benchmarks also show high errors: *mnemonics* seems marginally improved, while *par-mnemonics* shows a considerable regression.

For benchmarks from the *dacapo* and *scala-dacapo* suites, we see mixed results – most benchmarks (e.g., *fop*, *pmd*, *scaladoc*, *tmt*) show minor reductions of the max-RSS, while others (e.g., *lusearch*, *sunflow*, *apparat*) exhibit minor regressions.

In the microservice benchmarks, the results for the *spring petclinic* benchmarks are most promising, with a reduction of 6.08% (5.65% median reduction) and only a minor regression in the *helloworld* benchmark. While our approach also reduced the max-RSS in the *small* workload of the *quarkus tika* significantly, the other benchmarks of the suite show minor regressions. Similarly, the *quarkus* benchmarks mostly show regressions (0.90% GM, 1.19% median reduction).

Auxiliary Metrics

As mentioned in prior sections, we had to introduce additional checks for accesses to externalized fields and masked companion reference fields to ensure validity. Therefore, we expect a performance impact. Indeed, the standard benchmarks show a slight regression in terms of performance (2.14% GM and 1.69% median, Figure 14). For most benchmarks, this performance impact correlates with their improvement in terms of allocated bytes. The most notable exceptions are *scala-dacapo scaladoc*, *renaissance finagle-chirper*, and *renaissance finagle-http*. In all three benchmarks, we actually see many externalized objects. Despite that we also see that our approach increases the allocation counts for some of the most used types or introduces allocations of types that we do not see in the baseline runs. These factors may points towards compilation issues: As we insert additional code at field accesses, we may exceed budgets for certain compiler optimizations such as inlining or loop optimizations. Similarly, we might also prevent escape analysis and scalar replacement of certain allocations. As many of these optimizations also are based on heuristics, these individual regressions might by solved by retuning these heuristics for our approach.

Interestingly, the *renaissance scala-doku* benchmark shows an improvement in terms of run-time performance combined with improvements in other metrics as well. The performance of the microservice benchmarks is also impacted; the number of processed requests is decreased by 6.09% (GM, 5.60% median, Figure 15).

In addition to the charts presented above, we also compare the size of the generated image (the binary size). As we introduce additional code (cf. field access modifications in Section 4.2), new types (companion types), and new methods (cf. companion factory methods in Section 4.4.2) into the compiled binary, we expect a slight increase in the image size. Our evaluation shows that the image size increases by 2.16% (GM, 2.13% median) for standard benchmarks and by 3.36% (GM, 3.21% median) for microservice benchmarks.

Externalization Analysis

To evaluate our externalization approach, including our heuristic, we also evaluated how many objects are affected by field externalization and how many companion objects are created. Table 2 presents our findings for each benchmark. The *externalization ratio* specifies

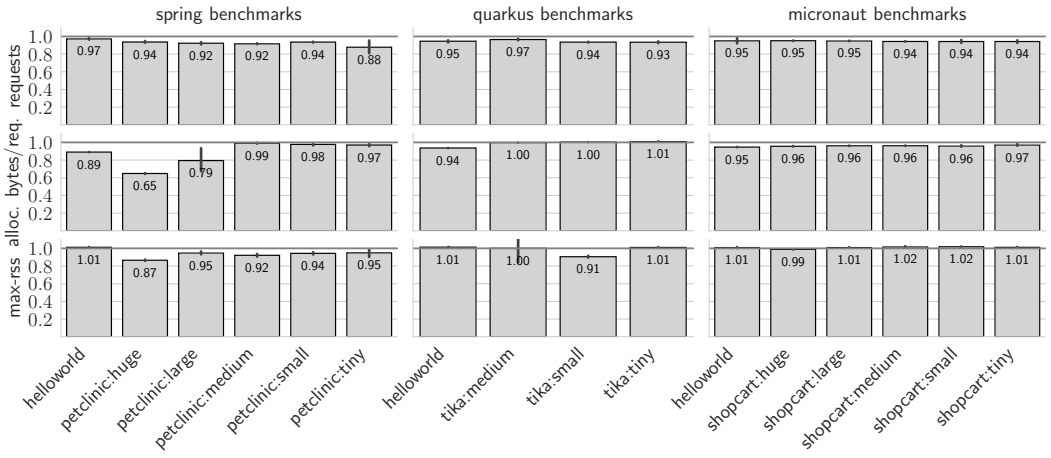

Figure 15 Evaluation of benchmark throughput (*requests*), memory allocation normalized by the performed requests (*allocated bytes/request*), and the max-RSS (*max-rss*) on microservice benchmarks relative to results on Native Image without our approach.

the ratio of objects in the benchmark that had externalized fields, whereas the *companion object ratio* represents the ratio of objects with externalized fields that required a companion object. The ratio of externalized objects varies greatly across benchmarks. For example, there are nearly no externalized objects in *scala-dacapo apparat*, whereas in *renaissance scrabble* 33.4% of the allocated objects have externalized fields. Overall, there is a tendency that benchmarks with a higher externalization ratio profit more in terms of reduction of total allocated bytes from field externalization, as shown by our memory measurements presented above. However, there are outliers as well: For example, the *dacapo xalan* benchmark is the benchmark with the second highest *externalization ratio*, but the allocated bytes are only reduced by 3% and the max-RSS is only reduced by 1%. The reason for the low impact in this benchmark is that the objects with externalized fields only make up a minor part of the overall memory consumption. Thus, big parts of the allocated memory are unaffected by field externalization. Furthermore, the per-object memory savings are quite low in this benchmark, i.e., only few fields are externalized for the types with the most allocations.

The *companion object ratio* should be quite low – in general below 5%, as that is the threshold of our heuristic(cf. Section 4.1). However, as will be discussed in Section 6 there could still be cases with higher companion object ratio even if our profiling information is accurate. In our results, *renaissance rx-scrabble* has the highest *companion object ratio* with 6.5%. We found that `java.util.stream.SliceOps$1`, which is a subclass of the externalized class `java.util.stream.AbstractPipeline` is responsible for creating more than 99% of the companion objects allocated in this benchmark. More specifically, all `java.util.stream.SliceOps$1` instances wrote non-default values to externalized fields and thus required the creation of companion objects. In theory, our heuristic should prevent such cases by not performing externalization when the *non-default value count* is too high. However, our heuristic can only consider the data gathered during profiling, and in this case the ratio of `java.util.stream.SliceOps$1` objects was lower compared to the other subclasses of `java.util.stream.AbstractPipeline` (which did not trigger as frequent companion object allocations) in the profiling run than in the actual benchmark run. One potential reason for this inaccurate profiling information is the reduced workload in the profiling run. We made a similar observation in the *petclinic* benchmarks. Here, the culprit

Table 2 Evaluation of the ratio of objects with externalized fields (externalization ratio, **ER**) compared to the number of total allocated objects. For the companion object ratio (**COR**), the amount of externalized objects that used a companion object was calculated.

is the `org.h2.mvstore.Page` class. We externalize almost all fields of this abstract class because the profiling data reports low usages. However, in the benchmark, we actually allocate a companion object for every `org.h2.mvstore.Page` object, suggesting that the objects of this class behave very differently in the real benchmark run compared to the profiling run. Despite these issues, the benchmark still shows good results across all workloads.

Discussion of Results

While a direct comparison is difficult due to the different benchmarks used, the results of our approach are generally more modest than those of related work [4, 11, 23]. However, this is somewhat expected as our field externalization approach is based on a modern compiler infrastructure without concessions regarding multithreading capability. The various optimizations that are already part of Native Image lower the potential of field externalization; completely unused fields, for example, are already removed by Native Image, so the potential of our approach is reduced.

The evaluation shows that our approach can achieve memory reductions in individual benchmarks while producing no significant regressions on others. Additionally, many results shows a trade-off between performance and memory utilization; some benchmarks achieved reductions in allocated bytes or max-RSS coupled with minor performance regressions. Programs targeted by our approach – cloud-native applications, microbenchmarks, etc. – typically run in environments where both factors, performance and memory usage, contribute to the overall service costs. As our approach can be enabled or disabled on a per-application basis, users can decide whether to use field externalization to, as an example, reduce the footprint of memory-bound applications.

6 Limitations

We prevent profiling and subsequent externalization of fields where we cannot safely adapt their accesses during compilation. We prevent externalization of fields of some internal types of Native Image, such as implementation classes of the garbage collector and the threading implementation. We also exclude types whose fields receive special treatment by the compiler, e.g., they are accessed unsafely via a known offset, or via `VarHandle` [44]. We further exclude volatile fields, as we currently cannot safely mimic their semantics after externalization.

Object serialization in Java makes heavy use of reflection [20]. Similar to how it handles reflection, JNI, and other dynamic features of Java, GraalVM Native Image requires user-supplied metadata to support serialization [47]. Consequently, this information could be used to also exclude fields affected by serialization from externalization.

Deallocation of Companion Objects

We designed our approach such that the allocation of a companion represents a one-way degradation. Hence, once a companion object for an object is allocated, there is no way to deallocate it, even if it is no longer needed at some later point (i.e., if all externalized fields in the companion object hold default values again). Only when the garbage collector collects the original object can the companion object also be collected. Chen et al. [11] solve this by identifying and collecting such "empty" companion objects during garbage collection. However, this requires tighter integration with the garbage collector and also increases the duration of collection cycles. As companion objects should only be created for few objects, empty companions should appear even less frequently. We think optimizing for such a niche case is not necessary.

Deficiencies of the Heuristics

Our heuristics are based on observations on individual fields. While this enables a very precise calculation in terms of the saved memory per externalized field, it also limits the decision on whether or not to externalize at all to thresholds on individual fields. As an example, if a class has 5 fields for which profiling – based on our threshold of 5% – suggests externalization, then our approach would externalize them all. However, the profiling could be misleading here: In the best scenario for our approach, the sets of objects that have non-default values for the respective externalized field are perfectly overlapping. Then only a maximum of 5% of the objects would require a companion object. However, if these sets are completely disjoint, up to 25% of the objects could require a companion object. Identifying such cases via profiling would require profiling the composition of the field values *per object*. However, tracking all field combinations is infeasible due to the associated exponential complexity.

7 Related Work

There is considerable related work on field and general memory footprint optimization techniques. However, most such works are implemented either on research compilers and VMs or in the context of a JIT compiler, which entails a different set of challenges but also opportunities compared to an AOT compiler. Nevertheless, they propose interesting and unique approaches that are in parts comparable to our work or propose other footprint optimization techniques using profiling information.

Chen et al. [11] implemented field externalization in the Kaffe VM [77], a Java Virtual Machine for embedded programs. They profile field usages and classify the fields into three levels based on their profiled value compositions: fields without a dominant value (level 0), fields with a dominant value other than the default value (level 1), and fields where the default value dominates (level 2). At run time, this information is picked up to, on the one hand, strip level 2 fields from objects in a similar manner to our approach and, on the other hand, *share* level 1 fields between objects. Similar to our approach, they use header bits to identify *compressed* (companion object not yet allocated) and *uncompressed/shared* objects (with allocated companion object/shared fields).

While they do not discuss their approach in the context of multithreading in detail, they seem to use some form of synchronization on accesses to externalized and shared fields. They note, however, that they can avoid the synchronization overhead in their target (embedded) JVMs, since they do not allow threads to preempt one another. Our approach is based on a standalone JVM, where multithreading and concurrency are much more widespread. Thus, as detailed in Section 4.2.1, much of the effort of our approach went into designing semantically valid access patterns to externalized fields that conform to the Java memory model. This also complicates integrating their field sharing approach into our work.

Their approach is based on a JIT compiler and ours is based on an AOT compiler. Thus we also have different challenges: They use the interpreter to mark instructions that access externalized fields, which subsequently allows the JIT compiler to optimize them. Our approach is based on a closed-world assumption, thus we have information about all types that occur in the application. However, since there is no interpreter that can perform some levels of profiling when processing objects with externalized fields, all access variants have to be compiled immediately. The results of our approach are hard to compare: They target embedded JVMs and, therefore, use a simulator and the SpecJVM98 benchmark suite [69] that has been retired since to gather benchmark results. We use a set of standard and microservice benchmarks to evaluate our approach.

Guo et al. [23] show an improvement to the aforementioned approach, again targeting an embedded JVM. They use the same field usage classification approach as Chen et al. [11] and generate meta-classes that describe the offsets of externalized and shared fields. As with Chen et al., the differences between our approach and theirs are that they target an embedded JVM, they scan the heap to gather profiling information, and the targeted benchmark set (SpecJVM98). Similarly, they do not mention their synchronization techniques to adhere to the Java memory model.

Ananian and Rinard [4] present a number of optimizations that also include field externalization to reduce the memory footprint of objects. This approach is implemented into a research Java AOT compiler (MIT FLEX compiler system). Their profiling approach is similar to ours; they introduce per-field counters in a separate profiling build and subsequently use a heuristic to select externalizable fields. They do not use companion objects that hold the externalized fields but use a hashtable that maps objects to their field values. The benefit

of using a hashtable is that one single non-default-value write does not produce that much overhead compared to the allocation of the companion object. However, the hashtable itself, as well as the keys, require extra storage and introduce further indirections. Native Image supports lazily appending the identity hash code field and the monitor field to objects [51]. Introducing a hashtable for types with externalized fields would also require the identity hash code field for all types, thus reducing the savings potential.

Sartor et al. [62] present and summarize a number of techniques related to object compression. These also include the original approaches by Chen et al. [11] and Ananian and Rinard [4]. They implemented their approach on the Jikes RVM [2] but performed the evaluation without the optimizing compiler. Hence, comparing the results of our approaches is difficult, as we measured the real effects of field externalization after AOT compilation.

There is also work about other object compression techniques: Venstermans et al. [74] reduce or completely remove object headers in the Jikes RVM [2] by allocating all objects of a specific type in a contiguous memory region and using a *side array* for the header bits and status information used by the garbage collector. Chen et al. [12] implemented a custom garbage collector for the Sun KVM [70] that compresses objects and arrays when space is needed. However, every access to a compressed object subsequently has to decompress it first. Therefore, they also implemented a partitioning mechanism for objects and arrays that also allows lazy allocation of the individual partitions when needed. We see these approaches as orthogonal to our work on field externalization. Their work could allow us to compress objects even further, even after field externalization.

8 Conclusion

In this work, we presented a novel field externalization approach for modern Java VMs that reduces the footprint of objects by removing fields that mostly hold the default value. We use profiling information to identify such fields and subsequently move them into separate *companion classes*, which are generated at compile time. If, at run time, an externalized field is accessed, the corresponding *companion object* is allocated that holds the externalized fields. The companion objects are referenced either via an additional injected field or a regular reference field that is reused as a *masked companion reference field*. Since our approach is integrated into a modern AOT compilation environment, GraalVM Native Image, we also introduce synchronization on accesses to externalized fields by using two header bits. An evaluation on a wide variety of benchmarks shows a modest but consistent reduction of the total allocated bytes across most benchmarks as well as a reduction in the max-RSS.

Overall, our work demonstrates the feasibility of field externalization in a state-of-the-art AOT compiler without sacrificing feature or language support but also highlights the challenges associated with it – particularly when adherence to the language semantics is of critical importance and when there is no run-time compilation or interpreter that enable fallbacks through recompilation.

Incremental Computing by Differential Execution

Abstract

Incremental computing offers the potential for significant performance gains by efficiently updating computations in response to changing data. However, traditional approaches are either problem-specific or use an inefficient all-or-nothing strategy of rerunning affected computations entirely. This paper presents differential semantics, a novel approach that directly embeds the propagation of changes into the semantics of a general-purpose programming language. Given a precise description of input changes, differential semantics rules define how these changes are tracked and propagated through core language constructs like assignments, conditionals, and loops to produce corresponding output changes. We formalize differential semantics and verify key properties, including correctness, using the Rocq proof assistant. We also develop and formally prove a set of optimizations, particularly for loop handling, that enable asymptotic performance improvements. An implementation of the semantics as a differential interpreter achieves order-of-magnitude speedups over recomputation on the Bellman-Ford shortest path algorithm.

1 Introduction

The field of incremental computing aims to develop programming abstractions for describing incremental computations: Computations that react to changes of their inputs efficiently. Most existing approaches follow the idea of selective recomputing [22]: They track which subcomputations are affected by an input change transitively and rerun these subcomputations when their up-to-date result is needed [5, 13]. However, this is an all-or-nothing approach: If a subcomputation is affected in any way, it has to be rerun. For example, consider a grammar checker that processes a large text document represented as a character string. Any change to the text will trigger significant recomputations. Better incremental computing must exploit *how* the input was changed, not just *if* it was changed.

In this paper, we propose incremental computing through differential execution. Here and in the remainder of this paper, we use *differential* to mean "dealing with differences". Hence, differential execution means to execute a program given a description of *how* its inputs are changed. We can exploit these change descriptions in two ways. First, we can use dedicated execution rules that react to input changes directly. For example, when the iteration count

of a loop is increased, it is sometimes sufficient to execute the extra loop iterations without repeating the previous ones. Second, we can integrate change-processing language primitives, which are often asymptotically faster than their non-incremental counterpart. For example, we can integrate differential operators from relational algebra, as known from live view maintenance in database systems. This paper focuses on the first aspect: How to provide differential execution rules that exploit how inputs have changed.

We study differential execution based on the big-step operational semantics of a small imperative language that features variable assignments, loops, and conditionals. We explain how to incrementalize these features by developing a differential big-step semantics that reacts to changes in the initial variable assignment. Specifically, while $\sigma \vdash s \Rightarrow \sigma'$ executes statement s in store σ, we define a differential semantics $\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$ that executes s based on the store change $\Delta\sigma$. We have implemented our formal model of differential execution in Rocq and use it to reason about the differential behavior of programs. First, we prove that the differential semantics does not get stuck and yields the same result as a recomputation from scratch:

$$\sigma \vdash s \Rightarrow \sigma' \ \wedge \ \sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma' \quad \rightarrow \quad \sigma \oplus \Delta\sigma \vdash s \Rightarrow \sigma' \oplus \Delta\sigma'.$$

And second, we can use the formal semantics to justify a number of important optimizations. For example, we prove that the differential semantics may skip statements that do not read changed variables from $\Delta\sigma$, and we develop provably correct optimizations for the differential execution of loops and conditionals. Compared to prior work on the incremental lambda calculus [9], which also processes change descriptions, we are the first to consider imperative language features and use a completely different methodology: differential semantics instead of type-driven program derivation targeting a standard semantics.

While this paper focuses on the formal development, we also want to demonstrate that the differential semantics enables efficient incremental computations. Unfortunately, a direct implementation of the differential semantics in an interpreter is inefficient because the semantics lacks caching of previously computed information. In particular, the differential semantics $\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$ expects the original store σ as input, which has to be computed for each statement unless we cache it. Therefore, we develop a differential interpreter based on the differential semantics, but incorporating caching and some verified optimizations. We demonstrate the efficiency of our differential interpreter empirically based on an imperative implementation of the Bellman-Ford shortest-path algorithm. Given changes to the initial edge weights, our differential interpreter computes updates in the shortest paths orders of magnitude faster than a recomputation could. The differential interpreter is implemented in Scala 3 and available open-source.[1]

In summary, this paper makes the following contributions:

- We define a static typing discipline for changes of a language's values, including typed patching and diffing (Section 3).
- We introduce the approach of differential execution based on the differential big-step semantics of an imperative language. We prove that the differential semantics preserves types, makes progress, and yields the correct result (Section 4).
- We propose, develop, and verify optimizations for differential execution that skip unaffected statements and improve the running time of loops and conditionals asymptotically (Section 5).

[1] `https://gitlab.rlp.net/plmz/artifacts/autoinc-interp-implementation-ecoop25`

- We implement an efficient differential interpreter based on our semantics (Section 6) and use it to incrementalize the Bellman-Ford algorithm, where it yields order-of-magnitude speedups (Section 7).

2 Differential Execution: Goals and Challenges

An incremental computation $\Delta f(\Delta x) = \Delta y$ reacts to input changes Δx and derives output changes Δy. How can we automatically provide Δf given the original function f?

In this work, we assume f is given through its source code s, such that $f(x) = y$ when $x \vdash s \Rightarrow y$. Our goal is to define a differential semantics $\sigma, x, \Delta x \vdash s \Rightarrow_\Delta \Delta y$ that can be used to process changes Δx of the program input. Note that only the input x can change; the source code s is not subject to change in this work. We can thus define $\Delta f(x, \Delta x) = \Delta y$ when $\sigma, x, \Delta x \vdash s \Rightarrow_\Delta \Delta y$, since we will see that the differential semantics is deterministic. The challenge of course is to define the differential semantics such that it is not only correct but also has efficient incremental performance when reacting to input changes. In this section, we motivate our approach through examples.

2.1 Differential execution for epidemiological models

In this paper, we explore differential execution for a statement-based imperative programming language called Imp. Imp features numeric and Boolean values that can be used in assignments, conditionals, and repeat loops, which iterate a loop body a fixed number of times

$$\begin{array}{lrcl} \text{(Statements)} & s & ::= & x := e \mid s; s \mid \textbf{if } e\ s\ s \mid \textbf{repeat } e\ s \\ \text{(Expressions)} & e & ::= & v \mid x \mid e + e \mid e - e \mid e * e \mid e^e \mid e > e \\ \text{(Stores)} & \sigma & & \end{array}$$

We use a big-step reduction semantics $\sigma \vdash s \Rightarrow \sigma'$ that takes a program s and an initial store σ as input, and yields an output store σ'. We can use this language to compute epidemiological models.

Epidemiological models are essential tools for understanding the spread of infectious diseases and informing public health interventions [15]. For example, consider a simplified model that simulates disease spread over a fixed number of n days:

```
# free variables n, I, and β must be bound in the initial store
α = 0.04
S = 0
repeat n:            # n is the number of days for which we model the disease spread
    S = S + I        # S is the cumulative infection count, which grows by I each day
    β = β + α        # β is the disease transmissibility, which grows by α each day
    I = I * 2.718^β  # I is the infected population, which grows exponentially based on β
```

We can now predict how a disease spreads in $n = 6$ days given an initial infectious population $I = 10$ and assuming a transmissibility of $\beta = 0.3$ Figure 1a shows the content of the store σ_i after iteration i of the loop (we omit `n` and α because they are constant). This constitutes the initial, non-incremental run of the program. Note that σ_0 shows the initial state of the model and $\sigma_{out} = \sigma_6$ is the final prediction.

When epidemiologists revise the initial parameters of the model, we want to update our prediction efficiently. In the following, we discuss three change scenarios. First, consider we want to change the initial infected population from 10 to 15. The differential store $\Delta\sigma_0$ in Figure 1b models this change. Our goal is to determine how the final prediction changes, that is, what is $\Delta\sigma_{out}$. To this end, we propose the use of differential execution:

$\sigma_0 = \{S \mapsto 0,\ I \mapsto 10,\ \beta \mapsto 0.3\}$
$\sigma_1 = \{S \mapsto 10,\ I \mapsto 14,\ \beta \mapsto 0.34\}$
$\sigma_2 = \{S \mapsto 24,\ I \mapsto 20,\ \beta \mapsto 0.38\}$
$\sigma_3 = \{S \mapsto 44,\ I \mapsto 30,\ \beta \mapsto 0.42\}$
$\sigma_4 = \{S \mapsto 74,\ I \mapsto 47,\ \beta \mapsto 0.46\}$
$\sigma_5 = \{S \mapsto 121,\ I \mapsto 77,\ \beta \mapsto 0.50\}$
$\sigma_{out} = \{S \mapsto 198, I \mapsto 132, \beta \mapsto 0.54\}$

(a) Stores σ_i after i iterations.

$\Delta\sigma_0 = \{I \mapsto \textbf{inc}\ 5\}$
$\Delta\sigma_1 = \{S \mapsto \textbf{inc}\ 5,\ I \mapsto \textbf{inc}\ 7\}$
$\Delta\sigma_2 = \{S \mapsto \textbf{inc}\ 12,\ I \mapsto \textbf{inc}\ 10\}$
$\Delta\sigma_3 = \{S \mapsto \textbf{inc}\ 22,\ I \mapsto \textbf{inc}\ 15\}$
$\Delta\sigma_4 = \{S \mapsto \textbf{inc}\ 37,\ I \mapsto \textbf{inc}\ 24\}$
$\Delta\sigma_5 = \{S \mapsto \textbf{inc}\ 61,\ I \mapsto \textbf{inc}\ 40\}$
$\Delta\sigma_{out} = \{S \mapsto \textbf{inc}\ 101,\ I \mapsto \textbf{inc}\ 68\}$

(b) Differential stores for $I \mapsto \textbf{inc}\ 5$.

$\Delta\sigma_{0\ldots6} = \{n \mapsto \textbf{inc}\ 3\}$
$\sigma_7 = \{S \mapsto 499,\ I \mapsto 357,\ \beta \mapsto 0.58\}$
$\sigma_8 = \{S \mapsto 856,\ I \mapsto 663,\ \beta \mapsto 0.62\}$
$\sigma_{out} = \{S \mapsto 1519,\ I \mapsto 1282,\ \beta \mapsto 0.66\}$
$\Delta\sigma_{out} = \{S \mapsto \textbf{inc}\ 1321,\ I \mapsto \textbf{inc}\ 1150,$
$\beta \mapsto \textbf{inc}\ 0.12,\ n \mapsto \textbf{inc}\ 3\}$

(c) Differential stores for $n \mapsto \textbf{inc}\ 3$.

$\Delta\sigma_{0\ldots4} = \{n \mapsto \textbf{dec}\ 5\}$
$\sigma_{out} = \{S \mapsto 111,\ I \mapsto 71,\ \beta \mapsto 0.46\}$
$\Delta\sigma_{out} = \{S \mapsto \textbf{dec}\ 1408,\ I \mapsto \textbf{dec}\ 1211,$
$\beta \mapsto \textbf{dec}\ 0.2,\ n \mapsto \textbf{dec}\ 5\}$

(d) Differential stores for $n \mapsto \textbf{dec}\ 5$.

Figure 1 Original and differential stores during execution of the epidemiological model.

Essentially, we rerun the program but only consider and compute changes. Starting from $\Delta\sigma_0$, differential execution of the loop body computes $\Delta\sigma_1$, showing how S and I are affected by the initial change of I. Differential execution continues to iterate the loop body until we reach $\Delta\sigma_6 = \Delta\sigma_{out}$. We observe that 5 additional infections on day 0 lead to 68 additional infections on day 6.

Providing the correct differential result is easy: Reexecute the program and compute the outputs' difference. The challenge for differential execution is to compute output changes efficiently by avoiding recomputations. For example, an increase of I in $\Delta\sigma_0$ does not affect β, which is why β does not occur in Figure 1b. Indeed, as we prove in Section 5, statements that do not read changed variables can be skipped during differential execution. It is shortcuts like this that we need to discover to make differential execution efficient.

For example, consider epidemiologists now want to know what happens after 9 instead of 6 days. We encode this change in $\Delta\sigma_0$ of Figure 1c. Note that we assume the prior change of I remains in place; changes occur in sequence and have to be undone explicitly if so desired. How can differential execution handle the change of n efficiently? In general, it is necessary to repeat each loop iteration to ensure input changes are propagated correctly. However, in our case, n only determines the number of iterations, but it is not used inside the loop body. We prove in Section 5 that in this case we can skip all previous iterations and directly continue with the new ones. Since iterations 7, 8, and 9 have not been executed before, we have to compute the resulting stores from scratch. The final result $\Delta\sigma_{out}$ is then defined by $\sigma_9 \ominus \sigma_6$. In general, when the original loop count n is increased by k, we only need to perform k instead of $n + k$ iterations, which yields significant speedups when $k \ll n$.

Lastly, consider epidemiologists want to rollback n from 9 to 4. This is a case where incremental computing has to trade-off memory and running time. If we still have σ_4 cached, we can compute $\Delta\sigma_{out}$ by $\sigma_4 \ominus \sigma_9$. Otherwise, we may have to do more recomputation. In our study of a formal semantics for differential execution, we ignore all concerns regarding caching. Later, in Section 6, we discuss how we implemented the formal semantics in an efficient interpreter and what caching strategies we considered.

2.2 Branch switching and worst-case complexity

A particular challenge for all kinds of incremental computing is what we call *branch switching*. A branch switch occurs when a change to the input data alters the control flow, causing a different branch of a conditional to be executed compared to the original run. For a simple example, consider this extreme case:

```
# main function with free variable x, which must be bound in the initial store
if x < 0:
    foo()
else:
    bar()
```

When `x` changes from negative to positive, the entire behavior of the program shifts: Instead of running `foo`, we end up running `bar`. This has two important consequences. First, the worst-case complexity of differential execution is at best equal to regular execution. Second, we must retain (or be able to reconstruct) the original state σ that is valid at the beginning of a branch. This state is necessary when a branch switch occurs, as input for executing the other branch. This indicates a lower bound on the memory necessary for differential execution if we want to avoid reconstructing previously seen states.

Does this mean that all hope is lost? No, not at all. Many conditionals do not amount to a reconfiguration of the program, but have a rather limited scope. For example, an improved epidemiological model may consider emergency measures, which are active when infections exceed a threshold T of 40 patients:

```
α = 0.04; γ = 0.02; S = 0; T = 40
repeat n:
    if I > T:           # do infectious cases exceed threshold T?
        β = β - γ       # emergency measures activated, transmissibility shrinks
    else:
        β = β + α       # no emergency measures, transmissibility grows
    S = S + I; I = I * 2.718^β
```

When we change the input variable I, this can now affect the control flow and lead to branch switching. However, the cost of re-executing one of the branches is limited in this case, and only results in different subsequent changes to β. One interesting issue that persists is that branch switching requires diffing between the original and the new state to determine the subsequent changes. In Section 5, we present an optimization that avoids this cost when branches execute similar code.

3 Values and Changes

While regular program execution operates on values, differential execution operates on changes. That is, changes are first-class objects in differential execution. Since the definition of changes is language-specific, we first introduce general rules for how to design well-behaved changes for a statically typed base language. We then define specific changes for our imperative language Imp.

3.1 Change validity, patching, and diffing

Changes must support two fundamental operations: *diffing* to produce changes from values ($new \ominus old$), and *patching* to apply changes to values ($base \oplus change$). Patching and diffing should act as inverses: $v_1 \oplus (v_2 \ominus v_1) = v_2$ and $(v \oplus \Delta v) \ominus v = \Delta v$. These laws are elemental for differential execution as they justify optimizations that avoid redundant work.

However, handling changes correctly is subtle and it is easy to break the second property. For example, consider $v = 2$ and $\Delta v = \mathbf{dec}\ 5$ for the naturals with $2 \oplus \mathbf{dec}\ 5 = 0$. Then,

$$(v \oplus \Delta v) \ominus v = 0 \ominus 2 = \mathbf{dec}\ 2 \neq \mathbf{dec}\ 5 = \Delta v.$$

The problem is that we tried to patch $v = 2$ with $\Delta v = \mathbf{dec}\ 5$, which is invalid because $2 - 5$ does not yield a natural number, and defaulting to 0 contradicts our inversion properties. The same problem occurs for other data types, such as strings, sets, and lists. For example, we get ("`ab`" $\oplus$ **drop** 5) $\ominus$ "`ab`" = "" $\ominus$ "`ab`" = **drop** 2 $\neq$ **drop** 5. Again, we tried to apply a patch that has an undefined behavior, and defaulting to the empty string breaks our inversion laws. Therefore, we follow the incremental lambda calculus [9] and restrict patching to valid changes. But rather than using Coq's dependent typing, we rely on a dedicated typing judgment $v \vdash \Delta v$. Patching and diffing then must satisfy the following properties:

$$\frac{v : \tau \qquad v \vdash \Delta v}{v \oplus \Delta v : \tau}\ \text{T-Patch} \qquad\qquad \frac{v_1 : \tau \qquad v_2 : \tau}{v_1 \vdash v_2 \ominus v_1}\ \text{V-Diff}$$

Patching is only defined when $v \vdash \Delta v$ and yields a value of the same type as v. Diffing is defined for any v_1 and v_2 of the same type, and it yields a valid change that can be applied to v_1. When defining differential execution, it is our responsibility to define changes Δv, validity $v \vdash \Delta v$, patching $\oplus$, and diffing $\ominus$ such that these typing rules hold.

On top of these typing rules for patching and diffing, we can now stipulate the inversion properties we require.

▶ **Property 3.1** (Patch-Diff Inversion)**.** For any well-typed values $v_1 : \tau$ and $v_2 : \tau$, patching inverts diffing: $v_1 \oplus (v_2 \ominus v_1) = v_2$.

▶ **Property 3.2** (Diff-Patch Inversion)**.** For any value v and valid change $v \vdash \Delta v$, diffing inverts patching: $(v \oplus \Delta v) \ominus v \equiv \Delta v$.

Note how the latter property uses equivalence $\equiv$ on changes rather than equality. This is due to the fact that changes often have non-unique representations and diffing might choose any equivalent representation. For example, **inc** 0 and **dec** 0 are equivalent but not equal. In general, $\Delta v_1 \equiv \Delta v_2$ iff for all v, $v \vdash \Delta v_1 \leftrightarrow v \vdash \Delta v_2$ and $v \oplus \Delta v_1 = v \oplus \Delta v_2$.

The above properties justify our use of **noc**, representing no change. Specifically, for any v, we have $v \oplus (v \ominus v) = v$ and therefore $\mathbf{noc} \equiv v \ominus v$. In practice, it is usually easy to decide if a given Δv is equivalent to **noc**.

3.2 Numeric and Boolean changes

Our imperative language Imp uses unsigned integers and Boolean values. We define changes for each type:

$$\begin{array}{ll} \text{(value changes)} & \Delta v ::= \Delta n \mid \Delta b \\ \text{(numeric changes)} & \Delta n ::= \mathbf{noc}_{\mathbb{N}} \mid \mathbf{inc}\ k \mid \mathbf{dec}\ k \\ \text{(Boolean changes)} & \Delta b ::= \mathbf{noc}_{\mathbb{B}} \mid \mathbf{neg} \end{array}$$

Numeric changes consist of no change ($\mathbf{noc}_{\mathbb{N}}$), increasing (**inc** k), and decreasing (**dec** k), where k is any natural number. Boolean changes consist of no change ($\mathbf{noc}_{\mathbb{B}}$) and negation (**neg**). Changes are only valid for an appropriately typed value, and **dec** k is only valid for numbers larger or equal to k:

$$\frac{v : \mathsf{Bool}}{v \vdash \mathbf{noc}_{\mathbb{B}}} \quad \frac{v : \mathsf{Bool}}{v \vdash \mathbf{neg}} \quad \frac{v : \mathsf{Num}}{v \vdash \mathbf{noc}_{\mathbb{N}}} \quad \frac{v : \mathsf{Num}}{v \vdash \mathbf{inc}\ k} \quad \frac{v : \mathsf{Num} \qquad v \geq k}{v \vdash \mathbf{dec}\ k}$$

Whenever $v \vdash \Delta v$, we can patch v while retaining its type as required by T-Patch. Moreover, differencing ensures $v_1 \vdash v_2 \ominus v_1$ as required by V-Diff.

$$
\begin{array}{ll}
n \oplus \mathbf{noc}_{\mathbb{N}} = n & n \ominus n = \mathbf{noc}_{\mathbb{N}} \\
n \oplus \mathbf{inc}\ k = n + k & n \ominus m = \mathbf{inc}\ (n - m), \text{ if } n > m \\
n \oplus \mathbf{dec}\ k = n - k & n \ominus m = \mathbf{dec}\ (m - n), \text{ if } m > n \\
b \oplus \mathbf{noc}_{\mathbb{B}} = b & b \ominus b = \mathbf{noc}_{\mathbb{B}} \\
b \oplus \mathbf{neg} = \neg b & b \ominus c = \mathbf{neg}, \text{ if } b \neq c
\end{array}
$$

We have modeled these changes and their operations in Rocq, where we proved they satisfy the respective typing rules as well as patch-diff and diff-patch inversion.

3.3 Lifting to stores

We have established how patching and diffing operate on individual values, but our imperative programs range over variables that map to values. Therefore, we need to lift changes and their operations from single values to entire stores $\sigma : x \to v$ that map variables to values. To this end, we define differential stores $\Delta\sigma : x \to \Delta v$, which map variables to value changes. Differential stores must satisfy the same properties as differential values: well-typed patching and diffing according to T-Patch and V-Diff, such that patch-diff and diff-patch inversion hold.

We start off by requiring stores to be well-typed given a store type $\Gamma : x \to \tau$. We define store typing $\Gamma \vdash \sigma$ and differential store validity $\sigma \vdash \Delta\sigma$ pointwise:

$$\frac{\forall x.\ \sigma(x) : \Gamma(x)}{\Gamma \vdash \sigma}\ \text{T-Store} \qquad \frac{\forall x.\ \sigma(x) \vdash \Delta\sigma(x)}{\sigma \vdash \Delta\sigma}\ \text{V-Store}$$

Then the following definitions of patching and diffing satisfy T-Patch and V-Diff:

$$
\begin{aligned}
\sigma \oplus \Delta\sigma &= \lambda x.\ \sigma(x) \oplus \Delta\sigma(x) \\
\sigma_1 \ominus \sigma_2 &= \lambda x.\ \sigma_1(x) \ominus \sigma_2(x)
\end{aligned}
$$

Patch-diff inversion holds because

$$\sigma_1 \oplus (\sigma_2 \ominus \sigma_1) \;=\; \lambda x.\ \sigma_1(x) \oplus (\sigma_2(x) \ominus \sigma_1(x)) \;=\; \lambda x.\ \sigma_2(x) \;=\; \sigma_2$$

and conversely diff-patch inversion is due to

$$(\sigma \oplus \Delta\sigma) \ominus \sigma \;=\; \lambda x.\ (\sigma(x) \oplus \Delta\sigma(x)) \ominus \sigma(x) \;\equiv\; \lambda x.\ \Delta\sigma(x) \;=\; \Delta\sigma(x).$$

Again, we have modeled differential stores in Rocq and proved the above properties formally there. This shows how to lift changes from values to stores, which provides the foundation for our differential semantics. The Rocq formalization is provided at

4 Differential Semantics: A Foundation for Incremental Computing

Incremental computing is all about eliminating redundant work in the face of input changes. In the pursuit of efficiency, incremental computing tries to cut as many corners as possible while retaining correctness. Our differential style of incremental computing is particularly susceptible to correctness errors, because we need to capture the precise difference of each computation output. In this section, we introduce the idea of differential semantics to capture the incremental behavior of a program. Specifically, we develop a differential semantics for the imperative language Imp from Section 2 with expressions and statements.

$$\frac{}{\sigma \vdash \textbf{true} \Rightarrow \textbf{true}} \qquad \frac{}{\sigma \vdash \textbf{false} \Rightarrow \textbf{false}} \qquad \frac{}{\sigma \vdash n \Rightarrow n}$$

$$\frac{}{\sigma \vdash x \Rightarrow \sigma(x)} \qquad \frac{\sigma \vdash e_1 \Rightarrow v_1 \qquad \sigma \vdash e_2 \Rightarrow v_2}{\sigma \vdash e_1 \odot e_2 \Rightarrow v_1 \odot v_2}$$

$$\frac{\sigma \vdash e \Rightarrow v}{\sigma \vdash x := e \Rightarrow [x \mapsto v]\sigma} \qquad \frac{\sigma \vdash s_1 \Rightarrow \sigma' \qquad \sigma' \vdash s_2 \Rightarrow \sigma''}{\sigma \vdash s_1; s_2 \Rightarrow \sigma''}$$

$$\frac{\sigma \vdash e \Rightarrow \textbf{true} \qquad \sigma \vdash s_1 \Rightarrow \sigma'}{\sigma \vdash \textbf{if}\ e\ s_1\ s_2 \Rightarrow \sigma'} \qquad \frac{\sigma \vdash e \Rightarrow \textbf{false} \qquad \sigma \vdash s_2 \Rightarrow \sigma'}{\sigma \vdash \textbf{if}\ e\ s_1\ s_2 \Rightarrow \sigma'}$$

$$\frac{\sigma \vdash e \Rightarrow 0}{\sigma \vdash \textbf{repeat}\ e\ s \Rightarrow \sigma} \qquad \frac{\sigma \vdash e \Rightarrow n+1 \qquad \sigma \vdash \textbf{repeat}\ n\ s \Rightarrow \sigma' \qquad \sigma' \vdash s \Rightarrow \sigma''}{\sigma \vdash \textbf{repeat}\ e\ s \Rightarrow \sigma''}$$

Figure 2 Standard big-step reduction semantics for Imp expressions and statements.

A differential semantics establishes a sound baseline for incremental computing, but it is not usually optimal. Instead, we separately introduce optimizations for the efficient incremental execution of programs and prove them correct with respect to the baseline differential semantics. To support the modular definition and verification of optimizations, we formulate the differential semantics compositionally for each language construct. But first, let us review the standard big-step semantics of our imperative language Imp.

4.1 Standard big-step semantics of Imp

We already introduced the syntax of Imp expressions, statements, and stores in Section 2. Figure 2 shows the standard semantics for Imp using two judgments. For expressions, we write $\sigma \vdash e \Rightarrow v$ to denote that expression e evaluates to value v under store σ. Expressions can read but cannot change the content of the store. The last reduction rule for expressions handles binary expressions $e_1 \odot e_2$. Imp supports a few binary operators $\odot \in \{+, -, *, >, \mathsf{exp}\}$, and we assume that $v_1 \odot v_2$ follows the standard arithmetic interpretation of these operators.

For statements, we write $\sigma \vdash s \Rightarrow \sigma'$ to denote that statement s executes under store σ, yielding a possibly updated store σ'. In these rules, the notation $[x \mapsto v]\sigma$ represents the store obtained from σ by updating the mapping of variable x to value v, while leaving all other mappings unchanged. For repeat loops, we skip the body when the iteration count is zero. Otherwise, we recursively evaluate the loop with a decremented count, followed by running the body. We opted for this left-recursive loop unrolling to simplify some of the proofs.

4.2 Differential semantics for Imp expressions

A differential semantics describes how a program's output changes in reaction to input changes. The inputs of our Imp programs are stores σ. We have described store changes $\Delta\sigma$ in Subsection 3.3. The output of an Imp program is also a store, but we first only consider Imp expressions. An Imp expression computes a value v, hence the differential semantics for Imp expressions computes a value change Δv. To this end, we define a differential reduction relation $\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \Delta v$ to compute how e's output changes:

$$\frac{e \in \{\textbf{true}, \textbf{false}\}}{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \textbf{noc}_\mathbb{B}}\ \text{D-Bool} \qquad \frac{}{\sigma, \Delta\sigma \vdash n \Rightarrow_\Delta \textbf{noc}_\mathbb{N}}\ \text{D-Num} \qquad \frac{}{\sigma, \Delta\sigma \vdash x \Rightarrow_\Delta \Delta\sigma(x)}\ \text{D-Var}$$

$$\frac{\sigma, \Delta\sigma \vdash e_1 \Rightarrow_\Delta \Delta v_1 \qquad \sigma, \Delta\sigma \vdash e_2 \Rightarrow_\Delta \Delta v_2 \qquad (\ \sigma \vdash e_1 \Rightarrow v_1\ ) \qquad (\ \sigma \vdash e_2 \Rightarrow v_2\ )}{\sigma, \Delta\sigma \vdash e_1 \odot e_2 \Rightarrow_\Delta \odot_\Delta(v_1, v_2, \Delta v_1, \Delta v_2)}\ \text{D-BinOp}$$

The first rules handle an expression e that is a Boolean or numeric constant. The value of constant expressions can not change, hence the output is a no change (**noc**). A variable x changes in accordance with $\Delta\sigma$. In particular, when an input is changed, reading from that input yields its change, which can then be propagated.

The last rule handles binary operators $\odot$ and delegates their differential behavior to dedicated functions $\odot_\Delta$. We allow these functions to use the original input values (v_1, v_2) and their changes (Δv_1, Δv_2). For example, for a differential multiplication $m * (n \oplus \textbf{inc}\ k)$, we need to know the original arguments to compute the output change **inc** $(m * k)$. While our implementation supports various operators, in this paper and the Rocq formalization we focus on establishing the core differential semantics. A complete treatment of differential operators is outside the scope of this paper.

Note that we required the original store σ during the differential execution of expressions only to recover the original arguments of binary operators. In places like these, we can expect an actual implementation to cache the previous evaluation result of each operand where needed. We highlight opportunities for caching in the reduction rules by putting preconditions in parentheses (*cached*) and slightly shading their background.

4.3 A differential semantics for Imp statements

We define the differential semantics for statements using the relation

$$\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$$

which executes statement s under differential store $\Delta\sigma$ and original store σ to yield an updated differential store $\Delta\sigma'$. The inference rules are shown in Figure 3.

Rule D-Assign evaluates the assigned expressions differentially and then updates the differential store. The store update is a destructive update, overwriting the previous change assigned to x. Together with rule D-Seq, this realizes change propagation behavior. For example, assume a program $x := a; y := x$ with $\Delta\sigma(a) = \Delta v$. Rule D-Seq runs the assignments in order. The first assignment sets $\Delta\sigma(x) = \Delta v$ because $\sigma, \Delta\sigma \vdash a \Rightarrow_\Delta \Delta v$. Then the second assignment sets $\Delta\sigma(y) = \Delta v$ because $\sigma', \Delta\sigma' \vdash x \Rightarrow_\Delta \Delta v$ Note that D-Seq also runs the first statement non-incrementally, but only to obtain σ', which is needed as input for s_2. The highlighting of this and other preconditions in Figure 3 indicates that the precondition's result can be retrieved from a cache in an actual implementation.

For conditional statements, we generally distinguish two situations: branch constant and branch switching. A conditional behaves branch-constant if the value of the condition does not change, handled by rules D-IF$_{\text{tt}}$ and D-IF$_{\text{ff}}$. These rules simply propagate changes to the relevant branch that was selected originally. Rules D-IF$_{\text{tf}}$ and D-IF$_{\text{ft}}$ handle branch switching, which happens when the condition's value changes. If the original value of the condition was **true** and now becomes **false**, then rule D-IF$_{\text{tf}}$ fires and performs branch switching as introduced in Subsection 2.2. Originally, we have executed s_1, but now we need to run s_2. Therefore, we execute s_2 from scratch and compute how its output differs from s_1. Rule D-IF$_{\text{ft}}$ is analogous and handles the case when the condition switches from **false** to **true**.

$$\frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \Delta v}{\sigma, \Delta\sigma \vdash x := e \Rightarrow_\Delta [x \mapsto \Delta v]\Delta\sigma}\ \text{D-Assign}$$

$$\frac{\sigma, \Delta\sigma \vdash s_1 \Rightarrow_\Delta \Delta\sigma' \quad (\,\sigma \vdash s_1 \Rightarrow \sigma'\,) \quad \sigma', \Delta\sigma' \vdash s_2 \Rightarrow_\Delta \Delta\sigma''}{\sigma, \Delta\sigma \vdash s_1; s_2 \Rightarrow_\Delta \Delta\sigma''}\ \text{D-Seq}$$

$$\frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{noc}_\mathbb{B} \quad (\,\sigma \vdash e \Rightarrow \mathbf{true}\,) \quad \sigma, \Delta\sigma \vdash s_1 \Rightarrow_\Delta \Delta\sigma'}{\sigma, \Delta\sigma \vdash \mathbf{if}\ e\ s_1\ s_2 \Rightarrow_\Delta \Delta\sigma'}\ \text{D-IF}_{\text{tt}} \qquad \frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{noc}_\mathbb{B} \quad (\,\sigma \vdash e \Rightarrow \mathbf{false}\,) \quad \sigma, \Delta\sigma \vdash s_2 \Rightarrow_\Delta \Delta\sigma'}{\sigma, \Delta\sigma \vdash \mathbf{if}\ e\ s_1\ s_2 \Rightarrow_\Delta \Delta\sigma'}\ \text{D-IF}_{\text{ff}}$$

$$\frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{neg} \quad (\,\sigma \vdash e \Rightarrow \mathbf{true}\,) \quad \sigma \oplus \Delta\sigma \vdash s_2 \Rightarrow \sigma_2 \quad (\,\sigma \vdash s_1 \Rightarrow \sigma_1\,)}{\sigma, \Delta\sigma \vdash \mathbf{if}\ e\ s_1\ s_2 \Rightarrow_\Delta \sigma_2 \ominus \sigma_1}\ \text{D-IF}_{\text{tf}} \qquad \frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{neg} \quad (\,\sigma \vdash e \Rightarrow \mathbf{false}\,) \quad \sigma \oplus \Delta\sigma \vdash s_1 \Rightarrow \sigma_1 \quad (\,\sigma \vdash s_2 \Rightarrow \sigma_2\,)}{\sigma, \Delta\sigma \vdash \mathbf{if}\ e\ s_1\ s_2 \Rightarrow_\Delta \sigma_1 \ominus \sigma_2}\ \text{D-IF}_{\text{ft}}$$

$$\frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{noc}_\mathbb{N} \quad (\,\sigma \vdash e \Rightarrow 0\,)}{\sigma, \Delta\sigma \vdash \mathbf{repeat}\ e\ s \Rightarrow_\Delta \Delta\sigma}\ \text{D-Rep-0}$$

$$\frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{noc}_\mathbb{N} \quad (\,\sigma \vdash e \Rightarrow n+1\,) \quad \sigma, \Delta\sigma \vdash \mathbf{repeat}\ n\ s \Rightarrow_\Delta \Delta\sigma' \quad (\,\sigma \vdash \mathbf{repeat}\ n\ s \Rightarrow \sigma'\,) \quad \sigma', \Delta\sigma' \vdash s \Rightarrow_\Delta \Delta\sigma''}{\sigma, \Delta\sigma \vdash \mathbf{repeat}\ e\ s \Rightarrow_\Delta \Delta\sigma''}\ \text{D-Rep+1}$$

$$\frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{dec}\ k \quad (\,\sigma \vdash e \Rightarrow n\,) \quad \sigma, \Delta\sigma \vdash \mathbf{repeat}\ (n-k)\ s \Rightarrow_\Delta \Delta\sigma' \quad (\,\sigma \vdash \mathbf{repeat}\ (n-k)\ s \Rightarrow \sigma'\,) \quad (\,\sigma \vdash \mathbf{repeat}\ n\ s \Rightarrow \sigma''\,)}{\sigma, \Delta\sigma \vdash \mathbf{repeat}\ e\ s \Rightarrow_\Delta (\sigma' \oplus \Delta\sigma') \ominus \sigma''}\ \text{D-Rep-Dec}$$

$$\frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{inc}\ k \quad (\,\sigma \vdash e \Rightarrow n\,) \quad \sigma, \Delta\sigma \vdash \mathbf{repeat}\ n\ s \Rightarrow_\Delta \Delta\sigma' \quad (\,\sigma \vdash \mathbf{repeat}\ n\ s \Rightarrow \sigma'\,) \quad \sigma' \oplus \Delta\sigma' \vdash \mathbf{repeat}\ k\ s \Rightarrow \sigma''}{\sigma, \Delta\sigma \vdash \mathbf{repeat}\ e\ s \Rightarrow_\Delta \sigma'' \ominus \sigma'}\ \text{D-Rep-Inc}$$

Figure 3 Differential semantics for Imp statements. Marked (preconditions) can be cached.

Finally, we provide four rules to handle repeat loops. The differential semantics for **repeat** e s depends crucially on how the iteration count changes. When the differential evaluation of e yields $\mathbf{noc}_\mathbb{N}$, the iteration count remains the same as in the original execution. In this case, we replay the loop but only do change propagation. If the iteration count is zero ($\sigma \vdash e \Rightarrow 0$), we simply return the input differential store unchanged, as no iterations need to be replayed. For a positive count ($\sigma \vdash e \Rightarrow n+1$), we unroll the loop recursively followed by a differential run of the loop body s. The resulting $\Delta\sigma''$ captures the cumulative effect of differentially executing all iterations.

When the iteration count is decreased ($\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{dec}\ k$), the process is more complicated. First, we propagate the changes for $(n-k)$ iterations to obtain $\Delta\sigma'$. Then we retrieve the original output after $(n-k)$ iterations σ' and patch it with $\Delta\sigma'$. This represents the updated output after $(n-k)$ iterations, but we need to know how it changed compared to n iterations. To this end, we compute the difference with σ'', which is the original output after n iterations.

Lastly, when the iteration count grows ($\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \textbf{inc}\ k$), we use a two-phase strategy. First, we execute the original n iterations differentially to obtain $\Delta\sigma'$. However, from here on out, we are dealing with iterations that have not occurred before. Therefore, in the second phase, we execute the additional k iterations non-incrementally. To this end, we compute the updated output after n iterations using $\Delta\sigma'$ and feed it as input for the remaining k iterations. Finally, we compute the difference with σ', which was the original output.

▶ **Example.** Consider the following program and stores: repeat x $\{y = y + z;\ z = z + 1\}$ with initial store $\sigma = \{x \mapsto 5,\ y \mapsto 7,\ z \mapsto 3\}$. The original output is $\sigma' = \{x \mapsto 5,\ y \mapsto 32,\ z \mapsto 8\}$. Now consider we apply the following input changes $\Delta\sigma = \{x \mapsto \textbf{inc}\ 2,\ y \mapsto \textbf{inc}\ 3,\ z \mapsto \textbf{inc}\ 5\}$. The example demonstrates how differential execution handles both loop counter changes (x) and variable changes (y, z). Specifically, here rule D-Rep-Inc is leading the execution and proceeds in the following steps:

1. Execute original 5 iterations differentially: $\Delta\sigma' = \{x \mapsto \textbf{inc}\ 2,\ y \mapsto \textbf{inc}\ 28,\ z \mapsto \textbf{inc}\ 5\}$.
2. Compute patched state after 5 iterations: $\sigma' \oplus \Delta\sigma' = \{x \mapsto 7,\ y \mapsto 60,\ z \mapsto 13\}$.
3. Execute new iterations (k = 2) from $\sigma' \oplus \Delta\sigma'$ to obtain $\sigma'' = \{x \mapsto 7,\ y \mapsto 87,\ z \mapsto 15\}$.
4. Compute differential output: $\sigma'' \ominus \sigma' = \{x \mapsto \textbf{inc}\ 2,\ y \mapsto \textbf{inc}\ 55,\ z \mapsto \textbf{inc}\ 7\}$.

4.4 Properties of differential semantics

Our differential semantics aims to replace recomputation with change-based execution. That is, when the original input σ is changed to $\sigma' = \sigma \oplus \Delta\sigma$, the differential semantics must be able to process $\Delta\sigma$ directly. For this to work, we need three guarantees:

Completeness: Whenever a program can execute under the original σ and the updated σ', then the differential semantics must derive an output change for $\Delta\sigma$.

Output validity: The output change must be valid for the original output.

From-scratch consistency Patching the original output with the output changes is consistent with a recomputation starting with σ'.

That is: We can obtain changes using the differential semantics, the changes can be used to patch the original output, and the patched output is correct. We have formalized these properties in Rocq and have a mechanized proof that shows our differential semantics satisfies them. Here, we only present the formal formulation of the properties.

In general, we only make claims about well-typed programs $\Gamma \vdash s$. The typing relation for statements and expressions is standard: variables are global and cannot change type. With this, we can formulate the properties of differential semantics.

▶ **Theorem 4.1** (Completeness). *Given a well-typed program $\Gamma \vdash s$, well-typed store $\Gamma \vdash \sigma$, and valid differential store $\sigma \vdash \Delta\sigma$. Whenever $\sigma \vdash s \Rightarrow \theta$ and $\sigma \oplus \Delta\sigma \vdash s \Rightarrow \theta'$ for arbitrary θ and θ', then $\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$ for some $\Delta\sigma'$.*

Proof sketch. By induction on the typing derivation of statement s. For base cases like Assign, we directly construct differential derivations. For compound statements like Seq and If, we apply induction hypotheses to substatements and compose their results. The critical case is Repeat, where we handle changes to the iteration count by carefully tracking execution states for each iteration. ◀

Completeness ensures we find output changes $\Delta\sigma'$. Note that for our Imp language, the original and update execution always succeeds for well-typed programs and stores, but richer languages may include run-time errors and divergence For Imp, completeness ensures that we have defined enough reduction rules to handle all well-typed execution states.

Validity guarantees that differential execution produces changes that are compatible with the values they will be patched with. This ensures we can safely apply all changes produced during execution.

▶ **Theorem 4.2** (Output validity). *Given a well-typed program* $\Gamma \vdash s$*, well-typed store* $\Gamma \vdash \sigma$*, and valid differential store* $\sigma \vdash \Delta\sigma$*. Whenever* $\sigma \vdash s \Rightarrow \sigma'$ *and* $\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$*, then* $\sigma' \vdash \Delta\sigma'$ *is valid for the original output.*

Proof sketch. By induction on the differential semantics derivation, showing each rule preserves validity when input changes are valid. Critical cases include branch switching and loop optimizations, where the type system ensures changes remain compatible with their target values. ◀

From-scratch consistency is our key correctness property – it proves that differential execution produces the same final results as re-running the program with changed inputs. This means users can trust that differential execution is just an optimization that does not affect program behavior.

▶ **Theorem 4.3** (From-Scratch Consistency). *Given a well-typed program* $\Gamma \vdash s$*, well-typed store* $\Gamma \vdash \sigma$*, and valid differential store* $\sigma \vdash \Delta\sigma$*. Whenever* $\sigma \vdash s \Rightarrow \sigma'$ *and* $\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$*, then* $\sigma \oplus \Delta\sigma \vdash s \Rightarrow \sigma' \oplus \Delta\sigma'$*.*

Proof sketch. By induction on differential semantics, proving patched original outputs match recomputation results. The key insight relies on our change operations satisfying algebraic properties like patch-diff and diff-patch inversion, ensuring consistency across all language constructs. ◀

We have formally verified all three theorems using the Rocq proof assistant. The complete mechanized proofs are available in the repository referenced in Section 3.

4.5 Mechanized Rocq formalization

We formalized the differential semantics of Imp in Rocq and proved completeness, output validity, and from-scratch consistency. The Rocq code is available open-source.[2] The Rocq formalization consists of approximately 1,450 lines of code and was important in shaping our theory of changes. A key challenge emerged when proving the diff-patch inversion property (Property 3.2) introduced in Section 3. While standard equality was sufficient for proving the patch-diff property (Property 3.1), we discovered it was inadequate for the diff-patch case. We needed a custom equivalence relation because multiple differential values (noc, incr 0, decr 0) can represent the same change semantically

The consistency proof (Theorem 4.3) was particularly challenging, especially for the increment case of repeat statements. The complexity of this case revealed that our initial induction hypothesis wasn't strong enough – an observation we only gained after successfully proving all other cases. This led to a reformulation of the theorem with a stronger induction hypothesis.

In our opinion, for the number of results we proved, our Rocq code is reasonably compact. This was achieved through careful proof automation: we developed custom tactics for common proof patterns and registered them as hints for Rocq's eauto system. This automation strategy significantly reduced the proof size.

5 Optimizations as Alternative Reduction Rules

To enhance the efficiency of our differential semantics, we introduce several optimizations which allow us to avoid unnecessary computations during execution. We present them as alternative reduction rules within our differential semantics. Each optimization we present is a shortcut: it lets us compute the same result more efficiently. To ensure these shortcuts are correct, we must prove they are *admissible*. This means that whenever we use an optimization rule to derive a result, we can also derive the same result (perhaps less efficiently) using only the standard rules from Figure 3. Formally, we define admissibility of a rule as follows.

▶ **Definition 5.1** (Rule Admissibility). *An optimization rule R with premises P and conclusion $\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$ is admissible if for any well-typed statement s, whenever P holds, there exists a derivation D using only standard rules that concludes $\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$.*

Admissibility ensures optimizations are behavior-preserving shortcuts. In the following sections, we present several optimizations. We have proved the admissibility for each of these rules in Rocq, working only with well-typed programs since well-typedness is essential for ensuring the soundness of our optimizations. We categorize the various optimizations into three main types: *short-circuiting optimizations*, *loop optimizations*, and *branch switching optimizations*, and discuss each in detail.

5.1 Short-Circuiting Rules

Short-circuiting rules enable bypassing differential computations entirely under certain conditions. We begin with a special case where all variables of a store map to no change. Then we generalize this rule to handle programs where only referenced variables are unchanged.

$$\frac{\Gamma \vdash s \qquad \sigma \vdash s \Rightarrow \sigma' \qquad \forall x.\ \Delta\sigma(x) = \mathbf{noc}}{\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma}\ \varepsilon\text{-Store}$$

The ε-Store rule shows that when every variable in the differential store maps to **noc**, differential execution preserves the input differential store unchanged. This optimization is useful because when no variables have changed at all, we can completely bypass differential execution, avoiding differential computations entirely. The rule is fundamentally sound since a program operating on unchanged inputs must produce unchanged outputs. The premise $\sigma \vdash s \Rightarrow \sigma'$ in the rule establishes that s executes successfully in the standard semantics, which is necessary for proving the rule's admissibility.

Consider the following program:

```
x = y + z
w = v * 2
```

With the differential store $\Delta\sigma = \{x \mapsto \mathbf{noc}, y \mapsto \mathbf{noc}, z \mapsto \mathbf{noc}, w \mapsto \mathbf{noc}, v \mapsto \mathbf{noc}\}$, the rule lets us skip differential execution entirely.

To handle more realistic scenarios where a differential store might contain changes to many variables but a specific program fragment only references unchanged variables, we need to precisely characterize when a fragment is unaffected by changes. We do this through the No-Change relation.

▶ **Definition 5.2** (No-Change Relation). *The no-change relation for expressions $\Gamma, \Delta\sigma \vdash^0_e e$ and statements $\Gamma, \Delta\sigma \vdash^0_s s$ indicates that under typing context Γ and differential store $\Delta\sigma$, all variables referenced in e or s map to $\mathbf{noc}_\tau$ of their respective type τ in Γ. This relation is defined inductively by the rules in Figure 4.*

$$\frac{}{\Gamma, \Delta\sigma \vdash^0_e \ \mathbf{true}} \qquad \frac{}{\Gamma, \Delta\sigma \vdash^0_e \ \mathbf{false}} \qquad \frac{}{\Gamma, \Delta\sigma \vdash^0_e \ n} \qquad \frac{\tau = \Gamma\ x \quad \Delta\sigma(x) = \mathbf{noc}_\tau}{\Gamma, \Delta\sigma \vdash^0_e \ x}$$

$$\frac{\tau = \Gamma\ x \quad \Delta\sigma(x) = \mathbf{noc}_\tau \quad \Gamma, \Delta\sigma \vdash^0_e \ e}{\Gamma, \Delta\sigma \vdash^0_s \ x := e} \qquad \frac{\Gamma, \Delta\sigma \vdash^0_s \ s_1 \quad \Gamma, \Delta\sigma \vdash^0_s \ s_2}{\Gamma, \Delta\sigma \vdash^0_s \ s_1; s_2}$$

$$\frac{\Gamma, \Delta\sigma \vdash^0_e \ e \quad \Gamma, \Delta\sigma \vdash^0_s \ s_1 \quad \Gamma, \Delta\sigma \vdash^0_s \ s_2}{\Gamma, \Delta\sigma \vdash^0_s \ \mathbf{if}\ e\ s_1\ s_2} \qquad \frac{\Gamma, \Delta\sigma \vdash^0_e \ e \quad \Gamma, \Delta\sigma \vdash^0_s \ s}{\Gamma, \Delta\sigma \vdash^0_s \ \mathbf{repeat}\ e\ s}$$

Figure 4 Inference rules for expressions and statements experiencing no change under $\Delta\sigma$.

Using this relation, we formulate our second optimization rule as follows:

$$\frac{\Gamma, \Delta\sigma \vdash^0_s \ s \qquad \Gamma \vdash s}{\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma}\ \textsc{No-Change}$$

The No-Change rule generalizes the ε-Store rule: when no variables referenced in s are affected by changes ($\Gamma, \Delta\sigma \vdash^0_s \ s$), any differential execution of s must preserve the input differential store. This optimization is particularly valuable as it allows us to skip computations even when some variables in the program have changed, as long as they aren't referenced in the code being optimized.

Consider our earlier program fragment in a larger context:

```
x = y + z
w = v * 2
# ... later code using 'a' ...
```

With differential store $\Delta\sigma = \{x \mapsto \mathbf{noc}, y \mapsto \mathbf{noc}, z \mapsto \mathbf{noc}, w \mapsto \mathbf{noc}, v \mapsto \mathbf{noc}, a \mapsto \mathbf{inc}\ 5\}$, the No-Change rule lets us skip the first two assignments even though a changes elsewhere in the program. This local reasoning about variable usage avoids wasteful expression evaluation – we don't compute changes that would inevitably be **noc**.

5.2 Loop Optimization Rules

Loop constructs often dominate execution time in incremental computations. We present three optimization rules for loops, each handling a different scenario where full recomputation can be avoided. We start with loop idempotence, then present rules for handling changes to iteration counts.

$$\frac{\begin{array}{ll} & n \geq 0 \\ \Gamma \vdash \sigma & \sigma \vdash e \Rightarrow n \\ \sigma \vdash \Delta\sigma & \sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \mathbf{noc} \qquad \sigma \vdash s \Rightarrow \sigma \qquad \sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma \end{array}}{\sigma, \Delta\sigma \vdash \mathbf{repeat}\ e\ s \Rightarrow_\Delta \Delta\sigma}\ \textsc{Loop-Idemp}$$

The Loop-Idemp rule provides a significant optimization opportunity: when we can prove that a loop body preserves both the store and differential store in a single iteration and there is no change in the number of loop iterations, we can completely skip executing the remaining iterations. This is valuable because without this rule, we would need to execute each iteration even though we know the final result would be unchanged.

Consider a loop with operations that cancel out:

```
repeat n:
    x = (x * 1) + (y - y)    # x remains unchanged through identities
    y = (y + x) - x          # y remains unchanged through inverse operations
```

When $\Delta\sigma = \{x \mapsto \textbf{noc}, y \mapsto \textbf{noc}\}$, we can skip all iterations since each iteration preserves the store through these reversing computations. While this example is deliberately simple, the Loop-Idemp rule becomes particularly powerful with richer language features. For instance, in a language with arrays and objects, this rule would recognize loops that appear to modify data structures but actually preserve their state, allowing us to skip such loops entirely when we can prove that their operations are self-cancelling.

Our two most powerful loop optimizations address scenarios where the loop count changes, but the loop body remains unaffected by changes in the differential store. That is, all variables in the loop are assigned **noc** in the input differential store. This optimization reduces computational effort by focusing only on the additional iterations introduced by the change in the loop count, thereby avoiding redundant execution of the unchanged loop body.

$$\frac{\begin{array}{lll}\Gamma, \Delta\sigma \vdash^0_s\ s & & \sigma \vdash \textbf{repeat}\ e\ s \Rightarrow \sigma' \\ \Gamma \vdash s & \sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \textbf{inc}\ m & \sigma' \vdash \textbf{repeat}\ m\ s \Rightarrow \sigma''\end{array}}{\sigma, \Delta\sigma \vdash \textbf{repeat}\ e\ s \Rightarrow_\Delta (\sigma'' \oplus \Delta\sigma) \ominus \sigma'}\ \textsc{Loop-Incr}$$

The Loop-Incr rule handles increases in iteration count. When the loop count increases by m iterations and the loop body references no changed variables ($\Gamma, \Delta\sigma \vdash^0_s\ s$), we can optimize by doing the following.

- Reusing the result σ' of the original execution
- Computing only the additional m iterations from σ' to get σ''
- Computing the differential results as $(\sigma'' \oplus \Delta\sigma) \ominus \sigma'$

The differential output captures how the loop's output differs after running the additional iterations. With cached results from the original execution, we only compute the m new iterations: $\sigma' \vdash \textbf{repeat}\ m\ s \Rightarrow \sigma''$ – precisely the work that must be done. This optimization avoids redoing unchanged iterations while still performing the genuinely new computation. However, when any variable read in the loop body changes (for example, if an array being summed changes), we cannot apply this optimization. This restriction is necessary – changes to variables in the loop body would produce different results in every iteration, invalidating our assumption that earlier iterations remain unchanged and in process invalidating the cached result σ'.

Consider the following example where we accumulate a sum with a variable count:

```
sum = 0
i = 0
repeat n:  # n increases from 5 to 7
  sum = sum + i
  i = i + 1
```

With $\Delta\sigma = \{n \mapsto \textbf{inc}\ 2, \texttt{sum} \mapsto \textbf{noc}, i \mapsto \textbf{noc}\}$, both `sum` and `i` are unchanged in the input store, allowing us to safely reuse cached results. After the original 5 iterations, we compute just 2 more iterations with values we haven't seen before. If instead we had $\Delta\sigma = \{n \mapsto \textbf{inc}\ 2, i \mapsto \textbf{inc}\ 1\}$, the change to `i` would affect every iteration's computation, forcing us to recompute all iterations with the new initial value.

When all premises remain as in the increment case, but with $\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \textbf{dec}\ m$ replacing the increment, we obtain an elegant formulation for the decrement case as shown below.

$$\frac{\begin{array}{lll} \Gamma, \Delta\sigma \vdash^0_s s & \sigma \vdash e \Rightarrow n & \sigma \vdash \textbf{repeat}\ e\ s \Rightarrow \sigma' \\ \Gamma \vdash s & \sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \textbf{dec}\ m & \sigma \vdash \textbf{repeat}\ (n-m)\ s \Rightarrow \sigma'' \end{array}}{\sigma, \Delta\sigma \vdash \textbf{repeat}\ e\ s \Rightarrow_\Delta (\sigma'' \oplus \Delta\sigma) \ominus \sigma'} \textsc{Loop-Decr}$$

For decreased iteration counts, the Loop-Decr rule is even more efficient than the increment case. If we have cached the original computation, we have access to both the original output σ' and the intermediate store σ'' after the $(n-m)^{th}$ iteration. Then, we can compute the final result directly with just a patch and a diff operation, without any loop execution. This makes the decrement case even more efficient than the increment case, where we still needed to perform m additional iterations. Again, this optimization requires $\Gamma, \Delta\sigma \vdash^0_s s$, as changes to loop body variables would invalidate our cached states.

Using the same summation example but with n decreasing from 5 to 3 and $\Delta\sigma = \{n \mapsto \textbf{dec}\ 2, \texttt{sum} \mapsto \textbf{noc}, i \mapsto \textbf{noc}\}$, we don't need to compute anything new from the normal execution. We can directly use our cached state after 3 iterations to compute the change.

In both the increment and the decrement case, we see that caching the original computation is important for efficiency. We discuss various strategies for caching computations in Section 6.1.

5.3 Branch Switching Rules

One of the main challenges in differential execution is handling branch switches efficiently, as we typically need to execute both branches and compare their stores. Consider a common pattern in imperative programs, where an if-statement contains only assignments to the same variable in both branches:

```
if (y) {
    x = z + 1
} else {
    x = z - 1
}
```

With branch switching, the standard differential semantics would compute the result by diffing the resulting stores corresponding to the two different branches that are taken. However, since only variable x changes between branches, we can update just one entry instead of the entire store. This targeted update of x based on the expressions' difference provides orders of magnitude in speedup over store-wide diffing, especially pronounced for large stores. We develop two optimizations here based on this insight.

$$\frac{\begin{array}{lll} & & \Gamma \vdash \textbf{if}\ e\ (x := e_1)\ (x := e_2) \\ & \sigma \vdash e \Rightarrow \textbf{true} & \sigma \vdash e_1 \Rightarrow v_1 \\ \Gamma \vdash \sigma & \sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \Delta v & \sigma \oplus \Delta\sigma \vdash e_2 \Rightarrow v_2 \\ \sigma \vdash \Delta\sigma & \textbf{true} \oplus \Delta v = \textbf{false} & \sigma, \Delta\sigma \vdash \textbf{if}\ e\ (x := e_1)\ (x := e_2) \Rightarrow_\Delta \Delta\sigma' \end{array}}{\Delta\sigma' \equiv [x \mapsto v_2 \ominus v_1]\Delta\sigma} \textsc{If-T-F}$$

The If-T-F rule handles the case where a condition switches from true to false. The rule requires both stores to be well-typed and the conditional statement itself to be well-typed. When the conditional expression e switches from true to false and both branches are assignments to the same variable x, we can directly compute the change to x as $v_2 \ominus v_1$, where v_1 is e_1's value in the original store and v_2 is e_2's value in the patched store.

For our example, suppose y was initially **true** and we have $\Delta\sigma = \{y \mapsto \textbf{neg}, x \mapsto \textbf{noc}, z \mapsto \textbf{noc}\}$ causing a branch switch. Instead of recomputing the entire store, we only need to update the entry corresponding to x as $(z-1) \ominus (z+1) = \textbf{dec}\ 2$. However, if branches modified different variables (e.g., `x = z + 1` vs `y = z - 1`), this optimization cannot apply – the changes aren't localized to a single variable.

$$\frac{\begin{array}{lll} & & \Gamma \vdash \textbf{if}\ e\ (x := e_1)\ (x := e_2) \\ & \sigma \vdash e \Rightarrow \textbf{false} & \sigma \vdash e_2 \Rightarrow v_2 \\ \Gamma \vdash \sigma & \sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \Delta v & \sigma \oplus \Delta\sigma \vdash e_1 \Rightarrow v_1 \\ \sigma \vdash \Delta\sigma & \textbf{false} \oplus \Delta v = \textbf{true} & \sigma, \Delta\sigma \vdash \textbf{if}\ e\ (x := e_1)\ (x := e_2) \Rightarrow_\Delta \Delta\sigma' \end{array}}{\Delta\sigma' \equiv [x \mapsto v_1 \ominus v_2]\Delta\sigma}\ \textsc{If-F-T}$$

The If-F-T rule handles the symmetric case where the condition switches from false to true. Its structure mirrors the true-to-false case, but computes $v_1 \ominus v_2$ since we are switching to the first branch.

This optimization significantly improves performance when stores are large, but changes are localized. In our Bellman-Ford implementation (Figure 5), this optimization avoids diffing the entire shortest-path table on each branch switch within the inner loop's conditional, leading to substantial speedups as shown in Section 7.

6 Implementing a Differential Interpreter

In this section, we describe the implementation of a differential interpreter based on the differential semantics. The implementation is written in Scala 3, is open source and available at `https://gitlab.rlp.net/plmz/artifacts/autoinc-interp-implementation-ecoop25`.

6.1 Caching to avoid Re-Computation

The differential semantics requires access to previous execution states when handling control flow constructs. Consider an if statement **if** $e\ s_1\ s_2$ where branch switching occurs, that is, when the condition's value changes from true to false or vice versa. We reiterate the relevant rule D-IF$_{\text{tf}}$ from Figure 3, highlighting in gray the computations that can be cached from the previous execution:

$$\frac{\sigma, \Delta\sigma \vdash e \Rightarrow_\Delta \textbf{neg} \qquad (\,\sigma \vdash e \Rightarrow \textbf{true}\,) \qquad \sigma \oplus \Delta\sigma \vdash s_2 \Rightarrow \sigma_2 \qquad (\,\sigma \vdash s_1 \Rightarrow \sigma_1\,)}{\sigma, \Delta\sigma \vdash \textbf{if}\ e\ s_1\ s_2 \Rightarrow_\Delta \sigma_2 \ominus \sigma_1}\ \text{D-IF}_{\text{tf}}$$

Applying this rule requires performing new computations while accessing cached results from the previous execution. Specifically, we must differentially evaluate the condition to get **neg** and execute the new branch s_2, while we can reuse the original condition evaluation result and the result of executing s_1. A similar requirement exists for repeat statements, which need stores from previous iterations to enable differential execution. This dependency on previous states explains why our differential reduction relation $\sigma, \Delta\sigma \vdash s \Rightarrow_\Delta \Delta\sigma'$ takes the previous store σ as input.

Re-computing previous results and propagating old states throughout differential execution incurs significant performance overhead. To address this, we develop an *initializing interpreter* that caches execution states. However, uniquely identifying cached states requires more than just statement identifiers, particularly for loops. Consider **repeat** 5 s where s executes five times – each iteration operates on a different store and thus requires its own cached state.

We solve this through path-sensitive identifiers that precisely track loop nesting structure. A path P starts at root R (nesting level 0) and records each enclosing loop's iteration count. For example, path $R, 2, 1$ indicates execution within the first iteration of an inner loop, nested within the second iteration of an outer loop. Our cache maps each execution point to its corresponding program state: $\textbf{cache} : \textbf{UID} \times \textbf{P} \mapsto \textbf{S}$, where UID uniquely identifies statements in the program, P captures the loop nesting context through iteration counts, and S represents the program state we need to cache.

Our caching strategy for conditional statements preserves three key pieces: the store before evaluating the condition, the condition's evaluated result, and the store after executing the chosen branch. This enables direct access to previously computed states, eliminating redundant recomputation during differential execution.

For repeat statements, we implement two strategies: a basic strategy that caches the initial store, iteration count, and final store, and an enhanced strategy that additionally caches intermediate states after each iteration. The enhanced strategy enables efficient implementation of the decrement optimization (Section 5.2) by providing direct access to any intermediate store from the original execution, eliminating the need for additional computation.

6.2 Additional Language-Features
