Pop(). We obtain the index j of the leftmost 1-bit of S_M in constant time using bitstring operations. Per definition, the minimum key of H is in $B[j]$. We perform the Peak operation on both heaps in $B[j]$. For the heap F containing the minimum key, we do F.Pop() in $O(1 + \log 2^j) = O(j)$ time to return the element $x_i \in H$ with the minimum key. Finally, we update $M[j]$ and S_M. We update $M[j]$ in constant time and iterate from j to 1. For each iteration ℓ, let $k > \ell$ be the minimum index where $S_M[k] = 1$. We obtain k in constant time using bitstring operations and update $S_M[\ell]$ by comparing $M[\ell]$ to $M[k]$. Thus, this update takes $O(j)$ time. By Invariant 1, $\log(b_i - a_i) \in O(j)$ and thus the H.Pop() takes $O(1 + \log(b_i - a_i))$ amortized time. ◀

▶ **Corollary 6.** *Algorithm 1 can be adapted to use* $O(m + \sum_{x_i \in V \setminus \{s\}} (1 + \log(b_i - a_i)))$ *time.*

4 Universal Optimality

We show that categorizing the running time of Dijkstra's algorithm by timestamps substantially simplifies its proof for universal optimality. For a given graph $G = (V, E)$ and a designated source vertex s, we define a *linearization* L of (G, s) as any permutation of $V \setminus \{s\}$ such that there exists some choice of edge weights $w' \in \mathbb{W}(G)$ where L is the solution to the single-source-shortest path problem on (G, s, w'). Let $\ell(G, s)$ denote the number of distinct linearizations of (G, s). Observe that $\Omega(\log \ell(G, s))$ is a comparison-based universal lower bound for the single-source shortest path problem. Indeed, any comparison-based algorithm has a corresponding binary decision tree with leaves representing possible outputs. With $\Omega(\ell(G, s))$ distinct outputs, there must exist a root-to-leaf path of length $\Omega(\log \ell(G, s))$.

Our approach. We fix the input $(G = (V, E), s, w)$ and execute Dijkstra's algorithm, which defines a set of n timestamp intervals $\{[a_i, b_i]\}_{i \in [n]}$. Each interval $[a_i, b_i]$ has a minimum size of 1 and corresponds to a unique vertex $x_i \in V \setminus \{s\}$. Dijkstra's algorithm operates in $O(m + \sum_{x_i \in V \setminus \{s\}} (1 + \log(b_i - a_i)))$ time. Since any algorithm must spend $\Omega(n + m)$ time to read the input, it remains to show that $\sum_{x_i \in V \setminus \{s\}} (1 + \log(b_i - a_i)) \in \Omega(n + \log \ell(G, s))$.

▶ **Lemma 7.** *For each vertex $x_i \in V \setminus \{s\}$, choose a real value $r_i \in [a_i, b_i]$. If all r_i are distinct, then the sequence L, which orders all x_i by r_i, is a linearization of (G, s).*

Proof. Consider the initial execution of Dijkstra's algorithm on (G, s, w). For each vertex $x_i \in V \setminus \{s\}$, there is a unique edge (u, x_i) that, upon inspection, pushes the element x_i onto the heap H. The set of these edges forms a spanning tree T rooted at s.

Denote by $\text{rank}(r_i)$ the rank of r_i in the ordered sequence L. We construct a new integer edge weighting w' such that running Dijkstra's algorithm on (G, s, w') outputs L. We set $w'(e) = \infty$ for all edges $e \in E \setminus T$. We then traverse T in a breath-first manner. For each edge $(x_j, x_i) \in T$, we observe that in our original run of Dijkstra's algorithm, the algorithm popped the vertex x_j before it pushed the vertex x_i onto the heap. It follows that for the intervals $\{[a_j, b_j], [a_i, b_i]\}$, the value $b_j \leq a_i$. Since $r_j \in [a_j, b_j]$, $r_i \in [a_i, b_i]$, and $r_j \neq r_i$ we may conclude that $\text{rank}(r_i) > (r_j)$. We assign to each edge $(x_j, x_i) \in T$ the positive edge weight $w'((x_j, x_i)) = \text{rank}(r_i) - \text{rank}(r_j)$. It follows that the distance in (G, E, w') from s to any vertex x_i is equal to $\text{rank}(r_i)$ and so Dijkstra's algorithm on (G, s, w') outputs L. ◀

What remains is to show that the number of ways to select distinct $r_i \in [a_i, b_i]$, correlates with the size of the timestamp intervals. This result was first demonstrated by Cardinal, Fiorini, Joret, Jungers, and Munro [1, the first 2 paragraphs of page 8 of the ArXiV version]. It was later paraphrased in Lemma 4.3 in [5].

▶ **Lemma 8** (Originally in [1], paraphrased by Lemma 4.3 in [5]). *Let $\{[a_i, b_i]\}$ be a set of n integer intervals where each interval has size at least 1. Let Z be the set of linear orders realizable by real numbers $r_i \in [a_i, b_i]$. Then $\sum_{i\in[n]} \log(b_i - a_i) \in O(n + \log|Z|)$.*

Proof. To illustrate the simplicity of this lemma, we quote the proof in [5]: For each i between 1 and n inclusive, choose a real number r_i uniformly at random from the real interval $[0, n]$, independently for each i. With probability 1, the r_i are distinct. Let L be the permutation of $[n]$ obtained by sorting $[n]$ by r_i. Each possible permutation is equally likely. If each $r_i \in [a_i, b_i]$ then L is in Z. The probability of this happening is $\prod_{i=1}^{k}(b_i - a_i)/n$. It follows that $|Z| \geq n! \cdot \prod_{i=1}^{n}(b_i - a_i)/n$. Taking logarithms gives $\log|Z| \geq \sum_{i=1}^{n} \log(b_i - a_i) + \log n! - n\log n$. By Stirling's approximation of the factorial, $\log n! \geq n\log n - n\log e$. The lemma follows. ◀

It follows that we can recreate the main theorem from [6]:

▶ **Theorem 9** (Theorem 1.2 in [6]). *Dijkstra's algorithm, when using a sufficiently efficient heap data structure, has a universally optimal running time.*

Proof. The running time of Dijkstra's algorithm with the input (G, s, w) is $O(m)$ plus the time needed for push and pop operations. With a timestamp-optimal heap, by Corollary 6, the algorithm thus takes $O(m + \sum_{x_i \in V\setminus\{s\}} (1 + \log(b_i - a_i)))$ total time. By Lemma 8, the total running time is then $O(m + n + \log|Z|)$, where $|Z|$ denotes the number of distinct linear orders created by choosing distinct real values $r_i \in [a_i, b_i]$. By Lemma 7: $|Z| \leq \ell(G, s)$, and so Dijkstra's algorithm with any timestamp-optimal heap runs in $O(m + n + \log \ell(G, s))$ time. Conversely, any algorithm that solves SSSP needs $\Omega(m + n)$ time to read the input, and $\Omega(\log \ell(G, s))$ is an information-theoretical universal lower bound. ◀

5 Conclusion

We study Dijkstra's algorithm for the single-source-shortest path problem and give an alternative proof that Dijkstra's algorithm is universally optimal. We consider our construction to be considerably simpler than the one in [6]. We find time stamps easier to define than the working set size of an element, and regard our timestamp optimal heap to be simpler in both its construction and analysis than the heap used in [5]. As an added benefit, we only rely on Fibonacci trees and bitstring manipulation and no involved data structures (e.g., the *fusion trees* used in [6]). We regard Section 4 as our main contribution, as it gives a very concise proof of universal optimality. We understand that algorithmic simplicity is subjective, and we leave it to the reader to judge the simplicity of our approach. We note, however, that proofs are unarguably shorter since the full version of [6] counts over 50 pages. We observe that both our paper and [6] must assume a word RAM and we consider it an interesting open problem to show universal optimality on a pointer machine.

Finally, we note that our data structure is equally general to [6]. In the full version, we show that our data structure, just as the one in [6], is also universally optimal if algorithmic running time is exclusively measured by the number of edge weight comparisons that the algorithm performs. While our proof is indeed new, different, and perhaps simpler than the previous one, it is not self-contained; for this reason, we relegate it to our full version.

Color Distance Oracles and Snippets: Separation Between Exact and Approximate Solutions

Noam Horowicz

Tsvi Kopelowitz
Bar-Ilan University, Ramat Gan, Israel

Abstract

In the *snippets* problem, the goal is to preprocess a text T so that given two pattern queries, P_1 and P_2, one can quickly locate the occurrences of the two patterns in T that are closest to each other, or report the distance between these occurrences. Kopelowitz and Krauthgamer [CPM2016] showed upper bound tradeoffs and conditional lower bounds tradeoffs for the snippets problem, by utilizing connections between the snippets problem and the problem of constructing a color distance oracle (CDO), which is a data structure that preprocess a set of points with associated colors so that given two colors c and c' one can quickly find the (distance between the) closest pair of points where one has color c and the other has color c'. However, the existing upper bound and lower bound curves are not tight.

Inspired by recent advances by Kopelowitz and Vassilevska-Williams [ICALP2020] regarding tradeoff curves for Set-disjointness data structures, in this paper we introduce new conditionally optimal algorithms for a $(1+\varepsilon)$ approximation version of the snippets problem and a $(1+\varepsilon)$ approximation version of the CDO problem, by applying fast matrix multiplication. For example, for CDO on n points in an array, if the preprocessing time is $\tilde{O}(n^a)$ and the query time is $\tilde{O}(n^b)$ then, assuming that $\omega = 2$ (where ω is the exponent of n in the runtime of the fastest matrix multiplication algorithm on two squared matrices of size $n \times n$), we show that approximate CDO can be solved with the following tradeoff

$$\begin{cases} a + 2b = 2 & \text{if } 0 \le b \le \frac{1}{3} \\ 2a + b = 3 & \text{if } \frac{1}{3} \le b \le 1. \end{cases}$$

Moreover, we prove that for exact CDO on points in an array, the algorithm of Kopelowitz and Krauthgamer [CPM2016], which obtains a tradeoff of $a + b = 2$, is essentially optimal assuming that the *strong all-pairs shortest paths* hypothesis holds for randomized algorithms. Thus, we demonstrate that the exact version of CDO is strictly harder than the approximate version. Moreover, this separation carries over to the snippets problem.

1 Introduction

In the *snippets* problem, introduced by Kopelowitz and Krauthgamer [17], the goal is to preprocess a text T so that given two pattern queries, P_1 and P_2, one can quickly locate the locations of the two patterns in T that are closest to each other, or report the distance between these locations. The snippets problem is motivated by many common text indexing applications, such as searching a corpus of documents for two query keywords. Often, the relevance of a document to the query is measured by the proximity of the two keywords within the document. The term *snippet* is derived from search engines often providing each result with a snippet of text from the document with the two keywords close to each other.

Kopelowitz and Krauthgamer [17] designed a tradeoff algorithm for the snippets problem based on a connection to a problem on colored points in metric spaces, which we define next.

Colored points and color distances

Let $\mathbf{M}$ be a metric space with distance function $d(\cdot,\cdot)$. Let $S \subseteq \mathbf{M}$ be a set of points where $|S| = n$. Let $\mathcal{C}$ be a set of *colors*. For sake of convenience we assume that $\mathcal{C} = [|\mathcal{C}|]$. Each point $p \in S$ has an associated color $c_p \in \mathcal{C}$. For a color $c \in \mathcal{C}$, let $P_S(c) = \{p \in S | c_p = c\}$. When S is clear from context we abuse notation and denote $P(c) = P_S(c)$.

For sets of points $A, B \subset \mathbf{M}$ and a point $p \in M$, let $d(p, A) = \min_{p' \in A}\{d(p, p')\}$ and let $d(A, B) = \min_{p' \in A}\{d(p', B)\} = \min_{p' \in A, \hat{p} \in B}\{d(p', \hat{p})\}$. We extend the definition of d to inputs of colors as follows. For colors $c, c' \in \mathcal{C}$ and point $p \in \mathbf{M}$, let $d(p, c) = d(p, P(c))$ and let $\delta_{c,c'} = d(c, c') = d(P(c), P(c'))$. We say that $\delta_{c,c'}$ is the *color distance* between c and c'. A natural problem is to construct a *color distance oracle* (CDO), which is defined as follows.

▶ **Problem 1** (The Color Distance Oracle (CDO) problem [17]). *Given a set $S \subseteq \mathbf{M}$ of n colored points with colors from $\mathcal{C}$, preprocess S to support the following query: given $c, c' \in \mathcal{C}$, return $\delta_{c,c'}$.*

In this paper we consider metrics defined by locations in an array of size s, and so the metric is the set[1] $[s]$, and the distance function of two points p and q is $d(p, q) = |p - q|$.

Multi-colored points and color hierarchies

A natural generalization of a colored set is to allow each $p \in S$ to be associated with a nonempty set of colors $c(p) \subseteq \mathcal{C}$, and in such a case S is said to be *multi-colored*. This version of the CDO problem is called the *multi-color distance oracle* (MCDO) problem. In general, representing $c(p)$ costs $\Theta(|c(p)|)$ space by explicitly listing all colors in $c(p)$. Thus, the input size is $n = \sum_{p \in S} |c(p)|$.

Nevertheless, there are interesting cases in which the lists of colors for each point are not required to be given explicitly. One such example, which we focus on, is when for every two colors $c, c' \in \mathcal{C}$, either one of the sets $P(c)$ and $P(c')$ contains the other, or the two sets are disjoint. In such a case, we say that $\mathcal{C}$ has a *color hierarchy* with respect to S (a formal terminology is that $\{P(c)\}_{c \in \mathcal{C}}$ is a laminar family), represented by a rooted forest (i.e., each tree has a root) T_S of size $O(|\mathcal{C}|)$. Each color c is associated with a vertex u_c in T_S, such that the descendants of u_c are exactly all the vertices $u_{c'}$ whose color c' satisfies $P(c') \subseteq P(c)$. We convert the forest T_S to a rooted tree by adding a dummy root vertex and making the dummy root the parent of all of the roots of the trees in the forest.

[1] Throughout this paper for a positive integer k we denote $[k] = \{1, 2, , \ldots, k\}$.

With the aid of T_S, a multi-colored set S that admits a color hierarchy can be represented using only $O(n + |\mathcal{C}|)$ machine words, because it suffices to store T_S and associate with each point p just one color c (the color with the lowest corresponding vertex in T_S); the other colors of p are implicit from T_S (the colors on the path from u_c to the root of T_S). Notice that $|\mathcal{C}| > n$ implies that there are at least two colors with the same point set. Thus, we make the simplifying assumption that all colors have different point sets[2], and so the input size is $O(n)$.

Thus, a natural extension of Problem 1 is the following.

▶ **Problem 2** (The Multi-Color Distance Oracle with a Color Hierarchy (MCDOCH) problem [17]). *Given a set $S \subseteq \mathbf{M}$ of n multi-colored points with colors from $\mathcal{C}$ which form a color hierarchy with respect to S, preprocess S to support the following query: given $c, c' \in \mathcal{C}$, return $\delta_{c,c'}$.*

Let a and b be real numbers such that the preprocessing and query times of a MCDOCH algorithm are $\tilde{O}(n^a)$[3] and $\tilde{O}(n^b)$, respectively. A tradeoff algorithm for the MCDOCH problem was presented in [17], where given parameter $1 \leq \tau \leq n$, the query time is $\tilde{O}(n^b) = \tilde{O}(\tau)$ and the preprocessing time is $\tilde{O}(n^a) = \tilde{O}(n^2/\tau) = \tilde{O}(n^{2-b})$. When ignoring sub-polynomial factors, this upper bound tradeoff is given by $a + b = 2$ where $0 \leq b \leq 1$ and $1 \leq a \leq 2$. Notice that the same tradeoff applies to the CDO problem.

In addition to the tradeoff algorithms, [17] proved a 3SUM based conditional lower bound (CLB) tradeoff[4] of $a + 2b \geq 2$ for the CDO problem (and hence for the MCDOCH problem), even when $\mathbf{M}$ is defined by locations in an array. Their CLB holds also for approximate versions of the CDO problem (see Theorem 8 in [17]), where for a fixed $\alpha > 1$, the answer to a color distance query between c and c' is required to be between $\delta_{c,c'}$ and $\alpha \cdot \delta_{c,c'}$.

Solving the Snippets problem

By designing a reduction from the snippets problem to the MCDOCH problem, [17] were able to design an algorithm for the snippets problem with essentially the same tradeoff: for a chosen parameter $1 \leq \tau \leq |T|$ their snippets algorithm uses $\tilde{O}(|T|^2/\tau)$ preprocessing time and answers queries in $\tilde{O}(|P_1| + |P_2| + \tau)$ time. The main idea in the reduction is to construct the suffix tree of T, assign a color to each vertex in the suffix tree, and for each leaf ℓ in the suffix tree, the corresponding location in T is assigned all of the colors on the path from ℓ to the suffix tree root. It is straightforward to see that the colors define a hierarchy and that T_S is exactly the suffix tree.

A complexity gap

The upper bound curve of $a+b = 2$ and the CLB tradeoff of $a+2b \geq 2$ form a complexity gap for the snippets and (approximate) CDO problems, which was left open by [17]. Moreover, based on the combinatorial Boolean Matrix Multiplication (BMM) hypothesis, [17, Theorem 8] implies that any algorithm that beats the $a + b = 2$ curve, even for approximate versions, must use non-combinatorial techniques, such as fast matrix multiplication (FMM) algorithms.

We remark that the CLB tradeoff given in [17] is based on a reduction from a SetDisjointness problem to the (approximate) CDO problem, and at the time [17] was published, the SetDisjointness problem was known to exhibit the same upper bound tradeoff and 3SUM

[2] If we happen to have several colors with the same point set, we ignore all of them but one during preprocessing, and use a straightforward mapping from the original coloring to the reduced coloring during query time.

[3] Throughout this paper we use the notation $\tilde{O}()$ to suppress sub-polynomial factors.

[4] The CLB tradeoff stated here is straightforward to derive from the statement of Theorem 4 in [17].

based CLB tradeoff [18]. However, recently Kopelowitz and Vassilevska-Williams [19] closed this complexity gap by, among other ideas, using FMM techniques. Thus, a natural question to ask is whether FMM can assist in obtaining improved algorithms for CDO problems.

Our results

We close the complexity gap for the $(1+\varepsilon)$ approximation versions of CDO and $MCDOCH$, where $\mathbf{M}$ is defined by locations in an array. Formally, the problems are defined as follows.

▶ **Problem 3** (The $(1+\varepsilon)$-Approximate Color Distance Oracle (ACDO) problem on an array)**.** *Let $\mathbf{M}$ be a metric defined by locations in an array of size n. Given a set $S \subset \mathbf{M}$ of n colored points with colors from $\mathcal{C}$ and a fixed real $0 \leq \varepsilon \leq 1$, preprocess S to support the following query: given two colors $c, c' \in \mathcal{C}$, return a value $\hat{\delta}$ such that $\delta_{c,c'} \leq \hat{\delta} \leq (1+\varepsilon)\delta_{c,c'}$.*

▶ **Problem 4** (The $(1+\varepsilon)$-Approximate Multi-Color Distance Oracle problem with a Color Hierarchy (AMCDOCH) on an array)**.** *Let $\mathbf{M}$ be a metric defined by locations in an array of size $\Theta(n)$. Given a set $S \subseteq \mathbf{M}$ of n multi-colored points with colors from $\mathcal{C}$ which form a color hierarchy with respect to S, and a fixed real $0 \leq \varepsilon \leq 1$, preprocess S to support the following query: given two colors $c, c' \in \mathcal{C}$, return a value $\hat{\delta}$ such that $\delta_{c,c'} \leq \hat{\delta} \leq (1+\varepsilon)\delta_{c,c'}$.*

Our first main result is a new tradeoff algorithm for ACDO, which is stated by the following theorem. Notice that the time complexities presented are dependent on $\omega \geq 2$, which is the exponent of n in the runtime of the fastest FMM algorithm on two squared matrices of size $n \times n$. The currently best upper bound on ω is $\omega < 2.371339$ given by [2]. However, for clarity, we choose to express our tradeoffs in terms of ω. We remark that ACDO is a special case of AMCDOCH, and so Theorem 6 implies Theorem 5. However, Theorem 5 is used in the proof of Theorem 6, so we explicitly state both theorems.

▶ **Theorem 5.** *For any real $0 \leq b \leq 1$, there exists an ACDO algorithm with preprocessing time $\tilde{O}(n^a)$ and query time $\tilde{O}(n^b)$ where*

$$\begin{cases} a + \dfrac{2}{\omega-1}b = 2 & \text{if } 0 \leq b \leq \dfrac{\omega-1}{\omega+1} \\ \dfrac{2}{\omega-1}a + b = \dfrac{\omega+1}{\omega-1} & \text{if } \dfrac{\omega-1}{\omega+1} \leq b \leq 1. \end{cases}$$

▶ **Theorem 6.** *For any real $0 \leq b \leq 1$, there exists an AMCDOCH algorithm with preprocessing time $\tilde{O}(n^a)$ and query time $\tilde{O}(n^b)$ where*

$$\begin{cases} a + \dfrac{2}{\omega-1}b = 2 & \text{if } 0 \leq b \leq \dfrac{\omega-1}{\omega+1} \\ \dfrac{2}{\omega-1}a + b = \dfrac{\omega+1}{\omega-1} & \text{if } \dfrac{\omega-1}{\omega+1} \leq b \leq 1. \end{cases}$$

Combining Theorem 6 with the reduction of the snippets problem to the MCDOCH problem given in [17], we obtain the following tradeoff for a $1+\varepsilon$ approximation version of the snippets problem.

▶ **Theorem 7.** *For any fixed $0 < \varepsilon \leq 1$, and $1 \leq a \leq 2$, there exists an algorithm that preprocesses a text T in $\tilde{O}(|T|^a)$ time such that given two pattern strings P_1 and P_2 where the distance between the closest occurrences of the two patterns in T is δ, the algorithm returns a value $\hat{\delta}$ such that $\delta \leq \hat{\delta} \leq (1+\varepsilon)\delta$ in $\tilde{O}(|P_1| + |P_2| + |T|^b)$ time, where*

$$\begin{cases} a + \dfrac{2}{\omega-1}b = 2 & \text{if } 0 \leq b \leq \dfrac{\omega-1}{\omega+1} \\ \dfrac{2}{\omega-1}a + b = \dfrac{\omega+1}{\omega-1} & \text{if } \dfrac{\omega-1}{\omega+1} \leq b \leq 1. \end{cases}$$

We remark that it is straightforward to adapt our ACDO and AMCDOCH algorithms (and hence our new approximate snippets algorithm) to return the two points (one of each color) that define the distance being returned (or the locations of the two patterns in the approximate snippets problem). For details, see the full version [12].

A complexity separation between exact and approximate solutions

We remark that by combining the reduction given in [17, Theorem 8] from SetDisjointness to the CDO problem with the CLBs for SetDisjointness given in [19, Theorem 6] for the case of $\omega = 2$ (which some researchers believe should be obtainable), Theorems 5, 6 and 7 are all conditionally optimal[5] (up to subpolynomial factors). A natural question to ask is whether one can design exact algorithms with the same tradeoff bounds. We provide evidence that this is not possible, based on a *strong* version of the popular all-pairs shortest paths (APSP) conjecture [7], thereby demonstrating a separation between CDO and ACDO.

The Strong-APSP hypothesis, introduced by Chan, Vassilevska-Williams and Xu [7], states that for a graph with $\hat{n}$ vertices[6], even if all of the edge weights are in[7] $[\hat{n}]$, APSP still does not have a truly subcubic algorithm. A closely related problem to APSP is the $(min, +)$-*matrix product* problem, where the input is two $\hat{n}$ by $\hat{n}$ matrices $A = \{a_{i,j}\}$ and $B = \{b_{i,j}\}$, and the output is the matrix $D = \{d_{i,j}\}$ where $d_{i,j} = \min_{1 \leq k \leq \hat{n}}(a_{i,k} + b_{k,j})$. Shoshan and Zwick [24] showed that solving APSP with weights $[M]$ is equivalent (in the sense of having the same runtime) to solving $(min, +)$-matrix product with entries in $[O(M)]$. Thus, the Strong-APSP hypothesis implies that there is no truly subcubic time $(min, +)$-matrix product algorithm even when all of the entries are in $[\hat{n}]$.

By reducing $(min, +)$-matrix product with entries in $[\hat{n}]$ to MCDO, we are able to prove the following CLB in Section 6, which matches the upper bound given in [17].

▶ **Theorem 8.** *Assuming the Strong-APSP conjecture, any algorithm for MCDO on n points in an array of size $O(n)$ with $\tilde{O}(n^a)$ preprocessing time and $\tilde{O}(n^b)$ query time, respectively, must obey $a + b \geq 2$.*

Moreover, we are able to leverage the ideas used in the proof of Theorem 8 to reduce $(min, +)$-matrix product with entries in $[\hat{n}]$ to CDO via a randomized reduction, thereby obtaining a CLB under the assumption that the Strong-APSP hypothesis holds even for randomized algorithms (either in expectation or with high probability).

▶ **Theorem 9.** *Assuming the Strong-APSP hypothesis for randomized algorithms, any algorithm for CDO on n points in an array of size $O(n)$ with $\tilde{O}(n^a)$ preprocessing time and $\tilde{O}(n^b)$ query time, respectively, must obey $a + b \geq 2$.*

The proof of Theorem 9 is based on the proof of Theorem 8, combined with probabilistic techniques in order to create instances that are not multi-colored. Due to space considerations, the proof is given in the full version [12]

[5] For Theorems 5 and 6, the optimality follows directly from applying [17, Theorem 8] and [19, Theorem 6]. For Theorem 7, the optimality follows since an approximate solution for the snippets problem can be used to solve ACDO on an array as follows: treat each color as a character, and then the array becomes a string. Preprocess the string using the snippets algorithm, so that given an ACDO query on two colors $c, \hat{c}$, query the snippets algorithm with patterns $P = c$ and $\hat{P} = \hat{c}$. Thus, the ACDO lower bound applies to approximate snippets.

[6] We use $\hat{n}$ to differentiate from $n = |S|$ in the various CDO problems.

[7] Actually, in [7] the weights are bounded by $\hat{n}^{3-\omega}$, but since $\omega \geq 2$ we can bound the weights by $\hat{n}$.

Theorem 9 combined with Theorem 5 implies that the exact version of CDO is strictly harder than the approximate version. Moreover, we remark that the CLBs for CDO apply also to the snippets problem, since the special case of $\mathbf{M}$ defined by locations in an array is captured by the snippets problem when P_1 and P_2 are each a single character. Thus, the CLB of Theorem 9 applies also to the snippets problem, and so the exact version of the snippets problem is also strictly harder than the approximate version.

Additional Related Work

A problem closely related to the CDO is the (approximate) vertex-labeled distance oracles for graphs (VLDO) problem, where the goal is to preprocess a colored graph G with n vertices, so that given a vertex query v and a color c, one can quickly return (an approximation of) $d(v, c)$. Hermelin, Levy, Weimann, and Yuster [11] introduced the VLDO problem and designed a solution using $O(kn^{1+1/k})$ expected space, with stretch factor $4k-5$ and $O(k)$ query time. They also showed how to reduce the space usage to $O(kN^{1/k})$ but the stretch factor is exponential in $2k-21$. Chechik [8] later showed how to lower the stretch back to $4k-5$. For planar graphs, Evald, Fredslund-Hansen, and Wulff-Nilsen [10] designed a near-optimal exact tradeoff using $n^{1+o(1)}$ space with $\tilde{O}(1)$ query time, or $\tilde{O}(n)$ space with $n^{o(1)}$ query time. Li, Ma, and Ning [21] designed a $1+\varepsilon$ approximation for planar graphs.

2 Preliminaries and Algorithmic Overview

Let $[n] = \{1, 2, \ldots, n\}$. Let $S \subset \mathbb{Z}$ be a set of n integers. Let $\max(S)$ be the largest integer in S and let $\min(S)$ be the smallest integer in S. For integers $i, j \in [n]$ where $i < j$, let $S[i, j] = \{p \in S : i \leq p \leq j\}$.

Our algorithms make use of the following Nearest Neighbor Search (NNS) data structures.

▶ **Problem 10** (The Nearest Neighbour Search problem [1, 4, 16, 25]). *Given a set $S \subseteq \mathbf{M}$ of size n, preprocess S to support the following query: given an integer p, return* $\operatorname{argmin}_{p' \in S}\{d(p, p')\}$.

▶ **Problem 11** (The Range Nearest Neighbour Search (RNNS) problem [5, 6, 9, 14, 15, 20, 22, 23]). *Given a set S of n integers, preprocess S to support the following query: given $i, j \in [n]$ and an integer p, return* $\operatorname{argmin}_{p' \in S[i,j]}\{d(p, p')\}$.

2.1 Algorithmic Overview

Generic (Approximate) CDO Algorithm

Our algorithm for ACDO is based on a generic algorithm whose structure follows the structure of the algorithm in [17] for the exact CDO problem. The generic algorithm is a classic heavy-light algorithm; our algorithms are a new *implementation* of the generic algorithm.

For an integer parameter $0 \leq \tau \leq n$, a color $c \in \mathcal{C}$ is said to be *heavy* if $\left|P(c)\right| \geq \tau$ and *light* otherwise. Let $\mathcal{H} = \{h_1, h_2, \ldots, h_{|\mathcal{H}|}\}$ be the set of heavy colors, and let $\mathcal{L}$ be the set of light colors. Notice that $|\mathcal{H}| \leq \frac{n}{\tau}$. In the preprocessing phase, for each color $c \in \mathcal{C}$, the algorithm stores $P(c)$ in an NNS data structure, denoted by NNS_c. In addition, the algorithm pre-computes a matrix $E^* = \{e^*_{i,j}\}$ of size $|\mathcal{H}| \times |\mathcal{H}|$, such that $\delta_{h_i,h_j} \leq e^*_{i,j} \leq (1+\varepsilon)\delta_{h_i,h_j}$. An ACDO query on $c, c' \in \mathcal{C}$ is processed as follows. If both $c, c' \in \mathcal{H}$, then, without loss of generality, $c = h_i$ and $c' = h_j$. In such a case the algorithm returns $e^*_{i,j}$, which is a $(1+\varepsilon)$ approximation of δ_{h_i,h_j}. Otherwise, without loss of generality, C is a light color, and the algorithm returns $\min_{\hat{p} \in P(c)}\{d(\hat{p}, c')\} = \delta_{c,c'}$, by performing $\left|P(c)\right| \leq \tau$ NNS queries on $\mathrm{NNS}_{c'}$, one for each point in C.

Time complexity

The preprocessing and query time costs of the generic algorithm depend on the implementation of the NNS data structure, and the time used for computing matrix E^*. Thus, we express the time complexity of the generic algorithm as a function of $T_{p,\mathrm{NNS}}(t)$, $T_{q,\mathrm{NNS}}(t)$, and $T_{E^*}(\mathcal{H})$, which are the preprocessing time and query time of the NNS data structure on a set of size t, and the time used to compute E^*, respectively. In the preprocessing phase, the algorithm computes E^* and creates an NNS data structure for each color in $\mathcal{C}$. Thus, the preprocessing time cost is

$$O(T_{E^*}(\mathcal{H}) + \sum_{c\in\mathcal{C}} T_{p,\mathrm{NNS}}(P(c))).$$

In the query phase, the time cost is dominated by executing at most τ NNS queries on a set of size at most n, and so the time cost is $O(\tau \cdot T_{q,\mathrm{NNS}}(n))$.

Constructing E^* and solving ACDO on an array

In Section 3 we describe an efficient algorithm for constructing E^* when $\mathbf{M}$ is the metric of integers. Our algorithm is structured as follows. For pairs of heavy colors whose color distance is smaller than some threshold, the algorithm computes their distance via a straightforward brute-force computation. The more challenging part is dealing with pairs of heavy colors with larger color distance. Our approach is to compute a series of Boolean matrices with specially designed properties, so that after the computation of the matrices we are able scan the matrices and deduce a $(1+\varepsilon)$ approximation for every pair of colors with a rather large distance color. We remark that to compute the matrices used for the approximations, our algorithm makes use of FMM, which, as noted in Section 1, is required for obtaining improvements in runtime compared to the exact solution of [17].

To complete the proof of Theorem 5, in Section 4 we analyze the runtime of the generic algorithm with the runtime of constructing E^* when $\mathbf{M}$ is defined by locations in an array, and by plugging in known NNS data structures.

Solving AMCDOCH on an array

In Section 5 we prove Theorem 6. Our algorithm is a reduction from AMCDOCH on an array to ACDO on an array. The structure of our reduction somewhat resembles the structure of the MCDOCH algorithm of [17]. In particular, in the algorithm of [17] they partition the points into sets of size τ, preprocess each set into an RNNS data structure, and for each pair of sets apply τ RNNS queries to compute the distance between the sets. To obtain a faster runtime, we compute the distance between every pair of sets by recoloring the input points using the sets as a new color scheme and then applying our ACDO algorithm with the new color set. One important property of our ACDO algorithm is that when a query takes place between two heavy colors, the query time is constant since the algorithm just looks up a single value in E^*. It turns out that essentially all of the colors in the new color set are heavy, and so after the preprocessing phase of our ACDO algorithm, we are able to compute the distance between a pair of sets in $O(1)$ time. This property turns out to be helpful for our AMCDOCH algorithm, which is described in Section 5.

3 Computing E^* when $\mathbf{M}$ is integers

In this section, we show how to compute matrix E^* when our metric $\mathbf{M}$ is one dimensional, and for $p, p' \in \mathbf{M}$ we have $d(p, p') = |p - p'|$. We make the simplifying assumption that $\min(S) = 1$ since, otherwise, one could shift S by subtracting $\min(S) - 1$ from each point.

Let W be a positive integer parameter that will be determined later. The construction algorithm for E^* has two conceptual parts. The first part deals with pairs of heavy colors with distance at most $\frac{1+2\varepsilon}{\varepsilon}W$, by computing the distances exactly using a brute-force method. The second part deals with pairs of heavy colors with distance greater than $\frac{1+2\varepsilon}{\varepsilon}W$. In this case, the algorithm computes an approximation of the distances by utilizing a series of matrices defined as follows.

Let $\ell_0 = \lfloor \log_{1+\varepsilon}(\frac{1}{\varepsilon}) \rfloor + 1$ and let $\ell_{max} = \lceil \log_{1+\varepsilon}(\max(S)) \rceil$. Let $A = \{a_{i,j}\}$ be a Boolean $|\mathcal{H}| \times \lceil \frac{\max(S)}{W} \rceil$ matrix where

$$a_{i,j} = \begin{cases} 1 & P(h_i) \cap S[(j-1)W + 1, jW] \neq \emptyset \\ 0 & \text{otherwise} \end{cases}$$

Thus, matrix A indicates for each heavy color and each block of size W in S which starts at a location following an integer multiple of W, whether the heavy color appears in the block or not.

For $\ell_0 \leq \ell \leq \ell_{max}$, let $B^{(\ell)} = \{b^{(\ell)}_{i,j}\}$ be a Boolean $\lceil \frac{\max(S)}{W} \rceil \times |\mathcal{H}|$ matrix where

$$b^{(\ell)}_{i,j} = \begin{cases} 1 & P(h_j) \cap S[(i-1)W + 1, iW + (1+\varepsilon)^\ell W] \neq \emptyset \\ 0 & \text{otherwise} \end{cases}$$

Matrix $B^{(\ell)}$ indicates for each block of size $W + (1+\varepsilon)^\ell W$ in S which starts at a location following an integer multiple of W, and for each heavy color, whether the heavy color appears in the block or not.

Let $E^{(\ell)} = A \cdot B^{(\ell)} = \{e^{(\ell)}_{i,j}\}$, where the product is a Boolean matrix product. Thus, $E^{(\ell)}$ roughly indicates for each pair of heavy colors whether their color distance is at most $W + (1+\varepsilon)^\ell W$.

In Section 3.1 we state and prove lemmas regarding the connections between the matrices $E^{(\ell)}$ and approximating color distances. In Section 3.2 we describe the algorithm for constructing E^*, and prove its correctness based on the lemmas of Section 3.1.

3.1 Properties of The $E^{(\ell)}$ Matrices

The following lemma describes a connection between entries of 0 in E^ℓ and lower bounds on color distances.

▶ **Lemma 12.** *For $h_i, h_j \in \mathcal{H}$ and integer $\ell_0 \leq \ell \leq \ell_{max}$, if $e^{(\ell)}_{i,j} = 0$ and $e^{(\ell)}_{j,i} = 0$, then $\delta_{h_i,h_j} > (1+\varepsilon)^\ell W$.*

Proof. Let $p \in P(h_i)$ and $p' \in P(h_j)$ be chosen such that $\delta_{h_i,h_j} = d(p, p')$. Assume towards a contradiction that $\delta_{h_i,h_j} \leq (1+\varepsilon)^\ell W$. We focus on the case of $p' \geq p$ and so $\delta_{h_i,h_j} = p' - p$; the proof for the case $p > p'$ is symmetrical. Thus, there exists an integer $1 \leq k \leq \lceil \frac{\max(S)}{W} \rceil$ such that $p \in S[(k-1)W + 1, kW]$ and so $a_{i,k} = 1$. Therefore,

$$p' = p + \delta_{h_i,h_j} \leq p + (1+\varepsilon)^\ell W \leq kW + (1+\varepsilon)^\ell W.$$

We conclude that $p' \in S[(k-1)W + 1, kW + (1+\varepsilon)^\ell W]$, implying that $b^{(\ell)}_{k,j} = 1$, and so $e^{(\ell)}_{i,j} = 1$, which is a contradiction. ◀

The following lemma shows a connection between colors with distance greater than $(\frac{1+2\varepsilon}{\varepsilon})W$ and entries in $E^{(\ell_0)}$ whose value is 0.

▶ **Lemma 13.** *For $h_i, h_j \in \mathcal{H}$, if $\delta_{h_i,h_j} > (\frac{1+2\varepsilon}{\varepsilon})W$ then $e^{(\ell_0)}_{i,j} = 0$ and $e^{(\ell_0)}_{j,i} = 0$.*

Proof. Assume by contradiction that $e^{(\ell_0)}_{i,j} = 1$ or $e^{(\ell_0)}_{j,i} = 1$. We focus on the case of $e^{(\ell_0)}_{i,j} = 1$; the proof for the case $e^{(\ell_0)}_{j,i} = 1$ is symmetrical. Since $e^{(\ell_0)}_{i,j} = 1$, there exists an integer $1 \leq k \leq \lceil \frac{\max(S)}{W} \rceil$ such that $a_{i,k} = 1$ and $b^{(\ell_0)}_{k,j} = 1$. Therefore, there exist points $p \in P(h_i)$ and $p' \in P(h_j)$ such that $p \in S[(k-1)W+1, kW]$ and $p' \in S[(k-1)W+1, kW+(1+\varepsilon)^{(\ell_0)}]$. Thus,

$$\begin{aligned}
\delta_{h_i,h_j} &= \min_{\hat{p}\in P(c), \tilde{p}\in P(c')} \{d(\hat{p},\tilde{p})\} \leq d(p,p') = \max\left(p-p', p'-p\right) \\
&= \max\left(W-1, (1+\varepsilon)^{(\ell_0)}W + W - 1\right) = (1+\varepsilon)^{(\ell_0)}W + W - 1 \\
&= (1+\varepsilon)^{\lfloor \log_{1+\varepsilon}(\frac{1}{\varepsilon})\rfloor+1}W + W - 1 \leq ((1+\varepsilon)^{\log_{1+\varepsilon}(\frac{1}{\varepsilon})+1} + 1)W - 1 \\
&< (\frac{1+2\varepsilon}{\varepsilon})W.
\end{aligned}$$

◀

The following lemma describes a connection between entries of 1 in E^ℓ and upper bounds on color distances.

▶ **Lemma 14.** *For $h_i, h_j \in \mathcal{H}$ and integer $\ell_0 \leq \ell \leq \ell_{\max}$, if $e^{(\ell)}_{i,j} = 1$, then $\delta_{h_i,h_j} < (1+\varepsilon)^{\ell+1}W$.*

Proof. If $e^{(\ell)}_{i,j} = 1$, then there exists an integer $1 \leq k \leq \lceil \frac{\max(S)}{W} \rceil$ such that $a_{i,k} = 1$ and $b^{(\ell)}_{k,j} = 1$. Hence, there exist $p \in P(h_i)$ and $p' \in P(h_j)$ such that $p \in S[(k-1)W+1, kW]$ and $p' \in S[(k-1)W+1, kW+(1+\varepsilon)^{\ell}W]$. Thus,

$$\begin{aligned}
\delta_{h_i,h_j} &\leq \left|p-p'\right| = \max(p-p', p'-p) \leq \max\left(W-1, (1+\varepsilon)^{\ell}W + W - 1\right) \\
&= (1+\varepsilon)^{\ell}W + W - 1 < ((1+\varepsilon)^{\ell} + 1)W.
\end{aligned}$$

Notice that $\lfloor \log_{1+\varepsilon}(\frac{1}{\varepsilon})\rfloor + 1 > \log_{1+\varepsilon}(\frac{1}{\varepsilon})$. Finally, since $\lfloor \log_{1+\varepsilon}(\frac{1}{\varepsilon})\rfloor + 1 = \ell_0 \leq \ell$, we have

$$(1+\varepsilon)^{\ell} \geq (1+\varepsilon)^{\lfloor \log_{1+\varepsilon}(\frac{1}{\varepsilon})\rfloor+1} > (1+\varepsilon)^{\log_{1+\varepsilon}(\frac{1}{\varepsilon})} = \frac{1}{\varepsilon},$$

and so $1 < \varepsilon(1+\varepsilon)^{\ell}$. Thus,

$$((1+\varepsilon)^{\ell} + 1)W < ((1+\varepsilon)^{\ell} + \varepsilon(1+\varepsilon)^{\ell})W = ((1+\varepsilon)^{\ell+1})W,$$

completing the proof. ◀

The following lemma shows that $e^{(\ell)}_{i,j}$ is weakly monotone increasing with respect to ℓ.

▶ **Lemma 15.** *For $h_i, h_j \in \mathcal{H}$, and $\ell_0 \leq \ell \leq \ell_{max}$, if $e^{(\ell)}_{i,j} = 1$, then for any $\ell < \ell' \leq \ell_{max}$ we have $e^{(\ell')}_{i,j} = 1$.*

Proof. If $e^{(\ell)}_{i,j} = 1$, then there exists an integer $1 \leq k \leq \lceil \frac{\max(S)}{W} \rceil$ such that $a_{i,k} = 1$ and $b^{(\ell)}_{k,j} = 1$. Thus, there exists $p \in P(h_i)$ such that $p \in S[(k-1)W+1, kW+(1+\varepsilon)^{\ell}W]$. Moreover, since $\ell < \ell'$, we have $S[(k-1)W+1, kW+(1+\varepsilon)^{\ell}W] \subseteq S[(k-1)W+1, kW+(1+\varepsilon)^{\ell'}W]$, and so $b^{(\ell')}_{k,j} = 1$. Finally, since $a_{i,k} = 1$, we conclude that $e^{(\ell')}_{i,j} = 1$. ◀

The following lemma shows that in $E^{(\ell_{max})}$, for each pair of heavy colors, there exists at least one corresponding 1 entry.

▶ **Lemma 16.** *For $h_i, h_j \in \mathcal{H}$, either $e_{i,j}^{(\ell_{max})} = 1$ or $e_{j,i}^{(\ell_{max})} = 1$.*

Proof. Assume by contradiction that $e_{i,j}^{(\ell_{max})} = 0$ and $e_{j,i}^{(\ell_{max})} = 0$. Let $p \in P(h_i)$ and $p' \in P(h_j)$ be chosen such that $\delta_{h_i,h_j} = d(p,p')$. Hence by Lemma 12, we have $\delta_{h_i,h_j} > (1+\varepsilon)^{\ell_{max}} W = (1+\varepsilon)^{\lceil \log_{1+\varepsilon} \frac{\max(S)}{W} \rceil} W$. Notice that $\max(S) \geq \delta_{h_i,h_j}$. Therefore,

$$\max(S) \geq \delta_{h_i,h_j} > (1+\varepsilon)^{(\lceil \log_{1+\varepsilon} \frac{\max(S)}{W} \rceil)} W \geq (1+\varepsilon)^{\log_{1+\varepsilon} \frac{\max(S)}{W}} W \geq \max(S),$$

which is a contradiction. ◀

In the following lemma we show the main property of the matrices $E^{(\ell)}$ used in the algorithm of Section 3.2 when dealing with pairs of heavy colors with color distance greater than $\frac{1+2\varepsilon}{\varepsilon} W$.

▶ **Lemma 17.** *For $h_i, h_j \in \mathcal{H}$, if $\delta_{h_i,h_j} > \frac{1+2\varepsilon}{\varepsilon} W$, then there exists a unique integer $\ell_0 \leq \ell \leq \ell_{max} - 1$ such that $e_{i,j}^{(\ell)} = e_{j,i}^{(\ell)} = 0$ and either $e_{i,j}^{(\ell+1)} = 1$ or $e_{j,i}^{(\ell+1)} = 1$.*

Proof. By Lemma 16, at least one of $e_{i,j}^{(\ell_{max})}$ and $e_{j,i}^{(\ell_{max})}$ must be 1. So assume without loss of generality that $e_{i,j}^{(\ell_{max})} = 1$. Since $\delta_{h_i,h_j} > \frac{1+2\varepsilon}{\varepsilon} W$, by Lemma 13 $e_{i,j}^{(\ell_0)} = 0$. Thus, by Lemma 15, there must exist exactly one $\ell_0 \leq \ell < \ell_{max}$ such that $e_{i,j}^{(\ell)} = 0$ and $e_{i,j}^{(\ell+1)} = 1$.

To complete the proof we show uniqueness. If $e_{i,j}^{(\ell_{max})} = e_{j,i}^{(\ell_{max})} = 1$, then assume towards a contradiction that there exist two different integers $\ell' \neq \hat{\ell}$ such that $e_{i,j}^{(\ell')} = 0$, $e_{j,i}^{(\ell')} = 0$, $e_{i,j}^{(\ell'+1)} = 1$, $e_{i,j}^{(\hat{\ell})} = 0$, $e_{j,i}^{(\hat{\ell})} = 0$, and $e_{j,i}^{(\hat{\ell}+1)} = 1$. Without loss of generality, $\ell' < \hat{\ell}$, and so by Lemma 15, $e_{i,j}^{(\ell'+1)} = 1$ and $\ell' < \hat{\ell}$ implies $e_{i,j}^{(\hat{\ell})} = 1$ which is a contradiction.

Otherwise, if at least one of $e_{i,j}^{(\ell_{max})}$ or $e_{j,i}^{(\ell_{max})}$ is 0, then since we assumed without loss of generality that $e_{i,j}^{(\ell_{max})} = 1$, we have $e_{j,i}^{(\ell_{max})} = 0$, which together with Lemma 15 implies that for all $\ell_0 \leq \ell' < \ell_{max}$, $e_{j,i}^{(\ell')} = 0$. Thus, ℓ is unique. ◀

3.2 Algorithm for Computing E^*

In this section, we describe the algorithm for computing E^*, prove its correctness and analyze its time cost. Pseudocode for the algorithm is given in Algorithm 1. The algorithm begins by a brute-force exact computation of color distances for all heavy colors h_i and h_i where $\delta_{h_i,h_j} \leq \frac{1+2\varepsilon}{\varepsilon} W$. The brute-force computation costs $O((\frac{1+2\varepsilon}{\varepsilon})Wn) = O(\frac{Wn}{\varepsilon})$ time.

The rest of the algorithm deals with the case of $\delta_{h_i,h_j} > \frac{1+2\varepsilon}{\varepsilon} W$. First, the algorithm computes the matrices $E^{(\ell)}$ from matrices A and $B^{(\ell)}$. The time cost of computing all $E^{(\ell)}$ is dominated by the cost of $\log_{1+\varepsilon}(\max(S)) = \Theta(\frac{\log \max(S)}{\varepsilon})$ matrix multiplications. Each multiplication is between a matrix of size $\frac{n}{\tau} \times \frac{\max(S)}{W}$ and a matrix of size $\frac{\max(S)}{W} \times \frac{n}{\tau}$. It is folklore knowledge that the matrix multiplication of two matrices of size $x \times y$ and $y \times z$ can be computed in $O\left(\frac{x \cdot y \cdot z}{\min(x,y,z)^{3-\omega}}\right)$. Thus, the time cost of computing the matrix multiplications is $O\left(\frac{n^2 \cdot \max(S)}{\tau^2 W \cdot \min(\frac{n}{\tau}, \frac{\max(S)}{W})^{3-\omega}} \frac{\log \max(S)}{\varepsilon}\right)$ time.

Finally, the algorithm utilizes the matrices $E^{(\ell)}$ to complete entries in E^* which correspond to heavy pairs of colors that were not covered by the brute-force computation. To do so, for each such pair $(h_i, h_j) \in \mathcal{H} \times \mathcal{H}$, the algorithm scans all $e_{i,j}^{(\ell)}$ to find the unique ℓ from

Algorithm 1 CONSTRUCT$E^*(S, \mathcal{H}, W, \varepsilon)$.

```
E* ← ∞
ℓ0 ← ⌊log_{1+ε}(1/ε)⌋ + 1; ℓmax ← ⌈log_{1+ε}(max(S))⌉

    Construct matrix B^(ℓ)
    E^(ℓ) ← A · B^(ℓ)
end for
for ℓ ← ℓ0 to ℓmax do
    for (h_i, h_j) ∈ H × H do
        if e^(ℓ)_{i,j} = e^(ℓ)_{j,i} = 0 and (e^(ℓ+1)_{i,j} = 1 or e^(ℓ+1)_{j,i} = 1) then
            e*_{i,j} ← (1 + ε)^(ℓ+2) W
        end if
    end for
end for
```

Lemma 17 such that $e^{(\ell)}_{i,j} = e^{(\ell)}_{j,i} = 0$ and either $e^{(\ell+1)}_{i,j} = 1$ or $e^{(\ell+1)}_{j,i} = 1$, and sets $e^*_{i,j}$ to be $(1+\varepsilon)^{\ell+2}W$. Computing the entries in E^* for all such pairs costs $O(|\mathcal{H}|^2 \frac{\log \max(s)}{\varepsilon})) = O((\frac{n}{\tau})^2 \frac{\log \max(s)}{\varepsilon}))$, which is dominated by the cost of the matrix multiplications performed during the computation of all of the $E^{(\ell)}$ matrices.

▶ **Lemma 18.** *There exists an algorithm that computes E^* in $\tilde{O}\left(\frac{Wn}{\varepsilon} + \frac{n^2 \cdot \max(S)}{\tau^2 W \cdot \min(\frac{n}{\tau}, \frac{\max(S)}{W})^{3-\omega}}\right)$ time, such that for $h_i, h_j \in \mathcal{H}$ we have $\delta_{h_i,h_j} \leq e^*_{i,j} \leq (1+\varepsilon)\delta_{h_i,h_j}$.*

Proof. The runtime of the algorithm follows from the discussion above.

If $\delta_{h_i,h_j} \leq \frac{1+2\varepsilon}{\varepsilon}W$, then there exist $p \in P(h_1)$ and $\hat{p} \in P(h_i)$ such that $\delta_{h_i,h_j} = |\hat{p} - p| \leq \frac{1+2\varepsilon}{\varepsilon}W$, and so, after the brute-force computation, we have $e^*_{i,j} = \delta_{h_i,h_j}$.

Otherwise, $\delta_{h_i,h_j} > \frac{1+2\varepsilon}{\varepsilon}W$, and so the algorithm sets $e^*_{i,j}$ to be $(1+\varepsilon)^{\ell+2}W$, where ℓ is the unique integer from Lemma 17, and in particular, $e^{(\ell)}_{i,j} = e^{(\ell)}_{j,i} = 0$ and either $e^{(\ell+1)}_{i,j} = 1$ or $e^{(\ell+1)}_{j,i} = 1$. By Lemmas 14 and 12, $\delta_{h_i,h_j} < (1+\varepsilon)^{\ell+2}W < (1+\varepsilon)^2\delta_{h_i,h_j}$.

Finally, to obtain a $(1+\varepsilon)$ approximation one can run the algorithm with approximation parameter $\varepsilon' = \frac{\varepsilon}{3}$, which does not affect the asymptotic time complexity. ◀

4 Proof of Theorem 5

In this section, we analyze the combination of the construction algorithm for E^* given in Section 3.2 together with the generic ACDO algorithm described in Section 2.1. However, we focus on the type of instances of ACDO which are used in Section 5 for solving the approximate snippets problem. In particular, our metric is defined by locations in an array of size n, and so we have $\max(S) = n$. Thus, in our case,

$$T_{E^*}(\mathcal{H}) = O\left(\frac{Wn}{\varepsilon} + \frac{n^\omega \max(\tau, W)^{3-\omega}}{\tau^2 W} \cdot \frac{\log n}{\varepsilon}\right).$$

If $n^{\frac{\omega-1}{\omega+1}} \log^{\frac{1}{2}} n \leq \tau \leq n$, then we choose $W = (\frac{n}{\tau})^{\frac{\omega-1}{2}} \log^{\frac{1}{2}} n$. In such a case, we have $W = (\frac{n}{\tau})^{\frac{\omega-1}{2}} \log^{\frac{1}{2}} n \leq \left(\frac{n}{n^{\frac{\omega-1}{\omega+1}}}\right)^{\frac{\omega-1}{2}} \log^{\frac{1}{2}} n = n^{\frac{\omega-1}{\omega+1}} \log^{\frac{1}{2}} n \leq \tau$, and so

$$T_{E^*}(\mathcal{H}) = O\left(\frac{(\frac{n}{\tau})^{\frac{\omega-1}{2}} n}{\varepsilon} \log^{\frac{1}{2}} n + \frac{n^\omega \tau^{3-\omega}}{\tau^2 (\frac{n}{\tau})^{\frac{\omega-1}{2}} \cdot \log^{\frac{1}{2}} n} \cdot \frac{\log n}{\varepsilon}\right) = O\left(\frac{n^{\frac{\omega+1}{2}}}{\varepsilon \tau^{\frac{\omega-1}{2}}} \log^{\frac{1}{2}} n\right).$$

If $1 \leq \tau \leq n^{\frac{\omega-1}{\omega+1}} \log^{\frac{1}{2}} n$, then we choose $W = \frac{n}{\tau^{\frac{2}{\omega-1}}} \cdot \log^{\frac{1}{\omega-1}} n$. In such a case we have $W = \frac{n}{\tau^{\frac{2}{\omega-1}}} \log^{\frac{1}{\omega-1}} n \geq \frac{n}{n^{\frac{\omega-1}{\omega+1} \cdot \frac{2}{\omega-1}}} \log^{\frac{1}{\omega-1}} n = n^{\frac{\omega-1}{\omega+1}} \log^{\frac{1}{\omega-1}} n \geq \tau$, and so

$$\begin{aligned} T_{E^*}(\mathcal{H}) &= O\left(\frac{n^2}{\varepsilon \tau^{\frac{2}{\omega-1}}} \log^{\frac{1}{\omega-1}} n + \frac{n^\omega (\frac{n}{\tau^{\frac{2}{\omega-1}}})^{2-\omega} \cdot \log(n)^{\frac{2-\omega}{\omega-1}}}{\tau^2} \cdot \frac{\log n}{\varepsilon}\right) \\ &= O\left(\frac{n^2}{\varepsilon \tau^{\frac{2}{\omega-1}}} \log^{\frac{1}{\omega-1}} n\right). \end{aligned}$$

Thus, to summarize we have shown

$$T_{E^*}(\mathcal{H}) = \begin{cases} \tilde{O}\left(\frac{n^2}{\varepsilon \tau^{\frac{2}{\omega-1}}}\right) & \text{for } 1 \leq \tau \leq n^{\frac{\omega-1}{\omega+1}} \\ \tilde{O}\left(\frac{n^{\frac{\omega+1}{2}}}{\varepsilon \tau^{\frac{\omega-1}{2}}}\right) & \text{for } n^{\frac{\omega-1}{\omega+1}} \leq \tau \leq n. \end{cases}$$

Notice that in either case, $T_{E*}(\mathcal{H}) = \Omega(\max(n^2/\tau^2), n)$.

For the NNS data structure we use the van Emde Boas [25] data structure which for a set of m points from integer universe $\{1, 2, \ldots, u\}$ has a preprocessing cost of $O(m \cdot \log\log u)$ and query time $O(\log\log u)$. In our setting, $u = n$, and so $T_{p,NNS}(P(c)) = O(|P(c)| \log\log n)$ and $T_{q,NNS}(n) = O(\log\log n)$.

Thus, the construction time of the ACDO algorithm is

$$\begin{aligned} O(T_{E^*}(\mathcal{H}) + \sum_{c \in \mathcal{C}} T_{p,\mathrm{NNS}}(P(c))) &= O(T_{E^*}(\mathcal{H}) + \sum_{c \in \mathcal{C}} |P(c)| \log\log n) \\ &= O(T_{E^*}(\mathcal{H}) + n \log\log n) \\ &= \tilde{O}(T_{E^*}), \end{aligned}$$

and the query time is $O(\tau \cdot T_{q,\mathrm{NNS}}(n)) = O(\tau \log\log n) = \tilde{O}(\tau)$. To complete the proof of Theorem 5, we plug $\tau = \tilde{O}(n^b)$ into $n^a = T_{E^*}(\mathcal{H})$, to obtain the following tradeoff curve for a fixed ε.

$$\begin{cases} a + \frac{2}{\omega-1} b = 2 & \text{if } 0 \leq b \leq \frac{\omega-1}{\omega+1} \\ \frac{2}{\omega-1} a + b = \frac{\omega+1}{\omega-1} & \text{if } \frac{\omega-1}{\omega+1} \leq b \leq 1. \end{cases}$$

▶ Remark 19. One feature of Theorem 5 algorithm, which is used in the proof of Theorem 6, is that the query cost for ACDO queries when both C and C' are heavy is $O(1)$ time since all the algorithm does is looking up the answer in E^*.

5 Proof Sketch of Theorem 6

The proof of Theorem 6 is inspired by the exact MCDOCH algorithm of [17], combined with a new observation which allows to leverage Theorem 5. Due to space considerations, in this section, we only highlight the differences between our algorithm for AMCDOCH and the exact MCDOCH algorithm of [17]. The complete proof of Theorem 6 is given in the full version [12].

The relevant part of the algorithm of [17] creates an array A of size n which is a permutation of the points in S, and preprocesses A into an RNNS data structure. Then, the algorithm partitions A into blocks of size τ, for an integer parameter $1 \leq \tau \leq n$. Let $\mathcal{I} = \{I_1, I_2 \dots I_{\lceil \frac{n}{\tau} \rceil}\}$ denote the set of blocks.

Following [17], the algorithm constructs a matrix $B = \{b_{i,j}\}$ of size $\lceil \frac{n}{\tau} \rceil \times \lceil \frac{n}{\tau} \rceil$, such that $b_{i,j} = d(I_i, I_j)$. To construct B, the algorithm of [17] performs τ RNNS queries for the computation of each entry in B. Computing B turns out to be the dominating component in the preprocessing runtime of [17].

To obtain a faster preprocessing time for the approximate setting, instead of constructing B, our algorithm constructs an *approximate* matrix $\hat{B} = \{\hat{b}_{i,j}\}$ where $d(I_i, I_j) \leq \hat{b}_{i,j} \leq (1+\varepsilon)d(I_i, I_j)$. The construction of $\hat{B}$ utilizes the algorithm of Theorem 5 as follows. Define a new coloring set $\hat{\mathcal{C}} = \{\hat{c_1}, \hat{c_2}, \dots \hat{c_{|\mathcal{I}|}}\}$ over the points in S, such that for each $\hat{c_i} \in \hat{\mathcal{C}}$ we have $P(\hat{c_i}) = I_i$. Notice that for every $i \neq j$, we have $I_i \bigcap I_j = \emptyset$, and so using the colors of $\hat{\mathcal{C}}$ on S, every point in S has only one color. Thus, the algorithm uses the algorithm of Theorem 5 on S, but with the colors of $\hat{\mathcal{C}}$, and the query time designed to be $\tilde{O}(n^b) = \tilde{O}(\tau)$. Now, $\hat{b}_{i,j}$ is set to be the answer of the ACDO query on colors $\hat{c}_i$ and $\hat{c}_j$, and so $d(I_i, I_j) = \delta_{\hat{c}_i, \hat{c}_j} \leq \hat{b}_{i,j} \leq (1+\varepsilon)\delta_{\hat{c}_i, \hat{c}_j} = (1+\varepsilon)d(I_i, I_j)$.

In the last step of the preprocessing phase, the algorithm preprocesses $\hat{B}$ (instead of B in [13]) using a $2D$ Range Minimum Query (2DRMQ) data structure [3] so that given a rectangle in $\hat{B}$, defined by its corners, the algorithm returns in $O(1)$ time the smallest value entry in the rectangle.

Answering queries and correctness

The process for answering a query is the same as in [17], but using $\hat{B}$ instead of B. Thus, the correctness of the algorithm needs to be proven given the use of $\hat{B}$.

As shown in [17], for each $c \in \mathcal{C}$, $P(c)$ is exactly the points in some interval $A[x_c, y_c]$. The challenging part is answering an AMCDOCH query between C and C', when $P(c)$ and $P(c')$ are disjoint. Thus, assume without loss of generality that $x_c \leq y_c < x_{c'} \leq y_{c'}$. For the description here, we assume that x_c (and $x_{c'}$) is the first location of some block, and y_c (and $y_{c'}$) is the last location of some block. The more general cases are covered in the full version of this paper [12], with an additional execution of $\tilde{O}(\tau)$ RNNS queries.

The query algorithm executes a 2DRMQ data structure query on the rectangle in $\hat{B}$ defined by corners $(\frac{x_c - 1}{\tau} + 1, \frac{x_{c'} - 1}{\tau} + 1)$ and $(\frac{y_c}{\tau}, \frac{y_{c'}}{\tau})$. Let $\hat{b}_{i,j}$ be the answer returned by the 2DRMQ query. Notice that there exist $p \in A[x_c, y_c]$ and $p' \in A[x_{c'}, y_{c'}]$ such that $\delta_{c,c'} = d(p, p')$. Thus, there exist integers $\frac{x_c - 1}{\tau} + 1 \leq i^* \leq \frac{y_c}{\tau}$, $\frac{x_{c'} - 1}{\tau} + 1 \leq j^* \leq \frac{y_{c'}}{\tau}$ such that $p \in I_{i^*}$ and $p' \in I_{j^*}$. Thus, $\delta_{c,c'} = d(p, p') = d(I_{i^*}, I_{j^*})$, and so

$$\begin{aligned}\hat{b}_{i,j} &= \min_{\frac{x_c-1}{\tau}+1 \leq \hat{i} \leq \frac{y_c}{\tau}, \frac{x_{c'}-1}{\tau}+1 \leq \hat{j} \leq \frac{y_{c'}}{\tau}} \{\hat{b}_{\hat{i},\hat{j}}\} \leq \min_{\frac{x_c-1}{\tau}+1 \leq \hat{i} \leq \frac{y_c}{\tau}, \frac{x_{c'}-1}{\tau}+1 \leq \hat{j} \leq \frac{y_{c'}}{\tau}} \{(1+\varepsilon)d(I_{\hat{i}}, I_{\hat{j}})\} \\ &\leq (1+\varepsilon)d(I_{i^*}, I_{j^*}) = (1+\varepsilon)\delta_{c,c'}.\end{aligned}$$

Time Complexity

For the RNNS data structure we use the solution of [23] which on n points (which is the size of A) has preprocessing time $O(n \log n)$ and query time $O(\log^{\varepsilon} n) = \tilde{O}(1)$.

By Remark 19 and the fact that each block has size $\tau = \tilde{O}(n^b)$, each ACDO query used for constructing $\hat{B}$ costs $O(1)$ time. So, after preprocessing the ACDO data structure, constructing $\hat{B}$ costs $O((\frac{n}{\tau})^2)$ time. The preprocessing time of the 2DRMQ data structure of [3] when applied to $\hat{B}$ is $\tilde{O}((\frac{n}{\tau})^2)$. Thus, since $T_{E^*}(n) = \Omega(\max(n^2/\tau^2), n))$, the total time cost of the preprocessing phase, which is composed of constructing the ACDO and RNNS data structures on A, computing $\hat{B}$, and preprocessing a 2DRMQ data structure, is

$$\tilde{O}\left(T_{E^*}(n) + (n/\tau)^2 + n\right) = \tilde{O}\left(T_{E^*}(n)\right) = \begin{cases} \tilde{O}\left(\dfrac{n^2}{\varepsilon \tau^{\frac{2}{\omega-1}}}\right) & \text{for } 1 \leq \tau \leq n^{\frac{\omega-1}{\omega+1}} \\ \tilde{O}\left(\dfrac{n^{\frac{\omega+1}{2}}}{\varepsilon \tau^{\frac{\omega-1}{2}}}\right) & \text{for } n^{\frac{\omega-1}{\omega+1}} \leq \tau \leq n \end{cases}$$

The query process consists of $O(\tau)$ RNNS queries, and a single 2DRMQ query. Thus, the query time cost is $O(\tau)$. Finally, similar to the proof of Theorem 5, we obtained the following tradeoff curve for a fixed ε.

$$\begin{cases} a + \dfrac{2}{\omega-1} b = 2 & \text{if } 0 \leq b \leq \dfrac{\omega-1}{\omega+1} \\ \dfrac{2}{\omega-1} a + b = \dfrac{\omega+1}{\omega-1} & \text{if } \dfrac{\omega-1}{\omega+1} \leq b \leq 1. \end{cases}$$

6 Proof of Theorem 8: CLB for Exact MCDO on an Array

To prove Theorem 8, we design a reduction from $(min, +)$-matrix product on values in $[\hat{n}]$ to MCDO. To do so, consider an *unbalanced* version of $(min, +)$-matrix product where A is of size $\hat{n} \times \hat{m}$, B is of size $\hat{m} \times \hat{n}$, and all of the values are bounded by some positive integer M. It is straightforward to show that for any $x \geq 0$ such that $\hat{m} = \hat{n}^x$, solving unbalanced $(min, +)$-matrix product with any polynomial time improvement over $(\hat{n}^2\hat{m})^{1-o(1)}$ time is equivalent to solving $(min, +)$-matrix product on balanced matrices with $\hat{m} = \hat{n}$ in $\hat{n}^{3-\Omega(1)}$ time. Thus, an algorithm for unbalanced $(min, +)$-matrix product with values bounded by $M = [\min(\hat{n}, \hat{m})] = \hat{n}$ in time less than $(\hat{n}^2\hat{m})^{1-o(1)}$ would refute the Strong-APSP hypothesis.

The reduction

Our goal is to design a reduction from the unbalanced $(min, +)$-matrix product problem with values bounded by $\hat{n} \geq \min(\hat{n}, \hat{m})$ to MCDO. In preparation for the proof of Theorem 9, we first describe the reduction using positive integer parameter M as the upper bound on the values in the input matrices, and during the analysis we set $M = \hat{n}$.

For each $a_{i,j}$, the algorithm defines a point $a'_{i,j} = (M - a_{i,j}) + 9Mj$ with color i. For each $b_{i,j}$, the algorithm defines a point $b'_{i,j} = b_{i,j} + 3M + 9Mi$ with color $\hat{n} + j$. Thus, the largest point defined is at most $O(M \cdot \hat{m})$, and there are $2\hat{n}$ colors. Notice that there cannot be two entries in the same row (column) of A (B) that define the same point. However, it is possible that $a_{i,j} = a_{i',j}$ for $i \neq i'$, and so $a'_{i,j} = a'_{i',j}$, but the two points have different colors. A similar phenomenon can happen to points defined by entries of B which share the same row. Thus, we merge all occurrences of the same point into a single occurrence but colored

with all of the colors of the pre-merge occurrences. The set of points, denoted by S, contains at most $2\hat{n}\hat{m}$ multi-colored points in a metric defined by an array of size $O(M\hat{m})$, and so the algorithm uses the MCDO algorithm to preprocess S. Finally, for each entry $d_{i,j}$ in D, the algorithm sets $d_{i,j} \leftarrow \delta_{i,\hat{n}+j} - 2M$ by performing a query on the MCDO data structure.

Correctness

Suppose $d_{i,j} = a_{i,k^*} + b_{k^*,j}$ for some $k^* \in [\hat{m}]$. For every $k \in [\hat{m}]$, by definition we have $b'_{k,j} > a'_{i,k}$ and so $\left|a'_{i,k} - b'_{k,j}\right| = b'_{k,j} - a'_{i,k} = b_{k,j} + a_{i,k} + 2M$. Since a'_{i,k^*} is colored with color i and $b'_{k^*,j}$ is colored with color $\hat{n} + j$, we have

$$\delta_{i,\hat{n}+j} - 2M \leq \left|a'_{i,k^*} - b'_{k^*,j}\right| - 2M = a_{i,k^*} + b_{k^*,j} = d_{i,j}. \tag{1}$$

Let $k', k'' \in [\hat{m}]$. If $k' \neq k''$, then

$$\begin{aligned}\left|a'_{i,k'} - b'_{k'',j}\right| &= \max\left(a'_{i,k'} - b'_{k'',j}, b'_{k'',j} - a'_{i,k'}\right) \\ &= \max\left(9M(k' - k'') - 2M - a_{i,k'} - b_{k'',j}, b_{k'',j} + a_{i,k'} + 9M(k'' - k') + 2M\right) \\ &\geq 5M.\end{aligned}$$

However, if $k' = k''$ then $a_{i,k'} + b_{k',j} + 2M \leq 4M$. Since $4M < 5M$, we have

$$\delta_{i,\hat{n}+j} = \min_{p \in P(i), p' \in P(\hat{n}+j)} \left\{\left|p - p'\right|\right\} = \min_{1 \leq \hat{k} \leq \hat{n}} \left\{\left|a'_{i,\hat{k}} - b'_{\hat{k},j}\right|\right\}.$$

Thus, there exists some $\hat{k} \in [\hat{m}]$ such that $\delta_{i,\hat{n}+j} = \left|a'_{i,\hat{k}} - b'_{\hat{k},j}\right| = a_{i,\hat{k}} + b_{\hat{k},j} + 2M \geq d_{i,j} + 2M$, and combined with Equation 1 we have $d_{i,j} = \delta_{i,\hat{n}+j} - 2M$.

Lower bound

Recall that in our setting $M = \hat{n}$. The reduction preprocesses an MCDO data structure on $n \leq 2\hat{n}\hat{m}$ points in an array metric of size $O(M\hat{m}) = O(n)$, and then answers $\hat{n}^2$ MCDO queries. If $t_p(n)$ and $t_q(n)$ are preprocessing and query times, respectively, of the MCDO data structure, then the Strong-APSP conjecture implies that $t_p(\hat{n}\hat{m}) + \hat{n}^2 \cdot t_q(\hat{n}\hat{m}) = (\hat{n}^2\hat{m})^{1-o(1)}$.

Recall that our goal is to prove that $a+b \geq 2-o(1)$. Thus, assume towards a contradiction that $a + b = 2 - \Omega(1)$, which, by straightforward algebraic manipulation, implies that $\frac{2a}{a-b} = 1 + \frac{2}{a-b} - \Omega(1)$. Moreover, since the unbalanced $(min, +)$-matrix product is hard for any choice of $x \geq 0$, we can choose $x = \frac{2}{a-b} - 1$ and so $\hat{n}\hat{m} = \hat{n}^{1+x} = \hat{n}^{\frac{2}{a-b}}$. Notice that $2 + \frac{2b}{a-b} = \frac{2a}{a-b}$ Thus, we have $t_p(\hat{n}\hat{m}) + \hat{n}^2 \cdot t_q(\hat{n}\hat{m}) = O(\hat{n}^{\frac{2a}{a-b}} + \hat{n}^{2+\frac{2b}{a-b}}) = O(\hat{n}^{\frac{2a}{a-b}}) = O(\hat{n}^{1+\frac{2}{a-b}-\Omega(1)}) < (\hat{n}^2\hat{m})^{1-o(1)}$, which contradicts the Strong-APSP hypothesis.

7 Conclusions and Open Problems

We have shown the existence of FMM based algorithms for both ACDO and the $(1+\varepsilon)$-approximate snippets problem which, assuming $\omega = 2$, are essentially optimal. Moreover, we proved CLBs for exact version of CDO, implying that the exact versions of CDO and the snippets problem are strictly harder than their approximate versions.

We remark that one immediate and straightforward way to improve our algorithms if $\omega > 2$ is to apply fast rectangular matrix multiplication ([2]). However, we chose not to describe such improvements since they are mostly technical and do not add any additional

insight to the problems that we address. Moreover, we remark that it is straightforward to adapt our CDO algorithms to return the two points (one of each color) that define the distance in addition to the actual distance (see the full version [12]).

Our work leaves open the task of designing improved algorithms for more general metrics such as higher dimensional Euclidean space.

Classical Algorithms for Constant Approximation of the Ground State Energy of Local Hamiltonians

François Le Gall
Graduate School of Mathematics, Nagoya University, Japan

Abstract

We construct classical algorithms computing an approximation of the ground state energy of an arbitrary k-local Hamiltonian acting on n qubits.

We first consider the setting where a good "guiding state" is available, which is the main setting where quantum algorithms are expected to achieve an exponential speedup over classical methods. We show that a *constant* approximation (i.e., an approximation with *constant relative accuracy*) of the ground state energy can be computed classically in $\mathrm{poly}\,(1/\chi, n)$ time and $\mathrm{poly}(n)$ space, where χ denotes the overlap between the guiding state and the ground state (as in prior works in dequantization, we assume sample-and-query access to the guiding state). This gives a significant improvement over the recent classical algorithm by Gharibian and Le Gall (SICOMP 2023), and matches (up to a polynomial overhead) both the time and space complexities of quantum algorithms for constant approximation of the ground state energy. We also obtain classical algorithms for higher-precision approximation.

For the setting where no guided state is given (i.e., the standard version of the local Hamiltonian problem), we obtain a classical algorithm computing a constant approximation of the ground state energy in $2^{O(n)}$ time and $\mathrm{poly}(n)$ space. To our knowledge, before this work it was unknown how to classically achieve these bounds simultaneously, even for constant approximation. We also discuss complexity-theoretic aspects of our results.

1 Introduction

1.1 Statement of our main results

Estimating the ground state energy of Hamiltonians is a central problem in both many-body physics and quantum complexity theory. Consider a k-local Hamiltonian

$$H = \sum_{i=1}^{m} H_i \tag{1}$$

acting on n qubits, with $k = O(1)$. Here each term H_i acts non-trivially on only k qubits (but does not need to obey any geometric locality). Let $\mathcal{E}(H)$ denote the ground state energy of H, i.e., its smallest eigenvalue. For any $\varepsilon > 0$, we say that an estimate $\hat{E}$ is an ε-approximation of $\mathcal{E}(H)$ if

$$\left|\hat{E} - \mathcal{E}(H)\right| \leq \varepsilon \sum_{i=1}^{m} \|H_i\|.$$

It is well known that computing a $1/\mathrm{poly}(n)$-approximation of $\mathcal{E}(H)$ is QMA-hard, even for $k = 2$ and for geometrically local Hamiltonians [24, 37, 41, 56, 58]. The Quantum PCP conjecture [4, 5] posits that there exists a constant $\varepsilon > 0$ such that computing an ε-approximation of $\mathcal{E}(H)$ is QMA-hard as well.

Despite these hardness results, efficient quantum algorithms for ground state energy estimation can be constructed when a good "guiding state" is available, i.e., when a quantum state $|\psi\rangle$ that has a good overlap $|\langle\psi|\psi_0\rangle|$ with a ground state $|\psi_0\rangle$ of H is given as an additional input or can be constructed easily (this problem has been called the "guided local Hamiltonian problem" in the recent literature [21, 28, 68]). More precisely, quantum phase estimation [40, 55] and more advanced techniques [67, 26, 30, 38, 51, 53, 54, 59] lead to the following result:

▶ **Fact 1.** *Given a quantum state with overlap χ with a ground state of H, there exists a quantum algorithm that computes with high probability an ε-approximation of $\mathcal{E}(H)$ in $\mathrm{poly}\big(\frac{1}{\chi}, \frac{1}{\varepsilon}, n\big)$ time and $O\big(n + \log(\frac{1}{\varepsilon})\big)$ space.*

When $\chi = 1/\mathrm{poly}(n)$ and $\varepsilon = 1/\mathrm{poly}(n)$, both the running time and the space complexity (i.e., the number of bits and qubits needed for the computation) are polynomial in n. Even for larger values of χ, the performance of this quantum algorithm can be significantly better than the performance of classical algorithms (which typically have running time exponential in n – see later for a detailed discussion). Combined with the fact that for several important applications (e.g., quantum chemistry) good candidates for guiding states can be efficiently constructed, ground state energy estimation is one of the most promising and most anticipated applications of quantum computers (we refer to, e.g., [1, 3, 7, 10, 49, 50, 60] for discussions of these applications).

In this work we investigate the classical complexity of this guided local Hamiltonian problem. A first issue is how to present the guiding state (which is a quantum state, i.e., an exponential-dimension vector) to a classical computer. As in prior works in dequantization [8, 22, 23, 25, 28, 29, 35, 46, 64, 65], we consider sample-and-query access:

- **(i)** for any $j \in [2^n]$ we can efficiently compute $\langle j|\psi\rangle$;
- **(ii)** we can efficiently sample from the probability distribution $p\colon [2^n] \to [0,1]$ that outputs j with probability $|\langle j|\psi\rangle|^2$.

The motivation for (ii), which is the central assumption in dequantized algorithms, is as follows: since measuring the quantum state $|\psi\rangle$ in the computational basis gives a sample from the probability p, it is natural (or "fair") to assume that in the classical setting this distribution is efficiently samplable as well.

Recently, Gharibian and Le Gall [28] constructed a classical algorithm computing an ε-approximation of $\mathcal{E}(H)$ in $n^{O(\log(1/\chi)/\varepsilon)}$ time by dequantizing quantum algorithms based on the Quantum Singular Value Transformation. Here is our main result:

▶ **Theorem 1** (Simplified version)**.** *Given sample-and-query access to a quantum state with overlap χ with a ground state of H, there exists a classical algorithm that computes with high probability an ε-approximation of $\mathcal{E}(H)$ in $\mathrm{poly}\big(\frac{1}{\chi^{1/\varepsilon}}, n\big)$ time and $\mathrm{poly}\big(n, \frac{1}{\varepsilon}\big)$ space.*

Our result significantly improves the running time of the algorithm from [28]. For instance, if $\chi = \Omega(1)$, i.e., if we have a good guiding state, our algorithm has time complexity $\mathrm{poly}(2^{1/\varepsilon}, n)$ instead of $n^{O(1/\varepsilon)}$ in [28]. If $\varepsilon = \Omega(1)$, i.e., if we want only constant precision, our algorithm has time complexity $\mathrm{poly}(1/\chi, n)$ instead of $n^{O(\log(1/\chi))}$ in [28]. Additionally, our approach only uses polynomial space. Comparing Theorem 1 with the bounds of Fact 1 shows that for *constant* precision, there exist a classical algorithm matching (up to a polynomial overhead) the performance of quantum algorithms.

Using the same technique, we also obtain the following result for the case where no guided state is given (i.e., the standard version of the local Hamiltonian problem):

▶ **Theorem 2** (Simplified version). *For any constant $\varepsilon > 0$, there exists a classical algorithm that computes with high probability an ε-approximation of $\mathcal{E}(H)$ in $2^{O(n)}$ time and* $\mathrm{poly}(n)$ *space.*

To our knowledge, before this work it was unknown how to achieve simultaneously running time $2^{O(n)}$ and space complexity $\mathrm{poly}(n)$ for ground state energy estimation of arbitrary local Hamiltonians (even for constant ε). We will further discuss the implications of our results in Section 1.3 after reviewing known classical approaches for ground state energy estimation in the next subsection.

1.2 Background on classical approaches for ground state energy estimation

There are two main classical approaches for estimating the ground state energy of a local Hamiltonian:

- The power method or its variant the Lanczos method [42, 43], which estimates the ground state using matrix-vector multiplications. Since the Hamiltonian is a (sparse) matrix of dimension 2^n, the time complexity is $O^*(2^n)$.[1] There are two main issues with this approach. First, it requires storing explicit vectors in memory, which leads to space complexity $\Omega(2^n)$ and significantly reduces its applicability. Second, it is unclear how a guiding state would help significantly reduce the time complexity (having a good guiding state does reduce the number of iterations, but each iteration still requires matrix-vector multiplications of matrices and vectors of dimension 2^n).
- Quantum Monte Carlo methods, which use sampling arguments to estimate the ground state without having to store explicitly the quantum state. This approach is especially useful for "stoquastic" Hamiltonians, i.e., Hamiltonians for which all the off-diagonal elements are real and non-positive, and has lead to the design of classical algorithms as well as as complexity-theoretic investigations of the complexity of the local Hamiltonian problem for stochastic Hamiltonians [17, 19, 15, 52]. While some of these techniques have been extended to a few classes of non-stoquastic local Hamiltonians, such as gapped local Hamiltonians [16] or arbitrary Hamiltonians with succinct ground state [36], for ground state energy estimation the "sign-problem" significantly limits its applications to arbitrary local Hamiltonians [32, 66]. It is also unclear how the guiding state would help reduce the time complexity.

A third approach is direct classical simulation of the quantum circuit used in Fact 1. There are several techniques for simulating quantum circuits on a classical computer. If the circuit acts on n qubits and has m gates, the Schrödinger method stores the entire state vector in memory and performs successive matrix-vector multiplications, using roughly $m2^n$ time and 2^n space. While the space complexity can in several cases be significantly reduced using matrix product states or more general tensor networks [13], those representations also require exponential space in the worst case. On the other hand, the Feynman method calculates an amplitude as a sum of terms, using roughly 4^m time and $m+n$ space (this approach was used by Bernstein and Vazirani [12] to prove the inclusion $\mathsf{BQP} \subseteq \mathsf{P}^{\#\mathsf{P}}$). Aaronson and Chen [2] have introduced a recursive version of the Feynman method, inspired by the proof of Savitch theorem [61], that works in $2^{O(n \log m)}$ time and $\mathrm{poly}(n, m)$ space.

[1] In this paper the notation $O^*(\cdot)$ suppresses the $\mathrm{poly}(n)$ factors.

Other prior works. Several ground state energy estimation classical algorithms have also been developed for special classes of Hamiltonians, such as one-dimensional gapped local Hamiltonians [44], quantum analogues of Max Cut [6, 31, 39, 48, 57], or Hamiltonians defined on structured graphs [9, 11, 14]. Additionally, there are a few works [18, 27, 33] achieving weaker (but still nontrivial) approximation ratios of the ground state energy, and a recent work [20] achieving a constant approximation ratio for any local Hamiltonian in time slightly better than 2^n (but not space-efficiently).

1.3 Implication of our results

We now discuss several implications of our results.

Better understanding of the quantum advantage. As already mentioned, Theorem 1 implies that for any constant precision parameter ε, we can construct classical ground state energy estimation algorithms with performance matching (up to a polynomial overhead) the performance of the best known quantum algorithms. While Ref. [28] already showed this for $\chi = O(1)$, Theorem 1 proves this result for any value $\chi \in (0, 1]$. This implies that (under the assumption that current quantum algorithms are optimal) there is no superpolynomial quantum advantage for the constant-precision guided local Hamiltonian problem and gives another strong evidence that exponential quantum advantage for ground state energy estimation (and applications to, e.g., quantum chemistry) comes from the improved precision achievable in the quantum setting.

Space-efficient classical ground state energy estimation algorithms. The second main contribution of this work is the design of space-efficient algorithms for ground state energy estimation. In particular, for the case where no guiding state is available, Theorem 2 gives a $2^{O(n)}$-time $\mathrm{poly}(n)$-space classical algorithm. As already mentioned, to our knowledge before this work it was unknown how to achieve simultaneously running time $2^{O(n)}$ time and space complexity $\mathrm{poly}(n)$ for arbitrary local Hamiltonians: even for constant ε, the best running time was $2^{O(n \log n)}$ by the approach by Aaronson and Chen [2].

Potentially practical classical ground state energy estimation algorithms. From a practical perspective, the potential of Theorem 1 is even more striking. In particular, for $\chi = \Omega(1)$, i.e., when we have access to a fairly good guided state (which is the case in some applications to quantum chemistry), we obtain a $\mathrm{poly}(2^{1/\varepsilon}, n)$-time $\mathrm{poly}(n)$-space classical algorithm. Note that the running time is polynomial even for $\varepsilon = 1/\log n$. Additionally, the running time is better than 2^n, which is the typically running time of other classical methods, even for precision as low as $\varepsilon = c/n$, for a small enough constant $c > 0$. While evaluating the practicality of our algorithm is beyond the scope of this paper, we hope our algorithms find applications in many-body physics.

Complexity-theoretic implications. In order to formally discuss complexity theoretic aspects of our results and their relations with standard complexity classes as BPP, BQP and QMA, we first need to introduce decision versions of our problems. As standard in Hamiltonian complexity theory, we add the promise that either (i) $\mathcal{E}(H) \leq a$ or (ii) $\mathcal{E}(H) > b$ holds, for some values $a, b \in [0, 1]$ such that $b - a > \varepsilon$, and ask to decide which of (i) or (ii) holds. This leads to the following (standard) decision version of the local Hamiltonian problem:

$\mathsf{LH}(\varepsilon)$ (Local Hamiltonian problem – decision version)

Input: $*$ a $O(1)$-local Hamiltonian H as in Equation (1) acting on n qubits
$*$ two numbers $a, b \in [0,1]$ such that $b - a > \varepsilon$

Promise: either (i) $\mathcal{E}(H) \leq a$ or (ii) $\mathcal{E}(H) > b$ holds

Goal: decide which of (i) or (ii) holds

As already mentioned, the problem $\mathsf{LH}(\varepsilon)$ is QMA-complete for $\varepsilon = 1/\mathrm{poly}(n)$. On the other hand, for any $\varepsilon = O(1)$ Theorem 2 leads to the inclusion

$$\mathsf{LH}(\varepsilon) \in \mathsf{BPTimeSpace}\left(2^{O(n)}, \mathrm{poly}(n)\right),$$

where $\mathsf{BPTimeSpace}(t(n), s(n))$ denotes the class of (promise) decision problems that can be solved with probability at least $2/3$ by a probabilistic Turing machine running in $t(n)$ time and using $s(n)$ space.

For the guided local Hamiltonian problem, another subtle issue is how to access the guiding state $|\psi\rangle$. So far we have assumed sample-and-query access to $|\psi\rangle$ when considering classical algorithms. While satisfactory when discussing algorithmic aspects of the problem (as we did so far), such "oracle" access to the input is problematic if we want to discuss relations with standard complexity classes such as BPP, BQP and QMA. Instead, we make the following assumptions: in the quantum setting, the description of a quantum polynomial-size circuit creating $|\psi\rangle$ is given as input; in the classical setting, the description of a classical polynomial-size circuit implementing sample-and-query access to $|\psi\rangle$ is given as input. This leads to the following decision version of the guided local Hamiltonian problem:

$\mathsf{GLH}(\varepsilon, \chi)$ (Guided Local Hamiltonian problem – decision version)

Input: $*$ a $O(1)$-local Hamiltonian H as in Equation (1) acting on n qubits
$*$ the description of a $\mathrm{poly}(n)$-size circuit implementing access to a quantum state $|\psi\rangle$ with overlap at least χ with the ground state of H
$*$ two numbers $a, b \in [0,1]$ such that $b - a > \varepsilon$

Promise: either (i) $\mathcal{E}(H) \leq a$ or (ii) $\mathcal{E}(H) > b$ holds

Goal: decide which of (i) or (ii) holds

Prior results on the hardness of the guided local Hamiltonian problem [21, 28] combined with Fact 1 imply that $\mathsf{GLH}(\varepsilon, \chi)$ is BQP-complete for $\varepsilon = 1/\mathrm{poly}(n)$ and constant χ. Ref. [28] also showed that this problem is in the class BPP for constant ε and constant χ. Theorem 1 enables us to strengthen this result and show that for constant ε, the inclusion $\mathsf{GLH}(\varepsilon, \chi) \in \mathsf{BPP}$ holds for $\chi = 1/\mathrm{poly}(n)$ as well.

These complexity-theoretic implications are summarized in Table 1.

1.4 Overview of the techniques

The full version of the paper [45] includes a 3-page overview of the techniques, which is omitted here due to space constraints.

2 Preliminaries

In this section we introduce notations and definitions, and present some useful lemmas.

Table 1 The complexity of the problems $\mathsf{LH}(\varepsilon)$ and $\mathsf{GLH}(\varepsilon, \chi)$.

	$\mathsf{LH}(\varepsilon)$	$\mathsf{GLH}(\varepsilon, \Theta(1))$	$\mathsf{GLH}\left(\varepsilon, \frac{1}{\mathrm{poly}(n)}\right)$
$\varepsilon = \Theta(1)$	in $\mathsf{BPTimeSpace}(2^{O(n)}, \mathrm{poly}(n))$ (Th. 2)	in BPP (Ref. [28])	in BPP (Th. 1)
$\varepsilon = \frac{1}{\mathrm{poly}(n)}$	QMA-complete (Refs. [37, 41])	BQP-complete (Refs. [21, 28])	

2.1 Notations

General notations. For any integer N we write $[N] = \{1, \ldots, N\}$. Define $\mathbb{R}[\mathrm{poly}(n)]$ as the set of all real numbers with binary expansion of polynomial length. More precisely, for any function $f\colon \mathbb{N} \to \mathbb{N}$, we define the set

$$\mathbb{R}[f(n)] = \left\{ \pm \left(a_0 + \sum_{i=1}^{f(n)} a_i 2^i + \sum_{i=1}^{f(n)} b_i 2^{-i} \right) \;\middle|\; a_0, \ldots, a_{f(n)}, b_1, \ldots, b_{f(n)} \in \{0,1\} \right\} \subseteq \mathbb{R}$$

of all real numbers with binary expansion of polynomial length $2f(n) + 2$ (including one bit for encoding the sign). Then $\mathbb{R}[\mathrm{poly}(n)]$ is the union of the $\mathbb{R}[f(n)]$ for all polynomial functions $f(n)$. We define $\mathbb{C}[f(n)]$ and $\mathbb{C}[\mathrm{poly}(n)]$ similarly, by requiring that both the real part and the imaginary part are in $\mathbb{R}[f(n)]$ and $\mathbb{R}[\mathrm{poly}(n)]$, respectively.

Vectors and matrices. In this paper we consider vectors in $\mathbb{C}^N$ and matrices in $\mathbb{C}^{N \times N}$, for some integer N, and write $n = \lceil \log_2(N) \rceil$. Note that this notation is consistent with the notation of Section 1, where we considered the special case $N = 2^n$. We usually write quantum states (i.e., unit-norm vectors) using Greek letters and Dirac notation, e.g., we use $|\psi\rangle$ or $|\varphi\rangle$. We write arbitrary vectors (i.e., vectors of arbitrary norm) using Roman letters, e.g., we use v or w.

For a matrix $A \in \mathbb{C}^{N \times N}$ and any $\ell \in [N]$, we denote the ℓ-th row of A by $A[\ell, \cdot]$. The matrix A is normal if it can be written $A = UDU^{-1}$ where D is a diagonal matrix with real entries and U is a unitary matrix. We use $\|A\|$ to denote the spectral norm of A, which is defined for a normal matrix as the maximum magnitude of the eigenvalues of A (and defined as square root of the maximum eigenvalue of A^*A, where A^* denotes the conjugate transpose of A, in general). This norm is submultiplicative, i.e., the inequality $\|AB\| \leq \|A\|\|B\|$ holds for any matrices $A, B \in \mathbb{C}^{N \times N}$. We also have $|u^* A v| \leq \|A\|\|u\|\|v\|$ for any $u, v \in \mathbb{C}^N$, where $\|u\|$ and $\|v\|$ denote the Euclidean norms of u and v, respectively.

Eigenvalues and overlap. Consider a normal matrix $A \in \mathbb{C}^{N \times N}$. Let $A = \sum_{i=1}^{2^n} \lambda_i |u_i\rangle\langle u_i|$ be its eigenvalue decomposition, with eigenvalues $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_{2^n}$ and corresponding orthonormal eigenvectors $|u_1\rangle, \ldots, |u_{2^n}\rangle$. We denote by $\mathcal{E}(A) = \lambda_1$ the smallest eigenvalue of A. For any $\sigma \geq 0$, let us write $S(A, \sigma) = \{i \in [N] \mid \lambda_i(A) \leq \mathcal{E}(A) + \sigma\}$. For any vector $w \in \mathbb{C}^N$, let

$$\Gamma_\sigma(A, w) = \sqrt{\sum_{i \in S(A,\, \sigma)} |\langle u_i | w \rangle|^2}$$

denote the overlap of w with the eigenspace corresponding to eigenvalues in $[\mathcal{E}(A)\,, \mathcal{E}(A) + \sigma]$. Note that the standard definition of the overlap (used in Section 1) corresponds to the case $\sigma = 0$.

2.2 Access to vectors and matrices

We now define the notions of access to vectors and matrices needed for this work. These notions are similar to prior works on dequantization [23, 46, 64], but we need to precisely discuss the encoding length and the space complexity.

We start with query access to a vector.

▶ **Definition 3.** *We have query access to a vector $w \in \mathbb{C}^N$ with encoding length $\mathsf{len}(w)$ and costs $\mathsf{qt}(w)$ and $\mathsf{qs}(w)$ if*

1. *for each $i \in [N]$, we have $w_i \in \mathbb{C}[\mathsf{len}(w)]$;*
2. *for any $i \in [N]$, the coordinate w_i can be obtained in $\mathsf{qt}(w)$ time and $\mathsf{qs}(w)$ space.*

If $\mathsf{len}(w), \mathsf{qt}(w), \mathsf{qs}(w) \leq \mathrm{poly}(n)$, we simply say that we have query access to w.

Next, we introduce the stronger notion of sample-and-query access to a vector.

▶ **Definition 4.** *We have sample-and-query access to a vector $w \in \mathbb{C}^N$ if*

1. *we have query access to w;*
2. *we can compute in $\mathrm{poly}(n)$ time[2] a sample from the distribution $p\colon [N] \to [0,1]$ such that $p(i) = \frac{|w_i|^2}{\|w\|^2}$ for each $i \in [N]$.*

When $\|w\| = 1$, Item 2 in Definition 4 states that we can efficiently sample from the same distribution as the distribution obtained when measuring the quantum state $\sum_{i=1}^N w_i|i\rangle$ in the computational basis.

We extend the notion of query access to matrices as follows:

▶ **Definition 5.** *We have query access to a matrix $B \in \mathbb{C}^{N\times N}$ if*

1. *for each $(i,j) \in [N]\times[N]$, we have $B[i,j] \in \mathbb{C}[\mathrm{poly}(n)]$;*
2. *for any $(i,j) \in [N]\times[N]$, the entry $B[i,j]$ can be obtained in $\mathrm{poly}(n)$ time;*
3. *for any $i \in [N]$, the number s_i of nonzero entries in $B[i,\cdot]$ can be obtained in $\mathrm{poly}(n)$ time;*
4. *for any $i \in [N]$ and any $\ell \in [s_i]$, the ℓ-th nonzero entry of $B[i,\cdot]$ can be obtained in $\mathrm{poly}(n)$ time.*

Items 3 and 4 in Definition 5 are needed to deal with sparse matrices.

2.3 Local Hamiltonians and matrix decompositions

We give below technical details about the description of local Hamiltonians and the matrix decompositions introduced in this work.

Description of local Hamiltonians. A k-local Hamiltonian acting on n qubits is a Hermitian matrix $H \in \mathbb{C}^{N\times N}$ with $N = 2^n$ that can be written as $H = \sum_{i=1}^m H_i$ with $m = \mathrm{poly}(n)$, where each term H_i is an Hermitian matrix acting non-trivially on at most k qubits. Each H_i can be described by a $2^k \times 2^k$ matrix representing its action on the k qubits on which it acts non-trivially. We assume that each entry of this description is in $\mathbb{C}[\mathrm{poly}(n)]$. This description is given as input. For convenience we also assume that we know $\|H_i\|$ for each $i \in [N]$.[3]

[2] Since a polynomial upper bound on the time complexity implies a polynomial upper bound on the space complexity, hereafter we omit to explicitly mention that the space complexity is $\mathrm{poly}(n)$ as well.

[3] Note that each $\|H_i\|$ can be computed from its description as a $2^k \times 2^k$ matrix. The computation is efficient when k is small, e.g., for $k = O(\log n)$, which is the most interesting regime for the local Hamiltonian problem.

Matrix decomposition. Here is the complete definition of the matrix decomposition we consider.

▶ **Definition 6.** *For a matrix A, an integer $s \geq 0$ and a real number $\kappa \in \mathbb{R}[\mathrm{poly}(n)]$, an (s, κ)-decomposition of A is a decomposition*

$$A = \sum_{i=1}^{m} A_i \quad \textit{with} \quad \sum_{i=1}^{m} \|A_i\| \leq \kappa$$

in which A_i is an s-sparse matrix for each $i \in [m]$. We always (implicitly) assume the following:

- *for each $i \in [m]$, we have query access to the matrix A_i;*
- *we know bounds $\kappa_1, \ldots, \kappa_m \in \mathbb{R}[\mathrm{poly}(n)]$ such that $\|A_i\| \leq \kappa_i$ for $i \in [m]$ and $\sum_{i=1}^{m} \kappa_i = \kappa$.*

If $\kappa = 1$, we simply call the decomposition an s-decomposition.

2.4 Lemmas

We present four lemmas that are needed to prove our results.

The first lemma is the "powering lemma" from [34] to amplify the success probability of probabilistic estimators (the formulation below for complex numbers is from [46, Lemma 3]):

▶ **Lemma 7** (Powering lemma)**.** *Consider a randomized algorithm that produces an estimate $\tilde{\mu}$ of a complex-valued quantity μ such that $|\tilde{\mu} - \mu| \leq \varepsilon$ holds with probability at least $3/4$. Then, for any $\delta > 0$, it suffices to repeat $O(\log(1/\delta))$ times the algorithm and take both the median of the real parts and the median of the imaginary parts to obtain an estimate $\hat{\mu}$ such that $|\hat{\mu} - \mu| \leq \sqrt{2}\varepsilon$ holds with probability at least $1 - \delta$.*

To perform eigenvalue estimation we will need a low-degree polynomial that approximates well the "rectangle" function. We will use the following result from [30].[4]

▶ **Lemma 8** (Lemma 29 in [30])**.** *For any $\xi \in (0, 1]$, any $\tau \in [0, 1)$ and any $\theta \in (0, 1 - \tau]$, there exists an efficiently computable polynomial $P \in \mathbb{R}[x]$ of degree $O\big(\frac{1}{\theta}\log(1/\xi)\big)$ such that $|P(x)| \in [0, 1]$ for all $x \in [-1, 1]$ and*

$$\begin{cases} P(x) \in [1 - \xi, 1] & \text{if } x \in [0, \tau], \\ P(x) \in [0, \xi] & \text{if } x \in [\tau + \theta, 1]. \end{cases} \tag{2}$$

We will use the following result from [63] that gives an upper bound on the coefficients of polynomials bounded in the interval $[-1, 1]$ (such as the polynomial from Lemma 8).

▶ **Lemma 9** (Lemma 4.1 in [63])**.** *Let $P(x) = \sum_{i=0}^{d} a_i x^i$ be a univariate polynomial of degree d such that $|P(x)| \leq 1$ for all $x \in [-1, 1]$. Then $\sum_{i=0}^{d} |a_i| \leq 4^d$.*

Finally, we discuss how to classically estimate the inner product $\langle \psi | w \rangle$ given sample-and-query access to a quantum state $|\psi\rangle$ and query access to a vector w. More precisely, we are considering the following problem:

[4] Lemma 8 follows by taking $t = \tau + \theta/2$ and $\delta' = \theta/2$ in Lemma 29 of [30]. The computability of the polynomial is discussed explicitly in [47, Appendix A.3].

$\mathsf{IP}(\varepsilon, \delta)$ (Estimation of Inner Product)

Input: $*$ sample-and-query access to a quantum state $|\psi\rangle \in \mathbb{C}^N$
$*$ query access to a vector $w \in \mathbb{C}^N$ with encoding length $\mathsf{len}(w)$ and costs $\mathsf{qt}(w)$ and $\mathsf{qs}(w)$

Output: an estimate $a \in \mathbb{C}$ such that

$$|a - \langle\psi|w\rangle| \leq \varepsilon \|w\|$$

holds with probability at least $1 - \delta$

Prior works on dequantization [23, 46, 64] have shown how to solve this problem efficiently. It can be easily checked that these approaches are space-efficient as well, leading to the following statement. For completeness we give a proof in the full version of the paper [45].

▶ **Lemma 10.** *For any $\varepsilon \in (0, 1]$ and any $\delta \in (0, 1]$, the problem $\mathsf{IP}(\varepsilon, \delta)$ can be solved classically in time $O^*\big(\mathsf{qt}(w)\,\varepsilon^{-2}\log(1/\delta)\big)$ and space $\mathsf{qs}(w) + O^*\Big(\Big(\mathsf{len}(w) + \log(1/\varepsilon)\Big)\log(1/\delta)\Big)$.*

3 Iterated Matrix Multiplication

In this section we show how to classically estimate the inner product $\langle\psi|B_r \cdots B_1|\varphi\rangle$ for sparse matrices $B_1, \ldots, B_r$ and two quantum states $|\psi\rangle$ and $|\varphi\rangle$ to which we have classical access. More precisely, we consider the following problem.

$\mathsf{IMM}(s, r, \varepsilon, \delta)$ (Estimation of Iterated Matrix Multiplication)

Input: $*$ query access to s-sparse matrices $B_1, \ldots, B_r \in \mathbb{C}^{N\times N}$
$*$ query access to a quantum state $|\varphi\rangle \in \mathbb{C}^N$
$*$ sample-and-query access to a quantum state $|\psi\rangle \in \mathbb{C}^N$

Output: an estimate $\hat{E} \in \mathbb{C}$ such that

$$\left|\hat{E} - \langle\psi|B_r \cdots B_1|\varphi\rangle\right| \leq \varepsilon \|B_1\| \cdots \|B_r\|$$

holds with probability at least $1 - \delta$

Here is the main result of this section.

▶ **Proposition 11.** *For any $s \geq 1$, any $r \geq 1$, any $\varepsilon \in (0, 1]$ and any $\delta \in (0, 1]$, the problem $\mathsf{IMM}(s, r, \varepsilon, \delta)$ can be solved classically in time*

$$O^*\big(s^r \varepsilon^{-2}\log(1/\delta)\big)$$

and space

$$O^*\big(r^2 + \big(r + \log(1/\varepsilon)\big)\log(1/\delta)\big).$$

The proof of Proposition 11 is based on the following lemma, which can be seen as a space-efficient version of the approach for iterated matrix multiplication used in [28, 62].

▶ **Lemma 12.** *There is a classical algorithm that implements query access to $B_r \cdots B_1|\varphi\rangle$ with encoding length $\mathsf{len}(B_r \cdots B_1|\varphi\rangle) = O^*(r)$ and costs $\mathsf{qt}(B_r \cdots B_1|\varphi\rangle) = O^*(s^r)$ and $\mathsf{qs}(B_r \cdots B_1|\varphi\rangle) = O^*\big(r^2\big)$.*

Proof. Here is the main idea: to obtain the ℓ-th entry of $B_r \cdots B_1|\varphi\rangle$, we only need to know the s nonzero entries of the ℓ-th row of B_r, which can be queried directly, together with the corresponding entries in the vector $B_{r-1} \cdots B_1|\varphi\rangle$, which can be computed recursively. The algorithm is described in pseudocode below.

```
Algorithm 𝒜(ℓ, r)      // computes ⟨ℓ|B_r ··· B_1|φ⟩
1  if r = 0 then
2  |  return ⟨ℓ|φ⟩ ;
3  else
4  |  z ← 0 ;
5  |  get the number of nonzero entries of the row B_r[ℓ, ·] and write it s' ;
6  |  for t from 1 to s' do
7  |  |  get the index of the t-th nonzero entry of B_r[ℓ, ·] and write it j ;
8  |  |  x ← B_r[ℓ, j] ;          // queries ⟨ℓ|B_r|j⟩
9  |  |  y ← 𝒜(j, r − 1) ;     // computes recursively ⟨j|B_{r−1} ··· B_1|φ⟩
10 |  |  z ← z + x · y ;
11 |  return z ;
```

We first analyze the correctness of the algorithm. Let $j_1, \ldots, j_{s'}$ represent the indices of the nonzero entries of the row $B_r[\ell, \cdot]$. Since

$$\langle \ell | B_r \cdots B_1 | \varphi \rangle = \sum_{t=1}^{s'} \langle \ell | B_r | j_t \rangle \langle j_t | B_{r-1} \cdots B_1 | \varphi \rangle,$$

Algorithm $\mathcal{A}(\ell, r)$ outputs $\langle \ell | B_r \cdots B_1 | \varphi \rangle$.

Let $\mathcal{T}(r)$ denote the running time of this procedure. We have $\mathcal{T}(r) \leq s\mathcal{T}(r-1) + O^*(s)$, and thus $\mathcal{T}(r) = O^*(s^r)$. For each $j \in [N]$, the entry $\langle j|\psi\rangle$ has a poly(n)-bit binary expansion. Each entry of the matrices $B_1, \ldots, B_r$ also has a poly(n)-bit binary expansion. This implies that $\mathsf{len}(B_r \cdots B_1|\varphi\rangle) = O^*(r)$. We finally consider the space complexity. The recursion tree has depth r. At each level of the recursion, the values x, y and z at Steps 8, 9 and 10 can be stored in $O^*(r)$ bits, and we need one $O(\log s)$-bit counter for storing the current value of t. The overall space complexity of the algorithm is thus $O^*(r(r + \log s)) = O^*\big(r^2\big)$. ◀

Proposition 11 is obtained by applying Lemma 10 to the vector $w = B_r \cdots B_1|\varphi\rangle$, for which we can implement query access from Lemma 12:

Proof of Proposition 11. From Lemma 12 we have query access to $w = B_r \cdots B_1|\varphi\rangle$ with encoding length $\mathsf{len}(w) = O^*(r)$ and costs $\mathsf{qt}(w) = O^*(s^r)$ and $\mathsf{qs}(w) = O^*\big(r^2\big)$. Using Lemma 10, we can then compute an estimate $a \in \mathbb{C}$ such that

$$|a - \langle \psi | B_r \cdots B_1 | \varphi \rangle| \leq \varepsilon \, \|B_r \cdots B_1 |\varphi\rangle\| \leq \varepsilon \, \|B_1\| \cdots \|B_r\|$$

holds with probability at least $1 - \delta$. The time and space complexity are

$$O^*\big(s^r \varepsilon^{-2} \log(1/\delta)\big)$$

and

$$O^*\big(r^2 + \big(r + \log(1/\varepsilon)\big) \log(1/\delta)\big),$$

respectively. ◀

4 Polynomial Transformations of Decomposable Matrices

In this section we show how to classically estimate the inner product $\langle\psi|P(A)|\varphi\rangle$ for a matrix A with an s-decomposition, a polynomial P, and two quantum states $|\psi\rangle$ and $|\varphi\rangle$ to which we have classical access. More precisely, we consider the following problem.

$\mathsf{PT}(s,d,\eta)$ (Estimation of Polynomial Transformation)

Input: $*$ a matrix $A \in \mathbb{C}^{N\times N}$ with an s-decomposition
$*$ a polynomial $P \in \mathbb{R}[x]$ of degree d with $|P(x)| \leq 1 \quad \forall x \in [-1,1]$
$*$ query access to quantum state $|\varphi\rangle \in \mathbb{C}^N$
$*$ sample-and-query access to a quantum state $|\psi\rangle \in \mathbb{C}^N$

Output: an estimate $\hat{E} \in \mathbb{C}$ such that

$$\left|\hat{E} - \langle\psi|P(A)|\varphi\rangle\right| \leq \eta \tag{3}$$

holds with probability at least $1 - 1/\exp(n)$

Here is the main result of this section.

▶ **Proposition 13.** *For any $s \geq 2$, any $d \geq 1$ and any $\eta \in (0,1] \cap \mathbb{R}[\mathrm{poly}(n)]$, the problem $\mathsf{PT}(s,d,\eta)$ can be solved classically in time $O^*\left(s^{c\cdot d}\eta^{-4}\right)$ time, for some universal constant $c > 0$, and space $O^*\left(d^2\right)$.*

The proof of Proposition 13 is based on the following lemma, whose proof is given after the proof of the proposition.

▶ **Lemma 14.** *For any $r \in \{0,\ldots,d\}$, any $\eta \in (0,1] \cap \mathbb{R}[\mathrm{poly}(n)]$ and any $\delta \in (0,1]$, there is a classical algorithm that computes an estimate $\hat{E}_r \in \mathbb{C}$ such that $\left|\hat{E}_r - \langle\psi|A^r|\varphi\rangle\right| \leq \frac{\eta}{4^d}$ holds with probability at least $1-\delta$ in time $O^*\left(s^r 2^{8d}\eta^{-4} d\log(1/\delta)\right)$ and space $O^*\left(d^2 + d\log(1/\delta)\right)$.*

Proof of Proposition 13. Let us write the polynomial P as $P(x) = \sum_{r=0}^{d} a_r x^d$. For any $\delta' \in (0,1]$, we describe how to compute an estimate $\hat{E}$ such that Equation (3) holds with probability at least $1-\delta'$. Taking $\delta' = 1/\exp(n)$ then proves the proposition.

For each $r \in \{0,\ldots,d\}$ such that $a_r \neq 0$, we apply Lemma 14 with $\delta = \frac{\delta'}{d+1}$ to obtain an approximation $\hat{E}_r$ of $\langle\psi|A^r|\varphi\rangle$ such that

$$\Pr\left[\left|\hat{E}_r - \langle\psi|A^r|\varphi\rangle\right| \leq \frac{\eta}{4^d}\right] \geq 1 - \frac{\delta'}{d+1}.$$

For each $r \in \{0,\ldots,d\}$ such that $a_r = 0$, we set $\hat{E}_r = 0$. We then output $\hat{E} = \sum_{r=0}^{d} a_r \hat{E}_r$. From the union bound and the triangle inequality, with probability at least $1-\delta'$ we have

$$\left|\hat{E} - \langle\psi|P(A)|\varphi\rangle\right| \leq \sum_{r=0}^{d} |a_r|\,|E_r - \langle\psi|A^r|\varphi\rangle| \leq \eta,$$

where we used Lemma 9 to derive the last inequality.

The time complexity is

$$O^*\left(\left(\sum_{r=0}^{d} s^r\right) 2^{8d}\eta^{-4} d\log\left(\frac{d}{\delta'}\right)\right) = O^*\left(s^d 2^{8d}\eta^{-4} d\log\left(\frac{d}{\delta'}\right)\right) = O^*\left(s^{c\cdot d}\eta^{-4}\right),$$

for some universal constant $c > 0$. The space complexity is

$$O^*\left(d^2 + d\log(d/\delta')\right) = O^*\left(d^2\right),$$

as claimed. ◀

Proof of Lemma 14. As in Definition 6, we write the s-decomposition of A as $A = \sum_{i=1}^{m} A_i$, where each A_i is an s-sparse matrix such that $\|A_i\| \leq \kappa_i$, with $\kappa_1 + \cdots + \kappa_m = 1$. Consider the probability distribution $p\colon [m]^r \to [0,1]$ defined as $p(x) = \kappa_{x_1} \cdots \kappa_{x_r}$ for any $x \in [m]^r$ (the condition $\kappa_1 + \cdots + \kappa_m = 1$ guarantees that this is a probability distribution). Define a random variable X as follows: sample a vector x from the distribution p, and set

$$X = \frac{\langle\psi|A_{x_1} \cdots A_{x_r}|\varphi\rangle}{p(x)}.$$

Repeat the above procedure $t = \left\lceil 64 \cdot 4^{2^d}/\eta^2 \right\rceil$ times and output the mean. Let Y denote the corresponding complex random variable. We have

$$\begin{aligned}
\mathbb{E}[Y] = \mathbb{E}[X] &= \sum_{x\in[m]^r} \langle\psi|A_{x_1} \cdots A_{x_r}|\varphi\rangle = \langle\psi|A^r|\varphi\rangle \\
\mathbb{V}[Y] &\leq \frac{1}{t}\mathbb{E}\left[|X|^2\right] \\
&= \frac{1}{t} \sum_{x\in[m]^r} \frac{|\langle\psi|A_{x_1} \cdots A_{x_r}|\varphi\rangle|^2}{\kappa_{x_1} \cdots \kappa_{x_r}} \\
&\leq \frac{1}{t} \sum_{x\in[m]^r} \frac{\|A_{x_1} \cdots A_{x_r}\|^2}{\kappa_{x_1} \cdots \kappa_{x_r}} \\
&\leq \frac{1}{t} \sum_{x\in[m]^r} \kappa_{x_1} \cdots \kappa_{x_r} \\
&= \frac{1}{t} \left(\kappa_1 + \cdots + \kappa_m\right)^r \\
&= \frac{1}{t}.
\end{aligned}$$

From Chebyshev's inequality, we thus obtain:

$$\Pr\left[|Y - \langle\psi|A^r|\varphi\rangle| \geq \frac{\eta}{2\sqrt{2}\cdot 4^d}\right] \leq \frac{8\cdot 4^{2d}}{\eta^2 t} \leq \frac{1}{8}. \tag{4}$$

We cannot directly use this strategy since we do not know $\langle\psi|A_{x_1} \cdots A_{x_r}|\varphi\rangle$. Instead, we estimate this quantity using Proposition 11. This leads to the following algorithm.

Algorithm $\mathcal{B}(\eta)$ `// estimates` $\langle\psi|A^r|\varphi\rangle$ `with precision` $\frac{\eta}{\sqrt{2}\cdot 4^d}$

$t \leftarrow \left\lceil 64 \cdot 4^{2d}/\eta^2 \right\rceil$;
$z \leftarrow 0$;
for i **from** 1 **to** t **do**
  Take a vector x according to the distribution p.
  Use Proposition 11 for the problem $\mathsf{IMM}\left(s, r, \frac{\eta}{2\sqrt{2}\cdot 4^d}, \frac{1}{8t}\right)$ to compute an estimate $\alpha \in \mathbb{C}$ of $\langle\psi|A_{x_1} \cdots A_{x_r}|\varphi\rangle$;
  $z \leftarrow z + \frac{\alpha}{t\cdot p(x)}$;
return z;

The complexity of Algorithm $\mathcal{B}(\eta)$ is dominated by the computation at Step 5, which is done t times. From Proposition 11, we obtain the upper bounds

$$O^*\big(t \cdot s^r 2^{4d} \eta^{-2} \log(8t)\big) = O^*\big(s^r 2^{8d} \eta^{-4} d\big)$$

and

$$O^*\left(r^2 + \left(r + \log\left(\frac{2\sqrt{2}\cdot 4^d}{\eta}\right)\right)\log(8t)\right) = O^*\big(r^2 + d^2\big) = O^*\big(d^2\big)$$

on the time and space complexities, respectively.

We now analyze the correctness of Algorithm $\mathcal{B}(\eta)$. Let Z be the random variable corresponding to the output of Step 7 when at Step 4 the vectors x's are the same vectors as in the random variable Y. For any choice of x at Step 4, the estimate α of Step 5 satisfies

$$|\alpha - \langle\psi|A_{x_1}\cdots A_{x_r}|\varphi\rangle| \leq \frac{\eta\,\kappa_{x_1}\cdots\kappa_{x_r}}{2\sqrt{2}\cdot 4^d} \tag{5}$$

with probability at least $1-1/(8t)$. Under the condition that Inequality (5) is always satisfied during the t repetitions, we have

$$|Z-Y| \leq \sum_x \frac{1}{t\cdot p(x)} \frac{\eta\,\kappa_{x_1}\cdots\kappa_{x_r}}{2\sqrt{2}\cdot 4^d} = \frac{\eta}{2\sqrt{2}\cdot 4^d},$$

where the sum is over the t vectors x chosen at Step 4. By the union bound, we thus have

$$\Pr\left[|Z-Y| > \frac{\eta}{2\sqrt{2}\cdot 4^d}\right] \leq \frac{1}{8}. \tag{6}$$

Combining Equation (4) and Equation (6) gives

$$\begin{aligned}\Pr\left[|Z - \langle\psi|A^r|\varphi\rangle| \leq \frac{\eta}{\sqrt{2}\cdot 4^d}\right] &\geq \Pr\left[|Z-Y| \leq \frac{\eta}{2\sqrt{2}\cdot 4^d} \text{ and } |Y - \langle\psi|A^r|\varphi\rangle| \leq \frac{\eta}{2\sqrt{2}\cdot 4^d}\right] \\ &\geq 1 - \Pr\left[|Z-Y| > \frac{\eta}{2\sqrt{2}\cdot 4^d}\right] - \Pr\left[|Y - \langle\psi|A^r|\varphi\rangle| > \frac{\eta}{2\sqrt{2}\cdot 4^d}\right] \\ &\geq \frac{3}{4}.\end{aligned}$$

We can then use Lemma 7 to obtain an estimate $\hat{E}_r \in \mathbb{C}$ such that $\left|\hat{E}_r - \langle\psi|A^r|\varphi\rangle\right| \leq \frac{\eta}{4^d}$ holds with probability at least $1-\delta$. Lemma 7 introduces a $\log(1/\delta)$ factor in the time complexity and an additive $O^*(d\log(1/\delta))$ term in the space complexity since for the computation of the medians we need to store $O(\log(1/\delta))$ values, each requiring $O^*(d)$ bits.[5] ◀

5 Eigenvalue Estimation

In this section we use the results proved in Section 4 to estimate the smallest eigenvalue of a normal matrix. We describe the most general problem we are solving in Section 5.1 and then prove Theorems 1 and 2 in Section 5.2.

[5] Here we are using the assumption $\kappa_i \in \mathbb{C}[\text{poly}(n)]$ for all $i \in [m]$, see Definition 6. This implies that $p(x)$ can be encoded in $O^*(r)$ bits and the output of Procedure $\mathcal{B}(\eta)$ in $O^*(d)$ bits.

5.1 General result

We consider the problem of estimating the smallest eigenvalue of a normal matrix with an (s, κ)-decomposition, given classical access to a guiding state. Here is the formal description of the problem:

$\mathsf{SE}(s, \chi, \varepsilon)$ `(Estimation of the Smallest Eigenvalue)`

Input: $*$ a normal matrix $A \in \mathbb{C}^{N \times N}$ with an (s, κ)-decomposition (for any κ)

$*$ sample-and-query access to a quantum state $|\psi\rangle \in \mathbb{C}^N$ with $\Gamma_{\frac{\varepsilon}{2}\kappa}(A, |\psi\rangle) \geq \chi$

Output: an estimate $E^* \in \mathbb{R}$ such that

$$|E^* - \mathcal{E}(A)| \leq \varepsilon\,\kappa \tag{7}$$

holds with probability at least $1 - 1/\exp(n)$

We prove the following theorem:

▶ **Theorem 15.** *For any $s \geq 2$ and any $\varepsilon, \chi \in (0, 1] \cap \mathbb{R}[\mathrm{poly}(n)]$, the problem $\mathsf{SE}(s, \chi, \varepsilon)$ can be solved classically in time $O^*\left(s^{\frac{c' \log(1/\chi)}{\varepsilon}}\right)$ time, for some universal constant $c' > 0$, and space $O^*\left(1/\varepsilon^2\right)$.*

Proof of Theorem 15. Let us define $A' = \frac{1}{2}(I + \frac{A}{\kappa})$ and write $T = \lceil 4/\varepsilon \rceil$. The (s, κ)-decomposition of A gives an $(s+1)$-decomposition of A'. Observe that A' has eigenvalues in the interval $[0, 1]$. The main idea is to divide this interval into T subintervals of length at most $\varepsilon/4$ and find in which subinterval $\mathcal{E}(A')$ lies in. Since $\mathcal{E}(A) = 2\kappa\mathcal{E}(A') - \kappa$, this will give an estimate of $\mathcal{E}(A)$.

Concretely, for any $t \in \{0, \ldots, T-1\}$, we consider the following test that checks if $\mathcal{E}(A')$ is "approximately" smaller than $t\frac{\varepsilon}{4}$. The approximation comes from the use of an estimator at Step 2 – details of the implementation of this step are discussed later.

$\mathsf{Test}(t)$ `// checks if` $\mathcal{E}(A')$ `is (approximately) smaller than` $t\frac{\varepsilon}{4}$

1 Let P be the polynomial of Lemma 8 with $\tau = t\frac{\varepsilon}{4}$, $\theta = \frac{\varepsilon}{4}$ and $\xi = \frac{\chi^2}{12}$;
2 Compute an estimate $\hat{E} \in \mathbb{C}$ such that $\left|\hat{E} - \langle\psi|P(A')|\psi\rangle\right| \leq \frac{\chi^2}{4}$;
3 **if** $\left|\hat{E}\right| \geq \frac{\chi^2}{2}$ **then** output "yes";
4 **else** output "no";

Let t^* be the smallest value of $t \in \{0, \ldots, T-1\}$ such that $\mathsf{Test}(t)$ outputs "yes". Define $E^* = t^*\frac{\varepsilon}{2}\kappa - \kappa$. The following claim, whose proof is given in the full version of the paper [45], guarantees that E^* is a correct estimate of $\mathcal{E}(A)$.

▷ Claim 16. $|E^* - \mathcal{E}(A)| \leq \varepsilon\,\kappa$.

We now discuss the implementation of Step 2. For any $\delta \in (0, 1]$, we describe how to compute an estimate E^* such that Equation (7) holds with probability at least $1 - \delta$. Taking $\delta = 1/\exp(n)$ then proves the theorem.

We use the algorithm of Proposition 13 for the problem $\mathsf{PT}(s, \deg(P), \chi^2/4)$ in order to obtain an estimator $\hat{E}$ such that $\left|\hat{E} - \langle\psi|P(A')|\psi\rangle\right| \leq \chi^2/4$ holds with probability at least $1 - \delta/T$. Since $\mathsf{Test}(t)$ is called at most T times, the union bound guarantees that with probability at least $1 - \delta$ no error occur during these tests. This implies that the output E^* satisfies the bound of Claim 16 with probability at least $1 - \delta$.

The overall time complexity is $O^*\big(T \cdot (s+1)^{c \cdot \deg(P)} \chi^{-8}\big) = O^*\Big(s^{\frac{c' \log(1/\chi)}{\varepsilon}}\Big)$, for some universal constant $c' > 0$. Since $\deg(P) = O^*(1/\varepsilon)$, the space complexity is $O^*\big(1/\varepsilon^2\big)$. ◀

5.2 Consequences: Theorems 1 and 2

We are now ready to give the full statements of Theorems 1 and 2 and prove them.

▶ **Theorem 14** (Full version). *Consider any $\varepsilon, \chi \in (0,1] \cap \mathbb{R}[\mathrm{poly}(n)]$. For any k-local Hamiltonian H on n qubits, given sample-and-query access to a quantum state $|\psi\rangle$ with*

$$\Gamma_{\frac{\varepsilon}{2}\kappa}(H, |\psi\rangle) \geq \chi,$$

where $\kappa = \sum_{i=1}^m \|H_i\|$, there is a classical algorithm that computes in $\mathrm{poly}\big(\frac{1}{\chi^{k/\varepsilon}}, n\big)$ time and $O^*\big(\frac{1}{\varepsilon^2}\big)$ space an estimate $\hat{E}$ such that

$$\left|\hat{E} - \mathcal{E}(H)\right| \leq \varepsilon \sum_{i=1}^m \|H_i\|$$

holds with probability at least $1 - 1/\exp(n)$.

Proof of Theorem 1. We apply Theorem 15 with $A = H$, $s = 2^k$ and $\kappa = \sum_{i=1}^m \|H_i\|$. ◀

▶ **Theorem 15** (Full version). *Consider any $\varepsilon \in (0,1] \cap \mathbb{R}[\mathrm{poly}(n)]$. For any k-local Hamiltonian H on n qubits, there is a classical algorithm that computes in $2^{O(kn/\varepsilon)}$ time and $O^*\big(\frac{1}{\varepsilon^2}\big)$ space an estimate $\hat{E}$ such that*

$$\left|\hat{E} - \mathcal{E}(H)\right| \leq \varepsilon \sum_{i=1}^m \|H_i\|$$

holds with probability at least $1 - 1/\exp(n)$.

Proof of Theorem 2. Let us write $H = \sum_{i=1}^{2^n} \lambda_i |u_i\rangle\langle u_i|$ the spectral decomposition of H, with $\lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_{2^n}$ and corresponding orthonormal eigenvectors $|u_1\rangle, \ldots, |u_{2^n}\rangle$, where $\lambda_1 = \mathcal{E}(H)$. We apply Theorem 1 with the Hamiltonian $H' = H \otimes I$ acting on $2n$ qubits (here I is the identity matrix acting on n qubits) and guiding state $|\Phi\rangle = \frac{1}{\sqrt{2^n}} \sum_{i=1}^{2^n} |i\rangle|i\rangle$, for which it is trivial to implement sample-and-query access. This is a maximally entangled state, which can also be written as $|\Phi\rangle = \frac{1}{\sqrt{2^n}} \sum_{i=1}^{2^n} |u_i\rangle|v_i\rangle$, for another orthonormal basis $\{|v_1\rangle, \ldots, |v_{2^n}\rangle\}$.

Let $t \in [2^n]$ denote the multiplicity of the ground state energy of H. The eigenspace corresponding to the ground state energy of H' is thus $\mathrm{span}\,\{|u_i\rangle|j\rangle \mid i \in [t], j \in [2^n]\}$. We have

$$\Gamma_0(H, |\Phi\rangle) = \sqrt{\sum_{i=1}^{t} \sum_{j=1}^{2^n} |(\langle u_i|\langle j|)|\Phi\rangle|^2} \geq \frac{1}{\sqrt{2^n}} \sqrt{\sum_{j=1}^{2^n} |\langle j|v_1\rangle|^2} = \frac{1}{\sqrt{2^n}}.$$

The conclusion follows from Theorem 1 with $\chi = 2^{-n/2}$. ◀

Core-Sparse Monge Matrix Multiplication

Improved Algorithm and Applications

Abstract

Min-plus matrix multiplication is a fundamental tool for designing algorithms operating on distances in graphs and different problems solvable by dynamic programming. We know that, assuming the APSP hypothesis, no subcubic-time algorithm exists for the case of general matrices. However, in many applications the matrices admit certain structural properties that can be used to design faster algorithms. For example, when considering a planar graph, one often works with a *Monge matrix* A, meaning that the *density matrix* $A^{\square}$ has non-negative entries, that is, $A^{\square}_{i,j} \coloneqq A_{i+1,j} + A_{i,j+1} - A_{i,j} - A_{i+1,j+1} \geq 0$. The min-plus product of two $n \times n$ Monge matrices can be computed in $\mathcal{O}(n^2)$ time using the famous SMAWK algorithm.

In applications such as longest common subsequence, edit distance, and longest increasing subsequence, the matrices are even more structured, as observed by Tiskin [J. Discrete Algorithms, 2008]: they are (or can be converted to) *simple unit-Monge matrices*, meaning that the density matrix is a permutation matrix and, furthermore, the first column and the last row of the matrix consist of only zeroes. Such matrices admit an implicit representation of size $\mathcal{O}(n)$ and, as shown by Tiskin [SODA 2010 & Algorithmica, 2015], their min-plus product can be computed in $\mathcal{O}(n \log n)$ time. Russo [SPIRE 2010 & Theor. Comput. Sci., 2012] identified a general structural property of matrices that admit such efficient representation and min-plus multiplication algorithms: the *core size* δ, defined as the number of non-zero entries in the density matrices of the input and output matrices. He provided an adaptive implementation of the SMAWK algorithm that runs in $\mathcal{O}((n+\delta)\log^3 n)$ or $\mathcal{O}((n+\delta)\log^2 n)$ time (depending on the representation of the input matrices).

In this work, we further investigate the core size as the parameter that enables efficient min-plus matrix multiplication. On the combinatorial side, we provide a (linear) bound on the core size of the product matrix in terms of the core sizes of the input matrices. On the algorithmic side, we generalize Tiskin's algorithm (but, arguably, with a more elementary analysis) to solve the core-sparse Monge matrix multiplication problem in $\mathcal{O}(n + \delta \log \delta) \subseteq \mathcal{O}(n + \delta \log n)$ time, matching the complexity for simple unit-Monge matrices. As witnessed by the recent work of Gorbachev and Kociumaka [STOC'25] for edit distance with integer weights, our generalization opens up the possibility of speed-ups for weighted sequence alignment problems. Furthermore, our multiplication algorithm is also capable of producing an efficient data structure for recovering the witness for any given entry of the output matrix. This allows us, for example, to preprocess an integer array of size n in $\widetilde{\mathcal{O}}(n)$ time so that the longest increasing subsequence of any sub-array can be reconstructed in $\widetilde{\mathcal{O}}(\ell)$ time, where ℓ is the length of the reported subsequence. In comparison, Karthik C. S. and Rahul [arXiv, 2024] recently achieved $\mathcal{O}(\ell + n^{1/2}\operatorname{polylog} n)$-time reporting after $\mathcal{O}(n^{3/2}\operatorname{polylog} n)$-time preprocessing.

1 Introduction

The *min-plus product* (also known as the distance product or the tropical product) of two matrices A and B is defined as a matrix $C = A \otimes B$ such that $C_{i,k} = \min_j (A_{i,j} + B_{j,k})$. The task of computing the min-plus product of two $n \times n$ matrices can be solved in $n^3/\exp(\Omega(\sqrt{\log n}))$ time [46], and it is fine-grained equivalent to the All-Pairs Shortest Path (APSP) problem [44], asking to compute the distances between every pair of vertices in a directed weighted graph on n vertices. While it is conjectured that APSP, and hence also the min-plus product, do not admit $n^{3-\Omega(1)}$-time solutions, faster algorithms exist for many special cases arising in numerous applications of the min-plus product; see, e.g., [2, 6, 10, 15–17, 23, 43, 47, 49]. Most of the underlying procedures rely on fast matrix multiplication for the standard $(+, \cdot)$-product.

Monge matrices constitute a notable exception: An $n \times n$ matrix A is a Monge matrix if its *density matrix* $A^{\square}$ is non-negative, that is, $A^{\square}_{i,j} \coloneqq A_{i+1,j} + A_{i,j+1} - A_{i,j} - A_{i+1,j+1} \geq 0$ holds for all $i, j \in [0\,..n-1)$. The min-plus product of two $n \times n$ Monge matrices can be computed in $\mathcal{O}(n^2)$ time using the SMAWK algorithm [1], and the resulting matrix still satisfies the Monge property. Monge matrices arise in many combinatorial optimization problems; see [7, 8] for surveys. One of the most successful applications is for planar graphs, where the distances between vertices on a single face satisfy the Monge property (see [18, Section 2.3]). This observation allowed for an $\widetilde{\mathcal{O}}(n)$-time[1] single-source shortest path algorithm for planar graphs (with negative real weights) [18], and the resulting techniques now belong to the standard toolkit for designing planar graph algorithms; see, e.g., [5, 11, 25].

Another important application of Monge matrices is in sequence alignment problems, such as *edit distance* and *longest common subsequence* (LCS), as well as in the related *longest increasing subsequence* (LIS) problem. Already in the late 1980s, Apostolico, Atallah, Larmore, and McFaddin [3] noted that the so-called *DIST matrices*, which (among others) specify the weighted edit distances between prefixes of one string and suffixes of another string, satisfy the Monge property. A modern interpretation of this observation is that these matrices store boundary-to-boundary distances in planar *alignment graphs* [37]; see also [4, 26, 32] for further early applications of DIST matrices and their Monge property.

In the late 2000s, Tiskin [39, 42] observed that the DIST matrices originating from the unweighted variants of edit distance, LCS, and LIS problems are more structured. For this, he introduced the notions of *unit-Monge matrices*, whose density matrices are permutation matrices (that is, binary matrices whose rows and columns contain exactly a single 1 entry each) and *simple Monge matrices*, whose leftmost column and bottommost row consist of zeroes. He also proved that the product of two simple unit-Monge matrices still belongs to this class and can be computed in $\mathcal{O}(n \log n)$ time provided that each matrix A is represented using the underlying permutation P_A [41]. By now, the resulting algorithm has found numerous applications, including for computing LCS and edit distance of compressed strings [19, 20, 24, 41], maintaining these similarity measures for dynamic strings [13, 22], approximate pattern matching [14, 40], parallel and distributed algorithms for similarity measures [31, 33], and oracles for substring similarity [12, 35, 36]. Furthermore, Tiskin's algorithm has been used to solve the LIS problem in various settings, such as dynamic [28],

[1] Throughout this paper, we use $\widetilde{\mathcal{O}}(\cdot)$ notation to suppress factors poly-logarithmic in the input size.

parallel [9], and distributed [30]. A disadvantage of Tiskin's original description (and even the later informal descriptions [29]) is its dependence on the algebraic structure known as the monoid of seaweed braids, which natively supports unweighted LCS only (tasks involving edit distance need to be reduced to LCS counterparts). This makes the algorithm difficult to generalize to weighted problems and extend even to seemingly simple questions such as recovering (an implicit representation of) the witness indices j such that $C_{i,k} = A_{i,j} + B_{j,k}$ [27].

Russo [34] identified the number of non-zero elements in $A^{\square}$, $B^{\square}$, and $(A \otimes B)^{\square}$, called the *core size* δ, as the parameter that enables fast min-plus matrix multiplication. It is easy to see that A, B, and $A \otimes B$ can be stored in $\mathcal{O}(n+\delta)$ space using a *condensed representation*, consisting of the *boundary entries* (the leftmost column and bottommost row, e.g., suffice) and *core elements*, i.e., the non-zero entries of the density matrix. Then, Russo's algorithm for the *core-sparse Monge matrix multiplication* problem computes the condensed representation of $A \otimes B$ in $\mathcal{O}((n+\delta)\log^2 n)$ time when provided with constant-time random access to A and B, and in $\mathcal{O}((n+\delta)\log^3 n)$ time given condensed representations of A and B.[2] Russo's algorithm has a very different structure than Tiskin's: it relies on a clever adaptation of the SMAWK algorithm [1] to provide efficient random access to C and then employs binary search to find individual non-zero entries of $C^{\square}$. This brings the question of unifying both approaches and understanding the complexity of core-sparse Monge matrix multiplication.

Our Results. We consider the core-sparse Monge matrix multiplication problem from the combinatorial and algorithmic points of view, and confirm that the core size is the right parameter that enables fast min-plus matrix multiplication. Let $\delta(A)$, or the core size of A, denote the number of non-zero elements in $A^{\square}$. We begin with analyzing, in Section 3, how the core size of $A \otimes B$ depends on the core sizes of A and B.

▶ **Theorem 1.1.** *Let A be a $p \times q$ Monge matrix, and let B be a $q \times r$ Monge matrix. We have $\delta(A \otimes B) \le 2 \cdot (\delta(A) + \delta(B))$.*

We stress that this the first bound on $\delta(A \otimes B)$ in terms of $\delta(A)$ and $\delta(B)$: the complexity analysis of Russo's algorithm [34] requires a bound on all $\delta(A)$, $\delta(B)$, and $\delta(A \otimes B)$.

Next, in Section 4, we generalize Tiskin's algorithm (but fully avoiding the formalism of the seaweed product) to solve the core-sparse Monge matrix multiplication problem. We believe that the more elementary interpretation makes our viewpoint not only more robust but also easier to understand. At the same time, the extension from simple unit-Monge matrices to general core-sparse Monge matrices introduces a few technical complications handled in the full version of the paper [21]. Notably, we need to keep track of the leftmost column and the bottommost row instead of assuming they are filled with zeroes. Further, the core does not form a permutation so splitting it into two halves of the same size requires some calculations.

▶ **Theorem 1.2.** *There is a (deterministic) algorithm that, given the condensed representations of a $p \times q$ Monge matrix A and a $q \times r$ Monge matrix B, in time $\mathcal{O}(p+q+r+(\delta(A)+\delta(B))\log(1+\delta(A)+\delta(B)))$ computes the condensed representation of $A \otimes B$.*[3]

[2] More precisely, Russo's algorithm builds a data structure that provides $\mathcal{O}(\log n)$-time random access to the entries of $A \otimes B$. Consequently, for repeated multiplication, we cannot assume constant-time access to the input matrices. Hence, $\mathcal{O}((n+\delta)\log^3 n)$ is a more realistic bound.

[3] In the technical sections of the paper we use the $\mathcal{O}(\cdot)$-notation conservatively. Specifically, we interpret $\mathcal{O}(f(x_1,\ldots,x_k))$ as the set of functions $g(x_1,\ldots,x_k)$ for which there are constants $c_g, N_g > 0$ such that $g(x_1,\ldots,x_k) \le c_g \cdot f(x_1,\ldots,x_k)$ holds for all valid tuples $(x_1,\ldots,x_k)$ satisfying $\max_i x_i \ge N_g$.

The above complexity improves upon Russo's [34] and matches Tiskin's [41] for the simple unit-Monge case. Thanks to the more direct description, we can easily extend our algorithm to build (in the same complexity) an $\mathcal{O}(n+\delta)$-size data structure that, given (i,k), in $\mathcal{O}(\log n)$ time computes the smallest *witness* j such that $C_{i,k} = A_{i,j} + B_{j,k}$.

Applications. As an application of our witness recovery functionality, we consider the problem of range LIS queries. This task asks to preprocess an integer array $s[0..n)$ so that, later, given two indices $0 \le i < j \le n$, the longest increasing subsequence (LIS) of the sub-array $s[i..j)$ can be reported efficiently. Tiskin [38, 41] showed that the LIS size ℓ can be reported in $\mathcal{O}(\log n)$ time after $\mathcal{O}(n \log^2 n)$-time preprocessing. It was unclear, though, how to efficiently report the LIS itself. The recent work of Karthik C. S. and Rahul [27] achieved $\mathcal{O}(n^{1/2} \log^3 n + \ell)$-time reporting (correct with high probability) after $\mathcal{O}(n^{3/2} \log^3 n)$-time preprocessing. It is fairly easy to use our witness recovery algorithm to deterministically support $\mathcal{O}(\ell \log^2 n)$-time reporting after $\mathcal{O}(n \log^2 n)$-time preprocessing; see Section 5 for an overview of this result. As further shown in the full version of the paper [21], the reporting time can be improved to $\mathcal{O}(\ell \log n)$ and, with the preprocessing time increased to $\mathcal{O}(n \log^3 n)$, all the way to $\mathcal{O}(\ell)$.

▶ **Theorem 1.3.** *For every parameter $\alpha \in [0,1]$, there exists an algorithm that, given an integer array $s[0..n)$, in time $\mathcal{O}(n \log^{3-\alpha} n)$ builds a data structure that can answer range LIS* reporting *queries in time $\mathcal{O}(\ell \log^{\alpha} n)$, where ℓ is the length of the reported sequence.*

In particular, there is an algorithm with $\mathcal{O}(n \log^3 n)$ preprocessing and $\mathcal{O}(\ell)$ reporting time and an algorithm with $\mathcal{O}(n \log^2 n)$ preprocessing and $\mathcal{O}(\ell \log n)$ reporting time.

In parallel to this work, Gorbachev and Kociumaka [22] used core-sparse Monge matrix multiplication for the *weighted edit distance* with integer weights. Theorem 1.2 allowed for saving two logarithmic factors in the final time complexities compared to the initial preprint using Russo's approach [34]. Weighted edit distance is known to be reducible to unweighted LCS only for a very limited class of so-called uniform weight functions [38], so this application requires the general core-sparse Monge matrix multiplication.

Open Problem. An interesting open problem is whether any non-trivial trade-off can be achieved for the *weighted* version of range LIS queries, where each element of s has a weight, and the task is to compute a maximum-weight increasing subsequence of $s[i..j)$: either the weight alone or the whole subsequence. Surprisingly, as we show in the full version of the paper [21], if our bound $\delta(A \otimes B) \le 2 \cdot (\delta(A) + \delta(B))$ of Theorem 1.1 can be improved to $\delta(A \otimes B) \le c \cdot (\delta(A) + \delta(B)) + \widetilde{\mathcal{O}}(p+q+r)$ for some $1 \le c < 2$, then our techniques automatically yield a solution with $\widetilde{\mathcal{O}}(n^{1+\log_2 c})$ preprocessing time, $\widetilde{\mathcal{O}}(1)$ query time, and $\widetilde{\mathcal{O}}(\ell)$ reporting time.

2 Preliminaries

▶ **Definition 2.1.** *A matrix A of size $p \times q$ is a* Monge matrix *if it satisfies the following* Monge property *for every $i \in [0..p-1)$ and $j \in [0..q-1)$:*

$$A_{i,j} + A_{i+1,j+1} \le A_{i,j+1} + A_{i+1,j}.$$

Furthermore, A is an anti-Monge matrix *if the matrix $-A$ (with negated entries) is a Monge matrix.*

Accordingly, whenever the expression inside $\mathcal{O}(\cdot)$ depends on multiple parameters, we sometimes add 1 or 2 to the arguments of logarithms to ensure formal correctness in corner cases.

In some sources, the following equivalent (but seemingly stronger) condition is taken as the definition of Monge matrices.

▶ **Observation 2.2.** *A matrix A of size $p \times q$ is a Monge matrix if and only if it satisfies the following inequality for all integers $0 \le a \le b < p$ and $0 \le c \le d < q$:*

$$A_{a,c} + A_{b,d} \le A_{a,d} + A_{b,c}.$$

Proof. It suffices to sum the inequality in Definition 2.1 for all $i \in [a..b)$ and $j \in [c..d)$. ◀

▶ **Definition 2.3.** *The* min-plus product *of a matrix A of size $p \times q$ and a matrix B of size $q \times r$ is a matrix $A \otimes B = C$ of size $p \times r$ satisfying $C_{i,k} = \min_{j \in [0..q)} A_{i,j} + B_{j,k}$ for all $i \in [0..p)$ and $k \in [0..r)$.*

For $i \in [0..p)$ and $k \in [0..r)$, we call $j \in [0..q)$ a witness *of $C_{i,k}$ if and only if $C_{i,k} = A_{i,j} + B_{j,k}$. We define the $p \times r$* witness matrix *$\mathcal{W}^{A,B}$ such that $\mathcal{W}^{A,B}_{i,k}$ is the smallest witness of $C_{i,k}$ for each $i \in [0..p)$ and $k \in [0..r)$.*

The min-plus product of two Monge matrices is also Monge.

▶ **Fact 2.4** ([48, Corollary A])**.** *Let A, B, and C be matrices such that $A \otimes B = C$. If A and B are Monge, then C is also Monge.*

In the context of Monge matrices, it is useful to define the core and the density matrix.

▶ **Definition 2.5.** *The* density matrix *of a matrix A of size $p \times q$ is a matrix $A^{\square}$ of size $(p-1)\times(q-1)$ satisfying $A^{\square}_{i,j} = A_{i,j+1} + A_{i+1,j} - A_{i,j} - A_{i+1,j+1}$ for $i \in [0..p-1), j \in [0..q-1)$.*

We define the core *of the matrix A as*

$$\operatorname{core}(A) \coloneqq \{(i, j, A^{\square}_{i,j}) \mid i \in [0..p-1), j \in [0..q-1), A^{\square}_{i,j} \neq 0\}$$

and denote the core size *of the matrix A by $\delta(A) \coloneqq |\operatorname{core}(A)|$. Furthermore, we define the* core sum *of the matrix A as the sum of the values of all core elements of A, that is,*

$$\delta^{\Sigma}(A) \coloneqq \sum_{i \in [0..p-1)} \sum_{j \in [0..q-1)} A^{\square}_{i,j}.$$

Note that, for a Monge matrix A, all entries of its density matrix are non-negative, and thus $\operatorname{core}(A)$ consists of triples (i, j, v) with some positive values v.

For any matrix A of size $p \times q$ and integers $0 \le a < b \le p$ and $0 \le c < d \le q$, we write $A[a..b)[c..d)$ to denote the contiguous submatrix of A consisting of all entries on the intersection of rows $[a..b)$ and columns $[c..d)$ of A. Matrices $A[a..b][c..d]$, $A(a..b][c..d)$, etc., are defined analogously.

3 Properties of δ and δ^{Σ}

In this section, we provide some useful properties of δ and δ^{Σ}. Most importantly, we show how to bound $\delta(A \otimes B)$ in terms of $\delta(A)$ and $\delta(B)$.
The following observation is a straightforward consequence of the definitions of δ^{Σ} and $A^{\square}$.

▶ **Observation 3.1.** *For a matrix A of size $p \times q$, and integers $0 \le a \le b < p$ and $0 \le c \le d < q$,*

$$A_{a,c} + A_{b,d} + \delta^{\Sigma}(A[a..b][c..d]) = A_{a,d} + A_{b,c}.$$

Proof. By the definition of $A^{\square}$, we have $A_{i,j} + A_{i+1,j+1} + A^{\square}_{i,j} = A_{i,j+1} + A_{i+1,j}$ for all $i \in [a..b)$ and $j \in [c..d)$. The desired equality follows by summing up all these equalities. ◀

An application of Observation 3.1 for $a = c = 0$ implies that every value of A can be uniquely reconstructed from A's core and the values in the topmost row and the leftmost column of A.

▶ **Definition 3.2.** *The* condensed representation *of a matrix A consists of the core of A as well as the values in the topmost row and the leftmost column of A.*

▶ **Observation 3.3.** *Any submatrix A' (not necessarily contiguous) of a Monge matrix A is Monge.*

Proof. By Observation 2.2, if A is Monge, the Monge property holds for every (not necessarily contiguous) 2×2 submatrix of A. In particular, it holds for contiguous 2×2 submatrices of A', and thus A' satisfies Definition 2.1. ◀

We next show a crucial property of the witness matrix.

▶ **Lemma 3.4** ([48, Theorem 1])**.** *For any two Monge matrices, A of size $p \times q$ and B of size $q \times r$, the witness matrix $\mathcal{W}^{A,B}$ is non-decreasing by rows and columns.*

Proof. We prove that $\mathcal{W}^{A,B}$ is non-decreasing by columns. The claim for rows is analogous. Fix some $i \in [0..p-1)$ and $k \in [0..r)$. Let $j^* \coloneqq \mathcal{W}^{A,B}_{i,k}$ and $j \in [0..j^*)$. As j^* is the smallest witness for (i,k), we have $A_{i,j} + B_{j,k} > A_{i,j^*} + B_{j^*,k}$. Using this fact and the Monge property for A, we derive

$$\begin{aligned} A_{i+1,j} + B_{j,k} &\geq (A_{i,j} + A_{i+1,j^*} - A_{i,j^*}) + B_{j,k} \\ &= (A_{i,j} + B_{j,k}) + (A_{i+1,j^*} - A_{i,j^*}) \\ &> (A_{i,j^*} + B_{j^*,k}) + (A_{i+1,j^*} - A_{i,j^*}) \\ &= A_{i+1,j^*} + B_{j^*,k}. \end{aligned}$$

Since $A_{i+1,j} + B_{j,k} > A_{i+1,j^*} + B_{j^*,k}$ for all $j \in [0..j^*)$, we conclude that $\mathcal{W}^{A,B}_{i+1,k} \geq j^* = \mathcal{W}^{A,B}_{i,k}$ holds as required. ◀

We now show how to bound $\delta^{\Sigma}(A \otimes B)$ in terms of $\delta^{\Sigma}(A)$ and $\delta^{\Sigma}(B)$.

▶ **Lemma 3.5.** *Let A be a $p \times q$ Monge matrix, and let B be a $q \times r$ Monge matrix. Then, $\delta^{\Sigma}(A \otimes B) \leq \min\{\delta^{\Sigma}(A), \delta^{\Sigma}(B)\}$.*

Proof. Let $C \coloneqq A \otimes B$. Denote $j \coloneqq \mathcal{W}^{A,B}_{0,0}$ and $j' \coloneqq \mathcal{W}^{A,B}_{p-1,r-1}$, where $j \leq j'$ due to Lemma 3.4. We have $C_{0,0} = A_{0,j} + B_{j,0}$ and $C_{p-1,r-1} = A_{p-1,j'} + B_{j',r-1}$. Furthermore, $C_{p-1,0} \leq A_{p-1,j} + B_{j,0}$ and $C_{0,r-1} \leq A_{0,j'} + B_{j',r-1}$ due to the definition of C. Hence, due to Observation 3.1, we obtain

$$\begin{aligned} \delta^{\Sigma}(C) &= C_{p-1,0} + C_{0,r-1} - C_{0,0} - C_{p-1,r-1} \\ &\leq (A_{p-1,j} + B_{j,0}) + (A_{0,j'} + B_{j',r-1}) - (A_{0,j} + B_{j,0}) - (A_{p-1,j'} + B_{j',r-1}) \\ &= A_{p-1,j} + A_{0,j'} - A_{0,j} - A_{p-1,j'} \\ &= \delta^{\Sigma}(A[0..p)[j..j']) \\ &\leq \delta^{\Sigma}(A). \end{aligned}$$

The inequality $\delta^{\Sigma}(C) \leq \delta^{\Sigma}(B)$ can be obtained using a symmetric argument. ◀

The following corollary says that every core element of $A \otimes B$ can be attributed to at least one core element of A and at least one core element of B.

▶ **Corollary 3.6.** *Let A be a $p \times q$ Monge matrix, let B be a $q \times r$ Monge matrix, and let $C := A \otimes B$. Consider integers $i \in [0..p-1)$ and $k \in [0..r-1)$ such that $C^{\square}_{i,k} \neq 0$. There exist integers $j_A, j_B \in [\mathcal{W}^{A,B}_{i,k} .. \mathcal{W}^{A,B}_{i+1,k+1})$ such that $A^{\square}_{i,j_A} \neq 0$ and $B^{\square}_{j_B,k} \neq 0$.*

Proof. Let $j = \mathcal{W}^{A,B}_{i,k}$ and $j' = \mathcal{W}^{A,B}_{i+1,k+1}$. By monotonicity of $\mathcal{W}^{A,B}$ (Lemma 3.4), we have $j \le \mathcal{W}^{A,B}_{i,k+1}, \mathcal{W}^{A,B}_{i+1,k} \le j'$. Thus, $C[i..i+1][k..k+1] = A[i..i+1][j..j'] \otimes B[j..j'][k..k+1]$. Due to Lemma 3.5, we have $0 < C^{\square}_{i,k} = \delta^{\Sigma}(C[i..i+1][k..k+1]) \le \delta^{\Sigma}(A[i..i+1][j..j'])$. Thus, there exists a core element in $A^{\square}[i..i+1)[j..j')$.

Symmetrically, $0 < C^{\square}_{i,k} = \delta^{\Sigma}(C[i..i+1][k..k+1]) \le \delta^{\Sigma}(B[j..j'][k..k+1])$, and there exists a core element in $B^{\square}[j..j')[k..k+1)$. ◀

We now use Corollary 3.6 to derive a bound on $\delta(A \otimes B)$ in terms of $\delta(A)$ and $\delta(B)$. The underlying idea is to show that every core element of C is either the first or the last one (in the lexicographic ordering) that the mapping of Corollary 3.6 attributes to the corresponding core element of A *or* B (see Figure 1 for why the opposite would lead to a contradiction).

▶ **Theorem 1.1.** *Let A be a $p \times q$ Monge matrix, and let B be a $q \times r$ Monge matrix. We have $\delta(A \otimes B) \le 2 \cdot (\delta(A) + \delta(B))$.*

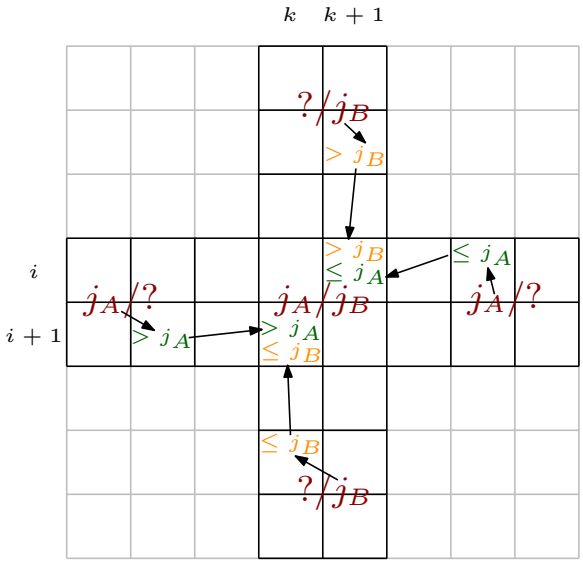

Figure 1 We consider the matrix of witnesses $\mathcal{W}^{A,B}$, drawn as an array with rows in $[0..p)$ indexed form top to bottom and columns in $[0..r)$ indexed from left to right. In the cells, we write bounds on the corresponding witnesses. In the grid nodes, we write the two values in $[0..q-1)$ derived from Corollary 3.6 for each core element of C. The center of the picture corresponds to a core value $C^{\square}_{i,k}$, attributed to $A^{\square}_{i,j_A}$ and $B^{\square}_{j_B,k}$, respectively. For a proof by contradiction, suppose that there are some core elements to the left and right of (i,k) attributed to $A^{\square}_{i,j_A}$ and some core elements above and below (i,k) attributed to $B^{\square}_{j_B,k}$. The arrows represent implications (based on Corollary 3.6 and Lemma 3.4), from which a contradiction follows: $j_A < \mathcal{W}^{A,B}_{i+1,k} \le j_B < \mathcal{W}^{A,B}_{i,k+1} \le j_A$.

Proof. Let $C \coloneqq A \otimes B$. Define a function $f_A : \mathrm{core}(C) \to \mathrm{core}(A)$ that maps every core element $(i, k, C^{\square}_{i,k}) \in \mathrm{core}(C)$ to $(i, j, A^{\square}_{i,j})$ for the smallest $j \in [\mathcal{W}^{A,B}_{i,k} .. \mathcal{W}^{A,B}_{i+1,k+1})$ with $A^{\square}_{i,j} \neq 0$; such a j exists due to Corollary 3.6. Analogously, we define a function $f_B : \mathrm{core}(C) \to \mathrm{core}(B)$ that maps every core element $(i, k, C^{\square}_{i,k}) \in \mathrm{core}(C)$ to $(j, k, B^{\square}_{j,k})$ for the smallest $j \in [\mathcal{W}^{A,B}_{i,k} .. \mathcal{W}^{A,B}_{i+1,k+1})$ with $B^{\square}_{j,k} \neq 0$; again, such a j exists due to Corollary 3.6.

▷ Claim 3.7. Every core element $c \in \mathrm{core}(C)$ is the lexicographically minimal or maximal one in its pre-image $f_A^{-1}(f_A(c))$ under f_A or its pre-image $f_B^{-1}(f_B(c))$ under f_B.

Proof. For a proof by contradiction, pick an element $c \coloneqq (i, k, C^{\square}_{i,k}) \in \mathrm{core}(C)$ violating the claim. Let $(i, j_A, A^{\square}_{i,j_A}) \coloneqq a \coloneqq f_A(c)$ and $(j_B, k, B^{\square}_{j_B,k}) \coloneqq b \coloneqq f_B(c)$. We make four symmetric arguments (all illustrated in Figure 1), with the first one presented in more detail.

1. Since c is not the minimal core element in $f_A^{-1}(a)$, we have $f_A(c') = a$ for some core element $(i', k', C^{\square}_{i',k'}) \coloneqq c' \in \mathrm{core}(C)$ that precedes c in the lexicographical order, denoted $c' \prec c$. Due to $f_A(c') = a = (i, j_A, A^{\square}_{i,j_A})$, we must have $i' = i$ and $j_A < \mathcal{W}^{A,B}_{i+1,k'+1}$. Since $i' = i$, then $c' \prec c$ implies $k' + 1 \leq k$. The monotonicity of the witness matrix (Lemma 3.4) thus yields $\mathcal{W}^{A,B}_{i+1,k'+1} \leq \mathcal{W}^{A,B}_{i+1,k}$. Overall, we conclude that $j_A < \mathcal{W}^{A,B}_{i+1,k}$.
2. Since c is not the maximal core element in $f_A^{-1}(a)$, we have $f_A(c') = a$ for some core element $c' \succ c$. In particular, $c' = (i, k', C^{\square}_{i,k'}) \in \mathrm{core}(C)$ for some $k' > k$. Then, $\mathcal{W}^{A,B}_{i,k+1} \leq \mathcal{W}^{A,B}_{i,k'} \leq j_A$ follows from Lemma 3.4 and $f_A(c') = a$, respectively.
3. Since c is not the minimal core element in $f_B^{-1}(b)$, we have $f_B(c') = b$ for some core element $c' \prec c$. In particular, $c' = (i', k, C^{\square}_{i',k}) \in \mathrm{core}(C)$ for some $i' < i$. Then, $\mathcal{W}^{A,B}_{i,k+1} \geq \mathcal{W}^{A,B}_{i'+1,k+1} > j_B$ follows from Lemma 3.4 and $f_B(c') = b$, respectively.
4. Since c is not the maximal core element in $f_B^{-1}(b)$, we have $f_B(c') = b$ for some core element $c' \succ c$. In particular, $c' = (i', k, C^{\square}_{i',k}) \in \mathrm{core}(C)$ for some $i' > i$. Then, $\mathcal{W}^{A,B}_{i+1,k} \leq \mathcal{W}^{A,B}_{i',k} \leq j_B$ follows from Lemma 3.4 and $f_B(c') = b$, respectively.

Overall, we derive a contradiction: $j_A < \mathcal{W}^{A,B}_{i+1,k} \leq j_B < \mathcal{W}^{A,B}_{i,k+1} \leq j_A$. ◁

As every core element of C is either the first or the last one in some pre-image under f_A or f_B, we get that $\delta(C) \leq 2 \cdot (\delta(A) + \delta(B))$. ◀

▶ **Example 3.8.** Note that the inequality for the core size from Theorem 1.1 is weaker than the inequality for the core sum from Lemma 3.5. We claim that this weakening is not an artifact of our proof. Consider the following Monge matrices

$$A = \begin{pmatrix} 0 & 4 & 5 & 6 \\ 0 & 1 & 2 & 3 \\ 0 & 1 & 2 & 0 \\ 0 & 1 & 2 & 0 \end{pmatrix}, \qquad B = \begin{pmatrix} 0 & 2 & 4 & 6 \\ 0 & 0 & 2 & 4 \\ 0 & 0 & 0 & 2 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \qquad C = \begin{pmatrix} 0 & 2 & 4 & 6 \\ 0 & 1 & 2 & 3 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}.$$

We have $C = A \otimes B$, $\delta(A) = 2$, $\delta(B) = 3$, and $6 = \delta(C) > \delta(A) + \delta(B) > \min\{\delta(A), \delta(B)\}$.

▶ Remark 3.9. To the best of our knowledge, Theorem 1.1 shows the first bound on the core size of $A \otimes B$ in terms of the core sizes of A and B. Previously, such a bound was only known for unit-Monge matrices [41]. In particular, our bound allows simplifying some time complexities of already existing algorithms. For example, [34, Lemma 18] shows how to compute the product of two explicitly given Monge matrices A and B in time $\mathcal{O}(p \log q + q \log r + \delta(A \otimes B) \log q \log r + (\delta(A) + \delta(B)) \log^2 q)$. Assuming that $r \in \mathrm{poly}(q)$, Theorem 1.1 tells us that we can drop the third summand in the time complexity.

4 Core-Sparse Monge Matrix Min-Plus Multiplication Algorithm

In this section, we present an algorithm that, given the condensed representations of two Monge matrices, computes the condensed representation of their $(\min,+)$-product. Even though the condensed representation itself does not provide efficient random access to the values of the matrix, the following fact justifies our choice of the representation of Monge matrices.

▶ **Fact 4.1** ([22, Lemma 4.4]). *There exists an algorithm that, given the condensed representation of a matrix A of size $p \times q$, in time $\mathcal{O}(p+q+\delta(A)\log(1+\delta(A)))$ builds a* core-based matrix oracle data structure $\mathsf{CMO}(A)$ *that provides $\mathcal{O}(\log(2+\delta(A)))$-time random access to the entries of A.*

Proof Sketch. By Observation 3.1 applied for $a = c = 0$, it suffices to answer orthogonal range sum queries on top of $\operatorname{core}(A)$. According to [45, Theorem 3], it can be done in $\mathcal{O}(\delta(A)\log(1+\delta(A)))$ preprocessing time and $\mathcal{O}(\log(2+\delta(A)))$ query time. ◀

▶ **Definition 4.2.** *Let A be a $p \times q$ matrix. For every $i \in [0..p-1)$, denote* $\operatorname{core}_{i,\cdot}(A) = \{(i, j, A^{\square}_{i,j}) \mid j \in [0..q-1), A^{\square}_{i,j} \neq 0\}$ *and* $\delta_{i,\cdot}(A) = |\operatorname{core}_{i,\cdot}(A)|$. *Analogously, for every $j \in [0..q-1)$, denote* $\operatorname{core}_{\cdot,j}(A) = \{(i, j, A^{\square}_{i,j}) \mid i \in [0..p-1), A^{\square}_{i,j} \neq 0\}$ *and* $\delta_{\cdot,j}(A) = |\operatorname{core}_{\cdot,j}(A)|$.

▶ **Observation 4.3.** $\delta(A) = \sum_{i\in[0..p-1)} \delta_{i,\cdot}(A) = \sum_{j\in[0..q-1)} \delta_{\cdot,j}(A)$.

We now design another matrix oracle as an alternative to $\mathsf{CMO}(A)$ for the situation in which one wants to query an entry of A that is adjacent to some other already known entry.

▶ **Lemma 4.4.** *There is an algorithm that, given the condensed representation of a $p \times q$ matrix A, in time $\mathcal{O}(p+q+\delta(A))$ builds a* local core oracle data structure $\mathsf{lco}(A)$ *with the following interface.*

Boundary access: *given indices $i \in [0..p)$ and $j \in [0..q)$ such that $i = 0$ or $j = 0$, in time $\mathcal{O}(1)$ returns $A_{i,j}$.*

Vertically adjacent recomputation: *given indices $i \in [0..p-1)$ and $j \in [0..q)$, in time $\mathcal{O}(\delta_{i,\cdot}(A)+1)$ returns $A_{i+1,j} - A_{i,j}$.*

Horizontally adjacent recomputation: *given indices $i \in [0..p)$ and $j \in [0..q-1)$, in time $\mathcal{O}(\delta_{\cdot,j}(A)+1)$ returns $A_{i,j+1} - A_{i,j}$.*

Proof. The local core oracle data structure of A stores all the values of the topmost row and the leftmost column of A, as well as two collections of lists: $\operatorname{core}_{i,\cdot}(A)$ for all $i \in [0..p-1)$ and $\operatorname{core}_{\cdot,j}(A)$ for all $j \in [0..q-1)$. The values of the topmost row and the leftmost column of A are already given. The lists $\operatorname{core}_{i,\cdot}(A)$ and $\operatorname{core}_{\cdot,j}(A)$ can be computed in $\mathcal{O}(p+q+\delta(A))$ time from $\operatorname{core}(A)$. Hence, we can build $\mathsf{lco}(A)$ in time $\mathcal{O}(p+q+\delta(A))$.

Boundary access can be implemented trivially. We now show how to implement the vertically adjacent recomputation. Suppose that we are given $i \in [0..p-1)$ and $j \in [0..q)$. Due to Observation 3.1, we have $A_{i,j} + A_{i+1,0} = A_{i+1,j} + A_{i,0} + \delta^{\Sigma}(A[i..i+1][0..j])$. Note that the values $A_{i,0}$ and $A_{i+1,0}$ can be computed in constant time using boundary access queries, and $\delta^{\Sigma}(A[i..i+1][0..j])$ can be computed from $\operatorname{core}_{i,\cdot}(A)$ in time $\mathcal{O}(\delta_{i,\cdot}(A)+1)$. Hence, $A_{i+1,j} - A_{i,j}$ can be computed in time $\mathcal{O}(\delta_{i,\cdot}(A)+1)$.

The horizontally adjacent recomputation is implemented analogously so that $A_{i,j+1} - A_{i,j}$ can be computed in time $\mathcal{O}(\delta_{\cdot,j}(A)+1)$. ◀

Note that vertically and horizontally adjacent recomputations allow computing the neighbors of any given entry $A_{i,j}$.

▶ **Lemma 4.5.** *Given the condensed representation of a $p \times q$ matrix A, the condensed representation of any contiguous submatrix A' of A can be computed in time $\mathcal{O}(p+q+\delta(A))$.*

Proof. Say, $A' = A[i..i'][j..j']$. Note that $\mathrm{core}(A')$ can be obtained in time $\mathcal{O}(\delta(A))$ by filtering out all elements of $\mathrm{core}(A)$ that lie outside of $[i..i') \times [j..j')$. It remains to obtain the topmost row and the leftmost column of A'. In time $\mathcal{O}(p+q+\delta(A))$ we build $\mathsf{lco}(A)$ of Lemma 4.4. By starting from $A_{i,0}$ and repeatedly applying the horizontally adjacent recomputation, we can compute $A[i..i][0..q)$ (and thus $A[i..i][j..j']$) in time $\mathcal{O}(\sum_{j\in[0..q)}(\delta_{\cdot,j}(A)+1)) = \mathcal{O}(q+\delta(A))$. The leftmost column of A' can be computed in time $\mathcal{O}(p+\delta(A))$ analogously. ◀

We now show a helper lemma that compresses "ultra-sparse" Monge matrices to limit their dimensions by the size of their core.

▶ **Lemma 4.6** (Matrix compression)**.** *There are two algorithms* `Compress` *and* `Decompress` *with the following properties: The* `Compress` *algorithm, given the condensed representations of a $p^* \times q^*$ Monge matrix A^* and a $q^* \times r^*$ Monge matrix B^*, in time $\mathcal{O}(p^* + q^* + r^* + \delta(A^*) + \delta(B^*))$, builds a $p \times q$ Monge matrix A and a $q \times r$ Monge matrix B such that $p \le \delta(A^*)+1$, $q \le \delta(A^*)+\delta(B^*)+1$, $r \le \delta(B^*)+1$, $\delta(A) = \delta(A^*)$, and $\delta(B) = \delta(B^*)$. The* `Decompress` *algorithm, given the condensed representations of A^*, B^*, and $A \otimes B$, where $(A, B) =$ `Compress`(A^*, B^*), computes the condensed representation of $A^* \otimes B^*$ in time $\mathcal{O}(p^* + r^* + \delta(A^*) + \delta(B^*))$.*

Proof Sketch. The `Compress` algorithm deletes all rows of A^* that do not contain any core elements and all columns of B^* that do not contain any core elements. This way, $p \le \delta(A^*)+1$ and $r \le \delta(B^*)+1$ are guaranteed. Furthermore, all core elements of these two matrices are preserved. If there are no core elements between rows i and $i+1$ of A^*, the corresponding entries of these two rows differ by some constant c, and thus all the entries of the row $i+1$ of $A^* \otimes B^*$ can be obtained from the corresponding entries of row i of $A^* \otimes B^*$ by adding c. Since we can recover c from A^*, no information about the answer is "lost" when deleting such rows. An analogous property holds for the removed columns of B^*. The `Decompress` algorithm reverses the row and column removals performed by the `Compress` algorithm.

The `Compress` algorithm also reduces the number q^* of columns of A^* and rows of B^* to $q \le \delta(A^*) + \delta(B^*) + 1$. Observe that if there are no core elements between columns j and $j+1$ of A^* and between rows j and $j+1$ of B^*, then the values $A^*_{i,j} + B^*_{j,k}$ and $A^*_{i,j+1} + B^*_{j+1,k}$ differ by a constant independent of i and k. Depending on the sign of this constant difference, we can delete either the j-th column of A^* and the j-th row of B^* or the $(j+1)$-th column of A^* and the $(j+1)$-th row of B^* so that we do not change the min-plus product of these matrices. By repeating this process for all indices j that do not "contribute" to the cores of A^* and B^*, we get $q \le \delta(A^*) + \delta(B^*) + 1$. The formal proof can be found in the full version of the paper [21]. ◀

Finally, we show our main Monge matrix multiplication algorithm.

▶ **Theorem 1.2.** *There is a (deterministic) algorithm that, given the condensed representations of an $n_1 \times n_2$ Monge matrix M_1 and an $n_2 \times n_3$ Monge matrix M_2, in time $\mathcal{O}(n_1 + n_2 + n_3 + (\delta(M_1) + \delta(M_2)) \log(1 + \delta(M_1) + \delta(M_2)))$ computes the condensed representation of $M_1 \otimes M_2$.*

Proof Sketch. We design a recursive divide-and-conquer procedure `Multiply`(A^*, B^*) (see Algorithm 1 for the details) and solve the problem by initially running `Multiply`(M_1, M_2). Given the matrices A^* and B^*, we first apply the `Compress` algorithm of Lemma 4.6 to

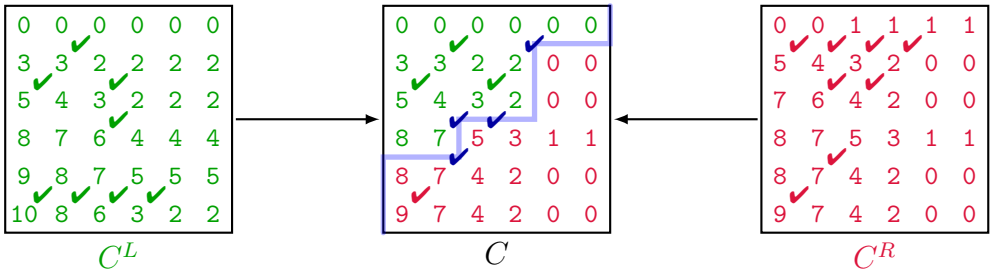

Figure 2 An example of how C is obtained from C^L and C^R. The blue ladder represents the border between the values that are inherited from C^L and the values that are inherited from C^R. Ticks correspond to the core elements: the green ticks are inherited from C^L, the red ticks are inherited from C^R, and the blue ticks represent the core element computed from scratch.

compress A^* and B^* into a $p \times q$ matrix A and a $q \times r$ matrix B respectively. We then compute the condensed representation of $C \coloneqq A \otimes B$ and finally use the `Decompress` algorithm of Lemma 4.6 to decompress C into $A^* \otimes B^*$.

If $p = r = 1$, we compute the matrix C trivially. Otherwise, we pick a splitting point $m \in (0..q)$, split the matrix A vertically into the matrix A^L of size $p \times m$ and the matrix A^R of size $p \times (q-m)$, and split the matrix B horizontally into the matrix B^L of size $m \times r$ and the matrix B^R of size $(q-m) \times r$. We pick m in such a way that it splits the cores of A and B almost equally across A^L and B^L and A^R and B^R, that is, $\delta(A^L) + \delta(B^L)$ and $\delta(A^R) + \delta(B^R)$ are at most $(\delta(A) + \delta(B))/2$. We recursively compute the condensed representations of the matrices $C^L \coloneqq A^L \otimes B^L$ and $C^R \coloneqq A^R \otimes B^R$. The resulting matrix C can be obtained as the element-wise minimum of C^L and C^R. Furthermore, one can see that, due to Lemma 3.4, in some top-left region of C, the values are equal to the corresponding values of C^L, and in the remaining bottom-right region of C, the values are equal to the corresponding values of C^R; see Figure 2. We find the boundary between these two regions by starting in the bottom-left corner of C and traversing it towards the top-right corner along this boundary. We use $\mathsf{lco}(C^L)$ and $\mathsf{lco}(C^R)$ to sequentially compute the subsequent entries along the boundary. Having determined the boundary, we construct the core of C by picking the core elements of C^L located to the top-left of this boundary, picking the core elements of C^R located to the bottom-right of this boundary, and computing the $C^\square$ values on the boundary from scratch. The values in the topmost row and the leftmost column of C can be trivially obtained as element-wise minima of the corresponding values in C^L and C^R. This concludes the recursive procedure; see Algorithm 1 for the pseudocode. This algorithm follows the classical divide-and-conquer framework, and thus its time complexity can be easily derived from Theorem 1.1. The full description of the algorithm, the proof of its correctness, and the formal analysis of its time complexity can be found in the full version of the paper [21]. ◀

If the $(\min, +)$-product of matrices represents the lengths of the shortest paths in a graph, the corresponding witness matrix allows computing the underlying shortest paths themselves. For that, we extend the presented algorithm to allow witness reconstruction.

▶ **Theorem 4.7.** *The algorithm of Theorem 1.2 can be extended so that, within the same time complexity, it also builds a data structure that takes $\mathcal{O}(n_1 + n_2 + n_3 + \delta(M_1) + \delta(M_2))$ space and provides $\mathcal{O}(\log(2 + \delta(M_1) + \delta(M_2)))$-time oracle access to $\mathcal{W}^{M_1, M_2}$.*

Algorithm 1 The algorithm from Theorem 1.2. Given the condensed representations of the Monge matrices A^* and B^*, the algorithm returns the condensed representation of $A^* \otimes B^*$.

```
1  Multiply(A*, B*) begin
2      A, B ← Compress(A*, B*);
3      p ← height of A; q ← width of A; r ← width of B;
4      if p = 1 and r = 1 then
5          C ← 1 × 1 matrix with the entry equal to min{A_{0,j} + B_{j,0} | j ∈ [0..q)};

28     return Decompress(A*, B*, C);
```

Proof Sketch. We slightly modify the algorithm of Theorem 1.2. For the leaf recursive calls with $p = r = 1$, we explicitly store the minimal witness of the only entry of C. In the non-leaf recursive calls, we store the correspondence between the indices in the compressed matrices A, B, C and the decompressed matrices A^*, B^*, C^*, as well as the border separating the values of C^L and C^R in C (the blue curve of Figure 2). Naively, this data takes space proportional to the time complexity of Theorem 1.2. Nevertheless, using bit-masks equipped with rank/select functionality, the total space complexity can be brought down to be linear in terms of the size of the input. To answer a query, we descend the recursion tree. In constant time we can find an entry of C corresponding to the queried entry of C^* and decide on which side of the border separating the values of C^L and C^R the queried entry of C is.

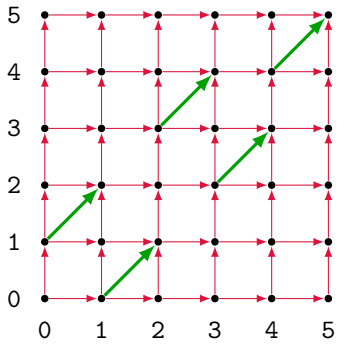

Figure 3 The alignment graph for $s = [1, 0, 3, 2, 4]$, with red edges of weight 0 and green edges of weight 1. The length of the longest path from the i-th vertex in the bottom row to the j-th vertex in the top row of this graph for $i < j$ is equal to $\mathsf{LIS}(s[i..j))$.

After that, we recurse into either $A^L \otimes B^L$ or $B^L \otimes B^R$. In the terminal recursion call with $p = r = 1$ we return the minimal witness that is stored explicitly. The time complexity of the algorithm is proportional to the depth of recursion. See the full version of the paper [21] for a formal description of the algorithm. ◀

5 Range LIS Queries: Sketch

One of the original applications of Tiskin's procedure for simple unit-Monge matrix multiplication [38, 41] is an algorithm that preprocesses a given sequence $(s[i])_{i\in[0..n)}$ of integers in $\mathcal{O}(n \log^2 n)$ time so that *Range Longest Increasing Subsequence* (Range LIS) queries can be answered in $\mathcal{O}(\log n)$ time. We show an alternative way of obtaining the same result using Theorem 1.2 and avoiding the seaweed braid formalism. The extension of Theorem 4.7 allows recovering the underlying longest increasing subsequence of length ℓ in $\mathcal{O}(\ell \log^2 n)$ time. Further $\mathcal{O}(n \log^3 n)$-time preprocessing allows for $\mathcal{O}(\ell)$-time recovery, which improves upon the result of [27].

Without loss of generality we assume that $(s[i])_{i\in[0..n)}$ is a permutation of $[0..n)$.[4] We use a popular tool for string similarity problems and interpret range LIS queries as computing the longest path between some pair of vertices of a corresponding *alignment graph* G^s; see Figure 3. The crucial property of G^s is that it is planar, and thus due to [18, Section 2.3], the matrix M^s of longest distances from the vertices in the bottom row to the vertices of the top row of this graph is anti-Monge.[5] Thus, the problem of constructing a data structure for range LIS queries is reduced to the problem of computing the condensed representation of M^s.

As $\mathsf{LIS}(s[i..j)) \le n$ for all $i, j \in [0..n]$ with $i < j$, all entries of M^s are bounded by $\mathcal{O}(n)$, and thus $\delta(M^s) = \mathcal{O}(n)$ holds due to Observation 3.1 and the fact that $\delta(M^S) \le \delta^\Sigma(M^S)$ holds for integer-valued matrices. We compute M^s in a divide-and-conquer fashion. We split the sequence s into subsequences s^{lo} and s^{hi} containing all values in $[0..\lfloor \frac{n}{2} \rfloor)$ and $[\lfloor \frac{n}{2} \rfloor..n)$ respectively, and recursively compute $M^{s^{\mathrm{lo}}}$ and $M^{s^{\mathrm{hi}}}$. After that, we note that $G^{s^{\mathrm{lo}}}$ and $G^{s^{\mathrm{hi}}}$

[4] In what follows, we reserve the word "permutation" for permutations of $[0..m)$ for some $m \in \mathbb{Z}_+$.
[5] Note that, in reality, some entries of this matrix are infinite. In the formal description of the algorithm, we augment the alignment graph so that the finite entries of this matrix are preserved and the infinite entries become finite.

are essentially compressed versions of the lower half and the upper half of G^s, respectively. Based on this, we transform $M^{s^{\text{lo}}}$ in $\mathcal{O}(n)$ time into the matrix of the longest distances from the vertices in the bottom row of G^s to the vertices in the middle row of G^s. Analogously, we transform $M^{s^{\text{hi}}}$ into the matrix of the longest distances from the middle row of G^s to the top row of G^s. To obtain M^s, it remains to $(\max, +)$-multiply these two matrices using Theorem 1.2. Every single recursive call takes time $\mathcal{O}(n \log n)$ dominated by the algorithm of Theorem 1.2. The whole divide-and-conquer procedure takes $\mathcal{O}(n \log^2 n)$ time. Given the condensed representation of M^s, we use Fact 4.1 to create an oracle for $\mathcal{O}(\log n)$-time range LIS queries, thus replicating the result of [41].

Compared to the results of [41], this algorithm operates directly on the local LIS values and thus can be easily converted into an algorithm for the reporting version of range LIS queries, where we want to not only find the length of the longest path in the alignment graph but to also compute the structure of the underlying path itself. For that, we simply use the witness reconstruction oracle of Theorem 4.7 to find the midpoint of the path and descend the recursion tree. This costs $\mathcal{O}(\log n)$ time per recursive call and allows reconstructing the entire length-ℓ LIS in time $\mathcal{O}(\ell \log^2 n)$. A similar recursive LIS reporting scheme is used in [9].

By treating increasing subsequences of length at most $\log^2 n$ separately, we further obtain an algorithm with $\mathcal{O}(n \log^3 n)$ preprocessing time and $\mathcal{O}(\ell)$ reporting time. It improves the result of [27] with $\mathcal{O}(n^{3/2} \operatorname{polylog} n)$-time preprocessing and $\mathcal{O}(\ell + n^{1/2} \operatorname{polylog} n)$-time reporting.

The formal proofs of the results in this section are given in the full version of the paper [21].

Abstract

A *covering path* for a finite set P of points in the plane is a polygonal path such that every point of P lies on a segment of the path. The vertices of the path need not be at points of P. A covering path is *plane* if its segments do not cross each other. Let $\pi(n)$ be the minimum number such that every set of n points in the plane admits a plane covering path with at most $\pi(n)$ segments. We prove that $\pi(n) \leq \lceil 6n/7 \rceil$. This improves the previous best-known upper bound of $\lceil 21n/22 \rceil$, due to Biniaz (SoCG 2023). Our proof is constructive and yields a simple $O(n \log n)$-time algorithm for computing a plane covering path.

1 Introduction

The problems of traversing points in the plane by polygonal paths are fundamental to discrete and computational geometry, and have been studied from both combinatorial and computational points of view. For instance one can refer to traversing a set of points by a non-crossing path [3, 14], or by a path that minimizes the total edge length [7, 28, 30, 31],[1] minimizes the longest edge length [10, 11], maximizes the shortest edge length [4, 5], minimizes the number of turns (or bends) [18, 32],[2] or minimizes the total or the largest turning angle [1, 2, 20].

In this paper we focus on traversing a set of points by a non-crossing polygonal path with a small number of segments. This problem has been studied before [12, 13, 18, 32], and is related to the classic nine-dot puzzle that asks to cover the vertices of a 3×3 grid by a polygonal path with no more than 4 segments [29], as in Figure 1.

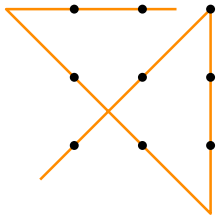

Figure 1 A non-plane covering path with four segments for the nine-dot puzzle.

Let P be a finite set of points in the plane. A *covering path* for P is a polygonal path (i.e., a path with straight-line segments) such that every point of P lies on some segment of the path. A vertex of a covering path can be any point in the plane (i.e., not necessarily a point in P). The segments of a covering path are also referred to as *links* [6] or *bends* [32] in the literature. A covering path with the smallest number of links is called a *minimum-link* or a *minimum-bend* covering path. A covering path is called *plane* or *non-crossing* if its segments do not cross each other. Figure 1 illustrates a covering path with 4 segments that is not plane.

In addition to their puzzling nature, dating back to 1914 [29], covering paths with a small number of segments are of interest in robotics and heavy machinery, where turning is an expensive operation [32]. Covering paths have also received considerable attention in recent years [6, 13, 18, 25]. Morić (in CCCG 2010) [17] and Welzl (in GWOP 2011) [17], and later Dumitrescu, Gerbner, Keszegh, and Tóth [18] raised challenging questions about covering paths, including the following.

▶ **Question 1.** *What is the minimum number $\pi(n)$ such that every set of n points in the plane can be covered by a non-crossing path with at most $\pi(n)$ straight-line segments?*

It is not hard to see that $n/2 \le \pi(n) \le n-1$, because any set of points can be covered by a plane path of $n-1$ segments (say by connecting the points from left to right), and each straight-line segment can cover at most two points (if no three points are collinear). Dumitrescu et al. [18] presented the first non-trivial lower and upper bounds:

$$\frac{5n}{9} - O(1) < \pi(n) < \left(1 - \frac{1}{601\,080\,391}\right) n.$$

[1] Known as the traveling salesperson path problem.
[2] Known as the minimum bend traveling salesperson problem.

The upper bound has been improved to $\lceil 21n/22 \rceil$ by Biniaz [12, 13]. The upper bounds are universal (i.e., any point set admits these bounds), while the lower bounds are existential (i.e., there exist point sets that achieve these bounds).

1.1 Our Contributions

We present an algorithm that constructs a plane covering path of at most $\lceil 6n/7 \rceil$ segments for any set of n points in the plane, which implies that $\pi(n) \leq \lceil 6n/7 \rceil$. The algorithm runs in $O(n \log n)$ time. This is optimal, because the problem of computing a plane covering path (even without the minimality constraint) has an $\Omega(n \log n)$ lower bound in the worst case in the algebraic decision tree model of computation – by a reduction from sorting [18].

Simplicity and differences to previous algorithms. Our algorithm shares similarities with the algorithms of Biniaz [12, 13] and Dumitrescu et al. [18] in terms of iteratively scanning the points from left to right. One limitation of the previous approaches is the use of *caps* and *cups* to save a segment in each iteration. A *k-cap* is a concave x-monotone chain of k points, and a *k-cup* is a convex x-monotone chain of k points. Dumitrescu et al. construct an 18-cap or 18-cup in each iteration of their algorithm [18], while Biniaz uses 5-caps or 5-cups [12, 13]. To ensure the existence of such caps or cups, at least 601080391 and 21 points are required, respectively, as implied by the Erdős-Szekeres theorem [19]. In contrast, our algorithm uses convex chains of points that are not necessarily x-monotone (hence neither a cap nor a cup).

Besides using a cap or a cup in each iteration, the previous algorithms [13, 18] partition the remaining scanned points (within the iteration) into certain subsets such that each subset is contained in a convex region, and the convex regions of all subsets are disjoint. The algorithms compute a covering path within each region, and then concatenate the paths and the cap or cup. The partitioning and the concatenation are nicely crafted so that the resulting path is plane. Our iterations are more straightforward and do not use complex partitioning – we consider three main cases based on the size of the convex hull of 5 points.

1.2 Related Problems and Results

If we allow crossings, one can obtain better upper bounds on the number of segments of covering paths. For example by repeatedly applying the Erdős-Szekeres theorem [19], one can obtain a covering path with at most $n/2 + O(n/\log n)$ segments [17, 18]. The optimization problem, which is to compute a minimum-link covering path for a set of points, is shown NP-hard by Arkin et al. [6]. The best known approximation algorithm, due to Stein and Wagner [32], has a ratio of $O(\log z)$ where z is the maximum number of collinear points.

A *covering tree* for a point set P is a tree with straight-line edges that cover every point of P. Covering trees are useful in red-blue separation [22], and in the construction of rainbow polygons [13, 21]. Let $\tau(n)$ be the minimum number such that every set of n points in the plane can be covered by a plane tree with at most $\tau(n)$ edges. It is known that $9n/17 - O(1) \leq \tau(n) \leq \lceil 4n/5 \rceil$ where the lower and upper bounds come from [18] and [13], respectively. The exact values of $\pi(n)$ and $\tau(n)$ for the vertices of the square grid have been determined by Keszegh [25].

Two other well-studied related problems to mention are covering points with minimum-link[3] axis-aligned paths [8, 9, 16, 24] or with a minimum number of lines [15, 23, 26, 27].

[3] For axis-aligned paths this is usually referred to as minimum-turn.

2 The Algorithm

In this section we prove the following theorem.

▶ **Theorem 1.** *Every set of n points in the plane admits a non-crossing covering path with at most $\lceil 6n/7 \rceil$ segments. Thus, $\pi(n) \leqslant \lceil 6n/7 \rceil$. Such a path can be constructed in $O(n \log n)$ time.*

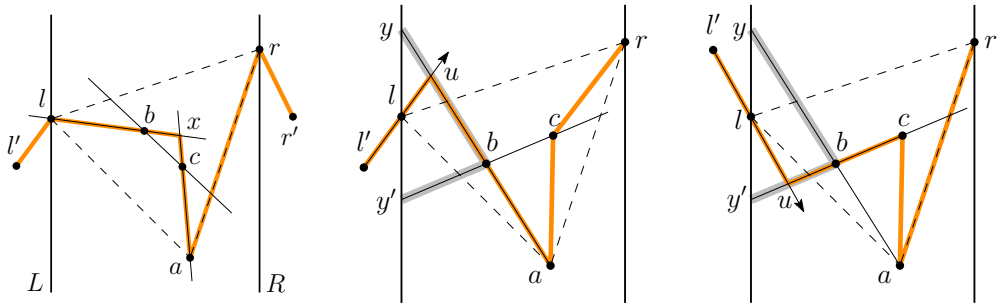
Our proof is constructive. We present an algorithm that computes, for any set P of n points in the plane, a non-crossing covering path with at most $\lceil 6n/7 \rceil$ segments.

Preliminaries. We denote the convex hull of a point set S by $\mathrm{CH}(S)$. For two points p and q we denote by $\ell(p, q)$ the line through p and q, by pq the line segment with endpoints p and q, and by $\overrightarrow{pq}$ the ray that emanates from p and passes through q. The concatenation of two paths, δ_1 and δ_2, that share an endpoint is denoted by $\delta_1 \oplus \delta_2$.

Our algorithm is iterative and scans the points from left to right. Note that via a suitable rotation we may assume that no two points of P have the same x-coordinate. In the first iteration we scan only one point. In each subsequent iteration except for the last, we scan 6 or 7 new points and cover them with 5 or 6 new segments, respectively. Thus the ratio of the number of new segments to the number of covered points in these *intermediate* iterations is at most $6/7$. In the last iteration we scan the (at most 6) remaining points.

We assume that, among the scanned points in each iteration, no three are collinear. Collinear points are typically easier to handle because one can cover three points by one segment – such cases can be handled by an argument similar to that of [13]. Let m represent the number of points that have been scanned so far and let l' represent the rightmost scanned point. We maintain the following invariant at the beginning of every iteration after the first.

Invariant. All m points that have been scanned so far are covered by a non-crossing path δ with at most $\lfloor 6m/7 \rfloor$ segments. The path δ lies to the left of the vertical line through l'. The degree of l' in δ is one if $m \geqslant 2$ and zero if $m = 1$.



The invariant holds after the first iteration, trivially. We now focus on how to handle each intermediate iteration; this is the main part of our algorithm and proof. The last iteration is described at the end. Note that the invariant has the floor-function, whereas Theorem 1 has the ceiling-function. As we will see, at the beginning of each iteration, the m points scanned so far are covered by at most $\lfloor 6m/7 \rfloor$ segments. After the last iteration, we have $m = n$ and this upper bound becomes $\lceil 6n/7 \rceil$.

In each intermediate iteration the new points are appended to the current path δ in a suitable way, without altering the structure of δ. In our descriptions we will use Δ to denote the resulting path.

We start by scanning 6 new points. Denote these points by l, a, b, c, r, r', where l is the leftmost, r' is the rightmost and r is the second rightmost point, as in Figure 2. Let $S = \{l, a, b, c, r\}$. Thus, S has all newly scanned points except for r'. Let L and R be the vertical lines through l and r, respectively. We refer to the region between L and R as *the slab*. Observe that l and r are both vertices of the boundary of $\mathrm{CH}(S)$. We consider three cases depending on the number of vertices on $\mathrm{CH}(S)$.

Case 1. $\mathrm{CH}(S)$ has 3 vertices. Without loss of generality, assume that a is the third vertex of $\mathrm{CH}(S)$, located below $\ell(l, r)$. Thus b and c are inside triangle $\triangle(a, l, r)$. The line $\ell(b, c)$ intersects exactly two edges of $\triangle(a, l, r)$. We consider three subcases.

- $\ell(b,c)$ intersects $\ell(l,r)$ and ar, as shown in Figure 2(a). The points l, b, c, and a form the vertices of a convex quadrilateral. After a suitable relabeling, we may assume that they appear in this order along the boundary of the quadrilateral. Then the intersection x of $\ell(a,c)$ and $\ell(l,b)$ lies in $\triangle(a,l,r)$. We form the path path (l',l,x,a,r,r') and append it to δ. Thus we cover the six new vertices (l,b,c,a,r,r') with five segments. The savings come from avoiding using segment bc.

(a) (b) (c)

Figure 2 CH(S) has three vertices. (a) $\ell(b,c)$ intersects lr and ar. (b) $\ell(b,c)$ intersects al and ar, and $\overrightarrow{l'l}$ intersects by. (c) $\ell(b,c)$ intersects al and ar, and $\overrightarrow{l'l}$ intersects by'.

- $\ell(b,c)$ intersects lr and al. This is symmetric to the previous case. We let l' and l play the role of r' and r. Points a,b,c,r form a convex quadrilateral, and we create the path (l',l,a,x,r,r').
- $\ell(b,c)$ intersects al and ar. We may assume, without loss of generality, that b is to the left of c. Then $\overrightarrow{ab}$ intersects L or $\overrightarrow{ac}$ intersects R. Because of symmetry, assume that $\overrightarrow{ab}$ intersects L. Their intersection, y, must be above l. Denote by y' the intersection point of $\ell(b,c)$ with L, as in Figure 2(b). Observe that y' is below l. In this setting $\overrightarrow{l'l}$ intersects either by or by', at a point u. If $\overrightarrow{l'l}$ intersects by, we set $\Delta = \delta \oplus (l',u,a,c,r,r')$ as in Figure 2(b), otherwise we set $\Delta = \delta \oplus (l',u,c,a,r,r')$ as in Figure 2(c). Either way we cover 6 vertices with 5 segments, by avoiding lb on our path.

Case 2. CH(S) has 5 vertices (i.e., l, a, b, c, r). By reflection and relabeling, there are two subcases to consider.

- The three vertices a, b, and c lie on the same side of lr (*wlog* below). We may assume that they appear in the order a,b,c from left to right; see Figure 3(a). Then the intersection point x of $\ell(l,a)$ and $\ell(b,c)$ lies in the slab. We set $\Delta = \delta \oplus (l',l,x,c,r,r')$.
- Two vertices, say a and b, lie on one side of lr (*wlog* below), and c lies on the other side. Assume that a is to the left of b. The intersection, u, of $\ell(l,a)$ and $\ell(r,b)$ must be in the slab, by convexity. If l' is above $\ell(l,c)$ then we set $\Delta = \delta \oplus (l',c,l,u,r,r')$, as shown in Figure 3(b). Symmetrically, if r' is above $\ell(r,c)$, we set $\Delta = \delta \oplus (l',l,u,r,c,r')$.
  Finally if l' is below $\ell(l,c)$ and r' is below $\ell(r,c)$, let v be the intersection point of $\ell(l',l)$ and $\ell(r,c)$; see Figure 3(c). By convexity, v is in the slab, so we can set $\Delta = \delta \oplus (l',v,r,a,b,r')$.

Case 3. CH(S) has 4 vertices: l,r,a,b. We consider two subcases.

Case 3a. a and b lie on different sides of lr. *Wlog,* a is below. The point c lies either in triangle $\triangle(a,b,l)$ or in triangle $\triangle(a,b,r)$. The configurations are symmetric so we show how

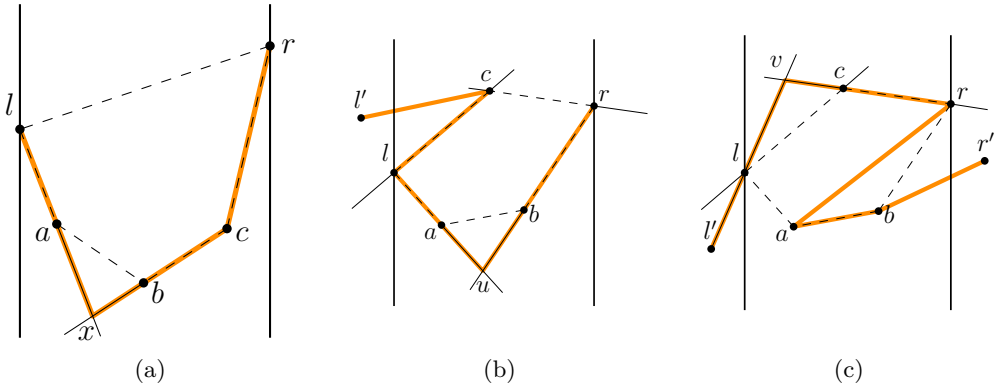


Figure 3 CH(S) has five vertices. (a) a, b, c lie on the same side of lr. (b) l' is above $\ell(l, c)$. (c) l' is below $\ell(l, c)$ and r' is below $\ell(r, c)$.

to handle the former. It is implied that c is to the left of $\overrightarrow{ab}$, which in turn implies that at least one of $\overrightarrow{ac}$ or $\overrightarrow{bc}$ intersects L. *Wlog,* assume that $\overrightarrow{ac}$ intersects L. The intersection point, y, must be above l. There are two subcases to consider:

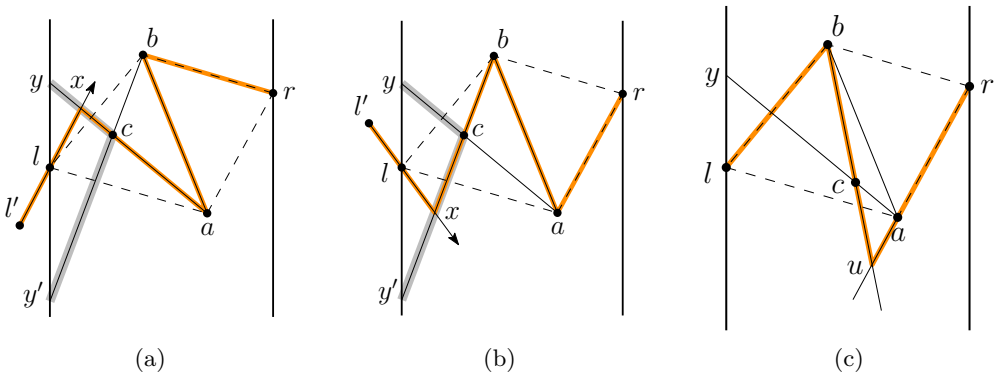

Figure 4 CH(S) has four vertices, the points a and b lie on different sides of lr, the point c is in $\triangle(a, b, l)$, and $\overrightarrow{ac}$ intersects L. (a) $\overrightarrow{bc}$ intersects L, and $\overrightarrow{l'l}$ intersects cy. (b) $\overrightarrow{bc}$ intersects L, and $\overrightarrow{l'l}$ intersects cy'. (c) $\overrightarrow{bc}$ intersects R.

- $\overrightarrow{bc}$ intersects L, at point y', which must be below l. Then either $\overrightarrow{l'l}$ intersects cy as in Figure 4(a), or it intersects cy' as in Figure 4(b). Either way, let the intersection point be x. Respectively, we set $\Delta = \delta \oplus (l', x, a, b, r, r')$ or we set $\Delta = \delta \oplus (l', x, b, a, r, r')$.
- $\overrightarrow{bc}$ intersects R, as in Figure 4(c). In this case the intersection point u of $\ell(b, c)$ and $\ell(r, a)$ lies in the slab. We set $\Delta = \delta \oplus (l', l, b, u, r, r')$.

Case 3b. a and b are on the same side of lr, (*wlog,* below; and also a is to the left of b). By convexity, the intersection point, x, of $\ell(l, a)$ and $\ell(r, b)$ is in the slab. If l' lies above $\ell(l, c)$, as in Figure 5(a), we set $\Delta = \delta \oplus (l', c, l, x, r, r')$. Symmetrically, if r' lies above $\ell(r, c)$, then we set $\Delta = \delta \oplus (l', l, x, r, c, r')$. It remains to consider the case when l' is below $\ell(l, c)$ and r' is below $\ell(r, c)$. We consider two subcases.

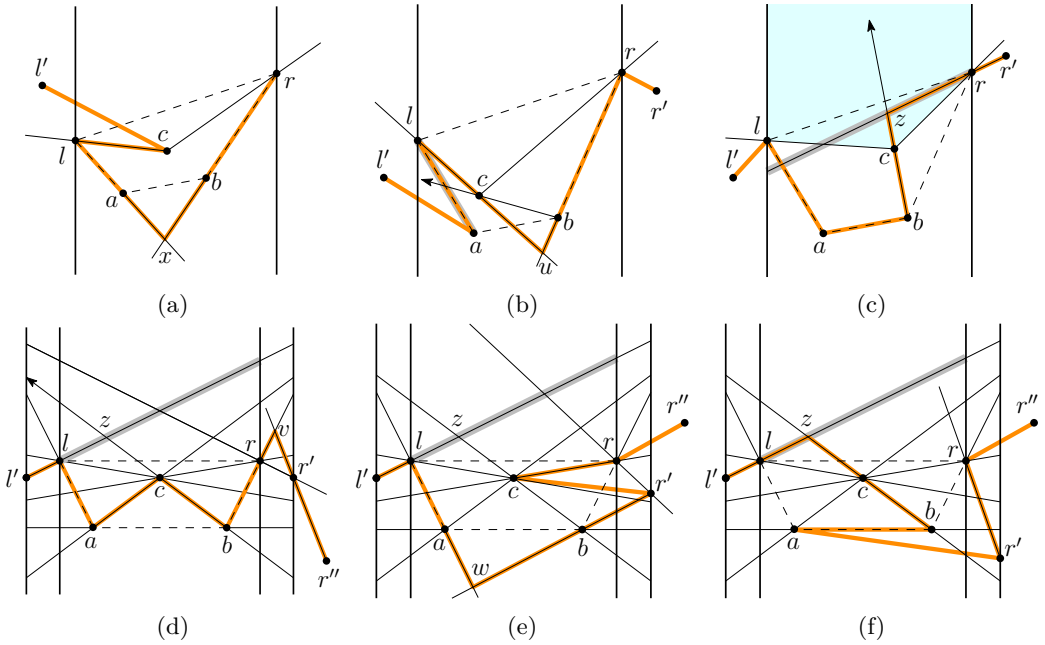

Figure 5 CH(S) has four vertices, a and b lie on the same side of lr. (a) l' is above $\ell(l,c)$. In (b)-(e) we have l' below $\ell(l,c)$ and r' below $\ell(r,c)$. (b) $\overrightarrow{bc}$ intersects al. (c) $\overrightarrow{bc}$ intersects $\overrightarrow{r'r}$ within the slab. (d) r'' is below $\ell(r,r')$. (e) r'' is above $\ell(r,r')$, and r' is above $\ell(a,b)$. (f) r'' is above $\ell(r,r')$, and r' is below $\ell(a,b)$.

- $\overrightarrow{bc}$ intersects al, as in Figure 5(b). In this case, the intersection point u of $\overrightarrow{lc}$ and $\overrightarrow{rb}$ is in the slab because c is to the right of l, and b is to the left of r. Moreover, since l is above $\overrightarrow{bc}$, u does not lie on either of the segments lc and rb. We set $\Delta = \delta \oplus (l', a, l, u, r, r')$. Symmetrically, if $\overrightarrow{ac}$ intersects br we can set $\Delta = \delta \oplus (l', l, u, r, b, r')$, but this does not seem to help or simplify the next case.
- $\overrightarrow{bc}$ does not intersect al. In this case $\overrightarrow{bc}$ lies in the wedge with counterclockwise boundary ray $\overrightarrow{bl}$ and clockwise boundary ray $\overrightarrow{br}$. Because l' is below $\ell(l,c)$ and r' is below $\ell(r,c)$, it follows that $\overrightarrow{bc}$ intersects at least one of the rays $\overrightarrow{l'l}$ and $\overrightarrow{r'r}$ within the slab. If the intersection is with $\overrightarrow{r'r}$ then the intersection point z must be inside the shaded region in Figure 5(c), i.e., above lr or in the triangle $\triangle(l,c,r)$. Accordingly, we set $\Delta = \delta \oplus (l', l, a, b, z, r')$. Otherwise, let z be the intersection of $\overrightarrow{bc}$ with $\overrightarrow{l'l}$. This is the case when we need to scan a new point.
  Let r'' be the next point, after r'. If r'' is below $\ell(r,r')$, then the intersection point v of $\ell(b,r)$ and $\ell(r'',r')$ is in the vertical slab between r and r'; we set $\Delta = \delta \oplus (l', l, a, c, b, v, r'')$ as in Figure 5(d). Otherwise, r'' is above $\ell(r,r')$. Now if r' is above $\ell(a,b)$, then the intersection point w of $\ell(l,a)$ and $\ell(r',b)$ lies in the slab, below $\ell(a,b)$; we set $\Delta = \delta \oplus (l', l, w, r', c, r, r'')$ as in Figure 5(e). Because r' is below $\ell(c,r)$, cr' does not intersect rr''. If r' is below $\ell(a,b)$, we set $\Delta = \delta \oplus (l', z, b, a, r', r, r'')$ as in Figure 5(f). In each case we cover seven new points (including r'') with six edges.

This is the end of an intermediate iteration. In each case, we append to δ a non-crossing path that lies in the vertical slab between l and the rightmost scanned point. Thus Δ is non-crossing. Moreover the degree of the rightmost point in Δ (which is r' or r'') is one.

In each case we have scanned 6 or 7 new points and covered them by 5 or 6 new segments, respectively. If we have scanned 6 points, then the total number M of scanned points is $M = m + 6$, and the number of segments of Δ is

$$|\Delta| = |\delta| + 5 \leqslant \left\lfloor \frac{6m}{7} \right\rfloor + 5 = \left\lfloor \frac{6m + 35}{7} \right\rfloor \leqslant \left\lfloor \frac{6M}{7} \right\rfloor .$$

If we have scanned 7 points, then $M = m + 7$, and we have

$$|\Delta| = |\delta| + 6 \leqslant \left\lfloor \frac{6m}{7} \right\rfloor + 6 = \left\lfloor \frac{6m + 42}{7} \right\rfloor = \left\lfloor \frac{6M}{7} \right\rfloor .$$

Therefore, the invariant holds after every intermediate iteration.

In the last iteration of the algorithm we are left with n' points where $1 \leqslant n' \leqslant 6$. We cover these points by an x-monotone path with $n' - 1$ segments and connect it to the rightmost scanned point (of the path that has been constructed so far) by an additional segment. This gives a non-crossing covering path for all points. The total number of segments in this path is at most

$$\left\lfloor \frac{6(n - n')}{7} \right\rfloor + (n' - 1) + 1 = \left\lfloor \frac{6(n - n') + 7n'}{7} \right\rfloor = \left\lfloor \frac{6n + n'}{7} \right\rfloor \leqslant \left\lfloor \frac{6n + 6}{7} \right\rfloor \leqslant \left\lceil \frac{6n}{7} \right\rceil .$$

Each iteration takes $O(1)$ time. Therefore, after rotating and sorting the points in $O(n \log n)$ time, the rest of the algorithm takes $O(n)$ time. This concludes the proof of Theorem 1.

▶ Remark 2. One could scan exactly 7 points in every intermediate iteration, and obtain the same upper bound. Our choice to scan 6 points whenever possible serves as a demonstration for the complexity of producing a non-crossing covering path with at most $5n/6$ segments.

▶ Remark 3. In contrast to the algorithms of [13] and [18], our algorithm does not rely on the existence of caps or cups to reduce the number of segments used. This has been illustrated in Figure 2(a) when c is to the right of a; in Figure 5(c) where z is to the left of c; and in Figure 5(f) when z is to the right of c.

▶ Remark 4. For the 7 points l', l, a, b, c, d, r, r' in Figure 5(d) we have not found a non-crossing path that starts at l', ends at r', covers all the points, and stays within the slab defined by l' and r'. This suggests the necessity of considering r'' in our algorithm.

3 Open Problems

A natural open problem is to narrow the gap between the lower bound $5n/9$ and the upper bound $6n/7$ for $\pi(n)$. It is not hard to see that a covering path with a minimum number of segments is a subset of the arrangement of the lines through the $\binom{n}{2}$ pairs of points. Thus one can find a covering path with a minimum number of segments in exponential time. It would be interesting to present a sub-exponential algorithm for computing such a path.

Abstract

We consider the List Update problem where the cost of each swap is assumed to be 1. This is in contrast to the "standard" model, in which an algorithm is allowed to swap the requested item with previous items for free. We construct an online algorithm Full-Or-Partial-Move (*Fpm*), whose competitive ratio is at most 3.3904, improving over the previous best known bound of 4.

1 Introduction

The List Update problem. In the online *List Update problem* [3, 20, 21], the objective is to maintain a set of items stored in a linear list in response to a sequence of access requests. The cost of accessing a requested item is equal to its distance from the front of the list. After each request, an algorithm is allowed to rearrange the list by performing an arbitrary number of swaps of adjacent items. In the model introduced by Sleator and Tarjan in their seminal 1985 paper on competitive analysis [25], an algorithm can repeatedly swap the requested item with its preceding item at no cost. These swaps are called *free*. All other swaps are called *paid* and have cost 1 each. As in other problems involving self-organizing data structures [7], the goal is to construct an *online* algorithm, i.e., operating without the knowledge of future requests. The cost of such an algorithm is compared to the cost of the optimal *offline* algorithm; the ratio of the two costs is called the *competitive ratio* and is subject to minimization.

Sleator and Tarjan proved that the algorithm *Move-To-Front* (*Mtf*), which after each request moves the requested item to the front of the list, is 2-competitive [25]. This ratio is known to be optimal if the number of items is unbounded. Their work was the culmination of previous extensive studies of list updating, including experimental results, probabilistic approaches, and earlier attempts at amortized analysis (see [15] and the references therein).

As shown in subsequent work, *Mtf* is not unique – there are other strategies that achieve ratio 2, such as *TimeStamp* [2] or algorithms based on work functions [9]. In fact, there are infinitely many algorithms that achieve ratio 2 [13, 21].

The uniform cost model. Following [24], we will refer to the cost model of [25] as *standard*, and we will denote it here by LUP_S. This model has been questioned in the literature for not accurately reflecting true costs in some implementations [24, 23, 22, 18], with the concept of free swaps being one of the main concerns.

A natural approach to address this concern, considered in some later studies (see, e.g., [24, 7, 21, 4, 12]), is simply to charge cost 1 for *any* swap. We will call it here the *uniform cost model* and denote it LUP_1. A general lower bound of 3 on the competitive ratio of deterministic algorithms for LUP_1 was given by Reingold *et al.* [24]. Changing the cost of free swaps from 0 to 1 at most doubles the cost of any algorithm, so *Mtf* is no worse than 4-competitive for LUP_1. Surprisingly, no algorithm is known to beat *Mtf*, i.e., achieve ratio lower than 4.[1].

Our main result. To address this open problem, we develop an online algorithm *Full-Or-Partial-Move* (*Fpm*) for LUP_1 with competitive ratio $\frac{1}{8}\cdot(23+\sqrt{17}) \approx 3.3904$, significantly improving the previous upper bound of 4.

Our algorithm *Fpm* remains 3.3904-competitive even for the *partial cost* function, where the cost of accessing location ℓ is $\ell - 1$, instead of the *full cost* of ℓ used in the original definition of List Update [25]. Both functions have been used in the literature, depending on context and convenience. For any online algorithm, its partial-cost competitive ratio is at least as large as its full-cost ratio, although the difference typically vanishes when the list size is unbounded. We present our analysis in terms of partial costs.

Fpm remains 3.3904-competitive also in the dynamic scenario of List Update that allows operations of insertions and deletions, as in the original definition in [25] (see the full version of the paper [14]).

Technical challenges and new ideas. The question whether ratio 3 can be achieved remains open. We also do not know if there is a *simple* algorithm with ratio below 4. We have considered some natural adaptions of *Mtf* and other algorithms that are 2-competitive for LUP_S, but for all we were able to show lower bounds higher than 3 for LUP_1.

As earlier mentioned, *Mtf* is 4-competitive for LUP_1. It is also easy to show that its ratio is not better than 4: repeatedly request the last item in the list. Ignoring additive constants, the algorithm pays twice the length of the list at each step, while any algorithm that just keeps the list in a fixed order, pays only half the length on the average.

The intuition why *Mtf* performs poorly is that it moves the requested items to front "too quickly". For the aforementioned adversarial strategy against *Mtf*, ratio 3 can be obtained by moving the items to front only *every other time* they are requested. This algorithm, called *Dbit*, is a deterministic variant of algorithm *Bit* from [24] and a special case of algorithm *Counter* in [24], and it has been also considered in [21]. In the full version of the paper [14], we show that *Dbit* is not better than 4-competitive in the partial cost model, and not better than 3.302-competitive in the full cost model.

[1] The authors of [21] claimed an upper bound of 3 for LUP_1, but later discovered that their proof was not correct (personal communication with S. Kamali).

One can generalize these approaches by considering a more general class of algorithms that either leave the requested item at its current location or move it to the front. We show that such a strategy cannot achieve ratio better than 3.25, even for just three items. A naive fix would be, for example, to always move the requested item half-way towards front. This algorithm is even worse: its competitive ratio is at least 6 (both those proofs are in the full version of the paper [14]).

We also show (see Section 5) via a computer-aided argument that, for LUP_1, the work function algorithm's competitive ratio is larger than 3, even for lists of length 5. This is in contrast to the its performance for the standard model, where it achieves optimal ratio 2 [9].

Our algorithm *Fpm* overcomes the difficulties mentioned above by combining a few new ideas. The first idea is a more sophisticated choice of the target location for the requested item. That is, aside from *full moves* that move the requested items to the list front, *Fpm* sometimes performs a *partial move* to a suitably chosen target location in the list. This location roughly corresponds to the front of the list when this item was requested earlier.

The second idea is to keep track, for each pair of items, of the work function for the two-item subsequence consisting of these items. These work functions are used in two ways. First, they roughly indicate which relative order between the items in each pair is "more likely" in an optimal solution. The algorithm uses this information to decide whether to perform a full move or a partial move. Second, the simple sum of all these pair-based work functions is a lower bound on the optimal cost, which is useful in analyzing the competitive ratio of *Fpm*.

Related work. Better bounds are known for randomized algorithms both in the standard model (LUP_S) and the uniform cost model (LUP_1). For LUP_S, a long line of research culminated in a 1.6-competitive algorithm [19, 24, 2, 6], and a 1.5-lower bound [26]. The upper bound of 1.6 is tight in the class of so-called projective algorithms, whose computation is uniquely determined by their behavior on two-item instances [8]. For LUP_1, the ratio is known to be between 1.5 [4] and 2.64 [24].

It is possible to generalize the uniform cost function by distinguishing between the cost of 1 for following a link during search and the cost of $d \geq 1$ for a swap [24, 4] This model is sometimes called the P^d model; in this terminology, our LUP_1 corresponds to P^1. While *Mtf* is 4-competitive for P^1, it does not generalize in an obvious way to $d > 1$. Other known algorithms for the P^d model (randomized and deterministic *Counter*, *RandomReset* and *TimeStamp*) have bounds on competitive ratios that monotonically decrease with growing d [24, 4]. In particular, deterministic *Counter* achieves ratio 4.56 when d tends to infinity [7] and for the same setting ($d \to \infty$) a recent result by Albers and Janke [4] shows a randomized algorithm *TimeStamp* that is 2.24-competitive.

A variety of List Update variants have been investigated in the literature over the last forty years, including models with lookahead [1], locality of reference [10, 5], parameterized approach [17], algorithms with advice [16], prediction [11], or alternative cost models [18, 22, 23]. A particularly interesting model was proposed recently by Azar *et al.* [12], where an online algorithm is allowed to postpone serving some requests, but is either required to serve them by a specified deadline or pay a delay penalty.

In summary, List Update is one of canonical problems in the area of competitive analysis, used to experiment with refined models of competitive analysis or to study the effects of additional features. This underscores the need to fully resolve the remaining open questions regarding its basic variants, including the question whether ratio 3 is attainable for LUP_1.

2 Preliminaries

Model. An algorithm has to maintain a list of items, while a sequence σ of access requests is presented in an online manner. In each step $t \geq 1$, the algorithm is presented an access request σ^t to an item in the list. If this item is in a location ℓ, the algorithm incurs cost $\ell - 1$ to access it. (The locations in the list are indexed $1, 2, ...$) Afterwards, the algorithm may change the list configuration by performing an arbitrary number of swaps of neighboring items, each of cost 1.

For any algorithm A, we denote its cost for processing a sequence σ by $A(\sigma)$. The optimal algorithm is denoted by Opt.

Notation. Let $\mathcal{P}$ be the set of all unordered pairs of items. For a pair $\{x, y\} \in \mathcal{P}$, we use the notation $x \prec y$ ($x \succ y$) to denote that x is before (after) y in the list of an online algorithm. (The relative order of x, y may change over time, but it will be always clear from context what step of the computation we are referring to.) We use $x \preceq y$ ($x \succeq y$) to denote that $x \prec y$ ($x \succ y$) or $x = y$.

For an input σ and a pair $\{x, y\} \in \mathcal{P}$, σ_{xy} is the subsequence of σ restricted to requests to items x and y only. Whenever we say that an algorithm serves input σ_{xy}, we mean that it has to maintain a list of two items, x and y.

2.1 Work Functions

Work functions on item pairs. For each prefix σ of the input sequence, an online algorithm may compute a so-called *work function* W^{xy}, where $W^{xy}(xy)$ (or $W^{xy}(yx)$) is the optimal cost of the solution that serves σ_{xy} and ends with the list in configuration xy (or yx). (Function W^{xy} also has prefix σ as an argument. Its value will be always uniquely determined from context.) The values of W for each step can be computed iteratively using straightforward dynamic programming. Note that the values of W are non-negative integers and $|W^{xy}(xy) - W^{xy}(yx)| \leq 1$.

Modes. For a pair $\{x, y\} \in \mathcal{P}$, we define its *mode* depending on the value of the work function W^{xy} in the current step and the mutual relation of x and y in the list of an online algorithm. In the following definition we assume that $y \prec x$.

- Pair $\{x, y\}$ is in mode α if $W^{xy}(yx) + 1 = W^{xy}(xy)$.
- Pair $\{x, y\}$ is in mode β if $W^{xy}(yx) = W^{xy}(xy)$.
- Pair $\{x, y\}$ is in mode γ if $W^{xy}(yx) - 1 = W^{xy}(xy)$.

For an illustration of work function evolution and associated modes, see Figure 1.

If a pair $\{x, y\}$ is in mode α, then the minimum of the work function W^{xy} is at configuration yx, i.e., the one that has y before x. That is, an online algorithm keeps these items in a way that "agrees" with the work function. Note that α is the initial mode of all pairs. Conversely, if a pair $\{x, y\}$ is in state γ, then the minimum of the work function W^{xy} is at configuration xy. In this case, an online algorithm keeps these items in a way that "disagrees" with the work function.

2.2 Lower Bound on OPT

Now we show how to use the changes in the work functions of item pairs to provide a useful lower bound on the cost of an optimal algorithm. The following lemma is a standard and straightforward result of the list partitioning technique [9].[2]

[2] There are known input sequences on which the relation of Lemma 1 is not tight [9].

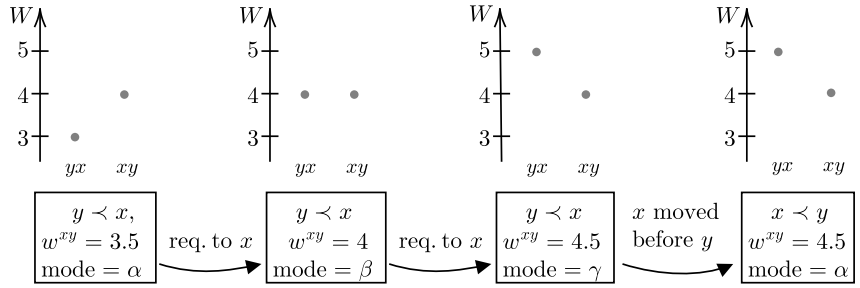

Figure 1 The evolution of the work function W^{xy}. Initially, W^{xy} has its minimum in the state yx and $y \prec x$ (in the list of an online algorithm). Thus, the mode of the pair $\{x, y\}$ is α. Next, because of the two requests to x, the value of $W^{xy}(yx)$ is incremented, while the value at xy remains intact. The mode is thus changed from α to β and then to γ. Finally, when an algorithm moves item x before y, the mode of the pair $\{x, y\}$ changes to α. The value of w^{xy} (the average of $W^{xy}(xy)$ and $W^{xy}(yx)$) increases by $\frac{1}{2}$ whenever the mode changes due to a request.

▶ **Lemma 1.** *For every input sequence σ, it holds that $\sum_{\{x,y\}\in\mathcal{P}} \textsc{Opt}(\sigma_{xy}) \le \textsc{Opt}(\sigma)$.*

Averaging work functions. We define the function w^{xy} as the average value of the work function W^{xy}, i.e.,

$$w^{xy} \triangleq \tfrac{1}{2} \cdot \big(W^{xy}(xy) + W^{xy}(yx) \big).$$

We use w^{xy}_t to denote the value of w^{xy} after serving the first t requests of σ, and define $\Delta_t w^{xy} \triangleq w^{xy}_t - w^{xy}_{t-1}$. The growth of w^{xy} can be related to $\textsc{Opt}(\sigma)$ in the following way.

▶ **Lemma 2.** *For a sequence σ consisting of T requests, it holds that $\sum_{t=1}^{T} \sum_{\{x,y\}\in\mathcal{P}} \Delta_t w^{xy} \le \textsc{Opt}(\sigma)$.*

Proof. We first fix a pair $\{x, y\} \in \mathcal{P}$. We have $w^{xy}_0 = \frac{1}{2}$ and $w^{xy}_T \le \textsc{Opt}(\sigma_{xy}) + \frac{1}{2}$. Hence, $\sum_{t=1}^{T} \Delta_t w^{xy} = w^{xy}_T - w^{xy}_0 \le \textsc{Opt}(\sigma_{xy})$. The proof follows by summing over all pairs $\{x, y\} \in \mathcal{P}$ and invoking Lemma 1. ◀

Pair-based OPT. Lemma 2 gives us a convenient tool to lower bound $\textsc{Opt}(\sigma)$. We define the cost of *pair-based* $\textsc{Opt}$ in step t as $\sum_{\{x,y\}\in\mathcal{P}} \Delta_t w^{xy}$. For a given request sequence σ, the sum of these costs over all steps is a lower bound on the actual value of $\textsc{Opt}(\sigma)$.

On the other hand, we can express $\Delta_t w^{xy}$ (and thus also the pair-based $\textsc{Opt}$) in terms of the changes of the modes of item pairs. See Figure 1 for an illustration.

▶ **Observation 3.** *If a pair $\{x, y\}$ changes its mode due to the request in step t then $\Delta_t w^{xy} = \frac{1}{2}$, otherwise $\Delta_t w^{xy} = 0$.*

3 Algorithm Full-Or-Partial-Move

For each item x, $\textsc{Fpm}$ keeps track of an item denoted θ_x and called the *target* of x. At the beginning, $\textsc{Fpm}$ sets $\theta_x = x$ for all x. Furthermore, at each time, $\textsc{Fpm}$ ensures that $\theta_x \preceq x$.

The rest of this section describes the overall strategy of algorithm $\textsc{Fpm}$. Our description is top-down, and proceeds in three steps:

- First we describe, in broad terms, what actions are involved in serving a request, including the choice of a move and the principle behind updating target items.

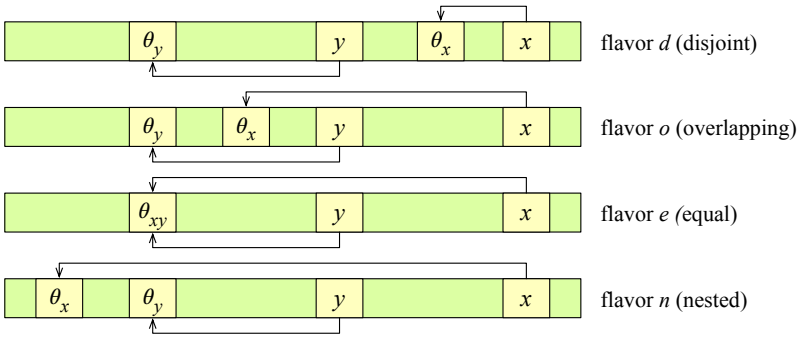

Figure 2 The flavor of a pair $\{x, y\}$ (where $y \prec x$) depends on the position of target θ_x with respect to items $\theta_y \preceq y \prec x$. In the figure for flavor e, we write θ_{xy} for the item $\theta_x = \theta_y$.

- Next, we define the concept of states associated with item pairs and their potentials.
- Finally, we explain how algorithm *FPM* uses these potential values to decide how to adjust the list after serving the request.

This description will fully specify how *FPM* works, providing that the potential function on the states is given. Thus, for any choice of the potential function the competitive ratio of *FPM* is well-defined. What remains is to choose these potential values to optimize the competitive ratio. This is accomplished by the analysis in Section 4 that follows.

Serving a request. Whenever an item z^* is requested, *FPM* performs the following three operations, in this order:

1. *Target cleanup.* If z^* was a target of another item y (i.e., $\theta_y = z^*$ for $y \neq z^*$), then θ_y is updated to the successor of z^*. This happens for all items y with this property.
2. *Movement of z^*.* *FPM* executes one of the two actions: a *partial move* or a *full move*. We will explain how to choose between them later.
   - In the partial move, item z^* is inserted right before θ_{z^*}. (If $\theta_{z^*} = z^*$, this means that z^* does not change its position.)
   - In the full move, item z^* is moved to the front of the list.
3. *Target reset.* θ_{z^*} is set to the front item of the list.

It is illustrative to note a few properties and corner cases of the algorithm.

- Target cleanup is executed only for items following z^*, and thus the successor of z^* exists then (i.e., *FPM* is well defined).
- If $\theta_{z^*} = z^*$ and a partial move is executed, then z^* is not moved, but the items that targeted z^* now target the successor of z^*.
- For an item x, the items that precede θ_x in the list were requested (each at least once) after the last time x had been requested.

Modes, flavors and states. Fix a pair $\{x, y\}$ such that $y \prec x$, and thus also $\theta_y \preceq y \prec x$. This pair is assigned one of four possible *flavors*, depending on the position of θ_x (cf. Figure 2):

- flavor d (**d**isjoint): if $\theta_y \preceq y \prec \theta_x \preceq x$,
- flavor o (**o**verlapping): if $\theta_y \prec \theta_x \preceq y \prec x$,
- flavor e (**e**qual): if $\theta_y = \theta_x \preceq y \prec x$,
- flavor n (**n**ested): if $\theta_x \prec \theta_y \preceq y \prec x$

For a pair $\{x, y\}$ that is in a mode $\xi \in \{\alpha, \beta, \gamma\}$ and has a flavor $\omega \in \{d, o, e, n\}$, we say that the *state* of $\{x, y\}$ is ξ^ω. Recall that all pairs are initially in mode α, and note that their initial flavor is d. That is, the initial state of all pairs is α^d.

We will sometimes combine the flavors o with e, stating that the pair is in state ξ^{oe} if its mode is ξ and its flavor is o or e. Similarly, we will also combine flavors n and e.

Pair potential. To each pair $\{x, y\}$ of items, we assign a non-negative *pair potential* Φ_{xy}. We abuse the notation and use ξ^ω not only to denote the pair state, but also the corresponding values of the pair potential. That is, we assign the potential $\Phi_{xy} = \xi^\omega$ if pair $\{x, y\}$ is in state ξ^ω. We pick the actual values of these potentials only later in Subsection 4.5.

We emphasize that the states of each item pair depend on work functions for this pair that are easily computable in online manner. Thus, FPM may compute the current values of Φ_{xy}, and also compute how their values would change for particular choice of a move.

Choosing the cheaper move. For a step t, let $\Delta_t \text{FPM}$ be the cost of FPM in this step, and for a pair $\{x, y\} \in \mathcal{P}$, let $\Delta_t \Phi_{xy}$ be the change of the potential of pair $\{x, y\}$ in step t. Let z^* denote the requested item. FPM chooses the move (full or partial) with the smaller value of

$$\Delta_t \text{FPM} + \sum_{y \prec z^*} \Delta_t \Phi_{z^* y},$$

breaking ties arbitrarily. Importantly, note that the value that FPM minimizes involves only pairs including the requested item z^* and items currently preceding it.

4 Analysis of Full-Or-Partial-Move

In this section, we show that for a suitable choice of pair potentials, FPM is 3.3904-competitive.

To this end, we first make a few observations concerning how the modes, flavors (and thus states) of item pairs change due to the particular actions of FPM. These are summarized in Table 1, Table 2, and Table 3, and proved in Subsection 4.2 and Subsection 4.3.

Next, in Subsection 4.4 and Subsection 4.5, we show how these changes influence the amortized cost of FPM pertaining to particular pairs. We show that for a suitable choice of pair potentials, we can directly compare the amortized cost of FPM with the cost of OPT.

4.1 Structural Properties

Note that requests to items other than x and y do not affect the mutual relation between x and y. Moreover, to some extent, they preserve the relation between targets θ_x and θ_y, as stated in the following lemma.

▶ **Lemma 4.** *Fix a pair $\{x, y\} \in \mathcal{P}$ and assume that $\theta_y \preceq \theta_x$ (resp. $\theta_y = \theta_x$). If FPM serves a request to an item z^* different than x and y, then these relations are preserved. The relation $\theta_y \prec \theta_x$ changes into $\theta_y = \theta_x$ only when θ_y and θ_x are adjacent and $z^* = \theta_y$.*

Proof. By the definition of FPM, the targets of non-requested items are updated (during the target cleanup) only if they are equal to z^*. In such a case, they are updated to the successor of z^*. We consider several cases.

- If $z^* \notin \{\theta_x, \theta_y\}$, the targets θ_x and θ_y are not updated.
- If $z^* = \theta_y = \theta_x$, both targets are updated to the successor of z^*, and thus they remain equal.

- If $z^* = \theta_y \prec \theta_x$, target θ_y is updated. If θ_y and θ_x were adjacent (θ_y was an immediate predecessor of θ_x), they become equal. In either case, $\theta_y \preceq \theta_x$.
- If $\theta_y \prec \theta_x = z^*$, target θ_x is updated, in which case the relation $\theta_y \prec \theta_x$ is preserved. ◀

4.2 Mode Transitions

Now, we focus on the changes of modes. It is convenient to look first at how they are affected by the request itself (which induces an update of the work function), and subsequently due to the actions of *FPM* (when some items are swapped). The changes are summarized in the following observation.

▶ **Observation 5.** *Let z^* be the requested item.*

- *Fix an item $y \succ z^*$. The mode transitions of the pair $\{z^*, y\}$ due to request are $\alpha \to \alpha$, $\beta \to \alpha$, and $\gamma \to \beta$. Subsequent movement of z^* does not further change the mode.*
- *Fix an item $y \prec z^*$. Due to the request, pair $\{z^*, y\}$ changes first its mode due to the request in the following way: $\alpha \to \beta$, $\beta \to \gamma$, and $\gamma \to \gamma$. Afterwards, if FPM moves z^* before y, the subsequent mode transitions for pair $\{z^*, y\}$ are $\beta \to \beta$ and $\gamma \to \alpha$.*

4.3 State Transitions

Throughout this section, we fix a step and let z^* be the requested item.

We analyze the potential changes for both types of movements. We split our considerations into three cases corresponding to three types of item pairs. The first two types involve z^* as one pair item, where the second item either initially precedes z^* (cf. Lemma 7) or follows z^* (cf. Lemma 8). The third type involves pairs that do not contain z^* at all (cf. Lemma 9).

While we defined 12 possible states (3 modes × 4 flavors), we will show that α^n, γ^d, and γ^o never occur. This clearly holds at the very beginning as all pairs are then in state α^d.

For succinctness, we also combine some of the remaining states, reducing the number of states to the following six: α^d, β^d, α^{oe}, β^o, β^{ne} and γ^{ne}. (For example, a pair is in state α^{oe} if it is in state α^o or α^e.) In the following we analyze the transitions between them. We start with a simple observation.

▶ **Lemma 6.** *Fix an item $y \neq z^*$. If FPM performs a full move, then the resulting flavor of the pair $\{z^*, y\}$ is d.*

Proof. Item z^* is moved to the front of the list, and its target θ_{z^*} is reset to this item, i.e., $z^* = \theta_{z^*}$. After the movement, we have $z^* \prec \theta_y$. This relation follows trivially if z^* is indeed moved. However, it holds also if z^* was already on the first position: even if $\theta_y = z^*$ before the move, θ_y would be updated to the successor of z^* during the target cleanup. The resulting ordering is thus $\theta_{z^*} = z^* \prec \theta_y \preceq y$, i.e., the flavor of the pair becomes d. ◀

▶ **Lemma 7.** *Fix $y \prec z^*$. The state transitions for pair $\{z^*, y\}$ are given in Table 1.*

Proof. First, suppose *FPM* performs a full move. The pair $\{z^*, y\}$ is swapped, which changes its mode according to Observation 5 ($\alpha \to \beta$, $\beta \to \alpha$, $\gamma \to \alpha$). By Lemma 6, the flavor of the pair becomes d. This proves the correctness of the transitions in row three of Table 1.

In the rest of the proof, we analyze the case when *FPM* performs a partial move. We consider three sub-cases depending on the initial flavor of the pair $\{z^*, y\}$. For the analysis of mode changes we will apply Observation 5.

Table 1 State transitions for pairs $\{z^*, y\}$ where $y \prec z^*$ right before the request to z^*.

State before move	α^d	β^d	α^{oe}	β^o	β^{ne}	γ^{ne}
State after partial move	β^{ne}	γ^{ne}	β^d or β^o or β^{ne}	α^{oe}	α^d	α^d
State after full move	β^d	α^d	β^d	α^d	α^d	α^d

Table 2 State transitions for pairs $\{z^*, y\}$ where $z^* \prec y$ right before the request to z^*.

State before move	α^d	β^d	α^{oe}	β^o	β^{ne}	γ^{ne}
State after move	α^d	α^d	α^d	α^d	α^d or α^{oe}	β^d or β^o or β^{ne}

- Before the movement, the flavor of the pair was d, i.e., $\theta_y \preceq y \prec \theta_{z^*} \preceq z^*$.
  The movement of z^* does not swap the pair, i.e., its mode transitions are $\alpha \to \beta$ and $\beta \to \gamma$. As θ_{z^*} is set to the list front, after the movement $\theta_{z^*} \preceq \theta_y \preceq y \prec z^*$, i.e., the flavor of the pair becomes either e or n. This explains the state transitions $\alpha^d \to \beta^{ne}$ and $\beta^d \to \gamma^{ne}$.
- Before the movement, the flavor of the pair was o, i.e., $\theta_y \prec \theta_{z^*} \preceq y \prec z^*$.
  Due to the movement, the pair is swapped, and its mode transitions are $\alpha \to \beta$ and $\beta \to \alpha$. As θ_{z^*} is set to the list front, we have $\theta_{z^*} \preceq \theta_y$. After the movement, $\theta_y \preceq z^* \prec y$, i.e., the flavor of the pair becomes either o or e. This explains the state transitions $\alpha^{oe} \to (\beta^o$ or $\beta^{ne})$ and $\beta^o \to \alpha^{oe}$.
- Before the movement, the flavor of the pair was e or n, i.e., $\theta_{z^*} \preceq \theta_y \preceq y \prec z^*$.
  The movement swaps the pair, and its mode transitions are $\alpha \to \beta$, $\beta \to \alpha$ and $\gamma \to \alpha$. After the movement $z^* \prec \theta_y$, and target θ_{z^*} is set to the list front, which results in $\theta_{z^*} \preceq z^* \prec \theta_y \preceq y$, i.e., the pair flavor becomes d. This explains the state transitions $\alpha^{oe} \to \beta^d$, $\beta^{ne} \to \alpha^d$, and $\gamma^{ne} \to \alpha^d$ ◀

▶ **Lemma 8.** *Fix $y \succ z^*$. The state transitions for pair $\{z^*, y\}$ are given in Table 2.*

Proof. The pair $\{z^*, y\}$ is not swapped due to the request, and thus, by Observation 5, its mode transition is $\alpha \to \alpha$, $\beta \to \alpha$, $\gamma \to \beta$.

If FPM performs a full move, the flavor of the pair becomes d by Lemma 6. This explains the state transitions $\alpha^d \to \alpha^d$, $\beta^d \to \alpha^d$, $\alpha^{oe} \to \alpha^d$, $\beta^o \to \alpha^d$, $\beta^{ne} \to \alpha^d$, and $\gamma^{ne} \to \beta^d$.

In the following, we assume that FPM performs a partial move, and we will identify cases where the resulting pair flavor is different than d. We consider two cases.

- The initial flavor is d, o or e. That is $\theta_{z^*} \preceq z^* \prec y$ and $\theta_{z^*} \preceq \theta_y \preceq y$. During the target cleanup, θ_y may be updated to its successor, but it does not affect these relations, and in particular we still have $\theta_{z^*} \preceq \theta_y$. Thus, when z^* is moved, it gets placed before θ_y. This results in the ordering $\theta_{z^*} \preceq z^* \prec \theta_y \preceq y$, i.e., the resulting flavor is d.
- The initial flavor is n, i.e., $\theta_y \prec \theta_{z^*} \preceq z^* \prec y$. As $\theta_y \neq z^*$, the target θ_y is not updated during the target cleanup. As z^* is moved right before original position of θ_{z^*}, it is placed after θ_y, and the resulting ordering is $\theta_{z^*} \preceq \theta_y \prec z^* \prec y$. That is, the flavor becomes o or e, which explains the state transitions $\beta^{ne} \to \alpha^{oe}$ and $\gamma^{ne} \to (\beta^o$ or $\beta^{ne})$. ◀

▶ **Lemma 9.** *Fix $y \prec x$, such that $x \neq z^*$ and $y \neq z^*$. State transitions for pair $\{x, y\}$ are given in Table 3.*

Table 3 State transitions for pairs $\{x, y\}$ where $x \neq z^*$ and $y \neq z^*$ right before the request to z^*.

State before move	α^d	β^d	α^{oe}	β^o	β^{ne}	γ^{ne}
State after move	α^d	β^d	α^{oe}	β^o or β^{ne}	β^{ne}	γ^{ne}

Proof. The mode of the pair $\{x, y\}$ is not affected by the request to z^*.

The flavor of the pair $\{x, y\}$ depends on mutual relations between x, y, θ_x and θ_y. By Lemma 4, the only possible change is that θ_x and θ_y were different but may become equal: this happens when they were adjacent and the earlier of them is equal to z^*. We consider four cases depending on the initial flavor of the pair.

- The initial flavor was e ($\theta_y = \theta_x \preceq y \prec x$). As θ_y and θ_x are not adjacent, the flavor remains e.
- The initial flavor was d ($\theta_y \preceq y \prec \theta_x \preceq x$). Suppose $\theta_y = z^*$. As $y \neq z^*$, we have $\theta_y = z^* \prec y \prec \theta_x$. That is, θ_x and θ_y are not adjacent, and thus the flavor remains d.
- The initial flavor was o ($\theta_y \prec \theta_x \preceq y \prec x$). In this case it is possible that θ_y and θ_x are adjacent and $z^* = \theta_y$. The flavor may thus change to e or remain o.
- The initial flavor was n ($\theta_x \prec \theta_y \preceq y \prec x$). Similarly to the previous case, it is possible that θ_x and θ_y are adjacent and $z^* = \theta_x$. The flavor may thus change to e or remain n. ◀

4.4 Amortized Analysis

We set $R = \frac{1}{8}(23 + \sqrt{17}) \leq 3.3904$ as our desired competitive ratio.

In the following, we fix a step t in which item z^* is requested. We partition $\mathcal{P}$ into three sets corresponding to the three types of pairs:

- $\mathcal{P}_1^t \triangleq \{\{y, z^*\} : y \prec z^*\}$ (pairs where z^* is the second item, analyzed in Table 1),
- $\mathcal{P}_2^t \triangleq \{\{y, z^*\} : z^* \prec y\}$ (pairs where z^* is the first item, analyzed in Table 2),
- $\mathcal{P}_3^t \triangleq \{\{x, y\} : x \neq z^* \wedge y \neq z^*\}$ (pairs where z^* is not involved, analyzed in Table 3).

For succinctness, wherever it does not lead to ambiguity, we omit subscripts t, i.e., write $\Delta\Phi_{xy}$ and Δw^{xy} instead of $\Delta_t\Phi_{xy}$ and $\Delta_t w^{xy}$. We also omit superscripts t in $\mathcal{P}_1^t$, $\mathcal{P}_2^t$, and $\mathcal{P}_3^t$.

Our goal is to show the following three bounds:

- $\Delta F_{PM} + \sum_{\{x,y\}\in\mathcal{P}_1} \Delta\Phi_{xy} \leq R \cdot \sum_{\{x,y\}\in\mathcal{P}_1} \Delta w^{xy}$,
- $\sum_{\{x,y\}\in\mathcal{P}_2} \Delta\Phi_{xy} \leq R \cdot \sum_{\{x,y\}\in\mathcal{P}_2} \Delta w^{xy}$,
- $\sum_{\{x,y\}\in\mathcal{P}_3} \Delta\Phi_{xy} \leq R \cdot \sum_{\{x,y\}\in\mathcal{P}_3} \Delta w^{xy}$.

Note that the left hand sides of these inequalities correspond to the portions of amortized cost of F_{PM} corresponding to sets $\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3$, while the right hand sides are equal to R times the corresponding portion of the cost of pair-based O_{PT}. Hence, if we can show the above inequalities for every step t, the competitive ratio of R will follow by simply adding them up.

As we show in the sections that follow, these bounds reduce to some constraints involving state potentials α^d, β^d, α^{oe}, β^o, β^{ne} and γ^{ne}. The bounds for $\mathcal{P}_2$ and $\mathcal{P}_3$, while they involve summations over pairs, can be justified by considering individual pairs and the needed constraints are simple inequalities between state potentials, summarized in the following assumption:

▶ **Assumption 10.** *We assume that*

- $\alpha^d = 0$,
- *all constants* β^d, α^{oe}, β^o, β^{ne} *and* γ^{ne} *are non-negative,*
- $\alpha^{oe} \leq \beta^{ne} + \frac{1}{2}R \leq \beta^o + \frac{1}{2}R$,
- $\max\{\beta^d, \beta^o\} \leq \gamma^{ne} + \frac{1}{2}R$.

The bound for $\mathcal{P}_1$ is most critical (not surprisingly, as it corresponds to requesting the second item of a pair). To analyze this bound, the needed constraints, besides the state potentials also need to involve the numbers of pairs that are in these states. This gives rise to a non-linear optimization problem that we need to solve.

4.4.1 Analyzing pairs from set $\mathcal{P}_1$

The proof of the following lemma is deferred to Subsection 4.5.

▶ **Lemma 11.** *There exist parameters α^d, β^d, α^{oe}, β^o, β^{ne} and γ^{ne}, satisfying Assumption 10, such that for any step t, it holds that $\Delta F_{PM} + \sum_{\{x,y\}\in\mathcal{P}_1} \Delta\Phi_{xy} \le R \cdot \sum_{\{x,y\}\in\mathcal{P}_1} \Delta w^{xy}$.*

4.4.2 Analyzing pairs from set $\mathcal{P}_2$

▶ **Lemma 12.** *For any step t, it holds that $\sum_{\{x,y\}\in\mathcal{P}_2} \Delta\Phi_{xy} \le R \cdot \sum_{\{x,y\}\in\mathcal{P}_2} \Delta w^{xy}$.*

Proof. Recall that $\mathcal{P}_2$ contains all pairs $\{z^*, y\}$, such that $z^* \prec y$. Thus, it is sufficient to show that $\Delta\Phi_{z^*y} \le R \cdot \Delta w^{z^*y}$ holds for any such pair $\{z^*, y\}$. The lemma will then follow by summing over all pairs from $\mathcal{P}_2$.

By Assumption 10, we have

$$\alpha^d - \alpha^{oe} \le 0, \tag{1}$$

$$\max\{\alpha^d, \alpha^{oe}\} - \beta^{ne} = \alpha^{oe} - \beta^{ne} \le \tfrac{1}{2}R, \tag{2}$$

$$\max\{\beta^d, \beta^o, \beta^{ne}\} - \gamma^{ne} = \max\{\beta^d, \beta^o\} - \gamma^{ne} \le \tfrac{1}{2}R. \tag{3}$$

We consider two cases depending on the initial mode of the pair $\{z^*, y\}$. In each case, we upper-bound the potential change on the basis of possible state changes of this pair (cf. Table 2).

- The initial mode of $\{z^*, y\}$ is α. By Table 2, this mode remains α, and thus by Observation 3, $\Delta w^{z^*y} = 0$. Then,

$$\begin{aligned} \Delta\Phi_{z^*y} &\le \max\left\{\alpha^d - \alpha^d, \alpha^d - \alpha^{oe}\right\} && \text{(by Table 2)} \\ &= 0 = R \cdot \Delta w^{z^*y}. && \text{(by (1))} \end{aligned}$$

- The initial mode of $\{z^*, y\}$ is β or γ. By Table 2, its mode changes due to the request to z^*, and hence, by Observation 3, $\Delta w^{z^*y} = \frac{1}{2}$. Then,

$$\begin{aligned} \Delta\Phi_{z^*y} &\le \max\{\alpha^d - \alpha^d, \alpha^d - \beta^d, \alpha^d - \alpha^{oe}, \alpha^d - \beta^o, \\ &\qquad \max\{\alpha^d, \alpha^{oe}\} - \beta^{ne}, \\ &\qquad \max\{\beta^d, \beta^o, \beta^{ne}\} - \gamma^{ne}\} && \text{(by Table 2)} \\ &\le \max\{-\beta^d, -\beta^o, \tfrac{1}{2}R, \tfrac{1}{2}R\} && \text{(by } \alpha^d = 0\text{, (1), (2) and (3))} \\ &= \tfrac{1}{2}R = R \cdot \Delta w^{z^*y}. \end{aligned}$$

◀

4.4.3 Analyzing pairs from set $\mathcal{P}_3$

▶ **Lemma 13.** *For any step t, it holds that $\sum_{\{x,y\}\in\mathcal{P}_3} \Delta\Phi_{xy} \le R \cdot \sum_{\{x,y\}\in\mathcal{P}_3} \Delta w^{xy}$.*

Proof. As in the previous lemma, we show that the inequality $\Delta\Phi_{xy} \le R \cdot \Delta w^{xy}$ holds for any pair $\{x, y\} \in \mathcal{P}_3$, i.e., for a pair $\{x, y\}$, such that $x \ne z^*$ and $y \ne z^*$. The lemma will then follow by summing over all pairs $\{x, y\} \in \mathcal{P}_3$.

Possible state transitions of such a pair $\{x, y\}$ are given in Table 3. Hence, such a pair either does not change its state (and then $\Delta\Phi_{xy} = 0$) or it changes it from β^o to β^{ne} (and then $\Delta\Phi_{xy} = \beta^{ne} - \beta^o \le 0$ by Assumption 10). In either case, $\Delta\Phi_{xy} \le 0 \le R \cdot \Delta w^{xy}$. ◀

4.4.4 Proof of R-competitiveness

We now show that the three lemmas above imply that F_{PM} is R-competitive.

▶ **Theorem 14.** *For an appropriate choice of parameters, the competitive ratio of F_{PM} is at most $R = \frac{1}{8}(23 + \sqrt{17}) \leq 3.3904$.*

Proof. Fix any sequence σ consisting of T requests. By summing the guarantees of Lemma 11, Lemma 12, and Lemma 13, we obtain that for any step t, it holds that

$$\Delta_t F_{PM} + \sum_{\{x,y\}\in\mathcal{P}} \Delta_t \Phi_{xy} \leq R \cdot \sum_{\{x,y\}\in\mathcal{P}} \Delta_t w^{xy}.$$

By summing over all steps, observing that the potentials are non-negative and the initial potential is zero (cf. Assumption 10), we immediately obtain that $F_{PM}(\sigma) \leq R \cdot \sum_{t=1}^{T} \sum_{\{x,y\}\in\mathcal{P}} \Delta w^{xy} \leq R \cdot O_{PT}(\sigma)$. The second inequality follows by Lemma 2. ◀

4.5 Proof of Lemma 11

Again, we focus on a single step t, in which the requested item is denoted z^*. We let A^d, B^d, A^{oe}, B^o, B^{ne}, C^{ne} be the number of items y preceding z^* such that pairs $\{z^*, y\}$ have states α^d, β^d, α^{oe}, β^o, β^{ne} and γ^{ne}, respectively. Let

$$V \triangleq [A^d, B^d, A^{oe}, B^o, B^{ne}, C^{ne}].$$

Note that $\|V\|_1$ is the number of items preceding z^*, and thus also the access cost F_{PM} pays for the request. Moreover, $A^d + B^d$ is the number of items that precede θ_{z^*}. We use $\odot$ to denote scalar product (point-wise multiplication) of two vectors.

We define three row vectors G_{OPT}, G_{PM}, and G_{FM}, such that

$$\begin{pmatrix} G_{\mathrm{PM}} \\ G_{\mathrm{FM}} \\ G_{\mathrm{OPT}} \end{pmatrix} = \begin{pmatrix} 1 & 1 & 2 & 2 & 2 & 2 \\ 2 & 2 & 2 & 2 & 2 & 2 \\ \frac{1}{2} & \frac{1}{2} & \frac{1}{2} & \frac{1}{2} & \frac{1}{2} & 0 \end{pmatrix} + \begin{pmatrix} \beta^{ne} & (\gamma^{ne} - \beta^d) & (\max\{\beta^d, \beta^o\} - \alpha^{oe}) & (\alpha^{oe} - \beta^o) & -\beta^{ne} & -\gamma^{ne} \\ \beta^d & -\beta^d & (\beta^d - \alpha^{oe}) & -\beta^o & -\beta^{ne} & -\gamma^{ne} \\ 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

Expressing costs as vector products. Recall that to prove Lemma 11, we need to relate the $\mathcal{P}_1$ portion of the amortized cost of F_{PM}, i.e., $\Delta F_{PM} + \sum_{\{x,y\}\in\mathcal{P}_1} \Delta\Phi_{xy}$ and the corresponding portion of the cost of pair-based O_{PT}, i.e., $\sum_{\{x,y\}\in\mathcal{P}_1} \Delta w^{xy}$. In the following two lemmas, we show how to express both terms as vector products.

▶ **Lemma 15.** *It holds that $\sum_{y\prec z^*} \Delta w^{z^* y} = G_{\mathrm{OPT}} \odot V$.*

Proof. The right-hand side of the lemma relation is equal to $\frac{1}{2}(A^d + B^d + A^{oe} + B^o + B^{ne})$. By Observation 5, due to request to z^*:

- $A^d + A^{oe}$ pairs change mode from α to β, and
- $B^d + B^o + B^{ne}$ pairs change mode from β to γ.

By Observation 3, each such mode change contributes $\frac{1}{2}$ to the left hand side of the lemma equation. Note that C^{ne} pairs of mode γ do not change their mode due to the request. ◀

▶ **Lemma 16.** *It holds that $\Delta F_{PM} + \sum_{y\prec z^*} \Delta\Phi_{z^* y} = G \odot V$, where*

- *$G = G_{\mathrm{PM}}$ if F_{PM} performs a partial move, and*
- *$G = G_{\mathrm{FM}}$ if F_{PM} performs a full move.*

Proof. First, assume that FPM performs a partial move. By the definitions of A^d, B^d, A^{oe}, B^o, B^{ne}, and C^{ne}, $\Delta FPM = [1,1,2,2,2,2] \odot V$. By Table 1,

$$\begin{aligned}\sum_{y \prec z^*} \Delta\Phi_{z^*y} &\\ &\leq \left[\beta^{ne} - \alpha^d, \gamma^{ne} - \beta^d, \max\{\beta^d, \beta^o, \beta^{ne}\} - \alpha^{oe}, \alpha^{oe} - \beta^o, \alpha^d - \beta^{ne}, \alpha^d - \gamma^{ne}\right] \odot V \\ &= \left[\beta^{ne}, \gamma^{ne} - \beta^d, \max\{\beta^d, \beta^o\} - \alpha^{oe}, \alpha^{oe} - \beta^o, -\beta^{ne}, -\gamma^{ne}\right] \odot V,\end{aligned}$$

where the second equality follows as $\alpha^d = 0$ and $\beta^o \geq \beta^{ne}$ (by Assumption 10). Thus, the lemma holds for a partial move.

Next, assume FPM performs a full move. Then, $\Delta FPM = [2,2,2,2,2,2] \odot V$. By Table 1,

$$\begin{aligned}\sum_{y \prec z^*} \Delta\Phi_{z^*y} &= \left[\beta^d - \alpha^d, \alpha^d - \beta^d, \beta^d - \alpha^{oe}, \alpha^d - \beta^o, \alpha^d - \beta^{ne}, \alpha^d - \gamma^{ne}\right] \odot V \\ &= \left[\beta^d, -\beta^d, \beta^d - \alpha^{oe}, -\beta^o, -\beta^{ne}, -\gamma^{ne}\right] \odot V,\end{aligned}$$

where in the second equality we used $\alpha^d = 0$ (by Assumption 10). Thus, the lemma holds for a full move as well. ◀

Recall that FPM is defined to choose the move that minimizes $\Delta FPM + \sum_{y \prec z^*} \Delta\Phi_{z^*y}$.

▶ **Corollary 17.** *It holds that* $\Delta FPM + \sum_{y \prec z^*} \Delta\Phi_{z^*y} = \min\{G_{\mathrm{PM}} \odot V, G_{\mathrm{FM}} \odot V\}$.

Finding Parameters. We may now prove Lemma 11, restated below for convenience.

▶ **Lemma 11.** *There exist parameters α^d, β^d, α^{oe}, β^o, β^{ne} and γ^{ne}, satisfying Assumption 10, such that for any step t, it holds that* $\Delta FPM + \sum_{\{x,y\} \in \mathcal{P}_1} \Delta\Phi_{xy} \leq R \cdot \sum_{\{x,y\} \in \mathcal{P}_1} \Delta w^{xy}$.

Proof. We choose the following values of the parameters:

$$\begin{aligned}&\alpha^d = 0 && \beta^d = \tfrac{1}{16}(5 + 3\sqrt{17}) \approx 1.086 && \alpha^{oe} = 2 \\ &\beta^o = \tfrac{1}{16}(1 + 7\sqrt{17}) \approx 1.866 && \beta^{ne} = \tfrac{1}{16}(9 - \sqrt{17}) \approx 0.305 && \gamma^{ne} = 2\end{aligned}$$

It is straightforward to verify that these values satisfy the conditions of Assumption 10. We note that relation $\alpha^{oe} \leq \beta^{ne} + \frac{1}{2}R$ holds with equality.

By Corollary 17, $\Delta FPM + \sum_{\{x,y\} \in \mathcal{P}_1} \Delta\Phi_{xy} = \Delta FPM + \sum_{y \prec z^*} \Delta\Phi_{z^*y} = \min\{G_{\mathrm{PM}} \odot V, G_{\mathrm{FM}} \odot V\}$. On the other hand, by Lemma 15, $\sum_{\{x,y\} \in \mathcal{P}_1} \Delta w^{xy} = \sum_{y \prec z^*} \Delta w^{z^*y} = G_{\mathrm{OPT}} \odot V$. Hence, it remains to show that $\min\{G_{\mathrm{PM}} \odot V, G_{\mathrm{FM}} \odot V\} \leq R \cdot G_{\mathrm{OPT}} \odot V$.

We observe that

$$\begin{aligned}G_{\mathrm{PM}} &= \tfrac{1}{16} \cdot \left[25 - \sqrt{17},\ \ 43 - 3\sqrt{17},\ 1 + 7\sqrt{17},\ 63 - 7\sqrt{17},\ 23 + \sqrt{17},\ 0\right], \\ G_{\mathrm{FM}} &= \tfrac{1}{16} \cdot \left[37 + 3\sqrt{17},\ 27 - 3\sqrt{17},\ 5 + 3\sqrt{17},\ 31 - 7\sqrt{17},\ 23 + \sqrt{17},\ 0\right].\end{aligned}$$

Let $c = \frac{1}{4}(\sqrt{17} - 1)$ and let $G_{\mathrm{COMB}} = c \cdot G_{\mathrm{PM}} + (1 - c) \cdot G_{\mathrm{FM}}$. Then,

$$G_{\mathrm{COMB}} = \tfrac{1}{16} \cdot \left[23 + \sqrt{17},\ 23 + \sqrt{17},\ 23 + \sqrt{17},\ 23 + \sqrt{17},\ 23 + \sqrt{17},\ 0\right].$$

Now for any vector V,

$$\begin{aligned}\min\{G_{\mathrm{PM}} \odot V, G_{\mathrm{FM}} \odot V\} &\leq c \cdot G_{\mathrm{PM}} \odot V + (1 - c) \cdot G_{\mathrm{FM}} \odot V \\ &= (c \cdot G_{\mathrm{PM}} + (1 - c) \cdot G_{\mathrm{FM}}) \odot V \\ &= G_{\mathrm{COMB}} \odot V = R \cdot G_{\mathrm{OPT}} \odot V,\end{aligned}$$

completing the proof. ◀

5 Final Remarks

The most intriguing question left open in our work is whether competitive ratio of 3 can be achieved. We have shown computationally (see the full version of the paper [14]) that 3-competitive algorithms exist for lists with up to 6 items.

However, even for short lists the definition of such 3-competitive algorithm remains elusive. For many online problems, the most natural candidate is the generic work function algorithm. This algorithm is 2-competitive in the LUP_S model [9]. However, our computer-aided calculation of its performance shows that its ratio is larger than 3 already for 5 items (see the full version of the paper [14]). It is 3-competitive for lists of length up to 4, though.

We do not know whether the analysis of FPM is tight. For the specific choice of parameters used in the paper, we verified that FPM is 3-competitive for lists of length 3, but not better than 3.04-competitive for lists of length 5 (see the full version of the paper [14]).

The focus of this paper is on the LUP_1 model (also known as P^1); we believe that the setting of $d = 1$ captures the essence and hardness of the deterministic variant. That said, extending the definition and analysis of FPM to the P^d model (for arbitrary d) is an interesting open problem that deserves further investigation.

Tolerant Testers for Subgraph-Freeness

Abstract

In this paper we study the problem of tolerantly testing the property of being H-free (which also implies distance approximation from being H-free).

In the general-graphs model, we show that for tolerant K_k-freeness testing can be achieved with query complexity that is polynomial in the arboricity of the input graph G, $arb(G)$, and independent of the size of G (for graphs in which the average degree is $\Omega(1)$).

Specifically for triangles, our algorithm distinguished graphs which are ϵ-close to being triangle-free from graphs that $3\epsilon(1+\eta)$-far from being triangle-free with expected query complexity which is $\tilde{O}(arb^3(G))$ (for constant η and ϵ).

For general k-cliques our algorithm distinguishes graphs which are ϵ-close to being K_k-free from graphs which are $\binom{k}{2}\epsilon(1+\eta)$-far from being K_k-free with expected query complexity which is polynomial in k, ϵ, γ and $arb(G)$.

We then generalize our result and provide a similar result for any motif H which is 2-connected of radius 1. This includes for example the wheel-graph.

Finally, we show that our tester can be applied to the bounded-degree model for tolerantly testing H-freeness for any motif H. The query complexity of the algorithm is polynomial in the degree bound, d, improving the previous state-of-the-art by Marko and Ron (TALG 2009) that obtained quasi-polynomial query complexity in d.

1 Introduction

The problem of testing H-freeness, where H is a small *motif* (namely, of size which is independent of the input graph), has received a lot of attention due to its fundamental importance for various fields including biology, sociology and network science. Detecting specific patterns, such as subgraphs, can reveal community structures, vulnerabilities, or anomalous behavior.

In the realm of property testing the decision problem is relaxed such that we are only aiming to distinguish graphs which are H-free from graphs that are *far* from being H-free (according to some predetermined distance measure). However, handling real-world data often means dealing with noise, incompleteness, or small errors. In these scenarios, tolerant testing (introduced by Parnas, Ron and Rubinfeld [15]) for H-freeness becomes crucial, as it allows us to distinguish graphs that are nearly H-free from those that are far from being H-free, thereby bypassing the problem of imperfections in the data. More specifically, a tolerant property testing algorithm is required to distinguish objects that are ϵ_1-close to having a given property $\mathcal{P}$ from objects that are ϵ_2-far from having $\mathcal{P}$, for some parameters

$0 \leq \epsilon_1 < \epsilon_2 \leq 1$. Clearly, by definition, tolerant-testing is at least as hard as testing. In fact, the separation between tolerant and non-tolerant testing can be very dramatic [8]. Another benefit of tolerant testing is that it implies (by a simple reduction) distance approximation where the ratio of approximation depends on the parameters ϵ_1, ϵ_2 (see more details in [15]). Therefore, whenever feasible, we should aim to develop tolerant testers, ideally without incurring a significant overhead in query complexity.

One of the early works on tolerant testing by Marko and Ron [13] showed that it is possible to tolerantly test H-freeness in the bounded-degree model [9] for any motif H with query complexity that is quasi-polynomial in the degree bound and independent of the size of the graph.

In the regime of non-tolerant testers, Levi [12] showed that it is possible to test triangle-freeness with query complexity that depends linearly in the arboricity of the graph (which is tight for graphs with arboricity $O(\sqrt{n})$) and is independent of the size of the graph (assuming the average degree is $\Omega(1)$). Since graphs of bounded degree have bounded arboricity, this result applies to a broader family of graphs. However, this tester is not tolerant.

One natural question is whether the result in [12] can be extended to show that tolerant testing of triangle-freeness (and ideally other motifs) is possible in the general-graphs model with query complexity that depends only on the arboricity of the graph. Such a result would also generalize [13] (since bounded-degree graphs inherently have bounded arboricity). Another important question is whether the query complexity of subgraph freeness in the bounded-degree model can be improved to be polynomial in the degree bound (rather than quasi-polynomial). In this paper, we answer both questions affirmatively.

1.1 Our Results

1.1.1 The general-graphs model

1.1.1.1 Tolerant Testing K_k-freeness

Our tester for the property of being K_k-free distinguishes graphs that are ϵ-close to being K_k free from graphs that are $\epsilon\binom{k}{2}(1+\eta)$-far from being K_k-free, where $\epsilon \in (0,1]$ and $\eta \in (0,1]$ are parameters. The expected query complexity of the algorithm is $\tilde{O}\left(\frac{k^4\theta^{2k-3}}{\eta^2\epsilon\bar{d}} + k^5\theta^{2k-4}\theta^{\min\{2,k-2\}}\right)$ where $\theta = \Theta(arb(G)/(\eta\epsilon))$ and $\bar{d}$ is the average degree (see Theorem 21).

Specifically, assuming $\bar{d} = \Omega(1)$, for the case of triangles, our algorithm distinguished graphs which are ϵ-close to being triangle-free from graphs that $3\epsilon(1+\eta)$-far from being triangle-free with expected query complexity which is $\tilde{O}(arb^3(G)) \cdot poly(\epsilon^{-1}, \eta^{-1}, k)$.

For k-cliques where $k > 3$, our algorithm distinguishes graphs which are ϵ-close to being K_k-free from graphs which are $\binom{k}{2}\epsilon(1+\eta)$-far from being K_k-free with expected query complexity which is $\tilde{O}(arb^{2k-2}(G)) \cdot poly(\epsilon^{-1}, \eta^{-1}, k)$.

1.1.1.2 Tolerant H-freeness for H which is 2-connected with radius 1

We extend our result and apply our tester for motifs that are 2-connected with radius 1. This includes for example the wheel-graph [1]. Specifically our tester distinguishes graphs that are ϵ-close to being H free from graphs that are $\epsilon|E(H)|(1+\eta)$-far from being H-free. The expected query complexity of the algorithm is $\tilde{O}\left(h^7/\eta^2 + h^3/(\eta\epsilon\bar{d})\right) \cdot \theta^{3h-2}$) where $\theta = \Theta(arb(G)/(\eta\epsilon))$ and $h = |V(H)|$ (see Theorem 28).

[1] Any connected graph with an additional vertex that is incident to all other vertices is 2-connected with radius 1.

Specifically, assuming $\bar{d} = \Omega(1)$, the expected query complexity of our tester is $\tilde{O}(arb^{3h-2}(G)) \cdot poly(\epsilon^{-1}, \eta^{-1}, h)$.

1.1.2 The bounded-degree graphs model

Tolerant H-freeness for any H

We show that our tolerant tester can be applied to the bounded-degree model to test H-freeness for any motif H. Specifically the tester distinguishes graphs that are ϵ-close to being H free from graphs that are $\epsilon|E(H)|(1+\eta)$-far from being H-free. The expected query complexity of the algorithm is $\tilde{O}\left(\left(h^7/\eta^2 + h^3/(\eta\epsilon\bar{d})\right) \cdot d^{3h-2}\right)$ where $h = |V(H)|$ and d is the degree bound.

Specifically, assuming $\bar{d} = \Omega(1)$, the expected query complexity of our tester is $\tilde{O}(d^{3h-2}) \cdot poly(\epsilon^{-1}, \eta^{-1}, h)$.

This improves the result in [13] that has query complexity that is quasi-polynomial in d to polynomial dependence in d.

▶ Remark 1. As noted in [13], the result of Bogdanov, Obata and Trevisan [2] implies a linear lower bound on the query complexity of approximating the distance from being triangle-freeness for some small multiplicative and/or additive error (even in bounded degree graphs). Therefore, we can not hope to obtain tolerant testers of subgraph freeness for all parameters ϵ_1, ϵ_2.

▶ Remark 2. As shown in [3], testing C_4-freeness requires $\Omega(n^{1/4})$ queries. Therefore we can not hope to obtain tolerant testers (in the general-graphs model) for general motifs whose query complexity depends only on the arboricity of the graph.

1.2 Our Algorithm

In this section we describe our algorithm for tolerantly test K_k-freeness. This gives a good perspective of our approach. The first ingredient of our algorithm, which also appears in [12], is to perform the test on a subgraph of G. This subgraph, which we refer to as G_θ is the graph after removing the edges between θ-heavy vertices, where a vertex is θ-heavy if its degree is at least θ where $\theta = \Theta(arb(G)/(\eta\epsilon))$. By doing this modification we might decrease the distance by at most $\Theta(\eta\epsilon)$, so if the graph is sufficiently far from being K_k-free, we will still have enough witnesses of violation. On the positive side, since this subgraph does not have edges in which both endpoints are θ-heavy, any K_k in this graph will include at most a single θ-heavy vertex and therefore can be revealed by exploring the neighborhood of the non-heavy vertices of the clique.

The second ingredient of our algorithm is to approximate the number of copies of K_k in G_θ (it will become clear later why we need to approximate this parameter). This can be done by sampling vertices, v, u.a.r. from G, checking if the degree of v is bounded by θ and if so selecting $k-1$ random indices in $[\theta]$. We then perform $k-1$ neighbor-queries on v, according to the selected indices, and check if the subgraph induced on these neighbors (if such neighbors exist) induces a $k-1$-clique. Thus, our sample space is of size $\Theta(n\theta^{k-1})$ and if the graph is ϵ-far from being K_k-free then we have at least ϵm copies of K_k so we need $\Theta(n\theta^{k-1}/(\epsilon m))$ (which is $O(arb(G)^{k-1}/\epsilon)$ when $\bar{d} = \Omega(1)$) trials to get a good approximation.

Before we describe the last ingredient of our algorithm we shall define the *H-copies graph* of G_θ, which we denote by $(G_\theta)^H$. In this graph the vertex set is the set of H-copies in G_θ and a pair of copies are adjacent iff they share at least one edge. Consider a maximal independent set (MIS), S, of this graph. By definition, the copies of this set are edge-disjoint.

Thus the minimum number of edges we need to remove from G_θ in order to make it H-free, which we denote by $dist_H(G_\theta)$, is at least $|S|$. On the other hand, by the maximality of S it follows that $dist_H(G_\theta) \leq |E(H)||S|$ (since we can remove all H-copies in G_θ by removing all the edges of the copies in S). Therefore if we can get a good approximation of *any* MIS of $(G_\theta)^H$, then we will get a good approximation (up to a $|E(H)|$-factor) to the distance of G_θ from being H-free. This is also true for any MIS that is constructed greedily according to some order on the vertices.

Fortunately, as shown by the ingenious work of Yoshida, Yamamoto and Ito [17], if we pick a random vertex v in a graph and a random ordering on the vertices of the graph then the expected number of recursive calls we need to perform in order to locally simulate the outcome of the greedy MIS algorithm on that graph (according to the random ordering we picked) equals the average degree of the graph plus 1. Therefore, we can get a good approximation to the *average* probability that a random H-copy belongs to a random greedy MIS (which is determined by a random ordering) by executing the local simulation on random H-copies and a random orderings (*both* selected uniformly and independently on each trial). Since the ratio between any MIS in a graph F to the total number of vertices in F is at most $1/(\Delta(F)+1)$, where $\Delta(F)$ denotes the maximum degree in F, we obtain that it suffices to evaluate the outcome of a greedy MIS (each time according to a new random ordering) on $\Theta(\Delta((G_\theta)^H))$ copies selected uniformly at random. This will give us a good approximation to the *average* probability that a random H-copy belongs to a random greedy MIS. When we multiply this by the approximation to the total number of H-copies we previously obtained, this will provide a good approximation to the distance of G from being H-free.

1.2.1 The extension for other motifs

We describe the above mentioned algorithm as a general framework for tolerant testing of H-freeness and then implement (according to the defined interface) the necessary specific procedures for testing K_k-freeness and then provide more general procedures for H-freeness of any motif H which is 2-connected and has radius 1. Finally, we show that the procedures for the latter family of motifs can be used to test H-freeness for any motif H in the bounded degree model.

1.3 Related Work

1.3.1 Tolerant tesing of H-freeness in the bounded degree model

As mentioned-above Marko and Ron [13] studied the problem of tolerantly testing H-freeness in the bounded degree model. They begin by describing a global algorithm that constructs a cover of edges by first performing $O(\log d)$ iterations in which the edges of some of the H-copies are added to the cover by a random process (that can be viewed as a distributed randomized algorithm for constructing a large independent set of copies) and then a single edge is added to the cover from each one of the uncovered copies. Since the global algorithm has a distributed nature they show they can locally simulate its outcome by performing $d^{O(\log d)}$ queries and therefore obtain a good approximation to the size of the cover which gives a good approximation to the distance from being H-free.

1.3.2 Non-tolerant testing of subgraph-freeness

In the bounded degree model Goldreich and Ron [9] observed that it is possible to test triangle freeness with query complexity $O(1/\epsilon)$ in graphs of maximum degree bounded by some constant.

The problem of testing triangle freeness in the general graph model was first studied by Alon, Kaufman, Krivelevich, Ron [1]. The query complexity of their algorithms depends on n and $\bar{d}$, the number of vertices in the graph and the average degree, respectively. They provided sublinear upper bounds for almost the entire range of parameters. Moreover, their upper bounds are at most quadratic in their lower bounds. However, they are tight only when $d_{\max} = O(\bar{d})$ and $\bar{d} \leq \sqrt{n}$, where $d_{\max}$ denotes the maximum degree and $\bar{d}$ denotes the average degree of the graph or when $\bar{d} = \Theta(1)$. Shortly after, Rast [16] and Gugelmann [10] improved the upper bound and lower bound of [1], receptively, for some ranges of the parameters.

More recently, Levi [12] studied the complexity of testing triangle freeness as a function of the arboricity of the graph (in the general graphs model). It was shown that the complexity of testing triangle freeness depends linearly in the arboricity of the graph for graphs in which the arboricity is $O(\sqrt{n})$ and the average degree is $\Omega(1)$.

Even more recently, Eden, Levi and Ron [3] studied the problem of testing C_k-freeness and showed that if the motif is not a k-clique then it is not always possible to provide a tester whose query complexity is independent of the size of the graph. In particular, they showed that testing C_4-freeness requires $\Omega(n^{1/4})$ queries.

1.3.3 Sublinear algorithms that receive the arboricity of the graph as a parameter

Several sublinear-time graph algorithms for counting and sampling give improved results when the graph G has bounded arboricity. This includes the following results. Eden, Ron and Rosenbaum [4] designed an algorithm for sampling edges almost uniformly.

Eden, Ron and Seshadhri [6] estimate the degree distribution moments of an undirected graph and in particular estimate the average degree of a graph.

In another paper, Eden, Ron and Seshadhri [7] give a $(1 \pm \epsilon)$-approximation for the number of k-cliques. In a more recent work, Eden, Ron, and Rosenbaum [5] showed that in this setting sampling cliques is harder than counting.

2 Preliminaries

We consider the general-graphs model [14, 11], where the algorithm can perform the following types of queries:

1. For any $v \in V$, query for v's degree;
2. For any vertex $v \in V$ and index i, query for v's i-th neighbor (if $i > d(v)$, then a special symbol is returned);
3. For any pair of vertices u, v, query whether $\{u, v\} \in E$.

We denote by $\Delta(G)$ the maximum degree of the graph G. We denote by $\delta_H(G)$ the distance of G from being H-free, namely, the fraction of edges that we need to remove from G to make it H-free. We denote by $dist_H(G) = \delta_H(G)|E(G)|$, namely, the minimum number of edges we need to remove from G in order to make is H-free. For a graph F we use $V(F)$ to denote its vertex set and $E(F)$ to denote its edge set.

When we say with high constant probability (w.h.c.p.) we mean we can adjust the high constant probability without changing the asymptotic complexity of the algorithm.

▶ **Definition 3** (Copies of a motif H). *For a graph G and a motif H, we say that a subgraph $\mathcal{H}$ of G is a copy of H in G if $\mathcal{H}$ is isomorphic to H.*

We use $n_H(G)$ to denote the number of H-copies in G.

Given a threshold θ, we call the vertices, v, in G such that $d_G(v) > \theta$, *θ-heavy* and otherwise we call them *θ-light*.

▶ **Definition 4** (The graph G_θ)**.** *For a graph $G = (V, E)$ and a threshold θ, the graph G_θ is the graph whose vertex set is V and its edge set is:*

$E \setminus \{\{u, v\} : u \text{ and } v \text{ are } \theta\text{-heavy}\}$.

▶ **Definition 5.** *The arboricity of a graph G, denoted by $arb(G)$, is the minimum number of forests into which the edges of the graph can be partitioned.*

It is known that for $\theta = arb(G)/\eta$ where $\eta \in (0, 1/2]$, $|E(G_\theta)| \geq (1 - 2\eta)m$ (see, e.g., Claim 4 in [12]).

We assume that the arboricity of the input graph G as well as the number of edges, m, and vertices, n, are known to the algorithm.

▶ Remark 6. If the algorithm is not provided with the arboricity of the graph, then it may run the procedure from [12] that obtains the *effective arboricity* of the graph. More specifically, it was shown in [12] how to obtain a value α^* that with high constant probability satisfies the following: (1) $\alpha^* \leq 2arb(G)$; (2) The number of edges between vertices whose degree is at least $\Theta(\alpha^*/\epsilon)$ is at most ϵm, which is suffices for our needs. Up to polylogarithmic factors in n and polynomial factors in $1/\epsilon$, the query complexity of the procedure is $O(arb(G))$ assuming the average degree is $\Omega(1)$.

2.1 The H-copies graph of G

In order to describe our algorithm we shall use the following definitions.

▶ **Definition 7.** *Given a graph $G = (V, E)$ and a motif H we define the H-copies graph of G, G^H to be the graph whose vertex set are the copies of H in G, $\mathcal{H}_1, \ldots, \mathcal{H}_\ell$ and $e = \{\mathcal{H}_1, \mathcal{H}_2\}$ belongs to the edge set of G^H iff $\mathcal{H}_1$ and $\mathcal{H}_2$ share at least one edge.*

Next, we define the notion of an estimator for the number of H-copies of a graph G. The estimator is given a guessed lower bound on $n_H(G_\theta)$. If the guess is accurate, the estimator produces a reliable estimate; otherwise, it does not significantly overshoot, as detailed in the following definition.

▶ **Definition 8.** *We say that an algorithm is a H-*copies number estimator *for a graph G if it receives as parameters s, a guess of a lower bound on $n_H(G)$, and γ, the approximation parameter, and possibly other parameters for which the following holds: If $s \leq n_H(G)$ then w.h.c.p. the return value of the algorithm is in $(1 \pm \gamma)n_H(G)$. Otherwise, w.h.c.p. it is at most $(1 + \gamma)s$.*

▶ Remark 9. The role of the guess is to provide some (indirect) control to the user of the estimator on the number of attempts to sample a copy from the graph by the estimator (e.g. if the graph is H-free then the estimator might make too many attempts to sample a H-copy with no success).

▶ **Definition 10.** *An algorithm $\mathcal{A}$ is a H-*copies oracle *of a graph $G = (V, E)$ if it supports the following queries.*

1. *On query* Random-copy *with parameters $t \in \mathbb{N}$ and $\delta \in (0, 1]$, it returns a copy of H in G uniformly at random or fails. If the number of copies in G is at least t then it returns a copy w.p. at least $1 - \delta$.*
2. *On query* All-neighbors*$(\mathcal{H})$, where $\mathcal{H}$ is a copy of H in G, it returns all the neighbors of $\mathcal{H}$ in G^H (see Definition 7).*

2.2 Local Simulation of Greedy Maximal IS

Our algorithm uses a local simulation of a greedy MIS algorithm. Algorithm 1 describes this local simulation. For a vertex set V, we let S_V denote the set of all permutations over V.

Algorithm 1 Local-Simulation-Greedy-MIS.

Input: Query access to a graph $G = (V, E)$ and parameters $\pi \in S_V$ and $v \in V$

1. Perform an All-Neighbors query on v and sort its neighbors according to π. Let $v_1, \ldots, v_\ell$ denote its neighbors according to this order.
2. For $i = 1, \ldots, \ell$:
   a. If v_i precedes v in π, recursively call Local-Simulation-Greedy-MIS with parameters π and v_i. If the return value is *YES* then return *NO*.
3. Return *YES*.

Let $R^G_\pi(v)$ denote the number of (recursive) calls to Local-Simulation-Greedy-MIS during the evaluation of Local-Simulation-Greedy-MIS on G, π and v. We shall use the following result from the work of Yoshida, Yamamoto and Ito [17].

▶ **Theorem 11** ([17]). *For any graph $G = (V, E)$ with n vertices and m edges,*

$$\mathbb{E}_{\pi \in S_V, v \in V}[R^G_\pi(v)] \leq 1 + \frac{m}{n} .$$

3 The algorithm for tolerant testing of H-freeness

Before describing our algorithm we first relate the distance from being H-free to the size of a Maximal-Independent-Set of G^H as stated in the following claim. We then use this relation to provide a relation between the expectation of a random variable to the distance from being H-free.

▷ Claim 12. For any maximal independent set of G^H, S, it holds that

$$|S| \leq dist_H(G) \leq |S| \cdot |E(H)|.$$

Proof. Since S is an independent set in G^H, it follows that any pair $\mathcal{H}_1, \mathcal{H}_\in \in S$ is a pair of edge-disjoint copies of H in G (by definition). Since S is maximal, it follows that if we remove for each $\mathcal{H} \in S$ all its edges from G then G becomes H-free (since we remove at least one edge from each copy of H in G). ◁

▷ Claim 13. For v that is drawn u.a.r. from $V(G^H)$ and π which is drawn u.a.r. from S_V it follows that:

$$\Pr[v \in MIS_\pi(G^H)] \in \left[\frac{dist_H(G)}{|E(H)|n_H(G)}, \frac{dist_H(G)}{n_H(G)}\right]. \tag{1}$$

Moreover,

$$\Pr[v \in MIS_\pi(G^H)] \geq 1/(\Delta(G^H) + 1). \tag{2}$$

Proof. By Claim 12, for any maximal IS in G^H, S, it holds that $\frac{dist_H(G)}{|E(H)|} \leq |S| \leq dist_H(G)$. Therefore, for any such S it holds that $\Pr[v \in S] \in \left[\frac{dist_H(G)}{|E(H)|n_H}, \frac{dist_H(G)}{n_H}\right]$, where v is drawn u.a.r. from $V(G_H)$. This is true since $|V(G_H)| = n_H$. Since $MIS_\pi(G^H)$ is maximal for any

π (by definition), the claim follows. Equation 2 follows from the fact that each vertex v in the independent set covers at most $d(v)+1$ vertices from the graph. Thus, any maximal independent set is of size at least $n_H(G)/(\Delta(G^H)+1)$, in particular, $MIS_\pi(G^H)$ (for any π). This concludes the proof. ◁

By using the previous claims we arrive to the following claim.

▷ Claim 14. If $s \geq n_H(G)$ then with high constant probability, the return value of Approximate-Average-MIS-In-Auxiliary-Graph is in

$$\left[(1-\gamma)\frac{dist_H(G)}{|E(H)|n_H(G)}, (1+\gamma)\frac{dist_H(G)}{n_H(G)}\right]. \tag{3}$$

Proof. Let E_1 denote the event that in all the executions of Step 2a of the algorithm, a copy of H was returned. By definition 10, the setting of δ and since $s \geq n_H(G)$, w.h.c.p., E_1 occurs. We henceforth assume E_1 occurs. Consider the random variable Z_i (see Step 2c of the algorithm). By construction Z_i takes values in $\{0,1\}$. By Claim 13, Equation 1, $\mathbb{E}(Z_i) \in \left[\frac{dist_H(G)}{|E(H)|n_H(G)}, \frac{dist_H(G)}{n_H(G)}\right]$. By Equation 2, $\mathbb{E}(Z_i) \geq 1/(\Delta(G^H)+1)$. The claim follows from the setting of ℓ and the multiplicative Chernoff's bound (see Theorem 30). ◁

Algorithm 2 Approximate-Average-MIS-In-Auxiliary-Graph.

Input: γ - approximation parameter, s - guess on a lower bound on $n_H(G)$, Δ - an upper bound on $\Delta(G^H)$, and access to H-copy oracle and H-copies estimator of G (see Definitions 8, 10)

1. Set $\ell = \Theta(\Delta/\gamma^2)$ and $\delta = \Theta(1/\ell)$.
2. For $i = 1, \ldots, \ell$
   a. Run a H-copy oracle of G with parameters s and δ, and obtain a H-copy, $\mathcal{H}$, uniformly at random.
   b. Draw π u.a.r. and run Algorithm 1 on $\mathcal{H}$, π and the H-copies oracle of G, (see Definition 7).
   c. Set $Z_i = 1$ if the algorithm returned YES and set $Z_i = 0$ otherwise.
3. Return $\hat{Z} = \sum_{i\in[\ell]} Z_i/\ell$.

Algorithm 3 Tolerant-Test-Subgraph-freeness.

Input: ϵ, η and query access to a graph G

1. Set $\gamma = \eta/64$ and $\theta = arb(G)/(2\gamma\epsilon)$
2. Run the number of H-copies estimator for the graph G_θ with parameters $\epsilon m/2$ and γ (see Definition 8) and obtain $\hat{n}$.
3. If $\hat{n}$ is less than ϵm then return ACCEPT.
4. Run Approximate-Average-MIS-In-Auxiliary-Graph on the graph G_θ with parameters $\epsilon m/2$ and γ and $\Delta((G_\theta)^H$. Let $\hat{Z}$ denote the returned value.
5. if $\hat{n}\hat{Z} > \epsilon m(1+\gamma)^2$ then return REJECT.

We next prove our main theorem for this section. In order to realize this theorem we provide in the next sections concrete H-copies oracles and H-copies number estimators (first for H which is a k-clique and then generalize, for H which is 2-connected and has radius 1).

▶ **Theorem 15.** *Given parameters $\epsilon \in (0,1]$, $\eta \in (0,1]$ and query access to a graph G,* Tolerant-Test-Subgraph-freeness *has the following guarantees. If G is ϵ-close to being H-free then w.h.c.p. it accepts G. If G is $\epsilon|E(H)|(1+\eta)$-far from being H-free then w.h.c.p. it rejects G.*

Proof. Assume G is ϵ-close to being H-free. If the algorithm accepts G in Step 3 then we are done. Otherwise, it follows that $\hat{n} \geq \epsilon m$.

Let E_1 denote the event that the estimator in Step 2 returns a good approximation as described in Definition 8. Conditioned on E_1 and the fact that $\hat{n} \geq \epsilon m$ it is implied that $n_H(G_\theta) \geq \epsilon m/2$ (assume otherwise and reach a contradiction to the fact that $\hat{n} \geq \epsilon m$ as $(1+\gamma) < 2$)) and hence its return value is in $(1 \pm \gamma) n_H(G_\theta)$.

Let E_2 denote the event that Approximate-Average-MIS-In-Auxiliary-Graph returns a good approximation as described in Claim 14. Conditioned on $E_1 \cap E_2$ we obtain that

$$\hat{n}\hat{Z} \in \left[(1-\gamma)^2 \frac{dist_H(G_\theta)}{|E(H)|}, (1+\gamma)^2 dist_H(G_\theta)\right]. \tag{4}$$

Since $dist_H(G_\theta) \leq dist_H(G) \leq \epsilon m$ we obtain that $\hat{n}\hat{Z} \leq (1+\gamma)^2 \epsilon m$ and hence the algorithm accepts G.

Assume G is β-far from being H-free where $\beta = \epsilon|E(H)|(1+\eta)$. By the setting of θ it follows that $dist_H(G_\theta) \geq (1-\gamma)\beta m$. Thus, $n_H(G_\theta) \geq (1-\gamma)\beta m$. Therefore, conditioned on $E_1 \cap E_3$ we obtain that $\hat{n} \in (1 \pm \gamma) n_H(G_\theta)$. In particular, it holds that $n_H(G_\theta) \geq \epsilon m/2$. Hence conditioned on $E_1 \cap E_2 \cap E_3$ we obtain that Equation 4 holds in this case as well. In particular $\hat{n}\hat{Z} \geq (1-\gamma)^3 \frac{\beta m}{|E(H)|} > \epsilon m (1+\gamma)^2$ (since $(1+\eta) > (1+2\gamma)^5 > (1+\gamma)^2/(1-\gamma)^3$). Thus, conditioned on $E_1 \cap E_2 \cap E_3$, the algorithm rejects G, as desired. ◀

▷ Claim 16. The expected query complexity of Tolerant-Test-Subgraph-freeness is bounded above by the query complexity of performing $\ell = \Theta(\Delta/\eta^2)$ random-copy queries to $(G_\theta)^H$ with parameters $s = \epsilon m/2$ and $\delta = \Theta(\eta^2/\Delta)$ (see Definition 7), $\Theta(\ell \cdot \Delta)$ all-neighbor queries to $(G_\theta)^H$, where $\Delta = \Delta((G_\theta)^H)$, and a single execution of a H-copies number estimator for G_θ (see Definition 8).

Proof. By construction, linearity of expectation and Theorem 11. ◁

4 The oracles for k-cliques

In this section we describe our K_k-copies oracle and K_k-copies number estimator. We conclude with our main theorem about tolerant testing of K_k-freeness (Theorem 21).

▷ Claim 17. For every iteration $j \in [t]$ of Algorithm 4 it holds that:

$$\mathbb{E}(Y_j) = n_{K_k}(G_\theta) / \left(n \cdot \binom{\theta}{k-1}\right). \tag{5}$$

Proof. Consider a copy, $\mathcal{K}$, of K_k in G_θ. Let $y(\mathcal{K})$ denote the number of θ-light vertices in $\mathcal{K}$. The probability that $\mathcal{K}$ is found in Step 2f of Approximate-K_k-copies-in-G_θ is exactly $y(\mathcal{K}) \cdot 1/(n\binom{\theta}{k-1})$. Conditioned on the event that indeed $\mathcal{K}$ was found in Step 2f of iteration j the probability that Y_j is set to be 1 is $1/y(\mathcal{K})$. Thus, for every j, $\Pr(Y_j = 1) = n_{K_k}(G_\Theta)/(n\binom{\theta}{k-1})$. The claim follows. ◁

▷ Claim 18. Approximate-K_k-copies-in-G_θ is a K_k-copies number estimator of the graph G_θ. Its query complexity is $O(k^2 n\binom{\theta}{k-1}/(\gamma^2 s))$.

Algorithm 4 Approximate-K_k-copies-in-G_θ .

Input: $\theta, s, \gamma \in (0, 1/2]$

1. Set $t = \Theta(n\binom{\theta}{k-1}/(\gamma^2 s))$
2. For $j = 1, \ldots, t$
   a. Sample a vertex $v \in V$ u.a.r. and a set of $k-1$ indexes, $i_1, \ldots, i_{k-1}$ u.a.r. from $\binom{[\theta]}{k-1}$.
   b. If v θ-heavy then set $Y_j = 0$ and go to the next iteration.
   c. Otherwise, query (v, i_ℓ) for each $\ell \in [k-1]$. Let $u_1, \ldots, u_{k-1}$ denote the respective return values.
   d. Let y denote the number of θ-light vertices in $\{u_i\}_{i\in[\ell]}$.
   e. If $y < k-2$ then set $Y_j = 0$ (there is more than a single θ-heavy vertex in the set).
   f. If the subgraph induced on $\{u_i\}_{i\in[\ell]}$ is a $(k-1)$-clique then set $Y_j = 1$ w.p. $1/(y+1)$. Otherwise set $Y_j = 0$.
3. Return $n \cdot \binom{\theta}{k-1} \cdot \sum_{j\in[t]} Y_j/t$.

Proof. For $s \leq n_{K_k}(G_\theta)$ the claim follows from Claim 16, the setting of t and multiplicative Chernoff's bound (see Theorem 30). To see the correctness of the second part, consider $s = n_{K_k}(G_\theta)$. By the first part of the claim, w.h.c.p. the return value of the algorithm is in $(1 \pm \gamma)n_{K_k}(G_\theta) = (1 \pm \gamma)s$. Namely, at most $(1+\gamma)s$. Now consider the case in which $s > n_{K_k}$. By a coupling argument, w.h.c.p. the return value is at most $(1+\gamma)s$ in this case. To see this, couple the return value of the algorithm to the return value of the algorithm on the graph after we add $s - n_{K_k}$ copies to the graph (arbitrarily). Since we added copies, the return value of the algorithm on the modified graph dominates the return value on the original graph (to see this consider executing the algorithm in parallel in both graphs - the outcome in the modified graph is always at least as high) but is guaranteed to be at most $(1+\gamma)s$ w.h.c.p. by the above. The claim about the query complexity follows from construction. This concludes the proof. ◁

Algorithm 5 Get-Random-K_k-Copy-in-G_θ .

Input: θ, s, δ

1. Repeat $\Theta(n\binom{\theta}{k-1}\log(1/\delta)/s)$ times:
   a. Sample a vertex $v \in V$ u.a.r. and a set of $k-1$ indexes, $i_1, \ldots, i_{k-1}$ u.a.r. from $\binom{[\theta]}{k-1}$.
   b. If v is not θ-light then break.
   c. Otherwise, query (v, i_ℓ) for each $\ell \in [k-1]$. Let $u_1, \ldots, u_{k-1}$ denote the respective return values.
   d. Let y denote the number of θ-light vertices in $\{u_i\}_{i\in[\ell]}$.
   e. If $y < k-2$ or if the subgraph induced on $\{u_i\}_{i\in[\ell]}$ is not a clique, then go to the next iteration.
   f. Otherwise, w.p. $1/(y+1)$, return the k-clique induced on v and $\{u_i\}_{i\in[\ell]}$.

▷ Claim 19. The query complexity of Get-Random-K_k-Copy-in-G_θ is $\Theta(k^2 n\binom{\theta}{k-1}\log(1/\delta)/s)$. If $s < n_{K_k}(G_\theta)$ then it returns a copy w.p. at least $1-\delta$.

Proof. For any copy of K_k, $\mathcal{K}$, in each iteration of the while-loop, the probability that we return $\mathcal{K}$ in Step 1f of the algorithm is exactly $1/(n\binom{\theta}{k-1})$. Therefore if the number of copies is greater than s then the probability that it will return a copy during in a single iteration is at least $s/(n\binom{\theta}{k-1})$. The claim follows by the setting of the number of iterations. ◁

Algorithm 6 K_k-All-Neighbors-in-G_θ .

Input: θ, $\mathcal{K}$

1. Set $C = \emptyset$
2. If $k = 3$, reveal the neighbors of all the θ-light vertices of $\mathcal{K}$. Let S denote the set of revealed neighbors. If there is a θ-heavy vertex, u, in $\mathcal{K}$, perform a pair query between u and each one of the vertices in S.
3. Otherwise, for each θ-light vertex, v, of $\mathcal{K}$: Reveal all the neighbors of v in G and then for each θ-light neighbor, reveal all its neighbors.
4. Add all the K_k-copies that were revealed in the previous steps that belong to G_θ (namely, that have at most one θ-heavy vertex) and share an edge with $\mathcal{K}$.
5. Return C.

▷ Claim 20. The query complexity of K_k-All-Neighbors-in-G_θ is $O(k\theta)$ for $k = 3$ and $O(k\theta^2)$ for $k > 3$.

Proof. The claim follows from construction. ◁

▶ **Theorem 21.** *There exists a tolerant tester for the property of being K_k-free that distinguishes graphs that are ϵ-close to being K_k free from graphs that are $\epsilon\binom{k}{2}(1+\eta)$-far from being K_k-free, where $\epsilon \in (0,1]$ and $\eta \in (0,1]$ are parameters. The expected query complexity of the algorithm is $\tilde{O}\left(\frac{k^4\theta^{2k-3}}{\eta^2\epsilon\bar{d}} + k^5\theta^{2k-4}\theta^{\min\{2,k-2\}}\right)$ where $\theta = \Theta(arb(G)/(\eta\epsilon))$.*

Proof. The theorem follows from the fact that $\Delta((G_\theta)^H) \leq \binom{k}{2}\theta^{k-2}$, Theorem 15 and claims 16-20. ◀

5 The oracles for 2-connected motifs of radius 1

In this section, H is a motif which is 2-connected and has radius 1. We make the following observation on the copies of H in G_θ.

▶ **Observation 22.** *For any copy of H, $\mathcal{H}$, in G_θ, at least one of the following holds:*

1. *there exists a θ-light vertex in $\mathcal{H}$ which is incident to all the vertices in $\mathcal{H}$.*
2. *there is exactly one θ-heavy vertex in $\mathcal{H}$.*

Proof. Let v be a vertex in $\mathcal{H}$ which is incident to all other vertices in $\mathcal{H}$ (such vertex exists since H has radius 1). If v is θ-light then Item 1 holds. Otherwise, v is θ-heavy. Since there are no edges in G_θ such that both endpoints are θ-heavy, the claim follows. ◀

We say that a BFS is a *θ-restricted* if it explores only the neighbors of the θ-light vertices it reaches. We say that an exploration *reveals a copy* $\mathcal{H}$ if all the vertices of $\mathcal{H}$ appeared in the exploration.

▷ Claim 23. Let H be a motif that is 2-connected and has radius 1. In every copy of H in G_θ, $\mathcal{H}$, for every θ-light vertex v in $\mathcal{H}$, a θ-restricted BFS from v of depth $|V(H)|$ reveals $\mathcal{H}$.

Proof. If item 1 of observation 22 holds, then clearly the claim follows. Otherwise, there is exactly one θ-heavy vertex, u, in $\mathcal{H}$. Since H is 2-connected, after we remove u from $\mathcal{H}$, $\mathcal{H}$ remains connected and its diameter is at most $|V(H)| - 1$. Thus, a θ-restricted BFS of depth $|V(H)| - 1$ from any θ-light vertex of $\mathcal{H}$ reveals all the θ-light vertices of $\mathcal{H}$. The claim follows from the fact that at least one of the θ-light vertices in $\mathcal{H}$ is a neighbor of u. ◁

Therefore, by Claim 23, finding for a θ-light vertex, v, all the H-copies in G_θ that include v, can be done by using $O(\theta^{|V(H)|})$ queries. Consequently, a query for all-neighbors in $(G_\theta)^H$ can be answered by making $O(|V(H)|\theta^{|V(H)|})$ queries to G. This can be achieved by going over all vertices of the queried copy, $\mathcal{H}$, and for each θ-light vertex, finding all its copies. From the union of these sets we then remove all the copies that do not share an edge with $\mathcal{H}$ and obtain all the neighbors of $\mathcal{H}$ in $(G_\theta)^H$.

To support random copy queries we assign each copy of H to its θ-light vertex of lowest id. To sample a H-copy u.a.r. from G_θ we first pick a vertex $v \in V$ u.a.r., if it is θ-light then we find all its H-copies as described above. We then pick a copy that is assigned to v u.a.r. and return it w.p. $a_{H,\theta}(v)/a^{max}_{H,\theta}$ where $a_{H,\theta}(v)$ denotes the number of copies that are assigned to v in G_θ and $a^{max}_{H,\theta}$ denotes the maximum number of copies that include a specific θ-light vertex (recall that the copies in G_θ are assigned only to θ-light vertices). Clearly, the above algorithm samples each copy of H in G_θ w.p. $1/(n \cdot a^{max}_{H,\theta})$. Consequently, the probability that it returns a copy is $n_H(G_\theta)/(n \cdot a^{max}_{H,\theta})$. Thus, the success probability of the algorithm depends on $a^{max}_{H,\theta}$). A straightforward upper-bound on $a^{max}_{H,\theta}$ is $|V(H)|!\binom{\theta^{|V(H)|}}{|V(H)|}$ where the first term is due to all possible labeling of the vertices and the second term is due to all possible ways to pick the vertices of the copy from the set of vertices we explored. In the next claim we provide a tighter bound on $a^{max}_{H,\theta}$.

▷ Claim 24. For any motif H, it holds that $a^{max}_{H,\theta} \leq |V(H)| \cdot \theta^{|V(H)|-1}$.

Proof. Fix an arbitrary labeling of H. Let $v \in V$. We next bound $a_{H,\theta}(v)$. Label the H-copies that v belongs to according to the fixed labeling of H (each copy has its own labeling). If there is more than one such labeling per copy (due to automorphism), pick one arbitrarily. We next describe a one-to-one mapping from the set of labeled copies to a set of sequences of integers. We then bound the cardinality of the latter set and obtain a bound on the number of H-copies that v belongs to and hence a bound on $a^{max}_{H,\theta}$. Fix a labeled copy of v, $\mathcal{H}$, and consider the BFS exploration of $\mathcal{H}$ starting at v, where vertices with smaller label are explored first. Given the label of v and the sequence of the vertices in $\mathcal{H}$ by their BFS order we can reconstruct the labels of all the vertices in the copy. The set of vertices and their labels are mapped to a single copy. Moreover, by the above, we can identify the copy by the identity of the root, its label and a sequence of $|V(H) - 1|$ indexes in $[\theta]$. Each index indicates the index of the respective element in its parent adjacency-list. The indexes are listed according to the BFS exploration. Since the identity of the root is known, we can inductively reconstruct the tree by the sequence of indexes. Note that the parents are always θ-light (while the leaves may be θ-heavy) therefore it suffices to use indexes in $[\theta]$. From the above we see that for a specific label of v there are at most $\theta^{|V(H)|-1}$ copies of H to which v belongs. Since there are $|V(H)|$ possible labels, we get the desired bound. ◁

▷ Claim 25. Approximate-H-copies-in-G_θ is a H-copies number estimator of the graph G_θ. Its query complexity is $O(n \cdot a^{max}_{H,\theta} \cdot \theta^{|V(H)|}/(\gamma^2 s))$.

Proof. The claim about the query complexity follows by construction. Consider the random variable Y_j which is defined in Approximate-H-copies-in-G_θ . Since $\mathbb{E}(Y_j) \geq n_H(G_\theta)/n$ and $Y_j \leq a^{max}_{H,\theta}$, for $s \leq n_H(G_\theta)$, by the setting of t and the multiplicative Chernoff's bound (Theorem 30), w.h.c.p the output of the algorithm is in $(1 \pm \gamma)n_H(G)$, as required. For $s > n_H(G_\theta)$, by a coupling argument, w.h.c.p. the output of the algorithm is at most $(1 + \gamma)$ (see more details in the proof of Claim 14). ◁

Algorithm 7 Approximate-H-copies-in-G_θ .

Input: $s, \gamma \in (0, 1/2], \theta$

1. Set $t = \Theta(n \cdot a^{max}_{H,\theta}/(\gamma^2 s))$
2. For $j = 1, \ldots, t$
   a. Sample a vertex $v \in V$ u.a.r.
   b. If v is not θ-light then set $Y_j = 0$ and go to the next iteration.
   c. Otherwise, perform a θ-restricted BFS from v to depth $|V(H)|$ and reveal all the H-copies assigned to v in G_θ. Set Y_j to be this number.
3. Return $n \cdot \sum_{j\in[t]} Y_j/t$.

Algorithm 8 Get-Random-H-Copy-in-G_θ .

Input: θ, s, δ

1. Repeat $\Theta(n \cdot a^{max}_{H,\theta} \log(1/\delta)/s)$ times:
   a. Sample a vertex $v \in V$ u.a.r.
   b. If v is θ-heavy then go to the next iteration.
   c. Otherwise, perform a θ-restricted BFS from v to depth $|V(H)|$ and reveal all the H-copies assigned to v in G_θ.
   d. Pick a random copy from the H-copies assigned to v and return it with probability $a_{H,\theta}(v)/a^{max}_{H,\theta}$.

▷ Claim 26. The query complexity of Get-Random-H-Copy-in-G_θ is $\Theta(\theta^{|V(H)|} \cdot n \cdot a^{max}_{H,\theta} \log(1/\delta)/s)$. It returns a H-copy w.p. at least $1 - \delta$.

Proof. The claim about the query complexity follows by construction. In each iteration of the algorithm, each copy of H is returned with probability $1/(n \cdot a^{max}_{H,\theta})$. Thus, in each iteration a copy is returned w.p. $n_H(G_\theta)/(n \cdot a^{max}_{H,\theta})$. Thus, if $s \leq n_H(G)$, a copy is returned w.p. at least $1 - \delta$ by the setting of the number of iterations. ◁

Algorithm 9 H-All-Neighbors-in-G_θ .

Input: θ

1. Set $C = \emptyset$
2. For each vertex v of $\mathcal{H}$:
   a. Reveal all the H-copies of v in G^θ by performing a θ-restricted BFS to depth $|V(H)|$ from v in G.
   b. Add to C all the revealed H-copies that share an edge with $\mathcal{H}$.
3. Return C.

▷ Claim 27. The query complexity of K_k-All-Neighbors-in-G_θ is $O(|V(H)|\theta^{|V(H)|})$.

Proof. By Construction. ◁

▶ **Theorem 28.** *There exists a tolerant tester for the property of being H-free for H that is 2-connected and has radius 1 that distinguishes graphs that are ϵ-close to being H free from graphs that are $\epsilon|E(H)|(1+\eta)$-far from being H-free, where $\epsilon \in (0, 1]$ and $\eta \in (0, 1]$ are parameters. The expected query complexity of the algorithm is $\tilde{O}\left(\left(h^7/\eta^2 + h^3/(\eta\epsilon\bar{d})\right) \cdot \theta^{3h-2}\right)$ where $\theta = \Theta(arb(G)/(\eta\epsilon))$ and $h = |V(H)|$.*

Proof. The theorem follows from the fact that $\Delta((G_\theta)^H) \leq h \cdot a^{max}_{H,\theta}$, Theorem 15 and claims 24–27. ◀

6 The tester for the bounded-degree model

Clearly, Tolerant-Test-Subgraph-freeness applies also to bounded degree graphs. Moreover, for the setting where $\theta = d + 1$ the graph G_θ is simply G and all the vertices in the graph are θ-light. Consequently, we can test H-freeness for *any* motif H by using the oracles in Section 5 without making any modifications [2]. We obtain the following result.

▶ **Theorem 29.** *There exists a tolerant tester, in the bounded degree model, for the property of being H-free for any motif H. Specifically the tester distinguishes graphs that are ϵ-close to being H free from graphs that are $\epsilon|E(H)|(1+\eta)$-far from being H-free, where $\epsilon \in (0,1]$ and $\eta \in (0,1]$ are parameters. The expected query complexity of the algorithm is $\tilde{O}\left(\left(h^7/\eta^2 + h^3/(\eta\epsilon\bar{d})\right) \cdot d^{3h-2}\right)$ where $h = |V(H)|$ and d is the degree bound.*

Proof. By the proof of Theorem 21. ◀

Abstract

Property Testing is a formal framework to study the computational power and complexity of sampling from combinatorial objects. A central goal in standard graph property testing is to understand which graph properties are testable with sublinear query complexity. Here, a graph property P is testable with a sublinear query complexity if there is an algorithm that makes a sublinear number of queries to the input graph and accepts with probability at least 2/3, if the graph has property P, and rejects with probability at least 2/3 if it is ε-far from every graph that has property P.

In this paper, we introduce a new variant of the bounded degree graph model. In this variant, in addition to the standard representation of a bounded degree graph, we assume that every vertex v has a unique label $\texttt{num}(v)$ from $\{1, \ldots, |V|\}$, and in addition to the standard queries in the bounded degree graph model, we also allow a property testing algorithm to query for the label of a vertex (but *not* for a vertex with a given label).

Our new model is motivated by certain graph processes such as a DFS traversal, which assign consecutive numbers (labels) to the vertices of the graph. We want to study which of these numberings can be tested in sublinear time. As a first step in understanding such a model, we develop a *property testing algorithm for discovery times of a DFS traversal* with query complexity $O(n^{1/3}/\varepsilon)$ and for constant $\varepsilon > 0$ we give a matching lower bound.

1 Introduction

Depth-first search (DFS) is one of the most useful and frequently used algorithmic primitives in graph algorithms. The DFS algorithm is known for well over a century [17, 23] as a technique for threading mazes and has been widely used in the design of graph and network algorithms since the late 1950s. DFS is a basic tool to traverse a graph in a structured way and is central to solve textbook problems such as connectivity, topological sorting [22], determining strongly connected components in directed graphs [21], biconnected components in undirected graphs [21], and to test planarity [15]. Because of its versatility and usefulness for solving many graph problems, DFS has become one of the most important tools in the design of algorithms for graphs, taught in the first year of many computing science study

programs. One of the most useful combinatorial properties of DFS is the *DFS numbering of vertices*, which is *the order in which a DFS algorithm discovers all vertices of the input graph* [21]. (See also Algorithms 1 and 2, where $N(v)$ denotes the set of neighbors of vertex v.)

Algorithm 1 DFS numbering of G.

Input: undirected graph $G = (V, E)$
Output: $\mathtt{num} : V \to \{1, \ldots, |V|\}$

```
1 mark all vertices as undiscovered
2 t ← 1 // smallest unused ID
3 for v ∈ V do // arbitrary order
4     if v is undiscovered then
        DSFVisit(v)
```

Algorithm 2 DSFVisit(v).

```
1 mark v as discovered
2 num(v) ← t
3 t ← t + 1
4 for u ∈ N(v) do // arbitrary order
5     if v is undiscovered then
        DSFVisit(v)
```

We remark that sometimes, e.g., in the widely used textbook by Cormen et. al. (see Chapter 20.3 in [5]), the DFS numbering is also used together with finishing numbers. We also remark that the labeling is not unique and depends on the ordering in which the vertices are traversed in the for-loops of Algorithms 1 and 2.

▶ **Definition 1** (DFS numberings). *Let $G = (V, E)$ be a labeled undirected graph on n vertices. A labeling $\mathtt{num} : V \to \{1, \ldots, n\}$ is called a* DFS numbering of G *if DFS gives rise to it for some order of processing the vertices in the for-loops of Algorithms 1 and 2.*

Given a wide applicability of DFS and DFS numbering, a natural problem is to verify whether a given graph is correctly DFS-numbered, i.e., the labels assigned to the vertices are a DFS numbering for some ordering of vertices and neighbors. The latter problem is easy to solve by simulating a DFS using the given numbering and locally verifying that the DFS is performed correctly. However, is it also possible to *approximately* verify whether the graph is properly DFS-numbered using a sampling based algorithm? An answer to this question sheds some light on how the local structure of a DFS-numbered graph (as implicitly given by the sample distribution) is related to the global DFS numbering.

We will study this question in the *framework of Property Testing* (see, e.g., the monographs [4, 9]). Property Testing provides a formal setting to study approximate decision problems. The goal is to distinguish objects that satisfy the tested property from those that are ε-far from every object that satisfies the property. Here, ε-far means that one has to modify more than an ε-fraction of the object's description to obtain an object that has the property. A property testing algorithm requires some form of sampling access to the object.

In this paper we will introduce a variant of the standard bounded-degree graph model [12] that in addition to the standard setting, allows also *label queries*. We will assume that there exists some labeling that assigns unique labels from the set $\{1, \ldots, |V|\}$ to the vertex set V, i.e., the labeling is a bijection $\mathtt{num} : V \to \{1, \ldots, |V|\}$. We say that a graph with maximum degree d is ε-far from a DFS-numbered graph, if we have to modify (insert or delete) more than $\varepsilon|V|$ edges to obtain a graph that is correctly DFS-numbered[1]. We do not allow to modify labels, though we notice that allowing to modify labels would also be a valid model (see Section 2.1 for some discussion). Our motivation to not consider it here was merely to stick as closely to the standard testing model as possible.

[1] While one often uses the bound of $\varepsilon d|V|$ edges instead of $\varepsilon|V|$ edges, in the setting when $d = O(1)$ these terms differ only by a constant factor and as such there are essentially indistinguishable.

In this new framework we study a fundamental problem of *whether the input labeled undirected graph is properly DFS-numbered* or *it is ε-far from having a valid DFS numbering*. Our main result is a tight (for constant d and ε) complexity bound for this task. First, we show that any tester for the DFS numbering requires $\Omega(n^{1/3})$ queries, and then, we complement this bound with an algorithm that tests DFS numbering with $O(n^{1/3}/\varepsilon)$ queries.

The proof of the lower bound (Theorem 7 in Section 4) is by constructing two families $(G_n)_{n\in\mathbb{N}}$ and $(B_n)_{n\in\mathbb{N}}$ of *good* and *bad* random labeled graphs for which we will show that distinguishing between these families is necessary for any DFS-tester. Then we will show that distinguishing between these families requires $\Omega(n^{1/3})$ queries.

The proof of the upper bound (Theorem 11 in Section 5) relies on a characterization of labelings that are ε-far from a valid DFS numbering. The characterization is described in a form of some conflicts between the labelings and we design two algorithms detecting such conflicts: one for local conflicts and one for global conflicts. By combining these two algorithms we will obtain an algorithm that tests DFS numbering with $O(n^{1/3}/\varepsilon)$ queries.

1.1 Related work

Property Testing was introduced by Rubinfeld and Sudan [20] and first studied in the dense graph setting by Goldreich and Ron [10]. Constant time testability in the dense graph model has been fairly well understood [2] and is closely related to the regularity lemma. In our paper we build upon the bounded degree graph model, as introduced by Goldreich and Ron [12]. First results in this model included testers for properties such as connectivity, k-connectivity and being Eulerian [12]; bipartiteness [11] and cycle freeness [6] can be tested in the bounded degree graph model in $O(\frac{\sqrt{n}}{\varepsilon^{O(1)}})$ time. A series of papers proved that every hyperfinite property of bounded degree graphs is testable in constant time [3, 7, 14, 18]. Also, every constant time testable property in bounded degree graphs is either finite or contains a hyperfinite property [8]. Furthermore, it is known that every first-order logic property of bounded degree graph with an $\exists\forall$ quantification is constant time testable while some properties with a $\forall\exists$ quantification are not [1]. Further works in the bounded degree graph model include, e.g., testability using proximity oblivious testers [13].

2 Preliminaries: The model

In this paper, let $G = (V, E)$ denote an undirected graph with $n = |V|$ vertices and $m = |E|$ edges. Let $N(v)$ denote the set of *neighbors of* v, i.e., $N(v) := \{u \in V : \{v, u\} \in E\}$, and d be an upper bound on the maximum number of edges incident to any vertex in V. We will assume that G is a labeled graph, i.e., there is a bijection (permutation) $\mathtt{num} : V \to [n]$ that assigns numbers to the vertices of G and we use $[n] := \{1, \ldots, n\}$.

2.1 Bounded degree graph model for *labeled* graphs

In this section we describe how our algorithm can access the input graph $G = (V, E)$ of maximum degree d with vertex labeling $\mathtt{num}$. Our model is a slight modification of the standard bounded degree graph model [12] that in addition *allows access to labels*. As usual in this model, we assume that $V = [n]$ and n as well as d are given to the algorithm. The algorithm can ask the following two types of queries and receives an answer in constant time:

- **Neighbor queries:** for every vertex $v \in V$ and every $1 \le i \le d$, one can query the ith neighbor of vertex v.
- **Label queries:** for every vertex $v \in V$, one can query the label of v, $\mathtt{num}(v)$.

Observe that we allow access to vertices and their neighbors, and we can check the label $\mathtt{num}(v)$ of any vertex v, ***but we have no access to vertices through their labels*** $\mathtt{num}$. In particular, *to access vertex v with a given label* $\mathtt{num}$*, we have to query the oracle until such vertex is returned.* This is a special feature distinguishing our model from the standard model used in graph property testing and making the problem challenging: we have a labeled graph, but we cannot access the graph (its vertices) through the labels! Instead, the only way to access the graph is by taking any vertex $v \in V = [n]$ and either querying its label $\mathtt{num}(v)$ (via the label query) or querying its ith neighbor (via a neighbor query).

The *query complexity* of a testing algorithm is the number of oracle queries.

A property testing algorithm (in short, *property tester*) for DFS-numbered graphs is an algorithm that has access to an input graph as described above and that accepts the input with probability at least 2/3, if G is a graph with $\mathtt{num}$ being a valid DFS-numbering. The algorithm rejects G with probability at least 2/3 if G is ε-far from having a valid DFS numbering $\mathtt{num}$ according to the following definition. (The algorithm developed in this paper is a *property tester with one-sided error*, i.e., it always accepts, if $\mathtt{num}$ is a DFS-numbering.)

▶ **Definition 2** (ε-far from DFS numberings in bounded degree graphs)**.** *Let $G = (V, E)$ be an undirected graph on n vertices with maximum degree at most d and let $\mathtt{num} : V \to [n]$ be a bijection that assigns labels to V. We say the labeled graph G $\mathtt{num}$* is ε-far from having a valid DFS numbering*, if one has to modify[2] more than εn edges in G to obtain a graph $G' = (V, E')$ of maximum degree at most d for which $\mathtt{num}$ is a valid DFS numbering.*

Implicitly labeled graphs. To simplify the presentation, we will often assume $\mathtt{num}(v) = v$. However, *we will not use this knowledge in the algorithm* as the model prevents us from querying $\mathtt{num}^{-1}$. Our tester will only ask for a random vertex or for a vertex that occurred as the neighbor of a previously queried vertex.

Further thoughts about the model: Modifying the labels. Observe that in general, it might be natural to consider a revised definition of a labeling $\mathtt{num}$ being ε-far from a valid DFS numbering, where while defining graph G' in Definition 2, in addition to edge modifications, one would allow also for modifications of the labels[3]. We observe that for bounded degree graphs, adding the labels modifications does not change the problem significantly.

▶ **Lemma 3.** *Let $\mathtt{num}$ be a permutation of V to $\{1, \ldots, n\}$. For a given bounded degree graph $G = (V, E)$, a labeling $\mathtt{num}$ is ε-far from a valid DFS numbering according to the edges modifications if and only if $\mathtt{num}$ is $\Theta(\varepsilon)$-far from a valid DFS numbering according to the edges and labels modifications.*

Proof. Observe that the number of modifications of the edges to obtain a valid DFS numbering is not smaller than the number of modifications of the edges and the labels to obtain a valid DFS numbering. Therefore, if for a given bounded degree graph G, a labeling $\mathtt{num}$ is ε-far from a valid DFS numbering according to the edges and labels modifications then $\mathtt{num}$ is also ε-far from a valid DFS numbering according to the edges modifications.

---

[2] Modification of the edges means edge insertions and deletions, i.e., we require $|E \triangle E'| > \varepsilon n$, where $\triangle$ is the symmetric difference.

[3] We use the following revised definition: a labeling $\mathtt{num}$ *is ε-far from a valid DFS numbering* of G if for any graph $G' = (V, E')$ of maximum degree at most d with a valid DFS numbering $\mathtt{num}'$ we have $|E \triangle E'| + |\{v \in V : \mathtt{num}(v) \neq \mathtt{num}'(v)\}| \geq \varepsilon n$.

For the other direction, if num is ε-far from a valid DFS numbering according to the edges modifications then we can simulate modification of the labels by modification of the edges: to assign a given label to a vertex we just remove all its incident edges and add all edges incident to the vertex with the label sought. (Observe that a vertex might have had some edges of its own that have to be removed but by correcting the labels one by one, we can ensure that once we fix vertex v by assigning it to label i with vertex u having label i before, then later we will have to fix the label of vertex u, resolving the issue.) Observe that if we apply this operation to all vertices with the labels to be changed, then we do not increase the maximum degree, and hence, modifying of k labels can be simulated by modifying at most $2dk$ edges. Therefore, if a labeling num is ε-far from a valid DFS numbering according to the edges modifications then num is also $(2d\varepsilon)$-far from a valid DFS numbering according to the edges and labels modifications. ◀

Why should the labels be a permutation? Our model assumes that the input labeling num is a permutation (bijection) of V to $\{1 \dots, n\}$, but it may be natural to consider the case when num is *not necessarily a permutation* but rather an arbitrary function from V to $\{1 \dots, n\}$, allowing repetitions of labels. Observe that already the simple problem of testing if num is a permutation or is ε-far from being a permutation (also known as the element distinctness problem) is known to require $\Theta(\sqrt{n}/\varepsilon)$ queries (see, e.g., [19]). In view of that bound, the best what we could hope for without assuming that num is a permutation of V to $\{1 \dots, n\}$ is to achieve query complexity of $\Theta(\sqrt{n}/\varepsilon)$. And this can be easily obtained by combining our algorithm in Theorem 11 with the known algorithms testing element distinctness, leading to a testing algorithm with $\Theta(\sqrt{n}/\varepsilon)$ queries.

3 Basic Properties of DFS Numberings

We begin with a review of basic DFS terminology, introduce some notions of our own, and make a few useful observations. (We also refer to standard textbooks, e.g., [5, 16].)

The DFS algorithm, as given in Algorithm 1, numbers every vertex even if G is *disconnected* due to the outer loop over all vertices. Every vertex is initially *undiscovered*. When DSFVisit(v) is called, v becomes *discovered*. We say v is *active* as long as the call DSFVisit(v) persists and is *finished* as soon as it ends. The vertex p that initiates the call of DSFVisit(v) is the *parent* of v. If the call of DSFVisit(v) is initiated from the outer loop then we say that v is an *orphan* with *virtual parent* 0. The idea is that the outer loop iterating over all vertices is like a call to DSFVisit(0) where 0 is a virtual vertex connected to all other vertices. Each connected component of G has exactly one orphan, which receives the smallest number in its connected component. At any point during the execution the *white path* consists of all active vertices including the virtual vertex 0, with every active vertex (other than 0) connected to its parent. The DFS numbers appear in increasing order along the white path. In an implicitly labeled graph $G = (V, E)$, we define $p(v)$ for $v \in V$ as

$$p(v) := \begin{cases} \max\{u \in N(v) \cap [v-1]\} & \text{if } N(v) \cap [v-1] \neq \emptyset \\ 0 & \text{otherwise.} \end{cases},$$

▷ Claim 4. If the numbers in an implicitly labeled graph correspond to a DFS numbering then $p(v)$ is the (possibly virtual) parent of v.

Proof. If v is an orphan then it has the smallest number in its connected component so $\{u \in N(v) : u < v\} = \emptyset$. Hence $p(v) = 0$, which is the virtual parent of orphans by definition.

Now assume v was discovered from a non-virtual parent $x \in V$. Then $x \in N(v)$ with $x < v$ so $x \in \{u \in N(v) : u < v\}$. To see that x is the maximum of $\{u \in N(v) : u < v\}$, consider $x' \in \{x+1, \dots, v-1\}$. Immediately before v is discovered, x is at the end of the white path, hence the largest active vertex. Since $x' > x$ has been discovered, x' must be finished. Hence all neighbours of x' have been discovered. Since v is not discovered we have $x \notin N(v)$ so $x \notin \{u \in N(v) : u < v\}$. ◁

Observe that any edge $e = \{u, v\}$ with $u < v$ in an implicitly labeled graph corresponds to an *interval* $[u, v]$ representing a range of elements with respect to the DFS numbering. The analysis of the inter-relation between such intervals plays a central role in our analysis.

▶ **Definition 5.** *A pair* $(v, \{u, w\}) \in V \times E$ *is a* ***conflicting pair*** *if* $p(v) < u < v < w$.

The following central lemma shows that the absence of conflicting pairs is necessary and sufficient for the validity of a DFS numbering (we defer a simple proof to the full version).

▶ **Lemma 6.** *Let* $G = (V, E)$ *be an implicitly labeled graph. The following are equivalent.*

(i) *G has a valid DFS numbering.*

(ii) *There exists no conflicting pair.*

4 Testing DFS Numbering Requires $\Omega(n^{1/3})$ Queries

In this section, we prove our first main result.

▶ **Theorem 7.** *Every property tester for the property of having a valid DFS-labeling has a query complexity of* $\Omega(n^{1/3})$.

Let $\varepsilon > 0$ be sufficiently small (any $\varepsilon \leq \frac{1}{33}$ would do). The proof of Theorem 7 is by constructing two families $(G_n)_{n\in\mathbb{N}}$ and $(B_n)_{n\in\mathbb{N}}$ of *good* and *bad* random labeled graphs for which we will show that distinguishing between these families is necessary for any DFS-tester. Then we will show that distinguishing between these families requires $\Omega(n^{1/3})$ queries.

4.1 Construction of good and bad random labeled graphs (G_n) and (B_n)

Let $n, N \in \mathbb{N}$. Each graph G_n and B_n consists of $\lfloor \frac{n}{8N} \rfloor$ *arms* of $8N$ vertices each. The roots of these arms are connected with some binary tree that is the same for G_n and B_n.

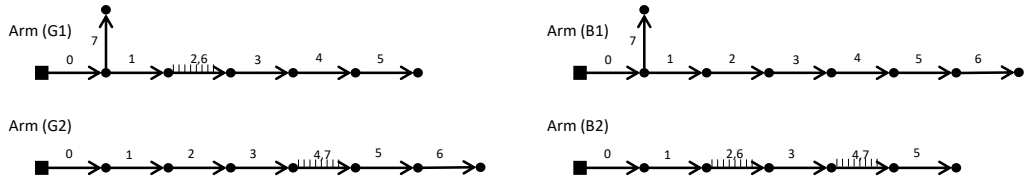
There are four types of arms, as described in details in Figure 1. Each arm of G_n is a copy of $(G1)$ or $(G2)$ chosen independently and uniformly at random. Similarly, each arm of B_n is a copy of $(B1)$ or $(B2)$ chosen independently and uniformly at random.

The labeling of G_n is then obtained by starting in the root of the tree T and using within the arms the relative ordering defined by the numbering of the arms $(G1)$ or $(G2)$. For an example, see, e.g., Figure 3. (Since each arm has the same number of vertices, the choice of one arm, whether in $(G1)$ or $(G2)$, does not affect the numbering of other arms.)

Similarly (see Figure 4), the labeling of B_n is defined by starting at a root of T and using within the arms the relative ordering defined by the numbering of the arms $(B1)$ or $(B2)$.

4.2 Properties of DFS numberings of random labeled graphs G_n and B_n

Let us first notice that our construction of good random labeled graphs $(G_n)_{n\in\mathbb{N}}$ easily ensures that they have valid DFS numberings (with probability 1).



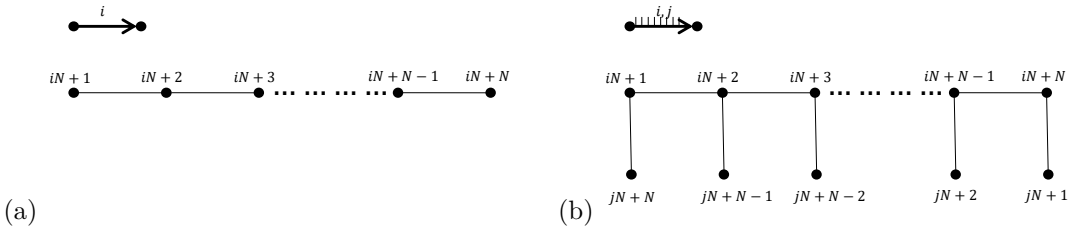


Figure 1 Four types of *arms* $(G1)$, $(G2)$, $(B1)$, and $(B2)$ used in our construction of $(G_n)_{n\in\mathbb{N}}$ and $(B_n)_{n\in\mathbb{N}}$. Each arm starts with a root, denoted by ■. Each link $\xrightarrow{\ i\ }$ corresponds to a path on N vertices and labels $iN+1,\ldots,i(N+1)$ ascending in the direction of the arrow (see Figure 2(a)). We also have a *comb graph* $\xrightarrow{\ i,j\ }$ (see Figure 2(b)), which is obtained from $\xrightarrow{\ i\ }$ by adding N new vertices, adding a matching between the new vertices and the vertices from $\xrightarrow{\ i\ }$, and labeling the new vertices with $jN+1,\ldots,(j+1)N$, this time descending in the direction of the arrow (i.e., the vertex with label $iN+k$ is adjacent to the vertex with label $jN+N-k+1$).

(a) (b)

Figure 2 Graphs corresponding to (a) a path $\xrightarrow{\ i\ }$ and (b) a comb graph $\xrightarrow{\ i,j\ }$.

▶ **Lemma 8.** *G_n has a valid DFS numbering.* ◀

A situation is different for bad random labeled graphs $(B_n)_{n\in\mathbb{N}}$. While the arms of type $(B1)$ also locally maintain a valid DFS-order, the arms of type $(B2)$ do not (because of the two comb graphs). As the result, the construction of $(B_n)_{n\in\mathbb{N}}$ typically gives labelings that are ε-far from valid DFS numberings.

▶ **Lemma 9.** *Let $0 \le \varepsilon \le \frac{1}{33}$ and let n be sufficiently large. Then B_n has a labeling that is ε-far from a valid DFS numbering with probability $1-o(1)$.*

Proof. Consider the numbering for $(B2)$. Let us fix any $k \in \{1,2,\ldots,N\}$ and focus on vertices p_1, c_1, p_2, c_2 with labels $2N+k, 7N-k+1, 4N+k, 8N-k+1$, respectively. (For example, in Figure 4 in the top branch (where numbers have an offset of 1), if we took $k=2$ then we would have $\langle p_1, c_1, p_2, c_2\rangle$ to be vertices with labels $\langle 11, 28, 19, 32\rangle$ in B_{64}.) Observe that the fact that $\mathtt{num}(p_1) < \mathtt{num}(p_2) < \mathtt{num}(c_1) < \mathtt{num}(c_2)$ implies that this is not a valid DFS numbering as long as c_1 is the DFS-child of p_1 and c_2 is the DFS-child of p_2. Therefore, to turn the labeled graph into one consistent with DFS numbering, one has to add or delete at least one edge incident to a vertex from $\{p_1, c_1, p_2, c_2\}$. Since such a quadruple is obtained for each $k \in \{1,\ldots,N\}$ and since each of these quadruples is disjoint (for example, in Figure 4, the there are four such quadruples formed by vertices with labels $\langle 10, 29, 18, 33\rangle$, $\langle 11, 28, 19, 32\rangle$, $\langle 12, 27, 20, 31\rangle$, and $\langle 13, 26, 21, 30\rangle$), one needs to modify at least $\frac{N}{2}$ edges to obtain a valid DFS numbering. Since the expected number of copies of $(B2)$ in B_n is $\frac{1}{2}\cdot\lfloor\frac{n}{8N}\rfloor$, the expected number of changes required in B_n to obtain a valid DFS numbering is at least $\frac{N}{4}\cdot\lfloor\frac{n}{8N}\rfloor$. For sufficiently large n, a standard Chernoff bound implies that graph B_n is $\frac{1}{33}$-far from having a valid DFS numbering with high probability. ◀

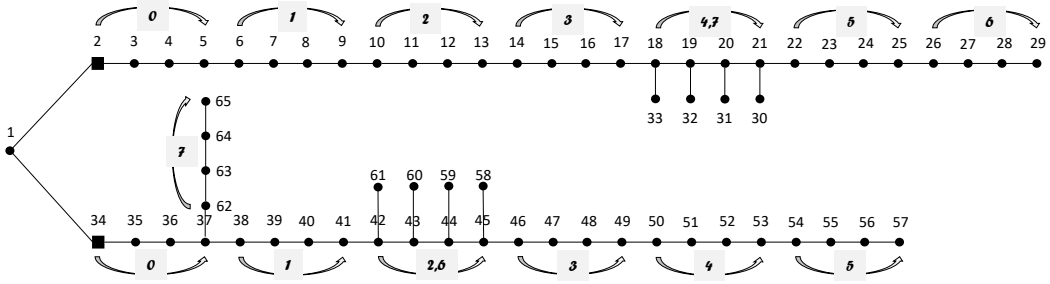

Figure 3 An example of labeling of G_n with $n = 64$, $N = 4$, using $\lfloor \frac{n}{8N} \rfloor = 2$ arms of size $8 \cdot 4 = 32$. Vertices with labels 1, 2, 34 are in the tree T, the top branch (with labels 2–33) corresponds to arm $(G2)$ and the bottom branch (with labels 34–65) corresponds to arm $(G1)$. For each arm, we also marked the corresponding parts defining it.

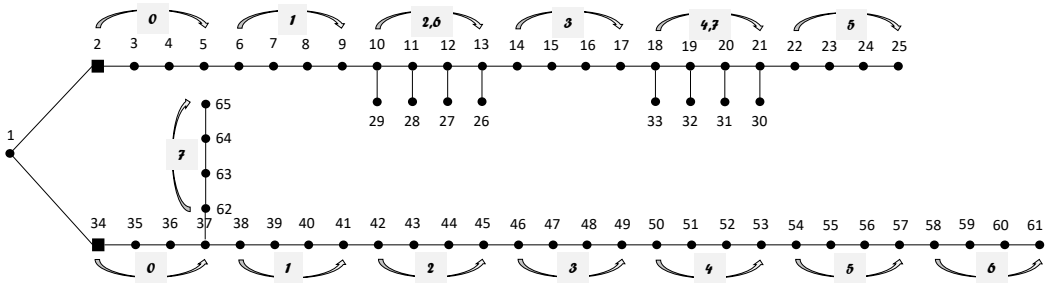

Figure 4 An example of labeling of B_n with $n = 64$, $N = 4$, using $\lfloor \frac{n}{8N} \rfloor = 2$ arms of size $8 \cdot 4 = 32$. Vertices with labels 1, 2, 34 are in the tree T, the top branch (with labels 2–33) corresponds to arm $(B2)$ and the bottom branch (with labels 34–65) corresponds to arm $(B1)$. For each arm, we also marked the corresponding parts defining it.

4.3 Hardness of distinguishing between good and bad labeled graphs

Our next central lemma provides a lower bound for the number of queries of any algorithm ALG that distinguishes between the families of random labeled graphs $(G_n)_{n\in\mathbb{N}}$ and $(B_n)_{n\in\mathbb{N}}$. We will assume that the input I_n for $n \in \mathbb{N}$ on which ALG requires q_n oracle queries is obtained by first selecting a random bit $b \in \{0, 1\}$ and then setting $I_n = \begin{cases} G_n & \text{if } b = 0, \\ B_n & \text{if } b = 1. \end{cases}$

▶ **Lemma 10.** *Let $0 < \xi \leq \frac{N^3}{n}$. For every randomized algorithm ALG' that receives I_n as input, performs $q_n \leq \sqrt{\frac{\xi n}{4N}}$ queries, and outputs a bit $b' \in \{0, 1\}$, we have $\Pr[b = b'] \leq \frac{1}{2} + \xi$.*

Proof. Let ALG' be an algorithm that receives I_n as its input. We assume that ALG' can query the oracle for any vertex u by submitting an ID of u, and the oracle returns the label $\mathfrak{num}(u)$ of u, and the IDs of all neighboring vertices. Further, without loss of generality, we assume that the IDs $1, \ldots, n$ are randomly assigned to the vertices of the graph. Therefore ALG' is limited to querying for a random vertex (a *random query*) or for a vertex that has been previously found as a neighbor of an earlier queried vertex (an *explorative query*).

Without loss of generality, we can assume that the vertices selected by random queries are chosen in the order $v_1, v_2, \ldots$ before the run of ALG'; let $V_R = \{v_1, \ldots, v_{q_n}\}$ be the sequence of these first q_n random vertices (ALG can select only these vertices). Let $\mathcal{E}$ be the random

event that no two vertices $u, u' \in V_R$ come from the same arm of I_n. We prove the following:

$$\Pr[\neg\mathcal{E}] \leq \xi \tag{1}$$
$$\Pr[b = b'|\mathcal{E}] = \tfrac{1}{2} \tag{2}$$

Observe that the two inequalities (1)–(2) imply Lemma 10:

$$\Pr[b = b'] = \Pr[b = b'|\mathcal{E}] \cdot \Pr[\mathcal{E}] + \Pr[b = b'|\neg\mathcal{E}] \cdot \Pr[\neg\mathcal{E}] \leq \tfrac{1}{2} \cdot 1 + 1 \cdot \xi \leq \tfrac{1}{2} + \xi \ .$$

In order to prove inequality (1), let us first define C to be the number of pairs $i \neq j$ with $i, j \leq q_n$ such that both v_i and v_j come from the same arm of I_n, or in other words, so that v_i and v_j belong to the same copy of arm $(B1)$. We have,

$$\mathbb{E}[C] = \sum_{1 \leq i < j \leq q_n} \Pr[v_i \text{ and } v_j \text{ are in the same arm}] \leq \binom{q_n}{2} \cdot \frac{8N}{n} \leq \frac{4q_n^2 N}{n} \leq \frac{4(\frac{\xi n}{4N})N}{n} \leq \xi \ .$$

Therefore we can conclude (1) by Markov's inequality: $\Pr[\neg\mathcal{E}] = \Pr[C \geq 1] \leq \mathbb{E}[C] \leq \xi$.

Next, we want to prove inequality (2). Let V_R^* be the set of vertices reachable from vertices in V_R in at most q_n steps, that is, $V_R^* = \{u : \exists_{1 \leq i \leq q_n} \operatorname{dist}(v_i, u) \leq q_n\}$. Let $I_n(V_R^*)$ be the subgraph of I_n induced by the vertex set V_R^*. We observe that ALG' will make its decision solely on seeing some subgraph of $I_n(V_R^*)$. Hence, the output b' of ALG' is a (random) function of $I_n(V_R^*)$. Now, we claim that conditioned on $\mathcal{E}$, the random variables b and $I_n(V_R^*)$ are stochastically independent, which in turn, would imply identity (2).

To prove that b and $I_n(V_R^*)$ are independent, let us consider a single vertex v_i from V_R and the subgraph $I_n(v_i)$ induced by vertices with distance at most q_n from v_i. If $I_n(v_i)$ contains at least one vertex from T, then $I_n(v_i)$ consists solely of some of the vertices from T and some vertices that are close to the roots of some of the arms (within parts denoted by $\xrightarrow{0}$ of the arms, since each such part has length N and we have $q_n \leq \frac{N}{2}$ since $q_n \leq \sqrt{\frac{\xi n}{4N}}$ and $\xi \leq \frac{N^3}{n}$). Since these parts are identical in G_n and B_n, such paths share no information on b.

Otherwise, if $I_n(v_i)$ contains no vertex from T, then $I_n(v_i)$ is a part of an arm of I_n. But then, due to $q_n \leq \frac{N}{2}$, at most one joint[4] of this arm is contained in $I_n(v_i)$. Since the labels of the roots of the arms are the same in G_n and B_n, it is always well-defined what the offset of a label within its arm is. For more details, see the full version of the paper. ◀

4.4 Hardness of testing DFS numbering (proof of Theorem 7)

By Lemmas 8 and 9, any algorithm ALG that accepts a labeled graph with a valid DFS numbering with probability at least $\frac{2}{3}$ and rejects a labeled graph with a DFS numbering that is ε-far (for $0 < \varepsilon \leq \frac{1}{33}$) from being valid DFS numbering with probability at least $\frac{2}{3}$, must be able to distinguish with probability at least $\frac{5}{8}$ between the families of good and bad random labeled graphs $(G_n)_{n \in \mathbb{N}}$ and $(B_n)_{n \in \mathbb{N}}$. However by Lemma 10, by setting $\xi = \frac{1}{8}$ and $N = \lfloor n^{1/3} \rfloor$, the tasks of distinguishing between these families requires $\Omega(n^{1/3})$ queries. ◀

5 Testing DFS Numbering with $O(n^{1/3}/\varepsilon)$ Queries

Our second main result shows that the lower bound in Theorem 7 is asymptotically tight.

[4] By a *joint* we mean an endpoint of a path or comb from which the arm was stitched together.

▶ **Theorem 11.** *Let $0 < \varepsilon < 1$. There is an algorithm that with oracle access to a labeled bounded degree undirected graph G on n vertices, performs $O(n^{1/3}/\varepsilon)$ queries to the oracle and accepts, if G has a valid DFS numbering, and rejects with probability at least $\frac{2}{3}$, if G is ε-far from having a valid DFS numbering.*

(One can show that our tester achieves also the same $O(n^{1/3}/\varepsilon)$ running time.)

For the rest of the section, let G be a corresponding labeled graph equipped with a possibly inappropriate DFS numbering $\mathtt{num} : V \to [n]$. As in Section 3, we assume that $\mathtt{num}$ *is implicit* so that we can, for instance, write $v < w$ for $v, w \in V$ instead of $\mathtt{num}(v) < \mathtt{num}(w)$.

Outline. Our approach to prove Theorem 11 is first to extend Lemma 6 (which characterizes valid DFS numberings) to describe a simple and useful property of labelings that are ε-far from a valid DFS numbering. In Lemma 13 in Section 5.1, we will show that if the numbering is ε-far from a valid DFS numbering then not only we have $\Omega(\varepsilon n)$ conflicting pairs (in the sense of Lemma 6), but in fact we have $\Omega(\varepsilon n)$ conflicting pairs that are "unrelated." Once we have this property, the task in hand will be to detect any of such conflicting pair. We observe that there are two types of conflicting pairs, *local pairs* involving vertices whose DFS numbers are close to each other, and *global conflicts*. In order to detect local conflicts, we first develop (in Section 5.2) some basic tools to traverse a given graph following DFS numbering. Once we know how to traverse the graph, we can design an algorithm that can determine if a given pair $(v, \{u, w\})$ is conflicting pair. Unfortunately, this algorithm is efficient only if vertex u or w is close to $p(v)$ or v (that is, if one of $\mathtt{num}(u) - \mathtt{num}(p(v))$, $\mathtt{num}(v) - \mathtt{num}(u)$, $\mathtt{num}(w) - \mathtt{num}(v)$ is small), and so we can use this approach to deal with local conflicts. In order to study global conflicts, we notice that if vertices u and w are far away from vertices $p(v)$ and v, then in fact a conflicting pair $(v, \{u, w\})$ can be also extended to multiple vertices v. Once we have that property, we will show that if we sample randomly $\Theta(n^{1/3}/\varepsilon)$ vertices and $\Theta(n^{1/3}/\varepsilon)$ edges, then if there were many global conflicts, then there would be one that is determined by one of the sampled vertices and one of the sampled edges.

5.1 Properties of labelings that are ε-far from any valid DFS numbering

We begin with describing a useful property of labelings that are ε-far from a valid DFS numbering that they have $\Omega(\varepsilon n)$ conflicting pairs that are "unrelated." Recall that by Lemma 6 a numbering is a valid DFS numbering if and only if there is no conflicting pair $(v, \{u, w\}) \in V \times E$ with $p(v) < u < v < w$. In that case, when $p(v) < u < v < w$, we speak of a conflict involving vertex v and edge $\{u, w\}$. While Lemma 6 characterizes valid and invalid DFS numberings, we will need a stronger claim about properties of numberings that are ε-far from valid DFS numberings. For that, we need to understand numberings that are not ε-far from valid DFS numberings because we can modify the input graph with at most εn edge modifications to ensure that the resulting graph will have a valid DFS numbering.

Observe that Lemma 6 provides a simple tool to edit the input labeled graph to obtain a valid DFS numbering – to remove all conflicting pairs. With that in mind, the following claim provides a simple fix to remove all conflicts involving a specific vertex or all conflicts involving a specific edge (notice that the resulting graph may violate our degree bound d, but one can address this issue using a "degree reduction framework," see the full version.

▶ **Lemma 12.** *Let $v \in V$ and $\{u, w\} \in E$ with $u < w$.*

- **(i)** *Adding the edge $\{v-1, v\}$ to G (and doing nothing if $\{v-1, v\}$ is already present) does not create any new conflicts and resolves all conflicts involving v.*
- **(ii)** *Removing $\{u, w\}$ from G and adding $\{w-1, w\}$ (if not already present) does not create any new conflicts and resolves all conflicts involving $\{u, w\}$.*

Proof.

(i) After the edit we have $p(v) = v - 1$ so no $u \in V$ can satisfy $p(v) < u < v$ any more, meaning all conflicts involving v are resolved. We do not create any new conflicts because $p(v-1)$ does not change and the new edge $\{v-1, v\}$ cannot be involved in a conflict because (again) no v' can satisfy $v - 1 < v' < v$.

(ii) Deleting $\{u, w\}$ clearly resolves all conflicts of this edge. However, new conflicts involving w may arise since $p(w)$ may change if we had $p(w) = u$ before. By (i) we can fix these by adding $\{w - 1, w\}$. ◀

Lemma 12 shows that adding or removing a few edges can resolve many related conflicts. We use this claim to show that in order for G to be ε-far from having a valid DFS numbering, not only do there have to be many conflicts, but in fact there have to be *many mutually unrelated conflicts*. To formalize this idea we consider the bipartite *conflict graph* $\mathcal{C} = (V, E, C)$ where $C \subseteq V \times E$ contains an edge $(v, \{u, w\})$ precisely if it is a conflicting pair. The intuition of mutually unrelated conflicts corresponds to a matching in $\mathcal{C}$. We have the following.

▶ **Lemma 13** (ε-far DFS numberings). *If G is ε-far from having a valid DFS numbering then there is a matching $M \subseteq C$ of size $|M| \geq \varepsilon n/5$ in $\mathcal{C}$.*

Proof. We will prove Lemma 13 by showing that if G is ε-far from having a valid DFS numbering then $\mathcal{C}$ has a vertex cover of size at least $\varepsilon n/5$, for if not, then we could modify at most εn edges of G to make the labeling to be a valid DFS numbering of the resulting graph. Then Lemma 13 follows from König's theorem.

Let $M \subseteq C$ be a maximum matching in $\mathcal{C}$. By Kőnig's theorem there is a vertex cover $\mathcal{VC} \subseteq V \cup E$ of size $|\mathcal{VC}| = |M|$, i.e., a set of vertices and edges of G (vertices of $\mathcal{C}$) such that for every conflict pair $(v, \{u, w\})$ (for every edge of $\mathcal{C}$) $v \in \mathcal{VC}$ or $\{u, w\} \in \mathcal{VC}$. We can fix all conflicts in G in $\leq 2|\mathcal{VC}|$ edits by applying for each $v \in \mathcal{VC} \cap V$ the fix of Lemma 12 (i) (one edit) and for each $\{u, w\} \in \mathcal{VC} \cap E$ the fix of Lemma 12 (ii) (two edits). We obtain a graph G^* with a valid DFS numbering. However, the vertices that appeared in a fix in the role of v or w may have degree $d + 1$ in G^*, higher than permitted. By our "degree reduction framework" (see full version), another $3|\mathcal{VC}|$ edits suffices to transform G^* into $G^{**} = (V, E^{**})$ with maximum degree d while maintaining the validity of the DFS numbering. Overall $|E^{**} \triangle E| \leq 5|\mathcal{VC}|$ and since G is ε-far we have $|E^{**} \triangle E| \geq \varepsilon n$. Hence $|M| = |\mathcal{VC}| \geq \varepsilon n/5$. ◀

Lemma 13 immediately implies a simple tester detecting ε-far instances: we randomly sample $\Omega(\sqrt{n/\varepsilon})$ vertices and $\Omega(\sqrt{n/\varepsilon})$ edges, and then with a constant probability one of the sampled vertices v and one of the sampled edges e will form a conflicting pair (v, e).

▶ **Corollary 14.** *There is an algorithm that with oracle access to a labeled bounded degree graph G on n vertices, performs $O(\sqrt{n/\varepsilon})$ queries to the oracle and accepts, if G has a valid DFS numbering, and rejects with probability $\frac{2}{3}$, if G is ε-far from having a valid DFS numbering.* ◀

In what follows, we will show how to improve this result, as promised in Theorem 11.

5.2 Navigating (would-be) DFS trees

In this section, we develop tools to find conflicting pairs for vertices. We first show how to traverse a graph using consecutive labels (a simple proof is deferred to the full version).

▶ **Fact 15.** *Let T be an ordered tree of bounded degree and S its canonical DFS ordering*[5]*. For a randomly selected vertex v from T, given oracle access to T, it is possible to locate the successor (and the predecessor) of v in S, if one exists, with $O(1)$ queries to T in expectation.*

Using Fact 15, we can prove the following lemma.

▶ **Lemma 16** (DFS-NEXT)**.** *There is an algorithm DFS-NEXT that for a given vertex $v \in V$:*

- *If the numbering of G is a valid DFS numbering then either vertex $v+1$ is returned or END-OF-COMPONENT is returned if v is the largest vertex in its connected component.*
- *The expected (over vertices in V) number of queries to G of algorithm DFS-NEXT is $O(1)$.*

There also exists an algorithm DFS-PREV with corresponding properties.

Proof. Let T be the ordered tree on $V \cup \{0\}$ rooted at 0 with the edges $\{p(v), v\}$ for $v \in V$ and children ordered ascending by number. If the numbering of G is a valid DFS numbering then (by Claim 4) T is precisely the DFS tree that gave rise to the numbering. We can navigate to successors and predecessors in T (by Fact 15) with an expected number of $O(1)$ queries to G per step. The only problem is that the virtual vertex 0 cannot be accessed and has unbounded degree. Whenever we would have to access it, we return END-OF-COMPONENT instead, which is appropriate because a valid DFS backtracks to 0 precisely if a connected component has been fully explored. (If the numbering of G is invalid, the produced answer may be meaningless, but it is still obtained within the claimed expected time budget.) ◀

5.3 Testing for conflicts

Lemma 13 implies that an ε-far instance has $\Omega(\varepsilon n)$ pairwise distinct vertices and edges involved in conflicts. In this section, we will extend that approach and study separately *local conflicting pairs* and *global conflicting pairs* in order to improve the tester from Corollary 14. This notion depend on a locality parameter that we will later choose as $\ell = n^{1/3}$.

▶ **Definition 17.** *Let $(v, \{u, w\}) \in V \subseteq E$ with $p(v) < u < v < w$ be a conflicting pair. We speak of a **local conflict** of the following (not mutually exclusive) types* **(L1)** *if $u - p(v) \leq \ell$ and $p(v) \neq 0$,* **(L2)** *if $v - u \leq \ell$,* **(L3)** *if $w - v \leq \ell$. In all other cases we speak of a **global conflict**:* **(G)** *if $p(v) = 0$ and $\max\{v-u, w-v\} > \ell$; or if $\max\{u - p(v), v-u, w-v\} > \ell$.*

Informally, local conflicts occur when u is close (in the sense of its DFS number) to $p(v)$ or v, or w is close v, in which case one can traverse the input graph to efficiently detect the conflict. For global conflicts, some more global approach will be needed.

5.3.1 Testing for local conflicts

We can detect local conflicts by sampling vertices at random and walking forwards and backwards in the (supposed) DFS order using Lemma 16 as follows.

▶ **Lemma 18.** *There is an algorithm that with $O(\ell/\varepsilon)$ queries in expectation accepts all valid DFS numberings and rejects with probability $2/3$ if there is a matching $M \subseteq V \subseteq E$ of size at least $\frac{\varepsilon n}{30}$ consisting of conflicting pairs of type* **(L1)**. *The same applies to types* **(L2)**, **(L3)**.

Proof. Consider the following procedure WALK-FROM-$p(v)$ that is given $v \in V$ as input. It first checks if $p(v) \neq 0$. If so, it attempts to locate vertices $p(v)+1, p(v)+2, \ldots$ using DFS-NEXT from Lemma 16 until one of the following happens.

[5] The DFS starts at the root and respects the order of children when visiting them in pre-order traversal.

- If DFS-NEXT reaches vertices out of order, then report the error.
- If DFS-NEXT reaches a vertex u that has a neighbour $w > v$ then report the error.
- If v or $p(v) + \ell$ is reached without finding an error, then conclude that v is not involved in a conflict of type **(L1)**.

Clearly WALK-FROM-$p(v)$ finds an error if v is involved in a conflict of type **(L1)** and by Lemma 16 it performs $O(\ell)$ queries in expectation (over all $v \in V$). Our algorithm to detect conflicts of type **(L1)** is now simply to repeat WALK-FROM-$p(v)$ for many v sampled uniformly at random. Since the $\frac{\varepsilon n}{30}$ vertices matched in M are pairwise distinct, a random vertex from V is involved in a conflict of type **(L1)** with probability $\frac{\varepsilon}{30}$. If we sample $\frac{60}{\varepsilon}$ vertices at random then the probability of sampling at least one v involved in a conflict of type **(L1)** is

$$\geq 1 - (1 - \varepsilon/30)^{60/\varepsilon} \geq 1 - \mathrm{e}^{-(\varepsilon/30)\cdot(60/\varepsilon)} = 1 - \mathrm{e}^{-2} \geq 2/3 \ .$$

The expected total number of queries amounts to $O(\ell/\varepsilon)$, which concludes the claim.

For conflicts of type **(L2)** a similar procedure WALK-BACKWARDS-FROM-v works. For conflicts of type **(L3)** a procedure WALK-FORWARDS-FROM-v would *not* work because DFS-NEXT might report END-OF-COMPONENT before w is reached (and without us being aware of w's existence). A procedure WALK-BACKWARDS-FROM-w does work, however. Note that we have to sample $\frac{60d}{\varepsilon}$ edges uniformly at random which is still $O(1/\varepsilon)$ because d is constant. ◀

5.3.2 Testing for global conflicts

Lemma 18 provides an efficient tool to detect local conflicts but for global conflicts we use a different approach. We rely on Lemma 13 that promises that there is a matching $M \subseteq V \subseteq E$ of size at least $\varepsilon n/10$ consisting of conflicting pairs. Therefore, if most of conflicts defining the matching M are global, we can use the following lemma.

▶ **Lemma 19.** *There is an algorithm that performs $O(\sqrt{n/\ell}/\varepsilon)$ queries in expectation and accepts all valid DFS numberings and that rejects with probability at least $2/3$ if there is a matching $M \subseteq V \subseteq E$ of size at least $\varepsilon n/10$ consisting of conflicting pairs of type (G).*

Proof. Let us partition matching M into strips $M_1 \oplus M_2 \oplus \cdots \oplus M_{\lceil \frac{n}{\ell} \rceil}$ according to the number of u, so that $M_j = \{(v, \{u, w\}) \in M : \lceil u/\ell \rceil = j\}$. Let us define sets $V_j := \{v \in V : \exists_{e \in E}\ (v, e) \in M_j\}$ and $E_j := \{e \in E : \exists_{v \in V}(v, e) \in M_j\}$. Let $\bar{v}_j$ be the median of V_j. Let V_j^- be those vertices from V_j that are at most $\bar{v}_j$ and E_j^+ those edges from E_j matched to a vertex that is at least $\bar{v}_j$. Let $m_j := |V_j^-|$ and note that $|E_j^+| = m_j$ and that $m_j \geq \frac{|M_j|}{2}$.

We claim that *every pair* in $V_j^- \times E_j^+$ is a conflicting pair. Indeed, let $v_1 \in V_j^-$, $\{u_2, w_2\} \in E_j^+$ with $u_2 < w_2$, and let $p_1 = (v_1, \{u_1, w_1\})$ and $p_2 = (v_2, \{u_2, w_2\})$ be the corresponding pairs in M_j. Then we observe the following:

$$p(v_1) \overset{(1)}{\leq} \max\{0, u_1 - \ell\} \overset{(2)}{<} u_2 \overset{(2)}{<} u_1 + \ell \overset{(1)}{<} v_1 \overset{(3)}{\leq} \bar{v}_j \overset{(3)}{\leq} v_2 \overset{(4)}{<} w_2 \ .$$

To see this, we notice the following:

(1) p_1 is of type (G). Hence $u_1 - p(v_1) > \ell$, unless $p(v_1) = 0$; moreover $v_1 - u_1 > \ell$;
(2) since both p_1 and p_2 are in M_j, we have $|u_1 - u_2| < \ell$;
(3) by the definition of V_j^- and E_j^+ the values of v_1 and v_2 fall on the respective side of the median $\bar{v}_j$;
(4) p_2 is a conflicting pair.

In view of the above, since every pair in $V_j^- \times E_j^+$ is a conflicting pair, we observe that over all j we do not just have $m = |M|$ conflicting pairs to work with, but a collection of bicliques with $\sum_{i=1}^{\lceil n/\ell \rceil} (m_j)^2$ conflicting pairs in total. If we happen to get hold of a $v \in V_j^-$ and an $e \in E_j^+$ for the same j, then we have a conflicting pair (v, e).

In order to find a conflicting pair using the approach above, let us sample (i.u.r.) s vertices from V and then (i.u.r.) s edges from E, where s will be set up momentarily.

For any $1 \leq i, r \leq s$, let $X_{i,r}$ to be the indicator random variable that the ith sampled element from V and the rth sampled element from E are (respectively) from the sets V_j^- and E_j^+ for the same j. Observe that if we define random variable X as $X = \sum_{i=1}^{s} \sum_{r=1}^{s} \mathbb{E}[X_{i,r}]$, then by the arguments above, if X is positive then we have detected a conflicting pair. Using the second moment method, we get prove the following lemma.

▶ **Lemma 20.** *Let $s \geq c\sqrt{\frac{n^3}{\ell \cdot |M|^2}}$ for a sufficiency large constant c and let $s = \omega((d/\varepsilon)^3)$. Then* $\Pr[X > 0] \geq 0.99$.

Hence, if we sample i.u.r. at least $c \cdot \sqrt{\frac{n^3}{\ell |M|^2}}$ vertices from V and at least $c \cdot \sqrt{\frac{n^3}{\ell |M|^2}}$ edges from E for a sufficiently large constant c, then with a constant probability we will detect a conflicting vertex. At the same time, if the DFS numbering is valid then the algorithm will accept it. This yields Lemma 19 since in our setting $|M| = \Omega(\varepsilon n)$ and $\ell = n^{1/3}$. ◀

5.4 Putting all together: the proof of Theorem 11

Now we are ready to complete the proof of Theorem 11. Our algorithm runs the algorithms from Lemma 18 (responsible or conflicts of type **(L1)**, **(L2)** and **(L3)**) and from Lemma 19 one after the other. If any of them rejects G then we reject G, otherwise we accept G. The *expected* total running time is $O(\ell/\varepsilon + \sqrt{n/\ell}/\varepsilon)$, which with $\ell = \Theta(n^{1/3})$ gives $O(n^{1/3}/\varepsilon)$ as claimed. (The query complexity can be made $O(n^{1/3}/\varepsilon)$ using Markov inequality.)

Concerning correctness, it is clear that instances with valid DFS numberings are always accepted. If G is ε-far from a valid DFS numbering then by Lemma 13 there is a matching $M \subseteq V \subseteq E$ of $|M| \geq \varepsilon n/5$ conflicting pairs. Since each matching edge falls into (at least) one type, at least one of the following statements holds.

- There is a matching $M_{\textbf{(L1)}}$ of $|M_{\textbf{(L1)}}| \geq \varepsilon n/30$ conflicting pairs of type **(L1)**.
- There is a matching $M_{\textbf{(L2)}}$ of $|M_{\textbf{(L2)}}| \geq \varepsilon n/30$ conflicting pairs of type **(L2)**.
- There is a matching $M_{\textbf{(L3)}}$ of $|M_{\textbf{(L3)}}| \geq \varepsilon n/30$ conflicting pairs of type **(L3)**.
- There is a matching $M_{\textbf{(G)}}$ of $|M_{\textbf{(G)}}| \geq \varepsilon n/10$ conflicting pairs of type **(G)**.

In each case, the corresponding algorithm rejects G with probability $2/3$ so overall we reject G with probability at least $2/3$. ◀

6 Conclusions

In this paper we introduced a variant of the standard bounded-degree graph model in the property testing setting that works for labeled graphs and allows also label queries. We demonstrated the strength of the model on our new study of DFS numbering. Our main technical contribution is a tight analysis for detecting whether the input labeled graph is properly DFS-numbered or it is ε-far from having a valid DFS numbering. We demonstrated that this task can be solved with $\Omega(n^{1/3}/\varepsilon)$ queries and also $\Omega(n^{1/3})$ queries are necessary.

We observe that while our analysis is presented for undirected graphs, similar arguments hold also for ***directed graphs***. The lower bound from Theorem 7 trivially extends to directed graphs and a careful pass through the algorithm in Theorem 11 shows that the analysis can be extended accordingly. However, to implement this algorithm efficiently in our setting, we need to allow access to incoming and outgoing edges. (See the full version of the paper.)

Our analysis can be also extended (but only for undirected graphs) to the ***DFS finishing numbers*** (FIN-numberings [5]). We can show that (for undirected graphs) a numbering $\mathtt{num} : V \to [n]$ is a valid FIN numbering iff the reverse numbering $\overleftarrow{\mathtt{num}}$ with $\overleftarrow{\mathtt{num}}(i) = n+1-i$ is a valid DFS numbering. This immediately implies that our results for testing valid DFS numberings extend to testing valid FIN numberings in undirected graphs.

Abstract

We propose two one-pass streaming algorithms for the $\mathcal{NP}$-hard hypergraph matching problem. The first algorithm stores a small subset of potential matching edges in a stack using dual variables to select edges. It has an approximation guarantee of $\frac{1}{d(1+\varepsilon)}$ and requires $\mathcal{O}((\frac{n}{\varepsilon})\log^2 n)$ bits of memory, where n is the number of vertices in the hypergraph, d is the maximum number of vertices in a hyperedge, and $\epsilon > 0$ is a parameter to be chosen. The second algorithm computes, stores, and updates a single matching as the edges stream, with an approximation ratio dependent on a parameter α. Its best approximation guarantee is $\frac{1}{(2d-1)+2\sqrt{d(d-1)}}$, and it requires only $\mathcal{O}(n)$ memory.

We have implemented both algorithms and compared them with respect to solution quality, memory consumption, and running times on two diverse sets of hypergraphs with a non-streaming greedy and a naive streaming algorithm. Our results show that the streaming algorithms achieve much better solution quality than naive algorithms when facing adverse orderings. Furthermore, these algorithms reduce the memory required by a factor of 13 in the geometric mean on our test problems, and also outperform the offline Greedy algorithm in running time.

1 Introduction

We propose two streaming algorithms for the hypergraph matching problem, derive their approximation ratios, and implement them to evaluate their practical performance on a large number of test hypergraphs. Recall that hypergraphs are a natural extension of graphs and can help to model our ever evolving earth and society. In a hypergraph, a hyperedge is a subset of vertices and can contain any number of them, instead of just two. The hypergraph matching problem asks for a set of vertex-disjoint hyperedges. Two common objectives in the hypergraph matching problem are to maximize the number or total weight of the matching hyperedges. The hypergraph matching problem has applications ranging from personnel scheduling [17] to resource allocations in combinatorial auctions [21]. The hypergraph matching problem with either of the objective functions is $\mathcal{NP}$-complete [24], but a simple Greedy algorithm is $1/d$-approximate, where d is the maximum size of a hyperedge [5, 28].

There are a few papers with computational studies for the hypergraph matching problem, in a single CPU in-memory setting [11] and in a distributed computing setting [23]. However, little to no attention was paid to increasing data sizes and approximation guarantees. Streaming and semi-streaming algorithms address this trend of ever-increasing data size. In a streaming setting, hyperedges arrive one by one in arbitrary order. The amount of memory that can be used is strictly bounded by the size of the final solution. In the case of hypergraph matching, this is $\Theta(n)$, where n is the number of vertices in the hypergraph, because every vertex can be matched at most once. For a semi-streaming setting, this criterion is relaxed to allow for an additional polylog factor. Furthermore, establishing a bound on the degree of suboptimality is essential for evaluating the solution's effectiveness. For matchings in graphs, there is a semi-streaming algorithm having an approximation guarantee of $\frac{1}{2}$ by Paz and Schwartzman [33].

The algorithm by Paz and Schwartzman requires one variable per vertex, the dual variable, and uses a stack to store candidate matching edges. When an edge appears in the stream, the algorithm adds it to a stack if its weight dominates the sum of the duals of its vertices, and then updates the duals with the difference between the edge weight and the sum of duals. Otherwise, the edge is discarded. After all edges have been streamed, non-conflicting edges are added from the stack beginning at the top. Ghaffari and Wajc [18] give a simplified proof of the approximation guarantee of this algorithm using the primal-dual linear programming framework.

Our contributions are as follows. We first propose a novel streaming framework for hypergraph matching and prove an approximation guarantee in relation to the largest hyperedge size by extending the stack-based algorithm of Paz and Schwartzman [33] to hypergraphs. In essence, our algorithm puts hyperedges that potentially belong to a good matching on a stack, and in the end computes a matching out of those hyperedges. Given the maximum hyperedge size d (the maximum number of vertices in a hyperedge), we use primal-dual techniques to prove a $\frac{1}{d(1+\varepsilon)}$ approximation factor, where $\epsilon > 0$ is a parameter to be chosen. Our most memory-saving algorithm requires $\mathcal{O}(n \log^2 n/\varepsilon)$ bits of space. We then propose a second family of algorithms which do not need a stack and require less space and work by greedily swapping hyperedges from the current matching with the incoming ones. Like the first stack-based algorithm, this algorithm family requires $\mathcal{O}(|E| \cdot d)$ work. They have an approximation guarantee depending on a factor $\alpha > 0$, which can be tuned to result in a guarantee of $\frac{1}{(2d-1)+2\sqrt{(d-1)d}}$. In experiments, we show the competitiveness of our approaches and benchmark them on a set of social link hypergraphs and a large set of instances from hypergraph partitioning. We compare our algorithms with a Naive streaming

algorithm that maintains a maximal matching in the hypergraph by adding a hyperedge from the stream to the match if it does not overlap in any vertex with the current matching edges, and a non-streaming Greedy algorithm. The stack-based algorithms reduce the memory consumption by up to 13 times in comparison to the non-streaming Greedy algorithm on social link hypergraphs. We investigate the impact of ordering the hyperedges in the stream and show that our stack algorithm can handle them better than the non-streaming Greedy and Naive streaming algorithms, while requiring only 26% more time than the Naive algorithm. We show the impact of the parameters α and ε on their respective algorithms.

The rest of the paper is organized as follows. After introducing the notation and related work in Section 2, we show our approximation guarantee for an adaptation of the Paz-Schwartzman semi-streaming algorithm and discuss further improvements in Section 3. Section 4 introduces our greedy swapping algorithm for streaming based on McGregors [31] algorithm. These approaches are then extensively evaluated by experiments in Section 5. We conclude in Section 6. The Appendix of the full version of the paper contains the proof of the approximation guarantee for the algorithm from Section 4, and additional statistics on the test problems as well.

2 Preliminaries

2.1 Basic Concepts

Hypergraphs. A *weighted undirected hypergraph* $H = (V, E, W)$ consists of a set V of n vertices and a set E of m hyperedges. Each hyperedge e is a subset of vertices and is assigned a positive weight by the weight function $W : E \to \mathbb{R}_{>0}$. The number of vertices in a hyperedge e is its size, and is denoted by $|e|$, and the maximum size of a hyperedge or rank of the hypergraph is denoted by $d := \max_{e \in E} |e|$. For clarity and brevity, we refer to a hyperedge simply as an edge when it is evident from the context that a hypergraph is under consideration.

Matching. A subset of (hyper-)edges $M \subset E$ is a *matching*, if all (hyper-)edges in M are pairwise disjoint, i.e., only at most one (hyper-)edge is selected at every vertex. A matching M is called maximal, if there is no (hyper-)edge in E which can be added to M without violating the matching constraint. The weight of a matching is defined by $W(M) := \sum_{e \in M} W(e)$ and a maximum matching is a matching with the largest weight.

Related $\mathcal{NP}$-hard Problems. The unweighted hypergraph matching problem is closely related to the maximum independent set and the k-set packing problems. Both problems are $\mathcal{NP}$-hard [27]. An independent set in a graph is a subset of vertices in which no two vertices are adjacent. There is a simple transformation from hypergraph matching to maximum independent set using the line graph of the hypergraph; in the line graph, every hyperedge becomes a vertex, and two such vertices are connected if the corresponding hyperedges share a common vertex. Given a ground set S and some subsets $S_1, \ldots, S_n$, each of size at most k, the k-set packing problem asks to select the maximum number of disjoint subsets. It can be translated to the hypergraph matching setting, by choosing the set S to correspond to the vertices V, while the subsets $S_1, \ldots, S_n$ correspond to the hyperedges.

(Semi-)Streaming Algorithms. If the input size exceeds the memory of a machine, a typical solution is to stream the input. There are several definitions for streaming in graphs and hypergraphs. When (semi-)streaming, the (hyper-)edges of a (hyper-)graph are usually

presented in an arbitrary (even adverse) order one-by-one in several passes. In this paper we consider having only one pass over the input. In a streaming setting, the memory is strictly bounded by the solution size and, hence, for matching in hypergraphs, it is limited by the number of vertices. When using the semi-streaming model the memory is bounded by $\mathcal{O}(n \cdot \text{polylog}(n))$.

Approximation Factors. Algorithms can be classified into three categories: exact algorithms, heuristics without approximation guarantees, and approximation algorithms. The quality of an approximation algorithm is measured by comparing its solution's value to that of an optimal solution. For an instance I of a maximization problem, let the optimum objective be denoted by $M(I)$. If an algorithm $\mathcal{A}$ is guaranteed to find a solution that is bigger than $\alpha M(I)$ for every instance, where $\alpha \in \mathbb{R}^+_{<1}$ and is chosen to be as large as possible, then $\mathcal{A}$ provides an α-approximation guarantee. In some communities, the convention is to report $\frac{1}{\alpha} > 1$ as the approximation ratio, although we do not follow it here. For an overview of techniques to design approximation algorithms, we refer the reader to Williamson and Shmoys [42].

(Integer) Linear Programs. Many optimization problems can be formulated as integer linear programs (ILP). In a maximization problem, an (integer) linear program finds an (integer) vector x with components x_i, that maximizes a linear cost function $\sum c_i x_i$ such that a constraint $Ax \leq b$, where A is a matrix, is satisfied, with typically additional constraints on the components of x, e.g., $x_i \geq 0$. If the variables of the problem are integer, some problems are $\mathcal{NP}$-hard, while other problems (where the constraint matrix is unimodular) are solvable in polynomial time [43]. When the integer constraint is dropped, any linear program is solvable in polynomial time [44]. For every linear program one can find a dual problem [42]. Given a maximization problem as described before, the dual problem is to find a vector $y_i \geq 0$, that minimizes $\sum b_i y_i$ subject to $A^T y \geq c$. The weak duality theorem [42] states that for any primal maximization problem, the dual minimization problem for any feasible solution has an objective value larger than the optimal solution of the primal problem. The strong duality theorem states that if the primal problem has an optimal solution then the dual is solvable as well and the optimum values are the same. For a more detailed introduction, we refer the reader to the Appendix of [42].

2.2 Related Work

Matching is a well-studied problem in computer science, and here we give a brief overview of matchings in graphs and hypergraphs.

Matching in Graphs and Streaming. The polynomial-time complexity of matchings in graphs is one of the classical results in theoretical computer science [12]. While Preis [36] presents the first linear time $\frac{1}{2}$-approximation, Drake and Hougardy [10] show a simpler algorithm with the same approximation ratio by path growing (PGA) in linear time. A number of other 1/2-approximation algorithms have been developed, including the proposal-based Suitor algorithm of Manne and Halappanavar [29]. Pettie and Sanders [34] propose a $\frac{2}{3} - \varepsilon$ approximation with expected running time of $\mathcal{O}(m \log \frac{1}{\varepsilon})$. The GPA algorithm by Maue and Sanders [30] bridges the gap between greedy and path-searching algorithms, showing that a combination of both works best in practice. Pothen, Ferdous and Manne [35] survey these approximation algorithms. Birn et al. [6] develop a parallel algorithm in the CREW PRAM model with $\frac{1}{2}$-approximation guarantee and $\mathcal{O}(\log^2 n)$ work. Feigenbaum et al. [14] present a $\frac{1}{6}$-approximation for the weighted matching problem in the semi-streaming setting

using a blaming-based analysis. McGregor [31] develop a multipass algorithm that returns a $\frac{1}{2+\varepsilon}$ approximation in $\mathcal{O}(\varepsilon^{-3})$ rounds, with the initial matching having an approximation guarantee of $\frac{1}{3+2\sqrt{2}}$. Paz and Schwartzman [33] give a $\frac{1}{2+\varepsilon}$-approximation algorithm, which employs a dual solution to admit candidate edges into a stack, while also updating the dual solution. The matching is constructed by removing edges from the top of the stack, and those that do not violate the matching property are added to the solution. The resulting matching is not necessarily maximal. Ghaffari and Wajc [18] provide a simpler proof of the approximation ratio using a primal-dual analysis. Ferdous et al. [15] show empirically that the algorithm by Paz and Schwartzman can compete quality-wise with offline $\frac{1}{2}$-approximation algorithms like GPA, while requiring less memory and time. Ferdous et al. [16] present two semi-streaming algorithms for the related weighted k-disjoint matching problem, building upon the algorithms of Paz and Schwartzman, and Huang and Sellier [25, 33] for streaming b-matching.

Hypergraph Matching. Hazan et al. [24] prove that for the maximum k-set packing problem there is no approximation within a factor of $\Omega(k/\log k)$ unless $\mathcal{P} = \mathcal{NP}$. This directly translates to d-uniform cardinality hypergraph matching, where every edge has size d, with $k = d$ and the number of edges selected is maximized. Dufosse et al. [11] investigate reduction rules and a scaling argument for finding large matchings in d-partite, d-uniform hypergraphs. There are several approximation results and local search approaches, most notably by Hurkens and Schrijver [26] and Cygan [7] with an approximation guarantee of $\mathcal{O}(\left(\frac{d+1+\varepsilon}{3}\right))$. Hanguir and Stein [23] propose three distributed algorithms to compute matchings in hypergraphs, trading off between quality guarantee and number of rounds needed to compute a solution.

The Greedy algorithm for maximum weight hypergraph matching, which considers hyperedges for matching in non-increasing order of weights, is $1/d$-approximate, where d is the maximum size of a hyperedge [5, 28]. For the weighted k-set packing problem Berman [4] introduces a local search technique. Improving on these results, Neuwohner [32] presents a way to guarantee an approximation threshold of $\frac{k}{2}$. We are not aware of any practical implementations of these techniques. For the more general weighted hypergraph b-matching problem, Großmann et al. [22] present effective data-reduction rules and local search methods. In the online setting, when hyperedges arrive in an adversarial order, and one must immediately decide to include the incoming hyperedge or not in the matching, Trobst and Udwani [40] show that no (randomized) algorithm can have a competitive ratio better than $\frac{2+o(1)}{d}$.

We are unaware of any studies or implementations for streaming hypergraph matching.

3 Stack-based Algorithm

We now present our first algorithm to tackle the hypergraph matching problem in the semi-streaming setting. Our algorithm uses dual variables to evaluate whether a streaming hyperedge is good enough to be retained in a stack. Once the stream has been ingested, the stack is evaluated from top to bottom to determine a matching, achieving an approximation guarantee of $\frac{1}{d(1+\varepsilon)}$. We also discuss a more permissive and lenient update function that allows more hyperedges into the stack. Finally, we discuss the space complexity of our algorithms.

Algorithm 1 shows our framework for computing a hypergraph matching in a streaming setting. This algorithm is an extension of an algorithm by Paz and Schwartzman [33] proposed for graphs. The algorithm starts with an empty stack and keeps a dual variable ϕ_v for each vertex v of the hypergraph. Throughout the algorithm the stack contains candidate hyperedges for inclusion in a matching.

For each streamed hyperedge e, the algorithm checks if the weight of the dual variables of e's vertices and thereby the solution can be improved by adding e to the stack. More precisely, with $\Phi_e := \sum_{v \in e} \phi_v$, the algorithm checks if $W(e) \geq \Phi_e(1+\varepsilon)$. The parameter $\varepsilon \in \mathbb{R}_{\geq 0}$ is used to trade quality for memory. A smaller ε yields a better approximation guarantee, while a higher ε yields a smaller memory consumption. With $\varepsilon = 0$, the algorithm no longer provides memory guarantees. If $W(e) \geq \Phi_e(1+\varepsilon)$, then e is added to the stack, and the dual variables of the vertices of e are then updated using an update function. The update functions that we consider take $\mathcal{O}(1)$ time per vertex.

After all hyperedges have been streamed, a matching containing only the hyperedges stored in the stack is computed. To do that, our algorithm takes the hyperedges in reverse order from the stack and adds non-overlapping hyperedges to the matching. Note that hyperedges processed earlier that have conflicting heavier (later) hyperedges will be ignored. This is crucial to prove the performance guarantee later. The amount of total work needed for scanning one hyperedge e is $\mathcal{O}(|e|)$, because we need to sum up the dual variables of e's vertices and update them.

The update functions determine whether an approximation guarantee can be provided and directly impact the results. Upon processing a hyperedge e, the update function applied to the dual variable of a vertex $v \in e$ can use the prior value ϕ_v and sum $\Phi_e := \sum_{v \in e} \phi_v$ as well as e's size and weight. We define the following update function for proving the approximation guarantee

$$\phi_v^{\text{new}} := \delta_{\text{g}}(e, \phi_v, \Phi_e, W(e)) := \phi_v + \overbrace{W(e) - \Phi_e}^{w'_e}. \tag{1}$$

The δ_{g} function is exactly the function used by Paz and Schwartzman [33]. For a hyperedge e added to the stack, the $\phi(v)$ value of its endpoints is increased by the potential gain in matching weight, $w'_(e)$. This follows since $\phi(v)$ stores the gain in weight of all earlier edges incident on v that have been added to the stack thus far.

We introduce a different update function later.

At the core of this method are the variables ϕ_v for each v and the update mechanism. These core components and local ratio techniques are used to prove the approximation guarantee in the original work [33]. We follow the structure of the proof derived from a primal-dual analysis [18].

3.1 Approximation Guarantee

We make use of the primal-dual framework for showing the approximation guarantee. For general linear programming concepts, we refer the reader to books [1, 44], and for an excellent overview of primal-dual approximation method to the book [42].

We show that using δ_{g} update function (1) in our algorithm leads to a $\frac{1}{d(1+\varepsilon)}$-approximation, when the stack is unwound and hyperedges are selected in that order which they are on the stack. When streaming the hyperedges in descending order of weights, we can prove that the Greedy algorithm achieves a $1/d$ approximation factor.

We now proceed with a primal-dual analysis of an ILP formulation of the hypergraph matching problem. In our formulation, there is a binary decision variable associated with each hyperedge to designate if that hyperedge is selected to be in the matching. The objective function is to maximize the sum of the weights of the selected hyperedges. The constraint is to select at most one hyperedge containing a given vertex. The linear programming relaxation, shown in Figure 1a, is obtained by dropping the binary constraint on the hyperedge variables.

Algorithm 1 Simple Streaming Algorithm.

```
1: procedure StackStreaming(H = (V, E, W))
2:     S ← emptystack
3:    ∀v ∈ V : φ_v = 0
4:    for e ∈ E in any (even adverse) order do
5:       Φ_e ← Σ_{v∈e} φ_v
6:       if W(e) < Φ_e(1 + ε) then
7:          next
8:       end if
9:       S.push(e)
10:      for v ∈ e do
11:         φ_v ← δ(e, φ_v, Φ_e, W(e)) {update}
12:      end for
13:   end for
14:   M ← ∅
15:   while S ≠ ∅ do
16:      e ← S.pop()
17:      if ∀f ∈ M : f ∩ e = ∅ then
18:         M ← M ∪ {e}
19:      end if
20:   end while
21: end procedure
```

The objective value of the relaxation is naturally greater or equal than the integer version of the linear program. The dual problem of the relaxed hypergraph matching is given in Figure 1b. Following the weak duality theorem for linear programs, we know that any feasible solution of the dual has an objective value greater or equal to the objective value of any feasible primal solution. Furthermore, the optimal value of the linear program $\mathrm{OPT}(LP)$ is equal for both problems (strong duality). The first step for the proof is to check that the variables $(1+\varepsilon)\sum_{v\in e}\phi_v$ (from Algorithm 1) constitute a valid dual solution.

▶ **Observation.** *Function δ_g and Algorithm 1 generate valid dual solutions for all $\varepsilon \geq 0$.*

Proof. For each hyperedge e not on the stack, there was enough weight in the ϕ_v values of its vertices, when e was scanned in Line 6. In the update for every added hyperedge to the stack, all vertices ϕ_v values are increased by $w(e) - \Phi_e$ such that clearly the sum of vertex ϕ_v values is higher than the weight of the hyperedge just added. Therefore, for any hyperedge it holds $\sum_{v\in e}\phi_v \geq W(e)$, satisfying the dual equation (2). ◀

Such a valid dual solution has a greater objective value then the optimum solution of the relaxed dual, and the LP duality theorem gives an upper bound for every matching, including the optimal one M^* by $W(M^*) \leq \mathrm{OPT}(LP) \leq (1+\varepsilon)\sum_v \phi_v$.

Now, we connect the changes to the dual variables with the hyperedges that have already been processed. Define

$$\Delta\phi^e = \begin{cases} \sum_{v\in e}(\delta_g(e,\phi_v,\Phi_e,W(e)) - \phi_v) = |e|\,(W(e)-\Phi_e) & \text{if } e \in S \\ 0 & \text{else} \end{cases} \tag{3}$$

as the change to the dual $\sum_v \phi_v$ by inspecting e. We give a bound for the change of the dual variable w.r.t. the preceding hyperedges in Lemma 1.

Figure 1 Primal and Dual LPs for Hypergraph Matching.

(a) LP

$$\begin{aligned} \text{maximize} \quad & \sum_{e \in E} W(e) x_e \\ \text{subject to} \quad & \\ & \forall v \in V \colon \sum_{e \ni v} x_e \leq 1 \\ & \forall e \in E \colon x_e \geq 0. \end{aligned}$$

(b) Dual LP

$$\begin{aligned} \text{minimize} \quad & \sum_{v \in V} \phi_v \\ \text{subject to} \quad & \\ & \forall e \in E \colon \sum_{v \in e} \phi_v \geq W(e) \\ & \forall v \in V \colon \phi_v \geq 0. \end{aligned} \tag{2}$$

▶ **Lemma 1.** *For a hyperedge e, let $W'_e := W(e) - \Phi_e$. For each hyperedge $e \in E$ added to stack S, if we denote its preceding neighboring hyperedges (including itself) by $\mathcal{P}(e) := \{c \mid c \cap e \neq \emptyset, c \text{ added before } e\} \cup \{e\}$, then $W(e) \geq \sum_{e' \in \mathcal{P}(e)} \frac{1}{d} \Delta\phi^{e'} = \sum_{e' \in \mathcal{P}(e)} W'_{e'}$.*

Proof. From the definition (3), we have $\Delta\phi^e = |e|\, W'_e$ for δ_{g}, because of line 11 of Algorithm 1. $\Phi_e := \sum_{v \in e} \phi_v$ is defined as the previous value of the dual variables before inspecting e. Each of these dual values ϕ_v consists of the sum $\sum_{c \in \mathcal{P}(e) \text{ s.t. } v \in c} W'_c$ for all preceding hyperedges. This leads to $\Phi_e = \sum_{v \in e} \phi_v \geq \sum_{c \in \mathcal{P}(e) \setminus \{e\}} \frac{1}{|e|} \Delta\phi^{e'} \geq \sum_{c \in \mathcal{P}(e) \setminus \{e\}} \frac{1}{d} \Delta\phi^c$. So we can conclude $W(e) = W'_e + \Phi_e \geq \frac{1}{d} \Delta\phi^e + \sum_{e' \in \mathcal{P}(e) \setminus \{e\}} \frac{1}{d} \Delta\phi^{e'}$. ◀

The previous bound relates the weight of a hyperedge to the change in dual variables by its predecessors. In conclusion, we show that our algorithm returns a $\frac{1}{d(1+\varepsilon)}$-approximation.

▶ **Lemma 2.** *Algorithm 1 with δ_{g} function guarantees a $\frac{1}{d(1+\varepsilon)}$-approximation.*

Proof. We show a lower bound on the weight of any matching M constructed by the algorithm. For any hyperedge e not in the stack, $\Delta\phi^e = 0$, as when a hyperedge is not pushed into the stack, no dual variables are updated. Furthermore, any hyperedge in the stack that is not included in the matching must be a previously added neighbor of a matching hyperedge as defined in Lemma 1. Therefore, Lemma 1 applies, and the weight can be lower-bounded. The sum of changes $\sum_e \Delta\phi^e$ to ϕ is equal to the sum of dual variables $\sum_v \phi_v$ at the end. We have

$$W(M) = \sum_{e \in M} W(e) \overset{\text{L. 1}}{\geq} \sum_e \frac{1}{d} \Delta\phi^e \geq \frac{1}{d} \sum_e \Delta\phi^e = \frac{1}{d} \sum_v \phi_v \overset{\text{LP Duality}}{\geq} \frac{1}{d(1+\varepsilon)} W(M^*).$$

◀

3.2 Improving Solution Quality

Now we look into optimizing the solution quality. The design space for optimizations is vast, therefore we focus on simple yet effective techniques. We propose a second update function allowing more hyperedges than δ_{g} into the stack, with the same approximation guarantee.

Lenient Update Function. The δ_{g} in Equation 1 builds a dual solution much larger than needed. For every successfully added hyperedge, the difference between the current dual solution and the weight of the hyperedge is added to every vertex of the hyperedge. We address this by combining it with a scaling argument. The resulting function is

$$\delta_{\text{lenient}}(e, \phi_v, \Phi_e, W(e)) := \phi_v + (W(e) - \Phi_e)/\,|e|\,. \tag{4}$$

This function produces a valid dual solution, and Lemma 1 also holds. For every previously added neighboring hyperedge e' the change $\Delta\phi^e = W'_{e'}$ was distributed over all vertices of the hyperedge, so $\Phi_e \geq \sum_{e' \text{ added before } } \frac{1}{d}\Delta\phi^{e'}$. Lemma 2 follows and gives us the desired approximation factor of $\frac{1}{d(1+\varepsilon)}$.

3.3 Space Complexity Analysis

The space complexity of δ_g and δ_{lenient} can be deduced by simple counting arguments. Let W be the maximum normalized weight of a hyperedge in the hypergraph, i.e., $W := \frac{\max_{e\in E} W(e)}{\min_{e\in E} W(e)}$, and let W be $\mathcal{O}(\text{poly}(n))$. We discuss both update functions separately.

Guarantee Function. On every vertex we can observe up to $1 + \log_{1+\varepsilon}(W)$ incrementing events, because every change in the dual variables has to be bigger by a factor of $(1 + \varepsilon)$. This causes the stack to contain $\mathcal{O}(\sum_v (1 + \log W/\varepsilon))$ vertices in its edges. Each vertex in an edge requires $\log n$ bits. Therefore, the overall space complexity is $\mathcal{O}((1/\varepsilon)n \log^2 n)$ bits since W is $\mathcal{O}(poly(n))$.

Lenient Function. This function updates ϕ_v for every vertex in an edge e added to the stack by $\frac{W(e)-\Phi_v}{d}$, resulting in $1 + d \cdot \log_{1+\varepsilon}(W)$ possible increases to reach the total sum of W. Following the same argument, the stack's space complexity in bits is $\mathcal{O}((1/\varepsilon)nd \log^2 n)$. Note that with this update function the algorithm is semi-streaming only if d is $\mathcal{O}(\text{polylog}(n))$.

The time complexity per edge is in $\mathcal{O}(d)$ and $\Omega(md)$ overall in the scanning phase, as for every edge its vertices need to be scanned and optionally updated once. The unwinding of the stack takes d checks per hyperedge, when reusing the memory of ϕ_v from the previous step. Overall, since the stack size is naturally bounded by m, the complexity of this algorithm is $\mathcal{O}(md)$. In Section 5.2 we show the difference in the stack size in experiments under several orderings of the input.

4 Greedy Swapping Algorithm

We now propose a second streaming algorithm that computes, stores, and updates a matching in the hypergraph as the edges stream. It is conceptually similar to a streaming matching algorithm for graphs [31]. It requires a constant amount of memory per vertex, has an approximation factor that depends on the maximum size of a hyperedge d and a parameter α and obtains high-quality matchings in practice.

The proposed approach is described in Algorithm 2. We store for every vertex v a reference to the current matching hyperedge containing v; the $\perp$ sign symbolizes that no matching hyperedge contains v. For simplifying the presentation, we define $W(\perp) = 0$. When we inspect a hyperedge e, we compute the sum of the weights of its adjacent hyperedges that are currently in the matching. If the weight of the incoming hyperedge is larger than $(1 + \alpha)$ times the previous conflicting hyperedges, we first remove the previous hyperedges from all their vertices. Afterwards we can set the reference to the new incoming hyperedge. The overall space consumption of this algorithm is $\mathcal{O}(n)$. There are n references involved, and each hyperedge of size d holds the d vertices referencing it. Removing a hyperedge is linear in d, because up to d vertices in $\mathcal{B}_v$ must be set to $\perp$; it follows that the total work is $\mathcal{O}(d \cdot |E|)$.

We show its approximation guarantee of $\frac{1}{(1+\alpha)(\frac{d-1}{\alpha}+d)}$, which is optimal for $\alpha = \sqrt{(d-1)/d}$, in the Appendix of the full version. In our experimental evaluation, we look at various values of $\alpha \in \{0, 0.1, 1\}$ and $\alpha = \sqrt{(d-1)/d}$. Note that for $\alpha = 0$ the algorithm has no guarantee.

Algorithm 2 Swapping streaming algorithm.

```

2:   ∀v ∈ V : B_v = ⊥{ Initialize best hyperedge to empty}
3:   W(⊥) := 0
4:   for e ∈ E in arbitrary order do
5:     C ← ⋃_{v∈e} B_v
6:     Φ_e ← W(C){ weight of hyperedges to be removed.}
7:     if W(e) ≥ (1 + α) · Φ_e then
8:       for v ∈ e do
9:         if B_v ≠ ⊥ then
10:          for w ∈ B_v do
11:            B_w ← ⊥ { Unmatch vertices in B.}
12:          end for
13:        end if
14:        B_v ← e
15:      end for
16:    end if
17:  end for
18:  M ← ⋃_{v∈V} B_v
19:  return M
20: end procedure
```

5 Experimental Evaluation

We now evaluate our algorithms with respect to solution quality, running time, and memory usage. Specifically, we address the following research questions:

- **RQ1:** How does the ordering of the hyperedges affect our metrics (memory, running time, and quality)?
- **RQ2:** How do other instance properties affect our algorithms in their memory needs?
- **RQ3:** How do our algorithms compare with offline greedy or naive streaming approaches?

5.1 Setup and Data Set

We implemented our approaches in C++ using g++-14.2 with full optimization turned on (-O3 flag). We tested on two identical machines, equipped with 128 GB of main memory and a Xeon w5-3435X processor running at 3.10 GHz having a L3 cache of 45 MB each. We repeat each experiment three times, and the results are compared only if experiments are run on the same machine and the same compute job. For memory consumption, we used the jemalloc malloc implementation [13]. The time needed for loading the hypergraph is not measured. We scheduled eight experiments (RQ1) and ten experiments (RQ2) to run in parallel, and the order of the experiments was randomized. In order to compare the results we use performance profiles as suggested by Dolan and Moré [9]. We plot the fraction of instances that could be solved within a factor $\tau < 1$ of the best result per instance. In the plot (Figure 7), the algorithm towards the top left corner is the best performer.

Our benchmark includes general hypergraphs that are primarily used for partitioning and social link hypergraphs generated from question-answering websites. In social link hypergraphs, a hypergraph matching can be used to summarize the overall websites, as it represents a subset of disjoint pages from different categories or users. In hypergraph

partitioning, matchings can be used to contract the hypergraph in a multilevel scheme. In a social hypergraph, each page (e.g., a post on StackOverflow or an article in Wikipedia) is considered as a hyperedge. The (Threads) graphs model participating users as vertices, whereas the (Tags) ones model the tags of the posts as vertices. We use three stackexchange networks by Benson et al. [3], and set the number of views as weights from [39]. For the StackOverflow instance, the weights are set by querying the public dataset from BigQuery [19]. We created an additional instance from this source. We also generated a new hypergraph from the English Wikipedia dump, where the categories represent the vertices and the articles represent the hyperedges. We selected a category as a vertex if it has at least 25 mentions, which resulted in 293K vertices for 8M articles. The access frequency of each article in December 2024 is set as weight. We answer **RQ1** and **RQ3** with this data set.

We use the hypergraph data set L_{HG} collected earlier [20] for hypergraph partitioning to address **RQ2** and **RQ3**. The set consists of 94 instances, spanning a wide range of applications from DAC routability-driven placement [41], general matrices [8] to SAT solving [2]. As weights we use $\max |e| - |e|$. This function maximizes the cardinality (number of edges matched). These instances have up to 1.4×10^8 hyperedges/-vertices and a maximum hyperedge size of 2.3×10^6 vertices. More statistics are in the Appendix of the full version.

For the stack-based approach of Section 3, we implemented the Guarantee and Lenient update functions. For simplicity, we refer to the algorithm with the stricter Guarantee function as Stack and the one with the lenient function as StackLenient. Both approaches can be configured by their ε parameter. The algorithms from Section 4 are named SwapSet. The SwapSet algorithm has a parameter $\alpha \geq 0$. For comparison, we use a non-streaming Greedy algorithm that sorts the hyperedges based on weight in descending order and greedily adds them to a matching. We also implemented a Naive streaming algorithm that maintains a maximal hypergraph matching (i.e, it includes a hyperedge if it is feasible w.r.t the current matching) in the order that they are streamed.

5.2 Impact of Streaming Order

We now investigate the impact of different streaming orders on our algorithms (**RQ1**). To this end, we stream the hyperedges of the social-link hypergraphs in three ways: by ascending weight, descending weight, and the original input order. The original input order is the order given by either the original files [3] or, in the case of the wikipedia instance, the order that the articles appear in the dump.

Memory. Figure 2 shows the geometric mean memory consumption for all approaches grouped by the ordering. Interestingly, for lower values of ε, the memory consumption is significantly higher for the ascending order, up to 2.97 times over the descending order (StackLenient $\varepsilon = 0$). For the swapping based algorithms (SwapSet) the differences between the orderings are only minimal, nearly reaching the memory consumption of the Naive algorithm. The Greedy algorithm utilizes the same amount of memory for all orderings, 13.43 times more memory than the stack approaches in the geometric mean. The ordering heavily affects our stack-based algorithms, but they still require less memory than the Greedy approach. The SwapSet algorithms are not significantly impacted by the order. Both results are in line with the theoretical results derived in Section 3.3 and 4.

Running time. In Figure 3 the geometric mean of the running times of the compared algorithms are shown. The Naive streaming algorithm is the fastest, requiring similar time over every ordering. The ascending ordering requires more time for both greedy swapping and

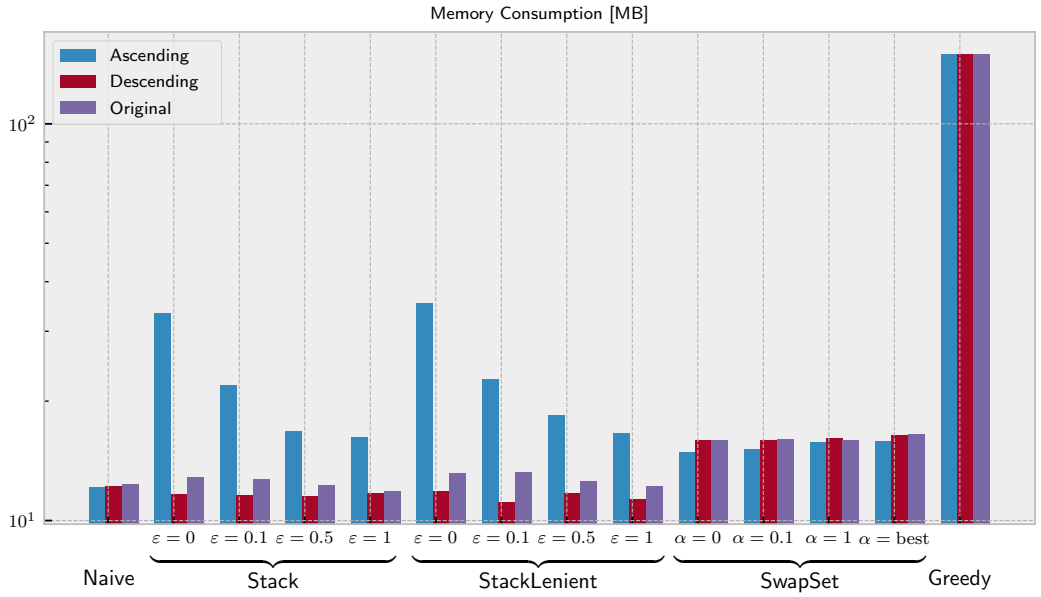

Figure 2 Geometric mean of the memory consumption on the social-link hypergraphs. Note the log-scale on the y-axis.

stack-based approaches since more replacements in the swapping algorithm and placements in the stack happen in that order. The stack-based approaches have a running time only 26% higher than the Naive. We observe that preordering the hyperedges speeds up the offline Greedy algorithm by a factor of 2.73 in comparison to the original ordering, but it is still slower than the stack-based algorithms. This is due to our use of std::sort that is partly optimized for ordered data. The running time of the SwapSet algorithms is comparable to the running time of Greedy with natural ordering. The cost for voiding edges in the SwapSet algorithm is higher than simply pushing edges on the stack. In general, the streaming process of Stack and StackLenient is similar to that of Naive. The small overhead is rooted in the required pass through the stack to build the matching. The ordering affects how many edges are added to the stack (see the following Memory section) and so the running time as well, but not as much as in the Greedy algorithm.

Quality. We present the geometric mean of the weights of matchings in Figure 4. As expected, the Greedy algorithm is not affected by the ordering since it computes its own order in the beginning. The quality of Naive algorithm is heavily affected by orderings, where the best weight is achieved when the hyperedges are streamed in descending order. On ascending and original order, the quality of the Naive is significantly worse. Under the descending orderings, the swapping algorithm (SwapSet) produces the same results as the Greedy algorithm, whereas the ascending order produces worse quality results in the SwapSet algorithm. The Stack and StackLenient approaches are more robust under different orderings and compute better quality matchings in the adversarial ascending order compared to other algorithms..

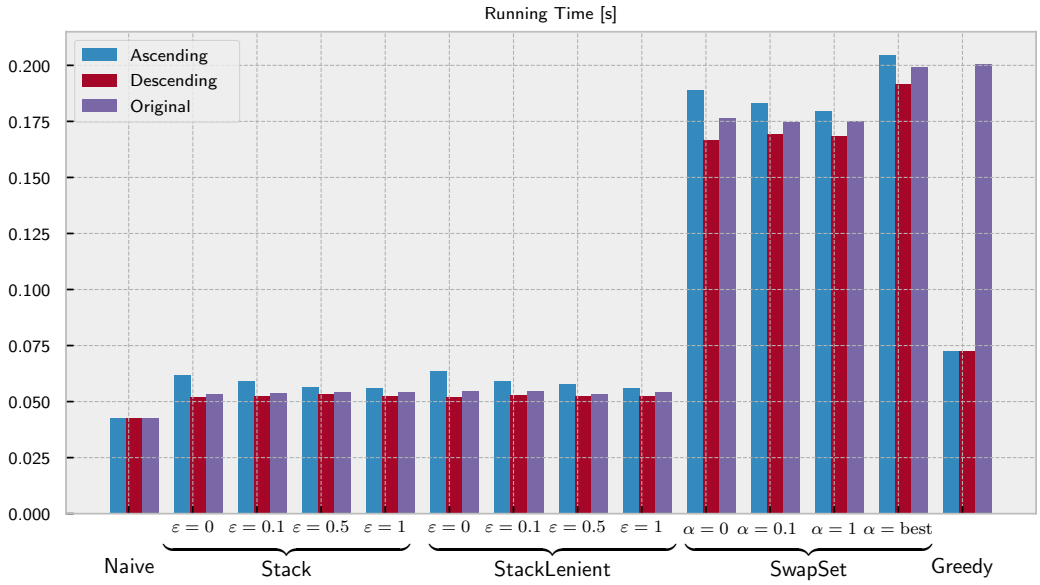

Figure 3 Geometric mean of running times on the social-link hypergraphs.

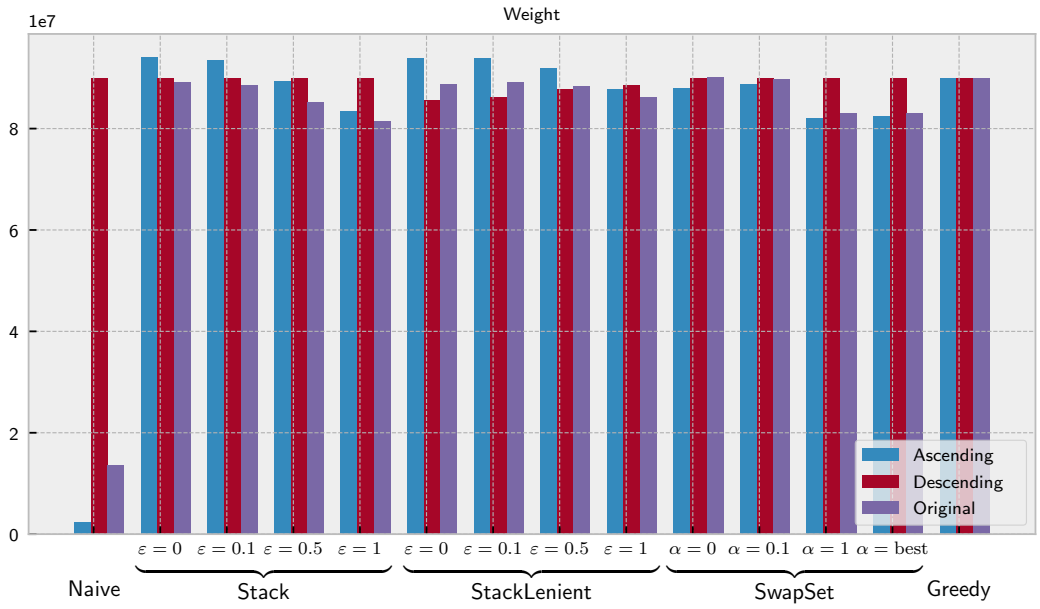

Figure 4 Geometric mean of weights on the social-link hypergraphs.

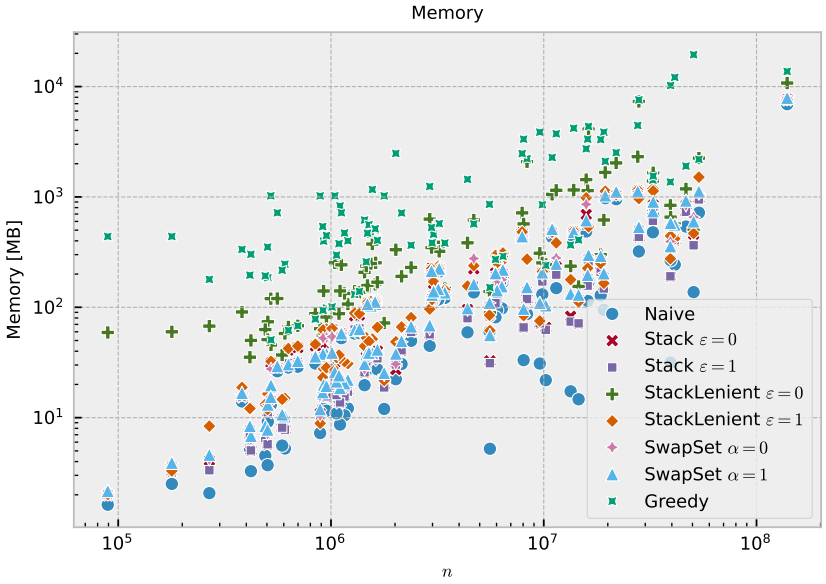

Figure 5 Geometric mean of the memory consumption on hypergraphs from partitioning plotted against the number of vertices.

5.3 Impact of Other Properties

We now test whether some other properties of the instances have an impact on the memory consumption of the algorithm (**RQ2**). Namely, we check if the number of vertices and the number of pins (sum of all edge sizes) are correlated with the memory consumption. We use the data set by Gottesbüren et al. [20] from hypergraph partitioning, which contains many larger-scale instances. This data set contains 94 diverse instances, making it more suitable for statistical testing. The ordering is the original ordering as given by the files in [20]. Instance details can be found in the Appendix of the full version. A hyperedge e in these instances has a weight of $(\max_{e \in E} |e|) - |e|$, optimizing the number of hyperedges matched. We set ε (and also α) to $\{0, 1\}$ since they represent the two extremes in terms of memory usage.

Number of Vertices. Figure 5 shows the memory consumption plotted against the number of vertices in each instance. The plot is on a log-log-scale. Naturally, Naive requires the least amount of memory. Our SwapSet algorithm follows, as well as the Stack algorithm and the StackLenient. Finally, the offline Greedy requires even more memory. This is also backed by the theoretical results of Sections 3.3 and 4. The higher the number of vertices, the smaller is the difference in magnitudes between the approaches. This is due to the additional memory needed for the list of finally matched hyperedges and the overhead in some allocations. The measured peak allocation may contain some overallocated memory caused by the growing result vectors.

Number of Pins. In Figure 6, a plot of the geometric mean memory consumption against the number of pins (sum of all edge sizes) for our approaches and the competitors is shown. Additionally, we added a linear regression line for the Greedy algorithm's memory consumption. The linear model achieves an R^2 score of 0.96 when (randomly) splitting the data set into a

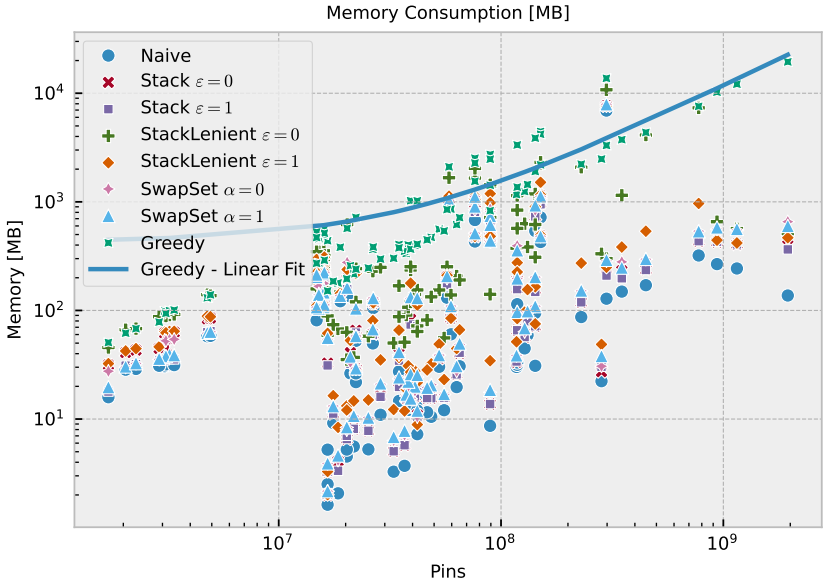

Figure 6 Geometric mean of the memory consumption on the hypergraphs from partitioning. Linear Regression line for the offline Greedy algorithm.

training ($n = 75$) and evaluation test set ($n = 19$), on the latter. This shows that the greedy algorithm requires memory linear in the number of pins since it loads the whole hypergraph at the start. Our proposed algorithms require less memory, especially the SwapSet algorithms nearly match the memory consumption of the Naive approach.

Other Properties. We also tested the dependence of the memory consumption on the average hyperedge size and the number of hyperedges, but found no pattern. Note that the number of pins is equal to the product of the number of edges and the average hyperedge size.

5.4 Comparison with Offline Greedy and Naive Streaming

In this section, we compare the algorithms on the instances stemming from hypergraph partitioning (**RQ3**). The Results on the social set of instances can be found in Section 5.2. Figure 7 shows a performance profile for the cardinality/size of the matchings for our algorithms as well as the Naive streaming and offline Greedy algorithm. The StackLenient variant with $\varepsilon = 0$ computes the biggest matchings and is the best performing algorithm, followed by SwapSet $\alpha = 0$. The Greedy algorithm has similar results to StackLenient $\varepsilon = 1$. The Stack $\varepsilon = 1$ and SwapSet $\alpha = 1$ are our worst-performing algorithms, having results very close to the Naive streaming algorithm. Their higher parameters ($\alpha = \varepsilon = 1$) cause the algorithm to converge to the naive algorithm.

6 Conclusion

We have proposed two (semi-)streaming algorithms for hypergraph matching. The first, inspired by Paz-Schwartzman [33], uses a stack and adds hyperedges to it, based on dual variables it keeps track of and updates according to an update function. The approximation

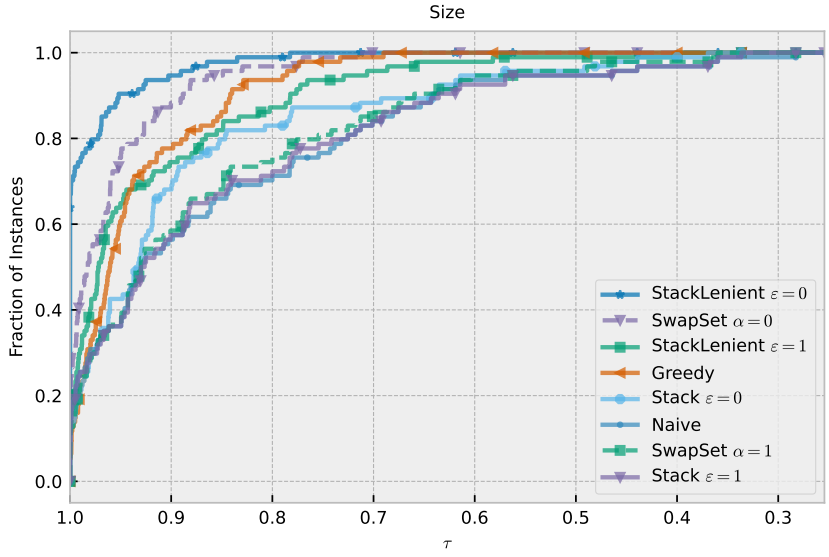

Figure 7 Performance Profile for the size of the matching in hypergraphs used in partitioning.

guarantee for this algorithm is $\frac{1}{d(1+\varepsilon)}$, and its running time per hyperedge is linear in hyperedge size. We have proposed two other update functions to be used in this algorithm. The proposed update functions result in a space complexity of $\mathcal{O}((1/\varepsilon)n\log^2 n)$ and $\mathcal{O}((1/\varepsilon)nd\log^2 n)$ bits. The second proposed algorithm works by greedily swapping out hyperedges and maintaining only one solution, requiring only $\mathcal{O}(n)$ memory. Inspired by McGregor's $\frac{1}{3+2\sqrt{2}}$-approximation guarantee [31], we have shown that if every swap increases the weight by at least $(1+\alpha)$, the algorithm has an approximation guarantee of $\frac{1}{(1+\alpha)\left(\frac{d-1}{\alpha}+d\right)}$. The best choice is $\alpha = \sqrt{(d-1)/d}$.

In extensive experiments, we have shown the competitiveness of the proposed algorithms in comparison to the standard non-streaming Greedy and a Naive streaming approach with respect to running time, memory consumption, and quality. We showed that the order of the hyperedges in the stream directly impacts the solution quality and that our stack algorithms handle worst-case orderings (like ascending weights for the Naive algorithm) even better than the offline Greedy algorithm. The running times of our Stack algorithm are only 26% higher than the Naive algorithm. Furthermore, we validated that the memory consumption for both families of algorithms is not linear in the number of pins, as it is for the Greedy algorithm; for the Stack approaches on the social link hypergraphs it is 13 times lower than Greedy. Lastly, we report that our algorithm obtains considerably better cardinality matchings in general hypergraphs from partitioning tasks.

Avenues of future work include improving the solution quality and extending to problems with relaxed capacity constraints. We aim to develop a streaming algorithm that can efficiently handle instances with capacity $b(v) > 1$ at each vertex, while maintaining a reasonable approximation ratio and computational overhead.

Online Metric TSP

Christian Bertram
University of Copenhagen, Denmark

Abstract

In the *online metric traveling salesperson problem*, n points of a metric space arrive one by one and have to be placed (immediately and irrevocably) into empty cells of a size-n array. The goal is to minimize the sum of distances between consecutive points in the array. This problem was introduced by Abrahamsen, Bercea, Beretta, Klausen, and Kozma [ESA'24] as a generalization of the *online sorting problem*, which was introduced by Aamand, Abrahamsen, Beretta, and Kleist [SODA'23] as a tool in their study of online geometric packing problems.

Online metric TSP has been studied for a range of fixed metric spaces. For 1-dimensional Euclidean space, the problem is equivalent to online sorting, where an optimal competitive ratio of $\Theta(\sqrt{n})$ is known. For d-dimensional Euclidean space, the best-known upper bound is $O(2^d\sqrt{dn\log n})$, leaving a gap to the $\Omega(\sqrt{n})$ lower bound. Finally, for the uniform metric, where all distances are 0 or 1, the optimal competitive ratio is known to be $\Theta(\log n)$.

We study the problem for a general metric space, presenting an algorithm with competitive ratio $O(\sqrt{n})$. In particular, we close the gap for d-dimensional Euclidean space, completely removing the dependence on dimension. One might hope to simultaneously guarantee competitive ratio $O(\sqrt{n})$ in general and $O(\log n)$ for the uniform metric, but we show that this is impossible.

1 Introduction

1.1 Problem definition

The *online metric traveling salesperson problem* (online metric TSP), recently introduced by Abrahamsen, Bercea, Beretta, Klausen, and Kozma [2], is as follows. Given a sequence $x_1, \ldots, x_n$ of points arriving one by one (with repetitions allowed) from a metric space (M, d), assign them bijectively to array cells $A[1], \ldots, A[n]$. The goal is to minimize $\sum_{i=1}^{n-1} d(A[i], A[i+1])$, which represents the length of the walk $A[1], \ldots, A[n]$. The problem is *online* in the sense that after receiving x_i, we must immediately and irrevocably set $A[j] = x_i$ for some previously unused array index j, without knowledge of x_k for $k > i$.

We can think of this as a metric traveling salesperson problem, where n cities are sequentially revealed, one by one, and must be placed on a unique date in the salesperson's n-day calendar. The cost to be minimized is the length of the final n-day trip.

In [2], the metric space is fixed as 1-dimensional Euclidean space, d-dimensional Euclidean space, or a space with uniform/discrete metric (where all distances are 0 or 1). In this paper, we study the problem for a general metric space, allowing the algorithm to query the distance $d(x_i, x_j)$ between x_i and x_j, if it has received x_i and x_j. Alternatively, the ith input can be assumed to be the vector $(d(x_i, x_1), d(x_i, x_2), \ldots, d(x_i, x_{i-1}))$.

The term "online TSP" has also been used for a different, older problem where a salesperson moves through the metric space at unit speed as cities are revealed [3]. In contrast, our problem consists of constructing a fixed travel plan through irrevocable online decisions.

1.2 Prior work

In [1], the *online sorting problem* is introduced as part of their study of various geometric translational packing problems. The online sorting problem is equivalent to online (metric) TSP in the Euclidean unit interval $[0, 1]$. They further essentially assume that the points 0 and 1 always show up in the input, which simplifies the analysis, as the optimal offline cost becomes 1. They present a deterministic algorithm with competitive ratio $O(\sqrt{n})$ for online sorting (where *competitive ratio* is the worst-case ratio between the algorithm's cost and the optimal offline cost), and show an $\Omega(\sqrt{n})$ lower bound for deterministic algorithms.

In [2], the online sorting algorithm from [1] is generalized to points from the real line $\mathbb{R}$, not necessarily including 0 and 1, by employing a careful *doubling technique*. They maintain the $O(\sqrt{n})$ competitive ratio, and generalize the $\Omega(\sqrt{n})$ lower bound to randomized algorithms.

In [2], they further generalize the problem to online metric TSP, and consider this problem for a few fixed metric spaces. For d-dimensional Euclidean space, they present an $O(2^d\sqrt{dn\log n})$ competitive ratio algorithm, leaving a gap to their $\Omega(\sqrt{n})$ lower bound. For use as a subroutine in this algorithm, they consider online TSP in the uniform metric, i.e. the metric where all distances are 0 or 1. They argue that this problem has interest in its own right, corresponding to minimizing the number of task switches in scheduling, and present a tight $\Theta(\log n)$ bound on the competitive ratio. Finally, they ask, as an open question, whether $O(\sqrt{n})$ is the optimal competitive ratio for arbitrary metrics.

1.3 Our results

Our main result is an optimal algorithm for online metric TSP in a general metric space, settling a question posed in [2].

▶ **Theorem 1.** *There exists a deterministic algorithm for online metric TSP with competitive ratio $O(\sqrt{n})$.*

This is optimal by the $\Omega(\sqrt{n})$ lower bound for the Euclidean unit interval [1], which holds even for randomized algorithms [2]. As a direct corollary, we get an optimal algorithm for online TSP in d-dimensional Euclidean space, improving upon the best-known $O(2^d\sqrt{dn\log n})$ competitive ratio algorithm [2], completely removing the dependence on dimension.

▶ **Corollary 2.** *There exists a deterministic algorithm for online TSP in d-dimensional Euclidean space with competitive ratio $O(\sqrt{n})$.*

Note, though, that the $O(\sqrt{n})$ bound of Theorem 1 does not match the known $\Theta(\log n)$ bound for online TSP with uniform metric [2]. One might hope for an even stronger algorithm, obtaining an asymptotically optimal competitive ratio for every fixed metric space. We show that no such algorithm exists, hinting that our algorithm is the best one can hope for.

▶ **Theorem 3.** *No randomized algorithm for online metric TSP obtains both $O(\log n)$ expected competitive ratio for the uniform metric and $O(\sqrt{n})$ expected competitive ratio in general.*

1.4 Structure of the paper

In Section 2, we recall relevant definitions and fix notation. In Section 3, we present our algorithm, proving Theorem 1 and Corollary 2. In Section 4, we confirm the worst-case optimality of our algorithm via known lower bounds, and then we show that no algorithm is simultaneously optimal for every fixed metric, proving Theorem 3.

2 Preliminaries

We will often let (M, d) be a metric space, where M is the set of points, and $d\colon M \times M \to \mathbb{R}_{\geq 0}$ is the metric. Our main examples are d-dimensional Euclidean space and the uniform metric.

The *uniform metric* is defined by $d(x, y) = 1$ for all $x \neq y$. This is also known as the *discrete metric*, but we adopt the former term for consistency with [2]. Any set of points can form a metric space under the uniform metric.

Though our algorithms run in polynomial time, we do not focus on their exact running times. Instead, we evaluate performance via *competitive analysis*, as is standard in the study of online algorithms. Let $\texttt{OPT}(X)$ denote the optimal offline cost for an input sequence $X \in M^n$. An online algorithm is said to have *competitive ratio* $C(n)$, for a function $C\colon \mathbb{N} \to \mathbb{R}$, if its cost is at most $C(n)\,\texttt{OPT}(X)$ for all $n \in \mathbb{N}$ and all $X \in M^n$.

In our setting, the cost is $\sum_{i=1}^{n-1} d(A[i], A[i+1])$, and $\texttt{OPT}(X)$ is the minimum value of this sum, minimized over all bijections from the input points in X to array cells $A[1], \ldots, A[n]$. By the triangle inequality, $\texttt{OPT}(X)$ is equal to the length of a shortest walk visiting all points in X. We will sometimes write $\texttt{OPT}(X)$ for a subset $X \subseteq M$, as the optimal offline cost is invariant under permutations and repetitions of the input points.

3 Our algorithm

Our algorithm is based on the algorithms for online sorting presented in [1] and [2]. Let us first give a high-level explanation of their approach. Denote by X' the set of currently received points. They consider an interval J containing X', and partition J into $\sqrt{n}$ subintervals. Specifically, they assume without loss of generality that $x_1 = 0$, and let J be the smallest interval of the form $[-2^k, 2^k]$ containing X', increasing k as necessary. Note that $\texttt{OPT}(X') \geq 2^{k-1}$, so the subintervals have size $O(\texttt{OPT}(X')/\sqrt{n})$. Similarly, they partition the array A into $2\sqrt{n}$ subarrays, called *blocks*. The algorithm generally places the input points into the array, such that no block contains points from different subintervals. This ensures, that they only pay a small $O(\texttt{OPT}(X')/\sqrt{n})$ cost between points inside each block, and pay a large $O(\texttt{OPT}(X'))$ cost only between blocks. The former cost is paid $O(n)$ times, and the latter $O(\sqrt{n})$ times, totaling a cost of $O(\sqrt{n}\,\texttt{OPT}(X'))$. It is always possible to place the first half of the points in this manner, after which they consider the remaining empty array cells as one contiguous array, and recursively fill this simulated array with the remaining input points. This leads to a total cost of $O(\sqrt{n}\,\texttt{OPT}(X))$ as the cost per recursion falls geometrically. Each time k is increased, we incur some additional cost of changing the intervals, but this only happens when the bound on $\texttt{OPT}(X')$ doubles, so again it all sums to $O(\sqrt{n}\,\texttt{OPT}(X))$.

Let us now give a high-level explanation of how we will extend this algorithm from the Euclidean line to a general metric space. There are two main problems to solve: the setting of $J = [-2^k, 2^k]$ and bound of $\texttt{OPT}(X') \geq 2^{k-1}$ no longer make sense. One might naively try letting J be a ball of radius 2^k, but this cannot generally be covered by $\sqrt{n}$ balls of radius $O(2^k/\sqrt{n})$. To see this, think of d-dimensional Euclidean space, where 2^d unit cubes are required to cover a cube of sidelength 2. This is related to why there is a term of size 2^d in

the best-known bound for d-dimensional Euclidean space [2]. We instead present an online algorithm maintaining a set of at most $\sqrt{n}$ balls of radius $r = \Theta(\texttt{OPT}(X')/\sqrt{n})$ covering all received input points. Only when $\texttt{OPT}(X')$ doubles, we allow changing the radius r and resetting the set. Of course, we don't know the value of $\texttt{OPT}(X')$, but it turns out that we can successfully use the minimum spanning tree weight as a (polynomial-time computable) proxy. This proxy will be essential when showing that our covering only needs $\sqrt{n}$ balls.

We begin the formal presentation of our algorithm with the above mentioned proxy.

▶ **Definition 4.** Let (M, d) be a metric space and $X \subseteq M$ a finite subset of points. When the metric d is clear from context, we denote by $\texttt{MST}(X)$ the total weight of a minimum spanning tree of the complete graph on X, where edge weights are given by d.

Computing exact metric TSP length is NP-hard, as follows by a straightforward reduction from the undirected Hamiltonian cycle problem, one of Karp's 21 NP-complete problems [5]. Luckily, there is a simple 2-approximation based on minimum spanning trees [6]. This well-known argument yields the following lemma, which tells us that $\texttt{MST}(X)$ is a good proxy of $\texttt{OPT}(X)$. We provide a proof in the full version of the paper [4].

▶ **Lemma 5.** *Let (M, d) be a metric space and $X \subseteq M$ a finite subset of points. Then $\texttt{MST}(X) \leq \texttt{OPT}(X) \leq 2\,\texttt{MST}(X)$.*

As sketched, our algorithm will cover the input points by a dynamic set of balls. Formally, we will work with a set of *centers* forming a *net* in the following standard manner.

▶ **Definition 6.** Let (M, d) be a metric space and $X \subseteq M$ a set of points. Let $r \geq 0$ be a real number. A subset $C \subseteq X$ is an *r-net* of X if

- for every $x \in X$, there exists a $c \in C$ with $d(c, x) \leq r$, and
- for every $c, c' \in C$ with $c \neq c'$, we have $d(c, c') > r$.

If so, we sometimes refer to each point in C as a *center*, and to r as the *radius* of the net.

Nets will be useful to us, because they are small in terms of our proxy, in the sense of the following lemma.

▶ **Lemma 7.** *Let (M, d) be a metric space, in which C is an r-net of a set $X \subseteq M$. Then $(|C| - 1)r \leq 2\,\texttt{MST}(X)$.*

Proof. By the triangle inequality, we have $\texttt{OPT}(X) \geq \texttt{OPT}(C)$. Combining this with Lemma 5, we get $2\,\texttt{MST}(X) \geq \texttt{OPT}(X) \geq \texttt{OPT}(C) \geq \texttt{MST}(C)$. Every edge in the complete graph on C has length at least r, and a tree on $|C|$ points has $|C| - 1$ edges, so $\texttt{MST}(C) \geq (|C| - 1)r$. ◀

When receiving a new point x, we will generally update our r-net by the following simple subroutine.

Increase-Net(C, r, x)
1. If no $c \in C$ has $d(x, c) \leq r$ then add x to C.

This subroutine allows us to maintain an r-net, for a fixed radius r. We state this as the following lemma, which follows directly from the definition.

▶ **Lemma 8.** *Let (M, d) be a metric space, in which C is an r-net of a set $X \subseteq M$, and let $x \in X$. Then running* Increase-Net(C, r, x) *modifies C only by insertion, such that C becomes an r-net of $X \cup \{x\}$.*

To facilitate analysis, let us introduce two pieces of notation. For a partially filled array A, we write $c(A) = \sum_{i \in I} d(A[i], A[i+1])$ for the *cost* of A, where I is the set of indices i for which both $A[i]$ and $A[i+1]$ are non-empty. Note that this matches the usual cost, when A is full. Secondly, we write $G(A)$ for the number of *gaps* in A, i.e. the number of non-trivial maximal contiguous empty subarrays of A.

We now present "half" of our algorithm, namely an algorithm handling the first $\lceil n/2 \rceil$ input points. First, we give a quick overview. The algorithm will partition the array A into $2\lfloor \sqrt{n} \rfloor$ blocks, and maintain an r-net C with at most $\lfloor \sqrt{n} \rfloor$ centers. If we get too many centers, we will reset the net with a larger radius. Each block may be *assigned* to a center, such that every center is assigned at most one block. Initially, every block is unassigned. Generally, if a newly received point lies within the ball of a center, it will be placed inside the block assigned to that center. The exact algorithm is as follows.

Fill-Most-Blocks(n, A, X)

1. Let $N_1 = \lfloor \sqrt{n} \rfloor$ and $N_2 = 2N_1$.
2. Partition A into N_2 subarrays, called *blocks*, of length at least $\lfloor n/N_2 \rfloor$.
3. Initialize $r = 0$ and $C = \emptyset$.
4. For each point x in the stream X:
   a. Increase-Net(C, r, x).
   b. If $|C| > N_1$:
      I. Unassign all blocks.
      II. Set $r = 4\,\mathtt{MST}(X')/N_1$, where X' is the set of known input points.
      III. Set $C = \{x\}$.
   c. Let $c \in C$ be a center with $d(x, c) \leq r$.
   d. If a full block B is assigned to c:
      I. Unassign B from c.
   e. If no block is assigned to c:
      I. Assign an unassigned non-full block to c.
   f. Let B be the block assigned to c.
   g. Place x in the left-most empty cell of B.

▶ **Lemma 9.** *Let (M, d) be a metric space and X be an online stream of $\lceil n/2 \rceil$ points in M. Let A be an empty array of length n. The deterministic algorithm* Fill-Most-Blocks(n, A, X) *irrevocably places each point from X in an empty cell of A, such that when all points have been placed, we have $G(A) \leq 2\sqrt{n}$ and $c(A) \leq 11\sqrt{n}\,\mathtt{OPT}(X)$.*

Proof. The following two claims show that the algorithm is well-defined.

▷ Claim. After step 4b, C is an r-net of a set containing x.

Proof. Clearly, the claim holds if step 4(b)III just ran, so let us show, that it also holds before and between these resets of the net. This follows by induction, where the base case is step 3 producing an r-net, and the induction step is step 4a with Lemma 8. ◁

▷ Claim. In step 4(e)I, there is always an unassigned non-full block to assign.

Proof. Assume for the sake of contradiction, that no unassigned non-full block exists. Then every block is either assigned or full. There are at most $|C| \leq N_1$ assigned blocks, so at least $N_2 - |C| \geq N_2 - N_1 = N_1$ blocks are full. Note that every assigned block contains at least one point, as right after assigning a block in step 4(e)I, it is given a point in step 4g. So at least

N_1 blocks contain at least $\lfloor n/N_2 \rfloor$ points, and the remaining blocks contain at least one point. This means that the total number of points in A is at least $N_1\lfloor n/N_2 \rfloor + N_1 \geq N_1 n/N_2 = n/2$. This contradicts the stream containing only $\lceil n/2 \rceil$ points, as in step 4(e)I the point x has yet to be placed. ◁

The following two claims show that the algorithm is correct.

▷ Claim. At termination, $G(A) \leq 2\sqrt{n}$.

Proof. Since every point is placed in the left-most empty cell of a block, there is at most one gap per block, so $G(A) \leq N_2 \leq 2\sqrt{n}$. ◁

▷ Claim. At termination, $c(A) \leq 11\sqrt{n}\,\texttt{OPT}(X)$.

Proof. The cost between two neighboring blocks is at most $\texttt{OPT}(X)$, so the total cost between neighboring blocks is at most $N_2\,\texttt{OPT}(X)$. It remains to bound the cost between neighboring cells inside a block. So let x and x' be points placed in neighboring cells inside a block B.

Consider first the case where the net was not reset (steps 4(b)I to 4(b)III) between x and x' being placed. Then B was assigned to the same center c with the same radius r both when x and x' were placed. Let X' be the set of points read right after both x and x' were placed. By the triangle inequality, $\texttt{OPT}(X') \leq \texttt{OPT}(X)$, so by Lemma 5, $d(x,x') \leq d(x,c) + d(c,x') \leq 2r = 8\,\texttt{MST}(X')/N_1 \leq 8\,\texttt{OPT}(X')/N_1 \leq 8\,\texttt{OPT}(X)/N_1$. Since at most $\lceil n/2 \rceil$ points are placed, the total cost between such pairs of points is at most $(\lceil n/2 \rceil - 1)8\,\texttt{OPT}(X)/N_1 \leq 4n\,\texttt{OPT}(X)/N_1$.

Consider now the case where the net was reset between x and x' being placed. Then $d(x,x') \leq \texttt{MST}(X')$ where X' is the set of points read at any point after placing both x and x'. This is a worse bound, but this case can only appear once per block per reset of the net. So the total cost for such pairs of points is at most $N_2\,\texttt{MST}(X')$ for each reset, where X' is the set of points read when resetting. Let X_1 be the set of points read at the point of a reset, or at the beginning of the algorithm, and X_2 be the set of points read at the point of the following reset or when the algorithm terminates. Right before the latter reset, $|C| > N_1$ and $r = 4\,\texttt{MST}(X_1)/N_1$. This is true even if X_1 is the set at the beginning of the algorithm, as then $X_1 = \emptyset$ and $r = 0$. So Lemma 7 gives us that $2\,\texttt{MST}(X_2) \geq (|C| - 1)r \geq N_1 4\,\texttt{MST}(X_1)/N_1 = 4\,\texttt{MST}(X_1)$, which simplifies to $\texttt{MST}(X_2) \geq 2\,\texttt{MST}(X_1)$. The total cost of this type across all rebuilds is thus no more than the geometric series $N_2 \sum_{i=0} 2^{-i}\,\texttt{MST}(X) = 2N_2\,\texttt{MST}(X) \leq 2N_2\,\texttt{OPT}(X)$, where the last inequality uses Lemma 5.

The total cost $c(A)$ at termination is thus at most $(N_2 + 4n/N_1 + 2N_2)\,\texttt{OPT}(X)$. It can be checked that $N_2 + 4n/N_1 + 2N_2 \leq 11\sqrt{n}$, finishing the proof. ◁

The combination of the above claims finishes the proof. ◀

We are now ready to present our full algorithm, which recursively applies Fill-Most-Blocks, analogously to [1, 2]. The algorithm begins by placing the first half of the input points into the array A using Fill-Most-Blocks. It then treats the remaining empty cells of A as a contiguous array A_{empty}. The algorithm proceeds recursively on A_{empty}, treating it as a standard array; however, when a point is placed in A_{empty}, it is actually placed into the corresponding cell of A. The exact algorithm is given below as Recursively-Fill-Most-Blocks.

▶ **Theorem 10.** *Let (M,d) be a metric space and X be an online stream of n points in M. Let A be an empty array of length n. The deterministic algorithm* Recursively-Fill-Most-Blocks(n,A,X) *irrevocably places each point from X in an empty cell of A, such that when all points have been placed, we have $c(A) \leq 52\sqrt{n}\,\texttt{OPT}(X)$.*

Recursively-Fill-Most-Blocks(n, A, X)
1. If $n = 0$ then return.
2. Let X_{prefix} be the stream consisting the first $\lceil n/2 \rceil$ points of X.
3. Fill-Most-Blocks$(n, A, X_{\text{prefix}})$.
4. Consider the empty cells of A as one contiguous array A_{empty}.
5. Let X_{suffix} be the stream consisting the remaining $\lfloor n/2 \rfloor$ points of X.
6. Recursively-Fill-Most-Blocks$(\lfloor n/2 \rfloor, A_{\text{empty}}, X_{\text{suffix}})$.

Proof. We will show a cost of at most $15(2+\sqrt{2})\sqrt{n}\,\texttt{OPT}(X)$ using strong induction on n. The base case $n = 0$ is trivial, so let us handle the inductive step. Let A' denote the array A after step 3. Then $G(A') \leq 2\sqrt{n}$ and $c(A') \leq 11\sqrt{n}\,\texttt{OPT}(X_{\text{prefix}}) \leq 11\sqrt{n}\,\texttt{OPT}(X)$ by Lemma 9 and the triangle inequality. By induction, we have $c(A_{\text{empty}}) \leq 15(2+\sqrt{2})\sqrt{n/2}\,\texttt{OPT}(X)$. The final cost $c(A)$ is the sum of $c(A')$, $c(A_{\text{empty}})$, and the costs between neighboring cells in A where exactly one of the cells was empty in A'. The latter is at most $2G(A')\,\texttt{OPT}(X) \leq 4\sqrt{n}\,\texttt{OPT}(X)$, as there are at most two such pairs of neighboring cells per gap in A'. The total cost becomes $c(A) \leq (11 + 15(2+\sqrt{2})/\sqrt{2} + 4)\sqrt{n}\,\texttt{OPT}(X) = 15(2+\sqrt{2})\,\texttt{OPT}(X)$. ◀

From Theorem 10, we immediately get Theorem 1 and Corollary 2. We have thus generalized the optimal upper bound for online sorting [2] to online metric TSP, in particular improving the best-known upper bound for online TSP in d-dimensional Euclidean space. In Section 4 we show, that our algorithm is optimal for both general online metric TSP, online TSP in d-dimensional Euclidean space, and more.

4 Optimality

It follows directly from a known lower bound for online sorting [1, 2] that our algorithm is optimal. Recall that online sorting is equivalent to online TSP in 1-dimensional Euclidean space.

▶ **Theorem 11** (Theorem 1 in [2]). *The (deterministic and randomized) competitive ratio of online TSP in the Euclidean unit interval* $[0, 1]$ *is* $\Omega(\sqrt{n})$.

In particular, this gives a lower bound of $\Omega(\sqrt{n})$ for general online metric TSP, showing that our $O(\sqrt{n})$ algorithm Recursively-Fill-Most-Blocks from Section 3 is optimal. Perhaps surprisingly, online metric TSP is no harder than online sorting.

Since the Euclidean unit interval lies inside d-dimensional Euclidean space, Theorem 11 also shows that our $O(\sqrt{n})$ algorithm is optimal for online TSP in d-dimensional Euclidean space. We have thus closed the gap for this problem, improving upon the best known upper bound of $O(2^d\sqrt{dn\log n})$ [2], notably removing the dependence on dimension.

Studying the proof of the above lower bound, we find the following generalization. Intuitively, the generalization gives us a lower bound of $\Omega(\sqrt{n})$ for online TSP in any metric space where we can draw a straight line segment (of length ℓ with endpoints a_0 and a_1) and pick m evenly spaced points along it.

▶ **Corollary 12.** *Let* (M, d) *be a metric space, such that for every* $m \in \mathbb{N}$*, there exist two points* $a_0, a_1 \in M$*, and a set* $X \subseteq M$ *of* m *points, such that, for* $\ell = \texttt{OPT}(X \cup \{a_0, a_1\})$*,*
- $d(x, y) \geq \ell/m$ *for all distinct* $x, y \in X$*, and*
- $d(a_0, x) + d(x, a_1) \geq \ell$ *for all* $x \in X$*.*

Then the competitive ratio of online TSP in (M, d) *is* $\Omega(\sqrt{n})$.

Proof. This follows from the proof of Theorem 11 presented in Section 2 of [2]. They work in the Euclidean unit interval, but only use the points $a_0 = 0$, $a_1 = 1$, and the set of points $X = \{0, 1/\sqrt{n}, \ldots, (\sqrt{n}-1)/\sqrt{n}\}$. Ignoring the concrete values of the points a_0, a_1, and those in X, it can easily be checked, that they only use the properties stated above, where $m = \sqrt{n}$ and $\ell = 1$. The proof also follows through for any other $\ell > 0$, where all distances in their proof simply scale by ℓ. ◀

This tells us that our algorithm is also optimal for online TSP in e.g. (subgroups of) normed vector spaces and Riemannian manifolds.

4.1 Impossibility of optimality for every fixed metric space

We have seen, that our $O(\sqrt{n})$ algorithm is optimal for general online metric TSP, as well as for online TSP in many fixed metric spaces. It is not optimal for every fixed metric space, though, as an algorithm with competitive ratio $O(\log n)$ is known for the uniform metric [2]. Motivated by this gap, one might ask whether there exists a stronger algorithm, which optimally solves online TSP in (M, d), for every fixed metric space (M, d). In this subsection, we show that no such algorithm exists. This hints, that the weaker optimality of our algorithm is the best one can hope for.

Specifically, we show that no algorithm is optimal both for the uniform metric and for a general metric space. This is the content of Theorem 3, which we restate and prove below.

▶ **Theorem 3.** *No randomized algorithm for online metric TSP obtains both $O(\log n)$ expected competitive ratio for the uniform metric and $O(\sqrt{n})$ expected competitive ratio in general.*

Proof. Assume for the sake of contradiction that such an algorithm $\mathcal{A}$ exists. Let us first informally explain our basic idea. Let U be a set of $n^{4/5}$ points with pairwise distance 1, and let x be a point with distance $n^{4/5}$ to every point in U. Consider an input consisting $n^{1/5}$ consecutive copies of U. Then the optimal offline cost is $\texttt{OPT}(U) = |U| - 1 = n^{4/5} - 1$. The only way for $\mathcal{A}$ to match this optimal cost, would be to maintain $\Omega(|U|) = \Omega(n^{4/5})$ gaps until completion. Similarly, since $\mathcal{A}$ actually must obtain nearly-optimal cost $O(n^{4/5} \log n)$, it must have at least $n^{3/5}$ gaps at some point. But when this happens, we can trick $\mathcal{A}$ by changing the remaining input to be copies of x, filling up all these gaps. Then the cost becomes at least $n^{3/5}n^{4/5}$ which breaks the promise of competitive ratio $O(\sqrt{n})$, since $\texttt{OPT}(U \cup \{x\}) = 2n^{4/5} - 1$.

We now formally prove the theorem. Let $\mathcal{X}$ be the random input served by Oblivious-Random-Adversary(n), which we define below.

Oblivious-Random-Adversary(n)
1. Let U be a set of $n^{4/5}$ points with pairwise distance 1.
2. Let x be a point with distance $n^{4/5}$ to every point in U.
3. While less than n points have been served:
   a. With probability $n^{-3/5}$:
      I. Let m be the number of points served.
      II. Serve $n - m$ copies of x.
   b. Otherwise:
      I. Serve a copy of the points in U.

By closely following the proof of Theorem 11, replacing their random input by $\mathcal{X}$, we get that the expected cost of any deterministic algorithm on $\mathcal{X}$ is $\Omega(n)$. A full proof can be found in the full version of the paper [4].

Let $\mathcal{A}(\mathcal{X})$ denote the cost of $\mathcal{A}$ on $\mathcal{X}$. Considering $\mathcal{A}$ as a random variable over deterministic algorithms, we get $\mathbb{E}[\mathcal{A}(\mathcal{X})] \in \Omega(n)$. We will now derive an upper bound contradicting this lower bound. To utilize our assumed competitive ratio for the uniform metric, note that $\mathcal{X}$ follows the uniform metric when $x \notin \mathcal{X}$. From the definition of Oblivious-Random-Adversary, we have $\Pr[x \in \mathcal{X}] = 1 - \Pr[x \notin \mathcal{X}] = 1 - (1 - n^{-3/5})^{n^{1/5}} \leq n^{-2/5}$, using Bernoulli's inequality. Using this bound, we get

$$\begin{aligned}\mathbb{E}[\mathcal{A}(\mathcal{X})] &= \Pr[x \in \mathcal{X}]\,\mathbb{E}[\mathcal{A}(\mathcal{X}) \mid x \in \mathcal{X}] + \Pr[x \notin \mathcal{X}]\,\mathbb{E}[\mathcal{A}(\mathcal{X}) \mid x \notin \mathcal{X}] \\ &\leq n^{-2/5}\,\mathbb{E}[\mathcal{A}(\mathcal{X}) \mid x \in \mathcal{X}] + \mathbb{E}[\mathcal{A}(\mathcal{X}) \mid x \notin \mathcal{X}].\end{aligned}$$

By assumption, $\mathcal{A}$ has competitive ratio $O(\sqrt{n})$ in general, and competitive ratio $O(\log n)$ when x is not in the input. It's easy to see that $\texttt{OPT}(\mathcal{X}) \in O(n^{4/5})$, so we have $\mathbb{E}[\mathcal{A}(\mathcal{X}) \mid x \in \mathcal{X}] \in O(n^{4/5}\sqrt{n})$ and $\mathbb{E}[\mathcal{A}(\mathcal{X}) \mid x \notin \mathcal{X}] \in O(n^{4/5} \log n)$. In total, $\mathbb{E}[\mathcal{A}(\mathcal{X})] \in O(n^{-2/5} n^{4/5} \sqrt{n} + n^{4/5} \log n) \subseteq o(n)$, contradicting $\mathbb{E}[\mathcal{A}(\mathcal{X})] \in \Omega(n)$. ◀

5 Open questions

Both [1] and [2] additionally study a variant of the problem with extra space. In this variant, the array is of length γn for some $\gamma > 1$, and empty cells are ignored in the cost function. A significant gap between the best-known upper and lower bound remains, even for online sorting of reals with extra space [1]. For the uniform metric, a tight $\Theta(1 + \log(\gamma/(\gamma - 1)))$ competitive ratio is known [2]. We repeat it as an open question to tighten the gap for online sorting of reals with extra space, and suggest the introduction of an algorithm for online metric TSP with extra space.

Institute of Mathematics, Physics and Mechanics, Slovenia

Abstract

We prove that the single-source shortest-path problem on disk graphs can be solved in $O(n \log n)$ expected time, and that it can be solved on intersection graphs of fat triangles in $O(n \log^3 n)$ time.

1 Introduction

Finding shortest paths in graphs is a classic topic covered in all basic courses and textbooks on algorithms. In the most basic setting, which is the setting we consider here, the graph is unweighted and the length of a path refers to the number of edges in the path. In the single-source shortest-path (SSSP) problem, the task is to compute shortest paths from a given vertex, the *source*, to all other vertices of the graph. The solution is represented using a so-called *shortest-path tree*.

The SSSP problem for a graph with n vertices and m edges can be solved in $O(n + m)$ time by breadth-first search, which is optimal if the graph is given as a collection of vertices and edges. In this paper we will consider the SSSP problem for implicitly defined graphs. In particular, we consider (planar) *intersection graphs*: graphs whose node set corresponds to a set $\mathcal{D}$ of n objects in the plane and that contain an edge (D, D') between two distinct objects $D, D' \in \mathcal{D}$ iff D and D' intersect. If the objects in $\mathcal{D}$ are disks then the intersection graph, which we denote by $\mathcal{G}^\times[\mathcal{D}]$, is called a *disk graph* – see Figure 1 – and if all disks have unit radius then it is called a *unit-disk graph*. Disk graphs are arguably the most popular and widely studied intersection graphs. One can solve the SSSP problem on intersection graphs by first constructing $\mathcal{G}^\times[\mathcal{D}]$ explicitly and then running breadth-first search. In the worst case, however, this requires $\Omega(n^2)$ time. This raises the question: is it possible to solve the SSSP problem on intersection graphs in subquadratic time in the worst case?

Given the basic nature of the SSSP problem and the prominence of (unit-)disk graphs, it is not surprising that this question has already been considered for such graphs. For unit disks, Roditty and Segal [24] noticed that the dynamic data structure of Chan [6] for

© Mark de Berg and Sergio Cabello;

nearest-neighbor queries can be used to solve the problem in $O(n \operatorname{polylog} n)$ expected time. Cabello and Jejčič [4] gave an $O(n \log n)$ algorithm and showed that this is asymptotically optimal in the algebraic decision-tree model. They remarked that Efrat noted that the semi-dynamic data structure of Efrat, Itai and Katz [14] also gives an algorithm with running time $O(n \log n)$. Finally, Chan and Skrepetos [8] provided a simpler $O(n \log n)$ algorithm. The above algorithms either use Delaunay triangulations [4] or fixed-resolution grids [8, 14]; these approaches are not applicable for disks of arbitrarily different sizes.

For arbitrary disks graphs, Kaplan et al. [20] and Liu [22] presented algorithms running in $O(n \log^4 n)$ time. This was recently improved by Klost [21], who presented a general framework for solving SSSP problems in intersection graphs. She used the framework to obtain an $O(n \log^2 n)$ algorithm for the SSSP problem on disk graphs, and to obtain an $O(n \log n)$ algorithm for intersection graphs of axis-aligned squares.

Our results. Our main result in this paper is an algorithm for the SSSP problem in disk graphs that runs in $O(n \log n)$ expected time. We obtain this result using a version of the framework proposed by Klost [21]; our specialized framework and its relation to Klost's framework are discussed in detail in Section 2. A core ingredient in the framework is a *clique-based contraction* of the intersection graph $\mathcal{G}^\times[\mathcal{D}]$: a graph obtained from $\mathcal{G}^\times[\mathcal{D}]$ by contracting certain cliques to single nodes. To compute such a clique-based contraction in $O(n \log n)$ time, we combine shifted quadtrees [5] and skip quadtrees [15] – powerful and beautiful concepts that we believe deserve more attention – with standard techniques for stabbing fat objects.

Our algorithm for computing a clique-based contraction not only applies to disk graphs but also to intersection graphs of *fat triangles*, that is, triangles all of whose internal angles are lower bounded by a fixed constant $\alpha > 0$ [2]. By combining this with a novel intersecting-detection data structure for fat triangles, we obtain an $O(n \log^3 n)$ algorithm for the SSSP problem on intersection graphs of fat triangles. We are not aware of previous work on the SSSP problem for fat triangles. The all-pairs shortest-path (APSP) problem, however, has been considered for fat triangles, by Chan and Skrepetos [9]. The algorithm they present runs in $O(n^2 \log^4 n)$ time, under the condition that the fat triangles have roughly the same size. (They also present an $O(n^2 \log n)$ algorithm for the APSP problem for arbitrary disk graphs, and an $O(n^2)$ algorithm for unit-disk graphs [8].) Running our new SSSP algorithm n times, once for each input triangle as the source, we obtain an APSP algorithm for arbitrarily-sized fat triangles that runs in $O(n^2 \log^3 n)$ time. This is faster and more general than the algorithm of Chan and Skrepetos. (The improvement for the APSP problem is mainly because of our new intersection-detection data structure for fat triangles; using this data structures in the existing algorithm [9] would also give an $O(n^2 \log^3 n)$ algorithm.)

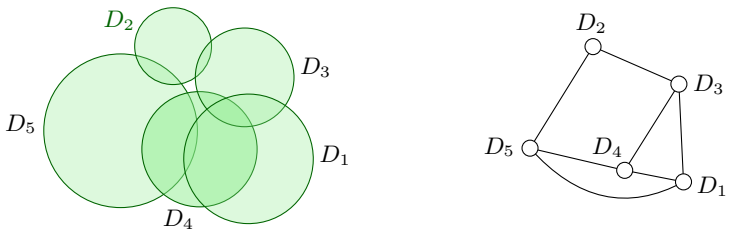

Figure 1 A set $\mathcal{D}$ of five disks (left) and their intersection graph (right).

In the full version of this work [11] we provide two enhancements: we obtain a *deterministic* $O(n \log n)$ algorithm for the SSSP problem in disk graphs and we reduce the running time for the SSSP problem on intersection graphs of fat triangles to $O(n \log^2 n)$. The basic structure of the algorithms is the same as here, but we improve some of the subroutines that we use.

On the model of computation. We use the real-RAM model – this is the standard model in computational geometry, which allows us for example to check in $O(1)$ time if two disks intersect – extended with an additional operation that allows us to compute a compressed quadtree on a set of n points in $O(n \log n)$ time. This extension is common when working with quadtrees; see the book by Har-Peled [19].

2 The framework

Our framework for computing a shortest-path tree on an intersection graph $\mathcal{G}^\times[\mathcal{D}]$ is an instantiation of the framework of Klost [21]. We describe it in detail to keep the paper self-contained and make the required subroutines explicit; at the end of this section we discuss the correspondence of our approach to that of Klost. For convenience, we will from now on not distinguish between the objects in the set $\mathcal{D}$ and the corresponding nodes in $\mathcal{G}^\times[\mathcal{D}]$.

Let $D_{\text{src}} \in \mathcal{D}$ be the given source node, and let $\mathcal{T}_{\text{sp}}$ be the shortest-path tree of $\mathcal{G}^\times[\mathcal{D}]$ that we want to compute for the given source. For an object $D \in \mathcal{D}$, let $\text{dist}[D]$ be the distance from D_{src} to D in $\mathcal{G}^\times[\mathcal{D}]$, and let $L_\ell := \{D \in \mathcal{D} : \text{dist}[\mathcal{D}] = \ell\}$. Thus, L_ℓ is the set of nodes at level ℓ in $\mathcal{T}_{\text{sp}}$. We follow the natural approach of computing $\mathcal{T}_{\text{sp}}$ level by level. To be able to go from one level to the next, we need a subroutine for the following problem.

> Bichromatic Intersection Testing. Given a set B of n_B blue objects and a set R of n_R red objects, report the blue objects that intersect at least one red object, and for each reported blue object, report a witness (a red object intersecting it).

A subroutine *BIT-Subroutine* that solves Bichromatic Intersection Testing allows us to compute $L_{\ell+1}$ by setting $R := L_\ell$ and $B := \mathcal{D}_{\text{cand}}$, where $\mathcal{D}_{\text{cand}}$ is a set of *candidate objects* that should contain all objects from $L_{\ell+1}$ and no objects from $L_{\leqslant \ell}$, where $L_{\leqslant \ell} := \bigcup_{i=0}^{\ell} L_i$. We could simply set $\mathcal{D}_{\text{cand}} := \mathcal{D} \setminus L_{\leqslant \ell}$, but this will not be efficient; we must keep the total size of the candidates sets over all levels ℓ under control. We do this using a so-called clique-based contraction, as defined next.

Let $\mathcal{G} = (V, E_{\mathcal{G}})$ be an (undirected) graph. We say that a graph $\mathcal{H} = (\mathcal{C}, E_{\mathcal{H}})$ is a *clique-based contraction* of $\mathcal{G}$ if

- each node $C \in \mathcal{C}$ corresponds to a clique in $\mathcal{G}$ and the cliques in $\mathcal{C}$ form a partition[1] of the nodes in V;
- there is an edge $(C, C') \in E_{\mathcal{H}}$ iff there are nodes $v \in C$ and $v' \in C'$ such that $(v, v') \in E_{\mathcal{G}}$.

Note that for each edge $(v, v') \in E_{\mathcal{G}}$ there exists a clique $C \in \mathcal{C}$ that contains both v and v', or there are cliques $C \ni v$ and $C' \ni v'$ such that $(C, C') \in E_{\mathcal{H}}$.

A clique-based contraction $\mathcal{H}$ of the intersection graph $\mathcal{G}^\times[\mathcal{D}]$ helps us to find good candidate sets. To see this, let $\mathcal{C}_\ell \subset \mathcal{C}$ denote the set of cliques[2] that contain at least one object from L_ℓ. Then any object $D \in L_{\ell+1}$ must be part of a clique C that is either in $\mathcal{C}_\ell$

[1] In our application, it would also be sufficient to require that each node in V appears in $O(1)$ cliques, but we do not need this extra flexibility.

[2] With a slight abuse of terminology, we not only use the term *clique* to refer a complete graph, but also to refer to a set of geometric objects whose intersection graph is a clique.

itself or that is a neighbor in $\mathcal{H}$ of a clique in $\mathcal{C}_\ell$. In other words, if $D \in L_{\ell+1}$ then $D \in C$ for some clique $C \in N_{\mathcal{H}}[\mathcal{C}_\ell]$, where $N_{\mathcal{H}}[\mathcal{C}_\ell]$ denotes the closed neighborhood of $\mathcal{C}_\ell$ in $\mathcal{H}$. Moreover, the objects in a clique are in at most two levels in the shortest-path three $\mathcal{T}_{\text{sp}}$, which helps to control the total size of the candidate sets. The following pseudocode describes our framework in detail. It does not explicitly construct the shortest-path tree itself (it only constructs the levels), but this is easy to do using the witnesses reported by *BIT-Subroutine*.

Algorithm 1 *SSSP-for-Geometric-Intersection-Graphs*$(\mathcal{D}, D_{\text{src}})$.

1: Construct a clique-based contraction $\mathcal{H} = (\mathcal{C}, E_{\mathcal{H}})$ of $\mathcal{G}^\times[\mathcal{D}]$
2: $L_0 \leftarrow \{D_{\text{src}}\}$; $\mathcal{C}_0 \leftarrow \{$the clique $C \in \mathcal{C}$ that contains $D_{\text{src}}\}$ ▷ D_{src} is the source
3: Label D_{src} as *ready*; $\ell \leftarrow 0$; *done* $\leftarrow$ FALSE.
4: **while** not *done* **do**
5: $\quad\mathcal{D}_{\text{cand}} \leftarrow \{D \in \mathcal{D} : D \in C$ for a clique $C \in N_{\mathcal{H}}[\mathcal{C}_\ell]$ and D is not *ready*$\}$
6: $\quad L_{\ell+1} \leftarrow$ *BIT-Subroutine*$(\mathcal{D}_{\text{cand}}, L_\ell)$
7: $\quad$**if** $L_{\ell+1} = \emptyset$ **then**
8: $\quad\quad L_\infty \leftarrow \mathcal{D} \setminus L_{\leqslant \ell}$; *done* $\leftarrow$ TRUE ▷ nodes in L_∞ are unreachable from D_{src}
9: $\quad$**else**
10: $\quad\quad \mathcal{C}_{\ell+1} \leftarrow \{C \in \mathcal{C} : C$ contains an object $D \in L_{\ell+1}\}$
11: $\quad\quad$ Label all objects in $L_{\ell+1}$ as *ready*; $\ell \leftarrow \ell + 1$

We obtain the following theorem.

▶ **Theorem 1.** *Let $\mathcal{D}$ be a set of n constant-complexity objects in the plane. Suppose that*
(i) *we can compute a clique-based contraction for $\mathcal{G}^\times[\mathcal{D}]$ in $T_{\text{ccg}}(n)$ time,*
(ii) *for any two subsets $B, R \subset \mathcal{D}$ we can solve* Bichromatic Intersection Testing *in $T_{\text{bit}}(n_B, n_R)$ time, where $n_B := |B|$ and $n_R := |R|$.*
Then we can compute a shortest-path tree in $\mathcal{G}^\times[\mathcal{D}]$ for a given source node $D_{\text{src}} \in \mathcal{D}$ in $O(T_{\text{ccg}}(n) + T_{\text{bit}}(n, n))$ time.

Proof. It is straightforward to prove by induction on ℓ that our algorithm correctly computes the levels L_ℓ of the shortest-path tree. To prove the bound on the running time, observe that Steps 1–3 take $O(T_{\text{ccg}}(n))$ time. It remains to bound the runtime of the while-loop.

For a clique $C \in \mathcal{C}$, let $\text{dist}[C] := \min_{D \in C} \text{dist}[D]$. Note that for objects D, D' in cliques $C, C' \in \mathcal{C}$ that are neighbors in $\mathcal{H}$, we have $|\,\text{dist}[D] - \text{dist}[D']\,| \leqslant 3$. Hence, D can only be in the candidate set $\mathcal{D}_{\text{cand}}$ in iterations of the while-loop where $\text{dist}[D] - 3 \leqslant \ell \leqslant \text{dist}[C] - 1$. Thus, if we denote the size of $\mathcal{D}_{\text{cand}}$ in iteration ℓ by n_ℓ, then the total time needed for Step 6 over all iterations is $\sum_\ell T_{\text{bit}}(n_\ell, |L_\ell|)$, where $\sum_\ell n_\ell \leqslant 3n$ and $\sum_\ell |L_\ell| \leqslant n$. Since $T_{\text{bit}}(n_B, n_R)$ is at least linear in n_B and n_R (and at most quadratic), we have $\sum_\ell T_{\text{bit}}(n_\ell, |L_\ell|) = O(T_{\text{bit}}(n, n))$. This also bounds the total runtime of Steps 7–11 over all iterations.

To bound the total time for Step 5, note that a clique C is only considered in iterations where $\text{dist}[C] - 2 \leqslant \ell \leqslant \text{dist}[C] + 2$. This implies that the total time to find the relevant cliques in Step 5 is $O(|E_{\mathcal{H}}|)$. The total time to inspect those cliques in order to find the candidate sets, is $O(\sum_{C \in \mathcal{C}} |C|)$. Thus, the total time for Step 5 over all iterations is $O(|E_{\mathcal{H}}| + \sum_{C \in \mathcal{C}} |C|)$, which can be bounded by $O(T_{\text{ccg}}(n))$. ◀

▶ Remark (relation to the framework of Klost). The framework presented above is an instantiation of the framework of Klost [21]: she also computes the shortest-path tree level by level as described above – this natural approach was also taken by earlier papers on

the SSSP problem on (unit-)disk graphs [4, 8, 9, 21] – and she also keeps the size of the candidate sets under control using an auxiliary graph. Klost uses a so-called *shortcut graph* $\mathcal{G}_{sc}$ as auxiliary graph. The nodes in $\mathcal{G}_{sc}$ correspond to the objects in $\mathcal{D}$, and the edge set E_{sc} is a superset of the edge set of $\mathcal{G}^{\times}[\mathcal{D}]$ such that for any edge $(D, D') \in E_{sc}$ we have that the distance between D and D' in $\mathcal{G}^{\times}[\mathcal{D}]$ is $O(1)$. As E_{sc} is a superset of the edge set of $\mathcal{G}^{\times}[\mathcal{D}]$, the size of E_{sc} can be quadratic, so $\mathcal{G}_{sc}$ needs to be constructed implicitly. Our clique-based contraction $\mathcal{H} = (\mathcal{C}, E_{\mathcal{H}})$ provides such an implicit shortcut graph, by defining $E_{sc} := \{ (D, D') : D \text{ and } D' \text{ are part of the same clique in } \mathcal{C} \text{ or of neighboring cliques} \}$.

3 The algorithm for disks

In this section we implement the framework presented above for the case where the input $\mathcal{D}$ is a set of n disks in the plane. We first explain how to create the cliques in our clique-based contraction $\mathcal{H}$ of $\mathcal{G}^{\times}[\mathcal{D}]$, and how to compute the edge set of $\mathcal{H}$. Using known results on Bichromatic Intersection Testing for disks we then obtain our final result.

Finding the cliques. Our algorithm to create the set of cliques is related to a recent construction by Chan and Huang [7, Section 3] of 3-hop spanners for disk graphs; we comment more on the similarities and differences later. The construction is based on so-called shifted quadtrees, introduced by Chan [5], which we describe next.

We start by defining hierarchical grids, a concept closely related to quadtrees; the connection will be made clear below. Let $o = (o_x, o_y)$ be any point in the plane. A *cell* in the hierarchical grid centered at o is any square of the form

$$\sigma(o, \ell, i, j) := \big[o_x + i \cdot 2^{\ell}, o_x + (i+1) \cdot 2^{\ell}\big) \times \big[o_y + j \cdot 2^{\ell}, o_y + (j+1) \cdot 2^{\ell}\big)$$

for integers $i, j, \ell \in \mathbb{Z}$. Note that $\sigma(o, \ell, i, j)$ is a translation of the square $[0, 2^{\ell}) \times [0, 2^{\ell})$ by the vector $o + (i \cdot 2^{\ell}, j \cdot 2^{\ell})$, and that the set $\Sigma(o, \ell) := \{\sigma(o, \ell, i, j) : i, j \in \mathbb{Z}\}$ forms a regular grid. Moreover, the grid $\Sigma(o, \ell - 1)$ is a refinement of the grid $\Sigma(o, \ell)$, obtained by partitioning each cell of $\Sigma(o, \ell)$ into four quadrants. We define the *hierarchical grid centered at* o, denoted by $\Gamma(o)$, to be the (infinite) collection $\{\Sigma(o, \ell) : \ell \in \mathbb{Z}\}$ of nested grids.

Define the *size* of any object D, denoted by $\text{size}(D)$, to be the side length of a smallest enclosing (axis-parallel) square of D. Thus $\text{size}(\sigma) = 2^{\ell}$ for any cell $\sigma \in \Sigma(o, \ell)$. We say that an object D is *c-aligned* with a hierarchical grid Γ, for a given constant $c > 0$, if there exists a cell σ in Γ such that $D \subset \sigma$ and $\text{size}(\sigma) \leqslant c \cdot \text{size}(D)$. Note that whether or not D is c-aligned with Γ only depends on the choice of the center o of the hierarchical grid. The definition of being c-aligned trivially implies the following.

▶ **Observation 2.** *Let D be an object that is c-aligned with a hierarchical grid Γ, and let σ be a cell of Γ such that D intersects the boundary $\partial\sigma$ of σ. Then* $\text{size}(D) \geqslant (1/c) \cdot \text{size}(\sigma)$.

Let $\mathcal{D}$ be a finite set of objects. In general, it is impossible to choose the center of a hierarchical grid Γ such that each object $D \in \mathcal{D}$ is c-aligned with Γ. However, Chan [5] has shown that, surprisingly, it *is* possible to pick a small number of different centers such that each object $D \in \mathcal{D}$ is c-aligned with at least one of the resulting hierarchical grids, for a suitable constant c. Even more surprisingly, we can select these centers independently of $\mathcal{D}$. The following lemma follows directly from Lemma 3.2 in Chan's paper.[3]

[3] Chan uses the term *shifted quadtree* in his lemma. To stress the fact that the shifts are independent of any input set on which one might build a quadtree, we prefer to use the term *hierarchical grid*.

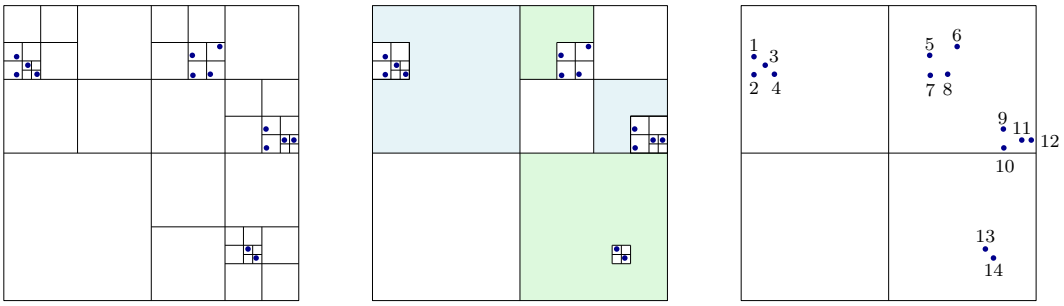

Figure 2 (i) A quadtree subdivision for a set P of points. (ii) The compressed-quadtree subdivision for P, with its donut cells marked. (iii) The ordering of the points to construct a skip quadtree.

▶ **Lemma 3** ([5]). *There is a collection Ξ of three hierarchical grids, each centered at a different point, with the following property: for any object D contained in the square $[0,1) \times [0,1)$ there is a hierarchical grid $\Gamma \in \Xi$ such that D is 6-aligned with Γ.*

Let P be a set of points, let Γ be a hierarchical grid centered at a given center o, and let σ_0 be a cell of Γ that contains P. Then we can construct a *quadtree* on P – see Figure 2(i) – whose root node corresponds to σ_0. Any node in this quadtree corresponds to a cell of Γ. Let $\mathcal{Q} = \mathcal{Q}(\sigma_0, P)$ be the corresponding *compressed quadtree* [19]. Each internal node ν of $\mathcal{Q}$ corresponds to a cell σ_ν of Γ and each leaf node μ corresponds to a region σ_μ that is either a cell of Γ or a donut cell; see Figure 2(ii). (A *donut cell* is the difference $\sigma_1 \setminus \sigma_2$ of two cells σ_1 and σ_2 of Γ with $\sigma_2 \subset \sigma_1$.) The *subdivision* defined by the compressed quadtree $\mathcal{Q}$ is the set of regions corresponding to the leaves of $\mathcal{Q}$; this subdivision is a decomposition of σ_0. Our algorithm to efficiently compute the cliques in the clique-based contraction combines the hierarchical grids of Lemma 3 with skip quadtrees [15], as explained next.

Skip quadtrees, defined by Eppstein, Goodrich, and Sun [15] are defined as follows. Let P be a set of n points inside a given starting cell σ_0 of a hierarchical grid Γ. We start by sorting the points in P in Z-order, as follows. First, order the points according to the quadrants from σ_0 they fall in: put the points in the NW-quadrant first, then those in the NE-quadrant, then those in the SW-quadrant, and finally those in the SE-quadrant. Next, recursively sort the points in each quadrant. Let $p_1, \ldots, p_n$ be the resulting sorted list of points; see Figure 2(iii). We now create a sequence $P = P_0 \supset P_1 \supset \cdots \supset P_t$, where P_i is obtained from P_{i-1} by deleting every other element (starting with the first element) and $|P_t| = 1$. From the sequence $P_0 \supset P_1 \supset \cdots \supset P_t$ we construct a sequence of compressed-quadtree *subdivisions* $\mathcal{Q}_0, \mathcal{Q}_1, \ldots, \mathcal{Q}_t$, each based on the same starting cell σ_0. The sequence $\mathcal{Q}_0, \mathcal{Q}_1, \ldots, \mathcal{Q}_t$ has the following properties, as illustrated in Figure 3:

- $\mathcal{Q}_t$ is equal to the square σ_0.
- $\mathcal{Q}_i$ is a refinement of $\mathcal{Q}_{i+1}$ for all $0 \leqslant i < t$, that is, each region in $\mathcal{Q}_i$ is contained in a unique region in $\mathcal{Q}_{i+1}$. Moreover, each region in $\mathcal{Q}_{i+1}$ contains $O(1)$ regions from $\mathcal{Q}_i$.
- Each region in $\mathcal{Q}_0$ contains at most one point from P.

We can view $\mathcal{Q}_t, \ldots, \mathcal{Q}_1, \mathcal{Q}_0$ as the levels of a tree $\mathcal{T}$, where a node ν at level i corresponds to a region R_ν of the subdivision $\mathcal{Q}_i$. In particular, the root of $\mathcal{T}$ corresponds to the starting square σ_0 and the leaves of $\mathcal{T}$ correspond to the regions in $\mathcal{Q}_0$ (which is the compressed-quadtree subdivision for the whole point set P with root σ_0). We call this tree structure[4] a *skip quadtree* for P with root σ_0. It can be constructed in $O(n \log n)$ time [15].

[4] The skip quadtree defined by Eppstein, Goodrich, and Sun is slightly more complicated, as it stores

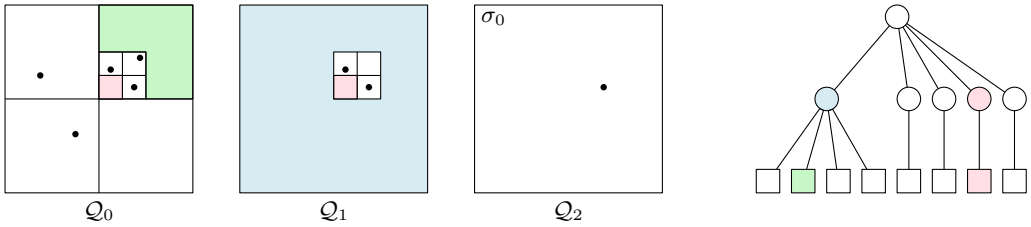

Figure 3 Example of the three compressed-quadtree subdivisions for a set of five points, and the resulting skip quadtree. Colors indicate the correspondence between regions and nodes.

Without loss of generality, we will assume henceforth that all the disks of $\mathcal{D}$ are fully contained in the unit square $[0,1) \times [0,1)$. Let Ξ be the collection of three hierarchical grids given by Lemma 3. Each disk D of $\mathcal{D}$ is 6-aligned with some hierarchical grid $\Gamma \in \Xi$, and we can find such a hierarchical grid for D in constant time.

Now consider a hierarchical grid Γ from the collection Ξ. Let $\mathcal{D}(\Gamma) \subset \mathcal{D}$ be the set of disks that are 6-aligned with Γ, where we put a disk that is 6-aligned with multiple grids into an arbitrary one of the corresponding sets $\mathcal{D}(\Gamma)$. We create a set $\mathcal{C}(\Gamma)$ of cliques, as follows.

1. Construct a skip quadtree $\mathcal{T}(\Gamma)$ on the set $P(\Gamma)$ of centers of the disks in $\mathcal{D}(\Gamma)$, where the starting square σ_0 of the skip quadtree is a cell of Γ that contains all the disks in $\mathcal{D}(\Gamma)$.
2. For each disk $D \in \mathcal{D}(\Gamma)$, follow a path in $\mathcal{T}(\Gamma)$ consisting of nodes μ whose region R_μ contains the center of D, until a node ν is reached such that D intersects ∂R_ν or a leaf is reached. Assign D to that node or leaf.
3. Let $\mathcal{D}_\nu \subset \mathcal{D}(\Gamma)$ be the set of disks assigned to an (internal or leaf) node ν in $\mathcal{T}(\Gamma)$. For each node ν, partition $\mathcal{D}_\nu$ into a set $\mathcal{C}_\nu$ of $O(1)$ cliques, as follows. If ν is a leaf and R_ν contains a disk – note that a leaf can contain at most one disk – then we create a singleton clique for that disk. Now suppose ν is an internal node. First, suppose R_ν is a square region. Because the disks in $\mathcal{D}_\nu$ are 6-aligned with Γ, we know that $\text{size}(D) \geqslant \frac{1}{6} \cdot \text{size}(R_\nu)$ for all $D \in \mathcal{D}_\nu$ intersecting ∂R_ν. Hence, we can create a set of $O(1)$ points such that each disk D is stabbed by at least one of them, which we use to create $\mathcal{C}_\nu$. If R_ν is a donut we proceed similarly, where we treat the disks intersecting the boundary of the hole of the donut – this hole can be much smaller than the donut – separately from the disks that only intersect the outer boundary of the donut. Finally, set $\mathcal{C}(\Gamma) := \bigcup_{\nu \in \mathcal{T}(\Gamma)} \mathcal{C}_\nu$.

Each clique that is generated by our algorithm is a so-called *stabbed clique*, that is, for each clique $C \in \mathcal{C}(\Gamma)$ there is a point stabbing all disks in C. We refer to the union of all the disks in C as a *flower*, which we denote by $F(C)$, and we let $\mathcal{F}(\Gamma) := \{F(C) : C \in \mathcal{C}(\Gamma)\}$ be the set of flowers corresponding to the cliques in $\mathcal{C}(\Gamma)$. Define $\text{ply}(S)$, the *ply* of a set S of objects in the plane, to be the maximum, over all points $q \in \mathbb{R}^2$, of the number of objects in S containing q. The following lemma states a property of our algorithm that will be crucial to efficiently compute the edges in the clique-based contraction.

▶ **Lemma 4.** *The algorithm above constructs in $O(n \log n)$ time a partition of $\mathcal{D}(\Gamma)$ into a set $\mathcal{C}(\Gamma)$ of stabbed cliques such that $\text{ply}(\mathcal{F}(\Gamma)) = O(\log n)$.*

more information than just the compressed-quadtree subdivisions. Since we do not need our structure to be dynamic, the simple hierarchy described above suffices.

Proof. Step 1 of the algorithm, constructing the skip quadtree $\mathcal{T}(\Gamma)$ on the set $P(\Gamma)$ of the centers of the at most n disks in $\mathcal{D}(\Gamma)$, can be done in $O(n \log n)$ time [15]. The depth of the skip quadtree is $O(\log n)$, and so Step 2 takes $O(\log n)$ time per disk and $O(n \log n)$ time in total. Step 3 takes $\sum_{v \in \mathcal{T}(\Gamma)} O(1 + |\mathcal{D}_v|)$ time, which is $O(n)$ because each disk is assigned to exactly one node. Hence, the total time for the algorithm is $O(n \log n)$.

To bound $\text{ply}(\mathcal{F}(\Gamma))$, consider an arbitrary point $q \in \mathbb{R}^2$. Recall that for each node ν in $\mathcal{T}(\Gamma)$ we created $O(1)$ stabbed cliques and, hence, $O(1)$ flowers. Thus, it suffices to prove the following claim: at each level of the skip quadtree $\mathcal{T}(\Gamma)$ there are only $O(1)$ nodes ν such that $q \in D$ for some disk D assigned to ν. To prove this claim, follow the search path of q in $\mathcal{T}(\Gamma)$, that is, the path consisting of nodes μ such that $q \in R_\mu$. Let $D \in \mathcal{D}$ be a disk that contains q, let ν be the node to which D is assigned, and let μ be the parent of ν. Then μ must lie on the search path of q. Indeed, D is fully contained in R_μ – otherwise D would have been assigned to μ – and so $q \in D \subset R_\mu$. Since any node in a skip quadtree has $O(1)$ children, this implies the claim. ◀

▶ Remark (relation to the spanner construction of Chan and Huang). In their algorithm for constructing a 3-hop spanner for $\mathcal{G}^\times[\mathcal{D}]$, Chan and Huang [7] create a collection of cliques in a similar way as we create our cliques. As they are only concerned with the size of the spanner, however, they do not analyze the time needed to construct it. The differences between our approach and theirs mainly stem from the necessity to construct the clique-based contraction $\mathcal{H}$ in $O(n \log n)$ time, as discussed next.

A first difference is that Chan and Huang use a centroid decomposition of a compressed quadtree instead of a skip quadtree. This is not a crucial difference – possibly we could have used a centroid decomposition as well, although working with a skip quadtree is more convenient. Another difference is that they work with a collection Ξ of hierarchical grids – they call them shifted quadtrees – such that, for each pair $D, D' \in \mathcal{D}$, there is at least one hierarchical grid $\Gamma \in \Xi$ such that both D and D' are aligned with Γ. This allows them to construct their spanner by applying the following procedure to each quadtree $\mathcal{Q}$ defined by the hierarchical grid Γ: (i) take a centroid node ν in a compressed quadtree $\mathcal{Q}$ and partition the set $\mathcal{D}_\nu$ of disks intersecting $\partial\sigma_\nu$ into $O(1)$ cliques, (ii) for each clique C, add a star graph on that clique to the spanner, (iii) for each disk D and each clique C intersected by D, add an edge (D, D') to the spanner, where $D' \in C$ is an arbitrary disk intersected by D, and (iv) recursively construct 3-hop spanners for the disks inside and outside σ_ν. The crucial difference lies in step (iii), where they add an edge from every disk D to a neighboring disk in each clique (if such a neighboring disk exists). It seems difficult to do this in $O(n \log n)$ time in total over all recursive calls. We therefore proceed differently: we first recursively construct cliques on the disks not intersecting $\partial\sigma_\nu$, and then we only add a single edge between two cliques if the corresponding flowers intersect. Such an approach would increase the spanning ratio if we were to use it to construct a spanner, but this is of no concern to us. The advantage of being more conservative is that we can compute the edges in our clique-based contraction in $O(n \log n)$ time, as explained next.

Computing the edges in the clique-based contraction. Let $\mathcal{C} := \bigcup_{\Gamma \in \Xi} \mathcal{C}(\Gamma)$ be the set of cliques generated by applying the procedure above to each hierarchical grid Γ in the collection Ξ given by Lemma 3. Let $\mathcal{F} := \bigcup_{\Gamma \in \Xi} \mathcal{F}(\Gamma)$ be the corresponding flower set. Note that $\text{ply}(\mathcal{F}) = O(\log n)$ by Lemma 4. To construct the edge set $E_\mathcal{H}$ of the clique-based contraction $\mathcal{H} = (\mathcal{C}, E_\mathcal{H})$, we must find all pairs $F, F' \in \mathcal{F}$ that intersect. Next we show how to do this in $O(n \log n)$ time.

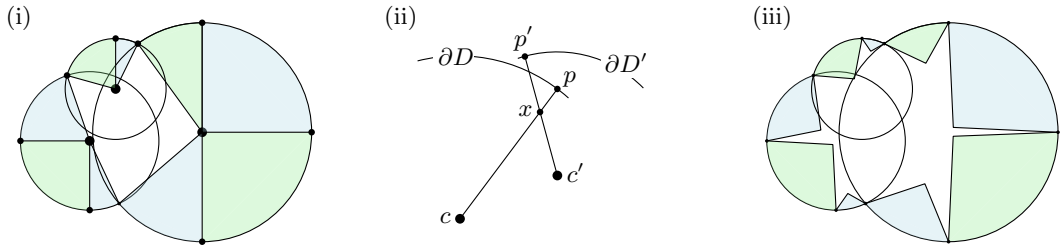

Figure 4 (i) The set Z_F of circular sectors defined by the boundary arcs of a flower F. Some boundary arcs have been cut into sub-arcs to ensure they span an angle of at most $\pi/2$. (ii) If $|px| < |p'x|$ then $p \in D'$; otherwise $p' \in D$. (iii) The modified sectors.

Consider a flower F defined by some clique C. The boundary ∂F of F is comprised of maximal pieces of the boundaries of the disks in C that show up on ∂F. We call these pieces *boundary arcs* and we denote the set of boundary arcs of a flower F by $\mathcal{B}(F)$. For a set $\mathcal{F}$ of flowers, we define $\mathcal{B}(\mathcal{F}) := \bigcup_{F\in\mathcal{F}} \mathcal{B}(F)$ to be the set of boundary arcs of the flowers in $\mathcal{F}$.

▶ **Lemma 5.** *Let $\mathcal{F}$ be a set of flowers that consist of n disks in total. Then the number of intersections between the boundary arcs in $\mathcal{B}(\mathcal{F})$ is $O(n \cdot \mathrm{ply}(\mathcal{F}))$.*

Proof. First, observe that $|\mathcal{B}(F)| = O(n_F)$, where n_F is the number of disks defining a flower $F \in \mathcal{F}$, since the union of a set of disks has linear complexity. Hence, $|B(\mathcal{F})| = O(n)$.

Now consider a boundary arc $\beta \in \mathcal{B}(F)$ of some flower $F \in \mathcal{F}$. We assume for simplicity that the angle spanned by the circular arc β is at most $\pi/2$; if this is not the case we can split β into at most four sub-arcs, and work with the sub-arcs instead. Let D be the disk that contributes the arc β, let c be the center of D, and let s_1 and s_2 be the segments that connect c to the endpoints of β. Together with β, these two segments bound a (convex) circular sector. Let Z_F be the set of such circular sectors created for the arcs in $\mathcal{B}(F)$; see Figure 4(i). We say that two sectors z, z' are *non-overlapping* if their interiors are disjoint.

▷ Claim. The sectors in the set Z_F are pairwise non-overlapping.

Proof. Consider two sectors $z, z' \in Z_F$. Let D, D' be the disks whose boundaries define z and z', respectively, and let c and c' be their centers. If $D = D'$ then obviously z and z' do not overlap, so assume that $D \neq D'$. Since a sector in Z_F cannot be fully contained in another sector in Z_F by construction, the sectors z, z' can only overlap if there is a proper intersection between their boundaries. Such an intersection can only happen between a segment s connecting c to an endpoint p of some boundary arc $\beta \subset \partial D$ and a segment s' connecting c' to an endpoint p' of some boundary arc $\beta' \subset \partial D'$. But then, by the triangular inequality, either $p \in D'$ or $p' \in D$ – see Figure 4(ii) for an illustration – contradicting that p and p' are both points on ∂F. ◁

Now consider a circular sector z, defined by some arc β. Let x be the apex of z (which coincides with the center of the disk D contributing β). If the angle at apex x is large enough then z is fat, but if the angle is very small then this is not the case. We therefore proceed as follows: we move the apex x towards the midpoint of β until the angle at x is slightly larger than $\pi/2$; see Figure 4(iii). It is easy to see that the modified region (which is no longer a circular sector) is fat and convex. Moreover, no two modified regions share an apex anymore. With a slight abuse of notation, from now on we use Z_F to denote the set of modified regions created for a flower $F \in \mathcal{F}$.

Let $Z(\mathcal{F}) := \bigcup_{F \in \mathcal{F}} Z_F$. Note that $|Z(\mathcal{F})| \leqslant 4 \cdot |\mathcal{B}(\mathcal{F})| = O(n)$ and that $\text{ply}(Z(\mathcal{F})) \leqslant 2 \cdot \text{ply}(\mathcal{F}) = O(\log n)$; the latter is true since the regions created for a single flower R are pairwise disjoint except at shared endpoints of boundary arcs. For each arc $\beta \in \mathcal{B}(\mathcal{F})$, there is a region $z \in Z(\mathcal{F})$ such that $\beta \subset \partial z$. Hence, the number of intersections between the arcs in $\mathcal{B}(\mathcal{F})$ is upper bounded by the number of intersections between the regions in $Z(\mathcal{F})$.

▷ Claim. The number of intersections between the regions in $Z(\mathcal{F})$ is $O(|Z(\mathcal{F})| \cdot \text{ply}(Z(\mathcal{F})))$.

Proof. The proof is standard, but we sketch it for completeness. We charge the intersection between two regions z, z' to the smaller of the two regions, and claim that each region is charged $O(\text{ply}(Z(\mathcal{F})))$ times. To see this, consider a region $z \in Z(\mathcal{F})$ and let b be the smallest enclosing disk of Z. Let b' be the disk with the same center as b such that $\text{radius}(b') = 2 \cdot \text{radius}(b)$. Due to the fatness of the regions in $Z(\mathcal{F})$, any region z' that intersects z and is at least as large as z, will cover a constant fraction of the area of b'. Hence, there can be at most $O(\text{ply}(Z(\mathcal{F})))$ such regions z'. ◁

This finishes the proof. ◀

Observe that two flowers F, F' intersect iff the following holds: a boundary arc of F intersects a boundary arc of F', or $F \subset F'$, or $F' \subset F$. Thus we can find all intersecting pairs of flowers – and, hence, all edges of the clique-based contraction $\mathcal{H}$ – as follows. (The algorithm below may report a pair of intersecting flowers multiple times, but this is not a problem.)

First, we construct the arrangement $\mathcal{A}(\mathcal{F})$ induced by the flower set $\mathcal{F}$. Next, for each vertex of $\mathcal{A}(\mathcal{F})$ that is the intersection of the boundaries of some pair of flowers F, F, we report that pair. Finally, we need to find the pairs of flowers F, F' such that $F \subset F'$. To this end, we traverse the dual graph of $\mathcal{A}(\mathcal{F})$, maintaining a list $\mathcal{L}$ of flowers containing the face we are currently in. Whenever we enter a flower F for the first time, we report the pairs (F, F') for the faces F' that are currently in the list $\mathcal{L}$.

We obtain the following lemma.

▶ **Lemma 6.** *Let $\mathcal{D}$ be a set of n disks in the plane. Then we can compute a clique-based contraction for $\mathcal{G}^{\times}[\mathcal{D}]$ in $O(n \log n)$ expected time.*

Proof. Computing the collection $\mathcal{C}$ of cliques takes $O(n \log n)$ time by Lemma 4. It remains to analyze the time needed to compute the edge set $E_{\mathcal{H}}$ of the clique-based contraction.

For each clique $C \in \mathcal{C}$, we can compute the corresponding flower $F(C)$ in $O(|C| \log |C|)$ time using a simple divide-and-conquer algorithm. Since each disk is part of only clique, this implies that the flower set $\mathcal{F}$ can be computed in $O(n \log n)$ time. Moreover, the total number of boundary arcs of the flowers is $O(n)$ because the complexity of a single flower is linear. Hence, we can construct the arrangement $\mathcal{A}(\mathcal{F})$ in $O(n \log n + k)$ expected[5] time, where k is the number of intersections between the boundary arcs, using a randomized incremental algorithm by Mulmuley [23]. Since $k = O(n \log n)$ by Lemmas 4 and 5, constructing the arrangement thus takes $O(n \log n)$ expected time. The traversal of the dual graph, including the maintenance of $\mathcal{L}$ takes $O(n \log n)$ time. Since the size of the list $\mathcal{L}$ is $O(\log n)$ at any time – this is because the ply of the flower set is $O(\log n)$ – we report at most $O(n \log n)$ pairs in total during the traversal. Thus, the total time to compute $E_{\mathcal{H}}$ is $O(n \log n)$. ◀

[5] We cannot use the deterministic algorithm for line-segment intersection by Chazelle and Edelsbrunner [10] because it does not work for curves. The deterministic algorithm for line-segment intersection by Balaban [3] also works for curves, but that algorithm does not seem to give enough information to construct the arrangement.

Putting it all together. Lemma 6 gives us the first ingredient we need to apply Theorem 1. The second ingredient is an algorithm that solves Bichromatic Intersection Testing for disks. As observed in previous papers [9, 21] this can be done in $O((n_B + n_R) \log n_R)$ time, as follows. First, compute the additively weighted Voronoi diagram $\mathrm{Vor}(R)$ on the centers of the set R of red disks, where the weight of a center is equal to the radius of its corresponding disk. Next, query with the center of each blue disk D in $\mathrm{Vor}(R)$ to find the red disk D' closest to D. Now D intersects $\bigcup R$, the union of the red disks, iff D intersects D'. Since $\mathrm{Vor}(R)$ can be computed in $O(n_R \log n_R)$ time [17], after which it can be preprocessed for logarithmic-time point location in $O(n_R \log n_R)$ time [13], we can solve Bichromatic Intersection Testing in $O((n_B + n_R) \log n_R)$ time. We thus obtain our main result.

▶ **Theorem 7.** *Let $\mathcal{D}$ be a set of n disks in the plane. Then we can compute a shortest-path tree in $\mathcal{G}^{\times}[\mathcal{D}]$ for a given source disk $D_{\mathrm{src}} \in \mathcal{D}$ in expected $O(n \log n)$ time.*

In the full version [11] we present a (slightly more complicated) deterministic algorithm to compute the edges of the clique-based contraction for $\mathcal{G}^{\times}[\mathcal{D}]$ in $O(n \log n)$ time. Using that algorithm instead of Lemma 6, we obtain an algorithm to compute shortest-path trees on disks graphs deterministically in $O(n \log n)$ time.

4 Extension to fat triangles

A triangle Δ is called *α-fat* if its minimum angle is at least α. Let $\mathcal{D} = \{\Delta_1, \ldots, \Delta_n\}$ be a set of α-fat triangles, where $\alpha > 0$ is some fixed absolute constant. From now on, we simply refer to the triangles in $\mathcal{D}$ as *fat triangles* and we refer to α as the *fatness constant*.

Constructing the clique-based contraction. Our approach to construct a clique-based contraction for fat triangles is similar to the algorithm for disks. We now go over the various ingredients and explain how to adapt them, if necessary.

We first observe that Lemma 3.2 from Chan's paper [5] actually holds for any type of objects. Hence, our Lemma 3 also holds for any type of objects. To construct the skip quadtree, the set $P(\Gamma)$ of disk centers is replaced by a set $P(\Gamma)$ that contains an arbitrary point in each object. Constructing the cliques can therefore be done in exactly the same way as before. Indeed, the crucial property was as follows: any set of disks intersecting the boundary of a region R_ν and whose size is at least $\frac{1}{6} \cdot \mathrm{size}(R_\nu)$, can be stabbed by $O(1)$ points. This property also holds for fat objects.

Now let C be a stabbed clique of fat triangles. We refer to the union of the triangles in C as a *spiky flower*, and we denote it by $F(C)$. As before, we let $\mathcal{C}(\Gamma)$ denote the set of cliques created by our algorithm, and we define $\mathcal{F}(\Gamma) := \{F(C) : C \in \mathcal{C}(\Gamma)\}$ to be the corresponding set of spiky flowers. Then Lemma 4 also holds for fat triangles – we can follow the proof verbatim, only replacing occurrences of "disk" by "fat triangle."

It remains to prove the equivalent of Lemma 5 for fat triangles. To keep the terminology similar to the case of disks, we will refer to the edges of a spiky flower F as *boundary segments*, and we denote the set of boundary segments of a flower F by $\mathcal{B}(F)$. Furthermore, we let $\mathcal{F} := \bigcup_{\Gamma \in \Xi} \mathcal{F}(\Gamma)$ denote the set of spiky flowers created by our algorithm, and we define $\mathcal{B}(\mathcal{F}) := \bigcup_{F \in \mathcal{F}} \mathcal{B}(F)$.

▶ **Lemma 8.** *Let $\mathcal{F}$ be a set of spiky flowers that consist of n fat triangles in total. Then the number of intersections between the boundary segments in $\mathcal{B}(\mathcal{F})$ is $O(n \cdot \mathrm{ply}(\mathcal{F}))$.*

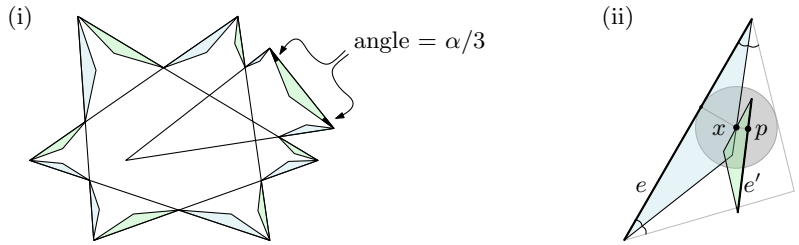

Figure 5 (i) The set Z_F of sectors defined by the boundary segments of a spiky flower F. (ii) The point p lies in D, which in turn lies inside the expanded sector.

Proof. We apply the same proof technique as in the proof of Lemma 5: we cover the boundary segments of each spiky flower F by a set Z_F of non-overlapping fat "sectors" contained in the flower, as explained below, from which the lemma follows.

The number of boundary segments of a spiky flower is $O(n_F)$, where n_F is the number of triangles defining F [1, Section 3.2]. We create the set Z_F for a spiky flower F as follows. For each boundary segment β of F, we create an isosceles triangle $z \subset F$ whose angles at the endpoints of β are $\alpha/3$, where α is the fatness constant of the triangles; see Figure 5. With a slight abuse of terminology, we refer to these isosceles triangles as sectors.

▷ Claim. The sectors in the set Z_F are pairwise non-overlapping.

Proof. Each sector z has one edge that corresponds to a boundary segment of F; we call this the *external edge* of z. The two other edges, which make an angle $\alpha/3$ with the external edge, are called *internal edges*.

Now assume for a contradiction that two sectors z, z' overlap. Since the external edge of any sector cannot properly intersect an (external or internal) edge of any other sector, there must be a crossing between an internal edge of z and an internal edge of z'. Let x be this crossing, and let e and e' be the external edges of z and z', respectively; see Figure 5(ii). Assume without loss of generality that the distance from x to e is at least the distance from x to e'. Let p be the point on e' nearest to x, and let D be the disk centered at x and touching e. Then p is contained in D. Moreover, D is contained in the triangle $\Delta \in \mathcal{D}$ contributing e to the boundary of the spiky flower F. Indeed, if we were to expand the sector z by making the angles at the endpoints of e equal to $2\alpha/3$ then $D \subset z$, and this expanded sector is contained in Δ. Thus, $p \in \Delta$, which contradicts that p lies on an external edge. ◁

As in the proof of Lemma 5, it now follows that the number of intersections between the sectors in $Z(\mathcal{F})$ is $O(|Z(\mathcal{F})| \cdot \text{ply}(Z(\mathcal{F})))$, which proves the lemma. ◀

As before, we have the following corollary. Its proof is the same as the proof of Lemma 6; the only difference is that we can now use the algorithm by Chazelle and Edelsbrunner [10] to construct the arrangement defined by the flowers, thus avoiding the use of randomization.

▶ **Corollary 9.** *Let $\mathcal{D}$ be a set of n fat triangles in the plane. Then we can compute a clique-based contraction for $\mathcal{G}^{\times}[\mathcal{D}]$ in $O(n \log n)$ time.*

Bichromatic Intersection Testing for fat triangles. The final ingredient that we need is an efficient algorithm for Bichromatic Intersection Testing for a set B of n_B blue triangles and a set R of n_R red triangles, where all triangles in $B \cup R$ are fat. Such an algorithm can be developed using standard machinery, as described next.

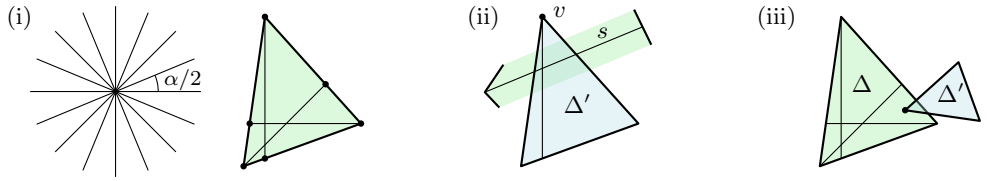

Figure 6 (i) The set A of canonical directions and the canonical chords of a triangle. (ii) Chord s intersects two sides of Δ' so it intersects a canonical chord of Δ'. (iii) All canonical chords of Δ miss Δ', so Δ' must have a vertex inside Δ.

Let $A := \{i \cdot (\alpha/2) : 0 \leqslant i \leqslant \lfloor 4\pi/\alpha \rfloor\}$ be a set of $O(1/\alpha) = O(1)$ *canonical directions*, where α is the fatness constant of the triangles. Define a *canonical segment* to be a segment whose direction is canonical, and define a *canonical chord* of a fat triangle Δ to be a canonical segment that connects a vertex of Δ to its opposite side; see Figure 6(i). Note that each vertex of Δ admits a canonical chord. Let $S(\Delta)$ be a set of three canonical chords of Δ, one per vertex of Δ, and let $P(\Delta)$ be the endpoints of these chords (including the vertices of Δ).

▶ **Observation 10.** *If a fat triangle Δ intersects a fat triangle Δ' then at least one of the following conditions holds:*

(i) *Δ contains a vertex of Δ';*
(ii) *a point from $P(\Delta)$ lies inside Δ';*
(iii) *a canonical chord from $S(\Delta)$ intersects a canonical chord from $S(\Delta')$.*

Proof. Suppose that condition (ii) does not hold. Then there is a canonical chord $s \in S(\Delta)$ that intersects two edges of Δ', or all canonical chords in $S(\Delta)$ are disjoint from Δ'. In the former case, s separates a vertex v of Δ' from its opposite side, which implies that s intersects the canonical chord of v; see Figure 6(ii). Thus, condition (iii) holds in this case. In the latter case, Δ' must have a vertex inside Δ and condition (i) holds; see Figure 6(iii). ◀

Observation 10 implies the following lemma.

▶ **Lemma 11.** *Let R be a set of n fat triangles. There exists a data structure of $O(n \log^2 n)$ size such that we can decide in $O(\log^3 n)$ time if a fat query triangle Δ intersects any triangle in R and, if so, report a witness triangle. The data structure can be built in $O(n \log^3 n)$ time.*

Proof. The data structure consists of three separate data structures, each handling one of the conditions in Observation 10.

For condition (i) we need a data structure for range searching with fat triangles in a set V of $3n$ points, namely the vertices of the triangles in R. As observed by Gray [18, page 14], such queries can be answered in $O(\log^3 n)$ time with a structure of size $O(n \log^2 n)$ that can be built in $O(n \log^3 n)$ time.

For condition (ii) we use a *union tree* on the triangles in R. This is a binary tree $\mathcal{T}$ whose leaves correspond to the triangles in R, and whose internal nodes store the union of the triangles in their subtree, preprocessed for point-location queries. Checking if a query point q is contained in any triangle in R can be done in $O(\log n)$ by performing a point location at the root of $\mathcal{T}$. If this is the case, then we can find a witness triangle in $O(\log^2 n)$ time by walking down $\mathcal{T}$, always proceeding to a child whose union contains q. Since the union complexity of n fat triangles is $O(n \log^* n)$ [2], the total amount of storage is $O(n \log^* n \log n)$. Note that the union at a node ν can be computed in $O(n_\nu \log^* n_\nu \log n_\nu)$ time from the unions of its two children by a simple plane-sweep algorithm, where n_ν is the number of triangles in the subtree of ν. Hence, the total preprocessing time is $O(n \log^* n \log^2 n)$.

To handle condition (iii) we proceed as follows. Let $S_R : \{s \in S(\Delta) : \Delta \in R\}$ be the set of canonical chords of the triangles in R. We will build $O(1/\alpha)$ different data structures on S_R, one for each of the $O(1/\alpha)$ possible directions of the query chord. To construct a data structure for a fixed direction of the query chord, we partition S_R into $O(1/\alpha)$ classes, one for each canonical direction in A, and we build a separate substructure for each class A_i. Assume wlog that the query chord is vertical and that the chords in A_i are horizontal. Then we can use an interval tree [12, Section 10.1] to answer queries in $O(\log n)$, using $O(n)$ space and $O(n \log n)$ preprocessing. (Using a point-location structure on the vertical decomposition of the chords in A_i is another option.) Thus the total amount of storage is $O(n/\alpha) = O(n)$, the total preprocessing is $O((n/\alpha) \log n) = O(n \log n)$, and the total query time is $O((1/\alpha) \log n) = O(\log n)$.

Since all data structure work within the claimed bounds, the lemma follows. ◀

We can now solve Bichromatic Intersection Testing for fat triangles in $O((n_B + n_R) \log^3(n_B + n_R))$ time, by querying with each triangle $\Delta \in B$ in the data structure provided by Lemma 11. This leads to the following theorem.

▶ **Theorem 12.** *Let $\mathcal{D}$ be a set of n fat triangles in the plane. Then we can compute a shortest-path tree in $\mathcal{G}^{\times}[\mathcal{D}]$ for a given source triangle $\Delta_{\text{src}} \in \mathcal{D}$ in $O(n \log^3 n)$ time.*

In the full version [11] we provide a better data structure for the range-query problem considered in Lemma 11: its construction time is $O(n \log^2 n)$ and each query is then answered in $O(\log^2 n)$ time. Using this data structure, we obtain an $O(n \log^2 n)$ algorithm to compute shortest-path trees on the intersection graph of fat triangles.

5 Concluding remarks

We presented the first algorithm for the SSSP problem in disk graphs that runs in $O(n \log n)$ (expected) time. We extended the algorithm to intersection graphs of fat triangles, where we obtain a worst-case running time of $O(n \log^3 n)$. In the full version [11] we provide a deterministic $O(n \log n)$ algorithm for the SSSP problem in disk graphs and improve the running time for intersection graphs of fat triangles to $O(n \log^2 n)$.

A natural question is whether the algorithm for fat triangles can be further improved. Another natural question is whether an $O(n \operatorname{polylog} n)$ algorithm is possible for intersection graphs of non-fat objects such as line segments. This is unlikely, however, because Hopcroft's problem – given a set L of n lines and a set P of n points, decide if any of the points lies on any of the lines – can be reduced to the SSSP problem for segments, and Hopcroft's problem has an $\Omega(n^{4/3})$ lower bound [16] in a somewhat restricted model of computation.

Abstract

We present an optimal partially-persistent external-memory search tree with amortized I/O bounds matching those achieved by the non-persistent B^ε-tree by Brodal and Fagerberg [SODA 2003]. In a partially-persistent data structure, each update creates a new version. All past versions can be queried, but only the current version can be updated. Operations should be efficient with respect to the size N_v of the accessed version v. For any parameter $0 < \varepsilon < 1$, our data structure supports insertions and deletions in amortized $\mathcal{O}\big(\frac{1}{\varepsilon B^{1-\varepsilon}} \log_B N_v\big)$ I/Os, where B is the external-memory block size. It also supports successor and range reporting queries in amortized $\mathcal{O}\big(\frac{1}{\varepsilon} \log_B N_v + K/B\big)$ I/Os, where K is the number of keys reported. The space usage of the data structure is linear in the total number of updates. We make the standard and minimal assumption that the internal memory has size $M \geq 2B$. The previous state-of-the-art external-memory partially-persistent search tree by Arge, Danner and Teh [JEA 2003] supports all operations in worst-case $\mathcal{O}(\log_B N_v + K/B)$ I/Os, matching the bounds achieved by the classical B-tree by Bayer and McCreight [Acta Informatica 1972]. Our data structure successfully combines buffering updates with partial persistence. The I/O bounds can also be achieved in the worst-case sense, by slightly modifying our data structure and under the requirement that the memory size $M = \Omega\big(B^{1-\varepsilon} \log_2(\max_v N_v)\big)$. For updates, where the I/O bound is $o(1)$, we assume that the I/Os are performed evenly spread out among the updates (by performing buffer-overflows incrementally). The worst-case result slightly improves the memory requirement over the previous ephemeral external-memory dictionary by Das, Iacono, and Nekrich (ISAAC 2022), who achieved matching worst-case I/O bounds but required $M = \Omega(B \log_B N)$, where N is the size of the current dictionary.

1 Introduction

Developing data structures for storing a set of keys from a totally ordered set subject to insertions, deletions, successor and predecessor queries, and range reporting queries is a fundamental problem in computer science. The classical solution in external-memory is the B-tree by Bayer and McCreight [5] which supports all the operations in worst-case $\mathcal{O}(\log_B N + K/B)$ I/Os, where N is the current size of the set, K is the number of reported keys, and B is the external-memory block size. While the B-tree achieves the optimal number of I/Os for queries, for any $0 < \varepsilon < 1$, the B^ε-tree by Brodal and Fagerberg [10] significantly improves update efficiency by attaching buffers to the internal nodes of a B-tree. This design supports updates with amortized $\mathcal{O}\big(\frac{1}{\varepsilon B^{1-\varepsilon}} \log_B N\big)$ I/Os. The $\varepsilon B^{1-\varepsilon}$ factor improvement

over traditional B-trees is significant when considering typical parameters of, e.g., $\varepsilon = 1/2$ and $B = 1000$ [4] and the B^ε-tree has found important applications in high-performance industry software such as TokuDB [9] and BetrFS [25].

Although the B^ε-tree optimizes update efficiency, it is *ephemeral*, like most dynamic data structures, meaning that each update overwrites the previous version, and only the current version can be queried. In many applications, maintaining access to past versions is beneficial or even essential. A *persistent* data structure supports such accesses, and in their seminal 1989 paper, Driscoll, Sarnak, Sleator, and Tarjan introduced general techniques for making ephemeral data structures persistent [20]. A *partially-persistent* data structure supports queries in all past versions of the data structure but only the current version can be updated. Multiple authors have adapted these techniques to the external-memory model, developing partially-persistent B-trees that support updates and queries in worst-case $\mathcal{O}(\log_B N_v + K/B)$ I/Os, where N_v is size of the accessed version v, matching the performance of classical B-trees [3, 6, 32].

In this paper, we present the first buffered partially-persistent external-memory search tree that retains the optimal update and query performance of the (ephemeral) B^ε-tree. Our approach combines buffering techniques, which are essential for efficient updates in external memory, with a geometric view of persistence.

1.1 The External-Memory Model

For problems on massive amounts of data that do not fit in internal memory, the standard model of computation is the I/O-model by Aggarwal and Vitter [1]. In this model, all computation occurs in an internal memory of size M, while an infinite external memory is used for storage. Data is transferred between internal and external memory in blocks of B consecutive elements, with each transfer counting as an I/O. The I/O complexity of an algorithm is defined as the total number of I/Os it performs, and the space usage is the maximum number of external-memory blocks used at any given time. The only operation we allow on stored keys are comparisons and we follow the standard assumption that the parameters $B \geq 2$ and $M \geq 2B$. Aggarwal and Vitter proved that the optimal bound for sorting in external memory is $\mathit{sort}(N) = \Theta\left(\frac{N}{B} \log_{M/B} \frac{N}{B}\right)$ I/Os [1]. An algorithm is called *cache oblivious* if it is designed without explicit knowledge of B and M but is still analyzed in the I/O model for arbitrary values of these parameters, assuming an optimal offline cache replacement strategy [22]. Some authors make stronger assumptions on the size of the internal memory, such as the *tall-cache assumption* $M \geq B^{1+\delta}$, for some constant $\delta > 0$. For cache-oblivious algorithms, a tall-cache assumption is necessary to achieve optimal comparison-based external-memory sorting [11].

Considering the I/O-behavior of algorithms can be crucial in practice, as demonstrated by Streaming B-trees [8], the generation of massive graphs for the LFR benchmark [24, 27, 28], and the FlashAttention algorithm used in Transformer models [15].

1.2 Interface of a Partially-Persistent Search Tree

A partially-persistent search tree stores an ordered set of keys supporting the interface below (in our examples we use integers, but our data structure works for any totally ordered set). Each version is identified by a unique integer version identifier v, with zero being the initial version and the *current* version denoted by v_c. Further, we let $\mathcal{S}_v$ denote the set of keys contained in version v, and N_v the size of $\mathcal{S}_v$. Initially $v_c = 0$ and $\mathcal{S}_{v_c} = \emptyset$. Updates

(insertions and deletions) can only be performed on the current set $\mathcal{S}_{v_c}$, and any update advances the current version identifier, i.e., each version of the set $\mathcal{S}_v$ only differs from the previous version $\mathcal{S}_{v-1}$ by at most a single key. Queries can be performed on any version.

- INSERT(x) Creates $\mathcal{S}_{v_c+1} = \mathcal{S}_{v_c} \cup \{x\}$, increments v_c, and returns v_c.
- DELETE(x) Creates $\mathcal{S}_{v_c+1} = \mathcal{S}_{v_c} \setminus \{x\}$, increments v_c, and returns v_c.
- RANGE(v, x, y) Reports all keys in $\mathcal{S}_v \cap [x, y]$ in increasing order.
- SEARCH(v, x) Returns the successor of x in $\mathcal{S}_v$, i.e., $\min\{y \in \mathcal{S}_v \mid x \leq y\}$.

1.3 Previous Work

In internal memory, the *fat node* and *node copying* techniques can make any ephemeral linked data structure partially-persistent with constant overhead in both time and space, if the in-degree of each node in the ephemeral structure is constant [20]. Becker, Gschwind, Ohler, Seeger, and Widmayer [6] and Varman and Verma [32] adapted these techniques to B-trees in external-memory. An elegant application of partial persistence appears in the design of linear space planar point location data structures [31]. In this setting, the underlying set consists of segments which are partially ordered (only a pair of segments intersected by a vertical line can be compared). To adapt this approach to the external-memory setting, Arge, Danner, and Teh strengthened the partially-persistent B-tree to require only a total order on keys alive at any given version, leading to a static external-memory point-location structure [3].

A different approach to persistence is to interpret it geometrically, see Figure 1(left), modeling it as a data structure problem on a dynamic set of vertical segments. Kolovson and Stonebraker explored this perspective [26], though their reliance on R-trees led to poor performance guarantees [23]. More recently, Brodal, Rysgaard, and Svenning [12] leveraged this geometric approach to develop *fully persistent* B-trees, which allow both queries and modifications to all past versions in $\mathcal{O}(\log_B N_v)$ I/Os. In a fully persistent data structure, updating a version corresponds to cloning it and then applying the modification to the newly cloned version, ensuring that existing versions remain unaffected. Such behavior contrasts with *retroactive data structures* [17], where updates recursively propagate to cloned versions.

Concurrently with the work on persistent data structures in external-memory, there were significant improvements to external-memory data structures by leveraging buffering techniques to always process multiple updates and/or queries together. These include the Buffer Tree by Arge [2] which can form the basis for external-memory sorting, priority queues and batched dynamic algorithms [21] in amortized $\mathcal{O}\left(\frac{1}{B}\log_{M/B}\frac{N}{B}\right)$ I/Os per operation. For a batched operation the answer might not be immediately returned, which is often sufficient, e.g., in many geometric plane-sweep algorithms where only the end result matters. For standard (non-batched) data structures, a line of work has investigated the update-query trade-off, beginning with the Buffered Repository Tree [14] performing updates in amortized $\mathcal{O}\left(\frac{1}{B}\log_B N\right)$ I/Os and queries in $\mathcal{O}(\log_2 N)$ I/Os. This was later generalized by the B^ε-tree [10] which corresponds to the Buffered Repository Tree for $\varepsilon \approx 0$ and to the standard B-tree for $\varepsilon \approx 1$. The amortized performance of the B^ε-tree was improved to high-probability [7] and worst-case [16] I/O bounds using stronger assumptions on the size of B and M (see Table 1).

1.4 Contribution

Combining the two lines of research on persistence and buffered data structures has remained an open challenge for the past 20 years, likely due to their seemingly conflicting principles. Persistence requires maintaining access to past versions without affecting their structure,

Table 1 Overview of results on the I/O complexity of ephemeral and partially-persistent search trees. Results marked by "am." hold amortized, and results marked by "rand." are randomized and hold with high probability. All other bounds are worst case. The parameter ε must satisfy $0 < \varepsilon < 1$. All results assume $M = \Omega(B)$, further † assumes $B = \Omega(\log N)$ and $M = \Omega\big(\max\{B \log^{\Theta(1)} N, B^2\}\big)$; ‡ assumes $M = \Omega(B \log_B N)$; and $*$ assumes $M = \Omega\big(B^{1-\varepsilon} \log_2(\max_v N_v)\big)$. For both queries and updates in [7, 16], we include the multiplicative dependency on $\frac{1}{\varepsilon}$ (that can be omitted when treating ε as a constant), allowing, for example, setting $\varepsilon = \frac{1}{\log_2 B}$. All ephemeral results use space linear in N and all partial persistence results use space linear in the total number of updates.

while buffers essentially hold updates to past versions before applying them. Our work demonstrates that these two ideas can be effectively unified by developing partially-persistent external-memory search trees that achieve bounds matching those of ephemeral B^ε-trees. In Section 2 we prove the following theorem.

▶ **Theorem 1.** *Given any parameter $0 < \varepsilon < 1$ and $M \geq 2B$, there exist partially-persistent external-memory search trees over any totally ordered set, that support* Insert *and* Delete *in amortized $\mathcal{O}\big(\frac{1}{\varepsilon B^{1-\varepsilon}} \log_B N_v\big)$ I/Os,* Search *in amortized $\mathcal{O}\big(\frac{1}{\varepsilon} \log_B N_v\big)$ I/Os, and* Range *in amortized $\mathcal{O}\big(\frac{1}{\varepsilon} \log_B N_v + K/B\big)$ I/Os. Here N_v denotes the number of keys contained in version v, and K the number of keys reported by* Range*. The space usage is linear in the total number of updates.*

Our construction is essentially a B^ε-tree with buffers of $\mathcal{O}(B)$ delayed updates at each internal node, leaves storing $\Theta\big(\frac{1}{\varepsilon} B \log_B N_v\big)$ updates, and where partially persistence is obtained using path copying of nodes, where an internal node is only copied when its buffer is empty.

The query Search can trivially also answer a member query "$x \in \mathcal{S}_v$?" by checking if Search(v, x) returns x. Our data structure also supports predecessor queries along with successor queries, as well as strict predecessor and successor queries, i.e., the returned key should be strictly smaller or larger than the query key x. The structure can also handle the case when $\mathcal{S}_0 \neq \emptyset$, where the initial structure can be constructed using $\mathcal{O}(1 + |\mathcal{S}_0|/B)$ I/Os (essentially this is Section 2.6, where a structure is constructed for a given sorted set of keys). Our data structure is stated as maintaining a set of keys, but it can easily be extended to

support dictionaries storing key-value pairs (each vertical segment in Figure 1 now stores a key-value pair, where the first axis is the key. Changing the value for key x at version v starts a new vertical segment at (x, v) with the new value).

In Section 3 we describe how to convert the amortized I/O bounds of Theorem 1 to worst-case bounds under the assumption that $M = \Omega\big(B^{1-\varepsilon}\log_2(\max_v N_v)\big)$ (Theorem 2), a weaker or equal assumption on the memory size than used in [7] and [16] for high-probability and worst-case bounds for B^ε-trees, respectively. Under the weakest assumption that $M \geq 2B$, we achieve the worst-case bounds in Theorem 3 with an additional term of at most $\mathcal{O}\big(sort\big(B^{1-\varepsilon}\log_2 N_v\big)\big)$ I/Os, where $B^{1-\varepsilon}\log_2 N_v$ is an upper bound on the number of buffered updates on a root-to-leaf path in our buffered B^ε-tree that should be flushed to a leaf. For updates, where the I/O bound can be $o(1)$, we assume that the I/Os are performed evenly spread out among the updates.

▶ **Theorem 2.** *Given any parameter $0 < \varepsilon < 1$ and $M = \Omega\big(B^{1-\varepsilon}\log_2(\max_v N_v)\big)$, there exist partially-persistent external-memory search trees over any totally ordered set, that support* Insert *and* Delete *in worst-case $\mathcal{O}\big(\frac{1}{\varepsilon B^{1-\varepsilon}}\log_B N_v\big)$ I/Os,* Search *in worst-case $\mathcal{O}\big(\frac{1}{\varepsilon}\log_B N_v\big)$ I/Os, and* Range *in worst-case $\mathcal{O}\big(\frac{1}{\varepsilon}\log_B N_v + K/B\big)$ I/Os. Here N_v denotes the number of keys contained in version v, and K the number of keys reported by* Range*. The space usage is linear in the total number of updates.*

▶ **Theorem 3.** *Given any parameter $0 < \varepsilon < 1$ and $M \geq 2B$, there exist partially-persistent external-memory search trees over any totally ordered set, that support* Insert *and* Delete *in worst-case $\mathcal{O}\big(\frac{1}{B^{1-\varepsilon}}\big(\frac{1}{\varepsilon}\log_B N_v + \gamma\big)\big)$ I/Os,* Search *in worst-case $\mathcal{O}\big(\frac{1}{\varepsilon}\log_B N_v + \gamma\big)$ I/Os, and* Range *in worst-case $\mathcal{O}\big(\frac{1}{\varepsilon}\log_B N_v + \gamma + K/B\big)$ I/Os, where $\gamma = sort\big(B^{1-\varepsilon}\log_2 N_v\big)$. Here N_v denotes the number of keys contained in version v, and K the number of keys reported by* Range*. The space usage is linear in the total number of updates.*

Note that, for example, when $N_v = 2^{\mathcal{O}(B^\varepsilon)}$ then $B^{1-\varepsilon}\log_2 N_v = \mathcal{O}(B)$ and $\gamma = \mathcal{O}(1)$ and the I/O bounds of Theorem 3 match those of Theorem 2, with only the assumption $M \geq 2B$. This observation can be further strengthened, as when $\gamma = \mathcal{O}\big(\frac{1}{\varepsilon}\log_B N_v\big)$ the I/O bounds match similarly, which holds when $N_v = 2^{B^\varepsilon\left(\frac{M}{B}\right)^{\mathcal{O}\left(\frac{B^\varepsilon}{\varepsilon\log_2 B}\right)}}$.

Outline of Data Structure. Previous work on partially-persistent search trees in external memory directly adapted the general pointer-based transformations for persistence [20]. In contrast, our approach embraces the geometric interpretation of partial persistence like in [12], where the state of the data structure is embedded in a two-dimensional plane with keys on the first axis and versions on the second axis, see Figure 1(left). Under this interpretation, each update corresponds to the start or end of a vertical segment in the plane. Since partially-persistent updates are applied to the current version, it always affects the top of the plane. Successor and predecessor queries correspond to horizontal ray shooting to the right and left, respectively, and range queries to reporting the intersections between a horizontal query segment among vertical segments.

To efficiently update and query the geometric view, we partition the plane into rectangles, each containing $\Theta\big(\frac{1}{\varepsilon}B\log_B \overline{N}\big)$ vertical segments in lexicographic order. For now, we assume that all versions have size $\Theta\big(\overline{N}\big)$, for a fixed $\overline{N}$. This assumption is lifted using global rebuilding, see Section 2.6. In the geometric persistent view, a vertical segment crossing multiple rectangles is split into multiple smaller segments, one for each rectangle, and each smaller segment is inserted into one rectangle.

At a high level, our data structure is divided into two parts, see Figure 1(right). The top part consists of all the open rectangles containing the current set $\mathcal{S}_{v_c}$, which may still be updated. The entry point of this data structure is a B^ε-tree T on the key axis to facilitate

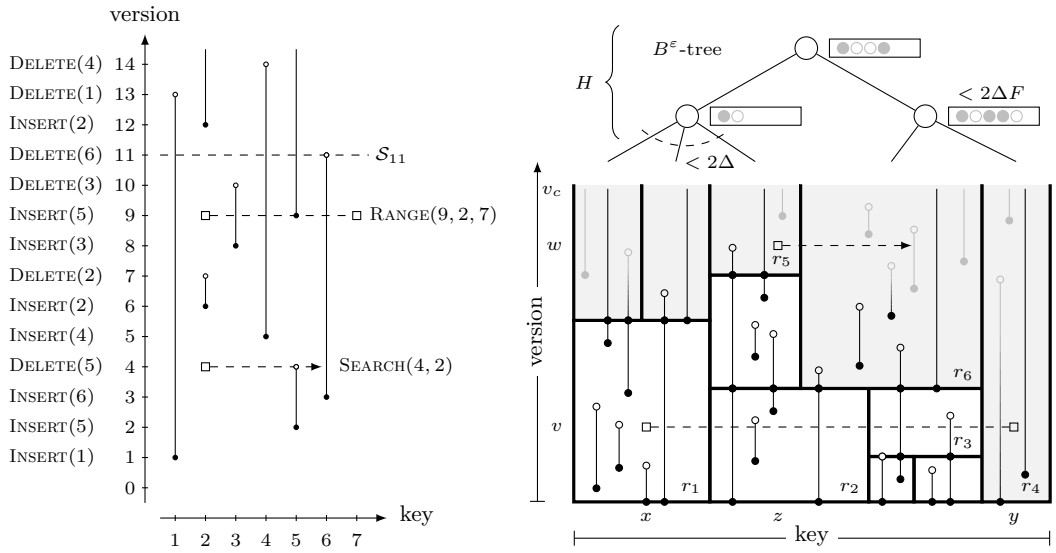

Figure 1 (Left) A list of updates performed on an initially empty set and the geometric interpretation of the updates. Vertical lines illustrate the half-open intervals of versions containing a key. Note that the key 3 is contained in versions $[8, 10[$, i.e., versions 8 and 9, whereas the key 2 is contained in version 6 and versions $[12, \infty[$. The topmost dashed line shows that version 11 of the set is $\mathcal{S}_{11} = \{1, 4, 5\}$, the dashed line segment at version 9 shows that the result of the query $\textsc{Range}(9, 2, 7)$ is $\{3, 4, 5, 6\}$, and the bottommost dashed arrow shows that the result of the successor search $\textsc{Search}(4, 2)$ is 6. (Right) A B^ε-tree of the open rectangles and below the geometric interpretation of the updates, split into multiple rectangles, where gray rectangles are open rectangles. The black endpoints represent updates present in the rectangles and the gray endpoints represent buffered updates present in the buffers at the internal nodes of the B^ε-tree. A query $\textsc{Range}(v, x, y)$ is represented as the dashed line between two square endpoints, spanning rectangles r_1, r_2, r_3, and r_4, and a successor query $\textsc{Search}(w, z)$ is represented as the dashed arrow from a square endpoint, spanning two rectangles r_5 and r_6. Black dots on vertical segments correspond to the upper endpoint of the segment in the rectangle below and the lower endpoint of the segment in the rectangle above.

buffered updates and to find the relevant rectangle(s) for updates and queries. Since updates are buffered, the geometric view stored in the rectangles may be incomplete, since buffered updates (segment endpoints) will first be added to the rectangle when buffers are flushed. The bottom part consists of all the finalized rectangles, i.e., rectangles which can be queried but not updated. The entry point to the bottom part is a point location data structure P to find the relevant rectangle(s) for a query. We implement P as an external-memory adaption of the classical planar point location solution using partial persistence [3, 31], more specifically a B-tree with path copying during updates.

2 The Buffered Persistent Data Structure

In this section, we describe our partially-persistent B^ε-tree structure. Versions are identified by the integers $0, 1, 2, \ldots$, where v_c denotes the identifier of the current version. We let $\mathcal{S}_v$ denote the set at version v, where keys are from some totally ordered set. The initial set $\mathcal{S}_0 = \emptyset$, and $\mathcal{S}_{v+1} = \mathcal{S}_v \cup \{x\}$ if the $v+1$'th update is $\textsc{Insert}(x)$, and $\mathcal{S}_{v+1} = \mathcal{S}_v \setminus \{x\}$ if the $v+1$'th update is $\textsc{Delete}(x)$. Note that $\mathcal{S}_{v+1} = \mathcal{S}_v$ if the $(v+1)$'th update inserts a key already in $\mathcal{S}_v$ or is deleting a key not in $\mathcal{S}_v$.

2.1 Geometric Interpretation of Partial Persistence

The problem has a natural geometric interpretation in a two-dimensional space, with the first dimension representing the keys and the second dimension representing the versions, see Figure 1(left). On this two-dimensional plane, a key x existing in a half-open interval of versions $[v, w[$, is represented by the vertical line segment $\{x\} \times [v, w[$, i.e., x is inserted in version v and deleted in version w. If $x \in \mathcal{S}_{v_c}$, then $w = +\infty$ (x has not been deleted yet).

2.2 Partitioning the Plane into Rectangles

We consider the sequence of versions partitioned into intervals $[v_0, v_1[, \ldots, [v_{k-1}, v_k[, [v_k, \infty[$, for some versions $0 = v_0 < v_1 < \cdots < v_k \leq v_c$. In Section 2.6 we show how to maintain the version intervals. We let $\overline{v} = v_k$ and $\overline{N} = |\mathcal{S}_{\overline{v}}|$. In the following, we consider the interval $[\overline{v}, \infty[$, which contains the current version v_c of the set. We allow up to $\alpha \cdot \overline{N}$ partially-persistent updates during this interval of versions for a constant $0 < \alpha < 1$, i.e., all versions v, $\overline{v} \leq v \leq v_c$, satisfy $(1-\alpha) \cdot \overline{N} \leq |\mathcal{S}_v| \leq (1+\alpha) \cdot \overline{N}$.

Our data structure is built around four parameters:

$$\Delta = \lceil B^{\varepsilon} \rceil \qquad H = 1 + \lceil \log_{\Delta} \overline{N} \rceil \qquad F = \lceil B^{1-\varepsilon} \rceil \qquad R = H \cdot 2\Delta \cdot F$$

The basic idea is to have a B^{ε}-tree T of degree at most $2\Delta - 1$ (and degree at least Δ, if only insertions can be performed, and degree at least 1 if deletions are allowed), where leaves (open rectangles) store between $4R$ and $10R$ updates (see Section 2.4) and all leaves are at the same level of T. In Section 2.5 we prove that H is an upper bound on the height of T (number of nodes on a root-to-leaf path, excluding the leaves). Each internal node of T will have a buffer of at most $2\Delta F = \Theta(B)$ updates yet to be applied to the leaves of the subtree rooted at the node. Note that R is an upper bound on the total number of buffered updates along a root-to-leaf path in T. The essential property of the parameters is that $R/B = \Theta(H) = \Theta(\frac{1}{\varepsilon} \log_B \overline{N})$.

The geometric plane defined in Section 2.1 is partitioned into a set of axis aligned rectangles $[x, y[\times [v, w[$, such that the number of updates in each rectangle is $\Theta(R)$. For each rectangle we store a list of the updates in the rectangle in lexicographical order by first the key and secondly the version of that update. Note that equal keys are group consecutively in the list. To allow efficiently locating a rectangle for a given version and key, we store a list indexed by version identifier, where we for each version v store a pointer to the root of a B-tree P_v over the rectangles left-to-right containing $\mathcal{S}_v$ (see Section 2.4). The tree P_v has degree $\Theta(B)$ and does not store buffered updates. Further, we require that each rectangle contains $\Omega(R)$ keys which are present in all versions the rectangle spans. We denote such a key as *spanning*. If $\overline{N} = \mathcal{O}(R)$, all updates are stored in a single list.

New updates are buffered, to achieve I/O efficient update bounds. The topmost rectangles, which cover the current version v_c, are all *open*, with all other rectangles being *closed*. Crucially, new updates are always performed in the current version. We maintain the invariant that for a buffered update, i.e., an update not having been flushed to the corresponding rectangle yet, the rectangle must be open.

For the open rectangles, we store a B^{ε}-tree T, such that recent updates to the open rectangles are buffered. We let the maximum degree of an internal node in T be $2\Delta - 1$. Each internal node of T contains a buffer of up to $2\Delta F$ updates, sorted lexicographically by key and version. Additionally, each update stores if the update is an insertion or deletion. Consider a full buffer, i.e., it contains at least $2\Delta F$ updates, where each update should be *flushed* to one of the at most $2\Delta - 1$ children. Then, there must exist a subset of least F updates that should be flushed to the same child.

The setup is illustrated on Figure 1(right). The vertical black and gray lines represent the version intervals containing a key. The black lines represent updates present in the list of updates contained in that rectangle, while the gray lines and endpoints represent updates contained in buffers of T, which are illustrated at the top of the figure.

2.3 Handling Queries and Updates

When performing $\textsc{Search}(v, x)$, first the rectangle r covering point (x, v) in the plane must be found. By using the B-tree P_v associated with version v, r can be found using $\mathcal{O}(H)$ I/Os. If r is closed, then all updates inside r are contained in the sorted list of updates stored in r, and these can be scanned in $\mathcal{O}(R/B)$ I/Os. If r is open, then the result of the successor query may be affected by buffered updates, which are not stored in r. The rectangle r must therefore be *actualized*, by merging all updates in buffers on the path from the root of T to r with the updates in r. The details of this operation are described in Section 2.4, where the actualize operation is shown to take amortized $\mathcal{O}(H)$ I/Os. After r is actualized, the query continues by scanning the updates of r. If the result of the successor query is not contained in the rectangle r, then by the spanning requirement, the result of the query must be in the neighboring rectangle to the right, that similarly is actualized if it is open. In total, the operation spends amortized $\mathcal{O}(H + R/B) = \mathcal{O}\big(\frac{1}{\varepsilon}\log_B \overline{N}\big)$ I/Os. Note that the operation easily can be modified to support member, predecessor, and strict predecessor or successor queries.

A $\textsc{Range}(v, x, y)$ query is performed very similarly to a $\textsc{Search}$ query. The query may however touch more than two rectangles. Note that for the at most two rectangles containing the endpoints of the query we do not necessarily report all keys they contain at version v. These rectangles can be found using amortized $\mathcal{O}(H + R/B)$ I/Os by the argument above. For each intermediate rectangle accessed (and possibly actualized if it is open), then by the spanning requirement, a constant fraction of the updates scanned result in reported keys. Since accessing a rectangle takes amortized $\mathcal{O}(H + R/B)$ I/Os, and each rectangle contains $\Theta(R) = \Theta(B \cdot H)$ keys at version v, then amortized $\mathcal{O}(1/B)$ I/Os are spent for each key reported for an intermediate rectangle. In total, a $\textsc{Range}$ query reporting K keys takes amortized $\mathcal{O}(H + R/B + K/B) = \mathcal{O}\big(\frac{1}{\varepsilon}\log_B \overline{N} + K/B\big)$ I/Os.

Each update, either an $\textsc{Insert}$ or $\textsc{Delete}$, is applied to the current version v_c of the set. The B^ε-tree T contains all buffered updates to the open rectangles, which cover the current version v_c. For an update operation, a tuple with the update and v_c is added to the root buffer of T, which is stored in internal memory. In Section 2.4 it is shown that adding the update to the root buffer and handling possible *buffer overflows* takes amortized $\mathcal{O}(H/F) = \mathcal{O}\big(\frac{1}{\varepsilon B^{1-\varepsilon}}\log_B \overline{N}\big)$ I/Os.

2.4 Flushing Buffers

To argue about the amortized cost of flushing the content of buffers down the tree T, we let the potential of each buffered update be $1/F$ multiplied by the height of the buffer the update is stored in, with the root buffer being at the largest height. One unit of released potential can cover $\mathcal{O}(1)$ I/Os. When adding an update to the tree, the root buffer is always stored in internal memory, and therefore no I/Os are needed to access it. However, the potential is increased by at most $1/F \cdot H$, and the operation therefore uses amortized $\mathcal{O}(H/F)$ I/Os.

Buffer Overflows. Each buffer at an internal node of T contains at most $2\Delta F$ updates. If a buffer contains more than $2\Delta F$ updates, then a *buffer overflow* is performed. Since each node of T has at most $2\Delta - 1$ children, at least F updates from the buffer must be to the same child. These updates can be moved together to the buffer of that child.

A buffer overflow can happen in two cases. Either when an update is placed into the root buffer as the result of an update operation, or when updates are placed into a buffer because the parent buffer is overflowing. Moving exactly F updates out of a buffer, is always sufficient to make an overflowing buffer non-overflowing again. A buffer overflow therefore only moves down a single path of T.

An overflowing buffer can be stored in $\mathcal{O}(1)$ blocks, since $2\Delta F + F = \mathcal{O}(B)$, and therefore the F updates to move can be found in $\mathcal{O}(1)$ I/Os. If the overflowing updates are moved to a child buffer, these can be inserted via a merge in $\mathcal{O}(1)$ I/Os. As F updates are moved one level down the tree, then the potential decreases by 1, which is enough to cover the $\mathcal{O}(1)$ I/O cost of the overflow operation.

If the child is not an internal node of T, but an open rectangle, then merging the F overflowing updates into the list of updates in the rectangle takes $\mathcal{O}(R/B) = \mathcal{O}(H)$ I/Os. As buffer overflows only move down a single path of the tree, then $\Omega(H)$ overflows must have occurred before the overflow reaches the open rectangle. Merging the overflow into the list of updates in the open rectangle therefore does not increase the asymptotic amortized number of I/Os performed.

Actualizing. When *actualizing* an open rectangle, all buffered updates to that open rectangle must be moved into the rectangle. Note that all relevant updates are in the buffers on the root-to-leaf path in T to the open rectangle. Each of these buffers contains at most $2\Delta F = \mathcal{O}(B)$ buffered updates. The total number of buffered updates on the path is at most $H \cdot 2\Delta \cdot F = R$. For each node on the path from the root down to the rectangle the following is done. Let U be the updates on the path from the levels above in sorted order. Initially, U is empty. To extend U for each level top-down, U is merged with the relevant updates of the next buffer. This requires $\mathcal{O}(1 + |U|/B)$ I/Os, by scanning U and the buffer. Since the U updates are moved one level down, they release potential $|U|/F \geq |U|/B$, that can cover $\Theta(|U|/B)$ I/Os, i.e., the amortized cost for actualizing one level of the tree is $\mathcal{O}(1)$ I/Os. As there are $\mathcal{O}(H)$ levels of the tree, the at most R relevant updates can be found in sorted order in amortized $\mathcal{O}(H)$ I/Os. They can then be merged with the updates in the open rectangle in $\mathcal{O}(R/B)$ I/Os. In total, the actualize operation requires amortized $\mathcal{O}(H + R/B) = \mathcal{O}(H)$ I/Os.

Finalizing. Each open rectangle is allowed to receive between R and $2R$ updates before it is *finalized*, converting it into a closed rectangle. When finalizing an open rectangle, all buffered updates to the rectangle are removed from T and merged with the rectangle, to ensure that all buffered updates in T are only to open rectangles. We now argue that open rectangles receive at most $2R$ updates in total by finalizing the rectangle as soon as R updates have been added to it. A finalize operation can be triggered from an actualize operation or from a buffer overflow. In both cases the number of updates in the rectangle before the operation is at most $R - 1$. An actualize operation may add at most R buffered updates to a rectangle, i.e., at most $2R - 1$ total updates are placed in a finalized rectangle. If the rectangle receives an update from a buffer overflow, then the overflow must have been triggered by an update in the root buffer. Buffered updates to add to the rectangle can only be the R updates in buffers on the path, and the new update, which in total is at most $(R - 1) + R + 1 = 2R$ updates to add to the open rectangle. Thus, by finalizing a rectangle as soon as it receives at least R updates, it will receive between R and $2R$ updates.

Spanning Requirement. We require that the first version of a rectangle contains $[4R, 8R[$ keys. When finalizing a rectangle, $[R, 2R]$ updates have been performed and therefore at least $2R$ of the initial keys are still present, that is, span all versions of the rectangle. This ensures that the $\Omega(R)$ spanning keys requirement is met. When finalizing a rectangle, $[2R, 10R[$ keys are contained in the rectangle at version v_c. New open rectangles must be created to span the key range of the closed rectangle, containing the keys present at version v_c. If $[4R, 8R[$ keys are present at version v_c, then a single rectangle suffices. If $[8R, 10R[$ keys are present at version v_c, then the range is *split* in two rectangles at the median key, both with $[4R, 5R]$ keys, and T must be updated as described below. Otherwise, at version v_c the rectangle contains $[2R, 4R[$ keys. In this case a sibling rectangle is finalized, to allow for a *merge* of two rectangles. The sibling rectangle holds $[2R, 10R[$ keys at version v_c. Concatenation the keys present at version v_c from the two closed rectangles gives a sorted list of $[4R, 14R[$ keys for a new open rectangle. A split may need to be performed if there are $8R$ or more keys, i.e., the result is one or two new open rectangles.

Updating the B^ε-Tree T. After finalizing open rectangles, the B^ε-tree must be updated accordingly. If an open rectangle was split, then a new child is added to the parent node in T of the updated rectangle. If this increases the degree of the node to 2Δ, it is split by distributing its children into two new nodes, each with degree Δ. Its buffer is also partitioned so that each buffered update is placed in the buffer containing its relevant child. Splitting the node further introduces a new child to the parent of the node. Note that this may cascade up the tree, but only on the path towards the root. If a merge of the rectangle occurs, then a child is deleted from the parent. When merging rectangles, the merged rectangles must be siblings in the tree. The rectangle is merged with the left or right neighbor rectangle, which has a nearest common ancestor with the rectangle in T, to ensure that the key range of existing nodes only increase. This may cause the degree of nodes to be below Δ. Notably, we do not merge internal nodes of T, as this could create a large buffer that requires multiple flushes in different directions, known as *flushing cascades* [7]. We instead allow nodes to have a degree down to one, where deleting the last child results in deleting the path of consecutive degree-one from the child towards the root. As we show in Section 2.5, this does not affect the asymptotic height of the tree.

Updating the rectangles and the B^ε-tree T upon finalizing therefore requires scanning $\mathcal{O}(R)$ keys and traversing a constant number of paths of length $\mathcal{O}(H)$ in T, which takes $\mathcal{O}(R/B + H) = \mathcal{O}(R/B)$ I/Os. As $\Omega(R)$ updates must be applied to a rectangle before finalizing it, this does not increase the asymptotic amortized cost of an update operation. Queries may also finalize rectangles, but already use amortized $\mathcal{O}(H)$ I/Os, causing no asymptotic query overhead.

Recall, that we maintain a list that for any version v stores a pointer to the root of a B-tree P_v over the rectangles left-to-right for version v. If the set of rectangles is unchanged from version $v_c - 1$ to v_c, we have $P_{v_c} = P_{v_c-1}$. If a rectangle is finalized during version v, the set of rectangles changes and we need to create a new P_{v_c} from P_{v_c-1}. Since only $\mathcal{O}(1)$ rectangles are removed and created in the new version, we can create P_{v_c} from P_{v_c-1} partially persistently by standard B-tree updates and rebalancing using naive *path copying* [31], using $\mathcal{O}(\log_B(N_v/R)) = \mathcal{O}(H)$ I/Os and $\mathcal{O}(H) = \mathcal{O}(R/B)$ blocks of space.

Space Usage. When finalizing a rectangle, $\Omega(R)$ updates must have occurred in that rectangle. New rectangles are then created, which in total copies $\mathcal{O}(R)$ updates, and one path of the tree is copied. As the height of the tree is at most $H = \mathcal{O}(R/B)$, and the updates

of the rectangles are stored in lists, the newly allocated space is $\mathcal{O}(R/B)$, which can be amortized over the $\Omega(R)$ updates required for the finalization to happen. In addition to the updates, initially $\overline{N}$ keys are stored across $\mathcal{O}\big(\overline{N}/R\big)$ rectangles in lists, and an initial balanced B^ε-tree is built on these initial rectangles, causing an initial space of $\mathcal{O}\big(\overline{N}/B\big)$ blocks. As the structure allows for at most $\alpha \cdot \overline{N}$ updates, the total space usage is $\mathcal{O}\big(\overline{N}/B\big)$ blocks.

2.5 Bounding the Tree Height

In this section we show that H is an upper bound on the height of the B^ε-tree T.

We define the *weight* of a node at height i in T to be the number of updates on keys in the key range of the node, and let w_i be a lower bound for the weight of a node at height i. The rectangles are at height 0 of the tree, with the nodes of the tree starting at height 1. The updates are both the $\overline{N}$ initial keys as well as the up to $\alpha \cdot \overline{N}$ additional updates. It holds that the weight of a node is the sum of the weights of its children. By induction on the number of updates we show that $w_i \geq B\Delta^i$ for all nodes at all heights, except for the root. First note that the inequality holds for $i = 0$, as any rectangle contains at least $4R \geq B$ updates when it was created. Initially, $\overline{N}$ updates are distributed into at most $\overline{N}/(4R)$ rectangles, where the number of updates in each rectangle is at least $4R \geq B$. Each internal node initially has degree $[\Delta, 2\Delta[$, except for the root that has degree $[2, 2\Delta[$. By induction on the tree height i, it holds that the initial tree satisfies $w_i \geq B\Delta^i$, except for the root. Each update affects a root-to-leaf path of the tree. If the tree is not updated, then the weights of the nodes on the path can only grow, and therefore the inequality holds. If rectangles are merged, then one rectangle disappears together with all the ancestors having only this single rectangle as a leaf. The other rectangle and its ancestors up to the least common ancestor of the two merged leaves get their key ranges expanded. It follows that the surviving nodes after merging rectangles only can have their key range increase, and therefore the inequality holds. If a split occurs in any node at height i, then the degree of the node before the split is 2Δ. The node is split into two nodes at height i, each with Δ children. The weight of each of the two nodes is therefore at least $\Delta \cdot w_{i-1} \geq \Delta \cdot B\Delta^{i-1} = B\Delta^i$. Therefore, it holds that $w_i \geq B\Delta^i$.

Since the number of updates is at most $(1+\alpha) \cdot \overline{N}$, we have $B\Delta^i \leq (1+\alpha) \cdot \overline{N}$ for all nodes at height i, except for the root. Since by definition $2 \leq \Delta \leq B$ and $\alpha < 1$, we have $\Delta^{i+1} \leq 2\overline{N}$, i.e., $i \leq \log_\Delta\big(2\overline{N}\big) - 1 \leq \log_\Delta \overline{N}$. The height of T is then at most the largest value of i satisfying this inequality, plus one for the root, i.e., the height of T is at most $1 + \log_\Delta \overline{N} \leq 1 + \lceil \log_\Delta \overline{N} \rceil = H$.

2.6 Global Rebuilding

The data structure above allows for an initial set of $\overline{N}$ keys to receive up to $\alpha \cdot \overline{N}$ persistent updates, for a constant $0 < \alpha < 1$. For any version v, we have $(1-\alpha) \cdot \overline{N} \leq N_v \leq (1+\alpha) \cdot \overline{N}$, i.e., $N_v = \Theta\big(\overline{N}\big)$. Therefore, the asymptotic costs of all operations also hold with $\overline{N}$ replaced by N_v.

To allow for more than $\alpha \cdot \overline{N}$ updates, we create multiple copies of the data structure above using global rebuilding [29, 30]. Whenever the current data structure reaches $\alpha \cdot \overline{N}$ updates, a new data structure is created with initial set $\mathcal{S}_{v_c}$ and $\overline{N}_{\text{new}} = |\mathcal{S}_{v_c}|$ (and new H and R parameters), with a new set of rectangles and a new B^ε-tree T, where all buffers are empty. We compute $\mathcal{S}_{v_c}$ by performing $\textsc{Range}(v_c, -\infty, \infty)$ in amortized $\mathcal{O}\big(\frac{1}{\varepsilon}\log_B \overline{N} + K/B\big) = \mathcal{O}\big(\overline{N}/B\big)$ I/Os. This actualizes all open rectangles which now can be closed. The new data

structure can be build using $\mathcal{O}(\overline{N}/B)$ I/Os by a single scan of the sorted list containing $\mathcal{S}_{v_c}$. In the old data structure $\alpha \cdot \overline{N}$ updates have been performed before this rebuild is performed. By amortizing the rebuild cost over these updates, the amortized cost of each update is increased by $\mathcal{O}(1/B)$ I/Os, i.e., the asymptotic amortized cost of an update is not increased. As the space usage of the new data structure is $\mathcal{O}(\overline{N}/B)$ blocks, a similar argument can be used to amortize the space usage over the updates, maintaining a linear space usage in the total number of updates. This concludes the proof of Theorem 1.

3 Worst-Case Bounds

In this section, we describe how to achieve worst-case I/O guarantees instead of amortized under progressively weaker assumptions on the internal memory size M. Previous approaches to improving the amortized performance of ephemeral B^ε-trees, both in the randomized [7] and worst-case [16] setting, assumed at least that $M = \Omega(\frac{1}{\varepsilon} B \log_B \overline{N}) = \Omega(HB)$, which allows all buffers on a path to be sorted in internal memory, i.e., $\mathcal{O}(sort(HB)) = \mathcal{O}(H)$ I/Os. First, in Section 3.1, we show that if $M = \Omega(HB)$, our persistent structure can be deamortized without asymptotic overhead, by applying incremental global rebuilding for handling changing $\overline{N}$ and performing the flushing along a root-to-leaf path incrementally. Then, in Section 3.2, we relax the assumption to $M = \Omega(B^{1-\varepsilon} \log_2 \overline{N})$ (Theorem 2). We apply the *subtracting game* studied by Dietz and Raman [18] to argue that the buffer of a node can at most store $\mathcal{O}(F \log_2 \Delta)$ updates towards each child, if we always recursively flush F updates to the child with most updates when a node receives F updates from its parent. This represents an improvement by a factor $B^\varepsilon / \log_2 B$ on the assumption for the size of the internal memory. Finally, in Section 3.3, we show worst-case results when only assuming $M \geq 2B$, which introduces a small additive overhead on all operations (Theorem 3). We employ *the zeroing* game by Dietz and Sleator [19, Theorem 5] to avoid a multiplicative overhead for RANGE queries, by incrementally splitting and merging the open rectangle with the most updates.

3.1 Large Internal Memory Assumption

We first consider the case when $M = \Omega(HB)$. When actualizing a rectangle (see Section 2.3), the buffers at the $\mathcal{O}(H)$ nodes along the root-to-leaf path, with a total size of $\mathcal{O}(HB)$, are merged to produce a sorted list of updates to apply to the rectangle. As shown in Section 2.4, this can be done in amortized $\mathcal{O}(H)$ I/Os, by merging the buffers top-down. In the worst case, this requires $\mathcal{O}(H^2)$ I/Os. By instead merging the buffers using an external memory sorting algorithm, the worst-case number of I/Os can be improved to $\mathcal{O}(sort(HB))$. Previous approaches to improving the amortized performance of B^ε-trees in the randomized [7] and worst-case [16] settings both assumed at least that $M = \Omega(HB)$, in which case the sorting term trivially disappears by performing the sorting internally after reading the H buffers into internal memory. The remaining challenge was handling flushing cascades, which occur when merging internal nodes of T results in large buffers requiring many flushes in different directions. For our structure, we avoid this issue, by never merging internal nodes, and instead maintain the height of T using global rebuilding. For the remainder of this section, we assume a large internal memory of size $M = \Omega(HB)$ and describe how to achieve worst-case guarantees by incrementally performing amortized work.

Queries. Finding and actualizing a relevant rectangle for a query takes $\mathcal{O}(H + sort(HB)) = \mathcal{O}(H)$ I/Os when $M = \Omega(HB)$. The worst case for a SEARCH and RANGE query is therefore $\mathcal{O}(H)$ and $\mathcal{O}((1 + K/R)\,H) = \mathcal{O}(H + K/B)$ I/Os, respectively. Note that for a RANGE query, for each rectangle that intersects the query, except for the leftmost and rightmost ones, $\Omega(R)$ keys are reported due to the $\Omega(R)$ spanning keys in each rectangle.

Updates. When performing an update, it may be the $\lceil \alpha \cdot \overline{N} \rceil$'th update, which triggers a global rebuild of the structure based on a new $\overline{N}$, which uses $\mathcal{O}(\overline{N}/B)$ I/Os, as described in Section 2.6. However, by performing the global rebuilding incrementally [29, 30] over the next $\Theta(\overline{N})$ updates, this does not increase the asymptotic worst-case number of I/Os of each update. While initializing the new structure there are still updates happening which must then be applied before it can take over. By performing updates to the new structure at a sufficiently fast rate compared to the live structure this ensures that they stay within a constant factor of each other in size until the new structure takes over. Therefore, only the I/O cost of an update without global rebuilding needs to be considered.

Updates are inserted in the root buffer of the B^ε-tree, as described in Section 2.4. By keeping the root buffer in internal memory this uses no I/Os. If the root buffer overflows, it may cause buffer overflows along a root-to-leaf path down to an open rectangle, which may then be finalized by performing an actualize operation followed by a path copy. The update therefore requires $\mathcal{O}(H)$ I/Os in total under the large internal memory assumption. However, each time the root buffer overflows, F updates are removed from it, meaning this occurs at most every Fth update. Thus, when the root buffer overflows, we incrementally apply the update to the structure over the next F updates, ensuring that $\mathcal{O}(H/F)$ I/Os are performed per update in the worst case. To not interfere with the incremental work, we place new updates in a separate buffer while it is in progress and merge them with the root buffer when it is finished. If a path copy has occurred, the root pointers of the F most recent versions must be updated to the new root. Since they are stored together in an array indexed by their version identifier this takes $\mathcal{O}(1)$ I/Os. If a query occurs while an update is being performed incrementally, we complete the update before executing the query. This does not increase the asymptotic worst-case number of I/Os for queries.

3.2 Smaller Buffers on All Paths Using the Subtraction Game

In the previous section, we showed that there is no overhead on worst-case queries and updates compared to the amortized bounds, if the internal memory can hold all keys on a root-to-leaf path towards the same open rectangle. To lower the possible number of such keys, we slightly change the flushing strategy described in Section 2.4 where we only performed a flush when a buffer overflowed. Instead, for every F'th update, we flush along an entire root-to-leaf path, always flushing towards the child where most of the updates are going. We still flush at most F keys, which preserves the property that internal nodes of T contain at most $2\Delta F$ updates. In the following, we show that this flushing strategy guarantees that all buffers contain $\mathcal{O}(F \log_2 \Delta)$ updates going towards the same child, and therefore also the same leaf. This implies that the assumption $M = \Omega(HF \log_2 \Delta) = \Omega(B^{1-\varepsilon} \log_2 \overline{N})$ is sufficient to achieve no overhead for worst-case queries and updates. This is a factor $\Theta(B^\varepsilon / \log_2 B)$ improvement over the previous smallest assumption on M [16].

We can view each node as playing the *subtracting game* studied by Dietz and Raman [18] for the number of updates $x_1, x_2, x_3, ..., x_{2\Delta-1}$ going towards each of its at most $2\Delta - 1$ children. When at most F updates are flushed towards a node, and δ_i new updates are going

towards the ith child, then variable x_i is increased by δ_i. We flush towards the child j where most of the updates are going which sets the variable $x_j = \max\{x_j - F, 0\}$. Following [18, Theorem 3], scaled by a factor of F, this guarantees $x_i = \mathcal{O}(F \log_2 \Delta)$ for any i.

We also need to consider how merging and splitting nodes in T impacts the subtraction games. Only leaves of T, corresponding to open rectangles, are merged. When an internal node is split, it corresponds to evenly distributing the x_i variables from one game to two new games, except for one variable that is split into two new variables, each with a smaller or equal value. When a leaf, i.e., an open rectangle, is merged or split, the one or two rectangles involved are first actualized, which sets their variables to zero, a stronger operation than subtracting. Thus, the variable for a new rectangle is always zero and variables on root-to-leaf paths to actualized rectangles may be decremented. In all cases and for all games, variables are either decremented without adding to the game, or a copy of an existing game is created, where all variables in the copy are equal or smaller in value than before. This concludes the proof of Theorem 2.

3.3 Improving Worst-Case Range Queries Using the Zeroing Game

In this section, we consider the small-memory setting with $M \geq 2B$, to overcome the theoretical limitation of the memory assumptions made in Sections 3.1 and 3.2. Actualizing a rectangle by merging the relevant updates on a root-to-leaf path to a rectangle requires $\mathcal{O}(H + \gamma)$ total I/Os, where $\gamma = \mathit{sort}\big(B^{1-\varepsilon} \log_2 \overline{N}\big)$. The construction from the previous section directly results in worst-case Search queries using $\mathcal{O}(H + \gamma)$ I/Os and updates using $\mathcal{O}\big(\frac{1}{F}(H + \gamma)\big)$ I/Os. However, since Range queries are performed by repeatedly searching for the $\Theta(1 + K/R)$ rectangles intersecting the query, the worst-case number of I/Os is $\Theta((1 + K/R)(H + \gamma)) = \Theta\Big(H + \gamma + \frac{K}{B}\Big(1 + \frac{\varepsilon \log_2 B}{B^\varepsilon} \log_{M/B}\big(B^{-\varepsilon} \log_2 \overline{N}\big)\Big)\Big)$, notably with a multiplicative non-constant overhead on the reporting term. In this section, we describe how to guarantee Range queries in worst-case $\Theta\big(H + \gamma + \frac{K}{B}\big)$ I/Os when $M \geq 2B$.

The worst-case I/O cost of a Range query can be improved by merging all the buffered updates to the open rectangles intersecting the query in a top-down, level-by-level fashion. That is, by essentially actualizing all the open rectangles intersected by the Range query simultaneously. We denote the updates already present in the rectangles the *partial output list*. Rather than applying the buffered updates to the rectangles, we merge them with the partial output list to obtain the final output. A given query Range(v, x, y) reports $\Omega(R)$ keys from each intermediate rectangles, i.e., all rectangles intersecting the query except for the two that contain the endpoints x and y. Thus, in $\mathcal{O}((1 + K/R)H + (R + K)/B) = \mathcal{O}(H + K/B)$ I/Os we can find all the relevant rectangles and compute the partial output list. To collect the buffered updates in T for the intermediate open rectangles in sorted order, we merge the updates down level-by-level. We only move down the updates to versions earlier or equal to v since only these can affect the query result. Once obtained, these updates are merged with the partial output list using linear I/Os to report the output of the Range query.

The buffered updates are stored in T, which contains the open rectangles at version v_c, however, the Range query is on the rectangles present at version v. Let T_v denote the B^ε-tree on open rectangles at version v, i.e., the state of T when version v was created. From T_v to T the tree may have changed, but no later updates are relevant for the query. Thus, the total number of relevant updates does not increase from T_v to T, and each update remains on the root-to-leaf path towards the open rectangle to which the update is relevant. The relevant updates in T can be collected in sorted lists ordered by level by traversing each root-to-leaf path in T towards open rectangles intersecting the query using $\mathcal{O}((1 + K/R)H)$

I/Os. To bound the I/Os to move the updates down level-by-level, we show that the total number of updates is $\mathcal{O}\big(B^{1-\varepsilon}\log_2 \overline{N} + K/H\big)$. To this end, we need the additional invariant that the buffer of a degree one node is empty, which we show how to obtain below. Let T'_v be the subtree of T_v consisting of all nodes on root-to-leaf paths to rectangles intersecting the query. Then split T'_v into two root-to-leaf paths p_x and p_y to x and y, respectively, along with all the subtrees hanging off p_x or p_y. For a node on p_x (symmetrically p_y) of degree at least two there may be one or more subtrees T_{sub} hanging off the node. Since only the nodes of T_{sub} with degree at least two have non-empty buffers, if T_{sub} has ℓ leaves, the number of buffered updates in T_{sub} is at most $\mathcal{O}((\ell-1)B)$. Thus, the number of buffered updates in T'_v excluding degree one nodes on p_x and p_y is $\mathcal{O}(K/H)$. A degree one node on p_x and p_y may have a large degree in T_v, but since it only has one child in the direction of the query, due to the subtracting game, it stores at most $\mathcal{O}(F\log_2\Delta)$ relevant updates. The number of degree one nodes on p_x and p_y is at most $2H$, and they together contribute $\mathcal{O}\big(B^{1-\varepsilon}\log_2\overline{N}\big)$ buffered updates, which we locate and sort separately using $\mathcal{O}(H+\gamma)$ I/Os. For the remaining $\mathcal{O}(K/H)$ buffered updates, we merge them level-by-level using $\mathcal{O}(H+K/B)$ I/Os. In total, the worst-case number of I/Os to perform a RANGE query is $\mathcal{O}(H+\gamma+K/B)$ I/Os.

Empty Buffers for Degree one Nodes. To ensure that each node of degree one has an empty buffer, we alter the buffer capacity of nodes to scale with the degree. Let the capacity of the buffer of a node with degree $d \geq 2$ be at most $F\cdot\min\{2d, 2\Delta\}$, with nodes of degree one having a buffer capacity of 0. When flushing a node, as the maximum number of updates in the buffer scales with the degree, then at least F updates going to the same child can be found when overflowing. When splitting a node, it must have degree 2Δ, resulting in the two new nodes having degree Δ, which therefore does not decrease the buffer capacity, and flushing is not needed. When a child of a node is removed due to merging rectangles, the degree of the node is decreased by one. If the degree remains at least two, at most two flushes are required to get the buffer capacity within bounds. Otherwise, if the degree drops from two to one, at most four flushes are needed. To avoid cascading merges of rectangles, we do not finalize a rectangle once it receives a certain number of updates. Instead, we finalize the rectangle that has received the most updates, provided it has received at least R updates. This last condition ensures a bound on the space usage. Including the initial flush from the root buffer, then when a rectangle is finalized, at most $5F$ updates have been flushed into open rectangles.

Let U_i denote the number of updates to the ith rectangle, excluding the initial insertions. We extend the data structure to include an array over all open rectangles, where index j stores a blocked-linked-list of all rectangles where the number of updates is $U_i = j$. Each rectangle has a double linked pointer between its location in the array of lists and the rectangle. This allows for moving a rectangle to a new entry in the array, when it receives updates, as well as finding a rectangle which has received the most updates, by scanning the list.

To show that U_i is bounded by $\mathcal{O}(R)$, we apply the *zeroing game* of Dietz and Sleator [19], using the variables $x_i = \max\left\{0, \frac{U_i - R}{5F}\right\}$ if rectangle i is open and $x_i = 0$ if it is closed. For open rectangles, x_i counts the number of units of $5F$ updates received beyond the first R updates. This ensures that the variables are incremented by at most 1 in total for each round, when at most 5 flushes of size at most F are flushed into the open rectangles. When finalizing a rectangle, it becomes closed, which ensures that $x_i = 0$, matching the zeroing step. We bound the total number of rectangles by $\overline{N}$ and therefore also the number of variables. Following [19, Theorem 5] and the refined analysis in [13, Theorem 4], we have that for

all i, $x_i \leq \log_2 \overline{N} + 1$ at all times. Consequently, it follows that $U_i \leq 5F(\log_2 \overline{N} + 1) + R$. It can be shown that $5F(\log_2 \overline{N} + 1) \leq 2R$ for $\overline{N} \geq 4$, by simplifying the inequality using $R = 2\Delta F\left(1 + \left\lceil \log_\Delta \overline{N} \right\rceil\right)$ and showing $\frac{5}{4}\left(1 + \frac{1}{\log_2 \overline{N}}\right) \leq \frac{\Delta}{\log_2 \Delta}$, for all $\Delta \geq 2$ and $\overline{N} \geq 4$. It therefore holds that each rectangle receives at most $U_i \leq 3R$ updates, due to the zeroing game. Thus, when finalizing a rectangle, at least R updates have been performed. Including the updates from the buffers on the path towards the rectangle, the total number of updates applied is between R and $4R$. By ensuring that each rectangle contains $[8R, 16R[$ initial keys, the rebalancing operations are possible, and the spanning requirement remains satisfied.

An update therefore performs at most 5 flushes using $\mathcal{O}(H)$ I/Os, along with locating and finalizing a single rectangle in respectively $\mathcal{O}(R/B) = \mathcal{O}(H)$ and $\mathcal{O}(H + \gamma)$ I/Os. Performing this operation incrementally allows for updates to spend worst-case $\mathcal{O}\left(\frac{1}{F}(H + \gamma)\right)$ I/Os. If a query happens while an incremental update is being performed, the incremental update is completed, using at most $\mathcal{O}(H + \gamma)$ I/Os, which does not increase the total cost of the query. When a SEARCH query happens, similar to the new RANGE query, we do not apply the relevant updates on the path to the open rectangle to avoid queries interfering with the zeroing game. This concludes the proof of Theorem 3.

4 Discussion and Open Problems

Global rebuilding, as described in Section 2.6, allows for constructing a partially-persistent set of any sorted set in a linear number of I/Os, without recreating the set by a sequence of insertions. Symmetrically, it is possible to *purge* all versions of the set older than some threshold without performing all updates again. This problem was first motivated by Becker, Gschwind, Ohler, Seeger, and Widmayer [6]. As our data structure consists of multiple independent data structures covering disjoint version intervals, then all data structures which only cover versions to be purged can be removed efficiently by a linear number of I/Os. For both use cases, space usage is asymptotically linear in the size of the oldest stored set and the number of updates performed.

Further, global rebuilding allows for a crude fully persistent data structure, which supports efficient buffered updates and queries, but where cloning past versions requires a linear number of I/Os. The fully persistent data structure by Brodal, Rysgaard, and Svenning [12] allows cloning past versions in worst case $\mathcal{O}(1)$ I/Os. They do, however, not buffer updates, which therefore are amortized and a factor $\mathcal{O}\left(\varepsilon B^{1-\varepsilon}\right)$ slower than our data structure. Our data structure is therefore better when there are many updates, but few clones of past versions happening. Further, our data structure is simpler. It remains an open problem to design buffered fully-persistent search-trees that remain efficient for clone operations.

In Section 3 we showed how to achieve worst-case bounds matching those of ephemeral B^ε-trees, when $M = \Omega\left(B^{1-\varepsilon} \log_2 N\right)$. This is an improvement by a factor $\Theta(B^\varepsilon / \log_2 B)$ on the required lower bound on M over the worst-case results of B^ε-trees by Das, Iacono, and Nekrich [16]. It remains an open problem to show a worst-case I/O lower bound dependency on M, or alternatively, to find a structure with worst-case I/O guarantees matching the amortized I/O bounds for $M = 2B$.

Abstract

We investigate the problem of constructing *fault-tolerant bases* in matroids. Given a matroid $\mathcal{M}$ and a redundancy parameter k, a k-fault-tolerant basis is a minimum-size set of elements such that, even after the removal of any k elements, the remaining subset still spans the entire ground set. Since matroids generalize linear independence across structures such as vector spaces, graphs, and set systems, this problem unifies and extends several fault-tolerant concepts appearing in prior research.

Our main contribution is a fixed-parameter tractable (FPT) algorithm for the k-fault-tolerant basis problem, parameterized by both k and the rank r of the matroid. This two-variable parameterization by $k + r$ is shown to be tight in the following sense. On the one hand, the problem is already NP-hard for $k = 1$. On the other hand, it is Para-NP-hard for $r \geq 3$ and polynomial-time solvable for $r \leq 2$.

1 Introduction

A basis in a d-dimensional vector space $\mathcal{V}$ is a set of exactly d linearly independent vectors $\{\mathbf{v}_1, \ldots, \mathbf{v}_d\}$. Any vector $\mathbf{x} \in \mathcal{V}$ then has a *unique* representation $\mathbf{x} = \alpha_1\mathbf{v}_1 + \cdots + \alpha_d\mathbf{v}_d$. However, if certain basis vectors are lost or corrupted – for instance, in a distributed storage system where vectors are stored across multiple servers that can malfunction – it may be challenging or impossible to accurately recover $\mathbf{x}$. The algorithmic question we address in this paper is: *For an expected number k of failures, what is the minimum-size k-fault-tolerant set of vectors that still guarantees data reconstructability?*

A natural way to capture the notions of basis and independence is through *matroids*, which generalize linear independence to a variety of combinatorial settings (like graphs, set systems, vector spaces). Let $\mathcal{M} = (E, \mathcal{I})$ be a matroid, and let k be a nonnegative integer. We say that $B \subseteq E$ is a *k-fault-tolerant basis* of $\mathcal{M}$ if B is a minimum-size set such that, for every subset $F \subseteq B$ of size at most k, we have $\mathsf{rank}(B \setminus F) = \mathsf{rank}(\mathcal{M})$. (All necessary matroid definitions appear in the Preliminaries section.) Equivalently, this condition means that $\mathsf{cl}(B \setminus F) = E$, where $\mathsf{cl}(\cdot)$ denotes matroid closure. Note that this concept generalizes the standard basis definition: a 0-fault-tolerant basis is simply a basis of $\mathcal{M}$. However, while every matroid has a basis, it may not admit a k-fault-tolerant basis for $k \geq 1$. We investigate the following problem.

Fault-Tolerant Basis

Input:	A matroid $\mathcal{M} = (E, \mathcal{I})$ and nonnegative integer k.
Task:	Find a k-fault-tolerant basis $B \subseteq E$ or correctly decide that none exists.

Let us give some examples of Fault-Tolerant Basis.

Linear Matroids. A *linear matroid* over a field $\mathbb{F}$ can be represented by a set of vectors $\{\mathbf{v}_1, \ldots, \mathbf{v}_m\}$ in a vector space $\mathcal{V} \subseteq \mathbb{F}^d$. The rank of the matroid corresponds to $\dim(\mathcal{V})$. A basis here is simply a set of d linearly independent vectors. A set of vectors $\{\mathbf{u}_1, \ldots, \mathbf{u}_r\}$ is k-fault-tolerant if, after removing up to k vectors, the remaining set still spans the entire subspace $\mathcal{V}$. Such concepts naturally arise in distributed storage – where vectors might be stored on different servers [11] – and in coding theory, where losing some symbols or vectors should not destroy the ability to recover the entire space [13].

Graphic Matroids. For a connected graph G, its *graphic matroid* $\mathcal{M}(G)$ has ground set $E(G)$, and a set $I \subseteq E(G)$ is independent if it forms a forest. A basis is thus a spanning tree of G. In this matroid, a set of edges $B \subseteq E(G)$ is k-fault-tolerant if, upon removing any k edges, the subgraph remains connected. Thus, a k-fault-tolerant basis is a $(k+1)$-edge connected spanning subgraph with minimum number of edges. This problem is known in the literature as k-Edge-Connected Spanning Subgraph [8, 14, 17]. It is motivated by network applications as its task is to compute a minimum-cost sub-network that is resilient against up to k link failures (see also [5]).

Gammoids. A *gammoid* is derived from a directed (or undirected) graph D. Let X and Y be two distinguished sets of vertices of $V(D)$. Within the set X, define a subset $U \subseteq X$ to be *independent* if there exist $|U|$ vertex-disjoint paths in G originating from vertices in Y and ending in the vertices of U. The basis of the gammoid is the maximum set of vertices from X that can be reached by vertex-disjoint paths from Y. In this case, a vertex set $Z \subseteq X$ is a k-fault-tolerant basis if upon removing any k vertices from Z, the remaining vertices are still linkable from sources in Y without losing rank. This problem is related to the problem of finding fault-tolerant disjoint paths studied by Adjiashvili et al. [1].

Transversal Matroids. A *transversal matroid* $\mathcal{M}(U, \mathcal{S})$ is described via a bipartite graph between a ground set U and a set of "target positions" $\mathcal{S}$. A set $I \subseteq U$ is independent if it can be matched injectively to distinct elements in $\mathcal{S}$. The basis of the transversal matroid is a maximum-size subset $I \subseteq U$ that can be perfectly matched into $\mathcal{S}$. Finding a k-fault-tolerant basis for a transversal matroids is naturally related to robust matching problems, where one wants to preserve a perfect (or maximum) matching under the loss of a few vertices or edges [12, 18].

1.1 Our Contribution

We investigate the parameterized complexity of Fault-Tolerant Basis under natural parameterizations by k and the rank r of the input matroid. (We refer to the textbook by Cygan et al. [10] for an introduction to parameterized complexity.) Our main result is that the problem is FPT when parameterized by both k and r.

▶ **Theorem 1.** *Fault-Tolerant Basis can be solved in* $(kr)^{\mathcal{O}(kr^4)} \cdot n^{\mathcal{O}(1)}$ *time on* n*-element matroids of rank at most* r *given by independence oracles.*

To prove Theorem 1, we design an algorithm that recursively decomposes the input matroid and identifies a small *core set* containing any possible k-fault-tolerant basis, thereby restricting the problem to a bounded search space. More precisely, the algorithm locates a set W of *important elements* with bounded size such that, if the input matroid $\mathcal{M}$ admits a k-fault-tolerant basis, then there is one contained entirely in W. The construction of W is guided by the observation (see Observation 7) that if X is a rank-r set with $r + k$ elements such that *every* r-element subset of X is independent, then X is already a k-fault-tolerant basis. Hence, finding such an X would immediately solve the problem. Otherwise, we identify an inclusion-maximal rank-r set X (of bounded size) such that for every r-element subset $Y \subseteq X$, the rank of Y is r. The crucial insight here is that the closure $\mathsf{cl}(X)$ of X can be expressed as the union of $\mathsf{cl}(S)$ over all $(r-1)$-element subsets S of X. We then proceed recursively, selecting elements of W by searching for analogous sets in the closures of each S, applying the same approach used to choose X. Once we have computed W, we determine whether a k-fault-tolerant basis exists within W by enumerating all candidate subsets via a brute-force algorithm. If such a basis is found, it is also a valid solution for the original matroid.

We then show that the result of Theorem 1 is tight. First, by adapting the results of Fomin et al. [15] for our purposes, we observe the following lower bound.

▶ **Proposition 2.** *It is* W[1]*-hard for the parameterization by* k *to decide whether a given linear matroid has a* k*-fault-tolerant basis.*

For the parameterization of Fault-Tolerant Basis by k, we remind that Fault-Tolerant Basis for graphic matroids is equivalent to finding a $(k+1)$-edge connected spanning subgraph with the minimum number of edges. As was shown by Fernandes [14], an n-vertex graph G has a 2-edge connected spanning subgraph with at most n edges if and only if G has a Hamiltonian cycle. Thus, Fault-Tolerant Basis is intractable already for $k = 1$. Taking into account the inapproximability lower bounds for higher connectivities established by Gabow et al. [17], we obtain the following observation.

▶ **Observation 3.** *For every integer* $k \geq 1$*, it is* NP*-hard to decide whether a graphic matroid* $\mathcal{M}$ *given with an integer* $b \geq 1$ *has a* k*-fault-tolerant basis of size at most* b*.*

For the parameterization by the rank, we establish a dichotomy – for any fixed $r \geq 3$, Fault-Tolerant Basis is intractable, but for $r \leq 2$, the problem can be solved in polynomial time. In fact, for $r \leq 2$, we solve the more general weighted variant of Fault-Tolerant Basis. In Weighted Fault-Tolerant Basis, we are given a matroid $\mathcal{M}$ together with a weight function $w \colon E(\mathcal{M}) \to \mathbb{Z}_{\geq 0}$, and the task is to find a set $B \subseteq E(\mathcal{M})$ of minimum total weight such that for any set $F \subseteq B$ of size at most k, $\mathsf{rank}(B \setminus F) = \mathsf{rank}(\mathcal{M})$. Our result is summarized in the following theorem.

▶ **Theorem 4.** *For any integer $r \geq 3$, it is* NP*-hard to decide whether a linear matroid $\mathcal{M}$ of rank r over rationals given together with integers k and b has a k-fault-tolerant basis of size at most b. For $r \leq 2$,* Weighted Fault-Tolerant Basis *can be solved in $\mathcal{O}(n^2)$ on matroids given by an independence oracle.*

In particular, one can find a k-fault-tolerant basis of vectors in $\mathbb{R}^2$ in polynomial time but the problem becomes NP-hard in $\mathbb{R}^3$. To obtain the hardness for $r \geq 3$, we use the result of Froese et al. [16] stating that, given a set P of points on the plane and a positive integer k, it is NP-hard to decide whether P contains at least k points in general position. To establish the claim for $r \leq 2$, it is convenient to show a more general result for partition matroids which may be of independent interest.

▶ **Proposition 5.** *Given an n-element partition matroid $\mathcal{M}$ with unit capacities together with a weight function $w\colon E(\mathcal{M}) \to \mathbb{Z}_{\geq 0}$ and integers $r, k \geq 0$, one can find in $\mathcal{O}(n^2)$ time either a set $X \subseteq E(\mathcal{M})$ of minimum weight such that, for any set $F \subseteq X$ of size at most k, it holds that $\mathsf{rank}(X \setminus F) \geq r$ or correctly decide that such a set does not exist.*

1.2 Related Work

Adjiashvili, Stiller, and Zenklusen [2] introduced a *Bulk-Robustness* model of combinatorial optimization. They studied several instances of this framework, including the Bulk-Robust Minimum Matroid Basis problem, which is most relevant to our work. In this setting, for a matroid $\mathcal{M} = (E, \mathcal{I})$, we are given a collection of *interdiction sets* $\Omega = \{F_1, F_2, \ldots, F_m\}$, where $F_i \subseteq E(\mathcal{M})$ for each $i \in \{1, \ldots, m\}$. The goal is to find a cheapest subset $X \subseteq E(\mathcal{M})$ such that $X \setminus F_i$ contains a basis of $\mathcal{M}$ for every $i \in \{1, \ldots, m\}$. Adjiashvili, Stiller, and Zenklusen provided an $\mathcal{O}(\log m + \log r)$-approximation algorithm for Bulk-Robust Minimum Matroid Basis, where r is the rank of the matroid. The problem Fault-Tolerant Basis can be viewed as a special case of Bulk-Robust Minimum Matroid Basis when Ω consists of all subsets of E of size k.

There are several prior works investigating fault-tolerance for classic optimization problems. The model of s-t-Path and s-t-Flow problems with safe and vulnerable edges was introduced by Adjiashvili et al. [1], who studied the approximability of these problems. Subsequently, generalizations were also studied [3, 7, 9]. Bentert et al. [5] studied the parameterized complexity of computing a fault-tolerant spanning tree. Approximation algorithms and inapproximability lower bounds for k-Edge-Connected Spanning Subgraph have been considered in [8, 14, 17, 19].

More generally, Fault-Tolerant Basis belongs to *robust optimization*, a branch of optimization that adapts classic optimization-theoretic tools to settings with uncertainty. For a comprehensive introduction, see the survey by Bertsimas et al. [6].

2 Preliminaries

We refer to the book of Oxley [21] for a detailed introduction to matroids. A pair $\mathcal{M} = (E, \mathcal{I})$, where E is a finite *ground* set and $\mathcal{I}$ is a family of subsets of the ground set, called *independent sets* of $\mathcal{M}$, is a *matroid* if it satisfies the following conditions, called *independence axioms*:

(I1) $\emptyset \in \mathcal{I}$.

(I2) If $A \subseteq B \subseteq E$ and $B \in \mathcal{I}$ then $A \in \mathcal{I}$.

(I3) If $A, B \in \mathcal{I}$ and $|A| < |B|$, then there is $e \in B \setminus A$ such that $A \cup \{e\} \in \mathcal{I}$.

We use $E(\mathcal{M})$ and $\mathcal{I}(\mathcal{M})$ to denote the ground set and the set of independent sets, respectively. An inclusion-maximal independent set B is called a *basis* of $\mathcal{M}$. We use $\mathcal{B}(\mathcal{M})$ to denote the set of bases of $\mathcal{M}$. All the bases of $\mathcal{M}$ have the same size called the *rank* of $\mathcal{M}$ and

denoted by $\mathsf{rank}(\mathcal{M})$. The *rank* of a subset $A \subseteq E(\mathcal{M})$, denoted by $\mathsf{rank}(A)$, is the maximum size of an independent set $X \subseteq A$; the function $\mathsf{rank}\colon 2^{E(\mathcal{M})} \to \mathbb{Z}$ is the *rank* function of M. A set $A \subseteq E(\mathcal{M})$ *spans* an element $x \in E(\mathcal{M})$ if $\mathsf{rank}(A \cup \{x\}) = \mathsf{rank}(A)$. The *closure* (or *span*) of A is the set $\mathsf{cl}(A) = \{x \in E(M) \mid A \text{ spans } x\}$. Closures satisfy the following properties, called *closure axioms*:

(CL1) For every $A \subseteq E(\mathcal{M})$, $A \subseteq \mathsf{cl}(A)$.
(CL2) If $A \subseteq B \subseteq E(\mathcal{M})$, then $\mathsf{cl}(A) \subseteq \mathsf{cl}(B)$.
(CL3) For every $A \subseteq E(\mathcal{M})$, $\mathsf{cl}(A) = \mathsf{cl}(\mathsf{cl}(A))$.
(CL4) For every $A \subseteq E(\mathcal{M})$, every $x \in E(\mathcal{M}) \setminus A$, and every $y \in \mathsf{cl}(A \cup \{x\}) \setminus \mathsf{cl}(A)$, $x \in \mathsf{cl}(A \cup \{y\})$.

For $S \subseteq E(M)$, the matroid obtained by *deleting* S, denoted by $\mathcal{M}' = \mathcal{M} - S$, is the matroid such that $E(\mathcal{M}') = E(\mathcal{M}) \setminus S$ and $\mathcal{I}(\mathcal{M}') = \{X \in \mathcal{I}(\mathcal{M}) \mid S \cap X = \emptyset\}$. Let $r \geq 0$ be an integer. The *r-truncation* of a matroid $\mathcal{M}$ is the matroid $\mathcal{M}'$ with $E(\mathcal{M}') = E(\mathcal{M})$ such that $X \in \mathcal{I}(\mathcal{M}')$ if and only if $X \in \mathcal{I}(\mathcal{M})$ and $|X| \leq r$. A matroid $\mathcal{M}$ is a *partition* matroid if there is a partition $(P_1, \ldots, P_d)$ of the ground set and a d-tuple $(c_1, \ldots, c_d)$ of positive integers, called capacities, such that a set $X \subseteq E(G)$ is independent if and only if $|X \cap P_i| \leq c_i$ for every $i \in \{1, \ldots, d\}$. A $d \times n$-matrix $\mathbf{A}$ over a field $\mathbb{F}$ is a *representation of a matroid $\mathcal{M}$ over $\mathbb{F}$* if there is a one-to-one correspondence f between $E(\mathcal{M})$ and the columns of $\mathbf{A}$ such that for any $X \subseteq E(\mathcal{M})$, it holds that $X \in \mathcal{I}(\mathcal{M})$ if and only if the columns in $\{f(x) \mid x \in X\}$ are linearly independent (as vectors of $\mathbb{F}^d$). If $\mathcal{M}$ has such a representation, then $\mathcal{M}$ has a *representation over* $\mathbb{F}$. A matroid $\mathcal{M}$ admitting a representation over $\mathbb{F}$ is said to be *linear*; a matroid is *binary* if it has a representation over $\mathsf{GF}[2]$.

In our algorithms for general matroids, we assume that input matroids are given by *independence oracles*. Such an oracle for a matroid $\mathcal{M}$, takes as input a set $X \subseteq E(\mathcal{M})$ and correctly answers in a constant time whether $X \in \mathcal{I}(\mathcal{M})$. We note that some matroids could be given explicitly, for example, by their representations.

3 Basic Observations

In this section, we prove a couple of simple results that will be helpful in the later discussion. Recall that for an integer $k \geq 0$, $B \subseteq E(M)$ is a k-fault-tolerant basis of a matroid $\mathcal{M}$ if B is a subset of minimum cardinality such that $\mathsf{rank}(B \setminus F) = \mathsf{rank}(\mathcal{M})$ for every subset $F \subseteq B$ of size at most k. We use the following bounds on the size of a k-fault-tolerant basis.

▶ **Proposition 6.** *Let $\mathcal{M}$ be a matroid with $\mathsf{rank}(\mathcal{M}) \geq 1$ and let $k \geq 0$ be an integer. Then for a k-fault-tolerant basis B of $\mathcal{M}$, it holds that*

$$\mathsf{rank}(\mathcal{M}) + k \leq |B| \leq (k+1)\mathsf{rank}(\mathcal{M}).$$

Proof. The lower bound immediately follows from the definition of a k-fault-tolerant basis. To show the upper bound, assume for the sake of contradiction that $|B| > (k+1)\mathsf{rank}(\mathcal{M})$. We iteratively construct sets $X_0, \ldots, X_k$ where $X_0 \subseteq B$ is an inclusion-maximal independent set in B, and for each $i \in \{1, \ldots, k\}$, X_i is an inclusion-maximal independent set in $B \setminus \left(\bigcup_{j=0}^{i-1} X_j\right)$. Since $\mathsf{rank}(B) = \mathsf{rank}(\mathcal{M})$ and $|B| > (k+1)\mathsf{rank}(\mathcal{M})$, such sets $X_0, \ldots, X_k$ exist. Set $B' = \bigcup_{i=0}^{k} X_i$. Consider an arbitrary $F \subseteq B$ of size at most k. By the pigeonhole principle, there is an index $i \in \{0, \ldots, k\}$ such that $X_i \cap F = \emptyset$. By construction, it holds that $B \setminus B' \subseteq B \setminus \left(\bigcup_{j=0}^{i-1} X_j\right) \subseteq \mathsf{cl}(X_i)$. Hence, $B \setminus F \subseteq (B' \setminus F) \cup (B \setminus B') \subseteq \mathsf{cl}(B' \setminus F)$. Because B is a k-fault-tolerant basis, $\mathsf{cl}(B \setminus F) = E(\mathcal{M})$. Thus,

$$E(\mathcal{M}) = \mathsf{cl}(B \setminus F) \subseteq \mathsf{cl}(\mathsf{cl}(B' \setminus F)) = \mathsf{cl}(B' \setminus F).$$

Since F was chosen arbitrarily, we obtain that B' is a k-fault-tolerant basis of $\mathcal{M}$. However, since $|B'| < |B|$, this contradicts the choice of B. ◀

We next argue that the bounds in Proposition 6 are tight. First, note that the lower bound is tight as the matroid $\mathcal{I}(\mathcal{M}) = \{X \subseteq E(\mathcal{M})\colon |X| \leq k\}$ proves. We next argue that the upper bound is also tight. Let $e_1, \ldots, e_r$ be a basis of $\mathbb{R}^r$. Let k and n be integers such that $0 \leq k < n$. Consider the linear matroid $\mathcal{M}$ with $E(\mathcal{M}) = \{je_i \mid 1 \leq i \leq r \text{ and } 1 \leq j \leq n\}$. It is easy to see that any k-fault-tolerant basis of $\mathcal{M}$ has to contain at least $k+1$ vectors of $\{je_i \mid 1 \leq j \leq n\}$ for each $i \in \{1, \ldots, r\}$. Thus, the size of a k-fault-tolerant basis is at least $(k+1)r$. From the other side, we have that, for $B = \{je_i \mid 1 \leq i \leq r \text{ and } 1 \leq j \leq k+1\}$, $\mathsf{rank}(B \setminus F) = r$ for any $F \subseteq E(\mathcal{M})$ of size at most k. Thus, B is a k-fault-tolerant basis of size $(k+1)r$ of $\mathcal{M}$.

Let $\mathcal{M}$ be a matroid. For a positive integer h, we say that a set $X \subseteq E(\mathcal{M})$ is *h-uniform* if $\mathsf{rank}(X) = h$ and $\mathsf{rank}(Y) = h$ for every subset $Y \subseteq X$ of size h. The definition and Proposition 6 yield the following.

▶ **Observation 7.** *Let $\mathcal{M}$ be a matroid of rank $r \geq 1$, $k \geq 0$ be an integer, and $B \subseteq E(\mathcal{M})$ be a set of size $k + r$. Then, B is a k-fault-tolerant basis of $\mathcal{M}$ if and only if B is r-uniform.*

Proof. If B is a k-fault-tolerant basis, then, for every set $F \subseteq B$ of size at most k, $\mathsf{rank}(B \setminus F) = r$. Since $|B| = k + r$, this implies that, for every set $X \subseteq B$ of size r, $\mathsf{rank}(X) = \mathsf{rank}(B) = r$, that is, B is r-uniform. For the opposite direction, if B is r-uniform, then, for any $X \subseteq B$ of size r, $\mathsf{rank}(X) = \mathsf{rank}(B) = \mathsf{rank}(\mathcal{M})$. Since $|B| = k + r$, it holds for any $F \subseteq B$ of size at most k that $\mathsf{rank}(B \setminus F) = \mathsf{rank}(\mathcal{M})$. This completes the proof. ◀

We conclude this section by proving Proposition 2 using the results of Fomin et al. [15]. In particular, they studied Rank h-Reduction. Here, the input is a binary matroid $\mathcal{M}$ given by its representation over $\mathsf{GF}[2]$ and two positive integers h and k. The task is to decide whether there is a set $X \subseteq E(\mathcal{M})$ of size at most k such that $\mathsf{rank}(\mathcal{M}) - \mathsf{rank}(\mathcal{M} - X) \geq h$.

▶ **Proposition 2.** *It is* W[1]*-hard for the parameterization by k to decide whether a given linear matroid has a k-fault-tolerant basis.*

Proof. We reduce from Rank h-Reduction parameterized by k, which is known to be W[1]-hard [15]. Let $(\mathcal{M}, h, k)$ be an instance of Rank h-Reduction where $\mathcal{M}$ is a binary matroid of rank r. We define $\mathcal{M}'$ to be the $(r - h + 1)$-truncation of $\mathcal{M}$. Notice that $\mathcal{M}'$ is a linear matroid and its representation (over a different field) can be constructed in polynomial time by the result of Lokshtanov et al. [20]. We claim that $\mathcal{M}'$ has no k-fault-tolerant basis if and only if $(\mathcal{M}, h, k)$ is a yes-instance of Rank h-Reduction.

To this end, note that $\mathcal{M}'$ has no k-fault-tolerant basis if and only if there is a set $X \subseteq E(\mathcal{M}')$ of size at most k such that $\mathsf{rank}(\mathcal{M}' - X) < \mathsf{rank}(\mathcal{M}') = \mathsf{rank}(\mathcal{M}) - h + 1$. Since $\mathsf{rank}(\mathcal{M}' - X) < \mathsf{rank}(\mathcal{M}) - h + 1$ if and only if $\mathsf{rank}(\mathcal{M}) - \mathsf{rank}(\mathcal{M} - X) \geq h$, $\mathcal{M}'$ has no k-fault-tolerant basis if and only if there is $X \subseteq E(\mathcal{M}')$ of size at most k such that $\mathsf{rank}(\mathcal{M}) - \mathsf{rank}(\mathcal{M} - X) \geq h$. This concludes the proof. ◀

We remark that since the hardness for Rank h-Reduction was proven by Fomin et al. [15] via a polynomial-time reduction from Clique, it is coNP-hard to decide whether a linear matroid has a k-fault-tolerant basis. We also note that the problem is in XP since we can decide in $n^{\mathcal{O}(k)}$ time whether an n-element matroid $\mathcal{M}$ has a k-fault-tolerant basis – simply check for each subset $X \subseteq E(\mathcal{M})$ of size k whether $\mathsf{rank}(\mathcal{M} - X) = \mathsf{rank}(\mathcal{M})$.

4 An FPT algorithm for the parameterization by rank and k

In this section, we prove Theorem 1. We construct a recursive branching algorithm that finds a set W of important elements of bounded size with the property that, if the input matroid $\mathcal{M}$ has a k-fault-tolerant basis, then there is a k-fault-tolerant basis $B \subseteq W$. Note that a k-fault-tolerant basis has minimum size by definition. Then, we select a k-fault-tolerant basis (if it exists) in W using brute force. The construction of W is inspired by Observation 7, which indicates that h-uniform sets are preferable in the construction of k-fault-tolerant bases. The following lemma is crucial for constructing W.

▶ **Lemma 8.** *Let $\mathcal{M}$ be a matroid of rank $r \geq 1$ and $k \geq 0$ be an integer. Let $X \subseteq E(\mathcal{M})$ be an h-uniform set of size at least $(h-1)[(k+1)r]^{r-1} + (k+1)r$ for some $1 \leq h \leq r$. Then, for any k-fault-tolerant basis B of $\mathcal{M}$, there is a k-fault-tolerant basis B' such that*

- **(i)** $B \setminus \mathsf{cl}(X) = B' \setminus \mathsf{cl}(X)$ *and*
- **(ii)** $B' \cap \mathsf{cl}(X) \subseteq X$.

Proof. Let B be a k-fault-tolerant basis of $\mathcal{M}$. If $B \subseteq \mathsf{cl}(X)$, then the claim is straightforward because in this case, $\mathsf{cl}(X) = E(\mathcal{M})$ and $r = h$. We can therefore select B' to be the set of $k+r$ arbitrary elements of X by Observation 7. We hence assume from now on that $B \setminus \mathsf{cl}(X) \neq \emptyset$.

Consider a k-fault-tolerant basis B' satisfying (i), that is, $B \setminus \mathsf{cl}(X) = B' \setminus \mathsf{cl}(X)$, such that the size of $B' \cap (\mathsf{cl}(X) \setminus X)$ is minimum. We claim that B' satisfies (ii), that is, $B' \cap \mathsf{cl}(X) \subseteq X$. Assume towards a contradiction that $B' \cap (\mathsf{cl}(X) \setminus X) \neq \emptyset$ and there is an element $x \in B' \cap (\mathsf{cl}(X) \setminus X)$. Let $Y = B' \setminus \{x\}$. Note that Y is not a k-fault-tolerant basis of $\mathcal{M}$. Hence, there is a set $F \subseteq Y$ of size at most k such that $\mathsf{rank}(Y \setminus F) < r$. Notice that $\mathsf{rank}(B' \setminus F) = r$ implies $\mathsf{rank}(Y \setminus F) = r - 1$. Denote by $\mathcal{F}$ the family of all sets $F \subseteq Y$ of size at most k such that $\mathsf{rank}(Y \setminus F) = r - 1$. For each $F \in \mathcal{F}$, let $Z_F \subseteq Y$ be an inclusion-maximal independent set in $Y \setminus F$ and let $\mathcal{Z} = \{Z_F \mid F \in \mathcal{F}\}$. Note that $\mathsf{cl}(Z_F) = \mathsf{cl}(Y \setminus F)$ and therefore $\mathsf{rank}(Z_F) = r - 1$ for each $F \in \mathcal{F}$. By Proposition 6, it holds that $|Y| \leq (k+1)r - 1$. Hence, $|\mathcal{Z}| \leq \binom{(k+1)r-1}{r-1} \leq [(k+1)r]^{r-1}$. We next show that $|\mathsf{cl}(Z_F) \cap X| \leq h - 1$ for each $F \in \mathcal{F}$.

To this end, assume towards a contradiction that $|\mathsf{cl}(Z_F) \cap X| \geq h$. Since X is h-uniform, we obtain that $X \subseteq \mathsf{cl}(\mathsf{cl}(Z_F) \cap X)$. Then $\mathsf{cl}(X) \subseteq \mathsf{cl}(\mathsf{cl}(Z_F) \cap X) \subseteq \mathsf{cl}(Z_F)$ and, in particular, $x \in \mathsf{cl}(Z_F) = \mathsf{cl}(Y \setminus F)$. However, in this case, $B' \setminus F = (Y \cup \{x\}) \setminus F \subseteq \mathsf{cl}(Y \setminus F)$. Since B' is a k-fault-tolerant basis, we have that $\mathsf{rank}(Y \setminus F) = \mathsf{rank}(B' \setminus F) = r$ contradicting $F \in \mathcal{F}$.

Recall that $|X| \geq (h-1)[(k+1)r]^{r-1} + (k+1)r$ and B' has at least one element outside X. Then, $|B'| \leq (k+1)r$ and therefore $|X \setminus B'| \geq (h-1)[(k+1)r]^{r-1} + 1$ by Proposition 6. Since $|\mathcal{Z}| < [(k+1)r]^{r-1}$ and, for each $F \in \mathcal{F}$, $|\mathsf{cl}(Z_F) \cap X| \leq h - 1$, a simple counting argument shows that there exists an element $y \in X \setminus B'$ such that $y \notin \mathsf{cl}(Z_F)$ for all $F \in \mathcal{F}$. Let $B^* = Y \cup \{y\} = (B' \setminus \{x\}) \cup \{y\}$. Note that by definition, (i) $B^* \setminus \mathsf{cl}(X) = B' \setminus \mathsf{cl}(X)$, (ii) $|B^* \cap (\mathsf{cl}(X) \setminus X)| < |B' \cap (\mathsf{cl}(X) \setminus X)|$, and (iii) $|B^*| = |B'|$. We next show that B^* is a k-fault-tolerant basis. Afterwards, we will show that this contradicts our choice of B'.

Towards the former, let $F \subseteq B^*$ be of size at most k. We prove that $\mathsf{rank}(B^* \setminus F) = r$. If $\mathsf{rank}(Y \setminus F) = r$, then $\mathsf{rank}(B^* \setminus F) \geq \mathsf{rank}(Y \setminus F) = r$. So we assume from now on that $\mathsf{rank}(Y \setminus F) < r$. Then, $\mathsf{rank}(Y \setminus F) = r - 1$ as shown above. Assume towards a contradiction that $y \in F$. Since $y \notin B'$, we have that $F' = (F \setminus \{y\}) \cup \{x\}$ is a subset of B' of size at most k. Since B' is a k-fault-tolerant basis, $\mathsf{rank}(B' \setminus F') = r$. However, $B' \setminus F' = Y \setminus F$ and $\mathsf{rank}(Y \setminus F) = r$, contradicting our assumption that $\mathsf{rank}(Y \setminus F) < r$. Hence, $y \notin F$ and therefore $F \subseteq Y$. Recall that $\mathsf{rank}(Y \setminus F) = r - 1$. This implies that $F \in \mathcal{F}$ and $Z_F \in \mathcal{Z}$. Since $y \notin \mathsf{cl}(Z_F)$ by the choice of y, $\mathsf{rank}(B^* \setminus F) = \mathsf{rank}((Y \setminus F) \cup \{y\}) > \mathsf{rank}(Y \setminus F) = r - 1$. Thus, $\mathsf{rank}(B^* \setminus F) = r$.

Since $\mathsf{rank}(B^* \setminus F) = r$ for every $F \subseteq B^*$ of size at most k and $|B^*| = |B'|$, we have that B^* is a k-fault-tolerant basis. However, we also obtain that (i) $B^* \setminus \mathsf{cl}(X) = B' \setminus \mathsf{cl}(X)$ and (ii) $|B^* \cap (\mathsf{cl}(X) \setminus X)| < |B' \cap (\mathsf{cl}(X) \setminus X)|$ contradicting the choice of B'. This shows that $B' \cap \mathsf{cl}(X) \subseteq X$ and completes the proof. ◀

Now we show how to construct a set W of important elements of bounded size.

▶ **Lemma 9.** *There is an algorithm that, given a matroid $\mathcal{M}$ of rank $r \geq 1$ with $\{e\} \in \mathcal{I}(\mathcal{M})$ for each $e \in E(\mathcal{M})$ and an integer $k \geq 0$, outputs a set $W \subseteq E(\mathcal{M})$ of at most $r^{r^2} \cdot [(k+1)r]^{r^3}$ elements in $(rk)^{\mathcal{O}(r^2)} \cdot n^{\mathcal{O}(1)}$ time such that $\mathcal{M}$ has a k-fault-tolerant basis if and only if $\mathcal{M}$ has a k-fault-tolerant basis $B \subseteq W$.*

Proof. Let $\mathcal{M}$ be a matroid of rank $r \geq 1$ such that $\{e\} \in \mathcal{I}(\mathcal{M})$ for any $e \in E(\mathcal{M})$ and let k be a non-negative integer. We construct a recursive branching algorithm $\textsc{Important}(\mathcal{M}, X)$ that takes as input a matroid $\mathcal{M}$ and a non-empty independent set $X \in \mathcal{I}(\mathcal{M})$, and outputs a set $Y \subseteq \mathsf{cl}(X)$ of size at most $|X|^{|X|^2} \cdot [(k+1)r]^{r|X|^2}$ with the property that for any k-fault-tolerant basis B of $\mathcal{M}$, there is a k-fault-tolerant basis B' such that

(i) $B \setminus \mathsf{cl}(X) = B' \setminus \mathsf{cl}(X)$ and
(ii) $B' \cap \mathsf{cl}(X) \subseteq Y$.

Let $h = |X|$. The base case is $h = 1$, where we do the following:

- Compute $\mathsf{cl}(X)$.
- If $|\mathsf{cl}(X)| < (k+1)r$, then set $Y := \mathsf{cl}(X)$ and output it.
- Otherwise, define Y to be the set of $(k+1)r$ arbitrary elements of $\mathsf{cl}(X)$ and output it.

For $h > 1$, we do the following:

- Compute $\mathsf{cl}(X)$.
- If $|\mathsf{cl}(X)| \leq (h-1)[(k+1)r]^{r-1} + (k+1)r$, then set $Y := \mathsf{cl}(X)$, output it, and stop.
- Find a h-uniform set $Z \subseteq \mathsf{cl}(X)$ that either has size $(h-1)[(k+1)r]^{r-1} + (k+1)r$ or is an inclusion-maximal h-uniform set of size at most $(h-1)[(k+1)r]^{r-1} + (k+1)r - 1$.
- If $|Z| = (h-1)[(k+1)r]^{r-1} + (k+1)r$, then set $Y := Z$ and output it.
- If Z is an inclusion-maximal h-uniform set of size at most $(h-1)[(k+1)r]^{r-1} + (k+1)r - 1$, then output $Y := \bigcup_{S \subseteq Z \text{ s.t. } |S|=h-1} Y_S$, where Y_S is the output of $\textsc{Important}(\mathcal{M}, S)$.

To compute an h-uniform set Z, we apply the following greedy procedure:

- Initially, set $Z := X$.
- While $Z \leq (h-1)[(k+1)r]^{r-1} + (k+1)r - 1$, do the following:
  - For every $x \in \mathsf{cl}(X) \setminus Z$, check whether $Z \cup \{x\}$ is h-uniform and set $Z := Z \cup \{x\}$ if this holds.
  - If $Z \cup \{x\}$ is not h-uniform for all $x \in \mathsf{cl}(X) \setminus Z$, then output Z and stop.
- If $Z = (h-1)[(k+1)r]^{r-1} + (k+1)r$, then output Z.

The crucial property of the algorithm is given in the following claim whose proof combines Lemma 8 and induction on h. Here and further, the proofs of the statements labeled ($\star$) are omited in this extended abstract and can be found in the full version of the paper [4].

▷ Claim 10 ($\star$). $\textsc{Important}(\mathcal{M}, X)$ outputs a set $Y \subseteq \mathsf{cl}(X)$ with the property that for any k-fault-tolerant basis B of $\mathcal{M}$, there is a k-fault-tolerant basis B' such that

(i) $B \setminus \mathsf{cl}(X) = B' \setminus \mathsf{cl}(X)$ and
(ii) $B' \cap \mathsf{cl}(X) \subseteq Y$.

It remains to analyze the size of Y and the running time. We next show an upper bound on the size of Y of $|Y| \leq h^{h^2} \cdot [(k+1)r]^{rh^2}$. We prove this via induction on h.

For $h = 1$, note that $|Y| \leq (k+1)r \leq h^{h^2} \cdot [(k+1)r]^{rh^2}$. For $h \geq 2$, consider any independent set $S \subseteq E(\mathcal{M})$ of size $h-1$. The algorithm outputs the set Y_S, which by the induction hypothesis, has size at most $N_{h-1} = (h-1)^{(h-1)^2}[(k+1)r]^{r(h-1)^2}$. By construction, we have

$$|Y| \leq \max\{(h-1)[(k+1)r]^{r-1} + (k+1)r, \binom{(h-1)[(k+1)r]^{r-1} + (k+1)r - 1}{h-1} N_{h-1}\}.$$

Observe first that

$$(h-1)[(k+1)r]^{r-1} + (k+1)r \leq h[(k+1)r]^r \leq h^{h^2} \cdot [(k+1)r]^{rh^2}. \tag{1}$$

For the second option, note that

$$\begin{aligned}
\binom{(h-1)[(k+1)r]^{r-1} + (k+1)r - 1}{h-1} N_{h-1} &\leq (h[(k+1)r]^r)^h \cdot N_{h-1} \\
&\leq (h[(k+1)r]^r)^h (h-1)^{(h-1)^2}[(k+1)r]^{r(h-1)^2} \\
&\leq h^h[(k+1)r]^{rh} \cdot h^{h^2-h}[(k+1)r]^{r(h^2-h)} \\
&\leq h^{h^2} \cdot [(k+1)r]^{rh^2}.
\end{aligned}$$

Combining this equation with Equation (1), we obtain the required upper bound for $|Y|$.

Finally, we evaluate the running time of Important and show that Important$(\mathcal{M}, X)$ runs in $(rk)^{\mathcal{O}(rh^2)} \cdot n^{\mathcal{O}(1)}$ time. To this end, notice that $\mathsf{cl}(X)$ can be constructed in polynomial time in the oracle model. To construct the h-uniform set Z of size $h(rk)^{\mathcal{O}(r)}$, we use the greedy procedure where for each $x \in \mathsf{cl}(X) \setminus Z$ for the considered Z, we go over all subsets S of Z of size $h-1$ and check whether $S \cup \{x\}$ is independent using the oracle. As $h \leq r$, the construction of Z can be done in $(kr)^{\mathcal{O}(rh)} \cdot n^{\mathcal{O}(1)}$ time. The algorithm makes $(rk)^{\mathcal{O}(rh)}$ recursive calls and the depth of the search tree is at most h. Summarizing, we obtain that the overall running time is $(rk)^{\mathcal{O}(rh^2)} \cdot n^{\mathcal{O}(1)}$.

To complete the proof and construct W, we call Important$(\mathcal{M}, X)$ for an arbitrary basis X of $\mathcal{M}$ and set $W = Y$ for the output set of the algorithm. Note that a basis can be found in polynomial time using the independence oracle. Then Claim 10 implies that if $\mathcal{M}$ has a k-fault-tolerant basis, then it also has one in W. Note that the other direction is trivial as $W \subseteq E(\mathcal{M})$. This concludes the proof. ◀

We are now ready to prove Theorem 1, which we restate here for convenience.

▶ **Theorem 1.** *Fault-Tolerant Basis can be solved in $(kr)^{\mathcal{O}(kr^4)} \cdot n^{\mathcal{O}(1)}$ time on n-element matroids of rank at most r given by independence oracles.*

Proof. Let $\mathcal{M}$ be a matroid of rank r and let $k \geq 0$ be an integer. Fault-Tolerant Basis is trivial for $r = 0$ and we can assume that $r \geq 1$. Notice that loops of $\mathcal{M}$, that is, elements e such that $\{e\} \notin \mathcal{I}(\mathcal{M})$ are irrelevant – a loop e is not included in any k-fault-tolerant basis and $e \in \mathsf{cl}(X)$ for any set $X \subseteq E(\mathcal{M})$. Hence, we can preprocess $\mathcal{M}$ and delete the loops. From now on, we assume that $\{e\} \in \mathcal{I}(\mathcal{M})$ for every $e \in E(\mathcal{M})$.

We apply the algorithm from Lemma 9, and in time $(rk)^{\mathcal{O}(r^3)} \cdot n^{\mathcal{O}(1)}$, find a set $W \subseteq E(\mathcal{M})$ of size at most $r^{r^2} \cdot [(k+1)r]^{r^3}$ such that whenever $\mathcal{M}$ has a k-fault-tolerant basis, $\mathcal{M}$ has a k-fault-tolerant basis $B \subseteq W$. We consider all candidate subsets B of W with $|B| \leq (k+1)r$ using the upper bound for the size of a k-fault-tolerant basis from Proposition 6. This

can be done in $(kr)^{\mathcal{O}(kr^4)}$ time. For each candidate set B of size at most $(k+1)r$, we verify whether B is a k-fault-tolerant basis as follows. In $\mathcal{O}([(k+1)r]^k)$ time, we check whether $\mathsf{rank}(B \setminus F) = r$ for every subset $F \subseteq B$ of size at most k. Among all candidate sets satisfying the above property, we select a set of minimum size which is a k-fault-tolerant basis of $\mathcal{M}$. The overall running time is $(kr)^{\mathcal{O}(kr^4)} \cdot n^{\mathcal{O}(1)}$. This concludes the proof. ◀

5 Partition matroids

In this section, we prove Proposition 5. The proof is based on the following structural lemma.

▶ **Lemma 11.** *Let $\mathcal{M}$ be a partition matroid with unit capacities for a partition $(P_1, \ldots, P_d)$ of the ground set. Let $X \subseteq E(\mathcal{M})$ and let $k \geq 0$ and $r \geq 1$ be integers. Then, the following properties hold.*

- **(i)** *If there is an integer $s \geq 1$ such that $|X| = s(r-1)+k+1$ and $|X \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$, then for any set $F \subseteq X$ of size at most k, $\mathsf{rank}(X \setminus F) \geq r$.*
- **(ii)** *If X is an inclusion-minimal set such that for any set $F \subseteq X$ of size at most k, $\mathsf{rank}(X \setminus F) \geq r$, then there is an integer $s \geq 1$ such that $|X| = s(r-1)+k+1$ and $|X \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$.*

Proof. To show (i), suppose that $|X| = s(r-1)+k+1$ and $|X \cap P_i| \leq s$ for each $i \in \{1, \ldots, d\}$ for some integer $s \geq 1$. Consider any subset $F \subseteq X$ of size at most k. Since $|X \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$, it holds that $|(X \setminus F) \cap P_i| \leq s$ and hence $|(X \setminus F) \cap P_i| > 0$ for at least $\left\lceil \frac{|X \setminus F|}{s} \right\rceil$ sets P_i. Since $\mathcal{M}$ is a partition matroid with unit capacities, this is also a lower bound on $\mathsf{rank}(X \setminus F)$ and therefore

$$\mathsf{rank}(X \setminus F) \geq \left\lceil \frac{|X \setminus F|}{s} \right\rceil \geq \left\lceil \frac{s(r-1)+1}{s} \right\rceil \geq r.$$

This proves that $\mathsf{rank}(X) \geq r$ and $\mathsf{rank}(X \setminus F) \geq r$ for any set $F \subseteq X$ of size at most k.

To prove (ii), suppose that X is an inclusion-minimal set with $\mathsf{rank}(X) \geq r$ such that for any set $F \subseteq X$ of size at most k, $\mathsf{rank}(X \setminus F) \geq r$ holds. We assume without loss of generality that $|X \cap P_1| \geq \cdots \geq |X \cap P_d|$.

If $r = 1$, then we set $s = \max\{|X \cap P_i| \mid 1 \leq i \leq d\}$. Trivially, $|X| \geq k+1$ and $|X \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$. We next show that $|X| = k+1$. Assume towards a contradiction that $|X| > k+1$. Any subset $X' \subseteq X$ of size $k+1$ satisfies $|X' \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$. Hence, $\mathsf{rank}(X' \setminus F) > 1$ for any set F of size at most k by (i). This contradicts the the minimality of X and shows $|X| = k+1$.

If $r \geq 2$, then $|X \cap P_{r-1}| \geq 1$ and we set $s = |X \cap P_{r-1}|$. We will next show that $|X| = s(r-1)+k+1$ and $|X \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$. Let $Y = \bigcup_{j=1}^{r-1}(X \cap P_j)$ and $Z = \bigcup_{j=r}^{d}(X \cap P_j)$. By definition of s, $|Y| \geq s(r-1)$.

If $|Z| \leq k$, then $\mathsf{rank}(X \setminus Z) = r-1 < r$, contradicting the choice of X. Thus, $|Z| \geq k+1$ and $|X| = |Y| + |Z| \geq s(r-1)+k+1$. There exist $Y' \subseteq Y$ such that $|Y' \cap P_j| = s$ for each $j \in \{1, \ldots, r-1\}$, and $Z' \subseteq Z$ such that $|Z'| = k+1$. Consider $X' = Y' \cup Z'$. By definition, $|X' \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$. Then, by (i), we have that $\mathsf{rank}(X') \geq r$ and for any set $F \subseteq X'$ of size at most k, $\mathsf{rank}(X' \setminus F) \geq r$. By the minimality of X, we conclude that $X = X'$. This proves (ii). ◀

We are now ready to prove Proposition 5, which we restate here.

▶ **Proposition 5.** *Given an n-element partition matroid $\mathcal{M}$ with unit capacities together with a weight function $w\colon E(\mathcal{M}) \to \mathbb{Z}_{\geq 0}$ and integers $r, k \geq 0$, one can find in $\mathcal{O}(n^2)$ time either a set $X \subseteq E(\mathcal{M})$ of minimum weight such that, for any set $F \subseteq X$ of size at most k, it holds that $\mathsf{rank}(X \setminus F) \geq r$ or correctly decide that such a set does not exist.*

Proof. Consider a weighted partition matroid $\mathcal{M}$ with unit capacities and a weight function $w\colon E(\mathcal{M}) \to \mathbb{Z}_{\geq 0}$. Let $k \geq 0$ and $r \geq 0$ be integers. Let also $(P_1, \ldots, P_d)$ be the partition of $E(\mathcal{M})$ defining $\mathcal{M}$. If $r = 0$, then the claim of the theorem is trivial as $X = \emptyset$ is a solution. Thus, we can assume that $r \geq 1$.

For an integer $s \geq 1$, we say that s is *feasible* if there exists a set $X \subseteq E(\mathcal{M})$ with $|X| = s(r-1) + k + 1$ such that $|X \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$. For each integer $1 \leq s \leq \max\{|P_i| \mid 1 \leq i \leq d\}$, we check whether s is feasible. This can be done by checking whether $\sum_{i=1}^{d} |\min\{|P_i|, s\}| \geq s(r-1) + k + 1$. If there is no feasible integer, then we conclude that there is no $X \subseteq E(\mathcal{M})$ with the property that $\mathsf{rank}(X \setminus F) \geq r$ for any subset $F \subseteq X$ of size at most k by Lemma 11. Otherwise, for every feasible s, we greedily choose a set X of minimum weight such that $|X| = s(r-1) + k + 1$ and $|X \cap P_i| \leq s$ for every $i \in \{1, \ldots, d\}$. Notice that the selection of such a set is equivalent to finding a minimum weight independent set of size $s(r-1) + k + 1$ in the partition matroid for $(P_1, \ldots, P_d)$ with the capacities $(c_1, \ldots, c_d)$ where $c_i = \min\{s, |P_i|\}$ for each $i \in \{1, \ldots, d\}$. By the well-known matroid properties [21], the greedy algorithm finds such a set X. By Lemma 11, we conclude that X is a minimum weight set such that for any set $F \subseteq X$ of size at most k, $\mathsf{rank}(X \setminus F) \geq r$. This concludes the description of our algorithm and its correctness proof.

To evaluate the running time, notice that the elements of $\mathcal{M}$ can be sorted by their weight in $\mathcal{O}(n \log n)$ time. Then we have at most n choices of s and for each s, the greedy algorithm works in $\mathcal{O}(n)$ time. Thus, the overall running time is in $\mathcal{O}(n^2)$, concluding the proof. ◀

As a corollary, we obtain the following for general matroids of rank at most two.

▶ **Corollary 12** ($\star$). *Weighted Fault-Tolerant Basis can be solved in $\mathcal{O}(n^2)$ on matroids of rank at most two given by an independence oracle.*

6 Complexity dichotomy for the parameterization by rank

In this section, we prove Theorem 4 which we restate here for convenience.

▶ **Theorem 4.** *For any integer $r \geq 3$, it is* NP*-hard to decide whether a linear matroid $\mathcal{M}$ of rank r over rationals given together with integers k and b has a k-fault-tolerant basis of size at most b. For $r \leq 2$, Weighted Fault-Tolerant Basis can be solved in $\mathcal{O}(n^2)$ on matroids given by an independence oracle.*

Proof. The claim for $r \leq 2$ is proven in Corollary 12. Thus, it remains to show the computational lower bound for $r \geq 3$. We show the claim for $r = 3$ and then explain how to extend it for any $r \geq 3$. We reduce from General Position Subset Selection. Recall that a set P of points on the Euclidean plane is said to be in general position if there are no three points on the same line on the plane. General Position Subset Selection is defined as follows. Given a set P of point on the plane and an integer $p \geq 1$, decide whether there is a subset $Q \subseteq P$ of at least p points in general position. The problem was shown to be NP-hard by Froese et al. [16] and the result holds for points with rational coordinates.

Let $(P = \left\{ \begin{pmatrix} x_1 \\ y_1 \end{pmatrix}, \ldots, \begin{pmatrix} x_n \\ y_n \end{pmatrix} \right\}, p)$ be an instance of General Position Subset Selection. We assume without loss of generality that $p \geq 3$ as any set of at most two points is in general position. We set $k = p - 3$, construct the set $E = \left\{ \begin{pmatrix} x_1 \\ y_1 \\ 1 \end{pmatrix}, \ldots, \begin{pmatrix} x_n \\ y_n \\ 1 \end{pmatrix} \right\}$ of vectors, and define $\mathcal{M}$ to be the linear matroid with the ground set E over rationals.

Note that $\mathsf{rank}(\mathcal{M}) \leq 3$ and that three distinct points $\begin{pmatrix} x_h \\ y_h \end{pmatrix}$, $\begin{pmatrix} x_i \\ y_i \end{pmatrix}$, and $\begin{pmatrix} x_j \\ y_j \end{pmatrix}$ of P are not on the same line if and only if $\mathsf{rank}\left(\left\{ \begin{pmatrix} x_h \\ y_h \\ 1 \end{pmatrix}, \begin{pmatrix} x_i \\ y_i \\ 1 \end{pmatrix}, \begin{pmatrix} x_j \\ y_j \\ 1 \end{pmatrix} \right\}\right) = 3$. This implies that for any $I \subseteq \{1, \ldots, n\}$, the points of $\left\{ \begin{pmatrix} x_i \\ y_i \end{pmatrix} \mid i \in I \right\} \subseteq P$ are in general position if and only if $\left\{ \begin{pmatrix} x_i \\ y_i \\ 1 \end{pmatrix} \mid i \in I \right\} \subseteq E$ is a 3-uniform set for $\mathcal{M}$. Hence, P has a subset of at least p points in general position if and only if there is a 3-uniform subset of E of size at least p. By Proposition 6, a k-fault-tolerant basis of $\mathcal{M}$ has size at least $p = k + 3$. By Observation 7, $\mathcal{M}$ has a k-fault-tolerant basis of size p if and only if (P, p) is a yes-instance of General Position Subset Selection. This concludes the proof for $r = 3$.

To see the claim for $r > 3$, we perform the same reduction but in r dimensions. The constructed vectors have a 0 in all but the first three dimensions (where they have the entries as constructed above). For each $4 \leq i \leq r$, we then add $k + 1$ vectors with zero-entries everywhere except for dimension i, where the entry is 1. Note that any k-fault-tolerant basis of the linear matroid over the constructed vectors has to contain all $(r - 3)(k + 1)$ newly added vectors. Moreover, it has to contain a set P of vectors such that after removing any k of them, the first three dimensions have to be spanned by the remaining vectors. This is equivalent to the case $r = 3$ and concludes the proof. ◀

7 Conclusion

In this paper, we initiate the study of the parameterized complexity of Fault-Tolerant Basis. Our main result is that the problem is fixed-parameter tractable when parameterized by both k and rank r of the input matroid. This positive algorithmic result is complemented by computational lower bounds showing NP-hardness for constant values for any one of the two parameters alone. Our results lead to several open questions.

First, we do not know whether our FPT result from Theorem 1 could be extended for Weighted Fault-Tolerant Basis. Our approach based on the choice of h-uniform sets is tailored for the unweighted case, and one may need different techniques in the presence of weights.

Second, is it possible to extend our result to the non-uniform model introduced by Adjiashvili et al. [1]? Here, we assume that the set of elements of a matroid $\mathcal{M}$ is partitioned into two subsets S and V of *safe* and *vulnerable* elements, respectively. Then, the task is to either find a set $B \subseteq E(\mathcal{M})$ of minimum size such that for any sets $F \subseteq V \cap B$ of size at most k, $\mathsf{rank}(\mathcal{M} - F) = \mathsf{rank}(\mathcal{M})$ or correctly report that such a set does not exist. Fault-Tolerant Basis is the special case of this problem with $S = \emptyset$.

Third, can our results be extended to the model introduced by Adjiashvili et al. [2] where not arbitrary sets of k elements can fail but possible failure scenarios are part of the input?

Finally, observe that our computational lower bounds from Proposition 2, Observation 3, and Theorem 4 do not exclude efficient algorithms for Fault-Tolerant Basis on special classes of matroids. In particular, we proved in Proposition 5 that Weighted Fault-Tolerant Basis can be solved in polynomial time on truncations of partition matroids with unit capacities. While it is straightforward to see that Weighted Fault-Tolerant

Basis can be solved in polynomial time for partition matroids with arbitrary capacities,[1] it is not clear whether the problem can be solved in polynomial time on their truncations. The problem complexity for other fundamental classes of matroids, like transversal matroids and gammoids, is another interesting open question.

Abstract

We propose sublinear algorithms for probabilistic testing of the discrete and continuous Fréchet distance – a standard similarity measure for curves. We assume the algorithm is given access to the input curves via a query oracle: a query returns the set of vertices of the curve that lie within a radius δ of a specified vertex of the other curve. The goal is to use a small number of queries to determine with constant probability whether the two curves are similar (i.e., their discrete Fréchet distance is at most δ) or they are "ε-far" (for $0 < \varepsilon < 2$) from being similar, i.e., more than an ε-fraction of the two curves must be ignored for them to become similar.

We present two algorithms which are sublinear assuming that the curves are t-approximate shortest paths in the ambient metric space, for some $t \ll n$. The first algorithm uses $O(\frac{t}{\varepsilon} \log \frac{t}{\varepsilon})$ queries and is given the value of t in advance. The second algorithm does not have explicit knowledge of the value of t and therefore needs to gain implicit knowledge of the straightness of the input curves through its queries. We show that the discrete Fréchet distance can still be tested using roughly $O(\frac{t^3+t^2 \log n}{\varepsilon})$ queries ignoring logarithmic factors in t. Our algorithms work in a matrix representation of the input and may be of independent interest to matrix testing.

Our algorithms use a mild uniform sampling condition that constrains the edge lengths of the curves, similar to a polynomially bounded aspect ratio. Applied to testing the continuous Fréchet distance of t-straight curves, our algorithms can be used for $(1+\varepsilon')$-approximate testing using essentially the same bounds as stated above with an additional factor of $\text{poly}(\frac{1}{\varepsilon'})$.

1 Introduction

We initiate the study of property testing for measures of curve similarity, motivated by the need for fast solutions for curve classification and clustering. Thus, our research lies at the intersection of property testing and computational geometry. While property testing is a very broad area, we believe this intersection has received far less attention than it deserves.

We also believe that property testing for well-studied measures such as the Fréchet distance is especially well-motivated due to its connections to other problems studied on the curves, such as clustering [3, 8], similarity search [1, 7, 14] and map reconstruction [4, 5].

Typically in property testing, we are given access to a (large) data set and the goal is to very quickly assess whether the data has a certain property. The classical notation of correctness is typically not suitable for property testing since these algorithms are intended to be randomized algorithms that access (very small) parts of data via queries. Instead, a property testing algorithm is considered correct if it can satisfy the following two conditions, with a probability close to 1 (e.g., at least $1-\gamma$ probability for some small value of γ): first, if the input has the desired property, the algorithm must return *accept* and second, if the input is "far" from having the property (under some suitable definition of "far"), the algorithm should *reject* the input. Our algorithms have *one-sided error*, meaning, they will not produce *false negatives* and thus rejection means that the input does not have the desired property.

For further reading on property testing, see [24, 2]. Here, we quickly review the main motivation for property testing in general and then we focus on computational geometry.

Property testing algorithms can be useful in many different scenarios. In particular, if the input is extremely large, it makes sense to obtain a quick approximate answer before deciding to run more expensive algorithms. This is especially useful if the testing algorithm has one-sided error; in that case, if the test returns *reject*, there is no need to do any extra work. For the Fréchet distance, there are applications [1, 7, 14] where negative filters are used to minimize expensive Fréchet distance computations; testing may be useful in such cases. Property testing is also useful if most inputs are expected to not have the desired property, or the input distribution is such that each input either has the property or it is "far" from having that property. In addition, the definition of property testing has a strong connection to topics in learning theory such as *probably approximately correct (PAC)* learners and this was in fact one of the important motivations behind its conception [23].

Another motivation for property testing is when small errors can be tolerated or objects that are close to having the desired property are acceptable outcomes; in this view, property testing is in spirit similar to approximation algorithms where an approximate answer is considered to be an acceptable output. In the context of similarity testing we can also compare it to a partial similarity measure. In fact, our chosen error model will be very close to a partial Fréchet distance [6]. For more details on motivations to study property testing see [17, 24]. See also the aforementioned references for more detailed results on property testing as surveying the known results on property testing is beyond the scope of this paper.

Computational geometry has a long tradition of using randomization and sampling to speed up algorithmic approaches [22, 19, 20, 18]. Property testing has received some attention within computational geometry, but is much less explored compared to other areas. There are fast and efficient testers for many basic geometric properties, such as convexity of a point set [13], disjointness of objects [13], the weight of Euclidean minimum spanning tree [10, 11, 12], clustering [21], the Voronoi property of a triangulation [13], ray shooting [9, 13], as well as LP-type problems [15].

Unlike in graph property testing, where it is assumed that we can sample a vertex uniformly at random, and query for its neighbors, it seems that, for geometric data, there is no commonly agreed upon query model. Different types of queries are used to access the data in the above cited works, such as range queries, cone nearest neighbor queries, queries for the bounding box of the data inside a query hyper-rectangle. In our paper, we use queries to the free space matrix of the two input curves, see Section 3 for the precise definition.

We mention that there is also work on matrix testing [16]. Compared to our setting, the input size is defined as n^2 – the number of entries needed to specify the matrix. In our case, we assume the input size to be n, the maximum of column and row dimension of the matrix.

2 Preliminaries

Let (M, d) be a metric space. We say a *(discrete) curve* P in (M, d) is an ordered point sequence $\langle p_1, \ldots, p_n \rangle$ with $p_i \in M$ for all $i = 1, \ldots, n$. We call the points of the curve *vertices*. We denote by $|P|$ the number of vertices in P and by $\ell(P)$ its *length*, which is defined as $\ell(P) = \sum_{i=1}^{n-1} d(p_i, p_{i+1})$. The *subcurve* of P between p_i and p_j is denoted by $P[i, j]$. A curve P is called *t-straight* if for any two vertices p_i and p_j in P, we have $\ell(P[i, j]) \leq t \cdot d(p_i, p_j)$. Denote by $[n]$ the set of integers from 1 to n and by $[n] \times [n] \subset \mathbb{N} \times \mathbb{N}$ the integer lattice of n times n integers. Given two curves $P = \langle p_1, \ldots, p_n \rangle$ and $Q = \langle q_1, \ldots, q_n \rangle$, we say that an ordered sequence $\mathcal{C}$ of elements in $[n] \times [n]$ is a *coupling* of P and Q, if it starts in $(1, 1)$, ends in (n, n) and for any consecutive tuples $(i, j), (i', j')$ in $\mathcal{C}$ it holds that $(i', j') \in \{(i + 1, j), (i, j + 1), (i + 1, j + 1)\}$. We define the *discrete Fréchet distance* between P and Q as follows

$$D_{\mathcal{F}}(P, Q) \coloneqq \min_{\text{coupling } \mathcal{C}} \max_{(i,j) \in \mathcal{C}} d(p_i, q_j).$$

For brevity, we simply call this the Fréchet distance between P and Q. The *free space matrix* of P and Q with distance value δ is an $n \times n$ matrix M_δ, where the i-th column corresponds to the vertex p_i of P and the j-th row corresponds to the vertex q_j of Q.

The entry $M_\delta[i, j]$ has the value 0 if $d(p_i, q_j) \leq \delta$ and 1 otherwise.[1] A coupling path $\mathcal{C}$ is the path through the $[n] \times [n]$ integer lattice defined by the coupling $\mathcal{C}$. We define the *cost* of such a path as $c(\mathcal{C}) = \sum_{(i,j) \in \mathcal{C}} M_\delta[i, j]$. Note that the Fréchet distance between P and Q is at most δ if and only if there exists a coupling path with cost 0 from $(1, 1)$ to (n, n).

Our analysis is based on a property of the free space matrix. We first define this property and then link the property to a certain class of well-behaved input curves.

▶ **Definition 1** (t-local). *Let M be a free space matrix of curves P and Q. We say that M is* t-local *if, for any tuples (i_1, j_1) and (i_2, j_2) with $M[i_1, j_1] = 0 = M[i_2, j_2]$, it holds that $|i_1 - i_2| \leq t \cdot (2 + |j_1 - j_2|)$ and $|j_1 - j_2| \leq t \cdot (2 + |i_1 - i_2|)$.*

See Figure 1 for a visualization. A consequence of this property is that zero-entries within one row or within one column cannot be too far away from each other.

▶ **Observation 2.** *Suppose M is t-local. If we have $M[i, j] = 0 = M[i, j']$, then we have $|j - j'| \leq 2t$. If we have $M[i, j] = 0 = M[i', j]$, we have $|i - i'| \leq 2t$.*

In the following, we argue why we think the t-locality assumption is reasonable. Note that t will not exceed n on any input. There are classes of well-behaved curves that satisfy the locality assumption for some $t \ll n$. Lemma 3 below shows that the free space matrix of approximate shortest paths is t-local. For simplicity, we impose the assumption that the lengths of the edges are bounded by a fixed multiple of δ, the query radius of the Fréchet distance. In the full version, we show that our approach can be adapted to work as well if the lengths of the edges are bounded by a constant multiple of any fixed value.

[1] Note we use 0 and 1 in switched roles compared to the conventions in the literature on the free space matrix. Our notation makes the cost-function of the path more intuitive.

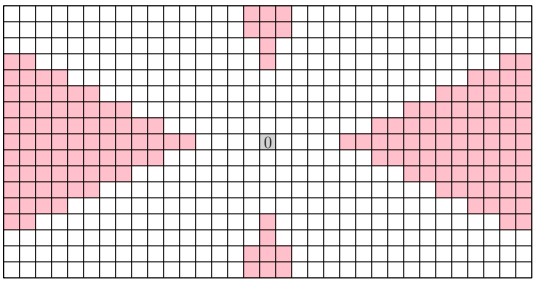

Figure 1 The red cells cannot be zero-entries if the gray cell is a zero-entry and the matrix is 2-local.

▶ **Lemma 3.** *Let P and Q be t-straight curves with edge lengths in $[\delta/\alpha, \alpha\delta]$ for some constant $\alpha \geq 1$. Let M be their free space matrix with distance value δ. Then, M is $\mathcal{O}(t)$-local.*

Proof. Let $(i_1, j_1), (i_2, j_2)$ be such that $M[i_1, j_1] = 0 = M[i_2, j_2]$ and $i_1 \leq i_2$. So we have $d(p_{i_1}, q_{j_1}) \leq \delta$ and $d(p_{i_2}, q_{j_2}) \leq \delta$. We also have $d(q_{j_1}, q_{j_2}) \leq \ell(Q[j_1, j_2]) \leq \alpha\delta\,|j_1 - j_2|$ because of the edge length constraint, where $Q[j_1, j_2]$ is replaced by $Q[j_2, j_1]$ if $j_2 < j_1$. Using the edge length constraint and t-straightness we derive $\frac{\delta}{\alpha}\,|i_2 - i_1| \leq \ell(P[i_1, i_2]) \leq t d(p_{i_1}, p_{i_2})$. These observations together with the triangle inequality yield

$$|i_2 - i_1| \leq \frac{\alpha t}{\delta}(d(p_{i_1}, q_{j_1}) + d(q_{j_1}, q_{j_2}) + d(q_{j_2}, p_{i_2})) \leq \alpha^2 t(2 + |j_2 - j_1|).$$

The other inequality is shown by reversing the roles of P and Q. ◀

3 Problem definition and results

The problem we study in this paper is the following. Assume we want to determine for two curves P and Q, each consisting of n vertices,[2] if their Fréchet distance is at most a given value of δ. We do not have direct access to the input curves. Instead, we have access to an oracle that returns the information in a given row or column of the δ-free space matrix in the form of a sorted list of indices of zero-entries. We call this a *query* and we want to determine $D_{\mathcal{F}}(P, Q) \leq \delta$ using as few (sublinear in n) queries as possible. Note that from the point of view of a data structure setting, our query corresponds to a classical ball range query with a vertex p of one curve and returns the list of vertex indices of the other curve that are contained in the ball of radius δ centered at p.

Our bounds on the number of queries will be probabilistic and will hold under a certain error model that allows for the coupling path to pass through a bounded number of one-entries. These are entries where the corresponding points are far from each other. In the full version, we discuss alternative error models and how they relate to our chosen error model.

▶ **Definition 4** ((ε, δ)-far)**.** *Given two curves P and Q consisting of n vertices each, we say that P and Q are (ε, δ)-far from each other if there exists no coupling path from $(1, 1)$ to (n, n) in the δ-free space matrix of cost εn or less.*

▶ **Definition 5** (Fréchet-tester)**.** *Assume we are given query-access to two curves P and Q, and we are given values $\delta > 0$ and $0 < \varepsilon < 2$. If the two curves have Fréchet distance at most δ, we must return "yes", and if they are (ε, δ)-far from each other w.r.t. the Fréchet distance, the algorithm must return "no", with probability at least $\frac{4}{5}$.*

[2] For ease of notation, our analysis assumes the input curves have the same number of vertices.

Results. We present two algorithms for testing whether a pair of input curves have discrete Fréchet distance at most a given real value δ. Assume that the algorithm has query access only to the δ-free space matrix of the input curves and that this matrix is t-local (see Definition 1). The first algorithm requires knowledge of t, and it uses $O(\frac{t}{\varepsilon}\log\frac{t}{\varepsilon})$ queries (Theorem 18). Note that this bound is intrinsically independent of n while t can be at most n, by the definition of locality. The second algorithm does not require knowledge of t in advance (and thus it can be applied to any matrix) and requires $\mathcal{O}((t^3+t^2\log n)\frac{\log\log t}{\varepsilon})$ many queries (Theorem 25). This algorithm gains its knowledge of t with a variant of monotonicity testing (Theorem 23). Using Lemma 3 these results directly imply the same bounds for the discrete Fréchet distance of t-straight curves with bounded edge lengths. In Section 6 we show how to apply our algorithms to testing the continuous Fréchet distance. As a result, we obtain essentially the same bounds with respect to t-straight curves while removing the assumption on the edge lengths entirely (Theorem 29).

Techniques. Our algorithms use the concept of permeability, which tests whether a specified subcurve has small partial Fréchet distance to any subcurve of the other curve. Concretely, the algorithm samples a block of consecutive columns (or rows) in the δ-free space matrix and checks if there is a coupling path of cost 0 passing somewhere through this block (see Algorithm 1). If the algorithm happens to find a block that does not satisfy this condition, then we know that the global Fréchet distance is larger than the distance parameter δ and the algorithm can safely return 'no'. The difficulty lies in proving that after a certain number of random queries, the algorithm can return 'yes' with sufficient certainty. To this end, we show that if the two curves are (ε,δ)-far then the algorithm, which tests subcurves of varying sizes up to roughly $O(\frac{t}{\varepsilon})$, is likely to sample a permeability query that would return 'no'.

In the full version, we discuss a simple tester for the Hausdorff distance and a simple t-approximate Fréchet tester. This algorithm merely tests for columns and rows that contain one-entries only and are therefore somewhat blocked for coupling paths in the free space matrix. The example in Figure 2 shows that such simple queries are not sufficient to test the Fréchet distance exactly.

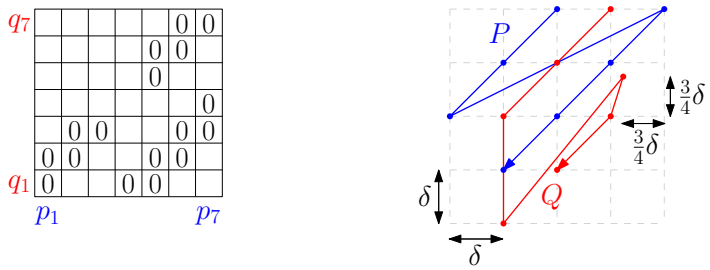

Figure 2 On the left we have M_δ for the curves on the right. All zero-entries are written.

4 Testing the discrete Fréchet distance

In this section, we describe and analyze a Fréchet tester under the assumption that the free space matrix is t-local for a given value of t.

4.1 The algorithm

The idea of Algorithm 1 is to sample a number of columns and rows and check whether there is locally a coupling path of cost zero possible. The following definition classifies when such a (local) path exists.

▶ **Definition 6** (Permeability). *We say a block $[i, i']$ of consecutive columns (resp., rows) from index i to index i' is* permeable *if there exists a coupling path of cost zero that starts in column (resp., row) i and ends in column (resp., row) i'.*

If a column (resp. row) is individually not permeable, i.e. it contains only one-entries, we call it a *barrier-column* (resp. *barrier-row*). Note that any non-permeable block of rows or columns is a witness to the fact that no global coupling path of cost 0 exists and that the algorithm can answer "no".

The algorithm first tests if the first or last entry (i.e. $M[1,1]$ or $M[n,n]$) is a one-entry. If not, it queries $\mathcal{O}\left(\frac{t}{\varepsilon}\right)$ randomly sampled columns and rows and checks if any of them is a barrier-column or barrier-row. In Lines 6-8 we sample $\mathcal{O}(\frac{t}{2^{i+1}})$ random intervals of length 2^{i+2} for each i from 0 to $\mathcal{O}\left(\log \frac{t}{\varepsilon}\right)$. We then check all corresponding blocks of columns and rows for permeability and if all blocks are permeable, we return "yes".

Algorithm 1 Fréchet-Tester1$(M, t, \varepsilon, k = \frac{24t}{\varepsilon}, c = 4)$.

1. **If** $M[1,1] = 1$ or $M[n,n] = 1$ **then return** "no".
2. **repeat** $\lceil k \rceil$ **times**:
3. $\quad j \leftarrow$ sample an index uniformly at random from $[n]$.
4. $\quad$ **if** row j or column j of M is a barrier-column or barrier-row **then return** "no".
5. $K \leftarrow \lceil \frac{\varepsilon n}{32t} \rceil - 1$, $\ell \leftarrow \lceil \frac{128t}{\varepsilon} \rceil$, let $\mathcal{J}$ be a set of intervals and set $\mathcal{J} \leftarrow \emptyset$.
6. **for** $i = 0, \ldots, \lfloor \log_2 \ell \rfloor$ **do**:
7. $\quad I \leftarrow$ sample $\lceil \frac{4cn}{2^{i+1}K} \rceil$ different indices uniformly at random from $\{0, 1, \ldots, \frac{n}{2^{i+1}} - 2\}$.
8. $\quad$ **for each** $j \in I$ **do**: add $[j2^{i+1}, (j+2)2^{i+1}]$ to $\mathcal{J}$.
9. **foreach** $[i, j] \in \mathcal{J}$ **do**
10. $\quad$ **if** block $[i, j]$ of consecutive columns is not permeable **then return** "no".
11. $\quad$ **if** block $[i, j]$ of consecutive rows is not permeable **then return** "no".
12. **return** "yes".

To check if a block of k columns (or rows) is permeable, the algorithm first performs k queries to obtain the positions of zero-entries in these columns (or rows), then we build the induced subgraph of the grid for these zero-entries, connect all neighboring zero-entries according to the possible steps of a coupling and then connect all zero-entries of the last column to a sink and all zero-entries of the first column from a source. It remains to check if there is a path from source to sink, which can be done in linear time since the graph is acyclic. The running time is linear in the total number of zero-entries queried. We call this a *permeability query*.

4.2 Basic properties of permeability

For two curves P and Q with n vertices each, and a t-local free space matrix, Algorithm 1 returns "no" only if it has determined that no coupling path of cost zero from $(1,1)$ to (n,n) can exist (by finding blocks of rows or columns that are not permeable). We need to show that it returns "yes" correctly with sufficiently high probability.

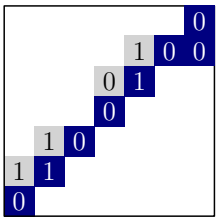

Figure 3 The blue path is a coupling path of cost 2. By adding the gray entries, we get a diagonal-restricted path of cost 5.

For technical reasons, our analysis uses a specific kind of coupling paths that are more restricted than the ones given in Section 2. We introduce them here and argue that it suffices to consider these coupling paths only.

▶ **Definition 7** (diagonal-restricted path). *A* diagonal-restricted path $\mathcal{C}$ *through the free space matrix* M *is a path corresponding to a coupling* $\mathcal{C}$ *in which for any consecutive tuples of the form* $(i,j),(i+1,j+1) \in \mathcal{C}$ *it holds that* $M[i,j] = 0 = M[i+1,j+1]$.

In other words, a diagonal-restricted path $\mathcal{C}$, is allowed to take diagonal steps in the free space matrix only if both entries are zero. Hence, any one-entry visited by $\mathcal{C}$ must be reached by either a vertical or horizontal step in M and it must be left by a vertical or horizontal step in M. This definition, which might seem overly technical at first sight, will simplify a lot of our arguments. The following observations show that it suffices to consider diagonal-restricted paths instead of all coupling paths in the analysis of a Fréchet tester.

▶ **Observation 8.** *For two curves* P *and* Q *with* n *vertices each, the following holds:*

- **i)** *There exists a diagonal-restricted path of cost zero from* $M_\delta[1,1]$ *to* $M_\delta[n,n]$ *if and only if there exists a coupling path of cost zero from* $M_\delta[1,1]$ *to* $M_\delta[n,n]$.
- **ii)** *If there is no diagonal-restricted path of cost at most* εn *through* M_δ *from* $M_\delta[1,1]$ *to* $M_\delta[n,n]$, *the curves are* $(\frac{\varepsilon}{3},\delta)$*-far. See Figure 3.*
- **iii)** *If* P *and* Q *are* (ε,δ)*-far, there is no diagonal-restricted path of cost at most* εn *through* M_δ *from* $M_\delta[1,1]$ *to* $M_\delta[n,n]$.

Below, we present three structural lemmas that help with the analysis of Algorithm 1. For the proofs of these lemmas, we refer to the full version. The first lemma considers a subpath of a diagonal-restricted path $\mathcal{C}$ that starts and ends in a zero-entry and visits only one-entries in between. We show that the bounding box of the two zero-entries must otherwise be filled with one-entries. Note that this lemma does not hold for general coupling paths of Section 2. Using it will simplify our analysis and is the main motivation for introducing Definition 7.

▶ **Lemma 9** (Box of ones). *Let* $\mathcal{C}$ *be a diagonal-restricted path of minimum cost. Let* $(i,j),(i',j') \in \mathcal{C}$ *be zero-entries such that* $\mathcal{C}$ *visits only one-entries between them. Then, for all tuples* $(k,l) \in \{(k,l) \mid i \le k \le i', j \le l \le j'\} \setminus \{(i,j),(i',j')\}$ *we have that* $M[k,l] = 1$.

We give a definition describing when two columns or rows satisfy the constraints for t-locality.

▶ **Definition 10.** *The columns* i_1 *and* i_2 pass t-locality *if any two zero-entries* (i_1,j_1) *and* (i_2,j_2) *in columns* i_1 *and* i_2 *satisfy* $|j_1 - j_2| \le t \cdot (2 + |i_1 - i_2|)$. *Similarly the rows* j_1 *and* j_2 pass t-locality *if any two zero-entries* (i_1,j_1) *and* (i_2,j_2) *in rows* j_1 *and* j_2 *satisfy* $|i_1 - i_2| \le t \cdot (2 + |j_1 - j_2|)$.

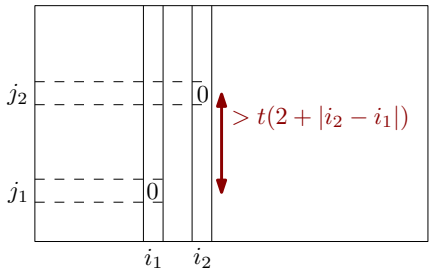

Figure 4 Two columns that do not pass t-locality.

A column (resp. row) can also pass t-locality with itself if $i_1 = i_2$ (resp. $j_1 = j_2$). Intuitively, two columns pass t-locality, when all their zero-entries are not too far away vertically. Note that all columns (resp. rows) pass t-locality with each other if M is t-local.

The second lemma shows that if an optimal diagonal-restricted path contains a long sequence of one-entries, then there must be many barrier-columns and barrier-rows.

▶ **Lemma 11** (Barrier Lemma). *Let $\mathcal{C}$ be a diagonal-restricted path of minimum cost. Suppose that there are two zero-entries $(i,j),(i',j') \in \mathcal{C}$ such that $\mathcal{C}$ visits no zero-entry and at least $4t$ one-entries in between them and suppose that all columns in $[i,i']$ and all rows in $[j,j']$ pass t-locality with each other. Then there is a total of at least $\lceil \frac{i'-i+j'-j}{2t} \rceil$ barrier-rows between j and j' and barrier-columns between i and i'.*

The third lemma shows that if an optimal diagonal-restricted path has a long stretch with relatively many one-entries on the path, there cannot be any long coupling path of cost zero in the same sequence of rows or columns of the matrix M, implying impermeability.

▶ **Lemma 12** (Impermeability Lemma). *Let $\mathcal{C}$ be a diagonal-restricted path through M of minimum cost. Suppose $(i,j),(i',j') \in \mathcal{C}$ with $j' - j > 2t$ (resp. $i' - i > 2t$) correspond to zero-entries in M and the subpath of $\mathcal{C}$ from (i,j) to (i',j') visits at least $4t-1$ one-entries and suppose that any column in $[i,i']$ and any row in $[j,j']$ passes t-locality with itself. Then, the block of columns $[i,i']$ (resp. rows $[j,j']$) is not permeable.*

4.3 Analysis of the algorithm

Algorithm 1 samples a range of intervals in Lines 6-8 which are then tested with a permeability query. For this subroutine we can prove the following lemma. For a proof see the full version.

▶ **Lemma 13.** *Let $\mathcal{I} = \{[i,j] \mid 1 \leq i < j \leq n\}$ be a set of all non-empty intervals from $[n]$ and let $X \subset \mathcal{I}$ be a set of K unknown intervals such that the length of each interval is at most ℓ and each element of $[n]$ is contained in at most c of these intervals for some constant $c \geq 1$. Lines 6-8 of Algorithm 1 select a subset $\mathcal{J} \subset \mathcal{I}$ of intervals with $\sum_{J \in \mathcal{J}} |J| = O(\frac{n \log \ell}{K})$ such that with probability at least $9/10$, at least one of the intervals in X is contained in at least one interval in $\mathcal{J}$.*

The next lemma shows that Algorithm 1 is very likely to return "no" in Line 4 if there are many barrier-columns and barrier-rows. The proof can be found in the full version.

▶ **Lemma 14.** *If the total number of barrier-columns and barrier-rows is more than $\frac{3n}{k}$, then Algorithm 1 returns "no" in Line 4 with probability at least $\frac{9}{10}$.*

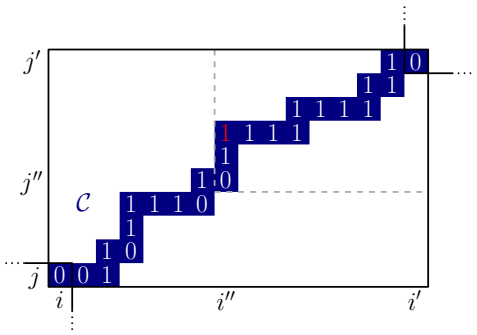

Figure 5 Example for grouping in the proof of Lemma 15 with $t = 2$. The group starts in (i, j). The red one-entry is the $(4t + 1)$-th one-entry in the group. So we stop the group at the next zero-entry (i', j'). Since it contains more than $8t$ one-entries, this is a hollow group. The entries $(i'', j''), (i', j')$ satisfy the conditions in the Barrier (Lemma 11).

▶ **Lemma 15** (Main Lemma). *Let M be t-local and $M[1, 1] = 0 = M[n, n]$. Suppose the total number of barrier-columns and barrier-rows is at most $\frac{\varepsilon n}{8t}$. Let $\mathcal{C}$ be a diagonal-restricted path with lowest cost through M and suppose that $c(\mathcal{C}) > \varepsilon n$. Then, with probability at least $\frac{9}{10}$ at least one sampled interval in the set $\mathcal{J}$ during the execution of Algorithm 1 corresponds to a non-permeable block of columns or rows.*

Proof. We first divide the path $\mathcal{C}$ into a minimum number of groups that each contain more than $4t$ one-entries and start and end with a zero-entry. A visualization of this can be seen in Figure 5. Here, the start of one group is the same entry as the end of the prior group. We do this greedily by following $\mathcal{C}$ until we have visited $4t + 1$ one-entries. Then, we end the group at the next zero-entry after that and repeat the process. Note that the last group may contain fewer than $4t + 1$ one-entries.

We will first show that there are not too many groups that contain more than $8t$ one-entries. Then, we will show that within the remaining groups, there are sufficiently many groups that are not too big. With these groups we then form the set X for the interval sampling in Lemma 13 (i.e., each interval in X will induce a permeability query that fails).

A group that contains more than $8t$ one-entries is called *hollow*, otherwise, it is *dense*.

▷ Claim 16. At most $\frac{\varepsilon n}{2}$ of the one-entries of $\mathcal{C}$ are in hollow groups.

For a proof of the claim, we refer to the full version. So we know that at least $\frac{\varepsilon n}{2}$ of the one-entries of $\mathcal{C}$ are in dense groups. Since a dense group contains at most $8t$ one-entries, we have at least $\lceil \frac{\varepsilon n}{16t} \rceil$ dense groups. Let G be a dense group that starts in (i, j) and ends in (i', j'). We say that $i' - i + j' - j + 2$ is the *size* of G. This corresponds to the sum of the number of columns and rows that it visits. In total, every row and column is counted at most twice by the definition of the groups. So the sum of all group sizes is at most $4n$. We observe that at least half of the groups (which are at least $\lceil \frac{\varepsilon n}{32t} \rceil$ many) have size at most $2 \cdot 4n / \lceil \frac{\varepsilon n}{16t} \rceil \leq \frac{128t}{\varepsilon}$. We call these groups *small*. At last, we create a set X of intervals so that we can apply Lemma 13 to it. Each of the intervals $[i, i']$ in X will have the property that either the block $[i, i']$ of consecutive columns or the block $[i, i']$ of consecutive rows is not permeable.

Let G be a small dense group and suppose it starts in (i, j) and ends in (i', j'). We observe that unless G is the very last group, it visits at least $4t + 1$ one-entries and therefore either visits more than $2t$ rows or more than $2t$ columns. In the first case, we can apply the

Impermeability Lemma to see that the block $[i, i']$ of columns is not permeable. So we add $[i, i']$ to X. In the second case, we can apply the Impermeability Lemma to see that the block $[j, j']$ of rows is not permeable. So we add $[j, j']$ to X. In the end the set X has at least $\lceil \frac{\varepsilon n}{32t} \rceil - 1$ elements and each of them has length at most $\frac{128t}{\varepsilon}$. If we take a closer look at the definitions of the groups, we see that all columns are only contained in one group except for the first and last column of each group. So we can say that every column is contained in at most two groups, i.e. at most two intervals of X. The same holds for rows. So, we have that each element of $[n]$ is contained in at most four of the intervals in X. So we can apply Lemma 13 to X with $\ell = \lceil \frac{128t}{\varepsilon} \rceil$, $K = \lceil \frac{\varepsilon n}{32t} \rceil - 1$, $c = 4$ to see that the algorithm samples one of the intervals from X with probability at least $\frac{9}{10}$. So the permeability query fails for the columns or for the rows with the respective interval, which yields the desired statement. ◀

▶ **Lemma 17.** *Algorithm 1 performs $\mathcal{O}(\frac{t}{\varepsilon} \log \frac{t}{\varepsilon})$ queries.*

Proof. Line 4 performs $\mathcal{O}(\frac{t}{\varepsilon})$ queries. By Lemma 13, Lines 6-8 sample a set $\mathcal{J}$ of intervals that contain a total of $\mathcal{O}(\frac{n \log \ell}{K})$ rows and columns. Each of these columns and rows cause a query in a permeability query. As $\ell = \lceil \frac{128t}{\varepsilon} \rceil$ and $K = \lceil \frac{\varepsilon n}{32t} \rceil - 1$, the claim follows. ◀

▶ **Theorem 18.** *Let $\delta > 0$ and $0 < \varepsilon < 2$ be given. Let P and Q be curves with n vertices such that their free space matrix with value δ is t-local and t is known. Then, Algorithm 1 is a Fréchet-tester that uses $\mathcal{O}(\frac{t}{\varepsilon} \log \frac{t}{\varepsilon})$ queries.*

Proof. If the Fréchet distance of P and Q is at most δ, there is a coupling path of cost 0 through M and Algorithm 1 always returns "yes". So we only need to determine the probability of a false positive. Suppose P and Q are (ε, δ)-far and therefore, a minimum cost diagonal-restricted path visits more than εn one-entries. If there are at least $\frac{\varepsilon n}{8t}$ barrier-columns and barrier-rows, we return "no" with probability at least $\frac{9}{10}$ in Line 4 by Lemma 14. If there are fewer than $\frac{\varepsilon n}{8t}$ barrier-columns and barrier-rows and we get past Line 4, we return "no" with probability at least $\frac{9}{10}$ in Lines 10 and 11 by the Lemma 15. So in any case, the probability for a false positive is at most $\frac{1}{10}$. The number of queries follows from Lemma 17. ◀

5 Locality-oblivious testing of the discrete Fréchet distance

Our main goal in this section is to obtain a Fréchet-tester that does not require an additional input (the value of t). Our approach for this is to first run a "tester" to find an estimate for t and then run Algorithm 1 with that parameter. Unfortunately, this combination is more complicated than just running two testers, for a number of different reasons: First, Algorithm 1 assumes that the matrix is t-local whereas the best we can do is to show that with some probability close to 1, it is "close" to being t-local. This change breaks the proof of correctness of Algorithm 1. The second complication is that we cannot plug in *any* tester for locality, we need a specific one for our analysis that also guarantees some additional properties. Guaranteeing these properties requires more queries than just testing for locality.

5.1 Testing the locality of the Free Space Matrix

To this end, we present a specific error model that is suitable for our purposes. In the following we define how t-locality of a matrix can be violated. First, it could be that two columns or rows do not pass t-locality according to Definition 10. In this case, we say that the respective columns or rows *fail t-locality*. We introduce a second definition that considers a single column and looks for violations of t-locality within that column and within the rows that have a zero-entry in this column.

▶ **Definition 19.** *A single column i (resp. row j)* fails second order t-locality *if either it contains two zero-entries $(i,j),(i,j')$ (resp. $(i,j),(i',j)$) with $|j'-j|>2t$ (resp. $|i'-i|>2t$) or if there exists a zero-entry (i,j) and two zero-entries (i_1,j) and (i_2,j) (resp. (i,j_1) and (i,j_2)) such that $|i_1-i_2|>2t$ (resp. $|j_1-j_2|>2t$). Otherwise, it* passes second order t-locality.

Intuitively, a single column fails second order t-locality if it has a zero-entry in a row that also has two zero-entries more than $2t$ distance apart (similar intuition holds for the rows). See Figure 6. Observe that if a matrix is not t-local then there either exists a pair of columns or rows that fail t-locality or a column or row that fails second order t-locality.

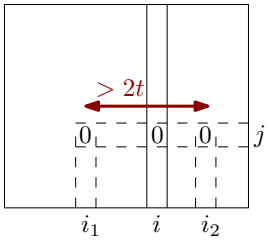

Figure 6 A column i fails second order t-locality.

We now want to define what it means for a matrix to be ζ-close to t-local. This definition is specifically designed to fit the Fréchet-tester in Section 5. Other, maybe more natural definitions of (t,ζ)-close may need different property-testers. However, testing t-locality is not our main focus in this paper.

▶ **Definition 20** (strongly (t,ζ)-local)**.** *We say that a free space matrix M is* strongly (t,ζ)-local *for some $t\geq 1$ and $\zeta\in[0,1]$ if we can partition the set of all columns and rows into two disjoint sets W and I with $|I|=\zeta n$ such that the following properties hold: i) columns $1,n$ and rows $1,n$ are in W, ii) any two columns and any two rows in W pass t-locality and iii) any row or column in W passes second order t-locality. We call the set W the* witness set *and the columns and rows in I* ignored.

If there are $(1-\zeta)n$ rows and $(1-\zeta)n$ columns such that no two of these rows or columns fail t-locality and none of these columns or rows fail second order t-locality, then they serve as a witness set to see that the matrix is $(t,2\zeta)$-local. Because of this, we will check for failures of t-locality and second order t-locality among the columns and rows.

▶ **Observation 21.** *When we query two columns i and i', we can check if they fail t-locality by comparing the lowest zero-entry in column i with the highest zero-entry in column i' and vice versa. Also, after querying a column i, testing for second order t-locality can be done with at most $2t+1$ additional row queries at all zero-entries of the column i.*

Our testing algorithm is quite simple and, in fact, it is an extension of the classic "monotonicity" testing in an array [2]. The algorithm is given in Algorithm 2.

▶ **Lemma 22.** *Given $\sigma>0$ and $t\geq 1$, Algorithm 2 returns "yes" if M is t-local; if M is not strongly $(2t,\sigma)$-local, it returns "no" with probability at least $\frac{9}{10}$. It uses $\mathcal{O}(\frac{t+\log n}{\sigma})$ queries.*

For a detailed proof of Lemma 22 we refer to the full version. The proof relies on standard techniques for monotonicity testing [2]. The Locality-tester is given a value t as an argument. Next, we show that it is also possible to obtain a good estimate of the locality, as well. The

Algorithm 2 Locality-tester(M,σ,t).

1. $T \leftarrow$ binary search tree of height $\lceil \log_2 n \rceil$ on $[n]$ with root $r = \lceil \frac{n}{2} \rceil$.
2. **repeat** $\lceil \frac{3}{\sigma} \rceil + 2$ times:
3. First two iterations: $i \leftarrow 1$ and $i \leftarrow n$. Later: Choose $i \in [2, n-1]$ unif. at random.
4. **If** column i or row i fails second order t-locality **then** return "no".
5. **foreach** j on the r-i-path in T **do**:
6. **If** columns i and j fail t-locality **then** return "no".
7. **If** rows i and j fail t-locality **then** return "no".
8. return "yes".

straightforward approach is to start with a small estimate for t, e.g., $t = 1$, use Algorithm 2 and every time it fails, we can double the t and keep repeating. Our algorithm is very similar to this approach. The difference is merely that we use different ζ values throughout the iterations and we call the locality tester multiple times for the same t.

▶ **Theorem 23.** *Suppose M is t^*-local and we are given $\zeta > 0$. We can design an algorithm that returns a value $t \leq 2t^*$ such that the matrix is strongly $(t, \zeta/t^2)$-local with probability at least $\frac{8}{9}$. The number of queries used is $\mathcal{O}(\frac{\log\log t}{\zeta}(t^3 + t^2 \log n))$.*

Proof. The algorithm operates in rounds. In the i-th round (starting from $i = 1$) we run Locality-tester(M, $\frac{\zeta}{2^{2(i+1)}}, 2^i$) for $2(1 + \log i)$ times. If the locality-tester returns "no" in any of these runs, we go to round $i + 1$, otherwise, we return $t = 2^{i+1}$.

First, we examine the number of queries. Let $i^* = \lceil \log t^* \rceil$. Then, the algorithm terminates before or in round i^* since no two columns or rows fail 2^i-locality for any $2^i \geq t^*$ and all rows and columns pass second order t^*-locality. So we have at most i^* rounds. In round i, we perform $\mathcal{O}((2 + 2\log i) \cdot \frac{2^{2(i+1)}}{\zeta} \cdot (2^i + \log n))$ queries by Lemma 22. The total number of all queries from round 1 to the last round (which is at most i^*) is $\mathcal{O}(\frac{\log\log t}{\zeta}(t^3 + t^2 \log n))$.

By Lemma 22, "no" answers are always correct. However, with probability at most $\frac{1}{10}$, the algorithm can return "yes" even though M is not $(2 \cdot 2^i, \frac{\zeta}{2^{2(i+1)}})$-local. As all the executions of the algorithm are independent, the probability that we get "yes" in all $2(1 + \log i)$ calls of the locality-tester in round i is at most $10^{-(2(1+\log i))} < \frac{1}{100i^2}$. Using a union bound, the probability that we return a value t while M is not $(t, \frac{\zeta}{t^2})$-local is at most $\sum_{i=1}^{\infty} \frac{1}{100i^2} < \frac{1}{9}$. ◀

5.2 The combined algorithm

We now present our algorithm for testing the Fréchet distance without knowing the locality parameter t in advance. Algorithm 3, uses the results from Section 5.1 to first estimate the locality of the matrix M and then uses the Fréchet-tester from Section 4 to decide if the Fréchet distance of the two curves is smaller or equal to δ.

Algorithm 3 Fréchet-tester2(M, ε).

1. $t \leftarrow$ Output of the Algorithm in Theorem 23 for M and $\zeta = \frac{\varepsilon}{1600}$.
2. **return** Fréchet-tester1($M, t, \varepsilon/3, \frac{4800t^2}{\varepsilon}, 2$).

The following lemma is analogous to the main lemma (Lemma 15) from Section 4. For a proof of this lemma we refer to the full version.

▶ **Lemma 24.** *Let $\varepsilon > 0$ and let M be strongly $(t, \frac{\varepsilon}{1600t^2})$-local and $M[1,1] = 0 = M[n,n]$. Suppose the total number of barrier-columns and barrier-rows is at most $\frac{\varepsilon n}{1600t^2}$. Let $\mathcal{C}$ be a diagonal-restricted path with lowest cost through M and suppose that $c(\mathcal{C}) > \varepsilon n$. Then, with probability at least $\frac{9}{10}$ at least one sampled interval in the set $\mathcal{J}$ in the call of Algorithm 1 during Algorithm 3 corresponds to a non-permeable block of columns or rows with probability at least $\frac{9}{10}$.*

▶ **Theorem 25.** *Let $\delta > 0$ and $0 < \varepsilon < 2$ be given. Let P and Q be curves with n vertices such that their free space matrix is t^*-local. Then, Algorithm 3 is a Fréchet-tester that uses $\mathcal{O}(((t^*)^3 + (t^*)^2 \log n)\frac{\log\log t^*}{\varepsilon})$ queries.*

Proof. The Locality-tester uses $\mathcal{O}(\frac{\log\log t^*}{\varepsilon}((t^*)^3 + (t^*)^2 \log n))$ queries. Since $t \leq 2t^*$, we need $\frac{(t^*)^2}{\varepsilon}$ queries to test for barrier-columns and barrier-rows and $\mathcal{O}\left(\frac{t^*}{\varepsilon}\log\left(\frac{t^*}{\varepsilon}\right)\right)$ queries for the permeability queries. The total number of queries follows since $\frac{t^*}{\varepsilon} \in \mathcal{O}(n^2)$.

If the Fréchet distance of P and Q is at most δ, Algorithm 3 will always return "yes". So we have to bound the probability of false positives. Assume that P and Q are (ε, δ)-far and therefore, a minimum cost diagonal-restricted path $\mathcal{C}$ through M has cost higher than εn. Suppose that M is strongly $(t, \frac{\varepsilon}{1600t^2})$-local for the output t of the algorithm from Theorem 23. By the same theorem, this happens with probability at least $\frac{8}{9}$. If the matrix contains more than $\frac{\varepsilon n}{1600t^2}$ barrier-columns and barrier-rows, the subroutine that calls Algorithm 1 returns "no" with probability at least $\frac{9}{10}$ by Lemma 14. If the matrix contains at most $\frac{\varepsilon n}{1600t^2}$ barrier-columns and barrier-rows and the algorithm proceeds until the interval sampling, we are in the setting of Lemma 24 and we return "no" with probability at least $\frac{9}{10}$. Therefore, the probability that the algorithm returns "no" is at least $\frac{8}{9} \cdot \frac{9}{10} = \frac{4}{5}$. So the probability of a false positive is at most $\frac{1}{5}$. ◀

6 Testing the continuous Fréchet distance

This section describes how the Fréchet-testers for the discrete Fréchet distance can be used to serve as $(1+\varepsilon')$-approximate Fréchet-testers for the continuous Fréchet distance. First, we define (ε, δ)-far for the continuous Fréchet-distance. Then, we explain how to use our Fréchet-testers on instances of the continuous Fréchet distance with this error model.

We first define the continuous Fréchet distance. We set F_n to be the set of all continuous non-decreasing functions $f\colon [0,1] \to [1,n]$ with $f(0) = 1$ and $f(1) = n$. Let P and Q be polygonal curves with n and m vertices. The *continuous Fréchet distance* is defined to be

$$\delta_{\mathcal{F}}(P,Q) = \min_{f\in F_n, g\in F_m} \max_{\alpha\in[0,1]} d(P(f(\alpha)), Q(g(\alpha))).$$

Now we want to introduce a possible error model for the continuous Fréchet distance. Given a value $\delta > 0$ and $f \in F_n$, $g \in F_m$, we define

$$\mathcal{P}_{f,g}(P,Q) \coloneqq \int_{d(P(f(t)),Q(g(t)))>\delta} (||(P\circ f)'(t)|| + ||(Q\circ g)'(t)||)dt$$

as the partial difference, namely the total length of the portions of the two curves P and Q that are not matched with distance at most δ by f and g. Building on this, we define the *partial Fréchet difference* to be

$$\mathcal{P}_{\delta}(P,Q) \coloneqq \min_{f\in F_n, g\in F_m} \mathcal{P}_{f,g}(P,Q).$$

This is essentially the same as the partial Fréchet distance as defined in [6].[3]

▶ **Definition 26** ((ε,δ)-far)**.** *Given two polygonal curves P and Q, we say that P and Q are (ε,δ)-far from one another w.r.t. the continuous Fréchet distance if $\mathcal{P}_\delta(P,Q) \geq \varepsilon(\ell(P)+\ell(Q))$.*

▶ **Definition 27** (μ-approximate Fréchet-tester)**.** *Assume we are given query-access to two curves P and Q, and we are given values $\delta > 0$ and $0 < \varepsilon < 1$. If the curves have continuous Fréchet distance at most δ, we must return "yes", if they are $(\varepsilon,\mu\delta)$-far from each other w.r.t. the continuous Fréchet distance, the algorithm must return "no", with probability at least $\frac{4}{5}$.*

In order to use the first Fréchet-tester introduced in this paper, we transform the polygonal curves into discrete curves by subsampling vertices along the edges of the curves. Denote by P_a the discrete curve that arises from P if we subsample vertices along the edges of P such that P visits a curve segment of length a in between any two vertices for some $a \in (0,\ell(P)]$. The last edge might be longer than a but shorter than $2a$. Hence, P_a has $\lfloor \frac{\ell(P)}{a} \rfloor$ edges. This yields that $D_{\mathcal{F}}(P_a,Q_a) - 2a < \delta_{\mathcal{F}}(P,Q) \leq D_{\mathcal{F}}(P_a,Q_a) + 2a$. If P is t-straight, so is P_a for any $a \in (0,\ell(P)]$. The next lemma shows that the notions of (ε,δ)-far are also related.

▶ **Lemma 28.** *Let $0 < a \leq \min\{\ell(P),\ell(Q)\}$. If P and Q are $(12\varepsilon,\delta+2a)$-far from each other, then P_a and Q_a are (ε,δ)-far from each other.*

For a proof see the full version. We adjust our query oracle such that it can access the free space matrix of P_a and Q_a. So we can apply the Fréchet-testers to P_a and Q_a for an adequate choice of a. We show that for given $\varepsilon' > 0$ and $0 < \varepsilon < 2$, we can choose a such that this yields a $(1+\varepsilon')$-approximate Fréchet-tester for the continuous Fréchet distance of P and Q. Let $\varepsilon'' > 0$. For $a = \varepsilon''\delta$, we test $P_{\varepsilon''\delta}$ and $Q_{\varepsilon''\delta}$ for the distance $\delta' := (1+2\varepsilon'')\delta$. We observe that $M_{\delta'}$ is $\mathcal{O}(\frac{t}{\varepsilon''})$-local if P and Q are t-straight. If $\delta_{\mathcal{F}}(P,Q) \leq \delta$, we have $D_{\mathcal{F}}(P_{\varepsilon''\delta},Q_{\varepsilon''\delta}) \leq \delta'$ and if P and Q are $(\varepsilon,\mu\delta)$-far, we have that $P_{\varepsilon''\delta}$ and $Q_{\varepsilon''\delta}$ are $(\frac{\varepsilon}{12},\delta')$-far for $\mu = 1+4\varepsilon'' = 1+\varepsilon'$ for $\varepsilon'' = \varepsilon'/4$. So, if we know t, we can apply the first Fréchet-tester for $\frac{\varepsilon}{12}$ and δ'. If t is unknown, we apply the second Fréchet-tester for the same values.

▶ **Theorem 29.** *Let $\delta,\varepsilon,\varepsilon' > 0$ be given and assume $\varepsilon < 1$. Let P and Q be t-straight curves with $\ell(P) = \ell(Q)$. If t is known, there exists a $(1+\varepsilon')$-approximate Fréchet-tester w.r.t. the continuous Fréchet distance that performs at most $\mathcal{O}\left(\frac{t}{\varepsilon\cdot\varepsilon'}\log\frac{t}{\varepsilon\cdot\varepsilon'}\right)$ queries. If t is unknown, there exists a $(1+\varepsilon')$-approximate Fréchet-tester w.r.t. the continuous Fréchet distance that performs at most $\mathcal{O}\left(\left((\frac{t}{\varepsilon'})^3 + (\frac{t}{\varepsilon'})^2\log\left\lceil\frac{\ell(P)}{\varepsilon'\delta}\right\rceil\right)\frac{\log\log\frac{t}{\varepsilon'}}{\varepsilon}\right)$ queries.*

A natural consequence of the above theorem is that for t-straight curves, the number of queries is bounded in terms of n and the aspect ratio of the input.

A Simple yet Exact Analysis of the MultiQueue

Stefan Walzer

Marvin Williams
Karlsruhe Institute of Technology, Germany

Abstract

The MultiQueue is a relaxed concurrent priority queue consisting of n internal priority queues, where an insertion uses a random queue and a deletion considers two random queues and deletes the minimum from the one with the smaller minimum. The *rank error* of the deletion is the number of smaller elements in the MultiQueue.

Alistarh et al. [2] have demonstrated in a sophisticated potential argument that the expected rank error remains bounded by $\mathcal{O}(n)$ over long sequences of deletions.

In this paper we present a simpler analysis by identifying the stable distribution of an underlying Markov chain and with it the long-term distribution of the rank error exactly. Simple calculations then reveal the expected long-term rank error to be $\frac{5}{6}n - 1 + \frac{1}{6n}$. Our arguments generalize to deletion schemes where the probability to delete from a given queue depends only on the rank of the queue. Specifically, this includes deleting from the best of c randomly selected queues for any $c > 1$.

1 Introduction

Priority queues maintain a set of elements from a totally ordered domain, with an *insert* operation adding an element and a *deleteMin* operation extracting the smallest element. They are a fundamental building block for a wide range of applications such as task scheduling, graph algorithms, and discrete event simulation. The parallel nature of modern computing hardware motivates the design of concurrent priority queues that allow multiple processing elements to insert and delete elements concurrently. *Strict*[1] concurrent priority queues (e.g., [19, 11, 7, 17]) suffer from poor scalability due to inherent contention on the smallest element [4, 8]. To alleviate this contention, in *relaxed* priority queues deletions should still preferentially extract small elements but need not always extract the minimum. In other words, the correctness requirement is turned into a quality measure: We speak of a *rank error* of $r - 1$ if the extracted element has rank r among all elements currently in the priority queue. In many scenarios, relaxed priority queues outperform strict priority queues, as the higher scalability outweighs the additional work caused by the relaxation. They are an active field of research and a vast range of designs has been proposed [10, 16, 22, 3, 18, 21, 15, 23].

The MultiQueue. The MultiQueue, initially proposed by Rihani et al. [16] and improved upon by Williams et al. [21], emerged as the state-of-the art relaxed priority queue. Due to its high scalability and robust quality, the MultiQueue inspired a number of follow-up works [15, 23]. Its design uses the *power-of-two-choices* paradigm and is delightfully simple: We use n (sequential) priority queues for some fixed $n \in \mathbb{N}$. Each insertion adds its element to a queue chosen uniformly at random and each deletion picks *two* queues uniformly at random and deletes from the one with the smaller minimum. Figure 1 illustrates the MultiQueue

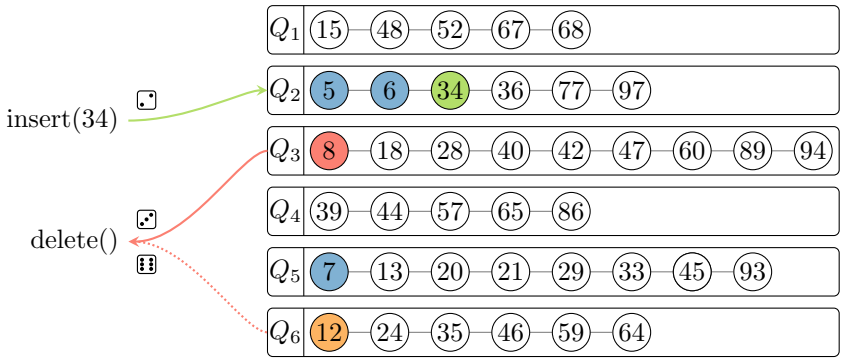

Figure 1 The MultiQueue with $n = 6$ queues and some elements already inserted. The shown insertion picks queue 2 to insert the element 34 (green). The shown deletion picks queues 3 and 6 with minima 8 (red) and 12 (orange), and deletes the 8 since it is smaller. The deletion exhibits a rank error of 3 due to the 3 smaller elements highlighted in blue.

with $n = 6$ queues. We can generalize this design to pick any number $c > 1$ of queues for deletions where even non-integer choices of c make sense: We would then pick $\lfloor c \rfloor + 1$ queues with probability $c - \lfloor c \rfloor$ and $\lfloor c \rfloor$ queues otherwise. In practice, the individual queues are protected by mutual exclusion locks, and n is proportional to the number of processing elements to find unlocked queues in (expected) constant time.

Existing theory on the MultiQueue. Our theoretical understanding of the MultiQueue is still incomplete. One obstacle is that the order of operations matters: Intuitively, deletions can cause the distribution of elements to drift apart and increase the expected rank error, while insertions of small elements can mask accumulated differences. This suggests that the worst-case setting is when following the insertion of sufficiently many elements, only deletions occur. Like Alistarh et al. [2], we exclusively consider this setting. At first glance, this process seems closely related to the classical balls-into-bins process, where balls are placed one after the other into the least loaded of two randomly chosen bins. Famously, the difference between the highest load and the average load for n bins is in $\mathcal{O}(\log \log n)$ with high probability for any number of balls. Numerous variants of the balls-into-bins process have been proposed and studied [5, 12, 6, 14]. However, reducing the process to a balls-into-bins process imposes multiple difficulties. The state of the MultiQueue is not fully described by the number of elements in each queue but also involves information about the ranks of the elements. Moreover, deleting an element from a queue can affect the ranks of elements in other queues. Despite these challenges, Alistarh et al. [2] managed to transfer the potential argument from the balls-into-bins analysis by Peres et al. [14] to a MultiQueue analysis via an intermediate "exponential process" that avoids correlations between the elements in the queues. They prove that the expected rank error is in $\mathcal{O}(n)$ and the expected worst-case rank error is in $\mathcal{O}(n \log n)$ for any number of deletions and any $c \in (1, 2]$, while the rank errors diverge

with the number of deletions for $c = 1$. In follow-up work, this technique is generalized to other relaxed concurrent data structures [1] and a process where each processing element has its own priority queue and "steals" elements from other processing elements with some probability [15].

Contribution. In this paper, we present an analysis of the MultiQueue that, compared to the potential argument by Alistarh et al. [2], is simultaneously simpler and more precise. We characterise the exact long-term distribution of the rank error for any $c > 1$ and any $n \in \mathbb{N}$. From this distribution we can derive, for instance, that the expected rank error for $c = 2$ is $\frac{5}{6}n - 1 + \frac{1}{6n}$. In addition to covering any $c > 1$, our analysis generalizes to all deletion schemes where the probability for a queue to be selected solely depends on the rank of the queue (when ordering the queues according to their smallest element).

We achieve this by modelling the deletion process as a Markov chain and observing that its stationary distribution can be described using a sequence of $n - 1$ independent geometrically distributed random variables. In the full version of this paper [20] we also apply our techniques to the elegant exponential process by Alistarh et al. [2], which we believe to be of independent interest.

Outline. First, in Section 2, we introduce the formal model of a generalized MultiQueue and the setting in which we analyze it. We then state our main results, including Theorem 1 that characterizes the long-term distribution of the ranks of the top-elements in the MultiQueue. In Section 3, we present our analysis of the generalized MultiQueue, leading to the proof of Theorem 1. We apply Theorem 1 to compute the expected rank error for any $c > 1$ and any $n \in \mathbb{N}$ in Section 4. Finally, in Section 5, we discuss implications and limitations of our results and outline possible future work.

2 Formal Model and Results

Analogous to Alistarh et al. [2], we analyze the MultiQueue in a simplified setting where only deletions occur.

The σ-MultiQueue. A σ-MultiQueue consists of n priority queues and a choice distribution σ on $[n]$ that captures a generalised deletion strategy (as explained below). The n queues are initially populated by randomly partitioning an infinite set $\{x_1 < x_2 < x_3 < \ldots\}$ of elements. [2] The queues, identified with the sets of elements they contain, are denoted by $Q_1, \ldots, Q_n$, indexed such that $\min Q_1 < \min Q_2 < \ldots < \min Q_n$. The minima are also called *top-elements*. We then perform a sequence of deletions. Each time, we select an index $i \in [n]$ according to σ and delete the top-element of Q_i. [3] Then, we relabel the queues such that their top-elements appear in ascending order again. Let $(Q_1^{(s)}, \ldots, Q_n^{(s)})$ be the sequence of queues after s deletions and $r_i^{(s)}$ the rank of the top-element $\min Q_i^{(s)}$ among $Q_1^{(s)} \cup \ldots \cup Q_n^{(s)}$, for any $s \in \mathbb{N}$ and $i \in [n]$.

Intuitively, σ should be biased towards smaller values of i, i.e., towards selecting queues with smaller top-elements, to ensure that the rank error does not diverge over time. Using the notation $\sigma_i := \Pr_{i^* \sim \sigma}[i^* = i]$ and $\sigma_{\leq i} := \Pr_{i^* \sim \sigma}[i^* \leq i]$, the formal requirement for σ turns out as:

[2] Note that every queue receives an infinite number of elements with probability 1.
[3] We write $[n]$ as a shorthand for $\{1, \ldots, n\}$.

$$\forall i \in [n-1] : \sigma_{\leq i} > \tfrac{i}{n} \qquad (\star)$$

If σ does not satisfy $(\star)$, the MultiQueue deletes too frequently from "bad" queues (i.e., with large top-elements) and the gap between "good" and "bad" queues increases over time. We prove a corresponding formal claim in the full version of this paper [20].

Surprisingly independent random variables. One might think that the ranks $r_1^{(s)} < \ldots < r_n^{(s)}$ are correlated in complex ways. While they *are* correlated, they effectively arise as the prefix sum of $n-1$ *independent* random variables. More precisely, our main theorem draws attention to the differences between the ranks of consecutive top-elements.

▶ **Theorem 1** (Proof in Section 3). *Let $(r_1^{(s)}, \ldots, r_n^{(s)})$ denote the ranks of the top-elements of a σ-MultiQueue with σ satisfying $(\star)$ after s deletions. Then $(r_1^{(s)}, \ldots, r_n^{(s)})$ converges in distribution to a sequence $(r_1, \ldots, r_n)$ of random variables where*

$$r_i = 1 + \sum_{j=1}^{i-1} \delta_j \text{ for } i \in [n] \text{ with } \delta_i \sim \mathrm{Geom}_1\Big(1 - \frac{i}{n\sigma_{\leq i}}\Big) \text{ for } i \in [n-1],$$

where $\mathrm{Geom}_1(p)$ denotes the geometric distribution of the number of Bernoulli trials with success probability p until (and including) the first success.

From the distribution of the ranks of the top-elements given by Theorem 1 it is straightforward to derive the rank error distribution.

▶ **Corollary 2** (Proof in Section 3). *Let $R^{(s)}$ denote the rank error exhibited by the deletion in step s in the σ-MultiQueue with σ satisfying $(\star)$. Then $R^{(s)}$ converges in distribution to the random variable R where*

$$R = r_{i^*} - 1 \text{ with } i^* \sim \sigma \text{ and } r_i \text{ as in Theorem 1.}$$

The expected rank error is (in the long run)

$$\mathbb{E}[R] = \sum_{i=1}^{n-1} \frac{\sigma_{\leq i}(1-\sigma_{\leq i})}{\sigma_{\leq i} - \frac{i}{n}}.$$

Application to the c-MultiQueue. For $c > 1$ we define the c-MultiQueue to be the σ-MultiQueue where σ is the distribution that corresponds to picking the best out of c randomly selected queues as described in Section 1. For instance, the probability to select one of the first i queues with $c = 2$ is $\sigma_{\leq i} = 1 - (1 - \frac{i}{n})^2$. Note that $(\star)$ is satisfied (see Lemma 8). We can then derive several useful quantities from Theorem 1, including the expected rank error.

▶ **Theorem 3.** *Consider the expectation $\mathbb{E}[R]$ of the rank error $R = r_{i^*} - 1$ of the c-MultiQueue in the long run (i.e., after convergence).*

(i) *For $c = 2$ we have $\mathbb{E}[R] = \frac{5}{6}n - 1 + \frac{1}{6n} = \frac{5}{6}n - \Theta(1)$.*

(ii) *For $c = 1 + \varepsilon$ with $\varepsilon \in (0,1)$, we have $\mathbb{E}[R] = (\frac{1}{\varepsilon} - \frac{\varepsilon}{6})n - \frac{1}{\varepsilon} + \frac{\varepsilon}{6n} = (\frac{1}{\varepsilon} - \frac{\varepsilon}{6})n - \mathcal{O}(1/\varepsilon)$.*

(iii) *For any $c > 1$ we have $n \cdot \int_0^1 f_c(x)\,dx - \frac{c}{c-1} \leq \mathbb{E}[R] \leq n \cdot \int_0^1 f_c(x)\,dx$, where $f_c : (0,1) \to \mathbb{R}$ is defined as follows using $\varepsilon := c - \lfloor c \rfloor \in [0,1)$*

$$f_c(x) = x^{\lfloor c \rfloor - 1}(1 - \varepsilon + \varepsilon x) \cdot \frac{1 - x^{\lfloor c \rfloor}(1 - \varepsilon + \varepsilon x)}{1 - x^{\lfloor c \rfloor - 1}(1 - \varepsilon + \varepsilon x)}.$$

(iv) *Cruder but simpler bounds for any $c \geq 2$ are: $\frac{n}{\lceil c \rceil} - \frac{c}{c-1} \leq \mathbb{E}[R] \leq \frac{n}{\lfloor c \rfloor - 1}$.*

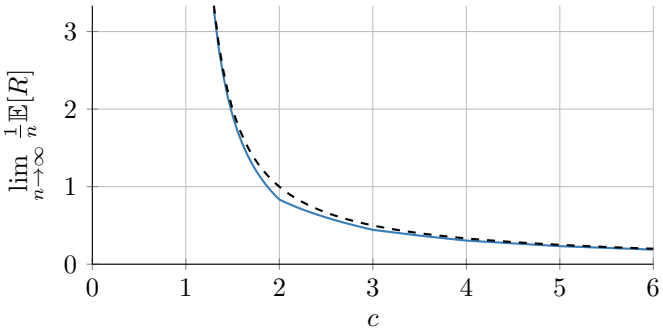

Figure 2 For large n, the c-MultiQueue has an expected rank error of $\mathbb{E}[R] = n \cdot \int_0^1 f_c(x)\,dx + o(n)$ where $f_c(x)$ is defined in Theorem 3. The solid line shows $c \mapsto \int_0^1 f_c(x)\,dx$ and hence the constant in front of the leading term. The dashed line $c \mapsto \frac{1}{c-1}$ is an asymptote for both $c \to 1$ and $c \to \infty$.

Figure 2 plots the expected asymptotic rank error per queue depending on c, and an approximation $\frac{1}{c-1}$. We also give concentration bounds for the rank error in Theorem 9.

The Exponential-Jump Process. As an intermediate step in their analysis, Alistarh et al. [2] introduce the "exponential process", where new top-elements are not given by the current state but generated by adding an exponential random variable to the current top-element. We reformulate this process as the equivalent *exponential-jump process* (EJP) as follows. The EJP involves n tokens on the real number line and a distribution σ on $[n]$. In every step, we sample $i^* \sim \sigma$ and $X \sim \mathrm{Exp}(1)$. We then identify the i^*th token from the left and move it a distance of X to the right. More formally, the state of the process is given by the sequence $t_1 < \ldots < t_n$ of positions of the tokens and the state transition can be described as

$$(t_1, \ldots, t_n) \rightsquigarrow \mathrm{sort}(t_1, \ldots, t_{i^*} + X, \ldots, t_n) \text{ where } i^* \sim \sigma \text{ and } X \sim \mathrm{Exp}(1). \tag{EJP}$$

We provide an exact analysis, which we believe to be of independent interest, and explain the connection between the EJP and the MultiQueue in the full version of this paper [20]. With the same methods as before, we analyse the differences $(d_1, \ldots, d_{n-1})$ with $d_i = t_{i+1} - t_i$.

▶ **Theorem 4.** *Let $n \in \mathbb{N}$ and let σ be a distribution on $[n]$ that satisfies $(\star)$. The EJP admits a stationary distribution π for the differences $(d_1, \ldots, d_{n-1})$ with*

$$\pi = \bigtimes_{i=1}^{n-1} \mathrm{Exp}(n \cdot \sigma_{\le i} - i).$$

In other words, the distances between neighbouring tokens are, in the long-run, mutually independent and exponentially distributed with parameters as given.

3 A Direct Analysis of the σ-MultiQueue

When analysing random processes, it is often a good idea to reveal information only when needed, keeping the rest hidden behind a veil of probability. In our case, the idea is to conceal the queue an element is in until the element becomes a top-element.

We discuss this idea using the example in Figure 3 where $n = 4$ queues are initially populated with the set $\mathbb{N}$.

In (a) we see an explicit representation of a possible state, where queues are labeled in increasing order of their top-elements. We can tell, for instance, that when removing the top-element 7 of queue 2 then the new top-element would be 9. In (b) we keep track of the

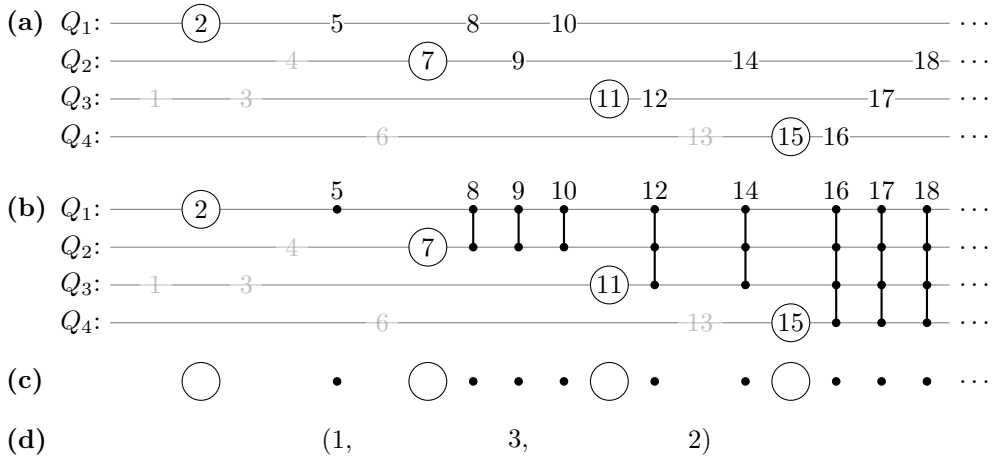

Figure 3 Increasingly abstract ways for modeling the state of a MultiQueue system with 4 queues. **(a)** contains all information. **(b)** assumes that the queues in which the elements reside has only been partially revealed. **(c)** abstracts away from concrete elements. **(d)** represents the information in (c) using numbers.

current and past top-elements of all queues but do not reveal ahead of time which queue each element of $\mathbb{N}$ is assigned to. As far as we know, the elements $16, 17, 18, \ldots$ are assigned to each of the four queues with equal probability. It is unavoidable that we obtain partial information, however: If an element is smaller than the top-element of some queue, it cannot possibly be contained in that queue. The elements 8, 9 and 10 are in queue 1 and 2 with probability 1/2 each, and the elements 12 and 14 are in queues 1, 2 and 3 with probability 1/3 each. Element 5 is surely contained in queue 1, but we can treat this as a degenerate probability distribution rather than as a special case. Note what happens when element 7 is deleted: First, 8 has a chance of 1/2 of being the new top-element of queue 2. If it turns out that 8 is not the new top-element, then 9 gets the same chance, then 10. If all three elements are rejected, then element 12 is considered, getting a chance of 1/3 (because it could still be in three queues) and so on.

Since we are only interested in the ranks of top-elements over time, we can forget the removed elements and the concrete element values and arrive at representation (c), showing n *balls* "◯" representing top-elements and *dots* "•" representing other elements. Equivalently, in (d) we list the sequence of dot-counts in between the balls, omitting the infinite number of dots to the right of the last ball.

We now represent the σ-MultiQueue as a Markov chain with states in $\mathbb{N}_0^{n-1}$ as in (d), borrowing language from (b) and (c) when useful. Since the state space is countably infinite, the role of the transition matrix is filled by an infinite family P of transition probabilities where $P(\vec{d}_{\text{start}}, \vec{d}_{\text{end}})$ denotes the probability to transition from state $\vec{d}_{\text{start}} \in \mathbb{N}_0^{n-1}$ to state $\vec{d}_{\text{end}} \in \mathbb{N}_0^{n-1}$. These probabilities are implicitly described below. We write $\vec{d}$ for a state $(d_1, \ldots, d_{n-1}) \in \mathbb{N}_0^{n-1}$ and $\vec{e}_i = 0^{i-1}10^{n-i-1} \in \{0,1\}^{n-1}$ denotes the ith unit vector for $i \in [n-1]$. We avoid special cases related to the last ball by defining $d_n = \infty$ and $\vec{e}_n = \vec{0}$.

A state $\vec{d}_{\text{start}}$ transitions to another state $\vec{d}_{\text{end}}$ via a sequence of *transitional states* $(\vec{d}, i) \in \mathbb{N}_0^{n-1} \times [n]$ in which one ball $i \in [n]$ (numbered from left to right) is marked as the *active ball*.

1. Given state $\vec{d}_{\text{start}}$, we sample $i^* \sim \sigma$ and obtain the transitional state $(\vec{d}_{\text{start}}, i^*)$.
   Interpretation: In terms of (c) we activate ball i^* and in terms of (b) we delete the top-element from queue Q_{i^*} and look for a new one.

2. As long as we are in a transitional state $(\vec{d}, i)$, there are two cases:

2.1 If $d_i > 0$, then with probability $(i-1)/i$ we continue with transitional state $(\vec{d} - \vec{e}_i + \vec{e}_{i-1}, i)$ and with probability $1/i$ the transition ends with state $\vec{d}_{\text{end}} = \vec{d} - \vec{e}_i$.
Interpretation: In terms of (c) the active ball decides to skip past the dot to the right of it, or consumes the dot and stops. In terms of (b), we reveal whether the next top-element candidate for Q_i is contained in Q_i; if it is, the candidate becomes the new top-element and we stop, otherwise we continue the search.

2.2 If $d_i = 0$, then we continue with transitional state $(\vec{d}, i+1)$.
Interpretation: In terms of (c) the active ball overtakes another ball, thereby becoming ball $i+1$. In terms of (b), we update the ordering of the queues since the new top-element of Q_i is now known to be larger than the top-element of queue Q_{i+1}.

For clarity, we illustrate the possible transitions for a concrete state $\vec{d}_{\text{start}} \in \mathbb{N}_0^{n-1}$ and resulting transition probabilities in Figure 4. We remark that the following analysis does not refer to the transition probabilities directly, but uses their implicit characterisation.

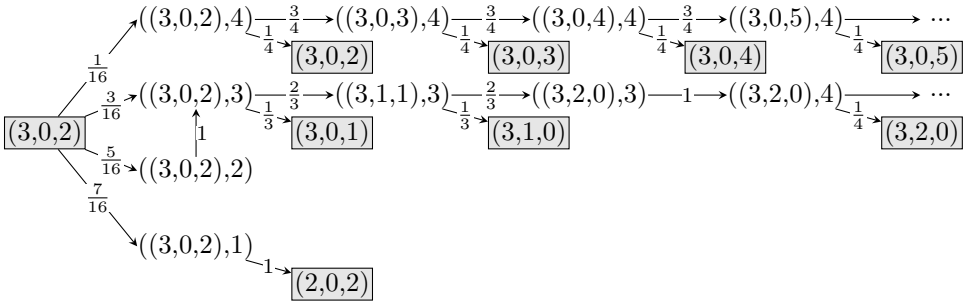

Figure 4 Possible states and transitional states reachable from $\vec{d}_{\text{start}} = (3,0,2)$ in a single state transition. The probabilities $\frac{1}{16}, \frac{3}{16}, \frac{5}{16}, \frac{7}{16}$ on the outgoing edges of $(3,0,2)$ assume the special case of the 2-MultiQueue. Taking the example $\vec{d}_{\text{end}} = (3,1,0)$, the probability to transition from $\vec{d}_{\text{start}}$ to $\vec{d}_{\text{end}}$ arises from the two corresponding paths as $P(\vec{d}_{\text{start}}, \vec{d}_{\text{end}}) = \frac{3}{16} \cdot \frac{2}{3} \cdot \frac{1}{3} + \frac{5}{16} \cdot 1 \cdot \frac{2}{3} \cdot \frac{1}{3}$.

We now state the main result of this section, which characterizes a stationary distribution of P. With this lemma, we can finally prove Theorem 1 and Corollary 2.

▶ **Theorem 5.** *Let $n \in \mathbb{N}$ and let σ be a distribution on $[n]$ that satisfies $(\star)$. The transition probabilities P admits the stationary distribution π given by*

$$\pi = \bigtimes_{i=1}^{n-1} \text{Geom}\Big(1 - \frac{i}{n \cdot \sigma_{\le i}}\Big),$$

where $\text{Geom}(p)$ denotes the geometric distribution of the number of failed Bernoulli trials with success probability p before the first success, and $\bigtimes$ denotes the direct product of distributions.

In particular, the $n-1$ components of $\vec{d} \sim \pi$ are *independent* random variables. We further make the following useful observation.

▶ **Observation 6.** *For any $\vec{d} \in \mathbb{N}_0^{n-1}$ and any $i \in [n]$ we have $\pi(\vec{d} + \vec{e}_i) = \pi(\vec{d}) \cdot \frac{i}{n \cdot \sigma_{\le i}}$.*

Proof of Observation 6. If $i = n$ then $\vec{e}_i = \vec{0}$ and $\sigma_{\le i} = 1$ so the claim is trivial. Now assume $i < n$. For any $\vec{d} \in \mathbb{N}_0^{n-1}$ we have

$$\pi(\vec{d}) = \prod_{i=1}^{n-1} (1-p_i)^{d_i} p_i \text{ where } p_i = 1 - \frac{i}{n \cdot \sigma_{\le i}}.$$

Hence, $\pi(\vec{d}+\vec{e}_i) = \pi(\vec{d}) \cdot (1-p_i)$ and the claim follows. ◀

The following auxiliary lemma captures the main insight required in the proof of Theorem 5.

▶ **Lemma 7.** *Let $\nu(\vec{d}, i) \in \mathbb{R}_{\geq 0}$ be the probability that a transitional state $(\vec{d}, i) \in \mathbb{N}_0^{n-1} \times [n]$ occurs when transitioning from state $\vec{d}_{\text{start}} \sim \pi$ according to P with σ satisfying $(\star)$. Then,*

$$\nu(\vec{d}, i) = \pi(\vec{d}) \cdot \sigma_{\leq i}.$$

Proof of Lemma 7. We prove $\nu(\vec{d}, i) = \pi(\vec{d}) \cdot \sigma_{\leq i}$ by induction. In the induction step we may assume that $\nu(\vec{d}', i') = \pi(\vec{d}') \cdot \sigma_{\leq i'}$ holds whenever $i' < i$ or when $i = i'$ and $d'_1 + \ldots + d'_{i-1} < d_1 + \ldots + d_{i-1}$. In general, there are three ways in which a transitional state $(\vec{d}, i)$ might be reached:

- **(i)** The transition started with $\vec{d} = \vec{d}_{\text{start}}$ and ball i was activated.
- **(ii)** Ball i has skipped a dot and we thus reached $(\vec{d}, i)$ from $(\vec{d} - \vec{e}_{i-1} + \vec{e}_i, i)$.
- **(iii)** Ball i has just overtaken another ball and we thus reached $(\vec{d}, i)$ from $(\vec{d}, i-1)$.

For $i = 1$, consider a transitional state $(\vec{d}, 1)$ where the first ball is active. Here, only (i) is possible since the first ball never skips a dot (transition ends with probability 1 in rule 2.1) and there is no ball to its left. The probability for $(\vec{d}, 1)$ to occur is thus

$$\nu(\vec{d}, 1) = \pi(\vec{d}) \cdot \sigma_1 = \pi(\vec{d}) \cdot \sigma_{\leq 1} \qquad \text{(recall that } \sigma_i := \Pr_{i^* \sim \sigma}[i^* = i] \text{ and } \sigma_{\leq i} := \Pr_{i^* \sim \sigma}[i^* \leq i]\text{)}.$$

For $i > 1$, there are two cases depending on whether $d_{i-1} > 0$, i.e., whether there is a dot in between ball $i-1$ and ball i. If $d_{i-1} > 0$, then only (i) and (ii) are possible, so

$$\begin{aligned}
\nu(\vec{d}, i) &= \pi(\vec{d}) \cdot \sigma_i + \nu(\vec{d} - \vec{e}_{i-1} + \vec{e}_i, i) \cdot (1 - \tfrac{1}{i}) \\
&= \pi(\vec{d}) \cdot \sigma_i + \pi(\vec{d} - \vec{e}_{i-1} + \vec{e}_i) \cdot \sigma_{\leq i} \cdot (1 - \tfrac{1}{i}) && \text{(Induction)} \\
&= \pi(\vec{d}) \cdot \sigma_i + \pi(\vec{d}) \cdot \frac{n \cdot \sigma_{\leq i-1}}{i-1} \cdot \frac{i}{n \cdot \sigma_{\leq i}} \cdot \sigma_{\leq i} \cdot (1 - \tfrac{1}{i}) && \text{(Observation 6)} \\
&= \pi(\vec{d})(\sigma_i + \sigma_{\leq i-1}) = \pi(\vec{d}) \cdot \sigma_{\leq i}.
\end{aligned}$$

If $d_{i-1} = 0$, then only (i) and (iii) are possible, so

$$\nu(\vec{d}, i) = \pi(\vec{d}) \cdot \sigma_i + \nu(\vec{d}, i-1) \overset{\text{ind.}}{=} \pi(\vec{d}) \cdot \sigma_i + \pi(\vec{d}) \cdot \sigma_{\leq i-1} = \pi(\vec{d}) \cdot \sigma_{\leq i}.$$ ◀

With Lemma 7 in place, we can now prove Theorem 5.

Proof of Theorem 5. Given a state $\vec{d}_{\text{start}} \sim \pi$, we transition to a new state $\vec{d}_{\text{end}}$ according to the transition probabilities P. To end in $\vec{d}_{\text{end}}$, we first need to reach the transitional state $(\vec{d}_{\text{end}} + \vec{e}_i, i)$ for some $i \in [n]$ and then decide to end the transition there. Note that we need $(\vec{d}_{\text{end}} + \vec{e}_i, i)$ rather than $(\vec{d}_{\text{end}}, i)$, since ending the transition (rule 2.1) reduces d_i by one. The probability to end in $\vec{d}_{\text{end}}$ is therefore

$$\begin{aligned}
\Pr[\vec{d}_{\text{end}} = \vec{d}] &= \sum_{i=1}^{n} \nu(\vec{d} + \vec{e}_i, i) \cdot \tfrac{1}{i} \overset{\text{Lem. 7}}{=} \sum_{i=1}^{n} \pi(\vec{d} + \vec{e}_i) \cdot \sigma_{\leq i} \cdot \tfrac{1}{i} \\
&\overset{\text{Obs. 6}}{=} \sum_{i=1}^{n} \pi(\vec{d}) \cdot \frac{i}{n \cdot \sigma_{\leq i}} \cdot \sigma_{\leq i} \cdot \tfrac{1}{i} = \pi(\vec{d}) \sum_{i=1}^{n} \tfrac{1}{n} = \pi(\vec{d}).
\end{aligned}$$

It follows that $\vec{d}_{\text{end}}$ is again distributed according to π and π is a stationary distribution. ◀

Finally, we prove Theorem 1 and Corollary 2.

Proof of Theorem 1. Let $\vec{d}^{(s)} = (d_1^{(s)}, \dots, d_{n-1}^{(s)})$ with $d_i^{(s)} = r_{i+1}^{(s)} - r_i^{(s)} - 1$. Then, $(\vec{d}^{(s)})_{s\in\mathbb{N}}$ is a Markov chain with transition probabilities P. Since we can reach $(0, \dots, 0)$ from any state and vice versa, the Markov chain is irreducible. The Markov chain is aperiodic since $(0, \dots, 0)$ can transition into itself (if ball n is activated and immediately stops). This implies that the stationary distribution π that we found is unique and that $\vec{d}^{(s)}$ converges in distribution to $d \sim \pi$ (see [13, Theorem 1.8.3]). Let $\vec{\delta}^{(s)} = (\delta_1^{(s)}, \dots, \delta_{n-1}^{(s)})$ with $\delta_i^{(s)} = d_i^{(s)} + 1$. Clearly, $(\vec{\delta}^{(s)})_{s\in\mathbb{N}}$ converges in the same way, except that the geometric random variables are shifted. By definition, we have $r_i^{(s)} = 1 + \sum_{j=1}^{i-1} \delta_j^{(s)}$ so the claimed distributional limit $(r_1, \dots, r_n)$ of $(r_1^{(s)}, \dots, r_n^{(s)})$ follows. ◀

Proof of Corollary 2. Theorem 1 states the ranks of the top-elements converge in distribution to $(r_1, \dots, r_n)$. The distribution for R follows from the fact that we select the queue to delete from according to σ and deleting an element with rank r yields a rank error of $r - 1$. Using the fact that $\mathbb{E}_{X\sim\mathrm{Geom}_1(p)}[X] = 1/p$, we have for the expected rank error

$$\begin{aligned}\mathbb{E}[R] = \mathbb{E}\left[r_{i^*} - 1\right] &= \sum_{i=1}^{n} \sigma_i \sum_{j=1}^{i-1} \mathbb{E}[\delta_j] = \sum_{j=1}^{n-1} \mathbb{E}[\delta_j] \sum_{i=j+1}^{n} \sigma_i = \sum_{j=1}^{n-1} \mathbb{E}[\delta_j] \cdot (1 - \sigma_{\le j}) \\ &= \sum_{j=1}^{n-1} \frac{n\sigma_{\le j}}{n\sigma_{\le j} - j} \cdot (1 - \sigma_{\le j}) = \sum_{j=1}^{n-1} \frac{\sigma_{\le j}(1 - \sigma_{\le j})}{\sigma_{\le j} - \frac{j}{n}}.\end{aligned}$$ ◀

4 Application to the c-MultiQueue

In this section we apply our results on the general σ-MultiQueue to the c-MultiQueue with $c > 1$. After checking in Lemma 8 that the corresponding σ satisfies $(\star)$, we proceed to compute expected rank errors (Theorem 3) and derive a concentration bound (Theorem 9). This involves straightforward (though mildly tedious) calculations.

▶ **Lemma 8.** *In the c-MultiQueue with $c = \lfloor c \rfloor + \varepsilon > 1$ we have*

$$\sigma_{\le i} = 1 - (1 - \tfrac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon\tfrac{i}{n}) \text{ for all } i \in [n], \text{ and } \sigma \text{ satisfies } (\star).$$

Proof. Recall that we sample $\lfloor c \rfloor$ queues with probability $1 - \varepsilon$ and $\lfloor c \rfloor + 1$ queues otherwise. We fail to select one of the first i queues only if none of them were sampled. Hence for $i < n$:

$$\begin{aligned}\sigma_{\le i} &= 1 - (1 - \varepsilon)(1 - \tfrac{i}{n})^{\lfloor c \rfloor} - \varepsilon(1 - \tfrac{i}{n})^{\lfloor c \rfloor + 1} = 1 - (1 - \tfrac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon + \varepsilon(1 - \tfrac{i}{n})) \\ &= 1 - (1 - \tfrac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon\tfrac{i}{n}) > 1 - (1 - \tfrac{i}{n}) = \tfrac{i}{n}.\end{aligned}$$

The inequality uses that we have $\lfloor c \rfloor \ge 2$, or $\varepsilon > 0$, or both. ◀

We now prove Theorem 3, restated here for easier reference.

▶ **Theorem 3.** *Consider the expectation $\mathbb{E}[R]$ of the rank error $R = r_{i^*} - 1$ of the c-MultiQueue in the long run (i.e., after convergence).*

(i) *For $c = 2$ we have $\mathbb{E}[R] = \frac{5}{6}n - 1 + \frac{1}{6n} = \frac{5}{6}n - \Theta(1)$.*

(ii) *For $c = 1 + \varepsilon$ with $\varepsilon \in (0, 1)$, we have $\mathbb{E}[R] = (\frac{1}{\varepsilon} - \frac{\varepsilon}{6})n - \frac{1}{\varepsilon} + \frac{\varepsilon}{6n} = (\frac{1}{\varepsilon} - \frac{\varepsilon}{6})n - \mathcal{O}(1/\varepsilon)$.*

(iii) *For any $c > 1$ we have* $n \cdot \int_0^1 f_c(x)\,dx - \frac{c}{c-1} \le \mathbb{E}[R] \le n \cdot \int_0^1 f_c(x)\,dx$, *where* $f_c : (0,1) \to \mathbb{R}$ *is defined as follows using* $\varepsilon := c - \lfloor c \rfloor \in [0,1)$

$$f_c(x) = x^{\lfloor c \rfloor - 1}(1 - \varepsilon + \varepsilon x) \cdot \frac{1 - x^{\lfloor c \rfloor}(1 - \varepsilon + \varepsilon x)}{1 - x^{\lfloor c \rfloor - 1}(1 - \varepsilon + \varepsilon x)}.$$

(iv) *Cruder but simpler bounds for any* $c \ge 2$ *are:* $\frac{n}{\lceil c \rceil} - \frac{c}{c-1} \le \mathbb{E}[R] \le \frac{n}{\lfloor c \rfloor - 1}$.

Proof of Theorem 3. We have just checked in Lemma 8 that σ satisfies $(\star)$ and computed $\sigma_{\le i} = 1 - (1 - \frac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon\frac{i}{n})$. We can therefore specialise the formula for the expected rank error from Corollary 2 by plugging in σ and simplifying, which yields

$$\begin{aligned}
\mathbb{E}[R] &= \sum_{i=1}^{n-1}(1 - \sigma_{\le i})\frac{\sigma_{\le i}}{\sigma_{\le i} - \frac{i}{n}} = \sum_{i=1}^{n-1}(1 - \tfrac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon\tfrac{i}{n})\frac{1 - (1 - \frac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon\frac{i}{n})}{1 - (1 - \frac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon\frac{i}{n}) - \frac{i}{n}} \\
&= \sum_{i=1}^{n-1}(1 - \tfrac{i}{n})^{\lfloor c \rfloor - 1}(1 - \varepsilon\tfrac{i}{n})\frac{1 - (1 - \frac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon\frac{i}{n})}{1 - (1 - \frac{i}{n})^{\lfloor c \rfloor - 1}(1 - \varepsilon\frac{i}{n})} && \text{(cancel } 1 - \tfrac{i}{n}\text{)} \\
&= \sum_{i=1}^{n-1}(\tfrac{i}{n})^{\lfloor c \rfloor - 1}(1 - \varepsilon + \varepsilon\tfrac{i}{n})\frac{1 - (\frac{i}{n})^{\lfloor c \rfloor}(1 - \varepsilon + \varepsilon\frac{i}{n})}{1 - (\frac{i}{n})^{\lfloor c \rfloor - 1}(1 - \varepsilon + \varepsilon\frac{i}{n})} && \text{(substitute } i \to n - i.\text{)} \\
&= \sum_{i=1}^{n-1} f_c(\tfrac{i}{n}). && \text{(using the definition of } f_c(x) \text{ given above.)}
\end{aligned}$$

We are now ready to prove claim (i). Using that $f_2(x) = x \cdot \frac{1-x^2}{1-x} = x \cdot (1 + x) = x + x^2$, we have

$$\begin{aligned}
\mathbb{E}[R] &= \sum_{i=1}^{n-1} f_2(\tfrac{i}{n}) = \sum_{i=1}^{n-1}\left(\tfrac{i}{n} + (\tfrac{i}{n})^2\right) = \frac{1}{n}\sum_{i=1}^{n-1} i + \frac{1}{n^2}\sum_{i=1}^{n-1} i^2 \\
&= \frac{n-1}{2} + \frac{(n-1)(2n-1)}{6n} = \tfrac{5}{6}n - 1 + \tfrac{1}{6n}.
\end{aligned}$$

Similarly, we can prove (ii). First, we simplify $f_c(x)$ for $c = 1 + \varepsilon$ with $\varepsilon \in (0,1)$:

$$\begin{aligned}
f_{1+\varepsilon}(x) &= (1 - \varepsilon + \varepsilon x) \cdot \frac{1 - x(1 - \varepsilon + \varepsilon x)}{\varepsilon - \varepsilon x} = (1 - \varepsilon + \varepsilon x) \cdot \frac{(1-x)(1 + \varepsilon x)}{\varepsilon(1-x)} \\
&= (1 - \varepsilon + \varepsilon x) \cdot \frac{1 + \varepsilon x}{\varepsilon} = \tfrac{1-\varepsilon}{\varepsilon} + (2 - \varepsilon)x + \varepsilon x^2.
\end{aligned}$$

We then get (omitting a simple calculation):

$$\begin{aligned}
\mathbb{E}[R] &= \sum_{i=1}^{n-1} f_{1+\varepsilon}(\tfrac{i}{n}) = \sum_{i=1}^{n-1}(\tfrac{1-\varepsilon}{\varepsilon} + (2 - \varepsilon)\tfrac{i}{n} + \varepsilon(\tfrac{i}{n})^2) \\
&= \tfrac{1-\varepsilon}{\varepsilon}(n-1) + (2 - \varepsilon)\tfrac{n(n-1)}{2n} + \varepsilon\tfrac{(n-1)n(2n-1)}{6n^2} = \ldots = (\tfrac{1}{\varepsilon} - \tfrac{\varepsilon}{6})n - \tfrac{1}{\varepsilon} + \tfrac{\varepsilon}{6n}.
\end{aligned}$$

We now turn our attention to general $c > 1$ again. Our goal is to approximate the sum by an integral. To bound the approximation error effectively, we will first show that f_c is monotonic. For this let us examine the fractional term $g_c(x)$ occurring in $f_c(x)$:

$$g_c(x) := \frac{1-x^{\lfloor c\rfloor}(1-\varepsilon+\varepsilon x)}{1-x^{\lfloor c\rfloor-1}(1-\varepsilon+\varepsilon x)} = 1+\frac{(x^{\lfloor c\rfloor-1}-x^{\lfloor c\rfloor})(1-\varepsilon+\varepsilon x)}{1-x^{\lfloor c\rfloor-1}(1-\varepsilon+\varepsilon x)}$$
$$= 1+\frac{x^{\lfloor c\rfloor-1}(1-x)(1-\varepsilon+\varepsilon x)}{1-x^{\lfloor c\rfloor-1}+\varepsilon x^{\lfloor c\rfloor-1}(1-x)} = 1+\frac{x^{\lfloor c\rfloor-1}(1-x)(1-\varepsilon+\varepsilon x)}{(1-x)\sum_{i=0}^{\lfloor c\rfloor-2}x^i+\varepsilon x^{\lfloor c\rfloor-1}(1-x)}$$
$$= 1+\frac{1-\varepsilon+\varepsilon x}{\sum_{i=1}^{\lfloor c\rfloor-1}x^{-i}+\varepsilon}. \tag{1}$$

From (1) we can see that $g_c(x)$ does not have a singularity at $x=1$ and by setting $g_c(1)=f_c(1)=1+\frac{1}{c-1}=\frac{c}{c-1}$ both functions are continuous on $[0,1]$. We also see from (1) that $g_c(x)$ is increasing in x and decreasing in c (recall that c determines $\varepsilon=c-\lfloor c\rfloor$). Because the other factor $x^{\lfloor c\rfloor-1}(1-\varepsilon+\varepsilon x)$ of $f_c(x)$ is also increasing in x and decreasing in c, we conclude that $f_c(x)$ as a whole is increasing in x and decreasing in c. This makes the upper and lower sums bounding the integral of f_c particularly simple:

$$\sum_{i=1}^{n-1}f_c(\tfrac{i}{n})=\sum_{i=0}^{n-1}f_c(\tfrac{i}{n})\le n\int_0^1 f_c(x)\,dx\le\sum_{i=1}^{n}f_c(\tfrac{i}{n})=f_c(1)+\sum_{i=1}^{n-1}f_c(\tfrac{i}{n})=\tfrac{c}{c-1}+\sum_{i=1}^{n-1}f_c(\tfrac{i}{n}).$$

By rearranging we obtain (iii). We now turn to the cruder bound (iv). We begin with $c\in\mathbb{N}\setminus\{1\}$. In this case we have $f_c(x)=x^{c-1}\cdot g_c(x)$ where $1\le g_c(x)\le\frac{c}{c-1}$ for all $x\in[0,1]$. This gives:

$$\tfrac{1}{c}=\int_0^1 x^{c-1}\,dx\le\int_0^1 f_c(x)\,dx\le\int_0^1 x^{c-1}\tfrac{c}{c-1}\,dx=\tfrac{c}{c-1}\int_0^1 x^{c-1}\,dx=\tfrac{1}{c-1}.$$

Combining this with (iii) gives $\frac{n}{c}-\frac{c}{c-1}\le\mathbb{E}[R]\le\frac{n}{c-1}$ when $c\in\mathbb{N}\setminus\{1\}$. When $c\notin\mathbb{N}$ we can use that $f_c(x)$ is decreasing in c and round conservatively to obtain the claimed result. ◀

▶ **Theorem 9.** *In the 2-MultiQueue[4], the highest rank error observed over a polynomial number of deletions is in $\mathcal{O}(n\log n)$ with high probability.*

Proof. We will use a tail bound by Janson [9, Theorem 2.1] on the sum of geometrically distributed random variables from. It reads

$$\Pr[X\ge k\cdot\mu]\le e^{-p_*\mu(k-1-\log k)}\text{ for any }k\ge 1,$$

where X is a sum of geometrically distributed random variables (with possibly differing success probabilities), p_* is the smallest success probability and $\mu=\mathbb{E}[X]$.

We apply this bound to $X=r_n-1$, which has the required form by Theorem 1. It is easy to check that $p_*=\delta_{n-1}=\frac{1}{n+1}=\Theta(\frac{1}{n})$ and

$$\mu=\mathbb{E}[X]=\sum_{i=1}^{n-1}\frac{1-(1-\frac{i}{n})^2}{1-(1-\frac{i}{n})^2-\frac{i}{n}}=\sum_{i=1}^{n-1}\frac{2-\frac{i}{n}}{1-\frac{i}{n}}=n-1+n\sum_{i=1}^{n-1}\tfrac{1}{i}=\Theta(n\log n).$$

Since the rank error R clearly satisfies $R\le r_n-1=X$ we have for k large enough

$$\Pr[R>k\cdot n\log n]\le\Pr[X>k\cdot n\log n]=e^{-\Theta(\frac{1}{n}n\log(n)k)}=n^{-\Theta(k)}.$$

By a union bound, the probability that we observe a rank error exceeding $k\cdot n\log n$ at some point during n^c deletions is at most $n^c\cdot n^{-\Theta(k)}$. For large enough k, this probability is still small. ◀

[4] A similar analysis for $c=1+\varepsilon$ is also possible.

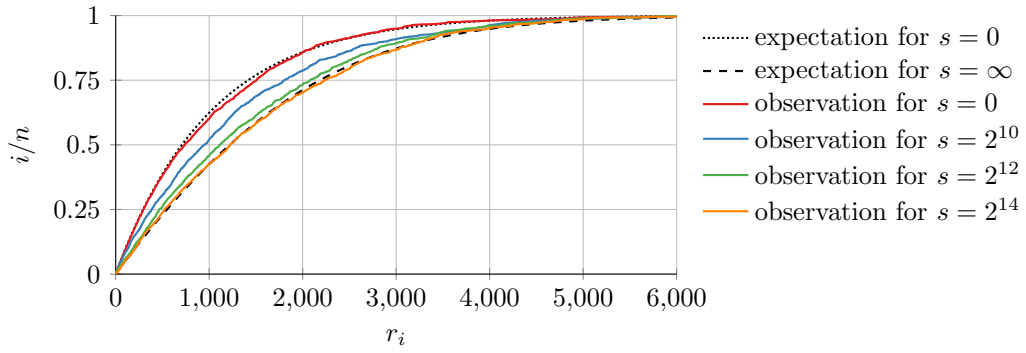

Figure 5 The convergence of the 2-MultiQueue with $n = 2^{10}$ to its stable state. After s deletions, let $r_i^{(s)}$ be the rank of queue i. The plot shows the observed ranks $i \mapsto r_i^{(s)}$ for some values of s, as well as the expected ranks $i \mapsto \mathbb{E}[r_i^{(0)}]$ and $i \mapsto \mathbb{E}[r_i^{(\infty)}]$ in the initial state and the converged state.

To give some intuition for how quickly the 2-MultiQueue converges to its stable state and for how close the observed ranks of top-elements are to their expectation we provide experimental data in Figure 5.

5 Future Work

While we have fully analyzed the long-term behavior of the MultiQueue in the deletion-only setting, there are still open questions in the general setting. Specifically, our methods are not directly applicable when insertions of arbitrary elements can happen after deletions. We conjecture that the deletion-only setting represents the worst-case in the sense that the expected rank error cannot be made worse even by adversarial insertions. On the flip side, we conjecture that the expected rank error is never better than before the first deletion. Our reasoning is as follows: Inserting sufficiently large elements does not affect deletions and is equivalent to inserting before deleting. When inserting many small elements, the state drifts towards the state where no deletions happened. In summary, we expect the state of the MultiQueue always to be "between" the insertion-only and the deletion-only setting, and that our analysis yields accurate predictions after sufficiently many deletions regardless of previous operations.

Our analysis applies directly to applications that do insert new elements after the first deletion, such as heap sort and simple batch job scheduling. A much broader range of applications, including Dijkstra's algorithm and discrete-event simulations, process elements in *monotonous* fashion, meaning that the elements deleted from the priority queue are monotonically increasing. When using a MultiQueue, newly inserted elements are unlikely to become top-elements, and we expect the state of the MultiQueue to stay "close" to the deletion-only setting.

Williams et al. [21] proposed the *delay* as an additional quality metric and *stickiness* as a way to increase throughput. The delay of an element e measures how many elements worse than e are deleted while e resides in the queue. Stickiness lets threads reuse the same queue for multiple consecutive operations. We believe that the delay can be analyzed directly with our approach and that the Markov chain can be adapted to handle stickiness as well.

In practice, it is relevant how fast the system stabilizes and converges to the postulated distributions of ranks or what rank errors are to be expected until then. Thus, analyzing the convergence speed is a natural next step.

Alistarh et al. [1] analyze the MultiQueue in concurrent settings where comparisons can become *stale*, meaning that after deciding which queue to delete from but before actually deleting from it, its top-element might change. We find it interesting whether our analysis can be adapted to this scenario as well.

Abstract

We study the *Pigeonhole Equal Subset Sum* problem, which is a total-search variant of the Subset Sum problem introduced by Papadimitriou (1994): we are given a set of n positive integers $\{w_1, \ldots, w_n\}$ with the additional restriction that $\sum_{i=1}^{n} w_i < 2^n - 1$, and want to find two different subsets $A, B \subseteq [n]$ such that $\sum_{i \in A} w_i = \sum_{i \in B} w_i$.

Very recently, Jin and Wu (ICALP 2024) gave a randomized algorithm solving Pigeonhole Equal Subset Sum in $O^*(2^{0.4n})$ time, beating the classical meet-in-the-middle algorithm with $O^*(2^{n/2})$ runtime. In this paper, we refine Jin and Wu's techniques to improve the runtime even further to $O^*(2^{n/3})$.

1 Introduction

Subset Sum is a fundamental NP-hard problem: given positive integers $w_1, w_2, \ldots, w_n$ and a target integer t, we want to find a subset $A \subseteq [n]$ such that $\sum_{i \in A} w_i = t$.[1] Subset Sum has a simple meet-in-the-middle algorithm in about $O(2^{n/2})$ time, given by Horowitz and Sahni in 1974 [13]. There has been a long line of research attempting to improve that meet-in-the-middle running time for Subset Sum [4, 5, 22, 3, 14, 8, 9, 12], but it remains open whether there exists an algorithm running in $O(2^{(1/2-\varepsilon)n})$ time for any constant $\varepsilon > 0$. The fastest known algorithm for Subset Sum only has a poly(n)-factor improvement over $O(2^{n/2})$ [12].

Despite the lack of progress on the time complexity of Subset Sum, there has been significant progress for solving *variants* of the problem. Examples include Equal Subset Sum [16], 2-Subset Sum and Shifted Sums [2], more general subset balancing problems [11], algorithms solving either Equal Subset Sum or Subset Sum [20], Merlin–Arthur protocols for Subset Sum [17, 1], Subset Sum in low space [7, 18], and quantum algorithms for Subset Sum [2]. There is also a large body of works on pseudo-polynomial-time algorithms and approximation schemes for Subset Sum and related problems (see e.g., [10] and the references therein). In this work, we focus on exact exponential-time algorithms.

[1] Throughout this paper, we write $[n] = \{1, \ldots, n\}$.

An important variant of Subset Sum is the Equal Subset Sum problem:

EQUAL SUBSET SUM [24]
Input: integers $w_1, w_2, \ldots, w_n$ where $|w_i| \leq 2^{\text{poly}(n)}$
Output: two different subsets $A, B \subseteq [n]$ such that $\sum_{i \in A} w_i = \sum_{i \in B} w_i$ (if exist).

Woeginger and Yu [24] first studied the Equal Subset Sum problem and showed that it is NP-Complete, similarly to Subset Sum. Since we can assume the solution satisfies $A \cap B = \emptyset$ (otherwise, we can return $(A \setminus B, B \setminus A)$ instead), a standard meet-in-the-middle approach can solve Equal Subset Sum in $O^*(3^{n/2}) \leq O^*(1.7321^n)$ time. Mucha, Nederlof, Pawlewicz, and Węgrzycki [16] gave a faster $O^*(1.7088^n)$-time algorithm in 2019, answering an open question of [23].[2]

A special case of the Equal Subset Sum problem is the *Pigeonhole Equal Subset Sum* problem (also sometimes called Pigeonhole Equal Sums). This problem is the focus of our paper.

PIGEONHOLE EQUAL SUBSET SUM [19]
Input: positive integers $w_1, w_2, \ldots, w_n$, with promise $\sum_{i=1}^{n} w_i < 2^n - 1$.
Output: two different subsets $A, B \subseteq [n]$ such that $\sum_{i \in A} w_i = \sum_{i \in B} w_i$.

Pigeonhole Equal Subset Sum is a *total search problem*, in that there always exists a solution; our goal is merely to find one. To see why this is true, note that there are 2^n subsets $S \subseteq [n]$, which can only attain $2^n - 1$ possible subset sums $\sum_{i \in S} w_i \in \{0, 1, \ldots, 2^n - 2\}$ due to the promise $\sum_{i=1}^{n} w_i < 2^n - 1$, so by the pigeonhole principle there must exist a pair of subsets with the same subset sum.

The Pigeonhole Equal Subset Sum problem was introduced by Papadimitriou in 1994 [19], and has been studied in the TFNP literature [6, 21]. It belongs to the total search complexity class PPP, and is conjectured to be PPP-complete [19].

Pigeonhole Equal Subset Sum can be solved faster than the best known Equal Subset Sum algorithm. Until very recently, the fastest known algorithm for Pigeonhole Equal Subset Sum had time complexity $O^*(2^{n/2})$, either by a simple binary search combined with the classical meet-in-the-middle approach by Horowitz and Sahni [13] (see a short description in [15, Section 2]), or by a mod-p dynamic programming algorithm by Allcock, Hamoudi, Joux, Klingelhöfer, and Santha [2, Theorem 6.2]. Recently, a major advance by Jin and Wu [15] gave a randomized algorithm for Pigeonhole Equal Subset Sum running in $O^*(2^{0.4n})$ time. Roughly speaking, the key idea of Jin and Wu was to show that a Pigeonhole Equal Subset Sum instance with very few solutions must satisfy a certain structural property: namely, the input numbers should resemble the geometric progression $1, 2, 4, \ldots, 2^{n-1}$ (see the formal statement in Lemma 4).

1.1 Our contribution

In this paper, we improve the time complexity of Jin and Wu [15]'s Pigeonhole Equal Subset Sum algorithm from $O^*(2^{0.4n})$ to the clean bound $O^*(2^{n/3})$:

▶ **Theorem 1** (Main). *Pigeonhole Equal Subset Sum can be solved by a randomized algorithm in $O^*(2^{n/3})$ time.*

[2] Throughout this paper, we use $O^*(\cdot), \Omega^*(\cdot)$ to hide $\text{poly}(n)$ factors, where n is the number of input integers.

Jin and Wu used similar techniques to give a *polynomial-space* algorithm for Pigeonhole Equal Subset Sum in $O^*(2^{0.75n})$ time, improving the straightforward $O^*(2^n)$-time polynomial-space algorithm based on binary search and meet-in-the-middle. We show that their polynomial-space algorithm can also be further improved:

▶ **Theorem 2.** *Pigeonhole Equal Subset Sum can be solved by a randomized algorithm in* $O^*(2^{2n/3})$ *time and* $\mathrm{poly}(n)$ *space.*

Our improved algorithms are based on the same structural property (see the formal statement in Lemma 4) proved by Jin and Wu [15], but we exploit it in a more efficient way. Jin and Wu [15] only exploited the property in the case when there are few solutions; if there are many solutions, they simply switched to a subsampling approach to try to hit a solution randomly, without using the structural property. In contrast, we make use of the structural property even in the case where there are many solutions, thereby improving the overall time complexity.

The rest of the paper is organized as follows: In Section 2, we give an overview of Jin and Wu's algorithm, describe their aforementioned structural property precisely, and extract a few lemmas from their work which are useful to us. Then in Section 3, we present our improved algorithm for Pigeonhole Equal Subset Sum, proving Theorem 1. In Section 4 we prove Theorem 2. Finally, we discuss some future research directions in Section 5.

2 A Summary of Jin and Wu's Algorithm

Throughout this paper, we use $w_1, \ldots, w_n$ to denote the input integers, and we use the shorthand $w(A) = \sum_{i \in A} w_i$ for the subset sum attained by the subset of indices $A \subseteq [n]$.

For an Equal Subset Sum instance $(w_1, \ldots, w_n)$ (not necessarily satisfying the pigeonhole promise), Jin and Wu [15] considered the parameter $F(w_1, \ldots, w_n)$ defined as follows:

▶ **Definition 3** ($f_t(\cdot)$ and $F(\cdot)$)**.** *For* $w_1, \ldots, w_n \in \mathbb{Z}$ *and* $t \in \mathbb{Z}$*, let*

$$f_t(w_1, \ldots, w_n) \coloneqq |\{S \subseteq [n] : w(S) = t\}|,$$

be the number of ways to achieve subset sum t*. When* $w_1, \ldots, w_n$ *are clear from the context, we abbreviate* $f_t = f_t(w_1, \ldots, w_n)$*.*

Then, define

$$F(w_1, \ldots, w_n) \coloneqq \sum_{t \in \mathbb{Z}} \max\{0, f_t - 1\}.$$

Observe that $F(w_1, \ldots, w_n) \in \{0, 1, \ldots, 2^n - 1\}$*.*

Note that an Equal Subset Sum instance $(w_1, \ldots, w_n)$ has a solution $A, B \subseteq [n], A \neq B, w(A) = w(B)$ if and only if $F(w_1, \ldots, w_n) \geq 1$.

Suppose the Pigeonhole Equal Subset Sum input instance consists of positive integers $w_1 < w_2 < \cdots < w_n$ (assuming no trivial solution $w_i = w_j, i \neq j$ exists) where $w([n]) < 2^n - 1$ (recall that this upper bound on the sum of all weights is the promise given by Pigeonhole Equal Subset Sum). Jin and Wu's key structural property relies on the following extra condition [15, Equation (1)]:

$$w([i]) \geq 2^i - 1, \text{ for all } i \in [n-1]. \tag{1}$$

That is, Equation (1) says that the total weight of the set $\{1, \ldots, i\}$ is at least $2^i - 1$. We may assume without loss of generality that Equation (1) holds. To see why, note that if $w([i]) < 2^i - 1$ for some $i \leq n-1$, then $\{w_1, \ldots, w_i\}$ is also a Pigeonhole Equal Subset Sum instance. We can solve this strictly smaller instance instead, and obtain a solution $A, B \subseteq [i] \subsetneq [n], A \neq B, w(A) = w(B)$. Hence, we may assume such i does not exist, so Equation (1) holds.

Using Equation (1), Jin and Wu [15] proved a key structural lemma for Pigeonhole Equal Subset Sum instances $(w_1, \ldots, w_n)$. Their lemma says that if $F(w_1, \ldots, w_n)$ is small, then the sequence $w_1, \ldots, w_n$ is close to the geometric progression $1, 2, 4, \ldots, 2^{n-1}$ with small additive error.

▶ **Lemma 4** ([15, Equation (8)]). *Suppose positive integers $w_1 < w_2 < \cdots < w_n$ satisfy $w([n]) < 2^n - 1$ and Equation (1). Then, for all $i \in [n]$,*

$$-i \cdot F(w_1, \ldots, w_n) \leq w_i - 2^{i-1} \leq F(w_1, \ldots, w_n). \tag{2}$$

Lemma 4 will be used in our improved algorithm as well. For completeness, in Section A we include a short proof of Lemma 4 given by Jin and Wu [15]. Jin and Wu gave two different algorithms, which we summarize below in Lemma 5 and Lemma 6. The first algorithm is suitable when the Pigeonhole Equal Subset Sum instance $(w_1, \ldots, w_n)$ has small $F(w_1, \ldots, w_n)$. It was obtained by using Lemma 4 to speed up the standard binary search and meet-in-the-middle approach:

▶ **Lemma 5** ([15, Lemma 4]). *Given parameter $1 \leq \Delta \leq 2^n/(3n^2)$, a Pigeonhole Equal Subset Sum instance $(w_1, \ldots, w_n)$ (where $w_i < w_{i+1}$) satisfying $F(w_1, \ldots, w_n) \leq \Delta$ and Equation (1) can be solved deterministically in $O^*(\sqrt{\Delta})$ time.*

The second algorithm of Jin and Wu works well when $F(w_1, \ldots, w_n)$ is large. The intuition is that, in this case there are many solutions, so one can perform subsampling and still expect at least one solution to survive. Jin and Wu used this subsampling idea to speed up the mod-p dynamic programming algorithm (which had previously been used for Subset Sum and related problems, e.g., [2, 4]):

▶ **Lemma 6** ([15, Lemma 5]). *Given parameter $2^{n/2} \leq \Delta < 2^n$, an Equal Subset Sum instance $(w_1, \ldots, w_n)$ with $F(w_1, \ldots, w_n) \geq \Delta$ can be solved in $O^*((2^{2n}/\Delta)^{1/3})$ time by a randomized algorithm.*

We remark that originally [15, Lemma 5] was stated for Pigeonhole Equal Subset Sum only. However, upon inspecting their proof, one can easily verify that the pigeonhole promise was never used, so that the algorithm actually works for Equal Subset Sum as well. This point turns out to be useful for our improvement later.

Jin and Wu's final algorithm for Pigeonhole Equal Subset Sum combines Lemma 5 and Lemma 6, and the overall runtime is balanced at the bottleneck case $\Delta \approx 2^{0.8n}$, leading to an overall worst case runtime of $O^*(2^{0.4n})$.

In Jin and Wu's algorithm, Lemma 4 was used in developing the algorithm of Lemma 5 (the algorithm for the small $F(w_1, \ldots, w_n)$ case), but was ignored in the case where $F(w_1, \ldots, w_n)$ is large. In our improved algorithm, we show how the structural property of Lemma 4 can be exploited even when $F(w_1, \ldots, w_n)$ is large. This will allow us to reduce the original Pigeonhole Equal Subset Sum instance to a small number of Equal Subset Sum instances, which have sizes much smaller than n (and still have large F-values).

3 Our Improvement for Pigeonhole Equal Subset Sum

In this section we prove our main Theorem 1. Let $w_1 < w_2 < \cdots < w_n$ be the input Pigeonhole Equal Subset Sum instance. Throughout, let $k \in \{0, 1, \ldots, n-1\}$ be such that

$$2^k \leq F(w_1, \ldots, w_n) < 2^{k+1}. \tag{3}$$

Our algorithm does not know the value of k in advance; instead, it tries all n possible values of k in parallel, and terminates as soon as any one of them succeeds. This only increases the runtime by an n factor. Hence, in the following we assume that the value of k is known.

We will separately consider the input items in $[n] \setminus [k] = \{k+1, \ldots, n\}$ and in $[k]$. At a high level, our algorithm performs the following two steps:

1. Guess a suitable pair of subsets $X, Y \subseteq [n] \setminus [k]$.
2. Find subsets $A_0, B_0 \subseteq [k]$ such that $w(A_0) - w(B_0) = w(Y) - w(X)$, i.e., $(A_0 \sqcup X, B_0 \sqcup Y)$ is a solution for Pigeonhole Equal Subset Sum.

For the first step, we will use Lemma 4 and Equation (3) to show that there are only $\mathrm{poly}(n)$ many pairs of $X, Y \subseteq [n] \setminus [k]$ that we need to consider. For the second step, we will reduce the task of finding A_0, B_0 to a smaller Equal Subset Sum instance with $(k+1)$ input integers and large F-value, which can be solved by Lemma 6. (In comparison, Jin and Wu's original algorithm applied Lemma 6 to solve Equal Subset Sum on n integers.)

Now we define the *close pairs*, which are the pairs of subsets (X, Y) that we need to consider for the first step:

▶ **Definition 7** (Close pairs). *Define the set of* close pairs *as*

$$\mathcal{C} := \{(X, Y) : X, Y \subseteq [n] \setminus [k] \text{ and } |w(X) - w(Y)| \leq (k+1)2^{k+1}\}.$$

Define the set of disjoint close pairs *as*

$$\mathcal{D} := \{(X, Y) \in \mathcal{C} : X \cap Y = \emptyset\}.$$

By the identity $w(X) - w(Y) = w(X \setminus Y) - w(Y \setminus X)$, we have

$$\mathcal{D} = \{(X \setminus Y, Y \setminus X) : (X, Y) \in \mathcal{C}\}. \tag{4}$$

The following simple lemma explains why it is sufficient to only consider close pairs:

▶ **Lemma 8.** *If $A, B \subseteq [n]$ and $w(A) = w(B)$, then $(A \setminus [k], B \setminus [k]) \in \mathcal{C}$.*

Proof. Since $w(A \setminus [k]) + w(A \cap [k]) = w(A) = w(B) = w(B \setminus [k]) + w(B \cap [k])$, we have

$$|w(A \setminus [k]) - w(B \setminus [k])| = |w(B \cap [k]) - w(A \cap [k])| \leq w([k]).$$

By the upper bounds in Lemma 4 and Equation (3), we have

$$w([k]) \leq \sum_{i=1}^{k} (2^{i-1} + F(w_1, \ldots, w_n)) < (k+1)2^{k+1}.$$

The claim then follows from the definition of $\mathcal{C}$. ◀

Now we bound the number of close pairs and disjoint close pairs:

▶ **Lemma 9.** *We have $|\mathcal{D}| \leq 200n^5$ and $|\mathcal{C}| \leq 200n^5 2^{n-k}$. Moreover, $\mathcal{D}$ can be computed in $\mathrm{poly}(n)$ time.*

Proof. First, we prove the claimed upper bound on $|\mathcal{D}|$. For $X \subseteq [n] \setminus [k]$, denote $\widetilde{w}(X) \coloneqq \sum_{i \in X} 2^{i-1}$. By Lemma 4 and Equation (3), for all $i \in [n]$,

$$|w_i - 2^{i-1}| \leq i \cdot F(w_1, \ldots, w_n) \leq n \cdot 2^{k+1}.$$

Hence, $|\widetilde{w}(X) - w(X)| \leq n^2 \cdot 2^{k+1}$ for all $X \subseteq [n] \setminus [k]$. Therefore, for all $(X, Y) \in \mathcal{D}$, we have $|\widetilde{w}(X) - \widetilde{w}(Y)| \leq |w(X) - w(Y)| + 2n^2 \cdot 2^{k+1} \leq (k+1)2^{k+1} + 2n^2 \cdot 2^{k+1} \leq 6n^2 2^k$. Now it remains to characterize all members of $\mathcal{D}'$ defined as

$$\mathcal{D}' \coloneqq \{(X, Y) \in 2^{[n]\setminus[k]} \times 2^{[n]\setminus[k]} : X \cap Y = \emptyset \text{ and } |\widetilde{w}(X) - \widetilde{w}(Y)| \leq 6n^2 2^k\} \supseteq \mathcal{D}.$$

Note that $(\emptyset, \emptyset) \in \mathcal{D}'$. Now consider any $(X, Y) \in \mathcal{D}'$ not equal to $(\emptyset, \emptyset)$, and let i be the maximum element in $X \cup Y$. By symmetry, we assume $i \in X$ without loss of generality, and thus $Y \subseteq [i-1] \setminus [k]$. Then,

$$\begin{aligned}\widetilde{w}(X) - \widetilde{w}(Y) &= \Big(2^{i-1} + \sum_{j \in X \setminus \{i\}} 2^{j-1}\Big) - \Big(\sum_{j=k+1}^{i-1} 2^{j-1} - \sum_{j \in \{k+1,\ldots,i-1\} \setminus Y} 2^{j-1}\Big) \\ &= 2^k + \sum_{j \in X \setminus \{i\}} 2^{j-1} + \sum_{j \in \{k+1,\ldots,i-1\} \setminus Y} 2^{j-1} \geq 0.\end{aligned}$$

On the other hand, $\widetilde{w}(X) - \widetilde{w}(Y) \leq 6n^2 2^k$ by definition of $\mathcal{D}'$. Hence, for every $j \in [i-1] \setminus [k]$ with $2^{j-1} \geq 6n^2 2^k$, we must have $j \in Y$ and $j \notin X$ (otherwise, 2^{j-1} would appear as a summand above, violating $\widetilde{w}(X) - \widetilde{w}(Y) \leq 6n^2 2^k$). Then, to fully determine (X, Y), it only remains to decide for each integer $k+1 \leq j < \log_2(6n^2 2^k) + 1$ whether j belongs to X, Y, or neither. There are at most $3^{\log_2(6n^2 2^k)+1-k} = 3^{\log_2(6n^2)+1} < 60n^4$ possible choices in total. Since there are up to n choices of i and two choices for whether i belongs to X or Y, we conclude that $|\mathcal{D}'| \leq 1 + 2 \cdot n \cdot 60n^4 < 200n^5$.

The above argument can be easily converted into an algorithm that computes the set $\mathcal{D}'$ in $\mathrm{poly}(n)$ time. Since $\mathcal{D}' \supseteq \mathcal{D}$, we have $|\mathcal{D}| \leq 200n^5$ as claimed, and we can also compute $\mathcal{D}$ in $\mathrm{poly}(n)$ time by checking every pair in $\mathcal{D}'$ for containment in $\mathcal{C}$.

Now we bound $|\mathcal{C}|$. Recall from Equation (4) that every $(X, Y) \in \mathcal{C} \subseteq 2^{[n]\setminus[k]} \times 2^{[n]\setminus[k]}$ can be mapped to $(X \setminus Y, Y \setminus X) \in \mathcal{D}$, and note that every $(X', Y') \in \mathcal{D}$ can only have at most 2^{n-k} pre-images in $\mathcal{C}$ under this mapping. Hence, $|\mathcal{C}| \leq 2^{n-k}|\mathcal{D}| \leq 200n^5 2^{n-k}$. ◀

The following lemma allows us to reduce the original problem to Equal Subset Sum instances on k or $k+1$ integers with large F-value:

▶ **Lemma 10.** *For sets $X, Y \subseteq [n] \setminus [k]$, define the k- or $(k+1)$-tuple $W_{X,Y}$ as*

$$W_{X,Y} \coloneqq \begin{cases} (w_1, \ldots, w_k) & \text{if } X = Y, \\ (w_1, \ldots, w_k, w(X) - w(Y)) & \text{if } X \neq Y. \end{cases} \tag{5}$$

Then, there must exist $(X, Y) \in \mathcal{D}$, such that $F(W_{X,Y}) \geq F(w_1, \ldots, w_n)/|\mathcal{C}|$.[3]

Before proving Lemma 10, we first use it to finish the proof of our main theorem:

[3] Note that in our definition of $W_{X,Y}$ for $(X, Y) \in \mathcal{D}$, the first case $X = Y$ happens only if $X = Y = \emptyset$. However we later will consider $W_{X,Y}$ where (X, Y) may not belong to $\mathcal{D}$.

Proof of Theorem 1 (assuming Lemma 10). As mentioned in the beginning of this section, we can assume the integer k defined by Equation (3) is known. We assume k satisfies

$$2^k \geq 200n^5 \cdot 2^{2n/3}, \tag{6}$$

since otherwise we can already use Lemma 5 to solve the Pigeonhole Equal Subset Sum instance $(w_1, \ldots, w_n)$ in $O^*(\sqrt{2^{k+1}}) = O^*(2^{n/3})$ time as required.

Compute $\mathcal{D}$ with $|\mathcal{D}| \leq \text{poly}(n)$ by Lemma 9 in $\text{poly}(n)$ time. Enumerate each $(X, Y) \in \mathcal{D}$, and then solve the Equal Subset Sum instance $W_{X,Y}$ (defined in Equation (5)) using Lemma 6. If the algorithm in Lemma 6 successfully finds a solution $(U, V), U \neq V$ in the instance $W_{X,Y}$ (where we can assume $U \cap V = \emptyset$ without loss of generality), then we distinguish between two cases:

- **Case where $U, V \subseteq [k]$:**
  Then, since $w(U) = w(V)$ and $U \neq V$, we can return (U, V) as a solution for the original Pigeonhole Equal Subset Sum instance $w_1, \ldots, w_n$.
- **Case where $k + 1 \in U \cup V$:**
  This can only happen in the $X \neq Y$ case, where $W_{X,Y}$ contains the extra $(k+1)$-th element $w(X) - w(Y)$. Without loss of generality assume $k + 1 \in U, k + 1 \notin V$. Then, define $A = (U \setminus \{k+1\}) \sqcup X$ and $B = V \sqcup Y$, both of which are subsets of $[n]$. Note that $A \neq B$ due to $X \neq Y$. Then we have $w(A) = w(U \setminus \{k+1\}) + w(X) = \big(w(V) - (w(X) - w(Y))\big) + w(X) = w(V) + w(Y) = w(B)$. So we can return (A, B) as a solution for the original Pigeonhole Equal Subset Sum instance $w_1, \ldots, w_n$.

Now we analyze the runtime. By Lemma 10, for at least one $(X, Y) \in \mathcal{D}$, $F(W_{X,Y}) \geq F(w_1, \ldots, w_n)/|\mathcal{C}| \geq (200n^5)^{-1} \cdot 2^{2k-n} =: \Delta$ (where we used Lemma 9 and Equation (3)). Then, applying Lemma 6 to solve $W_{X,Y}$ takes time $O^*((2^{2(k+1)}/\Delta)^{1/3}) = O^*\big(2^{n/3}\big)$. Note that the precondition $\Delta \geq 2^{(k+1)/2}$ required by Lemma 6 is satisfied due to Equation (6). We can try all $|\mathcal{D}| \leq \text{poly}(n)$ possibilities for the pair (X, Y) in parallel and run the algorithm of Lemma 6 until the earliest of them succeeds. The total time complexity is still $O^*(2^{n/3})$. ◀

It remains to prove Lemma 10.

Proof of Lemma 10. We will show that there exists a pair $(X, Y) \in \mathcal{C}$ satisfying the desired bound $F(W_{X,Y}) \geq F(w_1, \ldots, w_n)/|\mathcal{C}|$. Once this is shown, by $w(X) - w(Y) = w(X \setminus Y) - w(Y \setminus X)$ we have $W_{X \setminus Y, Y \setminus X} = W_{X,Y}$, so the pair $(X \setminus Y, Y \setminus X) \in \mathcal{D}$ also satisfies the desired bound, which would finish the proof.

We start by rewriting $F(W_{X,Y})$ as follows:

▷ Claim 11. For sets $X, Y \subseteq [n] \setminus [k]$ and integer t, define

$$h(X, t) \coloneqq \big|\big\{S \subseteq [n] : S \setminus [k] = X \text{ and } w(S) = t\big\}\big|,$$

which is the number of ways to extend X into $[n]$ to achieve a sum of t, and define

$$g(X, Y, t) \coloneqq \begin{cases} \max\{h(X, t) + h(Y, t) - 1, 0\} & \text{if } X \neq Y, \\ \max\{h(X, t) - 1, 0\} & \text{if } X = Y. \end{cases}$$

Then, $F(W_{X,Y}) = \sum_{t \in \mathbb{Z}} g(X, Y, t)$.

Proof of Claim 11. By definition of $h(X,t)$, observe that $h(X,t) = f_{t-w(X)}(w_1,\dots,w_k)$ (where $f_t(\cdot)$ was defined in Definition 3). Hence,

$$\begin{aligned} F(W_{X,X}) &= \sum_{t'\in\mathbb{Z}} \max\{f_{t'}(w_1,\dots,w_k)-1,0\} \\ &= \sum_{t\in\mathbb{Z}} \max\{f_{t-w(X)}(w_1,\dots,w_k)-1,0\} \\ &= \sum_{t\in\mathbb{Z}} \max\{h(X,t)-1,0\}. \end{aligned}$$

This finishes the proof for the $X=Y$ case. Now observe that

$$\begin{aligned} h(X,t)+h(Y,t) &= f_{t-w(X)}(w_1,\dots,w_k) + f_{t-w(Y)}(w_1,\dots,w_k) \\ &= f_{t-w(Y)}(w_1,\dots,w_k,w(X)-w(Y)), \end{aligned}$$

where the last equality can be seen from separately considering subsets of $\{w_1,\dots,w_k,w(X)-w(Y)\}$ which include $w(X)-w(Y)$ and those which do not. Therefore, if $X\neq Y$, then we similarly have

$$\begin{aligned} F(W_{X,Y}) &= \sum_{t'\in\mathbb{Z}} \max\{f_{t'}(w_1,\dots,w_k,w(X)-w(Y))-1,0\} \\ &= \sum_{t\in\mathbb{Z}} \max\{h(X,t)+h(Y,t)-1,0\} \end{aligned}$$

as desired. ◁

Now we relate $F(w_1,\dots,w_n)=\sum_{t\in\mathbb{Z}}\max\{f_t(w_1,\dots,w_n)-1,0\}$ to the expressions from Claim 11. For any t with $f_t(w_1,\dots,w_n)\geq 1$, fix an arbitrary $A_t\subseteq[n]$ with $w(A_t)=t$, and let $X_t \coloneqq A_t\setminus[k]$. Note that $h(X_t,t)\geq 1$. Then, by Lemma 8, every $Y\subseteq[n]\setminus[k]$ with $h(Y,t)\geq 1$ must satisfy $(X_t,Y)\in\mathcal{C}$. Hence,

$$\begin{aligned} f_t(w_1,\dots,w_n)-1 &= -1 + \sum_{Y\subseteq[n]\setminus[k]:h(Y,t)\geq 1} h(Y,t) && \text{(by definition of } f_t(\cdot) \text{ and } h(\cdot)) \\ &\leq -1 + \sum_{Y:(X_t,Y)\in\mathcal{C}} h(Y,t) \\ &= (h(X_t,t)-1) + \sum_{Y:(X_t,Y)\in\mathcal{C},Y\neq X_t} h(Y,t) \\ &\leq (h(X_t,t)-1) + \sum_{Y:(X_t,Y)\in\mathcal{C},Y\neq X_t} (h(X_t,t)+h(Y,t)-1) \\ &\leq \sum_{Y:(X_t,Y)\in\mathcal{C}} g(X_t,Y,t) \\ &\leq \sum_{(X,Y)\in\mathcal{C}} g(X,Y,t). \end{aligned}$$

This means that for all $t\in\mathbb{Z}$,

$$\max\{f_t(w_1,\dots,w_n)-1,0\} \leq \sum_{(X,Y)\in\mathcal{C}} g(X,Y,t).$$

By summing over all $t\in\mathbb{Z}$ and substituting using Claim 11, we get

$$F(w_1,\dots,w_n) \leq \sum_{(X,Y)\in\mathcal{C}} F(W_{X,Y}).$$

Then, by averaging, there exists $(X,Y)\in\mathcal{C}$ such that $F(W_{X,Y})\geq F(w_1,\dots,w_n)/|\mathcal{C}|$ as claimed. ◀

4 A Polynomial-Space Algorithm

In this section we prove Theorem 2. We use the following two lemmas from Jin and Wu [15], which can be viewed as polynomial-space versions of Lemma 5 and Lemma 6 respectively:

▶ **Lemma 12** ([15, Lemma 11]). *Given parameter $1 \leq \Delta \leq 2^n/(3n^2)$, a Pigeonhole Equal Subset Sum instance $(w_1, \ldots, w_n)$ (where $w_i < w_{i+1}$) satisfying $F(w_1, \ldots, w_n) \leq \Delta$ and Equation (1) can be solved deterministically in $\mathrm{poly}(n)$ space and $O^*(\Delta)$ time.*

▶ **Lemma 13** ([15, Lemma 13]). *Given parameter $1 \leq \Delta \leq 2^n$, an Equal Subset Sum instance $(w_1, \ldots, w_n)$ with $F(w_1, \ldots, w_n) \geq \Delta$ can be solved in $O^*(2^{1.5n}/\Delta)$ time and $\mathrm{poly}(n)$ space by a randomized algorithm.*

Again, although [15, Lemma 13] was originally stated for the Pigeonhole Equal Subset Sum problem, it actually works for Equal Subset Sum as well because the proof does not use the pigeonhole promise.

Proof sketch of Theorem 2. We follow the same proof outline of Theorem 1, except that we replace the exponential-space subroutines, Lemma 5 and Lemma 6, by their polynomial-space counterparts, Lemma 12 and Lemma 13, respectively. The resulting algorithm is correct and runs in polynomial space. It only remains to re-analyze the time complexity.

Recall that we can assume the integer $k \in \{0, 1, \ldots, n-1\}$ satisfying $2^k \leq F(w_1, \ldots, w_n) < 2^{k+1}$ (Equation (3)) is known. Let $M \in [1, 2^n/(3n^2)]$ be determined later. If $2^k \leq M$, we choose to use Lemma 12 and solve the given Pigeonhole Equal Subset Sum instance in $O^*(2^{k+1}) = O^*(M)$ time. If $2^k > M$, we follow the main proof of Theorem 1 to reduce the original problem to $\mathrm{poly}(n)$ many Equal Subset Sum instances of size $k+1$ (or k) in which at least one instance has F-value $\Omega^*(2^{2k-n})$, so the total time complexity of applying Lemma 13 becomes $O^*(2^{1.5k}/2^{2k-n}) = O^*(2^{n-0.5k}) \leq O^*(2^n/\sqrt{M})$. By choosing $M = 2^{2n/3}$, the overall time complexity becomes $O^*(M + 2^n/\sqrt{M}) = O^*(2^{2n/3})$. ◀

5 Open Questions

We list a few open questions related to this work.

- Can we improve the $O^*(2^{n/3})$ time complexity for Pigeonhole Equal Subset Sum? Can we improve the $O^*(1.7088^n)$ time complexity for Equal Subset Sum [16]?
- Can we obtain fast *deterministic* algorithms for Pigeonhole Equal Subset Sum? Our algorithm (and Jin and Wu's algorithm [15]) uses Lemma 6 which is based on random subsampling. To the best of our knowledge, the $O^*(2^{n/2})$-time algorithms via meet-in-the-middle ([2] or [15, Section 2]) remain the fastest known deterministic algorithms.
- The authors of [2] proposed a more difficult *Modular version* of Pigeonhole Equal Subset Sum problem, and obtained a $O^*(2^{n/2})$-time algorithm. In this problem, we are given integers $w_1, \ldots, w_n$ and a modulus $m \leq 2^n - 1$, and need to find two distinct subsets $A, B \subseteq [n]$ such that $\sum_{i \in A} w_i \equiv \sum_{i \in B} w_i \pmod{m}$. Can we improve the $O^*(2^{n/2})$ time complexity for Modular Pigeonhole Equal Subset Sum?
- The k-SUM problem can be viewed as the fine-grained or parameterized version of the Subset Sum problem. Analogously, we propose the following Pigeonhole Equal k-SUM problem (for fixed integers $k \geq 2$):

> Pigeonhole Equal k-SUM [19]
> **Input:** k length-n arrays $A_1, \ldots, A_k$ of integers from the range $[0, \frac{n^k-1}{k})$.
> **Output:** two different k-tuples $(i_1, \ldots, i_k), (j_1, \ldots, j_k) \in [n]^k$ such that $A_1[i_1] + \cdots + A_k[i_k] = A_1[j_1] + \cdots + A_k[j_k]$.

This is a total search problem, and the brute force algorithm runs in $O(n^k)$ time. It is easy to improve it to $\widetilde{O}(n^{\lceil k/2 \rceil})$ time, using the standard binary search with meet-in-the-middle (following the same idea as the warm-up Pigeonhole Equal Subset Sum algorithm described in [15, Section 2], except that we replace the $O^*(2^{n/2})$-time subroutine for counting Subset Sum solutions by the analogous $\widetilde{O}(n^{\lceil k/2 \rceil})$-time algorithm for k-SUM). Can we improve the runtime to faster than $\widetilde{O}(n^{\lceil k/2 \rceil})$, say for the $k = 3$ case?

A Proof of Lemma 4 by Jin and Wu

▶ **Lemma 4** ([15, Equation (8)]). *Suppose positive integers $w_1 < w_2 < \cdots < w_n$ satisfy $w([n]) < 2^n - 1$ and Equation (1). Then, for all $i \in [n]$,*

$$-i \cdot F(w_1, \ldots, w_n) \leq w_i - 2^{i-1} \leq F(w_1, \ldots, w_n). \tag{2}$$

The following proof of Lemma 4 was given by [15].

Proof. (Jin and Wu [15]) Recall our notations $w(A) = \sum_{i\in A} w_i$, $f_t = |\{A \subseteq [n] : w(A) = t\}|$. We abbreviate $F = F(w_1, \ldots, w_n) = \sum_{t\in\mathbb{Z}} \max\{f_t - 1, 0\}$. Recall our assumption from Equation (1):

$$w([i]) \geq 2^i - 1 \text{ for all } i \in [n-1]. \tag{1}$$

Since $w([n]) < 2^n - 1$, we know $f_t = 0$ for all $t \notin [0, 2^n - 1]$, and $\sum_{0\leq t<2^n} f_t = 2^n$. Then,

$$F = \sum_{0\leq t<2^n} \max\{f_t - 1, 0\} = \sum_{0\leq t<2^n} (f_t - \mathbf{1}[f_t \geq 1]) = 2^n - \sum_{0\leq t<2^n} \mathbf{1}[f_t \geq 1],$$

and thus

$$F = |\{0 \leq t < 2^n : f_t = 0\}|. \tag{7}$$

Since $f_t = 0$ for all $w([n]) < t < 2^n$, from Equation (7) we know $F \geq 2^n - 1 - w([n])$, and hence $w([n]) \geq 2^n - 1 - F$. Combined with Equation (1) for $i \in [n-1]$, we get

$$w([i]) \geq 2^i - 1 - F \text{ for all } i \in [n]. \tag{8}$$

Now we have the following claim:

▷ Claim 14. For all $i \in [n]$,

$$w_i \leq 2^{i-1} + F. \tag{9}$$

Summing Equation (9) over i gives

$$w([i]) \leq 2^i - 1 + iF \tag{10}$$

for all $i \in [n]$.

Proof of Claim 14. Fix $i \in [n]$. Let M be the number of subsets $S \subseteq [n]$ with $w(S) < w_i$. Since $w_i < w_{i+1} < \cdots < w_n$, any such S must be contained in $[i-1]$, and thus $M \leq 2^{i-1}$. On the other hand, $M = \sum_{t=0}^{w_i-1} f_t \geq w_i - |\{0 \leq t < w_i : f_t = 0\}| \geq w_i - F$ by Equation (7). Hence, $w_i \leq M + F \leq 2^{i-1} + F$. ◁

Comparing Equation (8) with Equation (10) gives

$$w_i = w([i]) - w([i-1]) \geq (2^i - 1 - F) - (2^{i-1} - 1 + (i-1)F) = 2^{i-1} - iF.$$

Together with Equation (9) we get the claimed bound

$$w_i - 2^{i-1} \in [-iF, F]$$

for all $i \in [n]$. ◀

Multicut Problems in Almost-Planar Graphs: the Dependency of Complexity on the Demand Pattern

Florian Hörsch
CISPA Helmholtz Center for Information Security, Saarbrucken, Germany

Dániel Marx
CISPA Helmholtz Center for Information Security, Saarbrückem, Germany

Abstract

Given a graph G, a set T of terminal vertices, and a demand graph H on T, the Multicut problem asks for a set of edges of minimum weight that separates the pairs of terminals specified by the edges of H. The Multicut problem can be solved in polynomial time if the number of terminals and the genus of the graph is bounded (Colin de Verdière [*Algorithmica, 2017*]). Restricting the possible demand graphs in the input leads to special cases of Multicut whose complexity might be different from the general problem.

Focke et al. [SoCG 2024] systematically characterized which special cases of Multicut are fixed-parameter tractable parameterized by the number of terminals on planar graphs. Moreover, extending these results beyond planar graphs, they precisely determined how the parameter genus influences the complexity and presented partial results of this form for graphs that can be made planar by the deletion of π edges. Continuing this line of work, we complete the picture on how this parameter π influences the complexity of different special cases and precisely determine the influence of the crossing number, another parameter measuring closeness to planarity.

Formally, let $\mathcal{H}$ be any class of graphs (satisfying a mild closure property) and let Multicut($\mathcal{H}$) be the special case when the demand graph H is in $\mathcal{H}$. Our first main result is showing that if $\mathcal{H}$ has the combinatorial property of having *bounded distance to extended bicliques*, then Multicut($\mathcal{H}$) on *unweighted* graphs is FPT parameterized by the number t of terminals and π. For the case when $\mathcal{H}$ does not have this combinatorial property, Focke et al. [SoCG 2024] showed that $O(\sqrt{t})$ is essentially the best possible exponent of the running time; together with our result, this gives a complete understanding of how the parameter π influences complexity on unweighted graphs. Our second main result is giving an algorithm whose existence shows that the parameter crossing number behaves analogously if we consider Multicut($\mathcal{H}$) on *weighted* graphs.

1 Introduction

Most NP-hard problems remain NP-hard when restricted to planar graphs, unless they become trivial or irrelevant on planar graphs. There are very few NP-hard problems that are polynomial-time solvable on planar graphs for some nontrivial and interesting reason. One such case is the Multiway Cut problem: given a graph G and a set $T \subseteq V(G)$ of *terminals*, the task is to find a *multiway cut* S of minimum weight, that is, a set $S \subseteq E(G)$

© Florian Hörsch and Dániel Marx;
licensed under Creative Commons License CC-BY 4.0

such that every component of $G \setminus S$ contains at most one terminal. Dahlhaus et al. [3] showed that Multiway Cut in general graphs is NP-hard even for three terminals, while it is polynomial-time solvable on planar graphs for every fixed number $|T|$ of terminals. The exponent of n in the algorithm of Dahlhaus et al. [3] is $O(|T|)$. Later, the dependence was improved to $O(\sqrt{|T|})$ [2, 10], which was shown to be optimal under the Exponential-Time Hypothesis (ETH) [1, 11]. The results were extended to bounded-genus graphs, again with an essentially best possible form of the exponent [1, 2].

Multicut is a generalization of Multiway Cut where not all terminals need to be separated from each other, but the input specifies which pairs of terminals need to be separated (and we do not care whether other pairs are separated or not).

Multicut	
Input:	A weighted graph G together with a set $T \subseteq V(G)$ of *terminals*; and a *demand graph* H with $V(H) = T$.
Output:	A minimum-weight set $S \subseteq E(G)$ such that u and v are in distinct components of $G \setminus S$ whenever uv is an edge of H.

Let us observe that Multiway Cut is the special case of Multicut when H is a complete graph on T. Colin de Verdière [2] presented an algorithm for Multicut where the exponent of the running time is $O(\sqrt{|T|})$, similarly to Multiway Cut. However, it is no longer clear anymore that this algorithm is a tight, optimal result and cannot be improved in some cases: it could be that there are special cases, special type of demand graphs where significantly better algorithms are possible. For example, if H is a biclique (complete bipartite graph), then Multicut can be solved in polynomial time by a reduction to a minimum weight $s - t$ cut problem. A very natural question to consider is the case when H is a complete 3-partite graph. This special case is the Group 3-Terminal Cut problem: given a graph G with three sets of terminals T_1, T_2, T_3, the task is to find a set S of edges of minimum total weight such that $G \setminus S$ has no path between any vertex of T_i and any vertex of T_j for all distinct $i, j \in [3]$. While a general Multicut algorithm solves Group 3-Terminal Cut with the exponent of the running time being the square root of the number of terminals, the lower bounds for Multiway Cut do not imply that this dependence is optimal.

Focke et al. [5] systematically analyzed which types of demand graphs make the problem more tractable. The question was explored in the following setting. Let $\mathcal{H}$ be a class of graphs (i.e., a set of graphs closed under isomorphism). Then we denote by Multicut($\mathcal{H}$) the special case of Multicut that contains only instances (G, H) where $H \in \mathcal{H}$. For example, if $\mathcal{H}$ is the class of cliques, then Multicut($\mathcal{H}$) is exactly Multiway Cut.

Ideally, for every class $\mathcal{H}$ of graphs, we would like to understand the best possible running time of Multicut($\mathcal{H}$) on planar graphs. In order to make the question more robust, Focke et al. [5] considered only classes $\mathcal{H}$ satisfying a mild closure property. We say that H' is a *projection* of H if H' can be obtained from H by deleting vertices and identifying pairs of independent vertices. Moreover, a class of graphs $\mathcal{H}$ is *projection-closed* if, whenever $H \in \mathcal{H}$ and H' is a projection of H, then $H' \in \mathcal{H}$ also holds. The intuition is that an instance having demand graph H' can be easily simulated by an instance having demand graph H, thus it is reasonable to assume we only consider classes of demand graphs closed under this operation.

Let us consider some easy cases first. As we mentioned before, the Multicut problem can be solved in polynomial time by a reduction to $s - t$ minimum cut if the demand graph is a biclique. Furthermore, if H has only two edges, then a similar reduction is known [8, 12]. Isolated vertices of H clearly do not play any role in the problem. We say that H is a *trivial pattern* if, after removing isolated vertices, it is either a biclique or has at most two edges.

An *extended biclique* is a graph that consists of a complete bipartite graph together with a set of isolated vertices. Let μ be the minimum number of vertices that need to be deleted to make a graph H an extended biclique. Then we say that H has distance μ to extended bicliques. Moreover, we say that a graph class $\mathcal{H}$ has *bounded distance to extended bicliques* if there is a constant μ such that every $H \in \mathcal{H}$ has distance at most μ to extended bicliques.

For planar graphs, Focke et al. [5] give the following characterization:

▶ **Theorem 1.1** ([5]). *Let $\mathcal{H}$ be a computable projection-closed class of graphs. Then the following holds for* Multicut($\mathcal{H}$) *on planar graphs.*

1. *If $\mathcal{H}$ has bounded distance to extended bicliques, then there is an $f(t)n^{O(1)}$ time algorithm.*
2. *Otherwise,*
   a. *There is an $f(t)n^{O(\sqrt{t})}$ time algorithm.*
   b. *Assuming* ETH*, there is a universal constant $\alpha > 0$ such that for any fixed choice of $t \geq 3$, there is no $O(n^{\alpha\sqrt{t}})$ algorithm, even when restricted to unweighted instances with at most t terminals.*

That is, depending on whether $\mathcal{H}$ has bounded distance to extended bicliques, the number t of terminals has to appear in the exponent. Focke et al. [5] precisely characterized how the complexity changes if we move from planar graphs to bounded-genus graphs. As we can see, the parameter genus can appear in the exponent in different ways, depending on $\mathcal{H}$.

▶ **Theorem 1.2** ([5]). *Let $\mathcal{H}$ be a computable projection-closed class of graphs. Then the following holds for* Multicut($\mathcal{H}$).

1. *If every graph in $\mathcal{H}$ is a trivial pattern, then there is a polynomial time algorithm.*
2. *Otherwise, if $\mathcal{H}$ has bounded distance to extended bicliques, then*
   a. *There is an $f(g,t)n^{O(g)}$ time algorithm.*
   b. *Assuming* ETH*, there is a universal constant $\alpha > 0$ such that for any fixed choice of $\vec{g} \geq 0$, there is no $O(n^{\alpha(\vec{g}+1)/\log(\vec{g}+2)})$ algorithm, even when restricted to unweighted instances with orientable genus at most $\vec{g}$ and $t = 3$ terminals.*
3. *Otherwise,*
   a. *There is an $f(g,t)n^{O(\sqrt{g^2+gt+t})}$ time algorithm.*
   b. *Assuming* ETH*, there is a universal constant $\alpha > 0$ such that for any fixed choice of $\vec{g} \geq 0$ and $t \geq 3$, there is no $O(n^{\alpha\sqrt{\vec{g}^2+\vec{g}t+t}/\log(\vec{g}+t)})$ algorithm, even when restricted to unweighted instances with orientable genus at most $\vec{g}$ and at most t terminals.*

Focke et al. [5] also considered a much more restricted extension of planar graphs than bounded-genus graphs: graphs that can be made planar by deleting a few edges. We use $\mathsf{planar} + \pi e$ for the class of graphs that can be made planar by removing at most π edges. Given an instance (G, H), we use π for the smallest integer such that G is in $\mathsf{planar} + \pi e$.

Observe that in Theorem 1.2, the algorithmic results are stated for the edge-weighted version, while the lower bounds are stated for the unweighted version. In fact, edge-weights do not make much difference in Theorem 1.2, as polynomial edge weights can be simulated by parallel edges without changing the genus of the graphs. However, this simulation can easily change the number π of edges that needs to be deleted to make the graph planar. This means that if we consider the influence of the parameter π on the running time, the edge-weighted and the unweighted problem may behave differently. Focke et al. [5] characterized the influence of this parameter in the edge-weighted case:

▶ **Theorem 1.3** ([5]). *Let $\mathcal{H}$ be a computable projection-closed class of graphs. Then the following holds for edge-weighted* Multicut($\mathcal{H}$).

1. *If every graph in $\mathcal{H}$ is a trivial pattern, then there is a polynomial-time algorithm.*
2. *Otherwise, if $\mathcal{H}$ has bounded distance to extended bicliques, then*
   a. *There is an $f(\pi,t)n^{O(\sqrt{\pi})}$ time algorithm.*
   b. *Assuming* ETH*, there is a universal constant $\alpha > 0$ such that for any fixed choice of $\pi \geq 0$, there is no $O(n^{\alpha\sqrt{\pi}})$ algorithm, even when restricted to instances in* planar $+ \pi e$ *with $t = 3$ terminals.*
3. *Otherwise,*
   a. *There is an $f(\pi,t)n^{O(\sqrt{\pi+t})}$ algorithm.*
   b. *Assuming* ETH*, there is a universal constant $\alpha > 0$ such that for any fixed choice of $\pi \geq 0$ and $t \geq 3$, there is no $O(n^{\alpha\sqrt{\pi+t}})$ algorithm, even when restricted to* planar $+ \pi e$ *instances with at most t terminals.*

Observe that π has a different form of influence on the exponent compared to genus: it is $O(\sqrt{\pi})$ instead of $O(g)$ in the case of bounded distance to extended bicliques, and $O(\sqrt{\pi+t})$ instead of $O(\sqrt{g^2+gt+t})$ in the unbounded distance case. Intuitively, having π extra edges is a much more restricted extension of planar graphs than having genus g, and consequently, the parameter π has a much weaker influence on the exponent than genus has.

For unweighted graphs, Focke et al. [5] showed that the problem is easier than the edge-weighted version and the parameter π can be removed from the exponent.

▶ **Theorem 1.4** ([5]). *Unweighted* Multicut *can be solved in time $f(\pi,t)n^{O(\sqrt{t})}$.*

However, this result leaves open the question what happens in unweighted Multicut($\mathcal{H}$) if $\mathcal{H}$ has bounded distance to extended bicliques. Based on Theorems 1.2 and 1.3, one would expect that it is possible to remove the number t of terminals from the exponent as well.

Our contributions

First, we resolve the remaining question about unweighted Multicut($\mathcal{H}$) and show that if $\mathcal{H}$ has bounded distance to extended bicliques, then both t and π can be removed from the exponent. Recall that μ is the number of vertices needed to be deleted to make the demand graph an extended biclique. Our first main result is the following algorithm.

▶ **Theorem 1.5.** *Unweighted* Multicut *can be solved in time $f(\pi,t)n^{O(\sqrt{\mu})}$.*

Observe that, in contrast to Theorem 1.4, only μ is in the exponent of the running time of the algorithm of Theorem 1.5. As $\mu \leq t$, this algorithm gives an independent proof of Theorem 1.4 with a very different proof technique. With Theorem 1.5 at hand, we can complete the picture for the complexity of unweighted Multicut($\mathcal{H}$):

▶ **Theorem 1.6.** *Let $\mathcal{H}$ be a computable projection-closed class of graphs. Then the following holds for unweighted* Multicut($\mathcal{H}$).

1. *If $\mathcal{H}$ has bounded distance to extended bicliques, then there is an $f(\pi,t)n^{O(1)}$-time algorithm.*
2. *Otherwise,*
   a. *There is an $f(\pi,t)n^{O(\sqrt{t})}$ algorithm.*
   b. *Assuming* ETH*, there is a universal constant $\alpha > 0$ such that for any fixed choice of $t \geq 3$, there is no $O(n^{\alpha\sqrt{t}})$-time algorithm, even when restricted to planar instances with at most t terminals.*

We consider yet another, even more restricted parameter measuring the distance from planar graphs: the *crossing number*, the minimum number of crossings needed when drawing the graph in the plane. Clearly, if a graph has a drawing with cr crossings, then we can remove a set of at most cr edges to make the graph planar. Thus the crossing number cr is always at least π, that is, an algorithm parameterized by π immediately gives an algorithm parameterized by cr.

Again, there is no straightforward reduction from the edge-weighted version to the unweighted version without increasing the crossing number. Thus both versions of the problem when parameterizing by crossing number are interesting. Clearly, the unweighted version is no harder than the edge-weighted one. Moreover, both versions parameterized by crossing number are no harder than their respective versions parameterized by π. But which of these versions are *strictly* harder than the others?

It turns out that, when parameterizing by crossing number, the edge weights do not change the hardness of the problem and both the edge-weighted and the unweighted versions parameterized by cr have the same complexity as the *unweighted* version parameterized by π. The following algorithm is our main result on the crossing number parameterization.

▶ **Theorem 1.7.** *Edge-weighted* Multicut *can be solved in time* $f(cr,t)n^{O(\sqrt{\mu})}$.

Together with Theorem 1.1, it implies the following complete classification for the complexity of Multicut($\mathcal{H}$) when parameterizing by cr:

▶ **Theorem 1.8.** *Let $\mathcal{H}$ be a computable projection-closed class of graphs. Then the following holds for edge-weighted* Multicut($\mathcal{H}$).

1. *If $\mathcal{H}$ has bounded distance to extended bicliques, then there is an $f(cr,t)n^{O(1)}$-time algorithm.*
2. *Otherwise,*
   a. *There is an $f(cr,t)n^{O(\sqrt{t})}$ algorithm.*
   b. *Assuming* ETH*, there is a universal constant $\alpha > 0$ such that for any fixed choice of $t \geq 3$, there is no $O(n^{\alpha\sqrt{t}})$-time algorithm, even when restricted to unweighted planar instances with at most t terminals.*

Note that the algorithmic results of Theorems 1.6 and 1.8 are incomparable: Theorem 1.6 considers only unweighted graphs, while Theorem 1.8 considers edge-weighted graphs, but under parameterization by a potentially much larger parameter.

Theorems 1.2–1.8 complete the picture of how different parameters measuring closeness to planarity influence the running time of Multicut($\mathcal{H}$) for different classes $\mathcal{H}$ (see Figure 1). Let us observe that the exact form of the influence is very different for the different parameters. As we explain below, the treewidth of the so-called multicut dual of the optimum solution is the main factor determining the exponent of the running time [2, 5]. The exponent $O(\sqrt{t})$ for planar graphs comes from the fact that a planar graph with $O(t)$ vertices (or faces) has treewidth $O(\sqrt{t})$. Intuitively, for nonplanar graphs, the situation changes as follows:

- **Genus.** If the genus is large, then a graph with t vertices can have treewidth larger than $O(\sqrt{t})$. The maximum possible treewidth is given by the (nonobvious) formula $O(\sqrt{g^2+gt+t})$. Therefore, the maximum treewidth of the multicut dual is $O(\sqrt{g^2+gt+t})$, giving a bound on the exponent of the running time.
- **Edge-weighted** planar $+\,\pi e$**.** With extra edges having infinite (or very large) weight, we can simulate multiple terminals at different parts of a planar graph. More precisely, a planar instance of Group 3-Terminal Cut with t terminals in each of the three groups can be reduced to an instance of Multiway Cut with three terminals if we connect

	genus	weighted planar $+ \pi e$	unweighted planar $+ \pi e$	crossing number
$\mathcal{H}$ with bounded distance to extended bicliques	$f(g,t)n^{O(g)}$	$f(\pi,t)n^{O(\sqrt{\pi})}$	$f(\pi,t)n^{O(1)}$ (*)	$f(cr,t)n^{O(1)}$ (*)
$\mathcal{H}$ with unbounded distance to extended bicliques	$f(g,t)n^{O(\sqrt{g^2+gt+t})}$	$f(\pi,t)n^{O(\sqrt{\pi+t})}$	$f(\pi,t)n^{O(\sqrt{t})}$	$f(cr,t)n^{O(\sqrt{t})}$ (*)

Figure 1 The running time of the algorithms for Multicut($\mathcal{H}$) with the different parameterizations. The new results of the paper are marked by (*). Note that, for every fixed projection-closed class $\mathcal{H}$, the exponents of the running time are tight (up to logarithmic factors).

the terminals in each group with a total of $\pi = 3(t-1)$ infinite-weight edges, creating a planar $+ \pi e$ instance. Thus these extra edges influence the running time exactly as extra terminals would do.

- **Unweighted planar $+ \pi e$.** We can always try to solve the problem by putting the π extra edges into the solution, removing them from G, and then solving the resulting planar instance. Of course, this might not always lead to an optimum solution, but can be up to π edges larger. However, this argument allows us to say that if the solution contains a cut that is "inefficient" in the sense that it is larger then the minimum cut by more than π, then the cut can be replaced by a minimum cut and the π extra edges, resulting in a strictly smaller solution. Using these type of arguments, the problem can be reduced to a planar setting where the number of faces of the multicut dual does not depend on π.
- **Crossing number.** Each crossing can increase the number of vertices of the multicut dual by one, thus the number of vertices and the treewidth of the multicut dual can be $O(t+cr)$ and $O(\sqrt{t+cr})$, respectively. However, all these extra vertices of the multicut dual are at fixed places determined by the crossing. As pointed out by Focke et al. [6] it is sufficient to consider the treewidth of the multicut dual *after removing all the vertices whose locations are fixed* (see Theorem 2.3). Indeed, after removing these vertices, the treewidth of the multicut dual does not depend on the crossing number.

Some remarks on two further notion of almost-planar graphs can be found in the full version.

2 Preliminaries

Some basic notation on sets, graphs, and multicuts can be found in the full version. We now give some less well-known, problem-specific definitions.

An *extended biclique decomposition* of a graph H is a partition (B_1, B_2, I, X) of $V(H)$ such that all vertices of I are isolated in $H - X$, $E(H)$ contains the edge t_1t_2 for all $t_1 \in B_1$ and $t_2 \in B_2$, and $H[B_i]$ is an edgeless graph for $i \in [2]$. We use $\mathcal{H}_\mu$ for the set of graphs H that admit an extended biclique decomposition (B_1, B_2, I, X) with $|X| \leq \mu$.

We now review the concept of so-called multicut duals, which will play a crucial role throughout the article. Recall that an instance (G, H) of Multicut is *planar* if G is given in the form of a graph cellularly embedded in the plane. Given a graph C that is embedded in the plane and in general position with G, we denote by $e_G(C)$ those edges of G that are crossed by at least one edge of C. The *weight* $w(C)$ of C is defined to be $w(e_G(C))$

where w is the weight function associated with G. A *multicut dual* for (G, H) is a graph C embedded in the plane that is in general position with G and has the property that, for every $t_1, t_2 \in V(H)$ with $t_1t_2 \in E(H)$, the terminals t_1 and t_2 are contained in different faces of C.

The following result is an immediate consequence of Lemmas 2.3 and 2.4 in [6].

▶ **Lemma 2.1.** *Let (G, H) be a planar instance of* Multicut *and C a minimum weight multicut dual for (G, H). Then $e_G(C)$ is a minimum weight multicut for (G, H).*

In order to make use of the topology of certain multicut duals, we need two results related to treewidth. The first one of the following two results provides a sufficient criterion for the treewidth of certain graphs being bounded and the second one allows to exploit bounded treewidth algorithmically.

The following result can be obtained from Theorem 3.2 in [4] and the fact that the treewidth of any graph can only be larger than its branchwidth by a constant factor.

▶ **Proposition 2.2.** *Let C be a planar graph that admits a 5-dominating set of size k for some positive integer k. Then $\mathrm{tw}(C) = O(\sqrt{k})$.*

An *extended* planar instance (G, H, F^*) of Multicut is a planar instance (G, H) of Multicut together with a set F^* of faces of G which is given with the input. Given a set F^* of faces of G and a multicut dual C for (G, H), let $C - F^*$ be the graph obtained from C by removing every vertex that is in a face of F^* and removing every edge that intersects a face of F^*. The following result is the restriction of Theorem 1.11 in [6] to the planar setting.

▶ **Theorem 2.3.** *Let (G, H, F^*) be an extended planar instance of* Multicut *such that every subcubic inclusionwise minimal minimum-weight multicut dual C satisfies $\mathrm{tw}(C - F^*) \leq \beta$. Then an optimum solution of (G, H) can be found in time $f(|F^*|, t)n^{O(\beta)}$.*

3 Edge-deletion distance to planarity

In this section, we give an overview of the proof of the following result, whose complete proof can be found in the full version.

▶ **Theorem 1.5.** *Unweighted* Multicut *can be solved in time $f(\pi, t)n^{O(\sqrt{\mu})}$.*

Throughout this section, we say that an instance (G, H) of Multicut is planar $+ \pi e$ if a set $E_\pi \subseteq E(G)$ is given with the instance such that $|E_\pi| = \pi$ and $G \setminus E_\pi$ is planar. We further use T for $V(H)$, W for $V(E_\pi)$, and G_0 for $G \setminus E_\pi$. Also, for some $S \subseteq E(G)$, we use S_0 for $S \setminus E_\pi$. We say that (G, H) is *connected* if G is connected.

The overall algorithmic strategy for Theorem 1.5 is to run an algorithm on the given instance that either produces a minimum multicut for the instance or computes a collection of instances for which the parameters in consideration are smaller and such that from minimum multicuts of all those instances, a minimum multicut for the original instance can be computed. We need the following definitions.

Given instances (G, H) and (G', H') of Multicut, (G', H') is a *subinstance* of (G, H) if G' is a labelled subgraph of G and H' is a labelled induced sungraph of H. Next, an *extended subinstance* of (G, H) consists of a set $S' \subseteq E(G)$ and a subinstance (G', H') of (G, H) with $E(G') \cap S' = \emptyset$. When we say that an extended subinstance $(S', (G', H'))$ has certain properties which can only be associated to an instance of Multicut, we refer to (G', H'). Next, we say that an extended subinstance $(S', (G', H'))$ of (G, H) is *optimumbound* for (G, H) if $S' \cup S''$ is a minimum multicut for (G, H) for every minimum multicut S'' for (G', H').

The main technical difficulty is to prove the following result, which shows that the above described reduction to smaller instances exists for connected instances. With this result at hand, Theorem 1.5 follows readily. In particular, if disconnected instances are created, they can easily be reduced to instances corresponding to the components of the graph. Further observe that μ cannot increase when moving to a subinstance as the new demand graph is an induced subgraph of the previous one.

▶ **Lemma 3.1.** *Let (G, H) be a connected* planar $+ \pi e$ *instance of* Multicut. *Then, in $f(\pi, t)n^{O(\sqrt{\mu})}$, we can run an algorithm that returns a set $S \subseteq E(G)$ and a collection $(S_i, (G_i, H_i))_{i\in[k]}$ of extended subinstances of (G, H) for some $k = f(\pi, t)$ such that for all $i \in [k]$, we have that $\pi(G_i) + |V(H_i)| < \pi(G) + |V(H)|$ holds and either S is a minimum multicut for (G, H) or there exists some $i \in [k]$ such that $(S_i, (G_i, H_i))$ is optimumbound for (G, H).*

We now give an overview of the proof of Lemma 3.1. Let (G, H) be a planar $+ \pi e$ instance of Multicut. The idea is to have a branching algorithm that gradually guesses more and more crucial information about a minimum multicut for (G', H') while the number of directions it branches into remains bounded. The current status of this procedure is displayed by a subpartition of the vertices of $V(G)$ with some extra properties. More formally, a *state* is a subpartition $\mathcal{P}$ of $V(G)$ with $W \cup T \subseteq \bigcup \mathcal{P}$ and $Y \cap (W \cup T) \neq \emptyset$ for all $Y \in \mathcal{P}$. Given a certain state, the objective is to understand whether there exists a minimum multicut S for (G, H) such that the structure of the components of $G_0 \setminus S$ reflects the structure of $\mathcal{P}$. In order to make this more formal, we need the following definitions: Given a set V and two subpartitions $\mathcal{P}^1$ and $\mathcal{P}^2$ of V, we say that $\mathcal{P}^2$ *extends* $\mathcal{P}^1$ if $|\mathcal{P}^1| = |\mathcal{P}^2|$ and for every $Y \in \mathcal{P}^1$, there exists some $\overline{Y} \in \mathcal{P}^2$ with $Y \subseteq \overline{Y}$ such that for any distinct $Y_1, Y_2 \in \mathcal{P}^1$, we have $\overline{Y_1} \neq \overline{Y_2}$. Given a set $S \subseteq E(G)$, we use S_0 for $S \cap E(G_0)$ and $\mathcal{K}(G_0 \setminus S_0)$ for the unique partition of $V(G)$ in which two vertices are in the same partition class if and only if they are in the same component of $G_0 \setminus S_0$. For a state $\mathcal{P}$, we say that a multicut S for (G, H) *respects* $\mathcal{P}$ if $\mathcal{K}(G_0 \setminus S_0)$ extends $\mathcal{P}$ and we say that a state is *valid* if there exists a minimum multicut for (G, H) respecting it. Further, $\mathcal{P}$ is *maximum valid* if $|\mathcal{P}|$ is maximum among all valid states.

The idea of our algorithm now consists of considering a valid state, choosing a vertex that is not contained in any class of the state and making the classes larger by adding this vertex to one of them. As we do not know which class this vertex should be added to, we try all classes of the state and branch in these directions. The difficulty is now to carefully choose the vertex in consideration and make some additional modifications on the states so that this procedure terminates sufficiently fast.

In order to be able to explain how this works, we first need some more definitions. Given disjoint sets $Y_1, Y_2 \subseteq V(G)$, we use $\lambda_{G_0}(Y_1, Y_2)$ to denote the size of the smallest set of edges in $E(G_0)$ whose deletion from G_0 results in a graph in which there exists no component containing both a vertex of Y_1 and a vertex of Y_2. Next, for a state $\mathcal{P}$ and some $Y \in \mathcal{P}$, we define $\alpha_{G,\mathcal{P}}(Y) = \lambda_{G_0}(Y, \bigcup \mathcal{P} \setminus Y) - \lambda_{G_0}(Y \cap (W \cup T), W \cup T \setminus Y)$. Intuitively speaking, this measure describes how much more costly it is to separate the class from the other classes of the state in comparison to only separating the corresponding elements of $W \cup T$. Given a state $\mathcal{P}$, we now classify its classes according to their value of α and the value of α of their neighboring classes. More formally, given a state $\mathcal{P}$ and some $Y \in \mathcal{P}$, we say that Y is *fat* in $\mathcal{P}$ if $\alpha_{G_0,\mathcal{P}}(Y) \geq \pi(t + 1) + 1$. For some $Y \in \mathcal{P}$ that is not fat, we say that Y is *fat-neighboring* in $\mathcal{P}$ if there exists some fat $Y' \in \mathcal{P}$, some $u \in Y$, and some $v \in Y'$ such that $uv \in E(G_0)$. Finally, for some $Y \in \mathcal{P}$ which is neither fat nor fat-neighboring in $\mathcal{P}$, we say that Y is *thin* in $\mathcal{P}$. We refer by $\mathcal{P}_{\text{fat}}, \mathcal{P}_{\text{f-n}}$, and $\mathcal{P}_{\text{thin}}$ to the fat, fat-neighboring, and thin classes of $\mathcal{P}$, respectively.

In order to make use of this distinction, we crucially need a structural property of minimum multicuts for (G, H). Namely, the following result shows that, for any minimum multicut S for (G, H) and any vertex set of a component of $G_0 \setminus S_0$, one of two things holds: either the value of α is not too large or a terminal of X is close to this vertex set in a certain sense, where (B_1, B_2, I, X) is an extended biclique decomposition of H. In order to measure this proximity of certain vertex sets with respect to a multicut, we introduce the following notion: Let $S \subseteq E(G)$, and $Y_1, Y_2 \subseteq V(G)$. Then we denote by $\text{dist}_{G_0,S_0}(Y_1, Y_2)$ the smallest integer q such that G_0 contains a Y_1Y_2-path P with $|E(P) \cap S_0| = q$. We are now ready to state the following structural result for minimum multicuts.

▶ **Lemma 3.2.** *Let (G, H) be a* planar $+ \pi e$ *instance of* Multicut*, let S be a minimum multicut for (G, H) and let $Y \in \mathcal{P}_{\text{fat}}$ for $\mathcal{P} = \mathcal{K}(G_0 \setminus S_0)$. Then $\text{dist}_{G_0,S_0}(Y, X) \leq 1$.*

We now explain the strategy of our algorithm. Given a state with an extra property that will be explained later, we choose a vertex that is not contained in any class of the state and has a neighbor in a thin class of the state in G_0. We then guess a partition class which this vertex will be added to and modify the state accordingly. In order to show the functionality of this algorithm, there are two points that need further explanation. First, we need to explain how to conclude when the described modification is no longer possible and second, we need to explain why this procedure terminates sufficiently fast.

We first explain the scenario that we can no longer execute the described modification, so there does not exist any vertex in the graph that is not contained in any class of the state $\mathcal{P}$ in consideration and that has a neighbor in a thin class of $\mathcal{P}$ in G_0. We call such a state *complete*, all other states are called *incomplete*. For complete states, we need to consider two different cases, depending on whether $\mathcal{P}$ contains a thin class.

The case that there exists a thin class Y can be handled with elementary means. Observe that for this thin class, all its neighbors in G_0 are contained in a different class of $\mathcal{P}$. Hence, if $\mathcal{P}$ is valid, then all edges in $\delta_{G_0}(Y)$ are contained in a minimum multicut for (G, H). We can hence delete these edges and solve the remaining instance, which turns out to be significatly smaller in a certain sense. This is subsumed in the following result.

▶ **Lemma 3.3.** *Let (G, H) be a connected* planar$+\pi e$ *instance of* Multicut *and let a complete valid state $\mathcal{P}$ of (G, H) with $\mathcal{P}_{\text{thin}} \neq \emptyset$ be given. Then in polynomial time, we can compute an optimumbound extended subinstance $(S', (G', H'))$ of (G, H) such that $\pi(G') + |V(H')| < \pi(G) + |V(H)|$.*

We now turn to the case that $\mathcal{P}$ does not contain a thin set. In order to handle this case, geometrical arguments on multicut duals will be needed. Namely, we show that if $\mathcal{P}$ is valid and does not contain a thin set, then the problem of finding a minimum multicut for (G, H) can be reduced to solving a planar instance of multicut, which can be solved sufficiently fast due to Theorem 2.3 and an argument on the treewidth of the multicut duals for this instance. Formally, we prove the following result, where $\tau(\mathcal{P})$ denotes the sum of the number of components of $G_0[Y]$ over all $Y \in \mathcal{P}$.

▶ **Lemma 3.4.** *Let (G, H) be a connected* planar $+ \pi e$ *instance of* Multicut *and let a complete maximum valid state $\mathcal{P}$ of (G, H) with $\mathcal{P}_{\text{thin}} = \emptyset$ be given. Then a minimum multicut for (G, H) can be computed in $f(\pi, \tau(\mathcal{P}))n^{O(\sqrt{\mu})}$.*

It remains to show that we can design our procedure so that we reach a complete state sufficiently fast. In order to keep track of the progress of our algorithm, we need a measure of how far advanced a given state is. To this end, given a state $\mathcal{P}$, we first define an integer $\kappa(\mathcal{P}, Y)$ for every $Y \in \mathcal{P}$ by

$$\kappa(\mathcal{P}, Y) = \left\{ \begin{array}{ll} 2(\pi(t+1)+1), & \text{for } Y \in \mathcal{P}_{\text{fat}}, \\ \pi(t+1)+1+\alpha_{G_0,\mathcal{P}}(Y), & \text{for } Y \in \mathcal{P}_{\text{f-n}}, \\ \alpha_{G_0,\mathcal{P}}(Y), & \text{for } Y \in \mathcal{P}_{\text{thin}}. \end{array} \right\}$$

Now, we define $\kappa(\mathcal{P}) = \sum_{Y \in \mathcal{P}} \kappa(\mathcal{P}, Y)$.

Our objective is to make the value of κ increase in each iteration of the algorithm. In order to make this possible, we need that the addition of a vertex to a given set in the state makes the value of α of this set increase. In order for that to hold, we need the classes in the state to be as large as possible in a certain sense. More precisely, given a graph G and two disjoint sets $Y_1, Y_2 \subseteq V(G)$, we say that a set Y_3 is *relevant* for (Y_1, Y_2) in G if $Y_1 \subseteq Y_3, Y_2 \cap Y_3 = \emptyset, d_G(Y_3) = \lambda_G(Y_1, Y_2)$ and Y_3 is maximum among all sets with these properties. Further, we say that a state $\mathcal{P}$ is *relevant* if for all $Y \in \mathcal{P}$, we have that Y is a relevant set for $(Y, \bigcup \mathcal{P} \setminus Y)$. Luckily, the following result whose proof needs some careful reconfiguration arguments, allows us to turn arbitrary states in consideration into relevant ones without dropping any important properties.

▶ **Lemma 3.5.** *Let a connected* planar $+ \pi e$ *instance* (G, H) *of* Multicut *and a state* $\mathcal{P}$ *of* (G, H) *be given. Then, in polynomial time, we can compute a relevant state* $\mathcal{P}'$ *of* (G, H) *such that* $|\mathcal{P}'| = |\mathcal{P}|, \tau(\mathcal{P}') \leq \tau(\mathcal{P})$, $\kappa(\mathcal{P}') \geq \kappa(\mathcal{P})$ *and, if* $\mathcal{P}$ *is maximum valid, then so is* $\mathcal{P}'$.

With this result at hand, we can handle incomplete states. As pointed out before, given an incomplete relevant state $\mathcal{P}$, we choose a vertex $u_0 \in V(G) \setminus \bigcup \mathcal{P}$ that has a neighbor in a thin class Y of $\mathcal{P}$. We now consider all states that are obtained by adding u_0 to one of these partition classes. If u_0 is added to a thin or a fat-neighboring partition class, then, as $\mathcal{P}$ is relevant, the value of α increases for this class and hence κ increases. If u_0 is added to a fat class, then Y becomes fat-neighboring and hence κ also increases. This shows that a complete state can be reached sufficiently fast. In order to apply Lemma 3.4, we also need to make sure that $\tau(\mathcal{P})$ does not increase too fast. However, this follows readily by construction. Our handling of relevant incomplete states is subsumed in the following result.

▶ **Lemma 3.6.** *Let* (G, H) *be a connected* planar $+ \pi e$ *instance of* Multicut *and let a relevant incomplete state* $\mathcal{P}$ *of* (G, H) *be given. Then, in polynomial time, we can compute a collection* $(\mathcal{P}^i)_{i \in [q]}$ *of* q *states of* (G, H) *for some* $q \leq \pi + t$ *such that* $\tau(\mathcal{P}^i) \leq \tau(\mathcal{P}) + 1$ *and* $\kappa(\mathcal{P}^i) > \kappa(\mathcal{P})$ *hold for all* $i \in [q]$ *and if* $\mathcal{P}$ *is maximum valid, then there exists some* $i \in [q]$ *such that* $\mathcal{P}^i$ *is maximum valid.*

The overall strategy for handling Lemma 3.1 is now to apply Lemma 3.5 and Lemma 3.6 until we are left with a collection of complete states. These can then be handled by Lemma 3.3 and Lemma 3.4.

4 Crossing number

In this section, a *drawing* of a graph G consists of a mapping of the vertices of G to points in the plane and a mapping of the edges of G to curves in the plane connecting their endpoints such that all vertices and edges of G are in general position except the required adjacencies and such that in any point not corresponding to a vertex, at most two edges intersect. An *edge crossing* refers to a point that does not correspond to a vertex and in which two edges intersect. Given an instance (G, H) of Multicut we use *cr* for the *crossing number* of a graph G, which is defined to be the smallest integer k such that there exists a drawing of G with exactly k edge crossings. The following is the main result of this section.

▶ **Theorem 1.7.** *Edge-weighted* Multicut *can be solved in time* $f(cr,t)n^{O(\sqrt{\mu})}$.

In order to make our algorithm work, rather than just the crossing number of a graph, we also need to have an optimal drawing available. This can be achieved through the following result due to Grohe [7].

▶ **Proposition 4.1.** *Given a graph* G*, there exists an algorithm that computes a drawing of* G *in the plane minimizing the number of crossings and that runs in time* $f(cr)n^{O(1)}$.

Formally, an instance (G,H) of Multicut is called *crossing-planar* if G is given as a drawing of a graph. Given a crossing-planar instance, we denote by E_{cr} the set of edges in $E(G)$ crossing at least one other edge of $E(G)$ and we set $\overline{cr} = |E_{cr}|$. Observe that $\overline{cr}$ can be arbitrarily large in comparison to cr as $\overline{cr}$ refers to the given drawing and cr to an optimal drawing of the abstract graph G. However, when considering an optimal drawing of G, we have $\overline{cr} \leq 2cr$ as every crossing involves 2 edges.

For our algorithm, it will be convenient to assume that the instances in consideration satisfy a technical extra condition. Namely, a crossing-planar instance (G,H) of Multicut is called *normalized* if every $e \in E_{cr}$ is of infinite weight. Observe that for any normalized crossing-planar instance (G,H) of Multicut, any finite multicut S of (G,H) and any $e \in E_{cr}$, we have that $V(e)$ is contained in one component of $G \setminus S$. Our main technical contribution is proving the restriction of Theorem 1.7 to normalized instances.

▶ **Theorem 4.2.** *There exists an algorithm that solves every normalized crossing-planar instance of* Multicut *and runs in* $f(\overline{cr},t)n^{O(\sqrt{\mu})}$.

The simple proof that Theorem 4.2 implies Theorem 1.7 is postponed to the full version. It remains to prove Theorem 4.2.

Given a normalized crossing-planar instance (G,H) of Multicut, we denote by $\mathcal{H}$ the set of graphs H' on $V(H) \cup V(E_{cr})$ and we use G' for $G \setminus E_{cr}$. Further, we let F^* denote the faces of G' which contain a pair of crossing edges in G. The main technical difficulty for the proof of Theorem 4.2 is contained in the following result.

▶ **Lemma 4.3.** *Let* (G,H) *be a normalized crossing-planar instance of* Multicut *admitting a multicut of finite weight. Then there exists* $H' \in \mathcal{H}$ *such that every minimum weight multicut for* (G',H') *is a minimum weight multicut for* (G,H) *and for every subcubic, inclusion-wise minimal minimum weight multicut dual* C *for* (G',H')*, we have* $\mathrm{tw}(C - F^*) = O(\sqrt{\mu})$.

Due to space restrictions, the full proof of Lemma 4.3 is postponed to the full version. We now give an overview of the proof of Lemma 4.3.

Let (B_1,B_2,I,X) be an extended biclique decomposition of H with $|X| = \mu$. Further, let S^* be a minimum weight multicut for (G,H) such that S^* minimizes the number of elements of $V(H) \cup V(E_{cr})$ that are in a component of $G \setminus S^*$ that also contains a terminal of X. In the following, we use $\overline{X}$ for the set of elements of $V(H) \cup V(E_{cr})$ that are in a component of $G \setminus S^*$ that also contains a terminal of X, we use $\overline{B_1}$ for the set of elements of $(V(H) \cup V(E_{cr})) \setminus \overline{X}$ that are in a component of $G \setminus S^*$ that also contains a terminal of B_1, and we use $\overline{B_2}$ for $(V(H) \cup V(E_{cr})) \setminus (\overline{X} \cup \overline{B_1})$. Observe that $(\overline{B_1}, \overline{B_2}, \overline{X})$ is a partition of $V(H) \cup V(E_{cr})$. We now define H' to be the complete multipartite graph on $V(H) \cup V(E_{cr})$ such that $\overline{B_1}$ and $\overline{B_2}$ are partition classes and such that for every component of $G \setminus S^*$ that contains at least one terminal of X, all the elements of $\overline{X}$ contained in this component form a partition class.

This finishes the description of H'. Observe that $H' \in \mathcal{H}$. Further observe that H is a subgraph of H'.The following two claims directly imply that every minimum weight multicut for (G', H') is also a minimum weight multicut for (G, H'). Claim 4.4 will be reused for the proof of the treewidth bound. These claims mainly follow from the construction of (G', H').

▷ Claim 4.4. Let S' be a multicut for (G', H'). Then S' is also a multicut for (G, H').

▷ Claim 4.5. S^* is a multicut for (G', H').

We are now ready to conclude that any minimum weight multicut S for (G', H') is a minimum weight multicut for (G, H). First observe that S is a multicut for (G, H) by Claim 4.4 and as H is a subgraph of H'. Further, by Claim 4.5 and the minimality of S, we obtain $w(S) \leq w(S^*)$ where w is the weight function associated to G. By the minimality of S^*, the statement follows.

In the following, let C be a subcubic, inclusion-wise minimal, minimum weight multicut dual for (G', H'). We will give the desired treewidth bound on C. Let $S' = E_G(C)$ and observe that S' is a minimum weight multicut for (G', H') by Lemma 2.1. It hence follows from the first part of the lemma that S' is also a minimum weight multicut for (G, H). Further, we use C' for $C - F^*$.

Our strategy for proving the second part of the lemma is to show that the faces of C' containing a terminal of $\overline{X}$ form a small set of faces that is close to every face of C' in a certain sense. We first give the following result showing that the number of such faces is small indeed. Its proof uses the fact that S^* is chosen so that the size of $\overline{X}$ is minimized and the fact that S' is a minimum weight multicut for (G, H).

▷ Claim 4.6. Let f be a face of C' that contains a terminal of $\overline{X}$. Then f also contains a terminal of X.

The next result uses the structure of H.

▷ Claim 4.7. Let $v \in V(C')$ with $d_{C'}(v) = 3$. Then v is incident to a face of C' that contains a terminal of $\overline{X}$.

We are now ready to conclude the desired treewidth bound on C'. Let C'' be a component of C'. For every face f of C'', we now introduce a vertex z_f that shares an edge with every vertex that is incident to f. Let C_0'' be the resulting graph. It turns out that C_0'' is a planar graph and the vertices corresponding to faces containing terminals of $\overline{X}$ form a 3-dominating set in C_0''. By Proposition 2.2 and $|A| \leq |X| \leq \mu$, we obtain that $\mathrm{tw}(C_0'') = O(\sqrt{\mu})$ and hence $\mathrm{tw}(C') = O(\sqrt{\mu})$. This allows to conclude Lemma 4.3.

With Lemma 4.3 at hand, it is easy to conclude Theorem 4.2. The proof can be found in the full version.

Abstract

We consider the Min-r-Lin($\mathbb{Z}_m$) problem: given a system S of length-r linear equations modulo m, find $Z \subseteq S$ of minimum cardinality such that $S - Z$ is satisfiable. The problem is NP-hard and UGC-hard to approximate in polynomial time within any constant factor even when $r = m = 2$. We focus on parameterized approximation with solution size as the parameter. Dabrowski, Jonsson, Ordyniak, Osipov and Wahlström [SODA-2023] showed that Min-2-Lin($\mathbb{Z}_m$) is in FPT if m is prime (i.e. $\mathbb{Z}_m$ is a field), and it is W[1]-hard if m is not a prime power. We show that Min-2-Lin($\mathbb{Z}_{p^n}$) is FPT-approximable within a factor of 2 for every prime p and integer $n \geq 2$. This implies that Min-2-Lin($\mathbb{Z}_m$), $m \in \mathbb{Z}^+$, is FPT-approximable within a factor of $2\omega(m)$ where $\omega(m)$ counts the number of distinct prime divisors of m. The high-level idea behind the algorithm is to solve tighter and tighter relaxations of the problem, decreasing the set of possible values for the variables at each step. When working over $\mathbb{Z}_{p^n}$ and viewing the values in base-p, one can roughly think of a relaxation as fixing the number of trailing zeros and the least significant nonzero digits of the values assigned to the variables. To solve the relaxed problem, we construct a certain graph where solutions can be identified with a particular collection of cuts. The relaxation may hide obstructions that will only become visible in the next iteration of the algorithm, which makes it difficult to find optimal solutions. To deal with this, we use a strategy based on shadow removal [Marx & Razgon, STOC-2011] to compute solutions that (1) cost at most twice as much as the optimum and (2) allow us to reduce the set of values for all variables simultaneously. We complement the algorithmic result with two lower bounds, ruling out constant-factor FPT-approximation for Min-3-Lin(R) over any nontrivial ring R and for Min-2-Lin(R) over some finite commutative rings R.

1 Introduction

Systems of linear equations are ubiquitous in computer science and mathematics [16] and methods like Gaussian elimination can efficiently solve linear systems over various rings. Equations and congruences over the ring of integers modulo m ($\mathbb{Z}_m$) are of central importance in number theory, but also have many applications in computer science, including complexity theory, coding theory, cryptography, hash functions and pseudorandom generators, see e.g. [3, 9, 11, 33]. Linear equations over modular rings can be solved in polynomial time, but the methods are not suited to dealing with inconsistent systems of equations. We consider the Min-r-Lin(R) problem which asks to find an assignment to a system of linear equation over the ring R that violates the minimum number of equations, and where each equation contains at most r distinct variables. This problem is NP-hard even when $r = 2$ and R is the simplest nontrivial ring $\mathbb{Z}_2$ [23]. We note that Min-r-Lin(R) for $r \in \mathbb{N}$ and finite ring R is a special case of MinCSP(Γ) for a finite constraint language Γ. This, and the more general Valued CSP, have been widely studied from many different perspectives, e.g. [4, 6, 22, 23, 31, 32].

Two common ways of coping with NP-hardness are approximation and parameterized algorithms, but neither of them seems sufficient in isolation to deal with Min-r-Lin($\mathbb{Z}_m$). Even Min-2-Lin over finite fields such as $\mathbb{Z}_2$ is conjectured to be NP-hard to approximate within any constant factor under the Unique Games Conjecture (UGC) [20]: see Definition 3 in [21] and the discussion that follows. The natural parameter for Min-r-Lin($\mathbb{Z}_m$) is the cost of the optimal solution (i.e. the number of equations not satisfied by it), which we denote by k. Under this parameterization, Min-2-Lin($\mathbb{Z}_m$) is fixed-parameter tractable when m is a prime, i.e. $\mathbb{Z}_m$ is a field, but W[1]-hard when m is not a prime power. Moreover, the problem Min-3-Lin is W[1]-hard for every nontrivial ring [8]. This motivates us to study *parameterized approximation* algorithms [14, 27]. This approach has received rapidly increasing interest (see, for instance, [13, 17, 18, 25, 26, 30]). Let $c \geq 1$ be a constant. A factor-c *FPT-approximation algorithm* takes an instance (I, k), runs in $O^*(f(k))$[1] time for an arbitrary computable function f, either returns that there is no solution of size at most k or returns that there is a solution of size at most $c \cdot k$. Thus, there is more time to compute the solution (compared to polynomial-time approximation) and the algorithm may output an oversized solution (unlike an exact FPT algorithm). [2] Our main result is the following. Let $\omega(m)$ be the number of distinct prime factors of m.

▶ **Theorem 1.** *For every $m \in \mathbb{Z}_+$, Min-2-Lin($\mathbb{Z}_m$) is* FPT*-approximable within $2\omega(m)$.*

We complement the result with two lower bounds. First, we show that allowing three or more variables per equation leads to W[1]-hardness of constant-factor approximation.

▶ **Theorem 2.** *Min-3-Lin(R) over every nontrivial ring R is W[1]-hard to approximate within any constant factor.*

[1] The notation $O^*(\cdot)$ hides polynomial factors in the input size.

[2] A decision c-approximation procedure for Min-2-Lin($\mathbb{Z}_m$) can be turned into an algorithm that returns a c-approximate solution using self-reducibility: if (S, k) is a yes-instance, then there exists a subset $S' \subseteq S$, $|S'| \leq c$, such that $(S - S', k - 1)$ is a yes-instance; moreover, such S' can be found by iterating over all subsets of size at most c, which incurs a polynomial overhead on the running time of the algorithm.

This result strengthens two previously known hardness results: (i) Min-3-Lin(R) is W[1]-hard [8] and (ii) Min-3-Lin(R) is NP-hard to approximate within any constant (which can easily be derived from [19]). While we focus on rings of the form $\mathbb{Z}_m$, the result of Theorem 1 begs the questions whether Min-2-Lin(R) is FPT-approximable within a constant factor for every finite commutative ring R. We answer this question in the negative.

▶ **Theorem 3** (See Theorem 17 for a more detailed statement.). *There exist finite commutative rings R such that Min-2-Lin(R) is W[1]-hard to approximate within any constant factor.*

Theorems 5.2 and 6.2 in [8] leave open the question of whether Min-2-Lin($\mathbb{Z}_{p^n}$) is FPT or W[1]-hard for a prime p and $n \geq 2$. The answer is unknown even for the smallest such ring – $\mathbb{Z}_4$. While our result implies that Min-2-Lin($\mathbb{Z}_{p^n}$) is FPT-approximable within a factor of 2, its exact parameterized complexity remains an intriguing open problem.

Full proofs for the results marked with a $\star$ can be found in the full version of the paper. Another version of this paper is available on arXiv [7]; it considers a broader class of rings, but gives worse approximation factors.

2 Preliminaries

For the basics of graph theory and parameterized complexity, we refer to [10, 12, 15, 29].

An expression $c_1 \cdot x_1 + \cdots + c_r \cdot x_r = c$ is a *(linear) equation over R* if $c_1, \ldots, c_r, c \in R$ and $x_1, \ldots, x_r$ are variables with domain R. This equation is *homogeneous* if $c = 0$. Let S be a set (or equivalently a system) of equations over R. Let $V(S)$ denote the variables in S, and we say that S is *consistent* if there is an assignment $\varphi : V(S) \to R$ satisfying all equations in S. An instance of the computational problem r-Lin(R) is a system S of equations in at most r variables over R, and the question is whether S is consistent. Linear equation systems over $\mathbb{Z}_m$ are solvable in polynomial time and the well-known procedure is outlined, for instance, in [1, p. 473]. We now define the computational problem when we allow some equations in an instance to be soft (i.e. deletable at unit cost) and crisp (i.e. undeletable).

Min-r-Lin(R)	
Instance:	A (multi)set S of equations over R with at most r variables per equation, a subset $S^\infty \subseteq S$ of crisp equations and an integer k.
Parameter:	k.
Question:	Is there a set $Z \subseteq S \setminus S^\infty$ such that $S - Z$ is consistent and $\lvert Z\rvert \leq k$?

We use crisp equations for convenience since they can be modelled by $k+1$ copies of the same soft equation. For an assignment $\alpha : V(S) \to R$, let $\mathrm{cost}_S(\alpha)$ be ∞ if α does not satisfy a crisp equation and the number of unsatisfied soft equations otherwise. We drop the subscript S when it is clear from context. We write $\mathrm{mincost}(S)$ to denote the minimum cost of an assignment to S.

3 FPT-Approximation Algorithm

3.1 Algorithm Summary

Let $p_1^{n_1} \cdots p_\ell^{n_\ell}$ be the prime factorization of $m \in \mathbb{Z}_+$. It is well known that $\mathbb{Z}_m$ is isomorphic to the direct sum $\bigoplus_{i=1}^{\ell} \mathbb{Z}_{p_i^{n_i}}$, and we can reduce the problem to the prime power case.

▶ **Proposition 4** (⋆). *Suppose that the ring R is isomorphic to a direct sum $\bigoplus_{i=1}^{\ell} R_i$. If* Min-2-Lin$(R_i)$ *is* FPT*-approximable within a factor c_i for all $i \in [\ell]$, then* Min-2-Lin(R) *is* FPT*-approximable within a factor $\sum_{i=1}^{\ell} c_i$.*

Now, consider the ring $\mathbb{Z}_{p^n}$ for a prime p and positive integer n. We start with a simplification step. An equation over a ring R is *simple* if it is either a binary equation of the form $u = rv$ for some $r \in R$ or a crisp unary equation $u = r$ for some $r \in R$. An instance S of 2-Lin(R) is simple if every equation in S is simple.

▶ **Lemma 5** (⋆). *Let m be positive integer and c be a constant. If* Min-2-Lin$(\mathbb{Z}_m)$ *restricted to simple instances is* FPT*-approximable within a factor c, then* Min-2-Lin$(\mathbb{Z}_m)$ *on general instances is* FPT*-approximable within a factor c.*

Now, suppose $n = 1$, i.e. we are working over a field $\mathbb{Z}_p$. Min-2-Lin$(\mathbb{Z}_p)$ can be solved exactly in FPT time (see. [8]); we will show a 2-approximation because it is illustrative of our approach. For an instance S of 2-Lin$(\mathbb{Z}_p)$, we construct a graph $G = G(S)$ with vertices x_i for every $x \in V(G)$ and $1 \leq i \leq p-1$ and special vertices s and t. For unary equations $x = r$ in S, add crisp edges sx_r if $r \neq 0$, and crisp edges $x_r t$ for every $1 \leq r \leq p-1$ if $r = 0$. For every binary equation e of the form $x = r \cdot y$, construct an edge bundle $B_e = \{x_{ri}y_i : 1 \leq i \leq p-1\}$ and add these edges to G. This completes the construction. We establish a correspondence between conformal st-cuts in $G(S)$ and assignments to S. Formally, for a set of vertices $X \subseteq V(G)$, let $\delta(X)$ be the set of edges with exactly one endpoint in X, i.e. $\delta(X)$ is the cut separating X and $\overline{X}$. If $U \subseteq V(G)$ is such that $s \in U$, $t \notin U$ and there is at most one vertex $x_i \in U$ for any $x \in V(S)$, we say that $\delta(U)$ is a *conformal st-cut*. To construct an assignment from a conformal cut U, map $x \mapsto i$ whenever $x_i \in U$ for some $i \in \{1, \ldots, p-1\}$, and otherwise $x \mapsto 0$; the reverse direction of the correspondence is obvious.

Let $b(U)$ be the number of edge bundles B_e intersected by $\delta(U)$. Then R being a field implies that $b(U)$ is exactly the cost of the assignment corresponding to U. More specifically, consider an equation $e = (x = r \cdot y)$, suppose $x_i, y_j \in U$ and $B_e \cap \delta(U) = \emptyset$. Then $i = rj$ because the edge $x_{rj}y_j$ is uncut and both its endpoints are reachable from s, so the assignment corresponding to U satisfies e. This guarantee is represented by B_e being a matching: view an edge $x_i y_j$ as encoding "$x = i$ if and only if $y = j$". To complete the algorithm for fields, we compute a conformal cut $\delta(U)$ with $b(U) \leq k$. Observe that $b(U) \leq k$ implies $\delta(U) \leq 2k$ because U contains at most one vertex per variable so $\delta(U)$ may intersect at most two edges of any bundle. Thus, for 2-approximation it suffices to compute a conformal cut of size $2k$, which is guaranteed to exist for yes-instances. However, when translating it back into a set of equations, we may delete $2k$ equations because all edges of our conformal cut may intersect distinct bundles. Finally, to compute a conformal cut in FPT time, we may use branching in the style of Digraph Pair Cut [24]: compute the closest st-cut (which is unique by submodularity of cuts), and if it is not conformal, then branch.

If we use the same approach naïvely over $\mathbb{Z}_{p^n}$, $n \geq 2$, then the bundles B_e stop being matchings. Consider the equation $e = (x = 2y)$ over $\mathbb{Z}_8$ (second graph from the left in Figure 1). Note that both y_2 and y_6 are adjacent to x_4 in B_e. Moreover, if $x = 4$ then either $y = 2$ or $y = 6$ so the dependencies cannot be captured by binary edges (even if one were to use directed graphs). Thus, we lose the connection between the number of bundles intersected by a conformal cut and the cost of the corresponding assignment. One idea for solving Min-2-Lin$(\mathbb{Z}_{p^n})$ is to retain the "if and only if" semantics of an edge by matching *sets* of values rather than individual values. More specifically, let us partition $\{1, \ldots, p^n - 1\}$ into classes $C_1, \ldots, C_\ell$ and build $G(S)$ with vertices s, t and $x_{C_1}, \ldots, x_{C_\ell}$ for all $x \in V(S)$. To keep the matching structure for an equation e, we want an edge $x_{C_i}y_{C_j}$ in B_e to mean

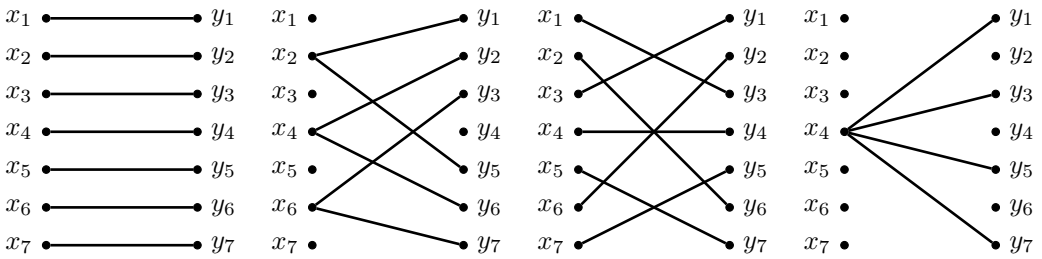

Figure 1 Graphs B_e corresponding to equations $x = 1 \cdot y$, $x = 2 \cdot y$, $x = 3 \cdot y$ and $x = 4 \cdot y$.

"$x \in C_i$ if and only if $y \in C_j$". For fields, we have used the most refined partition (every nonzero element is a class of its own). For other rings, a coarser partition is needed: e.g. if $R = \mathbb{Z}_8$, then 2 and 6 have to be in the same class (think of $x = 2y$). However, simply taking a coarser partition is not sufficient: indeed, the coarsest partition (putting all non-zero elements in the same class) has the required structure, but it only distinguishes between zero and nonzero values, and is not very useful algorithmically. Intuitively, we want to a partition such that a class assignment over $\mathbb{Z}_{p^n}$ allows us to rewrite our input as a set of equations over $\mathbb{Z}_{p^{n-1}}$ without increasing the cost too much.

A useful partition is obtained by viewing the elements of $\mathbb{Z}_{p^n}$ represented in base-p. Formally, every element $a \in \mathbb{Z}_{p^n}$ equals $\sum_{i=0}^{p-1} a_i p^i$, where the coefficients $a_0, \ldots, a_{p-1} \in \mathbb{Z}_p$ uniquely define a. Let $\vec{a} = (a_0, \ldots, a_{p-1})$, and for every $a \neq 0$, define $\mathrm{ord}(a) = \min\{i : a_i \neq 0\}$ to be the index of the first nonzero coordinate in $\vec{a}$, and $\mathrm{lsu}(a) = r_{\mathrm{ord}(a)}$ to be the least significant unit in $\vec{a}$. For completeness, let $\mathrm{ord}(0) = \mathrm{lsu}(0) = 0$. Let

$$a \equiv b \iff \mathrm{ord}(a) = \mathrm{ord}(b) \text{ and } \mathrm{lsu}(a) = \mathrm{lsu}(b).$$

This equivalence relation has two important properties. First, it is *matching*, i.e. $\{0\}$ is an equivalence class, and for every $i, j \in \mathbb{Z}_{p^n}$ and $r \in \mathbb{Z}_{p^n}$,

- if $i \equiv j$ then $ri \equiv rj$,
- if $i \not\equiv j$, then either $ri \not\equiv rj$ or $ri = rj = 0$.

Moreover, it is *absorbing*, meaning that

- $i \equiv j \implies p$ divides $i - j$ for all $i, j \in \mathbb{Z}_{p^n}$.

Let Γ_{p^n} denote the set of equivalence classes of $\equiv$, and $\Gamma_{p^n}^{\neq 0} = \Gamma_{p^n} \setminus \{\{0\}\}$. We will drop the subscript when it is clear from the context. The name "matching" comes from considering bipartite graphs $G_r^{\neq 0}$ defined by binary equations $u = rv$ for every $r \in R$ as follows: let $V(G_r) = \Gamma^{\neq 0} \uplus \Gamma^{\neq 0}$ and let there be an edge between two classes C_1 on the left and C_2 on the right if and only if $i = rj$ for some $i \in C_1$ and $j \in C_2$. Then $\equiv$ being matching implies that $G_r^{\neq 0}$ is a matching for every r, i.e. every vertex has degree at most 1.

▶ **Example 6.** Partition Γ_{3^2} (with elements written in base-3) has classes

$$\{01_3, 11_3, 21_3\}, \{02_3, 12_3, 22_3\}, \{10_3\}, \{20_3\}, \{00_3\}.$$

For another example, Γ_{2^3} has classes

$$\{001_2, 011_2, 101_2, 111_2\}, \{010_2, 110_2\}, \{100_2\}, \{000_2\}.$$

For a non-example, a coarser partition of $\mathbb{Z}_{2^3}$ into three classes

$$\{001_2, 011_2, 101_2, 111_2\}, \{010_2, 110_2, 100_2\}, \{000_2\}.$$

lacks the matching property (as is evident from the equation $x = 2y$ in Figure 1).

The matching property of $\equiv$ is crucial for the main algorithmic lemma, which we state below and prove in Section 3.2. A value assignment $\alpha : V(S) \to \mathbb{Z}_{p^n}$ *agrees with* a class assignment $\tau : V(S) \to \Gamma$ if $\alpha(v) \in \tau(v)$ for all $v \in V(S)$. A class assignment τ *respects* an equation e if it admits a satisfying assignment that agrees with τ, otherwise we say that τ *violates* e. Define the cost of a class assignment τ to be the number of equations in S that it violates. Note that every value assignment α uniquely defines a class assignment $\tau_\alpha : V(S) \to \Gamma_{p^n}$, so we say that α *strongly violates* an equation e if τ_α violates e. Clearly, an optimal assignment can violate at most k equations in S, and we can guess the number $q \in \{0, \ldots, k\}$ of strongly violated equations.

▶ **Lemma 7.** *Let p be a prime, n be a positive integer, and let k and q be integers with $k \geq q$. There is a randomized algorithm that takes a simple instance S of 2-Lin($\mathbb{Z}_{p^n}$) and integers k and q as input, and in $O^*(2^{O(k)})$ time returns a class assignment $\tau : V(S) \to \Gamma_{p^n}$ such that the following holds. Let Y be the set of equations in S violated by τ. Then have $|Y| \leq 2q$. Moreover, if S admits an assignment of cost at most k that strongly violates at most q equations, then with probability at least $2^{-O(k+q^2)}$, $S - Y$ admits an assignment of cost at most $k - |Y|/2$ that agrees with τ.*

While technical details are deferred to Section 3.2, we remark that we can no longer use branching in the style of Digraph Pair Cut when working over non-fields since some conformal cuts of low cost correspond to class assignments of high cost. For an extreme example over $\mathbb{Z}_8$, consider the system of equations $\triangle = \{x = 4, 2a = x, 3a = b, 3b = c, 3c = a\}$. By the construction of $G(\triangle)$, the vertex t is isolated and the connected component U of s contains vertices s, $x_{\{4\}}$, $a_{\{2,6\}}$, $b_{\{2,6\}}$ and $c_{\{2,6\}}$. Hence, $\delta(U)$ is empty and conformal, but the cost of $\triangle$ is at least 1 because the system is inconsistent (this follows from considering both possible values for a, which are 2 and 6). In fact, the cost is exactly 1 because it is sufficient to delete $2a = x$. To mitigate this issue of "invisible" future costs, we use shadow removal in the class assignment graph followed by branching on the shadow components.

Now, to explain how the absorbing property of $\equiv$ is used, we need some definitions. Choose an arbitrary representative element $C^\sim$ from every equivalence class $C \in \Gamma$. Consider a simple equation e and a class assignment $\tau : V(e) \to \Gamma$ to its variables that respects e. For unary equations $e = (u = r)$, define $e' = \text{next}(e, \tau)$ to be

$$u' = \frac{r - \tau(u)^\sim}{p}.$$

For binary equations $e = (u = rv)$, define $e' = \text{next}(e, \tau)$ to be

$$u' = rv' + \frac{r\tau(v)^\sim - \tau(u)^\sim}{p}.$$

The absorbing property implies that $\text{next}(e, \tau)$ is defined in both cases. Indeed, if $e = (u = r)$ and τ respects e, then $r \in \tau(u)$ and $r \equiv \tau(u)^\sim$, so p divides $r - \tau(u)^\sim$. If $e = (u = rv)$ and τ respects e, then there is an assignment $\alpha : \{u, v\} \to \mathbb{Z}_{p^n}$ such that $\alpha(u) = r\alpha(v)$, $\alpha(u) \in \tau(u)$ and $\alpha(v) \in \tau(v)$. Equivalently, $\alpha(u) - r\alpha(v) = 0$ and p divides both $\tau(u)^\sim - \alpha(u)$ and $\tau(v)^\sim - \alpha(v)$, hence p also divides any linear combination of these two values, particularly

$$r(\tau(v)^\sim - \alpha(v)) - (\tau(u) - \alpha(u)^\sim) = r\tau(v)^\sim - \tau(u)^\sim + (\alpha(u) - r\alpha(v)) = r\tau(u)^\sim - \tau(v)^\sim.$$

▶ **Lemma 8 (⋆).** *Let p be a prime and $n \in \mathbb{Z}_+$. Let e be a simple equation over $\mathbb{Z}_{p^n}$, and $\tau : V(e) \to \Gamma$ be a class assignment. Then τ respects e if and only if* $\text{next}(e, \tau)$ *is satisfiable over $\mathbb{Z}_{p^{n-1}}$.*

Now we combine all ingredients to prove the main theorem.

▶ **Theorem 1.** *For every $m \in \mathbb{Z}_+$, Min-2-Lin($\mathbb{Z}_m$) is* FPT*-approximable within $2\omega(m)$.*

Proof. Let $m = p_1^{n_1} \cdots p_\ell^{n_\ell}$ be the prime factorization of m. Note that $\omega(m) = \ell$, so by Proposition 4, it suffices to show that Min-2-Lin($\mathbb{Z}_{p^n}$) is FPT-approximable within factor 2 for every prime p and positive integer n. We proceed by induction on n. If $n = 1$, then we can use the algorithm of [8] for Min-2-Lin over fields to solve the problem exactly. Otherwise, let (S, k) be an instance of Min-2-Lin($\mathbb{Z}_{p^n}$). By Lemma 5, we may assume without loss of generality that S is simple.

Select a value $q \in \{0, \ldots, k\}$ uniformly at random and run the algorithm from Lemma 7 on (S, k, q) to produce a class assignment $\tau : V(S) \to \Gamma_{p^n}$. Let Y be the set of equations in S violated by τ. If $|Y| > 2q$, then reject (S, k). Otherwise, create an instance S' of 2-Lin($\mathbb{Z}_{p^{n-1}}$) with $V(S') = \{v' : v \in V(S)\}$ and $S' = \{\text{next}(e, \tau) : e \in S - Y\}$. Set $k' = k - \lceil |Y|/2 \rceil$ and pass (S', k') as input to the algorithm for Min-2-Lin($\mathbb{Z}_{p^{n-1}}$), and return the same answer.

Towards correctness, first assume (S, k) is a yes-instance, and let q be the number of equations strongly violated by an optimal assignment to S. Our guess for q is correct with probability $\frac{1}{k+1}$. By Lemma 7, with probability $2^{-O(q^2)}$, we have $|Y| \leq 2q$ and $S - Y$ admits an assignment of cost at most $k - |Y|/2$ that agrees with τ. By Lemma 8, the instance S' of 2-Lin($\mathbb{Z}_{p^{n-1}}$) we create has cost at most k', so we accept.

For the other direction, suppose the algorithm accepts. Then (S', k') is a yes-instance of Min-2-Lin($\mathbb{Z}_{p^{n-1}}$), and by Lemma 8, mincost$(S - Y) \leq k - |Y|/2$. Let Z be an optimal solution to $S - Y$. Then $Y \cup Z$ is a solution to S, and $|Y \cup Z| \leq |Y| + |Z| \leq 2(k - |Y|/2) + |Y| \leq 2k$.

We remark that all steps in the algorithm can be derandomized either by exhaustive branching or standard methods in [28]. ◀

3.2 Computing Class Assignments

This subsection is devoted to a proof of Lemma 7. To achieve this we introduce the class assignment graph (Section 3.2.1) and show that certain cuts in this graph correspond to class assignments (Section 3.2.2), which themselves correspond to solutions of Min-2-Lin($\mathbb{Z}_{p^n}$). We then use shadow removal and branching to compute these cuts (Section 3.2.3). Throughout this section, we consider the ring $\mathbb{Z}_{p^n}$ for prime number p and integer n.

3.2.1 The Class Assignment Graph

In what follows, let (S, k) be a simple instance of Min-2-Lin($\mathbb{Z}_{p^n}$) and let $\equiv$ be the matching and absorbing equivalence relation on $\mathbb{Z}_{p^n}$ defined in Section 3.1. Without loss of generality, we assume that every equation of S is consistent (otherwise we can remove the equation and decrease k by 1) and non-trivial (otherwise we can remove the equation). We first use the matching property of $\equiv$ to define the mapping $\pi_e : \Gamma_{p^n}^{\neq 0} \to \Gamma_{p^n}$ between equivalence classes for any equation $e = (ax = y)$ with $a \in \mathbb{Z}_{p^n} \setminus \{0\}$, as follows. For every $C \in \Gamma_{p^n}^{\neq 0}$, we set:

- $\pi_e(C) = 0$ if $ar = 0$ for every $r \in C$ and
- $\pi_e(C) = D$ otherwise, where D is the unique equivalence class such that e maps C to D. This is uniquely defined since $\equiv$ has the matching property.

For an equation $e = (x = a)$ with $a \in \mathbb{Z}_{p^n}$, we let π_e be the unique equivalence class $\Gamma_{p^n}(a)$ consistent with e. We can now define the *class assignment* graph $G = G(S)$; see Figure 2 for an illustration. The graph G has two distinguished vertices s and t together with vertices x_C

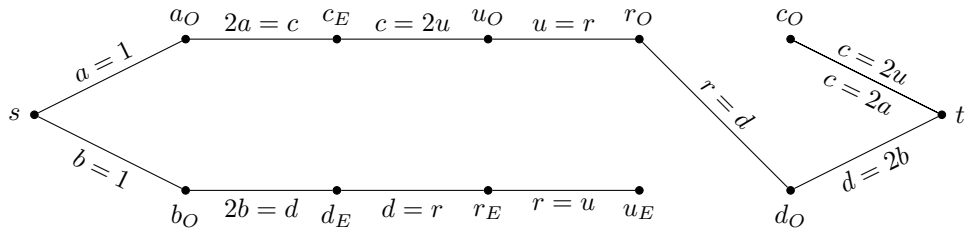

Figure 2 Let S be the instance of 2-Lin($\mathbb{Z}_4$) with variables a, b, c, d, u, r and equations $a = 1$, $b = 1$, $2a = c$, $c = 2u$, $u = r$, $2b = d$, and $d = r$. The figure illustrate the class assignment graph $G = G(S)$. Note that $\equiv$ has only two non-zero equivalence classes, namely, $E = \{2\}$ and $O = \{1, 3\}$. Every edge of G is annotated with the equation that implies it. A minimum conformal st-cut is given by the two edges that correspond to the equation $u = r$ and corresponds to the class assignment $a = O$, $b = O$, $c = E$, $d = E$, $u = O$, and $r = E$. Note that G has only one minimal conformal st-cut closest to s, namely $\{a_O c_E, b_O d_E\}$. This st-cut corresponds to the class assignment $a = O$, $b = O$, and $c = d = u = r = 0$. Therefore, the optimum solution for S only removes the equation $u = r$, however, any solution that corresponds to a minimum conformal st-cut closest to s has to remove the equations $2a = c$ and $2b = d$.

for every $x \in V(S)$ and every non-zero class $C \in \Gamma_{p^n}^{\neq 0}$. Moreover, G contains the following edges for each equation.

- For an equation $e = (ax = y)$ do the following. For every $C \in \Gamma_{p^n}^{\neq 0}$, add the edge $x_C y_{\pi_e(C)}$ if $\pi_e(C) \neq 0$. For every $D \in \Gamma_{p^n}^{\neq 0}$ such that $\pi_e^{-1}(D)$ is undefined, add the edge $y_D t$. If the equation is crisp, then the edges are crisp as well.
- For a crisp equation $e = (x = 0)$, add the crisp edge $x_C t$ for every class $C \in \Gamma_{p^n}^{\neq 0}$.
- For a crisp equation $e = (x = b)$, where $b \neq 0$, add the crisp edge $s x_{\pi_e}$.

Intuitively, every node of G corresponds to a Boolean variable and every edge e of G corresponds to an "if and only if" between the two Boolean variables connected by e. Moreover, every assignment φ of the variables of S naturally corresponds to a Boolean assignment, denoted by φ_G of the vertices in G by setting $s = 1$, $t = 0$, and:

- if $\varphi(x)$ belongs to the non-zero class C, then we set $x_C = 1$ and $x_{C'} = 0$ for every non-zero class C' not equal to C,
- if $\varphi(x) = 0$, we set $x_C = 0$ for every non-zero class C.

We say that an edge e of G is satisfied by φ if φ_G satisfies the "if and only if" Boolean constraint represented by that edge.

▶ **Observation 9.** *Let S be a simple instance of 2-Lin($\mathbb{Z}_{p^n}$), let φ be an assignment of S and pick $e \in S$. If φ satisfies e, then φ_G satisfies all edges corresponding to e in $G(S)$.*

3.2.2 Cuts in the Class Assignment Graph

In this section, we introduce *conformal cuts* and show how they relate to class assignments and solutions to Min-2-Lin($\mathbb{Z}_{p^n}$) instances. Let S be a simple instance of 2-Lin($\mathbb{Z}_{p^n}$) and $G = G(S)$. An st-cut Y in G is *conformal* if for every variable $x \in V(S)$ at most one vertex x_C for some $C \in \Gamma_{p^n}^{\neq 0}$ is connected to s in $G - Y$. Please refer to Figure 2 for an illustration of conformal cuts in the class assignment graph. If Y is a conformal st-cut in G, then we say that a variable x is *decided* with respect to Y if (exactly) one vertex x_C is reachable from s in $G - Y$; and otherwise we say that x is *undecided* with respect to Y. Moreover, we denote by τ_Y the assignment of variables of S to classes in Γ_{p^n} implied by Y, i.e. $\tau_Y(x) = 0$ if x is undecided and otherwise $\tau_Y(x) = C$, where C is the unique non-zero class in Γ_{p^n} such that

x_C is reachable from s in $G - Y$. We say that an assignment φ of S *agrees with* Y if $\varphi(x)$ is in the class $\tau_Y(x)$ for every variable x of S. Note that if some assignment agrees with Y, then Y is conformal. The following auxiliary lemma characterizes which edges of G are satisfied by an assignment φ of S after removing a set Y of edges from G.

▶ **Lemma 10.** *Let Y be a set of edges of G and let φ be an assignment of S. Then, φ_G satisfies all edges reachable from s in $G - Y$ if and only if φ_G sets all Boolean variables reachable from s in $G - Y$ to 1. Similarly, φ_G satisfies all edges reachable from t in $G - Y$ if and only if φ_G sets all Boolean variables reachable from t in $G - Y$ to 0.*

Proof. This follows because $\varphi_G(s) = 1$ and $\varphi_G(t) = 0$ for any φ and every edge of G corresponds to an "if and only if" between the variables corresponding to its two endpoints. ◀

For a set Z of equations of S, we let $\mathsf{ed}(Z)$ denote the set of all edges of G corresponding to an equation of Z. Conversely, for a set Y of edges of G, we let $\mathsf{eqn}(Y)$ denote all equations of S having a corresponding edge in Y. Moreover, if Y is an st-cut in G, we let $\mathsf{sep}(Y)$ denote the unique minimal st-cut contained in Y that is *closest* to s in G. Finally, for an optimal solution Z of S, we let $\overline{Z}$ be the set of equations $Z \setminus \mathsf{eqn}(\mathsf{sep}(\mathsf{ed}(Z)))$, i.e. all equations in Z that do not have an edge in $\mathsf{sep}(\mathsf{ed}(Z))$. We can now establish the connection between solutions of Min-2-Lin($\mathbb{Z}_{p^n}$) instances and conformal st-cuts in the class assignment graph.

▶ **Lemma 11** ($\star$)**.** *Let Z be a set of equations such that $S - Z$ is satisfiable and let $Y = \mathsf{ed}(Z)$. Then, $Y' = \mathsf{sep}(Y)$ satisfies:*

1. *Y' is a conformal st-cut.*
2. *$|Y'| \leq 2|\mathsf{eqn}(Y')| = 2|Z \setminus \overline{Z}|$.*
3. *There is a satisfying assignment for $S - Z$ that agrees with Y'.*

Proof Sketch. Let φ be a satisfying assignment of $S - Z$. Observation 9 implies that φ_G satisfies all edges of $G - Y$. Therefore, it follows from Lemma 10 that φ_G sets all vertices reachable from s in $G - Y$ to 1 and all vertices reachable from t in $G - Y$ to 0. Thus, Y is an st-cut, because otherwise t would have to be set to 1 by φ_G since it would be reachable from s in $G - Y$. Therefore, $Y' = \mathsf{sep}(Y)$ exists. Because Y' is closest to s, it holds that a vertex is reachable from s in $G - Y$ if and only if it is reachable from s in $G - Y'$. Therefore, if at least two vertices x_C and $x_{C'}$ for some distinct non-zero classes C and C' are reachable from s in $G - Y'$ for some variable x, then all of them must be set to 1 by φ_G, which is not possible due to the definition of φ_G. We conclude that Y' is conformal.

Towards showing that $|Y'| \leq 2|\mathsf{eqn}(Y')|$, it suffices to show that $|Y' \cap \mathsf{ed}(e)| \leq 2$ for every equation $e \in Z$. Note that because Y' is a minimal st-cut, it holds that one of the endpoints of every $y \in Y'$ is reachable from s in $G - Y'$. Therefore, because Y' is conformal, Y' can contain at most two edges in $\mathsf{ed}(e) = \{\, x_C y_{\pi_e(C)} \mid C \in \Gamma_{p^n}^{\neq 0} \wedge \pi_e(C) \neq 0 \,\} \cup \{\, y_D t \mid D \in \Gamma_{p^n}^{\neq 0} \wedge \pi_e^{-1}(D) \text{ is undefined} \,\}$ for every binary equation e of the form $ax = y$. Similarly, Y' can contain at most one edge in $\mathsf{ed}(e) = \{\, x_C t \mid C \in \Gamma_{p^n}^{\neq 0} \,\}$ for every unary equation e of the form $x = 0$. Finally, $|\mathsf{ed}(e)| = |\{s x_{\pi_e}\}| = 1$ for every unary equation e of the form $x = b$. Therefore, $|Y'| \leq 2|\mathsf{eqn}(Y')|$, and $Y' = Z \setminus \overline{Z}$ by definition.

Let D be the set of all variables of S such that no vertex x_C is reachable from s in $G - Y'$. Let φ' be the assignment for S such that $\varphi'(x) = 0$ if $x \in D$ and $\varphi'(x) = \varphi(x)$ otherwise. Clearly, φ' agrees with Y', because φ agrees with all variables not in D and all other variables are correctly set to 0 by φ'. It therefore only remains to show that φ' still satisfies $S - Z$, which we leave to the full version of the paper. ◀

3.2.3 Shadow Removal

We show how shadow removal (introduced in [28] and improved in [5]) can be used for computing conformal cuts that correspond to solutions of a MIN-2-LIN($\mathbb{Z}_{p^n}$) instance. We follow [5] and begin by importing some definitions, which we translate from directed graphs to undirected graphs to fit our setting; to get back to directed graphs one simply has to think of an undirected graph as the directed graph obtained after replacing each undirected edge with two directed arcs in both directions. Let G be an undirected graph. Let $\mathcal{F}$ be a set of connected subgraphs of G. A set $T \subseteq V(G)$ is an *$\mathcal{F}$-transversal* if T intersects every subgraph in $\mathcal{F}$. Conversely, if T is an $\mathcal{F}$-transversal, we say that $\mathcal{F}$ is *T-connected*.

▶ **Theorem 12** ([5]). *Let G be an undirected graph, $T \subseteq V(G)$ and $k \in \mathbb{N}$. There is a randomized algorithm that takes (G, T, k) as input and returns in $O^*(4^k)$ time a set $W \subseteq V(G) \setminus T$ such that the following holds with probability $2^{-O(k^2)}$. For every T-connected family of connected subgraphs $\mathcal{F}$ in G, if there is an $\mathcal{F}$-transversal of size at most k in $V(G) \setminus T$, then there is an $\mathcal{F}$-transversal $Y \subseteq V(G) \setminus (W \cup T)$ of size at most k such that every vertex $v \notin W \cup Y$ is connected to T in $G - Y$.*

The following lemma is crucial for the application of shadow removal (Theorem 12). Informally, it shows that if Z is a solution, i.e. a set of equations such that $S - Z$ is satisfiable, then we can obtain a (not too large) new solution $Z' = (\overline{Z} \cup \mathsf{eqn}(Y'))$ by replacing the corresponding conformal minimal sA-cut $Y = \mathsf{sep}(\mathsf{ed}(Z))$, where A is the set of vertices in G not reachable from s in $G - Y$, by any minimal sA-cut Y'.

▶ **Lemma 13.** *Let S be a simple instance of 2-LIN($\mathbb{Z}_{p^n}$) and $G = G(S)$. Moreover, let Z be a set of equations such that $S - Z$ is satisfiable, $Y = \mathsf{sep}(\mathsf{ed}(Z))$, A be the set of all vertices in G that are not reachable from s in $G - Y$, and let Y' be an sA-cut in G. Then, there is an assignment $\varphi : V(S) \to \mathbb{Z}_{p^n}$ of S that satisfies $S - Z'$ and agrees with Y', where $Z' = (\overline{Z} \cup \mathsf{eqn}(Y'))$.*

Proof. Lemma 11 implies that Y is conformal and there is a satisfying assignment φ for $S - Z$ that agrees with Y. Because Y' is also an sA-cut in G, if no vertex x_C is reachable from s in $G - Y$ for some variable x of S, then the same applies in $G - Y'$. Let D be the set of all variables x of S such that some vertex x_C is reachable from s in $G - Y$ but that is not the case in $G - Y'$. Let φ' be the assignment obtained from φ by setting all variables in D to 0. Then, φ' agrees with Y'. We claim that φ' also satisfies $S - Z'$, where $Z' = (\overline{Z} \cup \mathsf{eqn}(Y'))$.

Consider a unary equation e of $S - Z'$ on variable x. If $x \notin D$, then $\varphi'(x) = \varphi(x)$ and therefore φ' satisfies e (because e is crisp and therefore $e \notin Z$). So suppose that $x \in D$. If e is of the form $x = 0$, then φ' satisfies e. Otherwise, e is of the form $x = b$ for some $b \neq 0$ and $G - Y'$ contains the edge sx_{π_e}. Therefore, x_{π_e} is reachable from s in $G - Y'$ contradicting our assumption that $x \in D$.

Now, consider a binary equation $e = (ax = y)$ of $S - Z'$ on variables x and y and first consider the case when $e \in Z$. Clearly, if neither a vertex x_C nor a vertex y_C is reachable from s in $G - Y'$, then $\varphi'(x) = \varphi'(y) = 0$, so e is satisfied by φ'. We next show that either no vertex x_c or no vertex y_C is reachable from s in $S - Y'$. Suppose for a contradiction that x_{C_x} and y_{C_y} are reachable from s in $S - Y'$. Let h be an arbitrary edge in $\mathsf{ed}(e) \cap Y$; such an edge h exists because $e \in Z \setminus Z'$. Because Y is a minimal st-cut, it follows that exactly one endpoint of h is reachable from s in $G - Y$ and either x_C or y_C (endpoint of h) for some $C \in \Gamma_{p^n}$ must be reachable from s in $G - Y$. We assume without loss of generality that x_C is reachable from s in $G - Y$. Because Y' is an sA-cut and Y' does not contain h, x_C is not reachable from s in $G - Y'$. But then $C \neq C_x$ and both x_C and x_{C_x} are reachable from s in $G - Y$, which contradicts that Y is conformal. It remains to consider the case when there

is a vertex x_C that is reachable from s in $G - Y'$ but no vertex y_C is reachable from s in $G - Y'$; the case when there is a vertex y_C reachable from s in $G - Y'$ but no vertex x_C reachable from s in $G - Y'$ is analogous. Since $Y' \cap \mathsf{ed}(e) = \emptyset$, we obtain that $\pi_e(C) = 0$ since otherwise either t or some $y_{C'}$ would be reachable from s in $G - Y'$. Because $\varphi'(y) = 0$, it follows that e is satisfied by φ'. This completes the proof for the case when $e \in Z$.

Suppose instead that $e \notin Z$. In this case φ satisfies e and therefore φ' also satisfies e unless exactly one of x and y is not in D. We distinguish the following cases:

- $x \notin D$ and $y \in D$. If there is no vertex x_C that is reachable from s in $G - Y'$, then the same holds in $G - Y$ so $\varphi'(x) = \varphi(x) = \varphi'(y) = 0$, which shows that φ' satisfies e. Otherwise, let x_C be reachable from s in $G - Y'$. Then, $\pi_e(C) = 0$ since otherwise either t or $y_{\pi_e(C)}$ is also reachable from s in $G - Y'$ (because $Y' \cap \mathsf{ed}(e) = \emptyset$), which in the former case contradicts our assumption that Y' is an st-cut and which in the latter case contradicts our assumption that $y \in D$. Therefore, φ' satisfies e (because $\varphi'(y) = 0$).
- $x \in D$ and $y \notin D$. We first show that there is no vertex y_C that is reachable from s in $G - Y'$. Suppose there is such a vertex y_C. Then, $\pi_e^{-1}(C)$ is undefined since otherwise $x_{\pi_e^{-1}(C)}$ is reachable from s in $G - Y'$ (because $Y' \cap \mathsf{ed}(e) = \emptyset$), which contradicts our assumption that $x \in D$. But then $y_C t \in E(G - Y')$ and t is reachable from s in $G - Y'$, which contradicts our assumption that Y' is an st-cut. Hence, there is no vertex y_C that is reachable from s in $G - Y'$, which implies that the same holds in $G - Y$ so $\varphi'(y) = \varphi(y) = \varphi'(x) = 0$, which shows that φ' satisfies e. ◀

Let $G = G(S)$ and for a set $W \subseteq V(G)$, let $\delta(W)$ be the set of edges incident to a vertex in W and a vertex in $V(G) \setminus W$. The forthcoming Lemma 14 provides a version of shadow removal adopted to our problem. Informally, it provides us with a set $W \subseteq V(G)$ such that we only have to look for conformal st-cuts that are subsets of $\delta(W)$ to obtain our class assignment; in fact it even shows that for every component C of $G[W]$ either all edges in $\delta(C)$ are part of the cut or no edge of $\delta(C)$ is part of the cut. We will use this fact in Lemma 15 to find a conformal st-cut by branching on which components of $G[W]$ are reachable from s.

More formally, if Z is a set of equations such that $S - Z$ is satisfiable and A is the set of vertices not reachable from s in G minus the conformal st-cut $\mathsf{sep}(\mathsf{ed}(Z))$ (see Lemma 11), then the lemma provides us with a set $W \subseteq V(G)$ such that there is a conformal sA-cut Y' within $\delta(W)$ of size at most $2|Z \setminus \overline{Z}|$ such that there is an assignment $\varphi : V(S) \to \mathbb{Z}_{p^n}$ for the variables in S that satisfies $S - (\overline{Z} \cup \mathsf{eqn}(Y'))$ and agrees with Y'. The main idea behind the proof is the application of Theorem 12 to the set of all walks from s to A in G to obtain the set W and to employ Lemma 13 to obtain the new solution that corresponds to the minimum sA-cut $Y' \subseteq \delta(W)$.

▶ **Lemma 14 (⋆).** *Let S be a simple instance of 2-Lin($\mathbb{Z}_{p^n}$) and let $G = G(S)$. Moreover, let Z be a set of equations such that $S - Z$ is satisfiable, $Y = \mathsf{sep}(\mathsf{ed}(Z))$, let A be the set of all vertices in G that are not reachable from s in $G - Y$, and let $q = |Z \setminus \overline{Z}|$. There is a randomized algorithm that in $\mathcal{O}^*(4^{2q})$ time takes (G, q) as input and returns a set $W \subseteq V(G) \setminus \{s\}$ such that the following holds with probability $2^{-O(q^2)}$. There is a (minimal) sA-cut Y' of size at most $2q$ satisfying:*

1. *every vertex $v \notin W$ is connected to s in $G - Y'$,*
2. *$Y' \subseteq \delta(W)$,*
3. *there is satisfying assignment for $S - (\overline{Z} \cup \mathsf{eqn}(Y'))$ that agrees with Y'.*

Moreover, for every component C of $G[W]$ the following holds:

resume *either $Y' \cap \delta(C) = \emptyset$ or $\delta(C) \subseteq Y'$,*
resume *if $t \in C$, then $\delta(C) \subseteq Y'$,*
resume *if $x_\alpha, x_{\alpha'} \in C$ for some variable x and $\alpha \neq \alpha'$, then $\delta(C) \subseteq Y'$,*
resume *if C contains some x_α for some decided variable x w.r.t. Y', then $\delta(C) \subseteq Y'$.*

The following lemma now uses the set $W \subseteq V(G)$ computed in Lemma 14 to compute a set of at most $2^{\mathcal{O}(k)}$ conformal cuts $\mathcal{Y}$ which contains a cut Y with the following property. If S has a solution Z of size at most k such that $|Z \setminus \overline{Z}| = q$, then there is a subset $Z_2 \subseteq (Z \setminus \overline{Z})$ with for which Y serves as a 2-approximation: more precisely, $|Y| \leq 2|Z_2|$, $(Z \setminus Z_2) \cup Y$ is a solution to S, and $S - ((Z \setminus Z_2) \cup Y)$ admits a satisfying assignment that agrees with Y. Observe that the cost of $S - Y$ is at most $|Z \setminus Z_2| \leq k - |Y|/2$. Now Lemma 7 is an immediate consequence of Lemma 15, i.e. instead of returning the set $\mathcal{Y}$ of conformal cuts, we choose one conformal cut $Y \in \mathcal{Y}$ uniformly at random and output the class assignment corresponding to Y. The main idea behind computing $\mathcal{Y}$ is to use the fact that we only need to consider conformal cuts that are within $\delta(W)$ and this allows us to branch on which components of $G[W]$ are reachable from s (see also Property **4.** in Lemma 14).

▶ **Lemma 15** ($\star$). *Let S be a simple instance of 2-Lin($\mathbb{Z}_{p^n}$) and let k and q with $k \geq q$ be integers. There is a randomized algorithm that takes (S, k, q) as input and returns in $\mathcal{O}^*(2^{\mathcal{O}(k)})$ time a set $\mathcal{Y}$ of at most $2^{\mathcal{O}(k)}$ conformal cuts (each of size at most $2q$), such that if S has a solution Z of size at most k such that $q = |Z \setminus \overline{Z}|$ then with probability at least $2^{-O(k+q^2)}$ there is a cut $Y \in \mathcal{Y}$ with the following property: there is a partition $Z = Z_1 \cup Z_2$ where $\overline{Z} \subseteq Z_1$ and $|Y| \leq 2|Z_2|$, and an assignment that satisfies $S - (Z_1 \cup \mathsf{eqn}(Y))$ and agrees with Y.*

4 Hardness of FPT-Approximation

We complement the approximation algorithm with hardness results: we prove (1) that for finite, commutative, non-trivial rings R, Min-r-Lin(R) is W[1]-hard to FPT-approximate within any constant when $r \geq 3$ and (2) the existence of finite commutative rings R such that Min-2-Lin(R) is W[1]-hard to FPT-approximate within any constant.

Let G denote an arbitrary Abelian group. An expression $x_1 + \cdots + x_r = c$ is an *equation over* G if $c \in G$ and $x_1, \ldots, x_r$ are either variables or inverted variables with domain G. We say that it is an *r-variable equation* if it contains at most r distinct variables. A *cyclic* group is generated by a single element and every finite cyclic group C_n of order n is isomorphic to the additive group of $\mathbb{Z}_n$. Cyclic groups are the building blocks of more complex Abelian groups: the fundamental theorem of finite Abelian groups asserts that every finite Abelian group is a direct sum of cyclic groups whose orders are prime powers.

We consider the natural group-based variant Min-r-Lin(G) of the Min-r-Lin(R) problems in what follows. We first prove that Min-3-Lin(C_p), with p a prime, is not FPT-approximable within any constant if FPT $\neq$ W[1]. Our result is based on a reduction from a fundamental problem in coding theory: the Maximum Likelihood Decoding problem over $\mathbb{Z}_p$ with p prime. Here we are given a matrix $A \in \mathbb{Z}_p^{n \times m}$, a vector $b \in \mathbb{Z}_p^m$, and the goal is to find $x \in \mathbb{Z}_p^n$ such that $Ax = b$ with minimum Hamming weight, i.e. the one that minimizes $k = |\{i \in [n] : x_i \neq 0\}|$. The parameter is k. Theorem 5.1 in [2] proves that for every prime p, the problem MLD_p is W[1]-hard to approximate within any constant factor.

Intuitively, row i in $Ax = b$ is a linear equation $\sum_{j=1}^{n} a_{ij} x_j = b_j$, where $a_{ij}, b_j \in \mathbb{Z}_p$ are coefficients and x_j are variables. There is a straightforward way to subdivide long equations into ternary equations: for example, if we have an equation $x_1 + x_2 + x_3 + x_4 = 1$, we can introduce auxiliary variables y_1, y_2, y_3 and write

$$x_1 + x_2 - y_1 = 0, \quad y_1 + x_3 - y_2 = 0, \quad y_2 + x_4 - y_3 = 0 \quad \text{and} \quad y_3 = 1.$$

When summing up these equations, auxiliary variables cancel out and we obtain $x_1 + x_2 + x_3 + x_4 = 1$. Using this trick, we encode the constraints implied by the row equations of

$Ax = b$ as crisp ternary and unary equations. To encode the objective function, i.e. the fact that we are minimizing the Hamming weight of x, we add soft equations $x_j = 0$ for all $j \in [n]$. This way, breaking a soft equation corresponds to increasing the Hamming weight by 1. This hardness result for C_p, with p prime, can be lifted into the general case via two simple steps: algebraic manipulations allow us to show hardness for C_{p^l}, $l \geq 1$, and this implies hardness for Min-r-Lin(G) by recalling that G is a direct sum of cyclic groups of prime power order. We obtain the following due to the additive group of every ring being Abelian.

▶ **Theorem 16** (⋆). *Let R be a non-trivial finite ring. Min-r-Lin(R) is* W*[1]-hard to* FPT*-approximate within any constant factor when $r \geq 3$.*

We use Theorem 16 to demonstrate that there exist finite commutative rings such that Min-2-Lin(R) is W[1]-hard to FPT-approximate within any constant factor. Let R denote the 16-element polynomial ring $\mathbb{Z}_2[\mathsf{x},\mathsf{y}]/(\mathsf{x}^2,\mathsf{y}^2)$, i.e. the ring with coefficients from $\mathbb{Z}_2$ and indeterminates x,y with x^2 and y^2 factored out. An element $r \in R$ is thus a sum $r_{\mathsf{unit}} + r_x\mathsf{x} + r_y\mathsf{y} + r_{xy}\mathsf{xy}$, where $r_{\mathsf{unit}}, r_x, r_y, r_{xy} \in \mathbb{Z}_2$. The idea is to express equations of length 3 over $\mathbb{Z}_2$ using equations of length 2 over R. We illustrate this by considering an equation $a + b + c = 0$ over $\mathbb{Z}_2$. To express it using binary equations over R, we introduce a fresh variable v and three equations (1) $\mathsf{x}v = \mathsf{xy}b$, (2) $\mathsf{y}v = \mathsf{xy}a$, and (3) $(\mathsf{x}+\mathsf{y})v = -\mathsf{xy}c$. Summing up the first two equations, we obtain $(\mathsf{x}+\mathsf{y})v = \mathsf{xy}(a+b)$. Together with the third one, this implies $\mathsf{xy}(a+b+c) = 0$. On the other hand, any assignment that satisfies $\mathsf{xy}(a+b+c) = 0$ can be extended as $v = \mathsf{x}a + \mathsf{y}b$ to satisfy all three binary equations. With this in mind, it is not too difficult to prove the following with the aid of Theorem 16.

▶ **Theorem 17** (⋆). *Min-2-Lin(R) is* W*[1]-hard to* FPT*-approximate within any constant factor when $R = \mathbb{Z}_p[\mathsf{x}_1,\ldots,\mathsf{x}_k]/(\mathsf{x}_1^2,\ldots,\mathsf{x}_k^2)$, p prime, and $k \geq 2$.*

A Simple Algorithm for Trimmed Multipoint Evaluation

Nick Fischer
INSAIT, Sofia University "St. Kliment Ohridski", Bulgaria

Goethe University Frankfurt, Germany

Leo Wennmann
University of Southern Denmark, Odense, Denmark

Abstract

Evaluating a polynomial on a set of points is a fundamental task in computer algebra. In this work, we revisit a particular variant called *trimmed* multipoint evaluation: given an n-variate polynomial with bounded individual degree d and total degree D, the goal is to evaluate it on a natural class of input points. This problem arises as a key subroutine in recent algorithmic results [Dinur; SODA '21], [Dell, Haak, Kallmayer, Wennmann; SODA '25]. It is known that trimmed multipoint evaluation can be solved in near-linear time [van der Hoeven, Schost; AAECC '13] by a clever yet somewhat involved algorithm. We give a *simple* recursive algorithm that avoids heavy computer-algebraic machinery, and can be readily understood by researchers without specialized background.

1 Introduction

One of the most fundamental problems in computer algebra is to efficiently evaluate a polynomial P on some set of points, known as the *multipoint evaluation* problem. Besides its importance as one of the most basic algebraic primitives, this problem finds many further applications in computer algebra (such as modular composition and polynomial factorization) and in algorithm design beyond (in diverse fields such as computational geometry, coding theory and cryptography). The inverse task, to *interpolate* a polynomial from a given set of evaluations, is an equally important primitive.

For univariate polynomials, a textbook algorithm [10, 26] solves the multipoint evaluation problem in near-linear time. This algorithm generalizes to multivariate polynomials [20] (via a simple divide-and-conquer method sometimes referred to as *Yates' algorithm* [28]), however, only in the restricted setting where the evaluation points form a cartesian *grid*. Specifically, Yates' algorithm evaluates an n-variate polynomials with individual degree d on all points of a grid

$$Z = \{z_{1,0}, \dots, z_{1,d}\} \times \cdots \times \{z_{n,0}, \dots, z_{n,d}\}$$

in near-optimal time[1] $O^*((d+1)^n)$. Lifting this restriction to grid points has been the focus of a long and active line of research [18, 23, 15, 25, 6, 24, 2, 1] which, following breakthroughs by Umans [23] and Kedlaya and Umans [15], only recently culminated in an algorithm with almost-optimal running time $(d+1)^{(1+o(1))n}\operatorname{poly}(n, d, \log|\mathbb{F}|)$, for all finite fields $\mathbb{F}$ and for $(d+1)^n$ arbitrary evaluation points, due to Bhargava, Ghosh, Guo, Kumar and Umans [1]. This fully settles the multipoint evaluation problem for *dense* polynomials (over finite fields), but leaves open whether almost-linear time can also be achieved for (some classes of) *sparse* polynomials and evaluation points.

In this paper we focus on one natural such class, called *trimmed* multipoint evaluation, with important applications in the design of exact and parameterized algorithms. Trimmed multipoint evaluation can be solved in near-linear time by an algorithm due to van der Hoeven and Schost [25]. Our contribution is that we make this result accessible to modern algorithm design (beyond computer algebra) by distilling a particularly *simple* recursive algorithm.

Trimmed Multipoint Evaluation

In the trimmed multipoint evaluation problem we focus on the class of n-variate polynomials P with individual degree d *and total degree*[2] D. This is a very natural class of polynomials which, for $D \ll nd$, is exponentially sparser than polynomials with just an individual degree bound. As evaluation points we consider triangular subsets of grids Z defined by

$$\{(z_{1,\ell_1}, \ldots, z_{n,\ell_n}) : \ell \in \{0, \ldots, d\}^n,\ \ell_1 + \cdots + \ell_n \leq D\} \subseteq Z,$$

to which we will informally refer as *trimmed* grids. This is arguably the most naturally matching class of evaluation points. To see this, first observe that the number of relevant (i.e., possibly nonzero) coefficients of P equals exactly the number of grid points. We denote this number by $\binom{n}{\leq D}_d$ (which can be seen as an appropriate generalization of a binomial coefficient called an *extended* binomial coefficient). More importantly, it turns out that the polynomial P is *uniquely* determined by the evaluations on an appropriate trimmed grid, i.e., we can interpolate P given only these evaluations. Trimmed grids are, in a sense, the only sets of evaluation points satisfying this property; see [22].

Applications

Besides being a natural problem in its own right, our interest in trimmed multipoint evaluation stems mainly from its applications in the context of exponential-time algorithms, most notably in a line of research on solving systems of polynomial equations [17, 7, 13, 12]. In this problem the input consists of n-variate polynomials $P_1, \ldots, P_m$ over some finite field $\mathbb{F}_q$ with (total) degree Δ, and the task is to test if all polynomials simultaneously vanish at some point $x \in \mathbb{F}_q^n$, i.e., $P_1(x) = \cdots = P_m(x) = 0$. The initial breakthrough due to Lokshtanov, Paturi, Tamaki, Williams and Yu [17] established that this problem can be solved exponentially faster than brute-force, in time $(q-\epsilon)^n$ for some $\epsilon > 0$, whenever q and Δ are constant. This inspired several follow-up papers aiming to optimize the precise exponential running time [7, 13, 12]. Trimmed multipoint evaluation shows up as a critical subroutine in the algorithms due to

[1] Here and throughout, we write $O^*(\cdot)$ to omit polynomial factors in n and d.

[2] Recall that the *individual* degree d of a polynomial is the largest exponent of a variable in a monomial, whereas the *total* degree D is the largest sum of exponents in a monomial. E.g., $X_1^2X_2$ has individual degree $d = 2$ and total degree $D = 3$.

Dinur [13] (for multilinear polynomials, $d = q - 1 = 1$) and due to Dell, Haak, Kallmayer and Wennmann [12] (for general $d = q - 1 \geq 1$). Solving systems of polynomial equations in turn has many more applications on both the theoretical side – e.g., parity-counting directed Hamiltonian cycles [4] – and the practical side – e.g., the security of several so-called multivariate cryptosystems is based on the hardness of solving quadratic equations [13, 21, 16]. Especially for the latter it could be interesting to achieve simple, implementable algorithms.

In another closely related work, Björklund, Husfeldt, Kaski and Koivisto [5] considered trimmed[3] variants of the Zeta and Möbius transforms to develop fast algorithms for various exponential-time graph problems, such as computing the chromatic number for constant-degree-bounded graphs. The Zeta and Möbius transforms can be regarded as special cases of polynomial multipoint evaluation.[4]

State of the Art

The state of the art for trimmed multipoint evaluation, as mentioned before, is a clever algorithm with near-linear running time $O^*(\binom{n}{\leq D}_d)$ due to van der Hoeven and Schost [25]. Their algorithm is based on the classical concept of Newton interpolation (see e.g. [3]), suitably tailored to the trimmed problem (see also [27, 9, 22, 11, 14] for some more references with a more mathematical point of view). The algorithm also offers two additional benefits: (1) It even solves a strictly more general multipoint evaluation problem on arbitrary downward-closed sets of relevant coefficients and grid points. (2) van der Hoeven and Schost have optimized the lower-order factors achieving an algebraic algorithm with $O(nN \log^2 N \log\log N)$ field operations where $N = \binom{n}{\leq D}_d$. The potentially remaining lower-order improvements even persist in the univariate setting. Thus, all in all, the trimmed multipoint evaluation problem has already been satisfyingly resolved.

The only downside is that van der Hoeven and Schost's algorithm is arguably somewhat intricate – both in the sense that it can be technically demanding to understand, particularly for researchers outside the computer algebra community, and in that it relies on several textbook algebraic primitives, such as efficient conversions between polynomial bases [3] and the use of truncated Fourier transforms as an implementation detail to achieve further improvements.

Our Contribution

Our focus here is *not* to optimize the running time or generality of this state of the art. Instead, given the many exciting algorithmic applications our contribution is to make van der Hoeven and Schost's result for trimmed multipoint evaluation accessible to the algorithms community. We design a *simple* recursive algorithm that is teachable to researchers without any background in computer algebra. Moreover, our algorithm does not rely on any black-box algebraic primitives other than Gaussian elimination. As in [25], we also obtain an equally simple algorithm for the interpolation problem.

Our emphasis on simplicity clashes, however, with the additional benefits (1) and (2): (1) It seems hard to obtain a recursive algorithm for the more general problem, and (2) optimizing lower-order factors would involve dealing with more details. Besides, for exponential-time

[3] In fact, they consider a more general definition of "trimmed" allowing arbitrary downward-closed sets.

[4] Indeed, recall that the zeta transform of a function $f : \{0,1\}^n \to \mathbb{F}$ is defined as $(f\zeta)(X) = \sum_{Y \subseteq X} f(Y)$, where we identify sets $X \subseteq [n]$ with their indicator vectors $X \in \{0,1\}^n$. Consider the n-variate polynomial $P(x_1, \ldots, x_n) = \sum_{Y \subseteq [n]} f(Y) \prod_{i \in Y} x_i$, and observe that $(f\zeta)(X) = P(X)$. Thus, the zeta transform $f\zeta$ can be read off the evaluations of P on the grid $\{0,1\}^n$.

algorithms we are typically anyway not bothered with keeping track of polynomial factors. For these reasons we have decided to stick to the simplest version, resulting in a pleasingly simple 8-line algorithm.

Remark on Terminology

The term "trimmed" multipoint evaluation is inspired by the related algorithms for Zeta and Möbius transforms in [5]. It is not standard in the mathematical literature, where one more often encounters terms like "triangular subsets of tensor product grids". We adopt the "trimmed" terminology here as this paper is primarily intended for the algorithms community.

2 Preliminaries

We write $[n] = \{1, \dots, n\}$. Throughout, let $\mathbb{F}$ be a field and assume that we can evaluate field operations in unit time. For integers n, k, d with $n \geq 0$ and $d \geq 1$ we define the *extended binomial coefficient*

$$\binom{n}{k}_d = |\{\ell \in \{0, \dots, d\}^n : \ell_1 + \cdots + \ell_n = k\}|.$$

That is, $\binom{n}{k}_d$ counts the number of multisubsets of $[n]$ with size k and multiplicity at most d, or equivalently, the number of monomials with total degree k and individual degree at most d in an n-variate polynomial. In the same spirit we define the set

$$\binom{[n]}{k}_d = \{\ell \in \{0, \dots, d\}^n : \ell_1 + \cdots + \ell_n = k\}.$$

As a shorthand, we write $\binom{n}{\leq k}_d = \sum_{i=0}^{k} \binom{n}{i}_d$, and similarly define $\binom{[n]}{\leq k}_d = \bigcup_{i=0}^{k} \binom{n}{i}_d$. Further, we rely on the following generalization of Pascal's triangle; see [8].

▶ **Lemma 1** (Extended Pascal Triangle). *For $n, d \geq 1$ it holds that*

$$\binom{n}{k}_d = \sum_{j=0}^{d} \binom{n-1}{k-j}_d.$$

Throughout we refer to a set $Z = \{z_{1,0}, \dots, z_{1,d}\} \times \cdots \times \{z_{n,0}, \dots, z_{n,d}\}$ of field elements $z_{i,j}$ as a *grid*. To conveniently refer to the grid points we regularly write $Z_\ell = (z_{1,\ell_1}, \dots, z_{n,\ell_n})$ for $\ell \in \{0, \dots, d\}^n$. In particular, the subset of grid points Z_ℓ where ℓ ranges over $\binom{[n]}{\leq D}_d$ constitutes exactly a trimmed grid as introduced before.

3 Trimmed Multipoint Evaluation and Interpolation

In this section, we present a simple, algebraic algorithm for trimmed multipoint evaluation. As it is usually the case, the same algorithmic approach yields a simple algorithm for trimmed interpolation as well.

3.1 Key Ideas

The problem of evaluating univariate polynomials can be defined via the Vandermonde matrix. For $z_0, \dots, z_d \in \mathbb{F}$, define the (square) Vandermonde matrix $V \in \mathbb{F}^{(d+1)\times(d+1)}$ as

$$V = V(z_0, \dots, z_d) = \begin{pmatrix} 1 & z_0 & z_0^2 & \cdots & z_0^d \\ 1 & z_1 & z_1^2 & \cdots & z_1^d \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & z_d & z_d^2 & \cdots & z_d^d \end{pmatrix}.$$

Let $a \in \mathbb{F}^{d+1}$ be the coefficient vector of the univariate polynomial $P(X) = \sum_{i=0}^{d} a_i X^i$ of degree d. The evaluation of P at all points z_j with $j \in \{0, \dots, d\}$ can be expressed as the matrix-vector product $V \cdot a = y$ (indeed, each entry is of the form $y_j = \sum_{i=0}^{d} a_i z_j^i = P(z_j)$). Similarly, we can interpolate P from its evaluations $P(z_j)$ using the matrix-vector product $V^{-1} \cdot y = V^{-1} \cdot V \cdot a = a$. The generalization to multivariate polynomials is simple: Let $a \in \mathbb{F}^{(d+1)^n}$ be the coefficient vector of an n-variate polynomial P with individual degree d that we want to evaluate on all grid points in Z. Then the Kronecker product $V(z_{1,0}, \dots, z_{1,d}) \otimes \cdots \otimes V(z_{n,0}, \dots, z_{n,d}) \cdot a = y$ yields the vector $y \in \mathbb{F}^{(d+1)^n}$ of all grid point evaluations. The classical algorithm of Yates [28] allows to compute these evaluations recursively. Notably, this computation does *not* account for the total degree D and automatically results in a running time of $(d+1)^n$ for both multipoint evaluation and interpolation – even in our setting where the total degree D is much smaller than its maximal value nd. Consequently, we need more insights to tailor this approach to the trimmed requirements.

Idea 1: Recursion Scheme. Our goal is to achieve a running time that is linear in $\binom{n}{\leq D}_d$, i.e., in the number of grid points on which we want to evaluate a multivariate polynomial P. As a baseline, we start with a short explanation of Yates' algorithm: write $P(X_1, \dots, X_n) = \sum_{i=0}^{d} P_i(X_1, \dots, X_{n-1}) \cdot X_n^i$ to obtain $d+1$ many $(n-1)$-variate polynomials P_i of degree $D-i$, where each P_i can be seen as a coefficient of a univariate polynomial in X_n. By making $d+1$ many recursive calls of size $\binom{n-1}{\leq D}_d$, we compute the evaluations $P_i(Z_{\ell'})$ for all $\ell' \in \binom{[n-1]}{\leq D}_d$. We obtain all $P(Z_\ell)$ for $\ell \in \binom{[n]}{\leq D}_d$ by evaluating the univariate polynomials $\sum_{i=0}^{d} P_i(Z_{\ell'}) \cdot X_n^i$ at all grid points $z_{n,i}$. However, this does *not* exploit the degrees $D-i$ of the polynomials P_i in the recursive calls, and hence results in the running time of $(d+1)^n$.

Consider the following identity of the extended binomial coefficient that can be derived from Lemma 1

$$\binom{n}{\leq D}_d = \binom{n-1}{\leq D}_d + \binom{n-1}{\leq D-1}_d + \cdots + \binom{n-1}{\leq D-d}_d.$$

In light of this identity, in order to achieve a running time of $O^*\left(\binom{n}{\leq D}_d\right)$ we aim to design an algorithm with $d+1$ recursive calls on $n-1$ variables with total degrees $D, D-1, \dots, D-d$.

Idea 2: LU Decomposition. Our goal is an interleaving of the P_i's into polynomials Q_j satisfying two properties: (1) All evaluations $Q_j(Z_{\ell'})$ can be recursively computed in a call of size $\binom{n-1}{\leq D-j}_d$; in particular, Q_j must have degree $D-j$. (2) Simultaneously, we need to recover all evaluations $P(Z_\ell)$ from the recursively computed evaluations $Q_j(Z_{\ell'})$ for $\ell' \in \binom{[n-1]}{\leq D-j}_d$. Due to the degree restriction for the polynomials Q_j in (1) and evaluations $Q_j(Z_{\ell'})$ in (2), this coincides with a matrix factorization of $V = L \cdot U$ where U is upper-triangular and L lower-triangular, i.e., a LU decomposition.

Algorithm 1 `TrimmedEvaluation`(P).

Input : n-variate polynomial P of individual degree d and total degree D
Output : Evaluations $P(Z_\ell)$ for all $\ell \in \binom{[n]}{\leq D}_d$

if $n = 0$ **then return** the constant P.
Write $P(X_1, \ldots, X_n) = \sum_{i=0}^{d} P_i(X_1, \ldots, X_{n-1}) \cdot X_n^i$.
Compute the LU decomposition $V(z_{n,0}, \ldots, z_{n,d}) = L \cdot U$.
Compute the vector of polynomials

$$\begin{pmatrix} Q_0 \\ \vdots \\ Q_d \end{pmatrix} = \begin{pmatrix} U_{0,0} & \cdots & U_{0,d} \\ & \ddots & \vdots \\ & & U_{d,d} \end{pmatrix} \cdot \begin{pmatrix} P_0 \\ \vdots \\ P_d \end{pmatrix}.$$

for $j = 0, \ldots, d$ **do**
  Recursively call `TrimmedEvaluation`(Q_j) to evaluate $Q_j(Z_{\ell'})$ for $\ell' \in \binom{[n-1]}{\leq D-j}_d$.
for $\ell' \in \binom{[n-1]}{\leq D}_d$ **do**
  Let $k = \min\{d, D - \sum_{j=1}^{n-1} \ell'_j\}$ and compute all evaluations

$$\begin{pmatrix} P\big(Z_{(\ell',0)}\big) \\ \vdots \\ P\big(Z_{(\ell',k)}\big) \end{pmatrix} = \begin{pmatrix} L_{0,0} & & \\ \vdots & \ddots & \\ L_{k,0} & \cdots & L_{k,k} \end{pmatrix} \cdot \begin{pmatrix} Q_0(Z_{\ell'}) \\ \vdots \\ Q_k(Z_{\ell'}) \end{pmatrix}.$$

In more detail: Why is the LU decomposition useful in keeping the degrees of the polynomials Q_j "small"? Let $p = (P_0, \ldots, P_d)^T$ be the vector of polynomials P_i and consider the product $U \cdot p = (Q_1, \ldots, Q_d)^T = q$. Here, the upper triangular structure of U guarantees that each $Q_j = \sum_{i=j}^{d} U_{j,i} \cdot P_i$ has at most degree $D - j$, since the first non-zero entry in the j-th row of U corresponds to polynomial P_j of degree $D-j$ while all other P_i's with (possible) non-zero coefficients have a smaller degree. Additionally, we can also recover $P(Z_\ell)$ from only the recursively computed $Q_j(Z_{\ell'})$ as L has lower triangular structure – appropriately exploiting the fact that $L \cdot q = L \cdot U \cdot p = V \cdot p$.[5] With these ideas in mind, we are now in the position to present the algorithm in detail.

3.2 Trimmed Multipoint Evaluation

Throughout this section, we will prove the following theorem.

▶ **Theorem 2** (Trimmed Multipoint Evaluation). *Let P be an n-variate polynomial over $\mathbb{F}$ with individual degree d and total degree D, and let Z be a grid. The evaluations $P(Z_\ell)$ can be computed for all $\ell \in \binom{[n]}{\leq D}_d$ in time $O^*\big(\binom{n}{\leq D}_d\big)$.*

[5] The analogy to van der Hoeven and Schost's algorithm is as follows: Broadly speaking, their algorithm is based on efficient transformations between not only the coefficient and evaluation-based representations of polynomials, but also involving a third representation based on so-called *Newton polynomials*. In this terminology, the matrix U performs a basis change from the monomial basis to the Newton basis, and the matrix L performs a basic change from the Newton basis to the evaluation basis.

For the proof of Theorem 2, consider the algorithm `TrimmedEvaluation`. Throughout we assume that the algorithm has access to the grid Z and for simplicity, we omit Z in the recursive calls.

▶ **Lemma 3** (Correctness of `TrimmedEvaluation`). *Given an n-variate polynomial P over $\mathbb{F}$ with individual degree d and total degree D,* `TrimmedEvaluation` *correctly computes the evaluations $P(Z_\ell)$ for all $\ell \in \binom{[n]}{\leq D}_d$.*

Proof. Given a polynomial P and a grid Z, we show that `TrimmedEvaluation` correctly computes all evaluations $P(Z_\ell)$ by induction on n.

For $n = 0$, the polynomial P does not depend on any variable. Thus, we correctly return the constant P. For $n \geq 1$, we write $P(X_1, \ldots, X_n) = \sum_{i=0}^{d} P_i(X_1, \ldots, X_{n-1}) \cdot X_n^i$ to obtain $d+1$ many $(n-1)$-variate polynomials $P_0, \ldots, P_d$ of degrees $D, \ldots, D-d$, respectively. Formally, each polynomial P_i is the coefficient of P viewed as a univariate polynomial in X_n. Let $V := V(z_{n,0}, \ldots, z_{n,d})$ be a Vandermonde matrix. It is well-known that V is invertible if and only if all grid points $z_{n,i}$ are distinct, and in this case the LU decomposition $V = L \cdot U$ in Line 3 always exists (see e.g. [19]). Further, let $Q_0, \ldots, Q_d$ as computed in Line 4 of `TrimmedEvaluation`. Note that each polynomial $Q_j(X_1, \ldots, X_{n-1}) = \sum_{i=j}^{d} U_{j,i} \cdot P_i(X_1, \ldots, X_{n-1})$ has degree $D - j$. Indeed, the upper triangular structure of U guarantees that Q_j has at most degree $D - j$, because the first non-zero entry in the j-th row of U corresponds to the polynomial P_j of degree $D - j$ while all other P_i's with (possible) non-zero coefficients have a smaller degree.

Calling `TrimmedEvaluation`(Q_j), we recursively compute the evaluations $Q_j(Z_{\ell'})$ for all $\ell' \in \binom{[n-1]}{\leq D-j}_d$ in Lines 5 and 6. Next, we focus on any iteration ℓ' of the loop in Line 7. Let $k = \min\{d, D - \sum_{j=1}^{n-1} \ell'_j\}$, then we show that we correctly compute the evaluations $P(Z_\ell)$. For each $j \in \{0, \ldots, k\}$, we have

$$\begin{aligned}
\sum_{i=0}^{k} L_{j,i} \cdot Q_i(Z_{\ell'}) &= \sum_{i=0}^{d} L_{j,i} \cdot Q_i(Z_{\ell'}) \\
&= \sum_{i=0}^{d} L_{j,i} \cdot \sum_{m=0}^{d} U_{i,m} \cdot P_m(Z_{\ell'}) \\
&= \sum_{i=0}^{d} z_{n,j}^i \cdot P_i(Z_{\ell'}) \\
&= P\big(Z_{(\ell',j)}\big),
\end{aligned}$$

where the first equality follows from the fact that $L_{j,i} = 0$ whenever $i > k \geq j$. Notably, restricting the computation to k is crucial to ensure that we only use the evaluations $Q_j(Z_{\ell'})$ that we actually computed. This proves that `TrimmedEvaluation` correctly computes the evaluations $P\big(Z_{(\ell',0)}\big), \ldots, P\big(Z_{(\ell',k)}\big)$ in Line 8. Since each Z_ℓ can be expressed as some $Z_{(\ell',j)}$ as above, the loop in Line 7 recovers all evaluations $P(Z_\ell)$. As a result, the algorithm `TrimmedEvaluation` correctly computes all evaluations $P(Z_\ell)$. ◀

Lastly, we prove the running time of `TrimmedEvaluation`.

▶ **Lemma 4** (Running Time of `TrimmedEvaluation`). *The algorithm* `TrimmedEvaluation` *runs in time $O^*\big(\binom{n}{\leq D}_d\big)$.*

Proof. Let $T(n,d,D)$ be the running time of `TrimmedEvaluation`. The time to compute the LU decomposition in Line 4 and the matrix-vector products in Lines 5 and 9 can be bounded by $\mathrm{poly}(n,d)$. Consequently, the running time of the algorithm *without* the recursive calls in Line 7 is $\binom{n}{\leq D}_d \cdot M(n,d)$ for some function[6] $M(n,d) = \mathrm{poly}(n,d)$. Thus, the algorithm admits the following recurrence

$$T(n,d,D) \leq \binom{n}{\leq D}_d \cdot M(n,d) + \sum_{i=0}^{d} T(n-1,d,D-i).$$

By induction on n, we show that $T(n,d,D) \leq \binom{n}{\leq D}_d \cdot M(n,d) \cdot n$. Indeed, it holds that

$$\begin{aligned}
T(n,d,D) &\leq \binom{n}{\leq D}_d \cdot M(n,d) + \sum_{i=0}^{d} T(n-1,d,D-i) \\
&\leq \binom{n}{\leq D}_d \cdot M(n,d) + \sum_{i=0}^{d} \binom{n}{\leq D-i}_d \cdot M(n,d) \cdot (n-1) \\
&= \binom{n}{\leq D}_d \cdot M(n,d) + \sum_{i=0}^{d} \sum_{j=0}^{D-i} \binom{n-1}{j}_d \cdot M(n,d) \cdot (n-1) \\
&\leq \binom{n}{\leq D}_d \cdot M(n,d) + \sum_{j=0}^{D} \binom{n}{j}_d \cdot M(n,d) \cdot (n-1) \\
&= \binom{n}{\leq D}_d \cdot M(n,d) + \binom{n}{\leq D}_d \cdot M(n,d) \cdot (n-1) \\
&= \binom{n}{\leq D}_d \cdot M(n,d) \cdot n
\end{aligned}$$

Therefore, `TrimmedEvaluation` runs in time $O^*\big(\binom{n}{\leq D}_d\big)$. ◀

Combining Lemma 3 and Lemma 4 concludes the proof of Theorem 2.

3.3 Trimmed Interpolation

Throughout this section, we show that a polynomial can be (uniquely) interpolated from its evaluations on the trimmed grid points – using essentially the same algorithmic approach as in Section 3.2.

▶ **Theorem 5** (Trimmed Interpolation). *Let $\alpha_\ell \in \mathbb{F}$ for $\ell \in \binom{[n]}{\leq D}_d$, and let Z be a grid. The unique n-variate polynomial P with individual degree d and total degree D that satisfies $P(Z_\ell) = \alpha_\ell$ for all $\ell \in \binom{[n]}{\leq D}_d$ can be computed in time $O^*\big(\binom{n}{\leq D}_d\big)$.*

Consider the algorithm `TrimmedInterpolation` for the proof of Theorem 5. As before, we assume that the algorithm has access to the grid Z and for simplicity, we omit Z in the recursive calls.

[6] In our context, we are content with bounding $M(n,d) = \mathrm{poly}(n,d)$; however, let us remark that following van der Hoeven and Schost [25] we could achieve a dependence on d that is only polylogarithmic. The main insight is that the L- and U-factors of a Vandermonde matrix are sufficiently structured to support matrix-vector operations in time $O(d(\log d)^{O(1)})$.

Algorithm 2 `TrimmedInterpolation`$((\alpha_\ell)_\ell)$.

Input : Evaluations α_ℓ for all $\ell \in \binom{[n]}{\leq D}_d$
Output : Unique n-variate polynomial P of individual degree d and total degree D such that $P(Z_\ell) = \alpha_\ell$ for all $\ell \in \binom{[n]}{\leq D}_d$

1 **if** $n = 0$ **then return** the constant P.
2 Compute the LU decomposition $V(z_{n,0}, \dots, z_{n,d})^{-1} = L \cdot U$.
3 **for** $\ell' \in \binom{[n-1]}{\leq D-j}_d$ **do**
4 Let $k = \min\{d, D - \sum_{j=1}^{n-1} \ell'_j\}$ and compute all evaluations

$$\begin{pmatrix} \beta_{(\ell',0)} \\ \vdots \\ \beta_{(\ell',k)} \end{pmatrix} = \begin{pmatrix} U_{0,0} & \cdots & U_{0,k} \\ & \ddots & \vdots \\ & & U_{k,k} \end{pmatrix} \cdot \begin{pmatrix} \alpha_{(\ell',0)} \\ \vdots \\ \alpha_{(\ell',k)} \end{pmatrix}.$$

5 **for** $j = 0, \dots, d$ **do**
6 Recursively call `TrimmedInterpolation`$\big((\beta_{(\ell',j)})_{\ell'}\big)$ for $\ell' \in \binom{[n-1]}{\leq D-j}_d$ to interpolate the $(n-1)$-variate polynomial Q_j.
7 Compute the vector of polynomials

$$\begin{pmatrix} P_0 \\ \vdots \\ P_d \end{pmatrix} = \begin{pmatrix} L_{0,0} & & \\ \vdots & \ddots & \\ L_{d,0} & \cdots & L_{d,d} \end{pmatrix} \cdot \begin{pmatrix} Q_0 \\ \vdots \\ Q_d \end{pmatrix}.$$

8 Compute $P(X_1, \dots, X_n) = \sum_{i=0}^{d} P_i(X_1, \dots, X_{n-1}) \cdot X_n^i$.

▶ **Lemma 6** (Correctness of `TrimmedInterpolation`). *Given evaluations α_ℓ for $\ell \in \binom{[n]}{\leq D}_d$,* `TrimmedInterpolation` *correctly interpolates the unique n-variate polynomial P with individual degree d and total degree D such that $P(Z_\ell) = \alpha_\ell$.*

Proof. Given the evaluations α_ℓ for all $\ell \in \binom{[n]}{\leq D}_d$, we show that `TrimmedInterpolation` correctly interpolates the unique n-variate polynomial P by induction on n. If $n = 0$, simply return the constant P as it does not depend on any variable.

For the remainder of the proof we assume $n \geq 1$. Let $V := V(z_{n,0}, \dots, z_{n,d})$. It is well-known that V is invertible if and only if the grid points $z_{n,0}, \dots, z_{n,d}$ are distinct. Additionally, it implies that the LU decomposition in Line 2, namely $V^{-1} = L \cdot U$, always exists (see e.g. [19]).

In the following, we show that $P(Z_\ell) = \alpha_\ell$ for all $\ell \in \binom{[n]}{\leq D}_d$. Note that each Z_ℓ can be expressed as some $Z_{(\ell',j)}$ with $\ell' \in \binom{[n-1]}{\leq D-j}_d$ and $\sum_{i=1}^{n-1} \ell'_i + j \leq D$. Fix such a pair ℓ' and j, and let $k = \min\{d, D - \sum_{i=1}^{n-1} \ell'_i\}$. It holds that

$$\begin{aligned} P\big(Z_{(\ell',j)}\big) &= \sum_{i=0}^{d} z_{n,j}^i \cdot P_i(Z_{\ell'}) \\ &= \sum_{i=0}^{d} V_{j,i} \cdot \sum_{m=0}^{d} L_{i,m} \cdot Q_m(Z_{\ell'}) \end{aligned}$$

$$
\begin{aligned}
&= \sum_{i=0}^{d} V_{j,i} \cdot \sum_{m=0}^{d} L_{i,m} \cdot \beta_{(\ell',m)} \\
&= \sum_{i=0}^{d} V_{j,i} \cdot \sum_{m=0}^{d} L_{i,m} \cdot \sum_{h=0}^{k} U_{m,h} \cdot \alpha_{(\ell',h)} \\
&= \sum_{i=0}^{d} V_{j,i} \cdot \sum_{h=0}^{k} (V^{-1})_{i,h} \cdot \alpha_{(\ell',h)} \\
&= \sum_{h=0}^{k} I_{j,h} \cdot \alpha_{(\ell',h)} \\
&= \alpha_{(\ell',j)},
\end{aligned}
$$

where $I \in \mathbb{F}^{(d+1)\times(d+1)}$ is the identity matrix. The last equality uses the fact that $j \leq k$. Consequently, `TrimmedInterpolation` correctly interpolates the unique n-variate polynomial P with individual degree d and total degree D such that $P(Z_\ell) = \alpha_\ell$. ◀

As the recursion scheme of `TrimmedInterpolation` and `TrimmedEvaluation` are exactly the same, we refer to Lemma 4 for a proof of the running time of `TrimmedInterpolation`. This concludes the proof of Theorem 5.

Separating Two Points with Obstacles in the Plane: Improved Upper and Lower Bounds

Jack Spalding-Jamieson

Anurag Murty Naredla
University of Bonn, Germany

Abstract

Given two points in the plane, and a set of "obstacles" given as curves through the plane with assigned weights, we consider the **point-separation** problem, which asks for a minimum-weight subset of the obstacles separating the two points. A few computational models for this problem have been previously studied. We give a unified approach to this problem in all models via a reduction to a particular shortest-path problem, and obtain improved running times in essentially all cases. In addition, we also give fine-grained lower bounds for many cases.

Acknowledgements This work originated from a problem discussion group in the Fall of 2021, whose members collectively contributed to the discussion and development of some of this work's preliminary results in the "arrangement model", as well as a better understanding of the problem as a whole. In addition to the authors, this group included (in alphabetical order) Sam Barr, Therese Biedl, Reza Bigdeli, Anna Lubiw, Jayson Lynch, Karthik Murali, and Graeme Stroud.
In addition, we want to thank Jeff Erickson, Elizabeth Xiao, and Da Wei Zheng for helpful discussions about homology.

1 Introduction

Given points s and t in the plane, and a weighted set of **obstacles** $\mathcal{C}$ defined by simple closed curves (possibly also including their interiors), the (s,t) **point-separation problem** asks for a minimum-weight subset C of $\mathcal{C}$ such that any path from s to t intersects some obstacle in C. Equivalently, s and t are in different connected components of $\mathbb{R}^2 \setminus (\cup_{\gamma \in C} \gamma)$. We say such a subset **separates** s and t. An example of this problem can be found in Figure 1.

This is a natural problem that arises in various scenarios. As a toy application of this problem: Suppose every night your dog runs from his doghouse to your backpack to eat your homework, taking an unpredictable route (making use of windows and doors). You have noticed that your dog will forget about your homework if it smells a treat. You have a number of candidate locations to place treats, and you'd like to ensure your dog is distracted from your homework every day using the fewest treats possible. See Figure 2 for this example. Similar applications also arise when considering security (e.g., replacing the batteries in the fewest number of your dead security cameras to cover all possible paths from the entrance to your bank vault). Additionally, (s,t) point-separation has found an application as a tool for constant-factor approximation of the well-studied APX-hard problem "barrier-resilience" [13].

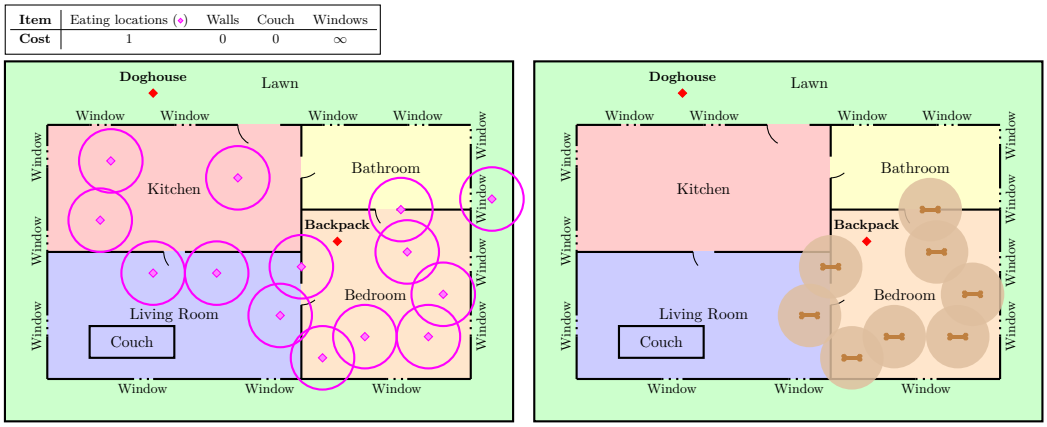

Figure 2 An example of the point-separation problem applied to placing distracting doggy treats around a house, with the minimum-weight solution on the right.

For brevity, we will henceforth say "curve" to mean a simple closed curve in $\mathbb{R}^2 \setminus \{s, t\}$. The algorithmic complexity of the (s, t) point-separation problem depends on the chosen computational model of the obstacles. Previous works use a few different models. We categorize and name the different classes of models used as follows:

- **Specific Obstacle-Type Models**: Assume the set of curves $\mathcal{C}$ takes on a special form with a standard representation, such as a set of disks, circles, or line segments.
- **The Oracle-based Intersection Graph Model**: Assume the existence of several $O(1)$-time oracles that would allow the computation of the **intersection graph** G of $\mathcal{C}$ (the graph whose vertices are exactly the curves $\mathcal{C}$ and whose edges correspond to pairwise intersections of these curves), as well as some additional information for each edge related to s and t (detailed in Section 2).
- **The Arrangement Model**: Assume the arrangement of $\mathcal{C}$ is provided as input, in the form of a plane (multi-)graph, with the faces corresponding to s and t labelled. This is a more graph-theoretic formulation. See Figure 3 for an example of such an arrangement.

Prior works discussing this problem each focused on only one of these paradigms, and the names for each paradigm are our own. We will not assume general position, so no paradigm is strictly more general than the others, since there are arrangements of n obstacles with $\Theta(n^2)$ pairwise intersections, but only $O(n)$ unique intersection points.

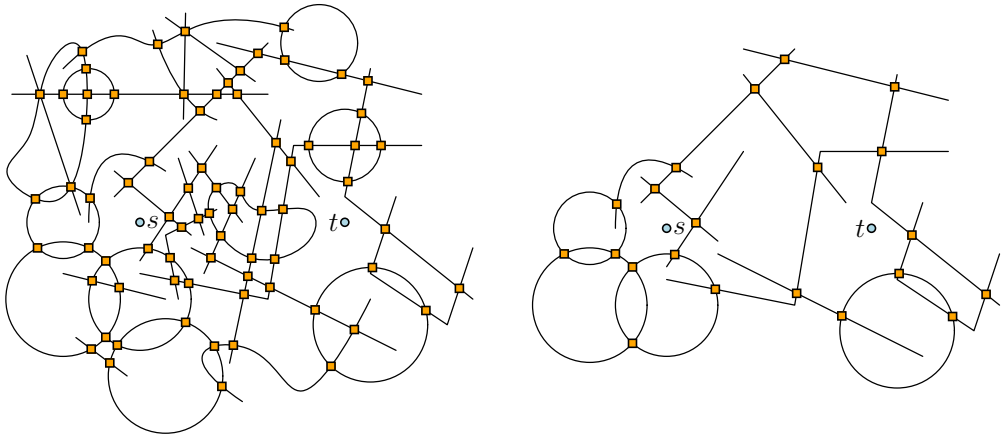

Figure 3 An arrangement representation of the instance in Figure 1, as well as an arrangement of a smaller instance.

In our work, our key method is to frame all models of this problem in terms of a "homology cover". Homology is a very broad topic in algebraic topology, which we will not attempt to summarize in this paper. We aim our paper at a typical computational geometry audience, and we will not assume prior knowledge of homology. We will present the necessary aspects in Section 2.

1.1 Prior Work (Brief)

In this subsection, we very briefly outline some key aspects of prior work. A significantly extended form of this section is in the appendix of the full version.

Most importantly for our methods, Kumar, Lokshtanov, Saurabh and Suri [13, Section 6] describe an algorithm that runs in polynomial time in the *arrangement model*. Their algorithm implicitly makes use of the homology cover (perhaps unintentionally), in the same sense that we will use it. In fact, their algorithm is in some ways analogous to an algorithm of Chambers, Erickson, Fox, and Nayyeri [5] for minimum-cuts (and maximum-flow) in surface graphs. These two algorithms are the main inspiration for our approach to the (s, t) point-separation at a high-level, in *all* models.

1.2 Results and Organization

We obtain improved algorithms for the (s, t)-point separation problem in several cases, which we outline in Table 1. As mentioned earlier, all of our positive results make use of a reduction to a shortest-path problem in the so-called "homology cover". We discuss this formulation in Section 2, and then again more rigorously in the appendix of the full version. Using this reduction, the upper bounds are then given in Section 3.

We also obtain several fine-grained lower bounds in Section 4. Our lower bounds also all have a shared foundation, which will be stated in Theorem 13. The resulting lower bounds are based on a few different hypotheses, and we give their details in the appendix of the full version.

Table 1 The time complexities of our algorithms for various obstacle models. In all cases, $n := |\mathcal{C}|$. For the arrangement model, k denotes the vertex count of the arrangement, and m is the number of obstacle-vertex incidences (so $m \geq k$). The notation $\Omega^*(\cdot)$ hides sub-polynomial factors. The notation † denotes that this is only true for one particular mutual dependence of k, m, and n (and is a slight abuse of notation). ω is the matrix-multiplication exponent ($\omega < 2.371339$ [2]). The lower bound results are given in the full version.

Model	Weights	Old	New	Cond. L.B.
Oracle	Yes	$O(n^3)$ [3]	$\widetilde{O}(n^{(3+\omega)/2})$ (Thm. 4)	$\Omega^*\left(n^2\right)$

2 Homology and Obstacles [Informal]

In this section, we will explain the main topological tools we will use to approach the (s, t) point-separation problem. However, this will be an information section, not requiring prior knowledge of any aspect of topology. Rather, we will give an equivalent formulation of the important pieces using simpler tools from computational geometry. We give a more formal treatment in the appendix of the full version. Throughout this section, we will make (implicit) assumptions of general position and such, but the deferred formal treatment does not need these.

At a high-level, there are two main steps to the constructions of our approach. First, we will discuss what it means for a *simple curve* to separate s and t, and what tools exist to classify such curves. Second, we will discuss what it means for a *set of obstacles* to separate s and t. That is, when does the union of the obstacles *contain* a simple curve separating s and t?

The simplest possible case of asking whether a simple curve separates s and t is characterized by the **point-in-polygon** problem, which asks: Given a point p and a (simple) polygon P, is p inside P? In fact, this is equivalent to asking if P separates p and the point

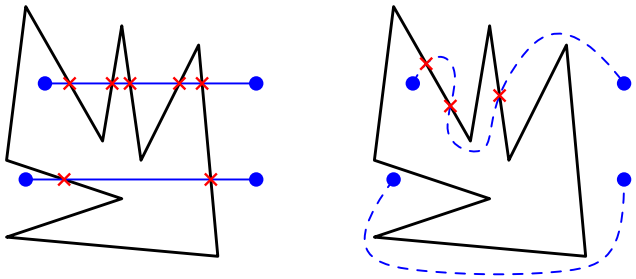

Figure 4 A demonstration of the algorithm for the point-in-polygon problem (left), as well as the problem of testing whether or not a polygon separates two points (middle). On the right, alternative paths for the separation problem are given.

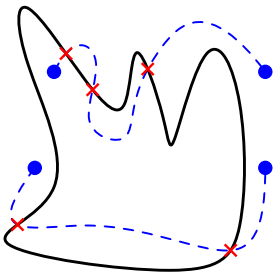

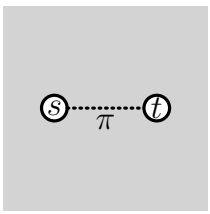

Figure 5 Examples of point-pairs separated or not separated by a given closed path between the pair, and the corresponding intersections of those curves.

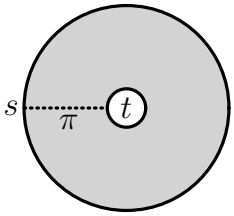
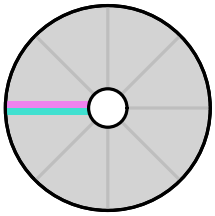


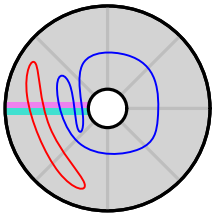
at infinity. There is a folklore algorithm for this problem that takes any ray r starting at p, and counts the number of intersections between r and P. Then, P contains p if and only if the number of intersections is odd. In fact, essentially the same algorithm can be used to test whether or not P separates two points p_1 and p_2. Rather than using a ray, take the segment $\overline{p_1p_2}$. Count the number of intersections between $\overline{p_1p_2}$ and P. The count is odd if and only if P separates p_1 and p_2. Moreover, there is in fact nothing special about rays or line segments in this problem. *Any* (closed) path between p_1 and p_2 would cross P the same number of times, modulo 2. See Figure 4 for examples for these algorithms.

All three of these algorithms are equivalent in a sense. In fact, there is a further generalization: Given two points s and t on the sphere, a simple and closed curve C (not covering s or t), and any $s-t$ path π, C separates s and t if and only if π crosses C an odd number of times (regardless of the choice of π). Since the extended plane is homeomorphic to the sphere, a ray in the plane corresponds to a (simple) path in the sphere. See Figure 5 for an example.

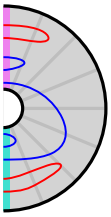


The problems we have discussed so far are all completely static, and the methods do not provide much structure for solving more difficult problems. One of the most common ways to extend the point-in-polygon problem is to fix the polygon (or curve) P, and aim to support fast queries of points. This problem is known as "point-location", and it is well-studied in computational geometry [12]. However, we want a different sort of structure: We have a fixed pair of points s and t, and we wish to classify the curves that separate them. Since we have fixed s and t, we can also fix the path π between them – in most cases, we will use the line segment $\overline{st}$. Then, the problem of classifying curves that separate s and t becomes the problem of classifying curves that cross $\overline{st}$ an odd number of times.

(a) s and t are punctures, π is a path between them.



(b) s and t are enlarged to become holes, and the space is an annulus.



(c) The two sides of π can be coloured to aid later notation.

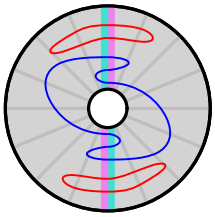


Figure 6 A demonstration of how the (extended) plane with two punctures is homeomorphic to the annulus.

(a) An annulus with a specified path π.

(b) The annulus is sliced open along the specified path π.

(c) Two copies of the sliced annulus are glued together.

Figure 7 The "cut and glue" construction of the homology cover, as well as how it maps a closed curve that separates the two boundaries (blue) and one that does not (red).

It will be helpful for demonstration to make some transformations to the space we work in. That is, we will perform a sequence of homeomorphisms. We start with the extended plane with the two marked points s and t, and the line segment $\overline{st}$ (see Figure 6a). No curves we will be classifying cross s or t, so we may assume there are punctures at s and t. We can enlarge these punctures into holes with a homeomorphism. Next, since we have the extended plane, we can make one of the punctures the outer face, obtaining an annulus (see Figure 6b and Figure 6c). In performing these steps, the line segment $\overline{st}$ becomes a path between the inner and outer boundaries of the annulus.

We now present a method for constructing an important space called the **homology cover**[1]. Take the specified path π between the two boundaries (see Figure 7a) and slice it open (see Figure 7b). Then, create a second copy of the sliced annulus, and glue them together in a way that matches up the orientations of the sliced ends (see Figure 7c).

Alternatively, an equivalent construction is to create two copies of the original space (whether that be the extended plane or the annulus), and use each side of the path from s to t as a (separate) "portal" between the two copies. A more general form of this "portal" idea has been studied in the form of "portalgons" [14, 15], of which the homology cover is essentially a special case. See Figure 8 for an example of this construction.

One important aspect of this construction is that it involves the connection of two identical copies of the annulus (i.e., the extended plane with punctures s and t). In Figure 7, we also show how this construction transforms two curves – one separating the two boundaries, and one not separating them. The structure we will make use of to study curves separating s and t in the plane ultimately stems from an important set of facts:

[1] We use the term "homology cover" to refer to the one-dimensional $\mathbb{Z}_2$-homology cover of the annulus.

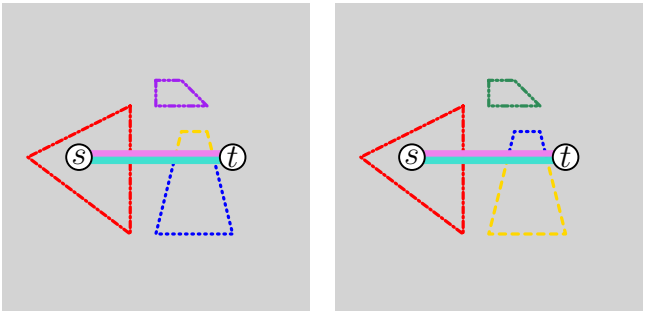

Figure 8 The "portal" construction of the homology cover. Each colour (or dot/dash pattern) is a single closed curve in the homology cover. The two solid lines are the portals.

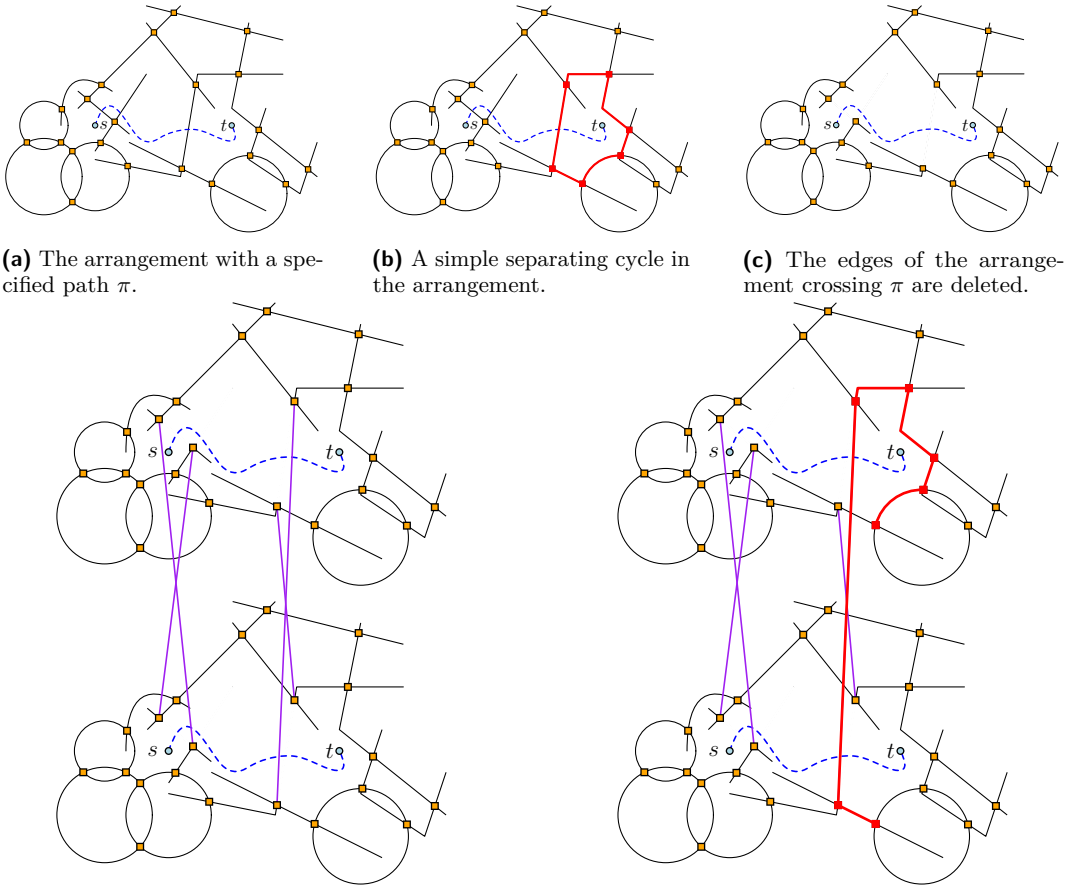
▶ **Fact 1.** *For a simple curve C in the annulus (or the plane) that gets mapped to the set C' in the homology cover, and a point p along C that gets mapped to corresponding points p_1 and p_2 in the homology cover, the following are all equivalent:*

- *C separates s and t.*
- *C' separates the two boundaries in the homology cover.*
- *C' has one connected component (i.e., it is one closed curve instead of two).*
- *The points p_1 and p_2 are connected by a path through C'.*



It is this last characterization that will be the most critical for obstacles. In particular, a consequence of this characterization is that if two corresponding points p_1 and p_2 in the homology cover (corresponding in the sense that they are identical points in different copies of the annulus/plane) have a simple path π between them, then that path can be mapped to a closed curve separating s and t.

2.1 Obstacles and the Homology Cover

We now have tools for characterizing *closed curves* that separate s and t. We'd now like to characterize *sets of obstacles* that separate s and t. In other words, we'd like to characterize unions of closed curves (obstacles) that contain a closed curve separating s and t. We'll give two different tools for this, first for the arrangement model, then for the oracle model. For simplicity, we will work exclusively with obstacles that do not *individually* separate s and t (that is, obstacles that get mapped to *two* separate closed curves in the homology cover). We will reduce to this case algorithmically at the start of Section 3.

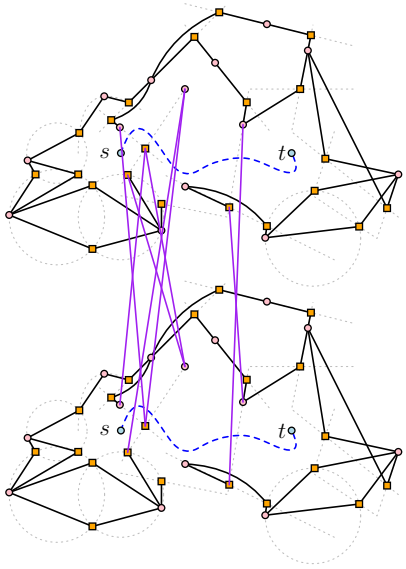
In the arrangement model of the (s,t) point-separation problem, we are given a plane graph D (the arrangement) with specified faces s and t (can be obtained from points via point-location), and a set of obstacles σ, each given as a connected subgraph. The homology cover has a simple graph-theoretic interpretation in this framework: Take any (simple) dual-path π of faces from s to t – this is will serve as the "portal". Next, create two copies D_1, D_2 of D, each with the faces s and t removed. We will create a combined graph $\overline{D}$ starting from the union of D_1 and D_2. For each edge $e = uv$ used in the dual-path π, delete e from both D_1 and D_2 (inside $\overline{D}$). Denote the corresponding vertices of u and v in each of D_1 and D_2 as u_1, v_1 and u_2, v_2, respectively. Then create new edges u_1v_2 and u_2v_1 in $\overline{D}$. This form of the homology cover is visualized in Figure 9.

With this particular arrangement structure Kumar, Lokshtanov, Saurabh and Suri [13, Section 6] built a graph using one vertex per obstacle-vertex incidence (in each copy of the plane graph). We will build a smaller graph of similar form to theirs. First, for each obstacle

(a) The arrangement with a specified path π.

(b) A simple separating cycle in the arrangement.

(c) The edges of the arrangement crossing π are deleted.



(d) Two copies of are created, and the deleted edges are added as "crossing" edges (in purple).

(e) A path between two copies of the same original vertex that would project onto the simple separating cycle in the original space from Figure 9b.

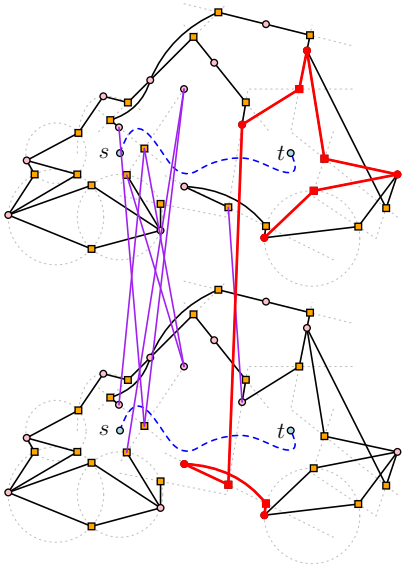


Figure 9 The construction of the homology cover for the second arrangement given in Figure 3.

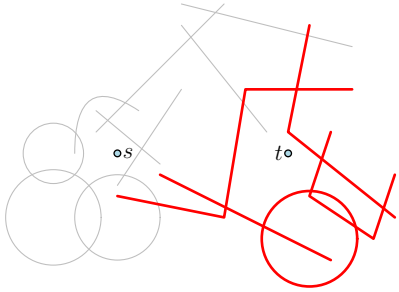
$C \in \sigma$ (which induces a subgraph of D), pick some arbitrary **canonical point** $x \in C$. Since this choice is arbitrary, it will sometimes be useful to assume it is a specific point – this will primarily be useful for specific obstacle types. Assume that x is also a vertex in the subgraph of D induced by C (and if it is not, modify D so that it is, with either a subdivision or a new degree-1 vertex). Note that since C is connected in D, every other vertex $x' \in C$ is connected to x by only edges in C. Given a plane graph D with faces s and t, a dual-path π, obstacles σ, and canonical points for each obstacle, the **auxiliary graph** H is a bipartite graph constructed as follows:



- The first set of vertices are the copies of arrangement vertices in the homology cover. For a vertex $v \in V(D)$, we denote these two copies v^+ and v^-.
- The second set of vertices are the copies of the obstacles/canonical points in the homology cover. For an obstacle $\gamma \in \sigma$, we denote these two copies as $(\gamma, -)$ and $(\gamma, +)$.
- The values $-$ and $+$ in each of the above are **indicator bits**, and can be stored as 0 and 1, respectively.
- A vertex copy v^{b_1} has an edge connecting it to a canonical point copy (γ, b_2) when:
  - $v \in \gamma$ (that is, the point v belongs to the obstacle γ in the arrangement), and...
  - The canonical point x of γ has a path through the edges of γ to v whose intersection

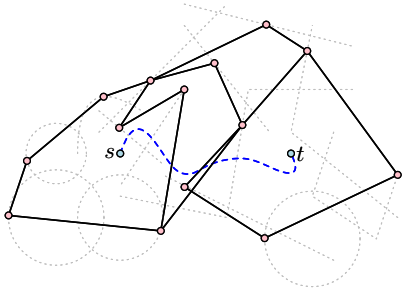
(a) A canonical point is added along each obstacle, and edges are created from the canonical point to each arrangement vertex along the obstacle, subject to the parity conditions.

(b) A shortest-path between the two copies of an obstacle's canonical point. The obstacles whose canonical points lie in this path form a set of obstacles separating s and t.

(c) The set of obstacles induced by the shortest path in Figure 10b.

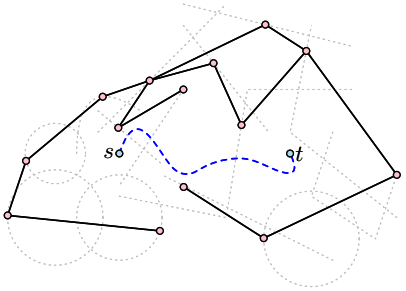
Figure 10 The construction of the auxiliary graph for the homology cover given in Figure 9.

with the edges of π has size $b_1 + b_2$ modulo 2 (i.e., if $b_1 = b_2$, the size must be even, and if $b_1 \neq b_2$, the size must be odd). Equivalently, the projected connected component of γ containing the canonical point copy (γ, b_2) also contains v^{b_1}.



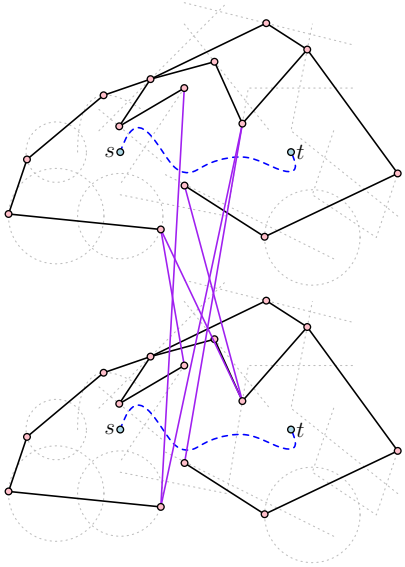
We visualize an example of the auxiliary graph in Figure 10.

The auxiliary graph is useful because the shortest path between any two corresponding vertex copies or (separately) any two corresponding canonical point copies both correspond exactly to the solution to the (s, t) point-separation problem. The high-level construction to prove this fact is as follows:

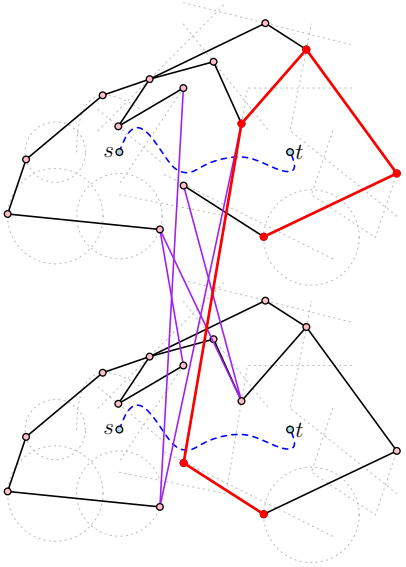


- Suppose there is a set of obstacles C. We'd like to determine when C separates s and t.
- Denote the set of copies of the obstacles in C in the homology cover as C', so that every element of C' is a closed curve representing one of the two connected components of an element of C projected into the homology cover.
- By Fact 1, we deduce that C separates s and t if and only if there is a path from v^+ to v^- along the union of obstacle copies in C', for some arrangement vertex v among pairs of elements in C only.

- Moreover, since each obstacle is connected, we may further assume that any such path visits each obstacle copy at most once, and moreover that it only visits each *obstacle* at most once.
- We may further assume that any such path visits the canonical point copy of each such obstacle copy, by inserting a path to and then from the canonical point copy while the obstacle copy is visited. Note that the resulting path may not be simple in the plane.
- Such paths also directly correspond to paths in the auxiliary graph, using only "obstacle vertices" corresponding to elements of C and the "arrangement vertices" incident to pairs of elements in C.
- With appropriate weights, the problem of finding the minimum-weight set C with this property then reduces to the problem of finding the pair v^+, v^- with the shortest distance in the auxiliary graph, so this is a shortest-path problem!
- A similar argument can show that an alternative algorithmic formulation is to find the pair $(\gamma, -), (\gamma, +)$ with the shortest-distance in the auxiliary graph.



This essentially completes the set of tools necessary for the arrangement model. These arguments are given in more detail in the appendix of the full version.



(a) The intersection graph with the path π.

(b) The intersection graph after deleting the edges whose underlying paths cross π an odd number of times.

(c) Two copies of the intersection graph are connected with "crossing" edges (in purple).

(d) A shortest-path in the homology cover between two copies of an obstacle.

Figure 11 How the intersection graph can be transformed into the intersection graph in the homology cover.

For the oracle model, the purpose of the oracles will be to construct the geometric intersection graph of the obstacle *copies* in the homology cover (which we will denote as $\overline{G}$). We will call $\overline{G}$ the **intersection graph in the homology cover**. See Figure 11 for an example. We will present two different constructions of this graph. They are equivalent, and each of them is quite simple, but they will serve two different purposes: The first will clarify which types of oracle queries are necessary, and provide an algorithmic construction. The second will instead build on the tools we have for the arrangement model, proving the correctness of another shortest-paths approach.

Let $\mathcal{C}$ denote the set of obstacles in the plane. We assume the canonical points for each obstacle are given (or implied) – they will be used by the oracle. We also assume some simple $s-t$ path π is fixed – this will also be used by the oracle. In most cases, π will be $\overline{st}$. The first construction of the graph is as follows:

- For each obstacle $\gamma \in \mathcal{C}$, create two vertices $(\gamma, -)$ and $(\gamma, +)$.
- For each pair of obstacles γ_1, γ_2 with canonical points x_1, x_2, and values $b_1, b_2 \in \{-, +\}$, we connect vertices (γ_1, b_1) and (γ_2, b_2) by an edge if there is a path from x_1 to x_2 in $\gamma_1 \cup \gamma_2$ crossing π exactly k times, for some k where $k \equiv b_1 + b_2 \pmod 2$.

Testing for this condition is actually the *only* type of oracle query needed (although we will also require support for the case when $\gamma_1 = \gamma_2$ later). Cabello and Giannopoulos [3] used a larger set of query types, but together they can be used to perform this type by carefully choosing the canonical points and fixing π to $\overline{st}$, so our variant of the oracle model is slightly more general (although practically equivalent).

We'd like a similar algorithmic property for the intersection graph in the homology cover $\overline{G}$ that we have for the auxiliary graph H. The second construction will be what gives us that property, by constructing $\overline{G}$ *from* H:

- For each arrangement vertex v^b in H, let its adjacent vertices be denoted $x_1, \ldots, x_k$. Delete v^b and create a clique over $\{x_1, \ldots, x_k\}$.
- After performing this for every arrangement vertex v^b, the result is *exactly* the intersection graph in the homology cover $\overline{G}$.
- Therefore, the set of vertices visited by the shortest path from some $(\gamma, -)$ to $(\gamma, +)$ (over all possible $\gamma \in \mathcal{C}$, breaking ties arbitrarily) corresponds to a minimum-weight set of obstacles separating s and t.

For specific obstacle types, we will usually work with $\overline{G}$, although we will do it implicitly. Hence, with the tools from this section, we can now discuss algorithms in all three model types as solutions to a certain form of shortest-path problem.

3 Algorithmic Results

In this section, we will devise algorithms for the (s, t) point-separation problem based on our homology cover structures. We will devise algorithms for all three model types: Some that work with the arrangements of curves, some that work with the "oracle model" (the intersection graph in the homology cover), and some that work with specific types of obstacles. Most of our algorithms are fairly simple reductions to various known shortest-path algorithms, greatly simplifying some of the previous approaches to the (s, t) point-separation problem. However, some of them are more involved.

In the previous section, we assumed no obstacle individually separated s and t. Before moving on, we quickly show this is enough:

▶ **Observation 2.** *Let $\mathcal{C}$ be a set of obstacles, and let s and t be points. Suppose an oracle exists that, for an obstacle $\gamma \in \mathcal{C}$, determines whether γ itself separates s and t, all in $O(1)$ time. Let $\mathcal{C}_0$ be the set of all obstacles that do. Then an instance of the weighted*

(unweighted) (s,t) point-separation problem over $\mathcal{C}$ can be reduced to an instance of the weighted (unweighted) (s,t) point-separation problem over $\mathcal{C} \setminus \mathcal{C}_0$ in $O(|\mathcal{C}|)$ time. In particular, such a reduction returns the best solution out of the solved subproblem (if any), and each of the individual obstacles forming solutions (if any).

3.1 General Weighted Obstacles in Oracle Model

With no significant further work, we already obtain some naïve algorithms by using a result in the appendix of the full version (or the constructions in Section 2):

▶ **Theorem 3.** *For points s and t, and a weighted set of obstacles $\mathcal{C}$ that have k pairwise intersections, the (s,t) point-separation problem can be solved in $O(|\mathcal{C}| \cdot k + |\mathcal{C}|^2 \log |\mathcal{C}|)$ time.*

Proof. Compute the intersection graph in the homology cover $\overline{G}$ of $\mathcal{C}$. For each $\gamma \in \mathcal{C}$, compute the shortest path from $(\gamma, -)$ to $(\gamma, +)$ in $\overline{G}$. The smallest such path induces the solution by a result in the appendix of the full version. Each shortest path can be computed in $O(k + |\mathcal{C}| \log |\mathcal{C}|)$ time by Dijkstra's algorithm with a Fibonacci heap [11], and there are $O(|\mathcal{C}|)$ total such paths. ◀

Note that Theorem 3 matches the result of [3], although the algorithm is much simpler. When $k \in \Theta(|\mathcal{C}|^2)$ (i.e., dense intersection graphs), this algorithm runs in $O(|\mathcal{C}|^3)$ time, which could also be obtained by running Floyd-Warshall for APSP instead of Dijkstra. It is not known if the general form of weighted APSP can be solved in "truly" subcubic time (see the appendix of the full version). However, since the weights are applied to vertices, not edges, there is a known faster algorithm (also discussed in the appendix of the full version):

▶ **Theorem 4.** *For points s and t, and a weighted set of obstacles $\mathcal{C}$, the (s,t) point-separation problem can be solved in $\widetilde{O}(|\mathcal{C}|^{(3+\omega)/2})$ time in the oracle model, where $2 \leq \omega < 2.371339$ is the matrix multiplication exponent.*

Proof. Apply the same reduction to APSP as before, but use the algorithm of Abboud, Fischer, Jin, Williams, and Xi [1] for APSP with real vertex weights. ◀

3.2 General Unweighted Obstacles in Oracle Model

We are also interested in the (s,t) point-separation problem for unit weights, which corresponds to shortest paths for unit weights. In this case, we can obtain faster algorithms:

▶ **Theorem 5.** *For points s and t, and an* unweighted *set of obstacles $\mathcal{C}$, the (s,t) point-separation problem can be solved in $O(|\mathcal{C}|^\omega \log |\mathcal{C}|)$ time, where $2 \leq \omega < 2.371339$ is the matrix multiplication exponent.*

Proof. Compute the intersection graph in some homology cover $\overline{G}$ of $\mathcal{C}$, and then run unweighted undirected APSP [16] on $\overline{G}$, for $O(|\mathcal{C}|^\omega \log |\mathcal{C}|)$ total time. ◀

3.3 General Weighted Obstacles in Arrangement Model

We can also obtain results using the arrangement instead of the intersection graph. The simplest of these is a slight modification of Theorem 3:

▶ **Theorem 6.** *For points s and t, a weighted set of obstacles $\mathcal{C}$, and an arrangement D, σ of $\mathcal{C}$, where σ is given as lists of vertices, let $m = \sum_{c \in \sigma} |c|$ be the total number of obstacle-vertex incidences. Then, the (s,t) point-separation problem can be solved in $O(\min(|\mathcal{C}|, |V(D)|) \cdot m + \min(|\mathcal{C}|, |V(D)|)^2 \log \min(|\mathcal{C}|, |V(D)|))$ time.*

Proof. Let $\overline{H}$ be the auxiliary graph in the homology cover, which has $O(m)$ vertices and edges. By a result in the appendix of the full version, it suffices to do one of the following:

- Compute the single-source shortest-path (SSSP) tree from each obstacle in $\overline{H}$.
- Compute the SSSP tree from each arrangement vertex in $\overline{H}$.

Let $k = \min(|\mathcal{C}|, |V(D)|)$. Each SSSP computation can be performed in $O(m + k \log k)$ time, and k such computations suffice to solve the problem. ◀

This theorem in particular is of note because as we will see later, it is essentially optimal assuming the APSP conjecture, at least in the case when $|\mathcal{C}| = \Theta(|V(D)|^2)$ and $m = \Theta(|\mathcal{C}|)$, as we will see in Section 4.

3.4 Restricted Obstacle Classes without Weights

As we will discuss in the appendix of the full version, Chan and Skrepetos [6, 7] studied APSP for several forms of unweighted/undirected geometric intersection graphs. Their intersection graphs are in the plane, but with some extra work it is possible to study intersection graphs in the homology cover, and consequently the unweighted (s, t) point-separation problem.

▶ **Theorem 7.** *For points s and t, and an* unweighted *set of obstacles $\mathcal{C}$. Let $\overline{\mathcal{C}}$ be the set of $2|\mathcal{C}|$ "mapped" obstacles in the homology cover. Let $SI(n, m)$ ("static intersection") be the time complexity for checking if each of n different objects in $\overline{\mathcal{C}}$ intersects any object in some subset $C \subset \overline{\mathcal{C}}$ of size $m = |C|$. Assume $SI(n, m)$ is super-additive, so that $SI(n_1, m_1) + SI(n_2, m_2) \leq SI(n_1 + n_2, m_1 + m_2)$. Then (s, t) point-separation over $\mathcal{C}$ can be solved in $O(nSI(n, n))$ time.*

Proof. Run APSP for the intersection graph in the homology cover via the algorithm of Chan [10, Theorem 2] (see further discussion in the appendix of the full version). ◀

To use this result, we need efficient algorithms for static intersection in the homology cover:

▶ **Lemma 8.** *For points s and t, the following values of $SI(n, n)$ hold for restricted obstacle types in the homology cover:*

Obstacle Class	$SI(n, n)$
General Disks	$O(n \log n)$
Axis-Aligned Line Segments	$O(n \log \log n)$
Arbitrary Line Segments	$O(n^{4/3} \log^{1/3} n)$

The proof of the lemma is left to the appendix of the full version. At a high-level, all cases are first reduced to the planar static intersection problem. In the case of line segments, this becomes the standard planar static intersection problem for line segments. For disks, this is not the case, and the algorithm is more involved.

The combination of these two results give an important corollary:

▶ **Corollary 9.** *For points s and t, the unweighted (s, t) point-separation problem can be solved in $O(n^2 \log \log n)$ time for axis-aligned line segments (or $O(1)$-length rectilinear polylines), $O(n^{7/3} \log^{1/3} n)$ time for line segments (or $O(1)$-length polylines), and $O(n^2 \log n)$ time for general disks or circles that do not contain both s and t.*

3.5 Restricted Obstacle Classes with Weights

We will now present a method for solving the weighted (s,t) point-separation problem using a tool called "biclique covers", which are essentially a tool for a type of graph sparsification.

For a graph $G = (V, E)$, a **biclique** in G is a complete bipartite subgraph ($A \times B \subset E$, where $A, B \subset V$ are disjoint). The **size** of a biclique is the number of vertices it contains ($|A| + |B|$). A **biclique cover** is a collection of bicliques in G covering the edges E, and its **size** is the the sum of all sizes in its bicliques. Biclique covers of geometric intersection graphs in two-dimensions are well-studied. We summarize known results in Table 2.

Table 2 Known results for biclique covers of 2D geometric intersection graphs. All of these results are stated and proven by Chan [8], although essentially all of the steps have appeared in a number of prior works. The notation $\widetilde{O}$ hides logarithmic factors. The notation $\widetilde{O}_k$ further assumes that k is constant. Note that axis-aligned line segment intersection graphs are K_3-free.

Graph Type	Cover Size	Construction Time
line segment intersection	$\widetilde{O}(n^{4/3})$	$\widetilde{O}(n^{4/3})$
Axis-aligned line seg. intersection	$\widetilde{O}(n)$	$\widetilde{O}(n)$
k-clique-free line seg. intersection	$\widetilde{O}_k(n)$	$\widetilde{O}_k(n)$

Biclique covers are useful in our case because they can be used for faster *vertex-weighted* shortest paths. In particular:

▶ **Lemma 10.** *Let $G = (V, E)$ be an n-vertex (undirected) graph with vertex-weights admitting a biclique cover of size $S(n)$ that can be constructed in $T(n)$ time. Then APSP over G can be solved in $O(T(n) + n \cdot S(n) \log(n))$ time.*

We leave the proof to the appendix of the full version.

These results aren't quite enough for the (s,t) point-separation problem, since what we need is actually a biclique cover *in the homology cover*. Fortunately, we can construct this:

▶ **Lemma 11.** *Let s and t be designated points in the plane, and let $\mathcal{C}$ be a set of line segments with $n = |\mathcal{C}|$. Let $\overline{G}$ be the intersection graph in the homology cover, and let G be the intersection graph in the plane. Then $\overline{G}$ has a homology cover of size $\widetilde{O}(n^{4/3})$ that can be found in $\widetilde{O}(n^{4/3})$ time. Moreover, if G contains no k-clique (including if $\mathcal{C}$ is a set of rectilinear segments, in which case G contains no 3-clique), then $\overline{G}$ has a homology cover of size $\widetilde{O}_k(n)$ that can be found in $\widetilde{O}_k(n)$ time.*

We leave the proof of this to the appendix of the full version as well. The proof is similar to that of Theorem 7.

The combination of these results gives the following theorem:

▶ **Theorem 12.** *For a weighted set of obstacles $\mathcal{C}$, and points s, t, the (s,t) point-separation can be solved in $\widetilde{O}(n^{7/3})$ time if $\mathcal{C}$ is a set of line segments, $\widetilde{O}(n^2)$ time if $\mathcal{C}$ is a set of axis-aligned line segments, and $\widetilde{O}_k(n^2)$ time if $\mathcal{C}$ is a set of line segments whose intersection graph has no k-clique. The same bounds hold if each obstacle is an $O(1)$-length polyline among lines of the same properties.*

Note that a biclique cover for $O(1)$-length polylines can be recovered from biclique covers over the individual line segments (adjusted slightly so that the line segments in the same polyline do not overlap).

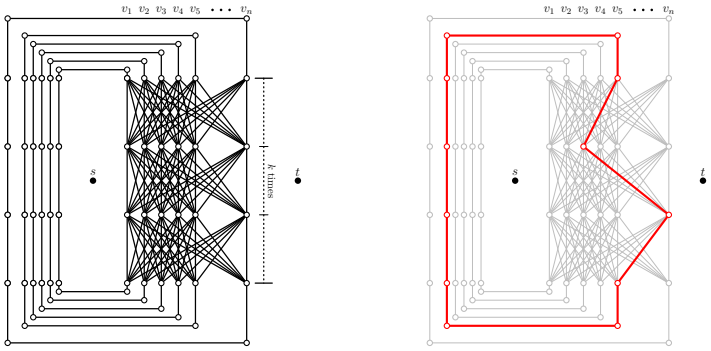


Figure 12 A demonstration of the sub-cubic reduction from min-weight k-walk to the (s,t) point-separation problem with line segments. Empty circles are used to annotate the ends segments.

4 Lower Bounds

In this section, we present several related fine-grained lower bounds for specific cases of the (s,t) point-separation problem. The main intermediate tool is the problem of finding a minimum-weight walk of length k in a directed graph, for a given k (or detecting if any walk of length k exists). All of our lower bounds are based on the following unified theorem:

▶ **Theorem 13.** *For a positively edge-weighted directed graph $G = (V, E)$ with n vertices and m edges with maximum edge-weight W, and an integer k, there exists three sets $\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_3$ of $2km + 6m$ obstacles, each with a weight equal to that of some edge in G, so that each of the following properties holds for one set:*

- *All obstacles are line segments.*
- *All obstacles are length-2 polylines, and the total number of unique intersection points of the obstacles is $k + 2(k+1)m + 4m = \Theta(km)$.*
- *All obstacles are length-3 rectilinear polylines.*

Moreover, there are points s and t in the plane so that G has a walk of length k with weight at most w if and only if there is some subset of $\mathcal{C}_i$ (for any $i \in \{1,2,3\}$) that separates s and t and has weight at most $w + (k+6)W$, so long as $w \leq kW$. Furthermore, each of $\mathcal{C}_1, \mathcal{C}_2, \mathcal{C}_3$ can be constructed in time proportional to their sizes.

Proof. For each property, we will construct a reduction from min-weight k-walk (for fixed k) in a directed edge-weighted graph to point separation, with the stated guarantees. The constructions for each property are essentially the same. We will focus on the line segment case, and explain the modifications afterwards.

The construction is visualized in Figure 12. For each vertex v_i ($i \in \{1, \ldots, n\}$), assign the column $x = i$. For each value $r \in [k+1]$, assign the row $y = r$. For each directed edge $(v_i, v_j) \in E$, with weight w_{v_i,v_j} create k line segments, each also with weight w_{v_i,v_j}. Each should go from the ith column to the jth column, and the rth row to the $(r+1)$th row (for each $r \in [k+1]$). We call these the **edge segments**. Pick s to be some point to the left of the columns, and t to be some point to the right. For the ith column, create a set of $k+6$ rectilinear line segments connecting the top point of the ith column to the bottom, so that the path formed by these line segments lies to the left of s at its x coordinate, ensuring that these line segments do not intersect the corresponding line segments generated for other columns, nor do they cross the minimal orthogonal rectangle containing the previous set of line segments. We call these the **vertex segments**. These two segment types form the entirety of the obstacles, so the stated time complexity follows. We need only prove correctness of the reduction.

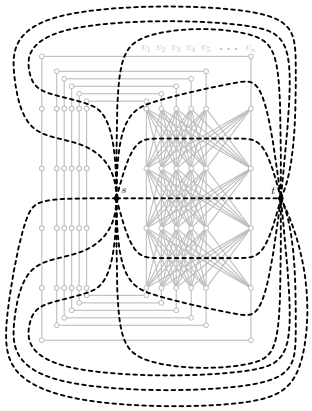

Figure 13 The finite set of (s, t) paths that need to be considered for the reduction of min-weight k-walk to the (s, t) point-separation problem with line segments.

A k-walk through G starting and ending at a vertex $v_i \in V$ corresponds exactly to a connected set of edge segments from the point $(i, 0)$ to (i, k), and both also have the same weight. The forward direction of the reduction follows: Given such a set of edge segments, a set of vertex segments of weight exactly $(k + 6)W$ exists (those for the ith column) so that the union of the two separates s and t, and has the specified weight. For the backwards direction of the reduction: For a set $C \subset \mathcal{C}$ with weight at most $w + (k + 6)W$, if $w \leq kW$, then it is only possible to have one maximal connected set of vertex segments in C. Each of the sets of (potential) obstacles crossed by paths in Figure 13 must have at least one obstacle chosen from them for the whole set to separate s and t, so at least one such maximal connected set of vertex segments must be in C. Hence, the total weight of the remaining obstacles in C is w, and some subset of these obstacles must themselves be a connected set of edge segments (one per row) corresponding exactly to a k-walk in G.

The two modified constructions with polylines are obtained by replacing the edge segments with polylines that have the desired properties. These cases are visualized in Figure 14. ◀

There are a number of fine-grained lower bounds for min-weight k-walk and k-walk detection. In particular, all such bounds hold for *fixed* k and graphs where k-walks and k-cycles coincide (which is itself always true for $k = 3$ in graphs with no self-loops, and is otherwise implied by a property called "k-circle-layered"). In the appendix of the full version, we discuss the following results that follow from known fine-grained bounds and Theorem 13:

If (s, t) point-separation can be solved in time...	for n obstacles that are...	then it would imply a new state-of-the-art algorithm for...
$O(n^{3/2-o(1)})$	weighted line segments	edge-weighted APSP
$O(n^{2-o(1)})$	weighted line segments	minimum-weight k-clique
$O(n^{2-o(1)})$	weighted length-3 rectilinear polylines	minimum-weight k-clique
$O(n^{3/2-o(1)})$	unweighted line segments	max-3-SAT
$O(n^{3/2-o(1)})$	unweighted length-3 rectilinear polylines	max-3-SAT
$O(n^{3/2-o(1)})$	weighted length-2 polylines with $O(\sqrt{n})$ unique intersection points and 3 intersection points per obstacle	edge-weighted APSP

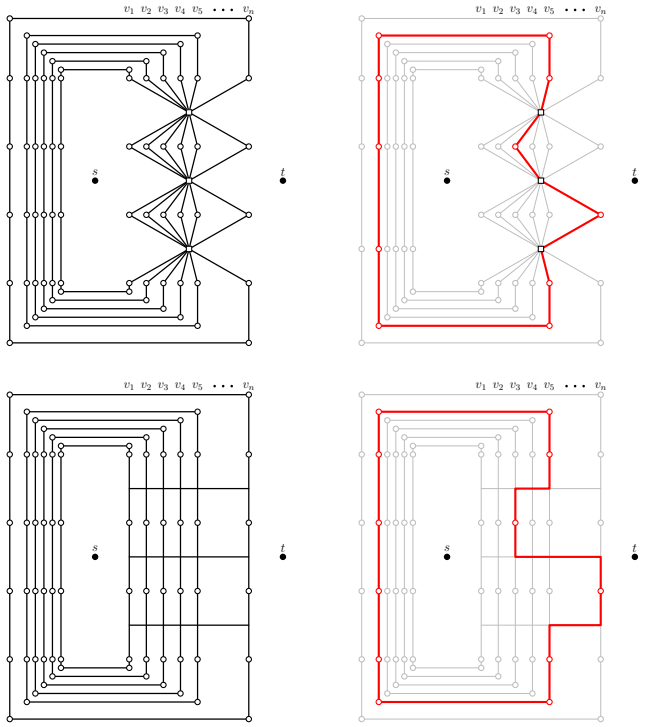

Figure 14 A demonstration of the reduction from min-weight k-walk to the (s,t) point-separation problem for length-2 polylines with few total intersection points, or length-3-rectilinear polylines.

5 Conclusion

We have discussed several upper and lower bounds for the (s,t) point-separation problem in various cases, and we conclude by briefly listing some of the most interesting open problems:

- Is there a near-quadratic algorithm for general weighted obstacles? Can a conditional lower bound (based on any popular hypotheses) excluding this possibility be formulated?
- Can a (truly) sub-quadratic algorithm be devised for disks, unit disks, or axis-aligned segments? Is there a non-trivial fine-grained lower bound in any of these cases?
- Are there faster algorithms or stronger lower bounds for the *unweighted* versions of the problem?

We note that it seems very likely that unit disks would admit a *slightly* sub-quadratic algorithm, since APSP is known to be solvable for unit disk graphs in (essentially) slightly sub-quadratic time [9], and the methods seem as though this method could plausibly be extended to the homology cover.

Abstract

Many differentially private and classical non-private graph algorithms rely crucially on determining whether some property of each vertex meets a threshold. For example, for the k-core decomposition problem, the classic peeling algorithm iteratively removes a vertex if its induced degree falls below a threshold. The sparse vector technique (SVT) is generally used to transform non-private threshold queries into private ones with only a small additive loss in accuracy. However, a naive application of SVT in the graph setting leads to an amplification of the error by a factor of n due to composition, as SVT is applied to *every vertex*. In this paper, we resolve this problem by formulating a novel *generalized* sparse vector technique which we call the *Multidimensional AboveThreshold (MAT) Mechanism* which generalizes SVT (applied to vectors with one dimension) to vectors with *multiple* dimensions. When applied to vectors with n dimensions, we solve a number of important graph problems with better bounds than previous work.

Specifically, we apply our MAT mechanism to obtain a set of improved bounds for a variety of problems including k-core decomposition, densest subgraph, low out-degree ordering, and vertex coloring. We give a *tight* local edge differentially private (LEDP) algorithm for k-core decomposition that results in an approximation with $O(\varepsilon^{-1} \log n)$ additive error and *no* multiplicative error in $O(n)$ rounds. We also give a new $(2+\eta)$-factor multiplicative, $O(\varepsilon^{-1} \log n)$ additive error algorithm in $O(\log^2 n)$ rounds for any constant $\eta > 0$. Both of these results are asymptotically tight against our new lower bound of $\Omega(\log n)$ for any constant-factor approximation algorithm for k-core decomposition. Our new algorithms for k-core decomposition also directly lead to new algorithms for the related problems of densest subgraph and low out-degree ordering. Finally, we give novel LEDP differentially private defective coloring algorithms that use number of colors given in terms of the *arboricity* of the graph.

1 Introduction

Designing and analyzing algorithms that satisfy *differential privacy* [23], the de facto standard for protecting user data, is a tricky task, with few general techniques. Among them, the *sparse vector technique (SVT)* is a well-known approach to make certain *threshold-based* computations privacy-preserving. This typically involves showing that the computation can be reduced to a sequence of black-box invocations of private *AboveThreshold* mechanisms, followed by some post-processing. Each such mechanism allows one to iteratively (and adaptively) query whether some real-valued property of the data is above some threshold, until the first "yes" response, at which point no further queries are possible.

While SVT was originally presented as a technique for *sequential* computations, recent work on concurrent composition [54] show that it is possible to interleave queries to different (AboveThreshold) mechanisms with (worst-case) privacy loss proportional to the number of concurrently queried mechanisms. However, this can be prohibitively large for applications (e.g., in parallel and distributed settings) where there is a large amount of concurrency and, in this case, one must exploit structural properties of the instance to obtain better guarantees.

To analyze these situations, we introduce a new mechanism, called *Multidimensional AboveThreshold (MAT)*, which allows one to query, *in parallel*, whether a number of different real-valued properties of the data are above some specified thresholds. We identify a condition on the sensitivity of the submitted queries that allows one to use MAT with far less privacy loss versus concurrent composition. By analyzing various non-private algorithms through the lens of our mechanism, we obtain private algorithms with substantially improved accuracy guarantees for a variety of important, recently studied graph problems.

All of our algorithms apply in the stringent, *local* model of (edge) differential privacy *(LEDP)*, where each user (here, a vertex in the graph) interactively discloses information about its data (here, its incident edges) in multiple *rounds* of communication with an *untrusted*[1] curator (or server), which produces the output. The *transcript* of messages sent throughout the interaction must be differentially private.

We now describe our contributions and the main related work in more detail (see Table 1 for a summary of our results). In the following, all graphs are simple (no self-loops), undirected, and contain n vertices. Furthermore, all mentioned additive error upper bounds hold *with high probability*, i.e., $1 - 1/n^c$, for any constant $c > 0$.

k-Core Decomposition. At a high level, core numbers measure the relative importance of vertices in a graph. Formally, given a graph G, the *core number* (or, *coreness*) of a vertex v in G is the largest $k_G(v) \in \mathbb{N}$ (or $k(v)$ if G is clear from context) for which there exists a subgraph H of G *containing* v such that every vertex in H has induced degree $\geq k_G(v)$. In the *k-core decomposition problem*, the goal is to output core numbers of all vertices in G.[2]

[1] The curator may accidentally leak their messages, e.g., due to security breaches. However, it is not malicious. This is referred to as "honest but curious" in the literature.

[2] We note that the k-core decomposition problem in the literature is sometimes used to refer to the problem of computing a hierarchy of *k-cores*, which are subgraphs of G induced by vertices with core number at least k [49]; note that it is not possible to emit such a hierarchy privately, so we (and prior work) focus on privately emitting core numbers for every vertex.

This problem has recently received much attention from the database and systems communities due its applications in community detection [1, 28, 31], clustering and data mining [16, 51], and other machine learning and graph analytic applications [37, 18, 19]; for a more comprehensive survey, see [43]. Due to the rapid increase of applications using sensitive user data, designing private algorithms for this problem is becoming increasingly important.

An algorithm is a (ϕ, ζ)-*approximation* for the k-core decomposition problem if, for every vertex v in the given graph, the *estimate* of the core number of v, as returned by the algorithm, lies between $k(v) - \zeta$ and $\phi \cdot k(v) + \zeta$. Dhulipala et al. [20] gave the first differentially private $(2+\eta, O(\varepsilon^{-1}\log^3 n))$-approximation algorithm for k-core decomposition in the ε-LEDP model, which runs in $O(\log n)$ rounds. They left it as an open question whether their multiplicative and additive approximation factors can be improved.

Our contributions. We answer their question in the affirmative. In particular, we give an *exact* (i.e., 1-approximate) algorithm and a $(2+\eta)$-approximate algorithm, both with $O(\varepsilon^{-1}\log n)$ additive error, which run in $O(n)$ and $O(\log^2 n)$ rounds, respectively.

▶ **Theorem 1.** *For $\varepsilon > 0$, there is an exact, $O(n)$-round ε-LEDP algorithm for the k-core decomposition problem, which has $O(\varepsilon^{-1}\log n)$ additive error, with high probability.*

▶ **Theorem 2.** *For $\varepsilon > 0$ and* constant *$\eta > 0$, there is a $(2+\eta)$-approximate, $O(\log^2 n)$-round ε-LEDP algorithm for the k-core decomposition problem, which has $O(\varepsilon^{-1}\log n)$ additive error, with high probability.*

Furthermore, we show that the additive errors of our algorithms are tight, by proving a matching lower bound of $\Omega(\varepsilon^{-1}\log n)$ on the additive error of any constant-approximation algorithm in the *centralized* model (EDP), where the algorithm has full access to user data (here, the input graph). Since the centralized model is less restricted than the local model, the same bound holds in the LEDP model, regardless of round complexity. We also show that interactivity is needed if one wants an exact algorithm with polylogarithmic additive error, by proving a lower bound of $\Omega(\sqrt{n})$ on the additive error of any exact, 1-round algorithm, when ε is a constant.

▶ **Theorem 3.** *For $\varepsilon > 0$ and $\phi \geq 1$, any ϕ-approximate ε-EDP algorithm for the k-core decomposition problem in the centralized model has $\Omega((\varepsilon\phi)^{-1}\log n)$ additive error, with constant probability.*

▶ **Theorem 4.** *For* constant *$\varepsilon > 0$, any 1-round, exact ε-LEDP algorithm for the k-core decomposition problem has $\Omega(\sqrt{n})$ additive error, with constant probability.*

Densest Subgraph. Another measure of importance, defined on *subsets* of vertices in a graph, is density. Formally, the *density* of a set of vertices S in a graph G, denoted $\rho_G(S)$ (or simply $\rho(S)$), is the ratio of the number of edges in the subgraph induced by S and the number of vertices in S, i.e., $|E(S)|/|S|$. In the *densest subgraph* problem, the goal is to output a set of vertices with the maximum density in a given graph.

This problem has been studied in the (centralized) private [29, 48], LEDP [21, 20], dynamic [13, 50], streaming [3, 12, 27, 46], and distributed [4, 53] settings; for a recent survey on densest subgraph and its variants, see [39].

An algorithm is a (ϕ, ζ)-*approximation* to the densest subgraph problem if the set of vertices S returned by the algorithm has density $\rho(S) \geq \rho^*/\phi - \zeta$, where ρ^* is the maximum density. In the ε-LEDP setting, Dhulipala et al. [20] gave a $(4+\eta, O(\varepsilon^{-1}\log^3 n))$-approximation for the densest subgraph problem. More recently, and concurrently with

this work, Dinitz et al. [21] gave a $(2+\eta, O((\varepsilon\eta)^{-1}\log^2 n))$-approximation algorithm, which runs in $O(\log n)$ rounds, in the ε-LEDP setting, and as well as an $(1, O(\varepsilon^{-1}\sqrt{\log \delta^{-1}}\log n))$-approximation, which runs in $O(n^2 \log n)$ rounds in the (ε, δ)-LEDP setting. On the other hand, there is a lower bound of $\Omega(\phi^{-1}\sqrt{\varepsilon^{-1}\log n})$ on the additive error of any ϕ-approximate algorithm for densest subgraph that satisfies (ε, δ)-edge differential privacy in the centralized model [29, 48] (when $\delta \leq n^{-O(1)}$).

Our contributions. We give a condition on when a (private) (ϕ, ζ)-approximation algorithm for k-core decomposition can be transformed into a (private) $(2\phi, \zeta)$-approximation algorithm for densest subgraph. We show that our algorithms for k-core decomposition satisfy the condition, obtaining the following improved bounds for densest subgraph.

▶ **Theorem 5.** *For $\varepsilon > 0$, there is a 2-approximate, $O(n)$-round ε-LEDP algorithm for the densest subgraph problem, which has $O(\varepsilon^{-1}\log n)$ additive error, with high probability.*

▶ **Theorem 6.** *For $\varepsilon > 0$ and* constant *$\eta > 0$, there is a $(4+\eta)$-approximate, $O(\log^2 n)$-round ε-LEDP algorithm for the densest subgraph problem, which has $O(\varepsilon^{-1}\log n)$ additive error, with high probability.*

We also give a simple 1-round algorithm using the randomized response technique together with brute-force, exponential time search. We believe this algorithm serves as an interesting example of what a lower bound for 1-round algorithms must be able to reason about.

▶ **Theorem 7.** *For $\varepsilon > 0$, there is an exact, 1-round ε-LEDP algorithm for the densest subgraph problem, which has $O((1+\varepsilon^{-1})\sqrt{n})$ additive error, with high probability.*

Low Out-Degree Ordering. A *low out-degree orientation* of a (undirected) graph is an orientation of the edges of the graph such that the out-degree of any vertex is minimized. A *low out-degree ordering* is a permutation of the vertices, which implicitly encodes a low out-degree orientation, i.e., each edge is oriented from its earlier endpoint to its later endpoint (with respect to the permutation). In the *low out-degree ordering problem*, the goal is to output a low out-degree ordering of a given graph.

Differentially private low out-degree ordering was introduced by [20] as a way to release an implicit solution to the low out-degree orientation problem. The latter has attracted a lot of attention in the non-private setting (see, e.g., [9, 13, 38, 53] and references therein) and has been used to improve the running time of algorithms for matching [47, 33], coloring [34], and subgraph counting [7, 8, 42].

The *degeneracy* of a graph is the maximum core number of any vertex in the graph. It is known that degeneracy is equal to the minimum out-degree that is achievable through any ordering. Hence, we state the out-degree obtained through our algorithms in terms of α, the degeneracy of the input graph. An algorithm is a (ϕ, ζ)-*approximation* for the low out-degree ordering problem if the algorithm's output encodes an orientation where each vertex has out-degree at most $\leq \phi \cdot \alpha + \zeta$. In the ε-LEDP model, Dhulipala et al. [20] gave a $(2+\eta, O(\varepsilon^{-1}\log^3 n))$-approximation to the low out-degree ordering problem, which runs in $O(\log n)$ rounds.

Our contributions. We improve the multiplicative factor and the additive error by giving an exact algorithm and a $(2+\eta)$-approximate algorithm, both with additive error $O(\varepsilon^{-1}\log n)$, which run in $O(n)$ and $O(\log n)$ rounds, respectively.

▶ **Theorem 8.** *For $\varepsilon > 0$, there is an exact, $O(n)$-round ε-LEDP algorithm algorithm for the low out-degree ordering problem, which has $O(\varepsilon^{-1}\log n)$ additive error, with high probability.*

▶ **Theorem 9.** *For $\varepsilon > 0$ and* constant *$\eta > 0$, there is a $(2+\eta)$-approximate, $O(\log^2 n)$-round ε-LEDP algorithm for the low out-degree ordering problem, which has $O(\varepsilon^{-1} \log n)$ additive error, with high probability.*

Defective Coloring. A (vertex) *coloring* of a graph G is an assignment of labels (or, *colors*) from the set $\{1, \ldots, n\}$ to the vertices of G. A coloring is (c, d)-*defective* if it uses at most c different colors, and each vertex has at most d neighbors with the same color; d is the *defectiveness* of the coloring. In the *defective coloring* problem, the goal is to output a (c, d)-defective coloring of a given graph with small c and d.

This problem (especially the case $d = 0$) has been widely studied in a variety of settings including the (centralized) private [15], dynamic [11, 34, 35, 52], distributed [30, 32, 45], and streaming [2, 10, 6] settings. In the ε-edge differential privacy setting, [15] recently gave the first (c, d)-defective coloring algorithm with $c = O(\Delta/\log n + \varepsilon^{-1})$ and $d = O(\log n)$, where Δ is the maximum degree of the input graph. They also showed that $d = \Omega(\log n/(\log c + \log \Delta))$ defectiveness is necessary if $\leq c$ colors are used. Although not explicitly stated, we believe their coloring algorithm can be also adapted to the ε-LEDP setting with the same bounds.

Our contributions. Using the approximate low out-degree ordering results and MAT, we give new algorithms for defective coloring under LEDP. In particular, the number of colors used by our algorithms scales with the arboricity α instead of the maximum degree. In small-arboricity graphs, the number of colors used by our algorithm can be significantly smaller than that of [15].

▶ **Theorem 10.** *For $\varepsilon > 0$, there is an $O(n)$-round ε-LEDP algorithm for the defective coloring problem that uses $O(1 + \alpha\varepsilon/\log n)$ colors, where α is the arborocity of the input graph, and has $O(\varepsilon^{-1} \log n))$ defectiveness, with high probability.*

▶ **Theorem 11.** *For $\varepsilon > 0$, there is an $O(\log^2 n)$-round ε-LEDP algorithm for the defective coloring problem that uses $O(\alpha\varepsilon \log n + \log^2 n)$ colors, where α is the arborocity of the input graph, and has $O(\varepsilon^{-1} \log n))$ defectiveness, with high probability.*

Efficient centralized algorithms. All of the bounds in the above theorems are stated for ε-LEDP algorithms but also are algorithms in the centralized model with the same approximation and additive error guarantees. All of our algorithms based on MAT can be implemented in the centralized model in near-linear time if we lose an additional multiplicative factor of $1 + \eta$ for any given constant $\eta > 0$. This nearly matches the best running times for sequential non-private k-core decomposition algorithms, while maintaining a near-optimal utility for private algorithms.

Concurrent, Independent Work. The recent concurrent, independent work of Dinitz et al. [21] provides a large set of novel results on (ε, δ)-DP, ε-LEDP, and (ε, δ)-LEDP densest subgraph, improving on the approximation guarantees of previous results. Their work is based on a recent result of Chekuri, Quanrud, and Torres [14] and the parallel densest subgraph algorithm of Bahmani, Kumar, and Vassilvitskii [4]. They offer improvements in the bounds in the central DP setting via the private selection mechanism of Liu and Talwar [41]. Note that their techniques are different from those presented here; furthermore, any c-approximate algorithm for densest subgraph translates to a $2c$-approximate algorithm for finding the degeneracy of the input graph (which is the value of the maximum k-core). Thus, no densest subgraph algorithm can obtain a better than 2-approximation of the maximum k-core value.

Subsequent Work. Using the MAT framework of this work, Dinitz et al. [22] gave new algorithms for node-differentially private bipartite matching, improving upon the results of [36]. They also gave the first algorithms for maximum matchings in general graphs under local edge-differential privacy, also crucially using the MAT framework. Complementing their algorithms, they show a matching lower bound for edge-private maximum matchings. This follow up work highlights the wide applicability of the MAT framework, giving nearly tight algorithms for various combinatorial problems under differential privacy.

Table 1 Summary of error bounds in the local model. Each upper bound is for a mechanism satisfying (ε, δ)-edge differential privacy and holds with high probability. An asterisk in the citation indicates that an algorithm is (ε, δ)-LEDP instead of ε-LEDP. Lower bounds are for ε-differential privacy and hold with constant probability.

2 Technical Overview

MAT. Our new *Multidimensional AboveThreshold* (MAT) mechanism generalizes the AboveThreshold mechanism [24] to support a d-dimensional vector of queries. Conceptually, one may think of MAT as running d copies of AboveThreshold in parallel, one per dimension. More precisely, suppose that the input dataset for (single-dimensional) AboveThreshold was from some domain $\mathcal{X}$, then the input for our mechanism is $X = (x_1, \ldots, x_d) \in \mathcal{X}^d$, a d-tuple of elements from $\mathcal{X}$. Our mechanism takes as input an adaptively chosen sequence $\vec{f_1}, \vec{f_2}, \ldots$ of *query vectors* and a *threshold vector* $\vec{T} = (T_1, \ldots, T_d)$. Each query vector specifies d *queries*, one for each dimension of the dataset, i.e., $\vec{f_i} = (f_{i,1}, \ldots, f_{i,d})$ and query $f_{i,j} : \mathcal{X} \to \mathbb{R}$ is on element x_j. The goal is to (privately) return, after each query vector $\vec{f_i}$, a response vector $\vec{a_i} \in \{\bot, \top\}^d$ indicating whether each query $f_{i,j}$ in the vector has *crossed corresponding*

threshold T_j, i.e., $\vec{a}_i = (a_{i,1}, \ldots, a_{i,d})$ and $a_{i,j}$ indicates whether $f_{i,j}(x_j) \geq T_j$ ($\perp$ for "no", $\top$ for "yes"). After some query $f_{i,j}$ has crossed its threshold, then all future queries $f_{i',j}$, for $i' > i$, on element x_j are ignored (e.g., the response is always $\perp$). It is assumed that new query vectors are submitted until each element has had a query that has crossed its corresponding threshold. In a nutshell, MAT allows one to infer, for each element x_j, an estimate $\tilde{r}(j)$ of the index $r(j)$ of the *first* query $f_{r(j),j}$ on x_j that crosses the threshold T_j.

Sensitivity condition. We define a fairly technical condition on the *sensitivity* of the queries, generalizing the ℓ_1 sensitivity in the 1-dimensional case, such that the error of MAT can be bounded in terms of the sensitivity. For intuition, we first describe a simple case of our sensitivity condition.

Suppose that two datasets $X = (x_1, \ldots, x_d)$ and $X' = (x'_1, \ldots, x'_d)$ are neighboring only if they differ on at most $k \ll d$ coordinates, i.e., there exists a set $S \subseteq [d]$ of at most k indices such that $x_i = x'_i$ for all $i \notin S$ and $x_i \sim x'_i$ for all $i \in S$. Furthermore, suppose that the absolute difference of each query (on the appropriate element in X and X') is bounded by 1, i.e., for any query vector $\vec{f} = (f_1, \ldots, f_d)$, each query f_j satisfies $|f_j(x_j) - f_j(x'_j)| \leq 1$. Since MAT runs d copies of AboveThreshold in parallel and the queries are adaptive, applying concurrent composition [54] in this case would predict that the privacy loss is proportional to d. However, by coupling the outputs of the queries on the indices *not* in S (where X and X' are identical), it seems fairly intuitive that the actual privacy loss *should* be proportional to k. Hence, as the error of AboveThreshold is inversely proportional to the privacy loss parameter, to obtain ε-differential privacy, we *should* have at most $k \ll d$ times the original error of AboveThreshold in this setting, i.e., $O(k\varepsilon^{-1} \log n)$ with high probability.

More generally, for an arbitrary neighboring relation and arbitrary queries, roughly speaking, we define the sensitivity D as the worst-case (over pairs of neighboring datasets X and X') sum of the maximum absolute difference in the outputs of the queries (on X and X'); see Section 4 for a formal definition. In particular, for the simple case described above, $D = k$. Using this definition, we formalize the above intuition and prove that MAT guarantees an error of $O(D\varepsilon^{-1} \log n)$ in our applications, with high probability.

Applications of MAT. We apply MAT to get new private algorithms for the k-core decomposition, densest subgraph, low out-degree ordering, and defective coloring problems. In each case, given a graph $G = (V, E)$ with n vertices, we show that some non-private algorithm can be simulated via MAT, for suitable definitions of "dataset" and "queries".

As a simple example, for the core decomposition problem, a dataset $X = (x_u : u \in V)$ is an n-tuple containing the set of neighbors x_u of each vertex u in G. (Hence, the domain $\mathcal{X}$ is the set of all subsets of V.) A query $f_S : \mathcal{X} \to \mathbb{R}$ counts the number of neighbors of the vertex that are *not* among some fixed set of vertices $S \subseteq V$, shifted by some fixed amount i, and "mirrored" by n, i.e., $f_S(x) = n - (|x \setminus S| - i)$. (Notice that $f_S(x_u) \geq n$ means that vertex u has at most i neighbors that are not among S.) In this case, the absolute difference of each query on two neighboring datasets (i.e., graphs that differ by at most an edge) is at most 1 and there are at most two elements that differ for two neighboring datasets (namely, at the endpoints of the differing edge). Hence, the simple case mentioned above applies and MAT guarantees an error of $O(\varepsilon^{-1} \log n)$, with high probability.

For core decomposition, we apply MAT to analyze a variant of the classic peeling algorithm of Matula and Beck [44], which iteratively peels (removes) the lowest degree vertex in the graph. In our variant of the classical algorithm, we view the algorithm as running n iterations of a *peeling process*. In the ith iteration, the algorithm repeatedly peels all vertices with

(induced) degree less than i until none are left. It is known that, at the end of the ith iteration, a vertex is alive (has not been peeled) if and only if it is in the i-core. It can be shown that the peeling process can be simulated by MAT via the queries mentioned above. Hence, with some post-processing, we can obtain core numbers with no multiplicative factor and the optimal (up to a constant factor against our lower bound) additive error of $O(\varepsilon^{-1} \log n)$, with high probability. Similarly, we apply MAT to analyze the more round-efficient $(2+\eta)$-approximate core decomposition algorithm of [20], obtaining optimal error, with high probability.

Using our new core decomposition algorithms, we achieve improved additive error bounds for both the densest subgraph and low out-degree ordering problems. In particular, we show that the 2-approximate densest subgraph with additive error $O(\varepsilon^{-1} \log n)$ is contained in the subgraph consisting of all vertices with the maximum estimated core numbers (as we run the peeling algorithm, it can be shown that these vertices necessarily induce a subgraph with sufficiently high minimum degree). Furthermore, all of our core decomposition algorithms directly return a low out-degree ordering with the same multiplicative and additive errors as the original core decomposition algorithms by taking the order in which the nodes are peeled.

We also apply MAT to defective coloring by using MAT to greedily pick colors for each vertex from the available colors that have not yet been occupied by too many neighbors. In particular, each dimension represents a vertex and color pair consisting of all vertices in the graph and all available colors. For dimension j representing pair (v, c), the queries ask whether the number of neighbors of v colored with c exceeded our defectiveness threshold $O(\varepsilon^{-1} \log n)$. If it has, we will remove c from v's available set of colors. Our low round coloring algorithm follows a similar structure, and is inspired by the non-private algorithm of [34] and uses our low out-degree ordering algorithm to implement a separate set of available colors for each of $O(\log^2 n)$ groups of vertices of similar core numbers.

Local lower bound. Our lower bound for 1-round, exact core decomposition in the local model is obtained by reduction to a problem in the *centralized* model, for which there is a strong lower bound. Specifically, it is known that, to privately answer $\Theta(n)$ *random* inner product queries on a secret $\{0,1\}^n$ vector, most responses need to have $\Omega(\sqrt{n})$ additive error [17]. Recently, [26] gave an elegant lower bound on the additive error of 1-round triangle counting algorithms in the local model using similar techniques.

In our case, we define a class of "query graphs", one per inner product query, in which the core number of a *fixed* vertex x is (roughly) the answer to the query. In addition to x, there are some *secret* vertices (and other vertices). For each secret vertex v, the existence of the edge $\{v, x\}$ is private information (which depends on the secret vector). Crucially, all neighborhoods of x and the secret vertices in *any possible query graph* appear in two specific query graphs, namely, ones corresponding to the all-ones and all-zeros query vectors, respectively. The neighborhoods of the remaining vertices do not depend on the secret vector.

Our approach to solving the inner product problem is now as follows. The centralized algorithm first simulates the 1-round local core decomposition algorithm on the two fixed graphs to determine the messages that x and the secret vertices would send in *any* query graph and saves these messages. Subsequently, when answering a query, the centralized algorithm *reuses* the saved messages for x and the secret vertices (without further privacy loss) when it simulates the core decomposition algorithm on the corresponding query graph. This allows it to answer many queries correctly.

Originally, we had a more complex, direct argument. We briefly mention it here to give an idea of what is going on "under the hood" of the reduction. Specifically, we showed that, on a class of random graphs (similar to the query graphs instantiated in our reduction), most

transcripts of a 1-round core decomposition algorithm have the property that, conditioned on seeing the transcript, the coreness of some (fixed) vertex still has high variance, $\Omega(n)$. This implies that the standard deviation of the additive error is $\Omega(\sqrt{n})$. We prefer the reduction argument, as it is simpler and gives a stronger result.

One-round algorithm for densest subgraph. In our single-round exact densest subgraph algorithm, the vertices send the server a noisy version of the incidence matrix of the graph by using randomized response. In particular, each vertex sends its row of the incidence matrix and, for each bit, it sends the actual bit with probability $p = e^{\varepsilon}/1 + e^{\varepsilon}$; the flipped bit is sent with probability $1 - p$. Using this, the server can create an unbiased estimator $\tilde{E}(S)$ for the number of edges $E(S)$ inside any *fixed* subset of vertices S. The key observation is that the standard deviation σ of the estimated density, i.e., $\tilde{E}(S)/|S|$, is $O(1 + \varepsilon^{-1})$ and the estimated density is distributed binomially. Hence, by a Chernoff bound, the estimated density is $\Omega(\sqrt{\log t})$ standard deviations away from the actual density with probability at most $1/t$. By taking a union bound over all S, we can upper bound the total error over *all* (exponentially many) subsets by $\alpha = O(\sigma\sqrt{n})$ with high probability. Hence, a *brute-force*, exponential-time search, which computes the maximum $\tilde{E}(S)/|S|$ over all subsets S, finds a subset whose density is at most α from the maximum density, with high probability. The union bound appears to be necessary, but it is conceivable that there are more clever search strategies that do not require looking at exponentially many subsets S.

3 Differential Privacy Background

We give some basic definitions and background on differential privacy in this section, see [25] for more details. Since we will only be working with graphs, we will state these results in terms of edge differential privacy for graph algorithms; we will also use the terms differential privacy and edge differential privacy interchangeably. Edge-neighboring graphs is a well-studied model for differential privacy (see e.g. [40] for a survey of such results) and protects the privacy of edges with highly sensitive information like disease transmission graphs.

▶ **Definition 12.** *Two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ are* edge-neighboring*, denoted by $G_1 \sim G_2$, if $V_1 = V_2$ and $|E_1 \oplus E_2| = 1$ (i.e., they have the same vertex set and they differ by exactly one edge).*

▶ **Definition 13.** *We use $\mathcal{G}$ to denote the set of undirected graphs. An algorithm $\mathcal{M} : \mathcal{G} \to \mathcal{Y}$ is* (ε, δ)-edge differentially private *((ε, δ)-edge dp) if for all edge-neighboring graphs $G \sim G'$ and every $S \subseteq \mathcal{Y}$, we have*

$$\Pr[\mathcal{M}(G) \in S] \leq \exp(\varepsilon) \cdot \Pr[\mathcal{M}(G') \in S] + \delta.$$

If $\delta = 0$, we say $\mathcal{M}$ is ε-edge differentially private (ε-edge DP). When $\mathcal{M}$ is defined over $\mathbb{N}$ or $\mathbb{R}$ instead, it is called ε-differentially private (ε-DP).

Next, we define two important properties of DP: composition and post-processing.

▶ **Lemma 14.** *Let $\mathcal{M}_1 : \mathcal{G} \to \mathcal{Y}_1$ and $\mathcal{M}_2 : \mathcal{G} \to \mathcal{Y}_2$ be ε_1- and ε_2-edge differentially private mechanisms, respectively. Then $\mathcal{M} : \mathcal{G} \to \mathcal{Y}_1 \times \mathcal{Y}_2$ defined by $\mathcal{M} = (\mathcal{M}_1, \mathcal{M}_2)$ is $(\varepsilon_1 + \varepsilon_2)$-edge differentially private.*

▶ **Lemma 15.** *Let $\mathcal{M} : \mathcal{G} \to \mathcal{Y}$ be an ε-edge differentially private mechanism. and $f : \mathcal{Y} \to \mathcal{Z}$ be an arbitrary randomized mapping. Then $f \circ \mathcal{M} : \mathcal{G} \to \mathcal{Z}$ is ε-edge differentially private.*

The ℓ_1-*sensitivity* of a function $f : \mathcal{G} \to \mathbb{R}^d$, denoted $\Delta_1(f)$, is the supremum of the quantity $\|f(x) - f(x')\|_1 = \sum_{i=1}^{d} |f(x)_i - f(x')_i|$, over all neighboring $G, G' \in \mathcal{G}$. The *Laplace* distribution (centered at 0) with *scale* $b > 0$ has probability density function $f(x) = \frac{1}{2b} \exp(-|x|/b)$. We write $X \sim \mathsf{Lap}(b)$ or just $\mathsf{Lap}(b)$ to denote a random variable X that is distributed according to the Laplace distribution with scale b.

▶ **Fact 3.1.** *If random variable $X \sim \mathsf{Lap}(b)$, then, for any $\beta > 0$, $\Pr[|X| > b \log(1/\beta)] \leq \beta$.*

▶ **Fact 3.2** (Theorem 3.6 in [25])**.** *Let $f : \mathcal{G} \to \mathbb{R}^d$ be any function, let $\epsilon > 0$, and let, for each $i \in [d]$, $X_i \sim \mathsf{Lap}(\Delta_1(f)/\epsilon)$. Then the* Laplace mechanism *$\mathcal{A}(x) = f(x) + (X_1, \ldots, X_d)$ is ϵ-differentially private.*

3.1 Local Edge Differential Privacy (LEDP)

The local model of differential privacy studies the setting where all private information is kept private by the individual parties, i.e. there exists no trusted curator. For graphs, the local model is called local edge differential privacy [20]. We now define this formally.

▶ **Definition 16.** *Let G be a graph. An ε-**local randomizer** $R : \mathbf{a} \to \mathcal{Y}$ for vertex v is an ε-edge differentially private algorithm that takes as input the set of its neighbors $N(v)$ in G, represented by an adjacency list $\mathbf{a} = (b_1, \ldots, b_{|N(v)|})$.*

Note that the information released via local randomizers is public to all nodes and the curator. The curator performs some computation on the released information and makes the result public via sending a message to all vertices. The overall computation is formalized via the notion of the transcript.

▶ **Definition 17.** *Let G be a graph. A* transcript *π is a vector consisting of 4-tuples $(S_U^t, S_R^t, S_\varepsilon^t, S_Y^t)$ – encoding the set of vertices chosen, the set of local randomizers assigned, the set of privacy parameters of the randomizers, and the set of randomized outputs produced – for each round t. Let S_π be the collection of all transcripts and S_R be the collection of all randomizers. Let STOP denote a special character indicating that the local randomizer's computation halts. A* protocol *is an algorithm $\mathcal{A} : S_\pi \to (2^{[n]} \times 2^{S_R} \times 2^{\mathbb{R}^{\geq 0}} \times 2^{\mathbb{R}^{\geq 0}}) \cup \{STOP\}$ mapping transcripts to sets of vertices, randomizers, and randomizer privacy parameters. The length of the transcript, as indexed by t, is its round complexity. Given $\varepsilon > 0$, a randomized protocol $\mathcal{A}$ on graph G is* ε-local edge differentially private *if the algorithm that outputs the entire transcript generated by $\mathcal{A}$ is ε-edge differentially private on graph G.*

The definition is difficult to parse, but it naturally corresponds to the intuition of vertices with private information communicating with an untrusted curator (represented by the protocol) so that the curator can compute some output that depends on the private data of the vertices (see also the discussion in [21]). At the beginning, the curator only knows the vertex set V and each vertex knows its incident edges, i.e., its neighborhood. In each round, a chosen subset of the vertices performs some computation using local randomizers on (a) their local edge information, (b) the outputs from previous rounds, and (c) the public information, so basically the whole transcript so far. The vertices then output a message which can be seen by all other vertices and the curator. The released information of each vertex is ε-dp since it computed based on the output of its local randomizer. In each round the curator can choose whom to query, what local randomizer they use, and what privacy parameters the randomizer uses. Since the curator's choice only depends on the transcripts from the previous rounds, this is exactly the definition of a protocol in the above definition.

Algorithm 1 Multidimensional AboveThreshold (MAT).

Input: Private graph G, adaptive queries $\{\vec{f}_1, \ldots, \vec{f}_n\}$, threshold vector $\vec{T}$, privacy ε, sensitivity D.
Output: A sequence of responses $\{\vec{a}_1, \ldots, \vec{a}_n\}$ where $a_{i,j}$ indicates if $f_{i,j}(G) \geq \vec{T}_j$

for $j = 1, \ldots, d$ **do**
  $\hat{T}_j \leftarrow \vec{T}_j + \mathrm{Lap}(2D/\varepsilon)$
end for

for each query $\vec{f}_i \in \{\vec{f}_1, \ldots, \vec{f}_n\}$ **do**
  for $j = 1, \ldots, d$ **do**
    Let $\nu_{i,j} \leftarrow \mathrm{Lap}(4D/\varepsilon)$
    if $f_{i,j}(G) + \nu_{i,j} \geq \hat{T}_j$ **then**
      Output $a_{i,j} = \top$
      Stop answering queries for coordinate j
    else
      Output $a_{i,j} = \bot$
    end if
  end for
end for

We end the discussion with a short remark on stateless/stateful vertices. As defined above, a local randomizer is only allowed to look at the past (public) transcript and its (private) neighborhood list to compute its output for the current round. This formal definition disallows the use of private states that persist across rounds in the local memory of a vertex. Private stateful behaviour is nonetheless crucial for implementing MAT locally, since we require each vertex to store its noisy threshold privately. This is not a problem, since one can implement a protocol as in [5, Lemma 8] to simulate private states using local randomizers.

4 Generalized Sparse Vector Technique

We introduce a simple, novel multidimensional generalization of the AboveThreshold mechanism, which is the basis of the algorithms in this paper. In the standard AboveThreshold mechanism from Section 3.6 in [25], we are given as input a threshold T and an adaptive stream of sensitivity 1 queries $f_1, f_2, \ldots$, and the goal is to output the first query which exceeds the threshold. In the multidimensional version, we have a d-dimensional vector of thresholds $\vec{T} = (T_1, \ldots, T_d)$ and an adaptive stream of ℓ_1-sensitivity D vector-valued queries $\vec{f}_1, \vec{f}_2, \ldots$. The goal is to output, for each coordinate $j \in [d]$, the first query i_j for which the j^{th} coordinate exceeds the threshold T_j. The pseudo-code is given in Algorithm 1.

Here D is defined as the sensitivity for *all* dimensions, i.e., for edge-neighboring $G \sim G'$,

$$D := \max_{G \sim G'} \left(\sum_{j \in [d]} \left(\max_{i \in [I_j]} \left(|f_{i,j}(G) - f_{i,j}(G')| \right) \right) \right), \tag{1}$$

where I_j is the number of queries in dimension j.

▶ **Theorem 18.** *Algorithm 1 is ε-differentially private.*

Proof. Fix $G \sim G'$ to be arbitrary edge-neighboring graphs. Let $\mathcal{A}(G)$ and $\mathcal{A}(G')$ denote the random variable representing the output of Algorithm 1 when run on G and G', respectively. For each coordinate $j \in [d]$, there is some $r(j) \in \{1, \ldots, n+1\}$ such that the output satisfies $a_{\cdot j} \in \{\top, \bot\}^{r(j)}$ and has the form that for all $i < r(j)$, $a_{i,j} = \bot$. We can assume without loss of generality that $a_{r(j),j} = \top$; if $r(j) < n+1$, this must be the case and if $r(j) = n+1$, we can simply ask an additional query which evaluates to ∞, independent of the dataset. Our goal is to show that for any output a, we have

$$\Pr[\mathcal{A}(G) = a] \leq \exp(\varepsilon) \cdot \Pr[\mathcal{A}(G') = a].$$

Observe that there are two sources of randomness in the algorithm: the noisy thresholds $\hat{T}_j$ for each $j \in [d]$ and the perturbations of the queries $\nu_{i,j}$ for each $j \in [d]$, $i \in [r(j)]$. We fix the random variables $\nu_{i,j}$ for each $j \in [d]$ and $i < r(j)$ by simply conditioning on their randomness; for neighboring graphs, we have a coupling between corresponding variables. For simplicity, we omit this from notation. The remaining random variables are $\hat{T}_j$ and $\nu_{r(j),j}$ for each $j \in [d]$; we will be taking probabilities over their randomness. The main observation needed is that the output of $\mathcal{A}$ is uniquely determined by the values of $r(j)$ for each $j \in [d]$. Thus, we can define the (deterministic, due to conditioning on the probabilities) quantity

$$g_j(G) \coloneqq \max\{f_{i,j}(G) + \nu_{i,j} : i < r(j)\}$$

for each $j \in [d]$ so that the event that $\mathcal{A}(G) = a$ is equivalent to the event where

$$\hat{T}_j > g_j(G) \text{ and } f_{r(j),j}(G) + \nu_{r(j),j} \geq \hat{T}_j \text{ for each } j \in [d]. \tag{2}$$

Let $p(\cdot)$ and $q(\cdot)$ denote the density functions of the random vectors consisting of $\hat{T}(j)$ and $\nu_{r(j),j}$ for each $j \in [d]$. Thus,

$$\Pr[\mathcal{A}(G) = a] = \Pr[\hat{T}_j \in (f_{r(j),j}(G) + \nu_{r(j),j}, g_j(G)) \ \forall j \in [d]]$$

Using v'_j to denote the value of $\nu_{r(j),j}$ and t'_j to denote the value of $\hat{T}_j$,

$$\Pr[\mathcal{A}(G) = a] = \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} p(\vec{t'}) q(\vec{v'}) \cdot \mathbb{1}\{t'_j \in (f_{r(j),j}(G) + v'_j, g_j(G)) \ \forall j \in [d]\} \, d\vec{v'} \, d\vec{t'} \tag{3}$$

Now, we make a change of variables from $\vec{v'}$ to $\vec{v}$ and $\vec{t'}$ to $\vec{t}$, with the change given by

$$v'_j = v_j + g_j(G) - g_j(G') + f_{r(j),j}(G') - f_{r(j),j}(G)$$
$$t'_j = t_j + g_j(G) - g_j(G')$$

for each $j \in [d]$. We have that $d\vec{t'}_j = d\vec{t}_j$, and $d\vec{v'}_j = d\vec{v}_j$ since the new variables differ from the old ones by a constant that is independent of $\vec{v}$ and $\vec{t}$. The term inside the indicator function in the integral now becomes

$$t_j + g_j(G) - g_j(G') \in (f_{r(j),j}(G) + v_j + g_j(G) - g_j(G') + f_{r(j),j}(G') - f_{r(j),j}(G), g_j(G)) \forall j \in [d]$$

which on subtracting $g_j(G) - g_j(G')$ gives

$$t_j \in (f_{r(j),j}(G') + v_j, g_j(G')) \forall j \in [d]$$

Thus, we can apply the change of variables to rewrite (3) as

$$\int_{\mathbb{R}^d} \int_{\mathbb{R}^d} p(\vec{t'}) q(\vec{v'}) \mathbb{1}\{t_j \in (f_{r(j),j}(G') + v_j, g_j(G')) \ \forall j \in [d]\} \, d\vec{v} \, d\vec{t}.$$

Since we have conditioned on the randomness of $\nu_{i,j}$ for each $j \in [d]$ and $i < r(j)$, we have $\|\vec{v'} - \vec{v}\|_1 \leq 2D$ and $\|\vec{t'} - \vec{t}\|_1 \leq D$ since the vectors $f_{i\cdot}(G)$ have sensitivity D, implying that the vectors $g_{\cdot}(G)$ also have sensitivity D. This implies that $p(\vec{t'}) \leq \exp(\varepsilon/2) \cdot p(\vec{t})$ and $q(\vec{v'}) \leq \exp(\varepsilon/2) \cdot q(\vec{v})$ by the properties of the Laplace distribution. We can thus upper bound the above integral by

$$\exp(\varepsilon) \cdot \int_{\mathbb{R}^d} \int_{\mathbb{R}^d} p(\vec{t}) q(\vec{v}) \mathbb{1}\{t_j \in (f_{r(j),j}(G') + v_j, g_j(G'))\ \forall j \in [d]\}\, d\vec{v}\, d\vec{t}$$

Rewriting the integral as the probability of an event, we get

$$\exp(\varepsilon) \cdot \Pr[\hat{T}_j \in (f_{r(j),j}(G') + \nu_{r(j),j}, g_j(G'))\ \forall j \in [d]].$$

Finally, by our observation in (2), this is equal to

$$\exp(\varepsilon) \cdot \Pr[\mathcal{A}(G') = a].$$

Putting the inequalities together, we get

$$\Pr[\mathcal{A}(G) = a] \leq \exp(\varepsilon) \cdot \Pr[\mathcal{A}(G') = a].$$

Since G, G' were arbitrary edge-neighboring graphs, this completes the proof. ◀

4.1 LEDP Multidimensional AboveThreshold (MAT) Mechanism

In our algorithms, we apply the multidimensional AboveThreshold mechanism in the special case where the queries $\vec{f_i}$ have $d = n$ coordinates, and each coordinate of the query corresponds to a node u in the graph G and only depends on the edges $e = (u, v)$ for $v \in V - \{u\}$. In other words, we have an instance of the AboveThreshold on each node $u \in V$, where the data used for the AboveThreshold instance is only the local (edge) data of u. We will show that in this setting, the multidimensional AboveThreshold mechanism can be implemented locally to satisfy local edge-differential privacy.

For clarity of notation, we index the coordinates of the queries and threshold vector by nodes $v \in V$ instead of indices $j \in [n]$. That is, each query consists of $\vec{f_{i,v}}$ for $v \in V$ and the threshold vector consists of $\vec{T_v}$ for $v \in V$. We will now present the changes needed for the local implementation. In Lines 1–3, let each node $u \in V$ compute and store its noisy threshold $\hat{T}_u$ using the public threshold $\vec{T}_u$. Then for each query $\vec{f_i}$ in lines 5–15, each node $u \in V$ can sample its own noise $\nu_{i,u}$ and check the condition $f_{i,u}(G) + \nu_{i,u} \geq \hat{T}_u$. The pseudocode is given in Algorithm 2, where actions performed by node v in the algorithm are performed their corresponding local randomizers, and we now show that this is locally edge-differentially private.

▶ **Theorem 19.** *Algorithm 2 is ε-locally edge differentially private.*

Proof. First, we need to show that the local randomizers are in fact edge-differentially private. This can be seen because each randomizers' output is a subset of the output of Algorithm 1 and it is only computed based on the incident edges of each vertex. In other words, the output is a post-processing of Algorithm 1, so the privacy guarantees follow from Theorem 18 and Lemma 15. Next, we argue that the transcript is also ε-edge differentially private. Recall that the transcript consists of the set of vertices chosen, the set of local randomizers assigned, the set of privacy parameters assigned, and the set of outputs. In the algorithm, the set of vertices chosen, the set of local randomizers assigned, and the set of privacy parameters assigned are all functions of the outputs from the previous rounds and the public information. Thus, it suffices to prove that the outputs are differentially private by post-processing (Lemma 15). But this was proven in Theorem 18, so we are done. ◀

Algorithm 2 Local Multidimensional AboveThreshold.

Input: Private graph G, adaptive queries $\{\vec{f}_i\}$, threshold vector $\vec{T}$, privacy ε, sensitivity D.

  Node v computes $\hat{T}_v \leftarrow \vec{T}_v + \text{Lap}(2D/\varepsilon)$ and stores it
end for

for each query $\vec{f}_i$ **do**
  for $v \in V$ **do**
    Node v samples $\nu_{i,v} \leftarrow \text{Lap}(4D/\varepsilon)$
    if $f_{i,v}(G) + \nu_{i,v} \geq \hat{T}_v$ **then**
      Node v outputs $a_{i,j} = \top$
      Node v outputs STOP, and stops answering queries
    else
      Node v outputs $a_{i,v} = \perp$
    end if
  end for
end for

5 LEDP k-Core Decomposition

In this section, we present one application of MAT by giving an improved algorithm for differentially private k-core decomposition. We first present a variant of the classical (non-private) algorithm for k-core decomposition in Section 5.1, and then show how to make it private in Section 5.2. We defer our other proofs to the full version.

5.1 A Variation of the Classical Algorithm

The classical peeling algorithm begins with the full vertex set V, which is the 0-core of the graph. Given the $(k-1)$-core, the algorithm computes the k-core via an iterative peeling process: the algorithm repeatedly removes all nodes v for which the induced degree is less than k, and labels the nodes which remain as being part of the k-core. Running this for k from 1 up to n gives the full algorithm, the pseudocode of which is given in Algorithm 3.

▶ **Theorem 20.** *For all $v \in V$, the output $\hat{k}(v)$ given by Algorithm 3 is the core number of v.*

Proof. We will inductively show that the algorithm recovers the k-core of the graph. The base case of $k = 0$ is easy. Now, assume that the algorithm finds the true $(k-1)$-core. Let $V(k)$ denote the subset of nodes which aren't removed in the iterative process for $k-1$ in Line 2. We have that each node $v \in V(k)$ has induced degree at least k in $V(k)$, or else it would have been removed. Thus, we know that the core numbers $k(v)$ is at least k for each $v \in V(k)$, so we have that $V(k)$ is a subset of the true k-core. Now, let K denote the true k-core. Since the k-core is always a subset of the $(k-1)$-core by definition, each node $v \in K$ is in V_t at the beginning of the iterations. Furthermore, we know that $v \in K$ is never removed from V_t since the induced degree is always at least k since $K \subseteq V_t$. Thus, we have that $V(k)$ is a superset of the true k-core as well. Thus, $V(k)$ is the true k-core for each k, so all nodes are labelled correctly. ◀

Algorithm 3 Threshold-Based k-core Decomposition Algorithm.

1 **Input:** Graph $G = (V, E)$.
2 **Output:** k-core value of each node $v \in V$

1: Initialize $V_0 \leftarrow V$, $t \leftarrow 0$, $\hat{k}(v) \leftarrow 0$ for all $v \in V$
2: **for** $k = 1, \ldots, n$ **do**
3: **repeat**
4: $t \leftarrow t + 1$, $V_t \leftarrow V_{t-1}$
5: **for** $v \in V_{t-1}$ **do**
6: **if** $d_{V_{t-1}}(v) < k$ **then**
7: $V_t \leftarrow V_t - \{v\}$
8: **end if**
9: **end for**
10: **until** $V_{t-1} - V_t = \emptyset$
11:
12: Update the core numbers $\hat{k}(v) \leftarrow k$ for all nodes $v \in V_t$
13: **end for**

5.2 Private Implementation of the Algorithm

It is difficult to turn the classical algorithm into a differentially private one because it has $\Omega(n)$ iterations, which causes us to incur $\tilde{\Omega}(n)$ additive error when using basic composition (Lemma 14). In fact, this was cited in [20] as the motivation for basing their algorithms on parallel/distributed algorithms for k-core decomposition, since those algorithms often have $\operatorname{poly}\log(n)$ round-complexity. Our main observation is that the private version of Algorithm 3 can be analyzed as a special case of the Multidimensional AboveThreshold mechanism, so it doesn't need to incur the $\Omega(n)$ additive error due to composition.

▶ **Theorem 21.** *Algorithm 4 is ε-edge differentially private.*

Proof. We will show that Algorithm 4 is an instance of the multidimensional AboveThreshold mechanism, implying that it is ε-edge differentially private. Specifically, we will show that its output can be obtained by post-processing the output of an instance of Algorithm 1. Indeed, consider the instance of the multidimensional AboveThreshold mechanism where the input graph is G, the privacy parameter is ε, and the threshold vector $\vec{T} = \vec{0}$ is the zero vector. We will now inductively (and adaptively) define the queries.

For each iteration t, the t^{th} query consists of the vector of $k - d_{V_{t-1}}(v)$ for each $v \in V$, where $V_0 = V$ as in the algorithm; note that this matches with the queries on Line 2 of the algorithm. First, observe that the sensitivity of the vector queries of $k - d_{V_{t-1}}(v)$ for each $v \in V$ is $D = 2$ since one edge change will only affect two coordinates of the query (each by 1), as needed in the privacy analysis. Next, observe that we can construct V_t from V_{t-1} using only the outputs $a_t(v)$ of the queries at the current iteration: given $v \in V_{t-1}$, we include v in V_t as well if and only if $a_t(v) = \perp$, which is equivalent to the condition in Line 2 of $d_{V_{t-1}}(v) + \nu_{t,v} \leq k + \tilde{\ell}(v)$[3]. Thus, this is a feasible sequence of adaptive queries for the AboveThreshold mechanism.

[3] Here, we implicitly assume that the randomness used by the algorithm and the AboveThreshold mechanism are the same. This is justified by a coupling of the random variables in the two algorithms. Specifically, we couple the noise added in Line 4 of the algorithm with the noise added in Line 2 of the AboveThreshold mechanism and couple the noise $\nu_{t,v}$ with $\nu_{i,j}$ in the AboveThreshold mechanism. It

Algorithm 4 ε-Differentially Private k-Core Decomposition.

Input: Graph $G = (V, E)$, privacy parameter $\varepsilon > 0$.
Output: An $(1, 120\log(n)/\varepsilon)$-approximate k-core value of each node $v \in V$

$V_0 \leftarrow V$, $t \leftarrow 0$, $k = 60\log n/\varepsilon$.

for $v \in V$ **do**
  $\tilde{\ell}(v) \leftarrow \text{Lap}(4/\varepsilon)$
end for

while $k \leq n$ **do**
  repeat
    $t \leftarrow t + 1$, $V_t \leftarrow V_{t-1}$
    for $v \in V_{t-1}$ **do**
      $\nu_{t,v} \leftarrow \text{Lap}(8/\varepsilon)$
      if $d_{V_{t-1}}(v) + \nu_{t,v} \leq k + \tilde{\ell}(v)$ **then**
        $V_t \leftarrow V_t - \{v\}$
      end if
    end for
  until $V_{t-1} - V_t = \emptyset$

  Update the core numbers $\hat{k}(v) \leftarrow k$ for all nodes $v \in V_t$
  $k \leftarrow k + 60\log n/\varepsilon$
end while

Since the sequence of subsets $\{V_t\}$ are obtained by post-processing the outputs $a_t(v)$ of the AboveThreshold mechanism, they are ε-differentially private by Theorem 18 and Lemma 15. By applying post-processing again, the sequence of pairs (V_t, k_t) for each iteration t is also ε-differentially private since the sequence k_t is public. Given the pairs (V_t, k_t) for each iteration t, we can now recover the approximate core numbers which the algorithm outputs by setting the core numbers as $\hat{k}(v) = k_t$ for each node in $V_t - V_{t-1}$. It is easily verified that this gives the exact same output as Algorithm 4, so we have ε-differential privacy for the algorithm by applying post-processing (Lemma 15) once again. ◀

▶ **Theorem 22.** *Algorithm 4 outputs* $(1, \frac{120\log n}{\varepsilon})$*-approximate core numbers* $\hat{k}(v)$ *with probability* $1 - O(\frac{1}{n^2})$.

Proof. By the density function of the Laplace distribution, we know that we have $|\nu_{t,u}| \leq \frac{40\log n}{\varepsilon}$ and $|\tilde{\ell}(u)| \leq \frac{20\log n}{\varepsilon}$ each with probability $\geq 1 - \frac{1}{n^5}$. Since there are at most $O(n^3)$ such random variables, taking a union bound over all nodes $u \in V$ and all iterations of the loops gives the above guarantee with probability $\geq 1 - O\left(\frac{1}{n^2}\right)$. We condition on the event that the above inequalities hold true for all $t \in [T]$ and $u \in V$ for the remainder of the proof.

Fix an arbitrary iteration k of the while loop starting on Line 7. Let H be the set of nodes remaining in V_t at the end of the while loop in Lines 8–16. We claim that (i) all nodes $u \in H$ have core number at least $k - \frac{60\log n}{\varepsilon}$ and (ii) all nodes $u \notin H$ have core number at most $k + \frac{60\log n}{\varepsilon}$. To see (i), consider the subgraph H; we claim that each node $u \in H$ has

is easy to see that for $\Delta = 2$, the random variables are exactly the same so the privacy guarantees of multidimensional AboveThreshold translates to privacy guarantees for our algorithm.

induced degree at least $k - \frac{60 \log n}{\varepsilon}$ in H. Indeed, since each node in H was not removed in the final iteration of the while loop in Lines 8–16, we have that $d_{H_t}(u) + \nu_{t,u} \geq k + \tilde{\ell}(u)$ for each $u \in H$. But since we have assumed $|\nu_{t,u}| \leq \frac{40 \log n}{\varepsilon}$ and $|\tilde{\ell}(u)| \leq \frac{20 \log n}{\varepsilon}$, our desired bounds follow directly by the triangle inequality. To see (ii), let's suppose for contradiction that the k-core value of u is $k(u) > \ell + \frac{60 \log n}{\varepsilon'}$. Then there exists a subgraph $u \in K \subseteq V$ where the induced degree of each node $v \in K$ is $d_K(v) \geq k(u)$. But for such a subgraph K, the condition in Line 12 will always be true (again, because $|\nu_{t,u}| \leq \frac{40 \log n}{\varepsilon}$ and $|\tilde{\ell}(u)| \leq \frac{20 \log n}{\varepsilon}$) so $K \subseteq H$. But since $u \in K$, this contradicts the fact that $u \notin H$.

Using the above bounds, we can now prove our desired results. First, consider an arbitrary node $u \in V$ labeled $\hat{k}(u)$ within the while loop in Lines 7–20 and not relabeled later. Since u was labeled $\hat{k}(u)$ in the current iteration, we have that $k(u) \geq \hat{k}(u) - \frac{60 \log n}{\varepsilon'}$. Since u was not relabelled in the next iteration where the threshold was $k = \hat{k}(u) + \frac{60 \log n}{\varepsilon}$, the node u was removed from V_t at that iteration. Consequently, we have $k(u) \leq k + \frac{60 \log n}{\varepsilon} = \hat{k}(u) + \frac{120 \log n}{\varepsilon}$ by what we just proved above. Since the output of our algorithm is $\hat{k}(u)$, the desired bounds follow directly. Now, let's consider an arbitrary node $u \in V$ labeled 0 at Line 2 at the beginning of the algorithm and not relabeled later. Since the node u was not relabelled at the first iteration where $k = \frac{60 \log n}{\varepsilon}$, it was removed from V_t at that iteration, implying that $k(u) \leq \frac{120 \log n}{\varepsilon}$. Hence, we have the desired approximation guarantees for all nodes. ◀

Incremental Maximization for a Broad Class of Objectives

Yann Disser
TU Darmstadt, Germany

David Weckbecker
TU Darmstadt, Germany

Abstract

We consider incremental maximization problems, where the solution has to be built up gradually by adding elements one after the other. In every step, the incremental solution must be competitive, compared against the optimum solution of the current cardinality. We prove that a competitive solution always exists when the objective function is monotone and β-accountable, by providing a scaling algorithm that guarantees a constant competitive ratio. This generalizes known results and, importantly, yields the first competitive algorithm for the natural class of monotone and subadditive objective functions.

1 Introduction

Large infrastructure projects are typically implemented sequentially over longer periods of time. In such settings, it makes sense to prioritize completion of parts of the project that already yield some benefit on their own. This raises the general question of how to compute incremental solutions with a good partial benefit throughout the course of the project. We model such settings mathematically by using the abstract framework of the *incremental maximization* (IncMax) problem.

In the IncMax problem, we are given a countable set of elements U, along with an objective function $f\colon 2^U \to \mathbb{R}_{\geq 0}$. We generally require f to be monotone, i.e., that $f(A) \leq f(B)$ for all $A \subseteq B \subseteq U$. An *incremental solution* π is a permutation $(e_1, e_2, \dots)$ of the elements in U that specifies the order in which the elements are to be included in the solution. The solution after step $C \in \mathbb{N}$ is then given by $\pi(C) := \{e_1, \dots, e_C\}$, and we denote the optimum solution value of cardinality C by

$$\textsc{Opt}(C) := \sup\{f(A) \mid A \subseteq U, |A| = C\}.$$

We say that the incremental solution π is *ρ-competitive* if $\textsc{Opt}(C) \leq \rho \cdot \pi(C)$ for all $C \in \mathbb{N}$. The *competitive ratio* of π is $\rho(\pi) := \inf\{\rho \geq 1 \mid \pi \text{ is } \rho\text{-competitive}\}$, the competitive ratio of a problem instance given by U and f is $\rho(U, f) := \inf_\pi \rho(\pi)$, and the competitive ratio of a set of instances $\mathcal{C}$ is $\rho(\mathcal{C}) := \sup\{\rho(U, f) \mid (U, f) \in \mathcal{C}\}$.

Clearly, we cannot hope for good incremental solutions in full generality: For example, if $f(E)$ is given by the value of a maximum flow using an edge set E in some underlying graph that consists of a short path of low capacity and a long path of high capacity, then we have to decide whether to invest in the short path to obtain some value early, or in the long path to achieve a high value as quickly as possible, but cannot ensure both simultaneously. generally, we must demand that the objective function has some form of a diminishing-returns property that requires the value of solutions to be explainable by the value of their parts, i.e., value cannot suddenly emerge upon completion of certain structures (such as paths in the flow example).

Diminishing returns are typically captured by submodular objective functions, i.e., functions $f\colon 2^U \to \mathbb{R}_{\geq 0}$ with $f(A)+f(B) \geq f(A\cup B)+f(A\cap B)$ for all $A, B \subseteq U$. In a classical result, Nemhauser et al. [25] showed that the obvious greedy algorithm, that adds to the current solution S the element e of largest marginal value $f(S\cup\{e\})-f(S)$ in each step, produces a $\frac{\mathrm{e}}{\mathrm{e}-1}$-competitive solution for submodular objectives. The most natural relaxation of submodularity that still intuitively captures diminishing returns is subadditivity, i.e., $f(A)+f(B)\geq f(A\cup B)$ for all $A, B \subseteq U$. While subadditivity is a classical and natural property that intuitively seems promising for incremental maximization, no bounds on the compatitive ratio were known to date.

Unable to bound the competitive ratio for subadditive objectives, Bernstein et al. [1] considered *accountable* functions f instead (see Figure 1 along with the following). A function $f\colon 2^U \to \mathbb{R}_{\geq 0}$ is called *accountable* if, for every finite and non-empty set $S \subseteq U$, there exists $e \in S$ with $f(S\setminus\{e\}) \geq \big(1-\frac{1}{|S|}\big)f(S)$. Intuitively, this property directly requires that the value of a set cannot suddenly emerge when adding its last element. Bernstein et al. [1] gave a $(\varphi+1)$-competitive scaling algorithm for accountable objectives, where $\varphi := (\sqrt{5}+1)/2$ denotes the golden ratio.

Note that submodular functions are accountable, and many combinatorial maximization problems, such as weighted (multidimensional) matching, set packing, coverage, knapsack, and many more, give rise to accountable objective functions (see [1]). On the other hand, not all subadditive functions are accountable. For a simple example, assume that the elements of U represent identical unit squares, and $f(S)$ is the diameter of the largest square that can be tiled with the elements in $S \subseteq U$. Then, $f(S) = \lfloor\sqrt{|S|}\rfloor$ grows strictly sublinearly in $|S|$ and is thus subadditive, but it is not accountable, as can be seen by considering $|S| = 4$, which yields $f(S\setminus\{e\}) = 1 < \frac{3}{2} = \big(1-\frac{1}{4}\big)f(S)$ for all $e \in S$. More generally, functions of the form $f(A) = \lfloor g(|A|)\rfloor$ with $g \in o(|A|)$ are subadditive, but not accountable.

Disser and Weckbecker [11] considered γ-α-augmentability as an alternative relaxation of submodularity that additionally maintains competitiveness of the greedy algorithm. A function is called γ-α-augmentable if, for all finite $A, B \subseteq U$, there exists $b \in B$ with $f(A\cup\{b\})-f(A) \geq \frac{\gamma f(A\cup B)-\alpha f(A)}{|B|}$. In this setting, the greedy algorithm has competitive ratio exactly $\frac{\alpha}{\gamma}\cdot\frac{\mathrm{e}^\alpha}{\mathrm{e}^\alpha-1}$.

In this paper, we provide a scaling algorithm that is competitive for an abstract class of functions that relaxes all above classes and includes, for the first time, all subadditive functions.

Our results

We introduce a class of functions based on an equivalent characterization of accountability given by Disser et al. [10]. They showed that a function $f\colon 2^U \to \mathbb{R}_{\geq 0}$ is accountable if and only if, for every finite $S \subseteq U$, there exists an ordering $(e_1,\dots,e_{|S|})$ of S with $f(\{e_1,\dots,e_i\}) \geq \frac{i}{|S|}f(S)$ for all $i \in \{1,\dots,|S|\}$. We relax this characterization as follows.

▶ **Definition 1.** *For $\beta \in (0,1]$, a function $f\colon 2^U \to \mathbb{R}_{\geq 0}$ is called* β-accountable *if, for every $S \subseteq U$, there exists an ordering $(e_1,\dots,e_{|S|})$ of the elements in S such that, for all $i \in \{1,\dots,|S|\}$,*

$$f(\{e_1,\dots,e_i\}) \geq \beta\frac{i}{|S|}f(S).$$

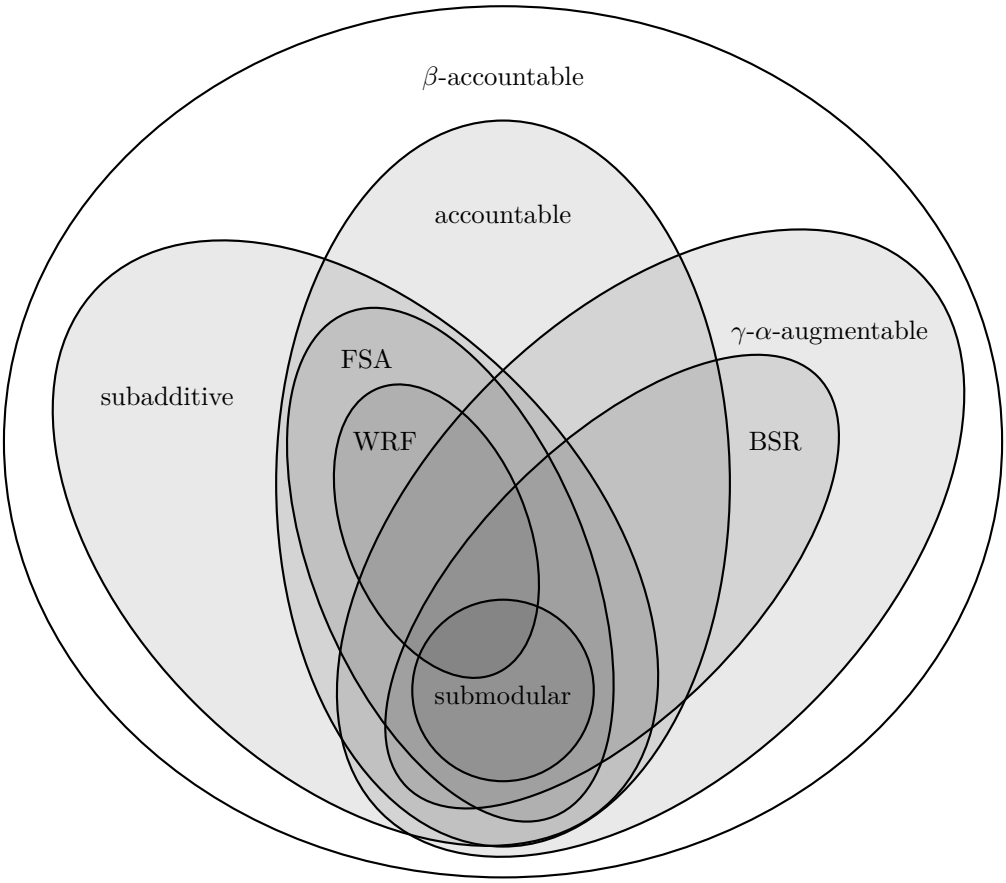

Figure 1 Relation of different function properties, including fractionally subadditivity (FSA), weighted rank functions (WRF), and functions of bounded submodularity ratio (BSR). For the depicted inclusions to hold simultaneously, we can set $\beta = \min\{\frac{1}{2}, \frac{\gamma}{\alpha}\}$.

This definition generalizes multiple other function properties (see Figure 1). In particular, accountable functions [10] correspond exactly to 1-accountable functions (by definition and [10]), every (monotone) γ-α-augmentable function [11] is $\frac{\gamma}{\alpha}$-accountable (Proposition 12), and every (monotone) subadditive function is $\frac{1}{2}$-accountable (Proposition 8).

We establish a general upper bound on the competitive ratio of incremental maximization with β-accountable objective via a scaling algorithm parameterized in β, and complement this result by a lower bound that is tight in the limit $\beta \to 0$ (see Figure 2).

▶ **Theorem 2.** *IncMax with a β-accountable objective has competitive ratio*

$$\rho \in \left[\frac{1}{\beta} \cdot \left(1 + \frac{1}{\lceil \frac{1}{\beta} \rceil + 1}\right), \frac{1}{2\beta} + 1 + \sqrt{\frac{1}{4\beta^2} + 1}\right].$$

Note that, for $\beta = 1$, the upper bound recovers the bound of $\varphi + 1 \approx 2.618$ of [1].

Importantly, Theorem 2 yields the first constant upper bound for the natural class of subadditive objective functions ($\beta = \frac{1}{2}$).

▶ **Theorem 3.** *IncMax with a subadditive objective has competitive ratio at most $2 + \sqrt{2}$.*

Furthermore, Theorem 2 also yields the following bound, which improves on the best known upper bound for γ-α-augmentable functions of [11] when $\gamma < \alpha \frac{e^\alpha}{e^\alpha - 1}$.

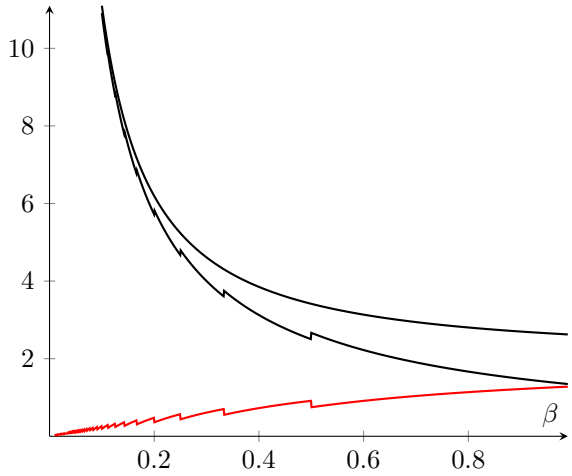

Figure 2 Plot of the bounds of Theorem 2, and their difference (red).

▶ **Theorem 4.** *IncMax with a γ-α-augmentable objective has competitive ratio at most*

$$\frac{\alpha}{2\gamma} + 1 + \sqrt{\frac{\alpha^2}{4\gamma^2} + 1}.$$

Related work

The general framework of incremental maximization was first proposed by Bernstein et al. [1]. They assumed that the objective is accountable and showed that in this case the competitive ratio of this problem is at most $\varphi + 1 \approx 2.618$. Utilizing a continuization technique, Disser et al. [10] showed a lower bound of 2.246 in this setting and provided evidence that the upper bound of $\varphi + 1$ is tight. Before the general framework was introduced, Zhu et al. [30] considered a special case of the problem where edges have to be added over time in order to maximize the number of internal nodes. They proved an upper bound of 12/7.

The performance of a simple greedy algorithm for this problem was investigated separately. Rado [27] showed that the greedy algorithm performs optimally if the objective function is modular. For submodular objectives, Nemhauser et al. [25] showed that the greedy algorithm has a competitive ratio of at most $\frac{\mathrm{e}}{\mathrm{e}-1}$. This is known to be tight due to Feige [12]. More recently, other classes of objectives were considered. Das and Kempe [6] introduced the submodularity ratio as a relaxation of submodularity and showed that the greedy algorithm has a competitive ratio of at most $\frac{\mathrm{e}^\gamma}{\mathrm{e}^\gamma-1}$ for objectives with submodularity ratio $\gamma \in [0, 1]$. This was later shown to be tight by Bian et al. [2] who also parametrized the bound by the curvature. A different relaxation of submodularity is α-augmentability. Here, the competitive ratio of the greedy algorithm is known to be at most $\frac{\mathrm{e}^\alpha}{\mathrm{e}^\alpha-1}$ due to Bernstein et al. [1]. Disser and Weckbecker [11] showed that this upper bound is tight and generalized this result by showing that the greedy algorithm has a competitive ratio of exactly $\frac{\alpha}{\gamma} \cdot \frac{\mathrm{e}^\alpha}{\mathrm{e}^\alpha-1}$ if the objective is γ-α-augmentable.

A generalization of the incremental maximization is the problem where, instead of an increasing cardinality constraint, one is faced with an increasing knapsack constraint. Under the assumption that the objective is modular, Megow and Mestre [22] provide an instance-sensitive near-optimal solution. Disser et al. [9] additionally assume that items that do not fit into the knapsack can be discarded and show that the competitive ratio in this setting is exactly 2. This result was later generalized to submodular objectives with a bounded curvature by Klimm and Knaack [20]. Kawase et al. [19] gave an upper bound of $\frac{2\mathrm{e}}{\mathrm{e}-1}$ on the

randomized competitive ratio of the incremental maximization problem under a knapsack constraint with submodular objective under the assumption that items that do not fit can be discarded. Instead of discarding items that do not fit, Navarra and Pinotti [24] assumed that every item fits into the knapsack and provided a 2-competitive algorithm for modular objectives. Disser et al. [8] assumed that the ratio between the largest and smallest value of a single element is bounded by some constant M and showed that the competitive ratio of the incremental maximization problem under a knapsack constraint with a fractionally subadditive objective lies between $\max\{2.618, M\}$ and $\max\{3.293\sqrt{M}, 2M\}$.

Disser et al. [7] considered an incremental budget constraint for the prize-collecting Steiner tree problem, where the objective does not obey a diminishing returns property and the authors had to resort to bicriterial approximation guarantees. Other variants of the incremental maximization problem include a variation where the goal is to maximize a sum-objective [18, 14, 29], or incremental solutions in a changing environment [16, 17, 28]. Incremental minimization considered, among others, for the k-center problem [15], the minimum latency problem [3, 13, 4], the k-median problem [23, 5, 21], and the facility location problem [26, 21].

2 Competitive Bounds

The best known algorithm to solve the IncMax problem with an accountable objective was presented in [1]. It follows the idea of calculating cardinalities $c_0, c_1, \dots$ and adding the optimum solution sets for these cardinalities one after the other, where the order of the elements within each set follows Definition 1. The cardinalities $c_0, c_1, \dots$ are calculated by setting $c_0 = 1$ and iteratively scaling via $c_{i+1} = \lceil \delta c_i \rceil$ for some $\delta > 1$.

Since β-accountability is closely related to accountability, we introduce a modified version of this algorithm to find an incremental solution for the IncMax problem with a β-accountable objective.

The algorithm Scaling$_\beta$ uses the scaling parameter

$$\delta = \frac{1}{2\beta} + 1 + \sqrt{\frac{1}{4\beta^2} + 1}$$

and chooses

$$c_1 \in \arg\max_{C \in \mathbb{N}} \frac{\textsc{Opt}(C)}{C}$$

in an arbitrary, but fixed way. Then, for $i \in \mathbb{N}$, it chooses

$$c_{i+1} \in \arg\max_{C \in \mathbb{N}, C \geq \delta c_i} \frac{\textsc{Opt}(C)}{C},$$

also in an arbitrary, but fixed way. Scaling$_\beta$ operates in phases, and in phase $i \in \mathbb{N}$, it adds the optimum solution of cardinality c_i in the order given by Definition 1.

We state the following observation.

▶ **Observation 5.** *For all $i \in \mathbb{N}$, we have*

(i) $c_{i+1} \geq \delta c_i$,
(ii) $\sum_{j=1}^{i} c_j \leq \frac{\delta}{\delta - 1} c_i$,
(iii) $\frac{\textsc{Opt}(c_i)}{c_i} \geq \frac{\textsc{Opt}(c)}{c}$ *for all* $c \in \mathbb{N}_{\geq \delta c_i}$.

Proof. (i) and (iii) follow immediately from the definition of c_i for all $i \in \mathbb{N}$.

Furthermore, we have

$$\sum_{j=1}^{i} c_j \overset{(i)}{\leq} \sum_{j=1}^{i} \left(\frac{1}{\delta}\right)^{i-j} c_i \leq \sum_{j=1}^{\infty} \left(\frac{1}{\delta}\right)^{i-j} c_i = \frac{\delta}{\delta - 1} c_i.$$

◀

We are now ready to prove an upper bound on the competitive ratio of $\textsc{Scaling}_\beta$.

▶ **Theorem 6.** *The algorithm $\textsc{Scaling}_\beta$ is δ-competitive for IncMax with a β-accountable objective function.*

Proof. Let π denote the incremental solution of $\textsc{Scaling}_\beta$. Let $C \in \mathbb{N}$ and $i \in \mathbb{N}$ such that $C \in \left(\sum_{j=1}^{i-1} c_j, \sum_{j=1}^{i} c_j\right]$. If $i = 1$, we let $x = 0$, otherwise, let

$$x = \frac{1}{\beta} \cdot \frac{\textsc{Opt}(c_{i-1})}{\textsc{Opt}(c_i)} c_i + \sum_{j=1}^{i-1} c_j, \tag{1}$$

i.e., we have

$$\textsc{Opt}(c_{i-1}) = \beta \frac{x - \sum_{j=1}^{i-1} c_j}{c_i} \textsc{Opt}(c_i).$$

The value x is chosen such that, if $C \geq x$, then the value of the partially added optimum solution of cardinality c_i in the solution $\pi(C)$ is at least as large as the value of the completely contained optimum solution of cardinality c_{i-1}.

Case 1: $C < \lceil \delta c_{i-1} \rceil$.
As $\pi(C)$ contains the optimum solution of cardinality c_{i-1}, by monotonicity, we have

$$\frac{\textsc{Opt}(C)}{f(\pi(C))} \leq \frac{\textsc{Opt}(C)}{\textsc{Opt}(c_{i-1})} \leq \frac{\textsc{Opt}(\lceil \delta c_{i-1} \rceil - 1)}{\textsc{Opt}(c_{i-1})} \overset{\text{Obs. 5 } (iii)}{\leq} \frac{\lceil \delta c_{i-1} \rceil - 1}{c_{i-1}} \leq \delta.$$

Case 2: $\lceil \delta c_{i-1} \rceil \leq C < x$.
Note that $C < x$ implies that $x > 0$, i.e., (1) holds. The solution $\pi(C)$ contains the optimum solution of cardinality c_{i-1}. Thus,

$$\begin{aligned}
\frac{\textsc{Opt}(C)}{f(\pi(C))} &\leq \frac{\textsc{Opt}(C)}{\textsc{Opt}(c_{i-1})} \\
&\overset{\text{Obs. 5 } (iii)}{\leq} \frac{\textsc{Opt}(c_i)}{\textsc{Opt}(c_{i-1})} \cdot \frac{C}{c_i} \\
&\leq \frac{\textsc{Opt}(c_i)}{\textsc{Opt}(c_{i-1})} \cdot \frac{x}{c_i} \\
&\overset{(1)}{=} \frac{1}{\beta} + \frac{\textsc{Opt}(c_i)}{\textsc{Opt}(c_{i-1})} \cdot \frac{1}{c_i} \sum_{j=1}^{i-1} c_j \\
&\overset{\text{Obs. 5 } (iii)}{\leq} \frac{1}{\beta} + \frac{c_i}{c_{i-1}} \cdot \frac{1}{c_i} \sum_{j=1}^{i-1} c_j \\
&\overset{\text{Obs. 5 } (ii)}{\leq} \frac{1}{\beta} + \frac{\delta}{\delta - 1} = \delta,
\end{aligned}$$

where the last equality follows from the definition of δ.

Case 3: $C \geq \lceil \delta c_{i-1} \rceil$, $C \geq x$.
If $i = 1$, by definition of c_1, we have

$$\frac{\textsc{Opt}(C)}{f(\pi(C))} \leq \frac{\textsc{Opt}(C)}{\beta \frac{C}{c_1} \textsc{Opt}(c_1)} \leq \frac{1}{\beta} < \delta.$$

Now, assume that $i \geq 2$, i.e., (1) holds. The solution $\pi(C)$ contains $C - \sum_{j=1}^{i-1} c_j$ elements from the optimum solution of cardinality c_i. Thus,

$$\begin{aligned}
\frac{\textsc{Opt}(C)}{f(\pi(C))} &\leq \frac{\textsc{Opt}(C)}{\beta\frac{C-\sum_{j=1}^{i-1} c_j}{c_i}\textsc{Opt}(c_i)} \\
&\overset{\text{Obs. 5 } (iii)}{\leq} \frac{1}{\beta}\cdot\frac{C}{C-\sum_{j=1}^{i-1} c_j} \\
&\overset{C\geq x}{\leq} \frac{1}{\beta}\cdot\frac{x}{x-\sum_{j=1}^{i-1} c_j} \\
&\overset{(1)}{=} \frac{1}{\beta}\left(1+\frac{\sum_{j=1}^{i-1} c_j}{\frac{1}{\beta}\cdot\frac{\textsc{Opt}(c_{i-1})}{\textsc{Opt}(c_i)}c_i}\right) \\
&= \frac{1}{\beta}+\frac{\textsc{Opt}(c_i)}{\textsc{Opt}(c_{i-1})}\cdot\frac{1}{c_i}\sum_{j=1}^{i-1} c_j \\
&\overset{\text{Obs. 5 } (iii)}{\leq} \frac{1}{\beta}+\frac{c_i}{c_{i-1}}\cdot\frac{1}{c_i}\sum_{j=1}^{i-1} c_j \\
&\overset{\text{Obs. 5 } (ii)}{\leq} \frac{1}{\beta}+\frac{\delta}{\delta-1} \\
&= \delta.
\end{aligned}$$

◀

We complement this upper bound with a lower bound, that, in particular, shows that for $\beta \to 0$, we cannot be better than $\frac{1}{\beta}$-competitive.

▶ **Theorem 7.** *For all $\beta \in (0,1]$, the competitive ratio of* IncMax *with a β-accountable objective function is at least*

$$\frac{1}{\beta}\cdot\left(1+\frac{1}{\lceil\frac{1}{\beta}\rceil+1}\right).$$

Proof. Let $k := \lceil\frac{1}{\beta}\rceil+2$ and $d := \frac{k-1}{k}\beta$. We define an instance where no incremental solution can have a competitive ratio better than $\frac{1}{d}$. Let $U = \{e_1,\dots,e_{k+1}\}$ be the groundset and $f\colon 2^U \to \mathbb{R}_{\geq 0}$ be the objective such that, for $S \subseteq U$,

$$f(S) = \begin{cases} \frac{kd}{\beta} = k-1, & \text{if } \{e_2,\dots,e_{k+1}\} \subseteq S, \\ \max\big\{|\{e_1\}\cap S|, |\{e_2,\dots,e_{k+1}\}\cap S|\cdot d\big\}, & \text{else.} \end{cases}$$

This objective is monotone because of the maximum in the definition and because $\frac{kd}{\beta} \geq kd$. We show that f is β-accountable. For this, let $S \subseteq U$. We have to show that there is an ordering $(e_{i_1},\dots,e_{i_{|S|}})$ of the elements in S such that $f(\{e_{i_1},\dots,e_{i_j}\}) \geq \beta\frac{j}{|S|}f(S)$ for all $j \in \{1,\dots,|S|\}$. If we have $e_1 \in S$ and $f(S) = 1$, we can simply choose e_1 to be the first element in the ordering and obtain

$$f(\{e_{i_1},\dots,e_{i_j}\}) = 1 = f(S) \geq \beta\frac{j}{|S|}f(S)$$

for all $j \in \{1,\dots,|S|\}$. Otherwise, if $e_1 \notin S$ or $f(S) > 1$, then, with $S' := S \cap \{e_2,\dots,e_{k+1}\}$, either $f(S) = \frac{kd}{\beta} = \frac{|S'|d}{\beta}$, or $f(S) = |S'|d \leq \frac{|S'|d}{\beta}$. In our ordering, we can put the elements from S' in the beginning and, for $j \in \{1,\dots,|S'|\}$, obtain

$$f(\{e_{i_1},\dots,e_{i_j}\}) \geq j\cdot d = \beta\frac{j}{|S'|}\frac{|S'|d}{\beta} \geq \beta\frac{j}{|S'|}f(S) \geq \beta\frac{j}{|S|}f(S).$$

If $S' = S$, we are done. Otherwise, $|S| = |S'| + 1$ holds and, for $j = |S|$, we have $f(\{e_{i_1}, \dots, e_{i_j}\}) = f(S) \geq \beta \frac{j}{|S|} f(S)$.

Let π be an incremental solution for this instance. We consider two cases. First, assume that e_1 is not the last element in the ordering π. We have

$$(k-1)d = \frac{\left(\left\lceil \frac{1}{\beta} \right\rceil + 1\right)^2}{\left\lceil \frac{1}{\beta} \right\rceil + 2} \beta > \frac{\left\lceil \frac{1}{\beta} \right\rceil^2 + 2\left\lceil \frac{1}{\beta} \right\rceil}{\left\lceil \frac{1}{\beta} \right\rceil + 2} \beta = \left\lceil \frac{1}{\beta} \right\rceil \beta \geq 1.$$

The solution $\pi(k)$ contains e_1 and $k-1$ elements from $\{e_2, \dots, e_{k+1}\}$. Thus,

$$f(\pi(k)) = \max\{1, (k-1)d\} = (k-1)d.$$

The optimum solution of cardinality k is the set $\{e_2, \dots, e_{k+1}\}$ with a value of $k-1$. Thus, in this case, the competitive ratio of π is at least $\frac{1}{d}$.

Now, consider the other case, i.e., e_1 is the last element in the ordering π. Then the solution $\pi(1)$ contains exactly one element from the set $\{e_2, \dots, e_{k+1}\}$ and has therefore value $f(\pi(1)) = d$. The optimum solution of cardinality 1 is $\{e_1\}$ with a value of 1. Thus, also in this case, the competitive ratio of π is at least $\frac{1}{d}$. ◀

In Figure 2, we plot the upper bound from Theorem 6 and the lower bound from Theorem 7 in black, as well as a plot of their difference in red. On the one hand, one can see that both bounds are unbounded for $\beta \to 0$. This seems plausible because for $\beta \to 0$, we have (almost) no guarantee that the value of large sets is bounded by the value of smaller sets. On the other hand, one can see in Figure 2 that the difference between upper and lower bound is almost 0 for $\beta \to 0$. Thus, in the limit $\beta \to 0$, ScalingBeta performs optimally.

3 Incremental Maximization for Subclasses

We employ the previous result to obtain new and improved bounds on the competitive ratio of IncMax with subadditive and γ-α-augmentable objectives.

3.1 Subadditivity

In order to derive results for IncMax with subadditive objectives, we compare β-accountability and subadditivity.

▶ **Proposition 8.** *Every monotone, subadditive function is $\frac{1}{2}$-accountable.*

Proof. Let $f\colon 2^U \to \mathbb{R}_{\geq 0}$ be monotone and subadditive, $S \subseteq U$ be finite, and $k := |S|$. We define $\ell := \lceil \log_2 k \rceil$, i.e., we have $2^{\ell-1} < k \leq 2^\ell$. Furthermore, we define $S_\ell := S$ and iteratively, for $j \in \{\ell - 1, \dots, 0\}$, $S_j \subseteq S_{j+1}$ with $|S_j| = \left\lceil \frac{k}{2^{\ell-j}} \right\rceil$ and $f(S_j) \geq \frac{1}{2} f(S_{j+1})$. This is possible as we will see now. We have $2\left\lceil \frac{k}{2^{\ell-j}} \right\rceil = \left\lceil 2\left\lceil \frac{k}{2^{\ell-j}} \right\rceil \right\rceil \geq \left\lceil \frac{k}{2^{\ell-j-1}} \right\rceil$, i.e., we can choose $A, B \subseteq S_j$ with $|A| = |B| = \left\lceil \frac{k}{2^{\ell-j}} \right\rceil$ and $A \cup B = S_{j+1}$. By subadditivity, we have $f(A) \geq \frac{1}{2} f(S_{j+1})$ or $f(B) \geq \frac{1}{2} f(S_{j+1})$. Thus, we can choose $S_j \in \{A, B\}$ with the desired properties.

Now, consider any order $(e_1, \dots, e_k)$ of S with $\{e_1, \dots, e_{|S_j|}\} = S_j$ for all $j \in \{0, \dots, \ell\}$. Let $i \in \{1, \dots, k\}$ and $j \in \{0, \dots, \ell\}$ such that $\left\lceil \frac{k}{2^{\ell-j}} \right\rceil \leq i < \left\lceil \frac{k}{2^{\ell-j-1}} \right\rceil$. This implies that $S_j \subseteq \{e_1, \dots, e_i\}$ and, because $i \in \mathbb{N}$, that $i < \frac{k}{2^{\ell-j-1}}$. Together with monotonicity of f, we obtain

$$f(\{e_1, \dots, e_i\}) \geq f(S_j) \geq \left(\frac{1}{2}\right)^{\ell-j} f(S_\ell) = \frac{1}{2^{\ell-j}} f(S) \geq \frac{1}{2} \frac{i}{k} f(S),$$

which yields $\frac{1}{2}$-accountability. ◀

We combine Theorem 6 and Proposition 8 to obtain an upper bound on the competitive ratio of IncMax with a subadditive objective. This immediately proves Theorem 3.

▶ **Theorem 3.** *IncMax with a subadditive objective has competitive ratio at most* $2+\sqrt{2}$.

We complement this upper bound on the competitive ratio of IncMax with subadditive objective functions by a lower bound. To this end, we employ separability of problem instances of incremental maximization, a property introduced in [10].

▶ **Definition 9.** *An instance of IncMax with objective* $f\colon 2^U \to \mathbb{R}_{\geq 0}$ *is called* separable *if there exist a partition* $U = U_1 \cup U_2 \cup \dots$ *of* U *and* densities $d_i > 0$ *such that, for all* $S \subseteq U$,

$$f(S) = \max_{i\in\mathbb{N}}\{|S\cap U_i|\cdot d_i\}.$$

▶ **Proposition 10.** *The objective function of every separable problem instance is subadditive.*

Proof. Let a separable instance with objective function $f\colon 2^U \to \mathbb{R}_{\geq 0}$ be given. Furthermore, let $U = U_1 \cup U_2 \cup \dots$ be a partition of U, and let $d_1, d_2, \dots > 0$ be the densities such that, for all $S \subseteq U$,

$$f(S) = \max_{i\in\mathbb{N}} |S\cap U_i|\cdot d_i.$$

In order to show subadditivity, we fix two sets $A, B \subseteq U$. Let $i^* \in \mathbb{N}$ be the index such that $f(A\cup B) = |(A\cup B)\cap U_{i^*}|\cdot d_{i^*}$. Then

$$\begin{aligned} f(A\cup B) &= |(A\cup B)\cap U_{i^*}|\cdot d_{i^*} \\ &= |A\cap U_{i^*}|\cdot d_{i^*} + |(B\setminus A)\cap U_{i^*}|\cdot d_{i^*} \\ &\leq |A\cap U_{i^*}|\cdot d_{i^*} + |B\cap U_{i^*}|\cdot d_{i^*} \\ &\leq \big(\max_{i\in\mathbb{N}} |A\cap U_i|\cdot d_i\big) + \big(\max_{i\in\mathbb{N}} |B\cap U_i|\cdot d_i\big) \\ &= f(A) + f(B). \end{aligned}$$

◀

This result yields that the (non-strict) competitive ratio of IncMax with subadditive objectives is at least that for separable instances. In [10], the authors show a lower bound of 2.246 on the competitive ratio in the separable setting. Thus, we obtain the following.

▶ **Corollary 11.** *The competitive ratio of IncMax with a subadditive objective function is at least* 2.246.

This bound is weaker than the lower bound of $\frac{8}{3}$ from Theorem 7 for IncMax with a $\frac{1}{2}$-accountable objective. Yet, note that the lower bound construction in the proof of Theorem 7 is not subadditive.

3.2 γ-α-Augmentability

We now turn to comparing β-accountability and γ-α-augmentability.

▶ **Proposition 12.** *For all* $\gamma \in (0,1]$ *and* $\alpha \geq 1$, *every monotone,* γ-α*-augmentable function is* $\frac{\gamma}{\alpha}$*-accountable.*

Proof. For $\gamma \in (0,1]$ and $\alpha \geq 1$, let $f\colon 2^U \to \mathbb{R}_{\geq 0}$ be monotone and γ-α-augmentable. Let $S \subseteq U$ be finite and $k := |S|$. By γ-α-augmentability, there exists an ordering $(e_1, \dots, e_k)$ of the elements in S such that, for all $i \in \{0, \dots, k-1\}$,

$$f(\{e_1,\dots,e_{i+1}\}) - f(\{e_1,\dots,e_i\}) \geq \frac{\gamma f(S) - \alpha f(\{e_1,\dots,e_i\})}{k-i}.$$

For $i \in \{0, \dots, k\}$, let $S_i := \{e_1, \dots, e_i\}$. Then, for $i \in \{0, \dots, k-1\}$, this yields

$$f(S_{i+1}) - f(S_i) \geq \alpha \frac{\frac{\gamma}{\alpha} f(S) - f(S_i)}{k-i} \overset{\alpha \geq 1}{\geq} \frac{\frac{\gamma}{\alpha} f(S) - f(S_i)}{k-i}. \tag{2}$$

To show $\frac{\gamma}{\alpha}$-accountability of f, we prove by induction that, for $i \in \{1, \dots, k\}$, we have

$$f(S_i) \geq \frac{\gamma}{\alpha} \frac{i}{k} f(S). \tag{3}$$

For $i = 0$, (2) yields

$$f(S_1) \geq \frac{1}{k}\left(\frac{\gamma}{\alpha} f(S) - f(\emptyset)\right) + f(\emptyset) = \frac{\gamma}{\alpha}\frac{1}{k} f(S) + \left(1 - \frac{1}{k}\right) f(\emptyset) \geq \frac{\gamma}{\alpha}\frac{1}{k} f(S),$$

where the last inequality follows from non-negativity of f.

Now, suppose that (3) holds for some $i \in \{0, \dots, k-1\}$. Then

$$\begin{aligned}
f(S_{i+1}) &\overset{(2)}{\geq} f(S_i) + \frac{\frac{\gamma}{\alpha} f(S) - f(S_i)}{k-i} \\
&= \frac{\gamma}{\alpha}\frac{1}{k-i} f(S) + \left(1 - \frac{1}{k-i}\right) f(S_i) \\
&\overset{(3)}{\geq} \frac{\gamma}{\alpha}\frac{1}{k-i} f(S) + \left(\frac{k-i-1}{k-i}\right)\frac{\gamma}{\alpha}\frac{i}{k} f(S) \\
&= \frac{\gamma}{\alpha}\frac{ki + k - i^2 - i}{(k-i)k} f(S) \\
&= \frac{\gamma}{\alpha}\frac{(k-i)(i+1)}{(k-i)k} f(S) \\
&= \frac{\gamma}{\alpha}\frac{i+1}{k} f(S),
\end{aligned}$$

which concludes the induction. ◀

We combine the results from Proposition 12 and Theorem 6 to obtain an upper bound on the competitive ratio of IncMax with a monotone and γ-α-augmentable objective. This immediately proves Theorem 4.

▶ **Theorem 13.** *For $\gamma \in (0, 1]$ and $\alpha \geq 1$, $\textsc{Scaling}_{\gamma/\alpha}$ has a competitive ratio of at most*

$$\frac{\alpha}{2\gamma} + 1 + \sqrt{\frac{\alpha^2}{4\gamma^2} + 1}$$

for IncMax with a γ-α-augmentable objective.

We compare this upper bound on the competitive ratio of IncMax with a γ-α-augmentable objective to

$$\frac{\alpha}{\gamma} \cdot \frac{\mathrm{e}^\alpha}{\mathrm{e}^\alpha - 1},$$

the competitive ratio of the greedy algorithm for IncMax with γ-α-augmentable objectives [11]. Let the ratio between the two upper bounds be denoted by

$$r(\gamma, \alpha) := \frac{\frac{\alpha}{2\gamma} + 1 + \sqrt{\frac{\alpha^2}{4\gamma^2} + 1}}{\frac{\alpha}{\gamma} \cdot \frac{\mathrm{e}^\alpha}{\mathrm{e}^\alpha - 1}} = \frac{\mathrm{e}^\alpha - 1}{\mathrm{e}^\alpha} \cdot \left(\frac{1}{2} + \frac{\gamma}{\alpha} + \sqrt{\frac{1}{4} + \frac{\gamma^2}{\alpha^2}}\right).$$

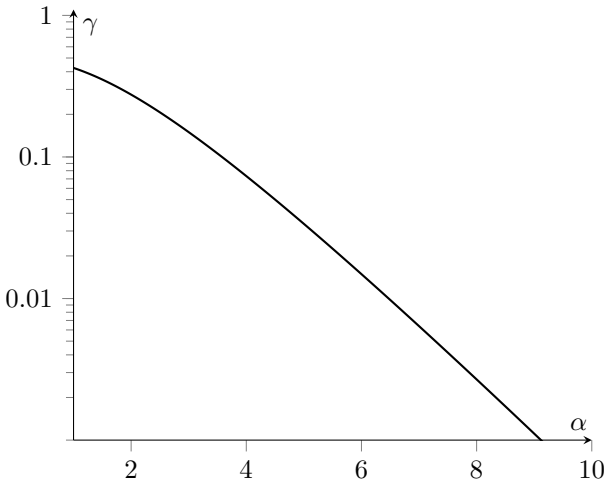

Figure 3 Plot of the value of γ depending on α for which $\textsc{Scaling}_{\gamma/\alpha}$ and the greedy algorithm achieve the same competitive ratio. For values of γ below this line, $\textsc{Scaling}_{\gamma/\alpha}$ performs better, and vice versa.

We have $\lim_{\gamma\to 0} r(\gamma,\alpha) = \frac{e^\alpha-1}{e^\alpha} < 1$, i.e., for small values of γ, $\textsc{Scaling}_{\gamma/\alpha}$ performs better than the greedy algorithm. Since $\gamma \in (0,1]$ and $\alpha \geq 1$, we have $r(\gamma,\alpha) = 1$ if and only if $\gamma = \alpha\frac{e^\alpha}{e^{2\alpha}-1}$. This value lies in the interval $\left(0, \frac{e}{e^2-1}\right] \subseteq (0, 0.426)$, and for $\alpha \to \infty$, approaches 0 (cf. Figure 3). Thus, for large $\alpha \geq 1$, the greedy algorithm performs better than $\textsc{Scaling}_{\gamma/\alpha}$ for almost all values of $\gamma \in (0,1]$. This is probably due to the fact that γ-α-augmentability is a property that relaxes an inequality that is a core estimate in the analysis of the the greedy algorithm for monotone and submodular functions.

Abstract

A temporal graph $\mathcal{G} = (G, \lambda)$ can be represented by an underlying graph $G = (V, E)$ together with a function λ that assigns to each edge $e \in E$ the set of time steps during which e is present. The reachability graph of $\mathcal{G}$ is the directed graph $D = (V, A)$ with $(u, v) \in A$ if and only if there is a temporal path from u to v. We study the Reachability Graph Realizability (RGR) problem that asks whether a given directed graph $D = (V, A)$ is the reachability graph of some temporal graph. The question can be asked for undirected or directed temporal graphs, for reachability defined via strict or non-strict temporal paths, and with or without restrictions on λ (simple, proper, or both). Answering an open question posed by Casteigts et al. (TCS 2024), we show that all variants of the problem are NP-complete, except for two variants that become trivial in the directed case. For undirected temporal graphs, we consider the complexity of the problem with respect to the solid graph, that is, the graph containing all edges that could potentially receive a label in any realization. We show that the RGR problem is fixed-parameter tractable for the feedback edge set number of the solid graph. As we show, the latter parameter can presumably not be replaced by smaller parameters like feedback vertex set number or treedepth, since the problem is W[2]-hard for them.

1 Introduction

Temporal graphs are graphs that change over time. The vertex set is often assumed to be fixed, and the edge set can differ from one time step to the next. The study of temporal graphs has attracted significant attention in recent years [5, 22, 23]. One way to represent a temporal graph $\mathcal{G}$ with vertex set V is as a sequence $(G_i)_{i \in [L]}$, where $G_i = (V, E_i)$ is the graph containing the edges that are present in time step i. If an edge e is present in time step i, we refer to (e, i) as a *time edge*, and call i a *time label* of edge e. A *strict temporal path* from vertex u to vertex v in $\mathcal{G}$ is a sequence of time edges forming a u-v-path whose time steps are strictly increasing. A *non-strict temporal path* is defined analogously, except that the time steps only need to be non-decreasing.

In this work, we initiate the study of designing temporal graphs whose dynamics *guarantee certain reachability requirements while preventing others*, a problem naturally arising in areas like epidemic control, transportation, and logistics. For example, in epidemic control, a central goal is to maintain a minimal degree of societal connectivity for critical services while preventing broader or specific temporal connections that could facilitate disease spread.

Given a temporal graph $\mathcal{G}$, its temporal reachability relation can be represented as a directed graph $D = (V, A)$, called the *reachability graph* of $\mathcal{G}$, with $(u, v) \in A$ for $u \neq v$ if and only if there exists a (strict or non-strict, respectively) temporal path from u to v in $\mathcal{G}$. We can now state our problem as that of *realizing* a given reachability graph D by finding a temporal graph $\mathcal{G}$ whose temporal connectivity is specified by D: each arc or non-arc of D represents a temporal reachability that *must* or *must not* be realized in $\mathcal{G}$, respectively. In particular, we want to know which directed graphs can arise as reachability graphs of temporal graphs, and how difficult it is to determine for a given directed graph D whether there exists a temporal graph $\mathcal{G}$ with reachability graph D. Interestingly, this formulation turns out to have been posed twice recently as an open question, by Casteigts et al. [3, Open question 5] and Döring [11]. In contrast to our work, those papers aim to understand the expressivity of various temporal graph models, using reachability graphs as a tool.

Part of our contribution is to resolve this open question, by showing that the associated decision problem is NP-complete. Actually, there are a number of variations of the question, as we may ask for an undirected or a directed temporal graph $\mathcal{G}$, for a temporal graph with a restricted kind of labeling (simple, proper, happy)[1], and may consider reachability with respect to strict or non-strict temporal paths. We show that all these variations are NP-hard if we ask for an undirected temporal graph, and also if we ask for a directed temporal graph except for two variations (strict temporal paths with arbitrary or simple labelings) that are known to become trivial in the directed case [11]. See Table 1 for an overview of these results.

On the positive side, we present the following algorithmic results. For a given digraph $D = (V, A)$, we refer to $\{u, v\}$ for $u, v \in V$ as a *solid* edge if both (u, v) and (v, u) are in A. Let $G = (V, E)$ be the undirected graph on V whose edge set is the set of solid edges. We refer to G as the *solid graph* of D. The structural properties of solid graphs turn out to be crucial for our problem. We show that all undirected problem variants can be solved in polynomial time if the solid graph is a tree. Furthermore, we give an FPT algorithm for the feedback edge set number of the solid graph. This parameter can presumably not be replaced by smaller parameters like feedback vertex set, treedepth, or pathwidth, since two undirected versions of our problem turn out to be W[2]-hard for these parameters.

We believe that reachability graphs of temporal graphs form an interesting class of directed graphs whose study has only recently begun. Our results on their structure and on recognizing such graphs could be of independent interest in the context of algorithmic problems in directed graphs.

Related work. As mentioned, our work falls into the area of temporal graph realization problems. In these problems, one is given some data about the behavior of a temporal graph, and the goal is to detect whether there actually is a temporal graph with this behavior (and to compute such a temporal graph if one exists). Klobas et al. [17] introduced the problem of deciding for a given matrix of fastest travel durations and a period Δ whether there exists a simple temporal graph $\mathcal{G}$ with period Δ with the property that the duration of the fastest

[1] simple $\hat{=}$ one label per edge, proper $\hat{=}$ no two adjacent edges share a label, happy $\hat{=}$ both proper and simple

Table 1 The complexity results for all variants of RGR. Red cells indicate NP-hard cases and green cells indicate cases that are trivial (and thus polynomial-time solvable).

undirected	Strict	Non-strict	directed	Strict	Non-strict

temporal path between any pair of nodes in $\mathcal{G}$ is equal to the value specified in the input matrix. Erlebach et al. [13] extended the problem to a multi-label version, where each edge is allowed up to ℓ time labels. Motivated by the design of transportation networks, a related problem with respect to upper-bounded travel durations was considered [19, 20, 21].

In an early example of a temporal network design problem studied by Kempe et al. [15], the goal was to *reconstruct* a temporal labeling restricted to a single label per edge, so that a designated root reaches via temporal paths all vertices in a set P while avoiding those in a set N. For multi-labeled temporal graphs, Mertzios et al. [18] studied the problem of designing a temporal graph that preserves the reachability relation or all paths of an underlying static graph while minimizing either the *temporality* (maximum number of labels per edge) or the *temporal cost* (total number of labels used). Göbel et al. [14] showed that it is NP-complete to decide whether the edges of a given undirected graph can be labeled with a single label per edge in such a way that each vertex can reach every other vertex via a strict temporal path. Notably, this problem becomes solvable in linear time when only the degree sequence of the underlying graph is given [4]. Other studies have focused on variants of minimizing edge deletions [12], vertex deletions [25], or edge delays [9] to restrict reachability, motivated, for instance, by epidemic containment strategies that limit interactions. Temporal network design is an active area of research, with further related questions explored for example in [1, 16, 7].

Casteigts et al. [3] studied the relationships between the classes of reachability graphs that arise from undirected temporal graphs if different restrictions are placed on the graph (simple, proper, happy [3]) and depending on whether strict or non-strict temporal paths are considered. They showed that reachability with respect to strict temporal paths in arbitrary temporal graphs yields the widest class of reachability graphs while reachability in happy temporal graphs yields the narrowest class. The class of reachability graphs that arise from proper temporal graphs is the same as for non-strict paths in arbitrary temporal graphs, and this class is larger than the class of reachability graphs arising from non-strict reachability in simple temporal graphs. Strict reachability in simple temporal graphs was also shown to lie between the happy case and the general strict case. Döring [11] completed the picture of a two-stranded hierarchy for undirected temporal graphs and also extended the study to directed temporal graphs. As noted earlier, Casteigts et al. [3] also posed the open question of whether there is a characterization of directed graphs that arise as reachability graphs of temporal graphs (or of some restricted subclass of temporal graphs), and how hard it is to decide whether a given directed graph is the reachability graph of some temporal graph. These questions were posed again by Döring [11]. This is in particular of interest because Casteigts et al. [6] showed that several temporal graph problems can be solved in FPT time with respect to temporal parameters defined over the reachability graph. In this paper, we resolve these open questions regarding the complexity of all directed and undirected variants.

Organization of the paper. In Section 2, we provide a formal problem definition and define the notions used in this work. In Section 3, we show upper and lower bounds for the required number of labels per edge in any realization and provide a single exponential algorithm for all problem variants. Afterwards, in Section 4, we analyze properties and define splitting operations based on bridge edges in the solid graph of the undirected versions of our problem. These structural insights will be mainly used in our FPT algorithm in Section 6, but also immediately let us describe a polynomial-time algorithm for instances where the solid graph is a tree in Section 4.2. In Section 5, we then provide NP-hardness results for all undirected problem versions as well as parameterized intractability results for two of them with respect to feedback vertex set number and treedepth. Afterwards, in Section 6, we provide our main algorithmic result: an FPT algorithm with respect to the feedback edge set number fes of the solid graph. This algorithm is achieved in three steps: Firstly, we apply our splitting operations of Section 4 and provide a polynomial-time reduction rule to simplify the instance at hand, such that all we need to deal with is a subset X^* of vertices of size $\mathcal{O}(\text{fes})$ for which the remainder of the graph decomposes into edge-disjoint trees that only interact with X^* via two leaves each. We call such trees *connector trees*. Secondly, we show that we can efficiently extend the set X^* to a set W^* of size $\mathcal{O}(\text{fes})$ such that each resulting connector tree for the set W^* is more or less independent from the remainder of the graph with respect to the interactions of temporal paths in any realization. All these preprocessing steps run in polynomial time. Afterwards, our algorithm enumerates all reasonable labelings on the edges incident with vertices of W^* and tries to extend each such labeling to a realization for D. As we show, there are only FPT many such reasonable labelings and for each such labeling, there are only FPT many possible extensions that need to be checked. Finally, in Section 7, we briefly discuss the directed version of the problem and provide NP-hardness results for all but the two trivial cases. Proofs of statements with ($\star$) are deferred to the full version.

2 Preliminaries

For definitions on parameterized complexity, the Exponential Time Hypothesis (ETH), or parameters like treedepth, we refer to the textbooks [10, 8].

For natural numbers i, j with $i \leq j$ we write $[i]$ for the set $\{1, \dots, i\}$ and $[i, j]$ for the set $\{i, \dots, j\}$. For an undirected graph $G = (V, E)$, we denote an edge between vertices u and v as $\{u, v\}$ or uv. By $N(v) = \{u \in V \mid vu \in E\}$ we denote the set of neighbors of u. The *degree* of v is the size of $N(v)$. An edge $e \in E$ is a *bridge* or *bridge edge* in a graph $G = (V, E)$ if deleting e increases the number of connected components. A vertex of degree 1 is a *pendant* vertex, and an edge incident with a pendant vertex is called a *pendant* edge.

We assume directed graphs have no parallel arcs and no self-loops, and we denote an arc from u to v by (u, v). A directed graph D is a *directed acyclic graph* (DAG) if it does not contain a directed cycle. The *degree* of a vertex v is the number of arcs containing v. For an undirected graph G, the *feedback edge set number* (*feedback vertex set number*) denotes the minimum number of edges (vertices) to remove from G to obtain an acyclic graph.

A temporal graph $\mathcal{G}$ with vertex set V and lifetime L is given by a sequence $(G_t)_{t\in[L]}$ of L static graphs $G_t = (V, E_t)$ referred to as *snapshots* or *layers*. The graph $\mathcal{G}_\downarrow = (V, E_\downarrow)$ with $E_\downarrow = \bigcup_{i\in[L]} E_i$ is called the *underlying graph* of $\mathcal{G}$. Alternatively, $\mathcal{G}$ can be represented by an undirected graph $G = (V, E)$ with $E \supseteq \bigcup_{t\in[1,L]} E_t$ and a labeling function $\lambda : E \to 2^{[1,L]}$ that assigns to each edge e the (possibly empty) set of time steps during which e is present, that is, $\lambda(e) = \{t \in [1, L] \mid e \in E_t\}$. We write $\mathcal{G} = (G, \lambda)$ in this case. In this representation we allow G to contain extra edges in addition to the edges of the underlying graph; such

edges e satisfy $\lambda(e) = \emptyset$. This is useful because in the problems we consider in this paper, there is a natural choice of a graph $G = (V, E)$, the *solid graph* defined below, that contains all edges of the underlying graph of every realization but may contain additional edges.

We assume that each layer of a temporal graph is an undirected graph unless we explicitly refer to directed temporal graphs. If $t \in \lambda(e)$, we refer to (e, t) as a *time edge*. A *temporal path* from u to v in $\mathcal{G}$ is a sequence of time edges $((e_j, t_j))_{j\in[\ell]}$ for some ℓ such that $(e_1, e_2, \ldots, e_\ell)$ is a u-v path in G and $t_1 \leq t_2 \leq \cdots \leq t_\ell$ holds in the non-strict case and $t_1 < t_2 < \cdots < t_\ell$ holds in the strict case.

A temporal graph is *proper* if no two adjacent edges share a label, *simple* if every edge has a single label, and *happy* if it is both proper and simple [3]. The reachability graph $\mathcal{R}(\mathcal{G})$ of a temporal graph $\mathcal{G}$ with vertex set V is the directed graph (V, A) with the same vertex set V and $(u, v) \in A$ if and only if $u \neq v$ and $\mathcal{G}$ contains a temporal path from u to v. Note that $\mathcal{R}(\mathcal{G})$ depends on whether we consider strict or non-strict temporal paths and can be computed in polynomial time in both cases [2]. We are interested in the following problem:

Reachability Graph Realizability (RGR)
Input: A simple directed graph $D = (V, A)$.
Question: Does there exist a temporal graph $\mathcal{G}$ with $\mathcal{R}(\mathcal{G}) = D$?

For yes-instances of RGR, we are also interested in computing a temporal graph $\mathcal{G}$ with $\mathcal{R}(\mathcal{G}) = D$. We refer to such a temporal graph as a *solution* or a *realization* for D, and we typically represent it by a labeling function. With the adjacency matrix representation of D in mind, we also write $D_{uv} = 1$ for $(u, v) \in A$ and $D_{uv} = 0$ for $(u, v) \notin A$.

We can consider RGR with respect to reachability via strict temporal paths or with respect to non-strict temporal paths. Furthermore, we can require the realization of D to be simple, proper, or happy. For proper and happy temporal graphs, strict and non-strict reachability coincide. Therefore, the distinct problem variants that we can consider are Any Strict RGR, Any Non-strict RGR, Simple Strict RGR, Simple Non-strict RGR, Proper RGR, and Happy RGR. Finally, we write DRGR instead of RGR if we are asking for a directed temporal graph that realizes D. We sometimes write URGR if we want to make it explicit that we are asking for an undirected realization.

The solid graph. If $D_{uv} = 1$ and $D_{vu} = 1$ for some $u \neq v$, we say that there is a *solid edge* between u and v. If $D_{uv} = 1$ and $D_{vu} = 0$, we say that there is a *dashed arc* from u to v. We use $G = (V, E)$ to denote the graph on V whose edge set is the set of solid edges, and we refer to this graph as the *solid graph* (of D). For URGR it is clear that only solid edges can receive labels in a realization of D, as the two endpoints of an edge that is present in at least one time step can reach each other. Bridges of the solid graph must receive labels, but a solid edge e that is not a bridge may not receive labels, as the endpoints of e could reach each other via temporal paths of length greater than one.

▶ **Observation 1.** *Let D be an instance of Any Strict URGR or Simple Strict URGR. Let λ be a realization of D and let $\{u, v\}$ and $\{v, w\}$ be solid edges that both receive at least one label under λ. If D contains neither the arc (u, w) nor the arc (w, u), then there is a label α such that $\lambda(\{u, v\}) = \lambda(\{v, w\}) = \{\alpha\}$.*

Note that for Proper URGR, Happy URGR, and all versions of Non-strict URGR, no realization for D can assign labels to both of two adjacent edges $\{u, v\}$ and $\{v, w\}$ if D contains neither (u, w) nor (w, u).

A path $P = (u_0 = u, \dots, u_\ell = v)$ from u to v in G is a *dense* u-v-path if there exist arcs $(u_i, u_j) \in A$ for all $0 \leq i < j \leq \ell$. In each undirected realization of D, each temporal path is a dense path in G.

We say that a realization λ is *frugal* if there is no edge e such that the set of labels assigned to e can be replaced by a smaller set while maintaining the property that λ is a realization. We say that a realization λ is *minimal* on edge e if it is impossible to obtain another realization by replacing $\lambda(e)$ with a proper subset. A realization is minimal if it is minimal on every edge e. Note that every frugal realization is also minimal.

3 Basic Observations and an Exponential Algorithm

We first provide upper and lower bounds for the number of labels per edge in realizations.

▶ **Lemma 2** (⋆). *Let D be an instance of URGR, and let e be a solid edge of G that is not part of a triangle.*

- *For* Any Strict *URGR, in each minimal realization of D, e receives at most two labels.*
- *For all other versions of URGR, in each minimal realization of D, e receives at most one label.*

For general edges, we show a linear upper bound with respect to the number of vertices.

▶ **Lemma 3** (⋆). *If a graph $D = (V, A)$ is realizable, then each minimal realization for D assigns at most $n = |V|$ labels per edge.*

Lemma 3 implies that all versions of URGR and DRGR under consideration are in NP. Next, we show that the bound of Lemma 3 is essentially tight for Any Strict URGR.

▶ **Theorem 4** (⋆). *For* Any Strict *URGR, there is an infinite family of directed graphs $\mathcal{B}$, such that for every $D = (V, A) \in \mathcal{B}$, where $G = (V, E)$ is the solid graph of D, (i) D is realizable and some edge $e \in E$ receives $\Omega(n)$ labels in every realization of D, where $n = |V|$, and (ii) G has a feedback vertex set of size 2 and a feedback edge set of size $\Theta(n)$.*

The proof of Theorem 4 is based on the construction of an instance with a solid graph that consists of a number of subgraphs, called pages, that all share a common edge, called the spine. The instance is such that all edges of each page (except the spine) must receive the same single label, and the labels increase from one page to the next. Furthermore, for every i the reachability matrix specifies that the top of the i-th page can reach the bottom of the $(i + 2)$-th page and of all later pages. This requirement can then only be realized by adding a label whose value lies between the labels of page i and $i + 2$ to the spine, thus forcing the spine to have a linear number of labels.

Based on the upper bounds on labels per edge/arc from Lemma 3, one can solve all problems under consideration via dynamic programming over subsets of already labeled edges/arcs. Roughly speaking, we design a dynamic program that stores entries for each subset A' of A and each time step i, on whether there is a temporal graph with lifetime i that has reachability graph $D' := (V, A')$. If Simple RGR or Happy RGR is considered, the table also needs to store the already labeled edges/arcs in the first i time steps, to ensure that none of these edges/arcs receive another label.

▶ **Theorem 5** (⋆). *Each version of URGR and DRGR under consideration can be solved in $2^{\mathcal{O}(|A|)} \cdot n^{\mathcal{O}(1)}$ time, where A denotes the arc set of the input graph.*

4 Solid Bridge Edges: Properties and Splitting Operations

In this section, we show several structural results as well as three splitting operations for graphs with bridge edges in the solid graph. These insights will be important for our FPT algorithm and will also simplify instances of URGR where the solid graph is a tree.

Consider a bridge edge $e = \{u, v\}$ whose deletion splits the solid graph G into connected components G_u and G_v, where G_u contains u and G_v contains v. A dashed arc (a, b) *spans* e if $a \in V(G_u)$ and $b \in V(G_v)$ or vice versa. Two arcs (a, b) and (c, d) span e in the same direction if they span e and either $a, c \in V(G_u)$ or $a, c \in V(G_v)$. If e has a single label in a realization, then it must be the case that the dashed arcs spanning e are "transitive" in the following sense: If dashed arcs (a, b) and (c, d) both span e in the same direction, then (a, d) and (c, b) must also be dashed arcs. This is because for any two temporal paths that pass through e in the same direction, the part of one path up to edge e can be combined with the part of the other path after e.

▶ **Definition 6.** *Consider a bridge edge $e = \{u, v\}$ whose deletion splits the solid graph G into connected components G_u and G_v. The edge e is a* special *bridge edge if there exist vertices a in G_u and b in G_v such that $D_{av} = 1$, $D_{ub} = 1$ and $D_{ab} = 0$ (or if the same condition holds with u and v exchanged). A bridge edge that is not special is called* non-special.

Intuitively, a special bridge edge is a bridge edge e such that there are dashed arcs spanning e in the same direction for which transitivity (as outlined above) is violated.

▶ **Lemma 7** (⋆). *In each frugal realization of D, every special bridge edge is assigned two labels and every non-special bridge edge is assigned a single label.*

▶ **Corollary 8.** *Let D be an instance of any version of URGR under consideration besides* Any Strict URGR. *If the solid graph of D contains a special bridge edge, then D is a no-instance.*

4.1 Splitting Into Subinstances

We now define splitting operations on bridges. First, consider non-special bridges.

▶ **Lemma 9** (Splitting at a non-special bridge). *Consider any variant of URGR. Let $e = \{u, v\}$ be a non-special bridge edge, and let G_u and G_v be the connected components of G resulting from the deletion of e. Then the instance D is realizable if and only if the subinstances induced by $V(G_u) \cup \{v\}$ and $V(G_v) \cup \{u\}$ are realizable.*

Proof. Let D_u and D_v denote the subinstances induced by $V(G_u) \cup \{v\}$ and $V(G_v) \cup \{u\}$, respectively. If D is realizable, then the realization λ induces realizations of the two subinstances D_u and D_v. If D_u and D_v are realizable, their realizations assign a single label to e, and these realizations can be chosen so that e receives the same label in both realizations. Hence, the union of the two realizations is a realization of D. ◀

By applying Lemma 9 repeatedly to a non-pendant non-special bridge edge until no such edge exists, we obtain subinstances in which all non-special bridge edges are pendant.

Now consider special bridges. Special bridge edges cannot occur in yes-instances of any variant of URGR except Any Strict URGR (see Corollary 8), so we only consider Any Strict URGR in the following. Let edge $e = \{u, v\}$ be a special bridge with G_u and G_v defined as above. If the instance is realizable, for every vertex in $V(G_u)$ there are at most three possibilities for which vertices in $V(G_v)$ it can reach, depending on whether it cannot reach v, can reach v at time α, or can reach v only at time β, where α and β with $\alpha < \beta$ are

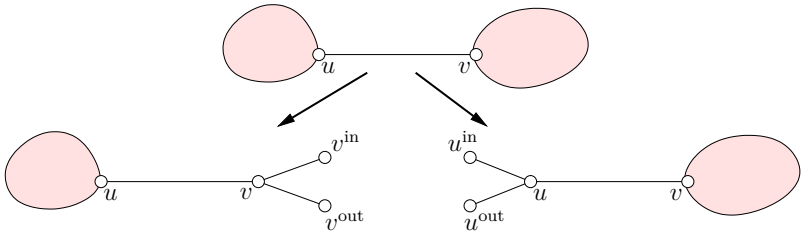

Figure 1 Illustration of the splitting operation at a special bridge $\{u, v\}$ (Lemma 11).

the labels assigned to e in the realization. The same holds with G_u and G_v exchanged. If this condition is violated, then the instance cannot be realized. The following definition captures this condition. For each vertex $w \in V(G_u)$, let $R_{u\to v}(w) = \{x \in V(G_v) \mid (w, x) \in A\}$, and define $R_{v\to u}(x)$ for $x \in V(G_v)$ analogously.

▶ **Definition 10.** *Let $e = \{u, v\}$ be a special bridge with G_u and G_v defined as above. We say that e is a special bridge edge with* plausible reachability *if the following conditions hold:*

- *If there exist vertices $a \in V(G_u)$ and $b \in V(G_v)$ such that $D_{av} = D_{ub} = 1$ and $D_{ab} = 0$, then every vertex $w \in V(G_u)$ satisfies $R_{u\to v}(w) \in \{\emptyset, R_{u\to v}(a), R_{u\to v}(u)\}$ with $\emptyset \subset R_{u\to v}(a) \subset R_{u\to v}(u)$. Otherwise, every vertex satisfies $R_{u\to v}(w) \in \{\emptyset, R_{u\to v}(u)\}$.*
- *The same condition holds with the roles of G_u and G_v exchanged.*

If there is a special bridge edge $\{u, v\}$ with plausible reachability, we can split the instance into two subinstances that can be solved separately, as illustrated in Figure 1. Each subinstance consists of the edge $\{u, v\}$ together with either G_u or G_v. For the subinstance containing $\{u, v\}$ and G_u, up to two new leaf vertices are attached to v, named v^{in} and v^{out} in the figure. Here, v^{in} represents the vertices in G_v that can reach u only by traversing $\{u, v\}$ using the larger of its two time labels, and v^{out} represents the vertices in G_v that can be reached from G_u only by traversing $\{u, v\}$ using the larger of its two time labels. The other subinstance is handled analogously.

▶ **Lemma 11** ((⋆), Splitting at a special bridge)**.** *Consider* Any Strict URGR*. Let $e = \{u, v\}$ be a special bridge edge with plausible reachability, and let G_u and G_v be the connected components of G resulting from the deletion of e. Then the instance D is realizable if and only if the two subinstances constructed as follows are realizable:*

- *To construct subinstance D_u, take the subgraph D' of D induced by $V(G_u) \cup \{v\}$ and attach one or two leaves to v as follows:*
  - *If there are vertices $a \in V(G_u)$ and $b \in V(G_v)$ with $D_{av} = D_{ub} = 1$ and $D_{ab} = 0$, then attach a leaf (called* out-leaf*) z to v with $D'_{zv} = 1$ and $D'_{az} = 1$ for all $a \in \{v\} \cup \{w \in V(G_u) \mid R_{u\to v}(w) = R_{u\to v}(u)\}$, and all other entries of D' involving z equal to 0.*
  - *If there are vertices $c \in V(G_v)$ and $d \in V(G_u)$ with $D_{cu} = D_{vd} = 1$ and $D_{cd} = 0$, then attach a leaf (called* in-leaf*) z' to v with $D'_{vz'} = 1$ and $D'_{z'a} = 1$ for all $a \in \{v\} \cup R_{v\to u}(c)$ and $D'_{z'z} = 1$ if an out-leaf z has been added, and all other entries of D' involving z' equal to 0.*

  Note that at least one of the two conditions above must be satisfied because e is a special bridge edge. The resulting instance D' is the desired subinstance D_u.
- *Subinstance D_v is constructed analogously, with the roles of u and v exchanged.*

Note that we cannot exhaustively apply the operation behind Lemma 11, since each application on a special bridge $\{u, v\}$ results into two new instances in which edge $\{u, v\}$ is again a special bridge. However, by recursively applying this operation on special bridges on

which the operation has not yet been applied, we eventually obtain instances, where each special bridge has at least one endpoint that has at most two other neighbors and both of them have a degree of 1.

Finally, we consider the case of two pendant edges that have a common neighbor and must receive the same single label in every realization. We argue that we can remove one of them from the instance provided their reachability requirements from/to the rest of the graph are the same. This is because a realization of the instance with one of the two pendant edges removed gives a realization of the original instance simply by labeling the pendant edge that was removed with the same label as the other pendant edge.

▶ **Lemma 12** ((⋆), Removal of redundant pendant vertices)**.** *Let D be an instance of URGR and let v and w be two degree-1 vertices with the same common neighbor u in G that satisfy $D_{vw} = D_{wv} = 0$. Then,*

- *for all variants of Non-strict URGR (including Proper URGR and Happy URGR), D is not realizable, and*
- *for Any Strict URGR and Simple Strict URGR, D is realizable if and only if (i) the subinstance D' resulting from D by deleting v is realizable and (ii) for each $x \in V \setminus \{v, w\}$, $D_{vx} = D_{wx}$ and $D_{xv} = D_{xw}$.*

4.2 Algorithms for Instances with a Tree as Solid Graph

Since all edges of trees are bridges, we now describe, based on our insights about labels in frugal realizations, an algorithm for instances of URGR where the solid graph is a tree.

▶ **Theorem 13.** *There is a polynomial-time algorithm for solving instances of Any Strict URGR for which the solid edges form a tree.*

Proof Sketch. Let $T = (V, E)$ denote the tree of solid edges. We first check that D satisfies several conditions that must hold if D is realizable. For example, if (u, v) is an arc, then (u, w) and (w, v) must also be arcs for every internal node w of the unique u-v-path in T. If one of these conditions is violated, D is not realizable. Otherwise, we construct a linear program (LP) that has two non-negative variables ℓ_e and h_e for each $e \in E$ that represent the lower and higher label of e, respectively, in a realization. Constraints $\ell_e = h_e$ for non-special edges and $\ell_e + 1 \leq h_e$ for special edges ensure that each edge receives the correct number of labels. For edges uv and vw such that $(u, w) \in A$, the constraints $\ell_{uv} + 1 \leq h_{vw}$ and $h_{uv} \leq \ell_{vw}$ ensure that there is a temporal u-w-path but no temporal w-u-path. Call a non-arc (u, v) *minimal* if it is the only arc missing in the direction from u to v on the path from u to v. For every minimal non-arc (u, v), we add constraints $h_{e_i} = \ell_{e_{i+1}}$ for every pair of consecutive edges e_i and e_{i+1} on the u-v path (which we show to consist of special edges except for the first and last edge, which are both non-special). For arcs (u, v) such that the first and last edge of the u-v-path are non-special and all other edges are special, we add the constraint $\sum_i (\ell_{e_{i+1}} - h_{e_i}) \geq 1$, where the sum is over all pairs of consecutive edges e_i, e_{i+1} of the u-v-path. We can show that the LP is feasible if and only if D is realizable. Furthermore, any feasible solution of the LP corresponds to a frugal realization with fractional labels, which can be made integral in a straightforward post-processing step. ◀

By testing additional conditions (such as the absence of special edges) before constructing the linear program, we can also use the approach to solve all other variants of URGR.

5 Hardness for Undirected Reachability Graph Realizability

In this section, we show that all considered versions of Undirected Reachability Graph Realizability are NP-hard, even on instances with a constant maximum degree. We obtain these hardness results by reductions from SAT, where we have a source s_i and a terminal vertex t_i for each clause c_i, such that D contains the dashed arc (s_i, t_i). The only way to realize such an arc is to follow a dense path that crosses through some variable gadget. We design a variable gadget for each variable x, for which the only way to realize it is to ensure that (i) only clauses that contain x positively can reach their terminal via this variable gadget, or (ii) only clauses that contain x negatively can reach their terminal over this variable gadget.

▶ **Theorem 14** (⋆). *Each version of URGR under consideration is NP-hard on directed graphs of constant maximum degree. Moreover, no version of URGR under consideration can be solved in $2^{o(|V|+|A|)} \cdot n^{\mathcal{O}(1)}$ time, unless the ETH fails.*

Hence, the running time of Theorem 5 can presumably not be improved significantly.

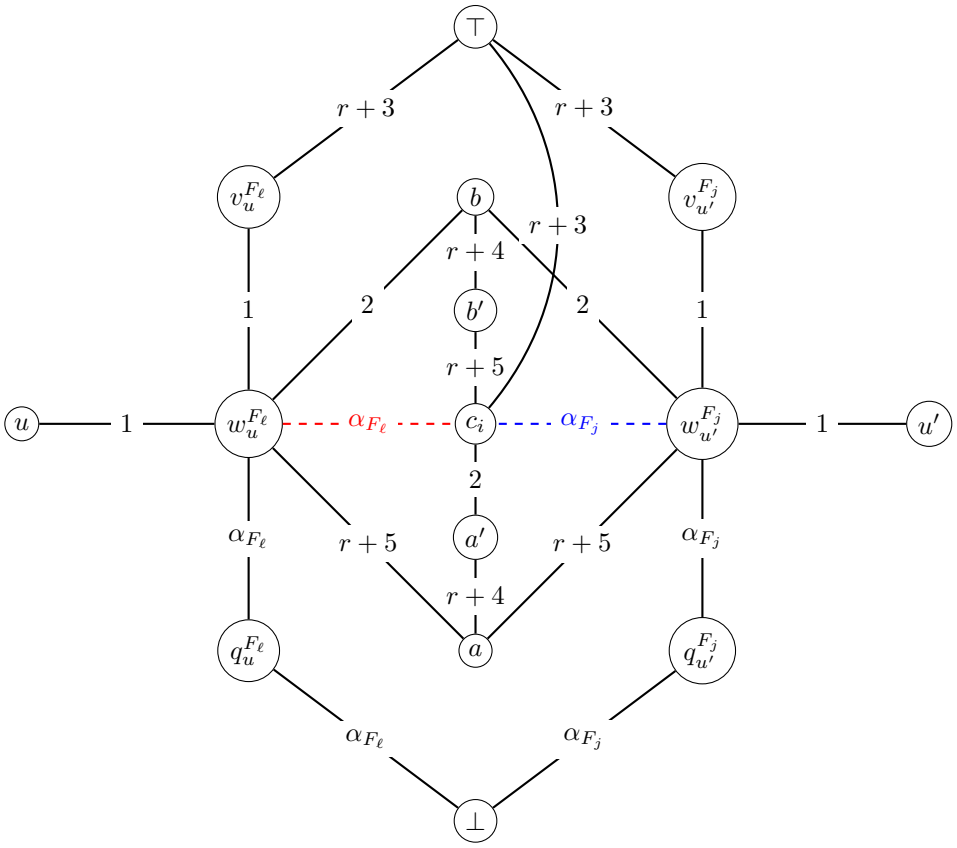
We now strengthen our hardness result for Any Strict URGR and Simple Strict URGR, which will highly motivate the analysis of parameterized algorithms for the parameter "feedback edge set number" of the solid graph, which we consider in Section 6.

▶ **Theorem 15** (⋆). *Any Strict URGR and Simple Strict URGR are W[2]-hard when parameterized by the feedback vertex set number and treedepth of the solid graph.*

Proof. We reduce from Set Cover which is W[2]-hard when parameterized by k [10].

Let $I := (U, \mathcal{F}, k)$ be an instance of Set Cover with $\mathcal{F} = \{F_1, \dots, F_r\}$. Assume without loss of generality that each element of U is contained in at least one hyperedge and that $\mathcal{F}$ has size at least k, as otherwise I could be solved trivially. We obtain a directed graph $D = (V, A)$ with solid graph $G = (V, E)$ as follows: The graphs contain the vertices $\{\top, a, a', b, b', \bot\}$, each element $u \in U$ as a vertex, and for each $i \in [1, k]$ the vertex c_i. Additionally, for each $F \in \mathcal{F}$ and each $u \in F$, G contain the vertices w_u^F, v_u^F, and q_u^F.

Next, we describe the solid edges of G, that is, the bidirectional arcs of D. See Figure 2 for the solid edges and dashed arcs of the main connection gadget of the instance.



The graph G contains the edges $\{a, a'\}$, $\{b, b'\}$, and for each $i \in [1, k]$, the edges $\{a', c_i\}$, $\{c_i, b'\}$, and $\{c_i, \top\}$. Moreover, for each $F \in \mathcal{F}$ and each $u \in F$, G contains the edges $\{u, w_u^F\}$, $\{w_u^F, a\}$, $\{w_u^F, b\}$, $\{\{w_u^F, c_i\} \mid i \in [1, k]\}$, $\{w_u^F, v_u^F\}$, $\{w_u^F, q_u^F\}$, $\{v_u^F, \bot\}$, and $\{q_u^F, \top\}$.

Finally, we describe the dashed arcs: D contains the dashed arcs (a', b), (b, a), $(a', \top)$, $(b, \top)$, and $(\top, b')$. For each $i \in [1, k]$, D also contains the dashed arcs (b, c_i) and (c_i, a). Let $u \in U$. Then, D contains the arc $(u, \top)$. Moreover, D contains the arcs (u, a), (u, b), (u, b'), and (u, c_i) for each $i \in [1, k]$. Additionally, for each hyperedge $F \in \mathcal{F}$ with $u \in F$, D contains the arcs (u, v_u^F), (v_u^F, a), (b, v_u^F), $(w_u^F, \top)$, (w_u^F, b'), (a', w_u^F), (q_u^F, v_u^F), (q_u^F, a), (q_u^F, b), (q_u^F, b'), and (q_u^F, c_i) for each $i \in [1, k]$. The only other dashed arcs in D are between v_u^F-vertices. Let $F_x, F_y \in \mathcal{F}$ with $x < y$ and let $u_x \in F_x$ and $u_y \in F_y$. Then, D contains the arc $(v_{u_x}^{F_x}, v_{u_y}^{F_y})$.

This completes the construction of D. First, we show the parameter bounds.

▷ Claim 16 (⋆). G has a feedback vertex set of size $k + 6$ and treedepth $\mathcal{O}(k)$.

We show that I is a yes-instance of Set Cover if and only if D is realizable via strict temporal paths. More precisely, we show that if I is a yes-instance of Set Cover, then there is a simple undirected temporal graph with strict reachability graph D. This then implies the correctness of the reduction for both Any Strict URGR and Simple Strict URGR.

	u	$\top$	v_u^F	w_u^F	q_u^F	a	a'	b	b'	$c_i, i \in [1,k]$	$\bot$
u		1	1	1	0	1	0	1	1	1	0
$\top$	0		0	0	1	0	0	0	1	1	0
v_u^F	0	0		1	0	1	0	0	0	0	1
w_u^F	1	1	1		1	1	0	1	1	1	0
q_u^F	0	1	1	1		1	0	1	1	1	0
a	0	0	0	1	0		1	0	0	0	0
a'	0	1	0	1	0	1		0	1	1	0
b	0	1	1	1	0	1	0		1	1	0
b'	0	0	0	0	0	0	0	1		1	0
$c_i, i \in [1,k]$	0	1	0	1	0	1	1	0	1		0
$\bot$	0	0	1	0	0	0	0	0	0	0	

Figure 2 Illustration of a part of the adjacency matrix of the W[2]-hardness reduction. The highlighted cells of the matrix indicate the dashed arcs. As we show, the labels α_{F_ℓ} and α_{F_j} need to be distinct if the hyperedges F_ℓ and F_j are distinct. Thus, for each $i \in [1,k]$, labeling both edges $\{w_u^{F_\ell}, c_i\}$ and $\{w_{u'}^{F_j}, c_i\}$ is not possible, as otherwise, there would be a temporal path from $w_u^{F_\ell}$ to $w_{u'}^{F_j}$ (or vice versa), which is not allowed.

We defer this proof to the full version and only provide an informal idea for the correctness. Intuitively, in each realization for D, for each $i \in [1,k]$, there can be at most one hyperedge $F \in \mathcal{F}$ for which edges between c_i and vertices of $W_F := \{w_u^F \mid u \in F\}$ can receive labels. This can be seen as follows: For each $w_{u'}^{F'} \in V$, (i) there is no dashed arc between $w_{u'}^{F'}$ and $\bot$ and (ii) there is no dashed arc between $v_{u'}^{F'}$ and c_i. Hence, Observation 1 implies that, if $\{w_{u'}^{F'}, c_i\}$ receives at least one label, then there is some $\alpha_{F'} \in \mathbb{N}$, such that the edges $\{w_{u'}^{F'}, c_i\}$ and $\{v_{u'}^{F'}, \bot\}$ receive the label set $\{\alpha_{F'}\}$ under λ. Based on the dashed arcs between the $v_{u'}^{F'}$-vertices, the label $\alpha_{F'}$ and the label $\alpha_{F''}$ are distinct for distinct hyperedges F' and F''. This then implies that there can be at most one hyperedge $F \in \mathcal{F}$ for which edges between c_i and vertices of W_F can receive labels, as otherwise, a strict temporal path between distinct $w_{u'}^{F'}$-vertices would be realized.

The edges with at least one label between c_i and w_u^F-vertices thus resemble a selection of at most one hyperedge of $\mathcal{F}$ for each $i \in [1,k]$. Since the only dense paths from a vertex $u \in U$ to $\top$ are of the form $(u, w_u^F, c_i, \top)$ for $i \in [1,k]$ and $F \in \mathcal{F}$ with $u \in F$, this selection of k hyperedges encodes a set cover, as the arcs $(u, \top)$ are realized over such dense paths. ◀

6 Parameterizing by the Feedback Edge Set Number

In this section we generalize our algorithm on tree instances of URGR to tree-like graphs. Recall that a feedback edge set of a graph G is a set F of edges of G, such that $G - F$ is acyclic. We denote by fes the feedback edge set number of the solid graph G of D, that is, the size of the smallest feedback edge set of G.

▶ **Theorem 17.** *Each version of URGR can be solved in* $\text{fes}^{\mathcal{O}(\text{fes}^2)} \cdot n^{\mathcal{O}(1)}$ *time.*

Recall that the parameter can presumably not be replaced by a smaller parameter like feedback vertex set number or treedepth (see Theorem 15). In the remainder of this section, we present the main idea for the proof of Theorem 17. We will only describe the algorithm for the most general version Any Strict URGR, but for all more restrictive versions, all arguments work analogously.

Definitions and Notations. Let $G = (V, E)$ be the solid graph and let F be a minimum size feedback edge set of G. We assume without loss of generality that G is connected, as otherwise, we can solve each connected component independently, or detect in polynomial time that D is not realizable if there are dashed arcs between different connected components of the solid graph. Moreover, let X denote the endpoints of the edges of F. Note that $|X| \leq 2 \cdot |F|$. We define the set V^* as the (unique) largest subset S of vertices of V that each have at least two neighbors in $G[S]$, that is, V^* is the 2-core [24] of G. This set can be computed in polynomial time. Moreover, we define $V' := V \setminus V^*$. Note that $X \subseteq V^*$, since F is a minimum-size feedback edge set. Since G is connected, for each vertex $v' \in V'$, there is a unique vertex $v \in V^*$ which has closest distance to v' among all vertices of V^*. For a vertex $v \in V^*$, denote by V_v the set of all vertices of V' for which v is the closest neighbor in V^*. Note that V_v might be empty. Since v' is in no cycle, removing v from G would result in v' ending up in a component that has no vertex of V^*. Hence, $T_v := G[\{v\} \cup V_v]$ is a tree for which we call v the *root*. Moreover, we call T_v the *pendant tree* of v.

Recall that each vertex of V^* has degree at least 2 in $G[V^*]$. Furthermore, $G - F$ is acyclic and thus $G[V^*] - F$ is a tree. Let Y_3 denote the set of all vertices of degree at least 3 in $G[V^*] - F$, and let Y_2 be the neighbors of $X \cup Y_3$ in $V^* \setminus (X \cup Y_3)$. Observe that each leaf of $G[V^*] - F$ is a vertex of X. Moreover, in each tree with ℓ leaves, there

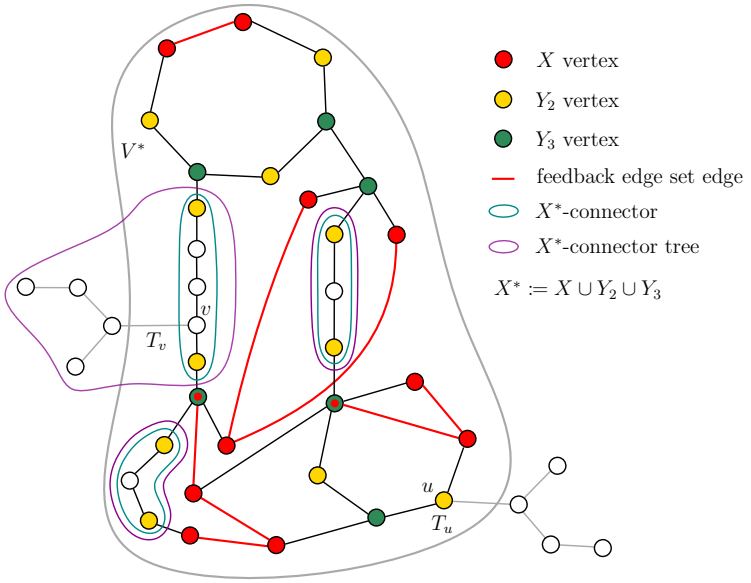


Figure 3 An illustration of the main definitions used by the FPT algorithm for parameter fes. The grey area contains the vertices of V^*, that is, the 2-core of G.

are $\mathcal{O}(\ell)$ vertices having (i) degree at least 3 or (ii) a neighbor of degree at least 3. This implies that $|Y_2 \cup Y_3| \in \mathcal{O}(|X|)$. Let $X^* := X \cup Y_2 \cup Y_3$. See Figure 3 for an illustration of these sets of vertices and some of the main definitions used in this section. By the above, $|X^*| \in \mathcal{O}(|X|) \subseteq \mathcal{O}(\text{fes})$. Recall that each vertex of Y_2 has degree exactly 2 in $G[V^*]$. Moreover, note that each vertex of $V^* \setminus X^*$ is part of a unique path P where each internal vertex of P is from $V^* \setminus X^*$ and the endpoints of P are from Y_2. For each such path, each internal vertex has degree exactly 2 in $G[V^*]$ and there are at most $|X^*| - 1$ such paths, since $G[V^*] - F$ is acyclic. Note that X^* contains all vertices that are part of triangles in $G[V^*]$ and thus in G. This implies that in each minimal realization of D, each edge incident with at least one vertex of $V \setminus X^*$ receives at most two labels (see Lemma 2). We now define the above mentioned paths between the vertices of Y_2 is a more general way.

▶ **Definition 18.** *Let W with $X^* \subseteq W \subseteq V^*$ and let P be a path of length at least 2 in $G[V^*]$ with endpoints a and b in W and all internal vertices from $V^* \setminus W$. We call P a* W-connector*. Moreover, let $C := G[V(P) \cup \bigcup_{q \in V(P) \setminus \{a,b\}} V_q]$. We call C a* W-connector tree *and the* extension *of P.*

Note that the endpoints of each X^*-connector are from Y_2 and thus have degree 2 in $G[V^*]$. Moreover, each internal vertex v of a W-connector P has degree exactly 2 in $G[V^*]$, that is, the only two neighbors of v in $G[V^*]$ are the predecessor and the successor of v in P. This also implies that each endpoint of a W-connector has degree exactly 2 in $G[V^*]$. Since each edge of P is incident with at least one vertex of $V \setminus W \subseteq V \setminus X^*$, in each minimal realization of D, each edge of each W-connector receives at most two labels (see Lemma 2). The latter also holds for each W-connector tree.

▶ **Observation 19.** *Let W with $X^* \subseteq W \subseteq V^*$. Then, there are $\mathcal{O}(|W| + \text{fes})$ edges between vertices of W in G and there are $\mathcal{O}(|W| + \text{fes})$ W-connectors. Moreover, for each vertex $q \in V \setminus (W \cup \bigcup_{w \in W} V_w)$, there is exactly one W-connector tree that contains q.*

Note that this is a general property of graphs with a feedback edge set of size fes.

Abstract Description of the Algorithm. Our algorithm uses two preprocessing steps.

In the first step, we will present a polynomial-time reduction rule based on the splitting operations presented in Section 4. With this reduction rule, we will be able to remove vertices from large pendant trees. After exhaustive application, for each vertex $x \in V^*$, the pendant tree T_x will have $\mathcal{O}(d_x)$ vertices, where d_x denotes the degree of x in $G[V^*]$.

In the second step, we extend the set X^* to a set $W^* \subseteq V^*$ such that each W^*-connector has some useful properties (we will define connectors with these properties as *nice connectors*). Intuitively, a connector P with extension C is nice if (i) in a realization for D, the arcs in $D[V(C)]$ can only be realized by temporal paths that are contained in the connector tree C, and (ii) for each arc between a vertex outside of C and a vertex inside of C, we can in polynomial time detect over which (unique) edge of the connector incident with one of its endpoints this arc is realized. As we will show, we can compute such a set W^* of size $\mathcal{O}(\text{fes})$ in polynomial time, or correctly detect that the input graph is not realizable. By the first part, we additionally get that the total number of vertices in pendant trees that have their root in W^* is $\mathcal{O}(|W^*| + \text{fes}) = \mathcal{O}(\text{fes})$.

The algorithm then works as follows: We iterate over all possible partial labelings λ on the $\mathcal{O}(\text{fes})$ edges incident with vertices of W^* or vertices of pendant trees that have their root in W^*. As we will show, we can assume that each of these edges will only receive $\mathcal{O}(\text{fes})$ labels in each minimal realization. For each such labeling λ, we need to check whether we can extend the labeling to the so far unlabeled edges, that is, the edges that are part of any W^*-connector tree. As we will show, we can compute for each such connector P with extension C in polynomial time a set L_P of $\mathcal{O}(1)$ labelings for the edges of C, such that if λ can be extended to a realization for D, then we can extend λ (independently from the other connectors) by one of the labelings in L_P. Since W^* has size $\mathcal{O}(\text{fes})$, there are only $\mathcal{O}(\text{fes})$ many W^*-connectors (see Observation 19) and for each such connector P, the set L_P of labelings has constant size. Our algorithm thus iterates over all possible $\mathcal{O}(1)^{\mathcal{O}(\text{fes})} = 2^{\mathcal{O}(\text{fes})}$ labeling combinations for the connectors and checks whether one of these combinations extends λ to a realization for D. Summarizing, we will show the following.

▶ **Proposition 20.** *In polynomial time, we can detect that D is not realizable, or compute a set W^* with $X^* \subseteq W^* \subseteq V^*$, such that the set of edges E^* that are (i) incident with at least one vertex of W^* or (ii) part of some pendant tree with root in W^*, has size $\mathcal{O}(\text{fes})$ and where for each labeling λ of the edges of E^*, we can in $2^{\mathcal{O}(\text{fes})} \cdot n^{\mathcal{O}(1)}$ time (a) compute a labeling that realizes D, or (b) detect that there no frugal realization for D that agrees with λ on the labels of all edges of E^*.*

The running time of this algorithm is then $\text{fes}^{\mathcal{O}(\text{fes}^2)} \cdot n^{\mathcal{O}(1)}$, since (i) all preprocessing steps run in polynomial time, (ii) we only have to consider $\text{fes}^{\mathcal{O}(\text{fes}^2)}$ labelings λ (since we prelabel $\mathcal{O}(\text{fes})$ edges with $\mathcal{O}(\text{fes})$ labels each), and (iii) for each labeling λ, we only have to check for $2^{\mathcal{O}(\text{fes})}$ possible ways to extend λ to a realization for D. To see the second part, we show that it is sufficient to assign only labels of $\{i \cdot 2 \cdot n \mid i \in \mathcal{O}(\text{fes}^2)\}$ in λ.

6.1 Technical Highlights and Difficulties of the Algorithm

We now describe in more detail the intuition about the two preprocessing steps, as well as the algorithm to compute a constant number of labelings for each nice connector.

Dealing with pendant trees. Recall that d_x denotes the degree of a vertex $x \in V^*$ in $G[V^*]$. To reduce each pendant tree T_x with $x \in V^*$ to a size of $\mathcal{O}(d_x)$, we first apply the three splitting operations of Section 4 to each edge of T_x incident with x. Since each of these edges

is a bridge and part of a tree, one of the two resulting instances produced by the splitting operations is then a tree and can be solved in polynomial time. We thus stick with the one resulting instance which is not a tree. As we show, by applying the splitting operations, we get that (i) for each special bridge $\{b, x\}$ of T_x incident with x, b has at most two neighbors besides x (namely, the possible in-leaf and the possible out-leaf) and (ii) for each non-special bridge $\{b, x\}$ of T_x incident with x, b is a leaf. This directly implies that T_x has depth 2 and the number of leaves of T_x is $\mathcal{O}(|B_x|)$, where B_x denotes the neighbors of x in T_x.

Thus, to reduce the size of T_x it suffices to reduce the number of vertices in B_x to $\mathcal{O}(d_x)$. To do so, we show that for each external edge e (that is, an edge that is incident with x but not contained in T_x), we can detect in polynomial time a set of at most 5 internal edges (that is, edges between x and vertices of B_x) that "surround" or "block" the edge e. Intuitively, in each realization for D, no other internal edge can share a label with e. This defines a total of $\mathcal{O}(d_x)$ internal edges that are surrounding or blocking. Let S_x denote these edges. Based on this set of edges, we then show that we can efficiently (i) detect that D is not realizable, or (ii) find a vertex b of B_x that (together with its possible leaf-neighbors) can safely be removed from D, if B_x has size $\omega(|S_x|)$. Hence, after exhaustive application of this operation, only $\mathcal{O}(|S_x|) \subseteq \mathcal{O}(d_x)$ vertices of B_x remain. Since each of these vertices only has at most two neighbors besides x, and these neighbors are leaves, the total size of T_x is then $\mathcal{O}(d_x)$.

Ensuring connectors with nice properties. We now give a more formal idea behind the definition of nice connectors. Let P be a connector with endpoints a and b, and let C be the extension of P. Then, P is nice, if (i) there is no dense path between a and b outside of $D[V(C)]$ and (ii) for each arc $(u, v) \in D$ between a vertex of C and a vertex outside of C, there is no dense (u, v)-path that goes over a or there is no dense (u, v)-path that goes over b.

Since the definition of nice connectors relies on the non-existence of dense paths between specific vertex pairs, detecting whether a connector is nice can presumably not be done in polynomial time.[2] To still achieve the goal of finding a desired set W^* where each connector is nice, we show the following: Whenever we have a set $W \supseteq X^*$ and a W-connector P, then we can in polynomial time (i) detect that D is not realizable or (ii) compute a constant number of vertices U_P of P, such that each subpath of P that is a $(W \cup U_P)$-connector is nice. That is, even though we cannot check efficiently whether the nice property is fulfilled for a given connector, we can ensure it by adding few vertices to our set. To compute the set W^*, we start with $W^* = X^*$ and iteratively add for each X^*-connector P the set U_P to W^*. Since $|X^*| \in \mathcal{O}(\text{fes})$ and there are $\mathcal{O}(\text{fes})$ X^*-connectors, the resulting set W^* also has size $\mathcal{O}(\text{fes})$. As we show, the update of W^* preserves the nice property of the connector before and after the update. In this way, we ensure that each W^*-connector is nice.

Dealing with nice connectors. Recall the definition of nice connectors. The first property essentially ensures that arcs in $D[V(C)]$ can only be realized via dense paths in $D[V(C)]$, which makes the local realization of $D[V(C)]$ in some sense independent from the remainder of D. The second property ensures that we only have one choice (with respect to dense paths inside of $D[V(C)]$) to realize an arc (u, v) between an internal and an external vertex.

We make use of these properties, since a nice connector P and its extension C only interact with the remainder of D via exactly two edges e_a and e_b. Moreover, both these edges receive at most two labels in every frugal realization. Assuming we are given the

[2] This is due to the fact that finding a dense path between two specific vertices can be shown to be NP-hard by reducing from Multicolored Clique.

labeling for e_a and e_b, we show that we can compute a constant number of labelings L_P for the edges of C, such that if there is a realization λ for D agreeing with the prelabeling of e_a and e_b, then we can replace the labels of λ on the edges of C by the labels of some labeling in L_P. The essential idea behind this algorithm is to build a constant number of tree instances in which we simulate how the connector interacts with the remainder of D in any possible labeling. As we show, we only have to (i) consider the cases for each of the edges e_a and e_b, whether there are temporal paths in λ that enter or exit C via e_a (e_b) via the smallest or largest label of e_a (e_b), and (ii) consider the cases whether some temporal paths under λ enter C via e_a and leave via e_b and whether they traverse the respective edges at their smallest or largest label. These are in total only a constant number of options. For each such option, we construct a tree instance of the problem obtained from $D[V(C)]$ by adding a constant number of vertices each to simulate the specific option. In some sense, these instances are generalizations of the instances built in the splitting rule for special bridges. Afterwards, we check for which of these instances we can find a labeling that agrees with the prelabeling on e_a and e_b and add such a labeling to L_P if it exists. The latter task can be performed in polynomial time, by using our linear program for tree instances.

7 The Complexity of Directed Reachability Graph Realizability

Finally, we consider the complexity of versions of Directed Reachability Graph Realizability. As already discussed by Döring [11], each directed graph D can be the strict reachability graph of a simple directed temporal graph. Hence, Any Strict DRGR and Simple Strict DRGR are always yes-instances and can thus be solved in polynomial time.

We now show that all DAGs and all transitive graphs are trivial yes-instances for each version of the problem.

▶ **Lemma 21** (⋆). *An instance $D = (V, A)$ of DRGR is a yes-instance, if (i) we consider Any Strict DRGR or Simple Strict DRGR, or (ii) D is a DAG or a transitive graph.*

Here, a directed graph $D = (V, A)$ is *transitive*, if for every distinct vertices $u, v, w \in V$ with $(u, v) \in A$ and $(v, w) \in A$, the arc (u, w) is also in A.

All other versions of DRGR are NP-hard even on graphs that are close to DAGs. More precisely, on graphs where a DAG can be obtained by removing a constant number of arcs.

▶ **Theorem 22** (⋆). *Proper DRGR, Happy DRGR, and all considered versions of Non-strict DRGR are NP-hard on graphs with a constant size feedback arc set. Moreover, none of these versions of DRGR can be solved in $2^{o(|V|+|A|)} \cdot n^{\mathcal{O}(1)}$ time, unless the ETH fails.*

8 Conclusion

We studied Reachability Graph Realizability and gave for both directed and undirected temporal graphs the complete picture for the classical complexity of all settings, answering this open problem posed by Casteigts et al. [3] and Döring [11]. For URGR, we additionally showed that the problem can be solved in FPT-time for the feedback edge set number fes of the solid graph. As we showed, this parameter cannot be replaced by smaller parameters like feedback vertex set number or treedepth of the solid graph, unless FPT = W[2].

There are several directions for future work: First, it would be interesting to see whether (some) versions of URGR admit a polynomial kernel for fes. Another interesting task is to determine whether Proper URGR, Happy URGR, or Non-strict URGR admits an FPT algorithm for feedback vertex set or treedepth. This is not excluded by our W[2]-hardness result, since that reduction only worked for Any Strict URGR and Simple Strict URGR.

Finally, one could analyze the parameterized complexity of Directed Reachability Graph Realizability with respect to directed graph parameters.

Faster Algorithm for Bounded Tree Edit Distance in the Low-Distance Regime

Tomasz Kociumaka

Ali Shahali
Sharif University of Technology, Tehran, Iran

Abstract

The *tree edit distance* is a natural dissimilarity measure between rooted ordered trees whose nodes are labeled over an alphabet Σ. It is defined as the minimum number of node edits – insertions, deletions, and relabelings – required to transform one tree into the other. The weighted variant assigns costs ≥ 1 to edits (based on node labels), minimizing total cost rather than edit count.

The unweighted tree edit distance between two trees of total size n can be computed in $\mathcal{O}(n^{2.6857})$ time; in contrast, determining the weighted tree edit distance is fine-grained equivalent to the All-Pairs Shortest Paths (APSP) problem and requires $n^3/2^{\Omega(\sqrt{\log n})}$ time [Nogler, Polak, Saha, Vassilevska Williams, Xu, Ye; STOC'25]. These impractical super-quadratic times for large, similar trees motivate the bounded version, parameterizing runtime by the distance k to enable faster algorithms for $k \ll n$.

Prior algorithms for bounded unweighted edit distance achieve $\mathcal{O}(nk^2 \log n)$ [Akmal & Jin; ICALP'21] and $\mathcal{O}(n + k^7 \log k)$ [Das, Gilbert, Hajiaghayi, Kociumaka, Saha; STOC'23]. For weighted, only $\mathcal{O}(n + k^{15})$ is known [Das, Gilbert, Hajiaghayi, Kociumaka, Saha; STOC'23].

We present an $\mathcal{O}(n + k^6 \log k)$-time algorithm for bounded tree edit distance in both weighted/unweighted settings. First, we devise a simpler weighted $\mathcal{O}(nk^2 \log n)$-time algorithm. Next, we exploit periodic structures in input trees via an optimized universal kernel: modifying prior $\mathcal{O}(n)$-time $\mathcal{O}(k^5)$-size kernels to generate such structured instances, enabling efficient analysis.

1 Introduction

The edit distance between two strings – the minimum cost of insertions, deletions, and substitutions needed to transform one string into the other – is one of the most widely used string similarity measures with numerous algorithmic applications. It provides a robust model for comparing sequential data and underpins techniques in fields such as computational biology, natural language processing, and text correction. Nevertheless, many data types exhibit hierarchical rather than linear structure. For example, RNA secondary structures, syntactic parse trees of natural language sentences, and hierarchical representations of documents and code all store information in tree-like forms. One can linearize such data and still use string edit distance, but the resulting alignments disregard the original hierarchical structure, and thus more expressive similarity measures are needed in most scenarios.

First introduced by Selkow [38], tree edit distance generalizes the notion of string edit distance to rooted ordered trees and forests with nodes labeled over an alphabet Σ. It quantifies the dissimilarity between two forests as the minimal cost of a sequence of node

edits – insertions, deletions, and relabelings – required to transform one forest into the other. This distance naturally captures both structural and label-based differences and serves as a core primitive in various algorithmic and applied domains, including computational biology [22, 39, 23, 45], analysis of structured data (such as XML and JSON files) [9, 13, 12, 20, 44], image processing [5, 26, 25, 36], and information extraction [16, 48]; see [6, 2] for surveys.

Tai [41] proposed the first polynomial-time algorithm for computing the tree edit distance: a dynamic programming procedure running in $\mathcal{O}(n^6)$ time, where n is the total number of nodes in the input forests. In the following decades, a sequence of works progressively improved the runtime. Zhang and Shasha [49] introduced an $\mathcal{O}(n^4)$-time algorithm, and then Klein [24] brought the complexity down to $\mathcal{O}(n^3 \log n)$. Subsequently, Demaine, Mozes, Rossman, and Weimann [17] presented an $\mathcal{O}(n^3)$-time solution, whereas Bringmann, Gawrychowski, Mozes, and Weimann [8] proved that a hypothetical $n^{3-\Omega(1)}$-time algorithm would violate the All-Pairs Shortest Paths (APSP) hypothesis in fine-grained complexity. Very recently, Nogler, Polak, Saha, Vassilevska Williams, Xu, and Ye [33] showed that computing the tree edit distance is, in fact, equivalent to the APSP problem, and the $n^3/2^{\Omega(\sqrt{\log n})}$ running time can be inherited from the state of the art for the latter task [46].

The aforementioned conditional lower bounds apply to the weighted tree edit distance only, where the cost of each edit depends on the involved labels. In the unweighted version with unit costs, a series of recent results achieved truly subcubic running time using fast matrix multiplication. Mao [29] presented an $\mathcal{O}(n^{2.9546})$-time solution, which was subsequently improved by Dürr [18] to $\mathcal{O}(n^{2.9148})$ and by Nogler et al. [33] to $\widetilde{\mathcal{O}}(n^{(3+\omega)/2}) = \mathcal{O}(n^{2.6857})$, where ω is the fast matrix multiplication exponent and $\widetilde{\mathcal{O}}(\cdot)$ hides $\operatorname{poly}\log n$ factors. The state-of-the-art conditional lower bound, inherited from string edit distance [4] and assuming the Orthogonal Vectors Hypothesis, prohibits $n^{2-\Omega(1)}$-time algorithms already if $|\Sigma| = 1$.

Bounded Tree Edit Distance. Even though the decades of research resulted in significantly faster tree edit distance algorithms, they also revealed fundamental challenges that explain the difficulty of this problem. A natural way of circumventing these barriers, paved by classical work for string edit distance [43, 31, 28], is to parameterize the running time not only in terms of the length n of the input forests but also the value k of the computed distance. This version of tree edit distance has originally been studied in the unweighted setting only. Touzet [42] adapted the ideas of Zhang and Shasha [49] to derive an $\mathcal{O}(nk^3)$-time algorithm, whereas Akmal and Jin [1] improved the running time to $\mathcal{O}(nk^2 \log n)$ based on the approach of Klein [24]. The latter running time remains the state-of-the-art for medium distances. In the low-distance regime, Das, Gilbert, Hajiaghayi, Kociumaka, Saha, and Saleh [15] achieved an $\widetilde{\mathcal{O}}(n + k^{15})$-time solution and subsequently improved the running time to $\mathcal{O}(n + k^7 \log k)$ [14]. They also studied the weighted version of the problem and presented an $\mathcal{O}(n + k^{15})$-time algorithm assuming that the weight function is normalized (each edit costs at least one unit; this prohibits arbitrary scaling) and satisfies the triangle inequality.

Still, the $\widetilde{\mathcal{O}}(n + \operatorname{poly}(k))$ running times for tree edit distance are much larger than for string edit distance and the related Dyck edit distance problem, which asks for the minimum cost of edits needed to make a given string of parentheses balanced (so that it represents a node-labeled forest). In the unweighted setting, the state-of-the-art running times are $\mathcal{O}(n + k^2)$ for string edit distance [28] and $\mathcal{O}(n + k^{5.442})$ for Dyck edit distance [21]. In the presence of weights, these complexities increase to $\widetilde{\mathcal{O}}(n + \sqrt{nk^3}) \le \widetilde{\mathcal{O}}(n + k^3)$ [10] and $\mathcal{O}(n + k^{12})$ [14], respectively. Thus, tree edit distance is a natural candidate for improvements.

Our Results. As the main contribution, we bring the time complexity of tree edit distance to $\widetilde{\mathcal{O}}(n+k^6)$. Even for unit weights, this improves upon the state of the art if $n^{1/7} \ll k \ll n^{1/4}$.

▶ **Theorem 1.1.** *There exists a deterministic algorithm that, given two forests F and G with n nodes in total, each with a label from an alphabet Σ, and oracle access to a normalized weight function $w : (\Sigma \cup \{\varepsilon\})^2 \to \mathbb{R}_{\geq 0}$ satisfying the triangle inequality, determines the tree edit distance $k \coloneqq \mathsf{ted}^w(F,G)$ in $\mathcal{O}(n + k^6 \log k)$ time.*

We also prove that the $\mathcal{O}(nk^2 \log n)$ running time by Akmal and Jin [1] remains valid in the presence of weights. This approach gives the best complexity when $n^{1/4} \ll k \ll n$.

▶ **Theorem 1.2.** *There exists a deterministic algorithm that, given two forests F and G, with n nodes in total, each with a label from an alphabet Σ, and oracle access to a normalized weight function $w : (\Sigma \cup \{\varepsilon\})^2 \to \mathbb{R}_{\geq 0}$, determines $k \coloneqq \mathsf{ted}^w(F,G)$ in $\mathcal{O}(nk^2 \log n)$ time.*

We believe that the original approach of Akmal and Jin [1] supports the weighted setting with minimal adjustments; nevertheless, we prove Theorem 1.2 using a slightly different algorithm that is better-suited for further optimizations. Both solutions are variants of Klein's dynamic programming [24] with some states pruned. The main difference is that we view the input forests as balanced sequences of parentheses and cast the tree edit distance as the minimum cost of a string alignment satisfying a certain consistency property. In our interpretation (Section 3), it is almost trivial to see that the classic pruning rules, originally devised to compute string edit distance in $\mathcal{O}(nk)$ time [43, 31], can be reused for tree edit distance in $\mathcal{O}(nk^2 \log n)$ time. In contrast, Akmal and Jin [1, Lemma 9] spend over four pages (on top of the analysis of [24]) to bound the number of states surviving their pruning rules.

Theorem 1.2 combined with the results of [14] lets us derive an $\mathcal{O}(n + k^7 \log k)$-time algorithm for weighted tree edit distance, matching the previously best running time for unit weights. This is due to the *universal kernel* that transforms the input forests to equivalent forests of size $\mathcal{O}(k^5)$ preserving the following capped tree edit distance value:

$$\mathsf{ted}^w_{\leq k}(F,G) = \begin{cases} \mathsf{ted}^w(F,G) & \text{if } \mathsf{ted}^w(F,G) \leq k, \\ \infty & \text{otherwise.} \end{cases}$$

▶ **Theorem 1.3** ([14, Corollary 3.20])**.** *There exists a linear-time algorithm that, given forests F, G and an integer $k \in \mathbb{Z}_+$, constructs forests F', G' of size $\mathcal{O}(k^5)$ such that $\mathsf{ted}^w_{\leq k}(F,G) = \mathsf{ted}^w_{\leq k}(F',G')$ holds for every normalized weight function w satisfying the triangle inequality.*

To bring the time complexity from $\widetilde{\mathcal{O}}(n+k^7)$ to $\widetilde{\mathcal{O}}(n+k^6)$, we adapt both Theorems 1.2 and 1.3. The main novel insight is that the dynamic-programming procedure behind Theorem 1.2 behaves predictably while processing regions with certain repetitive (periodic) structure. Upon an appropriate relaxation of the invariant that the dynamic-programming values satisfy, processing each repetition of the period can be interpreted as a single min-plus matrix-vector multiplication. When the period repeats many times, the same matrix is used each time, and thus we can raise the matrix to an appropriate power (with fast exponentiation) and then compute a single matrix-vector product; see Section 4 for details. This can be seen as a natural counterpart of an optimization used in [10] for string edit distance.[1]

[1] The matrices arising in the string edit distance computation in [10] are $\mathcal{O}(k) \times \mathcal{O}(k)$ Monge matrices, which allows for computing each matrix-vector product in $\mathcal{O}(k)$ time and each matrix-matrix product in $\mathcal{O}(k^2)$ time. In the context of tree edit distance, the Monge property is no longer satisfied, so the complexities increase to $\mathcal{O}(k^2)$ and $\mathcal{O}(k^3)$ respectively; in fact, computing the (weighted) tree edit distance is, in general, as hard as computing the min-plus product of two $n \times n$ arbitrary matrices [33].

Intuitively, the worst-case instances for the kernelization algorithm of Theorem 1.3 are close to having the necessary structure for our optimization to improve the worst-case running time. Unfortunately, the implementation in [14] controls the forest sizes only, and it needs to be modified to keep track of the more subtle instance difficulty measure. The biggest challenge is that the original algorithm proceeds in logarithmically many steps, each shrinking the forests by a constant fraction. In every step, the forests are partitioned into $\mathcal{O}(k)$ pieces of size $\mathcal{O}(n/k)$, and a constant fraction of pieces is shrunk to size $\mathcal{O}(k^4)$ each. A partition into pieces of equal "difficulty" would be much more challenging, so we instead take a different approach that lets us implement the reduction in a single step; see Section 5 for details. Notably, the kernelization algorithms for weighted string and Dyck edit distance already have single-step implementations in [14], but they crucially rely on the fact that the unit-weight variants of these problems can be solved faster, unlike for tree edit distance.

Related Work

The classical definition of tree edit distance [38] involves labeled rooted trees (or forests) with node labels. Many other variants have also been studied allowing, among others, unordered [47, 40], unrooted [40], and edge-labeled [3] trees; see also the surveys [2, 6].

The tree edit distance problem becomes easier not only when the computed distance is small but also when the input forests are of small depth [49, 11] or when the approximate distance suffices [3, 7, 37]. There is also a body of work focusing on practical performance and empirical evaluation, including sequential [34, 35] and parallel [19] implementations.

2 Preliminaries

Consistently with [14], we identify forests with the underlying Euler tours, interpreted as balanced strings of parentheses. This representation is at the heart of space-efficient data structures on trees [30, 32], and it allows for a simple definition of tree edits and a seamless transfer of many tools from strings to forests. Notably, Klein's algorithm [24] already uses substrings of the Euler tours of the input forests to identify the dynamic-programming states.

For an alphabet Σ, let $\mathsf{P}_\Sigma := \bigcup_{a\in\Sigma}\{(_a,)_a\}$ denote the set parentheses with labels in Σ. As formalized next, a *forest* with node labels over Σ is a *balanced* string of parentheses in P_Σ.

▶ **Definition 2.1.** *The set of* forests *with labels over* Σ *(*balanced strings *over* P_Σ*) is the smallest subset* $\mathcal{F}_\Sigma \subseteq \mathsf{P}_\Sigma^*$ *satisfying the following conditions:*

- $\varepsilon \in \mathcal{F}_\Sigma$,
- $F \cdot G \in \mathcal{F}_\Sigma$ *for every* $F, G \in \mathcal{F}_\Sigma$,
- $(_a \cdot F \cdot)_a \in \mathcal{F}_\Sigma$ *for every* $F \in \mathcal{F}_\Sigma$ *and* $a \in \Sigma$.

For a forest F, we define the set of *nodes* V_F as the set of intervals $[i\,..\,j] \subseteq [0\,..\,|F|)$ such that $F[i]$ is an opening parenthesis, $F[j]$ is a closing parenthesis, and $F(i\,..\,j)$ is balanced. A forest F is a *tree* if $[0\,..\,|F|) \in V_F$. For a node $u = [i\,..\,j] \in V_F$, we denote the positions of the opening and the closing parenthesis by $o(u) := i$ and $c(u) := j$. The label of u, that is, the character $a \in \Sigma$ such that $F[o(u)] = (_a$ and $F[c(u)] =)_a$, is denoted by $\mathsf{lbl}(u)$. A simple inductive argument shows that V_F forms a laminar family and, for every $i \in [0\,..\,|F|)$, there is a unique node $u \in V_F$ such that $i \in \{o(u), c(u)\}$; we denote this node by $\mathsf{node}_F(i)$. We also write $\mathsf{mate}_F(i)$ for the paired parenthesis, that is, $\mathsf{mate}_F(i) = j$ if $\{i, j\} = \{o(u), c(u)\}$.

We say that a node $u \in V_F$ *is contained* in a fragment $F[i\,..\,j)$ of a forest F if $i \le o(u) < c(u) < j$; we denote by $V_{F[i\,..\,j)} \subseteq V_F$ the set of nodes contained in $F[i\,..\,j)$. Moreover, u *enters* $F[i\,..\,j)$ if $o(u) < i \le c(u) < j$ and u *exits* $F[i\,..\,j)$ if $i \le o(u) < j \le c(u)$. In either of these two cases, we also say that u *straddles* $F[i\,..\,j)$.

We denote by $F_{[i..j)}$ the *subforest of F induced by $F[i..j)$*, which we obtain from F by deleting (the parentheses corresponding to) all nodes except for those contained in $F[i..j)$. Alternatively, one can obtain $F_{[i..j)}$ from $F[i..j)$ by deleting the opening parenthesis of every node that exits $F[i..j)$ and the closing parenthesis of every node that enters $F[i..j)$.

2.1 Tree Edits, Forest Alignments, and Tree Edit Distance

For an alphabet Σ, we define $\bar{\Sigma} := \Sigma \cup \{\varepsilon\}$, where ε is the empty string. We say that a function $w : \bar{\Sigma}^2 \to \mathbb{R}_{\geq 0}$ is *normalized* if $w(a,a) = 0$ and $w(a,b) \geq 1$ hold for distinct $a, b \in \bar{\Sigma}$.

Tree edit distance is classically defined using elementary edits transforming $F \in \mathcal{F}_\Sigma$:

Node insertion produces $F[0..i) \cdot (_a \cdot F[i..j) \cdot)_a \cdot F[j..|F|)$ for a balanced fragment $F[i..j)$ and a label $a \in \Sigma$, at cost $w(\varepsilon, a)$.

Node relabeling produces $F[0..o(u)) \cdot (_a \cdot F(o(u)..c(u)) \cdot)_a \cdot F(c(u)..|F|)$ for a node $u \in V_F$ and a label $a \in \Sigma$, at cost $w(\mathsf{lbl}(u), a)$.

Node deletion produces $F[0..o(u)) \cdot F(o(u)..c(u)) \cdot F(c(u)..|F|)$ for a node $u \in V_F$, at cost $w(\mathsf{lbl}(u), \varepsilon)$.

The tree edit distance $\mathsf{ted}^w(F,G)$ of two forests $F, G \in \mathcal{F}_\Sigma$ is then defined as the minimum cost of a sequence of edits transforming F to G. In this context, without loss of generality, we can replace w by its transitive closure. If, say $w(a,\varepsilon) > w(a,b) + w(b,\varepsilon)$, instead of directly deleting a node with label a, it is more beneficial to first change its label to b and only then perform the deletion. When w satisfies the triangle inequality, we are guaranteed that an inserted or relabeled node is never modified (deleted or relabeled) again. Consistently with modern literature [8, 14, 33], we use a more general *alignment-based* definition of $\mathsf{ted}^w(F,G)$ that enforces the latter condition even if w does not necessarily satisfy the triangle inequality.

▶ **Definition 2.2** (Alignment Graph [10]). *For strings $X, Y \in \Sigma^*$ and a weight function $w : \bar{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, we define the* alignment graph $\mathsf{AG}^w(X,Y)$ *as a grid graph with vertices $[0..|X|] \times [0..|Y|]$ and the following directed edges:*

- *horizontal edges $(x,y) \to (x+1,y)$ of cost $w(X[x],\varepsilon)$ for $(x,y) \in [0..|X|) \times [0..|Y|]$,*
- *vertical edges $(x,y) \to (x,y+1)$ of cost $w(\varepsilon, Y[y])$ for $(x,y) \in [0..|X|] \times [0..|Y|)$, and*
- *diagonal edges $(x,y) \to (x+1,y+1)$ of cost $w(X[x],Y[y])$ for $(x,y) \in [0..|X|) \times [0..|Y|)$.*

The alignment graph allows for a concise definition of a string *alignment*.

▶ **Definition 2.3** (Alignment). *For strings $X, Y \in \Sigma^*$ and a weight function $w : \bar{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, an* alignment *of $X[x..x')$ onto $Y[y..y')$, denoted by $\mathcal{A} : X[x..x') \rightsquigarrow Y[y..y')$, is a path from (x,y) to (x',y') in $\mathsf{AG}^w(X,Y)$, interpreted as a sequence of vertices. The* cost $\mathsf{ed}^w_{\mathcal{A}}(X[x..x'), Y[y..y'))$ *of the alignment $\mathcal{A}$ is the total costs of the edges that belong to $\mathcal{A}$.*

We write $\mathbf{A}(X[x..x'), Y[y..y'))$ for the set of all alignments of $X[x..x')$ onto $Y[y..y')$.

The edges of an alignment $\mathcal{A} = \mathbf{A}(X[x..x'), Y[y..y'))$ can be interpreted as follows:

- If $\mathcal{A}$ includes an edge $(\hat{x},\hat{y}) \to (\hat{x}+1,\hat{y})$ for some $\hat{x} \in [x..x')$ and $\hat{y} \in [y..y']$, then $\mathcal{A}$ *deletes* $X[\hat{x}]$, denoted by $X[\hat{x}] \rightsquigarrow_{\mathcal{A}} \varepsilon$.
- If $\mathcal{A}$ includes an edge $(\hat{x},\hat{y}) \to (\hat{x},\hat{y}+1)$ for some $\hat{x} \in [x..x']$ and $\hat{y} \in [y..y')$, then $\mathcal{A}$ *inserts* $Y[\hat{y}]$, denoted by $\varepsilon \rightsquigarrow_{\mathcal{A}} Y[\hat{y}]$.
- If $\mathcal{A}$ includes an edge $(\hat{x},\hat{y}) \to (\hat{x}+1,\hat{y}+1)$ for some $\hat{x} \in [x..x')$ and $\hat{y} \in [y..y')$, then $\mathcal{A}$ *aligns* $X[\hat{x}]$ to $Y[\hat{y}]$, denoted by $X[\hat{x}] \rightsquigarrow_{\mathcal{A}} Y[\hat{y}]$. If $X[\hat{x}] \neq Y[\hat{y}]$, then $\mathcal{A}$ *substitutes* $X[\hat{x}]$ for $Y[\hat{y}]$. If $X[\hat{x}] = Y[\hat{y}]$, then $\mathcal{A}$ *matches* $X[\hat{x}]$ with $Y[\hat{y}]$.

Insertions, deletions, and substitutions are jointly called character *edits*.

The weighted edit distance of fragments $X[x\,..\,x')$ and $Y[y\,..\,y')$ with respect to a weight function $w : \bar{\Sigma}^2 \to \mathbb{R}_{\geq 0}$ is defined as the minimum cost of an alignment:

$$\mathsf{ed}^w(X[x\,..\,x'), Y[y\,..\,y')) = \min_{\mathcal{A}\in\mathbf{A}(X[x\,..\,x'),Y[y\,..\,y'))} \mathsf{ed}^w_{\mathcal{A}}(X[x\,..\,x'), Y[y\,..\,y')).$$

We often consider alignments of the entire string X onto the entire string Y; we then used simplified notation including $\mathbf{A}(X,Y)$, $\mathsf{ed}^w_{\mathcal{A}}(X,Y)$, and $\mathsf{ed}^w(X,Y)$.

▶ **Definition 2.4** (Forest alignment)**.** *Consider forests $F, G \in \mathcal{F}_\Sigma$. An alignment $\mathcal{A} \in \mathbf{A}(F[f\,..\,f'), G[g\,..\,g'))$ is a* forest alignment *if it satisfies the following consistency condition:*

For every two aligned characters $F[\hat{f}] \rightsquigarrow_{\mathcal{A}} G[\hat{g}]$, also $F[\mathsf{mate}_F(\hat{f})] \rightsquigarrow_{\mathcal{A}} G[\mathsf{mate}_G(\hat{g})]$.

We write $\mathbf{FA}(F[f\,..\,f'), G[g\,..\,g')) \subseteq \mathbf{A}(F[f\,..\,f'), G[g\,..\,g'))$ for the set of forest alignments.

▶ Remark 2.5. Consider a forest alignment $\mathcal{A} \in \mathbf{FA}(F[f\,..\,f'), G[g\,..\,g'))$. Then,

- $\mathcal{A}$ deletes every character $F[\hat{f}]$ with $\hat{f} \in [f\,..\,f')$ and $\mathsf{mate}_F(\hat{f}) \notin [f\,..\,f')$,
- $\mathcal{A}$ inserts every character $G[\hat{g}]$ with $\hat{g} \in [g\,..\,g')$ and $\mathsf{mate}_G(\hat{g}) \notin [g\,..\,g')$.

Define $\overline{\mathsf{P}_\Sigma} = \mathsf{P}_\Sigma \cup \{\varepsilon\}$ and a mapping $\lambda : \overline{\mathsf{P}_\Sigma} \to \bar{\Sigma}$ such that $\lambda(\langle_a) = \lambda(\rangle_a) = a$ for each $a \in \Sigma$, and $\lambda(\varepsilon) = \varepsilon$. For a weight function $w : \bar{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, we define a corresponding weight function $\tilde{w} : \overline{\mathsf{P}_\Sigma}^2 \to \mathbb{R}_{\geq 0}$ so that $\tilde{w}(p,q) = \frac{1}{2}w(\lambda(p), \lambda(q))$ for all $p, q \in \overline{\mathsf{P}_\Sigma}$. The *cost* of a forest alignment $\mathcal{A} \in \mathbf{FA}(F[f\,..\,f'), G[g\,..\,g'))$ with respect to a weight function w is defined as $\mathsf{ted}^w_{\mathcal{A}}(F[f\,..\,f'), G[g\,..\,g')) := \mathsf{ed}^{\tilde{w}}_{\mathcal{A}}(F[f\,..\,f'), G[g\,..\,g'))$. Moreover, we define

$$\mathsf{ted}^w(F[f\,..\,f'), G[g\,..\,g')) = \min_{\mathcal{A}\in\mathbf{FA}(F[f\,..\,f'),G[g\,..\,g'))} \mathsf{ted}^w_{\mathcal{A}}(F[f\,..\,f'), G[g\,..\,g')).$$

For a threshold $k \in \mathbb{R}_{\geq 0}$, we set

$$\mathsf{ted}^w_{\leq k}(F[f\,..\,f'), G[g\,..\,g')) = \begin{cases} \mathsf{ted}^w(F[f\,..\,f'), G[g\,..\,g')) & \text{if } \mathsf{ted}^w(F[f\,..\,f'), G[g\,..\,g')) \leq k, \\ \infty & \text{otherwise.} \end{cases}$$

By Remark 2.5, the following value is non-negative for every $\mathcal{A} \in \mathbf{FA}(F[f\,..\,f'), G[g\,..\,g'))$:

$$\widetilde{\mathsf{ted}}^w_{\mathcal{A}}(F[f\,..\,f'), G[g\,..\,g')) \coloneqq \mathsf{ted}^w_{\mathcal{A}}(F[f\,..\,f'), G[g\,..\,g')) - \sum_{\substack{\hat{f}\in[f\,..\,f'):\\ \mathsf{mate}_F(\hat{f})\notin[f\,..\,f')}} \tilde{w}(F[\hat{f}], \varepsilon) - \sum_{\substack{\hat{g}\in[g\,..\,g'):\\ \mathsf{mate}_G(\hat{g})\notin[g\,..\,g')}} \tilde{w}(\varepsilon, G[\hat{g}]).$$

We naturally generalize this value to $\widetilde{\mathsf{ted}}^w(F[f\,..\,f'), G[g\,..\,g'))$.

▶ **Observation 2.6.** *For all forests $F, G \in \mathcal{F}_\Sigma$, fragments $F[f\,..\,f')$ and $G[g\,..\,g')$, and weight functions $w : \bar{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, we have $\widetilde{\mathsf{ted}}^w(F[f\,..\,f'), G[g\,..\,g')) = \mathsf{ted}^w(F_{[f\,..\,f')}, G_{[g\,..\,g')})$.*

3 $\mathcal{O}(nk^2 \log n)$-Time Algorithm

In this section, we reinterpret Klein's algorithm [24] and develop its $\mathcal{O}(nk^2 \log n)$-time variant.

3.1 Klein's Algorithm

Klein's algorithm [24] uses dynamic programming to compute $\mathsf{ted}(F_{[l_F..r_F)}, G_{[l_G..r_G)}) = \widetilde{\mathsf{ted}}(F[l_F..r_F), G[l_G..r_G))$ for $\mathcal{O}(n \log n)$ selected fragments $F[l_F..r_F)$ of F and all $\mathcal{O}(n^2)$ fragments $G[l_G..r_G)$ of G. We modify the algorithm slightly so that the computed value $\mathsf{ted}(F[l_F..r_F), G[l_G..r_G))$ includes the costs of deleting the single parentheses of nodes straddling $F[l_F..r_F)$ and inserting the single parentheses of nodes straddling $G[l_G..r_G)$.

Algorithm 1 `Klein`(l_F, r_F, l_G, r_G): Klein's algorithm for computing the tree edit distance.

Input: Two fragments $F[l_F..r_F)$ and $G[l_G..r_G)$ of the input forests
Output: Compute and store the value of $\mathsf{dp}[l_F, r_F, l_G, r_G]$

1 **if** $l_F = r_F$ **then** $\mathsf{result} \leftarrow \sum_{i \in [l_G..r_G)} \tilde{w}(\varepsilon, G[i])$;
2 **else if** $l_G = r_G$ **then** $\mathsf{result} \leftarrow \sum_{i \in [l_F..r_F)} \tilde{w}(F[i], \varepsilon)$;
3 **else**
4 $\quad u_F = \mathsf{node}_F(l_F)$, $v_F = \mathsf{node}_F(r_F - 1)$, $u_G = \mathsf{node}_G(l_G)$, $v_G = \mathsf{node}_G(r_G - 1)$;
5 $\quad$ **if** $u_F \notin V_{F[l_F..r_F)}$ **or** ($v_F \in V_{F[l_F..r_F)}$ **and** $\mathsf{size}(u_F) \le \mathsf{size}(v_F)$) **then**
6 $\quad\quad \mathsf{result} \leftarrow \mathsf{dp}[l_F + 1, r_F, l_G, r_G] + \tilde{w}(F[l_F], \varepsilon)$;
7 $\quad\quad \mathsf{result} \overset{\min}{\leftarrow} \mathsf{dp}[l_F, r_F, l_G + 1, r_G] + \tilde{w}(\varepsilon, G[l_G])$;
8 $\quad\quad$ **if** $u_F \in V_{F[l_F..r_F)}$ **and** $u_G \in V_{G[l_G..r_G)}$ **then**
9 $\quad\quad\quad \mathsf{result} \overset{\min}{\leftarrow} \tilde{w}(F[l_F], G[l_G]) + \mathsf{dp}[l_F + 1, c(u_F), l_G + 1, c(u_G)] + \tilde{w}(F[c(u_F)], G[c(u_G)]) + \mathsf{dp}[c(u_F) + 1, r_F, c(u_G) + 1, r_G]$;
10 $\quad$ **else**
11 $\quad\quad \mathsf{result} \leftarrow \mathsf{dp}[l_F, r_F - 1, l_G, r_G] + \tilde{w}(F[r_F - 1], \varepsilon)$;
12 $\quad\quad \mathsf{result} \overset{\min}{\leftarrow} \mathsf{dp}[l_F, r_F, l_G, r_G - 1] + \tilde{w}(\varepsilon, G[r_G - 1])$;
13 $\quad\quad$ **if** $v_F \in V_{F[l_F..r_F)}$ **and** $v_G \in V_{G[l_G..r_G)}$ **then**
14 $\quad\quad\quad \mathsf{result} \overset{\min}{\leftarrow} \mathsf{dp}[l_F, o(v_F), l_G, o(v_G)] + \tilde{w}(F[o(v_F)], G[o(v_G)]) + \mathsf{dp}[o(v_F) + 1, r_F - 1, o(v_G) + 1, r_G - 1] + \tilde{w}(F[r_F - 1], G[r_G - 1])$;
15 $\mathsf{dp}[l_F, r_F, l_G, r_G] \leftarrow \mathsf{result}$

The algorithm's implementation is provided in Algorithm 1. We use an operator $x \overset{\min}{\leftarrow} y$ that assigns $x \leftarrow y$ if $y < x$. We also remember which of these assignments were applied so that we can later trace back the optimal alignment based on this extra information stored.

In the corner case when $F[l_F..r_F)$ or $G[l_G..r_G)$ is empty, then the unique (and thus optimal) forest alignment pays for inserting or deleting all characters in the other fragment. If both $F[l_F..r_F)$ and $G[l_G..r_G)$ are non-empty, the algorithm considers nodes $u_F = \mathsf{node}_F(l_F)$, $u_G = \mathsf{node}_G(l_G)$, $v_F = \mathsf{node}_F(r_F - 1)$, and $v_G = \mathsf{node}_G(r_G - 1)$.

Let us first suppose that u_F and v_F are contained in $F[l_F..r_F)$. If the subtree of v_F is at least as large as the subtree of u_F, that is, $\mathsf{size}(v_F) \ge \mathsf{size}(u_F)$, where $\mathsf{size}(x) = c(x) - o(x) + 1$, then algorithm considers three possibilities: $F[l_F]$ is deleted, $G[l_G]$ is inserted, or $F[l_F]$ is aligned with $G[l_G]$. In the first two possibilities, we can pay for the deleted or inserted opening parenthesis and align the remaining fragments; see Lines 6–7. In the third possibility, the consistency condition in the definition of the forest alignments requires that $F[\mathsf{mate}_F(l_F)]$ is also aligned with $G[\mathsf{mate}_G(l_G)]$. In particular, the node u_G needs to be contained in $G[l_G..r_G)$ so that $\mathsf{mate}_G(l_G) = c(u_G)$ and $\mathsf{mate}_F(l_F) = c(u_F)$. Thus, we align $F(l_F..c(u_F))$ with $G(l_G..c(u_G))$, align $F(c(u_F)..r_F)$ with $G(c(u_G)..r_G)$, and pay for aligning u_F with u_G, that is $F[l_F]$ with $G[l_G]$ and $F[c(u_F)]$ with $G[c(u_G)]$; see Line 9. If $\mathsf{size}(v_F) < \mathsf{size}(u_F)$, the algorithm handles v_F and v_G in a symmetric way; see Lines 10–14.

If $u_F \notin V_{F[l_F..r_F)}$, we follow Lines 5–9 and effectively consider deleting $F[l_F]$ and inserting $G[l_G]$. Else, if $v_F \notin V_{F[l_F..r_F)}$, we follow the symmetric Lines 10–14.

Zhang and Shasha [49] use a very similar dynamic programming; in a baseline version, their algorithm always constructs the alignment from left to right instead of picking the side depending on u_F and v_F. Klein's optimization allows for an improved running time of $\mathcal{O}(n^3 \log n)$ instead of $\mathcal{O}(n^4)$. In the full version [27], we recall the proof of the following lemma.

▶ **Lemma 3.1.** *The recursive implementation of Algorithm 1 visits $\mathcal{O}(n \log n)$ fragments of F.*

Akmal and Jin's Algorithm. Akmal and Jin [1] reduce the time complexity of Klein's algorithm to $\mathcal{O}(nk^2 \log n)$ when computing $\mathsf{ted}_{\le k}(F, G)$. Their solutions prunes some dynamic programming states so that, in the surviving states, the differences between the sizes of the subforests $F_{[l_F..r_F)}$ and $G_{[l_G..r_G)}$ is at most k. This condition also holds for the difference between the sizes of $F_{[0..r_F)} \setminus F_{[l_F..r_F)}$ and $G_{[0..l_G)} \setminus G_{[l_G..r_G)}$, as well as between $F_{[l_F..|F|)} \setminus F_{[l_F..r_F)}$ and $G_{[l_G..|G|)} \setminus G_{[l_G..r_G)}$; see [1, Lemma 12]. As shown in [1, Lemma 13], for each subforest $F_{[l_F..r_F)}$, there are $\mathcal{O}(k^2)$ subforests $G_{[l_G..r_G)}$ satisfying these three conditions. With a careful implementation, the total number of states becomes $\mathcal{O}(nk^2 \log n)$.

3.2 Our Algorithm

Our variant of Klein's algorithm simply prunes all states with $|l_F - l_G| > 2k$ or $|r_F - r_G| > 2k$. In other words, we modify Algorithm 1 so that $\mathsf{dp}[l_F, r_F, l_G, r_G]$ is set to ∞ if either condition holds, and the existing instructions are executed otherwise. This does not increase the number $\mathcal{O}(n \log n)$ of visited fragments $F[l_F..r_F)$; see Lemma 3.1. For each of these fragments, trivially, at most $\mathcal{O}(k^2)$ fragments of G survive pruning, so the total number of states is $\mathcal{O}(nk^2 \log n)$. The correctness of the pruning rules follows from the fact that, for all forests F, G, the width of any alignment in $\mathbf{FA}(F, G)$ does not exceed twice its cost, where the width of an alignment $\mathcal{A} \in \mathbf{A}(X[x..x'), Y[y..y'))$ is defined as $\mathsf{width}(\mathcal{A}) = \max\{|\hat{x} - \hat{y}| : (\hat{x}, \hat{y}) \in \mathcal{A}\}$.

In the full version [27], we formalize this intuition using the notion of bounded forest alignments.

▶ **Definition 3.2.** *Let us fix a threshold $k \in \mathbb{Z}_+$ and consider fragments $F[f..f')$ and $G[g..g')$ of forests $F, G \in \mathcal{F}_\Sigma$. We call a forest alignment $\mathcal{A} \in \mathbf{FA}(F[f..f'), G[g..g'))$* bounded *if $\mathsf{width}(\mathcal{A}) \le 2k$. The family of* bounded forest alignments *is $\mathbf{BFA}_k(F[f..f'), G[g..g')) \subseteq \mathbf{FA}(F[f..f'), G[g..g'))$. For a weight function $w : \bar{\Sigma}^2 \to \mathbb{R}_{\ge 0}$, we denote*

$$\mathsf{bted}^w_k(F[f..f'), G[g..g')) = \min_{\mathcal{A} \in \mathbf{BFA}_k(F[f..f'), G[g..g'))} \mathsf{ted}^w_{\mathcal{A}}(F[f..f'), G[g..g')).$$

▶ **Lemma 3.3.** *The dp values computed using the pruned version of Algorithm 1 satisfy*

$$\mathsf{ted}^w(F[l_F..r_F), G[l_G..r_G)) \le \mathsf{dp}[l_F, r_F, l_G, r_G] \le \mathsf{bted}^w_k(F[l_F..r_F), G[l_G..r_G)).$$

In particular, the $\mathsf{dp}[0, |F|, 0, |G|]$ entry stores a value between $\mathsf{ted}^w(F, G)$ and $\mathsf{bted}^w_k(F, G)$. The following observation implies that this is enough to retrieve $\mathsf{ted}^w_{\le k}(F, G)$.

▶ **Observation 3.4.** *If $\mathsf{ted}^w(F, G) \le k$, then $\mathsf{ted}^w(F, G) = \mathsf{bted}^w_k(F, G)$.*

Proof. Consider the optimal forest alignment $\mathcal{A} \in \mathbf{FA}(F, G)$ with $\mathsf{ted}^w_{\mathcal{A}}(F, G) \le k$. For each edge $(f, g) \to (f', g')$, either $f - g = f' - g'$ (if the edge is diagonal) or $\big|(f-g)-(f'-g')\big| = 1$ and the edge cost is at least $\frac{1}{2}$ (if the edge is vertical or horizontal). Since $(0, 0) \in \mathcal{A}$ and the total cost of edges in $\mathcal{A}$ is at most k, every $(f, g) \in \mathcal{A}$ satisfies $|f - g| \le 2k$, i.e., $\mathsf{width}(\mathcal{A}) \le 2k$ and $\mathcal{A} \in \mathbf{BFA}_k(F, G)$. Hence, $\mathsf{bted}^w_k(F, G) \le \mathsf{ted}^w_{\mathcal{A}}(F, G) = \mathsf{ted}^w(F, G)$. The converse inequality $\mathsf{ted}^w(F, G) \le \mathsf{bted}^w_k(F, G)$ holds trivially due to $\mathbf{BFA}_k(F, G) \subseteq \mathbf{FA}(F, G)$. ◀

With minor implementation details needed to avoid logarithmic overheads for memoization using a sparse table dp (Akmal and Jin [1] ignore this issue), we achieve the following result.

▶ **Theorem 1.2.** *There exists a deterministic algorithm that, given two forests F and G, with n nodes in total, each with a label from an alphabet Σ, and oracle access to a normalized weight function $w : (\Sigma \cup \{\varepsilon\})^2 \to \mathbb{R}_{\geq 0}$, determines $k := \mathsf{ted}^w(F, G)$ in $\mathcal{O}(nk^2 \log n)$ time.*

4 Faster Algorithm for Repetitive Inputs

In this section, we present an optimized version of our $\mathcal{O}(nk^2 \log n)$-time algorithm capable of exploiting certain repetitive structures within the input forests F and G. The following notion of *free pairs* captures the structure that our algorithm is able to utilize.

▶ **Definition 4.1** (Free pair, free block)**.** *Consider forests $F, G \in \mathcal{F}_\Sigma$ and a fixed threshold $k \in \mathbb{Z}_+$. We call a pair of fragments $F[p_F \mathinner{..} q_F)$ and $G[p_G \mathinner{..} q_G)$ a* free pair *if*

- $|p_F - p_G| \leq 2k$, *and*
- *there exists a balanced string $R \in \mathcal{F}_\Sigma$ with $4k \leq |R| < 8k$ such that $F[p_F - |R| \mathinner{..} q_F + |R|) = R^{e+2} = G[p_G - |R| \mathinner{..} q_G + |R|)$ holds for some integer exponent $e \in \mathbb{Z}_+$.*

For that free pair, we call the fragment $F[p_F \mathinner{..} q_F)$ a free block *with period R and exponent e.*

Our improved algorithm assumes that the input forests F and G are augmented with a collection $\mathbf{F}$ of disjoint free blocks $F[p_F \mathinner{..} q_F)$, each associated with the underlying period R, exponent e, and the corresponding fragment $G[p_G \mathinner{..} q_G)$. The speed-up compared to the algorithm of Section 3 is noticeable if the free blocks in $\mathbf{F}$ jointly cover most of the characters of F, that is, the number of remaining *non-free* characters is asymptotically smaller than $|F|$.

▶ **Theorem 4.2.** *There exists a deterministic algorithm that, given forests $F, G \in \mathcal{F}_\Sigma$ of total length n, oracle access to a normalized weight function $w : \bar{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, a threshold $k \in \mathbb{Z}_+$, and a collection $\mathbf{F}$ of t disjoint free blocks in F such that m characters of F are not contained in any free block, computes $\mathsf{ted}^w_{\leq k}(F, G)$ in $\mathcal{O}(n \log n + mk^2 \log n + tk^3 \log n)$ time.*

Intuitively, the algorithm skips all the free blocks, which allows reducing the $\mathcal{O}(nk^2 \log n)$ running time of Theorem 1.2 to $\mathcal{O}(mk^2 \log n)$, i.e., the algorithm needs to pay for non-free characters only. Nevertheless, processing each free block takes $\mathcal{O}(k^3 \log n)$ extra time, and $\mathcal{O}(n \log n)$-time preprocessing time is still needed to avoid overheads for memoization.

Processing Free Blocks. To understand our speed-up, let us consider a free pair with period R and exponent e, that is, $F[p_F \mathinner{..} q_F) = R^e = G[p_G \mathinner{..} q_G)$. We picked the parameters so that $|R| \geq 4k \geq \mathsf{width}(\mathcal{A}) + |p_F - p_G|$, and thus every alignment $\mathcal{A} \in \mathbf{BFA}_k(F, G)$ aligns $F[p_F \mathinner{..} q_F) = R^e$ with a fragment $G[p'_G \mathinner{..} q'_G)$ contained in $G[p_G - |R| \mathinner{..} q_G + |R|) = R^{e+2}$. By the same argument, the image of every copy of R within $F[p_F \mathinner{..} q_F) = R^e$ is contained within the corresponding copy of R^3 within $G[p_G - |R| \mathinner{..} q_G + |R|) = R^{e+2}$. Moreover, when we align $F[p_F \mathinner{..} q_F)$ to $G[p'_F \mathinner{..} q'_F) \subseteq G[p_G - |R| \mathinner{..} q_G + |R|)$, it suffices to partition $G[p'_F \mathinner{..} q'_F)$ into e fragments and *independently* optimally align each copy of R in $F[p_F \mathinner{..} q_F)$ with the corresponding fragment of $G[p'_F \mathinner{..} q'_F)$. This is because R is balanced, so every node of R^e is contained within a single copy of R, and thus the consistency condition in Definition 2.4 does not impose any constraints affecting multiple copies of R.

The optimal costs of aligning R with relevant fragments of R^3 can be encoded in the following matrix, constructible in $\mathcal{O}(|R|^3 \log |R|)$ time using Algorithm 1 (Klein's algorithm).

▶ **Definition 4.3.** *For a balanced string $R \in \mathcal{F}_\Sigma$, we define a matrix M_R of size $(2|R|+1) \times (2|R|+1)$ with indices i, j in the range $[-|R| \,..\, |R|]$ as follows:*

$$M_R[i,j] = \begin{cases} \mathsf{ted}^w(R, R^3[|R|+i \,..\, 2|R|+j)) & \text{if } |R|+i \le 2|R|+j, \\ \infty & \text{otherwise.} \end{cases}$$

In order to derive the optimal costs of aligning $R^e = F[p_F \,..\, q_F)$ with the relevant fragments of $R^{e+2} = G[p_G - |R| \,..\, q_G + |R|)$, we simply compute the e-th power of M_R with respect to the min-plus product. Formally, the min-plus product of matrices $A \in \mathbb{R}^{I \times J}$ and $B \in \mathbb{R}^{J \times K}$ is a matrix $C \in \mathbb{R}^{I \times K}$ such that $C[i,k] = \min_{j \in J} A[i,j] + B[j,k]$ for $(i,k) \in I \times K$.

For each free block $F[p_F \,..\, q_F) = R^e \in \mathbf{F}$, we construct the matrix M_R^e in $\mathcal{O}(k^3 \log n)$ time using Algorithm 1 followed by fast exponentiation, which reduces to computing $\mathcal{O}(\log e)$ min-plus products. We apply the matrix whenever we are tasked with filling a $\mathsf{dp}[l_F, r_F, l_G, r_G]$ entry such that $F[p_F \,..\, q_F)$ is a prefix or a suffix of $F[l_F \,..\, r_F)$. Formally, if $l_F \le p_F < q_F = r_F$, then we use the following formula instead of following Algorithm 1:

$$\mathsf{dp}[l_F, r_F, l_G, r_G] \leftarrow \min_{p'_G \in [p_F - |R| \,..\, p_F + |R|]} \mathsf{dp}[l_F, p_F, l_G, p'_G] + M_R^e[p'_G - p_G, r_G - q_G]. \tag{1}$$

In the symmetric case of $l_F = p_F < q_F \le r_F$, we apply

$$\mathsf{dp}[l_F, r_F, l_G, r_G] \leftarrow \min_{q'_G \in [q_F - |R| \,..\, q_F + |R|]} \mathsf{dp}[q_F, r_F, q'_G, r_G] + M_R^e[l_G - p_G, q'_G - q_G]. \tag{2}$$

In the full version [27], we formalize the intuition above to prove that Equations (1) and (2) preserve the invariant of Lemma 3.3, that is,

$$\mathsf{ted}^w(F[l_F \,..\, r_F), G[l_G \,..\, r_G)) \le \mathsf{dp}[l_F, r_F, l_G, r_G] \le \mathsf{bted}_k^w(F[l_F \,..\, r_F), G[l_G \,..\, r_G)).$$

For (1), this boils down to the following lemma; the case of (2) is symmetric.

▶ **Lemma 4.4.** *Consider fragments $F[l_F \,..\, r_F)$, $G[l_G \,..\, r_G)$ of forests $F, G \in \mathcal{F}_\Sigma$, a normalized weight function $w : \bar{\Sigma}^2 \to \mathbb{R}_{\ge 0}$, and a threshold $k \in \mathbb{Z}_+$ such that $|r_F - r_G| \le 2k$. If there is a free pair $F[p_F \,..\, q_F) = G[p_G \,..\, q_G) = R^e$ such that $F[p_F \,..\, q_F)$ is a suffix of $F[l_F \,..\, r_F)$, then*

$$\begin{aligned} &\mathsf{bted}_k^w(F[l_F \,..\, r_F), G[l_G \,..\, r_G)) \\ &\quad \ge \min_{p'_G \in [p_F - |R| \,..\, p_F + |R|]} \mathsf{bted}_k^w(F[l_F \,..\, p_F), G[l_G \,..\, p'_G)) + M_R^e[p'_G - p_G, r_G - q_G] \\ &\quad \ge \min_{p'_G \in [p_F - |R| \,..\, p_F + |R|]} \mathsf{ted}^w(F[l_F \,..\, p_F), G[l_G \,..\, p'_G)) + M_R^e[p'_G - p_G, r_G - q_G] \\ &\quad \ge \mathsf{ted}^w(F[l_F \,..\, r_F), G[l_G \,..\, r_G)). \end{aligned}$$

We further argue in the full version [27] that the recursive implementation of Algorithm 1 augmented with the optimizations of (1) and (2) visits $\mathcal{O}(m \log n)$ fragments $F[l_F \,..\, r_F)$, where m is the number of non-free characters, including $\mathcal{O}(t \log n)$ fragments $F[l_F \,..\, r_F)$ for which (1) or (2) apply. Specifically, our optimized algorithm visits fragments $F[l_F \,..\, r_F)$ visited by the original Algorithm 1 and satisfying the following additional property: every free block $F[p_F \,..\, q_F) \in \mathbf{F}$ is either disjoint with $F[l_F \,..\, r_F)$ or contained in $F[l_F \,..\, r_F)$. Our implementation takes $\mathcal{O}(n \log n)$ extra preprocessing time to list fragments visited by Algorithm 1 and filter those satisfying the aforementioned property.

5 Universal Kernel with Improved Repetitiveness Guarantees

In this section, we outline our approach to strengthen Theorem 1.3 into the following result:

▶ **Theorem 5.1.** *There exists a linear-time algorithm that, given forests F, G and an integer $k \in \mathbb{Z}_+$, constructs forests F', G' of size $\mathcal{O}(k^5)$ such that $\mathsf{ted}^w_{\le k}(F', G') = \mathsf{ted}^w_{\le k}(F, G)$ holds for every normalized* quasimetric *w (weight function satisfying the triangle inequality), and a collection of $\mathcal{O}(k^3)$ disjoint free blocks in F' with $\mathcal{O}(k^4)$ non-free characters.*

Compared to Theorem 1.3, we require the presence of $\mathcal{O}(k^3)$ free blocks that jointly capture all but $\mathcal{O}(k^4)$ characters of the output forest F'; consult Definition 4.1. At the very high level, the proofs of both Theorems 1.3 and 5.1 consist in three steps: decomposing the input forests F and G into several pieces, identifying pieces that can be matched exactly, and replacing (pairs of) identical pieces with smaller equivalent counterparts.

Forest Decompositions and Piece Matchings. Following [14], we say that a *piece* of a forest F is a *subforest* – a balanced fragment $F[i\,..\,j)$ – or a *context* – a pair of fragments $\langle F[i\,..\,i'); F[j'\,..\,j)\rangle$ such that $F[i\,..\,j)$ is a tree and $F[i'\,..\,j')$ is balanced. We denote the set of pieces contained in a fragment $F[i\,..\,j)$ of F by $\mathcal{P}(F[i\,..\,j))$; we set $\mathcal{P}(F) = \mathcal{P}(F[0\,..\,|F|))$.

In isolation from F, a context can be interpreted as a pair of non-empty strings $C = \langle C_L; C_R\rangle \in \mathsf{P}^+_\Sigma \times \mathsf{P}^+_\Sigma$ such that $C_L \cdot C_R$ is a tree. The *composition* of contexts C, D results in a context $C \star D := \langle C_L \cdot D_L; D_R \cdot C_R\rangle$. Moreover, the composition of a context C and a forest H results in a tree $C \star H := C_L \cdot H \cdot C_R$. For any *decomposition* of a forest F into disjoint pieces, one can recover F using the concatenation and composition operations.

We define the *depth* of a context $C = \langle C_L; C_R\rangle$ to be the number nodes of $C_L \cdot C_R$ with the opening parenthesis in C_L and the closing parenthsis in C_R. Note that the depth of the context $C \star D$ is equal to the sum of the depths of C and D.

The following notion formalizes the concept of a matching between pieces of F and G.

▶ **Definition 5.2.** *For two forests F and G and a fixed threshold $k \in \mathbb{Z}_+$, a* piece matching *between F and G is a set of pairs $\mathcal{M} \subseteq \mathcal{P}(F) \times \mathcal{P}(G)$ such that:*

- *across all pairs $(f, g) \in \mathcal{M}$, the pieces $f \in \mathcal{P}(F)$ are pairwise disjoint, and*
- *there exists a forest alignment $\mathcal{A} \in \mathbf{FA}(F, G)$ of width at most $2k$ (i.e., $\mathcal{A} \in \mathbf{BFA}_k(F, G)$) that matches f to g perfectly for every $(f, g) \in \mathcal{M}$.*

The kernelization algorithm behind Theorem 1.3 repeatedly identifies a piece matching $\mathcal{M}$ of size $|\mathcal{M}| = \mathcal{O}(k)$ covering $\Omega(n)$ vertices of F and replaces each pair of matching pieces $(f, g) \in \mathcal{M}$ with a pair of "equivalent" pieces (f', g') of size $\mathcal{O}(k^4)$. After $\mathcal{O}(\log n)$ steps, this yields forests of size $\mathcal{O}(k^5)$. Our strategy relies on the following new result:

▶ **Theorem 5.3.** *There exists a linear-time algorithm that, given forests $F, G \in \mathcal{F}_\Sigma$ and a threshold $k \in \mathbb{Z}_{\ge 0}$, either certifies that $\mathsf{ted}(F, G) > k$ or constructs a size-$\mathcal{O}(k)$ piece matching $\mathcal{M}$ between F and G that leaves $\mathcal{O}(k^4)$ unmatched characters.*

The proof of Theorem 5.3, presented in the full version [27], reuses a subroutine of [14] to construct a decomposition $\mathcal{D} \subseteq \mathcal{P}(F)$ of F into $\mathcal{O}(n/k^3)$ pieces of size $\mathcal{O}(k^3)$ each. The next step is to build a piece matching $\mathcal{M} \subseteq \mathcal{D} \times \mathcal{P}(G)$ that leaves at most k pieces of $\mathcal{D}$ unmatched. We modify a dynamic-programming procedure from [14] so that, additionally, the unmatched characters of G form $\mathcal{O}(k)$ fragments. As a result, even though the obtained matching is of size $|\mathcal{M}| = \mathcal{O}(n/k^3)$, it is possible to reduce its size to $\mathcal{O}(k)$. For this, it suffices to repeatedly identify pairs of adjacent pieces $f, f' \in \mathcal{P}(F)$ matched to adjacent

pieces $g, g' \in \mathcal{P}(G)$, and then replace these pieces with their unions $f \cup f'$ and $g \cup g'$ (as formalized in the full version [27], two disjoint pieces are adjacent if their union, consisting of the characters contained in at least one of these pieces, can be interpreted as a piece).

Periodic Blocks and Red Characters. The main ingredient of our kernelization algorithm is a procedure that replaces a pair of matching pieces $(f, g) \in \mathcal{M}$ with a pair of "equivalent" smaller pieces (f', g'). Unlike [14], where the goal was to reduce the piece size to $\mathcal{O}(k^4)$, we aim to identify $\mathcal{O}(k^2)$ disjoint free blocks with $\mathcal{O}(k^3)$ non-free nodes within the replacement piece f'. Unfortunately, free blocks lack a canonical construction, and it would be tedious to maintain a specific selection while the forests change. Instead, we use the following notions:

▶ **Definition 5.4.** *For a fixed threshold $k \in \mathbb{Z}_+$, we say that a string $S \in \mathsf{P}^*_\Sigma$ forms a* periodic block *if it satisfies the following properties:*

- *$|S| \geq 42k$, that is, the fragment is of length at least $42k$, and*
- *S has a string period of length at most $4k$ with equally many opening and closing parentheses.*

For a string $T \in \mathsf{P}^*_\Sigma$, we denote by $\mathbf{B}_k(T)$ the set of fragments of T that are periodic blocks. For a context $C = \langle C_L; C_R \rangle$, we denote by $\mathbf{B}_k(C)$ the disjoint union of $\mathbf{B}_k(C_L)$ and $\mathbf{B}_k(C_R)$.

We partition the characters of $T \in \mathsf{P}^*_\Sigma$ into *black* and *red* based on the family $\mathbf{B}_k(T)$.

▶ **Definition 5.5.** *A character $T[i]$ of a string $T \in \mathsf{P}^*_\Sigma$ is* black *if there exists a periodic block $T[l\,..\,r) \in \mathbf{B}_k(T)$ such that $i \in [l + 5k\,..\,r - 5k)$. The remaining characters are* red*. We denote by $\mathsf{black}_k(T)$ and $\mathsf{red}_k(T)$ the sets of black and red characters of T.*

For a context $C = \langle C_L; C_R \rangle$, the sets $\mathsf{black}_k(C) = \mathsf{black}_k(C_L) \sqcup \mathsf{black}_k(C_R)$ and $\mathsf{red}_k(C) = \mathsf{red}_k(C_L) \sqcup \mathsf{red}_k(C_R)$ are defined as disjoint unions.

Piece Reduction. The following definitions in [14] formalize the concept of equivalent pieces.

▶ **Definition 5.6** ([14, Definition 3.4])**.** *For a threshold $k \in \mathbb{Z}_{\geq 0}$ and a weight function w, forests P, P' are called* $\mathsf{ted}^w_{\leq k}$-equivalent *if*

$$\mathsf{ted}^w_{\leq k}(F, G) = \mathsf{ted}^w_{\leq k}(F[0\,..\,l_F) \cdot P' \cdot F[r_F\,..\,|F|), G[0\,..\,l_G) \cdot P' \cdot G[r_G\,..\,|G|))$$

holds for all forests F and G with matching pieces $F[l_F\,..\,r_F) = P = G[l_G\,..\,r_G)$ satisfying $|l_F - r_G| \leq 2k$.

▶ **Definition 5.7** ([14, Definition 3.9])**.** *For a threshold $k \in \mathbb{Z}_{\geq 0}$ and a weight function w, contexts $P = \langle P_L; P_R \rangle$ and $P' = \langle P'_L; P'_R \rangle$ are called* $\mathsf{ted}^w_{\leq k}$-equivalent *if*

$$\mathsf{ted}^w_{\leq k}(F, G) = \mathsf{ted}^w_{\leq k}(F[0\,..\,l_F) \cdot P'_L \cdot F[l'_F\,..\,r'_F) \cdot P'_R \cdot F[r_F\,..\,|F|), \\ G[0\,..\,l_G) \cdot P'_L \cdot G[l'_G\,..\,r'_G) \cdot P'_R \cdot G[r_G\,..\,|G|))$$

holds for all forests F and G with matching pieces $\langle F[l_F\,..\,l'_F); F[r'_F\,..\,r_F)\rangle = P = \langle G[l_G\,..\,l'_G); G[r'_G\,..\,r_G)\rangle$ satisfying $|l_F - l_G| \leq 2k$ and $|r_F - r_G| \leq 2k$.

In the full version [27], we slightly modify the arguments of [14] to prove the following results:

▶ **Lemma 5.8** (see [14, Lemma 3.17])**.** *There is a linear-time algorithm that, given a forest P and a threshold $k \in \mathbb{Z}_+$, computes a forest P' with $|P'| \leq |P|$ and $|\mathsf{red}_k(P')| \leq 158k^2$ such that P and P' are $\mathsf{ted}^w_{\leq k}$-equivalent for every normalized quasimetric weight function w.*

▶ **Lemma 5.9** (see [14, Lemma 3.18])**.** *There is a linear-time algorithm that, given a context P and a threshold $k \in \mathbb{Z}_+$, computes a context P' with $|P'| \leq |P|$ and $|\mathsf{red}_k(P')| \leq 1152k^3$ such that P and P' are $\mathsf{ted}^w_{\leq k}$-equivalent for every normalized quasimetric weight function w.*

Complete Kernelization Algorithm. In the full version [27], we combine the above ingredients to formally prove Theorem 5.1. Our procedure first applies Theorem 5.3. Then, for every pair of matched pieces $(f, g) \in \mathcal{M}$, we use Lemma 5.8 or 5.9 (depending on piece type) to obtain an equivalent piece P' with $\mathcal{O}(k^3)$ red characters. The remaining (black) characters in P' can be traced back to $\mathcal{O}(k^2)$ periodic blocks and each periodic block within P' yields a free block in the output forest F' that covers the underlying black characters.

6 Summary

▶ **Theorem 1.1.** *There exists a deterministic algorithm that, given two forests F and G with n nodes in total, each with a label from an alphabet Σ, and oracle access to a normalized weight function $w : (\Sigma \cup \{\varepsilon\})^2 \to \mathbb{R}_{\geq 0}$ satisfying the triangle inequality, determines the tree edit distance $k := \mathsf{ted}^w(F, G)$ in $\mathcal{O}(n + k^6 \log k)$ time.*

Proof. First, suppose that the task is to compute $\mathsf{ted}^w_{\leq k}(F, G)$ for a given threshold k. In this case, we use the algorithm of Theorem 5.1, resulting in a pair of forests F', G' of size $\mathcal{O}(k^5)$ such that $\mathsf{ted}^w_{\leq k}(F', G') = \mathsf{ted}^w_{\leq k}(F, G)$, as well as a collection of $\mathcal{O}(k^3)$ free blocks in F' with $\mathcal{O}(k^4)$ non-free characters. Based on this, the algorithm of Theorem 4.2 computes $\mathsf{ted}^w_{\leq k}(F', G') = \mathsf{ted}^w_{\leq k}(F, G)$ in $\mathcal{O}(k^5 \cdot \log k^5 + k^4 \cdot k^2 \log k^5 + k^3 \cdot k^3 \log k^5) = \mathcal{O}(k^6 \log k)$ time. Including the $\mathcal{O}(n)$ running time of Theorem 5.1, we get $\mathcal{O}(n + k^6 \log k)$ total time.

In the absence of a given threshold, we consider a geometric sequence of thresholds $(d_i)_{i \in \mathbb{Z}_{\geq 0}}$, with $d_i = 2^i \cdot \lceil (n/\log n)^{1/6} \rceil$, and we compute $\mathsf{ted}^w_{\leq d_i}(F, G)$ for subsequent $i \in \mathbb{Z}_{\geq 0}$ until $\mathsf{ted}^w_{\leq d_j}(F, G) \leq d_j$ holds for some $j \in \mathbb{Z}_{\geq 0}$, which indicates $\mathsf{ted}^w(F, G) = \mathsf{ted}^w_{\leq d_j}(F, G)$.

Since $d_0 = \mathcal{O}((n/\log n)^{1/6})$, the initial iteration costs $\mathcal{O}(n + d_0^6 \log d_0) = \mathcal{O}(n)$ time. Consequently, if $k \leq d_0$, then the whole algorithm runs in $\mathcal{O}(n)$ time.

Due to $d_i \geq d_0 \geq (n/\log n)^{1/6}$, the running time of the ith iteration iteration is $\mathcal{O}(d_i^6 \log d_i)$. This sequence grows geometrically, so the total running time of the algorithm is dominated by the running time of the last iteration, which is $\mathcal{O}(d_j^6 \log d_j)$. If $k > d_0$, then $j > 0$ and, since the algorithm has not terminated one iteration earlier, $d_j = 2d_{j-1} < 2k$. Consequently, the overall running time is $\mathcal{O}(k^6 \log k)$ when $k > d_0$. ◀

The Planted Orthogonal Vectors Problem

Abstract

In the k-Orthogonal Vectors (k-OV) problem we are given k sets, each containing n binary vectors of dimension $d = n^{o(1)}$, and our goal is to pick one vector from each set so that at each coordinate at least one vector has a zero. It is a central problem in fine-grained complexity, conjectured to require $n^{k-o(1)}$ time in the worst case.

We propose a way to *plant* a solution among vectors with i.i.d. p-biased entries, for appropriately chosen p, so that the planted solution is the unique one. Our conjecture is that the resulting k-OV instances still require time $n^{k-o(1)}$ to solve, *on average*.

Our planted distribution has the property that any subset of strictly less than k vectors has the *same* marginal distribution as in the model distribution, consisting of i.i.d. p-biased random vectors. We use this property to give average-case search-to-decision reductions for k-OV.

1 Introduction

The security of cryptographic systems crucially relies on heuristic assumptions about average-case hardness of certain computational problems. Sustained cryptanalysis alongside technological advances such as large-scale quantum computers, put these hardness assumptions under constant risk of being invalidated. It is therefore desirable to try to design cryptographic schemes based on new computational problems, preferably ones whose hardness is well-studied.

The field of computational complexity developed over the last fifty years a good understanding of the hardness of certain problems – e.g., SAT is widely believed to require at least superpolynomial, maybe even exponential time [28] – however these are worst-case problems, and hence unsuitable for direct use as a basis for cryptography.

Fine-grained complexity [27] is a younger branch of computational complexity that studies "hardness of easy problems", i.e., problems known to be solvable in polynomial time but supposedly not faster than some specified polynomial, say not faster than in cubic time. It gives rise to *fine-grained cryptography* [6, 23, 25], the idea that it might be possible to build

cryptography, notably public-key encryption, based on conjectured average-case hardness of polynomial-time problems studied in fine-grained complexity. These problems are easier than NP-hard ones, but for polynomials of sufficiently high degree may still be hard enough to give honest parties an adequate advantage over malicious attackers.

1.1 The k-Orthogonal Vectors Problem

The Orthogonal Vectors (OV) problem [29], together with its generalization k-OV, is one of the three main hard problems studied in fine-grained complexity, alongside 3SUM and APSP [27]. Arguably, among the three, OV is the one whose (worst-case) hardness we understand the most – in particular because it is implied by the Strong Exponential Time Hypothesis (SETH) [16], which is about the very well studied SAT problem.

We say that vectors $u_1, ..., u_k \in \{0,1\}^d$ are *orthogonal* if, for all $j \in [d]$, $\prod_{\ell=1}^{k} u_\ell[j] = 0$, meaning that for every coordinate there is at least one zero entry among the k vectors. For $k \geq 2$, let $U_1, ..., U_k$ each be a collection of n d-dimensional binary vectors, which we view as matrices in $\{0,1\}^{n \times d}$. We denote by $U_{\ell,i}$ the i-th vector of U_ℓ. The k-Orthogonal Vectors problem (k-OV) asks whether there exist $(s_1, \ldots, s_k) \in [n]^k$ such that $U_{1,s_1}, U_{2,s_2}, \ldots, U_{k,s_k}$ are orthogonal.

Worst-case complexity. The naive algorithm solves k-OV in time $O(n^k d)$. For any fixed constant c, the algorithms by Abboud et al. [1] and Chan and Williams [8] solve OV in dimension $d = c \log n$ in time $O(n^{2-\varepsilon_c})$ with $\varepsilon_c > 0$. However, Gao et al. [13] conjecture that no such strongly subquadratic algorithm exists for superlogarithmic dimension $d = \omega(\log n)$. This conjecture (known as Low-dimension Orthogonal Vector Conjecture) is also implied by SETH [29]. Both the upper bound for $d = O(\log n)$ and the SETH-implied hardness for $d = \omega(\log n)$ generalize to k-OV, for any constant $k \geq 2$, where the running time barrier is n^k [27].

Average-case complexity. For cryptographic purposes we care about *average-case* hardness – because we want to be able to efficiently sample instances that are hard to solve (in contrast to only having an existential knowledge that there are some hard instances). Moreover, the sampler shall correctly tell (with good probability) whether its output is a YES- or NO-instance.

One way to achieve this is to embed a solution in an instance sampled from a distribution that generates NO-instances with good probability. This method of *planting* a solution has been applied to a number of problems, e.g., k-Clique [18] and (in the fine-grained setting) k-SUM [12, 2] (a generalization of 3SUM) and Zero-k-Clique [23] (a generalization of Zero-Triangle, which is a problem harder than both 3SUM and APSP), but not for (k-)OV. The following question remains wide-open [6, 11, 10]:

How to plant orthogonal vectors (so that they are hard to find)?

1.2 Our results

We propose a way of planting a solution in k-OV instances where each vector entry is i.i.d. according to a p-biased[1] coin flip, for an appropriately chosen value of p so that the planted solution is the only one in the instance, with good probability. We conjecture that solving these instances requires $n^{k-o(1)}$ time on average.

[1] We say that a random bit is p-biased if it equals 1 with probability p and equals 0 with probability $1-p$.

Let us remark that all our results are already nontrivial for $k = 2$, i.e., for the Orthogonal Vectors problem. However, from the point of view of cryptographic applications, larger values of k are more interesting (as they potentially offer a bigger advantage for the honest parties), so we present all our results in full generality.

Superlogarithmic dimension. The k-OV problem might have appeared as a poor candidate for a fine-grained average-case hard problem, as Kane and Williams [19] showed that for any fixed $p \in (0, 1)$, k-OV instances of i.i.d. p-biased entries can be solved in $O(n^{k-\varepsilon_p})$ time for some $\varepsilon_p > 0$ by AC0 circuits. However, such instances are only nontrivial for $d = \Theta(\log n)$,[2] a parameter setting which can be anyway solved in time $O(n^{k-\varepsilon})$, even in the worst case, using the algorithm of Chan and Williams [8]. To obtain a candidate hard distribution based on i.i.d. entries, we therefore choose to sample the entries as 1 with subconstant probability $p(n) = o(1)$, which leads to nontrivial instances in the superlogarithmic dimension regime $d = \omega(\log n)$. In the full version of the paper we present another simple argument why a logarithmic dimension is not sufficient, further justifying our choice.

The $(k-1)$-wise independence. Our planting procedure has the following notable property: any subset of $k - 1$ (or less) out of the k vectors that form the planted solution has the marginal distribution identical to that of $k - 1$ independently sampled vectors with i.i.d. p-biased random entries. In particular, each individual vector of the solution has the same marginal distribution as any other vector in the instance. This would not be true if we planted k random vectors conditioned on orthogonality (i.e., a type of solution that may appear spontaneously with small probability), because such vectors tend to be sparser than the expectation. This sparsity is what makes the Kane–Williams algorithm [19] work, and lack thereof makes our instances immune to that algorithmic idea.[3]

We note that the $(k - 1)$-wise independence property holds "for free" in natural distributions for k-SUM [2, 12] and Zero-k-Clique [23] because of the natural symmetry of cyclic groups $\mathbb{Z}_m$. However, it is a priori unclear how to get it for k-OV.

Finally, in Theorem 7, we argue that our distribution is *the unique* distribution over k-OV instances that has this property, explaining the title of this paper.

Search-to-decision reductions. To demonstrate the usefulness of the $(k - 1)$-wise independence property, we give a fine-grained average-case search-to-decision reduction for our conjectured hard k-OV distribution. Actually, we give two such reductions. The first one, in Section 6, is very simple, but it introduces an $O(\log n)$ overhead in the failure probability, so it is relevant only if the decision algorithm succeeds with probability higher than $1 - \frac{1}{\log n}$. The other reduction, in Section 7, looses only a constant factor in the failure probability. Even though we present both reductions specifically for k-OV, they are likely to generalize to any planted problem with the $(k - 1)$-wise independence property.

Planting multiple solutions. In the full version of the paper, we also argue that $(k-1)$-wise independence allow planting more than one solution in a single instance, which we believe might be useful for building cryptographic primitives.

[2] For larger (resp. smaller) d, almost all instances will be NO-instances (resp. YES-instances).

[3] Note though that the Kane–Williams algorithm does not run in truly subquadratic time in superlogarithmic dimension anyway, so above all it is the high dimension, not the $(k - 1)$-wise independence, that makes our distribution immune to all known attacks.

1.3 Technical overview

Planting. How do we generate k orthogonal vectors such that any $k-1$ of them look innocent? First of all, we can focus on generating a single coordinate, and then repeat the process independently for each of the d coordinates. Consider the joint distribution of k i.i.d. p-biased random bits. We need to modify it to set the probability of k ones to 0. If we just do it, and scale up the remaining probabilities accordingly, the probability of $k-1$ ones turns out wrong. After we fix that, the probability of $k-2$ ones is off, and so on, in a manner similar to the inclusion-exclusion principle. By doing this mental exercise we end up with a formula for the joint distribution of k bits in a single coordinate of the k vectors to be planted. How do we actually sample from this distribution? Since it has the $(k-1)$-wise independence property, the following approach must work: First sample $k-1$ i.i.d. p-biased bits, and then sample the k-th bit with probability depending on the number of ones among the first $k-1$ bits. In Section 3 we show how to set this last probability exactly.

Search-to-decision reductions. Both our reductions are based on the same basic idea: In order to find the planted solution, we replace some of the vectors in the input instance with newly sampled vectors with i.i.d. p-biased entries and run the decision algorithm on such a modified instance. If at least one of the planted vectors got resampled, the resulting instance has the same distribution as if no planting occurred (thanks to the $(k-1)$-wise independence), and so the decision algorithm returns NO with good probability. Otherwise the planted solution is still there and the decision algorithm likely says YES.

Our first reduction (see Section 6) applies this idea to perform a binary search. It introduces a factor of $k \log n$ overhead in the running time and also in the failure probability, because we need to take a union bound over all invocations of the decision algorithm returning correct answers.

Our second reduction (see Section 7) is an adaptation of a search-to-decision reduction for k-SUM due to Agrawal et al. [2]. In short, the reduction repeatedly resamples a random subset of vectors, runs the decision algorithm, and keeps track for each of the original vectors, how many times the decision algorithm returned YES when this vector was not resampled. Statistically, this count should be larger for vectors in the planted solution. A careful probabilistic analysis shows that this is indeed the case.

1.4 Open problems

Hardness self-amplification. Could a black-box method increase the success probability of algorithms solving (the search or decision variants of) the planted k-OV problem, at a small cost in the running time? If so, the lack of algorithms with high success probability for planted k-OV would then suggest that no algorithm can solve the problem even with just a small success probability – a property desirable, e.g., from the point of view of potential cryptographic applications.

Such hardness self-amplification was recently shown for (both the search and decision variants of) the planted clique problem by Hirahara and Shimizu [15]. In the world of fine-grained complexity, Agrawal et al. [2] showed hardness self-amplification for the planted k-SUM search problem and closely related problems. Hardness self-amplification for planted k-OV remains an open problem.

Because of the overhead in the failure probability induced by both of our search-to-decision reductions, hardness self-amplification for the decision variant of the planted k-OV problem in particular would mean that the hardness of the search problem could be based on a weak conjecture about the hardness of the decision problem, such as Conjecture 10.

Fine-grained asymmetric cryptography. A key goal of fine-grained cryptography is to devise an advanced asymmetric cryptography scheme – such as public key encryption – whose security is based on hardness of a well understood problem from fine-grained complexity. So far the closest to this goal seems to be the key exchange protocol due to LaVigne, Lincoln, and Vassilevska Williams [23], which is based on hardness of the planted Zero-k-Clique problem. Despite being based on a parameterized problem (that allows for arbitrary polynomial $n^{k-o(1)}$-hardness by simply choosing a large enough k), the protocol offers only quadratic security, i.e., breaking the encryption takes only quadratically more than it takes to encrypt and decrypt a message. This limitation seems inherent to the protocol because it is based on a similar idea as Merkle puzzles [24].

It is an open problem if fine-grained cryptography with superquadratic security is possible. We believe that k-OV could be a good hard problem for that purpose, because of a different structure, which addition-based problems, like k-SUM and Zero-k-Clique, are lacking.

We remark that the key exchange protocol of LaVigne, Lincoln, and Vassilevska Williams [23] can be adapted to work with our planted k-OV instead of the planted Zero-k-Clique problem, but naturally the protocol's security remains quadratic. One needs new techniques to break the quadratic barrier.

In recent work, Alman, Huang, and Yeo [5] show that if one-way functions do not exist then average-case hardness fine-grained assumptions on planted k-SUM and Zero-k-Clique are false for sufficiently large constant k. It might be possible to generalize their results to k-OV. However, a construction of public-key encryption from planted k-OV would be interesting even in a world where one-way functions do exist, as they are not known to imply superquadratic-gap public-key encryption [17].

Faster algorithms for average-case OV. Algorithms for random OV instances seem to be underexplored. Up until recently [4] it was not known if the average-case OV admits even a subpolynomial improvement compared to the worst case. With this paper we hope to inspire more research in this direction. We would even be happy to see our conjecture refuted.

A natural starting point for such an attack is the recent Alman–Andoni–Zhang algorithm [4] for random OV. It works in time $n^{2-\Omega(\log\log c/\log c)}$ for dimension $d = c\log n$, so it is not truly subquadratic for $d = \omega(\log n)$. However, in their setting, the hardest case is when the probability p of a one entry is chosen to make the *expected number of orthogonal pairs* a constant, while in our setting we use a higher value of p to lower the expectation to inverse polynomial – which means that in our setting the orthogonal pair "stands out more". It might seem plausible to adjust internal parameters of the algorithm (in particular, the so-called *group size*) to better exploit our setting. However, under closer inspection, it turns out that the key quantity in the analysis of the algorithm is the *expected inner product* of two random vectors, equal to $p^2 d$, which happens to be $\Theta(\log n)$ in both settings. Refuting our conjecture likely requires a new technical development beyond such an adjustment.

Finally, let us point out a related problem: the planted approximate maximum inner product problem, often referred to as the *light bulb* problem. Unlike planted OV, it is known to admit truly subquadratic $O(n^{1.582})$-time algorithms [26, 20, 21, 3]. This is in contrast with the worst-case complexities of the two problems, which are known to be equivalent under fine-grained reductions [9, 22].

A worst-case to average-case reduction. In the opposite direction than the previous open problem, one could try to show that our conjectured hardness of the planted k-OV problem is implied by one of well-studied worst-case hypotheses in fine-grained complexity, e.g., SETH.

This would require a worst-case to average-case reduction. So far, in fine-grained complexity, such reductions are only known for algebraic or counting problems [6, 14, 7, 11, 10], but not for decision nor search problems like ours.

2 The model distribution

Fix $k \geq 2$, and let $d = \alpha(n) \log n$ for $\alpha(n) = \omega(1)$. We define the family of *model distributions* $k{-}\mathrm{OV}_0^\alpha(n)$ that generate k matrices $U_1, ..., U_k \in \{0,1\}^{n \times d}$ where all entries are i.i.d. p-biased bits with probability

$$p = \left(1 - 2^{-\frac{2k}{\alpha(n)}}\right)^{\frac{1}{k}} \approx \left(\frac{2k\ln(2)}{\alpha(n)}\right)^{\frac{1}{k}}.$$

As will become apparent later, for the planting algorithm to work it is crucial that $p \leq 1/2$, but thanks to $\alpha(n) = \omega(1)$ this holds for large enough n.

We show that the model distribution indeed generates NO-solutions with good probability.

▶ **Lemma 1.** *A k-OV instance sampled from the model distribution $k{-}\mathrm{OV}_0^\alpha(n)$ is a NO-instance with probability at least $1 - \frac{1}{n^k}$.*

Proof. For a k-OV instance $\mathbf{U} = (U_1, \ldots, U_k) \sim k{-}\mathrm{OV}_0^\alpha(n)$, a fixed combination of vectors $u_1, \ldots, u_k$ (where $u_\ell \in U_\ell$) is orthogonal iff, for each coordinate $j \in [d]$, not all of the k vectors feature a one in that coordinate. Since k i.i.d. p-biased bits are all ones with probability p^k, the probability that $u_1, \ldots, u_k$ are orthogonal (determined by the all-ones event not occurring in any of the d coordinates) is:

$$\Pr[u_1, ..., u_k \text{ are orthogonal}] = \left(1 - p^k\right)^d = \left(2^{-\frac{2k}{\alpha(n)}}\right)^{\alpha(n)\log(n)} = n^{-2k}.$$

By linearity of expectation, the expected value for the number of solutions among all n^k possible combinations of k vectors, denoted by $c(\mathbf{U})$, is

$$\mathbb{E}[c(\mathbf{U})] = \sum_{\substack{u_i \in U_i \\ (1 \leq i \leq k)}} \Pr[u_1, \ldots, u_k \text{ are orthogonal}] = n^k \cdot n^{-2k} = \frac{1}{n^k}.$$

By Markov's inequality, this is also a bound on the probability of *any* solution occurring, i.e., $\Pr[c(\mathbf{U}) \geq 1] \leq \mathbb{E}[c(\mathbf{U})] = \frac{1}{n^k}$. Therefore, an instance sampled from $k{-}\mathrm{OV}_0^\alpha(n)$ is a NO-instance with probability at least $1 - \frac{1}{n^k}$. ◀

We remark that one can make the probability of sampling a NO-instance arbitrarily high. Indeed, in order to get the probability $1 - \frac{1}{n^c}$ it suffices to replace $2k$ with $k + c$ in the formula for the probability parameter p. However, having in mind the cryptographic motivation, $\frac{1}{n^k}$ seems to be a reasonable default choice for the failure probability of the sampler, because with the same probability the attacker can just guess the solution.

3 The planted distribution

To plant a solution at locations $s_1, \ldots, s_k \in [n]$ in an instance $\mathbf{U}$ sampled from $k{-}\mathrm{OV}_0^\alpha(n)$, we apply the following randomized algorithm.

Plant$(\mathbf{U}, s_1, \ldots, s_k)$.

1. For each coordinate $1 \leq j \leq d$:
   a. Let m be the number of ones among $U_{1,s_1}[j], \ldots, U_{k,s_k}[j]$.
   b. If $k - m$ is even, flip $U_{k,s_k}[j]$ with probability $\left(\frac{p}{1-p}\right)^{k-m}$. (Here we need $p \leq 1/2$.)
2. Return $\mathbf{U}$.

We justify this way of planting in Section 4. For now, observe that if all vectors $U_{1,s_1}, \ldots, U_{k,s_k}$ feature a one at coordinate j, we have $m = k$ and Plant flips the final bit $U_{k,s_k}[j]$ to a zero with probability

$$\left(\frac{p}{1-p}\right)^{k-m} = \left(\frac{p}{1-p}\right)^{0} = 1.$$

On the other hand, if the last coordinate is the single zero alongside $m = k - 1$ ones, then $k - m = 1$ is odd and Plant will never break orthogonality by flipping the last bit to a one. Thus, Plant$(\mathbf{U}, s_1, \ldots, s_k)$ outputs a YES-instance of k-OV with a solution at $s_1, \ldots, s_k$. We call the k vectors at these positions the *planted vectors*.

We sample YES-instances of k-OV by planting a solution in an instance $\mathbf{U} \sim k\text{−OV}_0^\alpha(n)$ at locations $s_1, \ldots, s_k$ chosen uniformly at random.

Distribution $k\text{−OV}_1^\alpha(n)$.

1. Sample $\mathbf{U}$ from $k\text{−OV}_0^\alpha(n)$.
2. Sample $(s_1, \ldots, s_k)$ uniformly at random from $[n]^k$.
3. Return Plant$(\mathbf{U}, s_1, \ldots, s_k)$.

The above observation about Plant immediately yields the following.

▶ **Lemma 2.** *A k-OV instance sampled from the planted distribution $k\text{−OV}_1^\alpha(n)$ is a YES-instance with probability* 1.

4 The $(k-1)$-wise independence of planted vectors

Our method of planting orthogonal vectors arises from the idea that for any planted problem, any proper "piece" of the planted solution should be indistinguishable from any comparable piece of the instance as a whole, conditioned on the latter still being consistent with being a part of a solution itself.

For example, in the case of planting a k-clique in a graph G this requirement is trivial. Indeed, the projection of the clique onto a smaller subset of $k' < k$ vertices yields a k'-clique, which are exactly those subgraphs of G of size k' which could feasibly belong to a solution.

In contrast to the previous example, in the case of k-SUM, any set of $k - 1$ elements $x_1, \ldots, x_{k-1}$ in an instance could feasibly be part of a solution, as one can always construct a k−th number x_k such that $\sum_{i=1}^{k} x_i = 0$. Thus, by the principle we described, to plant a solution in an instance with i.i.d. uniformly random elements, the marginal distribution of the distribution of planted solutions $(x_1, \ldots, x_k)$ given by any projection to $k - 1$ elements should itself be uniformly random. This holds true in the case of the planted k-SUM [2], where the planted solution is distributed uniformly over the set of all k-tuples that form valid k-SUM solutions. The case of planted Zero-k-Clique [23] is analogous. For both of these problems, planting by inserting k elements drawn from the model distribution conditioned on them forming a solution yields a distribution that follows the described principle.

This is different from the k-OV problem with a model distribution of i.i.d. vector entries. Here, as with k-SUM and Zero-k-Clique, any set of $k-1$ elements (in this case vectors) could form a solution to k-OV. All that is needed is for the last vector to feature a zero in all those coordinates where the other $k-1$ all were one. However, sparse vectors are far more likely to be part of a solutions than dense ones. Therefore, conditioning k i.i.d. p-biased vectors on being orthogonal yields a distribution which does not follow our principle: projecting onto any subset of $k' < k$ vectors results in vectors that are on average sparser than (and thus different from) k' i.i.d. p-biased vectors. As we will show now, our method of planting *does* satisfy this principle: Any subset of $k-1$ planted vectors are independent and identically distributed p-biased vectors.

Let $M \sim k\text{–}\mathrm{OV}_0^\alpha(n)$ and $\mathbf{U} = \mathsf{Plant}(M, s_1, \ldots, s_k)$. Recall that both sampling from the model distribution $k\text{–}\mathrm{OV}_0^\alpha(n)$ and the planting by Plant are independent and identical for each coordinate $j \in [d]$. Hence, all k-bit sequences $x = (U_{1,s_1}[j], U_{2,s_2}[j], \ldots, U_{k,s_k}[j]) \in \{0,1\}^k$, for all $j \in [d]$, are independent and identically distributed, according to a distribution whose probability density function we denote by $\mathcal{P}_k : \{0,1\}^k \to \mathbb{R}$.

▶ **Lemma 3.** *Let $x \in \{0,1\}^k$ and let m be the number of ones in x. Then*

$$\mathcal{P}_k(x) = p^m(1-p)^{k-m} - (-1)^{k-m}p^k.$$

Proof. Fix a coordinate $j \in [d]$. Let $X = (M_{1,s_1}[j], M_{2,s_2}[j], \ldots, M_{k,s_k}[j])$ be the random variable denoting the entries of the j-th coordinate among the vectors at locations $s_1, \ldots, s_k$ before planting. We proceed by case distinction.

Case 1. If $m-k$ is even, the probability of x occurring in the given coordinate $j \in [d]$ of the planted solution is given by

$$\begin{aligned}
\mathcal{P}_k(x) &= \Pr\left[X = x \text{ and } \mathsf{Plant} \text{ does not flip the final bit}\right] \\
&= p^m(1-p)^{k-m} \cdot \left(1 - \left(\frac{p}{1-p}\right)^{k-m}\right) \\
&= p^m(1-p)^{k-m} - 1 \cdot p^k \\
&= p^m(1-p)^{k-m} - (-1)^{k-m}p^k.
\end{aligned}$$

Case 2a. If $m-k$ is odd and $x = y1$ for some $y \in \{0,1\}^{k-1}$, then $x = y1$ may occur either directly in the model instance, or by $y0$ (for which $m-k$ is even) occurring in the model instance and Plant flipping the final bit:

$$\begin{aligned}
\mathcal{P}_k(x) &= \Pr\left[X = y1\right] + \Pr\left[X = y0 \text{ and } \mathsf{Plant} \text{ flips the final bit}\right] \\
&= p^m(1-p)^{k-m} + p^{m-1}(1-p)^{k-(m-1)} \cdot \left(\frac{p}{1-p}\right)^{k-(m-1)} \\
&= p^m(1-p)^{k-m} + p^k \\
&= p^m(1-p)^{k-m} - (-1)^{k-m}p^k.
\end{aligned}$$

Case 2b. Similarly, if $m-k$ is odd and $x = y0$ for some $y \in \{0,1\}^{k-1}$, then $x = y0$ can occur either directly in the model instance or by Plant flipping the final bit of the sequence $y1$:

$$\begin{aligned}\mathcal{P}_k(x) &= \Pr[X = y0] + \Pr[X = y1 \text{ and } \mathsf{Plant} \text{ flips the final bit}] \\ &= p^m(1-p)^{k-m} + p^{m+1}(1-p)^{k-(m+1)} \cdot \left(\frac{p}{1-p}\right)^{k-(m+1)} \\ &= p^m(1-p)^{k-m} + p^k \\ &= p^m(1-p)^{k-m} - (-1)^{m-k}p^k.\end{aligned}$$

◀

▶ Remark 4. Despite Plant acting only on the last collection U_k, Lemma 3 implies that the resulting distribution $k{-}\mathrm{OV}_1^\alpha(n)$ is invariant under permutation of the sequence of the k collections $U_1, \ldots, U_k$.

Having $\mathcal{P}_k$ as the distribution of planted vectors, rather than, e.g., the k-vector joint model distribution conditioned on orthogonality, ensures $(k-1)$-*wise independence* among the planted vectors. I.e., the projection of k planted vectors onto any subset of size $k' < k$ is identically distributed to k' vectors from the model distribution.

▶ **Lemma 5** ($(k-1)$-wise independence)**.** *Marginalizing any one of the k bits of $\mathcal{P}_k$ yields $k-1$ independent p-biased bits.*

Proof. By Remark 4 we may assume w.l.o.g. that the last bit is the one marginalized out. The lemma then follows from the definition of Plant, as the first $k-1$ entries of any coordinate in the planted vectors are unchanged from the model instance, and are therefore independent p-biased bits. ◀

This property is useful in bounding the probability of a planted instance containing a solution besides the planted one.

▶ **Lemma 6.** *A k-OV instance sampled from the planted distribution $k{-}\mathrm{OV}_1^\alpha(n)$ has more than one solution with probability less than $\frac{1}{n^k}$.*

Proof. While the k vectors at positions $s_1, \ldots, s_n$ are guaranteed to form a solution, by $(k-1)$-wise independence, *all* combinations of $0 \le k' < k$ of these vectors and $k-k'$ non-planted vectors form a set of k independent p-biased vectors which is therefore a solution to the k-OV problem with probability $(1-p^k)^d = \frac{1}{n^{2k}}$. By linearity of expectation,

$$\mathbb{E}[c(\mathbf{U})] = 1 + (1-p^k)^d \cdot (n^k - 1) < 1 + \frac{1}{n^k},$$

and the claim follows from Markov's inequality. ◀

4.1 Uniqueness

Our way of planting is unique in the following sense.

▶ **Theorem 7.** *Let $Q : \{0,1\}^k \to \mathbb{R}$ be a probability distribution such that $Q(1^k) = 0$ and that marginalizing any one of the k bits yields $k-1$ independent p-biased bits. Then $Q = \mathcal{P}_k$.*

Proof. We show that $Q(x) = \mathcal{P}_k(x)$ for all $x \in \{0,1\}^k$. Let m denote the number of ones in x. We proceed by induction over $k-m$, i.e., the number of *zeros* in x.

Base case: $k-m=0$. Then $m=k$ and $x=1^k$. Thus $Q(x) = Q(1^k) = 0 = \mathcal{P}_k(x)$.

Inductive case: $k - m > 0$. We assume w.l.o.g. that the $k - m$ zeros are the *last* bits of x, i.e., $x = 1^m 0^{k-m}$. Marginalizing the final $k - m > 0$ bits of Q yields $k - (k - m) = m$ independent p-biased bits, whereby the probability of all m remaining bits being ones is

$$p^m = \sum_{y \in \{0,1\}^{k-m}} Q(1^m y) = Q(\underbrace{1^m 0^{m-k}}_{=x}) + \sum_{\substack{y \in \{0,1\}^{k-m} \\ y \neq 0^{k-m}}} Q(1^m y).$$

Thereby,

$$\begin{aligned} Q(x) &= p^m - \sum_{\substack{y \in \{0,1\}^{k-m} \\ y \neq 0^{k-m}}} Q(1^m y) \\ &= p^m - \sum_{\substack{y \in \{0,1\}^{k-m} \\ y \neq 0^{k-m}}} \mathcal{P}_k(1^m y) && \text{(by the induction hypothesis)} \\ &= p^m + \mathcal{P}_k(x) - \sum_{y \in \{0,1\}^{k-m}} \mathcal{P}_k(1^m y) \end{aligned}$$

where the sum term is merely the probability of 1^m in the marginal distribution of $\mathcal{P}_k$, which by Lemma 5 in turn consists of m independent p-biased bits. Hence,

$$= p^m + \mathcal{P}_k(x) - p^m = \mathcal{P}_k(x). \qquad \blacktriangleleft$$

5 Conjectured hard problems

In this section we formally define the problems that we conjecture to require $n^{k-o(1)}$ time.

▶ **Definition 8** (Solving planted **decision** k-OV)**.** *Let $\mathcal{A}$ be an algorithm that given a k-OV instance $\mathbf{U}$ outputs either 0 or 1. For $\alpha(n) = \Omega(1)$, we say $\mathcal{A}$* solves *the* decision k-OV^α *problem with success probability $\delta(n)$, if for both $b \in \{0,1\}$ and large enough n,*

$$\Pr_{\mathbf{U} \sim k\text{-}OV_b^\alpha(n)}[\mathcal{A}(\mathbf{U}) = b] \geq \delta(n),$$

where randomness is taken over both the instance $\mathbf{U}$ and the random coins used by $\mathcal{A}$.

Similarly, we define a notion of recovering a solution from a planted instance.

▶ **Definition 9** (Solving planted **search** k-OV)**.** *Let $\mathcal{A}$ be an algorithm that given a k-OV instance $\mathbf{U}$ outputs a tuple $(s_1, ..., s_k) \in \{1, ..., n\}^k$. For a given $\alpha(n) = \Omega(1)$, we say $\mathcal{A}$* solves *the* planted search k-OV^α problem *with success probability $\delta(n)$ if for large enough n,*

$$\Pr_{\substack{\mathbf{U} \sim k-\mathrm{OV}_1^\alpha(n) \\ (s_1,...,s_k) \leftarrow \mathcal{A}(\mathbf{U})}}[U_{1,s_1}, ..., U_{k,s_k} \text{ are orthogonal}] \geq \delta(n),$$

where randomness is taken over both the instance $\mathbf{U}$ and the random coins used by $\mathcal{A}$.

Now we are ready to formally state our main conjecture.

▶ **Conjecture 10.** *For any $\alpha(n) = \omega(1)$ and $\varepsilon > 0$, there exists no algorithm $\mathcal{A}$ that solves the planted decision k-OV problem with any constant success probability $\delta > \frac{1}{2}$ in time $O(n^{k-\varepsilon})$.*

6 Search-to-decision reduction via binary search

We reduce the search problem of finding the planted solution to the decision problem of determining whether an instance contains a planted solution. This means that given a decision algorithm that can correctly distinguish whether an instance was sampled from the model or planted distribution with sufficient probability, one can recover the planted secret through this reduction. The reduction introduces a factor $O(\log n)$ increase in both the running time and error probability of the algorithm.

The idea is to find each planted vector using something akin to binary search on each collection U_i. We can split U_i into two partitions of roughly equal size and run the decision algorithm twice, on instances where one of the two partitions is first replaced by newly sampled p-biased vectors. The vector planted in U_i is guaranteed to be replaced in one of these cases, and by $(k-1)$-wise independence the resulting instance follows the model distribution. The search space is thus cut in half and we can recurse on this smaller search space to eventually find the planted vector.

▶ **Theorem 11** (Search-to-decision reduction). *Let $\alpha(n) = \mathrm{polylog}(n)$ and let $\mathcal{A}^{\mathrm{decide}}$ be an algorithm that solves the planted decision k-OV problem with success probability $1-\delta(n)$ in time $T(n)$. Then there exists an algorithm $\mathcal{A}^{\mathrm{search}}$ that solves the planted search k-OV problem with success probability at least $1-k\lceil\log n\rceil\cdot\delta(n)$ in expected time $\widetilde{O}(T(n)+n)$.*

Proof. Consider an instance $\mathbf{U} = (U_1,\ldots,U_k) \sim k{-}\mathrm{OV}_1^\alpha(n)$. First let us focus only on recovering the location $i\in[n]$ of the planted vector in the first collection U_1. The reduction begins with the "full" search space $S := [n]$, and narrows it down by half in each iteration, so that the desired i is recovered after $\lceil\log n\rceil$ iterations.

At each iteration, the current search space S is arbitrarily partitioned in two sets of equal size (up to one vector when $|S|$ is odd). The decision algorithm $\mathcal{A}^{\mathrm{decide}}$ is then executed on two new instances, where the respective sets of vectors in U_1 are replaced with newly sampled p-biased vectors.

By the $(k-1)$-wise independence, if the vector belonging to the solution is replaced, all vectors are independently and identically distributed p-biased vectors, i.e., the instance is distributed according to $k{-}\mathrm{OV}_0^\alpha(n)$. On the other hand, if the solution survives resampling, the instance remains distributed according to $k{-}\mathrm{OV}_1^\alpha(n)$. Therefore, the output of $\mathcal{A}^{\mathrm{decide}}$ is used to decide which of the two partition blocks should be assumed as the new search space.

The reduction is correct if $\mathcal{A}^{\mathrm{decide}}$ decides correctly at every iteration. Of course, $\mathcal{A}^{\mathrm{decide}}$ might fail with probability $\delta(n)$. By a union bound over all $\lceil\log n\rceil$ invocations of $\mathcal{A}^{\mathrm{decide}}$ this happens with probability at most $\lceil\log n\rceil\cdot\delta(n)$. Thereby $\mathcal{A}^{\mathrm{search}}$ recovers the location i of the first planted vector with success probability at least $1-\lceil\log n\rceil\cdot\delta(n)$.

As for the runtime, $\mathcal{A}^{\mathrm{decide}}$ with runtime $T(n)$ is invoked $O(\log n)$ times, and across all iterations $n-1$ vectors are resampled in total. Since a single p-biased bit can be sampled in expected time $O(-\log p) = O(\log\alpha(n)) = O(\log\log n)$, sampling a d-dimensional vector takes $\mathrm{polylog}(n)$ time in expectation. Therefore, recovering the location of the first planted vector takes time $\widetilde{O}(T(n)+n)$.

The same process is repeated another $k-1$ times to recover the locations of the planted vectors among $U_2,\ldots,U_k$. As k is constant, this does not increase the running time asymptotically but the success probability drops to $1-k\lceil\log n\rceil\cdot\delta(n)$. ◀

7 Search-to-decision reduction via counters

We present a second search-to-decision reduction, adapted from that of Agrawal et al. [2] for planted k-SUM. As in the method in Section 6, we use the fact that an algorithm $\mathcal{A}^{\text{decide}}$ for the decision k-OV problem, when given a planted k-OV instance with some of the vectors resampled, correctly detects whether any of the planted vectors were among the resampled vectors. However, instead of iteratively narrowing a pool of candidate vectors, we iterate this process on the entire instance, and, for each vector u, we keep count of the number of iterations in which u survived and $\mathcal{A}^{\text{decide}}$'s output was 1. After $O(\log(n))$ iterations we output the vectors with the highest counts among each of the k collections, which, as we show, coincides with the planted solution (with good probability).

▶ **Theorem 12** (Search-to-decision reduction). *For any $\alpha(n) = \text{polylog}(n)$, if there exists an algorithm that solves the planted decision k-OV problem with success probability at least $1 - \delta(n)$ in time $T(n)$, then there exists an algorithm that solves the planted search k-OV problem with success probability at least $1 - 13k \cdot \delta(n) - \frac{1}{n^k}$ in expected time $O\left(\left(T(n) + n\,\text{polylog}(n)\right)\log\frac{n}{\delta(n)}\right)$.*

In more detail, let Mix be the following randomized algorithm, which takes a k-OV instance $\mathbf{U}$ and resamples some of the vectors:

Algorithm Mix($\mathbf{U}$).

1. For each $\ell \in [k]$ and $i \in [n]$:
   a. With probability $1 - 2^{-\frac{1}{k}}$, replace $U_{\ell,i}$ by a newly-sampled p-biased vector
2. Output $\mathbf{U}$

For $\ell \in [k]$, let $R_\ell \subseteq [n]$ indicate the indices of the vectors of U_ℓ which are replaced by Mix. For a vector u in $\mathbf{U}$ and a given execution of Mix, we say u *survives* if Mix does not replace u. We say $\mathbf{s} = (s_1, \ldots, s_k)$ *survives* if U_{ℓ,s_ℓ} survives for each $\ell \in [k]$, i.e., $\forall_{\ell\in[k]} s_\ell \notin R_\ell$.

Now, let $B(\mathbf{s})$ be the binary random variable indicating whether $\mathbf{s}$ survives. Our chosen probability for Mix to resample a vector yields the following.

▶ **Lemma 13.** *For a k-OV instance $\mathbf{U}$ and any $\mathbf{s} \in [n]^k$, $\mathbf{s}$ survives with probability one half, i.e., $\Pr_{\text{Mix}}[B(\mathbf{s}) = 1] = \frac{1}{2}$.*

Proof. Each vector is independently picked to be replaced with probability $1 - 2^{-\frac{1}{k}}$. The chance of all k vectors surviving is

$$\Pr_{\text{Mix}}[B(\mathbf{s}) = 1] = \left(1 - \left(1 - 2^{-\frac{1}{k}}\right)\right)^k = 2^{-\frac{1}{k}\cdot k} = \frac{1}{2}. \qquad \blacktriangleleft$$

As laid out before, our search algorithm repeatedly executes Mix and then the given decision algorithm $\mathcal{A}^{\text{decide}}$. The hope is that the output of the latter correlates with the survival of the planted solution. We therefore also keep track of which vectors survive whenever $\mathcal{A}^{\text{decide}}$ believes there is still a planted solution in the instance output by Mix.

Algorithm $\mathcal{A}^{\text{search}}(\mathbf{U})$.

1. Initialize a counter $C_{\ell,i} := 0$ for each $\ell \in [k]$ and $i \in [n]$.
2. Repeat $m = \Theta(\log n)$ times:
   a. $\mathbf{V} \leftarrow \mathsf{Mix}(\mathbf{U})$
   b. $b := \mathcal{A}^{\text{decide}}(\mathbf{V})$
   c. If $b = 1$:
      i. Set $C_{\ell,i} := C_{\ell,i} + 1$ for every $U_{\ell,i}$ that was not replaced by Mix
3. Set $s_\ell := \arg\max_{i \in [n]} C_{\ell,i}$ for each $\ell \in [k]$
4. Output $\mathbf{s} = (s_1, \ldots, s_k)$

This works well for instances $\mathbf{U}$ where $\mathcal{A}^{\text{decide}}$ is good at detecting whether a particular solution survives. To capture this notion, we say an instance $\mathbf{U}$ is *good*, if it has only one solution, at some location $\mathbf{s}$, *and* the output of $\mathcal{A}^{\text{decide}}$ indicates whether $\mathbf{s}$ survives except for a small constant probability, i.e.,

$$\Pr[\mathcal{A}^{\text{decide}}(\mathsf{Mix}(\mathbf{U})) \neq B(\mathbf{s})] < \frac{1}{12k},$$

where the probability is taken over the internal randomness used by Mix.

In the following, let Sample be a randomized algorithm that outputs a planted instance sampled from $k{-}\mathrm{OV}_1^\alpha(n)$ as well as the location $\mathbf{s}$ of the planted solution.

▶ **Lemma 14.** *If $\mathcal{A}^{\text{decide}}$ solves the planted decision k-OV problem with success probability at least $1 - \delta(n)$, an instance $\mathbf{U} \sim k{-}\mathrm{OV}_1^\alpha(n)$ is* good *except with probability at most $12k \cdot \delta(n) + \frac{1}{n^k}$.*

Proof. An instance $\mathbf{U} \sim k{-}\mathrm{OV}_1^\alpha(n)$ contains only a single solution except with probability less than $\frac{1}{n^k}$. We will now show that for such $\mathbf{U}$ with only the planted solution, the decision algorithm $\mathcal{A}^{\text{decide}}$ correctly detects if this solution survives except with probability $< 12k \cdot \delta(n)$, from which the claim follows by a union bound.

First, consider the following distribution:

Distribution $k{-}\mathrm{OV}_B^\alpha(n)$.

1. $(\mathbf{U}, \mathbf{s}) \leftarrow \mathsf{Sample}$
2. $\mathbf{V} \leftarrow \mathsf{Mix}(\mathbf{U})$
3. Output $(\mathbf{V}, B(\mathbf{s}))$.

Observe that, if we condition on $B(\mathbf{s}) = 1$, the planted solution survives Mix, which merely resamples some of the i.i.d. p-biased vectors in the instance. Thus, $\mathbf{V}$ is distributed according to $k{-}\mathrm{OV}_1^\alpha(n)$. On the other hand, if $B(\mathbf{s}) = 0$, at least one of the planted vectors is replaced by a newly-sampled p-biased vector. By $(k-1)$-wise independence, the subset of planted vectors that survive are i.i.d. p-biased vectors, as are all other vectors in $\mathbf{V}$. Hence, conditioning on $B(\mathbf{s}) = 0$ yields the model distribution $k{-}\mathrm{OV}_0^\alpha(n)$.

Therefore, for the algorithm $\mathcal{A}^{\text{decide}}$, which solves the planted decision k-OV problem with success probability at least $1 - \delta(n)$, we have

$$\Pr_{(\mathbf{V},B) \leftarrow k{-}\mathrm{OV}_B^\alpha(n)}[\mathcal{A}^{\text{decide}}(\mathbf{V}) \neq B] \leq \delta(n).$$

Now, let $Z(\mathbf{U}, \mathbf{s})$ be the random variable that, for a given instance $\mathbf{U}$ with a solution planted at $\mathbf{s}$, denotes the probability of $\mathcal{A}^{\text{decide}}(\mathsf{Mix}(U)) \neq B(\mathbf{s})$, where the randomness is taken over the internal coins used by Mix. Then

$$\begin{aligned}\delta(n) &\geq \Pr_{(\mathbf{V},B)\leftarrow k\text{-OV}_B^\alpha(n)}[\mathcal{A}^{\text{decide}}(\mathbf{V}) \neq B] \\ &= \mathop{\mathbb{E}}_{(\mathbf{U},\mathbf{s})\leftarrow\mathsf{Sample}}\left[\Pr_{\mathsf{Mix}}[\mathcal{A}^{\text{decide}}(\mathsf{Mix}(\mathbf{U})) \neq B(\mathbf{s})]\right] \\ &= \mathop{\mathbb{E}}_{(\mathbf{U},\mathbf{s})\leftarrow\mathsf{Sample}}\left[Z(\mathbf{U},\mathbf{s})\right].\end{aligned}$$

By Markov's inequality,

$$\Pr_{(\mathbf{U},\mathbf{s})\leftarrow\mathsf{Sample}}\left[Z(\mathbf{U},\mathbf{s}) \geq \frac{1}{12k}\right] \leq 12k\,\mathbb{E}[Z(\mathbf{U},\mathbf{s})] \leq 12k\cdot\delta(n).$$

Next, observe that $\mathbf{s}$ is the only solution in the instance $\mathbf{U}$ output by Sample with good probability,

$$\Pr_{(\mathbf{U},\mathbf{s})\leftarrow\mathsf{Sample}}[\mathbf{U} \text{ has a solution besides } \mathbf{s}] = \Pr_{\mathbf{U}\leftarrow k\text{-OV}_1^\alpha(n)}[c(\mathbf{U}) > 1] < \frac{1}{n^k}.$$

Thus, by a union bound over this and our result in the first step, we find that an instance $\mathbf{U} \sim k\text{-OV}_1^\alpha(n)$ is good except with probability at most $12k\cdot\delta(n) + \frac{1}{n^k}$:

$$\begin{aligned}&\Pr_{\mathbf{U}\leftarrow k\text{-OV}_1^\alpha(n)}[\mathbf{U} \text{ is good}] \\ &= \Pr_{\mathbf{U},\mathbf{s}\leftarrow\mathsf{Sample}}\left[\mathbf{s} \text{ is the only solution of } \mathbf{U} \text{ and } Z(\mathbf{U},\mathbf{s}) < \frac{1}{12k}\right] \\ &\geq 1 - \Pr_{\mathbf{U},\mathbf{s}\leftarrow\mathsf{Sample}}[\mathbf{U} \text{ has a solution besides } \mathbf{s}] - \Pr_{\mathbf{U},\mathbf{s}\leftarrow\mathsf{Sample}}\left[Z(\mathbf{U},\mathbf{s}) \geq \frac{1}{12k}\right] \\ &> 1 - \frac{1}{n^k} - 12k\cdot\delta(n).\end{aligned}$$

◀

We now show that the search algorithm performs well on this large fraction of good instances.

▶ **Lemma 15.** *Let $\mathcal{A}^{\text{decide}}$ be an algorithm that solves the planted decision k-OV problem with success probability $1-\delta(n)$. Then $\mathcal{A}^{\text{search}}$ fails to recover the solution $\mathbf{s}$ of good instances with probability less than $\delta(n)$.*

Proof. Let $\mathbf{U}$ be a good instance with its only solution at $\mathbf{s}$. After t iterations, we expect the counters for vectors in the solution $\mathbf{s}$ to be the highest. Using the fact that $\frac{1}{\sqrt[k]{2}} < 1 - \frac{1}{2k}$, we find that for non-planted vectors, i.e., where $s_\ell \neq i$,

$$\begin{aligned}\mathbb{E}[C_{\ell,i}] &= t\cdot\Pr_{\mathsf{Mix}}\left[U_{\ell,i} \text{ survives and } \mathcal{A}^{\text{decide}}(\mathsf{Mix}(\mathbf{U})) = 1\right] \qquad (*) \\ &\leq t\cdot\left(\Pr_{\mathsf{Mix}}\left[U_{\ell,i} \text{ survives and } B(\mathbf{s}) = 1\right] + \Pr_{\mathsf{Mix}}\left[\mathcal{A}^{\text{decide}}(\mathsf{Mix}(\mathbf{U})) \neq B(\mathbf{s})\right]\right) \\ &< t\cdot\left(\frac{1}{\sqrt[k]{2}}\cdot\frac{1}{2} + \frac{1}{12k}\right) < t\cdot\left(\left(1-\frac{1}{2k}\right)\frac{1}{2} + \frac{1}{12k}\right) \\ &= t\left(\frac{1}{2} - \frac{2}{12k}\right).\end{aligned}$$

On the other hand, for planted vectors, i.e., where $s_\ell = i$,

$$\begin{aligned}\mathbb{E}[C_{\ell,i}] &\geq t \cdot \Pr_{\mathsf{Mix}}\left[\mathbf{s} \text{ survives and } \mathcal{A}^{\text{decide}}(\mathsf{Mix}(\mathbf{U})) = 1\right] \qquad (**)\\ &= t \cdot \Pr_{\mathsf{Mix}}\left[B(\mathbf{s}) = 1 \text{ and } \mathcal{A}^{\text{decide}}(\mathsf{Mix}(\mathbf{U})) = B(\mathbf{s})\right]\\ &\geq t \cdot \left(1 - \Pr_{\mathsf{Mix}}\left[B(\mathbf{s}) = 0\right] - \Pr_{\mathsf{Mix}}\left[\mathcal{A}^{\text{decide}}(\mathsf{Mix}(\mathbf{U})) \neq B(\mathbf{s})\right]\right)\\ &> t \cdot \left(1 - \frac{1}{2} - \frac{1}{12k}\right) = t \cdot \left(\frac{1}{2} - \frac{1}{12k}\right).\end{aligned}$$

Picking the k highest counters is guaranteed to yield the solution $\mathbf{s}$ if the ranges of the counters of the planted and non-planted vectors do not overlap, that is to say if no counter deviates from its expected value by half the difference of (the bounds on) the two expected values $(**)$ and $(*)$, which we denote by Δ:

$$\Delta := \frac{1}{2}\left[t \cdot \left(\frac{1}{2} - \frac{1}{12k}\right) - t \cdot \left(\frac{1}{2} - \frac{2}{12k}\right)\right] = t\frac{1}{24k}.$$

Each counter $C_{\ell,i}$ is the sum of t i.i.d. binary random variables. By a Chernoff bound, a counter $C_{\ell,i}$ for a vector which is not in the planted solution, i.e., $s_\ell \neq i$, exceeds its expected value by Δ with probability at most

$$\Pr\left[C_{\ell,i} \geq \mathbb{E}[C_{\ell,i}] + \Delta\right] < \exp\left(-2t\left(\frac{\Delta}{t}\right)^2\right) = \exp\left(-\frac{2t}{24^2 \cdot k^2}\right).$$

Similarly, a counter $C_{\ell,i}$ for a vector that *is* part of a planted solution ($s_\ell = i$) falls short of its expected value by Δ with at most the same probability

$$\Pr\left[C_{\ell,i} \leq \mathbb{E}[C_{\ell,i}] - \Delta\right] < \exp\left(-2t\left(\frac{\Delta}{t}\right)^2\right) = \exp\left(-\frac{2t}{24^2 \cdot k^2}\right).$$

For a choice of $t = \frac{24^2 \cdot k^2}{2} \cdot \log\frac{kn}{\delta(n)} = O\left(\log\frac{n}{\delta(n)}\right)$ iterations, both of these probabilities are at most $\frac{\delta(n)}{kn}$. If *none* of the $k \cdot n$ counters deviate by Δ, the ranges of counters for vectors at $\mathbf{s}$ and those for vectors not at $\mathbf{s}$ are disjoint and selecting for the highest counters is guaranteed to yield $\mathbf{s}$. Thus, by a union bound over all $k \cdot n$ counters, we fail to recover $\mathbf{s}$ with probability at most $kn \cdot \frac{\delta(n)}{kn} = \delta(n)$. ◀

We can now complete the proof of Theorem 12.

Proof of Theorem 12. By Lemma 14, an instance $\mathbf{U} \sim k\text{–OV}_1^\alpha(n)$ is good except with probability at most $12k \cdot \delta(n) + \frac{1}{n^k}$. By Lemma 15, $\mathcal{A}^{\text{search}}$ is able to recover the solution $\mathbf{s}$ from a good instance except with probability at most $\delta(n)$. By a union bound against the instance not being good or $\mathcal{A}^{\text{search}}$ failing on a good instance, $\mathcal{A}^{\text{search}}$ solves the planted search k-OV problem with success probability at least $1 - 13k\delta(n) - \frac{1}{n^k}$.

In each of the $O\left(\log\frac{n}{\delta(n)}\right)$ iterations, we execute both Mix and $\mathcal{A}^{\text{decide}}$ once and update the counters. Each execution of Mix samples, in expectation, $k \cdot n \cdot (1 - 2^{-\frac{1}{k}}) = O(n)$ new vectors, each of which can be sampled in $\text{polylog}(n)$ expected time as explained in the proof of Theorem 11. $\mathcal{A}^{\text{decide}}$ runs in time $T(n)$ and updating the counters takes linear time, for the total expected runtime of $O\left(\left(T(n) + n\,\text{polylog}(n)\right)\log\frac{n}{\delta(n)}\right)$. ◀

Abstract

In the parameterized problem #IndSub(Φ) for fixed graph properties Φ, given as input a graph G and an integer k, the task is to compute the number of induced k-vertex subgraphs satisfying Φ. Dörfler et al. [Algorithmica 2022] and Roth et al. [SICOMP 2024] conjectured that #IndSub(Φ) is #W[1]-hard for all non-meager properties Φ, i.e., properties that are nontrivial for infinitely many k. This conjecture has been confirmed for several restricted types of properties, including all hereditary properties [STOC 2022] and all edge-monotone properties [STOC 2024].

We refute this conjecture by showing that induced k-vertex graphs that are *scorpions* can be counted in time $O(n^4)$ for all k. Scorpions were introduced more than 50 years ago in the context of the evasiveness conjecture. A simple variant of this construction results in graph properties that achieve arbitrary intermediate complexity assuming ETH.

Moreover, we formulate an updated conjecture on the complexity of #IndSub(Φ) that correctly captures the complexity status of scorpions and related constructions.

1 Introduction

Counting small patterns in graphs is a fundamental problem in computer science, with applications in bioinformatics [39], network analysis [28, 38], databases [18], and other areas. In this paper, we focus on counting certain induced k-vertex graphs in a large n-vertex input graph G, for fixed k.

Counting Induced Copies of a Fixed Graph. The starting point of our investigation is the problem of counting induced H-copies for a fixed *individual* graph H. Formally, this problem asks for the number of sets $X \subseteq V(G)$ such that the induced subgraph $G[X]$ is isomorphic to H. We stress that H is considered fixed in this problem, and only G is the input. In particular, each such problem can be solved in time $O(n^k)$, which is polynomial in n for fixed k.

Some improvements over the trivial $O(n^k)$ running time are known: For example, triangles can be counted in $O(n^\omega)$ time [21], where $\omega < 2.372$ is the optimal exponent of $n \times n$ matrix multiplication [1]. This improvement can be lifted to cliques beyond K_3: Denoting by $C(K_k)$ the optimal exponent for counting k-cliques in n-vertex graphs, similar to the exponent of matrix multiplication, we have $C(K_k) \leq \omega \cdot \lceil k/3 \rceil$ (see [30]). Under the Exponential-Time Hypothesis ETH, there exists a fixed constant α such that $C(K_k) \geq \alpha \cdot k$ (see [4]).

Writing $C_{\text{ind}}(H)$ to denote the optimal exponent of counting induced H-subgraphs [5] for fixed H, a straightforward reduction shows that $C_{\text{ind}}(H) = C(K_k)$ for all k-vertex graphs H. In other words, for fixed k, all induced H-counting problems with k-vertex H are equally hard, and they require an exponent of $\Omega(k)$ under ETH. Compare this to counting not necessarily induced subgraphs, where different patterns can yield different complexity exponents: The number of subgraph copies of the edgeless k-vertex graph IS_k in an n-vertex graph is $\binom{n}{k}$ and can thus be computed in linear time, while counting k-cliques is hard.

Counting Patterns From a Set. In recent years, counting occurrences of individual k-vertex patterns H has been generalized to counting pattern occurrences from a fixed *set* of patterns [22, 23]. In this setting, we fix a number $k \in \mathbb{N}$ and a set $\mathcal{H}$ of k-vertex graphs. On input G, we wish to count the induced k-vertex subgraphs of G isomorphic to some $H \in \mathcal{H}$. This subsumes the problem of counting induced H-copies, but also allows us to address, e.g., the problem of counting connected k-vertex graphs [22].

Of course, for every set $\mathcal{H}$, this problem can be solved by counting induced H-copies for the individual graphs $H \in \mathcal{H}$, which readily implies an $O(n^{C(K_k)})$ time algorithm. Significantly faster algorithms were only known for *trivial* pattern sets $\mathcal{H}$, i.e., if the pattern set $\mathcal{H}$ is empty or contains all k-vertex graphs. In these cases, the output is just 0 or $\binom{n}{k}$, respectively. Also, for some pattern sets $\mathcal{H}$, slight improvements can be obtained over the $O(n^{C(K_k)})$ time algorithm [9], but no nontrivial set $\mathcal{H}$ of k-vertex graphs with exponent strictly less than $C(K_{\lfloor k/2 \rfloor})$ was known. In other words, counting induced patterns from a fixed set $\mathcal{H}$ of k-vertex graphs appeared to be either trivial or very hard.

Parameterized Complexity. In the literature, pattern counting is often phrased in terms of graph properties Φ that may hold on infinitely many graphs rather than finite sets $\mathcal{H}$. More specifically, in the problem #IndSub(Φ) for a fixed graph property Φ, the input is a graph G and $k \in \mathbb{N}$, and we ask to count the induced k-vertex subgraphs of G satisfying Φ. Compared to the previous setting, the pattern size k is now part of the input rather than a fixed constant, so the problem #IndSub(Φ) may not be polynomial-time solvable. We say that #IndSub(Φ) is *fixed-parameter tractable* if it can be solved in time $f(k) \cdot n^{O(1)}$ for a computable function f, and we would like to understand which properties Φ render #IndSub(Φ) fixed-parameter tractable.

In prior literature, all known properties Φ with fixed-parameter tractable #IndSub(Φ) are essentially trivial: Formally, we call Φ *meager* if the restriction $\Phi^{(k)}$ of Φ to k-vertex graphs (i.e., the k-th slice of Φ) is trivial for all but finitely many $k \in \mathbb{N}$. Meager computable properties Φ trivially render #IndSub(Φ) fixed-parameter tractable. Complementing this, the problem #IndSub(Φ) was conjectured to be #W[1]-hard for all other computable properties Φ. Here, #W[1] is the parameterized analogue of #P; it is known that ETH rules out fixed-parameter tractable algorithms for all #W[1]-hard problems (see, e.g., [15]).

▶ **Conjecture 1** ([12, 16, 37]). *For every property Φ that is computable and not meager, the problem* #IndSub(Φ) *is* #W[1]*-hard.*

This conjecture has been verified for general classes of properties Φ, e.g., properties that are closed under deleting edges [9, 13, 14] or deleting vertices [16], and other natural classes of properties [9, 22, 23, 35, 37]. This made it a plausible working hypothesis in the area.

Our Results. We show that **Conjecture 1 fails**. That is, we exhibit non-meager properties Φ such that $\#\textsc{IndSub}(\Phi)$ is fixed-parameter tractable – in fact, even polynomial-time solvable.

These counterexamples are derived from simple constructions that were introduced 50 years ago in the context of the *evasiveness conjecture* [27, 33, 26], a major open problem about the worst-case query complexity of graph properties. In the setting of the evasiveness conjecture, we are given a fixed graph property Φ, and we wish to decide whether an unknown k-vertex graph G is contained in Φ, where G can only be accessed via edge queries. More precisely, the vertex set $V(G)$ is known, and for two vertices v, w, we can query whether vw is an edge of G. Clearly, every property can be decided by querying all $\binom{k}{2}$ pairs of vertices, and the *evasiveness conjecture* postulates that this trivial worst-case upper bound is optimal for all *(edge-)monotone* properties.

However, when we drop the monotonicity requirement, properties Φ with linear query complexity $O(k)$ are known [27, 33], and it turns out that those examples can be used to refute Conjecture 1.

- As a simple counterexample, the property Ψ_{sink} of having a sink in a directed graph is nontrivial on graphs of fixed size $k \geq 2$, and hence not meager. Here, a graph D satisfies Ψ_{sink} if there is a vertex $s \in V(D)$ with $(v, s) \in E(D)$ for all $v \neq s$.[1] Nevertheless, $\#\textsc{IndSub}(\Psi_{\text{sink}})$ can be solved in linear time on directed graphs without antiparallel edges. We invite the reader to discover the algorithm themselves before proceeding to Section 3.1. This property actually presented the first counterexample to a (too strong) version of the evasiveness conjecture on directed graphs [33].
- A marginally more involved construction also works for undirected graphs: The *scorpion property* Ψ is a non-meager property of undirected graphs such that $\#\textsc{IndSub}(\Psi)$ can be solved in $O(n^4)$ time on general undirected graphs. Scorpions were the first counterexample to a (too strong) variant of the evasiveness conjecture for undirected graphs [27], prompting the restriction of this conjecture to monotone properties.
- We show more generally that $\#\textsc{IndSub}(\Psi)$ can be made gradually harder: For every $\ell \in \mathbb{N}$, we construct a *generalized scorpion property* Ψ_ℓ such that $\#\textsc{IndSub}(\Psi_\ell)$ can be solved in $O(n^{\ell+3})$ time, while ETH rules out $O(n^{\alpha \cdot \ell})$ time algorithms for a fixed constant $\alpha > 0$. Our construction also allows for ℓ to be a function in k. Under the Strong Exponential-Time Hypothesis SETH, we rule out $O(n^{\ell+2-\varepsilon})$ time algorithms.

Finally, informed by these counterexamples, we formulate a new hypothesis on the computational complexity of $\#\textsc{IndSub}(\Phi)$ for properties Φ. This new hypothesis is more technical and explained in Section 4. In a nutshell, it is based around the well-established fact that sums of induced pattern counts like the k-th slices $\#\text{IndSub}(\Phi^{(k)} \to G)$ can be expressed as linear combinations of (not necessarily induced) subgraph counts [5], and that such basis changes may help in understanding the complexity of a problem [5, 6, 9, 12, 13, 14, 16, 17, 24, 35, 37, 36].

[1] Contrary to contemporary notation, in which a *sink* is a vertex of out-degree 0, we use the term *sink* to refer to a vertex $s \in V(D)$ such that $(v, s) \in E(D)$ for all $v \neq s$. This follows the terminology of the original paper [33], which is still common in the context of the evasiveness conjecture.

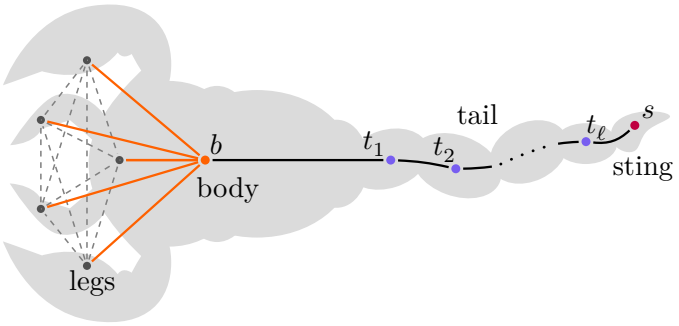

Figure 1 A graph H is an ℓ-scorpion if it has the above form: Dashed edges *may* be present in H or not, solid edges *must* be present, and non-drawn edges *must not* be present.

More specifically, the new hypothesis postulates that a useful phenomenon occurs when expressing the graph parameter $\#\mathrm{IndSub}(\Phi^{(k)} \to G)$ as a linear combination of subgraph counts: Any hard term in such a linear combination ensures hardness of the entire linear combination. General linear combinations of k-vertex subgraph counts do not enjoy this useful phenomenon. We demonstrate in Section 4 that our conjecture would imply useful new ways of proving hardness of $\#\mathrm{IndSub}(\Phi^{(k)} \to G)$.

Further Connections to the Evasiveness Conjecture. Notably, this work is not the first to draw connections between the evasiveness conjecture and the computational complexity of $\#\textsc{IndSub}(\Phi)$. Indeed, this connection was already made by Roth and Schmitt [35], who adapted the topological approach to the evasiveness conjecture, dating back to Kahn, Saks and Sturtevant [25], to prove lower bounds for $\#\textsc{IndSub}(\Phi)$ for certain graph properties Φ. In a similar spirit, [9] adapts a lower bound of $\Omega(k^2)$ on the query complexity of monotone graph properties due to Rivest and Vuillemin [32] to obtain hardness of $\#\textsc{IndSub}(\Phi)$ for monotone properties Φ. The present work complements these connections on the upper-bound side: We observe that standard examples of properties Φ with linear query complexity admit efficient algorithms for $\#\textsc{IndSub}(\Phi)$.

Currently, these connections seem to be restricted to specific examples and proof techniques. We believe that it is an interesting open question whether a general connection can be established in either direction. Without going into details, we point out that the *Fourier degree* of a property Φ (when Φ is restricted to a slice and viewed as a Boolean function) provides a lower bound both for the query complexity of Φ [31], and for the computational complexity of $\#\textsc{IndSub}(\Phi)$ [9]. However, in both cases, large Fourier degree is only known to give a *sufficient* criterion for hardness, so it does not establish a direct link between the query complexity of Φ and the complexity of $\#\textsc{IndSub}(\Phi)$.

2 Preliminaries

We write $\mathbb{N} = \{1, 2, 3, \dots\}$ and $[n] \coloneqq \{1, ..., n\}$ for $n \in \mathbb{N}$. For a set A, we write $\binom{A}{k}$ for the set of all k-element subsets of A.

Graph Theory. We follow standard textbooks [11] for graph-theoretic notation. Unless stated otherwise, graphs are simple (i.e., without multiedges or self-loops) and undirected. We write $V(G)$ and $E(G)$ for the vertex and edge set of G, respectively, and we write $N_G(v) \coloneqq \{u \mid uv \in E(G)\}$ for the neighborhood of $v \in V(G)$ in G.

A graph H is a *subgraph* of G, written $H \subseteq G$, if it can be obtained by deleting vertices and edges from G. For $X \subseteq V(G)$, we write $G[X]$ to denote the *induced subgraph* on X. For $S \subseteq E(G)$, we write $G[S]$ for the subgraph with vertex set $V(G)$ and edge set S. For $k, \ell \in \mathbb{N}$, we write K_ℓ for the complete ℓ-vertex graph, IS_ℓ for the edgeless ℓ-vertex graph, and $K_{\ell,k}$ for the complete bipartite graph on $\ell + k$ vertices.

Induced Subgraph Counts. A *graph property* Φ is a function that maps each graph G to $\{0,1\}$ and is invariant under isomorphisms, i.e., $\Phi(G) = \Phi(H)$ for all isomorphic graphs G, H. For $k \in \mathbb{N}$, the *k-th slice of* Φ, denoted by $\Phi^{(k)}$, is the restriction of Φ to k-vertex graphs. We implicitly identify $\Phi^{(k)}$ with the set of all k-vertex graphs G satisfying $\Phi(G) = 1$, and we use graph properties and sets of graphs interchangeably. For $k \in \mathbb{N}$ and a graph G, the number of k-vertex induced subgraphs $G[X]$ satisfying Φ will be denoted by

$$\#\mathrm{IndSub}(\Phi^{(k)} \to G) \coloneqq \sum_{\substack{X \subseteq V(G) \\ |X|=k}} \Phi(G[X]).$$

Moreover, we write $\#\mathrm{IndSub}(\Phi^{(k)} \to \star)$ for the map $G \mapsto \#\mathrm{IndSub}(\Phi^{(k)} \to G)$.

Complexity Theory. A *parameterized problem* consists of a function $P\colon \Sigma^* \to \mathbb{N}$ and a computable parameterization $\kappa\colon \Sigma^* \to \mathbb{N}$. It is *fixed-parameter tractable* (FPT) if there is a computable function f, a constant $c \in \mathbb{N}$, and a deterministic algorithm $\mathbb{A}$ that computes $P(x)$ in time $O(f(\kappa(x)) \cdot |x|^c)$ for all $x \in \Sigma^*$. We write $\#\textsc{IndSub}(\Phi)$ for the parametrized problem that gets as input a graph G and a *parameter* k, and computes $\#\mathrm{IndSub}(\Phi^{(k)} \to G)$.

For lower bounds, we rely on the *Exponential-Time Hypothesis* (ETH) [20], which asserts the existence of some $\varepsilon > 0$ such that the Boolean satisfiability problem on n-variable 3-CNF formulas cannot be solved in time $O(2^{\varepsilon \cdot n})$ (see also [10, Conjecture 14.1]). The *Strong Exponential-Time Hypothesis* (SETH) [19] states that for all $\varepsilon > 0$, there is a $k \geq 3$ such that Boolean Satisfiability on k-CNF formulas cannot be solved in $O(2^{(1-\varepsilon)\cdot n})$ (see also [10, Conjecture 14.2]).

3 Main Result

To present the idea underlying the tractability of scorpions, we first consider a variant for directed graphs, where this idea becomes particularly simple. Then we introduce scorpions and their generalizations and prove the claimed upper and lower complexity bounds. Finally, we use scorpions to show that a useful and previously known complexity lower bound on the complexity of $\#\textsc{IndSub}(\Phi)$ is tight.

3.1 Directed Graphs Containing a Sink

As a warm-up, we consider a property Ψ_{sink} of directed graphs that is nontrivial but yields a linear-time counting problem $\#\textsc{IndSub}(\Psi_{\mathrm{sink}})$. For this subsection, we momentarily consider directed graphs without antiparallel edges, i.e., at most one of the edges (u, v) and (v, u) may be present. The property Ψ_{sink} is defined to hold on H if there is a *sink* vertex $s \in V(H)$, i.e., a vertex s such that $(u, s) \in E(H)$ for all $u \in V(H) \setminus \{s\}$. This property is clearly nontrivial in every slice $k \geq 2$, as there are k-vertex graphs with a sink and k-vertex graphs without a sink (e.g., an in-star versus the edgeless graph).

Towards an algorithm, we observe crucially that every graph without antiparallel edges contains at most one sink, since two distinct sinks u, v would imply the presence of both edges (u, v) and (v, u). Hence, for an input graph G, the set of k-vertex sets containing a sink

$$\mathcal{X} \coloneqq \left\{ X \in \binom{V(G)}{k} \;\middle|\; G[X] \in \Psi_{\text{sink}} \right\}$$

can be partitioned, according to the unique sink, into

$$\mathcal{X} = \bigcup_{v \in V(G)} \mathcal{X}_v \quad \text{with} \quad \mathcal{X}_v \coloneqq \{X \in \mathcal{X} \mid v \text{ is the sink of } G[X]\}.$$

Finally, for fixed $v \in V(G)$, every set $X \in \mathcal{X}_v$ has the form $X = \{v, w_1, \ldots, w_{k-1}\}$ with all $w_1, \ldots, w_{k-1}$ pairwise distinct, distinct from v, and incoming neighbors of v, i.e., they satisfy $(w_i, v) \in E(G)$. Writing $\text{in}_G(v)$ for the number of incoming neighbors of v, it follows that

$$|\mathcal{X}_v| = \binom{\text{in}_G(v)}{k-1}.$$

Combining the above equations, we readily obtain a linear-time algorithm for $\#\textsc{IndSub}(\Psi_{\text{sink}})$ by computing $\text{in}_G(v)$ for all $v \in V(G)$ and evaluating the resulting formula

$$\#\text{IndSub}(\Psi^{(k)}_{\text{sink}} \to G) = \sum_{v \in V(G)} |\mathcal{X}_v| = \sum_{v \in V(G)} \binom{\text{in}_G(v)}{k-1}. \tag{1}$$

3.2 Generalized Scorpions

The algorithmic idea for counting k-vertex graphs with a sink vertex applies whenever the set $\mathcal{X}$ of induced subgraphs to be counted admits a partition into few sets $\mathcal{X}_i$ such that each $|\mathcal{X}_i|$ is easily determined. More specifically, we consider partitions in which each $\mathcal{X}_i$ is determined by the manifestation of a special small set of uniquely identifiable vertices (e.g., the sink vertex), while the subgraph induced by the other vertices is irrelevant.

To apply this idea to undirected graphs, we use a construction that was first presented in [27] for the so-called *evasiveness conjecture*, and which has become a standard example in this context (see, e.g., [26, Section 13.1]): A graph H is a *scorpion* if it can be obtained from an arbitrary graph H' with $|V(H')| \geq 2$ by adding fresh vertices b, t, s, making b adjacent to all of H', and then adding the edges bt and ts. The vertices b, t, s are usually called *body*, *tail* and *sting*, and it can be shown crucially (see Lemma 3 below) that these vertices are uniquely recoverable from H. Similarly to the arguments above, this allows us (in Theorem 4) to design an efficient algorithm to count induced scorpions.

In this paper, we prove these statements for a slightly generalized version of scorpions, since this allows us to obtain gradually harder properties. Towards this end, we replace the tail vertex t by a path of ℓ vertices $t_1, \ldots, t_\ell$. See also Figure 1.

▶ **Definition 2.** *For $\ell \in \mathbb{N}$, an* ℓ-scorpion *is a graph H with $|V(H)| \geq \ell + 4$ that admits a tuple of pairwise distinct vertices*

$$(\underbrace{b}_{\text{body of } H}, \underbrace{t_1, \ldots, t_\ell}_{\text{tail of } H}, \underbrace{s}_{\text{sting of } H}) \in V(H)^{\ell+2},$$

such that the following holds: Writing $Q \coloneqq \{b, t_1, \ldots, t_\ell, s\}$ and calling the vertices in $V(H) \setminus Q$ the legs *of H, we have that*

- *the graph $H[Q]$ is an induced path from the body b to the sting s,*
- *the body b is adjacent to all legs, and*
- *the body b is the only vertex in Q adjacent to legs.*

We define Ψ_ℓ as the class of all ℓ-scorpions.

The property Ψ_ℓ is non-meager for all $\ell \geq 1$: Indeed, for $k \geq \ell + 4$, at least one k-vertex scorpion exists (e.g., consisting of the sting, tail, body, and an independent set of legs), while the k-vertex graph K_k is not a scorpion.

Note that scorpion graphs are 1-scorpions. Also note that the definition speaks about "the" body, tail, and sting vertices, as if they were unique. Indeed, they are:

▶ **Lemma 3.** *If H is an ℓ-scorpion, then its body, tail, and sting are unique.*

Proof. Let $k = |V(H)|$ and recall that $k \geq \ell + 4$ by Definition 2. The body has degree $k - \ell - 1 \geq 3$. Since every leg has degree at most $k - \ell - 2$, we conclude that H contains exactly one vertex of degree $k - \ell - 1$; this uniquely identifies b.

The vertices not adjacent to b are precisely $t_2, \ldots, t_\ell, s$. Among these, s is the only vertex of degree 1 and is thus uniquely identified. The vertices $t_1, \ldots, t_\ell$ are uniquely identified by their distance from s, since vertex t_i is the only vertex at distance $\ell - i + 1$ from s. ◀

We use this lemma to show that #IndSub(Ψ_ℓ) can be solved in polynomial time for every fixed $\ell \geq 1$, similarly to the algorithm presented in Section 3.1.

▶ **Theorem 4.** *There is an algorithm that, given $k \geq \ell + 4$ and an n-vertex graph G as input, computes $\#\mathrm{IndSub}(\Psi_\ell^{(k)} \to G)$ in time $O(\ell \cdot n^{\ell+3})$.*

Proof. Let $\mathcal{X}$ be the set of induced k-vertex graphs in G that are ℓ-scorpions. In our proof, we use the uniqueness of body, tail, and sting to partition $\mathcal{X}$ into classes $\mathcal{X}_{\mathbf{q}}$ for $\mathbf{q} \in V(G)^{\ell+2}$ and then determine each $|\mathcal{X}_q|$ in linear time. Then the algorithm follows from

$$\#\mathrm{IndSub}(\Psi_\ell^{(k)} \to G) = |\mathcal{X}| = \sum_{\mathbf{q} \in V(G)^{\ell+2}} |\mathcal{X}_{\mathbf{q}}|. \tag{2}$$

More specifically, let $\mathcal{P} \subseteq V(G)^{\ell+2}$ denote the tuples inducing a path in G. Given $\mathbf{q} \in \mathcal{P}$ with $\mathbf{q} = (b, t_1, \ldots, t_\ell, s)$, let $\mathcal{X}_{\mathbf{q}} \subseteq \mathcal{X}$ denote the set of k-vertex ℓ-scorpions in G with body b, tail $t_1, \ldots, t_\ell$ and sting s. By Lemma 3, the sets $\mathcal{X}_{\mathbf{q}}$ for $\mathbf{q} \in \mathcal{P}$ partition $\mathcal{X}$, so (2) holds with $\mathcal{X}_{\mathbf{q}} = \emptyset$ for $\mathbf{q} \notin \mathcal{P}$. It remains to determine $|\mathcal{X}_{\mathbf{q}}|$ for $\mathbf{q} = (b, t_1, \ldots, t_\ell, s) \in \mathcal{P}$. We show that

$$|\mathcal{X}_{\mathbf{q}}| = \binom{|X_G(\mathbf{q})|}{k - \ell + 2} \quad \text{with } X_G(\mathbf{q}) \coloneqq \left| N_G(b) \setminus \bigcup_{v \in \{t_1, \ldots, t_\ell, s\}} N_G(v) \right|. \tag{3}$$

Indeed, since the $\ell + 2$ vertices in $\mathbf{q}$ induce a path, the set $\mathcal{X}_{\mathbf{q}}$ consists of all k-vertex sets X that contain $\{b, t_1, \ldots, t_\ell, s\}$ and $k - \ell - 2$ additional vertices (the legs) that are adjacent to b and not adjacent to any t_i or s. The number of such sets X is precisely $|\mathcal{X}_{\mathbf{q}}| = \binom{X_G(\mathbf{q})}{k-\ell+2}$.

An algorithm with the claimed running time follows from evaluating (2) term by term while using (3) to determine $|\mathcal{X}_{\mathbf{q}}|$. Indeed, $\mathcal{P}$ can be enumerated in time $O(n^{\ell+2})$ and $|\mathcal{X}_{\mathbf{q}}|$ for $\mathbf{q} \in \mathcal{P}$ can be computed via (3) in time $O(\ell n)$. ◀

Since Ψ_ℓ is non-meager for every $\ell \geq 1$, Theorem 4 refutes Conjecture 1 even with $\ell = 1$.

3.3 Lower Bounds Based on ETH

Next, we show that the running time obtained in Theorem 4 is essentially optimal under ETH. In particular, by choosing ℓ as a function of k, we can use ℓ-scorpions to obtain properties with varying computational difficulty.

To obtain the lower bound, we rely on a result from [6, 9, 37] that provides a lower bound based on the set of possible Hamming weights attained by a property Φ: Given a graph property Φ and $k \in \mathbb{N}$, we say that Φ *attains weight* ℓ *on slice* k if there is a graph $H \in \Phi$ with k vertices and ℓ edges. It *avoids weight* ℓ *on slice* k if it does not attain it. Note that every property attains between 0 and $\binom{k}{2}+1$ different weights on slice k, since the attained weights form a subset of $\{0, \dots, \binom{k}{2}\}$.

▶ **Theorem 5** ([9, Lemma 5.1] & [6, Theorem 7.1])**.** *Assuming* ETH*, there are* $N_0, \delta > 0$ *such that the following holds: If* $k \geq N_0$ *and* $0 < d \leq k/2$ *and* Φ *avoids at least* $d \cdot k$ *distinct weights and attains at least one weight, all on slice* k*, then no algorithm computes* $\#\mathrm{IndSub}(\Phi^{(k)} \to G)$ *in time* $O(n^{\delta \cdot d})$*.*

For $k \geq \ell + 4$, we can easily determine the number of weights attained by Ψ_ℓ on slice k: Since there is no freedom in choosing edges incident to body, tail and sting, this number is precisely $\binom{k-\ell-2}{2}+1$. Thus, the number of weights avoided by Ψ_ℓ on slice k is

$$\binom{k}{2} - \binom{k-\ell-2}{2} - 1 = k(\ell+2) - \frac{\ell(\ell+5)}{2} - 4.$$

For $k \geq 2\ell + 4$, it follows that Ψ_ℓ avoids at least $\ell/2 \cdot k$ weights on slice k. Being nontrivial, it attains at least one weight. Theorem 5 readily implies:

▶ **Corollary 6.** *Assuming* ETH*, there are* $N_0, \delta > 0$ *such that the following holds: If* $k \geq N_0$ *and* $0 < \ell \leq (k-4)/2$*, then no algorithm computes* $\#\mathrm{IndSub}(\Psi_\ell^{(k)} \to G)$ *in time* $O(n^{\delta \cdot \ell})$*.*

▶ Remark 7. The algorithm from Theorem 4 also demonstrates that the lower bound in Theorem 5 cannot be further improved. Indeed, Ψ_ℓ avoids at most $(\ell+2) \cdot k$ weights on slice k, but $\#\mathrm{IndSub}(\Phi^{(k)} \to G)$ can be solved in $O(n^{\ell+3})$ time. Therefore, ℓ-scorpions show that the bound in Theorem 5 is essentially tight.

With the lower bound of Corollary 6 at hand, we can obtain properties with varying computational complexity, by choosing ℓ dependent on k. For example, setting $\ell \approx \sqrt{k}$ yields a property Ψ_{sqrt} for which $\#\textsc{IndSub}(\Psi_{\mathrm{sqrt}})$ takes $n^{\Theta(\sqrt{k})}$ time under ETH. More generally, consider a monotone increasing $f\colon \mathbb{N} \to \mathbb{N}$ with $1 \leq f(k) \leq (k-4)/2$ for all $k \in \mathbb{N}$. We define $\Psi_f = \bigcup_{k \in \mathbb{N}} \Psi_{f(k)}^{(k)}$ to contain exactly the k-vertex $f(k)$-scorpions for all $k \in \mathbb{N}$.

▶ **Corollary 8.** *Let* $f\colon \mathbb{N} \to \mathbb{N}$ *be monotone increasing with* $1 \leq f(k) \leq (k-4)/2$*. Then* $\#\textsc{IndSub}(\Psi_f)$ *can be solved in time* $O(k \cdot n^{f(k)+3})$*, and assuming* ETH*, not in time* $O(n^{\alpha \cdot f(k)})$ *for a fixed constant* $\alpha > 0$*.*

In the full version of the paper, we combine results from Section 4 with a result from [3] to obtain the following lower bound under the Strong Exponential-Time Hypothesis SETH.

▶ **Proposition 9.** *Assuming* SETH*, for every* $\ell \geq 3$ *and* $\varepsilon > 0$*, there is no algorithm solving* $\#\textsc{IndSub}(\Psi_\ell)$ *in time* $O(n^{\ell+2-\varepsilon})$*.*

We stress that, in contrast to Corollaries 6 and 8, the SETH lower bound from Proposition 9 only holds for fixed ℓ, and not if ℓ is chosen as a function of k.

4 An Updated Conjecture Using the Subgraph Basis

Seeing what scorpions have done to Conjecture 1, it is natural to update the conjecture and reconsider the question when #IndSub(Φ) is fixed-parameter tractable. Towards this, we first observe that our counterexamples can be generalized in a number of ways while keeping their key features. This suggests that a dichotomy theorem for #IndSub(Φ) will have to encompass various tractable cases, as the following facts indicate:

- The key to the efficient algorithm in Theorem 4 is that body, tail and sting are uniquely identified in every ℓ-scorpion, and that no restrictions are imposed on the subgraph induced by the legs. As long as there is a constant-sized set of uniquely identifiable vertices and no restrictions on the remaining vertices, an efficient algorithm for #IndSub(Φ) follows.
- This however is not the final word: Observe that #IndSub(Φ) has the same complexity as #IndSub($\neg\Phi$), where $\neg\Phi$ contains exactly those graphs that are not contained in Φ (see, e.g., [37, Fact 2.3]). Notably, the non-scorpion property $\neg\Psi_\ell$ contains the complete graph on k vertices for every $k \geq \ell + 4$, which arguably has no constant-sized set of "uniquely identifiable" vertices.
- Beyond, we can also "nest" easy properties: For example, let Λ be the graph property containing all graphs H with $|V(H)| \geq 9$ so that (a) H is a 1-scorpion, with some set of legs X, and (b) $H[X]$ is not a 2-scorpion. Then #IndSub(Λ) can be solved in polynomial time using similar arguments as in Theorem 4.

The diversity of these examples suggests that a complexity classification for all properties Φ may be quite intricate. To obtain a new classification conjecture, we first express the induced subgraph counts arising in #IndSub(Φ) as linear combinations of (not necessarily induced) subgraph counts. Such basis changes among counting problems have already been used for #IndSub(Φ) before [6, 9, 12, 13, 14, 16, 35, 37].[2]

In the following, recall that $\Phi^{(k)}$ for $k \in \mathbb{N}$ is the restriction of Φ to k-vertex graphs and let #IndSub($\Phi^{(k)} \to \star$) be the number of induced k-vertex graphs satisfying $\Phi^{(k)}$ in an input graph. Likewise let #Sub($H \to \star$) denote the number of not necessarily induced H-subgraph copies in an input graph. Then there exists a finite set $\mathcal{H}$ of unlabeled graphs on exactly k vertices, and coefficients α_H for $H \in \mathcal{H}$, such that

$$\#\text{IndSub}(\Phi^{(k)} \to \star) = \sum_{H \in \mathcal{H}} \alpha_H \cdot \#\text{Sub}(H \to \star); \tag{4}$$

see [2, 5]. In fact, an explicit formula for the coefficients can be found through inclusion-exclusion: Given a graph property Φ and graph H, the coefficient α_H in (4) is given by the so-called *alternating enumerator* $\widehat{\Phi}(H)$ (see [9, 35]), sometimes defined without the $(-1)^{|E(H)|}$ factor below [12, 13, 14],

$$\widehat{\Phi}(H) \coloneqq (-1)^{|E(H)|} \sum_{S \subseteq E(H)} (-1)^{|S|} \Phi(H[S]).$$

Evaluating fixed finite linear combinations of k-vertex graphs as in (4) is asymptotically no harder than evaluating the individual H-subgraph counts with $\widehat{\Phi}(H) \neq 0$. For fixed graphs H, individual H-subgraph counts in turn can be evaluated in time $O(n^{\tau(H)+1})$, where

[2] Going further, the problem #IndSub(Φ) has already been expressed in the similar basis of *homomorphism counts*, and a dichotomy criterion was shown in terms of this basis [5]. However, the transformation into the homomorphism basis renders combinatorial interpretations of Φ opaque and only yields an implicit dichotomy criterion. In particular, all complexity results listed above were achieved using the *subgraph* basis rather than the homomorphism basis.

$\tau(H)$ is the vertex-cover number of H (see [5, Theorem 1.1]). In particular, this implies that $\#\textsc{IndSub}(\Phi)$ is fixed-parameter tractable when only graphs H of small vertex-cover number satisfy $\widehat{\Phi}(H) \neq 0$. More quantitatively, writing $\tau_\Phi(k)$ for the maximal vertex cover number among k-vertex graphs H with $\widehat{\Phi}(H) \neq 0$, we have:

▶ **Theorem 10** (see, e.g., [8, Theorem 3.6]). *For every computable graph property Φ, the problem $\#\textsc{IndSub}(\Phi)$ can be solved in time $f(k) \cdot n^{\tau_\Phi(k)+1}$ for a computable function f.*

Conversely, under certain conditions, a k-vertex graph H with $\widehat{\Phi}(H) \neq 0$ that is hard on its own also implies hardness of the entire linear combination. For example, under the guarantee that all patterns in the linear combination have the same number k of vertices, this occurs when some graph H with $\widehat{\Phi}(H) \neq 0$ has large treewidth (see, e.g., [12]). Large treewidth is however only a sufficient criterion, since counting k-matchings (and more generally, patterns of large vertex-cover number) is hard as well [7].

Knowing about a similar phenomenon for the related case of homomorphism counts, one[3] might be led to believe that linear combinations of k-vertex subgraph counts are hard if at least one pattern has large vertex-cover number. However, this hypothesis is too optimistic, as shown by k-partial determinants: These are weighted counts of k-vertex cycle covers C in a graph G, where C is counted with weight -1 if it contains an odd number of cycles, and with weight 1 otherwise. The patterns in the subgraph count expansion of k-partial determinants are precisely the cycle covers on k vertices. These do have large vertex-cover number, yet k-partial determinants can be computed in time $O(n^{\omega+1})$ due to the same cancellations that render usual determinants tractable.

In our updated version of Conjecture 1, we assert that such cancellations cannot occur for $\#\textsc{IndSub}(\Phi)$. That is, we assert that graphs of large vertex-cover number in the subgraph expansion of $\#\textsc{IndSub}(\Phi)$ indeed render the linear combination hard. Recall that $\tau_\Phi(k)$ denotes the maximal vertex cover number among k-vertex graphs H with $\widehat{\Phi}(H) \neq 0$.

▶ **Conjecture 11.** *If Φ is a computable property and the function τ_Φ is unbounded, then the problem $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$-hard.*

Note that, by Theorem 10, the problem $\#\textsc{IndSub}(\Phi)$ is fixed-parameter tractable if τ_Φ is bounded. Hence, Conjecture 11 formulates a complete characterization in terms of the subgraph basis expression of a property: For a computable property Φ, the problem $\#\textsc{IndSub}(\Phi)$ is fixed-parameter tractable if τ_Φ is bounded, and $\#\mathsf{W}[1]$-hard otherwise.

To the best of our knowledge, no counterexamples are known for Conjecture 11. Since k-partial determinants can be negative, they cannot be written as $\#\textsc{IndSub}(\Phi)$ for a property Φ, so they do not form a counterexample to our updated conjecture. Moreover, we verify that none of the generalized scorpion properties Ψ_ℓ for fixed $\ell \in \mathbb{N}$ refute it. More specifically, we prove that, for every $k \geq \ell + 4$,

$$\tau_{\Psi_\ell}(k) = \ell + 2. \tag{5}$$

Thus $\tau_{\Psi_\ell}(k) \in O(1)$ for fixed ℓ, so Ψ_ℓ does not satisfy the premises of Conjecture 11.

4.1 Scorpions in the Subgraph Basis

We prove (5) in this section. Recall the definition of tail, sting, body, and legs of an ℓ-scorpion S. We call an ℓ-scorpion S a *skeleton* if its legs form an independent set. Moreover, an *ℓ-scorpion fossil* is any graph S' obtained from an ℓ-scorpion skeleton S by adding an arbitrary

[3] Some did, see a superseded arXiv version of a related paper: `https://arxiv.org/abs/2407.07051v1`

number of edges uv with $u, v \in V(S)$ such that at least one of u, v is not a leg. (Considering Figure 1, a scorpion skeleton is obtained by removing all dashed edges. A scorpion fossil is obtained from a scorpion skeleton by adding arbitrary edges, but not between legs.)

To show (5), we prove the stronger statement that the graphs H occurring with non-zero coefficients $\widehat{\Psi_\ell}(H) \neq 0$ in the subgraph expansion of Ψ_ℓ are precisely the ℓ-scorpion fossils. This is indeed stronger: The vertex-cover number of ℓ-scorpion fossils is at most $\ell + 2$, since they retain the independent set on the legs. On the other hand, the augmented biclique $K^+_{\ell+2,k-\ell-2}$ obtained from a complete bipartite graph by turning the left side (one $\ell + 2$ vertices) into a clique is an ℓ-scorpion fossil of vertex-cover number $\ell + 2$.

▶ **Lemma 12.** *For every $\ell \in \mathbb{N}$ and every k-vertex graph H with $k \geq \ell+4$, we have $\widehat{\Psi_\ell}(H) \neq 0$ if and only if H is an ℓ-scorpion fossil.*

Proof. Let $\mathcal{S} \coloneqq \{S \subseteq E(H) \mid H[S] \in \Psi_\ell\}$. Similar to Theorem 4, we use the uniqueness of body, tail, and sting to partition $\mathcal{S}$ into classes $\mathcal{S}_{\mathbf{q}}$ for $\mathbf{q} \in V(H)^{\ell+2}$. More specifically, for a tuple $\mathbf{q} = (b, t_1, \ldots, t_\ell, s) \in V(H)^{\ell+2}$, let $\mathcal{S}_{\mathbf{q}}$ denote the set of all $S \in \mathcal{S}$ such that the scorpion $H[S]$ has body b, tail $t_1, \ldots, t_\ell$ and sting s. Note that we may have $\mathcal{S}_{\mathbf{q}} = \emptyset$.

By Lemma 3, the sets $\mathcal{S}_{\mathbf{q}}$ for $\mathbf{q} \in V(H)^{\ell+2}$ partition $\mathcal{S}$, which implies

$$\widehat{\Psi_\ell}(H) = (-1)^{|E(H)|} \cdot \sum_{S \in \mathcal{S}} (-1)^{|S|} = (-1)^{|E(H)|} \cdot \sum_{\mathbf{q} \in V(H)^{\ell+2}} \sum_{S \in \mathcal{S}_{\mathbf{q}}} (-1)^{|S|}. \tag{6}$$

In the following, for a tuple $\mathbf{q} \in V(H)^{\ell+2}$, we write $\mathrm{set}(\mathbf{q})$ for the set of entries of $\mathbf{q}$.

▷ Claim 13. If $\mathbf{q} \in V(H)^{\ell+2}$ is such that $\mathrm{set}(\mathbf{q})$ is not a vertex cover of H, then

$$\sum_{S \in \mathcal{S}_{\mathbf{q}}} (-1)^{|S|} = 0.$$

Proof. Let us first observe that the statement is trivial if $\mathcal{S}_{\mathbf{q}} = \emptyset$.

Let $E_{\mathbf{q}} \coloneqq \{e \in E(H) \mid e \cap \mathrm{set}(\mathbf{q}) = \emptyset\}$ be the edges of H without an endpoint in $\mathrm{set}(\mathbf{q})$. Since $\mathrm{set}(\mathbf{q})$ is not a vertex cover, we get $E_{\mathbf{q}} \neq \emptyset$. Observe that $F_{\mathbf{q}} \coloneqq S \setminus E_{\mathbf{q}} = S' \setminus E_{\mathbf{q}}$ for all $S, S' \in \mathcal{S}_{\mathbf{q}}$, because edges incident to body, tail or sting (i.e., edges incident to the vertices in $\mathbf{q}$) are fixed. Since edges between leg vertices can be chosen arbitrarily, we conclude that

$$\mathcal{S}_{\mathbf{q}} = \{F_{\mathbf{q}} \cup E'_{\mathbf{q}} \mid E'_{\mathbf{q}} \subseteq E_{\mathbf{q}}\}.$$

In particular, we obtain

$$\sum_{S \in \mathcal{S}_{\mathbf{q}}} (-1)^{|S|} = \sum_{E'_{\mathbf{q}} \subseteq E_{\mathbf{q}}} (-1)^{|F_{\mathbf{q}}| + |E'_{\mathbf{q}}|} = (-1)^{|F_{\mathbf{q}}|} \sum_{E'_{\mathbf{q}} \subseteq E_{\mathbf{q}}} (-1)^{|E'_{\mathbf{q}}|} = 0$$

since $E_{\mathbf{q}} \neq \emptyset$. ◁

Now, for the forward direction of the lemma, suppose that $\widehat{\Psi_\ell}(H) \neq 0$. Then there is some $\mathbf{q} = (b, t_1, \ldots, t_\ell, s)$ such that $\sum_{S \in \mathcal{S}_{\mathbf{q}}} (-1)^{|S|} \neq 0$. This implies that

(a) $\mathrm{set}(\mathbf{q})$ is a vertex cover of H by Claim 13, so the vertices in $V(H) \setminus \mathrm{set}(\mathbf{q})$ form an independent set in H, and

(b) $\mathcal{S}_{\mathbf{q}} \neq \emptyset$, i.e., there is some $S \subseteq E(H)$ such that $H[S]$ is an ℓ-scorpion with body b, tail $t_1, \ldots, t_\ell$ and sting s. Thus, the vertices in $V(H) \setminus \mathrm{set}(\mathbf{q})$ form the legs of $H[S]$.

These two properties together directly imply that H is an ℓ-scorpion fossil.

For the backward direction, suppose H is an ℓ-scorpion fossil, and let $\mathbf{q} = (b, t_1, \ldots, t_\ell, s)$ denote the tuple of body, tail, and sting of an underlying ℓ-scorpion skeleton. Then

(i) $\mathcal{S}_{\mathbf{q}} \neq \emptyset$,
(ii) $\mathrm{set}(\mathbf{q})$ is a vertex cover of H.

The first item holds because the underlying ℓ-scorpion skeleton is a witness to $\mathcal{S}_{\mathbf{q}} \neq \emptyset$, while the second item holds from the definition of ℓ-scorpion skeletons.

Now, let $A \subseteq V(H)^{\ell+2}$ denote the set of all tuples $\mathbf{q}'$ satisfying (i) and (ii). Then, for every $\mathbf{q}' \in A$ and every $S \in \mathcal{S}_{\mathbf{q}'}$, the legs of $H[S]$ form an independent set, since the vertices in $\mathbf{q}' \in A$ form a vertex-cover. This implies that $H[S]$ is an ℓ-scorpion skeleton, so S contains exactly $k-1$ edges, and we obtain

$$\sum_{S \in \mathcal{S}_{\mathbf{q}'}} (-1)^{|S|} = (-1)^{k-1} |\mathcal{S}_{\mathbf{q}'}| \quad \text{for all } \mathbf{q}' \in A. \tag{7}$$

On the other hand, for $\mathbf{q}' \in V(H)^{\ell+2} \setminus A$, the tuple $\mathbf{q}'$ violates (i), or $\mathbf{q}'$ violates (ii). We obtain directly (in the first case) or via Claim 13 (in the second case) that

$$\sum_{S \in \mathcal{S}_{\mathbf{q}'}} (-1)^{|S|} = 0 \quad \text{for all } \mathbf{q}' \in V(H)^{\ell+2} \setminus A. \tag{8}$$

Let us abbreviate $X_{\mathbf{q}'} \coloneqq \sum_{S \in \mathcal{S}_{\mathbf{q}'}} (-1)^{|S|}$. Then it follows that

$$\begin{aligned}
\widehat{\Psi_\ell}(H) &= (-1)^{|E(H)|} \sum_{\mathbf{q}' \in V(H)^{\ell+2}} X_{\mathbf{q}'} \\
&= (-1)^{|E(H)|} \left(\sum_{\mathbf{q}' \in V(H)^{\ell+2} \setminus A} X_{\mathbf{q}'} + \sum_{\mathbf{q}' \in A} X_{\mathbf{q}'} \right) \\
&= (-1)^{|E(H)|} \left(0 + \sum_{\mathbf{q}' \in A} (-1)^{k-1} |\mathcal{S}_{\mathbf{q}'}| \right) = (-1)^{|E(H)|+k-1} \sum_{\mathbf{q}' \in A} |\mathcal{S}_{\mathbf{q}'}| \neq 0,
\end{aligned}$$

where we used (7) and (8) in the third equality, and where the last inequality holds since $A \neq \emptyset$ and $\mathcal{S}_{\mathbf{q}'} \neq \emptyset$ for all $\mathbf{q}' \in A$. ◀

As discussed above, the lemma implies Equation (5) on the maximum vertex-cover number in the subgraph expansion of the scorpion property. Together with Theorem 10, the upper bound on the vertex-cover number gives an alternative proof that $\#\textsc{IndSub}(\Psi_\ell)$ is fixed-parameter tractable for $\ell \in \mathbb{N}$, with the same polynomial degree as in Theorem 4. We stress that similar arguments also work for the adaptations of the scorpion property discussed in the beginning of Section 4. For example, for the property Λ defined there, we get $\tau_\Lambda(k) \leq 7$ for every $k \in \mathbb{N}$.

4.2 Implications of the Conjecture

To conclude the paper and as a potential avenue for future work, we show that our refined Conjecture 11 would easily imply generalizations and variants of known hardness results.

Most of the recent works (see, e.g., [9, 12, 13, 14, 37]) prove hardness of $\#\textsc{IndSub}(\Phi)$ by identifying graphs with non-zero alternating enumerator and unbounded *treewidth* rather than vertex-cover number; this is a stronger property. More concretely, let $\eta_\Phi(k)$ denote the maximal treewidth among k-vertex graphs H with $\widehat{\Phi}(H) \neq 0$. If Φ is computable and η_Φ is unbounded, then $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$-hard (see, e.g., [9, Theorem 3.1]). However, showing that η_Φ is unbounded is often quite a challenge. Conjecture 11 postulates that it suffices for τ_Φ to be unbounded to obtain $\#\mathsf{W}[1]$-hardness, which is often much easier to show.

As a concrete example, previous work [12] established hardness of #IndSub(Φ) in the presence of infinitely many primes p with $\Phi(\mathrm{IS}_{2p}) \neq \Phi(K_{p,p})$, where IS_{2p} and $K_{p,p}$ are the edge-less and complete bipartite graphs, respectively. Similarly, for edge-monotone properties Φ, which are studied in [9, 13, 14], we typically obtain $\Phi(\mathrm{IS}_k) \neq \Phi(K_k)$ for all sufficiently large k. As we show below, Conjecture 11 implies that infinitely many *arbitrary* prime-order vertex-transitive graphs H_1, H_2 with $\Phi(H_1) \neq \Phi(H_2)$ suffice for hardness. A graph H is called *vertex-transitive* if for all vertices $u, v \in V(H)$ there exists an automorphism $\varphi \in \mathrm{Aut}(H)$ with $\varphi(u) = v$.

▶ **Proposition 14.** *Let Φ be a graph property such that, for infinitely many primes p, there are vertex-transitive graphs H_p^1, H_p^2 with p vertices and $\Phi(H_p^1) \neq \Phi(H_p^2)$. Then #IndSub($\Phi$) is #W[1]-hard assuming Conjecture 11.*

Proof. For a prime p, we say that a group Γ is a p-group if its order is a power of p, and we establish some facts about groups and graphs:

- **(I)** Each transitive group that operates on a set of p elements contains a transitive p-subgroup. This holds since Γ contains a cyclic group of order p, which is transitive (see the discussion before [29, Theorem 1] for more details).
- **(II)** Each vertex-transitive graph is regular. This is trivial.
- **(III)** Every d-regular k-vertex graph H with $d > 1$ has vertex-cover number $\tau(H) \geq k/2 - 1$: By [34], the independence number $\alpha(H)$ of H is at most $k/2+1$, so $\tau(H) = k - \alpha(H) \geq k/2 - 1$.

By the requirements of the proposition, there are infinitely many primes p such that there are vertex-transitive graphs H_p^1, H_p^2 with p vertices and $\Phi(H_p^1) \neq \Phi(H_p^2)$. Hence, there is an $i \in \{1, 2\}$ with $\Phi(H_p^i) \neq \Phi(\mathrm{IS}_p)$. Let $H_p \coloneqq H_p^i$ be this graph. Then $\mathrm{Aut}(H_p)$ contains a transitive p-subgroup Γ_p by (I). We say a subgraph F_p of H_p is a *fixed point of Γ_p in H_p* if $V(F_p) = V(H_p)$ and $\gamma(E(F_p)) = E(F_p)$ for all $\gamma \in \Gamma_p$, where $\gamma(E(F_p)) \coloneqq \{\gamma(u)\gamma(v) \mid uv \in E(F_p)\}$. Let $\mathrm{FP}(\Gamma_p, H_p)$ denote the set of fixed points of Γ_p in H_p (see [14, Appendix A] for more details on fixed points of group actions in graphs).

We show that there is a fixed point $F_p \in \mathrm{FP}(\Gamma_p, H_p)$ that has a non-zero alternating enumerator and $\tau(F_p) \geq p/2 - 1$. For this, let F_p be a fixed point in $\mathrm{FP}(\Gamma_p, H_p)$ with $\Phi(F_p) \neq \Phi(\mathrm{IS}_p)$ and $\Phi(F_p') = \Phi(\mathrm{IS}_p)$ for all $F_p' \in \mathrm{FP}(\Gamma_p, H_p)$ with $F_p' \subsetneq F_p$ (i.e., F_p' is a proper subgraph of F_p). Such a graph F_p exists since $H_p \in \mathrm{FP}(\Gamma_p, H_p)$ and $\Phi(H_p) \neq \Phi(\mathrm{IS}_p)$. Now, [13, Lemma 4.8] implies that $\widehat{\Phi}(F_p) \neq 0$. Moreover, [13, Lemma 3.1] implies that $\Gamma_p \subseteq \mathrm{Aut}(F_p)$, and hence F_p is vertex-transitive. Lastly, (II) and (III) yield that $\tau(F_p) \geq p/2 - 1$.

This means that we can find a sequence of graphs F_p with unbounded vertex cover number and $\widehat{\Phi}(F_p) \neq 0$, and thus #IndSub($\Phi$) is #W[1]-hard by Conjecture 11. ◀

Abstract

Constrained pathfinding is a classic yet challenging network optimization problem with broad applicability across many real-world domains. The Resource-Constrained Shortest Path (RCSP) problem focuses on finding cost-optimal paths that satisfy multiple resource constraints. In this paper, we propose a novel heuristic-guided search framework that accelerates constrained search in large-scale networks, including those with negative costs and resources, by leveraging efficient queuing and pruning strategies. Experimental results on real-world benchmark maps show that our framework achieves up to two orders of magnitude speedup over state-of-the-art methods, demonstrating its effectiveness in solving challenging RCSP instances within limited time.

1 Introduction

The Resource Constrained Shortest Path (RCSP) problem is a fundamental yet challenging network optimization problem. It focuses on finding cost-optimal paths between two nodes in a graph while adhering to constraints on the utilization of limited, potentially multidimensional resources. Many real-world problems can be modeled as an RCSP instance. Examples are planning time-constrained explorable non-shortest routes in roaming navigation applications [24], and finding energy efficient paths with detour limits for electric vehicles [4]. As a subproblem, RCSP has been utilized to solve orienteering problems [33], and the vehicle routing problem [12]. RCSP is an NP-Hard problem even for single resource constraint [16].

RCSP and its single-constraint variant, the Weight Constrained Shortest Path (WCSP) problem, have been studied in the literature for decades. Traditional solutions to RCSP are generally based on path ranking, dynamic programming (labeling) or branch-and-bound (B&B) approaches [25, 13], but recent studies have demonstrated that the labeling method is more effective for solving large-scale RCSP instances. The recent RCBDA* algorithm [31] is a labeling method that utilizes the dynamic programming approach presented in [29] to perform a bidirectional A* search guided by cost heuristics, using rigorous yet costly pruning rules to avoid exploring unpromising paths. Complete paths in this algorithm are

© Saman Ahmadi, Andrea Raith, and Mahdi Jalili;
licensed under Creative Commons License CC-BY 4.0

obtained by matching backward and forward partial paths, and the amount of a critical resource available to each search is half of the total budget. The authors concluded that RCBDA* can perform faster than two other existing RCSP approaches on many instances, namely the Pulse algorithm (B&B method) [22] and the CSP (path ranking) approach in [30]. A parallel bidirectional search framework on the basis of Pulse was later developed in [10], known as BiPulse. This algorithm utilizes the the queuing mechanism developed in [9] to limit the depth of the Pulse search and postpone the exploration of deep branches of the search tree, where halted partial paths are explored in a breadth-first search manner. The authors reported better performance and more solved cases with BiPulse compared to RCBDA*. Both BiPulse and RCBDA* received awards for their contribution to RCSP [15]. WCEBBA* [3], WCA* [6] and WCBA* [5] are three other A*-based methods that leverage fast pruning rules in recent bi-objective search literature [32, 2] to tackle constrained pathfinding more efficiently. Although all of the algorithms have been shown to outperform RCBDA* and BiPulse on large graphs, their application is limited to instances with a single resource constraint. Another recent A*-based RCSP method, called ERCA* [27], takes advantage of recent advancements in multi-objective search with A* [26, 28] to improve the efficiency of its pruning rules through binary search trees. Like other A*-based methods, the search in ERCA* is guided by cost heuristics and prunes unpromising paths. Its pruning involves rigorously discarding any path that exceeds the resource budget or is dominated (i.e., no better in cost and resource usage) by another previously extended path to the same node, both before and during path extension. The authors reported several orders of magnitude faster runtime for ERCA* when compared with BiPulse. However, the performance of ERCA* against RCBDA* remains unknown. All of the above algorithms are designed and evaluated for problem instances with non-negative cost and resources.

Contributions. This paper presents a novel and straightforward label-setting framework built upon A*, called NWRCA*, which incorporates effective search and lazy pruning strategies to accelerate constrained pathfinding in large-scale networks with negative costs and resources. We evaluate the framework in two variants that differ slightly in how they maintain search labels, and we investigate a faster method for computing A*'s heuristics that can potentially replace the conventional reweighting approach when dealing with negative-weight graphs. Extensive experiments demonstrate the success of the framework in solving difficult RCSP instances several orders of magnitude faster than ERCA* and RCBDA*.

2 Problem Definition

Consider an RCSP problem with d resource limits $\{R_1, R_2, \ldots, R_d\}$ is provided as a directed graph G with a set of vertices V and a set of edges $E \subseteq V \times V$. Every edge $e \in E$ of the graph has $d + 1 \in \mathbb{N}$ attributes, represented as $(cost, \mathbf{resources})$ where $\mathbf{resources} = \{resource_1, \ldots, resource_d\}$ is a form of vector (denoted boldface). An acyclic path π consists of n distinct vertices $\{v_1, v_2, v_3, \ldots, v_n\}$, where $n \leq |V|$ and $(v_i, v_{i+1}) \in E$ for $i \in \{1, \ldots, n-1\}$. The cost and resource usage of a path π are determined by summing the attributes of all edges that make up the path. The RCSP problem aims to find (at least) one *cost*-optimal paths π^* from $v_s \in V$ (start or origin) to $v_g \in V$ (goal or destination) such that the resource usages of the path are within the given limits, that is, we must have $resource_k(\pi^*) \leq R_k$ for each resource $k \in \{1, \ldots, d\}$.

In line with the notation in the RCSP literature, we refer to our search objects as *labels*. Each label l encapsulates the key information about a partial path from v_s and is associated with an end vertex $v \in V$ (last vertex of the path). Label l traditionally stores value pairs

g_l and $\mathbf{r}_l$ that measure the *cost* and **resources** of the path, respectively. Additionally, l includes p_l, a reference to the parent label of l, and f_l, an estimate of the *cost* of a complete path to v_g by extending l. Specifically, for each search label l associated with vertex v, we have $f_l = g_l + h_c(v)$ where $h_c(v)$ is a consistent *cost* heuristic function [17].

▶ **Definition 1.** *The heuristic function $h_c : V \to \mathbb{R}$ is admissible iff $h_c(v) \leq cost(\lambda^*)$ for every $v \in V$, where λ^* is a cost-optimal path from v to v_g. h_c is consistent if we have $h_c(v) \leq cost(v, u) + h_c(u)$ for every $(v, u) \in E$.*

We assume all operations on the resource vectors are performed element-wise. In addition, we use the $\preceq$ symbol for direct comparisons of resource vectors, e.g., $\mathbf{r}_l \preceq \mathbf{r}_{l'}$ denotes $resource_k$ of label l is no greater than that of label l' for all $k \in \{1, \ldots, d\}$. Analogously, we use the $\not\preceq$ symbol if the relation cannot be satisfied. We now define *dominance* over labels.

▶ **Definition 2.** *Label l' is weakly dominated by label l if we have $g_l \leq g_{l'}$ and $\mathbf{r}_l \preceq \mathbf{r}_{l'}$; l' is strongly dominated by l if $g_l \leq g_{l'}$ and $\mathbf{r}_l \preceq \mathbf{r}_{l'}$ but $g_l \neq g_{l'}$ or $\mathbf{r}_l \neq \mathbf{r}_{l'}$; l' is not dominated by l if $g_l \not\leq g_{l'}$ or $\mathbf{r}_l \not\preceq \mathbf{r}_{l'}$.*

3 Resource Constrained Pathfinding with A*

Constrained pathfinding with A* involves a systematic search by exploring labels in best-first order, meaning that the search is guided by the partial path with the smallest *cost* estimate or f-value. Each iteration involves three main steps:
i) Extraction: remove one least-*cost* label from a priority queue $\mathcal{Q}$, also known as *Open* list.
ii) Dominance pruning: skip exploring labels that are weakly dominated by at least one other label (with the same vertex);
iii) Expansion: generate new descendant labels, check them for feasibility (against resource limits), and, if not pruned, store them in $\mathcal{Q}$ for further expansion.
The search in this framework generally terminates once an optimal solution is found, or there is no label in $\mathcal{Q}$ to explore, where the latter means there is no feasible solution. If there is only one resource, it is shown that dominance pruning can be done in constant time when performing best-first search [5, 6]. Nonetheless, this is not the case in RCSP with multiple resources and the dominance pruning remains a costly task.

RCSP with negative weights. Many real-world RCSP problems deal with attributes that are negative in nature, such as energy recuperation in electric vehicles, or attributes that may exhibit negative values in specific circumstances, such as negative reduced costs in column generation or pricing problems [19]. Although recent A*-based RCSP solutions, such as ERCA* and RCBDA*, are primarily designed and evaluated for problem instances with non-negative edge attributes, they can be adapted to be used for instances with negative weights (but no negative cycles). This can be achieved through a graph reformulation phase, where all edge weights are shifted to non-negative values, for example, using Johnson's reweighting technique [21]. However, as we will show in this section, our constrained search framework can be applied directly to graphs with negative edge weights, provided that its *cost* heuristic is consistent. With this introduction, we now describe our new RCSP algorithm.

Our approach. Algorithm 1 presents the pseudocode of NWRCA*, our A*-based RCSP method that employs *lazy* dominance checks and can handle problem instances with negative edge weights (but no negative cycles). The algorithm begins by initializing a priority queue $\mathcal{Q}$ and a global cost upper bound $\overline{f}$, which maintains the best-known cost of any feasible solution found during the search. For each vertex $v \in V$, it also initializes a list $\mathcal{X}(v)$ to store

Algorithm 1 NWRCA*.

Input: An RCSP Problem $(G, v_s, v_g, \mathbf{R})$
Output: A set of non-dominated *cost*-optimal solution labels

1 $\mathcal{Q} \leftarrow \emptyset$, $\overline{f} \leftarrow \infty$
2 $\mathcal{X}(v) \leftarrow \emptyset \ \ \forall v \in V$
3 $h_c(v) \leftarrow$ optimal *cost* from v to v_g $\forall v \in V$
4 $\mathbf{h}_r(v) \leftarrow$ lower bound on **resources** from v to v_g $\forall v \in V$
5 $l \leftarrow$ new label associated with v_s
6 $g_l \leftarrow 0$, $\mathbf{r}_l \leftarrow \mathbf{0}_d$, $f_l \leftarrow h_c(v_s)$, $p_l \leftarrow \varnothing$
7 add l to $\mathcal{Q}$
8 **while** $\mathcal{Q} \neq \emptyset$ **do**
9 extract from $\mathcal{Q}$ label l with the smallest f-value
10 **if** $f_l > \overline{f}$ **then break**
11 $v \leftarrow$ vertex associated with the extracted label l
12 *dominated* $\leftarrow$ false
13 **for each** $l' \in \mathcal{X}(v)$ **do**
14 **if** $\mathbf{r}_{l'} \preceq \mathbf{r}_l$ **then**
15 *dominated* $\leftarrow$ true
16 **break**
17 **if** *dominated* = true **then continue**
18 **for each** $l' \in \mathcal{X}(v)$ **do**
19 **if** $\mathbf{r}_l \preceq \mathbf{r}_{l'}$ **then** remove l' from $\mathcal{X}(v)$
20 add l to $\mathcal{X}(v)$
21 **if** $v = v_g$ **then**
22 $\overline{f} \leftarrow f_l$
23 **continue**
24 **for each** successor u of v **do**
25 $l' \leftarrow$ new label associated with u
26 $g_{l'} \leftarrow g_l + cost(v, u)$
27 $\mathbf{r}_{l'} \leftarrow \mathbf{r}_l +$ **resources**(v, u)
28 $f_{l'} \leftarrow g_{l'} + h_c(u)$
29 $p_{l'} \leftarrow l$
30 **if** $\mathbf{r}_{l'} + \mathbf{h}_r(u) \not\preceq \mathbf{R}$ **then continue**
31 add l' to $\mathcal{Q}$
32 **return** $\mathcal{X}(v_g)$

the non-dominated labels resulting from all prior expansions (i.e., closed labels) associated with vertex v. Like other A*-based RCSP algorithms, NWRCA* requires a *cost* heuristic function h_c to establish f-values. To enhance pruning of unpromising paths, we also compute lower bounds on **resources** using an admissible heuristic function $\mathbf{h}_r : V \to \mathbb{R}^d$. These cost and resource heuristics can be computed using $1 + d$ single-objective Dijkstra runs [11], with re-expansions allowed to accommodate negative weights [20], assuming there are no negative cycles on any path from v_s to v_g in any dimension (cost or resources). A similar strategy has been explored in [1] for multi-objective search. As we will demonstrate in the experimental section, this heuristic construction method, despite its exponential worst-case complexity, often outperforms alternatives such as Johnson's reweighting technique [21] in practice. NWRCA* then initializes a label with v_s and inserts it into $\mathcal{Q}$. Each iteration of the main search starts at line 8. Let $\mathcal{Q}$ be a non-empty queue. The algorithm extracts in each iteration a label l with the smallest f-value (line 9) and attempts the following steps.

Lazy dominance check. NWRCA* borrows a lazy label pruning technique from the multi-objective search literature and delays dominance check of newly generated labels until they are extracted from $\mathcal{Q}$, as in [18] and [1]. Let l be a label extracted from $\mathcal{Q}$ with f-value within the global upper bound. Also let v be the end vertex associated with l. Because the first dimension is always explored in sorted f order (guaranteed in A* with a consistent heuristic), we observe that l is already weakly dominated by previous expansions in terms of *cost*. Note that all expansions with v use $h_c(v)$ as lower bound. As a result, all prior expansions of v must have exhibited g-value no smaller than g_l. This means that the dominance test can only be done by comparing the resource vector of l, that is, $\mathbf{r}_l$, with that of (potentially all) previous expansions stored in $\mathcal{X}(v)$. This process can be further improved by prioritizing the most recent expansion of v as the first (potentially more informed) candidate for a quick dominance check, prior to a more rigorous dominance check against the labels of $\mathcal{X}(v)$ [1]. The expansion of label l can be skipped if it is found to be dominated by any previously expanded label (lines 13-16). If l is determined to be non-dominated, NWRCA* removes from the $\mathcal{X}(v)$ list any label l' whose resource vector is weakly dominated by $\mathbf{r}_l$ (lines 18-19), and then adds l to $\mathcal{X}(v)$ for future dominance checks at vertex v (line 20). This removal is correct because any future label that would be dominated by l' will also be dominated by l, making it unnecessary to keep the now-redundant label in $\mathcal{X}(v)$.

Capturing solutions. A tentative solution path is found if the search extracts a non-dominated label associated with the goal vertex v_g (line 21). Expansion of solution labels is not necessary. However, in the absence of tie-breaking in $\mathcal{Q}$, new solutions may offer better resources than previous ones. NWRCA* takes care of this situation by maintaining only non-dominated labels associated with the goal vertex in $\mathcal{X}(v_g)$.

Expansion. l's expansion involves generating new descendant labels through v's successors (adjacent vertices). Given $\mathbf{h}_r$ as an admissible heuristic function, descendant labels with estimated resource usage exceeding the given limit $\mathbf{R}$ cannot lead to a feasible solution and can be pruned (line 30). Note that in the case of negative resources, new labels whose usage of **resources** exceeds the budget (i.e., $\mathbf{r}_{l'} \not\preceq \mathbf{R}$) can be pruned, provided that all partial paths are also required to satisfy the resource constraints (which is not assumed in this work). As part of NWRCA*'s lazy dominance pruning rule, newly generated labels are not checked for dominance against previously expanded labels or those still in $\mathcal{Q}$; instead, they are only checked when extracted from the queue. Thus, each descendant label will be added to $\mathcal{Q}$ if its estimated usage of **resources** to v_g is within $\mathbf{R}$.

Termination. NWRCA* explores labels based on their f-value in ascending order. Given $\overline{f}$ as global *cost* upper bound, the search can terminate safely once it extracts a label with f-value greater than $\overline{f}$ (line 10). Although this upper bound is initially unknown, it will get updated as soon as a feasible solution is discovered (line 22). The algorithm returns $\mathcal{X}(v_g)$, a set containing *cost*-optimal labels with non-dominated **resources** (line 32). If there is no solution to a given instance (i.e., v_g is never reached), this set would remain empty.

Example. We further elaborate on the key steps of NWRCA* by solving a sample RCSP instance with three edge attributes (two resources), depicted in Figure 1. We assume resource limits are $(R_1, R_2) = (3, 3)$. The vertices v_s and v_g denote *start* and *goal*, respectively. The graph is free of negative cycles, and the values inside each vertex denote h_c and (h_{r1}, h_{r2}), calculated prior to the main search via three single-objective backward searches. We briefly

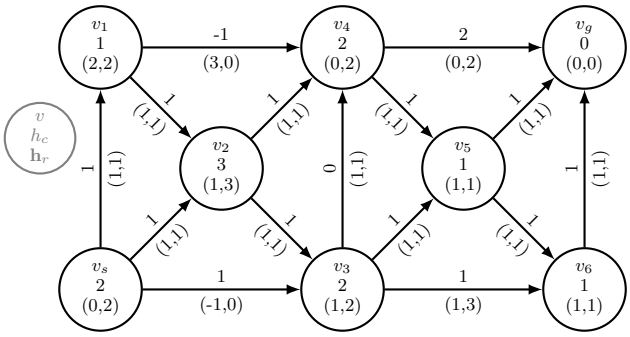

Figure 1 An RCSP instance with *cost* above and **resources** below edges ($d = 2$). Values inside the nodes denote vertex identifier, h_c and $\mathbf{h}_r$ of each vertex, listed from top to bottom.

explain all iterations (It.) of NWRCA* for the given instance, with the trace of $\mathcal{Q}$ and $\mathcal{X}$ sets provided in Table 1. Pruned labels of each iteration are shown in the third column. For label extractions, we adopt the Last-In, First-Out (LIFO) strategy in the event of ties in f-values of labels present in $\mathcal{Q}$. The queue is initialized with the first label l_1 associated with v_s.

- **It.1:** The search starts with expanding the initial label l_1. Since l_1 is the first expansion of v_s and thus non-dominated, it is stored in $\mathcal{X}(v_s)$. Expansion of l_1 generates three new labels: l_2, l_3, and l_4. l_2 and l_4 are added to $\mathcal{Q}$ but l_3 is pruned as its resource estimates are out of bounds, i.e., we have $\mathbf{r}_{l_3} + \mathbf{h}_r(v_2) \not\preceq \mathbf{R}$.
- **It.2:** There are two labels in $\mathcal{Q}$. l_2 has the smallest f-value and is expanded first. l_2 is non-dominated and its expansion generates l_5 and l_6 with v_2 and v_4, respectively. Both labels are pruned since their resource estimates are out of bounds.
- **It.3:** l_4, associated with v_3, is the only label in $\mathcal{Q}$ and is extracted. l_4 will be stored in $\mathcal{X}(v_3)$ as a non-dominated label. l_4's expansion generates three new labels: l_7, l_8, and l_9. However, only two of these are within the resource bounds and can be added to $\mathcal{Q}$. l_9 is out of bounds as we have $3 + 1 \not\leq 3$ for its second resource estimate.
- **It.4:** There are two labels in $\mathcal{Q}$, both with the same f-value. l_8 is extracted based on the LIFO strategy. l_8 is non-dominated, as this is the first expansion with v_4. Expansion of l_8 generates two new labels (l_{10} and l_{11}, both within the bounds) and adds them to $\mathcal{Q}$.
- **It.5:** l_{11} is extracted based on the LIFO strategy. l_{11} is non-dominated and its expansion generates two labels l_{12} and l_{13}, but only l_{12} is added into $\mathcal{Q}$ as the second resource estimate for l_{13} is not within the bound, i.e., we have $3 + 1 \not\leq 3$.
- **It.6:** There are three labels in $\mathcal{Q}$, all with the same f-value. The recent insertion l_{12} is extracted with v_g. This yields the first solution path, followed by updating $\overline{f} \leftarrow 3$. l_{12} does not get expanded.
- **It.7:** l_{10} is extracted, and it appears as a non-dominated solution. However, l_{10}'s resource vector $(0, 3)$ dominates that of the previous solution. Thus, l_{10} replaces l_{12} in $\mathcal{X}(v_g)$.
- **It.8:** l_7 is extracted. l_7 is a non-dominated label but dominates and replaces l_{11} in $\mathcal{X}(v_5)$. Expansion of l_7 generates two new labels (l_{14} and l_{15}). Both labels are within the resource bounds and thus added into $\mathcal{Q}$.
- **It.9:** l_{14} is extracted with v_g. l_{14} is non-dominated and is added to $\mathcal{X}(v_g)$. l_{14} does not dominate the previous solution.
- **It.10:** l_{15} is extracted. Given the *cost* upper bound updated in **It.6**, the search terminates due to $f_{l_{15}}$ surpassing the upper bound $\overline{f}$, i.e., we have $f_{l_{15}} = 4 > 3$.

Table 1 Tracking $\mathcal{Q}$ and $\mathcal{X}$ lists in each iteration (**It.**) of NWRCA* for Figure 1. The symbol $^{\uparrow}$ denotes the extracted label, and the last column shows pruned labels during the expansion phase.

It.	$\mathcal{Q}:\ [f_l, g_l, \mathbf{r}_l, v_l, p_l]$	$\mathcal{X}$	Generated but Pruned
1	$^{\uparrow}l_1 = [2, 0, (0,0), v_s, \varnothing]$	$\mathcal{X}(v_s) = \{l_1\}$	$l_3 = [4, 1, (1,1), v_2, l_1]$

10	$^{\uparrow}l_{15} = [4, 3, (2,3), v_6, l_{11}]$		

The example above shows how NWRCA* processes labels in the order of their f-value. As we observed in **It.6**, NWRCA* may capture a dominated solution in the absence of tie-breaking, but we discussed in **It.7** how the search refines the set $\mathcal{X}(v_g)$ in such circumstances to keep **resources** of solution paths non-dominated. We now briefly discuss the key differences of NWRCA* with two recent RCSP approaches, namely ERCA* and RCBDA*.

NWRCA* vs. ERCA*. Although both algorithms utilize best-first search to guide their constrained search, they differ in four key aspects regarding how labels are handled: (1) ERCA* checks labels for both dominance and resource usage once during expansion and again before expansion, whereas NWRCA* performs upper bound pruning only during expansion and dominance check only before expansion; (2) ERCA* explores labels in lexicographical order of their **resources** in case of ties between f-values in the queue (i.e., it compares labels based on resources in order, starting from the first resource), whereas NWRCA* does not perform tie-breaking; (3) ERCA* uses a specialized and relatively complex data structure (balanced binary search tree) to organize and dominance check labels during the search, whereas expanded labels in NWRCA* are stored in simple lists; (4) ERCA* immediately terminates upon finding a feasible solution, whereas NWRCA* terminates with all non-dominated solutions.

NWRCA* vs. RCBDA*. The algorithms differ in four key aspects: (1) RCBDA* conducts a bidirectional A* search, requiring a specialized and time-intensive procedure to handle frontier collisions (joining bidirectional labels), whereas NWRCA* performs a simple unidirectional search. (2) RCBDA* checks new labels for dominance against all previous expansions of the

vertex, whereas NWRCA* only checks against labels with non-dominated **resources**; (3) RCBDA* checks labels for dominance only during expansion, which can lead to the expansion of dominated labels, whereas NWRCA* performs dominance checks before expansion; (4) Similar to ERCA*, RCBDA* does not compute all non-dominated solutions.

4 Theoretical Results

This section provides a formal proof for the correctness of constrained search of NWRCA* and presents theoretical results on why the algorithm can solve RCSP instances with negative weights but no negative cycles. Throughout this section, we assume there is no negative cycle on any path from start vertex (v_s) to goal vertex (v_g) in any dimension, and thus consistent and admissible heuristic functions h_c and $\mathbf{h}_r$ can be computed for the problem instance.

▶ **Lemma 3.** *Assume the constrained A* search is guided by smallest (potentially negative) f-values. Let l_i and l_{i+1} be labels extracted from $\mathcal{Q}$ in two consecutive iterations of the search. We have $f_{l_i} \leq f_{l_{i+1}}$ if h_c is consistent.*

Proof. We distinguish two cases: i) if l_{i+1} was available in $\mathcal{Q}$ at the time l_i was extracted, the lemma is trivially true. ii) otherwise, l_{i+1} is the descendant label of l_i. For an edge (v, u) linking l_i to its descendant l_{i+1}, h_c's consistency ensures $h_c(v) \leq h_c(u) + cost(v, u)$. Adding the cost g_{l_i} to both sides of the inequality yields $f_{l_i} \leq f_{l_{i+1}}$. ◀

▶ **Corollary 4.** *Consider the sequence of labels $(l_1, l_2, ..., l_t)$ extracted from $\mathcal{Q}$. If h_c is consistent, then according to the conditions of Lemma 3, $i \leq j$ guarantees that $f_{l_i} \leq f_{l_j}$. In other words, the f-values of the extracted labels do not decrease throughout the process.*

▶ **Lemma 5.** *Suppose l' is extracted after l, both with the same vertex. l weakly dominates l' if $\mathbf{r}_l \preceq \mathbf{r}_{l'}$.*

Proof. Since l is extracted before l', we have $f_l \leq f_{l'}$ according to Corollary 4, and consequently $g_l \leq g_{l'}$. The other condition $\mathbf{r}_l \preceq \mathbf{r}_{l'}$ means that l' is no smaller than l in all resources, verifying l' is weakly dominated by l. ◀

▶ **Lemma 6.** *Let l' be a label weakly dominated by a previously explored label l, both associated with the same vertex. The expansion of l' is not necessary.*

Proof. We prove this by contradiction, assuming that l's expansion is necessary to obtain a *cost*-optimal and non-dominated solution path. As l weakly dominates l', it holds that $g_l \leq g_{l'}$ and $\mathbf{r}_l \preceq \mathbf{r}_{l'}$. In this scenario, the partial path represented by l' can be replaced with the one represented by l, resulting in a path that is better than or equal to the optimal solution path obtained via l'. If the resulting path is better, it contradicts the assumption of l''s expansion leading to a non-dominated or optimal solution. If both paths are identical in terms of *cost* and **resources**, it becomes clear that the expansion of l has been sufficient, and thus expanding l' is unnecessary, again contradicting the assumption. Therefore, we conclude that expanding the weakly dominated label l' is not necessary. ◀

▶ **Lemma 7.** *The expansion of label l is not necessary if $f_l \not\leq \overline{f}$ or $\mathbf{r}_l + \mathbf{h}_r \not\preceq \mathbf{R}$.*

Proof. Given that $\mathbf{h}_r$ is admissible, the second condition ensures that expanding l towards v_g cannot yield a solution within the resource limits. Similarly, since h_c is admissible, the first condition guarantees that l's expansion cannot produce a solution with a *cost* better than the best-known upper bound $\overline{f}$. Therefore, expanding l cannot contribute to any optimal solution path, and thus is not necessary. ◀

▶ **Theorem 8.** *NWRCA* produces all cost-optimal solution paths with non-dominated resources for the RCSP problem.*

Proof. The algorithm explores all feasible search labels from v_s towards v_g in best-first order, in search of all optimal solutions. Labels are checked for dominance (Lemma 5) before expansion, and weakly dominated ones can be safely pruned, as they offer no improvement over previously expanded labels (with the same vertex) in either *cost* or **resources** (Lemma 6). Labels violating the upper bounds can similarly be pruned safely (Lemma 7). The algorithm also retains only non-dominated labels in the $\mathcal{X}$ lists. This procedure is correct because if a recently extracted label l' weakly dominates a previously explored label l, then any future label l'' that would have been weakly dominated by l is already weakly dominated by l', rendering the storage of l redundant. Building on the above, we just need to show that the algorithm terminates with returning non-dominated labels. NWRCA* prunes all weakly dominated labels, but captures all non-dominated labels with v_g. However, since it does not process labels in any specific order of their **resources**, some tentative solutions may later appear dominated. Let l' be a new non-dominated solution extracted after solution l. We must have $f_l = f_{l'}$, otherwise the algorithm was terminated if $f_{l'} > \overline{f} = f_l$. In this case, the dominance check in lines 18-19 of Algorithm 1 removes l from $\mathcal{X}(v_g)$ if it is deemed to be weakly dominated by new solution l' (in terms of **resources**). Once the search exceeds $\overline{f}$, Corollary 4 ensures that expanding the remaining labels in $\mathcal{Q}$ cannot produce solutions with a primary cost better than $\overline{f}$. Thus, the termination criterion is correct, and NWRCA* returns $\mathcal{X}(v_g)$ as the set of all *cost*-optimal, non-dominated solution labels. ◀

5 Empirical Analysis

We evaluate the constrained search performance of NWRCA* against two recent A*-based RCSP approaches: the award-winning RCBDA* algorithm [31] and ERCA* [27]. We did not consider BiPulse [10] as prior work [27] has demonstrated that it is outperformed by ERCA*. The algorithms were evaluated on 600 instances across three maps (NY, BAY, and COL) from the 9th DIMACS Implementation Challenge[1], featuring road networks with 264K to 435K vertices and 733K to 1M edges. For each map, we generated 25 random (v_s,v_g) pairs to be evaluated on four levels of tightness, resulting in 100 test cases. We study each test case in scenarios with two and three resources ($d = 2, 3$). Following the RCSP literature, we define each resource limit R_k for $k \in \{1, \ldots, d\}$ based on the tightness of the constraint τ as:

$$\tau = \frac{R_k - h_{rk}}{ub_{rk} - h_{rk}} \quad \text{for } \tau \in \{20\%, 40\%, 60\%, 80\%\}$$

where ub_{rk} and h_{rk} represent the upper and lower bounds on $resource_k$ for paths from v_s to v_g, respectively. The upper bound is set by the (non-constrained) *cost*-optimal path. We choose the same τ for all resources.

To evaluate the algorithms on graphs with non-correlated but negative weights, following our previous work [1], we first enriched each map with Shuttle Radar Topography Mission[2] height data, and set the edge weights of each map with four new attributes as follows. The *cost* of each edge is the energy requirement of an electric vehicle with three passengers on board, using the energy model in [7]. The calculated energy can be negative in some downhill links due to energy recuperation. We deliberately did not impose a bound on

[1] http://www.diag.uniroma1.it/challenge9
[2] https://www2.jpl.nasa.gov/srtm/

battery capacity, enabling the use of plain constrained search for computing energy-efficient paths. We chose a penalized height function for $resource_1$. Given $height(v)$ as elevation of vertex v, the second attribute of link $(v,u) \in E$ is set to $2 \times (height(u) - height(v))$ for uphill links, and $height(u) - height(v)$ for downhill links (negative). For $resource_2$ and $resource_3$, we employed the (reversed) Johnson's technique to generate cycle-free but random negative weights in two steps: i) we first assigned a random integer in the [-100,0] range, known as potential, to each vertex; ii) we then set the third cost of each link $(v,u) \in E$ to be the potential difference between v and u, which was then added by a random integer in the [0, 10] range. The result is two sets of randomized negative weights in the [-100, 110] range with no negative cycle, which ensures the applicability of the selected algorithms over the instances. Note that the first and second dimensions cannot contain negative cycles due to the nature of the chosen metrics. The average percentage of negative weights observed across the maps for $[cost, resrource_1, resrource_2, resrource_3]$ is [10, 42, 45, 45]%, respectively.

Implementation. We used the publicly available C++ implementations of ERCA* and developed an improved version of RCBDA* in C++ based on its provided description. In doing so, we addressed a potential inefficiency in the design related to the label matching strategy of RCBDA*: rather than storing all expanded labels in a large pool and searching for complimentary labels (which adds unnecessary overhead in identifying the same matching vertex), we allocated a separate set for each vertex, optimizing the matching of partial paths during the bidirectional search. Additionally, the original description of RCBDA* does not include any dominance or infeasibility pruning rules. Nonetheless, our implementation incorporates these strategies, thereby improving its search efficiency. Both RCBDA* and ERCA* were provided with reweighted graphs (and budgets), ensuring that instances can be handled correctly in the presence of negative weights. We implemented our NWRCA* algorithm in C++, providing two variants that differ slightly in their label ordering mechanisms:

- NWRCA*$_{v1}$: (i) labels in $\mathcal{X}$ lists are maintained in lexicographical order based on their **r**-value, (ii) unexplored labels are ordered in a bucket-based queue and extracted using a LIFO strategy in the event of ties in their f-values (as in WCA* [6]).
- NWRCA*$_{v2}$: (i) labels in $\mathcal{X}$ lists are not maintained in any specific order, (ii) unexplored labels are ordered in a binary heap queue and extracted in lexicographical order of their resource estimates (i.e., $\mathbf{r} + \mathbf{h}_r$) in the event of ties in their f-values.

These variants allow us to investigate the impact of lexicographical label ordering in both $\mathcal{X}$ and $\mathcal{Q}$ lists on search performance. Note that the correctness of NWRCA* does not depend on labels being ordered lexicographically by *cost* and **resources** in $\mathcal{Q}$. Keeping non-dominated labels in lexicographical order within each $\mathcal{X}$ list in the first variant allows for partial traversal over labels of the list for both dominance checking and removal of dominated labels, but it incurs an additional sorting overhead (see [1] for more details). In contrast, the second variant provides faster insertion/removal of labels to/from the list (with minimal ordering overhead), but requires two linear scans over all labels in $\mathcal{X}$, one to ensure that a newly extracted label is non-dominated and another to remove any dominated labels from the list.

We compiled all C++ code using the GCC7.5 compiler and optimization level O3. The experiments were conducted on a single core of an Intel Xeon Platinum 8175 processor, clocked at 2.5GHz, with 16GB of RAM and a one-hour time limit per run. It is worth mentioning that RCBDA* and both variants of NWRCA* were implemented within the same framework, using the same data structures to manage labels. Therefore, the performance comparisons between the algorithms are head-to-head. Our code is publicly available[3].

		Instances with two resources $d = 2$					Instances with three resources $d = 3$				

Computation of heuristics. Our first analysis explores two approaches for computing heuristic functions for instances with three resources: (i) graph reformulation using Johnson's technique (as in ERCA*), and (ii) a modified version of Dijkstra's algorithm that allows for re-expansions. For the first approach, we used the improved Bellman-Ford algorithm [23, 8, 14] to reweight edge costs, followed by Dijkstra's to compute lower bounds. In case of RCBDA*, two rounds of lower-bound computation are required (one for the forward search and another for the backward search). Table 2 compares the average computation time for both approaches, assuming unidirectional heuristics are needed (as in ERCA* and NWRCA*). We observe that, the approach (i) requires a considerable amount of time to preprocess the graphs but enables faster computation of lower bounds, whereas the second approach, using modified Dijkstra's algorithm, delivers 3.5 to 4 times faster *overall* processing time without the need for reweighting in our (sparse) road networks. While approach (ii) can be advantageous in scenarios where the graph configuration changes between queries, it may be up to twice as slow compared to approach (i) when the search graph is static and already reweighted, though the difference is less than 0.5 seconds. Nonetheless, computing heuristic functions for NWRCA* using approach (ii) offers several benefits: i) it provides a simple yet efficient setup for constrained A* search with negative weights; ii) it eliminates the need for a time-intensive graph reformulation step, which is advantageous in dynamic scenarios; iii) it performs comparably to conventional methods when weights are non-negative (would be equivalent to standard Dijkstra).

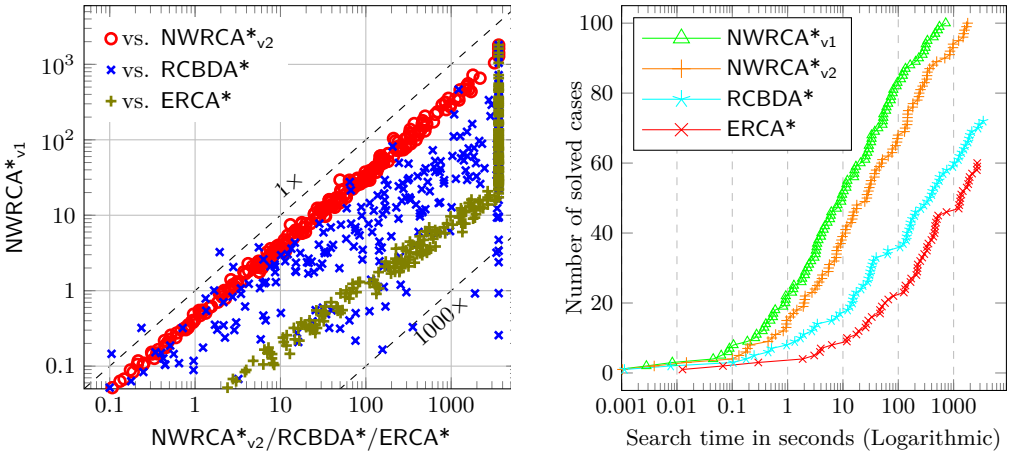

Figure 2 (Left) Runtime distribution of NWRCA*$_{v1}$ versus NWRCA*$_{v2}$ and the two other algorithms over all instances with $d = 3$. (Right) Algorithms' performance over the instances of the COL map with $d = 3$ (solved cases sorted based on runtime).

Algorithmic performance. Table 3 presents the experimental results for both scenarios ($d = 2, 3$). It displays the number of test cases successfully solved ($|\mathcal{P}|$), the arithmetic and geometric mean (Mean_A and Mean_G) and maximum constrained runtime observed (in seconds) by each algorithm. To enable a fair comparison of actual search performance across algorithms, and since all algorithms use same heuristic functions, we exclude preprocessing times (graph reformulation and lower bounding) from our runtime analyses. Therefore, the runtimes reported in this table refer solely to resource-constrained search time. All algorithms solved their easiest instances in less than 0.1 seconds. For unsolved cases, the search time is recorded as the timeout. It can be observed that both variants of NWRCA* have successfully solved almost all instances for each map in both scenarios, except for the BAY map where NWRCA*$_{v2}$ leaves four instances unsolved. The outperformance is even more pronounced in the BAY and COL maps with $d = 3$, where ERCA* and RCBDA* could solve less than 75% of cases. In terms of computation time, both variants of NWRCA* deliver significantly better performance than ERCA* and RCBDA* in all metrics. The detailed results reveal that NWRCA*$_{v1}$ consistently outperforms other algorithms, including NWRCA*$_{v2}$, across nearly all instances, successfully solving its most challenging case in under 31 minutes.

The parameter ϕ in the last column of Table 3 presents the (arithmetic) average slowdown factor for each algorithm relative to the top-performing algorithm, NWRCA*$_{v1}$. This factor is calculated by comparing the search time of each mutually solved instance with the corresponding search time of NWRCA*$_{v1}$, highlighting the relative slowdown. We also show in Figure 2 (Left) the runtime distribution of NWRCA*$_{v1}$ against other algorithms over instances of all maps with three resources ($d = 3$). Based on the results, NWRCA*$_{v2}$ performs nearly 2.5 times slower than NWRCA*$_{v1}$. This difference in performance is primarily due to NWRCA*$_{v2}$'s costly queuing process, which requires lexicographical ordering of labels in $\mathcal{Q}$ (tie-breaking with **resources**), and NWRCA*$_{v1}$'s more efficient label pruning mechanism. This improved pruning efficiency, in particular, stems from the partial traversal of the $\mathcal{X}$ lists, where non-dominated labels are maintained in lexicographical order of their **resources**.

Larger slowdown factors are observed for ERCA* and RCBDA*, with both algorithms being outperformed by up to two orders of magnitude on average. The more than one order of magnitude performance gap between ERCA* and NWRCA* is primarily due to NWRCA*'s more efficient lazy pruning strategy and its simpler yet effective data structure for dominance

checks, both contributing to significantly faster search times. In contrast, ERCA* suffers from a more rigid dominance pruning strategy that attempts to eliminate dominated and infeasible labels both at generation time and again upon extraction from the queue. While early dominance checks can help reduce queue size, they add computational overhead when applied to non-dominated labels. Furthermore, rechecking resource feasibility after extraction is redundant, as resource limits remain unchanged throughout the search, resulting in wasted computation and reduced efficiency.

Figure 2 (Right) also shows the number of solved cases for each algorithm, sorted by runtime, on the COL map with three resources. We observe that both variants of NWRCA* solve 60% of instances within 50 seconds, whereas ERCA* and RCBDA* require above 17 minutes to achieve the same success rate. In summary, both variants of NWRCA* demonstrate significantly faster performance than the state of the art in terms of computation time, with NWRCA*$_{v1}$ being approximately twice as fast as NWRCA*$_{v2}$.

ERCA* vs. RCBDA*. No performance comparison was provided between ERCA* and RCBDA* by the authors of ERCA*. Our results show that, while the improved RCBDA* algorithm solves more instances and achieves better average runtimes than ERCA* on certain maps, it does not consistently outperform ERCA*. The strong performance of RCBDA* in many instances is due to its bidirectional framework, which combines perimeter and alternating search strategies. In terms of worst-case runtime performance (Figure 2 (Left)), ERCA* generally performs better than RCBDA* but tends to be consistently around two orders of magnitude slower than NWRCA*$_{v1}$, whereas RCBDA* can be over three orders of magnitude slower than NWRCA*$_{v1}$ in some cases.

6 Conclusion

This paper introduced a novel, fast heuristic-guided label-setting approach with effective pruning mechanisms for efficiently solving resource-constrained shortest path (RCSP) problems in large-scale graphs. Unlike existing methods that aim to find a feasible solution, our framework identifies all non-dominated optimal solutions for a given RCSP instance. It also naturally handles instances with negative costs and resources, provided the cost heuristic is consistent and the search graph contains no negative cycles. We explored different configurations of the framework, distinguished by how heuristics are derived and how search labels are stored and explored during the search process. Experimental results highlight the importance of efficient ordering of labels in constrained search over large graphs and demonstrate the superiority of the proposed framework in solving challenging RCSP instances within tight time limits, outperforming state-of-the-art methods, including an enhanced version of the award-winning RCBDA* algorithm, by up to two orders of magnitude on average.

Fine-Grained Classification of Detecting Dominating Patterns

Jonathan Dransfeld

Mirza Redzic
Karlsruhe Institute of Technology, Germany

Abstract

We consider the following generalization of dominating sets: Let G be a host graph and P be a pattern graph P. A dominating P-pattern in G is a subset S of vertices in G that (1) forms a dominating set in G *and* (2) induces a subgraph isomorphic to P. The graph theory literature studies the properties of dominating P-patterns for various patterns P, including cliques, matchings, independent sets, cycles and paths. Previous work (Kunnemann, Redzic 2024) obtains algorithms and conditional lower bounds for detecting dominating P-patterns particularly for P being a k-clique, a k-independent set and a k-matching. Their results give conditionally tight lower bounds if k is sufficiently large (where the bound depends the matrix multiplication exponent ω). We ask: Can we obtain a classification of the fine-grained complexity for *all* patterns P?

Indeed, we define a graph parameter $\rho(P)$ such that if $\omega = 2$, then

$$\left(n^{\rho(P)} m^{\frac{|V(P)|-\rho(P)}{2}}\right)^{1\pm o(1)}$$

is the optimal running time assuming the Orthogonal Vectors Hypothesis, for all patterns P except the triangle K_3. Here, the host graph G has n vertices and $m = \Theta(n^\alpha)$ edges, where $1 \leq \alpha \leq 2$.

The parameter $\rho(P)$ is closely related (but sometimes different) to a parameter $\delta(P) = \max_{S \subseteq V(P)} |S| - |N(S)|$ studied in (Alon 1981) to tightly quantify the maximum number of occurrences of induced subgraphs isomorphic to P. Our results stand in contrast to the lack of a full fine-grained classification of detecting an arbitrary (not necessarily *dominating*) induced P-pattern.

1 Introduction

Among the most intensively investigated graph problems is the dominating set problem: Given a graph $G = (V, E)$, find a (small) vertex subset $S \subseteq V$ that *dominates* all vertices, i.e., for each $v \in V$, we have $v \in S$ or there is some $s \in S$ with $\{s, v\} \in E$. In many scenarios, one might not merely want to find *any* dominating set, but rather a dominating set S satisfying some additional requirements. Possibilities include S forming a connected subgraph, admitting a perfect matching, or more generally being connected by a prescribed topology (e.g., rings or cliques) or even being fully disconnected (i.e., forming an independent

set). In this work, we study a general form of such problems: For any pattern graph H, the (Non-induced) Dominating P-Pattern problem asks to determine, given a graph G, whether there exists a (non-)induced copy of P in G that dominates all vertices of G.

Indeed, for various patterns P, the structural properties of Dominating P-Patterns have been well investigated, e.g., Dominating Cliques [5, 7, 12, 15, 26, 27, 28], Dominating Independent Sets[1] [8, 9, 10, 29, 34], Dominating (Induced) Matchings [22, 37, 38], Dominating Cycles [17, 18] or Dominating Paths [19, 20, 42]. Recently, the algorithmic complexity of detecting Dominating P-Patterns in general graphs has been performed by Künnemann and Redzic, focusing on cliques, independent sets and perfect matchings [30] (see below for further details). In this work, we set out to understand the fine-grained complexity of this problem for *all* patterns P.

Note that the Dominating P-Pattern problem is the natural combination of two classic problems which are heavily studied in isolation: Dominating Set and P-Pattern Detection.

- *k-Dominating Set*: Dominating set is a notoriously difficult problem. When parameterized by the solution size k (i.e., $|S|$), it is the arguably most natural W[2]-complete problem and hard even to approximate within $f(k)$ factors [6, 24]. The best known algorithm is based on fast matrix multiplication and solves it in time $n^{k+o(1)}$ for all sufficiently large k [16]. This is tight in the sense that an $\mathcal{O}(n^{k-\epsilon})$-time algorithm for any $k \geq 3$ and $\epsilon > 0$ would refute the k-Orthogonal Vectors Hypothesis (k-OVH) and thus the Strong Exponential Time Hypothesis [36] (see Section 2 for details). Taking the graph sparsity (i.e., the number m of edges) into account as well, a recent result [21] gives upper and conditional lower bounds establishing a tight time complexity of $mn^{k-2\pm o(1)}$ if the matrix multiplication exponent ω is equal to 2.
- *P-Pattern Detection (aka Induced P-Subgraph Isomorphism):* The complexity of P-Pattern Detection for general P is sensitive to the considered pattern P. The probably most notable special case is k-Clique Detection. It is the most natural $W[1]$-complete problem and also resists good approximations [6, 31, 23]. Its best known algorithm solves it in time essentially $\mathcal{O}(n^{\frac{\omega}{3}k})$ [33][2] and is conjectured to be optimal, see, e.g., [1]. For other (classes of) patterns P, however, only partial results are known: While for any k-node pattern P, the problem can be reduced to k-Clique Detection, this approach is not necessarily optimal. E.g., all 4-node patterns except clique and independent set can be detected polynomially faster than the conjectured time for clique and independent set, see in particular [25, 16, 39, 13]. Despite significant effort (see [25, 16, 39, 14, 13] for a selection), the task of finding matching upper and conditional lower bounds appears far from completed. Let us remark that also for Non-induced P-Pattern Detection a fine-grained classification of all patterns P remains open (see, e.g., [32, 13]).

We ask: *How does the time complexity of Dominating P-Pattern relate to the complexity of P-Pattern Detection versus to the complexity of k-Dominating Set?* Can we, despite the lack of a complete classification for P-Pattern Detection classify the fine-grained complexity of **all** *dominating* patterns?

Previous work appears to indicate that the complexity should be governed by the domination aspect: By adapting the conditional lower bound of Patrascu and Williams for k-Dominating Set [36] (see also [21, 30]) it is not too difficult to obtain a conditional lower

[1] We remark that a Dominating Independent Set is equivalent to the well-studied notion of a Maximal Independent Set.
[2] If k is divisible by 3.

bound of $n^{k-o(1)}$ in dense graphs for *any* pattern P, based on k-OVH. However, the situation becomes much more interesting for *sparse* graphs. Here, it has already been observed that the fine-grained time complexity is highly sensitive to the specific pattern P. Specifically, Künnemann and Redzic [30] give some curious insights into selected patterns: (Here, to simplify the presentation, we assume that $\omega = 2$ and that k-OVH holds.)

- If P is the k-star (a tree with a root and $k-1$ leaves), the tight time complexity is $mn^{k-2\pm o(1)}$, i.e., even in very sparse graphs with $m = \Theta(n)$, we only save a linear factor in n compared to the $n^{k\pm o(1)}$ complexity in dense graphs.
- In contrast, if P is the clique with $k \geq 5$ vertices or the independent set with $k \geq 3$ vertices, we obtain a particularly simple case with tight time complexity of $(m^{\frac{k+1}{2}}/n)^{1\pm o(1)}$. In very sparse graphs with $m = \mathcal{O}(n)$, the resulting running time of $n^{\frac{k-1}{2}\pm o(1)}$ is less than the square root of the running time of $n^{k\pm o(1)}$ in dense graphs.
- Finally, the substantially different pattern of a perfect matching on $k \geq 4$ vertices achieves the only slightly worse time complexity of $m^{\frac{k}{2}\pm o(1)}$.

We remark that the above results suggest that in sparse graphs, Dominating P-Pattern shares an additional flavor with the P-Pattern *Enumeration* problem: It is not too difficult to obtain an algorithm whose running time is roughly bounded by the time required to list all occurrences of the pattern P. However, it turns out that this number alone cannot fully explain the time complexity: While for the case of perfect matchings, the time complexity coincides precisely with the maximum number of occurrences of the pattern, for others (e.g., independent sets or cliques), the time complexity is polynomially less than the maximum number of occurrences of the pattern. This begs the question: which other parameter of the pattern P captures the time complexity of Dominating P-Pattern?

Our results. To state the time complexity for any pattern P, we introduce the following graph parameter $\rho(P)$. Here for any graph P and $S \subseteq V(P)$, we let $N(S)$ denote the (open) neighborhood of the vertices S, where $N(\emptyset) = \emptyset$.[3]

▶ **Definition 1.1.** *Let P be an arbitrary pattern graph, and denote by $I(P) \subseteq V(P)$ the set of isolated nodes of P. Choose an* independent *set $S \subseteq V(P) \setminus I(P)$ maximizing $|S| - |N(S)|$; if S is not uniquely defined, take any choice maximizing $|S|$. We define*

$$\rho(P) := \begin{cases} |S| - |N(S)| & \text{if } S \neq \emptyset \\ -1 & \text{if } S = \emptyset. \end{cases}$$

and set

$$t_P(n,m) := n^{\rho(P)} \cdot m^{\frac{|V(P)|-\rho(P)}{2}}.$$

These quantities turn out similar (but sometimes different) to the maximum number of occurrences of the pattern graph P for patterns *without isolated nodes* (i.e., $I(P) = \emptyset$). Specifically, if $I(P) = \emptyset$ and $S \neq \emptyset$, the maximum number of induced copies of P in an n-vertex m-edge graph G is $\Theta(t_P(n,m))$. Indeed, for connected graphs G and patterns P, Alon [3] defines the parameter $\delta(P) := \max_{S \subseteq V(P)} |S| - |N(S)|$ and establishes $\Theta(n^{\delta(P)} m^{\frac{|V(P)|-\delta(P)}{2}})$ as the maximum number of induced copies of P in G whenever G has $m = \Theta(n)$ edges

[3] For any graph G, we will always denote by $V(G)$ and $E(G)$ its set of vertices and edges, respectively.

(which generalizes to arbitrary $m \geq n$).[4] Note that $\rho(P)$ and $\delta(P)$ may only differ for some patterns P with $\delta(P) = 0$, in which case $\rho(P) \in \{0, -1\}$. In contrast, if P contains isolated nodes (e.g., the case of Dominating Independent Set), the number of occurrences of P and $t_P(n, m)$ may differ vastly (e.g., between $\Theta(n^k)$ and $\Theta(m^{k/2})$).

Our results determine that for all patterns (possibly except the triangle K_3), $t_P(n, m)^{1\pm o(1)}$ is the conditionally tight time complexity of detecting a Dominating P-Pattern if $\omega = 2$. Put differently, for any pattern P (except K_3), we can easily determine the conditionally optimal running time (assuming $\omega = 2$)! Specifically, we obtain the following algorithmic result:

▶ **Theorem 1.2** (Upper Bound). *For any pattern graph P with at least 16 vertices, there is an algorithm solving Dominating P-Pattern problem in time $t_P(n, m)^{1+o(1)}$. Further, if $\omega = 2$, this algorithm exists for all patterns P except K_3.*

We remark that our algorithms have a running time close to $t_P(n, m)^{1\pm o(1)}$ even under current values of ω and small pattern sizes – the small polynomial overhead depends on ω and vanishes if $\omega = 2$ (except for the triangle K_3). Further, we complement our algorithmic result by a corresponding conditional lower bound of $t_P(n, m)^{1-o(1)}$ based on the k-Orthogonal Vectors Hypothesis (and thus the Strong Exponential Time Hypothesis).

▶ **Theorem 1.3** (Conditional Lower Bound). *For any pattern graph P with at least 2 vertices, there is no algorithm solving the P-Dominating Set problem in time $\mathcal{O}(t_P(n, m)^{1-\varepsilon})$ for any $\varepsilon > 0$ unless the k-Orthogonal Vectors Hypothesis fails.*

The only pattern P for which we do not obtain an algorithm matching the lower bound of Theorem 1.3 is the triangle K_3. For this pattern, our best algorithm only leaves a time overhead of $m^{1/3+o(1)}$ if $\omega = 2$, yielding a bound of $(t_{K_3}(n, m) \cdot m^{\frac{1}{3}})^{1+o(1)} = (m^{\frac{7}{3}}/n)^{1+o(1)}$ in this case.

▶ **Theorem 1.4.** *We can solve Dominating Triangle in time $\left(m^{1+\frac{2\omega}{\omega+1}}/n\right)^{1+o(1)}$.*

Technical Outline and Overview. In Section 3, we obtain our algorithmic results: We first study sufficiently large connected patterns P (different from K_3 and K_4), which we call *basic patterns*. We argue that there are only $\mathcal{O}(t_P(n, m))$ sets that might form a Dominating P-Pattern (using similar arguments to Alon [3]). Moreover, we show how to enumerate all such candidate sets in time $t_P(n, m)^{1+o(1)}$ in such a way that allows us to reduce to fast matrix multiplication to perform a dominance check as in Eisenbrand and Grandoni [16]. Notably, this approach introduces a polynomial overhead for K_3 and K_4, as the created matrices are too large compared to the lower bound. We handle these cases separately: Using a careful combination of ideas from sparse Triangle Counting [4] and sparse 2-Dominating Set [21], we are able to improve the algorithms for K_4 and K_3; if $\omega = 2$, this completely eliminates the overhead for K_4 and reduces the overhead for K_3 to $m^{1/3+o(1)}$. Finally, we extend our algorithm beyond connected patterns by showing how to handle isolated nodes:

[4] To clarify the correspondence, we remark that already Alon (see [3, proof of Lemma 8]) observed that in the definition of $\delta(P)$, one may without loss of generality let S range only over independent sets: for any set S maximizing $|S| - |N(S)|$, the set $S' = S \setminus (S \cap N(S))$ is an independent set with $|S'| - |N(S')| \geq |S| - |N(S)|$. Thus, whenever a nonempty set S maximizes $|S| - |N(S)|$, we have $\rho(P) = \delta(P)$. Alon proves that a connected m-edge graph G has a maximum number of $\Theta(m^{\frac{|V(P)|+\delta(P)}{2}})$ induced copies of P, where P is any connected pattern. The generalization to an arbitrary trade-off between n and m is implicit in our proofs.

We can no longer enumerate all candidate sets, as this number becomes too large. Instead, we apply a recursive approach similar to the algorithm for Dominating Independent Sets given in [30]. Here, particularly the case of a single isolated node requires great care.

Due to space reasons, our conditional lower bounds had to be deferred to the full version of the paper. Our conditional lower bound construction generalizes the ones in [30] (which in turn are based on [36, 21]): Specifically, we reduce from a version of the k-OV problem with carefully chosen set sizes. Intuitively, the parameter $\rho(P)$ spells out how to choose these sizes: (1) for every vertex $v \in S$, we have a set of n vectors, (2) for every vertex $v \in N(S)$, we have a set of m/n vectors, and (3) for every vertex $v \in V(P) \setminus (S \cup N(S))$, we have a set of $\sqrt{m}$ vectors. The precise construction requires care; in particular if $S = \emptyset$, we need to use an alternative choice of a single set of m/n vectors and $k-1$ sets of $\sqrt{m}$ vectors.

We additionally study variants of Dominating P-Pattern where we are given a set $\mathcal{Q}$ of patterns rather than a single pattern. The corresponding problem Dominating $\mathcal{Q}$-Pattern asks to detect a dominating set S that induces a subgraph isomorphic to *some* $P \in \mathcal{Q}$. A notable special case is the Non-Induced Dominating P-Pattern problem in which the task is to detect a dominating set S such that $G[S]$ contains P as a subgraph. Combining the following theorem with Theorems 1.2 and 1.3, our results settle the fine-grained complexity of Non-Induced Dominating P-Pattern for any pattern P except K_3 (assuming $\omega = 2$).

▶ **Theorem 1.5** (Dominating $\mathcal{Q}$-Pattern, Informal version). *Let Q be a finite set of patterns of identical order. The fine-grained complexity of Dominating $\mathcal{Q}$-Pattern is dominated by the pattern $P \in \mathcal{Q}$ with the highest time complexity.*

Due to the space restrictions, the proof of this theorem is provided only in the full version of the paper.

2 Preliminaries

For a $n \in \mathbb{N}$, $[n]$ denotes the set $\{1, \ldots, n\}$. For a set X, its power set is denoted by 2^X and the set of all subsets of size k by $\binom{X}{k}$. For two sets X, Y, by $X \times Y$ we denote a set of unordered pairs, i.e. $X \times Y := \{\{x, y\} \mid x \in X, y \in Y\}$. For a pattern graph P and a host graph G, we use k and n, respectively, to denote their order, i.e., number of vertices. As a shorthand for $\{u, v\}$, the notation uv denotes an edge between u and v. The set $N(v) = \{u \mid uv \in E\}$ is the *neighborhood* of v. The *closed neighborhood* of v is $N[v] = N(v) \cup \{v\}$. For a set of vertices $S \subseteq V$, by $N(S)$ (resp. $N[S]$), we denote the set $\bigcup_{v \in S} N(v)$ (resp. $\bigcup_{v \in S} N[v]$). Moreover, the subgraph of G *induced* by S is denoted by $G[S]$. For a vertex $v \in V$, the graph $G - v$ denotes the graph G with the vertex v deleted. Likewise, for a set $X \subseteq V$, we use $G - X := G[V \setminus X]$. A set of vertices $D \subseteq V$ dominates the graph G if every vertex of v is either in D or has a neighbor in D.

The matrix multiplication exponent $\omega \geq 2$ is the smallest constant such that there is an algorithm multiplying any two $n \times n$ matrices in $n^{\omega + o(1)}$ time. For two rectangular matrices of size $n_1 = n \times n_2$ and $n_2 \times n_3$, $\mathrm{MM}(n_1, n_2, n_3)$ denotes the time complexity of multiplying these matrices. Similarly, for matrix of size $n^a \times n^b$ and $n^b \times n^c$, $n^{\omega(a,b,c)+o(1)}$ denotes the time complexity of multiplying them. Further, $\alpha \leq 1$ is the largest constant such that $\omega(1, \alpha, 1) = 2$. The best known bounds for α and ω are $\omega \leq 2.3713$ [2], and $\alpha \geq 0.3213$ [41].

3 Algorithm for Pattern Dominating Set

In this section we develop the algorithms for Dominating P-Pattern problem for different choices of patterns P and prove the following main theorem as stated in the Introduction.

▶ **Theorem 1.2** (Upper Bound). *For any pattern graph P with at least 16 vertices, there is an algorithm solving Dominating P-Pattern problem in time $t_P(n,m)^{1+o(1)}$. Further, if $\omega = 2$, this algorithm exists for all patterns P except K_3.*

In order to prove this theorem, we proceed in three steps. We first develop algorithms for a class of patterns P we call *basic*: all patterns that contain no isolated vertices and are not isomorphic to a K_3 or K_4. We then handle patterns with isolated vertices and the remaining small cliques K_3, K_4 separately. An important ingredient that we use to speed up the dominance check is an approach via fast matrix multiplication due to Eisenbrand and Grandoni [16].

▶ **Lemma 3.1.** *Let X, Y be the sets of vertices and $\phi : 2^X \to \{0,1\}$ be a predicate such that for any $D \subseteq X$ we can check $\phi(D)$ in constant time. Let $\mathcal{V}_A, \mathcal{V}_B \subseteq 2^X$ be sets of subsets of X such that any subset $D \subseteq X$ that satisfies ϕ can be written as a union of two sets $A \in \mathcal{V}_A$ and $B \in \mathcal{V}_B$. Then in time $\mathrm{MM}(|\mathcal{V}_A|, |Y|, |\mathcal{V}_B|)$ we can enumerate all subsets of X that satisfy ϕ and dominate Y.*

We remark that in the k-Dominating Set algorithm [16], the predicate $\phi(D)$ from the previous lemma is true if $|D| = k$ and false otherwise. In our case, for a fixed pattern P, the predicate $\phi(D)$ will be true if the subgraph of G induced by D is isomorphic to P (i.e. $G[D] \cong P$).[5] Recall also our definition of the parameter $\rho(P)$, which will be relevant in this section.

▶ **Definition 1.1.** *Let P be an arbitrary pattern graph, and denote by $I(P) \subseteq V(P)$ the set of isolated nodes of P. Choose an* independent *set $S \subseteq V(P) \setminus I(P)$ maximizing $|S| - |N(S)|$; if S is not uniquely defined, take any choice maximizing $|S|$. We define*

$$\rho(P) \coloneqq \begin{cases} |S| - |N(S)| & \text{if } S \neq \emptyset \\ -1 & \text{if } S = \emptyset. \end{cases}$$

and set

$$t_P(n,m) \coloneqq n^{\rho(P)} \cdot m^{\frac{|V(P)|-\rho(P)}{2}}.$$

Let S be a (possibly empty) independent set of non-isolated vertices in P that maximizes the value $|S| - |N(S)|$ as in Definition 1.1. We define the *remainder* set R to be $V(P) \setminus N[S]$. The following observation follows directly from the fact that S is an independent set.

▶ **Observation 3.2.** *Let P be a pattern on k vertices and $S, N(S), R$ be as defined above. Then $S, N(S), R$ form a partition of $V(P)$.*

Before proceeding with the algorithm, we state another observation, that gives us a nice way to think about the value of $t_P(n,m)$ depending on whether set S is empty or not.

▶ **Observation 3.3.** *Let P be a pattern on k vertices and $S, N(S), R$ be the partition of $V(P)$ as defined above.*

- *If $S = \emptyset$, then $t_P(n,m) = \frac{m^{(k+1)/2+o(1)}}{n}$.*
- *If $S \neq \emptyset$, then $t_P(n,m) = t_{P[N[S]]}(n,m) \cdot m^{|R|/2}$.*

If we consider a partition into sets $S, N(S)$ and R similar as above, intuitively we have some structure on the parts S (independent set in P) and $N(S)$ (there exists a maximal matching that matches each vertex in $N(S)$ to a vertex in S), but we have very little structure on how the remainder set looks like. In the following lemma we show that we can decompose the remainder set R into much simpler subgraphs (disjoint edges and cycles).

[5] Note that verifying ϕ takes $f(|P|) = \mathcal{O}(1)$ time, for constant size patterns.

▶ **Lemma 3.4.** *Let S, $N(S)$ and R be a partition of $V(P)$ as defined above and assume that the induced subgraph $P[R]$ contains no isolated vertices. Then the following holds.*

- *There exists a spanning subgraph of $P[R]$ that is isomorphic to a disjoint union of edges and odd cycles.*
- *For any vertex $x \in R$, there exists a spanning subgraph of $P[R-x]$ that is isomorphic to a disjoint union of edges and odd cycles.*

The proof follows from a structural theorem proved in [11] together with the choice of the set S in Definition 1.1. For details we refer the reader to the full version of the paper. We are now equipped with all the tools we need to construct the algorithm for the first family of patterns P that we call *basic patterns*.

3.1 Basic Patterns

In this section we construct an algorithm that solves the P-Dominating Set problem in the (conditionally) optimal time for most of the patterns. More precisely, we say a pattern graph P is *basic* if: 1) it has at least three vertices; 2) it has no isolated vertices; 3) it is neither isomorphic to a K_3 nor a K_4. We prove the following theorem for basic patterns.

▶ **Theorem 3.5.** *For any basic pattern P on at least 16 vertices, there exists an algorithm solving the Dominating P-Pattern problem in time $t_P(n,m)^{1+o(1)}$. Moreover, if $\omega = 2$, this time complexity can be achieved for all basic patterns.*

The high level idea is to first decompose the pattern into (not necessarily induced) odd cycles, edges and isolated vertices, and then enumerate all possible *valid* choices for each of those parts efficiently, and then use Lemma 3.1 to check if the union of guessed parts induces a subgraph isomorphic to P, and if it dominates G. We first show that we can enumerate all subgraphs isomorphic to the remainder set R efficiently. Let $k := |V(P)|$ and $n := |V(G)|$. We say a vertex $v \in V(G)$ is *heavy* if $\deg(v) \geq \frac{n}{k} - 1$. We prove the following lemma in the full version of the paper.

▶ **Lemma 3.6.** *Let P be a basic pattern. Let $S, N(S), R$ be a partition of $V(P)$ as defined in Definition 1.1. Then the following holds.*

1. *We can enumerate all subgraphs of G that are isomorphic to $P[R]$ in time $\mathcal{O}(m^{|R|/2})$.*
2. *We can enumerate all subgraphs of G that are isomorphic to $P[R]$ and contain a heavy vertex in time $\mathcal{O}(\frac{m^{(|R|+1)/2}}{n})$.*

We now use the lemma above to handle the case when the decomposition into S, $N(S)$ and R as in Definition 1.1 yields $S = \emptyset$. Due to space constraints, we only sketch the proof here. The details can be found in the full version.

▶ **Lemma 3.7.** *Let P be a basic pattern and $S, N(S), R$ be a partition of $V(P)$ as defined in Definition 1.1, such that $S = \emptyset$. If the basic pattern P has at least 16 vertices, then there exists an algorithm solving Dominating P-Pattern in time $\left(\frac{m^{\frac{k-1}{2}}}{n}\right)^{1+o(1)} = t_P(n,m)^{1+o(1)}$. If $\omega = 2$, this time complexity can be achieved for all basic patterns P.*

Proof (sketch). If $S = \emptyset$, then $V(P) = R$ and Lemma 3.6 applies to all of P. Recall that any dominating set of size k contains a heavy vertex v_h (a vertex of degree at least $n/k - 1$), hence we can first guess this vertex in time $\mathcal{O}(\frac{m}{n})$. By Lemma 3.4, there is a spanning subgraph of P that is isomorphic to a disjoint union of edges and odd cycles and we can find such a spanning subgraph in $f(k) = \mathcal{O}(1)$ time. Assume that this decomposition yields α odd cycles and β disjoint edges. If $\beta > 0$, we show that we can decompose $P - v_h$ further into two graphs B_1, B_2 such that they satisfy the following conditions:

- Each B_i is a disjoint union of independent P_3's (paths of length two) and K_2's (independent edges), such that each copy of P_3 will correspond to a subgraph of G that is isomorphic to P_3 and whose all vertices either have degree at most $\sqrt{m}$, or one of the endpoints has degree at least $\sqrt{m}$. [6]
- $B_1 \cup B_2$ is a spanning subgraph of $P - v_h$.
- (Without loss of generality) $0 \leq |V(B_1)| - |V(B_2)| \leq 2$.
- We can enumerate all copies of G isomorphic to B_i that satisfy the degree constraints of P_3 in time $\mathcal{O}(m^{|B_i|/2})$.

In particular, for $k \geq 16$, we have $|V(B_1)| + |V(B_2)| = k - 1 \geq 15$, and combining this with the inequality above, we can conclude that $|V(B_1)| \geq |V(B_2)| \geq 7$. Using that the rectangular matrix multiplication constant $\alpha \geq 0.321$, and that $m \geq n$, we for the exponent

$$\omega(1, \frac{2}{|V(B_1')|}, 1) = \omega(1, \frac{2}{|V(B_2')|}, 1) = 2, \tag{1}$$

and hence we obtain for all $k \geq 16$:

$$\begin{aligned}
\mathcal{O}\left(\frac{m}{n}\,\mathrm{MM}\left(m^{\frac{|V(B_1')|}{2}}, n, m^{\frac{|V(B_2')|}{2}}\right)\right) &\leq \mathcal{O}\left(\frac{m}{n}\,\mathrm{MM}\left(m^{\frac{|V(B_1')|}{2}}, m, m^{\frac{|V(B_2')|}{2}}\right)\right) && (m \geq n)\\
&\leq \mathcal{O}\left(\frac{m}{n} \cdot m^{\frac{|V(B_1')|+|V(B_2')|}{2}+o(1)}\right) && (\text{Eq. 1})\\
&= \mathcal{O}\left(\frac{m}{n} \cdot m^{\frac{k-1}{2}+o(1)}\right) = \left(\frac{m^{\frac{k+1}{2}}}{n}\right)^{1+o(1)}.
\end{aligned}$$

If on the other hand $\beta = 0$ (i.e. the decomposition contains only copies of odd cycles), we proceed similarly, but the best bound on the size difference between B_1 and B_2 is $0 \leq |V(B_1)| - |V(B_2)| \leq 3$, which is not good enough in general. To get around this issue, we distinguish between two cases. If there exists a vertex in $P - v_h$ that is mapped to a vertex of degree $\geq \sqrt{m}$ in G, we can make sure that there exists a copy of P_3 whose one endpoint will be mapped to a vertex in G that has degree at least $\sqrt{m}$. We can decompose this P_3 further into an edge and a vertex of degree $\geq \sqrt{m}$, and intuitively use these components to "re-balance" the sets $V(B_1)$ and $V(B_2)$ as above. If on the other hand all vertices in $P - v_h$ are mapped to vertices in G that have degree at most $\sqrt{m}$, we then know that if $|Y| := |G - N_G[v_h]| \geq (k-1)\sqrt{m} + 1$, there is no valid solution. If on the other hand $|Y| \leq (k-1)\sqrt{m}$, by Lemma 3.1, we can find any such solution in time bounded by $\mathcal{O}\left(\frac{m}{n}\,\mathrm{MM}\left(m^{\frac{|V(B_1)|}{2}}, \sqrt{m}, m^{\frac{|V(B_2)|}{2}}\right)\right)$. Similarly as in previous case, for $k \geq 16$, we get that $|V(B_1)| \geq |V(B_1)| \geq 6$ and again since $\alpha \geq 0.321$, we obtain $\omega(1, \frac{1}{|V(B_1)|}, 1) = \omega(1, \frac{1}{|V(B_2)|}, 1) = 2$. Hence, we can bound the time complexity as

$$\begin{aligned}
\mathcal{O}\left(\frac{m}{n}\,\mathrm{MM}\left(m^{\frac{|V(B_1)|}{2}}, \sqrt{m}, m^{\frac{|V(B_2)|}{2}}\right)\right) &\leq \mathcal{O}\left(\frac{m}{n} \cdot \left(\sqrt{m}\right)^{|V(B_1)|+|V(B_2)|+o(1)}\right)\\
&= \mathcal{O}\left(\frac{m}{n} \cdot \left(\sqrt{m}\right)^{k-1+o(1)}\right) = \left(\frac{m^{\frac{k+1}{2}}}{n}\right)^{1+o(1)} \quad \blacktriangleleft
\end{aligned}$$

The second case for basic patterns is that the decomposition into S, $N(S)$ and R as in Definition 1.1 yields $S \neq \emptyset$. Intuitively this case is simpler than the one above, since we can use the sets $S, N(S)$ to simulate $\beta > 0$, even if $\beta = 0$ and "balance" the sets $V(B_1)$ and $V(B_2)$. We only sketch the proof, as the details are quite similar to the ones above.

[6] Hence in G we will be able to enumerate all subgraphs isomorphic to P_3 that fulfill this degree requirement in time $\mathcal{O}(m^{3/2})$.

▶ **Lemma 3.8.** *Let P be a basic pattern and $S, N(S), R$ be a partition of $V(P)$ as defined in Definition 1.1, such that $S \neq \emptyset$. If the basic pattern P has at least 16 vertices, then there exists an algorithm solving Dominating P-Pattern in time $\left(n^{|S|-|N(S)|}m^{|N(S)|+\frac{|R|}{2}}\right)^{1+o(1)} = t_P(n,m)^{1+o(1)}$. If $\omega = 2$, this time complexity can be achieved for all basic patterns P.*

Proof (sketch). Similarly as above, construct the sets B_1 and B_2 by finding a spanning subgraph of $P[R]$ that consists of union of independent P_3's and K_2's and distributing the connected components as equally as possible. Clearly, we have that $|V(B_1)| + |V(B_2)| = |R|$, and (without loss of generality) $0 \leq |V(B_1)| - |V(B_2)| \leq 3$. Since $S \neq \emptyset$, also $N(S) \neq \emptyset$ (by definition S contains no isolated vertices), hence we can distribute the edges from a perfect matching between the set $N(S)$ and some subset of S of size $|N(S)|$ (such perfect matching always exists by Hall's marriage theorem) between the sets B_1 and B_2 similarly as in previous lemma to obtain graphs B_1', B_2'. Clearly, it holds that $|V(B_1')| + |V(B_2')| = 2|N(S)| + |R|$ and (without loss of generality) $0 \leq |V(B_1')| - |V(B_2')| \leq 2$. We then define the graphs Q_1, Q_2 that consist of $\lfloor \frac{|S|-|N(S)|}{2} \rfloor$ and $\lceil \frac{|S|-|N(S)|}{2} \rceil$ isolated vertices respectively. Similarly as above, we can enumerate all subgraphs of G isomorphic to $B_i' \cup Q_i$ in time $\mathcal{O}\left(n^{|Q_i|}m^{\frac{|B_i'|}{2}}\right)$. Also, by similar arguments as above, we have that for $k \geq 16$, the matrices are "thin enough" that rectangular matrix multiplication techniques can be used to obtain the tight running time of

$$\begin{aligned} \mathrm{MM}\left(n^{|Q_1|}m^{\frac{|B_1'|}{2}}, n, n^{|Q_2|}m^{\frac{|B_2'|}{2}}\right) &\leq \left(n^{|Q_1|+|Q_2|}m^{(|B_1'|+|B_2'|)/2}\right)^{1+o(1)} \qquad (k \geq 16) \\ &\leq \left(n^{|S|-|N(S)|}m^{\frac{2|N(S)|+|R|}{2}}\right)^{1+o(1)} \end{aligned}$$

◀

3.2 Small Cliques

In this section, we deal with the remaining small patterns, i.e., the cliques of size at most 4. We note that in [30] the K_2 was already settled, so it remains to settle the cliques of size 3 and 4. In particular, this section is dedicated to proving the following two main theorems.

▶ **Theorem 3.9.** *For a Dominating Triangle, there exists a deterministic $\left(\frac{m^{1+\frac{2\omega}{\omega+1}}}{n}\right)^{1+o(1)}$-time algorithm and a randomized $m^{\frac{\omega+1}{2}+o(1)}$-time algorithm.*

▶ **Theorem 3.10.** *There is a randomized algorithm solving K_4-Dominating Set in time $\left(\frac{m^{(\omega+3)/2}}{n}\right)^{1+o(1)}$. If $\omega = 2$, this is $\left(\frac{m^{5/2}}{n}\right)^{1+o(1)} = t_{K_4}(n,m)^{1+o(1)}$.*

We start with the simple deterministic algorithm for Dominating Triangle problem that uses a reduction to the *All-Edges-Triangle-Counting* problem. This problem asks for a given tripartite graph $G = (V_1 \cup V_2 \cup V_3, E)$ to determine, for every edge e in $(V_1 \times V_2) \cap E$, how many triangles in G contain e. It is well known that this problem can be solved in time $m^{\frac{2\omega}{\omega+1}+o(1)}$ (see e.g. [4]). We remark that any $\mathcal{O}(m^{\frac{4}{3}-\varepsilon})$-time algorithm would refute the 3-SUM and the APSP Hypothesis [35, 40], giving matching lower bounds if $\omega = 2$.

▶ **Lemma 3.11** (All-Edge Triangle Counting, see [4])**.** *There is an algorithm solving All-Edges-Triangle-Counting in time $m^{\frac{2\omega}{\omega+1}+o(1)}$.*

By using this lemma, we are able to solve the problem in $\mathcal{O}\left(t_{K_3}(n,m)\right) \cdot m^{\frac{\omega-1}{\omega+1}+o(1)}$, which evaluates to $\mathcal{O}\left(t_{K_3}(n,m)\right) \cdot m^{\frac{1}{3}+o(1)}$ if $\omega = 2$. By a more careful approach, we are able to construct a randomized algorithm that uses a bloom-filter inspired approach similar to the

one in [21], to achieve $\mathcal{O}\left(t_{K_3}(n,m)\right) \cdot \frac{n}{\sqrt{m}}$, which is better whenever $m \in \Omega(n^{1.10283})$ with current value of ω and $m \in \Omega(n^{1.2})$ if $\omega = 2$, giving us the second part of the Theorem 3.9. We remark that although this value can be slightly improved by using a more careful analysis, it seems that in order to match the lower bound, a new technique will be required. We now sketch the approach of the deterministic algorithm and give the details to both algorithms in the full version of the paper.

▶ **Proposition 3.12.** *There exists a deterministic algorithm solving Dominating Triangle in time* $\left(\frac{m^{1+\frac{2\omega}{\omega+1}}}{n}\right)^{1+o(1)}$. *If* $\omega = 2$, *this equals* $\left(\frac{m^{7/3}}{n}\right)^{1+o(1)}$.

Proof (sketch). We first guess a heavy vertex w (a vertex satisfying $\deg(w) \geq n/3 - 1$). We then run a breadth-first-search from w and let $(X_0 = \{w\}, X_1, \ldots, X_n)$ be the obtained BFS layering. Note that for any $\ell \geq 3$, if X_ℓ is non-empty, we can conclude that there is no dominating clique that contains w and we can proceed with the next choice of the heavy vertex. Otherwise, finding any dominating triangle in G that contains w is equivalent to finding an edge u, v in X_1 that dominates all vertices in X_2. For any vertex u, we write $N_2(u) := N(u) \cap X_2$. Using the principle of inclusion-exclusion, we can write $|N_2(u) \cup N_2(v)| = |N_2(u)| + |N_2(v)| + |N_2(u) \cap N_2(v)|$. We note that for any pair of vertices $u, v \in X_1$ the value $|N_2(u) \cap N_2(v)|$ corresponds to the number of triangles containing the edge uv. Hence, by employing the algorithm from Lemma 3.11, we obtain the desired time. ◀

On the other hand, by coming up with a more involved argument, we are able to construct a randomized algorithm that matches the lower bound (up to resolving the matrix multiplication exponent ω) for the remaining small pattern, namely Dominating 4-Clique. The algorithm starts similarly as above. That is, we first guess a heavy vertex w in time $\mathcal{O}\left(\frac{m}{n}\right)$, and then we partition the vertices into two sets X_1 and X_2 based on the distance from w and thus reduce to detecting a triangle in X_1 that dominates X_2. We then consider two cases based on the size of X_2. If $|X_2| \leq 3\sqrt{m}$, this turns out to be quite easy, and boils down to using standard matrix multiplication algorithms (with a bit more careful analysis). If on the other hand $|X_2| > 3\sqrt{m}$, we then either reduce to counting cliques (triangles and K_4's) in a certain restricted setting, or use the randomized bloom-filter based approach of [21] (with a finer-grained analysis) to achieve the desired running time. This approach gives us the proof of Theorem 3.10 and we provide the detailed proof in the full version of the paper.

3.3 Handling Isolated Vertices

In the last two subsections we considered the graphs that have no isolated vertices. It remains to prove that we can obtain a tight classification even for patterns with isolated vertices. In particular, we prove the following theorem.

▶ **Theorem 3.13.** *Let P be any pattern graph with k vertices and $1 \leq r \leq k$ isolated vertices. There is a randomized algorithm that enumerates all dominating P-patterns in time $t_P(n,m) \cdot m^{\frac{\omega-2}{2}+o(1)}$ with high probability. If $\omega = 2$, this is $t_P(n,m)^{1+o(1)}$.*

We again consider two cases separately, namely when $r \geq 2$ and $r = 1$. In the first (simpler) case of $r \geq 2$, we aim to reduce to the Maximal r-Independent Set problem, which is known to have efficient algorithm in sparse graphs (see [30]). We enumerate all subgraphs of G that correspond to the induced subgraph of P that does not contain isolated vertices, and then after removing the closed neighborhood of the enumerated subgraph, we run the Maximal

r-Independent Set algorithm on the remaining part. By a careful analysis, we obtain the desired time. We provide a sketch of the proof here, for the full proof, see the full version of the paper.

▶ **Lemma 3.14.** *Let P be a pattern with $2 \leq r \leq k$ isolated vertices. Then there exists a randomized algorithm solving P-Dominating Set in time $\left(t_P(n,m) \cdot m^{(\omega-2)/2}\right)^{1+o(1)}$ with high probability. If $\omega = 2$, this is equal to $(t_P(n,m))^{1+o(1)}$.*

Proof (sketch). If $r = k$, then this problem is precisely the Maximal k-Independent Set problem, and by [30] can be solved in the time bounded by $\left(\frac{m^{(k-1)/2+\omega/2}}{n}\right)^{1+o(1)}$, as desired. Hence, we may assume that $2 \leq r \leq k-2$ (if P contains at least one edge, then at least two vertices have degree ≥ 1). Let $X := \{x \in V(P) : \deg_P(x) \geq 1\}$ and $Y := V(P) \setminus X$ be the set of non-isolated and isolated vertices in P respectively. Let $S, N(S), R$ be the partition of $V(P)$ as in Definition 1.1. We can enumerate all induced subgraphs of G isomorphic to $P[X]$ in some time $\mathcal{O}\left(t^{(1)}_{P[X]}(n,m)\right)$ (the ratio of the size of this set to $t_{P[X]}(n,m)$ depends only on whether the set S is empty or not). For each enumerated subgraph H, we appeal to the randomized Dominating r-Independent Set algorithm from [30] on the graph $G - N[H]$ that runs in $\mathcal{O}\left(t^{(2)}_r(n,m)\right)$ (depends on which vertex from P is mapped to a heavy vertex). It is straightforward to see that this algorithm is correct. We conclude the proof by showing that the product of $t^{(1)}_{P[X]}(n,m)$ and $t^{(2)}_r(n,m)$ is in all cases bounded by $t_P(n,m)$ (see the full version of the paper for details). ◀

Things get slightly more complicated when dealing with patterns that only have one isolated vertex. In particular, the preprocessing part of the algorithm above takes in the worst case $\Theta\left(t_{P[X]}(n,m) \cdot m\right)$, while for pattern graphs with only one isolated vertex, we have $t_P(n,m) = \mathcal{O}\left(t_{P[X]}(n,m) \cdot \sqrt{m}\right)$. To circumvent this overhead, we employ a more careful analysis and use a hashing-based approach similar to that in Section 3.2. We first provide an algorithm for two special cases of some of the smallest patterns that exhibit this structure and then the idea is to reduce any pattern to one of these special cases.

▶ **Lemma 3.15.** *Let G be a graph with n vertices and m edges, and let $Y \subseteq V(G)$ be a subset of vertices of G. Then we can construct an algorithm that w.h.p. enumerates all choices of three vertices u, v, w in time $m^{(\omega+1)/2+o(1)}$, such that the following is satisfied.*

- *The vertex w is contained in Y and satisfies $\deg(w) < \sqrt{m}$.*
- *Vertices u and v are adjacent in G and both of them are non-adjacent to w in G (i.e. the induced subgraph $G[\{u, v, w\}]$ is isomorphic to an edge and an isolated vertex).*
- *$Y \subseteq N[u] \cup N[v] \cup N[w]$.*

Proof. Without loss of generality, assume that $\deg(u) \geq \deg(v)$. Let t be such that $t \leq \deg(u) \leq 2t$. Assume first that $t \leq \sqrt{m}$. Then each vertex u, v, w has degree bounded by $\mathcal{O}(\sqrt{m})$ and so, if there exists a valid triple that dominates Y, the size of Y must also be bounded by $\mathcal{O}(\sqrt{m})$. Hence by Lemma 3.1 we can enumerate all valid triples in time $\mathrm{MM}(m, \sqrt{m}, \sqrt{m}) \leq m^{(\omega+1)/2+o(1)}$, as desired.[7] For the rest of this proof we assume that $t \geq \sqrt{m}$. We now proceed to enumerate all valid triples u, v, w such that $\deg(v) \leq \sqrt{m}$. To this end, we run the following routine. For each of the $\mathcal{O}(m/t)$ valid choices for the vertex u, construct the tripartite graph $H_u = (V^{(1)}_u \cup V^{(2)}_u \cup V^{(3)}_u, E_u)$, where $V^{(1)}_u$ corresponds to a

[7] Since vertices u, v are adjacent, there are at most m choices for this pair, and w is by assumption in Y, and $|Y| \leq \mathcal{O}(\sqrt{m})$

copy of $N(u)$, while $V_u^{(2)}$ and $V_u^{(3)}$ each correspond to a copy of the set $Y - N(u)$. The set of edges E_u is constructed naturally, that is, for each pair $x \in V_u^{(i)}, y \in V_u^{(j)}$ for $i \neq j$ we add an edge xy if and only if the edge between the corresponding vertices is present in G (we assume that each vertex is adjacent to itself in G). It is easy to see that for any fixed u, any valid choice of v, w corresponds precisely to a choice of $v \in V_u^{(1)}$ and $w \in V_u^{(2)}$ such that the following two conditions are satisfied: 1) $V_u^{(3)} \subseteq N(w) \cup N(v)$ and 2) $vw \notin E(H_u)$. Now, since we are only enumerating triples u, v, w where both v, w have degrees at most $\sqrt{m}$, if for a fixed u the set $V_u^{(3)}$ contains more than $2\sqrt{m}$ vertices, we can conclude that no pair v, w satisfies both conditions and proceed with the next choice of u. On the other hand, if $|V_u^{(2)}| = |V_u^{(3)}| \leq 2\sqrt{m}$, by Lemma 3.1, for any fixed u, we can enumerate all the valid pairs of non-adjacent vertices v, w that dominate $Y - N(u)$ in time

$$\begin{aligned} T_u(n,m) &\leq \mathrm{MM}\left(V_u^{(1)}, V_u^{(3)}, V_u^{(2)}\right) \\ &\leq \mathrm{MM}\left(t, \sqrt{m}, \sqrt{m}\right) \\ &\leq \mathcal{O}\left(\frac{t}{\sqrt{m}}\right) \mathrm{MM}\left(\sqrt{m}, \sqrt{m}, \sqrt{m}\right) && (t \geq \sqrt{m}) \\ &\leq t \cdot m^{\frac{\omega-1}{2}+o(1)}. \end{aligned}$$

Repeating this for each of the possible $\mathcal{O}(m/t)$ many choices of vertex u yields the desired time. It remains to enumerate the triples of vertices u, v, w where $\deg(v) \geq \sqrt{m}$. Recall also that $2t \geq \deg(u) \geq \deg(v)$ and $t \geq \sqrt{m}$. Hence, since by the first condition of the Lemma, we are only interested in the triples u, v, w with $\deg(w) \leq \sqrt{m} \leq t$, if the set Y contains more than $5t$ vertices, we can conclude that no triple u, v, w satisfies $Y \subseteq N[u] \cup N[v] \cup N[w]$. Hence, we can assume that $Y \leq 5t$. Let B be a matrix whose rows correspond to adjacent pairs of vertices u, v with $t \leq \deg(u) \leq 2t$ and $\deg(v) \geq \sqrt{m}$ and whose columns correspond to the set Y. We set the entry $B[(u,v), y]$ to 0 if either u or v are adjacent to y and to 1 otherwise. Similarly, we construct a matrix C whose columns correspond to the set of vertices $w \in Y$ such that $\deg(w) \leq \sqrt{m}$ and the rows correspond to Y. Set the entry $B[y, w]$ to 1 if w and y are adjacent (we understand that each vertex is adjacent to itself) and 0 otherwise. Notice that u, v, w dominate Y if and only if $(B \cdot C)[(u,v), w] = \sum_k B[w,k]$ (each vertex that is not dominated by the pair (u,v) is dominated by w). Also notice that the matrix B is an $\mathcal{O}\left(\frac{m\sqrt{m}}{t}\right) \times \mathcal{O}(t)$ and C is an $\mathcal{O}(t) \times \mathcal{O}(t)$ matrix with at most m non-zeros. Hence by a Lemma from [21] (see full version for details), we can enumerate with high probability all valid triples u, v, w in time $\sqrt{m} \cdot m^{\omega/2+o(1)} = m^{\frac{\omega+1}{2}+o(1)}$, as desired. We remark that we enumerate all valid triples for any fixed t in the claimed time. To enumerate all the valid triples, simply run the previous algorithm $\mathcal{O}(\log(n))$ times, once for each $\ell \in 1, \ldots, \lfloor \log(n) \rfloor$, setting $t = 2^\ell$. ◀

An almost identical argument as in previous lemma can also be used to show that we can efficiently enumerate the solutions that are isomorphic to $C_{2r+1} + K_1$.

▶ **Lemma 3.16.** *Let G be a graph with n vertices and m edges, and let $Y \subseteq V(G)$ be a subset of vertices of G. Then we can construct an algorithm that w.h.p. enumerates all choices of $2r+2$ vertices $x_1, \ldots, x_{2r+1}, w$ in time $m^{r+\omega/2+o(1)}$, such that the following is satisfied.*

- *The vertex w is contained in Y and satisfies $\deg(w) < \sqrt{m}$.*
- *Vertices $x_1, \ldots, x_{2r+1}$ form a cycle in G (not necessarily induced) and w is not adjacent to any of the vertices x_i in G.*
- *$Y \subseteq N[w] \cup N[x_1] \cup \cdots \cup N[x_{2r+1}]$.*

The idea for any pattern with precisely one isolated vertex v is to decompose the pattern into sets $S, N(S), R$ as in Definition 1.1, and then depending on whether the set S is empty or not, we either directly reduce to the setting of Lemma 3.15, or first apply Lemma 3.4 to decompose R into edges and odd cycles, and then reduce to either the setting of Lemma 3.15, or that of Lemma 3.16. For the lack of space, we give the detailed proof in the the full version of the paper.

▶ **Proposition 3.17.** *Let P be a pattern with one isolated vertex. Then there exists a randomized algorithm solving P-Dominating Set in time $\mathcal{O}(t_P(n,m)) \cdot m^{\frac{\omega-2}{2}+o(1)}$.*

Abstract

Given a set S of n keys, a k-perfect hash function (kPHF) is a data structure that maps the keys to the first m integers, where each output integer can be hit by at most k input keys. When $m = \lceil n/k \rceil$, the resulting function is called a *minimal* k-perfect hash function (MkPHF). Applications of kPHFs can be found in external memory data structures or to create efficient 1-perfect hash functions, which in turn have a wide range of applications from databases to bioinformatics.

Several papers from the 1980s look at external memory data structures with small internal memory indexes. However, actual k-perfect hash functions are surprisingly rare, and the area has not seen a lot of research recently. At the same time, recent research in 1-perfect hashing shows that there is a lack of efficient kPHFs. In this paper, we revive the area of k-perfect hashing, presenting four new constructions. Our implementations simultaneously dominate older approaches in space consumption, construction time, and query time. We see this paper as a possible starting point of an active line of research, similar to the area of 1-perfect hashing.

1 Introduction

Given a set S of n keys, a k-perfect hash function (kPHF) is a data structure that maps the keys to the first m non-negative integers $[m]$, called *bins* in the following. Each output bin can be hit by at most k input keys. The output for any key not in S is undefined, so a k-perfect hash function does not need to store the input set. For $k = 1$, there is a wide

range of constructions covering different trade-offs between space consumption, query time, and construction time. The area is an active field of research with several publications each year [27, 28, 30, 31, 9, 20, 16, 3, 29, 17, 37]. However, there has been little prior work on k-perfect hashing. While several papers from the 1980s look at internal memory indexes for external hash tables, these are not full k-perfect hash functions. We refer to Section 3 for details. In this paper, we present four new k-perfect hash function constructions. Each covers a different trade-off between the three main performance metrics – space consumption, construction time, and query time.

Minimality. When $m = \lceil n/k \rceil$, we obtain a *minimal* k-perfect hash function (MkPHF) [26]. When using the MkPHF to partition 1-PHFs [30, 31], it might be beneficial to look at a stricter definition where all output bins contain exactly k keys, except possibly the last. The approaches presented in this paper fulfill the stricter definition. An alternative definition of non-minimal kPHFs could be that we could fill each output bin with either exactly k keys or 0 keys. For $k = 1$, this results in an ordinary non-minimal PHF and achieves a significant reduction in space consumption. However, for $k > 1$, the resulting space consumption is the same as the one of MkPHFs [33].

Applications. k-perfect hashing has a wide range of applications. In external memory hash tables, kPHFs can return the page on which a key is stored. External memory is usually accessed with page granularity anyway, so having to scan the page for the key only causes negligible overhead. Compared to a 1-PHF, however, this can significantly reduce the space needed. For internal memory hash tables it can be beneficial to store more than one key in each table cell [12]. Using an MkPHF, we can completely fill such a hash table. A k-perfect hash function can also be used to make the construction of 1-perfect hash functions more uniform by dividing the input to same-size partitions [30, 31].

Our Contributions. In this paper, we present four new or significantly improved k-perfect hash function constructions. Threshold-based bumping was previously only briefly described as an ad-hoc solution to aid 1-perfect hashing [30, 31]. In Section 4, we extend it through optimal thresholds and CONSENSUS-coded [31] thresholds. Perfect hashing through bucket placement [37, 20, 2] generalizes to k-perfect hashing in an obvious way. In Section 5, we introduce an optimal bucket assignment function. RecSplit [9] is a known 1-PHF, which we extend to a k-PHF in Section 6. Finally, we introduce a variant of the external memory hash table PaCHash [23] that can be used as an MkPHF in Section 7. To the best of our knowledge, we then give the first experimental evaluation of different k-perfect hash functions in Section 8.

2 Preliminaries

In this section we show the space lower bound for minimal k-perfect hash functions. We then explain preliminary data structures that we use throughout this paper.

Space Lower Bounds. The space lower bound for representing a minimal k-perfect hash function is rather easy to prove [32, 2, 23]. Let the n input keys be a subset of a universe of size u. There are $\binom{u}{n}$ possible input sets. Each behavior of an MkPHF can cover at most $\binom{u/(n/k)}{k}^{n/k}$ input sets. Therefore, the number of bits we need is at least

Table 1 Space lower bound for different values of k.

k	1	2	4	10	100	1000
Bits per key	1.443	0.943	0.589	0.300	0.046	0.006

$$\log_2 \left(\frac{\binom{u}{n}}{\binom{u/(n/k)}{k}^{n/k}} \right) \overset{n^2 \in o(u)}{\approx} n \cdot \left(\log_2(e) - \log_2(k^k/k!)/k \right) = n \cdot \left(\frac{\log_2(2\pi k)}{2k} + \Theta\left(\frac{1}{k^2}\right) \right).$$

In Table 1, we give a range of example values. The space lower bounds become more complex for non-minimal k-perfect hashing, and no tight bounds are known yet [2].

Retrieval Data Structures. A retrieval data structure stores a static function $f : S \to \{0,1\}^r$ with r-bit output values. It can return arbitrary results for any key not in S. This makes it possible to represent it using just rn bits. Bumped Ribbon Retrieval (BuRR) [7] is based on solving a system of linear equations and has a space consumption of $1.01rn$ bits in practice.

Elias-Fano Coding. Let $(a_i)_{i\in[n]}$ be a monotonically increasing sequence of integers. To store this sequence with Elias-Fano coding [8, 11], we split each integer into two parts. We store the lower $L = \lceil \log_2(a_{n-1}/n) \rceil$ bits directly in a packed array. Then we store the remaining upper bits $(h_i)_{i\in[n]}$ as a bit vector where the bits at indices $h_i + i$ are 1, and all other bits are 0. On this bit vector, we have $h_i = \text{select}_1(i) - i$. Together with a lookup in the packed array, we get constant access time. In total, storing the sequence needs $n \cdot (2 + \lceil \log_2(a_{n-1}/n) \rceil) + o(n)$ bits of space [8, 11].

Golomb-Rice Coding. For a parameter L, Golomb-Rice coding [14, 38] divides an integer x into the two parts $h = \lfloor x/2^L \rfloor$ and $l = x \bmod 2^L$. It encodes l using L bits in binary coding, and h in unary coding. Golomb-Rice coding is optimal for geometrically distributed x with $p = 2^{-L}$. We can store a sequence of integers with constant time access by using a common array for the lower bits, concatenating the upper bits, and using a select data structure.

3 Related Work

We now explain k-perfect hash functions and similar external memory hashing data structures from the literature. Note that Alon et al. [1] and Berman et al. [4] use the variable k for the range of the output values in 1-perfect hashing, which is now usually called m. In an online setting when building hash tables, Frei and Wehner [13] call a family of hash functions k-*ideal* if there is, for any input set of size n, some hash function that is k-perfect.

3.1 k-Perfect Hash Functions

Brute-Force Search. Similar to what can be done for 1-perfect hashing [34], we can use brute-force search to construct k-perfect hash functions. We use a hash function that can be parameterized by a seed value, changing its behavior completely. We greedily start trying seed values until we come across one seed where the hash function is k-perfect on our given input set. Then storing the index of that seed in binary coding is enough to represent the k-perfect hash function. Unfortunately, like for 1-perfect hashing, we need an exponential

number of hash function evaluations, making the approach unfeasible for large input sets. Mairson [32] shows that the probability of a random function being an MkPHF can be described by the multinomial coefficient $(n/k)^{-n}\binom{n}{\underbrace{k, k, \ldots, k}_{n/k \text{ times}}}$.

Bucket Placement. Perfect hashing through bucket placement [37, 20, 2] is a class of 1-perfect hash functions. The idea is to hash the input keys to small buckets of expected size λ, where λ is a tuning parameter usually in the range 2–6 keys. For each bucket, we then greedily search for a hash function seed such that the keys in that bucket do not collide with previous keys. After placing all buckets, we compress the list of seeds while retaining fast access. The first buckets are easier to place because all bins are empty. It is therefore helpful to insert the buckets in decreasing order of size. In CHD [2], the keys are hashed uniformly to the buckets. Despite sorting, the last buckets are still much harder to place than the first. Therefore, PHOBIC [20] introduces an optimal *bucket assignment function* $\beta : [0, 1] \to [0, 1]$. A key with a normalized hash value $x \in [0, 1]$ is then assigned to bucket $\lceil \beta(x)n/\lambda \rceil$. The bucket assignment function makes the first buckets much larger to allow even smaller buckets towards the end, resulting in roughly the same success probability of a seed in all buckets.

Bucket placement can be used as a k-perfect hash function by allowing up to k collisions for each output bin. The implementation [6] of CHD supports only non-minimal k-perfect hashing. In Section 5, we extend the idea through an optimized bucket assignment function.

Predecessor Dictionary. Pagh [36] suggests hashing all input keys with a hash function of range $[n^3]$ and sorting them by hash value. Now map the keys linearly to the output bins and store the smallest hash value in each bin. For a given hash value x, a *predecessor query* can give the largest value y in the list such that $y \leq x$. The index of that value is the k-perfect output bin. We implement a variant in Section 7.

Threshold-Based Bumping. Threshold-based bumping [30] is an ad-hoc solution to k-perfect hashing introduced for simplifying a 1-perfect hash function. The idea is to first hash all keys to $\lceil 0.9n/k \rceil$ bins. The constant of 0.9 is selected arbitrarily in the paper, ensuring that there are few bins that receive fewer than k keys. An additional hash function uniformly assigns a fingerprint value $\in (0, 1]$ to each key. For each bin, threshold-based bumping then stores a threshold such that at most k keys in the bin have fingerprints below or equal to the threshold. It *bumps* keys with fingerprints larger than the threshold to a second layer of the same data structure. To reduce the space consumption and to enable fast access, we restrict ourselves to a small list of possible thresholds and only store the index into the list. Threshold-based bumping has similarities with perfect hashing through fingerprinting [35] (which essentially uses 1-bit thresholds) and separator hashing [15, 25] (see Section 3.2). The idea of bumping is also used in BuRR [7], which solves a system of linear equations and bumps conflicting rows.

To make the resulting function *minimal* k-perfect, keys bumped in the second layer have to be placed into the empty slots left in the bins. Threshold-based bumping does that by storing an Elias-Fano coded list of bins that still have slots left. Using a minimal 1-PHF on the bumped keys, it can map each key to one of the empty slots. Refer to Figure 1 for an illustration. Queries hash the key to a bin. Most keys can immediately return the bin index because their fingerprint is below the threshold. Some have to look at the next layer and few have to query the fallback 1-PHF. In Section 4, we extend the approach through an optimal selection of threshold values, as well as more efficient overloading to minimize the number of bins with less than k keys.

3.2 External Memory Hash Tables

In external memory hash tables, a goal is to find objects while only accessing a small number of external memory pages. For this, different internal memory index data structures have been proposed. These index data structures are very similar to k-perfect hash functions. The main difference is that they either need to inspect more than one external memory page or that they do not fully utilize the external memory, meaning that they are not *minimal* k-perfect. Still, these data structures use similar ideas as MkPHFs or can even be adapted to MkPHFs.

Separator Hashing. Separator hashing [15, 25, 24] is a static, external memory hash table that guarantees a single disk access for each query. Each key has a *probe sequence* of output bins and a *fingerprint sequence*, both determined through a sequence of hash functions. For each external memory page, it stores a threshold value for the fingerprint, also called *separator*. When querying a key, we look at the bins along its probe sequence. If the key's fingerprint for that bin is smaller than the separator, we found the corresponding page. Otherwise, we continue scanning. A problem with the technique, especially for high load factors, is that bumped keys map back into the same range of bins. This causes a series of dependent memory accesses during queries, and complicates the construction.

External Robin-Hood Hashing. Instead of displacing keys based on their fingerprint, *external robin-hood hashing* [5] displaces the keys that are at the smallest index of their probe sequence. The internal memory then stores, for each page, the smallest distance of a contained key to its home address. Queries iterate over the distance array starting from their home address until the distance is at least what is stored in the array. If multiple keys have the same home address, more than one external memory page has to be searched.

Extendible Hashing. The idea of *extendible hashing* [10] is to store an internal memory table holding pointers. Each row points to an external memory page holding the keys hashed to that table row. If the keys hashed to several (adjacent) table rows fit onto an external memory page together, extendible hashing stores the same pointers multiple times. The approach achieves a load factor of about 69% [36].

PaCHash. PaCHash [23] is designed as a static external memory hash table with variable-length keys. However, we only explain the case that each external memory page can hold k fixed-length keys. Then PaCHash uses a hash function of range $[a \cdot n/k]$, where a is a tuning parameter. This divides the keys into different buckets.[1] For each external memory page, we store the index of the first bucket overlapping it. Using Elias-Fano coding (see Section 2), this takes $n/k(2 + \log(a))$ bits. To locate a key, we perform a predecessor query on that sequence to determine which external memory page should be loaded. If a bucket overlaps the page boundaries, the index cannot determine whether the key is on the page or on the previous page. In that case, which happens for roughly $1/a$ of the queries, PaCHash loads both adjacent pages. In Section 7, we explain how we can adapt PaCHash to an MkPHF.

[1] For consistency within this paper, we interchange the terms *bin* and *bucket* of the PaCHash paper.

Listing 1 Query algorithm of k-perfect hashing trough threshold-based bumping. Hash function h_X uniformly maps into the set X.

```
Function query(key ∈ S)
  numBins := ⌈(n/k)/γ⌉
  bin := h_[numBins](key)
  thresholdIndex := thresholds[bin]
  fingerprint := h_[0,1](key)
  if fingerprint ≤ T_thresholdIndex
    return bin
  else // bumped to next layer
    return numBins + query next layer
```

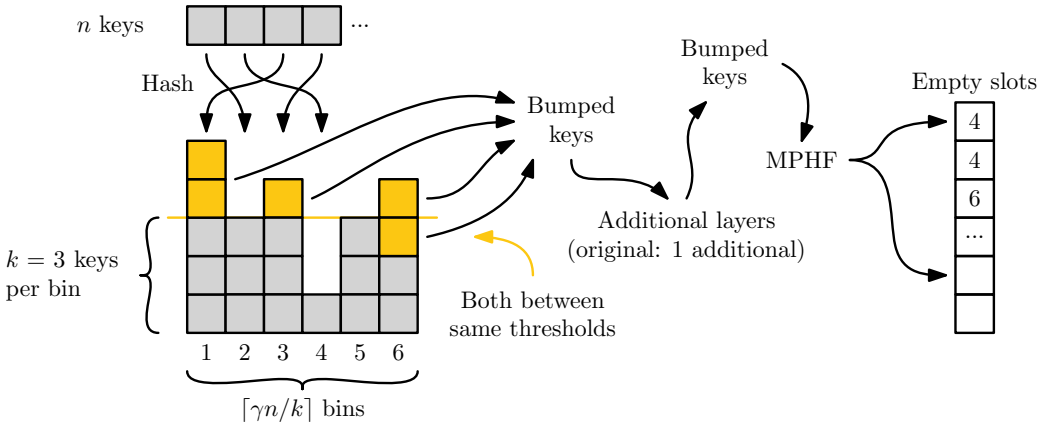

Figure 1 Threshold-based k-perfect hashing. Figure adapted from [30].

4 k-Perfect Hashing Through Threshold-Based Bumping

Threshold-based bumping is introduced in ShockHash-Flat [30] as an ad-hoc implementation to aid 1-perfect hashing. In this section, we enhance it significantly. Remember from Section 3.1 that threshold-based bumping hashes each key directly to a bin. Additionally, we hash each key to determine a uniform fingerprint value $\in (0, 1]$. Each bin stores a threshold such that at most k keys with fingerprints smaller than or equal to the threshold remain. The other keys are *bumped* to another layer of the same data structure. Figure 1 gives an illustration.

4.1 Overloading

To make it more likely that each bin receives at least k keys, we *overload* the bins to contain more than k keys in expectation. While the ad-hoc implementation [30] already overloads the first layer, we now take this to its logical conclusion and overload all layers. More concretely, we start with $\lceil \frac{n}{k\gamma} \rceil$ bins where $\gamma > 1$ is the overloading factor. We determine the thresholds to store, which leaves us with n' bumped keys. From the remaining output bins, we then use $\lceil \frac{n'}{k\gamma} \rceil$ bins for the next layer. We continue this as long as the total number of bins used is still smaller than $\lceil \frac{n}{k} \rceil$. Only for the remaining keys, we have to use 1-perfect hashing to puzzle them back into the under-filled bins. Even with overloading, we maintain expected constant query times and expected linear construction times. Preliminary experiments

with $k = 1000$ show that overloading all layers reduces the number of keys bumped in the last layer from 0.2% (with the original two layers) to 0.02% (with 5 layers). Because the fallback 1-PHF needs non-negligible space, this reduces the overall space consumption. In our implementation, we use the 1-PHF FiPS [27] due to its small constant space overhead when using it for small sets.

4.2 Optimizing the Thresholds

For fast access we use a fixed number of bits to represent the threshold of each bin, which gives us t possible threshold values. In the following we consider the value of those t thresholds. For each bin we then only store the index of the threshold. We model the fingerprint of a key as a uniformly distributed hash value $x \in (0, 1]$. If x is greater than the threshold of the key's bin, the key is bumped. It is less likely that we need threshold values close to 0 because the expected number of keys in each bin is $k\gamma$. The ad-hoc implementation [30] therefore heuristically uses uniformly spaced thresholds in $[\frac{2}{3}, 1]$. In this section, we derive an optimal selection of thresholds.

Our goal is to find the t thresholds $T_1 < \cdots < T_t \in [0, 1]$ such that they minimize the expected number of empty slots. As a fallback option, we use $T_1 = 0$, bumping all keys. We also use $T_t = 1$. A value of $T_t < 1$ would mean that keys in the range $(T_t, 1]$ always get bumped, which would counteract our increased load factor. Therefore, we need to determine the values of the remaining $t - 2$ thresholds. The number of keys in a bin is binomially distributed. To simplify analysis, we approximate the number of keys using a Poisson distribution with γk keys in expectation. We consider the sorted fingerprints $0 < x_1 < x_2 < \dots$ of the keys. The distance between any two consecutive keys $(x_{i+1} - x_i)$ and between 0 and x_1 is exponentially distributed with an expected distance of $1/(\gamma k)$. Hence, it is equivalent to obtain the fingerprints by sampling consecutive fingerprints using this exponential distribution until we pass 1. However, for notational convenience we sample an infinite number of fingerprints in this way and allow them to exceed 1. This does not change the distribution of the fingerprints smaller 1.

To minimize the number of empty slots we always choose the highest possible threshold that is still smaller than x_{k+1}, since we need to ensure that at most k keys remain in the bin. Hence, threshold T_i is chosen if $T_i < x_{k+1} \leq T_{i+1}$ for $i \in [t]$ and we formally set $T_{t+1} := \infty$ to simplify notation. A fingerprint x_j results in an empty slot if it is bumped ($x_j > T_i$) *and* it is one of the k keys which we want to keep in the bin ($x_j < x_{k+1}$). If we know x_{k+1}, then the k smaller fingerprints are uniformly distributed in the range $(0, x_{k+1})$. Hence, the expected number of empty slots is $k\frac{x_{k+1}-T_i}{x_{k+1}}$. The fingerprint x_{k+1} follows a gamma distribution with shape $k + 1$ and rate γk. Let $\phi(x)$ be the density function of that gamma distribution. We can calculate the expected number of empty slots of the bin as

$$\begin{aligned} E := \mathbb{E}[\text{empty slots}] &= \int_0^\infty \mathbb{E}[\text{empty slots} \mid x_{k+1} = s]\phi(s)\mathrm{d}s \\ &= \sum_{i=1}^{t} \int_{T_i}^{T_{i+1}} \mathbb{E}[\text{empty slots} \mid x_{k+1} = s]\phi(s)\mathrm{d}s \\ &= \sum_{i=1}^{t} \int_{T_i}^{T_{i+1}} k\frac{s - T_i}{s}\phi(s)\mathrm{d}s \end{aligned} \tag{1}$$

For E to be minimal, its derivative with respect to $T_2, \ldots, T_{t-1}$ must be zero. We have:

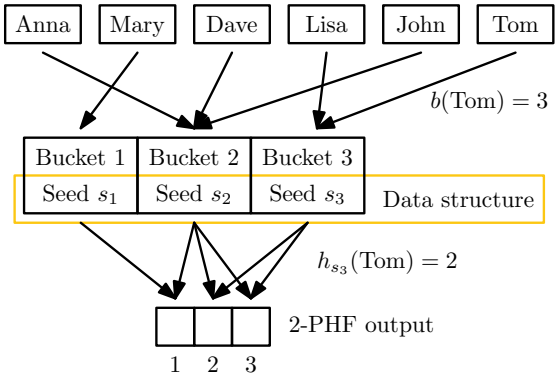
$$\begin{aligned} 0 \stackrel{!}{=} \frac{\mathrm{d}E}{\mathrm{d}T_i} &= \frac{\mathrm{d}}{\mathrm{d}T_i}\int_{T_{i-1}}^{T_i} k\frac{s-T_{i-1}}{s}\phi(s)\mathrm{d}s + \frac{\mathrm{d}}{\mathrm{d}T_i}\int_{T_i}^{T_{i+1}} k\frac{s-T_i}{s}\phi(s)\mathrm{d}s \\ &= k\left(\frac{T_i - T_{i-1}}{T_i}\phi(T_i) - \int_{T_i}^{T_{i+1}} \frac{1}{s}\phi(s)\mathrm{d}s\right) \\ &\iff T_{i-1} = T_i - \frac{T_i}{\phi(T_i)}\int_{T_i}^{T_{i+1}} \frac{1}{s}\phi(s)\mathrm{d}s \end{aligned} \tag{2}$$

If we knew T_t and T_{t-1} we could inductively obtain the remaining thresholds. However, we only know that $T_t = 1$ and $T_1 = 0$. Our implementation therefore fixes $T_t = 1$ and uses binary search of T_{t-1} until T_1 is close to 0. This minimizes the number of empty slots under the necessary conditions $T_t = 1$ and $T_1 = 0$. For better intuition, we show in the full version of this paper [18] that the density of thresholds follows a gamma distribution for $t \to \infty$. The query algorithm of our data structure is shown in Listing 1.

4.3 Tighter Packing With Retrieval

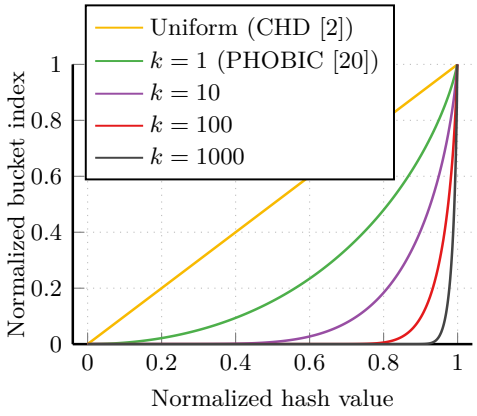
Sometimes there is more than one key between the relevant thresholds. If we take the smaller threshold, we keep empty slots that we later need to repair. If we take the larger threshold, we would have more than k keys in the bin. In this case, we extend the data structure by querying a 1-bit retrieval data structure (see Section 2) on all keys that have fingerprints between these two thresholds. The bit tells us whether this key should be kept in the bin or if it should be bumped. This costs us 1 bit per key for all keys between thresholds, even the ones we do *not* bump. However, overall, this reduces space because each bumped key leaving an empty slot costs us several bits of space later to repair. The technique trades some query time for reduced space consumption.

4.4 CONSENSUS-Coded Thresholds



CONSENSUS [31] is a technique for space-efficiently storing seeds for randomized data structures. It basically uses a fixed number of bits to store the seed of each subtask. This means that for some subtasks, there might be multiple successful seeds that can be represented with these bits, while for other tasks, there might be none. The novel idea of CONSENSUS is to concatenate the current seed with previous seeds. This means that if we change one seed, we completely change the meaning of all following seeds. That way, if one task has no successful seeds, we can backtrack to another successful seed in a previous task and get a completely new chance for success in the current task.

While the thresholds in threshold-based k-perfect hashing are not classical seeds, we can still apply the CONSENSUS idea. The similarity is that for some bins, we might have more than one threshold that gives a sufficiently small number of empty slots, while for other bins, there might be none. We now use the thresholds of previous bins as a seed value when determining the fingerprints of the next bin. Selecting a different threshold in a previous bin therefore gives us a new chance to reduce the number of empty slots.



A problem with this approach is that there might be some bins that are much larger than γk caused by uniformly hashing keys to bins. Even if we try another hash function seed, the bins are biased towards having too many keys. Therefore, finding a seed such that exactly k keys are below one of the thresholds is unlikely. However, we still have the option to bump too many keys and repair the empty slots later. We need this option anyway because there

Listing 2 Query algorithm of k-perfect hashing trough bucket placement. Hash function h_X uniformly maps into the set X.

```
Function query(key ∈ S)
  bucket := ⌊(n/λ) · β_k(h_[0,1](key))⌋
  seed := seeds[bucket]
  return h_[⌈n/k⌉](key, seed)
```

(a) Illustration of the data structure using $k = 2$.

(b) Bucket assignment functions for different values of k.

Figure 2 Minimal k-perfect hashing through bucket placement.

might be bins that are not full enough. Therefore, for each actual size of a bin, we determine how many keys we have to accept bumping if we want to have at least one valid threshold in expectation. We then accept a seed if the number of empty slots is less than this limit.

5 k-Perfect Hashing Through Bucket Placement

Remember from Section 3.1 that perfect hashing through bucket placement [37, 20, 2] first hashes n keys to $\frac{n}{\lambda}$ buckets. For each bucket, it then searches for a hash function seed that can place the keys without collisions. The *bucket assignment function* $\beta : [0,1] \to [0,1]$ varies the expected size of each bucket such that placing each bucket has the same success probability. Figure 2a gives an illustration of the idea and Listing 2 describes the query algorithm. The idea generalizes trivially to k-perfect hashing, where we now place a bucket if all output bins stay below k collisions. Because k-perfect hashing has different success probabilities than 1-perfect hashing, we need a different bucket assignment function β_k. In this section we show how to choose β_k such that each bucket has approximately the same success probability.

We first need some general observations about bucket assignment functions. For key x, the expected size of its bucket with normalized index $\beta_k(x)$ is $\lambda/\beta_k'(x)$.[2] Let us assume that an x-fraction of keys is already mapped to bins. Then let $p_k(x)$ be the probability that a

[2] In the close neighborhood of x and for infinitesimal δ, a δ-fraction of the hash range (used by δn keys in expectation) is shared by a $(\beta_k'(x) \cdot \delta)$-fraction of the $\frac{n}{\lambda}$ buckets. The quotient is $\delta n/(\beta_k'(x)\delta\frac{n}{\lambda}) = \lambda/\beta_k'(x)$ [20].

random bin is not full at this point in the construction process. When placing a bucket of size s, a seed is successful if all keys map to bins that are not full yet which has a probability of $p_k(x)^s$ (ignoring self collisions). The optimal solution for $k = 1$ satisfies that $p_k(x)^{\lambda/\beta'_k(x)}$ is some constant [20]. Because λ is a constant, the equation simplifies to $p_k(x)^{1/\beta'_k(x)} = C_k$. Rearranging gives

$$\beta'_k(x) = \ln(p_k(x))/\ln(C_k). \tag{3}$$

For $k = 1$, a bin is full if there is a single key mapped to it. We therefore have $p_1(x) = 1 - x$ and $\beta'_1(x) = \ln(1 - x)/\ln(C_1)$. The constant C_k has to be chosen such that all keys are placed after the last bucket, i.e. $\beta_k(1) = 1$. After integration and proper choice of C_1 we have $\beta_1(x) = x + (1 - x)\ln(1 - x)$, the optimal bucket assignment function for $k = 1$ [20]. The difficulty for $k > 1$ is finding $p_k(x)$. Once we have $p_k(x)$, we use Equation (3) to obtain the bucket assignment function. Note that we assume without proof that using Equation (3) is still optimal for $k > 1$.

Model. To determine $p_k(x)$, we model the following process where we insert bk keys into b bins of capacity k. We initialize a counter $c_i = 0$ for each bin $i \in [b]$. The keys are handled sequentially as described in the following. For each key we uniformly sample bins. Sampling a bin $s \in [b]$ has two possible outcomes:

- $c_s < k$ (*Success*): We increment the counter c_s by one and continue with the next key.
- $c_s \geq k$ (*Failure*): In this case, we also increment the counter c_s by one. Note that this does *not* change anything in terms of success probabilities, since the bin is already full anyway. We continue with sampling a new bin for the same key.

Determining $p_k(x)$ Numerically. The reason for incrementing the counter even if the bin is full is that the counter of each bin now follows a Poisson distribution (assuming that the number of bins b is large). We show how $p_k(x)$ can be expressed as the solution of an integro-differential equation in the full version of this paper [18]. However, solving this equation is numerically unstable. In the following we give a numerically stable solution for $p_k(x)$. We repeatedly choose values μ. We use each μ as the expected value of the Poisson distribution that describes the distribution of the counters. For each μ we calculate the probability p that a key is inserted successfully, as well as the fraction of inserted keys x. Hence, for each μ we obtain p and x which we use to numerically determine $p_k(x)$. We choose the values μ such that the distance of consecutive x values is sufficiently small. The success probability p for a given μ is the probability that $c_s < k$, which we calculate using the cumulative distribution function of the Poisson distribution. To determine the fraction of inserted keys x for a given expected value μ we consider the counter of the bins as described in the model. For a bin where the counter is higher than k, we charge k successfully inserted keys, because all other incrementations are from failures. We then divide by k, since we are interested in the relative number of inserted keys. Let X follow a Poisson distribution with mean μ then $x = \frac{1}{k}(\mathbb{E}[X \mid X \leq k] + k\mathbb{P}[X > k]) = \frac{1}{k}\mathbb{E}[X \mid X \leq k] + \mathbb{P}[X > k]$.

The Bucket Assignment Function. The final bucket assignment function can be obtained by numerically evaluating the integral of Equation (3) for $\beta_k(x)$. The constant C_k can be ignored by normalizing the integral as a last step such that the boundary condition $\beta_k(1) = 1$ is met. Refer to Figure 2b for an illustration of the bucket assignment functions with different values of k. Larger k make the function more aggressive, further increasing the size of the first buckets. For example, for $k = 100$, 82% of the keys are hashed to 1% of buckets. Our implementation tabulates the bucket assignment function for specific k and uses linear interpolation to maintain a fast query time.

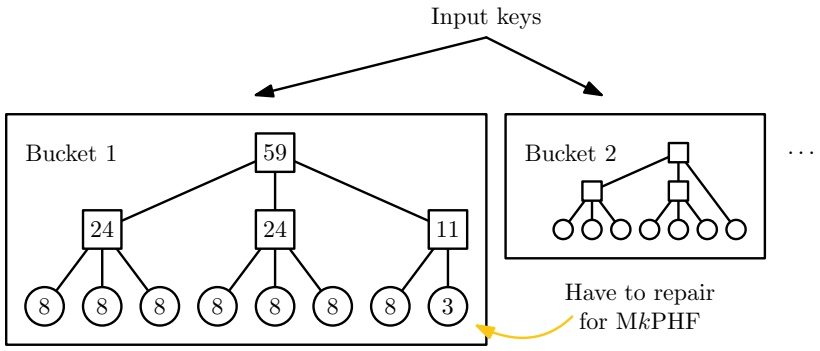


Figure 3 Illustration of RecSplit with $k = 8$ and lowest-layer fanout $\ell = 3$.

6 k-Perfect RecSplit

RecSplit [9] is a very space-efficient 1-perfect hash function. We first explain RecSplit and then show how we adapt it to a k-perfect hash function.

RecSplit. RecSplit [9] first hashes each key to a bucket of expected size b, where b is a tuning parameter with default value $b = 2000$ in the implementation. Within each bucket, RecSplit then uses brute-force to search for a hash function seed that divides the keys into two (or more) subsets. The number of these subsets (*fanout*) depends on the *splitting strategy*. This continues recursively until we are left with small input sets of $\leq \ell$ keys in the leaf nodes. These subsets are small enough that it is feasible to search for a perfect hash function using brute-force. RecSplit stores the hash function seeds determined at each node using Golomb-Rice coding (see Section 2) in DFS order. An Elias-Fano coded sequence (see Section 2) stores where the encoding of each bucket starts, as well as the total number of keys before it. A query traverses the splitting tree of the corresponding bucket, evaluating the hash function in each node. When descending into a subtree, it sums up the number of keys in sibling nodes left to it. Therefore, the final hash function value is given by the number of keys before the bucket, the number of keys to the left in the tree, and the final brute-force hash function value in the leaf. The RecSplit splitting strategy ensures that all subtrees except possibly the last are a complete tree where each leaf node receives exactly ℓ keys. Therefore, only the very last leaf in any tree can have a size smaller than ℓ. We illustrate RecSplit in Figure 3. Through the use of the buckets, RecSplit achieves linear time construction and constant time queries.

Main Idea. Our k-perfect adaptation of RecSplit is (almost) straight-forward. We perform splittings until we are left with leaves of size k. These then do not need to store seeds. We now use the parameter ℓ to select the fanout of the layer above. The main difficulty is that the last leaf in each bucket can have size $< k$. This would make the result a non-minimal kPHF. In Section 6.1, we explain how we can merge the leaves of adjacent buckets in order to get output bins of size k. As an alternative, in Section 6.2, we explain *nested* k-perfect hashing. This can avoid the problem by ensuring that each bucket's size is a multiple of k.

6.1 Merging Leaves of Size $< k$

From the prefix sum of bucket sizes, we know the number of keys x before each bucket. We start placing the output of the bucket's tree at the offset $\lfloor x/k \rfloor$. This means that we do not leave space for the previous bucket's leaves of size $< k$. Only if the total number of keys in

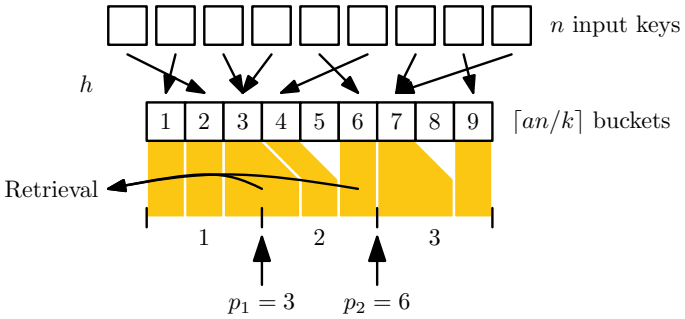

Figure 4 Illustration of PaCHash for k-perfect hashing with $a = k = 3$. Queries for keys hashed to bucket 3 cannot directly determine whether their output bin is 1 or 2 by looking at the cut-points p_i. Therefore, they have to query a retrieval data structure. For the single key in bin 6, the placement would actually be unambiguous. However, from looking at p_2, we cannot see that all keys in bin 6 have to map to the left of the threshold. Therefore, we still need to query the retrieval data structure. For p_2, can store either 6 or 7. We select the bin with fewer keys to reduce the number of keys in the retrieval data structure.

non-full leaves exceeds k, we get an additional output bin. For this, we calculate a splitting hash function on the last leaf that splits away the keys needed to fill the leaf. We store the splitting seed as an additional hash function seed in the Golomb-Rice coded seeds.

During queries, if we arrive in a leaf of size $< k$, there are two cases. (1) If the remainder of the bucket position does not cross k, we scan forward the following buckets until one does. The output bin is then the last bin of that bucket. (2) If the current bucket is the one letting the remainder cross k, we evaluate the splitting hash function. Then we either return the last bin of the current bucket, or we scan forward like in the first case.

Note that this means that we have to scan forward the bucket sizes when querying a leaf of size $< k$. However, because the number of keys in a bucket is random and much larger than k, we can assume we get a uniform random remainder. Therefore, in expectation, we only have to scan two buckets.

6.2 Avoiding Leaves of Size $< k$ Through Nesting

Another technique is to completely avoid leaves of size $< k$ in the first place. We can use a minimal b-perfect hash function (where k divides b) to partition the keys. In general, we can nest different k-perfect hash functions to interpolate their trade-offs. One function (maybe fast and less space-efficient) can map the input set to buckets of k' keys. Then, in each bucket, we can construct a k-perfect hash function. We could use the idea to implement a k-perfect version of CONSENSUS-RecSplit. However, nesting different kPHFs would introduce another dimension of experiments and make this paper harder to follow. We therefore do not go into detail about nesting or k-perfect CONSENSUS-RecSplit.

7 k-Perfect PaCHash

As we explain in Section 3.2, PaCHash hashes each key to one of $\lceil an/k \rceil$ buckets. The variable a is a tuning parameter. For each output bin i, it stores the first bucket p_i overlapping it using Elias-Fano coding (see Section 2). A predecessor query on that list then maps the bucket to the respective output bin. Figure 4 illustrates the data structure. During queries, if a searched bucket is contained in the sequence, it is not clear whether the key is supposed

Listing 3 Query algorithm of k-perfect PaCHash. If the range returned by the internal memory data structure is ambiguous, we have to query the retrieval data structure. Hash function h_X uniformly maps into the set X.

```
Function query(key ∈ S)
    b := h_{⌈an/k⌉}(x)
    find i such that p_{i-1} < b ≤ p_i                    // predecessor query
    if p_i = b
      i := i − 1                                          // b may start in previous block
    find first j such that p_j > b                        // predecessor query or scan
    if i = (j − 1)
      return i
    else
      return i + retrievalQuery(key)                      // (j-1-i)-bit retrieval
```

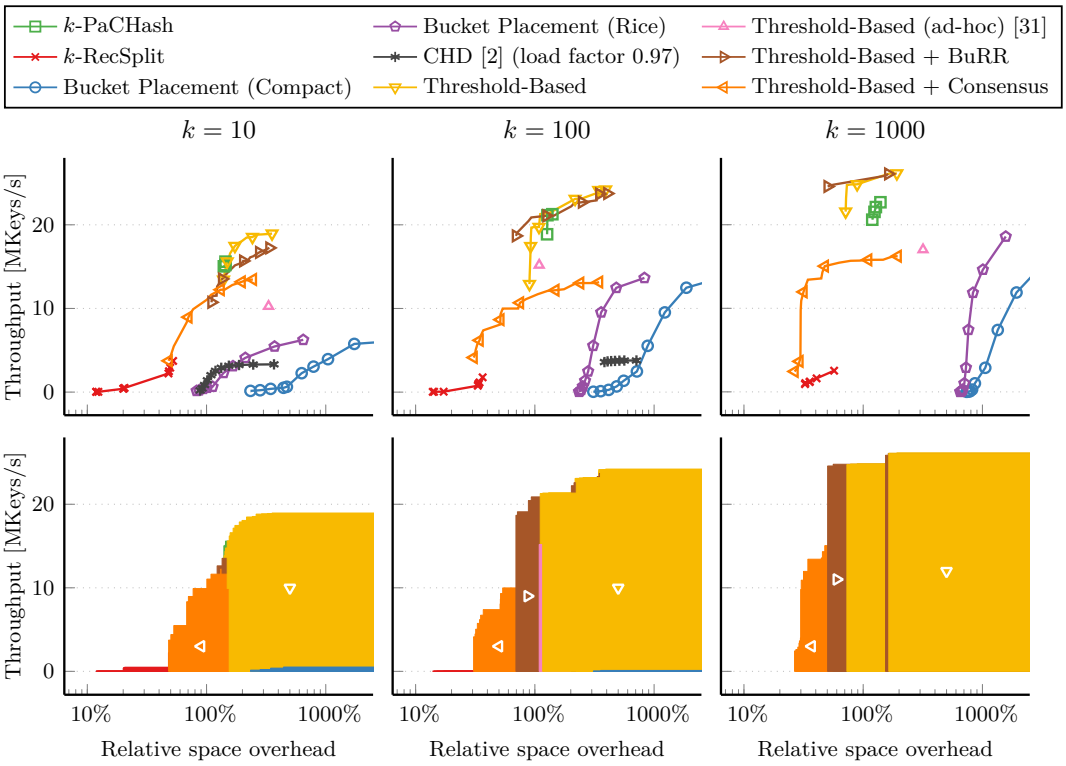
to be in the bin or in the bin before. In fact, it might be possible that d bins store the same bucket index. We get a similar problem if a bucket starts exactly at a bin boundary. Then the index cannot tell whether the bucket overlaps or not. The external memory implementation then loads all $d + 1$ candidate bins. However, for k-perfect hashing, we need a different strategy.

***k*-Perfect Adaptation.** To decide for one of the $d + 1$ bins using only the index data structure, we use a $\lceil \log_2(d+1) \rceil$ bit retrieval data structure (see Section 2). The stored value tells us which of the bins to return. Since we rarely need more than one bit, we simply store the numbers bitwise in a single 1-bit retrieval data structure. Listing 3 gives the pseudocode of the query algorithm. PaCHash expects $1/a$ of the queries to load one external memory page too much [23]. In the context of k-perfect hashing, this means that for $1/a$ of the queries, the output bin is ambiguous. This means that the retrieval data structure essentially stores n/a bits. By selecting $a = k$, we get a total space consumption of $n/k(3 + \log(k))$, which already gets close to the lower bound for large k (see Section 2). An advantage of the technique is that its construction through (integer) sorting and a single scan is very simple. Like the other approaches it takes linear time. Queries take expected constant time due to the distribution of values in the Elias-Fano data structure [23]. This adaptation is briefly mentioned in previous papers [27, 31] but without an implementation. The CONSENSUS paper [31] gives a simple analysis for the resulting space consumption.

8 Evaluation

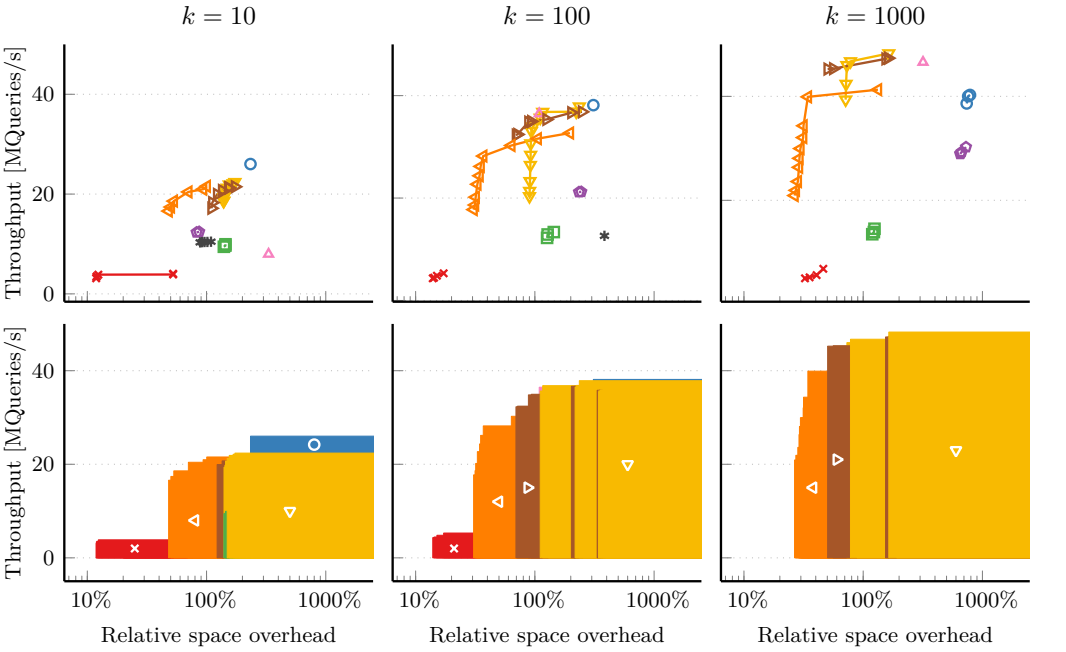
In this section, we compare our approaches with CHD [2], as well as the ad-hoc implementation of threshold-based bumping [31] from the literature. While CHD is not *minimal* k-perfect, we still include it in our comparison with a load factor of 97% to give a feeling for the performance of our approaches. With this paper, we build a foundation for future work on k-perfect hashing, contributing implementations for future papers to compare against.

We run our experiments on an Intel i7 11700 processor with 8 cores and a base clock speed of 2.5 GHz. The machine runs Rocky Linux 9.5 with Linux 5.14.0. We use the GNU C++ compiler version 11.2.0 with optimization flags `-O3 -march=native`. Following the practice in 1-perfect hashing [20, 27, 28], our input set consists of 100 million random strings of uniform random length $\in [10, 50]$. Because all approaches hash the input keys anyway, the choice of the input set is not very important. Our source code is public under the General Public License [19].



Because each approach has configuration parameters, it can cover a range of trade-offs between space consumption, construction time, and query time. To give an intuitive overview, we give visual plots showing different parameters of each approach. Figure 5a gives the trade-off between construction time and space consumption for three different values of k. Figure 5b gives the trade-off between query time and space consumption. We also give a *dominance map* [27, 7, 28] of the trade-off. For each point having a specific trade-off between construction time and space consumption, the dominance map in Figure 5a shows the approach achieving the best query time. As such, it can be seen as a "front view" of the 3-dimensional Pareto space. The dominance map in Figure 5b shows the method with the fastest construction for a given trade-off between space consumption and query performance. We show a selection of representative configurations from the Pareto front in the full version of this paper [18]. In the following, we discuss the different approaches in detail.

Threshold-Based Bumping. Compared to the ad-hoc implementation [31], our implementation of threshold-based bumping offers up to 3 times smaller space overhead due to the optimized thresholds. Only for $k = 100$, the linearly spaced ad-hoc thresholds happen to be close to optimal, so we only achieve small space improvements. For growing k, threshold-based bumping gets closer to the space lower bound, while the space overhead of most other approaches increases. Figure 5a also shows that our implementation is up to 50% faster to construct than the next best technique. This is mainly because the ad-hoc implementation fully sorts the keys by their bin and fingerprint, while we only partition by the bin and then use quickselect [21] to find the k-th key. By packing using retrieval, we can achieve smaller space consumption. This has only a small influence on construction and query times. Finally, using CONSENSUS-coded thresholds, we achieve smaller space consumption but slower construction and queries.



Hash and Displace. For the hash and displace technique, Rice coding (see Section 2) achieves lower space consumption than compact coding at the same construction time. This comes at the cost of slower queries, as can be seen in Figure 5b, due to the select queries. Compared to CHD [2], an implementation from the literature, our construction is much faster. Even though we use CHD with a load factor of just 97%, our construction gets close to its space consumption. The CHD implementation from the literature crashes for $k = 1000$, while our implementation supports large k as well. Our measurements show that the hash and displace technique with compact coding is fast to query, especially for smaller k. This is in contrast to the implementation from the literature, which has much slower queries. In general, the hash and displace technique seems not competitive for k-perfect hashing, especially for large k.

***k*-RecSplit.** Our k-perfect adaptation of RecSplit achieves the smallest space consumption. With just 10% overhead over the lower bound, it has a large margin to the next smallest competitor. This is not surprising, since the RecSplit paper [9] shows that the recursive splitting idea converges towards the space lower bound. However, its construction is significantly slower than the other approaches in Figure 5a. Because splittings become even more expensive for large k, we do not include the configuration with 10% space overhead for $k = 1000$. The queries are slow compared to other approaches.

***k*-PaCHash.** Our k-perfect adaptation of PaCHash is very simple to describe and fast to construct through sorting followed by a linear scan. However, its queries are slow due to the predecessor queries in the Elias-Fano coded sequence of bucket indexes.

(a) Space consumption versus construction time. The bottom row shows dominance maps indicating the approach with the fastest queries, given a specific trade-off between space and construction time.

(b) Space consumption versus query time. The bottom row shows dominance maps indicating the approach with the fastest construction, given a specific trade-off between space and query time.

Figure 5 Comparison of minimal k-perfect hash functions. A relative space overhead of 100% means that the data structure needs twice the lower bound. Refer to Table 1 for a table with lower bounds in bits per key.

9 Conclusion

To our knowledge, we present the first paper fully dedicated to presenting k-perfect hash functions. The area of k-perfect hashing has been known for a long time, but has not received a lot of attention. With the advent of very space-efficient 1-perfect hash functions, however, the area is becoming more and more relevant. In this paper, we kickstart the development of kPHFs by introducing four new or significantly improved constructions. Our constructions cover various trade-offs between space consumption, construction time, and query time.

With threshold-based bumping, we significantly improve a k-perfect hash function that was previously only described briefly as an ad-hoc solution in 1-perfect hashing papers [30, 31]. We achieve a significant reduction in bumped keys by combining it with retrieval, and we optimize the threshold function. By combining the idea with CONSENSUS coded seeds, we achieve a significant reduction in space consumption while retaining its fast queries. We also extend the idea of perfect hashing through bucket placement by optimizing the bucket assignment function for k-perfect hashing. As a very space-efficient alternative, we adapt RecSplit [9] to construct k-perfect hash functions. The main difficulty is to merge leaf nodes that have size $< k$. Finally, we adapt PaCHash [23] to a k-perfect hash function by combining it with a retrieval data structure.

Our extensive evaluation compares our new techniques with competitors from the literature. Our constructions are simultaneously faster to construct, faster to query, and more space-efficient than previous approaches. The most promising techniques are threshold-based bumping and k-RecSplit. While k-RecSplit achieves the best space consumption, it is slow to construct and query. Threshold-based bumping is very fast to construct and query while still giving competitive space consumption.

Future Work. This paper revives the research area of k-perfect hashing. In the future, we expect a wide range of new techniques, like there is in 1-perfect hashing. The approaches presented in this paper give a starting point outlining the trade-off. Especially our improvements to threshold-based bumping can now be used to improve the space efficiency of CONSENSUS-RecSplit [31]. An open theoretical problem is the space lower bound for non-minimal k-perfect hashing.

Cut-Query Algorithms with Few Rounds

The Harry Weinrebe Professorial Chair of Computer Science, Weizmann Institute of Science, Rehovot, Israel

Abstract

In the cut-query model, the algorithm can access the input graph $G = (V, E)$ only via cut queries that report, given a set $S \subseteq V$, the total weight of edges crossing the cut between S and $V \setminus S$. This model was introduced by Rubinstein, Schramm and Weinberg [ITCS'18] and its investigation has so far focused on the number of queries needed to solve optimization problems, such as global minimum cut. We turn attention to the round complexity of cut-query algorithms, and show that several classical problems can be solved in this model with only a constant number of rounds.

Our main results are algorithms for finding a minimum cut in a graph, that offer different tradeoffs between round complexity and query complexity, where $n = |V|$ and $\delta(G)$ denotes the minimum degree of G: (i) $\tilde{O}(n^{4/3})$ cut queries in two rounds in unweighted graphs; (ii) $\tilde{O}(rn^{1+1/r}/\delta(G)^{1/r})$ queries in $2r+1$ rounds for any integer $r \geq 1$ again in unweighted graphs; and (iii) $\tilde{O}(rn^{1+(1+\log_n W)/r})$ queries in $4r+3$ rounds for any $r \geq 1$ in weighted graphs. We also provide algorithms that find a minimum (s,t)-cut and approximate the maximum cut in a few rounds.

1 Introduction

Graph cuts are a fundamental object in computer science with numerous applications, in part because they are a basic example of submodular functions. Recall that a set function $f : 2^V \to \mathbb{R}$ is *submodular* if it satisfies the diminishing-returns property

$$\forall A \subset B \subset V, \forall v \notin B, \quad f(A \cup \{v\}) - f(A) \geq f(B \cup \{v\}) - f(B).$$

From the viewpoint of submodular optimization, it is natural to study the complexity of graph algorithms in the *cut-query model*, which correspond to value queries to the submodular function. Here, the input graph $G = (V, E, w)$ can be accessed only via oracle queries to its cut function, namely to $\mathrm{cut}_G : 2^V \to \mathbb{R}$, given by

$$\forall S \subseteq V, \qquad \mathrm{cut}_G(S) := \sum_{e \in E:\ |e \cap S| = 1} w(e).$$

Here and throughout $w(e) > 0$ is the weight of the edge $e \in E$, precluding edges of zero weight as they cannot be detected by the algorithm. As usual, an unweighted graph models unit weights, i.e., $w(e) = 1$ for all e.

The *query complexity* of an algorithm is the number of queries it makes in the worst-case. While this is often the primary performance measure, it is highly desirable that algorithms can be parallelized, as such algorithms can utilize better the available computing resources. The literature on the parallelization of submodular optimization [9, 24, 25, 18], relies on a measure called *round complexity*, which count the number of sequential rounds of queries the algorithm makes.[1]

▶ **Definition 1.1** (Round Complexity). *An algorithm has* round complexity r *if it performs r rounds of queries, meaning that queries in round $t \in [r]$ can depend only on the answers to queries in previous rounds $1, \ldots, t-1$. An algorithm is called* non-adaptive *if it uses a single round of queries.*

We study the cut-query model, from the perspective of round complexity focusing on the problem of finding a global minimum cut. Previous work [33, 31, 3, 2] shows that a minimum cut of a graph can be found using $O(n)$ queries in unweighted graphs and $\tilde{O}(n)$ queries in weighted graphs. However, it paid no attention to the algorithms' round complexity, and we fill this gap by studying the tradeoff between round complexity and query complexity.

An analysis of the round complexity of existing algorithms, with some simple modifications, shows that it is possible to find a global minimum cut of a graph using $\tilde{O}(n)$ queries with round complexity $\tilde{O}(\log^2 n)$ [33, 31]. It should be noted that other algorithms do require round complexity $\Omega(n)$ [3, 2]. As another baseline, it is possible to recover the entire graph using $O(n^2)$ deterministic non-adaptive queries [14],[2] which clearly suffices to find a minimum cut. This motivates our main question

▶ **Question 1.2.** *What is the tradeoff between the round complexity and the query complexity of finding a global minimum cut in the cut-query model?*

1.1 Main Results

We show that the polylogarithmic round complexity of previous work is not necessary for finding a global minimum cut. We begin by presenting two results for unweighted graphs. The first one shows that using even two rounds, we can substantially improve on the $O(n^2)$ query complexity of the naive algorithm. All of our algorithms return a vertex set $S \subseteq V$ and the value of the minimum cut. In the case of unweighted graphs the algorithms can also report the edges of the cut using one additional round of queries and with the same asymptotic query complexity.

▶ **Theorem 1.3** (Unweighted Minimum Cut with 2 rounds). *Given an unweighted graph G on n vertices, it is possible to find a minimum cut of G using $\tilde{O}(n^{4/3})$ cut queries in 2 rounds. The algorithm is randomized and succeeds with probability $1 - n^{-2}$.*

We further provide a smooth tradeoff between the number of queries and the number of rounds, namely $\tilde{O}(n^{1+1/r}/\delta(G)^{1/r})$ cut queries with in $2r$ rounds, where $\delta(G) \geq 1$ is the minimum degree of G.[3]

[1] The aforementioned references use the term *adaptivity*, which is the number of rounds minus one.

[2] $\tilde{O}(|E|)$ queries suffice, however without some bound on the size of the graph the algorithm must make $O(n^2)$ queries in the worst case.

[3] We can assume that the graph is connected since connectivity can be checked using $\tilde{O}(n)$ cut queries in 1 round (non-adaptive) [4].

▶ **Theorem 1.4** (Unweighted Minimum Cut with $O(r)$ rounds). *Given an unweighted graph G on n vertices and a parameter $r \in \{1, 2, \ldots, \log n\}$, it is possible to find a minimum cut of G using $\tilde{O}(rn^{1+1/r}\delta(G)^{-1/r})$ cut queries in $2r+1$ rounds. The algorithm is randomized and succeeds with probability $1 - n^{-1}$.*

We also obtain a similar tradeoff also for weighted graphs.

▶ **Theorem 1.5** (Weighted Minimum Cut Graphs with $O(r)$ rounds). *Given a weighted graph G on n vertices with integer edge weights bounded by W, and a parameter $r \in \{1, 2, \ldots, \log n\}$, it is possible to find a minimum cut of G using $\tilde{O}(rn^{1+(1+\log_n W)/r})$ cut queries in $4r+3$ rounds. The algorithm is randomized and succeeds with probability $1 - n^{-2}$.*

Finally, we note that our techniques can also be applied to approximating the maximum cut and finding a minimum (s,t)-cut with low adaptivity. Furthermore, our result for weighted minimum cuts can also be applied to finding a minimum cut in dynamic streams, providing a smooth tradeoff between the number of passes and the storage complexity of the algorithm. This holds since each cut query in a given round can be computed using $O(\log n)$ storage in a single pass by simply counting the edges in the cut. Therefore, the round complexity of our algorithm translates immediately to the number of passes required by a streaming algorithm. These results are detailed in the full version of the paper.

1.2 Related Work

Algorithms in the cut query model. In recent years there have been several works on cut problems in the cut-query model, most of which focused on query complexity and not round complexity. We will discuss the known results for several problems in the cut-query model.

Beginning with finding a minimum cut, $O(n)$ randomized queries suffice for simple graphs [33, 3]. Meanwhile, finding a minimum cut in a weighted graph requires $\tilde{O}(n)$ randomized queries [31]. Finally, in a recent work it was shown that non-trivial deterministic algorithms exist for finding the minimum cut of a simple graph using $\tilde{O}(n^{5/3})$ queries [2]. For the easier problem of determining whether a graph is connected, it is known that $O(n)$ randomized queries suffice [19, 30]. Additionally, there exists a one round randomized algorithm for connectivity that uses $\tilde{O}(n)$ queries [4].

Moving to the problem of finding a minimum (s,t)-cut. In [33] it was shown that it is possible to compute the minimum (s,t)-cut of a simple graph using $O(n^{5/3})$ queries, by showing that using a cut sparsifier it is possible to find a small set of edges that contains the minimum (s,t)-cut. This query complexity was matched in the deterministic setting by [2].

We also mention the problem of finding a $1-\epsilon$ approximation of the maximum cut. One way to achieve this is by constructing a cut sparsifier, this was show in [33] for simple graphs and in [32] for weighted graphs, both using $\tilde{O}(\epsilon^{-2}n)$ cut queries. Furthermore, an algorithm for 1/2-approximation using $O(\log n)$ cut queries in one round and a lower bound of $\tilde{\Omega}(n)$ on the query complexity needed to find a $1-\epsilon$ approximation of the maximum cut are also known [32].

Finally, there have been several works on graph problems in different query models, such as additive queries [22, 14, 15], quantum cut queries [29, 6, 3], matrix multiplication queries [34, 6, 3], Bipartite Independent Set queries [11, 4, 1] and more.

Adaptivity in submodular optimization. In recent years, there has been a growing interest in the adaptivity of algorithms for submodular optimization. This line of work was initiated by the work of [9], which showed that constrained submodular maximization can be solved

within a constant approximation factor in $O(\log n)$ rounds with a polynomial number of queries, the work also provides a matching lower bound. A string of later works improved on the query complexity and the approximation guarantee, culminating in an algorithm with an optimal $1 - 1/e$ approximation using $\tilde{O}(n)$ queries [9, 7, 8, 24, 25, 21]. The round complexity of unconstrained submodular maximization was also studied in [20].

The adaptivity of algorithms for submodular minimization was also studied in several works. It was shown that solving the minimum (s, t)-cut problem in weighted graphs using $O(\log n)$ rounds of queries requires $\tilde{\Omega}(n^2)$ queries [5]. For more general submodular functions, a bound of $\Omega(n/\log n)$ rounds for algorithms with a polynomial number of queries is known [16, 10, 17]. Note that all these hard instances are non symmetric, and hence do not apply to the minimum cut problem. It remains open to study the round complexity of symmetric submodular minimization problems in future work.

2 Technical Overview

Each of our three algorithms for minimum cut is based on a different insight. Our two-round algorithm uses contractions in the style of [28] to create a smaller graph that preserves the minimum cut. Similar contractions have been used in several minimum cut algorithm [28, 26, 3], however the existing algorithms aim to reduce the number of vertices in the graph, while our variant, called τ-star contraction, reduces the number of edges.

Our $(2r)$-round algorithm for unweighted graphs employs a known approach of applying a contraction procedure and then packing (in the contracted graph) edge-disjoint forests. The main challenge to ensure that forests are edge disjoint when packing them in parallel, and we overcome it by leveraging an elegant connection to cut sparsification, which shows that amplifying the sampling probabilities of the sparsifier construction by a factor of k ensures finding k edge-disjoint forests.

Our algorithm for weighted minimum cut follows the approach of [31], which constructs a $(1 \pm \epsilon)$-cut-sparsifier and then solves a monotone-matrix problem that is easily parallelizable. Prior work in the cut-query model provided cut sparsifiers [33, 32], but their core step of weight-proportional edge sampling requires $O(\log n)$ rounds. We eliminate this bottleneck with our two-round weight-proportional edge sampling primitive (Lemma 2.2), and thereby build a $(1 \pm \epsilon)$-cut-sparsifier in $3r$ rounds, and complete the entire algorithm in $O(r)$ rounds.

A common thread to all our algorithms is the use of edge sampling, both directly as part of the algorithms and to construct complex primitives such as forest packings and cut sparsifiers. In edge sampling, the input is a source vertex s and a target vertex set $T \subseteq V \setminus \{s\}$, and the goal is to sample an edge from $E(s, T) \coloneqq E \cap (\{s\} \times T)$. We need two types of edge sampling, both returning a sampled edge $e \in E(s, T)$ and its weight $w(e)$. The first one is *uniform edge sampling*, which picks each $e \in E(s, T)$ with equal probability $1/|E(v, T)|$ regardless of its weight, similarly to l_0 sampling; the second one is *weight-proportional edge sampling*, which picks each $e \in E(s, T)$ with probability $w(e)/w(E(v, T))$, similarly to l_1 sampling. In unweighted graphs these two definitions clearly coincide.

Weight-proportional edge sampling was used extensively in previous algorithms for the cut-query model [33, 31, 3, 32], although it had a naive implementation that requires $O(\log n)$ rounds. This naive implementation, which was proposed in [33], follows a binary search approach. Each step partitions the set T at random into two sets T_1, T_2 of equal cardinality, and finds the total weight of the edges in $E(s, T_1)$ and $E(s, T_2)$. The algorithm then decides whether to continue with T_1 or T_2 randomly in proportion to their weights. This approach clearly requires $\Omega(\log n)$ rounds, which exceeds the $O(1)$ round complexity we aim for, and furthermore yields only weight-proportional sampling, while some of our algorithms require uniform sampling in weighted graphs.

2.1 Edge Sampling Primitives

Our first technical contribution is a procedure for non-adaptive uniform edge sampling using $O(\log^3 n/\log\log n)$ queries that returns the weight of the sampled edge. An algorithm for uniform edge sampling using $O(\log^3 n)$ cut queries in one round (i.e. non-adaptively) was proposed in [4].[4] However, their algorithm is based on group testing principles using BIS queries[5] and returns only the endpoints of the edge, but not its weight, though it is probably not difficult to adapt their algorithm to return the weight as well. Our algorithm slightly improves on the query complexity of their algorithm, while also returning the edge's weight in the same round.

▶ **Lemma 2.1** (Uniform Edge Sampling). *Given a (possibly weighted) graph G on n vertices, a source vertex $s \in V$, and a target vertex set $T \subseteq V \setminus \{s\}$, one can return an edge e uniformly sampled from $E(s,T)$, along with its weight $w(e)$, using $O(\log^3 n/\log\log n)$ cut queries in one round, i.e, non-adaptively. The algorithm succeeds with probability $1-n^{-4}$.*

The algorithm works by subsampling the vertices in T into sets $T = T_0 \supseteq T_1 \supseteq \ldots \supseteq T_{\log n}$, and finds a level i such that $0 < |E(s,T_i)| \leq O(\log n)$. It then leverages sparse recovery techniques to recover all the edges in $E(s,T_i)$ and return one of them at random. To perform this algorithm in one round the algorithm recovers $w(E(s,T_i))$ and performs the queries needed for sparse recovery for all levels in parallel. It then applies the sparse recovery algorithm to the last level with non-zero number of edges, i.e. the last level with $w(E(s,T_i)) > 0$. We note that it is easy to decrease the query complexity of Lemma 2.1 by a factor of $O(\log n)$ by adding a round of queries and performing the sparse recovery only on the relevant level.

Our second procedure performs weight-proportional edge sampling in two rounds.

▶ **Lemma 2.2** (Weight-Proportional Edge Sampling). *Given a graph G on n vertices with integer edge weights bounded by W, a source vertex $s \in V$, and a target vertex set $T \subseteq V \setminus \{s\}$, one can return an edge e from $E(s,T)$, along with its weight $w(e)$, sampled with probability $w(e)/w(E(s,T))$ using $O(\log^2 n \log^2(nW))$ queries in two rounds. The algorithm succeeds with probability $1-n^{-4}$.*

The algorithm follows the same basic approach as the uniform edge sampling primitive, i.e. creating nestled subsets $T = T_0 \supseteq T_1, \supseteq \ldots \supseteq T_{\log(nW)}$ by subsampling. However, instead of recovering only the edges that were sampled into the last level with non-zero weight, the algorithm recovers in each level i all edges $e \in E(s,T_i)$ such that $w(e) \approx w(E(s,T))/2^i$. The recovery procedure is based on a Count-Min data structure [23], which we show can be implemented using few non-adaptive cut queries. The algorithm then uses another round of queries to learn the exact weights of all edges that were recovered in all the levels. It then concludes by sampling an edge from the distribution $\{p_e\}$, where for every edge e recovered in the i-th level, it sets $p_e \propto 2^i w(e)/w(E(s,T))$; with probability $1-\sum_e p_e$, the algorithm fails. Since the probability of being sampled into the i-th level is 2^{-i}, these probabilities yield the desired distribution over the recovered edges.

To prove that the algorithm returns an edge with high probability, we show that there is a constant probability that the outlined procedure returns some edge $e \in E(s,T)$, and hence repeating the algorithm $O(\log n)$ times yields with high probability an edge sampled from

[4] The algorithm requires $O(\log^2 n \log(1/\delta))$ cut queries and succeeds with probability $1-\delta$, setting $\delta = n^{-2}$ yields the bound.

[5] A BIS query is given two disjoint sets $A, B \subseteq V$ and returns true if there exists some edge connecting A, B and false otherwise.

$E(s,T)$ with the desired distribution. The query complexity of the algorithm is dominated by the Count-Min data structure, which requires $O(\log n \log(nW))$ cut queries in each level. Applying the recovery procedure on $O(\log(nW))$ levels, and repeating the procedure $O(\log n)$ times yields the stated query complexity.

2.2 Unweighted Minimum Cut in Two Rounds

The key idea of our algorithm is to apply an edge contraction technique that produces a graph with substantially fewer edges while preserving each minimum cut with constant probability. We then recover the entire contracted graph using a limited number of cut queries by applying existing graph recovery methods using $\tilde{O}(m)$ additive queries [22, 14]. We show that it is possible to simulate k additive queries using $O(n+k)$ cut queries, which allows us to recover a graph with $m \geq \tilde{O}(n)$ edges using $O(m)$ cut queries.

▶ **Corollary 2.3.** *Given a weighted graph G on n vertices and m edges, one can recover the graph G using $O(m+n)$ non-adaptive cut queries.*

While there has been frequent use of contraction procedures for finding minimum cuts, existing algorithms focused on reducing the number of vertices in the graph [28, 26, 3], typically to $\tilde{O}(n/\delta(G))$. This does not suffice to guarantee a graph with few edges, for example, applying such a contraction on a graph G with minimum degree $\delta(G) = \log^2 n$ and $\Omega(n)$ vertices of degree n, might yield a graph with $\tilde{\Omega}(n^2)$ edges. In contrast, our goal is to reduce the number of edges in the graph, allowing efficient recovery of the contracted graph using Corollary 2.3. The main technical contribution of this section is a new contraction algorithm, which we call τ-star contraction, that reduces the number of edges to $\tilde{O}((n/\tau)^2 + n\tau)$.

Our contraction algorithm is a thresholded version of the star-contraction algorithm introduced in [3]. The original version of the star-contraction algorithm of [3] can be roughly described as follows. Sample a subset of *center vertices* $R \subseteq V$ uniformly at random with probability $p = O(\log n/\delta(G))$. For every $v \in V \setminus R$, choose uniformly a vertex in $r \in N_G(v) \cap R$ and contract the edge (v,r), keeping parallel edges, which yields a contracted multigraph G'. The main guarantee of the algorithm is that if the minimum cut of G is non-trivial, i.e. not composed of a single vertex, then $\lambda(G) = \lambda(G')$ with constant probability, where $\lambda(G)$ denotes the value of a minimum cut in a graph. The following theorem states this formally.

▶ **Theorem 2.4** (Theorem 2.2 in [3])**.** *Let $G = (V,E)$ be an unweighted graph on n vertices with a non-trivial minimum-cut value $\lambda(G)$. Then, the star-contraction algorithm yields a contracted graph G' that,*

1. *has at most $O(n \log n/\delta(G))$ vertices with probability at least $1 - 1/n^4$, and*
2. *has $\lambda(G') \geq \lambda(G)$ always, equality is achieved with probability at least $2 \cdot 3^{-13}$.*

Note that in the cut query model, the algorithm cannot contract an edge because the underlying cut function remains constant. However, it can simulate the contraction of $e = (u,v)$ by merging the vertices u and v into a supervertex in all subsequent queries, which yields a contracted cut function. We now define our *τ-star contraction* algorithm.

▶ **Definition 2.5** (τ-star contraction)**.** *Given an unweighted graph $G = (V,E)$ on n vertices and a threshold $\tau \in [n]$, τ-star contraction is the following operation.*

1. *Let $H = \{v \in V \mid d(v) \geq \tau\}$ be the set of high-degree vertices.*
2. *Form the set $R \subseteq V$ by sampling each $v \in V$ independently with probability $p = \Theta(\log n/\tau)$.*
3. *For each $u \in H \setminus R$, pick an edge from $E(u,R)$, if non-empty, uniformly at random and contract it (keeping parallel edges).*

Notice that τ-star contraction depends on uniform edge sampling, since each vertex $u \in H \setminus R$ samples a neighbor in R. In our case, we can use the uniform edge sampling procedure described above to sample edges uniformly from $E(u, R)$.

We now sketch the proof that τ-star contraction yields a graph with few edges. To bound the number of edges, partition the vertices remaining after the contraction into two sets, R, i.e. the center vertices sampled in the sampling process, and $L = V \setminus H$, i.e. the low degree vertices. This analysis omits vertices in $H \setminus R$ that were not sampled into R or contracted, because every $v \in H \setminus R$ has in expectation $d_G(v) \cdot \log n/\tau \in \Omega(\log n)$ neighbors in R; hence with high probability it will have some neighbor in R and be contracted.

To bound the number of edges observe that $|R| \leq \tilde{O}(n/\tau)$ with high probability, and hence the number of edges between vertices in R is $O(|R|^2) \leq \tilde{O}(n^2/\tau^2)$. In addition, since the degree of the vertices of L is bounded by τ, the total number of edges incident on L, even before the contraction, is $O(n\tau)$. Hence, the total number of edges in G' is with high probability $\tilde{O}(n^2/\tau^2 + n\tau)$. The following lemma, proved in the full version of the paper, formalizes the guarantees of τ-star contraction.

▶ **Lemma 2.6.** *Let $G = (V, E)$ be an unweighted graph on n vertices with a non-trivial minimum-cut $\lambda(G)$ and let $\tau \in [n]$. A τ-star contraction of G gives G' that,*
1. *has at most $\tilde{O}(n^2/\tau^2 + n\tau)$ edges with probability at least $1 - 1/n^4$, and*
2. *has $\lambda(G') \geq \lambda(G)$ always, equality is achieved with probability at least $2 \cdot 3^{-13}$.*

We present in Algorithm 1 a procedure for finding the global minimum cut in two rounds using τ-star contraction. We will use it to prove Theorem 1.3, but first we need the following claim.

Algorithm 1 Unweighted Minimum Cut in 2 Rounds.

1: **Input:** Graph $G = (V, E)$
2: **Output:** A minimum cut $\mathcal{C} \subseteq V$
3: sample a set $R \subseteq V$ uniformly with probability $p = 400 \cdot \log n/\tau$
// Query round 1
4: query $\text{cut}_G(v)$ for all $v \in V$ ▷ find $d_G(v)$ for all $v \in V$
5: for each $v \in V \setminus R$, let $n(v) \leftarrow$ a random neighbor in $N_G(v) \cap R$ ▷ use Lemma 2.1
6: $\tau \leftarrow \max\{n^{1/3}, \delta(G)\}$
7: $V' \leftarrow V$
8: **for** $v \in \{V \setminus R \mid \text{cut}_G(v) \geq \tau\}$ **do**
9: update V' by contracting the edge $(v, n(v))$
// Query round 2
10: recover $G' = (V', E')$ with $\tilde{O}(n^{2-2/3} + n^{1+1/3})$ queries ▷ use Corollary 2.3, assuming $|E'| = \tilde{O}(n^{2-2/3} + n^{1+1/3})$
11: **return** $\min(\lambda(G'), \delta(G))$ ▷ can return also a set $S \subseteq V$ achieving the cut

▷ Claim 2.7. With probability $1 - n^{-3}$, line 9 of Algorithm 1 implements τ-star contraction with $\tau = \max\{n^{1/3}, \delta(G)\}$.

Proof. Notice that R is sampled uniformly from V and that line 9 is executed only for vertices in $H \setminus R$. It remains to show that the edge $(v, n(v))$ is sampled uniformly from $N_G(v) \cap R$, which indeed follows from Lemma 2.1. To analyze the success probability, note that the algorithm samples at most n edges in line 5 and by the guarantee of Lemma 2.1 this fails with probability at most $n \cdot n^{-4} = n^{-3}$. ◁

Proof of Theorem 1.3. The main argument is that Algorithm 1 finds a minimum cut of G with constant probability. Then, running this algorithm $O(\log n)$ times in parallel and returning the minimum output obtained gives the desired result. Notice that by Lemma 2.6, the connectivity of G' can only increase, hence, if the algorithm finds a minimum cut of G in some execution it will be returned. We assume throughout the proof that in all executions of the algorithm the size guarantee of Lemma 2.6 holds, i.e. $|E'| = \tilde{O}(n^{2-2/3} + n^{1+1/3})$, note that this holds with probability $1 - \tilde{O}(n^{-4})$. Using a union bound with Claim 2.7 above, we find that the algorithm succeeds with probability at least $1 - n^{-2}$.

By Claim 2.7 the graph G' is the result of the τ-star contraction with $\tau = n^{1/3}$, and thus $\lambda(G') = \lambda(G)$ with constant probability by Lemma 2.6. Therefore, recovering the graph G' and returning the minimum of $\lambda(G')$ and $\delta(G)$ gives a minimum cut of G with constant probability.

To bound the query complexity, observe that the query complexity of the algorithm is dominated by the number of queries in the graph recovery step, which is given by $\tilde{O}(n^{2-2/3} + n^{1+1/3}) = \tilde{O}(n^{4/3})$. In the first round, we use $\tilde{O}(n)$ queries as finding the degree of each vertex requires n queries, and sampling a neighbor in $E(v, R)$ can be done using $O(\log^3 n / \log\log n)$ queries by Lemma 2.1. This concludes the analysis of the query complexity of the algorithm, which is $\tilde{O}(n^{4/3})$.

Finally, notice that the algorithm proceeds in two rounds; in the first round the algorithm only queries the degrees of the vertices and samples an edge in $E(v, R)$ for every v, which does not require any prior information on the graph. In the second round, it recovers G' round using Corollary 2.3. This concludes the proof of Theorem 1.3. ◀

2.3 Unweighted Minimum Cut in $2r$ rounds

This section provides an algorithm for finding a minimum cut in $2r$ rounds, thus proving Theorem 1.4. The algorithm uses a known approach of first applying a contraction algorithm, yielding a graph with $\tilde{O}(n/\delta(G))$ vertices, and then packing $\delta(G)$ edge-disjoint forests in the contracted graph. The main challenge in adapting this algorithm to low round complexity, is ensuring that the forests are edge disjoint when packing them in parallel. This is achieved by leveraging a connection to cut sparsification, which shows that sampling edges with probabilities amplified by a factor of k relative to those needed for sparsifier construction ensures finding k edge disjoint forests within the sampled subset. We note that we also offer another algorithm for finding a minimum cut, that has slightly worse query complexity of $O(rn^{1+1/r})$, and is based on constructing a cut sparsifier and the results of [33], see the full version of the paper.

The contraction we use is the 2-*out contraction* procedure of [26], which is obtained by sampling uniformly two edges incident to each vertex and contracting all the sampled edges. The following theorem states the guarantees of the 2-out contraction.

▶ **Theorem 2.8** (Theorem 2.4 in [26]). *Let $G = (V, E)$ be an unweighted graph on n vertices with a non-trivial minimum-cut value $\lambda(G)$. Then, applying a 2-out contraction algorithm gives G' where,*

1. *G' has at most $\tilde{O}(n/\delta(G))$ vertices with high probability, and*
2. *has $\lambda(G') \geq \lambda(G)$ always, equality is achieved with constant probability.*

The other building block of the algorithm is maximal k-packing of forests.

▶ **Definition 2.9** (Maximal k-Packing of Forests). *Given a (possibly weighted) graph G, a maximal k-packing of forests is a set of edge-disjoint forests $T_1, \ldots, T_k$ that are maximal, i.e. for every $i \in [k]$ and $e \in E \setminus \cup_j T_j$, the edge set $T_i \cup \{e\}$ contains a cycle.*

▶ **Lemma 2.10.** *Given a (possibly weighted) graph G on n vertices and parameters $r \in \{1, \ldots, \log n\}$ and $k \in [n]$, one can find a maximal k-packing of forests of G using $\tilde{O}(krn^{1+1/r})$ cut queries in $2r$ rounds. The algorithm is randomized and succeeds with probability $1 - n^{-4}$.*

We now outline the algorithm of Lemma 2.10, for further details see the full version of the paper. The algorithm begins by creating a set of empty trees $T_1, \ldots, T_k$. Then, in each of $r-1$ rounds it uniformly samples $\tilde{O}(kn^{1+1/r})$ edges from the graph, augments the trees $\{T_i\}$ by adding all sampled edges that do not form a cycle, and contracts all vertices that are connected in all trees. We show that the number of edges decreases by an $n^{1/r}$ factor in each round; hence, after $r-1$ rounds the number of remaining edges is $O(n^{1+1/r})$. Finally, the algorithm recovers all remaining edges by sampling $\tilde{O}(n^{1+1/r})$ edges uniformly, which recovers all edges by a standard coupon collector argument, and augments the trees appropriately.

To guarantee the decrease in the number of edges we leverage an elegant connection to cut sparsifier contraction. The seminal work [13] showed that if we sample (and reweight) every edge with probability proportional to its strong connectivity, then the resulting graph approximates all the cuts of the original graph with high probability.

▶ **Definition 2.11** (Strength of an Edge)**.** *Let $G = (V, E, w)$ be a weighted graph. We say that $S \subseteq V$ is* κ-strong *if the minimum cut of the induced graph $G[S]$ is at least κ. An edge $e \in E$ is κ-strong if it is contained within some κ-strong component S.*

We also need the following lemma concerning the existence of κ-strong components in a graph.

▶ **Lemma 2.12** (Lemma 3.1 in [12])**.** *Every weighted graph H with n vertices and total edge weight at least $\kappa(n-1)$ must have a κ-strong component.*

We can now detail the process of edge reduction of Lemma 2.10. Let G be a graph with m edges and n vertices. Observe that after one round of sampling, the algorithm contracts every $(m/n^{1+1/r})$-strong component of G, and thus by Lemma 2.12 the number of edges remaining in the graph is at most $m/n^{1/r}$. Let $C \subseteq V$ be a maximal $\Omega(m/n^{1+1/r})$-strong component of G, and assume the algorithm samples every edge of the graph with probability $p_e \approx k/\kappa$. In expectation the algorithm samples at least $p_e \cdot m/n^{1+1/r} \approx k$ edges crossing each cut $S \subseteq C$, which also holds with high probability by standard concentration and cut counting results. Therefore, for every $u, v \in C$, the minimum cut in the sampled subgraph has at least k edges, hence they are connected in k edge disjoint forests and will be contracted. In conclusion, in every iteration the algorithm contracts all $(m/n^{1+1/r})$-strong components of the graph, and the number of edges in the graph decreases by a factor of $n^{1/r}$.

Proof of Theorem 1.4. The algorithm begins by performing a 2-out contraction on G to obtain a graph G' with $\tilde{O}(n/\delta(G))$ vertices which preserves each non-trivial minimum cut of G with constant probability by Theorem 2.8. In parallel, the algorithm learns $\delta(G)$ by querying the degree of each vertex. Then, it packs $k = \delta(G)$ trees $\{T_i\}_{i=1}^{k}$ in G' using Lemma 2.10. Notice that since the minimum cut of G is at most $\delta(G)$ and each edge has weight at least 1 then $\delta(G)$ trees in G' will include all edges in the minimum cut. Hence, returning the minimum between $\delta(G)$ and the minimum cut of $H = (V, E_H = \cup_i T_i)$ will yield the minimum cut of G with constant probability. To amplify the success probability we repeat the algorithm $O(\log n)$ times in parallel and return the minimum cut found.

To analyze the query complexity notice that by Lemma 2.1, sampling the edges for the 2-out contraction takes $\tilde{O}(n)$ queries in one round. Hence, the algorithm constructs G' in $\tilde{O}(n)$ queries in one round. Then, it packs $k = \delta(G)$ trees in G', which has only $\tilde{O}(n/k)$ vertices, using $\tilde{O}(\delta(G)r(n/\delta(G))^{1+1/r})$ queries in $2r$ rounds by Lemma 2.10. Hence, overall the algorithm require $\tilde{O}(\delta(G)^{-1/r}rn^{1+1/r})$ queries in $2r+1$ rounds.

We conclude the proof by analyzing the success probability of the algorithm. Our implementation of the 2-out contraction succeeds with probability $1 - n \cdot n^{-4}$ since it only requires sampling $O(n)$ edges using Lemma 2.1. Then, each tree packing succeeds with probability $1 - 2n^{-2}$ by Lemma 2.10. By a union bound, the entire algorithm succeeds with probability $1 - n^{-1}$, which concludes the proof of Theorem 1.4. ◀

2.4 Weighted Minimum Cut in $O(r)$ rounds

In this section we give an overview of our algorithm for minimum cut in a weighted graph with low adaptivity. It is an adaptation of the minimum cut algorithm of [31], which reduces the problem to constructing a cut sparsifier and solving a monotone matrix problem which is easily parallelizable. The main difficulty lies within the construction of a cut sparsifier; while previous work in the cut-query model already provided cut sparsifiers [33, 32], its core step, weight-proportional edge sampling, uses $O(\log n)$ rounds. Our main technical contribution here is our two-round weight-proportional edge sampling primitive (Lemma 2.2), which enables the construction of a $(1 \pm \epsilon)$-cut-sparsifier in $3r$ rounds and the completion of the entire reduction within $O(r)$ rounds.

The algorithm of [31] for finding a minimum cut in a weighted graph is actually based on the 2-respecting minimum-cut framework of [27]; where a spanning tree $T \subseteq E$ is called 2-*respecting* for a cut $C \subseteq E$ if $|C \cap T| \leq 2$. The main insight here is that a given a spanning tree T that is 2-respecting for a minimum cut C, there are only $O(n^2)$ cuts that one needs to check to find a minimum cut, and they correspond to all pairs of edges in T. Originally [27], proposed a clever dynamic algorithm to calculate all these cuts quickly. In contrast, the algorithm of [31] leverages the structure of the 2-respecting spanning tree to show that the number of potential cuts is actually much smaller; restricting attention to sub-trees, $\{T_i\}$, that are all paths and whose total size is bounded. Furthermore, when T is a path the task of finding a minimum cut reduces to the following problem.

▶ **Definition 2.13** (Monotone Matrix Problem). *Let $A \in \mathbb{R}_+^{a \times a}$ be a matrix. For every column j denote the first row in which j attains its minimum value by j_s and the last row in which j attains its minimum value by j_t. The matrix is called* monotone *if for every $i > j$ we have $j_t \leq i_s$; i.e. the row in which the minimum value is found increases monotonically as we move to the right.*

The monotone matrix problem *is to find the minimum value of a monotone matrix (of dimension $a \times a$) while querying the value of as few entries as possible.*

In the context of the minimum cut problem, each entry in the matrix corresponds to a cut in G and can be recovered using a single cut query. We summarize some results from [31] in the following lemma, whose proof is provided in the full version of the paper.

▶ **Lemma 2.14.** *Assume there is an algorithm to construct a $(1 \pm \epsilon)$-cut-sparsifier for a graph G on n vertices using $q_S(n)$ queries in $r_S(n)$ rounds, and an algorithm that solves the monotone matrix problem on instances of size n using $q_M(n)$ queries in $r_M(n)$ rounds. If in addition the function q_M is convex, then it is possible to find a minimum cut of G using $\tilde{O}(q_S(n) + q_M(n) + n)$ cut queries in $r_S(n) + r_M(n) + 2$ rounds.*

Therefore, in order to find a minimum cut it suffices to construct a cut sparsifier and then solve the monotone matrix problem. Our main technical contribution in this section is a construction of a cut sparsifier with low adaptivity. We begin by formally defining the notion of a cut sparsifier.

▶ **Definition 2.15.** *Let $G = (V, E, w)$ be a weighted graph and let $H = (V, E_H, w_H)$ be a weighted subgraph of G. We say that H is a* $(1 \pm \epsilon)$-cut-sparsifier *of G if,*

$$\forall S \subseteq V, \qquad \mathrm{cut}_H(S) \in (1 \pm \epsilon)\mathrm{cut}_G(S).$$

▶ **Lemma 2.16.** *Given a weighted graph $G = (V, E, w)$ on n vertices with integer edge weights bounded by W, and a parameter $r \in \{1, 2, \ldots, \log n\}$, one can construct a $(1+\epsilon)$-cut-sparsifier of G using $\tilde{O}(\epsilon^{-2} r n^{1+(1+\log_n W)/r})$ cut queries and $3r + 3$ rounds. The algorithm is randomized and succeeds with probability $1 - n^{-2}$.*

We now sketch the proof of Lemma 2.16, for more details see the full version of the paper. The sparsifier construction is similar to the one in [33, 32] but modified to work in r rounds. It follows the sampling framework of [13], that shows that if one samples every edge in a graph with probability proportional to its strong connectivity, then the sampled graph is a $(1 \pm \epsilon)$-cut-sparsifier with high probability. The algorithm is based on iteratively finding the strongest components of the graph using weight-proportional edge sampling, assigning a strength estimate to all their edges, and contracting them. It repeats this process until all vertices are contracted. Finally, it samples all the edges in the graph according to their strength estimates, and returns the sampled edges as the sparsifier.

Our algorithm improves on the round complexity of the existing constructions in two ways: the first one is the adoption of a two-round weight-proportional sampling algorithm that eliminates an $O(\log n)$ factor in the round complexity. The second improvement is in the number of contraction steps performed. The algorithm of [33, 32] uses $O(\log(nW))$ steps, where in each step strengths are approximated within factor 2. Our algorithm uses instead r steps, where each step contracts all components with strength within an $n^{(1+\log_n W)/r}$ factor. Since the maximum component strength is $O(n^{1+\log_n W})$, the algorithm can contract all the components within r steps.

Our second technical contribution is an algorithm that solves the monotone matrix problem in few rounds, the proof is provided in the full version of the paper.

▶ **Lemma 2.17.** *There exists an algorithm that solves the monotone matrix problem on instances of size n using $\tilde{O}(n^{1+1/r})$ queries in r rounds.*

The algorithm for the monotone matrix problem in [31] uses a divide-and-conquer approach. At each step the algorithm reads the entire middle column j of the matrix A and finds the minimum value in the column. Then, it splits the matrix into two submatrices $A_L = A[1, \ldots, j_s; 1, \ldots, j]$ and $A_R = A[j_t, \ldots n; j+1, \ldots n]$ based on the location of the minimum value in the column. The algorithm is guaranteed to find the minimum value in each column by the monotonicity property of the matrix. Finally, it is easy to verify that as the size of the problem decreases by factor 2 in each iteration, the overall complexity of the algorithm is $\tilde{O}(n)$.

Unfortunately, the algorithm of [31] requires $O(\log n)$ rounds to complete all the recursion calls. Our algorithm instead partitions the matrix into $n^{1/r}$ blocks and then recurses on each block, which requires a total of $O(n^{1+1/r})$ queries in r rounds.

To conclude this section, notice that Theorem 1.5 follows by combining Lemma 2.14, Lemma 2.16, and Lemma 2.17.

2.5 Open Questions

Optimal Tradeoff Between Rounds vs Queries Complexity. An interesting open question is whether our constructive results have matching lower bounds or, alternatively, if better algorithms exist. Currently, there are no known query lower bounds even for algorithms

that use a single round of queries. We note that connectivity can be solved in one round with $\tilde{O}(n)$ queries [4], however it remains unclear whether this can be extended to finding a minimum cut, or whether there exists a lower bound of $\Omega(n^{1+\epsilon})$ cut queries for one round algorithms.

Adaptivity of Deterministic Algorithms. A deterministic algorithm for finding a minimum cut in simple graphs using $\tilde{O}(n^{5/3})$ cut queries was recently shown in [2], however its round complexity is polynomial in n, and it seems challenging to achieve polylogarithmic round complexity. In comparison, graph connectivity can be solved deterministically using $\tilde{O}(n^{1+1/r})$ cut queries in $O(r)$ rounds [4],[6] though these techniques do not seem to extend to finding a minimum cut.

Abstract

We introduce a 0.611-approximation algorithm for Quantum MaxCut and a $\frac{1+\sqrt{5}}{4} \approx 0.809$-approximation algorithm for the EPR Hamiltonian of [12]. A novel ingredient in both of these algorithms is to *partially* entangle pairs of qubits associated to edges in a matching, while preserving the direction of their single-qubit Bloch vectors. This allows us to interpolate between product states and matching-based states with a tunable parameter.

1 Introduction

Given a graph $G(V, E, w)$ with positive edge weights $w : E \to \mathbb{R}_+$ and a 2-local Hamiltonian term h, define the n-qubit Hamiltonian

$$H_G \stackrel{\text{def}}{=} \sum_{(i,j)\in E(G)} w_{ij} \cdot h_{ij} \,,$$

where h_{ij} is the local term h applied on qubits (i, j). For two particular local terms h, we are interested in the problem of computing the maximum energy of H_G, which we denote as $\lambda_{max}(H_G)$, for any G. This is not an easy task in general: deciding if $\lambda_{max}(H_G)$ is above some threshold with inverse polynomial accuracy is known to be QMA-hard [18].

In the first problem, we choose the local term

$$h_{ij}^{QMC} \stackrel{\text{def}}{=} \frac{1}{2}\left(I_iI_j - X_iX_j - Y_iY_j - Z_iZ_j\right) = 2\left|\psi_-\right\rangle_{ij}\left\langle\psi_-\right|_{ij} \,,$$

where $|\psi_-\rangle = \frac{1}{\sqrt{2}}\left(|01\rangle - |10\rangle\right)$ is the singlet state. This problem has recently been studied under the name *Quantum MaxCut* (QMC) [7]. In the statistical mechanics literature, Hamiltonians H_G defined by h^{QMC} are instances of the zero-field quantum Heisenberg $\mathrm{XXX}_{1/2}$ model. The decision version of QMC is QMA-hard [18].

In the second problem, we choose the local term

$$h_{ij}^{EPR} \stackrel{\text{def}}{=} \frac{1}{2}\left(I_iI_j + X_iX_j - Y_iY_j + Z_iZ_j\right) = 2\left|\phi_+\right\rangle_{ij}\left\langle\phi_+\right|_{ij} \,,$$

where $|\phi_+\rangle = \frac{1}{\sqrt{2}}\left(|00\rangle + |11\rangle\right)$. This problem, named *EPR* by [12], is thought to be easier than QMC, since Hamiltonians H_G defined by h^{EPR} are *stoquastic* (sign-problem free) [18, 5]. In fact, it is not yet clear if EPR can be solved in polynomial time.

In lieu of exactly computing $\lambda_{max}(H_G)$, we may try to *approximate* this value. In both problems, the local term h is positive semidefinite, so $\lambda_{max}(H_G) \geq 0$. We judge an approximation by its *approximation ratio*. Suppose we can find efficiently computable functions ℓ, u such that for all graphs G,

$$0 \leq \ell(G) \leq \lambda_{max}(H_G) \leq u(G) \,.$$

Then, the approximation ratio α is at least

$$\alpha \geq \min_G \frac{\ell(G)}{\lambda_{max}(H_G)} \geq \min_G \frac{\ell(G)}{u(G)} \,.$$

In most works, the upper bound u is determined by solving a semidefinite programming (SDP) relaxation of the maximization problem [3, 7, 16, 19, 20, 9]. The source of such SDP relaxations are generally hierarchies of SDPs that provide increasingly better upper bounds u at the cost of solving larger-sized SDPs. The quantum moment-SOS hierarchy, typically based on Pauli operators, is widely employed for quantum local Hamiltonian problems. This hierarchy is an instance of the NPA hierarchy [15] and is also known as the quantum Lasserre hierarchy [16]. The second level of the quantum moment-SOS hierarchy is necessary for good approximations, since critical monogamy-of-entanglement properties begin to emerge at that level [16, 17].

The lower bound ℓ is usually determined by an algorithm that prepares a state with this energy. Several approximation algorithms have been proposed for QMC and EPR, using product states [7, 16, 17, 12], matchings [1, 16, 17, 14, 10, 8], and short variational

circuits [1, 13, 12, 11, 8]. During the preparation of this manuscript, the best known approximation ratios for these problems were improved to $\alpha \geq 0.603$ for QMC [8] and $\alpha \geq \frac{1+\sqrt{5}}{4} \approx 0.809$ for EPR [11].

We provide a new algorithm for both problems. For each algorithm, we start from a good product state. We then choose a matching in G and *partially* rotate matched qubits towards an entangled state. Our novel contribution is to perform this rotation such that individual single-qubit Bloch vectors are preserved, up to a rescaling of magnitude. This allows us to evaluate the energy of our entangled state in terms of the energy of the product state. For EPR, we use a *fractional* matching and provide a circuit-based algorithm. For QMC, we explicitly describe a tensor-product of single and two-qubit states, which interpolates between the product state and an *integer* matching-based state with a single tunable parameter. For QMC, we additionally introduce the technique of choosing a maximum-weight matching with respect to *rescaled* edge weights. One interpretation of this approach is that we widen the search space of our algorithm to include matchings other than the maximum-weight matching of G. Combining these techniques allows us to achieve state-of-the-art approximation ratios on each problem:

▶ **Theorem 1.** *For EPR,* $\alpha \geq \frac{\varphi}{2} \approx 0.809$*, where* $\varphi \stackrel{\text{def}}{=} \frac{1+\sqrt{5}}{2} \approx 1.618$ *is the golden ratio.*

▶ **Theorem 2.** *For QMC,* $\alpha \geq 0.611$*.*

▶ Remark 3. Theorem 1 was shown simultaneously and independently by [11] using a different algorithm. The algorithm of [11] also *partially* entangles edges while preserving single-qubit marginals. However, we believe both our algorithm and analysis are simpler.

▶ Remark 4. Theorem 2 requires an improved upper bound in addition to new algorithmic techniques. The technique of finding a matching with respect to rescaled edge weights was simultaneously and independently used by [8]; however, they use this as part of an improved approximation algorithm for QMC on triangle-free graphs rather than general graphs. Our QMC approximation does rely on a strengthening by [8] of a class of upper bounds first used in the work [14]. Without this strengthened bound, we still achieve an approximation ratio $\alpha \geq 0.610$.

Our approximation algorithm finds a quantum state ρ_G such that $\mathrm{Tr}\left(H_G \rho_G\right) \geq \ell(G)$. For the EPR Hamiltonian, the analysis of our algorithm is optimal: there exist graphs G (such as the single-edge graph) where

$$\frac{\ell(G)}{u(G)} \leq \frac{\langle \psi_G | H_G | \psi_G \rangle}{\lambda_{max}(G)} = \frac{1+\sqrt{5}}{4}.$$

For QMC, however, it is possible that a better analysis of this algorithm (particularly of $u(G)$) would give a larger approximation ratio.

We stress the novelty of this work is *new algorithmic techniques* for QMC and EPR. We use these techniques to immediately improve the approximation ratios for each algorithm, however we believe that these techniques, potentially combined with previous methods, may lead to further improvements in approximation ratios for both algorithms. In the remainder of this work, we introduce necessary notation, describe each algorithm, and prove Theorems 1 and 2. We defer some technical lemmas to the appendix, which can be found in the full version of this paper [2].

2 Preliminaries

2.1 Graph theory

Let $G(V, E, w)$ denote a graph with vertex set V, edge set E, and positive edge weights $w : E \to \mathbb{R}_+$. In this work, we always take $V = [n] \stackrel{\text{def}}{=} \{1, 2, \ldots, n\}$. We let $W_G \stackrel{\text{def}}{=} \sum_{(i,j)\in E} w_{ij}$. When G is inferred by context, we simply write W. Define $N(v)$ as the set of neighbors of a vertex $v \in V$. For convenience, we index edges by either e or (i, j), or simply ij in subscripts.

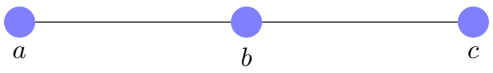
A fractional *matching* of a graph $G(V, E, w)$ is a function $m : E(G) \to [0, 1]$ that assigns a value to each edge in G, such that the sum over values $\sum_{j\in N(i)} m_{ij}$ is at most 1 for any vertex i. If $m_{ij} \in \{0, 1\}$ for all edges (i, j), we say that m is an *integral* matching. For an integral matching m, we say an edge (i, j) is in the matching if $m_{ij} = 1$. The *weight* $\mathrm{Wt}(m)$ of a matching m is defined as $\mathrm{Wt}(m) \stackrel{\text{def}}{=} \sum_{(i,j)\in E(G)} w_{ij}\, m_{ij}$. We define FM_G (or M_G) to be the maximum total weight of any fractional (or integral) matching of G. For convenience, we sometimes let M_G also denote the set of edges in the maximum-weight integral matching of G. When the graph is clear from context we drop the subscript G. Optimal integral and fractional matchings can be computed in polynomial time, for example with linear programming [6].

2.2 Quantum computation

We refer to $\vec{\sigma} = (X, Y, Z)$ as the canonical Pauli matrices. As such, we can define the *Bloch vector* $\vec{B}(\rho)$ of any 1-qubit density matrix ρ as the vector (b_x, b_y, b_z) in the unit sphere S^2 such that

$$\rho = \frac{1}{2}(I + \vec{B}(\rho) \cdot \vec{\sigma}) \stackrel{\text{def}}{=} \frac{1}{2}(I + b_x X + b_y Y + b_z Z)\,.$$

Pure states correspond to unit Bloch vectors. Let $|\psi_-\rangle = \frac{1}{\sqrt{2}}(|01\rangle - |10\rangle)$ be the *singlet state*, and $|\phi_+\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |11\rangle)$ be the *EPR state*.



2.3 Previous algorithms

In our work, we use two previously known algorithms as subroutines:

1. The algorithm PROD takes a graph $G(V, E, w)$ as an input, and outputs a good product state ρ_{PROD}. For EPR, we define $\rho_{PROD} \stackrel{\text{def}}{=} |0\rangle^{\otimes n} \langle 0|^{\otimes n}$. For QMC, we define PROD to be the output of the [7] rounding algorithm applied to the some fixed constant level k of the quantum moment-SOS hierarchy, as in [17] and [14]. This is the only part of our algorithm for QMC that relies on an SDP. As described in [17, Sec 2.2], the output from the SDP can be interpreted as a *pseudo-density matrix*. It is called a *pseudo*-density matrix because it satisfies only some of the constraints of a valid density matrix. Furthermore, the SDP at any constant ℓ can be solved in polynomial time.
2. The algorithm MATCH takes a graph $G(V, E, w)$ as an input, and outputs a product of 2-qubit states ρ_{MATCH}. It was first formally proposed in [14]. The algorithm first finds a maximum-weight integral matching M_G. For EPR (and for QMC), it outputs the tensor product of $|\phi_+\rangle_{ij} \langle\phi_+|_{ij}$ (and $|\psi_-\rangle_{ij} \langle\psi_-|_{ij}$ for QMC) for every pair of vertices (i, j) in the matching, and the maximally mixed state for every vertex i not in the matching. This obtains energy 2 on matched edges and 1/2 on unmatched edges, for a total of $(3\mathrm{M}_G + W_G)/2$.

3 Our Algorithms

To motivate our algorithms, consider the following simple graph G:

This graph is bipartite, so QMC and EPR are equivalent under local rotations [12]. We thus focus on EPR for simplicity. It is easy to compute that $\lambda_{max}(H_G) = 3$. The optimal product state ρ_{PROD} is $\rho_0^{\otimes 3}$, where $\rho_0 \stackrel{\text{def}}{=} |0\rangle\langle 0|$, and achieves energy 2. The algorithm MATCH computes the maximum matching $\mathrm{M}_G = \{(a,b)\}$ and returns the state ρ_{MATCH} as described in Section 2. This state gains energy 2 on edge (i,j) and 1/2 on edge (b,c), achieving total energy 5/2. Thus, the algorithm of [14], which returns the better of ρ_{PROD} and ρ_{MATCH}, achieves $5/6 \approx 0.833$ of the optimal energy.

Our algorithms do better by interpolating between ρ_{PROD} and ρ_{MATCH}, rather than taking the better of the two. For our example G, the unitary

$$U = e^{i\theta\left(\frac{X_a - Y_a}{\sqrt{2}} \otimes \frac{X_b - Y_b}{\sqrt{2}}\right)},$$

takes ρ_{PROD} to ρ', a tensor product of a two-qubit state ρ_{ab} and a single-qubit state ρ_c. The parameter θ sets the entanglement for ρ_{ab}: when $\theta = 0$, ρ_{ab} is a product state; when $\theta = \pi/4$, ρ_{ab} is fully rotated into the EPR state. As such, we view this approach as smoothly interpolating between ρ_{PROD} and ρ_{MATCH} in superposition. It can be easily verified that the energy obtained by ρ' on edge (a,b) is $\mathrm{Tr}\left[h_{ab}^{EPR}\rho'\right] = 1 + 2\cos\theta\sin\theta$, and the single qubit marginals of a and b are given by

$$\rho'_a \stackrel{\text{def}}{=} \mathrm{Tr}_{bc}[\rho'] = \cos 2\theta\rho_0 + 2\sin^2\theta I = \rho'_b\,.$$

In particular, note that the single qubit marginals are simply rescaled and shifted by the identity. This fact aids in the analysis: we can still evaluate the energy of (b,c) in terms of ρ_{PROD}, even though the edge is not in our matching:

$$\begin{aligned}
\mathrm{Tr}\left[h_{bc}^{EPR}\rho'\right] &= \mathrm{Tr}\left[h_{bc}^{EPR}\left(\rho'_b \otimes \rho'_c\right)\right] \\
&= \mathrm{Tr}\left[h_{bc}^{EPR}\left(\rho'_b \otimes \rho_0\right)\right] \\
&= \mathrm{Tr}\left[h_{bc}^{EPR}\left(\left(\cos 2\theta\rho_0 + 2\sin^2\theta\ (I/2)\right) \otimes \rho_0\right)\right] \\
&= \mathrm{Tr}\left[h_{bc}^{EPR}\left(\cos 2\theta\rho_{PROD} + \sin^2\theta\, I \otimes \rho_0\right)\right] \\
&= \cos 2\theta + \sin^2\theta = \cos^2\theta\,.
\end{aligned}$$

Thus the total energy is given by

$$\mathrm{Tr}\left[(h_{ab}^{EPR} + h_{bc}^{EPR})\rho'\right] = 1 + 2\cos\theta\sin\theta + \cos^2\theta\,.$$

The parameter θ can be optimized over; in this example, taking $\theta \approx .554$ yields

$$\mathrm{Tr}\left[(h_{ab}^{EPR} + h_{bc}^{EPR})\rho'\right] \approx 2.618,$$

outperforming both ρ_{PROD} and ρ_{MATCH}.

In this example, the analysis simplifies nicely because the initial product state is the symmetric state $\rho_0^{\otimes n}$, and because the graph is bipartite. For EPR on general graphs, we provide a circuit-based algorithm that prepares an entangled state based on a *fractional* matching in the graph. This state still works by *partially* entangling edges according to the

matching while preserving single-qubit marginals, but it does not have a simple interpretation in terms of ρ_{MATCH}. We leave open the possibility that a $(\frac{1+\sqrt{5}}{4})$-approximation algorithm can be achieved with a tensor product of one and two-qubit states that simply interpolates between ρ_{PROD} and ρ_{MATCH}. For QMC, our algorithm does indeed interpolate between ρ_{PROD} and ρ_{MATCH}. However the algorithm and analysis become slightly more complicated. Crucial to our analysis is the following lemma:

▶ **Lemma 5** (Energy obtained by QMC algorithm on matched and unmatched edges). *Given two 1-qubit pure states ρ_i, ρ_j and a real parameter $\theta \in [0, \pi/2]$, there exists a 2-qubit pure state ρ_{ij} such that*

$$\begin{aligned}
\mathrm{Tr}\big[h^{QMC}\rho_{ij}\big] &= \frac{(1+\sin\theta)\left(1-\vec{B}(\rho_i)\cdot\vec{B}(\rho_j)\right)}{2}\,,\\
\vec{B}(\mathrm{Tr}_j[\rho_{ij}]) &= \cos\theta\cdot\vec{B}(\rho_i)\,,\\
\vec{B}(\mathrm{Tr}_i[\rho_{ij}]) &= \cos\theta\cdot\vec{B}(\rho_j)\,.
\end{aligned}$$

The last two constraints in Lemma 5 indicate that the Bloch vectors of the single-qubit marginals of ρ_{ij} are rescaled Bloch vectors of ρ_i and ρ_j, respectively. This is analogous to the argument in our example, where the marginals are rescaled and shifted by the identity. This again allows us to compute the energy of unmatched edges in terms of ρ_{PROD}. The parameter θ again sets the entanglement in ρ_{ij}: when $\theta = 0$, ρ_{ij} is a product state; when $\theta = \pi/2$, ρ_{ij} is maximally entangled. The proof of Lemma 5 is given in the appendix of [2].

3.1 EPR

Using the intuition from our example, we introduce the following algorithm for EPR:

▶ **Algorithm 1** (Fractional matching algorithm for EPR). *Given a weighted graph $G(V, E, w)$:*

1. *Define the 1-qubit Hamiltonian*

$$P \stackrel{\text{def}}{=} \frac{1}{\sqrt{2}}(X - Y)\,,$$

and the angle

$$\theta \stackrel{\text{def}}{=} \frac{\ln(\varphi)}{2} \approx 0.240\,, \tag{1}$$

where $\varphi = \frac{1+\sqrt{5}}{2}$ is the golden ratio.

2. *Find a fractional matching $(m_{uv})_{(u,v)\in E}$ of maximum weight (e.g., via linear programming).*
3. *Output the state*

$$|\chi\rangle \stackrel{\text{def}}{=} \prod_{(u,v)\in E} e^{i\gamma_{uv}P_uP_v}\,|0\rangle^{\otimes n}\,, \tag{2}$$

where

$$\gamma_{uv} = \frac{1}{2}\cos^{-1}\exp\left[-\theta\cdot m_{uv}\right] \;\in\; [0, \pi/2]\,. \tag{3}$$

The unitary $e^{i\gamma P_uP_v}$ rotates the state $|00\rangle_{ij}$ towards the Bell state $|\phi^+\rangle$; this circuit was proposed in the approximation algorithm of [12].

3.2 QMC

Our algorithm for QMC relies on the following subroutine, which we call PMATCH since it places partially entangled 2-qubit states on the edges of a matching, while MATCH places maximally entangled states:

▶ **Algorithm 2** (PMATCH). *Given a weighted graph $G(V, E, w)$ and a real parameter $\theta \in [0, \pi/2]$:*

1. *Prepare the state $\rho_{PROD} = \bigotimes_{i\in[n]} \rho_i$ by running the* PROD *algorithm on QMC from Section 2 for some fixed, constant SDP level ℓ.*
2. *For each edge $(i, j) \in E$, compute $t_{ij} \stackrel{\text{def}}{=} \vec{B}(\rho_i) \cdot \vec{B}(\rho_j)$ from ρ_{PROD}.*
3. *Find a maximum-weight integral matching $\widetilde{M} \subseteq E$ on the* reweighted *graph $G(V, E', \widetilde{w})$, where*

$$\widetilde{w}_{ij} = w_{ij} \cdot \left(\frac{\sin\theta \left(1 - t_{ij}\left(1 + \sin\theta\right)\right)}{2} \right)^{+}, \tag{4}$$

   and $E' = \{(i, j) \in E \mid \widetilde{w}_{ij} > 0\}$. Here, we use the notation $(\cdot)^+ \stackrel{\text{def}}{=} \max(0, \cdot)$ from [14].
4. *Let $\rho_{PMATCH}(\theta)$ be the state starting from ρ_{PROD}, but for each edge (i, j) in $\widetilde{M}$, replace $\rho_i \otimes \rho_j$ with the state ρ_{ij} described in Lemma 5, parametrized by ρ_i, ρ_j, θ.*
5. *Output the state $\rho_{PMATCH}(\theta)$.*

Our algorithm for QMC chooses the better of the algorithms PMATCH and MATCH:

▶ **Algorithm 3** (Combined algorithm for QMC). *Given a weighted graph $G(V, E, w)$:*

1. *Prepare the state ρ_{MATCH} by running the* MATCH *algorithm from Section 2.*
2. *Prepare the state $\rho_{PMATCH}(\theta)$ by running* PMATCH *with parameter $\theta = 1.286$.*
3. *Output the state out of ρ_{MATCH} and $\rho_{PMATCH}(\theta)$ obtaining larger energy on the QMC Hamiltonian H_G.*

4 Analysis

We upper-bound the maximum energy $\lambda_{max}(H_G)$ of QMC and EPR Hamiltonians using a quantifiable *monogamy of entanglement*:

▶ **Lemma 6** (Monogamy of Entanglement, e.g. [14, Lemma 1]). *For both EPR and QMC, and for all graphs $G(V, E, w)$, we have*

$$\lambda_{max}(H_G) \leq W_G + \mathrm{FM}_G\,.$$

For QMC, our analysis improves with better upper bounds on $\lambda_{max}(H_G)$. We use an inequality of the form $W_G + \mathrm{M}_G/d$; this first appears in [14, Lemma 4] with the constant $d = 4/5$. By a detailed analysis and numerical verification on graphs with up to 13 vertices, this constant was recently improved to $14/15$ in [8]:

▶ **Lemma 7** (Strengthened monogamy of entanglement, [8, Lemma 3.10]). *For QMC, and for all graphs $G(V, E, w)$, we have*

$$\lambda_{max}(H_G) \leq W_G + \frac{\mathrm{M}_G}{d}\,,$$

where $d = \frac{14}{15}$. Additionally, the bound holds for the optimal value of the 13-th level of the quantum moment SoS hierarchy.

4.1 EPR

We now prove Theorem 1. Given the state in Equation (2)

$$|\chi\rangle \stackrel{\text{def}}{=} \prod_{(i,j)\in E} e^{i\gamma_{ij} P_i P_j} |0\rangle^{\otimes n} , \tag{5}$$

[12, Lemma 9] showed that the energy on the local term h_{ij}^{EPR} is at least

$$\langle\chi| h_{ij}^{EPR} |\chi\rangle \geq \frac{1}{2} \left(1 + A_{ij} B_{ij} + \sin 2\gamma_{ij} \cdot (A_{ij} + B_{ij})\right) , \tag{6}$$

where

$$A_{ij} \stackrel{\text{def}}{=} \prod_{k\in N(i)\setminus\{j\}} \cos 2\gamma_{ik} ,$$
$$B_{ij} \stackrel{\text{def}}{=} \prod_{k\in N(j)\setminus\{i\}} \cos 2\gamma_{jk} .$$

In Algorithm 1, the output state $|\chi\rangle$ is in the form of Equation (5). Using the angles γ_{ij} specified by Equation (3), we have

$$A_{ij} = \exp\left[-\theta \sum_{k\in N(i)\setminus\{j\}} m_{ik}\right] \geq \exp\left[-\theta(1 - m_{ij})\right] , \tag{7}$$

$$B_{ij} = \exp\left[-\theta \sum_{k\in N(j)\setminus\{i\}} m_{jk}\right] \geq \exp\left[-\theta(1 - m_{ij})\right] , \tag{8}$$

$$\sin 2\gamma_{ij} = \sqrt{1 - \cos^2 2\gamma_{ij}} = \sqrt{1 - \exp\left[-2\theta m_{ij}\right]} . \tag{9}$$

The inequalities in the first two lines follow because m is a matching. For example, we have $m_{ij} + \sum_{k\in N(i)\setminus\{j\}} m_{ik} \leq 1$. Using Equation (6), the energy of $|\chi\rangle$ on h_{ij}^{QMC} is at least

$$T(\theta, m_{ij}) \stackrel{\text{def}}{=} \frac{1}{2}\left(1 + \exp\left[-2\theta(1 - m_{ij})\right] + 2\sqrt{1 - \exp\left[-2\theta m_{ij}\right]} \exp\left[-\theta(1 - m_{ij})\right]\right) . \tag{10}$$

We combine Equation (10) with Lemma 6 to bound the approximation ratio on any graph $G(V, E, w)$:

$$\frac{\langle\chi| H_G |\chi\rangle}{\lambda_{max}(H_G)} \geq \frac{\sum_{(i,j)\in E} w_{ij} \cdot T(\theta, m_{ij})}{\sum_{(i,j)\in E} w_{ij} (1 + m_{ij})} .$$

Each term in the numerator and denominator is positive, so the approximation ratio is at least the approximation ratio of the worst edge

$$\min_{(i,j)\in E} \frac{T(\theta, m_{ij})}{1 + m_{ij}} \geq \min_{x\in[0,1]} \frac{T(\theta, x)}{1 + x} . \tag{11}$$

Recall from Equation (1) that we take $\theta = \frac{1}{2}\ln\varphi$. We empirically identified θ as the angle that maximizes the approximation ratio in this analysis. Substituting this value into $T(\theta, x)$ in Equation (10), the RHS of Equation (11) yields the minimization problem

$$\min_{x\in[0,1]} \left[\frac{1}{2(1+x)}\left(1 + \varphi^{-(1-x)} + 2\sqrt{1 - \varphi^{-x}} \cdot \varphi^{-\frac{1}{2}(1-x)}\right)\right],$$

whose value is found to be $\varphi/2$ by the following lemma:

▶ **Lemma 8.** *Given* $\varphi \stackrel{\text{def}}{=} \frac{1+\sqrt{5}}{2}$*, we have that*

$$\min_{x\in[0,1]} \left[\frac{1}{2(1+x)}\left(1+\varphi^{-(1-x)}+2\sqrt{1-\varphi^{-x}}\cdot\varphi^{-\frac{1}{2}(1-x)}\right)\right] = \frac{1+\sqrt{5}}{4} = \frac{\varphi}{2}\,. \tag{12}$$

The proof of Lemma 8 is given in the appendix of [2].

4.2 QMC

We now analyze Algorithm 3 and prove the 0.611-approximation in Theorem 2. We first introduce some helpful notation. Fix a graph $G(V, E, w)$. Let $\tilde{\rho}$ be the pseudo-density matrix outputted by solving the SDP of the level-ℓ quantum moment-SOS hierarchy (described in Section 2.3). We define

$$g_{ij} \stackrel{\text{def}}{=} \mathrm{Tr}[h_{ij}^{QMC}\tilde{\rho}]\,, \qquad s_{ij} \stackrel{\text{def}}{=} \frac{1}{3}\mathrm{Tr}[(X_iX_j + Y_iY_j + Z_iZ_j)\tilde{\rho}]\,.$$

The first value is the energy obtained by $\tilde{\rho}$ on h_{ij}^{QMC}; the second value is the expected value of $\tilde{\rho}$ with respect to the traceless components of the term h_{ij}^{QMC}. It is straightforward to show that $g_{ij} = \frac{1}{2}(1-3s_{ij})$. The output of the SDP gives an upper bound to the optimal energy:

$$\lambda_{max}(H_G) \leq \sum_{(i,j)\in E} w_{ij}\cdot g_{ij} = \sum_{(i,j)\in E} w_{ij}\cdot\frac{1-3s_{ij}}{2}\,. \tag{13}$$

Fix a positive integer k and suppose Lemma 7 is true for $d = \frac{2k}{2k+1}$. Then, consider a *reweighting* $\widetilde{G}(V, E, u)$ of the graph G where $u_{ij} \geq 0$. Let $x \in \mathbb{R}^E$ be a vector with

$$x_{ij} \stackrel{\text{def}}{=} d\,(g_{ij}-1)^+ = d\left(-\frac{1+3s_{ij}}{2}\right)^+.$$

Here, we again use the notation $(\cdot)^+ \stackrel{\text{def}}{=} \max(\,\cdot\,, 0)$ from [14], which ensures

$$\left(-\frac{1+3s_{ij}}{2}\right)^+ \in [0,1]\,, \qquad \forall (i,j)\in E.$$

It is shown (e.g. in [8, Lemma 3.4]) that x is in the *integral* matching polytope of $\widetilde{G}$. This means that x is a convex combination of integral matchings $\{m_\ell\}_{1\leq\ell\leq k}$. Since the weight of any integral matching m_ℓ on $\widetilde{G}$ is at most $\mathrm{M}_{\widetilde{G}}$, the weight of x on $\widetilde{G}$ is also at most $\mathrm{M}_{\widetilde{G}}$. Thus,

$$\sum_{(i,j)\in E} u_{ij}\cdot d\cdot\left(-\frac{1+3s_{ij}}{2}\right)^+ \leq \mathrm{M}_{\widetilde{G}}\,. \tag{14}$$

Equation (14) in this context was first used in [16] and also appears in [14, Lemma 4] and [10, Lemma C.2].

We now find a lower bound for the energy obtained by the matching state $\rho_{PMATCH}(\theta)$ in PMATCH. We consider the energy on a case-by-case basis in the following lemma:

▶ **Lemma 9.** *Consider the state ρ_{PMATCH} and matching $\widetilde{M}$ from Algorithm 2. For $x \in \{0,1,2\}$, let $\widetilde{S}_x$ be the subset of edges not in $\widetilde{M}$ (e.g. $\widetilde{S}_x \subseteq E \setminus \widetilde{M}$) where each edge in $\widetilde{S}_x$ has x matched endpoints in $\widetilde{M}$. Then the energy of ρ_{PMATCH} on an edge (i,j) is exactly*

$$\mathrm{Tr}\left[h_{ij}^{QMC}\rho_{PMATCH}\right] = \begin{cases} \frac{1}{2}\left(1+\sin\theta\right)\left(1-t_{ij}\right), & (i,j)\in\widetilde{M}, \\ \frac{1}{2}(1-t_{ij}), & (i,j)\in\widetilde{S}_0, \\ \frac{1}{2}\left(1-t_{ij}\cos\theta\right), & (i,j)\in\widetilde{S}_1, \\ \frac{1}{2}\left(1-t_{ij}\cos^2\theta\right), & (i,j)\in\widetilde{S}_2. \end{cases}$$

where, t_{ij} is defined in Algorithm 2.

Proof. The case when $(i,j)\in\widetilde{M}$ follows directly from how we choose ρ_{PMATCH} in Algorithm 2, Step 4. For all other edges, recall that t_{ij} is the inner product of the Bloch vectors of qubits i and j with respect to the product state ρ_{PROD}. The reduced density matrix of ρ_{PMATCH} on qubits i and j is a product state $\sigma_i\otimes\sigma_j$. By [12, Lemma 10], the energy of $\sigma_i\otimes\sigma_j$ on h_{ij}^{QMC} is

$$\frac{1}{2}\left(1-\vec{B}(\sigma_i)\cdot\vec{B}(\sigma_j)\right).$$

We handle each remaining case separately:

1. $(i,j)\in\widetilde{S}_0$: Here, the product state is exactly $\rho_i\otimes\rho_j$, and so $\vec{B}(\sigma_i)\cdot\vec{B}(\sigma_j) = t_{ij}$ by definition.[1]
2. $(i,j)\in\widetilde{S}_1$: Without loss of generality, i belongs to a matched edge in $\widetilde{M}$ and j is not in a matched edge. Lemma 5 implies that $\vec{B}(\sigma_i)$ is rescaled to $\vec{B}(\sigma_i)\cos\theta$, and so $\vec{B}(\sigma_i)\cdot\vec{B}(\sigma_j) = t_{ij}\cos\theta$.
3. $(i,j)\in\widetilde{S}_2$: i and j belong to two different matched edges. Therefore, it has *both* Bloch vectors rescaled, i.e. $\vec{B}(\sigma_i)\cdot\vec{B}(\sigma_j) = \left(\vec{B}(\rho_i)\cdot\vec{B}(\rho_j)\right)\cos^2\theta = t_{ij}\cos^2\theta$. ◀

Lemma 9 allows us to compute the energy obtained by the state $\rho_{PMATCH}(\theta)$:

$$\begin{aligned}
&\mathrm{PMATCH}(\theta) \stackrel{\text{def}}{=} \sum_{(i,j)\in E} w_{ij}\cdot\mathrm{Tr}[h_{ij}^{QMC}\rho_{PMATCH}] \\
&= \sum_{(i,j)\in\widetilde{M}} \frac{w_{ij}}{2}\left(1+\sin\theta\right)\left(1-t_{ij}\right) + \sum_{(i,j)\in\widetilde{S}_0}\frac{w_{ij}}{2}\left(1-t_{ij}\right) \\
&\qquad + \sum_{(i,j)\in\widetilde{S}_1}\frac{w_{ij}}{2}\left(1-t_{ij}\cos\theta\right) + \sum_{(i,j)\in\widetilde{S}_2}\frac{w_{ij}}{2}\left(1-t_{ij}\cos^2\theta\right) \\
&= \sum_{(i,j)\in E}\frac{w_{ij}}{2}\left(1-t_{ij}\cos^2\theta\right) + \sum_{(i,j)\in\widetilde{M}}\frac{w_{ij}}{2}\left(\left(1+\sin\theta\right)\left(1-t_{ij}\right)-\left(1-t_{ij}\cos^2\theta\right)\right) \\
&\qquad + \sum_{(i,j)\in\widetilde{S}_0}\frac{w_{ij}t_{ij}}{2}\left(\cos^2\theta-1\right) + \sum_{(i,j)\in\widetilde{S}_1}\frac{w_{ij}t_{ij}}{2}\left(\cos^2\theta-\cos\theta\right) \\
&= \sum_{(i,j)\in E}\frac{w_{ij}}{2}\left(1-t_{ij}\cos^2\theta\right) + \sum_{(i,j)\in\widetilde{M}}\frac{w_{ij}}{2}\left(\sin\theta\left(1-t_{ij}\left(1+\sin\theta\right)\right)\right) \\
&\qquad - \sum_{(i,j)\in\widetilde{S}_0}\frac{w_{ij}t_{ij}}{2}\sin^2\theta + \sum_{(i,j)\in\widetilde{S}_1}\frac{w_{ij}t_{ij}}{2}\left(\cos^2\theta-\cos\theta\right). \qquad (15)
\end{aligned}$$

[1] Although $\widetilde{M}$ is a maximum matching, its edge set E' is a subset of E, and so $\widetilde{S}_0$ may be non-empty.

Note that $\widetilde{M}$ is a maximum-weight *integral* matching with respect to the rescaled weights defined in Equation (4). Thus, we can invoke Equation (14) to replace the sum over $\widetilde{M}$ in Equation (15) with a sum over E. Since the rescaled weights are positive for all edges in $\widetilde{M}$, we have

$$\begin{aligned}\mathrm{PMATCH}(\theta) \geq \sum_{(i,j)\in E} \frac{w_{ij}}{2}\left(1 - t_{ij}\cos^2\theta + d\big(\sin\theta\,(1 - t_{ij}\,(1+\sin\theta))\big)\left(-\frac{1+3s_{ij}}{2}\right)^+\right) \\ - \sum_{(i,j)\in\widetilde{S}_0} \frac{w_{ij}t_{ij}}{2}\sin^2\theta + \sum_{(i,j)\in\widetilde{S}_1} \frac{w_{ij}t_{ij}}{2}\left(\cos^2\theta - \cos\theta\right). \end{aligned} \tag{16}$$

Note that t_{ij} is a random variable because PROD is a randomized algorithm. The analysis of PROD in [7] is based on [4], which shows that $\mathbb{E}[t_{ij}] = F(s_{ij})$. A definition of F in the context of QMC appears in [17, Equation 3]. For our purposes, it is enough to note that F is an odd function because it has the form

$$F(s) = c \cdot s \cdot G(s^2)\,, \tag{17}$$

where $c > 0$ is a constant and $G \geq 0$ is a hypergeometric function. Since Equation (16) is linear in t_{ij}, we use linearity of expectation to conclude

$$\begin{aligned}&\mathbb{E}[\mathrm{PMATCH}(\theta)] \geq \\ &\sum_{(i,j)\in E} \frac{w_{ij}}{2}\left(1 - F(s_{ij})\cos^2\theta + d\sin\theta\,(1 - F(s_{ij})\,(1+\sin\theta))\left(-\frac{1+3s_{ij}}{2}\right)^+\right) \\ &\quad - \sum_{(i,j)\in\widetilde{S}_0} \frac{w_{ij}}{2}F(s_{ij})\sin^2\theta + \sum_{(i,j)\in\widetilde{S}_1} \frac{w_{ij}}{2}\Big(\big(\cos^2\theta - \cos\theta\big)\;F(s_{ij})\Big). \end{aligned} \tag{18}$$

The following lemma lets us analyze the performance of Algorithm 3, which takes the better of two algorithms, MATCH and PMATCH.

▶ **Lemma 10** (Reducing worst-case bounds to a single edge). *Suppose we have a collection of k approximation algorithms $\{A_\ell\}_{\ell\in[k]}$ and an upper bound on the maximum energy $\lambda_{max}(H_G) \leq \sum_{e\in E} w_e b_e$, where $b_e \in B = (0, b_{max}]$ for all $e \in E$, and b_{max} is a constant. Furthermore, suppose that the energy that algorithm A_ℓ earns on edge e is a function of b_e, which we denote $a_\ell(b_e)$, such that A_ℓ earns $\sum_{e\in E} w_e\, a_\ell(b_e)$. Then, by running each of $A_{\ell\in[k]}$ and taking the output with the maximum energy, we can obtain an approximation ratio*

$$\alpha \geq \max_{\mu_\ell}\ \min_{b} \sum_{\ell} \mu_\ell \frac{a_\ell(b)}{b},$$

where the maximum is taken over valid probability distributions

$$\{\ \mu \mid \sum_{\ell\in[k]} \mu_\ell = 1,\ 0 \leq \mu_\ell \leq 1\ \forall \ell \in [k]\ \}\,,$$

and the minimum is taken over $b \in B$.

Proof. Given a specific graph G, outputting the best of A_ℓ is at least as good as outputting the result of A_ℓ with probability μ_ℓ, for all $\ell \in [k]$ and for any possible μ. Now, given a fixed distribution μ, the approximation ratio is at least

$$\begin{aligned}
\alpha &\geq \sum_\ell \mu_\ell \frac{\sum_{e\in E} w_e\, a_\ell(b_e)}{\sum_{e\in E} w_e b_e} \\
&= \sum_\ell \mu_\ell \sum_{e\in E} \left(\frac{w_e b_e}{\sum_{e\in E} w_e b_e}\right) \frac{a_\ell(b_e)}{b_e} \\
&\geq \min_{e\in E} \sum_\ell \mu_\ell \frac{a_\ell(b_e)}{b_e} \\
&\geq \min_{b\in B} \sum_\ell \mu_\ell \frac{a_\ell(b)}{b}\,.
\end{aligned}$$

The third line follows because

$$\left\{\frac{w_e b_e}{\sum_{e\in E} w_e b_e}\right\}_{e\in E}$$

is a distribution over E. Since the statement is true for all possible distributions μ, we take the maximum over μ to finish the lemma. ◀

We apply Lemma 10 with the SDP upper bound in Equation (13) and our two algorithms MATCH and PMATCH as described in Algorithm 3. For PMATCH, we consider the minimum of three different functions, depending on if an edge is in $\widetilde{S}_0$, in $\widetilde{S}_1$, or otherwise. For MATCH, we derived in Section 2.3 that the energy obtained by MATCH on G is $\frac{3\mathrm{M}+W}{2}$. Since M is a maximum-weight matching with respect to G, we may invoke Equation (14) to express

$$\mathrm{M} \geq \sum_{(i,j)\in E} w_{ij} \cdot d \cdot \left(-\frac{1+3s_{ij}}{2}\right)^+,$$

implying that MATCH achieves energy at least

$$\frac{3\mathrm{M}+W}{2} \geq \sum_{(i,j)\in E} \frac{w_{ij}}{2}\left(1+3d\left(-\frac{1+3s_{ij}}{2}\right)^+\right).$$

We have lower-bounded the energy that each algorithm earns on an edge (i,j) as a function of s_{ij}. Note that the SDP upper bound is trivial (i.e. at most 0) when $s_{ij} \geq \frac{1}{3}$, so we may search over $s \in [-1, 1/3)$. Altogether, Lemma 10 implies that Algorithm 3 obtains approximation ratio at least

$$\begin{aligned}
\alpha \geq \max_{\mu\in[0,1],\,\theta\in[0,\pi/2]} \min\Big\{ &\min_{s\in[-1,1/3)} \ \mu\, E_{PM}(\theta) + (1-\mu)E_M, \\
&\min_{s\in[-1,1/3)} \ \mu\, E'_{PM}(\theta) + (1-\mu)E_M, \\
&\min_{s\in[-1,1/3)} \ \mu\, E''_{PM}(\theta) + (1-\mu)E_M \Big\},
\end{aligned} \tag{19}$$

$$E_{PM}(\theta) \stackrel{\text{def}}{=} \frac{1 - F(s)\cos^2\theta + d\sin\theta\,(1 - F(s)\,(1+\sin\theta)) \cdot \left(-\frac{1+3s}{2}\right)^+}{1-3s}, \tag{20}$$

$$E'_{PM}(\theta) \stackrel{\text{def}}{=} \frac{1 - F(s)\cos\theta + d\sin\theta\,(1 - F(s)\,(1+\sin\theta)) \cdot \left(-\frac{1+3s}{2}\right)^+}{1-3s}, \tag{21}$$

$$E''_{PM}(\theta) \stackrel{\text{def}}{=} \frac{1 - F(s) + d\sin\theta\,(1 - F(s)\,(1+\sin\theta)) \cdot \left(-\frac{1+3s}{2}\right)^+}{1-3s}, \tag{22}$$

$$E_M \stackrel{\text{def}}{=} \frac{1 + 3\,d\,(-\frac{1+3s}{2})^+}{1-3s}. \tag{23}$$

In the above, μ is demoted to a scalar (which fully describes a probability distribution over two variables). Equation (23) is the approximation ratio obtained by MATCH on an edge with $s = s_{ij}$. The expected approximation ratio obtained by PMATCH is Equation (22) on an edge in $\widetilde{S}_0$, Equation (21) on an edge in $\widetilde{S}_1$, and is Equation (20) on all other edges.

We further simplify Equation (19). Recall that F is an odd function (Equation (17)). So, for all $\theta \in [0, \pi/2]$ we have $E''_{PM}(\theta) \le E'_{PM}(\theta) \le E_{PM}(\theta)$ when $s > 0$ and $E_{PM}(\theta) \le E'_{PM}(\theta) \le E''_{PM}(\theta)$ when $s \le 0$. So we may rewrite Equation (19) as

$$\alpha \ge \max_{\mu\in[0,1],\,\theta\in[0,\pi/2]} \min\left\{ \min_{s\in[-1,0)} \mu\,E_{PM}(\theta) + (1-\mu)E_M,\ \min_{s\in[0,1/3)} \mu\,E''_{PM}(\theta) + (1-\mu)E_M \right\}. \tag{24}$$

One may then search over the three free parameters μ, θ, and s using an enumeration of the feasible ranges. For a more efficient approach, it is also possible to solve a linear program where the number of variables and constraints is based on an enumeration of the feasible ranges for s and θ. We obtain $\alpha > 0.611$ for $d = 14/15$ at $\theta = 1.286$ and $\mu = 0.861$. By Lemma 7, our algorithm thus achieves a 0.611-approximation in expectation if $\ell = 13$. If the factor d in Lemma 7 is improved to 1, we would obtain $\alpha > 0.614$ at $\theta = 1.288$ and $\mu = 0.881$.

▶ Remark 11. We may simplify Equation (19) by assuming $s \in [-1, 0)$. This is because if $s \in [0, 1/3)$ then $E_M \ge 1$ and $E''_{PM}(\theta) \ge 1$ for all $\theta \in [0, \pi/2]$. This follows from F being odd, and in addition $|F(s)| \le |s|$ for all $s \in [-1, 1]$.

5 Discussion

In this work, we introduce two novel techniques for constructing algorithms for the Quantum MaxCut and EPR Hamiltonians on arbitrary graphs. The main techniques are a) *partially* entangling edges in a matching towards an entangled state while maintaining the direction of the marginal Bloch vectors as b) choosing matching with respect to *reweighted* graphs. We show that these techniques immediately lead to state-of-the-art approximation ratios for both problems. We believe that these techniques may be combined with other methods to obtain further improvements, and encourage further studies in this direction.

A Combinatorial Proof of Universal Optimality for Computing a Planar Convex Hull

Ivor van der Hoog
IT University of Copenhagen, Denmark

Abstract

For a planar point set P, its convex hull is the smallest convex polygon that encloses all points in P. The construction of the convex hull from an array I_P containing P is a fundamental problem in computational geometry. By sorting I_P in lexicographical order, one can construct the convex hull of P in $O(n \log n)$ time which is worst-case optimal. Standard worst-case analysis, however, has been criticized as overly coarse or pessimistic, and researchers search for more refined analyses.

For an algorithm A, worst-case analysis fixes n, and considers the maximum running time of A across all size-n point sets P and permutations I_P of P. Output-sensitive analysis fixes n and k, and considers the maximum running time across all size-n points sets P with k hull points and permutations I_P of P. Universal analysis provides an even stronger guarantee. It fixes a point set P and considers the maximum running time across all permutations I_P of P.

Kirkpatrick, McQueen, and Seidel [SICOMP'86] consider output-sensitive analysis. If the convex hull of P contains k points, then their algorithm runs in $O(n \log k)$ time. Afshani, Barbay, Chan [FOCS'07] prove that the algorithm by Kirkpatrick, McQueen, and Seidel is also universally optimal. Their proof restricts the model of computation to any algebraic decision tree model where the test functions have at most constant degree and at most a constant number of arguments. They rely upon involved algebraic arguments to construct a lower bound for each point set P that matches the universal running time of [SICOMP'86].

We provide a different proof of universal optimality. Instead of restricting the computational model, we further specify the output. We require as output (1) the convex hull, and (2) for each internal point of P a witness for it being internal. Our argument is shorter, perhaps simpler, and applicable in more general models of computation.

1 Introduction

Convex hulls are a central topic in computational geometry. By sorting a point set P in lexicographical order, one can construct its convex hull in $O(n \log n)$ time, which is worst-case optimal. Traditional worst-case analysis often faces criticism for being overly coarse or pessimistic. To address these concerns, researchers introduced more nuanced complexity measures that account not only for the input size but also for additional parameters that

© Ivor van der Hoog, Eva Rotenberg, and Daniel Rutschmann;
licensed under Creative Commons License CC-BY 4.0

capture the difficulty of the instance. A classical example is output-sensitive analysis, where the running time analysis depends on the output size [7]. Other algorithms measure their performance by the spread of the point set, defined as the ratio of the maximum to minimum pairwise distances among the points [4]. More examples include algorithmic complexity parametrized on various geometric characteristics of P, such as the ratio of circumradii to inradii or the number of reflex angles in an input polygon [3, 8].

This paper improves upon the work by Afshani, Barbay, and Chan [1] (see also their journal version [2]). They observe that, for geometric problems, the worst-case algorithmic analysis contains a double maximum. They only consider *correct* algorithms, which we formally define in the preliminaries. For now, denote by $\mathbb{P}_n$ all point sets of size n and for any $P \in \mathbb{P}_n$ by $\mathbb{I}_P$ all size-n arrays that contain the points of P in some order. For an algorithm A, denote by $\rho(A, I_P)$ its runtime when the input is I_P. Then, for a fixed correct algorithm A and input size n, the worst-case running time is:

$$\text{worst-case}(A, n) := \max_{P \in \mathbb{P}_n} \max_{I_P \in \mathbb{I}_P} \rho(A, I_P).$$

An algorithm A is worst-case optimal if there exists no algorithm A' whose worst-case running time is asymptotically smaller than that of A. Prior works perform a finer-grained analysis by restricting the first maximum. For example, output-sensitive running time is defined as:

$$\text{output-sensitive}(A, n, k) := \max_{P \in \mathbb{P}_n \text{ and } P \text{ has } k \text{ points on the convex hull}} \max_{I_P \in \mathbb{I}_P} \rho(A, I_P).$$

Afshani, Barbay, and Chan [1] obtain an even stronger quality guarantee by eliminating the first maximum all-together. They call their notion of optimality *instance-optimality in the order-oblivious setting*. Recently, this notion has been called *universal optimality* [5, 6, 9]. For a fixed point set P, we define the *universal* running time of an algorithm A as:

$$\text{universal}(A, P) := \max_{I_P \in \mathbb{I}_P} \rho(A, I_P).$$

An algorithm A is universally optimal if for all point sets P, there exists no algorithm A' whose universal running time is asymptotically smaller than that of A. Observe that any universally optimal algorithm is automatically output-sensitive.

Contribution. Afshani, Barbay, Chan prove that the algorithm by Kirkpatrick, McQueen, and Seidel [7] is universally optimal.[1] Their proof restricts the model of computation to any algebraic decision tree model where the test functions have at most constant degree and have at most a constant number of arguments. They present an involved algebraic argument to construct a lower bound for each point set P that matches the universal running time of [7].

Here, we give a different proof. Rather than restricting the model of computation, we give a more extensive but natural specification of the output. We call a point of P *internal* if it does not appear on the boundary of the convex hull. We require that any algorithm computes (1) the convex hull and (2) for each internal point a witness for its being internal. For a point set P, we apply a simple combinatorial counting argument over all outputs to obtain a lower bound that matches the universal running time of [7]. Our argument is shorter, arguably simpler, and holds in more general models of computation.

[1] We note that the paper has only Kirkpatrick and Seidel as authors. However, a footnote remarks that McQueen suggests an adaption to the algorithm. Only with this adaption, the algorithm becomes universally optimal.

2 Preliminaries

We follow [1] and assume that the input points lie in general position. I.e., P contains no duplicates and no collinear triples. For any integer n, we denote by $\mathbb{P}_n$ all planar point sets of n points that lie in general position. We denote by $\mathbb{I}_P$ all arrays of size n that store P.

▶ **Definition 1.** *For a planar point set P, its* convex hull $\mathrm{CH}(P)$ *is the minimum convex region that contains all points in P.*

▶ **Definition 2.** *For a planar point set P, its* convex hull vertices $\mathrm{ch}(P)$ *are the points in P that lie on the boundary of* $\mathrm{CH}(P)$.

The Convex Hull Problem. Our input is an array $I_P \in \mathbb{I}_P$ of n points P in general position. Convex hull algorithms output $\mathrm{ch}(P)$ in cyclical ordering. For our analysis, we further require that the output contains, for all points in $P - \mathrm{ch}(P)$, a *witness* that they are internal:

▶ **Definition 3.** *For any $p \in P$, a triangle t (whose corners lie in P) is a* witness *of p if p is contained in the interior of t.*

▶ **Observation 4.** *A point $p \in P$ does not lie on the boundary of* $\mathrm{CH}(P)$ *if and only if there exists at least one witness of p.*

Requiring the output to contain witnesses is a natural condition as it is effectively asking the algorithm A to verify its correctness. The concept of certification and verifiability is central to the design of algorithms. Without this requirement, there are oblivious decision trees (defined below) that compute the convex hull in $O(k \log n)$ time.

Formalising output. Our output consists of two lists: A *hull list* H encodes $\mathrm{ch}(P)$ in cyclical order, and a *witness list* W defines for each point in $P - \mathrm{ch}(P)$ a witness. Formally, a *hull list* $H = (h_1, \ldots, h_k)$ of I_P is a sequence of integers such that the points $I_P[h_i]$, for $i \in [k]$, are precisely the k points on the boundary of $\mathrm{CH}(P)$ in their cyclical ordering. We require that $I_P[h_1]$ is the leftmost point of $\mathrm{ch}(P)$. A *witness list* (we refer ahead to Figure 1) of I_P is a sequence $W = (a_i, b_i, c_i)_{i=1}^{n}$ of integer triples such that:

- $a_i = b_i = c_i = -1$ if $I_P[i]$ lies on $\mathrm{CH}(P)$, and otherwise
- the triangle $(I_P[a_i], I_P[b_i], I_P[c_i])$ is a witness of $I_P[i]$.

Algorithms. We define an *algorithm* for convex hull construction as any comparison-based algorithm that receives any ordered set of planar points I_P and outputs a hull list and witness list of I_P. Given a fixed input I_P and an algorithm A, the *running time* $\rho(A, I_P)$ is the number of instructions used by A to terminate on the input I_P.

Decision trees. For $n \in \mathbb{N}$, we define an *abstract decision tree* T as a tree whose inner nodes have two children. The inner nodes contain no additional information. Its leaves contain two ordered lists. The first is an arbitrary list of integers and the second is a list of n integer triples. We define an *oblivious* decision tree T as any abstract decision tree such that for any point set $P \in \mathbb{P}_n$, and any $I_P \in \mathbb{I}_P$, there exists a root-to-leaf path in T where the two lists at the leaf are a hull list and witness list of I_P, respectively. We denote by $\mathcal{T}_n^O$ the set of all oblivious decision trees for $n \in \mathbb{N}$.

▶ **Definition 5.** *A comparison-based algorithm A is* correct *if for any input I_P it outputs a correct hull and witness list. Observe that any correct comparison-based algorithm A for convex hull construction has, for each n, a corresponding oblivious decision tree in $\mathcal{T}_n^O$.*

Worst-case optimality. Let $\mathcal{A}$ denote the set of all correct algorithms. For an algorithm $A \in \mathcal{A}$ the *worst-case running time* is defined as

$$\text{worst-case}(A, n) := \max_{P \in \mathbb{P}_n} \max_{I_P \in \mathbb{I}_P} \rho(A, I_P).$$

An algorithm is worst-case optimal if there exists a constant c such that, for all n large enough, $\text{worst-case}(A, n) \leq c \cdot \min_{A' \in \mathcal{A}} \text{worst-case}(A', n)$.

▶ **Observation 6.** *For any algorithm A and n, the worst-case running time of A is lower bounded by the minimum height among all decision trees in $\mathcal{T}_n^O$. Formally, $\forall A \in \mathcal{A}, \forall n \in \mathbb{N}$,*

$$\text{worst-case}(A, n) = \max_{P \in \mathbb{P}_n} \max_{I_P \in \mathbb{I}_I} \rho(A, I_P) \geq \min_{T \in \mathcal{T}_n^O} \text{Height}(T).$$

Universal optimality. Afshani, Barbay and Chan [1] introduce a strictly stronger notion of algorithmic optimality which they call *instance optimality in the order-oblivious setting.* We will instead use the equivalent modern term *universal optimality* [5, 6, 9]. Intuitively, an algorithm is *universally optimal* if it is worst-case optimal for every fixed point set P. Formally, we define the *universal* running time of an algorithm A and point set P as

$$\text{universal}(A, P) := \max_{I_P \in \mathbb{I}_P} \rho(A, I_P).$$

An algorithm is universally optimal if there exists a constant c such that for all P, $\text{universal}(A, P) \leq c \cdot \min_{A' \in \mathcal{A}} \text{universal}(A', P)$. To show universal optimality, we introduce the concept of *clairvoyant decision trees.* For a fixed point set P, a *clairvoyant decision tree* T is an abstract decision tree such that for any input $I_P \in \mathbb{I}_P$, there exists a root-to-leaf path in T such that the two lists at the leaf are a hull list and witness list of I_P, respectively. We denote by $\mathcal{T}_P^C$ the set of all clairvoyant decision trees for a fixed planar point set P.

▶ **Observation 7.** *For any planar point set P in general position, for any algorithm A, the universal running time of A is lower bounded by the minimum height amongst all clairvoyant decision trees in $\mathcal{T}_P^C$. Formally, for all planar point set P in general position, for all $A \in \mathcal{A}$,*

$$\text{universal}(A, P) = \max_{I_P \in \mathbb{I}_I} \rho(A, I_P) \geq \min_{T \in \mathcal{T}_P^C} \text{Height}(T).$$

Prior work. Kirkpatrick, McQueen, and Seidel [7] give an efficient algorithm to compute for any point set P its convex hull. We present this algorithm in Section 4 and observe that it naturally produces a hull list and a witness list. Afshani, Barbay, and Chan [1] show that the algorithm in [7] is universally optimal in a somewhat restricted model of computation which we define below. We note for the reader that this definition is not vital to our analysis.

▶ **Definition 8** (Definition 3.1 [1])**.** *A function $f : (\mathbb{R}^d)^c \mapsto \mathbb{R}$ is* multilinear *if the restriction of f is a linear function from R^d to R when any $(c-1)$ of the c arguments are fixed. Equivalently, f is multilinear if $f((x_{11}, \ldots, x_{1d}), \ldots, (x_{c1}, \ldots, x_{cd}))$ is a multivariate polynomial function that never multiplies coordinates of the same point.*

In the *multilinear decision tree model* [1], algorithms can access the input points only through tests of the form $f(p_1, \ldots, p_c) > 0$ for a multilinear function f with c constant.

▶ **Theorem 9** (Theorem 3.5+3.6 in [1])**.** *The algorithm in [7] is universally optimal for dimension $d = 2$ in the multilinear decision tree model.*

We instead show universal optimality by a counting all possible hull and witness lists:

▶ **Theorem 10.** *If we define $\mathcal{A}$ as the set of all* correct *comparison-based convex hull algorithms (Definition 5) then the algorithm in [7] for $d = 2$ is universally optimal.*

3 Creating a universal lower bound

Let P be a point set of n points in general position. We use our definition of hull lists and witness lists to show a universal lower bound. That is, we define a quantity Q such that for all algorithms $A \in \mathcal{A}$, $\text{Universal}(A, P) \geq Q$. To this end, we explore the definition of a witness list. Recall that $\mathbb{I}_P$ is the set of all $n!$ arrays that contain P. Consider any list $W = (a_i, b_i, c_i)_{i=1}^{n}$ of integer triples.

For a fixed W, there can be many $I_P \in \mathbb{I}_P$ for which W is a witness list. For example, let P be a point set containing $n-3$ points in a small ball around $(0,0)$, and the three corners (α, β, γ) of a unit equilateral triangle centred at $(0,0)$ (we refer to Figure 1). Let:

$$W = ((-1,-1,-1),(-1,-1,-1),(-1,-1,-1),(0,1,2),(0,1,2),\ldots,(0,1,2)).$$

Any $I_P \in \mathbb{I}_P$ which contains (α, β, γ) in the first three positions has W as a witness list. Specifically, there are $3! \cdot (n-3)!$ arrays $I_P \in \mathbb{I}_P$ which have W as a witness list. There does not exist any other witness list W^* where more than $3!(n-3)!$ arrays in $\mathbb{I}_P$ have W^* as a witness list. We use this maximum quantity for our lower bound:

▶ **Definition 11.** *Let P be a point set and $W = (a_i, b_i, c_i)_{i=1}^{n} \subset \mathbb{Z}^{n\times 3}$. We define*

$$V(P, W) := \left\{ I_P \in \mathbb{I}_P \middle| W \text{ is a witness list of } I_P \right\}.$$

We consider the maximal number of input arrays that can have the same witness list:

$$V_{\max}(P) := \max_{W \in \mathbb{Z}^{n\times 3}} |V(P, W)|.$$

▶ **Theorem 12.** *Let P be a point set of n points and A be any algorithm in $\mathcal{A}$, then*

$$\text{universal}(A, P) \in \Omega\Big(n + |\operatorname{ch}(P)| \cdot \log n + \log \frac{n!}{V_{\max}(P)}\Big).$$

Proof. Any algorithm must spend $\Omega(n)$ time to read the input. Denote by ℓ the minimum height across all clairvoyant decision trees in $\mathcal{T}_P^C$. By Observation 7, $\Omega(\ell)$ is a universal lower bound. What remains is to bound ℓ. Let $k = |\operatorname{ch}(P)|$. Let T be an arbitrary clairvoyant decision tree in $\mathcal{T}_P^C$. Recall that each leaf of T stores a hull list and a witness list.

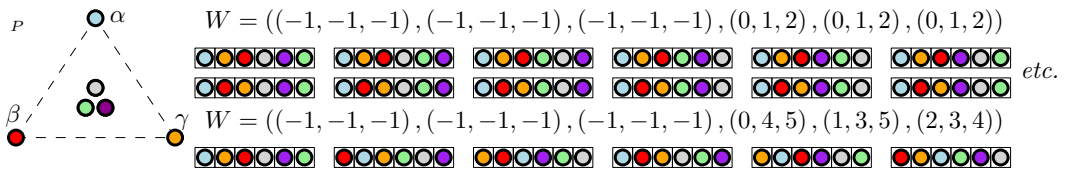

Figure 1 For $W = ((-1,-1,-1),(-1,-1,-1),(-1,-1,-1),(0,1,2),(0,1,2),(0,1,2))$ there are 36 $I_P \in \mathbb{I}_P$ for which W is a witness list (any array that assigns (α, β, γ) to the first three cells). For $W = ((-1,-1,-1),(-1,-1,-1),(-1,-1,-1),(0,4,5),(1,3,5),(2,3,4))$ there are only 6.

For any input $I_P \in \mathbb{I}_P$, there is a unique hull list of I_P. It follows that the number of distinct hull lists, and therefore the number of distinct leaves of T, across all I_P is at least $\frac{n!}{(n-k)!}$. Hence, $\ell \geq \log(\frac{n!}{(n-k)!}) \in \Omega(k \log n)$. For any input $I \in \mathbb{I}_P$, there is at least one leaf in T containing a witness list W of I. Therefore,

$$n! = |\mathbb{I}_P| \leq \sum_{\ell \in L} |V(P, W)| \leq (\#\text{ leaves of } T) \cdot V_{\max}(P) \quad \Rightarrow \quad \ell \geq \log \frac{n!}{V_{\max}(P)}. \qquad \blacktriangleleft$$

4 Analysing Kirkpatrick-McQueen-Seidel

Kirkpatrick and Seidel present an output-sensitive algorithm for computing the convex hull for a planar point set [7]. McQueen suggests a modification to the algorithm by Kirkpatrick and Seidel in Footnote 2 of [7]. The modified algorithm, depicted in Algorithm 1, is universally optimal. We first describe their algorithm. Next, we construct a geometric object that we will call a *quadrangle tree* and use it to analyse the running time of Algorithm 1.

High-level overview. Their algorithm is recursive and it constructs the *upper convex hull* of P. The original input consists of an unordered array I_P, from which they find the leftmost and rightmost vertex of P in linear time. Each recursive call has as input some set $S \subset P$ and two points $p_\ell, p_r \in S$ such that (p_ℓ, p_r) is an edge of $\mathrm{CH}(S)$ (Figure 2) – we assume that the line segment between the leftmost and rightmost vertex lies on $\mathrm{CH}(P)$. Otherwise, this line segment splits the problem into two independent convex hull construction problems.

Given (S, p_ℓ, p_r), the algorithm first finds a point $m \in S$ with the median x-coordinate in linear time. It then finds in linear time an edge (p_i, p_j) of $\mathrm{CH}(P) \cap S$ with $(p_i, p_j) \neq (p_\ell, p_r)$ such that m lies inside or on the quadrangle $Q = (p_\ell, p_r, p_j, p_i)$ (Q may also be a triangle, for example when $p_i = p_\ell$). The algorithm partitions S in linear time into three sets:

- S_1 consists of all points of S that lie above or on the line $p_\ell p_i$,
- S_2 consists of all points of S that lie above or on the line $p_r p_j$, and
- $S^* = S - S_1 - S_2$. S^* lies within Q and, therefore, its points are not on the convex hull. Through Q we assign these points a witness in $O(|S^*|)$ time at no asymptotic overhead.

The algorithm recurses on S_1 and S_2, using the segments (p_ℓ, p_i) and (p_r, p_j), respectively.

4.1 Runtime analysis

We propose a novel fine-grained runtime analysis of this algorithm. To this end, we define what we will call the *quadrangle tree* (we refer to Figure 3 (a)).

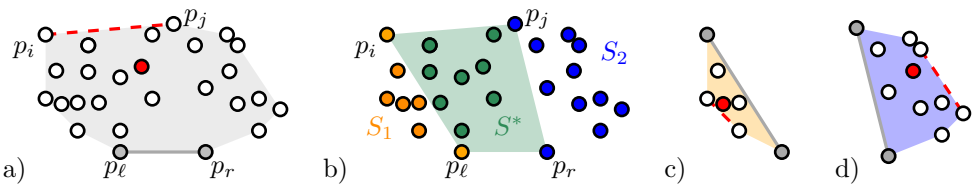

Figure 2 (a) The input are the points and the grey segment. We compute the point m with median x-coordinate and the edge (p_i, p_j). (b) Given $Q = (p_\ell, p_r, p_j, p_i)$, we partition the points into three sets: S_1, S^*, S_2. (c + d) We recurse on S_1 and S_2 using their respective edges of Q.

Algorithm 1 Kirkpatrick-McQueen-Seidel(unordered point set S, edge (p_ℓ, p_r) of $\mathrm{CH}(S)$) [7].

Require: $S = \{p \in P \mid p \text{ lies on or above the line } p_\ell p_r\}$ and $p_\ell, p_r \in \mathrm{ch}(P)$.

if $p_\ell = p_r$ **then**
  Append p_ℓ to the hull list
  return
end if
$m \leftarrow \arg\mathrm{median}\,\{x(p) \mid p \in S\}$
$(p_i, p_j) \leftarrow$ edge of $\mathrm{CH}(S)$ such that $m \in Q = (p_\ell, p_r, p_j, p_i)$ *bridge-finding* [7].
$S_1 \leftarrow \{p \in S \mid p \text{ lies on or above the line } p_\ell p_i\}$
$S_2 \leftarrow \{p \in S \mid p \text{ lies on or above the line } p_j p_r\}$
$S^* \leftarrow S - S_1 - S_2$
Kirkpatrick-McQueen-Seidel$(S_1, (p_\ell, p_i))$
Kirkpatrick-McQueen-Seidel$(S_2, (p_j, p_r))$
GiveWitness(S^*, p_ℓ, p_r, p_j, p_i) *Note that this last step is not explicit in [7].*

▶ **Definition 13.** *A* rooted convex polygon (C, p, q) *is a convex polygon C together with an edge pq of C. Given distinct vertices of r, s of C the line rs splits C into two pieces (one piece is empty if rs is an edge of C). Let C^{rs} denote the piece that* does not *contain pq.*

▶ **Definition 14.** *A* quadrangle tree $\mathcal{Q}$ *of a rooted convex polygon (C, p, q) is a binary tree in which every node stores a quadrangle spanned by (up to) four vertices of C, such that:*

- *The quadrangle at the root node is spanned by p, q, s, r where rs is an edge of C. We allow for $p = r$ and/or $q = s$.*
- *If $q \neq r$, then the root has a child node whose subtree is a quadrangle tree of (C^{pr}, p, r).*
- *If $s \neq p$, then the root has a child node whose subtree is a quadrangle tree of (C^{qs}, q, s).*

Given a point set P and a quadrangle tree $\mathcal{Q}$, the *population* of the root node are all points in P that lie on or inside the quadrangle $pqrs$, except for those that lie on the line pq. Observe that, since we assume that P lies in general position, the population of the root node equals all points in the interior of $pqrs$ plus: r if $p \neq r$ and s if $q \neq s$.

▶ **Observation 15.** *Given the input array I_P, the algorithm by Kirkpatrick, McQueen and Seidel finds the leftmost and rightmost vertices of P in linear time. For each point set P Algorithm 1 constructs, independent of the input ordering $I_P \in \mathbb{I}_P$, a quadrangle tree $\mathcal{Q}$ where each call of Kirkpatrick-McQueen-Seidel(S, (p_ℓ, p_r)) uniquely corresponds to a node (C, p, q) in $\mathcal{Q}$ with $C = \mathrm{CH}(S)$, $p = p_\ell$ and $q = p_r$.*

Ordered downdrafts. For a point set P and a quadrangle tree $\mathcal{Q}$ of $\mathrm{CH}(P)$, we create an *ordered downdraft*. Intuitively, this is a mapping $\varphi : P - ch(P) \to P$ such that for each $p \in P - ch(P)$, the point $\varphi(p)$ lies deeper in the quadrangle tree, or, in the same node as p but farther from the corresponding root edge. This is our most technically involved definition.

▶ **Definition 16** (Figure 3(b))**.** *We define for any quadrangle tree $\mathcal{Q}$ of $\mathrm{CH}(P)$ a partial order $\prec_{\mathcal{Q}}$ on P. For $p \in P$, let $r(p)$ be the node in $\mathcal{Q}$ within whose population p lies. Let $H_{r(p)}$ be the halfplane defined by the rooted edge of $r(p)$. For $p, q \in P$, we say that $p \prec_{\mathcal{Q}} q$ if*

- *$r(p)$ is a strict ancestor of $r(q)$, or*
- *$r(p) = r(q)$, and q lies deeper inside the halfspace $H_{r(p)}$ than p.*

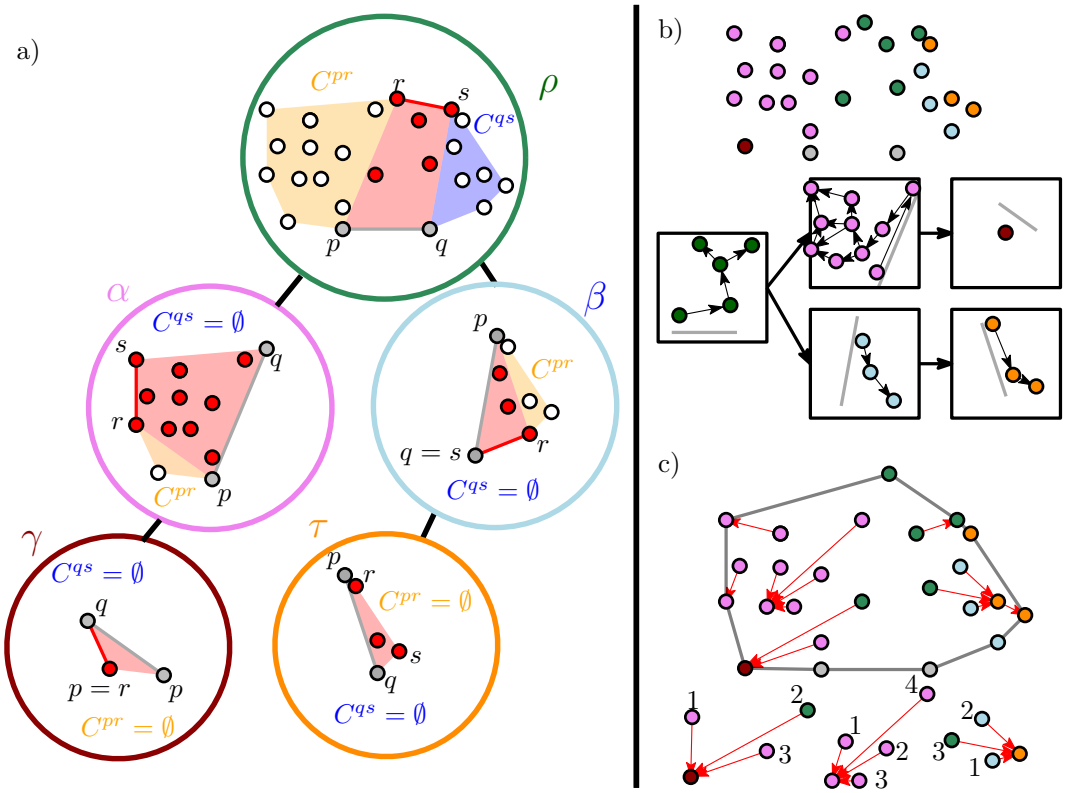

Figure 3 (a) From a rooted polygon (C, p, q) we construct a quadrangle tree $\mathcal{Q}$ with six nodes: $\rho, \alpha, \beta, \gamma, \tau$. For each node in the tree, the red coloured vertices indicate its population.
(b) We assign all points $p \in P$ a colour based on $r(p)$. For example, for all pink points p the node $r(p)$ equals $\alpha \in \mathcal{Q}$. We illustrate a partial order over the points in P where for all p, q with $r(p) = r(q)$ the point $p \prec_{\mathcal{Q}} q$ if and only if p lies further from the line supporting the grey segment.
(c) We create an ordered downdraft φ by mapping each point in $P - ch(P)$ to a point in P. For all points q where multiple points in P map to q, we create a linear order over $\varphi^{-1}(\{q\})$.

Given a quadrangle tree $\mathcal{Q}$, we define a *downdraft* φ as a map that maps each point in $P - \mathrm{ch}(P)$ to a point in P. Specifically, it maps the point either to a quadrangle lower in the tree, or to a point in the same quadrangle that is strictly further away from the root edge.

▶ **Definition 17.** *Let P be a point set and $\mathcal{Q}$ be a quadrangle tree for* $\mathrm{ch}(P)$*. A* downdraft *for $(P, \mathcal{Q})$ is a map $\varphi : (P - \mathrm{ch}(P)) \to P$ such that $\forall p \in P$, we have $p \prec_{\mathcal{Q}} \varphi(p)$.*

Given any downdraft φ and point $q \in P$, the *fiber* $\varphi^{-1}(\{q\})$ is the set of all points $p \in P$ that get mapped to q.

▶ **Definition 18** (Figure 3(c))**.** *An* ordered downdraft $\overline{\varphi} = (\varphi, \prec_{\overline{\varphi}})$ *of $(P, \mathcal{Q})$ is a downdraft φ of $(P, \mathcal{Q})$ plus a total order $\prec_{\overline{\varphi}}$ on each fiber $\varphi^{-1}(\{p\})$ for $p \in P$. We define:*

$\mathrm{OD}(P, \mathcal{Q})$ to be the set of all ordered downdrafts of $(P, \mathcal{Q})$.

4.2 A universal upper bound

Let A denote the Kirkpatrick-McQueen-Seidel algorithm. Recall that Algorithm 1 naturally creates a quadrangle tree $\mathcal{Q}$ of $\mathrm{CH}(P)$, where each call of $\mathrm{A}(S, (p_\ell, p_r))$ uniquely corresponds to a node (C, p, q) in $\mathcal{Q}$ with $C = \mathrm{CH}(S)$, $p = p_\ell$ and $q = p_r$. We show a universal upper bound for the running time of A by counting the number of ordered downdrafts of $\mathcal{Q}$.

▶ **Theorem 19.** *Let P be a planar point set in general position with n points. Let $\mathcal{Q}$ be the corresponding quadrangle tree from Observation 15 and let A denote the algorithm by Kirkpatrick, McQueen and Seidel which as input receives some $I_P \in \mathbb{I}_P$ (and the leftmost and rightmost point in P). Then there exists a constant c such that*

$$\forall I_P \in \mathbb{I}_P, \quad \rho(A, I_P) \leq c \cdot \left(n + \log \frac{n^n}{|\operatorname{OD}(P, \mathcal{Q})|}\right).$$

In Section 5, we show that Algorithm 1 is universally optimal by combining the upper bound from Theorem 19 with the lower bound from Theorem 12.

The proof. Every node in $\mathcal{Q}$ corresponds to a call $A(S, (p_\ell, p_r))$ with $p_\ell \neq p_r$. The quadrangle at this node is $p_\ell p_r p_j p_i$, and its child nodes correspond to the calls $A(S_1, (p_\ell, p_i))$ and $A(S_2, (p_j, p_r))$. We denote the subtree of this node by $\mathcal{Q}(S)$. We put $\mathcal{Q} = \mathcal{Q}(P)$.

▶ **Lemma 20.** *Let S, S_1, S_2 be the sets in some recursive call of Algorithm 1. Then*

$$|\operatorname{OD}(S, \mathcal{Q}(S))| \leq |S|^{|S \setminus (S_1 \cup S_2)|} \cdot |\operatorname{OD}(S_1, \mathcal{Q}(S_1))| \cdot |\operatorname{OD}(S_2, \mathcal{Q}(S_2))|.$$

Proof. First, we show the following upper bound:

$$|\operatorname{OD}(S, \mathcal{Q}(S))| \leq |S|^{|S \setminus (S_1 \cup S_2)|} \cdot |\operatorname{OD}(S_1 \cup S_2, \mathcal{Q}(S))|.$$

Indeed, any ordered downdraft in $\operatorname{OD}(S, \mathcal{Q}(S))$ can be obtained from an ordered downdraft in $\operatorname{OD}(S_1 \cup S_2, \mathcal{Q}(S))$ by placing each element of $S \setminus (S_1 \cup S_2)$ in some fiber, and by placing it at some point in the ordering of the fiber. Within a fiber, an element of S can be placed in at most $|S|$ different ways.

Finally, note that all points in $S_1 - CH(P)$ lie in the left child of $\mathcal{Q}(S)$ and all points in $S_2 - CH(P)$ lie in its right child. Thus, any downdraft over $(S_1 \cup S_2, \mathcal{Q}(S))$ may be obtained by constructing downdrafts over $(S_1, \mathcal{Q}(S_1))$ and $(S_2, \mathcal{Q}(S_2))$ independently, and thus

$$|\operatorname{OD}(S_1 \cup S_2, \mathcal{Q}(S))| = |\operatorname{OD}(S_1, \mathcal{Q}(S_1))| \cdot |\operatorname{OD}(S_2, \mathcal{Q}(S_2))|. \quad \blacktriangleleft$$

For any call $A(S, (p_\ell, p_r))$ made during the execution of the Kirkpatrick-McQueen-Seidel algorithm, let $T(S)$ denote total running time spent on this call (including recursion). Since both median finding and bridge finding take $O(|S|)$ time, there is an absolute constant c such that:

$$T(S) \leq T(S_1) + T(S_2) + c \cdot |S|. \qquad \text{For this constant } c\text{, we show:}$$

▶ **Lemma 21.** *Denote for any call $A(S, (p_\ell, p_r))$ by $T(S)$ the time spent on executing the call (including all time spent during recursion). Then*

$$T(S) \leq c \cdot \left(|S| + |S| \log |S| - \log |\operatorname{OD}(S, \mathcal{Q}(S))|\right).$$

Proof. We use induction over $|S|$. If $p_\ell = p_r$, then $|S| = 1$ and $T(S) \leq c$. Otherwise, let $n = |S|, n_1 = |S_1|, n_2 = |S_2|$. By induction,

$$\begin{aligned} T(S) &\leq T(S_1) + T(S_2) + c \cdot |S| \\ &\leq c \cdot \left(n_1 + n_2 + n_1 \log n_1 + n_2 \log n_2 - \log |\operatorname{OD}(S_1, \mathcal{Q}(S_1))| - \log |\operatorname{OD}(S_2, \mathcal{Q}(S_2))| + n\right) \\ &\leq c \cdot \left(n_1 \log(2n_1) + n_2 \log(2n_2) - \log |\operatorname{OD}(S_1, \mathcal{Q}(S_1))| - \log |\operatorname{OD}(S_2, \mathcal{Q}(S_2))| + n\right) \end{aligned}$$

Since, S_1, S_2 are computed via the median x-coordinate, $n_1, n_2 \leq \frac{n}{2}$. By Lemma 20,

$$-\log|\operatorname{OD}(S_1, \mathcal{Q}(S_1))| - \log|\operatorname{OD}(S_2, \mathcal{Q}(S_2))| \leq -\log|\operatorname{OD}(S, \mathcal{Q}(S))| + (n - n_1 - n_2)\log n$$

Therefore,

$$\begin{aligned} T(S) &\leq c \cdot \Big(n_1 \log n + n_2 \log n - \log|\operatorname{OD}(S, \mathcal{Q}(S))| + (n - n_1 - n_2)\log n) + n\Big) \\ &= c \cdot \Big(n + n\log n - \log|\operatorname{OD}(S, \mathcal{Q}(S))|)\Big) \end{aligned}$$ ◀

We now apply Lemma 21 to the first call $A(P, (p_\ell, p_r))$ of Algorithm 1. Note that per definition, $\mathcal{Q}(P) = \mathcal{Q}$ and $|P| = n$. Lemma 21 guarantees that, regardless of the order I_P we receive the input P in, the running time is at most

$$c \cdot \Big(n + n\log n - \log|\operatorname{OD}(P, \mathcal{Q})|)\Big) = c \cdot \Big(n + \log \frac{n^n}{|\operatorname{OD}(P, \mathcal{Q})|}\Big),$$

which proves Theorem 19.

5 Showing Universal Optimality

In Section 3, we showed for each point set P a universal lower bound (Theorem 12). This bound uses the quantity $V_{\max}(P)$. This quantity is the maximum m, for which there exists a list $W = (a_i, b_i, c_i)_{i=1}^n \subset \mathbb{Z}^{n\times 3}$ with m inputs $I_P \in \mathbb{I}_P$ for which W is a witness list of I_P.

In Section 4, we showed an upper bound for Algorithm 1 (Theorem 19). For each input I_P, the execution of Algorithm 1 on I_P (together with an edge between the leftmost and rightmost vertex in I_P) defines a *quadrangle tree* $\mathcal{Q}$. Our upper bound uses the quantity $|\operatorname{OD}(P, \mathcal{Q})|$. This quantity counts the maximum number of ordered downdrafts of $(P, \mathcal{Q})$.

Here, we show that Algorithm 1 is universally optimal by correlating these two quantities. We achieve this through two intermediate quantities: the number of *corner assignments* of W and the number of *hull lists* of P.

▶ **Definition 22.** *Let $W = (a_i, b_i, c_i)_{i=1}^n$. A* corner assignment *picks a corner for each of the n triangles in W. Formally, it is a map $C : [n] \to [n]$ such that $C(i) \in \{a_i, b_i, c_i\}$ for all $i \in [n]$. Let $\operatorname{CA}(W)$ denote the set of all corner assignments of W. Note that $|\operatorname{CA}(W)| = 3^n$.*

▶ **Definition 23.** *We define $\operatorname{HL}(P)$ as the set of all lists of $k = |ch(P)|$ integers such that $\forall H \in \operatorname{HL}(P)$ there exists an input $I_P \in \mathbb{I}_P$ where H is a hull list of I_P. Note that $|\operatorname{HL}(P)| = \frac{n!}{(n-k)!} \leq n^k$.*

▶ **Lemma 24.** *Let W be an arbitrary witness for P. Let $\mathcal{Q}$ be an arbitrary quadrangle tree for P. There exists an injective map*

$$\Phi : V(P, W) \hookrightarrow \operatorname{OD}(P, \mathcal{Q}) \times \operatorname{CA}(W) \times \operatorname{HL}(P).$$

Proof. Fix $I_P \in V(P, W)$. By our canonical ordering of the hull lists, there exists exactly one $H \in HL(P)$ for which H is a hull list of I_P. We define our map Φ by additionally constructing for I_P a corner assignment C and ordered downdraft $\overline{\varphi}$.

For $i \in [n]$, observe that if $I_p[i]$ is not in $\operatorname{ch}(P)$ then $I_p[i]$ lies strictly inside the triangle formed by $(I_P[a_i], I_P[b_i], I_P[c_i])$. Therefore, at least one of $I_P[i] \prec_{\mathcal{Q}} I_P[a_i], I_P[i] \prec_{\mathcal{Q}} I_P[b_i]$ or $I_P[i] \prec_{\mathcal{Q}} I_P[c_i]$ holds. We construct the corner assignment C by arbitrarily choosing for

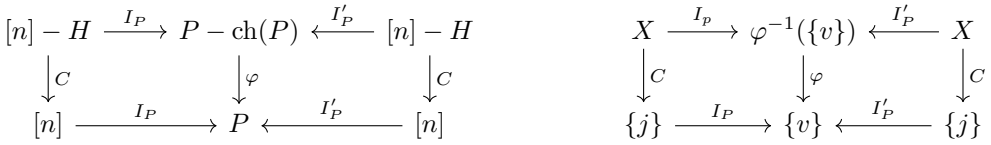

Figure 4 (left) the commuting diagram corresponding to (I_P, I'_P, φ, C). (right) In our proof, we chase this diagram from v encountering the integer j, the set X, and the fiber $\varphi^{-1}(\{v\})$.

each $i \in [n]$, the value $C(i) \in \{a_i, b_i, c_i\}$ such that $I_P[i] \prec_{\mathcal{Q}} I_P[C(i)]$. We then construct a downdraft φ by setting $\varphi(I_P[i]) = I_P[C(i)]$. To obtain an ordered downdraft, we order for all $q \in P$ each fiber $\varphi^{-1}(\{q\})$ via the following rule:

$$\forall I_P[i], I_P[j] \in \varphi^{-1}(\{q\}) : \qquad I_P[i] \prec_{\overline{\varphi}} I_P[j] \quad \Leftrightarrow \quad i < j$$

Then $\overline{\varphi}$ is an ordered downdraft and we have defined the map $\Phi(I_P) = (\overline{\varphi}, C, H)$.

We now show that this map Φ is injective. Suppose that I_P and I'_P are elements of $V(P, W)$ such that $\Phi(I_P) = (\overline{\varphi}, C, H) = \Phi(I'_P)$. Observe that, per definition, the hull list $H \in \Phi(I_P) = \Phi(I'_P)$ is a sequence of integers with the following property: if u is the x'th point on $\mathrm{ch}(P)$ then $I_P[H[x]] = I'_P[H[x]] = u$. Suppose for the sake of contradiction that there exist integers $i, i' \in [n]$ with $i \neq i'$ such that $u = I_P[i] = I'_P[i']$. We pick the pair (i, i') such that u is maximal in the partial order $\prec_{\mathcal{Q}}$.

First, consider the case where u is a point on $\mathrm{ch}(P)$. Let u be the x'th element in the canonical ordering of $\mathrm{ch}(P)$. Then $u = I_P[H[x]] = I'_P[H[x]]$. However, we chose u such that $u = I_P[i] = I'_P[i']$ and so $i = i'$, a contradiction.

Alternatively, suppose that $u \notin \mathrm{ch}(P)$. By maximality of our choice of u, it follows that for all points v' with $u \prec_{\mathcal{Q}} v'$, there exists a unique integer j' such that $v' = I_P[j'] = I'_P[j']$. We define $v := \varphi(u)$. By the definition of a downdraft, $u \prec_{\mathcal{Q}} v$ and so there is a unique integer $j \in [n]$ with $v = \varphi(u) = I_P[j] = I'_P[j]$.

We observe that the objects I_P, I'_P, φ and C are all maps. In Figure 4 we illustrate the diagram corresponding to these maps. Recall that H is the hull list of both $\Phi(I_P)$ and $\Phi(I'_P)$. The left diagram in Figure 4 commutes. Indeed, by our definition of the downdraft φ, we chose φ such that $\varphi(I_p[x]) = I_P[C(x)]$ for all $x \in [n] \setminus H$.

Consider chasing the left square of this diagram from $v = \varphi(u)$ (see Figure 4, right). From v, we may first apply I_P^{-1} to obtain j. We then apply C^{-1} to j to get a set of indices $X := C^{-1}(I_P^{-1}(\{v\}))$. Conversely, we may chase this diagram from v by first applying φ^{-1} to obtain a set of points, and then applying I_P^{-1} to obtain a set of indices. Since the diagram commutes, also $I_P^{-1}(\varphi^{-1}(\{v\})) = X$. Next, we focus on the right square of the diagram. Since $v = I'_P[j]$, we have $C^{-1}(I'^{-1}_P(\{v\})) = X$. We may chase the right square from v by first applying φ^{-1} to obtain a set of points, and then applying I'^{-1}_P. Since this diagram commutes, it follows that $I'^{-1}_P(\varphi^{-1}(\{v\})) = X$ too. We now use this set X to obtain a contradiction:

We assumed that $(\overline{\varphi}, C, H) = \Phi(I_P) = \Phi(I'_P)$. Recall that $\prec_{\overline{\varphi}}$ induces a total order on $\varphi^{-1}(\{v\})$. Per definition of $\Phi(I_P)$, all points $p \in \varphi^{-1}(\{v\})$ are ordered by their index x defined via $p = I_P[x]$. The rank of a value u with respect to an ordered set is its index in the order. We can consider the rank of u in two sets: X and $\varphi^{-1}(\{v\})$. Recall that we ordered for all $q \in P$ each fiber $\varphi^{-1}(\{q\})$ via the following rule:

$$\forall\, I_P[a], I_P[b] \in \varphi^{-1}(\{q\}) : \qquad I_P[a] \prec_{\overline{\varphi}} I_P[b] \quad \Leftrightarrow \quad a < b$$

It follows that the rank of u satisfies:

$$\mathrm{Rank}_{\prec_{\overline{\varphi}}}\left(u, \varphi^{-1}(\{v\})\right) = \mathrm{Rank}_{<}\left(i, I_P^{-1}(\varphi^{-1}(\{v\}))\right) = \mathrm{Rank}_{<}\left(i, X\right)$$

Similarly,

$$\mathrm{Rank}_{\prec_{\overline{\varphi}}}\Big(u, \varphi^{-1}(\{\varphi(u)\})\Big) = \mathrm{Rank}_{<}\Big(i', C^{-1}(\{j\})\Big) = \mathrm{Rank}_{<}\Big(i', X\Big).$$

Since i and i' both have the same rank in X, it follows that $i = i'$, contradiction. This shows that $I_P = I'_P$, so our constructed map Φ is injective. ◀

The above lemma immediately implies the following relation between $V_{\max}(P)$ and $\mathrm{OD}(P, \mathcal{Q})$:

▶ **Corollary 25.** *For every quadrangle tree $\mathcal{Q}$ for P,*

$$V_{\max} \leq |\,\mathrm{OD}(P, \mathcal{Q})| \cdot 3^n \cdot n^k.$$

Finally, we are ready to show universal optimality of Algorithm 1:

▶ **Theorem 10.** *If we define $\mathcal{A}$ as the set of all* correct *comparison-based convex hull algorithms (Definition 5) then the algorithm in [7] for $d = 2$ is universally optimal.*

Proof. Let $\mathcal{Q}$ denote the quadrangle tree that corresponds to executing Algorithm 1. We apply Theorem 19 to note that there exists a constant c such that:

$$\max_{I_P \in \mathbb{I}_P} \rho(A, I_P) \leq c \cdot \Big(n + \log \frac{n^n}{|\,\mathrm{OD}(P, \mathcal{Q})|}\Big).$$

By Corollary 25,

$$\log \frac{n^n}{|\,\mathrm{OD}(P, \mathcal{Q})|} \leq \log \frac{3^n \cdot n^k \cdot n^n}{V_{\max}} = n \log(3) + k \log n + \log \frac{n^n}{V_{\max}}$$

Since $\log(3) \leq 2$ and $\log n^n \leq 2n + \log n!$, this yields

$$\log \frac{n^n}{|\,\mathrm{OD}(P, \mathcal{Q})|} \leq 4n + k \log n + \log \frac{n!}{V_{\max}}$$

We may now apply the universal lower bound from Theorem 12 to obtain the theorem. ◀

Abstract

The problem of identifying the satisfiability threshold of random 3-SAT formulas has received a lot of attention during the last decades and has inspired the study of other threshold phenomena in random combinatorial structures. The classical assumption in this line of research is that, for a given set of n Boolean variables, each clause is drawn uniformly at random among all sets of three literals from these variables, independently from other clauses. Here, we keep the uniform distribution of each clause, but deviate significantly from the independence assumption and consider richer families of probability distributions. For integer parameters n, m, and k, we denote by $\mathcal{F}_k(n,m)$ the family of probability distributions that produce formulas with m clauses, each selected uniformly at random from all sets of three literals from the n variables, so that the clauses are k-wise independent. Our aim is to make general statements about the satisfiability or unsatisfiability of formulas produced by distributions in $\mathcal{F}_k(n,m)$ for different values of the parameters n, m, and k.

Our technical results are as follows: First, all probability distributions in $\mathcal{F}_2(n,m)$ with $m \in \Omega(n^3)$ return unsatisfiable formulas with high probability. This result is tight. We show that there exists a probability distribution $\mathcal{D} \in \mathcal{F}_3(n,m)$ with $m \in O(n^3)$ so that a random formula drawn from $\mathcal{D}$ is almost always satisfiable. In contrast, for $m \in \Omega(n^2)$, any probability distribution $\mathcal{D} \in \mathcal{F}_4(n,m)$ returns an unsatisfiable formula with high probability. This is our most surprising and technically involved result. Finally, for any integer $k \geq 2$, any probability distribution $\mathcal{D} \in \mathcal{F}_k(n,m)$ with $m \in O(n^{1-1/k})$ returns a satisfiable formula with high probability.

1 Introduction

Satisfiability of propositional formulas (SAT) is one of the most renowned problems in theoretical computer science. It appeared in the first lists of NP-complete problems independently proposed by Cook and Levin [44], and is pivotal for many developments in modern complexity theory. Today, many lower bounds on the running time of algorithms rely on the Exponential Time Hypothesis for solving SAT [11, 18, 36, 37]. On the practical side, SAT solvers are frequently deployed in hardware circuit design, model checking, program verification, automated planning and scheduling, as well as in solving real-life instantiations

of combinatorial optimization problems such as FCC spectrum auctions. Modern SAT solvers often find solutions to large industrial instances with thousands or even millions of variables despite the NP-hardness of the problem. However, there is still a large discrepancy between the performance of SAT solvers on those instances and theoretical average-case predictions, which have been studied in great depth under the line of research on *random SAT*.

Random SAT

A j-CNF formula ϕ over n variables is composed of m OR-clauses, each containing exactly j literals of j different variables. In the most commonly studied random SAT model, a formula ϕ is generated uniformly at random from all possible j-CNF formulas over n variables and m clauses. The most prominent theoretical question related to random SAT is to identify the satisfiability threshold r_j such that $\lim_{n\to\infty} \mathbf{Pr}[\phi \text{ is satisfiable}]$ is equal to 0 when $m/n > r_j$, and equal to 1 when $m/n < r_j$. It has been established [15] that 2-SAT has $r_2 = 1$, and its phase transition window [10] is $m \in [n - \Theta(n^{1/3}), n + \Theta(n^{1/3})]$. For $j \geq 3$, the asymptotic j-SAT threshold was shown to be $2^j \log 2 - \frac{1}{2}(1 + \log 2) \pm o_j(1)$ as $j \to \infty$ [17] (improving previous results from [3]), while for large enough j the exact value of r_j was determined in [20]. However, the question of identifying r_j for small values of j remains open. In particular, random 3-SAT has attracted a lot of attention. For the lower bound part, it has been shown in a series of papers [15, 12, 32, 1, 35, 39] that $r_3 \geq 3.52$ (the currently best known bound is due to [35, 39]). The upper bound part is studied by [27, 38, 21, 19]; the currently best known bound is $r_3 < 4.49$ due to [19]. The estimate $r_3 \approx 4.26$ was derived from numerical experiments [40] (see also [14, 41]).

A more recent line of work [29, 30, 31, 42] extends the standard model of random j-SAT to non-uniform distributions. Their motivation comes from the empirical observation that, in practice, CNF formulas often have rather different frequencies/probabilities for the n variables to appear in each clause (following a power-law distribution instead of a uniform one). Namely, Friedrich and Rothenberger [31] proposed a non-uniform random model, where the literals $\{x_i, \overline{x_i}\}_{i\in[n]}$ are selected independently at random in each clause c of the random j-CNF with $\mathbf{Pr}[x_i \in c] = \mathbf{Pr}[\overline{x_i} \in c] = p_i$ and where probabilities $\mathbf{p} = (p_i)_{i\in[n]}$ may vary across different variables. They find satisfiability threshold $r_2(\mathbf{p})$ of non-uniform random 2-SAT for certain regimes depending on $\mathbf{p}$. However, the non-uniform model of [31] does not capture the community biases/correlations (i.e., the fact that certain variables are more likely to appear together in a clause), which are often observed in practice [6]. This leads us to the question of whether it is possible to relax the strong independence assumption in the existing random SAT literature.

Relaxation of independence

We first observe that it does not make much sense to study distributions of SAT formulas with arbitrary correlations over the clauses. Indeed, by allowing correlation between several clauses, one may enforce that the random formula ϕ contains large fixed sub-formulas corresponding to NP-hard SAT variants. This would be at odds with our goal of studying average-case complexity. Therefore, we must keep a certain degree of independence in the distribution of instances. We propose to consider the relaxation of mutual independence over m clauses in a random formula ϕ *to k-wise independence* for a small constant k. To keep the new model tractable, we focus on 3-SAT and uniform distribution of literals within each clause. I.e., we assume that (i) every 3-OR-clause c of a random 3-CNF formula ϕ has three literals of three distinct variables drawn uniformly at random among all such triplets of literals

and that (ii) given this marginal distribution of each clause $c \sim F_{\text{uni.}}$, the distribution $\mathcal{D}$ over the clause set C in ϕ is only k-wise independent instead of the mutually independent distribution $\mathcal{D}_{\text{Ind.}} = (F_{\text{uni.}})^{\otimes m}$ in the standard model. This is a natural generalization that has been considered in a number of different settings but, to the best of our knowledge, not in the context of random SAT. Note that the smaller k is, the bigger the set of possible distributions $\mathcal{D}$. Furthermore, for small values of k, a k-wise independent distribution $\mathcal{D}$ can still capture a large class of dependencies among clauses but at the same time does not allow correlation between any k-tuples of clauses. In mathematical terms, the family of discrete k-wise independent distributions naturally appears when we map the set of distributions to the set of their low-degree moments. Specifically, if a distribution $\mathcal{D}$ is supported on the n-dimensional binary cube $\texttt{supp}(D) = \{-1, 1\}^n$, then all its moments of degree up to k can be described as $\mu(D) = (\mathbf{E}[\prod_{i \in S} x_i])_{|S| \le k}$. As low-degree moments (basically, the image of μ) are extremely important in statistical analysis, it is equally important to study the kernel of the aforementioned mapping, which exactly corresponds to the family of k-wise independent distributions. Let us provide additional justifications of our framework by discussing some of the theoretical work on random 3-SAT and on other settings with a similar k-wise independence relaxation.

Pseudo-randomness. Historically, the k-wise relaxation of independence has been actively used in the literature on derandomization and pseudo-randomness, as it allows to significantly reduce the amount of random bits needed to generate random objects. For example, Alon and Nussboim [5] consider random Erdős-Rényi graphs and examine the minimal degree k of independence needed to achieve a variety of graph properties and statistics (such as connectivity, existence of perfect matchings, existence of Hamiltonian cycles, clique and chromatic numbers, etc.) that match those in the mutually independent case. Benjamini et al. [9] consider similar questions for monotone boolean functions. The motivation in [5] comes from the fact that there are efficient constructions of k-wise independent distributions with "low degree of independence" (say $k = O(\log n)$) that utilize only polylog(n) random bits, i.e., much fewer than the polynomial number of random bits required to generate mutually independent distributions. While some of this motivation can be applied to our setting of random 3-SAT, it is a conceptually different story. Indeed, the perspective of pseudo-random generation is through the lenses of "probability theory", where one controls the distributions and can simply choose one that satisfies necessary conditions such as, e.g., $(\log n)$-wise independence. On the other hand, our motivation stems from "statistics", as our ideal model should have a reasonable fit to empirical observations. So, we would like to use as minimal assumptions as possible and study small (constant) degrees of independence.

Refutability of 3-SAT. While the research on lower bounds for random 3-SAT often comes up with certain simple heuristics that efficiently find a satisfying assignment (see the surveys by Achlioptas [2] and Flaxman [26]), it is extremely hard to find an efficient refutation of a unsatisfiable 3-SAT formula. Indeed, the common approach to refute a given SAT formula is proof in resolution. Chvatal and Szemeredi [16] first showed that a random 3-CNF formula with $m = \Theta(n)$ clauses (which is almost surely unsatisfiable) almost surely admits exponential size proof in resolution. Later, Ben-Sasson and Wigderson [8] derived similar result for much larger $m = O(n^{3/2-\varepsilon})$. On the positive side, [28] gave the first polynomial time algorithm via spectral techniques that almost surely[1] refutes a random

[1] Refutation in this case is an algorithm with one-sided error: it always refutes the formula correctly by

3-SAT formula with $m = n^{3/2+\varepsilon}$ clauses. The best known bound on m is due to Feige and Ofek [25] who proved that, for a sufficiently large constant c, random 3-SAT formulas with $m = c \cdot n^{3/2}$ clauses can be almost surely refuted in polynomial time using another spectral graph algorithm. We note that a similar situation (extremely high probability of unsatisfiability for a random formula and inability to efficiently confirm it) is unlikely to happen in our k-clause independent model for constant k. Indeed, the main proof approach for dealing with arbitrary k-wise independent distribution is to define a k-wise statistic, which differentiates any satisfiable formula from a typical unsatisfiable one.

Testing k-wise independence. The property of k-wise independence of a distribution with n components can be tested using $n^{O(k)} = \text{poly}(n)$ many samples in polynomial time, when k is a constant [4, 43]. This is a useful property to have, as it allows one to verify with only polynomially many instances of random 3-SAT, whether these instances conform to k-wise independence or not.

Robust mechanism design. A recent line of work in robust mechanism design also considers families of k-wise independent Bayesian priors in single and multi-unit auctions [13, 22, 33, 34]. Their motivation is similar to ours, as they also rely on the statistical point of view to justify the extension of the results for mutual independent priors typically assumed in Bayesian mechanism design to k-wise independent ones.

1.1 Problem formulation

We consider random 3-CNF formulas with n variables generated from a distribution $\mathcal{D}$ over m clauses, where the mutual independence assumption over clauses is relaxed to k-wise independence. We use the term *k-clause independence* to refer to such distributions. We denote such families of distributions by $\mathcal{F}_k(n, m)$, where each $\mathcal{D} \in \mathcal{F}_k(n, m)$ has identical marginals uniformly distributed over all possible OR-clauses and those marginals are only assumed to be k-wise independent in $\mathcal{D}$. We would like to understand the following question for small values of k:

> How does the satisfiability threshold r_3 of random 3-SAT formulas behave under any k-clause independent distribution $\mathcal{D} \in \mathcal{F}_k(n, m)$?

As the distribution $\mathcal{D}$ is not unique, there might be a large gap between lower and upper estimates of r_3. To this end, we formally define the *lower satisfiability threshold* $\texttt{LST}_k(n)$ as an upper bound on m, such that a random formula ϕ drawn from a distribution in $\mathcal{F}_k(n, m)$ with $m \leq \texttt{LST}_k(n)$ clauses has $\mathbf{Pr}[\phi \text{ is satisfiable}] \geq \frac{2}{3}$. Similarly, the *upper satisfiability threshold* $\texttt{UST}_k(n)$ is a lower bound on m, such that the random formula ϕ with $m \geq \texttt{UST}_k(n)$ clauses has $\mathbf{Pr}[\phi \text{ is satisfiable}] \leq \frac{1}{3}$. What kind of bounds on upper $\texttt{UST}_k(n)$ and lower $\texttt{LST}_k(n)$ thresholds should we expect?

Reasonable expectations

The condition $\mathcal{D} \in \mathcal{F}_k(n, m)$ only says something about configurations of at most k clauses and does not put any other restrictions on the random formula $\phi \sim \mathcal{D}$. As the degree of independence k is a small constant, any argument that gives bounds on $\texttt{LST}_k$ or $\texttt{UST}_k$ can only rely on statistics of at most a constant number of clauses. Hence, it is rather likely that bounds on $\texttt{LST}_k$ and $\texttt{UST}_k$ come together with efficient procedures of, respectively, finding a satisfying assignment for a random formula ϕ, or certifying that ϕ is not satisfiable. Hence, given the prior work on random 3-SAT for $\mathcal{D}_{\text{Ind.}} \in \mathcal{F}_k(n, m)$, we get the following picture:

---

producing certain certificates, or says that the formula might be correct.

Upper satisfiability threshold. The best known result for refuting 3-CNF formulas efficiently is due to Feige and Ofek [25], who show how to do it only for a large number of clauses $m = c \cdot n^{3/2}$. Furthermore, for any smaller number of clauses $m = O(n^{3/2-\varepsilon})$, a random 3-CNF formula is likely to have only exponential in n proof size for any unsatisfiability proof in resolution [8]. Hence, it is out of reach to aim for a better bound on $\mathtt{UST}_k(n)$ than $O(n^{3/2})$ while relying only on k-wise independence for some constant k. In fact, the best known positive result on *efficiently computable proofs* of unsatisfiability in resolution is due to Beame et al. [7], who show that an ordered DLL algorithm executed on a random 3-SAT instance with $m = \Omega(n^2/\log n)$ clauses terminates in polynomial time.

Lower satisfiability threshold. As the proofs for the lower bounds on r_3 often establish simple procedures that find satisfying assignments with high probability, it is still possible that $\mathtt{LST}_k(n)$ is of similar order $\Theta(n)$ as the lower bounds on r_3 for $\mathcal{D}_{\text{Ind.}}$. Thus, the most ambitious result would be to show that $\mathtt{LST}_k(n) \le c_k \cdot n$ for constant c_k that increases with k. A more modest goal is to aim for $\mathtt{LST}_k(n) = o(n)$ for a constant k, where $\mathtt{LST}_k(n) \to \Theta(n)$ as $k \to +\infty$.

1.2 Our results

We obtain the following bounds on the upper and lower satisfiability thresholds $\mathtt{UST}_k(n)$ and $\mathtt{LST}_k(n)$ for various values of k.

Upper satisfiability thresholds

We first consider small degrees of independence, i.e., $k \in \{2, 3\}$. In both cases, we show that $\mathtt{UST}_k(n) = \Theta(n^3)$, meaning that one needs almost all possible clauses in a 3-clause (as well as 2-clause) independent formula to ensure that it is unsatisfiable (see **Theorem 4** and **Theorem 7**). The most nontrivial part is to construct the distribution $\mathcal{D} \in \mathcal{F}_3(n, m)$ with $m = \Theta(n^3)$ and $\mathbf{Pr}[\phi \text{ is satisfiable}] \ge \frac{2}{3}$. Our construction is based on "3-XOR formulas" (i.e., OR-clauses that have either one or three literals that are satisfied by a randomly planted truth assignment), which aligns well with the intuition developed in previous work [24, 25]. The main technical difficulty is to ensure k-clause independence by adding a small fraction of unsatisfiable instances and checking all k-wise statistics.

Our most exciting and technically involved result (see **Theorem 8**) is our proof that $\mathtt{UST}_4(n) = O(n^2)$, i.e., a random formula $\phi \sim \mathcal{D}$ with $m = \Omega(n^2)$ clauses is unsatisfiable with large probability for any 4-clause independent distribution $\mathcal{D} \in \mathcal{F}_4(n, m)$. It is worth noting that such a bound is much harder to get under the 4-wise independence assumption than in the case of a mutually independent distribution $\mathcal{D}_{\text{Ind.}}$. Indeed, Feige and Ofek [25] describe a very simple refutation algorithm for $m = \Theta(n^2)$ that fixes a variable x and considers all clauses containing x or $\overline{x}$ (there will be $\Theta(n)$ such clauses in expectation). Then, after deleting x (or $\overline{x}$), one can reduce the problem to the refutation of the respective random 2-CNF sub-instance, which can be easily verified in polynomial time and has a low satisfiability threshold of $r_2 = 1$. This simple approach obviously fails for 4-clause independent distributions. We instead construct a bipartite multigraph $G(\phi)$ between pairs of distinct literals on one side and all singleton literals on the other, in which every OR-clause in ϕ corresponds to three different edges. We then carefully examine the statistic $\kappa(\phi)$ that counts $K_{2,2}$ subgraphs in $G(\phi)$ for a random $\phi \sim \mathcal{D}$. We find that the expected value of $\kappa(\phi)$ for random ϕ is only slightly larger than its absolute minimal value, while at the same time $\kappa(\phi)$ is significantly larger than its expectation when ϕ is satisfiable. Our argument

bears certain similarities with the argument in [25], which also looked at intersections of two literals between pairs of clauses but used the 3-XOR principle and a differently constructed non-bipartite graph.

Lower satisfiability thresholds

We show (in **Theorem 14**) that $\texttt{LST}_k(n) \geq \Omega(n^{1-1/k})$ for any $k \geq 2$. I.e., any k-clause independent random formula is satisfiable with high probability if it contains at most $O(n^{1-1/k})$ clauses. The argument is simple: for any k-clause independent distribution, we look at the 3-uniform hypergraph that corresponds to the variables of a random formula ϕ produced according to this distribution, and argue that this graph does not have Berge-cycles, with high probability. We also provide an informal justification that this bound is asymptotically tight, i.e., that $\texttt{LST}_k(n) = O(n^{1-1/k})$. Specifically, we outline a plausible approach for constructing a k-clause independent distribution with $m = O(n^{1-1/k})$ clauses such that most of its formulas are unsatisfiable. Our approach is built upon existing constructions of dense hyper-graphs with large girth. It is interesting to note that, in both the proof of the $\texttt{LST}_k(n) = \Omega(n^{1-1/k})$ result and the approach for showing that $\texttt{LST}_k(n) = O(n^{1-1/k})$, we only need to consider variables and can completely ignore the distribution over the literals.

2 Preliminaries

Let $x_1, x_2, \cdots, x_n$ be n boolean variables. A literal ℓ is a boolean variable or the negation of it. For convenience, we usually represent a literal as a variable-sign pair, i.e., $\ell = (x_i, s)$, where s is the positive sign $\texttt{+}$ if the literal is a boolean variable and the negative sign $\texttt{-}$ if it is its negation. We define $\Sigma(n) = \{\texttt{+}, \texttt{-}\}^n$. An instance of the *Satisfiability* problem in conjunctive normal form (or *SAT instance*, for short) is a boolean formula over a subset of the n variables which is a conjunction of disjunctive clauses, each clause containing literals with different variables. In a 3-SAT instance, every clause has exactly 3 literals. Each SAT instance C can be described as a multiset of clauses. We denote the size of an instance C as $m = |C|$.

Given the number of variables n, let $X(n)$ be the set of variables. Let $T(n)$ be the set of all unordered triplets of variables $T(n) = \{(x_i, x_j, x_k) \mid x_i, x_j, x_k \in X(n), i < j < k\}$ and $\mathcal{T}(n)$ be the set of all possible clauses, i.e., all triplets with literals of different variables. We will usually omit the dependency of X, T, and $\mathcal{T}$ on n, when the value of n is clear from the context. To refer to the variable (the set of variables) or the sign (the set of signs) of a literal (a clause $c \in C$), we define operators $\text{Var}(\cdot)$ and $\text{Sign}(\cdot)$, so that if, e.g., $c = ((x_1, \texttt{+}), (x_2, \texttt{-}), (x_3, \texttt{+}))$, then $\text{Var}(c) = (x_1, x_2, x_3)$ and $\text{Sign}(c) = (\texttt{+}, \texttt{-}, \texttt{+})$.

A *truth assignment* is a vector $\sigma \in \{0, 1\}^n$, where 1 or 0 at the σ_i coordinate corresponds to the "true" or "false" value of x_i, respectively. A truth assignment σ is *satisfying* for an instance C when each clause $c \in C$ has at least one true literal under σ. An instance C is *satisfiable* if there exists a satisfying assignment; otherwise, C is *unsatisfiable*.

The random 3-SAT model assumes that the instance is drawn from a probability distribution over all possible 3-SAT instances with m clauses and n variables. The main object of study in such a model is the probability of such a random instance being satisfiable as a function of n and m.

2.1 Random 3-SAT without mutual independence

In the standard random 3-SAT model, each clause is drawn uniformly at random among all clauses in $\mathcal{T}(n)$, independently from the other clauses. A constructive definition is given by Model 1. We denote the distribution over instances generated by Model 1 as $\mathcal{D}_{\text{Ind.}}$.

MODEL 1 Selects a 3-SAT instance uniformly at random from all possible instances.

Input: Integers $n \geq 3$ and $m \geq 1$
Output: A 3-SAT instance with n variables and m clauses
$C \leftarrow \emptyset$;
for $l \leftarrow 1, \ldots, m$ **do**
  pick a literal triplet (ℓ_1, ℓ_2, ℓ_3) uniformly at random from $\mathcal{T}(n)$;
  $c \leftarrow (\ell_1, \ell_2, \ell_3)$;
  $C \leftarrow C \cup \{c\}$;
end
return C;

Our main focus will be on k-wise relaxations of the independent distribution.

▶ **Definition 1** (k-clause independent random SAT). *A distribution $\mathcal{D}$ for selecting a random SAT instance is k-clause independent if the set of any fixed k clauses $S \subseteq C$ is distributed uniformly at random over all k-tuples of possible clauses, i.e.,*

$$\mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[c_i = t_i, \forall i \in [k]] = \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}_{Ind.}}[c_i = t_i, \forall i \in [k]] = \prod_{i\in[k]} \mathbf{Pr}[c_i = t_i].$$

for every $c_1, \ldots, c_k \in C$ and $t_1, \ldots, t_k \in \mathcal{T}$. We denote the family of all k-clause independent distributions with m clauses over n variables as $\mathcal{F}_k(n, m)$.

We remark that, in contrast to the random 3-SAT model (Model 1), which defines a single distribution for given n and m, the family $\mathcal{F}_k(n, m)$ contains many different distributions.

By definition, the probability of any event A_S that depends only on a subset S of at most k clauses in the k-clause independent distribution $\mathcal{D}$ is the same as for $\mathcal{D}_{\text{Ind.}}$. I.e., the expectations of the indicator function $\mathbb{I}[A_S]$ are the same for $\mathcal{D}$ and $\mathcal{D}_{\text{Ind.}}$. Hence, by linearity of expectation, any statistic that involves only $k' \leq k$ clauses must be the same for $\mathcal{D}$ and $\mathcal{D}_{\text{Ind.}}$, i.e.,

$$\mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\sum_{\substack{S\subseteq C,\\ |S|=k'}} \mathbb{I}\left[A_S\right]\right] = \mathop{\mathbf{E}}_{C\sim\mathcal{D}_{\text{Ind.}}}\left[\sum_{\substack{S\subseteq C,\\ |S|=k'}} \mathbb{I}\left[A_S\right]\right]. \tag{1}$$

We would like to understand what are the largest/smallest possible number of clauses for a random 3-SAT formula to be almost surely satisfiable/unsatisfiable under any k-clause independent distribution. Using $SAT(C)$ to denote the event that the SAT instance C is satisfiable, we define the following satisfiability "thresholds".

▶ **Definition 2** (Upper satisfiability threshold). *The upper satisfiability threshold $\texttt{UST}_k(n)$ is defined as follows. For integer $n \geq 3$, $\texttt{UST}_k(n)$ is the minimum integer m such that*

$$\mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[SAT(C)] \leq 1/3, \quad \forall \mathcal{D} \in \mathcal{F}_k(n, m).$$

▶ **Definition 3** (Lower satisfiability threshold). *The lower satisfiability threshold $\mathtt{LST}_k(n)$ is defined as follows. For integer $n \geq 3$, $\mathtt{LST}_k(n)$ is the maximum integer m such that*

$$\mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[\neg SAT(C)] \leq 1/3, \quad \forall \mathcal{D} \in \mathcal{F}_k(n,m).$$

Extending the line of research on the standard random 3-SAT model, we would like to have as tight estimates of $\mathtt{UST}_k(n)$ and $\mathtt{LST}_k(n)$ as possible.

3 Tight bounds for the upper satisfiability threshold $\mathtt{UST}_2(n)$

We begin with a technical warm up and prove asymptotically tight bounds on the upper satisfiability threshold of 2-clause independent random 3-SAT.

▶ **Theorem 4.** $\mathtt{UST}_2(n) = \Theta(n^3)$.

Theorem 4 follows by the next two lemmas. Lemma 5 provides an upper bound on $\mathtt{UST}_2(n)$. In the proof, we introduce the technique that we will use later in Section 5 to get a much more involved upper bound on $\mathtt{UST}_4(n)$.

▶ **Lemma 5.** *For any $\mathcal{D} \in \mathcal{F}_2(n,m)$ with $m \geq 56\binom{n}{3}$, $\mathbf{Pr}_{C\sim\mathcal{D}}[SAT(C)] \leq 56\binom{n}{3}/m$.*

Proof. Let $\xi(C) \stackrel{\text{def}}{=\!=} \sum_{c_i,c_j\in C} \mathbb{I}[c_i = c_j]$ be the number of identical clause pairs in the instance C. On the one hand, Equation (1) implies that the expectation of $\xi(C)$ is the same when C is drawn from a 2-clause independent distribution and $\mathcal{D}_{\text{Ind.}}$. On the other hand, if an instance C has a satisfying assignment, at least $1/8$ of possible clauses from $\mathcal{T}$ must not appear in C, which means that the value of $\xi(C)$ is significantly higher than its expectation. These two observations will allow us to get the desired bound on the probability $\mathbf{Pr}_{C\sim\mathcal{D}}[SAT(C)]$.

Let $\mathcal{D} \in \mathcal{F}_2(n,m)$ and define $p \stackrel{\text{def}}{=\!=} \mathbf{Pr}_{C\sim\mathcal{D}}[SAT(C)]$. We shall derive two lower bounds on the value the random variable $\xi(C)$ can get: an unconditional lower bound $\mathtt{LB}[\xi]$ (not far from $\mathbf{E}_{C\sim\mathcal{D}}[\xi(C)]$) and a lower bound $\mathtt{LB}[\xi \mid SAT]$ on $\xi(C)$ when C is satisfiable (this will be significantly larger than $\mathbf{E}_{C\sim\mathcal{D}}[\xi(C)]$). We note that

$$\begin{aligned}\mathbf{E}_{C\sim\mathcal{D}}[\xi(C)] &= \mathbf{Pr}[SAT(C)] \cdot \mathbf{E}[\xi(C) \mid SAT(C)] \\ &\quad + \mathbf{Pr}[\neg SAT(C)] \cdot \mathbf{E}[\xi(C) \mid \neg SAT(C)] \\ &\geq p \cdot \mathtt{LB}[\xi \mid SAT] + (1-p) \cdot \mathtt{LB}[\xi]. \end{aligned} \tag{2}$$

We next derive $\mathbf{E}_{C\sim\mathcal{D}}[\xi(C)]$, $\mathtt{LB}[\xi]$, and $\mathtt{LB}[\xi \mid SAT]$. We denote as $M \stackrel{\text{def}}{=\!=} |\mathcal{T}| = 8\binom{n}{3}$ the number of possible clauses and $\lambda \stackrel{\text{def}}{=\!=} m/M > 1$. First, we observe that

$$\mathbf{E}_{C\sim\mathcal{D}}[\xi(C)] = \sum_{c_i,c_j\in C} \mathbf{E}\left[\mathbb{I}\left[c_i = c_j\right]\right] = \frac{m^2-m}{2} \cdot \mathbf{Pr}[c_i = c_j] = \frac{m^2-m}{2\cdot M} = m \cdot \frac{\lambda \cdot M - 1}{2 \cdot M}. \tag{3}$$

To derive the lower bounds $\mathtt{LB}[\xi]$ and $\mathtt{LB}[\xi \mid SAT]$, we observe that any given clause type $t \in \mathcal{T}$ contributes $\binom{d_t}{2}$ pairs to $\xi(C)$, where $d_t \stackrel{\text{def}}{=\!=} \sum_{c\in C} \mathbb{I}[c = t]$ is the number of type t clauses in C. I.e.,

$$\xi(C) = \sum_{t\in\mathcal{T}} \frac{d_t^2 - d_t}{2}, \qquad \text{where } \sum_{t\in\mathcal{T}} d_t = m. \tag{4}$$

The minimum of $\xi(C) = \frac{1}{2}\sum d_t^2 - \frac{m}{2}$ under the constraint $\sum d_t = m$ is achieved when all the d_t variables are equal, i.e., equal to $\frac{m}{|\mathcal{T}|} = \lambda$. Thus, we get the following lower bound $\texttt{LB}[\xi]$ on $\xi(C)$:

$$\xi(C) \geq \texttt{LB}[\xi] \stackrel{\text{def}}{=\!=} \frac{1}{2}\sum_{t\in\mathcal{T}} \lambda^2 - \frac{m}{2} = m\cdot\frac{\lambda-1}{2}. \tag{5}$$

To derive the lower bound $\texttt{LB}[\xi \mid SAT]$ on $\xi(C)$ for a satisfiable formula C, we note that at least a $\frac{1}{8}$-fraction of the clause types are not present in C. I.e., at least $\frac{M}{8}$ of the d_t variables have value equal to 0 in (4). Similarly to (5), the minimum value of $\xi(C)$ is achieved when all the remaining $\frac{7M}{8}$ d_t variables are equal to each other, getting the value $\frac{8\cdot m}{7\cdot M}$. That is,

$$\xi(C) \geq \texttt{LB}[\xi \mid SAT] \stackrel{\text{def}}{=\!=} \frac{7\cdot M}{8}\cdot\left(\frac{8\lambda}{7}\right)^2 - \frac{m}{2} = m\cdot\frac{\frac{8}{7}\lambda-1}{2}. \tag{6}$$

We plug the bounds (3), (5), and (6) into (2) to get

$$m\cdot\frac{\lambda\cdot M-1}{2\cdot M} \geq p\cdot m\cdot\frac{\frac{8}{7}\lambda-1}{2} + (1-p)\cdot m\cdot\frac{\lambda-1}{2}.$$

After simple algebraic transformation, this is equivalent to the inequality $1-\frac{1}{M} \geq \frac{p}{7}\lambda$, which implies that $p \leq \frac{7\cdot M}{m} = 56\binom{n}{3}/m$. ◀

To lower-bound $\texttt{UST}_2(n)$, we use a specific 2-clause independent distribution, which is depicted as Model 2. The next lemma proves the correctness of our construction. The proof is deferred to the full version.

▶ **Lemma 6.** *Model 2 defines a 2-clause independent probability distribution that generates 3-SAT instances of size $\Omega(n^3)$ that are satisfiable with probability at least $1-O(n^{-3})$.*

MODEL 2 Selects a 3-SAT instance according to a 2-clause independent distribution.

Input: Integer $n \geq 3$
Output: A 3-SAT instance C with n variables and $m = \binom{n}{3}$ clauses

- With probability $1-\binom{n}{3}^{-1}$, construct a satisfiable instance C:
  1. Match $m = \binom{n}{3}$ clauses to all different $T(n)$ variable triplets uniformly at random;
  2. Pick a random truth assignment $\sigma \sim \texttt{Uni}[\{0,1\}^n]$;
  3. For each clause $c \in C$ matched to the variable triplet $(x_i, x_j, x_k) \in T(n)$
     - Pick a random sign triplet (s_1, s_2, s_3) of the same parity with $(\sigma_i, \sigma_j, \sigma_k)$ (i.e., $\mathbb{I}[s_1 = \texttt{-}] + \mathbb{I}[s_2 = \texttt{-}] + \mathbb{I}[s_3 = \texttt{-}] + \sigma_i + \sigma_j + \sigma_k = 0 \mod 2$);
     - Let clause $c \leftarrow ((x_i, s_1), (x_j, s_2), (x_k, s_3))$;
- With probability $\binom{n}{3}^{-1}$, sample C from distribution $\mathcal{D}_{\texttt{uni-var}}$ defined as follows:
  1. Pick a random **single** variable triplet $(x_i, x_j, x_k) \sim \texttt{Uni}[T(n)]$;
  2. For each clause $c \in C$
     - Pick a random sign triplet $(s_1, s_2, s_3) \sim \texttt{Uni}[\{\texttt{+},\texttt{-}\}^3]$;
     - Let clause $c \leftarrow ((x_i, s_1), (x_j, s_2), (x_k, s_3))$;

4 A tight lower bound for $\texttt{UST}_3(n)$

Clearly, Lemma 5 also provides an upper bound on $\texttt{UST}_3(n)$. The proof of the next statement follows by presenting a matching lower bound through Model 3.

▶ **Theorem 7.** *$\texttt{UST}_3(n) = \Theta(n^3)$.*

MODEL 3 Selects a 3-SAT instance according to a 3-clause independent distribution.

Input: Integer $n \geq 3$ and even integer $m \leq \frac{1}{3} \cdot \binom{n}{3}$.
Output: A 3-SAT instance C with n variables and m clauses.
Set $p \stackrel{\text{def}}{=\!=} (m-1) \cdot \left(\binom{n}{3}^{-1} - \frac{1}{3}\binom{n}{3}^{-2} \right)$ and $q \stackrel{\text{def}}{=\!=} \binom{n}{3}^{-2}$;

- With probability $1-p-q$, construct a satisfiable instance C:
  1. Match C clauses to m different variable triplets in $T(n)$ uniformly at random;
  2. Pick a random truth assignment $\sigma \sim \texttt{Uni}[\{0,1\}^n]$;
  3. For each clause $c \in C$ matched to the variable triplet $(x_i, x_j, x_k) \in T(n)$
     - Pick a random sign triplet (s_1, s_2, s_3) of the same parity with $(\sigma_i, \sigma_j, \sigma_k)$ (i.e., $\mathbb{I}\left[s_1 = \texttt{-}\right] + \mathbb{I}\left[s_2 = \texttt{-}\right] + \mathbb{I}\left[s_3 = \texttt{-}\right] + \sigma_i + \sigma_j + \sigma_k = 0 \mod 2$);
     - Let clause $c \leftarrow ((x_i, s_1), (x_j, s_2), (x_k, s_3))$;
- With probability p, construct an instance C with $m/2$ different variable triplets:
  1. Uniformly at random match C to $\frac{m}{2}$ different variable triplets in $T(n)$ (exactly 2 clauses in C per one variable triplet);
  2. For each clause $c \in C$ assigned to the variable triplet $(x_i, x_j, x_k) \in T(n)$
     - Pick a random sign triplet $(s_1, s_2, s_3) \sim \texttt{Uni}[\{\texttt{+}, \texttt{-}\}^3]$;
     - Let clause $c \leftarrow ((x_i, s_1), (x_j, s_2), (x_k, s_3))$;
- With probability q, sample C from distribution $C \sim \mathcal{D}_{\texttt{uni-var}}$ as follows:
  1. Pick a random single variable triplet $(x_i, x_j, x_k) \sim \texttt{Uni}[T(n)]$;
  2. For each clause $c \in C$
     - Pick a random sign triplet $(s_1, s_2, s_3) \sim \texttt{Uni}[\{\texttt{+}, \texttt{-}\}^3]$;
     - Let clause $c \leftarrow ((x_i, s_1), (x_j, s_2), (x_k, s_3))$;

We give an explicit construction (see Model 3) of a 3-clause independent distribution $\mathcal{D} \in \mathcal{F}_3(n, m)$ with n variables and (an even number of) $m \leq \frac{1}{3} \cdot \binom{n}{3}$ clauses, such that $\mathbf{Pr}_{C \sim \mathcal{D}}[SAT(C)] \geq 2/3 - O(n^{-6})$. Our construction in Model 3 follows the same pattern as in Model 2, but uses an additional step and minor modifications to ensure 3-clause independence.[2] The proof is deferred to the full version.

5 An upper bound for $\texttt{UST}_4(n)$

Our next result is rather surprising as it indicates that 4-wise independence allows for a steep decrease in the upper satisfiability threshold compared to 2- and 3-wise independence.

▶ **Theorem 8.** $\mathit{UST}_4(n) = O(n^2)$.

Proof. We will prove the theorem by showing that for any positive integers n and m and any 4-clause independent probability distribution $\mathcal{D} \in \mathcal{F}_4(n, m)$, it holds $\mathbf{Pr}_{C \sim \mathcal{D}}[SAT(C)] \leq O\left(\max\left\{\frac{n^2}{m}, \frac{1}{\sqrt{n}}\right\}\right)$. The claim is obvious for $n < 10$. We will assume that $n \geq 10$ and $m \leq \sqrt{10} \cdot n^{5/2}$, and will show that $\mathbf{Pr}_{C \sim \mathcal{D}}[SAT(C)] \leq \frac{4288 \cdot n^2}{m}$ for every 4-clause independent probability distribution $\mathcal{D} \in \mathcal{F}_4(n, m)$. Note that for $m > \sqrt{10} \cdot n^{5/2}$, the probability bound of $O\left(\frac{1}{\sqrt{n}}\right)$ follows by selecting uniformly at random a subset of $\sqrt{10} \cdot n^{5/2}$ clauses.

We will use a graph representation of 3-SAT instances defined as follows. Given a 3-SAT instance C consisting of m clauses over n variables, the bipartite multi-graph $G(C) = (L \cup R, E)$ has a node corresponding to each (unordered) pair of literals $\{\ell_1, \ell_2\}$ from different variables at the left node side L and a node corresponding to each literal ℓ at the right node

[2] The first and third block of Model 3 correspond to the two blocks of Model 2. The only difference in the first block is that the matching of C is not to all the variable triplets in $T(n)$ but only to m of them.

side R. Hence, $|L| = 4\binom{n}{2}$ and $|R| = 2n$. For every clause $c = (\ell_1, \ell_2, \ell_3)$ of C, $G(C)$ has the three edges between the node corresponding to the pair of literals (ℓ_i, ℓ_j) and the node corresponding to literal ℓ_{6-i-j} for $(i,j) \in \{(1,2),(1,3),(2,3)\}$.

The main proof idea of Theorem 8 is to analyze the statistic $\kappa(C)$ defined as the number of distinct $K_{2,2}$ subgraphs in graph $G(C)$. Namely, we first derive an upper bound on the expectation $\mathbf{E}_{C\sim\mathcal{D}}[\kappa(C)]$ (see Lemma 9) when C is drawn from the 4-clause independent probability distribution $\mathcal{D} \in \mathcal{F}_4(n,m)$. We then give two lower bounds on the value of the random variable $\kappa(C)$ by considering an underlying simple subgraph of $G(C)$. Note that the underlying simple subgraph corresponds to a smaller instance $\widetilde{C}$ with $\widetilde{m}$ distinct clauses, in which we remove all duplicated clauses in C. As we show in Lemma 10, this does not significantly reduce the size of the instance. Our first lower bound (Lemma 11) on $\kappa(\widetilde{C})$ holds for any instance $\widetilde{C}$ and is very close to the upper bound on the expectation of $\kappa(C)$. On the other hand, when $\widetilde{C}$ is satisfiable, we manage to give a significantly stronger lower bound on $\kappa(\widetilde{C})$ in Lemma 12. We then conclude the proof of Theorem 8 by relating all these upper and lower bounds with $\mathbf{E}_{C\sim\mathcal{D}}[\kappa(C)]$ in Lemma 13. We defer the proofs of Lemmas 9, 10, 11, and 12 to the full version.

▶ **Lemma 9.** *For any $\mathcal{D} \in \mathcal{F}_4(n,m)$, it holds that $\mathbf{E}_{C\sim\mathcal{D}}[\kappa(C)] \le \frac{81m^4}{64n^6} + \frac{729m^3}{32n^4}$.*

▶ **Lemma 10.** $\mathbf{E}_{C\sim\mathcal{D}}[\widetilde{m}^4] \ge m^4 - \frac{125}{6}\cdot m^3 \cdot n^2$.

▶ **Lemma 11.** *Let C be an instance with n variables and $\widetilde{m}$ distinct clauses. Then,*

$$\kappa(\widetilde{C}) \ge \frac{81\widetilde{m}^4}{64n^6} - \frac{27\widetilde{m}^3}{8n^4}.$$

▶ **Lemma 12.** *Let C be a statisfiable instance with n variables and $\widetilde{m}$ distinct clauses. Then*

$$\kappa(\widetilde{C}) \ge \frac{82\widetilde{m}^4}{64n^6} - \frac{123\widetilde{m}^3}{16n^4}.$$

▶ **Lemma 13.** *For any $\mathcal{D} \in \mathcal{F}_4(n,m)$, we have $\mathbf{E}_{C\sim\mathcal{D}}[\kappa(C)] \ge \frac{81m^4}{64n^6} - \frac{1215m^3}{32n^4} + \frac{m^4}{64n^6} \cdot \mathbf{Pr}_{C\sim\mathcal{D}}[SAT(C)]$.*

Proof. We prove the lemma with the following derivation:

$$\begin{aligned}
\mathop{\mathbf{E}}_{C\sim\mathcal{D}}[\kappa(C)] &\ge \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\kappa(\widetilde{C})\right] \\
&= \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\kappa(\widetilde{C})|SAT(C)\right]\cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[SAT(C)] \\
&\quad + \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\kappa(\widetilde{C})|\neg SAT(C))\right]\cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[\neg SAT(C)] \\
&\ge \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\frac{82\widetilde{m}^4}{64n^6} - \frac{123\widetilde{m}^3}{16n^4}\middle| SAT(C)\right]\cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[SAT(C)] \\
&\quad + \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\frac{81\widetilde{m}^4}{64n^6} - \frac{27\widetilde{m}^3}{8n^4}\middle|\neg SAT(C)\right]\cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[\neg SAT(C)] \\
&\ge \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\frac{82\widetilde{m}^4}{64n^6} - \frac{123\widetilde{m}^3}{16n^4}\right] - \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\frac{\widetilde{m}^4}{64n^6}\middle|\neg SAT(C)\right]\cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[\neg SAT(C)] \\
&\ge \frac{82}{64n^6}\mathop{\mathbf{E}}_{C\sim\mathcal{D}}[\widetilde{m}^4] - \frac{123m^3}{16n^4} - \frac{m^4}{64n^6}\cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[\neg SAT(C)] \\
&\ge \frac{82m^4}{64n^6} - \frac{861m^3}{32n^4} - \frac{123m^3}{16n^4} - \frac{m^4}{64n^6}\cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[\neg SAT(C)]
\end{aligned}$$

$$= \frac{81m^4}{64n^6} - \frac{1107m^3}{32n^4} + \frac{m^4}{64n^6} \cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[SAT(C)]\,,$$

as desired. The second inequality follows by Lemmas 12 and 11, the fourth one by the fact $\widetilde{m} \le m$, and the fifth one by Lemma 10. ◀

Now, Lemmas 9 and 13 yield

$$\frac{81m^4}{64n^6} - \frac{1215m^3}{32n^4} + \frac{m^4}{64n^6} \cdot \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[SAT(C)] \le \mathop{\mathbf{E}}_{C\sim\mathcal{D}}[\kappa(C)] \le \frac{81m^4}{64n^6} + \frac{729m^3}{32n^4},$$

which implies the desired bound $\mathbf{Pr}_{C\sim\mathcal{D}}[SAT(C)] \le \frac{4288\cdot n^2}{m}$. Theorem 8 follows. ◀

6 Bounds on the lower satisfiability threshold

In this section, we present our upper bound on the lower satisfiability threshold and explain why we believe that it is the tight bound for every degree of independence.

▶ **Theorem 14.** *For every integer $k \ge 2$, $\mathtt{LST}_k(n) = \Omega(n^{1-1/k})$.*

Proof. We prove the theorem by showing that for every integers $n \ge 3$ and $m \le \frac{1}{12}\cdot n^{1-1/k}$, any k-clause independent distribution $\mathcal{D} \in \mathcal{F}_k(n,m)$ satisfies $\mathbf{Pr}_{C\sim\mathcal{D}}[\neg SAT(C)] \le 1/3$.

Let $G(C) = (V,E)$ be a 3-uniform hypergraph defined by an instance C drawn from a k-clause independent distribution $\mathcal{D}$, $V = X(n)$ and $E = \{\mathrm{Var}(c)\}_{c\in C}$, i.e., every node in G represents a variable and every hyperegde in G represents the variable triplet of a clause. We consider simple *Berge-cycles* (or, simply, cycles) of length $\ell \ge 2$. A cycle of length $\ell > 2$ is defined as a set of ℓ distinct hyperedges $e_1, e_2, \ldots, e_\ell \in E$ such that pairs of consecutive edges share exactly one vertex ($|e_i \cap e_{i+1}| = 1$ and $|e_\ell \cap e_1| = 1$) and all other pairs of hyperedges are disjoint. In a cycle of length $\ell = 2$, the two hyperedges e_1 and e_2 have at least two vertices in common. We similarly define a path of length $\ell \ge 2$, where pairs of consecutive edges share exactly one vertex ($|e_i \cap e_{i+1}| = 1$ for $i \in [\ell-1]$) and all other pairs of hyperedges are disjoint. We observe that any unsatisfiable instance must contain a subgraph H in G such that every variable in H appears in at least two hyperedges of H, which in turn implies that G has a cycle. That translates into the following upper bound on the probability that instance $C \sim \mathcal{D}$ is not satisfiable:

$$\begin{aligned}
\mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[\neg SAT(C)] &\le \mathop{\mathbf{Pr}}_{C\sim\mathcal{D}}[\exists \text{ cycle in } G(C)] \le \sum_{\ell\ge 2} \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\mathsf{Cycle}_\ell(G(C))\right] \\
&\le \mathop{\mathbf{E}}_{C\sim\mathcal{D}}[\mathsf{Path}_k(G(C))] + \sum_{\ell=2}^{k-1} \mathop{\mathbf{E}}_{C\sim\mathcal{D}}\left[\mathsf{Cycle}_\ell(G(C))\right] \\
&= \mathop{\mathbf{E}}_{C\sim\mathcal{D}_{\mathrm{Ind.}}}[\mathsf{Path}_k(G(C))] + \sum_{\ell=2}^{k-1} \mathop{\mathbf{E}}_{C\sim\mathcal{D}_{\mathrm{Ind.}}}\left[\mathsf{Cycle}_\ell(G(C))\right]. \qquad (7)
\end{aligned}$$

In the above derivation, $\mathsf{Cycle}_\ell(G(C))$ counts the number of distinct cycles of length ℓ in G, and $\mathsf{Path}_k(G(C))$ counts the number of distinct paths of lengths k in G. For each ordered tuple of k hyperedges in G (there are $k!\cdot\binom{m}{k}$ such orderings), we can easily calculate the probability that they form a path. Thus,

$$\mathop{\mathbf{E}}_{C\sim\mathcal{D}_{\mathrm{Ind.}}}[\mathsf{Path}_k(G(C))] = k!\cdot\binom{m}{k}\cdot\frac{3\cdot\binom{n-3}{2}}{\binom{n}{3}}\cdot\prod_{t=3}^{k}\frac{2\cdot\binom{n-2t+1}{2}}{\binom{n}{3}} \le m^k\cdot\frac{9}{n}\cdot\left(\frac{6}{n}\right)^{k-2}. \qquad (8)$$

For each ordering of k edges, the first edge e_1 can be chosen arbitrarily; the second edge has exactly one vertex in common with e_1 and the remaining two vertices are chosen from $[n] \setminus e_1$ vertices; each of the remaining edges e_t for $t \geq 3$ has exactly one of the two vertices of e_{t-1} different from $e_{t-1} \cap e_{t-2}$ and has two other vertices chosen from $[n] \setminus (e_1 \cup \ldots \cup e_{t-1})$. The upper bound follows after simplifying each of the terms. We similarly derive an upper bound on $\mathbf{E}[\mathsf{Cycle}_\ell(G(C))]$ for $\ell \geq 3$ as follows:

$$\mathop{\mathbf{E}}_{C \sim \mathcal{D}_{\text{Ind.}}} \left[\mathsf{Cycle}_\ell(G(C))\right] \leq \frac{1}{6} \cdot \ell! \cdot \binom{m}{\ell} \cdot \left[\frac{3 \cdot \binom{n-3}{2}}{\binom{n}{3}} \cdot \prod_{t=3}^{\ell-1} \frac{2 \cdot \binom{n-2t+1}{2}}{\binom{n}{3}}\right] \cdot \frac{4 \cdot (n-2\ell+1)}{\binom{n}{3}},$$

where for each ordering of ℓ edges (now $2\ell \geq 6$ orderings correspond to the same cycle), the probabilities to choose the first $\ell - 1$ edges can be computed in the same way as for Path_k; for the last hyper-edge e_ℓ, there are $4 = 2 \cdot 2$ ways to select a vertex of $e_{\ell-1}$ together with a vertex of e_1, and $n - 2\ell + 1$ choices for the new vertex in $[n] \setminus (e_1 \cup \ldots \cup e_{\ell-1})$. Hence,

$$\mathop{\mathbf{E}}_{C \sim \mathcal{D}_{\text{Ind.}}} \left[\mathsf{Cycle}_\ell(G(C))\right] \leq m^\ell \cdot \left[\frac{9}{n} \cdot \left(\frac{6}{n}\right)^{\ell-3}\right] \cdot \frac{4}{n^2} = \frac{1}{6}\left(\frac{6m}{n}\right)^\ell. \tag{9}$$

For $\ell = 2$ we have

$$\mathop{\mathbf{E}}_{C \sim \mathcal{D}_{\text{Ind.}}} \left[\mathsf{Cycle}_2(G(C))\right] = \binom{m}{2} \cdot \frac{3 \cdot (n-3) + 1}{\binom{n}{3}} = \frac{3m \cdot (m-1) \cdot (3n-8)}{n \cdot (n-1) \cdot (n-2)} \leq \left(\frac{3m}{n}\right)^2. \tag{10}$$

We conclude the proof by plugging estimates (8),(9), and (10) into (7).

$$\begin{aligned}\mathbf{Pr}\left[\neg SAT(C)\right] &\leq \frac{2}{3}\frac{(6m)^k}{n^{k-1}} + \left(\frac{3m}{n}\right)^2 + \frac{1}{6}\sum_{\ell=3}^{k-1}\left(\frac{6m}{n}\right)^\ell \\ &\leq \frac{2}{3 \cdot 2^k} + \frac{1}{16} + \frac{1}{6} \cdot \left(\frac{1}{2^3} + \frac{1}{2^4} + \ldots + \frac{1}{2^{k-1}}\right) < \frac{1}{3}.\end{aligned}$$

The second inequality follows since $m \leq \frac{1}{12} \cdot n^{1-1/k}$. ◀

6.1 On the tightness of the $O(n^{1-1/k})$ bound for $\mathtt{LST}_k(n)$

Theorem 14 says that k-wise independence of $\mathcal{D} \in \mathcal{F}_k(n, m)$ is enough to guarantee satisfiability of a random formula $C \sim \mathcal{D}$ for the number of clauses m of order $n^{1-1/k}$. On the other hand, for the mutually independent distribution $\mathcal{D}_{\text{Ind.}}$ a random formula is unsatisfiable with high probability for $m = O(n)$. Furthermore, our analysis in Theorem 14 is essentially tight and it seems unlikely that there is a better bound than $m = O(n^{1-1/k})$. We discuss below why this is the case, by outlining a plausible way for constructing k-clause independent distribution $\mathcal{D} \in \mathcal{F}_k(n, m)$ with $\mathbf{Pr}_{C \sim \mathcal{D}}[\neg SAT(C)] \geq \frac{2}{3}$ and $m = \Theta(n^{1-1/k})$.

Informal outline of the construction

In our construction of the k-clause independent distribution $\mathcal{D}$ we are only concerned with the distribution of clauses over variables, as all literals will be assigned uniformly at random and independently. Then, a sufficient condition for a random formula $C \sim \mathcal{D}$ to be unsatisfiable with large probability is that the 3-uniform hypergraph $G(C)$ constructed in Theorem 14 has a dense subgraph, i.e., a subgraph on $|V(H)|$ vertices (corresponding to variables in C) with at least $|E(H)| \geq 100 \cdot |V(H)|$ hyperedges. Indeed, one can simply count the expected number of satisfying assignments of a random formula ϕ_H on $V(H)$ variables and

$|E(H)|$ fixed clauses with randomly assigned literals: initially, all $2^{|V(H)|}$ assignment are satisfying, but then, as we add $|E(H)|$ clauses one-by-one, the expected number of satisfying assignments reduces each time exactly by a factor 7/8 (each satisfying assignment disappears with probability 1/8). At the end, we get that the expected number of satisfying assignments is $\left(\frac{7}{8}\right)^{100|V(H)|} \cdot 2^{|V(H)|} < 0.01$, which means that ϕ is unsatisfiable most of the times.

Now, we want to make sure that our hypergraph $G(C)$ often has such a "dense" subgraph H, to get an unsatisfiable random formula. Notice that H needs only have a constant number of vertices. Also, note that according to the analysis in Theorem 14, we need to avoid any cycles of length smaller than or equal to k, as the probability of having such a cycle is of order $o(1)$ in $G(C)$ for $m = c \cdot n^{1-1/k}$ and any k-clause independent distribution $C \sim \mathcal{F}_k(n, m)$. Luckily, there are many construction of such 3-uniform hypergraphs H on $|V(H)| = O(1)$ vertices with large number of hyperedges $|E(H)| \geq 100|V(H)|$, and also of large girth $g(H) \geq k + 1$ (e.g., see [23]). We shall "plant" H (essentially insert H as a connected component into G) with large probability in our construction. However, we need to make sure that by inserting H into our graph G, we still have enough room to match $\mathbf{Pr}[c_i = t_i, \forall i \in S] = \prod_{i \in S} \mathbf{Pr}[c_i = t_i]$ for all $S : |S| \leq k$. Next, we give a high level idea how one could achieve this.

As usual for the construction of distributions with identical marginals, we symmetrize $\mathcal{D}$ over all possible permutations of variables in $C \sim \mathcal{D}$. Then, our goal is to match the expected numbers for each isomorphism class of configurations of k hyperedges in $G(C)$ for $C \sim \mathcal{D}$ with $C \sim \mathcal{D}_{\text{Ind.}}$. It is useful to take note of the structure of hypergraph $G(C)$ for $C \sim \mathcal{D}_{\text{Ind.}}$ when $m = c \cdot n^{1-1/k}$: it consists of connected components, each of which is a tree of size at most k; the number of connected components of size k is a constant that grows slightly faster than linearly in c and, more generally, the number of connected components of size $k - j$ is $\Theta(n^{j/k})$. There is also a $o(1)$ probability event of having a Berge-cycle or a connected component of size at least $k + 1$ in $G(C)$ for $C \sim \mathcal{D}_{\text{Ind.}}$. We can ignore in our construction of $\mathcal{D}$ those events, by adding small probability mass to $\mathcal{D}$ that consists of $\mathcal{D}_{\text{Ind.}}$ conditional on any of these rare events (can be easily achieved via rejection sampling from $\mathcal{D}_{\text{Ind.}}$). In this way, we only need to worry about matching expected numbers of forest configurations of size k in $G(C)$ between $C \sim \mathcal{D}$ and $C \sim \mathcal{D}_{\text{Ind.}}$. We can pick the constant in $m = c \cdot n^{1-1/k}$ sufficiently large, so that the constant size subgraph H contributes fewer trees of each type than their respective expected numbers in $G(C)$ for $C \sim \mathcal{D}_{\text{Ind.}}$. Then, we can add a few more connected components that are trees of size k to $C \sim \mathcal{D}$, so that we match k-wise statistics on all tree configurations with $C \sim \mathcal{D}_{\text{Ind.}}$. By having H and a few trees of size k in the graph $G(C)$ for $C \sim \mathcal{D}$, we only utilize a constant number of variables. Then, we would like to keep adding smaller connected components that consist of trees with strictly less than k hyperedges and eventually match k-wise statistics on all forest-like configurations of size k.

It seems plausible that the approach outlined above should work and yield a k-clause independent distribution $\mathcal{D}$. Apart from heavy notation that would be needed to formalize all steps in the above outline, the main technical hurdle is to ensure that statistics for all "forest-like" configurations of k hyperedges with more than one connected component are perfectly matched with $G(C)$ for $C \sim \mathcal{D}_{\text{Ind.}}$. Note, however, that even if our approach fails and there is a stronger version of Theorem 14 with $m = \omega(n^{1-1/k})$ and $\mathbf{Pr}_{C \sim \mathcal{D}}[SAT(C)] \geq \frac{2}{3}$ for any k-clause independent distribution $\mathcal{D}$, such a theorem would require a rather nontrivial argument that relies on subtle dependencies between multiple k-wise statistics.

Optimal Antimatroid Sorting

Benjamin Aram Berendsohn
Max Planck Institute for Informatics, Saarbrücken, Germany

Abstract

The classical *comparison-based sorting* problem asks us to find the underlying total ordering of a given set of elements, where we can only access the elements via comparisons. In this paper, we study a *restricted* version, where, as a hint, a set T of possible total orderings is given, usually in some compressed form.

Recently, an algorithm called *topological heapsort* with optimal running time was found for case where T is the set of topological orderings of a given directed acyclic graph, or, equivalently, T is the set of linear extensions of a partial ordering [Haeupler et al. 2024]. We show that a simple generalization of topological heapsort is applicable to a much broader class of restricted sorting problems, where T corresponds to a given *antimatroid*.

As a consequence, we obtain optimal algorithms for the following restricted sorting problems, where the allowed total orders are ...

- ... restricted by a given set of *monotone precedence formulas*;
- ... the *perfect elimination orders* of a given chordal graph; or
- ... the possible *vertex search orders* of a given connected rooted graph.

1 Introduction

One of the fundamental problems in theoretical computer science is *sorting*. It has a wide variety of applications in practice [24] and is frequently used as an introduction to design and analysis of algorithms.

Perhaps the most intensely studied variant is *comparison-based sorting*, where one can only access the input elements via comparisons (otherwise, we assume the standard word RAM model). This excludes bucket sort, radix sort, and other integer-sorting techniques [10, 16, 15]. The well-known *information-theoretic bound (ITB)* states that comparison-based sorting requires $\log(n!) \approx n \log n$ comparisons in the worst case, and many algorithms asymptotically matching this bound are known.

In this paper, we study a restricted variant of comparison-based sorting. In addition to the n elements to be sorted, we are give a set T of possible total orders, with the guarantee that the actual order of the input is contained in T. Call this the *T-sorting problem*. Note that T may be very large compared to n, so it makes sense to consider variants of the problem where T is given in some compressed form. Regardless of that, the ITB for the T-sorting problem is $\log |T|$, so perhaps the first question to ask is: Can we solve the T-sorting problem with only $\mathcal{O}(\log |T|)$ comparisons?

In turns out that the answer is *yes* if $|T| \geq 2^{\Omega(n)}$. Fredman [9] showed how to solve the T-sorting problem with $\mathcal{O}(n + \log |T|)$ comparisons. This algorithm assumes that T is given explicitly and is thus entirely impractical. Fredman also showed that there exist sets T with $|T| \in \mathcal{O}(n)$ where the T-sorting problem requires $\Omega(n)$ comparisons, which means the ITB is not always tight.

Most later work on this problem has been focused on the special case where T is the set of linear extensions of a partial order P, given by its Hasse diagram. It is known that $\mathcal{O}(\log |T|)$ comparisons are sufficient, that is, the ITB is tight (even when $\log T \leq n$). After

decades of research [21, 9, 29, 19, 2, 5, 33], eventually, two algorithms were found that are simultaneously comparison-optimal and running-time optimal [14, 32]. Both algorithms actually solve the slightly more general *DAG sorting* problem: Given is a directed acyclic graph G, and T is taken as the set of topological orderings of G. Note that each DAG G defines a partial order P (though G may contain some "unnecessary" edges), and T is the set of linear extensions of P.

Most important for our purposes is the *topological heapsort* algorithm of Haeupler, Hladík, Iacono, Rozhon, Tarjan, and Tětek [14]. This was the first DAG-sorting algorithm with optimal running time $\mathcal{O}(|V(G)| + |E(G)| + \log|T|)$, though it makes $\Theta(|V(G)| + \log|T|)$ comparisons, which is non-optimal if $|T|$ is small. Achieving comparison optimality requires further modifications, which we discuss later.

We briefly describe topological heapsort. Let G be the given DAG. At the beginning, identify the set S of sources (vertices of in-degree 0) of G, and insert them into a priority queue Q. In each following step, we first find and remove the minimum element x from Q. Then, we remove x from G. This may create several new sources, which we all insert into Q. Repeat until Q is empty. It is easy to see that this algorithm is *correct* if the underlying total order of the vertices is indeed a topological ordering of G. Haeupler et al. achieve optimal running time by using a special priority queue with the so-called *working-set property*.

Let us now try to generalize topological heapsort to solve the general T-sorting problem. Suppose that instead of the graph G, we are given a black-box data structure D that reports all elements that are the minimum of at least one ordering $\tau \in T$. After "removing" the first k elements $x_1, x_2, \ldots, x_k$, let D report all elements y such that $x_1x_2\ldots x_ky$ is a prefix of some ordering $\tau \in T$ (the *available* elements). Again, it is easy to see that topological heapsort with this data structure is *correct*. But is it optimal?

The main contribution of this paper (Section 3) is to show that topological heapsort has optimal running time if T corresponds to a class of structures called *antimatroids*, which are a generalization of partial orders, when we disregard the running time for the data structure D. We additionally show that, for several possible representations of antimatroids, we can implement D such that its total running time is linear in the size of the input, so the running time stays optimal (Section 4). Finally, we show how to additionally achieve comparison optimality (Section 5). The full version of the paper contains various omitted proofs, as well as a discussion of several generalizations of antimatroids where topological heapsort is *not* optimal. In the remainder of this section, we give an informal definition of antimatroids, and discuss some related work.

Antimatroids. Fix a set T of total orderings, and consider the black-box data structure D mentioned above. Recall that, for each sequence $x_1, x_2, \ldots, x_k$ of $k \geq 0$ elements, D tells us the set of *available* elements y such that $x_1x_2\ldots x_ky$ is a prefix of some $\tau \in T$. It is clear that any set T can be described in this way. Intuitively, T is an *antimatroid* if the following conditions apply. First, once an element becomes available, it stays available until it is chosen (availability is *monotone*); and second, availability of an element can only depend on the *set* of elements chosen so far (but not their order).

The first condition can be nicely related to topological heapsort: It means that our priority queue Q at no point contains unavailable elements. The second condition may seem more surprising, but it turns out to be also necessary for optimality of topological heapsort and tightness of the ITB (for details, see the full version of the paper).

Antimatroids were first studied by Dilworth [7] in lattice theory. Later, they were found to be special cases of so-called *greedoids* [25, 26], which are structures admitting a certain greedy optimization procedure. A common alternative definition of antimatroids treats them as *set systems*; this definition can be related to *matroids* (hence the name), which are also special cases of greedoids. We refer to the surveys of Björner and Ziegler [1] and Korte, Schrader, and Lovász [27] for more.

Related work. Optimal algorithms are known [17, 4, 29] for *merging* two sorted lists; this corresponds to a partial order consisting of exactly two disjoint chains. Merging can be generalized to *multiway merging*, where the input is split into any number of sorted lists; here, the ITB is known to be related to the *Shannon entropy* of the list lengths. Multiway merging is important for pratical sorting algortihms that exploit *runs* in a given unsorted sequence (see, e.g., Gelling, Nebel, Smith, and Wild [11]).

A different special case of the T-sorting problem concerns the case where the set T is the permutations that *avoid* a certain pattern π.[1] It is known that $T \leq c_\pi^n$ for some constant c_π depending on π, so the ITB is linear in this case. Opler [31] gave an optimal linear-time algorithm for the pattern-avoiding sorting problem, which works even when the pattern π is unknown. We refer to his paper for more information on that problem.

The $X + Y$*-sorting problem* is a restricted sorting problem where, interestingly, the ITB is *not* tight. Here, two sets $X, Y \subset \mathbb{R}$ of size k each are given, and we need to sort the set $\{x + y \mid x \in X, y \in Y\}$ of size $n = k^2$. If only comparisons of the form $x + y < x' + y'$ with $x, x' \in X$, $y, y' \in Y$ are allowed, then this is a restricted sorting problem by our definition. It is known that the number of possible orderings is only $k^{\Theta(k)}$ [9], which makes the ITB $\Omega(k \log k) = \Omega(\sqrt{n} \log n)$; however, Fredman [9] showed that $\Omega(k^2)$ comparisons are needed. It is currently unknown if an algorithm with optimal running time $\Theta(k^2)$ exists.

Finally, a question closely related to restricted sorting is finding *balanced pairs*, which are comparisons that split the set of possible total orders into two parts of approximately equal size. There is a body of work on balanced pairs in partial orders [21, 9, 29, 2, 3], and the concept has been generalized to antimatroids [8].

2 Preliminaries

All the following definitions are taken from Björner and Ziegler [1] with only slight changes.

Words and languages. Let an *alphabet* Σ be a set of *letters*. A *word* on Σ is a finite sequence of letters. We write words without commas as $\alpha = x_1 x_2 \dots x_n$, where $x_i \in \Sigma$, and we write $\alpha\beta$ for the concatenation of two words α and β. We denote the length of a word α by $|\alpha|$. The *support* $\tilde{\alpha}$ of a word α is the set of letters contained in it, and the empty word is denoted by ε.

A word α is *simple* if each letter occurs at most once in it (i.e., $|\tilde{\alpha}| = |\alpha|$), and α is a *permutation* of Σ if each letter occurs precisely once in it. The set of all simple words on Σ is denoted by Σ_s^*, and a *simple language* is a subset $L \subseteq \Sigma_s^*$. We denote the set of permutations contained in a simple language by $\mathcal{P}(L)$, and we call L *full* if $|\mathcal{P}(L)| > 0$.

[1] A permutation τ of a set X *avoids* a permutation π of $[k]$ if τ contains no subsequence that is order-isomorphic to π, according to some fixed total order on X. This restricted sorting problem is usually formulated in a different, but equivalent way where X is given as a sequence that is known to avoid a pattern.

Partial orders. A partial order on a set Σ is denoted with a capital letter, like P, and we write $\prec_P$ for the actual partial order relation. Total orders are treated as permutations of the underlying set Σ. Whenever necessary, we write $\prec_\pi$ for the total order relation corresponding to the permutation π, i.e., we have $x \prec_\pi y$ if x precedes y in π. An *oracle* for a total order π is a black-box function that answers queries of the form $x \prec_\pi y$ in constant time.

Antimatroids. An *antimatroid* (sometimes called *antimatroid language*) is a simple language $A \subseteq \Sigma_s^*$ that satisfies the following two axioms:

- **(i)** For all $\alpha \in \Sigma_s^*$ and $x \in \Sigma \setminus \tilde{\alpha}$, if $\alpha x \in A$, then $\alpha \in A$. (A is closed under taking prefixes.)
- **(ii)** For each $\alpha, \beta \in A$ with $\tilde{\alpha} \not\subseteq \tilde{\beta}$, there is some $x \in \tilde{\alpha} \setminus \tilde{\beta}$ such that $\beta x \in A$.

Axiom (i) is called *accessibility* and implies that every word in L can be *built* by starting with ε and successively appending letters, without ever leaving L. Axiom (ii) ensures the two "availability properties" of antimatroids mentioned in the introduction.

In this paper, we only consider *full* antimatroids (recall that this means $\mathcal{P}(A) \neq \emptyset$).[2] A full antimatroid A is completely determined by $\mathcal{P}(A)$; in fact, A is exactly the set of prefixes of $\mathcal{P}(A)$. However, not every set of permutations can be described by an antimatroid; for example, any antimatroid on $\Sigma = \{x, y, z\}$ that contains xyz and zyx also contains xzy.

Throughout this paper, we use a different formalism, which is closer to the informal definition of antimatroids given in the introduction. For an alphabet Σ, a *precedence function* for a letter $x \in \Sigma$ is a function $p_x \colon 2^{\Sigma \setminus \{x\}} \to \{0, 1\}$ that is *monotone*, i.e., we have $p_x(X) \leq p_x(Y)$ if $X \subseteq Y \subseteq \Sigma$. A *monotone precedence system (MPS)* on Σ is a collection $S = \{p_x\}_{x \in \Sigma}$ of precedence functions. The *language* of S is the set

$$\mathcal{L}(S) = \{x_1 x_2 \dots x_k \mid \forall i \in [k] : p_{x_i}(\{x_1, x_2, \dots, x_{i-1}\}) = 1\}.$$

The full version of the paper contains a proof that monotone precedence systems indeed characterize (full) antimatroids. In the following, we write $\mathcal{P}(S) = \mathcal{P}(\mathcal{L}(S))$ for convenience.

▶ **Example 1.** Let P be a partial order on a set Σ. Define $S = \{p_x\}_{x \in \Sigma}$ with $p_x(X) = 1$ if and only if $\{y \in \Sigma \mid y \prec_P x\} \subseteq X$. It is easy to see that $\mathcal{P}(S)$ is exactly the set of linear extensions of P. Thus, antimatroids generalize partial orders.

▶ **Example 2.** Let $\Sigma = \{a, b, c\}$, and consider the MPS S with $p_a(X) = p_b(X) = 1$ for all $X \subseteq \Sigma$, and $p_c(X) = 1$ iff $a \in X$ or $b \in X$. Then $\mathcal{P}(S) = \{abc, bac, acb, bca\}$. Since $\mathcal{P}(S)$ contains both acb and its reverse bca, but not all possible orderings, it is *not* the set of linear extensions of any partial order. Thus, antimatroids *strictly* generalize partial orders.

Priority queues. The central data structure of topological heapsort is the *working-set priority queue*. This is a priority queue (like the well-known *binary heap* [34]) with the so-called *working-set property*. Informally, this property ensures that extracting an element is fast if that element has been inserted only shortly before. We omit the precise definitions here, since they are not needed for our proofs, and refer to Haeupler et al. [14] for more details.

[2] Some authors define antimatroids to be always full [27].

3 Generalized topological heapsort

Let us now formally state the antimatroid-sorting meta-problem. Given is a set Σ, an antimatroid A on Σ, and a comparison oracle for a permutation $\pi \in \mathcal{P}(A)$. The task is to output π (or, equivalently, output Σ in sorted order according to the oracle comparisons $\prec_\pi$). Note the assumption $\pi \in \mathcal{P}(A)$ in particular implies that A is full.

We call this a meta-problem since the precise representation of A is unspecified. We discuss some possible representations in Section 4. For now, we give a meta-algorithm for the problem (Algorithm 1), using the characterization of A as a monotone precedence system S.

Algorithm 1 Topological heapsort for antimatroids.

Input: Set Σ, MPS $S = \{p_x\}_{x\in\Sigma}$, comparison oracle for some $\pi \in \mathcal{P}(S)$.
Initialize working-set priority queue Q that contains each $x \in \Sigma$ with $p_x(\emptyset) = 1$
$\alpha \leftarrow \varepsilon$
while Q is not empty **do**
  Delete the minimum from Q and append it to α
  For each $x \in \Sigma \setminus (\tilde{\alpha} \cup Q)$, add it to Q if $p_x(\tilde{\alpha}) = 1$
return α

We can already show correctness of our meta-algorithm regardless of implementation details.

▶ **Lemma 3.** *Topological heapsort is correct for every input* (Σ, S, π).

Proof. Let $S = \{p_x\}_{x\in\Sigma}$ and $\pi = x_1, x_2, \ldots, x_n$. We need to show that topological heapsort produces $\alpha = \pi$.

Since $\pi \in \mathcal{P}(S)$, we have $p_{x_i}(\{x_1, x_2, \ldots, x_{i-1}\}) = 1$ for each $i \in [n]$. In particular, this means that $p_{x_1}(\emptyset) = 1$, so x_1 is contained in Q at the start. Since also $x_1 \prec_\pi x_i$ for all $i > 1$, the first element added to α is indeed x_1. Suppose now that we have $\alpha = x_1 x_2 \ldots x_{i-1}$ at the start of some iteration. Since $p_{x_i}(\tilde{\alpha}) = 1$, we have $x_i \in Q$. Since $x_i \prec_\pi x_j$ for all $j > i$, the algorithm next appends x_i to α. By induction, the algorithm indeed returns π. ◀

Two parts of the algorithm are left unspecified: How to identify the initial elements in Q, and the elements inserted in each iteration. We now define an abstract data structure for this task. A *candidate data structure* C for a monotone precedence system $S = \{p_x\}_{x\in\Sigma}$ maintains a set $X \subseteq \Sigma$, initially $X = \emptyset$, and supports the following two operations:

- C.`init`(): Set $X \leftarrow \emptyset$ and report all $x \in \Sigma$ with $p_x(\emptyset) = 1$.
- C.`step`(x): Given $x \in \Sigma \setminus X$ with $p_x(X) = 1$, report all $y \in \Sigma$ with $p_y(X) = 0$ and $p_y(X \cup \{x\}) = 1$. Then, add x to X.

Observe that C allows at most $|\Sigma|$ calls to `step` after `init`, one for each $x \in \Sigma$. Further, parameters of `step` calls form a sequence $x_1 x_2 \ldots x_k \in \mathcal{L}(S)$. The *total time* for C, written $t^{\text{total}}(C)$, is the overall time for one call to `init` and a valid sequence of `step` calls, in the worst case.

Clearly, any correct candidate data structure can be used to finish the implementation of topological heapsort. The actual implementation will heavily depend on the given representation of the antimatroid; see Section 4.

3.1 Running time analysis

Since we want our analysis to be independent of the candidate data structure, we split the work done by topological heapsort into two essential parts.

- The total time $t^{\text{total}}(C)$ spend by the candidate data structure, as defined above.
- The time required to initialize Q (given the initial elements), delete the minimum from Q, and insert given elements into Q in each step. Call this the *queue time* t^{Q}.

Since the loop performs at most $n = |\Sigma|$ iterations, the running time of topological heapsort is $t^{\text{total}}(C) + t^{\text{Q}} + \mathcal{O}(n)$.

Note that the queue time does *not* depend on the representation of S at all. In the following, we show that t^{Q} is always $\mathcal{O}(n + \log|\mathcal{P}(S)|)$, by reducing to the special case where S is a *partial order*, which has been solved by Haeupler et al. [14]. The number of comparisons can be as large as the queue time, which is not optimal if $\log(|\mathcal{P}(S)|) \ll n$. In Section 5, we improve this bound to the optimal $\mathcal{O}(\log|\mathcal{P}(S)|)$ by modifying the algorithm.

Partial orders. Let G be a directed acyclic graph with n vertices and m edges, and consider the set $\mathcal{T}(G)$ of topological orderings of G. Clearly, $\mathcal{T}(G)$ is the set of linear extensions of a partial order on $V(G)$. Thus, $\mathcal{T}(G)$ is an also antimatroid in $V(G)$ (see Example 1).

It is easy to implement a candidate data structure for $\mathcal{T}(G)$ via the standard topological sorting algorithm [18, 23], with total running time $\mathcal{O}(m + n)$. Haeupler et al. [14] showed that the queue time of topological heapsort is optimal for partial orders:

▶ **Lemma 4** (Haeupler et al. [14]). *Let S be a monotone precedence system corresponding to a partial order on a set Σ, and let $\pi \in \mathcal{P}(S)$ be a total order on Σ. Then, for topological heapsort with input (Σ, S, π), we have $t^{\text{Q}} \in \mathcal{O}(|\Sigma| + \log|\mathcal{P}(S)|)$.*

General antimatroids. We now generalize Lemma 4 to antimatroids. We need the following definition. The *transcript* of a run of topological heapsort on an input (Σ, S, π) is the sequence $(Q_0, Q_1, \ldots, Q_n)$, where Q_0 is the set of elements initially in the priority queue, and Q_i for $i \in [n]$ is the set of elements in the priority queue after the i-th step. Observe that, if $\pi = x_1 x_2 \ldots x_n$, then $x_i \in Q_{i-1}$, and $x_i \notin Q_j$ for each $j \geq i$. See Figure 1 for an example.

A crucial fact that we use in the proof below is that the queue time t^{Q} *only* depends on the transcript of the run. In particular, two runs on inputs (Σ, S, π) and (Σ, S', π) that have the same transcript also have the same queue time, even if $S \neq S'$.

▶ **Theorem 5.** *Let S be a monotone precedence system on Σ, and let $\pi \in \mathcal{P}(S)$ be a total order on Σ. Then, for topological heapsort with input (Σ, S, π), we have $t^{\text{Q}} \in \mathcal{O}(|\Sigma| + \log|\mathcal{P}(S)|$.*

Proof. Consider a run of topological heapsort on (Σ, S, π) with transcript $(Q_0, Q_1, \ldots, Q_n)$, and let $\pi = x_1 x_2 \ldots x_n$.

We now define a partial order P on Σ. For each $i \in [n]$, let $x_i \prec_P y$ for each $y \in \Sigma \setminus (Q_0 \cup Q_1 \cup \dots Q_{i-1})$. Informally, we have $x \prec_P y$ if x is deleted from the priority queue before y is inserted. Let S_P be the monotone precedence system corresponding to P. Clearly, $\pi \in \mathcal{P}(S_P)$. We claim the following:

(i) The transcript of running topological heapsort on (Σ, S_P, π) is again $(Q_0, Q_1, \dots, Q_n)$.

(ii) $\mathcal{P}(S_P) \subseteq \mathcal{P}(S)$.

We first explain how this implies the theorem. By Lemma 4, running topological heapsort on (Σ, S_P, π) has queue time $\mathcal{O}(|\Sigma| + \log|\mathcal{P}(S_P)|)$. By claim (i), running topological heapsort on (Σ, S, π) has the same queue time (since the transcript is the same), which, by claim (ii), is at most $\mathcal{O}(|\Sigma| + \log|\mathcal{P}(S)|)$, as required.

We now prove claim (i). Let $(Q'_0, Q'_1, \dots, Q'_n)$ be the transcript of running topological heapsort on (Σ, S_P, π). Each $y \in Q_0$ is a minimal element of P by definition, so $Q_0 \subseteq Q'_0$. On the other hand, each $y \notin Q_0$ satisfies $x_1 \prec_P y$ by definition and thus $y \notin Q'_0$, so $Q_0 = Q'_0$.

Now take some $j \in [n]$ and assume that by induction, we have $Q_i = Q'_i$ for all $i < j$. For each $y \in Q_j$, we have $\{z \in \Sigma \mid z \prec_P y\} \subseteq \{x_1, x_2, \dots, x_j\}$, and $y \notin \{x_1, x_2, \dots, x_j\}$, so $y \in Q'_j$ by definition. On the other hand, each $y \notin Q_j$ satisfies either (a) $y \in \{x_1, x_2, \dots, x_j\}$ or (b) $y \notin Q_0 \cup Q_1 \cup \dots \cup Q_j$. (a) directly implies $y \notin Q'_j$ (y is removed earlier). (b) implies $x_{j+1} \prec_P y$, which again implies $y \notin Q'_j$.

We finish the proof with claim (ii). Let $\alpha = x'_1 x'_2 \dots x'_n \in \mathcal{P}(S_P)$. We show that $\alpha \in \mathcal{P}(S)$, i.e., that for each $i \in [n]$, we have $p_{x'_i}(\{x'_1, x'_2, \dots, x'_{i-1}\}) = 1$.

Let $y \in \Sigma$, and let k be minimal such that $y \in Q_k$. Let $X_k = \{x_1, x_2, \dots, x_k\}$. First, by definition of Q_k, we have $p_y(X_k) = 1$. Second, we have $\{x \in \Sigma \mid x \prec_P y\} = X_k$ by minimality of k. Now suppose $y = x'_i$, and let $X'_{i-1} = \{x'_1, x'_2, \dots, x'_{i-1}\}$. Then $p'_y(X'_{i-1}) = 1$, implying $X'_{i-1} \supseteq X_k$. By monotonicity, we have $p_y(X'_{i-1}) \geq p_y(X_k) = 1$, as desired. ◀

Remark. The technique of constructing an auxiliary partial order is inspired by the work of Haeupler, Hladík, Rozhoň, Tarjan, and Tětek [12] (we discuss further connections in Section 4.2). In fact, the exact partial order P in the proof of Theorem 5 appears in the revised version[3] of the paper that introduced topological heapsort [14]. They observe that P is an *interval order*, which means $|\mathcal{P}(P)|$ is relatively easy to bound and can be related to the working-set bound.

The algorithm of van der Hoog, Rotenberg, and Rutschmann [32] is also analyzed with the help of interval orders, but seemingly cannot be easily generalized to antimatroids.

4 Antimatroid representations

In this section, we consider several representations of antimatroids (some only covering special cases), and discuss how to implement candidate data structures (CDSs) for these representations. If C is a CDS for an animatroid A with some representation, then we call C *efficient* if $t^{\text{total}}(C) \in \mathcal{O}(n)$, where n is the size of the representation (in machine words). Theorem 5 implies that topological heapsort with an efficient CDS has optimal running time.

4.1 Precedence formulas

We first consider an explicit representation of general full antimatroids based on monotone precedence systems. The *precedence formula representation* of a full antimatroid A on Σ is a collection $\{F_x\}_{x \in \Sigma}$, where F_x is a monotone boolean formula on the variable set $V_x = \Sigma \setminus \{x\}$. (A *monotone* boolean formula allows only the operators $\vee$ and $\wedge$ and the constants 0 and 1, notably prohibiting the negation $\neg$.)

[3] An earlier preprint [13] used a different proof technique.

Each formula F_x represents a precedence function p_x as follows: For $Y \subseteq \Sigma$, we let $p_x(Y)$ be the value of F_x when setting each $y \in Y$ to 1, and each $y \in X \setminus (Y \cup \{x\})$ to 0. Since any monotone function f can be represented as a monotone boolean formula, this representation is suitable for every antimatroid. In the following, we assume each formula is given as a linked list of symbols with each variable, operator, constant, or parenthesis in the formula occupying one machine word. Other representations, like parsing trees and circuits, are also possible.

An CDS C for $\{F_x\}_{x\in\Sigma}$ is implemented as follows. We need two preprocessing steps. First, for each formula, we simplify it. We repeatedly replace substrings $(1 \wedge x) \to x$, $(1 \vee x) \to 1$, $(0 \wedge x) \to 0$, and so on, in linear overall time. Afterwards, we have $F_x = 1$ for each x with $p_x(\emptyset) = 1$.

Second, compute a directed graph G, where $V(G) = \Sigma$, and $(x, y) \in E(G)$ if F_y contains the variable x. For each such edge, we store a list of pointers to each occurrence of x within F_y. Note that the size of G (including pointers) is at most the total size of all formulas.

The initial candidate set reported by `init()` is the set of sources in G. `step`(x) is implemented as follows: For each out-neighbor y of x, replace each occurrence of x in F_y with 1. Then, simplify F_y as outlined above, and report y if $F_y = 1$ after the simplification. Finally, remove x from the graph. To see that the data structure is correct, observe that after calling `step`(x) on each x in some set $X \subset \Sigma$, we have $F_y = 1$ for each y with $p_y(X) = 1$.

The total running time is linear, since each edge is visited once, and simplification is linear overall. Thus, the data structure is efficient, and so:

▶ **Theorem 6.** *Given an antimatroid A on Σ in a precedence formula representation of length n, we can solve the $\mathcal{P}(A)$-sorting problem in optimal time $\mathcal{O}(n + \log|\mathcal{P}(A)|)$.*

There are two representations of antimatroids that are similar to precedence formulas: *rooted set collections* and *alternative precedence structures* [27]. These roughly correspond to precedence formulas in conjuctive normal form and disjunctive normal form, respectively. A third related characterization with so-called *elementary ranking conditions* [30] is used in linguistics (see the full version of the paper for details). In the following, we discuss two more examples that only apply to subclasses of antimatroids.

4.2 Vertex search and distance orderings

Given a connected graph G and a designated root $r \in V(G)$, the *vertex search antimatroid* on (G, r), written $A^{\mathrm{VS}}_{G,r}$, contains the empty word ε as well as each simple word $v_1 v_2 \dots v_k$ where $v_1 = r$ and each prefix $v_1 v_2 \dots v_i$ induces a connected subgraph of G. The words in $A^{\mathrm{VS}}_{G,r}$ model each way of traversing the graph in a manner similar to BFS or DFS. The basic idea is easily extended to directed graphs; here we require that each prefix $v_1 v_2 \dots v_i$ induces a subgraph of G where every vertex is reachable from $r = v_1$. (We assume that each vertex is reachable from r in G.)

It is easy to see that $A^{\mathrm{VS}}_{G,r}$ is indeed an antimatroid; for example, as a precedence formula for each vertex $v \neq r$, take $F_v = u_1 \vee u_2 \vee \dots \vee u_k$, where $u_1, u_2, \dots, u_k$ are the neighbors (resp. in-neighbors) of v. However, not every antimatroid is a vertex search antimatroid.

Again, the restricted sorting problem for vertex search antimatroids is solved in optimal time with the precedence formula representation given above.

The vertex search antimatroid plays a role in the *distance ordering* problem, a variant of single-source shortest path (SSSP) problem. Given is an edge-weighted directed graph (G, w) with a designated root r, and the task is to order the vertices by distance from r. Recently, Haeupler et al. [12] showed that Dijkstra's classical SSSP is *universally optimal* when equipped with a certain working-set heap (which is more powerful than the one presented in Section 2).

Universally optimal means, informally, that for every fixed graph, the algorihtm is worst-case optimal w.r.t. the weight function. In fact, they essentially match the information-theoretic lower bound with a running time of $\mathcal{O}(\log |T| + |V(G)| + |E(G)|)$, where T is the set of possible distance orderings for the input graph G with root r, with any weight function.

We now demonstrate a strong connection between antimatroid sorting and the distance ordering problem.[4] First off, the set T of possible distance orderings is precisely the vertex search antimatroid (see the full version of the paper for a proof). Thus, we can run topological heapsort to find a distance ordering with optimal running time – *if* we are allowed to directly compare two vertices. That means comparing the distances of two vertices to r, which we cannot do in the distance ordering problem (without computing the distances first).

Still, it can be seen that the *transcript* (see the proof of Theorem 5) of a run of Dijsktra's algorithm on an input (G, w, r) is the same as running topological heapsort on the corresponding vertex search antimatroid. This gives an alternative proof of universal optimality; details are found in the full version of the paper. It should be noted that Haupler et al. also give an algorithm that is universally optimal in both time and number of comparisons, which is harder (c.f. Section 5).

4.3 Elimination orderings

An undirected graph is *chordal* if has no induced cycles of length four or more. It is well-known that chordal graphs can be characterized by the existence of *perfect elimination orderings (PEOs)*. A PEO is obtained by successively removing *simplicial* vertices, that is, vertices whose neighborhood form a clique.

The set of elimination orderings form an antimatroid, also known as the *simplicial vertex pruning* [1] or *simplicial shelling* [27] antimatroid. Given a graph G, we can define the simplicial vertex pruning antimatroid A_G^{SVP} via the MPS $\{p_v\}_{v \in V(G)}$ with

$$p_v(U) = \begin{cases} 1, & \text{if } v \text{ is simplicial in } G - U; \\ 0, & \text{otherwise.} \end{cases}$$

A candidate data structure for A_G is essentially a data structure that maintains the set of simplicial vertices in G under simplicial vertex deletion.

There are known static and fully-dynamic algorithms to compute simplicial vertices in *arbitrary* graphs [22, 28]. Since we only care about chordal graphs and only need vertex deletion, we can use a relatively simple data structure based on *clique trees*. Details are found in the full version of the paper. The total running time of removing all vertices is $\mathcal{O}(m + n)$. Thus, we can solve the corresponding restricted sorting problem in optimal time.

5 Comparison optimality

In this section, we modify the topological heapsort algorithm to only use an optimal $\mathcal{O}(\log |\mathcal{P}(S)|)$ comparisons, instead of $\mathcal{O}(|\Sigma| + \log |\mathcal{P}(S)|)$, while keeping the optimal running time. The special case of partial orders was again solved by Haeupler et al. [14]. Our algorithm is similar, but some non-trivial adaptation is required.

First of all, note that the additional $\mathcal{O}(n)$ term is only relevant when $|\mathcal{P}(S)| \leq 2^{o(n)}$. In the partial order/DAG-sorting case, Haeupler et al. [14] showed that this condition implies the existence of a long directed path in the DAG. Observe that such a path is pre-sorted. We prove a corresponding fact for antimatroids (Section 5.1).

[4] Such a connection is not surprising, since the technique used in the analysis of Dijkstra's algorithm [12] inspired the original analysis of topological heapsort [14] and large parts of this paper.

Haeupler et al. then proceed roughly as follows. They first compute a set of *marked* vertices on the pre-sorted path. Intuitively, the marked vertices represent the interaction with the remainder of the graph: The removal of unmarked vertices does not affect "availability" of vertices outside of the path. This means that often, a large set of unmarked vertices can be removed at once, without any additional comparisons.

This strategy cannot be adapted to general antimatroids in a straight-forward way, since the availability constraints are too complex to preprecompute a small set of marked vertices. We instead use the following three-step algorithm (given is an antimatroid A on Σ):

1. Compute a long pre-sorted sequence β (Section 5.1).
2. Sort the set $\Gamma = \Sigma \setminus \tilde{\beta}$, using topological heapsort on the sub-antimatroid of A *induced* by Γ (Section 5.2). This gives us a sorted sequence γ.
3. Merge the two sequences β and γ, utilizing the antimatroid constraints (Section 5.3).

All three steps can be implemented efficiently using a candidate data structure for A. We obtain:

▶ **Theorem 7.** *Given a set Σ, a candidate data structure C for an antimatroid A on σ, and an oracle for a total order $\pi \in \mathcal{P}(A)$, we can sort Σ w.r.t. $\prec_\pi$ in time $\mathcal{O}(t^{\text{total}}(C) + \log|\mathcal{P}(A)|)$ and with $\mathcal{O}(\log|\mathcal{P}(A)|)$ comparisons.*

This means that each efficient candidate data structure presented in Section 4 yields a comparison-optimal sorting algorithm.

5.1 Bottlenecks in antimatroids

Let $S = \{p_x\}_{x\in\Sigma}$ be a monotone precedence system on Σ. The *layer sequence* of S is a partition of Σ into nonempty *layers* $L_1, L_2, \ldots, L_k$ inductively defined as follows:

- $L_1 = \{x \in \Sigma \mid p_x(\emptyset) = 1\}$.
- $L_i = \{x \in \Sigma \setminus \bar{L}_{i-1} \mid p_x(\bar{L}_{i-1}) = 1\}$, where $\bar{L}_{i-1} = L_1 \cup L_2 \cup \cdots \cup L_{i-1}$, for each $2 \le i \le k$.

Observe that a layer sequence exists if and only if $\mathcal{P}(S) \neq \emptyset$, and that a layer sequence is always unique. If a candidate data structure C is available, we can compute the layer sequence in $\mathcal{O}(t^{\text{total}}(C))$ time as follows: Call $C.\texttt{init}()$ and add the reported elements to L_1. Then, call $C.\texttt{step}(x)$ for each $x \in L_1$, add the reported elements to L_2, and so on.

▶ **Lemma 8.** *Let S be a monotone precedence system with k layers. Then $|\mathcal{P}(S)| \ge 2^{n-k}$.*

Proof. We essentially follow Haeupler et al. [14]. Let $L_1, L_2, \ldots, L_k$ be the layer sequence for S. For each $i \in [k]$, let α_i be an arbitrary permutation of L_i. We claim that the word $\alpha = \alpha_1\alpha_2\ldots\alpha_k$ is contained in $\mathcal{P}(S)$. Indeed, if $x \in L_i$, then all $y \in \bar{L}_{i-1}$ precede x in α. Since $p_x(\bar{L}_{i-1}) = 1$ by definition of L_i, we have $\alpha \in \mathcal{P}(S)$.

There are $\prod_{i=1}^{k} |L_i|!$ ways of constructing α. Writing $n_i = |L_i|$ and $n = |\Sigma|$, we have

$$|\mathcal{P}(S)| \ge \prod_{i=1}^{k} n_i! \ge \prod_{i=1}^{k} 2^{n_i-1} = 2^{n-k}. \qquad \blacktriangleleft$$

We now proceed to show how to find a long sequence $x_1x_2\ldots x_k \in \Sigma_{\text{s}}^*$ such that for all $i \in [k-1]$, we have $x_i \prec_\alpha x_{i+1}$ for all $\alpha \in \mathcal{P}(A)$; in other words, the sequence is pre-sorted. In the DAG-sorting case, we can simply take a longest path in the DAG. Here, we need a different approach, which is also related to the technique of Haeupler et al. [14].

▶ **Lemma 9.** *Let $L_1, L_2, \ldots, L_k$ be the layers of a monotone precedence system S, and let $\pi \in \mathcal{P}(S)$. Then, for all $1 \le i < j \le k$ and $y \in L_j$, there exists an $x \in L_i$ such that $x \prec_\pi y$.*

Proof. Suppose the lemma does not hold for some pair $i < j$, i.e., there exists some $y' \in L_j$ such that $y' \prec_\pi x$ for all $x \in L_i$. Let $y = \min_\pi(\Sigma \setminus \bar{L}_i) = \min_\pi(L_{i+1} \cup L_{i+2} \cup \cdots \cup L_k)$. Since $y \preceq_\pi y'$, we have $y \prec_\pi x$ for all $x \in L_i$, implying that actually $y = \min_\pi(\Sigma \setminus \bar{L}_{i-1})$. This means that $p_y(\bar{L}_{i-1}) = 1$, implying that $y \in L_i$, a contradiction. ◀

An element $x \in \Sigma$ is a called a *bottleneck* if it is the only element in its layer. Let t be the number of bottlenecks and let k be the number of layers. Since each non-bottleneck layer contains at least two vertices, we have $n - t \geq 2(k - t)$, which implies $n - k \geq \frac{n-t}{2}$. By Lemma 8, we have

▶ **Corollary 10.** *Let S be an MPS with t bottleneck elements. Then $|\mathcal{P}(S)| \geq 2^{(n-t)/2}$.*

The *bottleneck sequence* $\beta = b_1 b_2 \dots b_t$ of S contains all bottlenecks, ordered by the layer they appear in. Lemma 9 implies that, for every permutation $\pi \in \mathcal{P}(S)$, we have $b_1 \prec_\pi b_2 \prec_\pi \cdots \prec_\pi b_t$. Overall, we obtain

▶ **Lemma 11.** *Let S be an MPS on Σ, and write $n = |\Sigma|$. Then there exists a sequence $\beta = b_1 b_2 \dots b_t$ that appears as a subsequence in every $\pi \in \mathcal{P}(S)$, and $|\mathcal{P}(S)| \geq 2^{(n-t)/2}$. Moreover, given a candidate data structure C for S, we can compute β in time $\mathcal{O}(t^{\text{total}}(C))$.*

5.2 Sorting subsets

In this section, we show how to sort the non-bottleneck elements $\Sigma \setminus \tilde{\beta}$ of an antimatroid A. Recall that a candidate data structure C is given, and we want to sort in overall time $\mathcal{O}(t^{\text{total}}(C) + \log|\mathcal{P}(A)|)$, with $\mathcal{O}(\log|\mathcal{P}(A)|)$ comparisons (see Theorem 7). We show how to sort any subset $\Gamma \subseteq \Sigma$ within this budget.

We first need some definitions. Let Σ be an alphabet. Given a word α and a subset $\Gamma \subseteq \Sigma$, the *restriction* of α to Γ, written $\alpha|_\Gamma$, is obtained by removing all letters in $\Sigma \setminus \Gamma$ from α. For a simple language $L \subseteq \Sigma_s^*$, let $L|_\Gamma = \{\alpha|_\Gamma \mid \alpha \in L\}$. It is known that if $A \subseteq \Sigma_s^*$ is an antimatroid, then the restriction $A|_\Gamma$ is also an antimatroid (called the *trace* [27, 1]).

Let us now assume we have a candidate data structure C_Γ for $A|_\Gamma$. Then we can use topological heapsort to sort Γ. The running time is $t^{\text{total}}(C_\Gamma) + \mathcal{O}(\log|\mathcal{P}(A|_\Gamma)|)$, and we need $\mathcal{O}(|\Gamma| + \log|\mathcal{P}(A|_\Gamma)|)$ comparisons. First, observe that $|\mathcal{P}(A|_\Gamma)| \leq |\mathcal{P}(A)|$, since the restriction operation surjectively maps $\mathcal{P}(A|_\Gamma)$ to $\mathcal{P}(A)$. Second, recall that $|\Gamma| \leq 2\log|\mathcal{P}(A)|$ if Γ is obtained by removing all bottleneck elements (Corollary 10). If we further assume that $t^{\text{total}}(C_\Gamma) \leq \mathcal{O}(t^{\text{total}}(C))$, then we are within the budget of Theorem 7.

It remains to build a candidate data structure C_Γ for $A|_\Gamma$ with $t^{\text{total}}(C_\Gamma) \leq \mathcal{O}(t^{\text{total}}(C))$. Suppose C is given. Then C_Γ.`init`() is implemented as follows. First, call C.`init`(), and store the result in a set Y. Then, we repeat the following as long as there is an element $y \in Y \setminus \Gamma$: Discard y, call C.`step`(y), and add all reported elements to Y. At the end, report the final set Y.

To implement C_Γ.`step`(y), we similarly first call C.`step`(y), store the result in a set Y, and perform the repeated replacement as above.

The (rather technical) correctness proof for C_Γ is found in the full version of the paper. The running time is clearly $t^{\text{total}}(C) + \mathcal{O}(|\Sigma|) = \mathcal{O}(t^{\text{total}}(C))$. Thus, we have:

▶ **Lemma 12.** *Given a set Σ, a subset $\Gamma \subseteq \Sigma$, a candidate data structure C for an antimatroid A on Σ, and an oracle for a total order $\pi \in \mathcal{P}(A)$, we can sort Γ w.r.t. $\prec_\pi$ in time $\mathcal{O}(t^{\text{total}}(C) + \log|\mathcal{P}(A)|)$ and with $\mathcal{O}(|\Gamma| + \log|\mathcal{P}(A)|)$ comparisons.*

5.3 Merging

We now want to optimally merge under antimatroid constraints:

▶ **Theorem 13.** *Let A be an antimatroid on Σ, let $\pi \in \mathcal{P}(A)$, and let Γ, Δ be a partition of Σ. Let $\gamma = \pi|_\Gamma$ and $\delta = \pi|_\Delta$. Let $R \subseteq \mathcal{P}(A)$ contain each permutation $\rho \in \mathcal{P}(A)$ such that $\rho|_\Gamma = \gamma$ and $\rho|_\Delta = \delta$.*

Given Σ, γ, δ, an oracle for π, and a candidate data structure C for A, we can compute π in time $\mathcal{O}(t^{\text{total}}(C) + \log|R|)$ and with $\mathcal{O}(|\Delta| + \log|R|)$ comparisons.

A proof of Theorem 13 is given in the full version of the paper. The algorithm used can be seen as a simplified version of Haeupler et al.'s *heapsort with lookahead* algorithm [14]; in fact, if the antimatroid A is given as a collection of precedence formulas, it simplifies to a partial order under the assumption that γ and δ are sorted. (However, our proof works with general candidate data structures.)

5.4 Putting things together

We now prove Theorem 7. First, we compute the bottleneck sequence β with Lemma 11. Then, we use Lemma 12 to sort the subset $\Gamma = \Sigma \setminus \tilde{\beta}$. In other words, if π is the underlying total order, we compute $\gamma = \pi|_\Gamma$. Finally, we merge β and γ using Theorem 13. The overall running time is $\mathcal{O}(t^{\text{total}}(C) + \log|\mathcal{P}(A)| + \log|R|)$, and we use $\mathcal{O}(\log|\mathcal{P}(A)| + |\Gamma| + \log|R|)$ comparisons, where R is as defined in Theorem 13. Note that $R \subseteq \mathcal{P}(A)$. Moreover, we have $|\Gamma| = n - |\beta| \leq 2\log|\mathcal{P}(A)|$ by Lemma 11. Thus, we need $\mathcal{O}(t^{\text{total}}(C) + \log|\mathcal{P}(A)|)$ time and $\mathcal{O}(\log|\mathcal{P}(A)|)$ comparisons, as desired.

6 Conclusion

In this paper, we have shown that the basic variant of *topological heapsort* nicely generalizes to the problem of sorting antimatroids, and its running time stays optimal. We also showed how the algorithm can be modified to be comparison-optimal in the antimatroid case, which in particular implies that the information-theoretic bound is tight for antimatroids. Since topological heapsort is not optimal for further generalizations like *greedoids* (see the full version of the paper), perhaps antimatroids are the most general structure that can be sorted "greedily". The question whether the information-theoretic bound for greedoids holds, and whether greedoids can be sorted efficiently in some other way, is left open.

For another interesting open question, let us consider an important class of antimatroids that was omitted from Section 4. *Convex shelling antimatroids* [6, 27, 1] are obtained by progressively removing points from the convex hull of a given point set. A candidate data structure for such an antimatroid would be a certain kind of *decremental convex hull* data structure. The total running time of this data structure cannot be linear as in the other examples, since computing the convex hull can take superlinear time [20]. Is there a candidate data structure for the convex shelling antimatroid that is fast enough to sort optimally?

Parameterized Algorithms for Computing Pareto Sets

Abstract

The problem of computing the set of Pareto-optimal solutions has been studied for a variety of multiobjective optimization problems. For many such problems, algorithms are known that compute the Pareto set in (weak) output-polynomial time. These algorithms are often based on dynamic programming and by weak output-polynomial time, we mean that the running time depends polynomially on the size of the Pareto set but also on the sizes of the Pareto sets of the subproblems that occur in the dynamic program. For some problems, like the multiobjective minimum spanning tree problem, such algorithms are not known to exist and for other problems, like multiobjective versions of many NP-hard problems, such algorithms cannot exist, unless $\mathcal{P} = \mathcal{NP}$.

Dynamic programming over tree decompositions is a common technique in parameterized algorithms. In this paper, we study whether this technique can also be applied to compute Pareto sets of multiobjective optimization problems. We first derive an algorithm to compute the Pareto set for the multicriteria s-t cut problem and show how this result can be applied to a polygon aggregation problem arising in cartography that has recently been introduced by Rottmann et al. (GIScience 2021). We also show how to apply these techniques to also compute the Pareto set of the multiobjective minimum spanning tree problem and for the multiobjective TSP. The running time of our algorithms is $\mathcal{O}(f(w) \cdot \text{poly}(n, p_{\max}))$, where f is some function in the treewidth w, n is the input size, and $p_{\max}$ is an upper bound on the size of the Pareto sets of the subproblems that occur in the dynamic program. Finally, we present an experimental evaluation of computing Pareto sets on real-world instances of polygon aggregation problems. For this matter we devised a task-specific data structure that allows for efficient storage and modification of large sets of Pareto-optimal solutions. Throughout the implementation process, we incorporated several improved strategies and heuristics that significantly reduced both runtime and memory usage, enabling us to solve instances with treewidth of up to 22 within reasonable amount of time. Moreover, we conducted a preprocessing study to compare different tree decompositions in terms of their estimated overall runtime.

1 Introduction

Multiobjective optimization problems arise naturally in many contexts. When booking a train ticket, one might be interested in minimizing the travel time, the price, and the number of changes. Similarly when planning a new infrastructure, companies often have to find a compromise between reliability and costs, to name just two illustrative examples. For multiobjective optimization problems there is usually not a single solution that is optimal for all criteria simultaneously, and hence, one has to find a trade-off between the different criteria. Since it is not a priori clear which trade-off is desired, one often studies the set of *Pareto-optimal solutions* (also known as *Pareto set*), where a solution is Pareto-optimal if it is not dominated by any other solution, i.e., there does not exist another solution that is better in at least one criterion and at least as good in all other criteria. The reasoning behind this is that a dominated solution cannot be a reasonable compromise of the different criteria and it makes sense to restrict one's attention to only the Pareto-optimal solutions.

A lot of research in multiobjective optimization deals with algorithms for computing the Pareto set and with studying the size of this set for various optimization problems. If this set is not too large then it can be presented to a (human) decision maker who can select a solution. The Pareto set also has the important property that any monotone function that combines the different objectives into a single objective is optimized by a Pareto-optimal solution. This means, in order to optimize such a function, one could first generate the Pareto set and then pick the best solution from this set.

This approach is only reasonable if there are not too many Pareto-optimal solutions. While in the worst case the Pareto set can be of exponential size for almost all multiobjective optimization problems, it has been observed that the Pareto set is often small in practice (see, e.g., [16, 23]). It has also been shown in the probabilistic model of smoothed analysis that for many problems the expected size of the Pareto set is polynomial if the input is subject to a small amount of random noise [10, 5]. This motivates the development of algorithms for computing the Pareto set that have polynomial running time with respect to the output size.

In the literature such output-sensitive algorithms have been developed for different multiobjective optimization problems (e.g., for the multiobjective shortest path problem [12, 17, 29], multiobjective flow problems [15, 24], and the knapsack problem when viewed as a bicriteria optimization problem [25]). There is, however, a small caveat. Since these algorithms are usually based on dynamic programming, they are not output-polynomial in the strict sense but they solve certain subproblems of the given instance and their running times depend not only polynomially on the size of the Pareto set of the entire instance but also polynomially on the sizes of the Pareto sets of the subproblems. While in theory it could be the case that some of the subproblems have Pareto sets of exponential size while the Pareto set of the entire instance is small (see, e.g., [9]), this behavior is neither observed in experiments nor does it occur in probabilistic input models. Hence, algorithms that are output-polynomial in the weak sense that their running time depends polynomially on the sizes of the Pareto sets of all subproblems that occur in the dynamic program are useful and state-of-the-art for many multiobjective optimization problems. For some problems such output-sensitive algorithms are not known to exist. In particular, for the multiobjective spanning tree problem no algorithm is known that computes the Pareto set in output-polynomial time (not even in the weak sense).

Dynamic programming is a common technique in parameterized algorithms. For many graph problems, dynamic programming on tree decompositions is applied to obtain fixed-parameter tractable (FPT) algorithms with respect to the treewidth of the input graph.

In this paper, we explore for the first time the potential of dynamic programming on tree decompositions for computing Pareto sets. First we design an algorithm for the multicriteria s-t cut problem and apply it on a problem from cartography that has recently been introduced by Rottmann et al. [28] and that was the original motivation for our research.

Rottmann et al. study maps with building footprints and present a new model how less detailed maps can be derived from a given map. Their method is based on viewing the problem as a bicriteria optimization problem. It is assumed that the plane containing the building footprints is triangulated and a set of triangles to glue together some of the buildings is to be selected that on the one hand minimizes the total area and on the other hand minimizes the total perimeter. Rottmann et al. present an algorithm that computes the set of extreme nondominated solutions (i.e., the set of solutions that optimize a linear combination of the objectives), which is a subset of the Pareto set. They ask if it is also possible to compute the entire Pareto set in some output-efficient way.

We show how a treewidth-based algorithm can be used to compute the Pareto set for the s-t cut problem. The running time of this algorithm is FPT in the treewidth and output-polynomial in the weak sense, i.e., it is of the form $\mathcal{O}(f(w) \cdot \text{poly}(n, p_{\max}))$ where f is some function in the treewidth w, n denotes the input size, and $p_{\max}$ denotes an upper bound on the size of the Pareto sets of the subproblems that occur in the dynamic program.

As a special case, the results for the multiobjective s-t cut algorithm directly translate to the cartography problem by computing the whole Pareto set in FPT time and being output-polynomial in the weak sense. We experimentally analyze the computation of Pareto sets for this cartography problem on real-world datasets by designing a specialized data structure, developing heuristics, and integrating additional implementation-specific techniques tailored to the task.

1.1 Our Results

We first consider the multiobjective s-t cut problem and its special case, the triangle aggregation problem [28]: Given some polygons P and triangles T, the goal is to find all Pareto-optimal subsets $T' \subseteq T$ minimizing both the total area and perimeter of $P \cup T'$. This problem arises in cartography, where the goal is to compute a less detailed map from a given map. Here the polygons are building footprints and the space between these footprints is triangulated. By including triangles, one can glue together these building footprints, leading to a less detailed version of the map. We show that the multiobjective s-t cut problem implies an algorithm to compute the Pareto set in time $\mathcal{O}(nw \cdot 2^w \cdot p_{\max}^2 \log(p_{\max}))$ for this problem, where w is the treewidth of the triangle adjacency graph.

In the full version of the paper, we show that this method for computing Pareto sets can also be applied for other multiobjective optimization problems, such as the multiobjective minimum spanning tree problem (MST) and the multiobjective traveling salesman problem (TSP). For both, we present algorithms with running time $\mathcal{O}(nw^{\mathcal{O}(w)} \cdot p_{\max}^2 \log^{d-2}(w^{\mathcal{O}(w)} \cdot p_{\max}^2))$ where w is the treewidth of the input graph, n is the number of vertices in the graph, $p_{\max}$ is the size of the largest Pareto set computed in one of the subproblems of the dynamic program, and $d \geq 2$ is the (constant) number of different objectives. This shows that the Pareto set can be efficiently computed for graphs with small treewidth if the Pareto sets of the subproblems are not too large, which is often the case in realistic inputs.

Finally, we experimentally evaluate our algorithm on real-world datasets. We introduce new heuristic pruning techniques, runtime estimates for tree decompositions and their root, memory optimization, multi-threading, and other improvements for reducing runtime and memory usage.

1.2 Related Work

Output-polynomial time algorithms (at least in the weak sense) are known for many problems. Examples include the multiobjective shortest path problem [12, 17, 29], multiobjective flow problems [15, 24], and the knapsack problem when viewed as a bicriteria optimization problem [25]. For the multiobjective spanning tree problem such algorithms are not known and there are only results on the set of extreme nondominated solutions. This is a subset of the Pareto set and it contains all solutions that optimize some linear combination of the different objectives. For the multiobjective spanning tree problem it is known that there are only polynomially many extreme nondominated solutions [14], and efficient algorithms for enumerating them exist [2].

Rottmann et al. [28] introduce the triangle aggregation problem under the objective of map simplification by grouping multiple building footprints together. They show that, similar to the multiobjective minimum spanning tree problem, there exist only a polynomial number of nondominated extreme solutions and they present an algorithm to compute this set in polynomial time. They also provide an extensive experimental study of their algorithms on real-world data sets showing that the model captures nicely the intention to aggregate building footprints to obtain less detailed maps. They put it as an open question whether or not it is possible to also compute the set of Pareto-optimal solutions in an output-efficient way.

Motivated by the observation that for many problems the Pareto set is often small in applications, the number of Pareto-optimal solutions has been studied in the probabilistic framework of smoothed analysis in a sequence of articles [27, 22, 10, 5]. It has been shown for a large class of linear integer optimization problems (which contains in particular the multiobjective MST problem and the multiobjective TSP) that the expected number of Pareto-optimal solutions is polynomially bounded if the coefficients (in our case, the edge weights) are independently perturbed by random noise. Formally, the coefficients of $d-1$ out of the d objectives are assumed to be independent random variables with adversarially chosen distributions with bounded density. It is shown that not only the expected number of Pareto-optimal solutions is bounded polynomially in this setting but also all constant moments, so in particular the expected squared number of Pareto-optimal solutions is also polynomially bounded. Combined with this, our results imply that the Pareto set for the multiobjective MST problem, the multiobjective TSP and the multiobjective s-t cut problem can be computed in expected FPT running time $\mathcal{O}(f(w) \cdot \text{poly}(n))$ in the model of smoothed analysis.

While dynamic programming over tree decompositions is a well-established technique, using it effectively in practice comes with more difficulties than simply minimizing the width of the decomposition. In experiments the runtime of an algorithm can vary largely for different tree decompositions with the same width.

Bodlaender and Fomin [8] introduced the concept of the *f-cost* of a tree decomposition, which sums up a cost function f applied to the bag sizes across all nodes. This framework formalizes the observation that not all nodes contribute equally to runtime or memory, and that practical efficiency can benefit from structurally favorable decompositions.

The f-cost approach was later extended and evaluated experimentally by Abseher et al. [1] using machine learning to select a tree decomposition based on different features such as bag sizes, branching factors, and node depths. With their method they could often select a decomposition that performs well in practice. Kangas et al. [18] used the same model for the problem of counting linear extensions, confirming the value of such estimators, and suggesting the average join-node depth as a good single feature for estimating runtime.

Beyond selection heuristics, tree decompositions have also been studied with respect to memory efficiency. Charwat et al. [11] explored compressed representations of intermediate states using decision diagrams, and Betzler et al. [6] proposed anchor-based compression techniques to reduce hard drive memory usage.

In our case, we not only solve an optimization problem, but compute the entire set of Pareto-optimal solutions. This makes memory usage more sensitive to the structure of join operations and limits the applicability of pointer-based or diagram-compressed representations. To address this, we develop a custom estimation strategy for predicting both runtime and memory usage, based on predicting the number of Pareto-optimal solutions at each node and the runtime impact of join operations. We then select a decomposition based on a combination of both runtime and memory usage. Details of this procedure are provided in the full version of the paper.

2 Preliminaries

Let $[i] := \{1, \dots, i\}$. We consider an arbitrary optimization problem with a constant number $d \in \mathbb{N}$ of objectives to be minimized. Each (feasible) solution s is mapped to a cost vector $f(s) = (f(s)_1, \dots, f(s)_d) \in \mathbb{R}^d$ where f is our objective function. A solution s_1 is said to *dominate* another solution s_2 if $f(s_1)_i \leq f(s_2)_i$ for all $i \in [d]$ and there exists some $j \in [d]$ such that $f(s_1)_j < f(s_2)_j$. We write $s_1 \prec s_2$ to denote that s_1 dominates s_2. The set of all non-dominated solutions is called the *Pareto set*. These definitions extend naturally to optimization problems where a subset of objectives is to be maximized instead of minimized. In the following we assume that all objectives are to be minimized, but all arguments and results can be adapted analogously when some (or all) objectives are to be maximized.

Let $\mathcal{P}_1$ and $\mathcal{P}_2$ be two sets of Pareto-optimal solutions. We define their combined Pareto set as $\mathcal{P}_1 + \mathcal{P}_2 := \{p \in \mathcal{P}_1 \cup \mathcal{P}_2 \mid p \text{ is Pareto-optimal in } \mathcal{P}_1 \cup \mathcal{P}_2\}$, their union as $S^{\mathcal{P}_1,\mathcal{P}_2} := \{p_1 \cup p_2 \mid p_1 \in \mathcal{P}_1, p_2 \in \mathcal{P}_2\}$, which contains all pairwise unions of solutions from $\mathcal{P}_1$ and $\mathcal{P}_2$, and the Pareto set of $S^{\mathcal{P}_1,\mathcal{P}_2}$ as $\mathcal{P}_1 \oplus \mathcal{P}_2 := \{s \in S^{\mathcal{P}_1,\mathcal{P}_2} \mid s \text{ is Pareto-optimal in } S^{\mathcal{P}_1,\mathcal{P}_2}\}$.

2.1 Treewidth

Our algorithms rely on dynamic programming over a *tree decomposition*. The concept of tree decomposition and *treewidth*, introduced by Robertson and Seymour [26], provide a measure of how similar a graph is to a tree. Many $\mathcal{NP}$-hard problems become tractable on graphs with small treewidth. Computing the optimal treewidth is $\mathcal{NP}$-hard [3], but it is FPT with respect to the treewidth [7], and a tree decomposition of width at most $2 \cdot w(G)$ can be computed in linear time using approximation algorithms [21]. Hence, we assume that our algorithm starts from such an approximate decomposition if no optimal one is available. In the following, we briefly introduce the notation used for tree decompositions.

▶ **Definition 1** (Tree decomposition). *A tree decomposition of a graph $G = (V, E)$ is a pair $\mathcal{T} = (\mathbb{T} = (\{t_1, \dots, t_m\}, E), \{X_t\}_{t \in V(\mathbb{T})})$ where $\mathbb{T}$ is a tree and each node $t \in V(\mathbb{T})$ is associated with a bag $X_t \subseteq V$, such that the following conditions hold:*

- $\bigcup_{t \in V(\mathbb{T})} X_t = V(G)$*, i.e., every vertex of G appears in at least one bag,*
- $\forall \{u, v\} \in E(G)\ \exists t \in V(\mathbb{T}) : u \in X_t \wedge v \in X_t$*, i.e., for every edge $\{u, v\} \in E(G)$ the vertices u and v must appear together in at least one bag,*
- $T_u = \{t \in V(\mathbb{T}) \mid u \in X_t\}$ *is a connected subtree of $\mathbb{T}$ for every $u \in V(G)$.*

The *width* of a tree decomposition is $w(\mathcal{T}) := \max_{t \in V(\mathbb{T})} |X_t| - 1$, and the *treewidth* $w(G)$ is the smallest possible *width* of a tree decomposition. We denote with V_t the union of vertices that were introduced at t or some child of t. In the following, we write w for the width of the tree decomposition used by our algorithm, which may be larger than $w(G)$ if an approximation is used.

We assume we have a *nice tree decomposition*, which is a binary tree decomposition rooted at some node $r \in V(\mathbb{T})$ with $X_r = \emptyset$ and with four specific node types:

- **Leaf node**: Let t be a node with no child nodes. Then t is a *Leaf node* iff $X_t = \emptyset$.
- **Introduce node**: Let $t_{\text{parent}}, t_{\text{child}}$ be two nodes in $V(\mathbb{T})$, where t_{parent} has exactly one child t_{child}. Then t_{parent} is an *Introduce node* iff $X_{t_{\text{parent}}} = X_{t_{\text{child}}} \cup \{v\}$ for some $v \in V(G)$.
- **Forget node**: Let $t_{\text{parent}}, t_{\text{child}}$ be two nodes in $V(\mathbb{T})$, where t_{parent} has exactly one child t_{child}. Then t_{parent} is a *Forget node* iff $X_{t_{\text{parent}}} \cup \{v\} = X_{t_{\text{child}}}$ for some $v \in V(G)$.
- **Join node**: Let $t_{\text{parent}}, t^1_{\text{child}}, t^2_{\text{child}}$ be three nodes in $V(\mathbb{T})$, where t_{parent} has exactly two children t^1_{child} and t^2_{child}. Then t_{parent} is a *Join node* iff $X_{t_{\text{parent}}} = X_{t^1_{\text{child}}} = X_{t^2_{\text{child}}}$.

From any tree decomposition of width w, a nice tree decomposition of the same width with $\mathcal{O}(|V(G)| \cdot w)$ nodes can be computed in polynomial time [13].

The algorithm works as follows: Given an instance $G = (V, E)$ and a cost function $c : E \to \mathbb{R}^d$, it first computes a nice tree decomposition $(\mathbb{T}, \{X_t\}_{t \in V(\mathbb{T})})$. In each leaf node the Pareto sets are initialized as empty sets. Then, for each node t, depending on its type, the algorithm recursively computes the set of Pareto-optimal solutions for each subproblem at this node. We distinguish between the functions `computeLeafNode`, `computeIntroduceNode`, and `computeForgetNode`, corresponding to their respective node types, and show correctness assuming that the Pareto sets for all child nodes are correctly computed.

3 Multiobjective s-t cut problem

We consider the problem of computing all Pareto-optimal s-t cuts in a graph. Given a graph $G' = (V \cup \{s, t\}, E')$ with $n = |V|$ and a cost function $c' : E' \to \mathbb{R}^d$, a cut corresponds to a subset $S \subseteq V$. The cost of a cut S is defined as the sum of costs of all edges crossing from $S \cup \{s\}$ to $(V \setminus S) \cup \{t\}$. Let $\delta(S) := \{\{u, v\} \in E' \mid u \in S \cup \{s\}, v \in (V \setminus S) \cup \{t\}\}$ be the set of edges cut by S. The cost of S is given by $\sum_{e \in \delta(S)} c'(e)$. We now wish to compute all s-t cuts that are Pareto-optimal. Without loss of generality, we assume $\{s, t\} \notin E'$, since such an edge only introduces a constant shift in cost to every Pareto-optimal solution.

We denote $\delta(A, B) := \{\{u, v\} \in E' \mid u \in A, v \in B\}$ for $A, B \subseteq V(G')$ as the set of edges between vertices in A and B that are being cut. We define $c : 2^{V(G')} \times 2^{V(G')} \to \mathbb{R}^d$ with $c(A, B) = \sum_{e \in \delta(A,B)} c'(e)$ for any subsets $A, B \subseteq V(G')$. For simplicity, for a single vertex $p \in V(G')$ and subset $A \subseteq V(G')$, we write $c(p, A)$ instead of $c(\{p\}, A)$.

Let $G = G'[V]$ be the subgraph induced by V. Given a nice tree decomposition $(\mathbb{T}, \{X_t\}_{t \in V(\mathbb{T})})$ for G, we compute for each node $t \in V(\mathbb{T})$ and subset $S \subseteq X_t$ the Pareto set $\mathcal{P}_t^S$ consisting of all Pareto-optimal solutions $p \subseteq V_t$ with $p \cap X_t = S$. We refer to such a subset S as a *selection*. Every such solution p has cost $c'(\delta(p)) = c(p, V \setminus p) + c(p, t) + c(V \setminus p, s)$. We refer to such an instance by a pair (t, S).

▶ **Theorem 2.** *For an arbitrary s-t cut instance $(G' = (V \cup \{s, t\}, E'), c')$ with cost function $c' : E \to \mathbb{R}^d$, we can compute the set of Pareto-optimal s-t cuts in time $\mathcal{O}(nw \cdot 2^w \cdot p_{\max}^2 \log^{\max\{d-2,1\}}(p_{\max}^2))$ if a nice tree decomposition of graph $G = G'[V]$ with width w is provided.*

In the following we describe how to compute the Pareto set for each node type. For each instance (t, S), the set of Pareto-optimal solutions is stored in an entry $D[t, S]$. For simplicity, we assume that $D[t, S]$ contains the actual corresponding Pareto set. Since the algorithm only depends on the cost vectors and selection S, in the actual implementation we will only save their cost vectors and reconstruct each solution by additionally storing pointers to the solutions from which it originated. Since we assume d as a constant, the encoding length of every Pareto-optimal solution is constant as well. Proofs of the following lemmas are provided in the full version of the paper.

`computeLeafNode`(t, S): For a leaf node t, we have only one solution $D[t, \emptyset] = \{\emptyset\}$.

`computeIntroduceNode`(t, S): Assume we have $X_t = X_{t'} \cup \{v\}$. If $v \notin S$, then $D[t, S] = D[t', S]$. If $v \in S$, then v is only adjacent to vertices in $X_{t'}$ and $V \setminus V_t$. If $X_{t'}$ is fixed, placing v on the same side of the cut as s only changes the cost of every solution by a fixed amount. Therefore we have $D[t, S] = D[t', S \setminus \{v\}]$, and their costs change by $c(v, X_{t'} \cup (V \setminus V_t) \cup \{t\}) - 2c(S \setminus \{v\}, v) - c(s, v)$.

▶ **Lemma 3.** *If node t introduces some vertex v and has a child t' for which $D[t', S]$ has been computed, then* `computeIntroduceNode`(t, S) *computes $D[t, S]$ in time $\mathcal{O}(p_{\max})$ for any partition S.*

`computeForgetNode`(t, S): Assume we have $X_t = X_{t'} \setminus \{v\}$. To obtain $D[t, S]$, we compute the union of the sets $D[t', S]$ and $D[t', S \cup \{v\}]$ and then remove all dominated solutions.

▶ **Lemma 4.** *If node t forgets some vertex v and has a child t' for which all possible sets $D[t', S']$ have been computed, then* `computeForgetNode`(t, S) *computes $D[t, S]$ in time $\mathcal{O}(p_{\max} \log^{d-2}(p_{\max}))$.*

For the correctness of `computeJoinNode`(t, S), the following lemma will be useful:

▶ **Lemma 5.** *For each Pareto-optimal solution $p \subseteq V$ and any node $t \in V(\mathbb{T})$, the solution $p \cap V_t$ is Pareto-optimal in the instance $(t, X_t \cap p)$.*

`computeJoinNode`$(t, \mathcal{S})$: Assume we have $X_t = X_{t_1} = X_{t_2}$. Since X_t separates $V_{t_1} \setminus X_t, V_{t_2} \setminus X_t$ and $V \setminus V_t$, we can combine every solution from $D[t_1, S]$ with every solution from $D[t_2, S]$ and then remove all dominated ones.

▶ **Lemma 6.** *If node $t \in V(\mathbb{T})$ is a join node with children $t_1, t_2 \in V(\mathbb{T})$ and sets $D[t_1, S]$ and $D[t_2, S]$ have been correctly computed, then* `computeJoinNode`(t, S) *computes $D[t, S]$ in time $\mathcal{O}(p_{\max}^2 \log^{\max\{d-2,1\}}(p_{\max}^2))$.*

Proof of Theorem 2. The correctness follows directly from the previous lemmas for the different node types, and from $D[r, \emptyset]$ being the Pareto set for the entire instance.

The runtime is dominated by the join nodes. Our nice tree decomposition contains $\mathcal{O}(nw)$ nodes, and for each node t the number of subsets $S \subseteq X_t$ is bounded by 2^{w+1}. Computing $D[t, S]$ at a join node takes time $\mathcal{O}(p_{\max}^2 \log^{\max\{d-2,1\}}(p_{\max}^2))$. Hence, the total running time is bounded by $\mathcal{O}(nw \cdot 2^w \cdot p_{\max}^2 \log^{\max\{d-2,1\}}(p_{\max}^2))$. ◀

The technique of computing the Pareto set for the s-t cut problem can also be applied to other multiobjective optimization problems as well. To illustrate this, we show how to compute the Pareto set for the multiobjective MST problem and the multiobjective TSP problem. Proofs of the following theorems are provided in the full version of the paper.

▶ **Theorem 7.** *For an arbitrary multiobjective spanning tree instance $(G = (V, E), c)$ with $d \geq 2$ objectives and cost function $c : E \to \mathbb{R}^d$, we can compute the set of Pareto-optimal spanning trees in time $\mathcal{O}(n(2w)^{\mathcal{O}(w)} \cdot p_{\max}^2 \log^{\max\{d-2,1\}}((2w)^{\mathcal{O}(w)} \cdot p_{\max}^2))$, if a nice tree decomposition of graph G with width w is provided.*

▶ **Theorem 8.** *For an arbitrary multiobjective traveling salesman instance $(G = (V, E), c)$ with $d \geq 2$ objectives and cost function $c : E \to \mathbb{R}^d$, we can compute the set of all Pareto-optimal tours in time $\mathcal{O}(n(3w+3)^{\mathcal{O}(w)} \cdot p_{\max}^2 \cdot \log^{\max\{d-2,1\}}((3w+3)^{\mathcal{O}(w)} \cdot p_{\max}^2))$, if a nice tree decomposition of graph G with width w is provided.*

4 Experiments

In this section we present the experimental evaluation of our proposed algorithm for a special case of the multiobjective s-t cut problem: the bicriteria polygon aggregation problem, introduced by Rottmann et al. [28]. An instance (T, P) consists of a set $P = \{p_1, \ldots, p_m\}$ of polygons and a set $T = \{t_1, \ldots, t_n\}$ of triangles. For any polygon $s \in T \cup P$, let $A(s) > 0$ denote its area and $P(s) > 0$ its perimeter. Given a set of triangles $S \subseteq T$, we define $A(S)$ as the total area of $S \cup P$ and $P(S)$ as the total perimeter of $S \cup P$. The goal is to compute the Pareto set $\mathcal{P}$ of subsets $S \subseteq T$ minimizing both $A(S)$ and $P(S)$.

As with many multiobjective optimization problems, the set of Pareto-optimal solutions for the bicriteria polygon aggregation problem can be of exponential size. In fact, one can more generally show that the bicriteria polygon aggregation problem can be seen as a generalization of the bicriteria knapsack problem. The statement on the size of the Pareto set follows as a corollary. The proof of the following theorem is provided in the full version of the paper.

▶ **Theorem 9.** *For every instance I of the bicriteria knapsack problem, there exists an instance I' of the bicriteria triangle aggregation problem such that there is a one-to-one correspondence between the Pareto-optimal solutions in I and I'.*

Our implementation follows the methodology outlined in Section 3, is written in Java, and was evaluated on the datasets used by Rottmann et al.[28], which consist of triangle aggregation problems derived from various cities and villages in Germany. The source code is available at `https://github.com/Tarek-pub/Bicriteria_Aggregation`.

We use the s-t cut construction from Rottmann et al. [28] to generating each instance. Additionally, we remove vertices corresponding to polygons from the graph G, resulting in a more compact, yet equivalent graph structure. To reduce complexity, weights (i.e. area and perimeter) are rounded to one decimal place (perimeter in decimals), and only unique-weight solutions are retained. Tree decompositions are computed using the JDrasil framework [4]. Several observations during development led to significant improvements in runtime and memory usage, which we integrated iteratively into the implementation and quantify through an analysis on the Ahrem dataset (Table 1). Experiments were run using 16 threads of an Intel Core i9-13900 with 100GB RAM. Multiple tree decompositions were generated for exactly 1 hour using 16 threads.

Further implementation details are provided in the full version of the paper, including an extended description of optimizations and a complete list of datasets with corresponding runtimes and memory usage.

As noted in Section 3, it suffices to store only the overall cost of a solution, rather than the full set of triangles included. The actual solutions can be reconstructed later by maintaining, additionally to the cost, pointers to the solutions from which the current one originated.

Table 1 Performance comparison of different algorithmic improvements on the dataset Ahrem.
*: These values are extrapolated based on sampled subproblems and scaled proportionally to estimate full runtimes (more details are provided in the full version of the paper).
**: For the versions before choosing a good root or tree decomposition, we chose the median rated root / tree decomposition in this table for a fair comparison.

Algorithm improvement	Runtime [h]	Storage usage [GiB]

Introduce-join-forget nodes	7.0 (−15%)	122 (−92%)
Summary	**−99.95%**	**−96.71%**

We briefly describe the data structure used in our implementation, as well as a rough description of the algorithm adaptations. Each solution p is represented as a weighted pair $(A(p), P(p))$ for area and perimeter.

4.1 Outsourcing and Pruning

Initially, the implementation was unable to solve even small datasets, such as Osterloh (treewidth 14), due to RAM exhaustion reaching up to 100GB. To solve this problem, we implemented an efficient outsourcing strategy that stores all currently unneeded solutions onto a hard drive, keeping only the necessary solutions in RAM. Each solution is stored as a 16-byte entry in a dedicated *origin-pointer* file. Each DP table $D[t, S]$ is stored in a separate *surface-pointer* file, containing solution IDs and their weights. These files are kept on disk and only loaded into RAM when needed. This data structure allowed solving Osterloh without exceeding RAM limits, but other datasets remained unsolvable due to hard drive usage growing up to 2TB. To free up disk space, we remove obsolete surface-pointer files and, when necessary, run a slow in-place pruning step to clean the origin-pointer file. This involves recursively marking only reachable entries by following their pointers and compacting the file accordingly. Pruning is only triggered when space is critically low, based on conservative estimates of future storage use. These strategies prevented further storage issues, but many datasets were still unsolvable due to excessive runtime, particularly in join nodes. For example, the runtime required to solve the Ahrem dataset at this stage was estimated at approximately 13,768 hours, or one and a half year worth of CPU.

4.2 Choosing an appropriate tree decomposition

When generating multiple tree decompositions for the same graph, we observed that both the decomposition structure and the choice of the root node can significantly affect performance. Similar to Abseher et al. [1], we therefore generate multiple tree decompositions for the same graph and select one that is expected to yield good performance. However, our approach differs in two important aspects: First, since we consider a concrete algorithm rather than a general class of dynamic programming approaches, we can simulate its execution to approximate actual performance. Second, we do not only estimate runtime but also account for memory consumption, selecting the decomposition that minimizes a weighted combination of both. To this end, each decomposition is traversed in postorder, and we estimate the number of solutions at each node to predict resource usage.

Earlier versions of our approach focused solely on minimizing runtime, which did not always lead to reduced memory usage (see Table 1). Only in the final version did we optimize both runtime and memory simultaneously. Incorporating this performance estimator into the algorithm led to a significant improvement in runtime. For the Ahrem dataset we estimated a runtime decrease to around 7,130 hours, a 48% decrease in the estimated runtime.

In an experiment with 100 decompositions for the instance Osterloh, our estimator selected the decomposition that ranked first in both runtime and storage. The correlation between the predicted score and actual performance was 0.91 for runtime and 0.97 for storage. We obtained similarly strong results when estimating performance for different root node choices, again observing a high correlation between predicted and actual runtime and memory usage. These results suggest that our estimator reliably selects either the best tree decomposition or at least one that still performs well with regards to runtime and memory consumption.

4.3 Join node algorithm

Let t be a join node with children t_1 and t_2. For each subset $S \subseteq X_t$, we compute $\mathcal{P}_t^S = \mathcal{P}_{t_1} \oplus \mathcal{P}_{t_2}$ by combining all solutions $p_1 \in \mathcal{P}_{t_1}^S$ with all solutions $p_2 \in \mathcal{P}_{t_2}^S$ and subsequently remove all dominated solutions. To do this efficiently, we employ a lexicographical ordering of the input lists and process the combinations using a min-heap. Assume $|\mathcal{P}_{t_1}^S| \leq |\mathcal{P}_{t_2}^S|$. We initialize a min-heap with one heap node for each $p_1 \in \mathcal{P}_{t_1}^S$, each pointing to the first entry in $\mathcal{P}_{t_2}^S$. We then repeatedly extract the root of the min-heap, process the corresponding solution pair (p_1, p_2), and increment its pointer to reference the next solution $p_2' \in \mathcal{P}_{t_2}^S$ that follows p_2 in lexicographical order. If such a solution p_2' exists, we update the heap accordingly, otherwise, we remove the heap node from the data structure. This process continues until the heap is empty, ensuring that every valid solution pair has been considered. This min-heap mechanism ensures that all candidate pairs are enumerated in lexicographical order, which enables an efficient check for Pareto-optimality.

4.4 Optimizing join node computations

As with many dynamic programming algorithms over a nice tree decomposition, join nodes are the main computational bottleneck. At each join node t we needed to compute $\mathcal{P} = \mathcal{P}_1 \oplus \mathcal{P}_2$ for two Pareto sets $\mathcal{P}_1, \mathcal{P}_2$ exactly $2^{|X_t|}$ many times. Computing $\mathcal{P}_1 \oplus \mathcal{P}_2$ for $d \geq 2$ can be done in $\mathcal{O}(p_{\max}^2 \log^{\max\{d-2,1\}}(p_{\max}^2))$. In the worst case, $\mathcal{P}_1 \oplus \mathcal{P}_2$ can contain up to $|\mathcal{P}_1| \cdot |\mathcal{P}_2|$ many solutions if every combination is Pareto-optimal. By considering every combination $(p_1, p_2) \in \mathcal{P}_1 \times \mathcal{P}_2$ and filtering out all dominated ones, this becomes very time-consuming. However, in practice we observed only a roughly linear growth in size relative to the larger input Pareto set. This discrepancy indicated that many combinations were computed that would ultimately be discarded. To circumvent this problem, we utilize a heuristic pruning strategy to efficiently exclude many non-Pareto-optimal combinations at the same time.

We construct a heuristic set $\mathcal{H}$ for $\mathcal{P}$ using a small subset of $\mathcal{P}_1$ and $\mathcal{P}_2$. Afterwards we partition $\mathcal{P}_1, \mathcal{P}_2$ and $\mathcal{H}$ into multiple sections and compute lower bounds for each section in $\mathcal{P}_1, \mathcal{P}_2$ and upper bounds for $\mathcal{H}$. We then iterate over all combinations of lower bounds and compare them with the upper bounds. If a combination of lower bounds is entirely dominated by all upper bounds, we can conclude that no solution in these sections will be Pareto-optimal (PO) in $\mathcal{P}$ and safely skip them in the min-heap. To construct $\mathcal{H}$, we apply the same optimization recursively until a base case is reached. Furthermore, we apply multi-threading for each join node t, enabling parallel computation of multiple entries $D[t, S]$ at the same time.

Table 2 Overview over some of the datasets we managed to solve. For all datasets see the full version of the paper.

Dataset	w	Time [h]	Storage [GIB]	#PO Solutions	Percentage nonextreme	Graph #Vertices	Graph #Edges	$\lvert V(\mathbb{T})\rvert$
Osterloh	14	0.15	5.8	83055	99.43	1717	1887	7586
Ahrem	17	3.1	122	219969	98.99	5280	5607	21778
Lottbek	19	10.5	355	316567	99.48	5595	6101	24426
Erlenbach	22	70.7	1754	303565	99.47	5644	6284	25682

The heuristic pruning process introduces a trade-off between its own runtime and the efficiency gains from skipping combinations. By selecting appropriate parameters, we achieved a favorable balance, reducing the runtime by nearly 98% and ultimately solving Ahrem in under seven days.

4.5 Join-forget nodes

To further improve runtime and reduce memory usage, we analyzed recurring patterns in the algorithm process that allowed for optimization. In many instances, after computing a join node, many of these solutions were immediately discarded in subsequent forget nodes. To address this inefficiency, we introduce a new node type, called *join-forget* node, which merges a join node with subsequent forget nodes into a single operation. Formally, for a join node t in the tree decomposition, if its unique parent and all ancestors up to the next non-forget node are forget nodes, we replace t and all these forget nodes by a single join-forget node t'. This new node retains the original bag X_t and additionally stores the set F of forgotten vertices from the removed forget nodes.

We consider which lists would be merged in the upcoming forget nodes of the original join node while combining solutions in the min-heap. More specifically, for a join-forget node with forgotten vertices F, we only create a min-heap for each subset $S' \subseteq X_t \setminus F$. Each such heap allows us to efficiently iterate over all combinations from the union $\bigcup_{S \in \{S' \cup F' \mid F' \subseteq F\}} \{p_1 \cup p_2 \mid p_1 \in \mathcal{P}^S_{t_1}, p_2 \in \mathcal{P}^S_{t_2}\}$.

This setup also enhances our join node heuristic. Instead of computing a heuristic set $\mathcal{H}$ and upper bounds for each pair $\mathcal{P}^S_{t_1}, \mathcal{P}^S_{t_2}$ separately, we reuse the join-forget structure. Specifically, for each subset $S' \subseteq X_t \setminus F$, we compute the same heuristic set $\mathcal{H}$ for all $S \in \{S' \cup F' \mid F' \subseteq F\}$. We do so by using subsets of $\mathcal{P}^S_{t_1}$ and $\mathcal{P}^S_{t_2}$ for all such S. As before, we recursively apply this heuristic until a small base case is reached. A side effect of this strategy is that it significantly increases RAM usage, as each thread now requires not just three lists in memory (namely $\mathcal{P}^S_{t_1}, \mathcal{P}^S_{t_2}$ and $\mathcal{P}^S_{t_1} \oplus \mathcal{P}^S_{t_2}$), but up to $2^{|F|+1} + 1$ lists.

This strategy led to another significant boost in runtime for many of our datasets. For the Ahrem dataset, using join-forget nodes reduced the runtime by 95%, allowing us to solve the instance in almost 8 hours. Moreover, storage usage also decreased by 59%. We emphasize that the improvements are not solely due to the use of join-forget nodes, but by adapting the tree decomposition performance estimator accordingly as well.

4.6 Introduce-join-forget nodes

Together with the newly defined join-forget node, we searched for new patterns in the algorithm computations to reduce the storage consumption further. To this end, we introduce a second node type called *introduce-join-forget* node, which further generalizes the concept

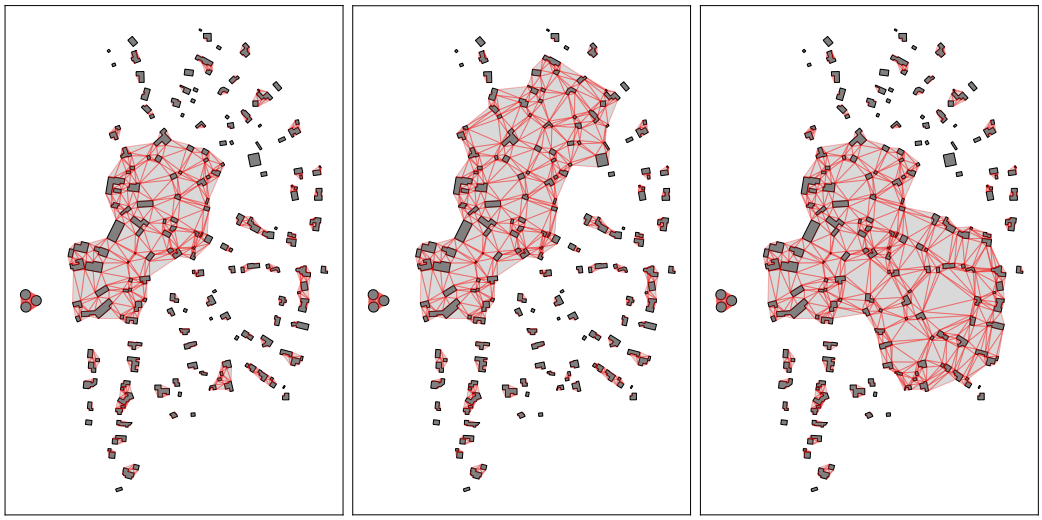

Figure 1 Three PO aggregations of the dataset Osterloh. Input polygons are filled dark gray, chosen triangles are filled light gray. Middle: nonextreme solution. Left/Right: Closest extreme solutions to the nonextreme solution.

of join-forget nodes. After replacing applicable structures with join-forget nodes, we consider each join-forget node t with child nodes t_1, t_2, where at least one child (t_1, t_2, or both) is an introduce node. We remove all consecutive introduce nodes among the children and store their introduced vertices as additional information in t.

A major inefficiency of standard introduce nodes arises from the exponential growth in possible subsets $S \subseteq X_t$. When a new vertex v is introduced, each existing solution $p \in \mathcal{P}_t^S$ for $S \subseteq X_t \setminus \{v\}$ is, with a constant weight adjustment, duplicated for both S and $S \cup \{v\}$. This significantly increases both memory usage and I/O overhead in the outsourcing step, making it a significant bottleneck. To resolve this, we avoid explicit duplication of solutions in introduce-join-forget nodes. Let $I \subseteq X_t$ be the set of vertices whose introduction was skipped on one side. If a set $\mathcal{P}^S$ is required for the min-heap computations and $S \cap I \neq \emptyset$, we instead load the solutions of the surface-pointer file of $\mathcal{P}^{S \setminus I}$ and add the constant weight adjustments according to $S \cap I$. Additionally, we create an origin-pointer entry for such a solution only if they are identified as Pareto-optimal in the min-heap. This strategy also reduces the growth of the origin-pointer file.

Together with adapting the performance estimator, this final improvement reduced the memory consumption by an additional 92%, resulting in a total of only 122GB of storage required for the Ahrem dataset, while also achieving a further 15% decrease in runtime, bringing the total runtime down to 7 hours.

5 Results

Using an efficient data structure and multiple algorithmic improvements described in Section 4, we were able to compute the full Pareto set for many datasets, including instances with treewidths of up to 22, within a reasonable amount of time. Table 2 shows a subset of datasets we successfully solved. All of these computations were performed on a high performance computing system. We used 96 threads of two Intel Xeon “Sapphire Rapids” 2.10GHz and about two terabytes of storage.

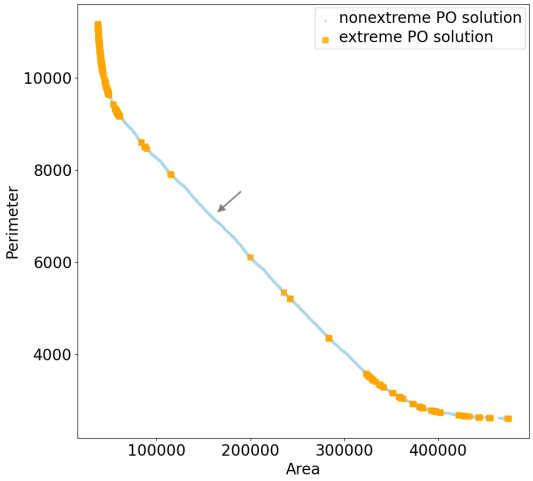

Figure 2 The weights of all PO solutions of Osterloh. The arrow indicates which nonextreme solution is shown in Figure 1.

For the polygon aggregation problem, it is known that all extreme solutions are hierarchically compatible [28]. In Figure 1 we illustrate this by showing two consecutive extreme solutions p_1, p_2 and one nonextreme solution p' that lies between them (i.e. $A(p_1) < A(p') < A(p_2)$ and $P(p_1) > P(p') > P(p_2)$). While the nonextreme solution p' is also a viable aggregation, it exhibits a significantly different structure compared to the extreme solutions. Focusing solely on extreme solutions may lead to large gaps in the solution space, as seen in Figure 2.

Across the datasets we solved, extreme solutions accounted for only less than one percent of the total PO solutions on average. As a result, computing the set of nonextreme solutions can therefore lead to a significant richer range of solutions for the user to choose from, while the extreme solutions are forced being hierarchical depending on each other.

We published a tool to interactively investigate all PO solutions for the dataset Osterloh. The tool is available at `https://github.com/Tarek-pub/Bicriteria_Aggregation_plotting`.

6 Conclusions

We presented the first algorithms for computing Pareto sets using dynamic programming over tree decompositions and showed that this framework can naturally be applied to various multiobjective optimization problems. The main motivation for our work was the article of Rottmann et al. [28], who raised the question of whether it is possible to compute the Pareto set in output-polynomial time. We also conducted an experimental analysis of the polygon aggregation problem on real-world instances and developed several techniques to improve both runtime and memory usage.

We want to highlight that the theoretical running times of our algorithms are only worst-case bounds. In practice, because not every bag in a tree decomposition has the maximum possible size and the number of join nodes is often relatively small, the actual running time will usually be smaller. Additionally, it is a common phenomenon for multiobjective optimization that Pareto sets are not too large for real-world inputs. Hence, the dependency on the size of the largest Pareto set is not prohibitive in practice. For problems like the multiobjective minimum spanning tree problem, the multiobjective TSP, and many other problems, this is further supported by theoretical results in smoothed analysis, which shows that Pareto sets are expected to be polynomially bounded when instances are randomly perturbed [10].

On Estimating the Quantum ℓ_α Distance

Yupan Liu
Graduate School of Mathematics, Nagoya University, Japan

Qisheng Wang
School of Informatics, University of Edinburgh, UK

Abstract

We study the computational complexity of estimating the quantum ℓ_α distance $\mathrm{T}_\alpha(\rho_0, \rho_1)$, defined via the Schatten α-norm $\|A\|_\alpha := \mathrm{tr}(|A|^\alpha)^{1/\alpha}$, given $\mathrm{poly}(n)$-size state-preparation circuits of n-qubit quantum states ρ_0 and ρ_1. This quantity serves as a lower bound on the trace distance for $\alpha > 1$. For any constant $\alpha > 1$, we develop an efficient *rank-independent* quantum estimator for $\mathrm{T}_\alpha(\rho_0, \rho_1)$ with time complexity $\mathrm{poly}(n)$, achieving an *exponential* speedup over the prior best results of $\exp(n)$ due to Wang, Guan, Liu, Zhang, and Ying (*IEEE Trans. Inf. Theory* 2024). Our improvement leverages efficiently computable *uniform* polynomial approximations of *signed* positive power functions within quantum singular value transformation, thereby eliminating the dependence on the rank of the states.

Our quantum algorithm reveals a dichotomy in the computational complexity of the Quantum State Distinguishability Problem with Schatten α-norm (QSD_α), which involves deciding whether $\mathrm{T}_\alpha(\rho_0, \rho_1)$ is at least $2/5$ or at most $1/5$. This dichotomy arises between the cases of constant $\alpha > 1$ and $\alpha = 1$:

- For any $1 + \Omega(1) \leq \alpha \leq O(1)$, QSD_α is BQP-complete.
- For any $1 \leq \alpha \leq 1 + \frac{1}{n}$, QSD_α is QSZK-complete, implying that no efficient quantum estimator for $\mathrm{T}_\alpha(\rho_0, \rho_1)$ exists unless BQP = QSZK.

The hardness results follow from reductions based on new rank-dependent inequalities for the quantum ℓ_α distance with $1 \leq \alpha \leq \infty$, which are of independent interest.

1 Introduction

Closeness testing of quantum states is a central topic in quantum property testing [58], which aims to develop (efficient) quantum testers for properties of quantum objects. This problem is also closely related to verifying the functionality of quantum devices, such as Q_0 and Q_1, which are commonly designed to prepare the respective n-qubit (mixed) quantum states ρ_0 and ρ_1. The goal of (tolerant) quantum state testing is to design efficient quantum

algorithms that test whether ρ_0 is 2/5-far from or 1/5-close to ρ_1 with respect to a given closeness measure. Notably, this problem generalizes classical (tolerant) distribution testing (see [20] and [35, Chapter 11]) from a non-commutative perspective.

When the "source codes" of distribution- or state-preparation circuits are given, a surprising correspondence was established between such closeness testing problems – measured by the ℓ_1 norm distance [66, 37] or entropy difference [36] – and interactive proof systems that admit statistical zero-knowledge (SZK). This correspondence links closeness testing problems to both complexity theory and cryptography. A similar correspondence was later identified in the quantum world: closeness testing of quantum states with respect to the trace distance (given by Schatten 1-norm) [77, 78], denoted by QSD, or the von Neumann entropy difference [10] was shown to be QSZK-complete.[1]

In contrast, when the closeness measure follows an ℓ_2-norm-like definition, such as the Hilbert-Schmidt distance or the quantum linear entropy, the corresponding closeness testing problems are in BQP using the SWAP test [17, 27]. Taken together, these results reveal a dichotomy in the complexity of closeness testing: when the measure is ℓ_1-norm-like, the problems are QSZK-hard and their query or sample complexities have *polynomial* dependence on the dimension or rank of the states; whereas for ℓ_2-norm-like measures, the problems are contained in BQP and their query or sample complexities are *rank-independent*.

What about the closeness testing problems with respect to generalizations that approximates the trace distance or the von Neumann entropy? The quantum ℓ_α distance, defined as $\mathrm{T}_\alpha(\rho_0, \rho_1) \coloneqq \frac{1}{2}\operatorname{tr}(|\rho_0 - \rho_1|^\alpha)^{1/\alpha}$ via the Schatten α-norm, generalizes both the trace distance ($\alpha = 1$) and the Hilbert-Schmidt distance ($\alpha = 2$). Similarly, the quantum q-Tsallis entropy $\mathrm{S}_q(\rho)$ extends both von Neumann entropy ($q = 1$) and quantum linear entropy ($q = 2$).

Interestingly, prior results show a divergence in behavior for closeness measures looser than the ℓ_2 norm: The closeness testing problem with respect to $\mathrm{T}_\alpha(\rho_0, \rho_1)$, denoted by QSD_α (see Definition 17), is in BQP only for *even* integer $\alpha \geq 2$ via the Shift test [27]; while for odd integers $\alpha \geq 3$, the query and sample complexities generally depend on the rank [71]. However, the techniques in [27] yield BQP algorithms for estimating $\mathrm{S}_q(\rho)$ for *all* integer $q \geq 2$. A recent work [53] further explored the closeness testing problem with respect to $\mathrm{S}_q(\rho_0) - \mathrm{S}_q(\rho_1)$, and extended the observed dichotomy from integers – where the transition occurs between $q = 1$ and $q \geq 2$ – to a continuous setting, showing a sharp distinction between $q = 1$ and any constant $q > 1$. These results naturally lead to an intriguing question:

▶ **Problem 1.** What is the computational complexity of the closeness testing problem with respect to $\mathrm{T}_\alpha(\rho_0, \rho_1)$? Does a similar dichotomy hold between $\alpha = 1$ and constants $\alpha > 1$, or does the complexity vary largely depending on whether α is even or odd?

Why study ℓ_α problems for possibly non-integer $\alpha > 1$? The trace distance ($\alpha = 1$) is a fundamental closeness measure of quantum states, capturing the maximum success probability of quantum state discrimination [41, 40] and playing a key role in applications such as the security of quantum key distribution [11, 63]. For $\alpha > 1$, such as $\alpha = 1.001$, the quantum ℓ_α distance provides a natural lower bound on the trace distance, and addressing Problem 1 could make this bound efficiently computable. Moreover, insights from ℓ_α problems have previously contributed to progress on well-studied ℓ_1 problems, as seen in [49].

Beyond their connections to ℓ_1 problems, ℓ_α problems for $\alpha > 1$ are of independent interest. In classical scenarios, they have applications in machine learning (e.g., [46]), as well as in streaming and sketching algorithms (e.g. [43]). In quantum scenarios, the Hilbert-

[1] The QSZK containment of the closeness testing problem with respect to the trace distance, denoted by $\mathrm{QSD}[a(n), b(n)]$, holds only in the polarizing regime $a(n)^2 - b(n) \geq 1/O(\log n)$, as shown in [77, 78]. A recent work [51] slightly improved the parameter regime for this containment.

Schmidt distance ($\alpha = 2$) is widely used in quantum information theory (e.g., [42, 61]), and more recently, has been leveraged in designing near-term (variational) quantum algorithms (e.g., [5, 28]). Consequently, positive answers to Problem 1 may offer new opportunities to refine, extend, or develop techniques relevant to these areas.

A classical counterpart to Problem 1 was investigated in [69] nearly a decade ago. The main takeaway aligns with [53]: For constant $\alpha > 1$, the sample complexity for distinguishing whether $\mathrm{TV}_\alpha(D_0, D_1)$ is at least $2/5$ or at most $1/5$ is *independent* of the dimension of the probability distributions D_0 and D_1,[2] fewer samples are needed as α increases. Classically, these upper bounds can be achieved by drawing a polynomial number of samples and computing the ℓ_∞ norm distance between the resulting empirical distributions. However, this approach does not directly extend to the quantum world: (1) quantum states ρ_0 and ρ_1 are generally not simultaneously diagonalizable; and (2) even when they are, estimating their eigenvalues associated with the unknown common eigenbasis remains challenging. Addressing these challenges is central to resolving Problem 1, which is the focus of our work.

1.1 Main results

We begin by stating our first main theorem, which provides a positive answer to Problem 1 when α lies in the range $1 + \Omega(1) \le \alpha \le O(1)$:

▶ **Theorem 2** (Quantum estimator for T_α, informal). *Given quantum query access to the state-preparation circuits of n-qubit quantum states ρ_0 and ρ_1, for any constant $\alpha > 1$, there is a quantum algorithm for estimating $\mathrm{T}_\alpha(\rho_0, \rho_1)$ within additive error $1/5$ and query complexity $O(1)$. If the state-preparation circuits have $\mathrm{poly}(n)$-size descriptions, then the algorithm' time complexity is $\mathrm{poly}(n)$. Thus, for any constant $\alpha > 1$, QSD_α is in* BQP.

More precisely, for a given additive error ϵ, the explicit query complexity of Theorem 2 is $O(1/\epsilon^{\alpha+1+\frac{1}{\alpha-1}})$ (see Theorem 14). In combination with the samplizer [74, 75], estimating $\mathrm{T}_\alpha(\rho_0, \rho_1)$ can be done using $\widetilde{O}(1/\epsilon^{3\alpha+2+\frac{2}{\alpha-1}})$ samples of ρ_0 and ρ_1 (see Theorem 16). Both upper bounds can be expressed as $\mathrm{poly}(1/\epsilon)$ for the regime $1 + \Omega(1) \le \alpha \le O(1)$. In addition, if the state-preparation circuits of ρ_0 and ρ_1 have size $L(n) = \mathrm{poly}(n)$, then Theorem 2 implies a quantum algorithm with time complexity $\widetilde{O}(L/\epsilon^{\alpha+1+\frac{1}{\alpha-1}})$, or equivalently, $\mathrm{poly}(n, 1/\epsilon)$.

Previous quantum algorithms for estimating the quantum ℓ_α distance for constant $\alpha > 1$ have all relied on its powered variant, specifically the powered quantum ℓ_α distance:

$$\Lambda_\alpha(\rho_0, \rho_1) \coloneqq \frac{1}{2}\,\mathrm{tr}(|\rho_0 - \rho_1|^\alpha) = 2^{\alpha-1} \cdot \mathrm{T}_\alpha(\rho_0, \rho_1)^\alpha.$$

Thus, for $1 < \alpha \le O(1)$, the estimates of $\mathrm{T}_\alpha(\rho_0, \rho_1)$ and $\Lambda_\alpha(\rho_0, \rho_1)$ are polynomially related.

When $\alpha > 1$ is an even integer, estimating $\mathrm{T}_\alpha(\rho_0, \rho_1)$ follows from a folklore result via the Shift test [27], using $O(1/\epsilon)$ queries or $O(1/\epsilon^2)$ samples.[3] However, for odd integer $\alpha > 1$, no efficient quantum algorithm is known in general. Closeness testing of quantum states with respect to $\mathrm{T}_\alpha(\rho_0, \rho_1)$ for $\alpha = 3$, with query complexity $O(1/\epsilon^{3/2})$, has been noted only in [32]. For general non-integer constants $\alpha > 1$, the quantum query complexity of estimating $\mathrm{T}_\alpha(\rho_0, \rho_1)$ was studied in [71], with polynomial dependence on the maximum rank r of ρ_0 and ρ_1. A technical comparison of our approach with this result is provided in Section 1.2.

[2] The closeness measure $\mathrm{TV}_\alpha(D_0, D_1)$ represents the classical ℓ_α distance based on the ℓ_α norm and generalizes the total variation distance, which is recovered at $\alpha = 1$.

[3] The sample complexity was noted in [62, Equations (83) and (84)].

By combining our efficient quantum estimator for $\mathrm{T}_\alpha(\rho_0,\rho_1)$ in the regime $1+\Omega(1) \le \alpha \le O(1)$ (Theorem 2) with our hardness results for QSD_α (Theorem 3), we identify a sharp phase transition between the case of $\alpha = 1$ and constant $\alpha > 1$, addressing Problem 1. For clarity, we summarize our main theorems and the quantitative bounds on quantum query and sample complexities, derived from both our results and prior work, in Table 1.

Table 1 Computational, query, and sample complexities of QSD_α for $1 \le \alpha \le O(1)$.

(*) For any $\alpha(n) \in \left[1, 1+\frac{1}{n}\right]$, the promise problem $\mathrm{QSD}_\alpha[a,b]$ is contained in QSZK only under the polarizing regime $a(n)^2 - b(n) \ge 1/O(\log n)$, which can be slightly improved when $\alpha = 1$ (see Footnote 1). However, establishing containment in a complexity class typically requires the natural regime $a(n) - b(n) \ge 1/\mathrm{poly}(n)$, as in Theorem 2.

Finally, we present our second main theorem, which addresses the computational hardness of QSD_α, as outlined in Theorem 3. In this context, PureQSD$_\alpha$ refers to a restricted variant of QSD_α (see also Definition 17), where the states of interest are pure.

▶ **Theorem 3** (Computational hardness of QSD_α)**.** *The promise problem* QSD_α *captures the computational power of the respective complexity classes in the corresponding regimes of* α*:*

(1) Easy regimes: *For any* $1 \le \alpha \le \infty$, PureQSD$_\alpha$ *is* BQP*-hard. As a corollary,* QSD_α *is* BQP*-complete for* $1+\Omega(1) \le \alpha \le O(1)$*.*

(2) Hard regimes: *For any* $1 \le \alpha \le 1+\frac{1}{n}$, QSD_α *is* QSZK*-complete, where the* QSZK *containment of* $\mathrm{QSD}_\alpha[a,b]$ *only holds for the polarizing regime* $a(n)^2 - b(n) \ge 1/O(\log n)$*.*

1.2 Proof techniques: BQP containment for α constantly above 1

At a high level, Quantum Singular Value Transformation (QSVT) [34] implies that the main challenge in designing a quantum algorithm based on a smooth function – e.g., Grover search [38] and the OR function, or the HHL algorithm [39] and the multiplicative inverse function (see [57] for more examples) – reduces to finding an efficiently computable polynomial approximation. Once such an approximation is obtained, the algorithm follows directly using techniques from [34], with its efficiency determined entirely by the polynomial's properties.

Now we focus on quantum algorithms for estimating the powered quantum ℓ_α distance. We begin by reviewing [71] and then provide a high-level overview of our approach.

The quantum query complexity of estimating the quantum ℓ_α distance for non-integer α was first considered in [71, Theorem IV.1]. Their approach begins with the identity

$$2\Lambda_\alpha(\rho_0,\rho_1) = \|\rho_0 - \rho_1\|_\alpha^\alpha = \mathrm{tr}\left(|\nu_-|^{\alpha/2}\Pi_{\nu_+}|\nu_-|^{\alpha/2}\right),$$

where $\nu_\pm = \rho_0 \pm \rho_1$ and Π_{ν_+} denotes the projector onto the support subspace of ν_+. According to this identity, they aim to prepare a quantum state that is a block-encoding of (normalized) $|\nu_-|^{\alpha/2}\Pi_{\nu_+}|\nu_-|^{\alpha/2}$.[4] To this end, they first prepare a quantum state that is a block-encoding of Π_{ν_+}, and then perform a unitary operator that is a block-encoding of $|\nu_-|^{\alpha/2}$ on it.[5] Finally, the (unnormalized) powered quantum ℓ_α distance, $\Lambda_\alpha(\rho_0, \rho_1)$, can be obtained by estimating the trace of $|\nu_-|^{\alpha/2}\Pi_{\nu_+}|\nu_-|^{\alpha/2}$ using quantum amplitude estimation [16]. After the error analysis, their approach was shown to have query complexity $\widetilde{O}(r^{3+1/\{\alpha/2\}}/\epsilon^{4+1/\{\alpha/2\}}) = \mathrm{poly}(r, 1/\epsilon)$.[6] The dependence on the rank is *inherent* in the approach of [71], as they have to prepare a rank-dependent quantum state that is a block-encoding of Π_{ν_+}, making the rank parameters unavoidable in the error analysis.

To overcome this technical issue, we utilize an identity different from theirs:

$$2\Lambda_\alpha(\rho_0, \rho_1) = \|\rho_0 - \rho_1\|_\alpha^\alpha = \mathrm{tr}\Big(\rho_0 \cdot \mathrm{sgn}(\nu_-) \cdot |\nu_-|^{\alpha-1}\Big) - \mathrm{tr}\Big(\rho_1 \cdot \mathrm{sgn}(\nu_-) \cdot |\nu_-|^{\alpha-1}\Big).$$

The idea is to estimate the terms $\mathrm{tr}(\rho_j \cdot \mathrm{sgn}(\nu_-) \cdot |\nu_-|^{\alpha-1})$ for $j \in \{0, 1\}$ individually, and then combine them to obtain an estimate of $\Lambda_\alpha(\rho_0, \rho_1)$. Our algorithm is sketched as follows:

1. Find a good approximation polynomial for $\mathrm{sgn}(x) \cdot |x|^{\alpha-1}$.
2. Implement a unitary block-encoding U of $\mathrm{sgn}(\nu_-) \cdot |\nu_-|^{\alpha-1}$ using Quantum Singular Value Transformation (QSVT) [34] and Linear Combinations of Unitaries (LCU) [23, 15], given the state-preparation circuits of ρ_0 and ρ_1.
3. Perform the Hadamard test [3] on U and ρ_j with outcome $b_j \in \{0,1\}$ for each $j \in \{0,1\}$.
4. Estimate $\Lambda_\alpha(\rho_0, \rho_1)$ by computing the expected value of $b_0 - b_1$.

Our algorithm is actually inspired by the trace distance estimation in [72], which corresponds to the case of $\alpha = 1$. However, the approach in [72] still has a rank-dependent query complexity of $\widetilde{O}(r/\epsilon^2)$, compared to the $\widetilde{O}(r^5/\epsilon^6)$ in [71].[7] Nevertheless, we discover an approach for estimating the quantum ℓ_α distance with a *rank-independent* complexity as long as α is constantly greater than 1. Specifically, we use the best uniform approximation polynomial $P_d(x)$ (of degree d) for the function $\mathrm{sgn}(x) \cdot |x|^q$, as given in [31, Theorem 8.1.1]:

$$\max_{x\in[-1,1]} \big|P_d(x) - \mathrm{sgn}(x) \cdot |x|^q\big| \to \frac{1}{d^q}, \text{ as } d \to \infty.$$

Our use of the best uniform approximation by polynomials is inspired by the recent work [53] on estimating the q-Tsallis entropy of quantum states for non-integer q, where they used the best uniform approximation polynomial for x^q in the non-negative range $[0, 1]$ (given in [67]). The difference is that in our case, we have to further consider the sign of x, thereby requiring the polynomial approximation to behave well in the negative part. It turns out that the polynomial approximation given in [31] is suitable for our purpose. Having noticed this, we then use the now standard techniques (used in [48, 53]) such as Chebyshev truncations and the de La Vallée Poussin partial sum (cf. [65]) to construct efficiently computable asymptotically best approximation polynomials such that

$$\max_{x\in[-1,1]} \left|P(x) - \frac{1}{2}\,\mathrm{sgn}(x) \cdot |x|^q\right| \le \epsilon, \quad \max_{x\in[-1,1]} |P(x)| \le 1, \text{ and } \deg(P) = O\left(\frac{1}{\epsilon^{1/q}}\right).$$

[4] See Definition 10 for the formal definition of block-encoding.
[5] This is because of the evolution of subnormalized density operators [71, Lemma II.2].
[6] Here, $\{x\} \coloneqq x - \lfloor x \rfloor$ denotes the fractional part of x.
[7] Some readers may wonder if our approach applies to trace distance estimation ($\alpha = 1$) to remove the rank dependence in quantum query and sample complexities in [72]. However, the answer is generally no, as the rank dependence is intrinsic to trace distance estimation due to the polynomial dependence of the rank in the quantum query and sample complexities lower bounds (see [52, Section 2.2.2] in the full version).

Using this efficiently computable polynomial (with $q = \alpha - 1$) and with further analysis, we can then estimate the quantum ℓ_α distance to within additive error ϵ with the desired query upper bound in Theorem 2. Moreover, using the (multi-)samplizer [74, 75], a quantum query-to-sample simulation, we can also achieve the desired sample upper bound.

1.3 Proof techniques: QSZK completeness for $\alpha > 1$ near 1

To establish the BQP- and QSZK-hardness results in Theorem 3, we reduce the promise problems QSD and PureQSD ($\alpha = 1$) to the corresponding promise problems QSD_α and $\mathrm{PureQSD}_\alpha$ for appropriate ranges of α. The key technique underlying these reductions is the following rank-dependent inequalities that generalize the case of $\alpha = 2$ from [24, 25]:

▶ **Theorem 4** (T_α vs. T, informal). *For any states ρ_0 and ρ_1 and $\alpha \in [1, \infty]$, it holds that:*

$$2^{1-\frac{1}{\alpha}} \cdot \mathrm{T}_\alpha(\rho_0, \rho_1) \leq \mathrm{T}(\rho_0, \rho_1) \leq 2\big(\mathrm{rank}(\rho_0)^{1-\alpha} + \mathrm{rank}(\rho_1)^{1-\alpha}\big)^{-\frac{1}{\alpha}} \cdot \mathrm{T}_\alpha(\rho_0, \rho_1). \tag{1}$$

For $\alpha = \infty$, the inequalities hold in the limit as $\alpha \to \infty$.

The proof of Theorem 4 follows from considering orthogonal positive semi-definite matrices ς_0 and ς_1 satisfying $\rho_0 - \rho_1 = \varsigma_0 - \varsigma_1$, and analyzing their properties carefully.

We then illuminate the hardness results in Theorem 3:

- For the easy regime, Equation (1) becomes an equality when both ρ_0 and ρ_1 are pure states. This equality implies the BQP-hardness of $\mathrm{PureQSD}_\alpha$, along with the query and sample complexity lower bounds for all $1 \leq \alpha \leq \infty$, establishing Theorem 3(1).
- For the hard regime, Equation (1) is *sensitive* to α. Particularly, for $\alpha = 1 + \frac{1}{n}$, if quantum states ρ_0 and ρ_1 are τ-far, meaning $\mathrm{T}(\rho_0, \rho_1) \geq \tau$, it follows only that $\mathrm{T}_{\alpha=1+\frac{1}{n}}(\rho_0, \rho_1) \geq \tau/2$. However, when $\alpha \leq 1 + \frac{1}{n^{1+\delta}}$ for any arbitrarily small constant δ, the same trace distance condition ensures that $\mathrm{T}_\alpha(\rho_0, \rho_1) \geq \tau$ as $n \to \infty$, leading to the QSZK hardness result in Theorem 3(2) and distinct query complexity lower bounds in Table 1.

Lastly, we explain the QSZK containment in the hard regime. Simply combining Theorem 4 and the QSZK containment of QSD from [77, 78] does not work, as the resulting QSZK containment of $\mathrm{QSD}_\alpha[a, b]$ holds only for $a(n)^2/2 - b(n) \geq 1/O(\log n)$, which is even weaker than the polarizing regime defined in Footnote 1. To address this, we establish a *partial* polarization lemma for T_α (Lemma 25), which ensures that for quantum states ρ_0 and ρ_1 where $\mathrm{T}(\rho_0, \rho_1)$ is either at least a or at most b, we can construct new quantum states $\widetilde{\rho}_0$ and $\widetilde{\rho}_1$ such that $\mathrm{T}_\alpha(\widetilde{\rho}_0, \widetilde{\rho}_1)$ is either at least $\frac{1}{2} - \frac{1}{2}e^{-k}$ or at most $1/16$, as long as the parameters a and b are in the polarizing regime. Theorem 3(2) follows by combining this partial polarization lemma for T_α with the polarization lemma for T in [77].

1.4 Discussion and open problems

While the quantum ℓ_α distance $\mathrm{T}_\alpha(\cdot, \cdot)$ and its powered version $\Lambda_\alpha(\cdot, \cdot)$ are almost computationally interchangeable for $1 \leq \alpha \leq O(1)$, their behavior differs greatly when $\alpha = \infty$:

- The quantity $\mathrm{T}_\infty(\rho_0, \rho_1)$ corresponds to the largest eigenvalue $\lambda_{\max}$ of $(\rho_0 - \rho_1)/2$. The associated promise problem QSD_∞ is BQP-hard and contains in QMA.[8] However, establishing a BQP containment appears challenging, as $(\rho_0 - \rho_1)/2$ does not directly admit an efficiently computable basis – unlike its classical counterpart in [69], which does.

[8] The verification circuit in the QMA containment simply follows from phase estimation [45], where a (normalized) eigenvector corresponding to $\lambda_{\max}$ serves as a witness state.

- The quantity $\Lambda_\infty(\rho_0, \rho_1)$ takes values in $\{0, 1/2, 1\}$ for any states ρ_0 and ρ_1, and is nonzero if and only if the states are orthogonal, with at least one being pure. Thus, even the pure-state-restricted variant of the associated promise problem, PurePoweredQSD$_\infty[1, 0]$, is $\mathsf{C_{=}P}$-hard (see [52, Appendix A] in the full version). Here, $\mathsf{C_{=}P} = \mathsf{coNQP}$ [2, 80], a subclass of PP that provides a precise variant of BQP, ensuring acceptance for all *yes* instances.

This fundamental difference between these quantities raises an intriguing question on QSD$_\infty$:

(a) What is the computational complexity of the promise problem QSD$_\infty$, defined by $\mathrm{T}_\infty(\cdot, \cdot)$? Can we show that QSD$_\infty$ is also in BQP, or is it inherently more difficult?

Another open problem concerns quantitative bounds for QSD$_\alpha$:

(b) Can the query and sample bounds in Table 1 be improved, particularly for the regime $1 + \Omega(1) \leq \alpha \leq O(1)$? Moreover, can tight bounds be established when the states have *small support*, analogous to the classical case in [69, Table 1]?

1.5 Related works

Schatten p-norm estimation $\mathrm{tr}(|A|^p)$ of $O(\log n)$-local Hermitian A on n qubits to within additive error $2^{n-p}\epsilon\|A\|^p$ for $\epsilon(n) \leq 1/\operatorname{poly}(n)$ and real $p(n) \leq \operatorname{poly}(n)$ was shown to be $\mathsf{DQC1}$-complete in [19]. Given a unitary block-encoding of a matrix A, in [56], they presented a quantum algorithm that estimates the Schatten p-norm $(\mathrm{tr}(|A|^p))^{1/p}$ to relative error ϵ for integer p, where a condition number κ satisfying $A \geq I/\kappa$ is required for the case of odd p.

The query complexity of N-dimensional quantum state certification (i.e., determine whether two quantum states are identical or ϵ-far) with respect to trace distance was shown to be $O(N/\epsilon)$ in [32]. The query complexity of trace distance estimation was shown to be $\widetilde{O}(r^5/\epsilon^6)$ in [71] and later improved to $\widetilde{O}(r/\epsilon^2)$ in [72], where r is the rank of the quantum states, confirming a conjecture in [25] that low-rank trace distance estimation is in BQP. Both Low-rank trace distance and fidelity estimations are known to be BQP-complete [1, 72]. Based on the approach of [72], space-bounded quantum state discrimination with respect to trace distance was shown to be BQL-complete in [48]. In addition to trace distance, fidelity is another important measure of the closeness between quantum states. The query complexity of fidelity estimation was shown to be $\widetilde{O}(r^{12.5}/\epsilon^{13.5})$ in [76] and later improved to $\widetilde{O}(r^{5.5}/\epsilon^{6.5})$ in [71] and to $\widetilde{O}(r^{2.5}/\epsilon^5)$ in [33]. Recently, the query complexity of pure-state trace distance and fidelity estimations was shown to be $\Theta(1/\epsilon)$ in [70] and was recently extended in [29] to estimating fidelity of a mixed state to a pure state.

In addition to the query complexity, the sample complexity has also been studied in the literature. In [7], the sample complexity of N-dimensional quantum state certification was shown to be $\Theta(N/\epsilon^2)$ with respect to trace distance and $\Theta(N/\epsilon)$ with respect to fidelity. The sample complexity of trace distance estimation is known to be $\widetilde{O}(r^2/\epsilon^5)$ in [72] and that of fidelity estimation is known to be $\widetilde{O}(r^{5.5}/\epsilon^{12})$, where r is the rank of quantum states. The sample complexity of pure-state squared fidelity estimation is known to be $\Theta(1/\epsilon^2)$ via the SWAP test [17], where the matching lower bound was given in [4]. Recently, the sample complexity of pure-state trace distance and fidelity estimations was shown to be $\Theta(1/\epsilon^2)$ in [73], which was achieved by using the samplizer in [75].

2 Preliminaries

We assume a fundamental knowledge of quantum computation and quantum information theory. For an introduction, we refer the reader to the textbook [59].

We adopt the following notations throughout the paper: (1) $[n] \coloneqq \{1, 2, \ldots, n\}$; (2) $\widetilde{O}(f)$ denotes $O(f \operatorname{polylog}(f))$, while $\widetilde{\Omega}(f)$ denotes $\Omega(f/\operatorname{polylog}(f))$; and (3) $|\bar{0}\rangle$ represents $|0\rangle^{\otimes a}$ for integer $a > 1$. In addition, the Schatten α-norm of a matrix A is defined as $\|A\|_\alpha \coloneqq \left(\operatorname{tr}(|A|^\alpha)\right)^{1/\alpha}$, where $|A| \coloneqq \left(A^\dagger A\right)^{1/2}$. For simplicity, we use the notation $\|A\|$ to denote the operator norm (equivalently, the Schatten ∞-norm) of a matrix A.

2.1 Closeness measures for quantum states

We start by defining the trace distance and providing useful properties of this distance:

▶ **Definition 5** (Trace distance). *Let ρ_0 and ρ_1 be two quantum states that are mixed in general. The trace distance between ρ_0 and ρ_1 is defined by*

$$\mathrm{T}(\rho_0, \rho_1) \coloneqq \frac{1}{2} \operatorname{tr}(|\rho_0 - \rho_1|) = \frac{1}{2} \operatorname{tr}\Big(\left((\rho_0 - \rho_1)^\dagger (\rho_0 - \rho_1)\right)^{1/2}\Big).$$

Notably, the trace distance is a distance metric (e.g., [79, Lemma 9.1.8]).

Next, we define the quantum ℓ_α distance and its *powered* version, which generalize the trace distance ($\alpha = 1$) using the Schatten norm. Notably, the quantum ℓ_α distance coincides with the Hilbert-Schmidt distance when $\alpha = 2$:

▶ **Definition 6** (Quantum ℓ_α distance and its powered version). *Let ρ_0 and ρ_1 be two quantum states that are mixed in general. The quantum ℓ_α distance $\mathrm{T}_\alpha(\cdot, \cdot)$ and its powered version $\Lambda_\alpha(\cdot, \cdot)$ between ρ_0 and ρ_1 are defined as follows*:

$$\mathrm{T}_\alpha(\rho_0, \rho_1) \coloneqq \frac{1}{2} \|\rho_0 - \rho_1\|_\alpha \quad \text{and} \quad \Lambda_\alpha(\rho_0, \rho_1) \coloneqq \frac{1}{2} \|\rho_0 - \rho_1\|_\alpha^\alpha.$$

Here, the Schatten α-norm of $\rho_0 - \rho_1$ is given by $\|\rho_0 - \rho_1\|_\alpha \coloneqq \left(|\rho_0 - \rho_1|^\alpha\right)^{1/\alpha}$.

By the monotonicity of the Schatten norm, e.g., [6, Equation (1.31)], it holds that:

$$\forall \alpha \geq 1, \quad 0 \leq \Lambda_\alpha(\rho_0, \rho_1) \leq \mathrm{T}_\alpha(\rho_0, \rho_1) \leq \mathrm{T}(\rho_0, \rho_1) \leq 1.$$

As a corollary of the Davis convexity theorem [26], the quantum ℓ_α distance $\mathrm{T}_\alpha(\cdot, \cdot)$ also serves as a distance metric, whereas its powered version $\Lambda_\alpha(\cdot, \cdot)$ does not. Further inequalities for the trace distance and the quantum ℓ_α distance are given in the full version, particularly in [52, Section 2.1].

Lastly, we require the following relationship for additive error estimation between the quantum ℓ_α distance and its powered version. The proof is provided in the full version, specifically in [52, Proposition 2.5].

▶ **Proposition 7** (T_α vs. powered T_α). *The quantum ℓ_α distance $\mathrm{T}_\alpha(\cdot, \cdot)$ and its powered version $\Lambda_\alpha(\cdot, \cdot)$ are related through the equality $\mathrm{T}_\alpha(\rho_0, \rho_1) = 2^{\frac{1}{\alpha}-1} \cdot \Lambda_\alpha(\rho_0, \rho_1)^{\frac{1}{\alpha}}$. Accordingly, if x is an estimate of $\Lambda_\alpha(\rho_0, \rho_1)$ to within additive error ϵ, then $2^{\frac{1}{\alpha}-1} \cdot x^{\frac{1}{\alpha}}$ serves as an estimate of $\mathrm{T}_\alpha(\rho_0, \rho_1)$ to within additive error $2^{\frac{1}{\alpha}-1} \cdot \epsilon^{\frac{1}{\alpha}}$.*

2.2 Closeness testing of quantum states via state-preparation circuits

We begin by defining the closeness testing of quantum states with respect to the trace distance, denoted as $\mathrm{QSD}[a, b]$,[9] and two variants of this problem:

[9] While Definition 8 aligns with the classical counterpart of QSD defined in [66, Section 2.2], it is slightly less general than the definition in [77, Section 3.3]. Specifically, Definition 8 assumes that the input length m and the output length n are *polynomially equivalent*, whereas [77, Section 3.3] allows for cases where the output length (e.g., a single qubit) is *much smaller* than the input length.

▶ **Definition 8** (Quantum State Distinguishability Problem, QSD, adapted from [77, Section 3.3]). *Let Q_0 and Q_1 be quantum circuits acting on m qubits ("input length") and having n specified output qubits ("output length"), where $m(n)$ is a polynomial function of n. Let ρ_i denote the quantum state obtained by running Q_i on state $|0\rangle^{\otimes m}$ and tracing out the non-output qubits. Let $a(n)$ and $b(n)$ be efficiently computable functions. Decide whether*:

- Yes: *A pair of quantum circuits (Q_0, Q_1) such that $\mathrm{T}(\rho_0, \rho_1) \geq a(n)$;*
- No: *A pair of quantum circuits (Q_0, Q_1) such that $\mathrm{T}(\rho_0, \rho_1) \leq b(n)$.*

Furthermore, we denoted the restricted version, where ρ_0 and ρ_1 are pure states, as PureQSD.

In this work, we consider the *purified quantum access input model*, as defined in [77], in both white-box and black-box scenarios:

- **White-box input model**: The input of the problem QSD consists of descriptions of polynomial-size quantum circuits Q_0 and Q_1. Specifically, for $b \in \{0, 1\}$, the description of Q_b includes a sequence of polynomially many 1- and 2-qubit gates.
- **Black-box input model**: In this model, instead of providing the descriptions of the quantum circuits Q_0 and Q_1, only query access to Q_b is allowed, denoted as O_b for $b \in \{0, 1\}$. For convenience, we also allow query access to $Q_b^\dagger$ and controlled-Q_b, denoted by $O_b^\dagger$ and controlled-O_b, respectively.

In addition to query complexity, defined within the black-box input model, *sample complexity* refers to the number of copies of quantum states ρ_0 and ρ_1 needed to accomplish a specific closeness testing task. Useful lemmas on computational hardness and quantitative lower bounds for query and sample complexities are available in the full version, specifically in [52, Section 2.2].

2.3 Polynomial approximations

We now present useful tools on best uniform polynomial approximations. In addition, definitions and lemmas on Chebyshev expansion and truncations can be found in the full version, particularly in [52, Section 2.3.2].

Let $f(x)$ be a continuous function defined on the interval $[-1, 1]$ that we aim to approximate using a polynomial of degree at most d. We define P_d^* as a *best uniform approximation* on $[-1, 1]$ to f of degree d if, for any degree-d polynomial approximation P_d of f, it holds that $\max_{x\in[-1,1]}|f(x) - P_d^*(x)| \leq \max_{x\in[-1,1]}|f(x) - P_d(x)|$.

The best uniform (polynomial) approximation of positive (constant) powers $|x|^\alpha$ was first established by Serge Bernstein [14, 13]. However, the focus here is on the best uniform approximation of *signed* positive powers $\mathrm{sgn}(x)|x|^\alpha$, as stated in Lemma 9. This result is often attributed to Bernstein's work (see, e.g., [68, Equation (10.2)]), and a proof of a more general version can be found in [31, Theorem 8.1.1].

▶ **Lemma 9** (Best uniform approximation of signed positive powers, adapted from [31, Theorem 8.1.1]). *For any positive real (constantly large) order α, let $P_d^* \in \mathbb{R}[x]$ be the best uniform polynomial approximation for $f(x) = \mathrm{sgn}(x)|x|^\alpha$ of degree $d = \left\lceil (\beta_\alpha/\epsilon)^{1/\alpha} \right\rceil$, where β_α is a constant depending on α. Then, for sufficiently small ϵ, $\max_{x\in[-1,1]} |P_d^*(x) - f(x)| \leq \epsilon$.*

2.4 Quantum algorithmic toolkit

In this subsection, we recap the quantum singular value transformation. Additional quantum algorithmic tools, including useful quantum algorithmic subroutines and the quantum samplizer can be found in the full version, specifically in [52, Sections 2.4.2 and 2.4.3].

2.4.1 Quantum singular value transformation

We start by defining block-encoding:

▶ **Definition 10** (Block-encoding). *A linear operator A on an $(n+a)$-qubit Hilbert space is said to be an (α, a, ϵ)-block-encoding of an n-qubit linear operator B, if $\|\alpha(\langle 0|^{\otimes a} \otimes I_n)A(|0\rangle^{\otimes a} \otimes I_n) - B\| \leq \epsilon$, where I_n is the n-qubit identity operator and $\|\cdot\|$ is the operator norm.*

Then, we state the quantum singular value transformation:

▶ **Lemma 11** (Quantum singular value transformation, [34, Theorem 31]). *Suppose that unitary operator U is a (α, a, ϵ)-block-encoding of Hermitian operator A, and $P \in \mathbb{R}[x]$ is a polynomial of degree d with $|P(x)| \leq \frac{1}{2}$ for $x \in [-1, 1]$. Then, we can implement a quantum circuit $\tilde{U}$ that is a $(1, a+2, 4d\sqrt{\epsilon/\alpha} + \delta)$-block-encoding of $P(A/\alpha)$, by using $O(d)$ queries to U and $O((a+1)d)$ one- and two-qubit quantum gates. Moreover, the classical description of $\tilde{U}$ can be computed in deterministic time* $\mathrm{poly}(d, \log(1/\delta))$.

3 Efficient quantum algorithms for estimating quantum ℓ_α distance

In this section, we present efficient quantum algorithms for estimating the quantum ℓ_α distance $\mathrm{T}_\alpha(\rho_0, \rho_1)$ when $\alpha \geq 1 + \Omega(1)$. These algorithms utilize either queries to state-preparation circuits or samples of the states ρ_0 and ρ_1. The core of our approach is an *efficient* uniform approximation to *signed* positive constant power functions (Lemma 12), which provides a uniform error bound over the entire interval $[-1, 1]$.

This uniform polynomial approximation enables a query-efficient quantum algorithm for estimating $\mathrm{T}_\alpha(\rho_0, \rho_1)$ through its powered version $\Lambda_\alpha(\rho_0, \rho_1)$, as shown in Theorem 14. As a result, we establish a BQP containment of the promise problem QSD_α defined in Section 4. Additionally, by leveraging the multi-samplizer in [73], we devise a sample-efficient quantum algorithm for estimating $\mathrm{T}_\alpha(\rho_0, \rho_1)$, detailed in Theorem 16.

3.1 Efficient uniform approximations of signed positive powers

Using the averaged Chebyshev truncation specified in [52, Section 2.3.2] in the full version, we provide an *efficiently computable* uniform polynomial approximation of *signed* positive constant powers (see also [52, Lemma 3.1]):

▶ **Lemma 12** (Efficient uniform polynomial approximation of signed positive powers). *Let α be a positive real (constantly large) number. For any $\epsilon \in (0, 1/2)$, there is a degree-d polynomial $P_d \in \mathbb{R}[x]$, where $d = \left\lceil (\beta'_\alpha/\epsilon)^{1/\alpha} \right\rceil$ and β'_α is a constant depending on α, that can be deterministically computed in $\widetilde{O}(d)$ time. For sufficiently small ϵ, it holds that*:

$$\max_{x\in[-1,1]} \left| \frac{1}{2}\mathrm{sgn}(x)|x|^\alpha - P_d(x) \right| \leq \epsilon \quad \textit{and} \quad \max_{x\in[-1,1]} |P_d(x)| \leq 1.$$

More specifically, the degree-d uniform approximation of signed positive powers (see Lemma 9) ensures that the degree-$(2d-1)$ averaged Chebyshev truncation (given in [52, Equation 2.3]) achieves almost the same approximation error bound, with efficiently computable Chebyshev coefficients. The complete proof is available in the full version, specifically in [52, Section 3.1].

3.2 Quantum ℓ_α distance estimation for constantly large $\alpha > 1$

3.2.1 Query-efficient quantum algorithm for estimating powered T_α

We now present efficient quantum query algorithms for estimating $\Lambda_\alpha(\rho_0, \rho_1)$ and $\mathrm{T}_\alpha(\rho_0, \rho_1)$, as presented in [52, Lemma 3.2] in the full version, and the complete proof is provided in [52, Section 3.2.1]:

▶ **Lemma 13** (Powered quantum ℓ_α distance estimation via queries). *Suppose that Q_0 and Q_1 are unitary operators that prepare purifications of mixed quantum states ρ_0 and ρ_1, respectively. For every constantly large $\alpha \geq 1 + \Omega(1)$, there is a quantum query algorithm that estimates $\Lambda_\alpha(\rho_0, \rho_1)$ to within additive error ϵ by using $O(1/\epsilon^{1+\frac{1}{\alpha-1}})$ queries to Q_0 and Q_1.*

By combining Proposition 7 with Lemma 13 for additive error ϵ^α, we obtain a quantum query algorithm for estimating $\mathrm{T}_\alpha(\rho_0, \rho_1)$ when $\alpha \geq 1 + \Omega(1)$ is constantly large, as also stated in [52, Theorem 3.3] in the full version:

▶ **Theorem 14** (Quantum ℓ_α distance estimation via queries). *Suppose that Q_0 and Q_1 are unitary operators that prepare purifications of mixed quantum states ρ_0 and ρ_1, respectively. For every constantly large $\alpha \geq 1 + \Omega(1)$, there is a quantum query algorithm that estimates $\mathrm{T}_\alpha(\rho_0, \rho_1)$ to within additive error ϵ by using $O(1/\epsilon^{\alpha+1+\frac{1}{\alpha-1}})$ queries to Q_0 and Q_1.*

3.2.2 Sample-efficient quantum algorithm for estimating powered T_α

We proceed by describing efficient quantum sample algorithms for $\Lambda_\alpha(\rho_0, \rho_1)$ and $\mathrm{T}_\alpha(\rho_0, \rho_1)$, as stated in Lemma 15 and in [52, Lemma 3.4] in the full version. Our sample algorithms are obtained by combining the quantum query algorithm from Lemma 13 with the samplizer [74, 75]. The corresponding explanatory framework is presented in in [52, Algorithm 1], and the detailed proof is given in [52, Section 3.2.2].

▶ **Lemma 15** (Powered quantum ℓ_α distance estimation via samples). *For every constantly large $\alpha \geq 1 + \Omega(1)$, $\Lambda_\alpha(\rho_0, \rho_1)$ can be estimated to within additive error ϵ on a quantum computer by using $\widetilde{O}(1/\epsilon^{3+\frac{2}{\alpha-1}})$ samples of ρ_0 and ρ_1.*

By combining Proposition 7 with Lemma 15 for additive error ϵ^α, we obtain a quantum sample algorithm for estimating $\mathrm{T}_\alpha(\rho_0, \rho_1)$ when $\alpha \geq 1 + \Omega(1)$ is constantly large, as also stated in [52, Theorem 3.5] in the full version:

▶ **Theorem 16** (Quantum ℓ_α distance estimation via samples). *For every constantly large $\alpha \geq 1 + \Omega(1)$, there is a quantum sample algorithm that estimates the quantum ℓ_α distance $\mathrm{T}_\alpha(\rho_0, \rho_1)$ to within additive error ϵ by using $\widetilde{O}(1/\epsilon^{3\alpha+2+\frac{2}{\alpha-1}})$ samples of ρ_0 and ρ_1.*

4 Hardness and lower bounds for α constantly above 1

We begin by introducing a generalization of QSD from [77], where the trace distance is replaced with the quantum ℓ_α distance as the closeness measure:

▶ **Definition 17** (Quantum State Distinguishability Problem with Schatten α-norm, QSD_α). *Let Q_0 and Q_1 be quantum circuits acting on m qubits ("input length") and having n specified output qubits ("output length"), where $m(n)$ is a polynomial function of n. Let ρ_i denote the quantum state obtained by running Q_i on state $|0\rangle^{\otimes m}$ and tracing out the non-output qubits. Let $a(n)$ and $b(n)$ be efficiently computable functions. Decide whether*:

- Yes: *A pair of quantum circuits (Q_0, Q_1) such that $\mathrm{T}_\alpha(\rho_0, \rho_1) \geq a(n)$;*
- No: *A pair of quantum circuits (Q_0, Q_1) such that $\mathrm{T}_\alpha(\rho_0, \rho_1) \leq b(n)$.*

Moreover, we denoted the restricted version, where ρ_0 and ρ_1 are pure states, as $\mathrm{PureQSD}_\alpha$.

In the remainder of this section, we establish rank-dependent inequalities between the quantum ℓ_α distance and the trace distance (Theorem 18) in Section 4.1. These inequalities facilitate reductions that demonstrate the BQP hardness (Theorem 21) and derive quantitative lower bounds on queries and samples (Theorem 22) for PureQSD$_\alpha$ in Section 4.2.

4.1 Rank-dependent inequalities between T_α and the trace distance

We generalize the rank-dependent inequalities between the (squared) Hilbert-Schmidt distance and the trace distance, as demonstrated in [24, Appendix G] and [25, Theorem 1] for the case of $\alpha = 2$, to all $1 \le \alpha \le \infty$:

▶ **Theorem 18** (T_α vs. T)**.** *Let ρ_0 and ρ_1 be quantum states. The following holds*:
(1) *For any α in the range $1 \le \alpha < \infty$,*

$$2^{1-\frac{1}{\alpha}} \cdot \mathrm{T}_\alpha(\rho_0,\rho_1) \le \mathrm{T}(\rho_0,\rho_1) \le 2\big(\mathrm{rank}(\rho_0)^{1-\alpha} + \mathrm{rank}(\rho_1)^{1-\alpha}\big)^{-\frac{1}{\alpha}} \cdot \mathrm{T}_\alpha(\rho_0,\rho_1).$$

(2) *For $\alpha = \infty$, $2 \cdot \mathrm{T}_\infty(\rho_0,\rho_1) \le \mathrm{T}(\rho_0,\rho_1) \le 2\min\{\mathrm{rank}(\rho_0),\mathrm{rank}(\rho_1)\} \cdot \mathrm{T}_\infty(\rho_0,\rho_1)$.*

It is worth noting that Item 1 and Item 2 in Theorem 18 are consistent, specifically

$$\lim_{\alpha\to\infty} \big(\mathrm{rank}(\rho_0)^{1-\alpha} + \mathrm{rank}(\rho_1)^{1-\alpha}\big)^{-\frac{1}{\alpha}} = \min\{\mathrm{rank}(\rho_0),\mathrm{rank}(\rho_1)\}.$$

Additionally, the inequalities in Theorem 18 sharpen the inequalities between the trace norm and the Schatten norm (see, e.g., [6, Equation (1.31)]):

$$\forall 1 \le p \le \infty, \quad \|A\|_p \le \|A\|_1 \le r_A^{1-1/p} \cdot \|A\|_p. \tag{2}$$

By considering the maximum rank of ρ_0 and ρ_1, we can derive a simplified form of Theorem 18 for convenience:

▶ **Corollary 19** (T_α vs. T, simplified)**.** *For any quantum states ρ_0 and ρ_1, the following holds*:

$$\forall 1 \le \alpha < \infty, \quad 2^{1-\frac{1}{\alpha}} \cdot \mathrm{T}_\alpha(\rho_0,\rho_1) \le \mathrm{T}(\rho_0,\rho_1) \le (2\max\{\mathrm{rank}(\rho_0),\mathrm{rank}(\rho_1)\})^{1-\frac{1}{\alpha}} \cdot \mathrm{T}_\alpha(\rho_0,\rho_1).$$

Moreover, for pure quantum states, Theorem 18 yields the following equality:

▶ **Corollary 20** ($\mathrm{T}_\alpha = \mathrm{T}$ for pure states)**.** *For any pure states $|\psi_0\rangle\langle\psi_0|$ and $|\psi_1\rangle\langle\psi_1|$, we have*:

$$\forall 1 \le \alpha \le \infty, \quad 2^{1-\frac{1}{\alpha}} \cdot \mathrm{T}_\alpha(|\psi_0\rangle\langle\psi_0|,|\psi_1\rangle\langle\psi_1|) = \mathrm{T}(|\psi_0\rangle\langle\psi_0|,|\psi_1\rangle\langle\psi_1|).$$

The proof of Theorem 18 (see also [52, Theorem 4.2] in the full version) relies on the positive semi-definite matrices ς_0 and ς_1, defined for each $b \in \{0,1\}$ as $\varsigma_b := \frac{1}{2}\big((-1)^b(\rho_0-\rho_1) + |\rho_0-\rho_1|\big)$. These matrices are orthogonal and satisfy the relation $\rho_0 - \rho_1 = \varsigma_0 - \varsigma_1$. The complete proof is provided in [52, Section 4.1].

4.2 Computational hardness and lower bounds

We first state the computational hardness result of PureQSD$_\alpha$ with $1 \le \alpha \le \infty$, obtained by a reduction from PureQSD, which is BQP hard [64], as stated in Theorem 21 and in [52, Theorem 4.5]. The proof can be found in the full version, specifically in [52, Section 4.2].

▶ **Theorem 21** (PureQSD$_\alpha$ is BQP-hard)**.** *For any $1 \le \alpha \le \infty$ and $n \ge 2$, it holds that*:

$$\mathrm{PureQSD}_\alpha\Big[2^{\frac{1}{\alpha}-1} \cdot \big(1-2^{-n}\big),\ 2^{\frac{1}{\alpha}-1-n}\Big] \text{ is BQP-hard.}$$

Next, we provide lower bounds on the query and sample complexities for PureQSD_α by reducing to those for PureQSD in [70], as presented in Theorem 22 and in [52, Theorem 4.6]. The proof is provided in the full version, particularly in [52, Section 4.2].

▶ **Theorem 22** (PureQSD_α). *For any $1 \leq \alpha \leq \infty$ and $0 < \epsilon < 2^{\frac{1}{\alpha}-2}$, there exist n-qubit pure states $|\psi_0\rangle$ and $|\psi_1\rangle$ such that deciding whether $\mathrm{T}_\alpha(|\psi_0\rangle\langle\psi_0|, |\psi_1\rangle\langle\psi_1|)$ is at least ϵ or exactly 0 requires*:
(1) Queries: *In the purified quantum access model, the quantum query complexity is $\Omega(1/\epsilon)$.*

(2) Samples: *The quantum sample complexity is $\Omega(1/\epsilon^2)$.*

5 Quantum ℓ_α distance estimation for $\alpha > 1$ near 1

In this section, we establish that QSD_α is QSZK-complete for $1 \leq \alpha \leq 1 + \frac{1}{n}$ (see also [52, Theorem 5.1] in the full version), extending the prior result that QSD ($\alpha = 1$) is QSZK-complete, as shown in [77]:

▶ **Theorem 23** (QSD_α is QSZK-complete for $\alpha > 1$ near 1). *Let $a(n)$ and $b(n)$ be efficiently computable functions such that $0 \leq b < a \leq 1$. Then, for any $1 \leq \alpha \leq 1 + \frac{1}{n}$, it holds that*:

For any $a(n)^2 - b(n) \geq 1/O(\log n)$, $\text{QSD}_\alpha[a, b]$ is in QSZK.

Moreover, $\text{QSD}_\alpha[a, b]$ is QSZK-hard if $a(n) \leq 1/2 - 2^{-n^\tau - 1}$ and $b(n) \geq 2^{-n^\tau - \frac{1}{n+1}}$ for every constant $\tau \in (0, 1/2)$ and sufficiently large integer n.

The main challenge in proving Theorem 23 is to establish a QSZK containment of QSD_α under the polarizing regime $a(n)^2 - b(n) \geq 1/O(\log n)$.[10] A direct approach, combining the inequalities between T and T_α (Corollary 19) with the QSZK containment of QSD from [77, 78], only yields a QSZK containment of $\text{QSD}_\alpha[a, b]$ under a *weaker* regime, $a(n)^2/2 - b(n) \geq 1/O(\log n)$. To circumvent this, we provide a (partial) polarization lemma for T_α (Lemma 25), which enables us to achieve the desired QSZK containment in Theorem 23.

The remainder of this section establishes the QSZK containment of QSD_α in Section 5.1. We then show the QSZK hardness of QSD_α (Theorem 26) and derive quantitative lower bounds on query complexity (Theorem 27) and sample complexity (Theorem 28) in Section 5.2.

5.1 QSZK containment via a partial polarization lemma for T_α

▶ **Theorem 24** (QSD_α is in QSZK). *Let $a(n)$ and $b(n)$ be efficiently computable functions satisfying $0 \leq b < a \leq 1$. Then, the following holds*:

$$\textit{For any } \alpha \in \left[1, 1 + \frac{1}{n}\right] \textit{ and any } a(n)^2 - b(n) \geq \frac{1}{O(\log n)}, \text{QSD}_\alpha[a, b] \textit{ is in QSZK.}$$

The proof of Theorem 24 (see also [52, Theorem 5.2] in the full version) can be found in [52, Section 5.1]. The main technical tool is a *partial* polarization lemma for T_α (see also [52, Lemma 5.3]), which ensures that any pair (a, b) within the polarizing regime can be made *constantly* separated:

[10] Notably, similar to the classical cases [12], by reducing to the Quantum Jensen-Shannon Divergence Problem (QJSP) or the Measured Quantum Triangular Discrimination Problem (measQTDP) introduced in [51], the QSZK containment of QSD_α holds slightly beyond the polarizing regime.

▶ **Lemma 25** (A partial polarization lemma for T_α). *Let Q_0 and Q_1 be quantum circuits that prepare quantum states ρ_0 and ρ_1, respectively. There is a deterministic procedure that, given an input (Q_0, Q_1, a, b, k) where $a(n)^2 - b(n) \geq 1/O(\log n)$, outputs new quantum circuits $\widetilde{Q}_0$ and $\widetilde{Q}_1$ that prepare the states $\widetilde{\rho}_0$ and $\widetilde{\rho}_1$, respectively. The resulting states satisfy that*:

$$\begin{aligned} \text{For any } \alpha \in [1, 1+1/n], \quad \mathrm{T}_\alpha(\rho_0, \rho_1) \geq a \quad &\Longrightarrow \quad \mathrm{T}_\alpha(\widetilde{\rho}_0, \widetilde{\rho}_1) \geq (1 - e^{-k})/2, \\ \mathrm{T}_\alpha(\rho_0, \rho_1) \leq b \quad &\Longrightarrow \quad \mathrm{T}_\alpha(\widetilde{\rho}_0, \widetilde{\rho}_1) \leq 1/16. \end{aligned}$$

Here, the states $\widetilde{\rho}_0$ and $\widetilde{\rho}_1$ are defined over $\widetilde{O}\Big(nk^{O\left(\frac{b\ln(2/a^2)}{a^2-b}\right)}\Big)$ qubits. Moreover, when $k \leq O(1)$ or $a^2 - b \geq \Omega(1)$, the time complexity of the procedure is $\mathrm{poly}\Big(|Q_0|, |Q_1|, k, \exp\big(\frac{b\ln(1/a^2)}{a^2-b}\big)\Big)$.

In analogy with polarization lemmas for various classical [12, 21, 66] and quantum [51, 77] closeness measures, the proof of Lemma 25 proceeds by separately reducing the errors on both sides of the problem QSD_α. This is achieved using the XOR lemma ([52, Lemma 5.4]) and the direct product lemma ([52, Lemma 5.5]) for T_α. The full statements of these two lemmas, along with the full proofs of all three, are given in the full version, particularly in [52, Section 5.1].

5.2 Computational hardness and lower bounds for $\alpha > 1$ near 1

▶ **Theorem 26** (QSD_α is QSZK-hard). *For any positive constant $\delta > 0$ that can be made arbitrarily small, the following holds for sufficiently large n:*

(1) *For any $1 \leq \alpha \leq 1 + \frac{1}{n^{1+\delta}}$, $\forall \tau \in (0, 1/2)$, $\mathrm{QSD}_\alpha\big[1 - \gamma_{\delta,\tau}(n), \gamma'_{\delta,\tau}(n)\big]$ is QSZK-hard, where $\gamma_{\delta,\tau}(n) \coloneqq 1 - 2^{-\frac{n+1}{n^{1+\delta}+1}} + 2^{-n^\tau - \frac{n+1}{n^{1+\delta}+1}}$ and $\gamma'_{\delta,\tau}(n) \coloneqq 2^{-n^\tau - \frac{1}{n^{1+\delta}+1}}$.*

(2) *For any $1 + \frac{1}{n^{1+\delta}} < \alpha \leq 1 + \frac{1}{n}$, $\forall \tau \in (0, 1/2)$, $\mathrm{QSD}_\alpha\big[\frac{1}{2} - 2^{-n^\tau - 1}, 2^{-n^\tau - \frac{1}{n+1}}\big]$ is QSZK-hard.*

The proof of Theorem 26 (see also [52, Theorem 5.6]), based on reductions to QSD that is QSZK-hard [77, 78], is provided in the full version, particularly in [52, Section 5.2]. For any n-qubit state ρ of rank r, let ρ_{U} be the corresponding n-qubit state whose eigenvalues are uniformly distributed over the support of ρ. Next, we can establish the following lower bounds (see also [52, Theorem 5.7]), and the proof also can be found in [52, Section 5.2]:

▶ **Theorem 27** (Query complexity lower bounds for QSD_α). *The following query complexity lower bounds hold in the purified quantum query access model, depending on the range of α, where $\delta > 0$ is a constant that can be made arbitrarily small*:

(1) *For any $1 + \frac{1}{n^{1+\delta}} < \alpha \leq 1 + \frac{1}{n}$ and $0 < \epsilon \leq 2^{\frac{1}{\alpha} - 2}$, there exist an n-qubit state ρ of rank r and the corresponding state ρ_{U} such that deciding whether $\mathrm{T}_\alpha(\rho, \rho_{\mathsf{U}})$ is at least ϵ or exactly 0 requires $\Omega(r^{1/3})$ queries.*

(2) *For any $1 \leq \alpha \leq 1 + \frac{1}{n^{1+\delta}}$, there exist a constant $\epsilon > 0$ such that, for some n-qubit state ρ of rank r and the corresponding state ρ_{U}, estimating $\mathrm{T}_\alpha(\rho, \rho_{\mathsf{U}})$ to within additive error ϵ requires $\widetilde{\Omega}(r^{1/2})$ queries.*

By leveraging the same reduction used to prove Theorem 27(1), the rank-dependent sample complexity lower bound (given in [52, Lemma 2.10(2)] in the full version) for estimating the trace distance $\mathrm{T}(\cdot, \cdot)$ can be extended to the quantum ℓ_α distance $\mathrm{T}_\alpha(\cdot, \cdot)$ with $1 \leq \alpha \leq 1 + \frac{1}{n}$, as also stated in [52, Theorem 5.8]:

▶ **Theorem 28** (Sample complexity lower bound for QSD_α). *For any $1 \leq \alpha \leq 1 + \frac{1}{n}$ and $0 \leq \epsilon \leq 2^{\frac{1}{\alpha} - 2}$, there exists an n-qubit state ρ of rank r and the corresponding state ρ_{U} such that deciding whether $\mathrm{T}_\alpha(\rho, \rho_{\mathsf{U}})$ is at least ϵ or exactly 0 requires $\Omega\big(r/\epsilon^2\big)$ samples of ρ.*

Abstract

We show the existence of *length-constrained expander decomposition* in directed graphs and undirected vertex-capacitated graphs. Previously, its existence was shown only in undirected edge-capacitated graphs [24, 21]. Along the way, we prove the multi-commodity maxflow-mincut theorems for length-constrained expansion in both directed and undirected vertex-capacitated graphs. Based on our decomposition, we build a *length-constrained flow shortcut* for undirected vertex-capacitated graphs, which roughly speaking is a set of edges and vertices added to the graph so that every multi-commodity flow demand can be routed with approximately the same vertex-congestion *and* length, but all flow paths only contain few edges. This generalizes the shortcut for undirected edge-capacitated graphs from [20]. Length-constrained expander decomposition and flow shortcuts have been crucial in the recent algorithms in undirected edge-capacitated graphs [20, 23]. Our work thus serves as a foundation to generalize these concepts to directed and vertex-capacitated graphs.

1 Introduction

Expander decomposition found its early applications in property testing [17], clustering [32], and approximation algorithms [10] and, for the last two decades, has been the crucial ingredient in important developments of fast graph algorithms. This includes the first almost-linear time algorithms for spectral sparsifiers and Laplacian solvers [46], approximate

max flow [33, 45, 42], deterministic global min cut [35], exact max flow [12], as well as many almost-optimal dynamic algorithms for minimum spanning trees [41], shortest paths [14, 4], sparsifiers [5], k-edge-connectivity [30], minimum cuts [31, 16], and more [18]. Significant effort [43, 8, 13, 7, 37, 36, 27, 1, 19, 11] has focused on constructing expander decomposition itself. Below, we discuss two successful orthogonal generalizations of expander decomposition.

Vertex and Directed Expander Decomposition. In 2005, Chekuri, Khanna, and Shepherd [10] showed that the construction of expander decomposition in undirected edge-capacitated graphs naturally extends to work in undirected vertex-capacitated graphs and applies them for approximating all-or-nothing vertex-capacitated flow problems. Later, this was extended to directed graphs, an even more general setting [9].[1]

Since 2020, almost-linear time expander decomposition algorithms in these generalized settings have been developed [3, 39, 27, 47] and found impressive applications. For the vertex-capacitated ones, they were crucial for the fastest deterministic vertex connectivity algorithms [44, 40] and data structures for connectivity queries under vertex failures [39, 38, 29]. For the directed ones, they were used for dynamic algorithms in directed graphs [3] and the new combinatorial approaches for exact max flow [15, 2].

Length-Constrained Expander Decomposition and Flow Shortcuts. More recently, Haeupler, Räcke, and Ghaffari [24] introduced *length-constrained expanders* (LC-expanders). At a very high level, these are graphs such that any "reasonable" demand can be routed with low congestion *and* length. In contrast, normal expanders only guarantee low congestion. [24] constructed LC-expander decomposition and applied it to show universally optimal distributed algorithms. In general, LC-expander decomposition is much more effective for problems that simultaneously concern length and congestion.

Based on the new decomposition, [20] introduced the notion of *LC-flow shortcut*[2], a new kind of graph augmentation. Roughly speaking, an LC-flow shortcut is a set of edges and vertices added to the graph so that every multi-commodity flow demand can be routed with approximately the same congestion *and* length, but all flow paths only have a few edges. We use steps, which count the number of edges, to distinguish between edge lengths. This is formalized as follows (see Section 2 for background).

▶ **Definition 1** (Length-Constrained Flow Shortcut). *Given a graph $G = (V, E)$, we say an edge set E' (possibly with endpoints outside V) is a t-step flow shortcut of G with length slack λ and congestion slack κ if*

- *(Forward Mapping) for every demand D routable in G with congestion 1 and length h, D is routable in $G \cup E'$ with congestion 1, length λh, and maximum step t, and*
- *(Backward Mapping) for every demand D on $V(G)$ routable in $G \cup E'$ with congestion 1 and length h, D is routable in G with congestion κ and length h.*

In any undirected edge-capacitated graph, [20] showed, for any $\epsilon > 0$, the existence of a $O(1/\epsilon^2)$-step LC-flow shortcut E' of size $|E'| \leq O(n^{1+O(\epsilon)}\text{polylog}(n))$ with length slack $O(1/\epsilon^3)$ and congestion slack $n^{O(\epsilon)}$.[3] Combined with newly developed close-to-linear time LC-expander decomposition [21, 22], they also obtained a close-to-linear time construction for LC-flow shortcuts albeit with worse quality.

[1] In fact, expander decomposition was only implicit in [10, 9] as their definitions were specific to their applications. The purely graph-theoretic definition was later formalized in [3].

[2] It was called a *low-step flow emulator* in [20].

[3] The shortcut E' in [20] actually has $O(1/\varepsilon^4)$ length slack and $O(1/\varepsilon^2)$ maximum step, but this is only because they tried to ensure that all endpoints of E' are in V. Allowing endpoints outside V, one can replace their *router* with a star and improve the quality to be as we stated.

LC-flow shortcuts have led to significant further progress. This includes the first close-to-linear time constant-approximation algorithm for minimum cost multi-commodity flow [20]. The dynamic but weaker version of flow shortcuts was also the key object in the first deterministic dynamic constant-approximate distance oracle with $O(n^\epsilon)$ update time [23].

However, all applications of LC-expander decomposition until now are limited to undirected edge-capacitated graphs.

1.1 Our Results

To extend the reach of the expander decomposition paradigm further, the history above suggests the following research question:

Can we construct length-constrained expander decomposition and flow shortcuts beyond undirected edge-capacitated graphs?

Indeed, we answer this question affirmatively. In this paper, we focus on the existential results, but the arguments naturally give polynomial-time algorithms. For future work, we are working towards almost-linear-time constructions, which would lead to further applications for minimum cost (multi-commodity) flow in vertex-capacitated and directed graphs. Below, we discuss our contribution in more detail.

Length-Constrained Directed and Vertex Expander Decompositions. We formalize the notions of length-constrained expanders in directed graphs and in undirected vertex-capacitated graphs. Then, we show the existence of length-constrained expander decomposition in directed graphs (Theorem 10) and in undirected vertex-capacitated graphs (Theorem 11). Along the way, we also show that the definition of length-constrained expanders based on cuts is almost equivalent to the characterization based on multi-commodity flow (Theorems 9 and 12). This can be viewed as a version of the approximate multicommodity maxflow mincut theorem [34] but for length-constrained expansion in directed and vertex-capacitated graphs. While this part does not require technical novelty, it is an important foundation for our paper and, we believe, for future work using this concept.

Length-Constrained Vertex-Capacitated Flow Shortcuts. Our main technical contribution (Theorem 14) is to show that, for any undirected *vertex-capacitated* graph and any $\epsilon > 0$, there exists a $2^{O(\frac{1}{\epsilon})}$-step flow shortcut E' of size $|E'| = O(n^{1+O(\epsilon)}\text{polylog}(n))$ with length slack $O(1/\epsilon^3)$ and congestion slack $n^{O(\epsilon)}$. This generalizes the flow shortcut of [20] in undirected edge-capacitated graphs.

Our trade-off between size, length slack, and congestion slack matches the one of [20]. However, our step-bound is $2^{O(\frac{1}{\epsilon})}$ instead of $O(1/\epsilon^2)$. This is due to technical barriers unique to vertex-capacitated graphs, which also requires us to use very different analysis. We leave as a very interesting open problem if it is possible to obtain $\text{poly}(1/\epsilon)$ steps.

We note that obtaining similar LC-flow shortcuts on directed graphs is currently out of reach because it would give the breakthrough on *reachability shortcuts*. Given a graph $G = (V, E)$, an edge set E' is a t-step reachability shortcut of G if, for every pair of vertices $u, v \in V$, u can reach v in G if and only if u can reach v in $G \cup E'$ using at most t steps. Observe that an LC-flow shortcut in a directed graph is strictly stronger than a reachability shortcut. It is a major open problem whether there exists a $n^{o(1)}$-step reachability shortcut of size $n^{1+o(1)}$.[4]

[4] When endpoints of E' must be in V, [26, 28, 6] already showed that there is no $\Omega(n^{1/4})$-step reachability shortcut of size $O(n)$. The lower bounds extend to the shortcut of size $n^{1+\epsilon}$ with a worse step bound.

2 Preliminaries

We give some brief background on length-constrained expansion. A *demand* $D : V \times V \to \mathbb{R}_{\geq 0}$ assigns value to pair of vertices (u, v) and D is *h-length* is it assigns non-zero values only to vertex pairs of distance $\text{dist}_G(u, v) \leq h$ in G. A demand D is *routable* with congestion κ and length λ if there exists a multi-commodity flow routing D with congestion κ and length λ. D *respects* a *node-weighting* $A : V \to \mathbb{R}_{\geq 0}$ if for each vertex u, $\sum_v D(u, v) \leq A(u)$. Let $|A| = \sum_{u \in V} A(u)$. For any $s \geq 1$, A is *(h, s)-length ϕ-expanding in* G if every h-length A-respecting demand is routable with length hs and congestion $O(\frac{\log n}{\phi})$.[5] A length-constrained cut C assigns to each edge an integral length increase, and $G - C$ is the graph G applied with the length increase from cut C. We informally say that G is a *length-constrained expander (LC-expander)* if a node-weighting A whose support is the whole vertex set V is expanding in G. An (h, s)-length ϕ-expander decomposition for A is a length-constrained cut C such that A is (h, s)-length ϕ-expanding in $G - C$.

We use standard graph terminology, deferring details to the full version for further (standard) preliminaries for directed graphs and vertex-capacitated graphs.

2.1 Our Techniques

Next, we give a technical overview of our LC-flow shortcut on vertex-capacitated graphs. We will explain how the strategy used in [20] fails in our setting and how we overcome the obstacle. For simplicity, here we only consider graphs with *unit capacity*. Also, we only construct a slightly weaker notion of LC-flow shortcut in the sense that, it receives an additional length parameter h and the forward mapping only guarantees that every demand routable in G with length $h' \leq h$ and congestion 1 is routable in $G \cup E'$ with length λh, congestion 1 and step t.

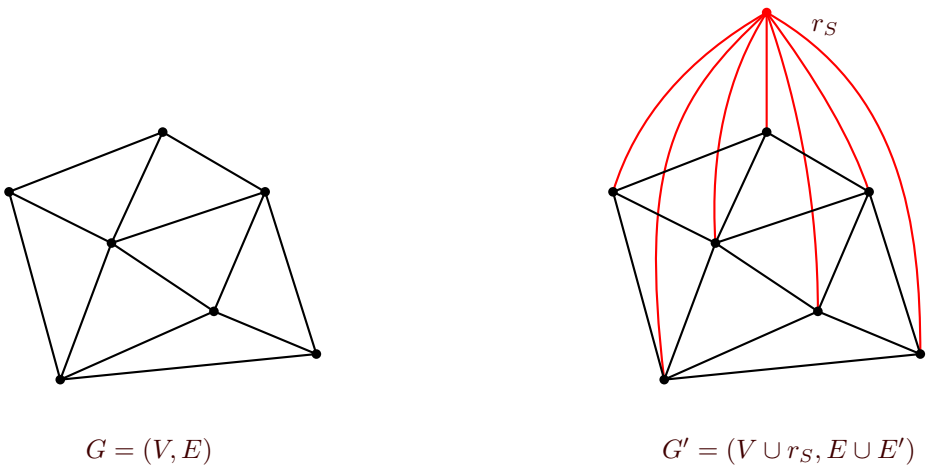

Figure 1 An LC-flow shortcut of a low-diameter LC-expander.

Warm-up: Shortcutting LC-expanders. Before explaining the obstacle, we first show how to shortcut an LC-vertex expander as a warm-up. Suppose that a node-weighting A is (h, s)-length ϕ-vertex expanding in G. Say, $A := \mathbb{1}_V$ (i.e., $A(v) = 1$ for all $v \in V$).

[5] Our definition in the paper (Definition 7) is actually cut-based. This almost-equivalent flow-based definition follows from Theorem 12 and is more convenient in this overview.

Suppose further that G has diameter at most h. In this case, our shortcut is simply a star S connecting each original vertex v to a Steiner vertex r_S with an (hs)-length $A(v)$-capacity edge. We can shortcut any feasible flow in G with 2 steps. An illustrative example is shown in Figure 1. The length slack is $O(s)$ since an h-length original feasible flow is mapped forward to a $(2hs)$-length feasible flow in the star. The congestion slack is $O(\log n/\phi)$ because any feasible flow in the star induces an h-length A-respecting demand. Since A is (h,s)-length ϕ-expanding in G, we route such demand in G with congestion $O(\log n/\phi)$ and without length increasing.

In general, the diameter can be large. Thus, we can construct a *sparse neighborhood cover* to decompose the graph into clusters with diameter h, such that (1) for each vertex v, there is a cluster containing all vertices within distance h/s from v, and (2) each vertex is inside $n^{O(1/s)}$ clusters. Then, we can construct a shortcut by adding an (hs)-edge-length star on each cluster. By a similar argument, we obtain a flow shortcut graph for (h/s)-length original flows with length slack $O(s^2)$, congestion slack $O(n^{O(1/s)}\log n/\phi)$ and step 2.

So far, when we build an LC-flow shortcut for an LC-expander, the vertex-capacitated setting presents no difficulties compared to the edge-capacitated setting, because the above simple approach works in both settings. However, the differences between the two settings arise when generalizing this approach to general graphs via expander hierarchies.

Previous Approach: Shortcutting General Graphs via Boundary-Linkedness. The key idea of [20] is to exploit a hierarchy of *boundary-linked* LC-expander decomposition, defined as follows. Let G be an edge-unit-capacity graph. Initialize the node-weight $A_0 = \deg_G$. For each level $0 \le i \le d$, compute a cut $C_{i+1} \subseteq E$ of size $|C_{i+1}| \approx \phi|A_i|$ such that $A_i + \deg_{C_{i+1}}$ is (h,s)-length ϕ-expanding in $G - C_{i+1}$ where $\deg_{C_{i+1}}(v)$ counts the number of C_{i+1}-edges incident to v.[6] The cut C_{i+1} is called the *boundary-linked* LC-expander decomposition for A_i because it gives a stronger expansion guarantee of $A_i + \deg_{C_{i+1}}$ instead of just A_i. Then, we set $A_{i+1} := \deg_{C_{i+1}}$ and continue to the next level $i+1$. By setting $\phi = 1/(n^{O(1/s)}n^{\varepsilon})$, we have that $d = O(1/\varepsilon)$ and $A_{d+1} = 0$.

From the above construction, we conclude that, for each i, $A_i + A_{i+1}$ is (h,s)-length ϕ-expanding in $G - C_{i+1}$. Therefore, as we have seen in the warm-up, we can add stars on the support of $A_i + A_{i+1}$ so that any flows routing h-length $(A_i + A_{i+1})$-respecting demands in $G - C_{i+1}$ can be shortcut.

Now consider a feasible h-length flow in G. The boundary-linkedness suggests a natural *bottom-up* shortcut scheme. For each flow path P, we can think of routing P's *head packet* and *tail packet* (initially at P's left and right endpoints, denoted by u_0 and v_0) to the same place via shortcuts. Take the head packet as an example. Start with $u_0 \in \mathrm{supp}(A_0) = V$. At each level $0 \le i \le d-1$, let u_{i+1} be the left endpoint of the first $P \cap C_{i+1}$-edge behind u_i. By definition, $u_{i+1} \in \mathrm{supp}(A_{i+1})$ and P's subpath between u_i and u_{i+1} is disjoint from C_{i+1}, so we can use star graphs at level i to route the head packet from u_i to u_{i+1} within 2 steps. In sum, each of the head and tail packets is routed from the bottom up until they reach $u_d, v_d \in \mathrm{supp}(A_d)$, and the top-level star graphs can route them together. The total number of steps is $O(d) = O(1/\epsilon)$[7].

[6] In the actual construction, C_{i+1} assigns fractional values to edges and is called a *moving cut*, defined in Section 3. Here, we assume C_{i+1} is a classic edge cut for simplicity.

[7] We note that the step bound in [20] is $O(1/\epsilon^2)$ because they used powers of expander graphs instead of star graphs to avoid creating vertices outside G, which brought another $O(1/\epsilon)$ factor.

The Obstacle from Vertex Cuts. The overall strategy of the above approach is to shortcut flow paths from a vertex of A_i to an endpoint of edges in C_{i+1}. This was possible since the boundary-linked expander decomposition guarantees that $A_i + \deg_{C_{i+1}}$ is expanding.

In the vertex-capacitated graph, however, the cut $C_{i+1} \subseteq V$ is now a vertex set. To follow the same strategy, we have two natural options. We shortcut flow from a vertex of A_i to either (1) a vertex in C_{i+1}, or (2) a neighbor of C_{i+1}.

In the first case, the strategy requires that $A_i + C_{i+1}$ is expanding in $G - C_{i+1}$. This is trivially impossible because C_{i+1} is not even in the graph $G - C_{i+1}$. In the second case, let $N(C_{i+1})$ denote the neighbors of C_{i+1} that are not in C_{i+1}. The strategy requires $A_i + N(C_{i+1})$ is expanding in $G - C_{i+1}$. However, possibly $N(C_{i+1})$ is very big and has size $|N(C_{i+1})| = \Omega(n|C_{i+1}|)$. It is unlikely that expander decomposition exists to guarantee the expansion of such a large node-weighting. Even if it exists, we would set $A_{i+1} = N(C_{i+1})$ and, hence, we cannot guarantee $|A_{i+1}| \ll |A_i|$. So the number of levels of the hierarchy is unbounded.

In either option, this overall strategy fails in the vertex-capacitated graphs. At a very high level, this is because edges have two endpoints while vertices may have an unbounded number of neighbors.

Our Approach: Top-Down Analysis without Boundary-linkedness. We construct a similar hierarchy of LC-vertex expander decomposition *without* boundary-linkedness as follows. Let $G = (V, E)$ be a vertex-unit-capacity graph. Initialize node-weighting $A_0 = \mathbb{1}_V$. At each level $0 \le i \le d$, computes a cut $C_{i+1} \subseteq V$ such that A_i is (h, s)-length ϕ-vertex-expanding in $G - C_{i+1}$, and set $A_{i+1} := \mathbb{1}_{C_{i+1}}$. In particular, the top level d has $C_{d+1} = \emptyset$. The LC-vertex-expander decomposition guarantees $|C_{i+1}| \approx \phi|A_i|$, so the number d of levels is $O(1/\epsilon)$ by choosing proper ϕ.

Next, we construct the shortcut as follows. For each i, by the expansion of A_i, we can add stars on the support of A_i into our shortcut so that any flows routing h-length A_i-respecting demands in $G - C_{i+1}$ can be shortcut. To analyze the shortcut quality, we will no longer try to route from A_i to A_{i+1} as in the edge-capacitated setting, because we no longer have boundary-linkedness guarantee.

Our analysis is instead *top-down*. At each level i, we shortcut the current flow path as much as possible, and then the prefix and suffix that have not yet been shortcut will be deferred to lower levels as subproblems. To be more concrete, say our initial goal is to shortcut a flow path P in a feasible h-length original flow. At each level $0 \le i \le d$, assume we will receive a subpath P' of P with length at most h in $G - C_{i+1}$ (note that P is a valid input to the top level d because C_{d+1} is empty). We will shortcut P' using star graphs at levels up to i as follows (see Figure 2 for an illustration when $i = 1$).

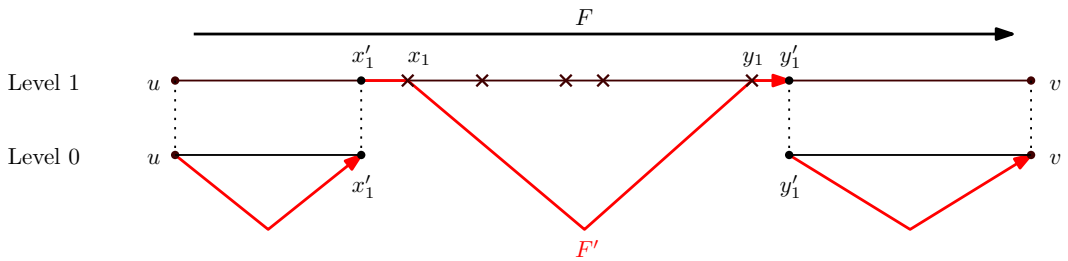

Figure 2 A toy example of forward mapping given we have 2 levels in total. Crossings represent cut vertices in C_1 along the witness path $P_{u,v}$.

Step 1. Let x_i and y_i be the first and last P'-vertices in $\text{supp}(A_i)$ respectively. We can easily shortcut the subpath $P'[x_i, y_i]$ (i.e. the subpath from x_i to y_i) within 2 steps using the star graphs at level i.

Step 2. Let x'_i be the P'-vertex right before x_i and let y'_i be the P'-vertex right after y_i. We regard shortcutting the prefix $P'[u, x'_i]$ and the suffix $P'[y'_i, v]$ as two subproblems at level $i-1$, where u, v are endpoints of P'. Note that both $P'[u, x'_i]$ and $P'[y'_i, v]$ has length at most h in $G - C_i$ because they are disjoint from C_i by definition.

Step 3. After the recursion, we obtain shortcuts for both $P'[u, x'_i]$ and $P'[y'_i, v]$. The shortcut for P' is given by concatenating shortcuts for $P'[u, x'_i], P'[x_i, y_i]$ and $P'[y'_i, v]$ using two original edges (x'_i, x_i) and (y_i, y'_i).

It is not hard to see the final step bound is $2^{O(d)} = 2^{O(1/\epsilon)}$ since the recursion has d levels and each level has two branches. We note that the actual argument is more complicated because the cuts C_i are actually moving cuts which have fractional cut values, and there is no clear partition of P' into 3 parts.

3 Length-Constrained Directed Expansion

In this section, we follow the theory of length-constrained expansion and extend it to the setting of directed graphs. We start with the generalization of notations from length-constrained expanders, which serves as the foundation for subsequent results. Next, we characterize length-constrained expansion in directed graphs with routing, and show the existence of length-constrained directed expander decomposition.

Basic Concepts of Length-Constrained Directed Expansion. The following definition of moving cuts and separation was introduced by Haeupler, Wajc and Zuzic in [25].

▶ **Definition 2** (Length-Constrained Cut). *An h-length moving cut $C : E \mapsto \{0, \frac{1}{h}, \frac{2}{h}, \ldots, 1\}$ assigns to each edge e a fractional cut value between zero and one which is a multiple of $\frac{1}{h}$. The* size *of C is defined as $|C| = \sum_e u(e) \cdot C(e)$. The length increase associated with the h-length moving cut C is denoted with $\ell_{C,h}$ and defined as assigning an edge e the length increase $\ell_{C,h}(e) = h \cdot C(e)$. Any moving cut which only assigns cut values equal to either 0 or 1 is called a pure moving cut. We define the degree of a moving cut over vertex v to be $\deg_C(v) = \sum_{e \ni v} u_G(e) \cdot C(e)$.*

▶ **Definition 3** (h-Length Separated Demand). *For any demand D and any h-length moving cut C, we define the amount of h-length separated demand as the sum of demands between vertices that are h-length separated by C. We denote this quantity with $\text{sep}_h(C, D)$, i.e.,*

$$\text{sep}_h(C, D) = \sum_{u,v:\text{dist}_{G-C}(u,v)>h} D(u, v).$$

▶ **Definition 4** (h-Length Sparsity of a Cut C for Demand D). *For any demand D and any h-length moving cut C with $\text{sep}_h(C, D) > 0$, the h-length sparsity of C with respect to D is the ratio of C's size to how much demand it h-length separates i.e.,*

$$\text{spars}_h(C, D) = \frac{|C|}{\text{sep}_h(C, D)}.$$

Above we generalize the definition of length-constrained moving cut w.r.t arbitrary directed h-length demand. However, for the definition of a directed length-constrained expander, we restrict to symmetric h-length demands.

▶ **Definition 5** ((h,s)-Length Sparsity of a Cut w.r.t. a Node-Weighting). *The (h,s)-length sparsity of any $h \cdot s$-length moving cut C with respect to a node-weighting A is defined as:*

$$\text{spars}_{(h,s)}(C, A) = \min_{A\text{-respecting } h\text{-length symmetric demand } D} \text{spars}_{h\cdot s}(C, D).$$

Intuitively, $(h \cdot s)$-length sparsity of a cut measures how much it $h \cdot s$-length separates h-length demand w.r.t its own size. Furthermore, for a given node-weighting, we associate the sparsest cut w.r.t the node-weighting with its conductance.

▶ **Definition 6** ((h,s)-Length Conductance of a Node-Weighting). *The (h,s)-length conductance of a node-weighting A in a graph G is defined as the (h,s)-length sparsity of the sparsest $h \cdot s$-length moving cut C with respect to A, i.e.,*

$$\text{cond}_{(h,s)}(A) = \min_{h\cdot s\text{-length moving cut } C} \text{spars}_{(h,s)}(C, A).$$

▶ **Definition 7** ((h,s)-Length ϕ-Expanding Node-Weightings). *We say a node-weighting A is (h,s)-length ϕ-expanding if the (h,s)-length conductance of A in G is at least ϕ.*

To see the connection, in the full version, we explain how our notion of length-constrained directed expansion generalizes the non-length-constrained version. Lastly, we give the formal definition of length-constrained directed expander decompositions as follows:

▶ **Definition 8** (Length-Constrained Directed Expander Decomposition). *Given a graph $G = (V, E)$, a directed (h,s)-length ϕ-expander decomposition for a node-weighting A with length slack s and cut slack κ is an $h \cdot s$-length cut C of size at most $\kappa \cdot \phi|A|$ such that A is (h,s)-length ϕ-expanding in $G - C$.*

Routing Characterization of Length-Constrained Directed Expansion. The definition of ϕ-expanding characterizes the sparsity of moving cuts in directed graphs. With the routing characterization, we further show that sparsity is closely related to demand routing.

▶ **Theorem 9** (Routing Characterization of Length-Constrained Directed Expanders). *Given a directed graph G and node-weighting A, for any $h \geq 1$, $\phi < 1$ and $s \geq 1$ we have:*

- *If A is (h,s)-length ϕ-expanding in G, then every A-respecting h-length symmetric demand can be routed in G with congestion at most $O(\frac{\log N}{\phi})$ and length at most $h \cdot s$.*
- *If A is not (h,s)-length ϕ-expanding in G, then some A-respecting h-length symmetric demand cannot be routed with congestion at most $\frac{1}{2\phi}$ and length at most $\frac{h\cdot s}{2}$.*

The proof idea of Theorem 9 is similar to the undirected case as shown in [24], and for completeness, we restate and adapt the proof for the directed setting in the full version.

Existence of Length-Constrained Directed Expander Decompositions. Now, we prove the existence of length-constrained directed expander decompositions. The following theorem formally states the result:

▶ **Theorem 10.** *For any $G = (V, E)$, a node-weighting A, $h > 1$, $\alpha \geq 1$, $\phi < 1$ and a length slack parameter $s = O(\log n)$, there is a directed (h,s)-length ϕ-expander decomposition for A with cut slack $\kappa = O(n^{O(\frac{1}{s})} \log n)$.*

The proof of Theorem 10 closely follows the undirected-case proof in [24], and we append it in the full version for completeness. The basic idea is that, unless the graph is already an (h, s)-length ϕ-expander for node-weighting A, we can repeatedly identify and apply cuts with (h, s)-sparsity less than ϕ. The union of these cuts ultimately renders the graph as an (h, s)-length ϕ-expander. To bound for the total size of all cuts, we sum individual cut sizes. However, since each cut size depends on the sparsity associated with different demands, analysis becomes complex. Thus, we first introduce a special base demand, called exponential demand to relate all other demands in terms of sparsity. Using this, we apply a potential argument to prove the above main theorem.

In the full version, we further discuss *boundary-linked* LC-directed expander decomposition (also called *linked* LC-directed expander decomposition). Expander decompositions with boundary-linkedness have been shown to be very useful in the length-constrained undirected setting and the classic (i.e. non-length-constrained) setting.

4 Length-Constrained Vertex Expansion

In this section we extend the theory of length-constrained expander decomposition to vertex-capacitated graphs. The basic concepts of length-constrained vertex expansion are analogous to those of length-constrained directed expansion in Section 3. The major difference is that now a moving cut C can assign cut values to both vertices and edges. See the full version for preliminaries and formal description of the basic concepts of vertex-capacitated graphs.

The main results of this section is the existence of length-constrained expander decomposition for vertex-capacitated graphs (Theorem 11) and the routing characterization of length-constrained vertex expanders (Theorem 12).

▶ **Theorem 11** (Existential (h, s)-length Expander Decomposition for Vetex-Capacitated Graphs)**.** *For any vertex-capacitated graph $G_{\text{vc}} = (V_{\text{vc}}, E_{\text{vc}})$, node-weighting A_{vc}, $h > 1$, $\phi < 1$ and a length slack parameter $s = O(\log n)$, there is an (h, s)-length ϕ-expander decomposition for A with cut slack $\kappa = O(n^{O(\frac{1}{s})} \log n)$.*

▶ **Theorem 12** (Routing Characterization of Length-Constrained Vertex Expanders)**.** *Given a vertex-capacitated graph G_{vc} and node-weighting A_{vc}, for any $h \geq 1$, $\phi < 1$ and $s \geq 1$ we have:*

- *If A_{vc} is (h, s)-length ϕ-expanding in G_{vc}, then every h-length A_{vc}-respecting demand can be routed in G_{vc} wth congestion at most $O(\frac{\log N}{\phi})$ and dilation at most $h \cdot s$.*
- *If A_{vc} is not (h, s)-length ϕ-expanding in G_{vc}, then some h-length A_{vc}-respecting demand cannot be routed with congestion at most $\frac{1}{6\phi}$ and dilation at most $\frac{h \cdot s}{2}$.*

The proofs of above are in the full version. We introduce a reduction that transforms vertex-capacitated graphs into directed edge-capacitated graphs to show the equivalence, which is crucial for the proofs of Theorem 11 and Theorem 12.

5 Length-Constrained Vertex-Capacitated Flow Shortcuts

In this section, we show the existence of LC-flow shortcuts in vertex-capacitated graphs. The Definition 13 below generalizes Definition 1 of LC-flow shortcuts in the sense that an additional length parameter h is given and the forward mapping only holds for demands routable in G with congestion 1 and length at most h.

Algorithm 1 LC-FlowShortcut(G, ϵ, h).

Initialize $A_0 = u_{V(G)}$, where $u_{V(G)}$ denotes the vertex capacity function of G.
Initialize $s = 1/\epsilon$, $\phi = 1/(n^{\epsilon}\kappa)$ ($\kappa = O(n^{O(1/s)} \log n)$ is the cut slack from Theorem 11).
Initialize $i \leftarrow 0$.
while $|A_i| > 0$ **do**
  for j from 1 to $\lceil \log_2 h \rceil$ **do**
    $h_j \leftarrow 2^j, h_{\mathrm{cov},j} = 4h_j, h_{\mathrm{diam},j} = h_{\mathrm{cov},j} \cdot s$.
    $C_{i+1,j} \leftarrow$ an $(h_{\mathrm{diam},j}, s)$-length ϕ-expander decomposition of A_i in G by Theorem 11.
    $\mathcal{N}_{i,j} \leftarrow$ a neighborhood cover with covering radius $h_{\mathrm{cov},j}$, diameter $h_{\mathrm{diam},j}$ in $G - C_{i+1,j}$ by Theorem 2.1 in the full version.
    $H_{i,j} = \bigcup_{S \in \mathcal{N}_{i,j}} H_S$, where H_S is the $h_j s$-length A_i-capacitated star graph on S.
  end for
  $A_{i+1} = \sum_j \frac{h_{\mathrm{diam},j} \cdot s}{h_j} \cdot \deg_{C_{i+1,j}} = 4s^2 \cdot \sum_j \deg_{C_{i+1,j}}$.
end while
Return $E' = \bigcup_{i,j} E(H_{i,j})$.

▶ **Definition 13** (Length-Constrained Flow Shortcut). *Given a graph $G = (V, E)$, we say an edge set E' (possibly with endpoints outside V) is an t-step h-LC-flow shortcut of G with length slack λ and congestion slack κ if*

- *(Forward Mapping) for every demand D routable in G with congestion 1 and length $h' \le h$, D is routable in $G \cup E'$ with congestion 1, length $\lambda h'$, and maximum step t, and*
- *(Backward Mapping) for every demand D on $V(G)$ routable in $G \cup E'$ with congestion 1 and length h', D is routable in G with congestion κ and length h'.*

We note that in [20] there is an analogous but weaker definition of h-LC-flow shortcut, in which the forward mapping only guarantee that D is routable in $G \cup E'$ with length λh instead of $\lambda h'$ (and the same congestion and step). That is, the length slack in Definition 13 is *competitive* in the sense that it upper bounds the ratio between the lengths of the shortcut flow and the original flow. Hence, by choosing a sufficiently large h, the total length of vertices and edges in G, an h-LC-flow shortcut is automatically an LC-flow shortcut.

▶ **Theorem 14.** *Given a vertex-capacitated graph G with parameters $\epsilon = \Omega(\frac{1}{\log n})$, there exists a t-step LC-flow shortcut E' with length slack $O(1/\epsilon^3)$, congestion slack $O(n^{O(\epsilon)} \log^3 n/\epsilon^2)$, $t = 2^{O(\frac{1}{\epsilon})}$ and size $|E'| \le O(n^{1+O(\epsilon)} \log n/\epsilon^2)$.*

Theorem 14 is the main theorem of this section. In what follows, actually we will focus on constructing h-LC-flow shortcut. Setting $h = (m+n)N$ gives the LC-flow shortcut in Theorem 14.

5.1 The Construction

The construction of the flow shortcut graph G' is given by Algorithm 1. The star graphs in Algorithm 1 are formally defined in Definition 15.

▶ **Definition 15** (Star Graphs). *Given a graph G with a node-weighting A and a length parameter h, the h-length A-capacitated star graph on some $S \subseteq V(G)$, denoted by H_S, has*

$$V(H_S) = (\mathrm{supp}(A) \cap S) \cup \{r_S\} \text{ and } E(H_S) = \{(v, r_S) \mid v \in V(H_S) \setminus \{r_S\}\},$$

where the vertex r_S is a Steiner vertex serving as the center and $V(H_S) \setminus \{r_S\}$ are original vertices. The length and capacity of each original vertex is unchanged, while r_S has length 1 and capacity $\sum_{v \in S} A(v)$. Each edge (v, r_S) has length h and capacity $A(v)$.

In short, Algorithm 1 mainly constructs a length-constrained expander hierarchy

$$\{A_i, C_{i+1,j} \mid 0 \le i \le d, 1 \le j \le \lceil \log_2 h \rceil\}$$

where d is the largest i such that $|A_i| > 0$. We point out that $C_{d+1,j}$ is a zero cut for all j. Then the shortcut graph G' is obtained by adding star graphs on neighborhoods of each LC-expander $G - C_{i+1,j}$.

We remark that we do LC-expander decompositions with different length parameters h_j at one level because we aim at a shortcut graph with length slack significantly smaller than its step bound. Intuitively, if we only use LC-expanders with length parameter around h to shortcut an original h-length flow path P, then inevitably each step will have length around h, which means the length slack cannot go far below the number of steps. Now, providing LC-expanders with different length parameters, when we want to shortcut a subpath of P with length h' far smaller than h, we can choose the appropriate LC-expander to obtain a shortcut with length around h' instead of h. Another benefit is that this automatically gives a competitive length slack (this is why in Definition 13 we define the length slack of h-LC-flow shortcut to be competitive).

We first argue the size bound of E'. Observe that, in Algorithm 1, we have $|C_{i+1,j}| \le \kappa\phi|A_i| \le |A_i|/n^\epsilon$ by Theorem 11. In Algorithm 1, the width of each neighborhood cover $\mathcal{N}_{i,j}$ is $\omega = n^{O(1/s)}s = n^{O(\epsilon)}/\epsilon$ by Theorem 2.1 in the full version. Furthermore, because in Algorithm 1 we have $|A_{i+1}| \le 4s^2 \sum_{j'} |C_{i+1,j'}| \le 4s^2 \log h |A_i|/n^\epsilon = O(\log N/(\epsilon^2 n^\epsilon))|A_i|$, we can upper bound d by $d \le O(\log |A_0|/\log(\epsilon^2 n^\epsilon/\log N)) = O(1/\epsilon)$. Finally, by the algorithm, we have

$$|E'| \le O(d \log h) \cdot \omega \cdot n = O(n^{1+O(\epsilon)} \log n/\epsilon^2).$$

Next we show the quality of the shortcut. Before that, we introduce a helper lemma Lemma 16, which shows the demands that each $H_{i,j}$ can route within small steps. We defer its proof to the full version.

▶ **Lemma 16.** *For each i, j, any demand $\hat{D}$ that is $h_{\mathrm{cov},j}$-length in $G - C_{i+1,j}$, A_i-respecting and $u_{V(G)}$-respecting can be routed in $H_{i,j}$ with length $2h_{\mathrm{diam},j}s + 1$, congestion 1 and step 2.*

Now we show that the shortcut E' constructed by Algorithm 1 has length slack $O(1/\epsilon^3)$, congestion slack $n^{O(\epsilon)}$ and step $2^{O(1/\epsilon)}$. To do this, it suffices to show the quality of the forward mapping and backward mapping, i.e. Lemma 17 and Lemma 18, whose proofs are given in Section 5.2 and the full version. Let $G' = G \cup E'$ be the shortcut graph.

▶ **Lemma 17** (Forward Mapping). *For any feasible h-length flow F in G, there is a feasible flow F' routing $\mathrm{Dem}(F)$ in G' with $\mathrm{leng}(F') \le \mathrm{leng}(F) \cdot O(1/\epsilon^3)$ and $\mathrm{step}(F') \le 2^{O(1/\epsilon)}$.*

▶ **Lemma 18** (Backward Mapping). *For any feasible flow F' in G' such that $V(\mathrm{Dem}(F')) \subseteq V(G)$, there is a flow F routing $\mathrm{Dem}(F')$ in G with $\mathrm{leng}(F) \le \mathrm{leng}(F')$ and $\mathrm{cong}(F) \le n^{O(\epsilon)}$.*

5.2 Forward Mapping: Proof of Lemma 17

We will employ a top-down argument. Start from the top level d. At the beginning of processing a level $i \geq 0$, we are given a feasible flow F_i with the following invariant: each flow path $P \in \text{path}(F_i)$ has $\text{leng}(P, G - C_{i+1,j}) \leq h_{\text{cov},j} = 4h_j$, where j is the minimum index s.t. $h_j \geq \text{leng}(P, G)$ (which means $h_j/2 \leq \text{leng}(P, G) \leq h_j$). Initially at the top level d, we set $F_d = F$. Note that F_d satisfies the invariant above because $C_{d+1,j}$ is a zero cut for any j.

First, at the bottom level $i = 0$, we can easily shortcut every flow path in F_0. For each star graph $H_{0,j}$, we assign it a demand $\hat{D}_{0,j}$ which sums over $\text{Dem}(P)$ for each flow path $P \in \text{path}(F_0)$ such that j is the minimum index with $h_j \geq \text{leng}(P, G)$. Observe that each $\hat{D}_{0,j}$ is an $h_{\text{cov},j}$-length in $G - C_{1,j}$ and A_0-respecting, so it can be routed in $H_{0,j}$ with length $2h_{\text{diam},j}s + 1$, congestion 1 and step 2 by Lemma 16.

From now on we consider levels $i \geq 1$. When processing a level i, for each flow path $P \in \text{path}(F_i)$, we may shortcut some subpaths of P using shortcut edges in H. The subpaths of P that have not been shortcut will be added to F_{i-1}, meaning that they are deferred to lower levels to get shortcut. At the end, the final F_{i-1} should ensure the invariants above, and we proceed to the lower level $i - 1$.

Now we will explain the shortcut at a level $i \geq 1$ in detail. Fix a flow path $P \in \text{path}(F_i)$. Let j be the minimum index such that $h_j \geq \text{leng}(P, G)$. We consider two cases.

Case 1: Defer. When $4s^2 \cdot \sum_{j'} C_{i,j'}(P) \leq 3$, we simply add P to F_{i-1}. We have

$$\text{leng}(P, G - C_{i,j}) = \text{leng}(P, G) + h_{\text{diam},j} \cdot s \cdot C_{i,j}(P) \leq 4h_j \leq h_{\text{cov},j},$$

where the inequality is by $\text{leng}(P, G) \leq h_j$, $h_{\text{diam},j} = 4sh_j$ and $C_{i,j}(P) \leq 3/(4s^2)$. Therefore, in this case, the flow path added to F_{i-1} satisfies the invariant.

Case 2: Shortcut. Now suppose $4s^2 \cdot \sum_{j'} C_{i,j'}(P) > 3$. Let u and v be P's endpoints. We say u is the left side and v the right side. For each $0 \leq k \leq |P|$, we refer to w_k as the P-vertex with k steps away from u. In particular, $w_0 = u$ and $w_{|P|} = v$.

We now define two functions $x : V(P) \to \mathbb{R}$ denoting the *budgets* of P-vertices from the left and the right respectively: for each vertex $w_k \in V(P)$,

$$x_P(w_k) = 4s^2 \sum_{j'} C_{i,j'}(w_{k-1}, w_k) + C_{i,j'}(w_k) + C_{i,j'}(w_k, w_{k+1}).$$

In particular,

$$x_P(w_0) = 4s^2 \sum_{j'} C_{i,j'}(w_0) + C_{i,j'}(w_0, w_1) \text{ and}$$

$$x_P(w_{|P|}) = 4s^2 \sum_{j'} C_{i,j'}(w_{|P|-1}, w_{|P|}) + C_{i,j'}(w_{|P|}).$$

Let k_L be the minimum index such that $\sum_{0 \leq k \leq k_L} x_P(w_k) \geq 1$, and symmetrically let k_R be the maximum index such that $\sum_{k_R \leq k \leq |P|} x_P(w_k) \geq 1$. To avoid clutter, we let $L = \{w_0, ..., w_{k_L}\}$ and $R = \{w_{k_R}, ..., w_{|P|}\}$. The following Claim 19 says that L and R have at most one common vertex.

▷ Claim 19. $k_L \leq k_R$.

Proof. By the definition of k_L and k_R, we have

$$\sum_{0\le k\le k_L-1} x_P(w_k) < 1 \text{ and } \sum_{k_R+1\le k\le |P|} x_P(w_k) < 1.$$

However, $\sum_{0\le k\le |P|} x_P(w_k) \ge 4s^2 \sum_{j'} C_{i,j'}(P) > 3$. This means there exists a vertex w_k with $k_L - 1 < k < k_R + 1$, which implies $k_L \le k_R$ ◁

We assign each vertex $w \in L \cup R$ a *load* $x'_P(w) \le x_P(w)$, satisfying that $\sum_{w\in L} x'_P(w) = 1$ and $\sum_{w\in R} x'_P(w) = 1$. We consider the following three-phase strategy to route $F_i(P)$ flow units from u to v. *Phase 1:* the vertex u sends $F_i(P)$ flow units and each $w \in L$ receives $F_i(P)x'_P(w)$ units. *Phase 2:* Each vertex $w \in L$ sends $F_i(P)x'_P(w)$ units and each vertex $w \in R$ receives $F_i(P)x'_P(w)$ units. *Phase 3:* Each vertex $w \in R$ sends exactly $F_i(P)x'_P(w)$ units, and the vertex v receives $F_i(P)$ units.

The First and Third Phases. Roughly speaking, for the first and third phases, we will add their corresponding original flows into F_{i-1}, meaning that they will be deferred to lower levels to get shortcut.

Regarding the first phase, recall that for each $w_k \in L$, we want to route $F_i(P)x'(w_k)$ units from u to w_k. To do this, we add into F_{i-1} a flow path $P_k = P[w_0, w_{k-1}]$ with value $F_i(P)\cdot x'(w_k)$. That is, we require the lower levels to give a shortcut that routes $F_i(P)\cdot x'(w_k)$ from u to w_{k-1} (the P-vertex one step closer to u than w_k). Then, we route $F_i(P)x'(w_k)$ units from w_{k-1} to w_k using the original edge $(w_{k-1}, w_k) \in E(G)$.

The third phase is handled in a similar way. For each $w_k \in R$, we route $F_i(P)x'(w_k)$ flow units from w_k to w_{k+1} using the original edge (w_{k-1}, w_k), and then we add into F_{i-1} a flow path $P_k = P[w_{k+1}, v]$ with value $F_i(P) \cdot x'(w_k)$.

To proceed to the lower level $i-1$, it remains to show that the flow paths added into F_{i-1} satisfy the invariant. Consider a flow path $P_k = P[u, w_{k-1}]$ added from the first phase (where $w_k \le L$, i.e. $0 \le k \le k_L$). We want to show that $\text{leng}(P_k, G - C_{i,j_k}) \le h_{\text{cov},j_k}$, where j_k is the minimum index such that $h_{j_k} \ge \text{leng}(P_k, G)$. By the definition of the budget function x, we have $\sum_{j'} C_{i,j'}(P_k) \le \frac{1}{4s^2} \sum_{0\le k'\le k-1} x_P(w_{k'}) < 1/(4s^2)$, where the second inequality is by $k \le k_L$ and $\sum_{0\le k'\le k_L-1} x_P(w_{k'}) < 1$ (from the definition of k_L). In particular, $C_{i,j_k}(P_k) \le 1/(4s^2)$. Because C_{i,j_k} is an $(h_{\text{diam},j_k} s)$-length moving cut, we have

$$\text{leng}(P_k, G - C_{i,j_k}) = \text{leng}(P_k, G) + h_{\text{diam},j_k} \cdot s \cdot C_{i,j_k}(P_k) \le 2h_{j_k} \le h_{\text{cov},j_k},$$

as desired, where the first inequality uses $h_{\text{diam},j_k} = 4sh_{j_k}$. By a similar argument, we can show that each flow path added from the third phase also satisfies the invariant, so we will not explain it in detail.

The Second Phase. The second phase is where the shortcut happens. We define an arbitrary (multi-commodity) demand $\hat{D}_{i,P}$ capturing this single-commodity demand. Namely, $\hat{D}_{i,P}$ satisfies that (1) $|\hat{D}_{i,P}| = F_i(P)$; (2) for each $w \in L$, $\hat{D}_{i,P}(w, \cdot) = F_i(P)x'_P(w)$; and (3) for each $w \in R$, $\hat{D}_{i,P}(\cdot, w) = F_i(P)x'_P(w)$. We will *assign* $\hat{D}_{i,P}$ to $H_{i,j}$, meaning that we route $\hat{D}_{i,P}$ using shortcut edges in $H_{i,j}$.

By the above assignment, for each $H_{i,j}$ at level i, its total assigned demand, denoted by $\hat{D}_{i,j}$, sums over $\hat{D}_{i,P}$ of all $P \in \text{path}(F_i)$ s.t. j is the minimum index with $h_j \ge \text{leng}(P, G)$. The following Lemma 20 showing that $\hat{D}_{i,j}$ can be routed with low steps, small length and congestion 1, and we defer the proof to the full version.

▶ **Lemma 20.** *For each $H_{i,j}$ at level i, its total assigned demand $\hat{D}_{i,j}$ can be routed in $H_{i,j}$ with length $2h_{\mathrm{diam},j}s + 1$, congestion 1 and step 2.*

Quality of the Forward Mapping. It remains to show that $\mathrm{Dem}(F)$ can be routed in $G' = G \cup \bigcup_{i,j} H_{i,j}$ with length $\mathrm{leng}(F) \cdot O(1/\epsilon^3)$, congestion 1 and step $2^{O(1/\epsilon)}$. The proof for this can be found in the full version.

Deterministic Approximation Algorithm for Graph Burning

Matej Lieskovský
Faculty of Mathematics and Physics, Computer Science Institute of Charles University, Prague, Czech Republic

Abstract

Graph Burning models a contagion spreading in a network as a process such that in each step one node is infected and also the infection spreads to all neighbors of previously infected nodes. Formally, the burning number $b(G)$ of a given graph $G = (V, E)$, possibly with edge lengths, is the minimum number g such that there exists a sequence of nodes $v_1, \ldots, v_g$ satisfying the property that for each $w \in V$ there exists $i \in \{1, \ldots, g\}$ so that the distance between w and v_i is at most $g - i$.

We present an elegant deterministic 2.314-approximation algorithm for the Graph Burning problem on general graphs with arbitrary edge lengths. This algorithm matches the approximation ratio of the previous randomized 2.314-approximation algorithm and improves on the previous deterministic 3-approximation algorithm.

1 Introduction

Graph Burning was introduced by Bonato et al. [2, 1] as a model of a contagion or information spreading in social networks. It demonstrates how strategically selecting a sequence of nodes to "infect" while letting this infection spread over time may reach the entire network relatively quickly. Formally, we study the following process, where *burned* nodes in a graph represent the infected part of the network.

We are given a graph G and a sequence S of length g where the individual elements $S_1, \ldots, S_g$ of the sequence are either nodes of the graph or "null". At time $t = 0$, no nodes are burned. At time $t = 1$, we burn node S_1. At each time step $t > 1$, all neighbors of already burned nodes also become burned and we also burn node S_t unless S_t is "null". If all nodes are burned at time $t = g$, we call S a *burning sequence* of G of length g. The burning number $b(G)$ of a graph G is the length of its shortest burning sequence.

We can also view a burning sequence as a set of centers where the center (v, r) corresponds to S_{g-r} being the node v, ensuring that any node w with distance $d(w, v) \leq r$ is burned. This generalizes naturally in the presence of arbitrary edge lengths and showcases the relation of Graph Burning to the k-Center problem. We call r the *radius* of center (v, r).

We know that $b(G) \leq |V(G)|$ holds for all graphs. If we prove that some algorithm finds a valid burning sequence of length g in polynomial time whenever $g \geq \lfloor \rho\, b(G) \rfloor$ for some ρ, then we can create a ρ-approximation algorithm for the Graph Burning problem by trying all possible values of g. For the rest of this paper, we talk about these algorithms that take the target value of g as input and take as granted that they imply the corresponding approximation algorithms.

1.1 Our results

We present a simple α-approximation algorithm for the Graph Burning problem on graphs with arbitrary edge lengths where $\alpha = 2e^2/(e^2-1) < 2.314$. We use this value of α throughout the paper.

1.2 Previous results

Bonato and Kamali [3] adapted a well-known greedy 2-approximation algorithm for the k-Center problem into a $(3 - 2/b(G))$-approximation algorithm for Graph Burning. A direct greedy algorithm was given by García-Díaz, Pérez-Sansalvador, and Rodríguez-Hénríquez [5]. We are not aware of any better deterministic algorithms for general graphs.

Lieskovský, Sgall, and Feldmann [11] gave a randomized $(\alpha + \varepsilon)$-approximation algorithm for Graph Burning as well as a pair of lower bounds – 4/3 for graphs with unit-length edges and 2 for graphs with edge lengths. Their algorithm repeatedly selects an arbitrary uncovered node and uses randomization to select a radius, creating a new center. Martingales are used to estimate the number of centers needed and a collision resolution method inspired by linear probing prevents the creation of multiple centers with the same radius.

Approximation algorithms and approximation schemes were developed for various special graph classes by Bonato and Kamali [3], Bonato and Lidbetter [4] and others, ultimately resulting in a PTAS for graphs of small treewidth by Lieskovský and Sgall [10].

2 Definitions and algorithm

In this section we first establish some fundamental concepts and then describe our algorithm. The concepts established in this section will be crucial for the analysis of our algorithm in the following two sections.

2.1 Fundamental concepts

For the analysis of our algorithm, we fix a graph G and some optimal solution OPT, which we will view as set of centers (v, r) with radii from 0 to $b(G) - 1$. In the interest of clarity we will, for the rest of this paper, use "centers" exclusively to refer to centers in this optimal solution while the algorithm will be modifying a "sequence" of nodes of some given length g, until it becomes a valid burning sequence of the graph.

We assign each node $w \in V$ to a unique center $c_{\text{OPT}}(w)$ that is covering it (i.e., $d(w, v) \leq r$), thus creating a partition of the set of nodes of the graph.

For every center (v, r) we denote the set of nodes assigned to it as $V(v, r)$. We say that a center (v, r) is *covered* by a sequence S if all nodes in $V(v, r)$ are burned by the sequence.

A central part of our algorithm is the process for modifying the sequence. We view the sequence S as a queue of length g and use the procedure $\text{push}(v, S)$ to add v to the front of the sequence and remove the last element. Thus if $S = S_1, S_2, S_3, \ldots, S_{g-1}, S_g$, then $\text{push}(v, S) = v, S_1, S_2, S_3, \ldots, S_{g-1}$.

Our algorithm works in *cycles*, selecting one unburned node and pushing it into the sequence in each cycle. Note that cycles are distinct from the time steps in the definition of the Graph Burning problem. We number the cycles starting from 0. We say that a center (v, r) is *serviced* whenever any node in $V(v, r)$ is selected by the algorithm.

Suppose that a $w \in V(v, r)$ is selected in cycle i. At the start of cycle $i + 1$, w is at the start of the burning sequence, ensuring that all nodes within distance $g - 1$ from it are burned by the sequence. With each further cycle, the node is moved to later position in the sequence, reducing the area it ensures the burning of.

▶ **Observation 1.** *If center (v, r) is serviced in cycle i, then it will be covered at the start of cycles $i+1$ to $i+g-2r$.*

2.2 Our algorithm

The algorithm is given a graph G and a guess g for the burning number. It starts with a sequence of length g where all elements are "null", which obviously leaves all nodes unburned. While any such unburned nodes remain, the algorithm selects one of them arbitrarily and pushes it into the sequence. When no unburned nodes remain, the sequence S is a valid burning sequence of G.

Algorithm 1 Deterministic Approximation Algorithm for Graph Burning.

```
1: function BURN(graph G, g ∈ ℕ)
2:     S ← queue containing g "null" elements
3:     while an unburned node exists do
4:         select arbitrary unburned node v
5:         S ← push(v, S)
6:     return S
```

3 Simple results

In this section, we analyse our algorithm at three different levels of detail, resulting in gradually improving approximation ratios. We also show a general observation about the Graph Burning problem in Subsection 3.3. The results from this section will play a minor role in the handling of some special cases by the final analysis of our algorithm in Section 4.

3.1 Proof of 3-approximation

This simple proof matches the previous result of Bonato and Kamali.

▶ **Lemma 2.** *Assuming $g \geq 3b(G)-2$, the algorithm always concludes in at most $b(G)$ cycles.*

Proof of Lemma 2. Given that centers have radius at most $b(G)-1$, any center serviced before cycle $b(G)$ will, by Observation 1, still be covered at the start of cycle $b(G)$. Given that there are at most $b(G)$ centers, the algorithm concludes no later than at the start of cycle $b(G)$ as all centers will be covered. ◀

3.2 Easy improvement

Observe what might happen if we were to run the algorithm with $g = 3b(G)-3$. If the algorithm services the center with radius $b(G)-1$ in cycle 0, then it is possible that this center is no longer covered at the start of cycle $b(G)$, preventing the algorithm from concluding. Fortunately, this can be fixed by running the algorithm for one more cycle as the second largest center, with radius $b(G)-2$, can stop being covered no earlier than at the start of cycle $b(G)+2$

▶ **Lemma 3.** *Assuming $g \geq 3b(G)-3$, the algorithm always concludes in at most $b(G)+1$ cycles.*

Proof of Lemma 3. Let us separate the 1 "large" center with $r = b(G) - 1$ and the $b(G) - 1$ "small" centers with $r \leq b(G) - 2$. Any small serviced center will be covered at the start of cycle $b(G) + 1$.

At the start of cycle $b(G) - 1$, at least $b(G) - 1$ centers have been serviced and are covered, leaving at most one center uncovered. Over the next 2 cycles, only the single large center can become uncovered. Thus the algorithm concludes no later than at the start of cycle $b(G) + 1$ as all centers will be covered. ◀

3.3 General observation

Note that slight improvements such as Lemma 3 are generally easy for Graph Burning, as demonstrated by the following observation:

▶ **Observation 4.** *If, for some $\rho \geq 2$, there exists an algorithm $\mathcal{A}$ that, assuming $g \geq \lfloor \rho\, b(G) \rfloor$, always finds a burning sequence of length g in $O(f(n))$ time, then, for any $k \leq b(G)$, there exists an algorithm $\mathcal{B}$ that always finds a burning sequence of length $g - k$ in $O(n^k f(n))$ time.*

Proof of Observation 4. Algorithm $\mathcal{B}$ is given a graph G and a guessed burning number g. For each of the $O(n^k)$ possible length-k prefixes of a burning sequence of length $g - k$, it uses algorithm $\mathcal{A}$ to look for a burning sequence of length $g - 2k$ for the uncovered part of the graph.

One of those prefixes is $P = v_1, v_2, v_3, \ldots, v_k$ such that all $(v_i, b(G) - i)$ are centers of OPT. Since $g - k \geq b(G)$, these k centers are covered by any burning sequence of length $g - k$ that starts with prefix P. The uncovered part of the graph thus has a burning number at most $b(G) - k$ and algorithm $\mathcal{A}$ will be able to find a burning sequence of length $g - 2k$. ◀

3.4 More significant improvement

In order to motivate further exploration of our algorithm, let us now show that our algorithm is indeed capable of finding burning sequences of length $\rho\, b(G)$ where $\rho < 3$. In particular, we demonstrate that $g \geq \frac{8}{3} b(G)$ is sufficient and the algorithm concludes in $\left\lceil \frac{4}{3} b(G) \right\rceil$ cycles.

We use Observation 1 to show how long each center stays covered after being serviced. At the start of each cycle of our algorithm, each center of OPT is in one of the following three states.

1. Untouched - this center has not been serviced yet and might thus be uncovered.
2. Covered - this center has been serviced in the last $g - 2r$ cycles and thus is covered.
3. Expired - this center has last been serviced more than $g - 2r$ cycles ago and thus might not be covered any more.

For the purposes of our analysis, we will divide the cycles of the algorithm into two phases, with each phase shorter than $b(G)$ cycles. During the first phase, the algorithm is only servicing untouched centers. When sufficiently many cycles have passed for a center to possibly become expired, the algorithm enters the second phase. During the second phase, the algorithm services the remaining untouched centers and any expired centers. The second phase concludes before any center can expire for the second time and we show that all centers must be covered.

We divide the centers into a smaller number of large centers and a larger number of small centers. Small centers are the centers with $r < \frac{2}{3} b(G)$. When serviced, these remain covered for $> \frac{4}{3} b(G)$ cycles, which is at least the number of cycles used by the algorithm. Thus they do not become expired. Large centers are the centers with $r \geq \frac{2}{3} b(G)$. When serviced, these remain covered until the end of the phase, but might expire during the second phase if covered during the first phase.

After carefully setting the length of the phases, we show that sufficiently many small centers must be serviced during the first phase so that any untouched small centers and all large centers can be serviced during the second phase. This ensured that all centers are covered even if all the large centers have expired.

▶ **Lemma 5.** *Assuming $g \geq \frac{8}{3}b(G)$, the algorithm always concludes in at most $\lceil \frac{4}{3}b(G) \rceil$ cycles.*

Proof of Lemma 5. A center (v, r) is called large if $r \geq \frac{2}{3}b(G)$. Note that there are at most $\lfloor \frac{1}{3}b(G) \rfloor$ large centers. The remaining centers are small; they have radius $r < \frac{2}{3}b(G)$ and there are at most $\lceil \frac{2}{3}b(G) \rceil$ small centers. The first phase consists of $\lceil \frac{2}{3}b(G) \rceil$ cycles and the second phase consists of $\lfloor \frac{2}{3}b(G) \rfloor$ cycles.

All centers have $r \leq b(G) - 1$. By Observation 1, any center serviced during the first phase is still covered at the start of cycle $\lceil \frac{2}{3}b(G) \rceil$. Thus, at the end of the first phase, $\lceil \frac{2}{3}b(G) \rceil$ centers have been serviced and are covered, leaving at most $\lfloor \frac{1}{3}b(G) \rfloor$ uncovered centers.

Small centers have $r < \frac{2}{3}b(G)$ and thus any serviced small center will still be covered at the start of cycle $\lceil \frac{4}{3}b(G) \rceil$. Thus, during the second phase, only the large centers can become uncovered and there are at most $\lfloor \frac{1}{3}b(G) \rfloor$ large centers. In total, no more than $\lfloor \frac{2}{3}b(G) \rfloor$ centers need to be serviced during the second phase, and the algorithm concludes no later than at the end of the second phase. ◀

4 2.314-approximation ratio

The entirety of this section is devoted to the proof of the following theorem, which is the main result of this paper.

▶ **Theorem 6.** *Assuming $g \geq \lfloor \alpha b(G) \rfloor$, the algorithm always concludes in at most $O((b(G))^2)$ cycles.*

First, we focus on a single center (v, r). In an approach inspired by problems such as Bamboo Garden [7][9] and Pinwheel Scheduling [8][6], we imagine a timer that starts at 1, is reset to zero whenever the algorithm services the center, and otherwise increases with every cycle so that the timer is ≥ 1 whenever the center might be uncovered.

Second, we look at all the centers of OPT and consider the sum of their timers. This sum starts at $b(G)$ and, if g is large enough, decreases with every cycle. Given that all centers must be covered if the sum is less than 1, we proceed to show that $g \geq \lfloor \alpha b(G) \rfloor$ is indeed large enough, completing the proof.

Proof of Theorem 6. Let us define a potential $\Phi_i(v, r)$ for center (v, r) at the start of the i-th cycle as follows:

$$\Phi_0(v, r) = 1 \tag{1}$$

$$\Phi_{i+1}(v, r) = \begin{cases} 0 & \text{if center } (v, r) \text{ was serviced during the } i\text{-th cycle} \\ \Phi_i(v, r) + \dfrac{1}{g - 2r} & \text{otherwise} \end{cases} \tag{2}$$

Observe that, if $\Phi_i(v, r) < 1$, then center (v, r) is covered at the start of the i-th cycle.

We now define the overall potential at the start of the i-th cycle as the sum of potentials for all centers of OPT and observe that, whenever $\Phi_i < 1$, all centers must be covered.

$$\Phi_i = \sum_{(v,r) \in \text{OPT}} \Phi_i(v, r)$$

We claim that if center (v, r) is serviced in cycle i, then

$$\Phi_{i+1} = \Phi_i + \Delta - \left(1 + \frac{1}{g - 2r}\right)$$

where

$$\Delta = \sum_{r=0}^{b(G)-1} \frac{1}{g - 2r}.$$

The positive term Δ accounts for the increase of the potential of all centers. The negative term $(1 + 1/(g - 2r))$ accounts for the change of the potential of the serviced center (v, r). This is because $\Phi_i(v, r) \geq 1$ must be true for (v, r) to be serviced in cycle i and $\Phi_{i+1}(v, r) = 0$ if (v, r) was serviced in cycle i, which means that the potential is not only decreased by 1, but also does not increase by $1/(g - 2r)$ already included in Δ.

We will show that $\Delta \leq 1$ for $g \geq \lfloor \alpha b(G) \rfloor$. To see that this implies the theorem, first observe that $1 + 1/(g - 2r) \geq 1 + 1/g$ and thus we will get $\Phi_{i+1} \leq \Phi_i - 1/g$. Since $\Phi_0 = b(G)$, algorithm concludes in at most $g \cdot b(G)$ cycles. For $g \leq \frac{8}{3} b(G)$ the theorem follows directly, while for $g > \frac{8}{3} b(G)$ we use Lemma 5 to get the conclusion of the theorem.

It remains to prove that $\Delta \leq 1$. The value of α was set to satisfy the following integral equation:

$$\int_0^{b(G)} \frac{1}{\alpha b(G) - 2x}\, dx = \left[-\frac{\ln(\alpha b(G) - 2x)}{2}\right]_{x=0}^{b(G)} = \frac{\ln(\alpha) - \ln(\alpha - 2)}{2} = 1.$$

We express Δ as a similar integral:

$$\Delta = \sum_{r=0}^{b(G)-1} \frac{1}{g - 2r} = \int_0^{b(G)} \frac{1}{g - 2\lfloor x \rfloor}\, dx.$$

To complete the proof, it is now sufficient to show that the following holds:

$$\int_0^{b(G)} \frac{1}{g - 2\lfloor x \rfloor}\, dx \leq \int_0^{b(G)} \frac{1}{\alpha b(G) - 2x}\, dx.$$

We first observe that this holds whenever $g \geq \alpha b(G)$, using a straightforward substitution for g and a simple upper bound on $\lfloor x \rfloor$. This makes it possible for us to get an α-approximation algorithm by using Observation 4.

Finally, we give a full proof of $\Delta \leq 1$ for all $g \geq \lfloor \alpha b(G) \rfloor$. We separate the integration into intervals where $2\lfloor x \rfloor$ is constant, seeking to prove for all natural $a < b(G)$:

$$\int_a^{a+1} \frac{1}{g - 2\lfloor x \rfloor}\, dx \leq \int_a^{a+1} \frac{1}{\alpha b(G) - 2x}\, dx.$$

The following trivially holds:

$$\int_a^{a+1} \frac{1}{g - 2\lfloor x \rfloor}\, dx = \int_a^{a+1} \frac{1}{g - 2a}\, dx = \frac{1}{g - 2a}.$$

Consider the function $f(z) = 1/(g + 1 - 2z)$. It is convex on $(-\infty, (g + 1)/2)$ and thus for every $z < b(G) \leq g/2$ we have $f(z) \leq \int_{z-1/2}^{z+1/2} f(x)\, dx$. Using this for $z = a + 1/2$ we get the following:

$$\frac{1}{g - 2a} = f(a + 1/2) \leq \int_a^{a+1} f(x)\, dx = \int_a^{a+1} \frac{1}{g + 1 - 2x}\, dx \leq \int_a^{a+1} \frac{1}{\alpha b(G) - 2x}\, dx$$

where the last inequality follows from $g + 1 \geq \lfloor \alpha b(G) \rfloor + 1 \geq \alpha b(G)$. This concludes the proof of $\Delta \leq 1$ and thus the proof of Theorem 6. ◀

5 Conclusion

We have shown a simple deterministic algorithm for Graph Burning that achieves good approximation ratios when thoroughly analysed. Despite this, a significant gap remains between our result and the lower bounds of [11].

Abstract

Randomised algorithms often employ methods that can fail and that are retried with independent randomness until they succeed. Randomised data structures therefore often store indices of successful attempts, called seeds. If n such seeds are required (e.g., for independent substructures) the standard approach is to compute for each $i \in [n]$ the smallest successful seed S_i and store $\vec{S} = (S_1, \ldots, S_n)$.

The central observation of this paper is that this is not space-optimal. We present a different algorithm that computes a sequence $\vec{S'} = (S'_1, \ldots, S'_n)$ of successful seeds such that the entropy of $\vec{S'}$ undercuts the entropy of $\vec{S}$ by $\Omega(n)$ bits in most cases. To achieve a memory consumption of $\mathrm{OPT} + \varepsilon n$, the expected number of inspected seeds increases by a factor of $\mathcal{O}(1/\varepsilon)$.

We demonstrate the usefulness of our findings with a novel construction for minimal perfect hash functions that, for n keys and any $\varepsilon \in [n^{-3/7}, 1]$, has space requirement $(1+\varepsilon)\mathrm{OPT}$ and construction time $\mathcal{O}(n/\varepsilon)$. All previous approaches only support $\varepsilon = \omega(1/\log n)$ or have construction times that increase exponentially with $1/\varepsilon$. Our implementation beats the construction throughput of the state of the art by more than two orders of magnitude for $\varepsilon \leq 3\%$.

1 Introduction

The construction of randomised data structures can sometimes fail, so the data structures need to store indices of successful attempts called *seeds*.[1] In this paper, we present a technique that finds and encodes successful seeds in a space-efficient and time-efficient way.

When searching a single seed, we may imagine an infinite sequence of i.i.d. Bernoulli random variables, called a *Bernoulli process*, that indicate which natural numbers lead to success and that can be inspected one by one. To model the task of finding a *sequence* of seeds we use a *sequence* of Bernoulli processes as follows. In this paper $[n] \coloneqq \{1, \dots, n\}$ and $\mathbb{N}_0 \coloneqq \mathbb{N} \cup \{0\}$.

▶ **Definition 1** (Seed Search and Encoding Problem (SSEP)). *Let $n \in \mathbb{N}$ and $p_1, \dots, p_n \in (0, 1]$. Given for each $i \in [n]$ a Bernoulli process $\vec{B}^{(i)} = (B^{(i)}_j)_{j \in \mathbb{N}_0}$ with parameter p_i, the task is to craft a bitstring M that encodes for each $i \in [n]$ a successful seed $S_i \in \mathbb{N}_0$, i.e. $B^{(i)}_{S_i} = 1$.*

Our primary goals are to minimise the length of M in bits, and to minimise for each $i \in [n]$ the number T_i inspected Bernoulli random variables from $\vec{B}^{(i)}$. Moreover, the time to decode S_i given $p_1, \dots, p_n$, M and $i \in [n]$ should be constant. The optimal values for the expectation of $|M|$ and T_i are the following (for a proof see the full version of this paper [24]).

$$M^{\mathrm{OPT}} = \sum_{i=1}^{n} \log_2(1/p_i) \text{ and } T_i^{\mathrm{OPT}} = 1/p_i \text{ for } i \in [n]. \tag{1}$$

1.1 Ad-Hoc Solutions

We briefly consider two natural strategies for solving the SSEP to build intuition. The obvious strategy (MIN) is to encode the smallest successful seeds, i.e. define

$$S_i \coloneqq \min\{j \in \mathbb{N}_0 \mid B^{(i)}_j = 1\} \text{ and } \vec{S}_{\mathrm{MIN}} \coloneqq (S_1, \dots, S_n) \tag{MIN}$$

and let M be an optimal encoding of $\vec{S}_{\mathrm{MIN}}$. Perhaps surprisingly, this requires $\Omega(n)$ bits more than the optimum if $p_1, \dots, p_n$ are bounded away from 1.

▶ **Lemma 2** (MIN is fast but not space-efficient, proof in full version [24]). *If M encodes $\vec{S}_{\mathrm{MIN}}$ then $\mathbb{E}[T_i] = T_i^{\mathrm{OPT}}$ for all $i \in [n]$ but $\mathbb{E}[|M|] \geq M^{\mathrm{OPT}} + \sum_{i=1}^{n} 1 - p_i$.*

Another simple strategy (UNI) is to encode the smallest seed that is simultaneously successful for all Bernoulli processes, i.e. we define

$$S_* = \min\{j \in \mathbb{N}_0 \mid \forall i \in [n] : B^{(i)}_j = 1\} \text{ and } S_i = S_* \text{ for all } i \in [n]. \tag{UNI}$$

This yields a bitstring M of minimal length but requires total time $\sum_{i=1}^{n} T_i = \exp(\Omega(n))$ if $p_1, \dots, p_n$ are bounded away from 1.

▶ **Lemma 3** (UNI is space-efficient but slow, proof in full version [24]). *If M encodes S_* then $\mathbb{E}[|M|] = M^{\mathrm{OPT}} + \mathcal{O}(1)$ but $\mathbb{E}[\sum_{i=1}^{n} T_i] \geq \prod_{i=1}^{n} 1/p_i \gg \sum_{i=1}^{n} T_i^{\mathrm{OPT}}$.*

[1] Throughout this paper, we use the *Simple Uniform Hashing Assumption*, as do many works before us [5, 29, 28, 22, 21, 14, 7]. This is equivalent to saying that we assume access to an infinite sequence of uniformly random and independent hash functions, each identified by its index (seed). The assumption is an adequate model for practical hash functions and can be justified in theory using the "split-and-share" trick [6].

1.2 The Consensus Algorithm

We present an algorithm for the SSEP designed to simultaneously get close to both optima. We call it *Combined Search and Encoding for Successful Seeds*, or Consensus for short. We summarise the guarantees of the stronger of two variants here.

▶ **Theorem 4** (Main result, informal version of Theorem 7). *For any $\varepsilon > 0$ the full Consensus algorithm with high probability solves the SSEP with $|M| \leq M^{\mathrm{OPT}} + \varepsilon n + \mathcal{O}(\log n)$ and $\mathbb{E}[T_i] = \mathcal{O}(T_i^{\mathrm{OPT}}/\varepsilon)$ for all $i \in [n]$. Each seed S_i is a bitstring of fixed length found at a predetermined offset in M.*

Note that if the geometric mean of $p_1, \ldots, p_n$ is at most $\frac{1}{2}$ then $M^{\mathrm{OPT}} \geq n$ and the leading term εn in our space overhead is at most $\varepsilon M^{\mathrm{OPT}}$.[2]

Intuition. First reconsider the MIN-strategy. It involves the sequence $\vec{S}_{\mathrm{MIN}} = (S_1, \ldots, S_n)$ with some entropy $H(\vec{S}_{\mathrm{MIN}})$. There are two issues with storing $\vec{S}_{\mathrm{MIN}}$. The superficial issue is that each number in the sequence follows a geometric distribution, and it is not obvious how to encode $\vec{S}_{\mathrm{MIN}}$ in space close to $H(\vec{S}_{\mathrm{MIN}})$ while preserving fast random access to each component.[3] The deeper issue is that $\vec{S}_{\mathrm{MIN}}$ is not what a space-optimal approach should encode in the first place. This is demonstrated by the fact that even an optimal encoding of $\vec{S}_{\mathrm{MIN}}$ needs space $H(\vec{S}_{\mathrm{MIN}})$, which UNI undercuts by $\Omega(n)$ bits.

Consensus deals with both issues simultaneously. The idea is to store for each $i \in [n]$ a natural number $1 \leq \sigma_i \leq 2^{\varepsilon}/p_i$. This allows for fixed width encoding of σ_i using $\varepsilon + \log_2 1/p_i$ bits. If we simply used $S_i = \sigma_i$ then the expected number of successful choices for σ_i would be $2^{\varepsilon} > 1$. The problem would be, of course, that the actual number of successful choices might be zero for many $i \in [n]$. So instead we interpret σ_i as a *seed fragment* and define S_i to be a concatenation of seed fragments up to and including σ_i. This way, if we run out of choices for σ_i, we can hope that a different successful choice for earlier seed fragments will allow for a successful choice for σ_i as well. We can construct the sequence $(\sigma_1, \ldots, \sigma_n)$ using backtracking. We explain our algorithm in detail in Section 2. The main technical challenge is to bound the additional cost this brings.

1.3 Motivation: Seed Sequences in Randomised Data Structures

Randomised data structures frequently use seeds to initialise pseudo-random number generators or as additional inputs to hash functions. Since a seed normally counts how often a construction has been restarted, a seed $S \in \mathbb{N}_0$ implies that work $\Omega(S+1)$ has been carried out, meaning any reasonably fast algorithm yields seeds that are only a few bits to a few bytes in size. This does not, however, imply that seeds contribute only negligibly to overall memory consumption. That is because some data structures partition their input into many small parts called *buckets* and store a seed for each of these buckets. The seeds may even make up the majority of the stored data. This is the case for many constructions of perfect hash functions, but also occurs in a construction of compressed static functions [2], which, in turn, enable space-efficient solutions to the approximate membership problem and the relative membership problem. The way we phrased the SSEP implicitly assumes that buckets are handled independently. We discuss a slight generalisation in the full version [24].

[2] It is possible to get $\mathbb{E}[|M|] \leq M^{\mathrm{OPT}} + \varepsilon \min(M^{\mathrm{OPT}}, n) + \mathcal{O}(\log n)$ and $\mathbb{E}[T_i] = \mathcal{O}(T_i^{\mathrm{OPT}}/\varepsilon)$ in general. This requires work if many p_i are close to 1 such that $M^{\mathrm{OPT}} = o(n)$. In that case we can "summarise" subsequences of $p_1, \ldots, p_n$ using essentially the UNI strategy and then apply our main theorem to a shorter sequence $\tilde{p}_1, \ldots, \tilde{p}_{n'}$ with $n' \leq M^{\mathrm{OPT}} + \mathcal{O}(1)$. We decided against integrating this improvement into our arguments as it interferes with clarity.

[3] The standard solution [32] using Golomb-Rice coding [11, 31] comes with $\Omega(n)$ bits of overhead.

Minimal Perfect Hash Functions. As an application of CONSENSUS we discuss the construction of minimal perfect hash functions (MPHFs). An MPHF on a set X of keys maps these keys to a range $[|X|]$ without collisions. The function does not necessarily have to store X explicitly. The space lower bound is $\mathrm{OPT}_{\mathrm{MPHF}} = |X| \log_2(e) - \mathcal{O}(\log |X|)$ bits assuming the universe of possible keys has size $\Omega(|X|^2)$ [1, 26, 25, 9]. While a succinct construction has long been known [12], its space overhead is fixed to $\varepsilon = \Theta(\frac{\log^2 \log n}{\log n})$ and large in practice. Many recent practical approaches for constructing MPHFs involve a brute force search for seed values that map certain subsets of the keys in favourable ways [30, 7, 14, 22, 21]. Those that do, all combine aspects of the MIN-strategy (store smallest working seeds) and the UNI-strategy (let a single seed do lots of work) and achieve a space budget of $(1+\varepsilon) \cdot \mathrm{OPT}_{\mathrm{MPHF}}$ only in time $|X| \cdot \exp(\Omega(1/\varepsilon))$ (see Section 5.1). In this paper we break this barrier for the first time. While we give the details in Section 5, the clean version of our result is the following.

▶ **Theorem 5** (Bucketed CONSENSUS-RecSplit). *For any $\varepsilon \in [n^{-3/7}, 1]$ there is an MPHF data structure with space requirement $(1 + \mathcal{O}(\varepsilon))\mathrm{OPT}_{\mathrm{MPHF}}$, expected construction time $\mathcal{O}(n/\varepsilon)$ and expected query time $\mathcal{O}(\log 1/\varepsilon)$.*

1.4 Overview of the Paper

The structure of the paper is as follows. In Section 2, we explain CONSENSUS in detail, as well as state the main theoretic results. In Sections 3 and 4 we then prove the results. We give an application of CONSENSUS to minimal perfect hashing in Section 5 and also briefly evaluate our practical implementation. Finally, we conclude the paper in Section 6.

2 Combined Search and Encoding for Successful Seeds

In this section we present two variants of our CONSENSUS algorithm. The first aims for conceptual clarity but produces seeds of length $\Omega(n)$ bits that cannot be decoded efficiently. The second is more technical but solves this problem.

In the following we always assume that $n \in \mathbb{N}$, $p_1, \ldots, p_n \in (0, 1]$ and $\varepsilon \in (0, 1]$ are given and $\vec{B}^{(i)} = (B_j^{(i)})_{j \in \mathbb{N}_0}$ is a Bernoulli process with parameter p_i for all $i \in [n]$.

A Branching Process. Let $k_1, \ldots, k_n \in \mathbb{N}$ be a sequence of numbers.[4] Consider the infinite tree visualised in Figure 1. It has $n+2$ layers, indexed from 0 to $n+1$. The root in layer 0 has an infinite number of children and nodes in layer $1 \leq i \leq n$ have k_i children each, with 0-based indexing in both cases. Edges between layer i and $i+1$ are associated with the variables $B_0^{(i)}, B_1^{(i)}, B_2^{(i)}, \ldots$ from top to bottom where $B_j^{(i)} = 0$ indicates a *broken* edge depicted as a dotted line. For convenience, we make another definition. For any $0 \leq \ell \leq n$ and any sequence $(\sigma_0, \sigma_1, \ldots, \sigma_\ell) \in \mathbb{N}_0 \times \{0, \ldots, k_1 - 1\} \times \ldots \times \{0, \ldots, k_\ell - 1\}$ consider the node reached from the root by taking in layer $0 \leq i \leq \ell$ the edge to the σ_i-th child. We define $\sigma_0 \circ \ldots \circ \sigma_\ell$ to be the index of the reached node within layer ℓ.

The Simplified CONSENSUS Algorithm. In CONSENSUS, we search for a non-broken path from the root of the tree to a leaf node using a DFS, see Algorithm 1. Note that such a path exists with probability 1 because the root has infinitely many children. The path is given by

[4] It may help to imagine that $k_i \approx 2^\varepsilon / p_i$.

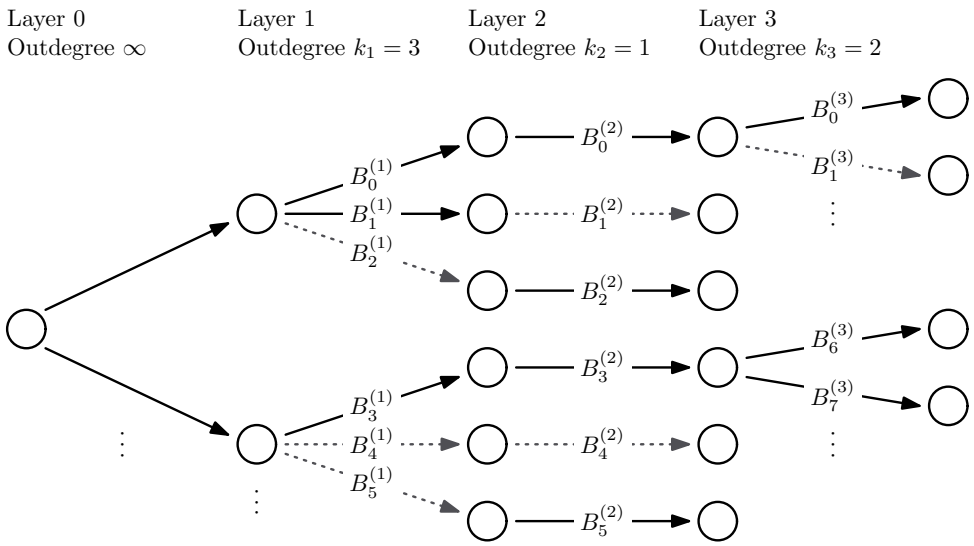

Figure 1 A visualisation of the tree underlying the search of the simplified CONSENSUS algorithm.

the sequence of choices $(\sigma_0, \dots, \sigma_n) \in \mathbb{N}_0 \times \{0, \dots, k_1 - 1\} \times \dots \times \{0, \dots, k_n - 1\}$ made in each layer. The returned sequence can be encoded as a bitstring M. Then $S_i \coloneqq \sigma_0 \circ \dots \circ \sigma_i$ is a successful seed for each $i \in [n]$ by construction. The merits of the approach are summarised in the following theorem.

▶ **Theorem 6** (Performance of Simplified CONSENSUS). *Given $n \in \mathbb{N}$, $p_1, \dots, p_n \in (0, 1]$ and $\varepsilon \in (0, 1]$ let $k_1, \dots, k_n \in \mathbb{N}$ be a sequence of numbers satisfying*[5] $\prod_{j=1}^{i} p_j k_j 2^{-\varepsilon} \in [1, 2]$ *for all $i \in [n]$. Then Algorithm 1 solves the SSEP with $\mathbb{E}[T_i] = \mathcal{O}(T_i^{\mathrm{OPT}}/\varepsilon)$ and $\mathbb{E}[|M|] \leq M^{\mathrm{OPT}} + \varepsilon n + \log_2 1/\varepsilon + \mathcal{O}(1)$.*

Full CONSENSUS Algorithm. The main issues with the simplified CONSENSUS algorithm are that $(\sigma_0, \dots, \sigma_n)$ is awkward to encode in binary and that using $\sigma_0 \circ \dots \circ \sigma_i$ directly as the seed S_i makes for seeds of size $\Omega(n)$ bits, which are inefficient to compute and handle. We solve these issues with three interventions.

1. We introduce a word size $w \in \mathbb{N}$ and encode σ_0 using w bits (hoping that it does not overflow, see below).
2. We demand that $k_1, \dots, k_n \in \mathbb{N}$ are powers of two, i.e. $k_i = 2^{\ell_i}$ for $\ell_i \in \mathbb{N}_0$. With our definition of "$\circ$", the binary representation of the number $\sigma_0 \circ \dots \circ \sigma_i$ now simply arises by concatenating the binary representations of $\sigma_0, \dots, \sigma_i$ (where σ_j is encoded using ℓ_j bits and σ_0 is encoded using w bits).
3. Instead of defining S_i to be $\sigma_0 \circ \dots \circ \sigma_i$, we define S_i to be the w-bit suffix of $\sigma_0 \circ \dots \circ \sigma_i$. We will show that this truncation is unlikely to cause collisions, i.e. any two sequences $(\sigma_0, \dots, \sigma_i)$ and $(\sigma'_0, \dots, \sigma'_i)$ we encounter have distinct suffixes $S_i \neq S'_i$. Intuitively, this guarantees that the search algorithm will always see "fresh" random variables and does not "notice" the change.

The full algorithm is given as Algorithm 2, using notation defined in Figure 2. Our formal result is as follows.

[5] Ideally we would want $k_j \coloneqq \frac{2^{\varepsilon}}{p_j}$ but the integer constraint on the k_j forces us to be more lenient.

Algorithm 1 Simplified CONSENSUS.

Input: $n, (p_1, \dots, p_n), (k_1, \dots, k_n)$ and $B_0^{(i)}, B_1^{(i)}, \dots \sim \mathrm{Ber}(p_i)$ for all $i \in [n]$.
Output: $(\sigma_0, \dots, \sigma_n)$ with $0 \le \sigma_i < k_i$ such that $B^{(i)}_{\sigma_0 \circ \sigma_1 \circ \dots \circ \sigma_i} = 1$ for all $i \in [n]$.
Algorithm Simplified-CONSENSUS:

```
for σ_0 ∈ {0, 1, 2, ...} do
    (σ_1, i) ← (0, 1)
    while i > 0 do
        if B^(i)_{σ_0 ∘ ... ∘ σ_i} = 1 then
            if i = n then
                return M = (σ_0, ..., σ_n)
            i ← i + 1
            σ_i ← 0
        else // backtrack and/or next seed
            while i > 0 and σ_i = k_i − 1 do
                i ← i − 1
            if i > 0 then
                σ_i ← σ_i + 1
```

Algorithm 2 Full CONSENSUS.

Input: $n, w, (p_1, \dots, p_n), (\ell_1, \dots, \ell_n)$ and $B_0^{(i)}, \dots, B_{2^w-1}^{(i)} \sim \mathrm{Ber}(p_i)$ for all $i \in [n]$.
Output: either $\perp$ or M as in Figure 2 such that $B_{S_i}^{(i)} = 1$ for all $i \in [n]$.
Algorithm Full-CONSENSUS:

```
for σ_0 ∈ {0, 1, ..., 2^w − 1} do // bounded
    (σ_1, i) ← (0, 1)
    while i > 0 do
        if B^(i)_{S_i} = 1 then // S_i as in Figure 2
            if i = n then
                return M = (σ_0, ..., σ_n)
            i ← i + 1
            σ_i ← 0
        else // backtrack and/or next seed
            while i > 0 and σ_i = 2^{ℓ_i} − 1 do
                i ← i − 1
            if i > 0 then
                σ_i ← σ_i + 1
return ⊥ // can fail
```

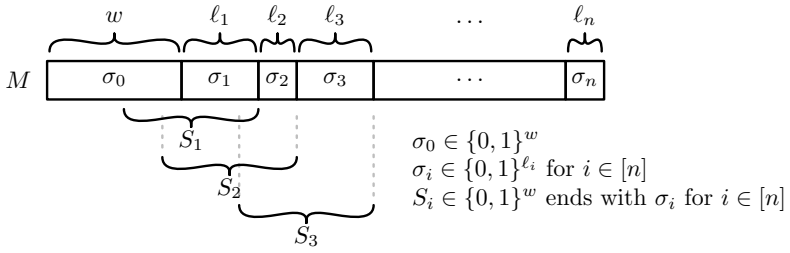

Figure 2 The bitstring M returned by the full CONSENSUS algorithm and the notation used to refer to relevant substrings.

▶ **Theorem 7** (Performance of Full CONSENSUS). *Let $c > 0$ be an arbitrary constant. Given $n \in \mathbb{N}$, $p_1, \dots, p_n \in (n^{-c}, 1]$ and $\varepsilon \in (n^{-c}, 1]$, let $\ell_1, \dots, \ell_n \in \mathbb{N}_0$ be the unique sequence of numbers such that*

$$\sum_{j=1}^{i} \ell_j \coloneqq \left\lceil \varepsilon i + \sum_{j=1}^{i} \log_2(1/p_i) \right\rceil \text{ for } i \in [n].$$

Assume we run Algorithm 2 with these parameters and $w \ge (2 + 7c) \log_2 n$.[6] Then there is an event E with $\Pr[E] = 1 - \mathcal{O}(n^{-c})$ that implies that the run solves the SSEP, producing a bitstring M with $|M| = \lceil M^{\mathrm{OPT}} + \varepsilon n + w \rceil$ containing $S_i \in \{0,1\}^w$ at offset $\sum_{j=1}^{i} \ell_j$ for all $i \in [n]$. Moreover, $\mathbb{E}[T_i \mid E] = \mathcal{O}(T_i^{\mathrm{OPT}}/\varepsilon)$ for all $i \in [n]$.

[6] We did not attempt to improve the constant "$2 + 7c$" and expect that $w = 64$ is enough in practice.

In particular the result guarantees that S_i can be inferred efficiently given M and i provided that $\sum_{j=1}^{i} \log_2(1/p_i)$ can be computed efficiently given i. In practice it is fine to use approximations of p_i.[7] Note that the expectation of T_i is only bounded conditioned on a good event E, which is defined in Section 4. To obtain an unconditionally bounded expectation, Algorithm 2 should be modified to give up early in failure cases.[8]

Special Cases and Variants. An important special case is $p_1 = \ldots = p_n = p$. With $b = \log_2 1/p$ the space lower bound is then simply $M^{\mathrm{OPT}} = bn$ bits. If we apply Theorem 7 with $\varepsilon \in (0,1)$ then the lengths $\ell_1, \ldots, \ell_n$ of the seed fragments $\sigma_1, \ldots, \sigma_n$ are all either $\lceil b+\varepsilon \rceil$ or $\lfloor b+\varepsilon \rfloor$ with an average approaching $b+\varepsilon$. Assuming $b \notin \mathbb{N}$ it may be tempting to use $\varepsilon = \lceil b \rceil - b$ such that all seed fragments have the same length $b+\varepsilon \in \mathbb{N}$. Similarly, we could pick ε such that $b+\varepsilon$ is a "nice" rational number, e.g. $b+\varepsilon = b' + \frac{1}{2}$ for $b' \in \mathbb{N}$ such that $\ell_1, \ldots, \ell_n$ alternate between $b'+1$ and b'.

In some cases it may be reasonable to choose $\varepsilon > 1$. Even though Consensus ceases to be more space efficient than MIN, it still has the advantage that seeds are bitstrings of fixed lengths in predetermined locations. We decided against formally covering this case in Theorem 7, but argue for the following modification in the full version [24] of this paper.

▶ Remark 8. The guarantees of Theorem 7 also hold for $\varepsilon \in [1, \log n]$, except that

$$\mathbb{E}[T_i \mid E] = T_i^{\mathrm{OPT}}(1 + \exp(-\Omega(2^{\varepsilon})) + n^{-c}) \qquad \text{(instead of } \mathbb{E}[T_i \mid E] = \mathcal{O}(T_i^{\mathrm{OPT}}/\varepsilon)\text{)}.$$

It may also be worthwhile to consider variants of Consensus that use different values of the overhead parameter ε in different parts of M to minimise some overall cost. Such an idea makes sense in general if we augment the SSEP to include specific costs c_i associated with testing the Bernoulli random variables belonging to the ith family.

3 Analysis of Simplified Consensus

We begin by reducing the claim of Theorem 6 to a purely mathematical statement given in Lemma 9, which we prove in Section 3.2.

3.1 Reduction of Theorem 6 to Lemma 9

Recall the tree defined in Section 2 and illustrated in Figure 1. For any $i \in [n+1]$ consider a node v in layer i. Let q_i be the probability that there is an unbroken path from v to a node in layer $n+1$. (This probability is indeed the same for all nodes in layer i.) In the last layer, we have $q_{n+1} = 1$ by definition. For all $1 \le i \le n$ we have $q_i = 1 - (1 - p_i q_{i+1})^{k_i}$ since $p_i q_{i+1}$ is the probability that an unbroken path via a specific child of v exists, and since there is an independent chance for each of the k_i children. The technical challenge of this section is to show that the q_i are not too small.

▶ **Lemma 9.** *Under the conditions of Theorem 6 we have $q_i = \Omega(\varepsilon)$ for all $i \in [n]$.*

This lemma implies Theorem 6 as follows.

[7] Our implementation uses fixed point arithmetic (integers counting "microbits") to avoid issues related to floating point arithmetic not being associative and distributive.

[8] To do so we need not decide whether E occurs. We can simply count the number of steps and abort when a limit is reached.

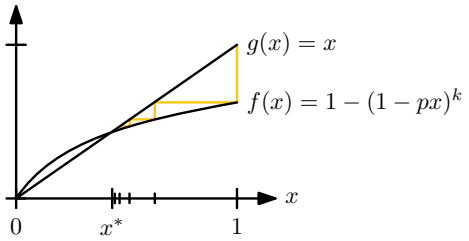

Figure 3 For $p_1 = \ldots = p_n = \frac{1}{4}$ and $k_1 = \ldots = k_n = 5$ (thus $\varepsilon = \log_2(5/4) \approx 0.32$) the values $q_{n+1}, q_n, q_{n-1}, \ldots$ (marked as ticks on the x-axis) arise by iteratively applying $f(x) = 1 - (1 - px)^k$ to the starting value of 1. Each q_i is at least the fixed point $x^* \approx 0.45$ of f.

Proof of Theorem 6. Let T_i for $i \in [n]$ be the number of Bernoulli random variables from the family $(B_j^{(i)})_{j \in \mathbb{N}_0}$ that are inspected. This corresponds to the number of edges between layers i and $i+1$ that are inspected by the DFS. With probability p_i such an edge is unbroken and, if it is unbroken, then with probability q_{i+1} the DFS will never backtrack out of the corresponding subtree and hence never inspect another edge from the same layer. This implies $T_i \sim \text{Geom}(p_i q_{i+1})$ and thus $\mathbb{E}[T_i] = \frac{1}{p_i q_{i+1}} = \mathcal{O}(T_i^{\text{OPT}}/\varepsilon)$ where the last step uses $T_i^{\text{OPT}} = 1/p_i$ and Lemma 9.

Concerning the space to encode $M = (\sigma_0, \ldots, \sigma_n)$, there are two parts to consider. The "fixed width" numbers $(\sigma_1, \ldots, \sigma_n) \in \{0, \ldots, k_1 - 1\} \times \ldots \times \{0, \ldots, k_n - 1\}$ can be encoded using $\lceil \log_2 \prod_{i \in [n]} k_i \rceil$ bits. By the assumption on $(k_i)_{i \in [n]}$ we have $\prod_{i \in [n]} k_i \leq 2 \cdot \prod_{i \in [n]} 2^\varepsilon / p_i$ and can bound the space by

$$1 + \log_2 \prod_{i \in [n]} k_i \leq 1 + \log_2 \left(2 \prod_{i \in [n]} \frac{2^\varepsilon}{p_i} \right) \leq 2 + \varepsilon n + \sum_{i \in [n]} \log_2 \frac{1}{p_i} = M^{\text{OPT}} + \varepsilon n + \mathcal{O}(1).$$

The "variable width" number $1 + \sigma_0 \in \mathbb{N}$ has distribution $1 + \sigma_0 \sim \text{Geom}(q_1)$ because σ_0 is the 0-based index of the first node in layer 1 with an unbroken path to layer $n+1$. Again by Lemma 9 we have $\mathbb{E}[1 + \sigma_0] = \frac{1}{q_1} = \mathcal{O}(1/\varepsilon)$. Using Jensen's inequality [15, 27] and the fact that $\log_2$ is concave, the expected number of bits to encode σ_0 is hence bounded by

$$\mathbb{E}[\lceil \log_2(1 + \sigma_0) \rceil] \leq 1 + \log_2 \mathbb{E}[1 + \sigma_0] = 1 + \log_2(\mathcal{O}(1/\varepsilon)) = \log_2 1/\varepsilon + \mathcal{O}(1).$$

Summing the contributions of both parts yields a bound on $\mathbb{E}[|M|]$ as claimed. ◀

3.2 Proof of Lemma 9

To understand the proof of Lemma 9 it may help to consider a simplified case first. Assume $p_1 = \ldots = p_n = p$ and $k_1 = \ldots = k_n = k$ with $kp = 2^\varepsilon$, i.e. k is slightly larger than $\frac{1}{p}$. We have $q_i = 1 - (1 - pq_{i+1})^k$, which motivates defining $f(x) = 1 - (1 - px)^k$ such that q_i arises by iteratively applying f to an initial value of $q_{n+1} = 1$. From the illustration in Figure 3 we see that q_i can never drop below the largest fixed point x^* of f, and it is not hard to show that $x^* = \Omega(\varepsilon)$.

Our full proof has to deal with a setting that is much less clean. The values p_i and k_i depend on i, yielding a distinct function f_i for each $i \in [n]$ and $p_i k_i \approx 2^\varepsilon$ is only true in the sense of a geometric average over $\Omega(1/\varepsilon)$ consecutive indices. We hence analyse compositions $f_a \circ \ldots \circ f_{b-1}$ for sufficiently large $b - a = \Theta(1/\varepsilon)$. We begin with some definitions.

- Let $f_i(x) = 1 - (1 - p_i x)^{k_i}$. Note that this gives $q_i = (f_i \circ \ldots \circ f_n)(1)$ for $i \in [n+1]$.

- For any set $I = \{a, \dots, b-1\}$ let $P_I = \prod_{i \in I} p_i$, $K_I = \prod_{i \in I} k_i$, and $F_I = f_a \circ \dots \circ f_{b-1}$. Note that the assumption of Theorem 6 gives

$$P_I K_I \cdot 2^{-\varepsilon|I|} = \underbrace{P_{\{1,\dots,b-1\}} K_{\{1,\dots,b-1\}} 2^{-\varepsilon(b-1)}}_{\in[1,2]} \Big(\underbrace{P_{\{1,\dots,a-1\}} K_{\{1,\dots,a-1\}} 2^{-\varepsilon(a-1)}}_{\in[1,2]} \Big)^{-1} \in [\tfrac{1}{2}, 2].$$

- Let $\varepsilon_0 := \lceil 2\varepsilon^{-1} \rceil^{-1}$. Its role is to be a number satisfying $\varepsilon_0 = \Theta(\varepsilon)$, $\varepsilon_0^{-1} \in \mathbb{N}$, and $(2^\varepsilon)^{\varepsilon_0^{-1}} \in [4, 8]$. In particular, if $I = \{a, \dots, b-1\}$ with $b - a = \varepsilon_0^{-1}$ then

$$P_I K_I = \underbrace{P_I K_I 2^{-\varepsilon|I|}}_{\in[\frac{1}{2},2]} \cdot \underbrace{2^{\varepsilon|I|}}_{\in[4,8]} \in [2, 16].$$

- Lastly, let $C = 8$ and $\varepsilon_1 = \varepsilon_0 / C$.

These definitions are designed to make the proof of the following lemma as simple as possible. No attempt was made to optimise constant factors.

▶ **Lemma 10.** *Let $I = \{a, \dots, b-1\} \subseteq [n]$. The following holds.*

(i) *For all $i \in [n]$ and $x \in [0, 1]$: $f_i(x) \geq p_i k_i x - (p_i k_i x)^2/2$.*

(ii) *If $b - a \leq \varepsilon_0^{-1}$ then $F_I(x) \geq P_I K_I x(1 - C|I|x)$ for $x \in [0, \varepsilon_1]$.*

(iii) *If $b - a = \varepsilon_0^{-1}$ then $F_I(\varepsilon_1/2) \geq \varepsilon_1/2$.*

Proof.

(i) e^{-x} satisfies the following bounds: $1 - x \leq e^{-x} \leq 1 - x + x^2/2$ for $x > 0$. We get the left claim by integrating $e^{-x} \leq 1$ for $t \in [0, x]$ to get $1 - e^{-x} \leq x$. Integrating again for $t \in [0, x]$ gives the right claim. Applying to $f_i(x)$ we get

$$f_i(x) = 1 - (1 - p_i x)^{k_i} \geq 1 - e^{-p_i k_i x} \geq 1 - (1 - p_i k_i x + (p_i k_i x)^2/2) = p_i k_i x - (p_i k_i x)^2/2.$$

(ii) We use induction on $b - a$. For $b - a = 0$ we have $I = \emptyset$, $F_I = \mathrm{id}$ as well as $P_I = K_I = 1$ and the claim holds. Let now $I = \{a, \dots, b-1\}$ with $b - a \leq \varepsilon_0^{-1}$and $I' = \{a + 1, \dots, b - 1\}$. We assume the claim holds for I'. Let $x \in [0, \varepsilon_1]$.

$$\begin{aligned}
F_I(x) = (f_a \circ F_{I'})(x) &\overset{\text{monotonic}}{=} f_a(F_{I'}(x)) \overset{\text{induction}}{\geq} f_a(P_{I'} K_{I'} x(1 - C|I'|x)) \\
&\overset{\text{(i)}}{\geq} p_a k_a P_{I'} K_{I'} x(1 - C|I'|x) - (p_a k_a P_{I'} K_{I'} x(1 - C|I'|x))^2/2 \\
&= P_I K_I x(1 - C|I'|x) - (P_I K_I x(1 - \underbrace{C|I'|x}_{\leq C\varepsilon_0^{-1}\varepsilon_1 = 1 < 2}))^2/2 \quad \text{and hence } (1 - C|I'|x)^2 \leq 1 \\
&\geq P_I K_I x(1 - C|I'|x) - (P_I K_I x)^2/2 = P_I K_I x(1 - x(C|I'| + \underbrace{P_I K_I}_{\leq 16 = 2C}/2)) \\
&\geq P_I K_I x(1 - x(C|I'| + C)) = P_I K_I x(1 - C|I|x).
\end{aligned}$$

(iii) By applying (ii) and using $C\varepsilon_0^{-1}\varepsilon_1 = 1$ we get

$$F_I(\varepsilon_1/2) \overset{\text{(ii)}}{\geq} \underbrace{P_I K_I}_{\geq 2} \tfrac{\varepsilon_1}{2} \underbrace{(1 - C\varepsilon_0^{-1} \tfrac{\varepsilon_1}{2})}_{= \frac{1}{2}} \geq \varepsilon_1/2.$$ ◀

The proof of Lemma 9 is now immediate:

Proof of Lemma 9. Let $i \in [n]$. Partition $I = \{i, \dots, n\}$ into contiguous intervals $I_1, \dots, I_k$ such that $F_I = F_{I_1} \circ \dots \circ F_{I_k}$ with $|I_1| \leq \varepsilon_0^{-1}$ and $|I_j| = \varepsilon_0^{-1}$ for $j \in \{2, \dots, k\}$. Then by repeated applications of Lemma 10 (iii), one application of Lemma 10 (ii) and the monotonicity of the relevant functions we get

$$q_i = F_I(1) \geq F_I(\varepsilon_1/2) = F_{I_1}(F_{I_2}(\dots(F_{I_k}(\varepsilon_1/2))\dots)) \overset{\text{(iii)}}{\geq} F_{I_1}(\varepsilon_1/2)$$
$$\overset{\text{(ii)}}{\geq} P_{I_1} K_{I_1} \frac{\varepsilon_1}{2}(1 - C|I_1|\frac{\varepsilon_1}{2}) = \underbrace{P_{I_1} K_{I_1} 2^{-\varepsilon|I_1|}}_{\geq \frac{1}{2}} \underbrace{2^{\varepsilon|I_1|}}_{\geq 1} \frac{\varepsilon_1}{2}(1 - \underbrace{C|I_1|\frac{\varepsilon_1}{2}}_{\leq \frac{1}{2}}) \geq \frac{\varepsilon_1}{8}. \quad \blacktriangleleft$$

4 Analysis of Full Consensus

Full Consensus performs a DFS in a tree as depicted in Figure 1 in much the same way as simplified Consensus, with two differences. First, the root node only has 2^w children (not infinitely many) and the probability that an unbroken path exists is therefore strictly less than 1. Secondly, when examining the outgoing edge of index σ_i of some node in layer i, then its status is no longer linked to B^i_Σ for $\Sigma = \sigma_0 \circ \dots \circ \sigma_i$. Instead Σ is divided as $\Sigma = \text{prefix}(\Sigma) \circ \text{suffix}(\Sigma)$ where $\text{suffix}(\Sigma) \in \{0,1\}^w$ and $B^i_{\text{suffix}(\Sigma)}$ is used. To prepare for the proof of Theorem 7, we present a coupling to, and a claim about simplified Consensus.

A Coupling between Simplified and Full Consensus. Consider the following natural coupling. Let $B^{(i)}_j$ for $i \in [n]$ and $j \in \mathbb{N}_0$ be the random variables underlying simplified Consensus and $\tilde{B}^{(i)}_S$ for $i \in [n]$ and $S \in \{0,1\}^w$ the random variables underlying full Consensus. The coupling should ensure that $B^{(i)}_\Sigma = \tilde{B}^{(i)}_{\text{suffix}(\Sigma)}$ for all pairs (i, Σ) such that simplified Consensus inspects $B^{(i)}_\Sigma$ and does not at an earlier time inspect $B^{(i)}_{\Sigma'}$ with $\text{suffix}(\Sigma') = \text{suffix}(\Sigma)$. In other words, for any pair (i, S), if simplified consensus inspects at least one variable $B^{(i)}_\Sigma$ with $\text{suffix}(\Sigma) = S$ then $\tilde{B}^{(i)}_S$ equals the earliest such variable that is inspected.

This implies that the runs of simplified and full Consensus behave identically as long as, firstly, σ_0 never reaches 2^w and, secondly, simplified Consensus never *repeats a suffix*, by which we mean inspecting $B^{(i)}_\Sigma$ for some pair (i, Σ) such that $B^{(i)}_{\Sigma'}$ with $\text{suffix}(\Sigma) = \text{suffix}(\Sigma')$ was previously inspected. In the following, by a *step* of Consensus we mean one iteration of its main while-loop, which involves inspecting exactly one random variable.

▷ Claim 11. Simplified Consensus repeats a suffix in step t with probability at most $\frac{t}{2^w}$.

Proof. Assume simplified Consensus is about to inspect $B^{(i)}_{\Sigma^*}$. Call $S \in \{0,1\}^w$ a *blocked suffix* if there exists $\Sigma \in \{0,1\}^*$ such that $S = \text{suffix}(\Sigma)$ and $B^{(i)}_\Sigma$ was previously inspected. This necessitates $\text{prefix}(\Sigma) < \text{prefix}(\Sigma^*)$. Clearly, step t repeats a suffix if $\text{suffix}(\Sigma^*)$ is blocked. A crucial observation is that the DFS has exhaustively explored all branches of the tree associated with any prefix less than Σ^* and the order in which this exploration has been carried out is no longer relevant. The symmetry between all nodes of the same layer therefore implies that every suffix is blocked with the same probability. Since at most t suffixes can be blocked at step t, the probability that Σ^* is blocked (given our knowledge of (i, Σ^*)) is at most $\frac{t}{2^w}$. ◁

Proof of Theorem 7. First note that the choice of $(\ell_1, \dots, \ell_n)$ made in Theorem 7 amounts to a valid choice of $(k_1 = 2^{\ell_1}, \dots, k_n = 2^{\ell_n})$ for applying Theorem 6. Indeed, for each $i \in [n]$ there exists some $\text{err}_i \in [1, 2)$ related to rounding up such that

$$\prod_{j=1}^{i} p_j k_j 2^{-\varepsilon} = \Big(\prod_{j=1}^{i} p_j\Big) 2^{\sum_{j=1}^{i} \ell_j} 2^{-\varepsilon i} = \Big(\prod_{j=1}^{i} p_j\Big) 2^{\lceil \varepsilon i + \sum_{j=1}^{i} \log_2(1/p_i)\rceil} 2^{-\varepsilon i}$$
$$= \Big(\prod_{j=1}^{i} p_j\Big) 2^{\varepsilon i + \sum_{j=1}^{i} \log_2(1/p_i)} \cdot \mathrm{err}_i 2^{-\varepsilon i} = \mathrm{err}_i \in [1,2]$$

as required. The number $T = \sum_{i=1}^{n} T_i$ of steps taken by simplified Consensus satisfies $\mathbb{E}[T] = \mathcal{O}(\sum_{i=1}^{n} \frac{1}{p_i \varepsilon}) = \mathcal{O}(n^{1+2c})$. By Markov's inequality T exceeds its expectation by a factor of n^c with probability at most n^{-c} so with probability at least $1 - \mathcal{O}(n^{-c})$ simplified Consensus terminates within $T_{\text{limit}} = n^{1+3c}$ steps.

By Claim 11 and a union bound the probability that simplified Consensus repeats a suffix within its first T_{limit} steps is at most $\sum_{t=1}^{T_{\text{limit}}} t/2^w = \mathcal{O}(T_{\text{limit}}^2/2^w) = \mathcal{O}(n^{2+6c}/2^w)$. By choosing $w \geq (2+7c)\log_2 n$ this probability is $\mathcal{O}(n^{-c})$. This choice also guarantees that σ_0 never exceeds 2^w during the first T_{limit} steps. Let now $E = \{T \leq T_{\text{limit}}\} \cap \{\text{no repeated suffix in the first } T_{\text{limit}} \text{ steps}\}$. By a union bound $\Pr[E] = 1 - \mathcal{O}(n^{-c})$ and by our coupling E implies that simplified and full Consensus explore the same sequence of nodes in their DFS and terminate with the same sequence $\sigma_0, \ldots, \sigma_n$ with $\sigma_0 < 2^w$. In particular full Consensus succeeds in that case as claimed.

The updated bound on $|M|$ simply reflects that σ_0, which in simplified Consensus had expected length $\log_2 1/\varepsilon + \mathcal{O}(1)$ now has fixed length $w = \mathcal{O}(\log n)$. Lastly, if T_i and $\tilde{T}_i$ denote the number of Bernoulli trials from the i-th family inspected by simplified and full Consensus, respectively, then conditioned on E we have $T_i = \tilde{T}_i$ so

$$\mathbb{E}[\tilde{T}_i \mid E] = \mathbb{E}[T_i|E] \leq \mathbb{E}[T_i]/\Pr[E] = \mathcal{O}(\mathbb{E}[T_i]) = \mathcal{O}(T_i^{\text{OPT}}/\varepsilon). \quad \blacktriangleleft$$

5 Application to Minimal Perfect Hashing

In this section, we apply the Consensus idea to the area of minimal perfect hash functions (MPHFs). Recall from Section 1.3 that an MPHF for a given set X of n keys maps each key in X to a unique integer from $[n]$.

5.1 Existing Strategies for Constructing MPHFs

We begin with a brief overview of established approaches with a focus on those we need. Detailed explanations are found in [18, 19].

Partitioning. Most approaches randomly partition the input into small *buckets* using a hash function and then construct an MPHF on each bucket separately. The natural way to obtain an MPHF on the entire input involves storing the bucket-MPHFs and prefix sums for the bucket sizes. Storing the prefix sums can be avoided when the partitioning uses a k-perfect hash function, as is done in ShockHash-Flat [21], and as we do in Section 5.3.

Hagerup and Tholey [12] demonstrate that partitioning into tiny buckets of size $\mathcal{O}(\frac{\log n}{\log\log n})$ when suitably combined with exhaustive tabulation of MPHFs on tiny inputs yields an approach with construction time $\mathcal{O}(n)$, query time $\mathcal{O}(1)$ and space overhead $\varepsilon = \Theta(\frac{\log^2 \log n}{\log n})$. Unfortunately the analysis requires astronomical values of $n \geq \max(\exp(\omega(1/\varepsilon)), 2^{150})$ [4] and is restricted to these rather large ε.

Below we explain *monolithic* variants of MPHFs, i.e. constructions not using partitioning, which are typically combined with partitioning to obtain faster *bucketed* variants.

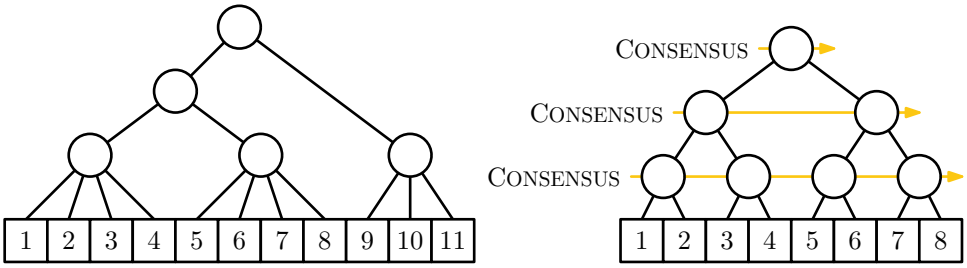

Figure 4 A general splitting tree and a balanced binary splitting tree as used in Section 5.2.

Recursive Splitting. A recursive splitting strategy [7] involves a predefined *splitting tree*, which is a rooted tree with n leaves.[9] See Figure 4 (left) for an example with $n = 11$. An MPHF for an input set of size n is given by a family of functions containing for each internal node v of the tree a *splitting hash function* f_v that maps keys to the children of v. Together, the family $(f_v)_v$ must describe a recursive partitioning of the input set into parts of size 1. The MPHF is queried for a key x by starting at the root. The splitting hash functions are evaluated on x and the resulting path is followed until a leaf is reached, the index of which is returned. Each f_v is identified by a seed that is found using trial and error. In the original paper [7] seeds are stored using Golomb-Rice coding [11, 31]. To keep the space overhead low, the last layer of the splitting tree uses ℓ-way splits for relatively large ℓ (5–16 in practice), which makes splitting hash functions costly to find.

Multiple-Choice Hashing. We randomly assign a set $\{h_1(x), \ldots, h_k(x)\} \subseteq [n(1+\varepsilon)]$ of candidates to each key hoping that a choice $\sigma(x) \in \{1, \ldots, k\}$ can be made for each key such that $x \mapsto h_{\sigma(x)}(x)$ is injective. A perfect hash function is then given by a retrieval data structure that stores σ [4, 10, 20]. A recent variant ShockHash [22, 21] achieves record space efficiency by using the aggressive configuration $\varepsilon = 0$ and $k = 2$ (combined with partitioning and recursive splitting). Many retries are needed until σ exists.

Bucket Placement. A general strategy with many variants assigns a random bucket $f(x) \in \{1, \ldots, b\}$ to each key and considers for each bucket $i \in [b]$ several (hash) functions $g_{i,1}, g_{i,2}, \ldots$ with range $[n]$. A choice $\sigma(i)$ is stored for each bucket such that $x \mapsto g_{f(x),\sigma(f(x))}(x)$ is a bijection. Typically, the values $\sigma(i)$ are chosen greedily in decreasing order of bucket sizes [30, 14, 1], but backtracking has also been considered [33, 8] (in a different sense than Consensus).

5.2 Monolithic Consensus-RecSplit

We now describe a variant of recursive splitting in an idealised setting with $n = 2^d$ that uses Consensus to be particularly space efficient. The idea is simple. The data structure consists of $n - 1$ two-way splitting hash functions, i.e. hash functions with range $\{0, 1\}$, arranged in a balanced binary tree with n leaves, see Figure 4 (right).

This means that during construction for a key set S we have to select the splitting hash functions from top to bottom such that each function splits the part of S arriving at its node perfectly in half. The data structure is entirely given by a sequence of $n - 1$ seeds that identify the splitting hash functions. If we search and encode these seeds using the Consensus algorithm, we obtain the following result.

[9] In the original paper [7], the lowest level is suppressed, with correspondingly changed terminology.

▶ **Theorem 12** (Monolithic CONSENSUS-RecSplit). *Let $n = 2^d$ for $d \in \mathbb{N}$ and $\varepsilon \in [\frac{1}{n}, 1]$. Monolithic-RecSplit is an MPHF data structure with space requirement* $\mathrm{OPT}_{\mathrm{MPHF}} + \mathcal{O}(\varepsilon n + \log^2 n)$*, expected construction time* $\mathcal{O}(\max(n^{3/2}, \frac{n}{\varepsilon}))$ *and query time* $\mathcal{O}(\log n)$*.*

Proof. We use a separate CONSENSUS data structure per level of the splitting tree and construct them from top to bottom. Consider level $\ell \in \{0, \dots, d-1\}$ of the tree, which contains 2^ℓ nodes responsible for $n_\ell = 2^{d-\ell}$ keys each. The probability that a given seed for a splitting hash function amounts to a perfect split for n_ℓ keys is $p(n_\ell) = \binom{n_\ell}{n_\ell/2} \cdot 2^{-n_\ell}$ by a simple counting argument. A standard approximation gives $p(n_\ell) = \Theta(1/\sqrt{n_\ell})$.

By applying Theorem 7 with $p_1 = \ldots = p_{2^\ell} = p(n_\ell)$, $\varepsilon_\ell = \min(1, \varepsilon \cdot n_\ell^{3/4})$ and $w = \mathcal{O}(\log n)$ we obtain a data structure encoding 2^ℓ successful seeds. The expected number of seeds inspected is $\mathcal{O}(\frac{1}{p(n_\ell)\varepsilon_\ell})$ for each node, which corresponds to expected work of $\mathcal{O}(\frac{n_\ell}{p(n_\ell)\varepsilon_\ell}) = \mathcal{O}(n_\ell^{3/2}/\varepsilon_\ell)$ per node when seeds are tested by hashing all n_ℓ relevant keys.[10] For the total expected work w_ℓ in level ℓ there are, up to constant factors, the following two options.

$$\text{if } \varepsilon_\ell = \varepsilon \cdot n_\ell^{3/4} \text{ then } w_\ell = \frac{n_\ell^{3/2}}{\varepsilon n_\ell^{3/4}} \cdot 2^\ell = \frac{n_\ell^{3/4} 2^\ell}{\varepsilon} = \frac{2^{(d-\ell)\cdot 3/4 + \ell}}{\varepsilon} = \frac{n^{3/4} \cdot 2^{\ell/4}}{\varepsilon}.$$

$$\text{if } \varepsilon_\ell = 1 \text{ then } w_\ell = n_\ell^{3/2} \cdot 2^\ell = 2^{(d-\ell)\cdot 3/2 + \ell} = n^{3/2} \cdot 2^{-\ell/2}.$$

The formula for the first case is maximised for $\ell = d-1$ giving $w_{d-1} = \Theta(n/\varepsilon)$. The formula for the second case is maximised for $\ell = 0$ giving $w_0 = n^{3/2}$. Since both describe geometric series we get $\sum_{\ell=0}^{d-1} w_\ell = \mathcal{O}(w_0 + w_{d-1}) = \mathcal{O}(n^{3/2} + n/\varepsilon) = \mathcal{O}(\max(n^{3/2}, n/\varepsilon))$ as desired.

The space requirement for level ℓ is $|M_\ell| = 2^\ell \cdot \log_2(1/p(n_\ell)) + \varepsilon_\ell 2^\ell + \mathcal{O}(\log n)$. To bound the sum $\sum_{\ell=0}^{d-1} |M_\ell|$ we look at the terms in $|M_\ell|$ separately. For the first, we will use that $\prod_{\ell=0}^{d-1} p(2^{d-\ell})^{2^\ell} = \frac{n!}{n^n}$, which can be checked by induction: $d = 0$ is clear. For $d > 0$ we have

$$\prod_{\ell=0}^{d-1} p(2^{d-\ell})^{2^\ell} = p(n) \cdot \prod_{\ell=1}^{d-1} p(2^{d-\ell})^{2^\ell} = p(n) \cdot \Big(\prod_{\ell=1}^{d-1} p(2^{d-\ell})^{2^{\ell-1}} \Big)^2$$

$$= p(n) \cdot \Big(\prod_{\ell=0}^{d-2} p(2^{d-1-\ell})^{2^\ell} \Big)^2 \overset{\text{Ind.}}{=} p(n) \cdot \Big(\frac{(n/2)!}{(n/2)^{n/2}} \Big)^2 = \binom{n}{n/2} 2^{-n} \cdot \Big(\frac{(n/2)!}{(n/2)^{n/2}} \Big)^2 = \frac{n!}{n^n}.$$

The leading terms in $|M_\ell|$ therefore add up to

$$\sum_{\ell=0}^{d-1} 2^\ell \cdot \log_2(1/p(n_\ell)) = \log_2 \Big(1/ \prod_{\ell=0}^{d-1} p(n_\ell)^{2^\ell} \Big) = \log_2 \big(\frac{n^n}{n!} \big) = n \log_2 e - \mathcal{O}(\log n).$$

The overhead terms $\varepsilon_\ell \cdot 2^\ell$ are geometrically increasing in ℓ. This is because

$$\frac{\varepsilon_{\ell+1} \cdot 2^{\ell+1}}{\varepsilon_\ell \cdot 2^\ell} = \frac{\min(1, \varepsilon \cdot n_{\ell+1}^{3/4})}{\min(1, \varepsilon \cdot n_\ell^{3/4})} \cdot 2 = \frac{\min(1, \varepsilon \cdot (2^{d-\ell-1})^{3/4})}{\min(1, \varepsilon \cdot (2^{d-\ell})^{3/4})} \cdot 2 \geq 2^{-3/4} \cdot 2 = 2^{1/4} > 1.$$

The sum of the overhead terms is therefore dominated by the last term $\varepsilon_{d-1} 2^{d-1} \leq \varepsilon n \cdot 2^{-1/4}$ giving $\sum_{\ell=0}^{d-1} \varepsilon_\ell \cdot 2^\ell \leq \varepsilon n / (2^{1/4} - 1) < 6\varepsilon n$. Overall we get as claimed

$$\text{space} = \sum_{\ell=0}^{d-1} |M_\ell| \leq n \log_2 e + 6\varepsilon n + \mathcal{O}(\log^2 n).$$

[10] Dividing the work per node by ε_ℓ gives $-n_\ell^{3/2}/\varepsilon_\ell^2$. Our choice of $\varepsilon_\ell \sim n_\ell^{3/4}$ (as long as $\min(1, \cdot)$ does not kick in) is desired to ensure that using extra bits amounts to roughly the same reduction of work in each level, such that we have a consistent trade-off between time and space.

A query needs to extract one seed from each of the $d = \log_2 n$ CONSENSUS data structures. Since each uses uniform values for $p_1 = \ldots = p_{n_\ell}$, the product $\prod_{j=1}^{i} p_j = p(n_\ell)^i$ is easy to compute in constant time, which is sufficient to find each seed in constant time, so we get a query time of $\mathcal{O}(d)$ in total. ◀

5.3 Bucketed CONSENSUS-RecSplit

We now replace the upper layers of Monolithic CONSENSUS-RecSplit with a minimal k-perfect hash function [13]. This reduces query time as there are fewer layers to traverse and reduces construction time because the splits in the top layers are the most expensive ones to compute. Most importantly, it enables efficiently handling input sizes that are not powers of two.

For any $k \in \mathbb{N}$ a minimal k-perfect hash function for a set S of n keys is a data structure mapping the elements of S to buckets indexed with $[\lceil n/k \rceil]$ such that each bucket $i \in [\lfloor n/k \rfloor]$ receives exactly k keys. If k does not divide n then bucket $\lceil n/k \rceil$ receives between 1 and $k-1$ leftover keys. It has long been known that the space lower bound for such a data structure is $\approx n(\log_2 e - \frac{1}{k}\log_2 \frac{k^k}{k!})$ [1], shown to be $\approx \frac{n}{2k}\log 2\pi k$ in [16]. In the full version of this paper [24] we outline a compact minimal k-perfect hash function with, in expectation, $\mathcal{O}(\frac{n}{k}\log k)$ bits of space, constant query time, and linear construction time.

We call our resulting MPHF Bucketed CONSENSUS-RecSplit. Its performance is as follows (previously stated in Section 1.3).

▶ **Theorem 5** (Bucketed CONSENSUS-RecSplit). *For any $\varepsilon \in [n^{-3/7}, 1]$ there is an MPHF data structure with space requirement $(1 + \mathcal{O}(\varepsilon))\mathrm{OPT}_{\mathrm{MPHF}}$, expected construction time $\mathcal{O}(n/\varepsilon)$ and expected query time $\mathcal{O}(\log 1/\varepsilon)$.*

Proof. The idea is to use our monolithic construction but replace the top-most layers with a k-perfect hash function. More precisely, we choose $k = 2^{\lfloor \frac{4}{3}\log_2 1/\varepsilon \rfloor} = \Theta(\varepsilon^{-4/3})$ and construct a minimal k-perfect hash function F for the input set. As discussed in the full version, the construction time of F is $\mathcal{O}(n)$, the expected query time is $\mathcal{O}(1)$ and the space consumption is $\mathcal{O}(\frac{n}{k}\log k) = \mathcal{O}(\varepsilon n)$ bits, all well within the respective budgets. The resulting $\lfloor n/k \rfloor$ buckets of k keys each (a power of 2) are recursively split like in our monolithic data structure, which takes at most $\mathrm{OPT}_{\mathrm{MPHF}} + \mathcal{O}(\varepsilon n)$ bits of space (the $\mathcal{O}(\log^2 n)$ term is dominated by $\mathcal{O}(\varepsilon n)$). Since we make no assumptions on n there might be up to $k-1$ leftover keys assigned to an extra bucket. For these we construct a separate MPHF F' with range $\{\lfloor n/k \rfloor \cdot k + 1, \ldots, n\}$. Since $k \sim \varepsilon^{-4/3} = \varepsilon \cdot \varepsilon^{-7/3} \leq \varepsilon n$ pretty much any compact (not necessarily succinct) MPHF is good enough here, provided it supports queries in logarithmic time. Queries evaluate F first and, if mapped to a regular bucket, evaluate a sequence of $\log_2 k$ splits, or, if mapped to the extra bucket, evaluate F'. This takes $\mathcal{O}(\log k) = \mathcal{O}(\log 1/\varepsilon)$ time in the worst case.

Concerning construction time, note that the top-most level in use has nodes of size $n_\ell = k \leq \varepsilon^{-4/3}$ and the definition of ε_ℓ we made simplifies to $\varepsilon_\ell = n_\ell^{3/4} \cdot \varepsilon$ without the "$\min(1, \cdot)$". By an argument in Theorem 12, the construction time is then dominated by the bottom layer and bounded by $\mathcal{O}(n/\varepsilon)$ as claimed. ◀

5.4 Experiments

To demonstrate that CONSENSUS-RecSplit is viable in practice, we give an implementation and compare it to other MPHF constructions from the literature.[11] We only include the most space-efficient previous approaches with space consumption below 1.6 bits per key and

[11] We run single-threaded experiments on an Intel i7 11700 processor with a base clock speed of 2.5 GHz. The sizes of the L1 and L2 data caches are 48 KiB and 512 KiB per core, and the L3 cache has a size of

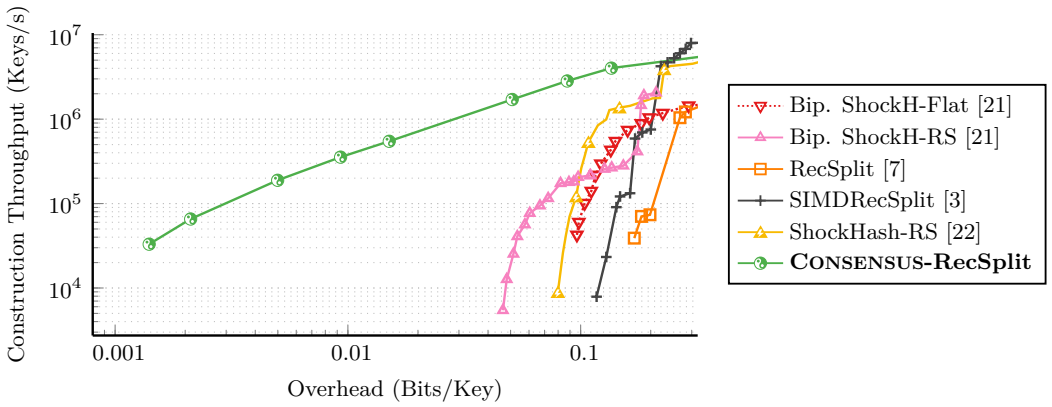

Figure 5 Experimental evaluation of very space-efficient MPHF algorithms, showing the trade-off between space consumption and construction throughput. Because CONSENSUS-RecSplit is focused on space consumption, we only include approaches that achieve below 1.6 bits per key.

refer to [18, 19] for a detailed comparison of state-of-the-art perfect hashing approaches with larger space consumption. Our implementation departs from the algorithmic description in Section 5.3 by using the threshold-based k-perfect hash function [21, 13]. We postpone further tuning and parallelisation efforts to a future paper.

Figure 5 shows the trade-off between space consumption and construction time of CONSENSUS-RecSplit. In the full version [24] we also give a table. The performance of all previous approaches degrades abruptly for smaller overheads because of their exponential dependency on $1/\varepsilon$ while CONSENSUS-RecSplit shows an approximately linear dependence on $1/\varepsilon$ as predicted in Theorem 5. The space lower bound for MPHFs is $\log_2 e \approx 1.443$ bits per key. The previously most space-efficient approach, bipartite ShockHash-RS [21], achieves 1.489 bits per key. In about 15% of the construction time, CONSENSUS-RecSplit achieves a space consumption of just 1.444 bits per key. At a space consumption of 1.489 bits per key, CONSENSUS-RecSplit is more than 350 times faster to construct than the previous state of the art.

Queries take 150–250 ns depending on k and therefore the depth of the splitting tree (see full version), so their performance is not too far from compact configurations of RecSplit (100 ns) and bipartite ShockHash-RS (125 ns). Future work can improve on the query performance by storing the seeds needed for each query closer to each other. We can adapt bucketed CONSENSUS-RecSplit by constructing one CONSENSUS data structure storing seeds bucket by bucket instead of an independent data structure for each layer. Preliminary experiments show up to 30% faster queries with moderately slower construction at the same space consumption. Splittings higher up in the tree not only have a smaller success probability, but are also more costly to test. We are therefore incentivised to select a different space overhead parameter ε for each splitting within the same CONSENSUS data structure. We leave this generalisation of CONSENSUS to non-uniform ε for future work.

16 MiB. The page size is 4 KiB. We use the GNU C++ compiler version 11.2.0 with optimization flags `-O3 -march=native`. Like previous papers [19, 21, 22, 14, 3], we use 100 million random string keys of uniform random length [10..50] as input. The source code is available on GitHub [17, 23].

6 Conclusion

This paper concerns data structures that store sequences of successful seeds, i.e. values known to influence pseudo-random processes in desirable ways. Normally these seeds are first found independently of each other using trial and error and then encoded separately. In this paper we show that, perhaps surprisingly, this wastes $\Omega(1)$ bits per seed compared to a lower bound.

We present the CONSENSUS approach, which **co**mbi**n**es **s**earch and **en**coding of **su**ccessful **s**eeds and reduces the space overhead to $\mathcal{O}(\varepsilon)$ bits at the price of increasing the required work by a factor of $\mathcal{O}(1/\varepsilon)$.

To demonstrate the merits of our ideas in practice, we apply it to the construction of minimal perfect hash functions. CONSENSUS-RecSplit is the first MPHF to achieve a construction time that only depends linearly on the inverse space overhead. Despite using the same recursive splitting idea as [7], the space overhead is, for the same construction throughput, up to two orders of magnitude smaller in practice.

Future Work. Given our promising results, we intend to continue working on CONSENSUS-RecSplit, in particular looking into parallelisation and improving query times. We also believe that CONSENSUS can be applied to other randomised data structures, including but not limited to other perfect or k-perfect hash functions, retrieval data structures and AMQ-filters. We give a first result on k-perfect hash functions using CONSENSUS in [13].

Faster Exponential Algorithms for Cut Problems via Geometric Data Structures

László Kozma

Junqi Tan
Institut für Informatik, Freie Universität Berlin, Germany

Abstract

For many hard computational problems, simple algorithms that run in time $2^n \cdot n^{O(1)}$ arise, say, from enumerating all subsets of a size-n set. Finding (exponentially) faster algorithms is a natural goal that has driven much of the field of *exact exponential algorithms* (e.g., see Fomin and Kratsch, 2010). In this paper we obtain algorithms with running time $O(1.9999977^n)$ on input graphs with n vertices, for the following well-studied problems:

- d-Cut: find a proper cut in which no vertex has more than d neighbors on the other side of the cut;
- Internal Partition: find a proper cut in which every vertex has at least as many neighbors on its side of the cut as on the other side; and
- (α, β)-Domination: given *intervals* $\alpha, \beta \subseteq [0, n]$, find a subset S of the vertices, so that for every vertex $v \in S$ the *number* of neighbors of v in S is from α and for every vertex $v \notin S$, the number of neighbors of v in S is from β.

Our algorithms are exceedingly simple, combining the *split and list* technique (Horowitz and Sahni, 1974; Williams, 2005) with a tool from computational geometry: *orthogonal range searching* in the moderate dimensional regime (Chan, 2017). Our technique is applicable to the decision, optimization and counting versions of these problems and easily extends to various generalizations with more fine-grained, *vertex-specific* constraints, as well as to *directed*, *balanced*, and other variants.

Algorithms with running times of the form c^n, for $c < 2$, were known for the first problem only for constant d, and for the third problem for certain special cases of α and β; for the second problem we are not aware of such results.

1 Introduction

For many hard computational problems, simple algorithms that run in time $2^n \cdot n^{O(1)}$ can be obtained, say, by enumerating all subsets of a size-n set. Obtaining speedups of a factor exponential in n is a natural goal that has driven much of the field of *exact exponential algorithms*, motivating the development of powerful and general algorithmic techniques.

Landmark successes include Independent Set [30], Subset Sum [18], Hamiltonian Cycle [4], Max Cut [33], 3-CNF SAT [27], to name just a few. While all NP-hard, these problems admit algorithms running in time c^n with $c < 2$, significantly faster than simple enumeration or dynamic programming over subsets.[1] We refer to the textbook of Fomin and Kratsch [16] for a broad overview of such results and techniques, as well as to the earlier, influential survey of Woeginger [34].

[1] For the problems we mention, n refers to the most natural problem-specific input parameter, e.g., the number of vertices for graph problems, the number of variables for CNF SAT, or the number of elements for Set Cover or Subset Sum.

From a practical point of view, replacing a runtime of 2^n by (say) 1.999^n is, of course, rarely consequential, especially if the latter algorithm is more complicated. Yet, such improvements often point at problem-specific algorithmic structure that can be further exploited. Also, the search for algorithms that break such "triviality barriers" has often led to the invention of powerful algorithmic techniques that have found broader applications; examples include *branch and reduce*, *measure and conquer*, or *split and list*.

Yet, the set of techniques known to lead to such speedups is not large and several important problems seem to resist improvements beyond 2^n (Graph Coloring, CNF SAT, Set Cover, TSP are prominent examples). The hypothesis that no substantially faster algorithm exists for CNF SAT (the *SETH Conjecture* [19]) has become a cornerstone of fine-grained complexity theory, and other barriers are similarly conjectured (e.g., the *Set Cover Conjecture* [10, 21]). There are also many lesser known problems "stuck" at 2^n, where the existing techniques do not seem applicable. Problems where such a barrier was recently bypassed include, e.g., various scheduling [11, 25], bin packing [24], clustering [1, 13], multicut [23] and multiway cut [8, 35] problems, to mention just a few.

Restricted cut problems. In this paper, we mainly consider *cut* problems in graphs, with certain natural restrictions on how vertices may interact with the cut. We focus on decision problems (whether a cut of the required form exists); in all cases, an actual cut can be constructed with minimal overhead.

Our first problem is $\boxed{d\text{-Cut}}$: given an undirected graph $G = (V, E)$ and an integer d, find a bipartition $V = V_L \cup V_R$, where V_L, V_R are nonempty disjoint sets, so that each vertex $v \in V$ has at most d neighbors on the other side of the partition. Precisely, denoting by $N(v)$ the (open) set of neighbors of v, we require $|N(v) \cap V_R| \leq d$ for all $v \in V_L$ and $|N(v) \cap V_L| \leq d$ for all $v \in V_R$. The value d is arbitrary, in particular, it may depend on n.

The problem can be seen as a natural *min-max* variant of the famous Min Cut problem. While Min Cut is polynomial time solvable, d-Cut is NP-hard, even for $d = 1$ [9].

The d-Cut problem was studied by Gomes and Sau [12] as a natural generalization of the well-known Matching Cut problem (the case $d = 1$). Graphs admitting a matching cut are known as *decomposable* and have been extensively studied, e.g., see Graham [17], Chvátal [9], and Bonsma [5]. For Matching Cut, Komusiewicz, Kratsch, and Le [20] give an $O(1.3071^n)$ time algorithm, using a reduction to CNF SAT. For the general d-Cut problem, Gomes and Sau obtain a runtime of the form $O(c_d^n)$ where c_d grows at least as $(2^d - 1)^{\frac{1}{d}}$. As such, the base is smaller than 2 for *fixed* d, but cannot, in general, be bounded away from 2; the existence of an algorithm with runtime $O((2 - \varepsilon)^n)$ for $\varepsilon > 0$ was left open by Gomes and Sau. In fact, the SAT-based algorithm of Komusiewicz also applies to d-Cut, resulting in a polynomial number of $(d + 2)$-CNF SAT instances with n variables. Under the SETH conjecture [19], the running time of this approach also cannot be bounded as $O((2 - \varepsilon)^n)$.

We note that the related Max Cut problem can be solved in time $O(1.73^n)$ by reduction to fast matrix multiplication [33], this technique however, seems not to extend to d-Cut.

A second general cut problem we consider is $\boxed{(\alpha, \beta)\text{-Domination}}$. Here, we seek a bipartition $V = V_L \cup V_R$, where $|N(v) \cap V_L| \in \alpha$ for all $v \in V_L$ and $|N(v) \cap V_L| \in \beta$ for all $v \in V_R$. Note that α and β are subsets of the set $\{0, 1, \ldots, n\}$.

This formulation, introduced by Telle [31], generalizes many natural structures and problems in graphs, such as Independent Set, Dominating Set, Induced Matching, etc., by setting α and β to particular values (we refer to [31, 14] for a list of special cases). While the fully general case seems hopeless, it is perhaps most natural to require α and β to

be intervals, i.e., of the form $\alpha = [\alpha', \alpha'']$, $\beta = [\beta', \beta'']$. This already captures most, if not all of the interesting special cases. Notice, however, that the problem does not strictly generalize d-Cut; while setting $\beta = [0, d]$ enforces the degree constraint on V_R, the admissible degrees for vertices in V_L depend on their original degrees in G.

The problem was studied from the point of view of exponential algorithmics by Fomin, Golovach, Kratochvíl, Kratsch, and Liedloff [14]. They obtain algorithms with runtime c^n for $c < 2$ in the special case $|\alpha| = |\beta| = 1$, as well as in some cases where α and β are not necessarily intervals, e.g., when $|\alpha| + |\beta| = 3$ or when α and β are generated by arithmetic sequences; these latter cases fall outside of our definition. The same authors, in a different paper [15] also consider other special cases. These require some combination of α and β being disjoint, finite, or successor-free (i.e., not containing consecutive integers). As such, the conditions are not comparable with our requirement for α and β to be intervals; in our case, α and β may overlap arbitrarily, may be infinite, but cannot have gaps.

The third problem we consider is Internal Partition. Here, we seek a bipartition $V = V_L \cup V_R$, where V_L and V_R are nonempty and every vertex has at least half of its neighbors on its own side of the partition. Formally, for all $v \in V_L$ we have $|N(v) \cap V_L| \geq |N(v) \cap V_R|$, and for all $v \in V_R$ we have $|N(v) \cap V_L| \leq |N(v) \cap V_R|$.

Such a partition, called an *internal partition*, arises in many settings (in the literature the terms *friendly-*, *cohesive-*, or *satisfactory-* partition are also used). Determining whether a graph admits an internal partition is NP-hard [3]; this is in contrast to *external partitions* (where every vertex has at least half of its neighbors on the other side), which always exist. Research has mostly focused on conditions that guarantee the existence of an internal partition, e.g., see Thomassen [32], Stiebitz [29], and the survey of Bazgan, Tuza, and Vanderpooten [3]. A long-standing conjecture is that every sufficiently large r-regular graph has an internal partition; e.g., see Ban and Linial [2] and Linial and Louis [22] for recent partial results. We are not aware of algorithms with runtime of the form $O((2-\varepsilon)^n)$ for deciding the existence of an internal partition.

All three problems can trivially be solved in time $2^n \cdot n^{O(1)}$. Our main result improves this for all three problems.

▶ **Theorem 1.** *The d-Cut, (α, β)-Domination, and Internal Partition problems can be solved in time $O(1.9999977^n)$.*

While we state our results for the decision problems (does a bipartition with the given property exist?), we can also easily extend them to the *optimization* versions of the problems (maximize or minimize the left side $|V_L|$ of the cut while satisfying the constraint), and to the *counting* versions (count the number of cuts with the given property). The optimization view is most natural for (α, β)-Domination, where special cases include the task of finding e.g., a maximum independent set, a minimum dominating set, etc. (of course, for some of the well-known special cases faster algorithms already exist).

Additional constraints on the cuts (e.g., requiring V_L to be of a certain size, say $|V_L| = n/2$), or making the edges directed (and extending the conditions accordingly to in- or out-neighborhoods) can easily be accommodated, as will be clear later.

Our algorithms also extend naturally to more fine-grained, *vertex-specific* conditions. For d-Cut, this could mean setting an upper bound d_v for each vertex v on the number of neighbors across the cut, and possibly, a vertex-specific *lower bound* on the same quantity. For (α, β)-Domination, we could set specific intervals $[\alpha_v, \beta_v]$ for each vertex v; these may even depend on the degree of v in the input, or on other properties of the graph.

Overview of our approach. In spite of the unwieldy bound on the running time, our approach is conceptually exceedingly simple, and all three problems are tackled in essentially the same way.

Our starting point is the *split and list* technique originally used by Horowitz and Sahni [18] for Subset Sum: Given a set $X = \{x_1, \ldots, x_n\}$, find a subset of X whose elements add up to a given value t.

The technique works by splitting X into $X_A = \{x_1, \ldots, x_{\lfloor n/2 \rfloor}\}$ and $X_B = X \setminus X_A$. Then, the sets $\mathcal{S}_A$, resp., $\mathcal{S}_B$ of the possible sums given by subsets of X_A, resp., X_B are computed. The problem now amounts to searching, for all $x \in \mathcal{S}_A$, for a matching pair $t - x \in \mathcal{S}_B$. This can be solved in time $O(n)$ by binary search if $\mathcal{S}_B$ is sorted, which can be achieved by an $O(n2^{n/2})$ time preprocessing. An overall runtime of $O(n2^{n/2})$ results.

We can view the sorting/searching part of the algorithm as storing $\mathcal{S}_B$ in an efficient comparison-based dictionary (say, a balanced binary search tree). Our extension of the technique amounts to replacing this dictionary with a more sophisticated multidimensional search structure.

In particular, we use the *orthogonal range search* data structure of Chan [7]. Such a data structure stores a set of N vectors from $\mathbb{R}^d$. A *dominance range query* $q \in \mathbb{R}^d$ returns the number (or the list) of vectors stored that are upper bounded by q on every coordinate. Precisely, a stored vector $y = (y_1, \ldots, y_d)$ is reported for query vector $q = (q_1, \ldots, q_d)$ if $y_i \leq q_i$ for all $i \in \{1, \ldots, d\}$.

In most applications of range searching, the dimension d is assumed constant, however, Chan's data structure allows for d that is polylogarithmic in N. As we only need $d \in O(\log N)$, we state the result in this form. Note that dominance range queries can be reduced to *orthogonal range queries*, where each query is specified by an axis-parallel hypercube (box), and vice versa (by doubling the number of dimensions). In our application, we always formulate our queries as dominance range queries.

A small remark on the computational model is in order. While the data structure is defined for vectors in $\mathbb{R}^d$, assuming a real RAM with constant time operations, in our application all vector coordinates are integers in $\{-2n, \ldots, 2n\}$, our results thus hold in more realistic models such as the word RAM, or even if we account for the number of bit-operations.

The result we rely on takes the following form.

▶ **Lemma 2** (Chan [7]). *We can preprocess N vectors from $\mathbb{R}^d$ for $d \leq c \log_2 N$, and store them in a data structure that serves a sequence of N dominance range queries in a total time (including the preprocessing) $N^{2-\varepsilon_c}$, where $\varepsilon_c > 0$ depends only on c.*

We use this geometric data structure to solve the mentioned graph cut problems similarly to the split and list technique sketched above. We split the set of vertices in two equal parts, and form all possible bipartitions of both parts. Combining two such bipartitions into one requires checking whether they are "compatible", i.e., whether their union satisfies the degree constraints. This can, in all three cases, be verified with dominance range queries on appropriately preprocessed degree vectors. We precisely state and prove our results in Section 2.

In Section 3 we derive an exact constant ε_c for Lemma 2 in our setting; this is not easy to read off directly from previous work, as results are stated in asymptotic notation, e.g., $\varepsilon_c \in 1/O(\log c)$ where c is allowed to be (slightly) superconstant. In our application, as we will show, $c = 16$ and $\varepsilon_c \geq 3 \cdot 10^{-6}$ are feasible, which for $N = 2^{n/2}$ yield the stated runtime.

Chan [7] gives several different implementations that result in a bound of the form given in Lemma 2. We work out the constant in the exponent for the variant that appears the simplest [7, § 2.1]. It is a randomized, "purely combinatorial" implementation, i.e., not using

fast matrix multiplication or other algebraic tools. The data structure allows for an *online* sequence of queries. As in our setting the queries are *offline* (i.e., known upfront), we could use one of the more efficient offline, as well as deterministic versions from [7], to obtain a similar, possibly better constant; we refrain from this to keep the presentation simple.

While the use of a geometric data structure may seem surprising in a graph theoretic context (its implementation involves an intricate lopsided recursion reminiscent of k-d-trees), Chan's technique did have previous graph-applications, although mostly in the polynomial-time regime, e.g., for the all pairs shortest paths problem [7]. For a different flavor of applying orthogonal range searching (in constant dimensions) to graph algorithms, see [6].

After presenting our results (Section 2) and deriving a precise constant bound for the base of the running time (Section 3), in Section 4 we give some final thoughts.

2 Results

We use standard graph notation. A bipartition (cut) of an undirected graph $G = (V, E)$ is a partitioning (V_L, V_R) of the set of vertices, i.e., $V = V_L \cup V_R$ and $V_L \cap V_R = \emptyset$. A *proper* bipartition is one where both V_L and V_R are nonempty. We denote the open neighborhood of a vertex v by $N(v)$, i.e., $N(v) = \{u \in V : uv \in E\}$. For convenience, for a set $A \subseteq V$ we denote $N_A(v) = N(v) \cap A$.

2.1 Internal partition

We start with the Internal Partition problem whose solution is the simplest. We first formally define the problem.

Internal partition
Input: An undirected graph $G = (V, E)$.
Output: Is there a proper bipartition (V_L, V_R) of V such that
- $|N_{V_L}(v)| \geq |N_{V_R}(v)|$ for all $v \in V_L$,
- $|N_{V_R}(v)| \geq |N_{V_L}(v)|$ for all $v \in V_R$.

In words, every vertex has at least half of its neighbors in its own part.

Algorithm. We now describe our algorithm for Internal Partition. Start by choosing an arbitrary subset V_A of V of size $\lfloor n/2 \rfloor$ and let $V_B = V \setminus V_A$. For ease of notation, assume $V_A = \{v_1, \ldots, v_{\lfloor n/2 \rfloor}\}$, $V_B = \{v_{\lfloor n/2 \rfloor + 1}, \ldots, v_n\}$.

We consider every possible bipartition of V_A and every possible bipartition of V_B. Our goal is to identify a "matching pair", i.e., a bipartition (S, R) of V_A and a bipartition (S', R') of V_B so that $(S \cup S', R \cup R')$ is a valid bipartition of V, satisfying the given degree constraints.

To achieve this, we encode every proper bipartition (S, R) of V_A as a vector $q = q_S$ and every proper bipartition (S', R') as a vector $p = p_{S'}$, both of dimension $2n$. Our encoding is meant to ensure that $(S \cup S', R \cup R')$ is a feasible solution for Internal Partition if and only if $q \geq p$, i.e., vector q dominates vector p. Intuitively, p is a *data vector* stored in the data structure, and q is a *query vector*.

We define $q_S = (q_1^1, \ldots, q_n^1, q_1^2, \ldots, q_n^2)$ as follows. For all $i = 1, \ldots, n$:
- if $v_i \in S$, then $q_i^1 = |N_S(v_i)| - |N_R(v_i)|$, and $q_i^2 = n$,
- if $v_i \in R$, then $q_i^1 = n$, and $q_i^2 = |N_R(v_i)| - |N_S(v_i)|$,
- if $v_i \in V_B$, then $q_i^1 = |N_S(v_i)| - |N_R(v_i)|$, and $q_i^2 = |N_R(v_i)| - |N_S(v_i)|$.

Intuitively, the entries q_i^1 and q_i^2 store the "excess degree" of v_i to its own part. The two groups of entries correspond to the two inequalities in the definition of the problem. If $v_i \in V_A$, then its assignment to either set $S \subseteq V_L$ or $R \subseteq V_R$ is already determined, so only one of the two inequalities is relevant to v_i. Accordingly, we set one of q_i^1 and q_i^2 to the correct excess degree, while we set the other to a large value (n) that ensures dominance. If $v_i \in V_B$, then its assignment to V_L or V_R is not yet determined, and thus, we compute the excess degrees to both parts.

Symmetrically, for every proper bipartition (S', R') of V_B, we create a vector $p_{S'} = (p_1^1, \ldots, p_n^1, p_1^2, \ldots, p_n^2)$ as follows. For all $i = 1, \ldots, n$:

- if $v_i \in S'$, then $p_i^1 = |N_{R'}(v_i)| - |N_{S'}(v_i)|$, and $p_i^2 = -n$,
- if $v_i \in R'$, then $p_i^1 = -n$, and $p_i^2 = |N_{S'}(v_i)| - |N_{R'}(v_i)|$,
- if $v_i \in V_A$, then $p_i^1 = |N_{R'}(v_i)| - |N_{S'}(v_i)|$, and $p_i^2 = |N_{S'}(v_i)| - |N_{R'}(v_i)|$.

The algorithm now stores all vectors $p_{S'}$ in a data structure and queries, for each vector q_S, whether it dominates any of the stored vectors. If a dominating pair is found, then the output is yes, otherwise no.

Both the number of stored vectors and the number of queries is at most $N = 2^{\lceil \frac{n}{2} \rceil}$. The construction of the vectors clearly takes time polynomial in n per vector.

Of course, comparing each pair directly would yield no runtime improvement. However, by applying the data structure of Lemma 2, we can solve the problem in time $O((2^{1-\varepsilon_c/2})^n)$ time, where $c = 4$, since the dimension is $2n = 4 \log_2 N$.

We required (S, R) and (S', R') to be *proper* bipartitions of V_A and V_B, to avoid a possible trivial solution where one part is empty. This means that we need to check the cases $S = \emptyset$ or $R = \emptyset$ against all proper bipartitions of V_B and the cases $S' = \emptyset$ or $R' = \emptyset$ against all proper bipartitions of V_A. These special cases require time $2^{n/2} \cdot n^{O(1)}$, which is absorbed in the overall runtime.

Correctness. We must show that V admits a feasible bipartition if and only if there is some q_S that dominates some $p_{S'}$.

Suppose that (V_L, V_R) is a feasible bipartition, and let V_A, V_B be the algorithm's choice, so $S = V_A \cap V_L$ and $S' = V_B \cap V_L$, and $R = V_A \cap V_R$ and $R' = V_B \cap V_R$ are among the sets considered. The case when one of S, S', R, R' is empty is handled separately, and a solution can clearly be found. Otherwise, let q_i^k, p_i^k, for $i \in \{1, \ldots, n\}$ and $k \in \{1, 2\}$ denote the entries of q_S and $p_{S'}$, as defined above.

If $v_i \in S \subseteq V_L$, or if $v_i \in S' \subseteq V_L$, then $q_i^1 - p_i^1 = |N_S(v_i)| - |N_R(v_i)| + |N_{S'}(v_i)| - |N_{R'}(v_i)| = |N_{V_L}(v_i)| - |N_{V_R}(v_i)|$. This must be nonnegative from the feasibility condition. For the second part, if $v_i \in S \subseteq V_L$, then $q_i^2 = n$, and $p_i^2 = |N_{S'}(v_i)| - |N_{R'}(v_i)|$, which clearly yields $q_i^2 \geq p_i^2$. If $v_i \in S' \subseteq V_L$, then $q_i^2 - p_i^2 = |N_R(v_i)| - |N_S(v_i)| + n \geq 0$.

If $v_i \in R \subseteq V_R$, or if $v_i \in R' \subseteq V_R$, then $q_i^2 - p_i^2 = |N_R(v_i)| - |N_S(v_i)| - |N_{S'}(v_i)| + |N_{R'}(v_i)| = |N_{V_R}(v_i)| - |N_{V_L}(v_i)|$, again, nonnegative from the feasibility condition. For the first part, if $v_i \in R \subseteq V_R$, then $q_i^1 = n$, and $p_i^1 = |N_{R'}(v_i)| - |N_{S'}(v_i)|$, which yields $q_i^1 \geq p_i^1$. If $v_i \in R' \subseteq V_R$, then $q_i^1 - p_i^1 = |N_S(v_i)| - |N_R(v_i)| + n \geq 0$.

Conversely, if $q_S \geq p_{S'}$, then from the corresponding $q_i^1 \geq p_i^1$ we obtain $N_{S \cup S'}(v_i) \geq N_{V \setminus (S \cup S')}(v_i)$ for all $v_i \in S \cup S'$. From $q_i^2 \geq p_i^2$ we obtain $N_{V \setminus (S \cup S')}(v_i) \geq N_{S \cup S'}(v_i)$ for all $v_i \in V \setminus (S \cup S')$. This means that $(V_L, V_R) = (S \cup S', V \setminus (S \cup S'))$ is a feasible solution.

2.2 d-Cut and (α, β)-Domination

Let us formally state our other two problems.

d-Cut
Input: An undirected graph $G = (V, E)$ and a nonnegative integer d.
Output: Is there a proper bipartition (V_L, V_R) of V such that
- $|N_{V_L}(v)| \leq d$ for all $v \in V_R$,
- $|N_{V_R}(v)| \leq d$ for all $v \in V_L$.

In words, every vertex is incident to at most d edges that cross (V_L, V_R).

(α, β)-Domination
Input: An undirected graph $G = (V, E)$ and intervals $\alpha, \beta \subseteq [0, n]$.
Output: Is there a proper bipartition (V_L, V_R) of V such that
- $|N_{V_L}(v)| \in \alpha$ for all $v \in V_L$,
- $|N_{V_L}(v)| \in \beta$ for all $v \in V_R$.

We next introduce a general problem formulation that allows for vertex-specific constraints and that extends both problems.

Interval-Constrained Cut
Input: An undirected graph $G = (V, E)$ and nonnegative integers $a'_v, a''_v, b'_v, b''_v, c'_v, c''_v, d'_v, d''_v$ for all v.
Output: Is there a proper bipartition (V_L, V_R) of V such that
- $|N_{V_L}(v)| \in [a'_v, a''_v]$ for all $v \in V_L$,
- $|N_{V_R}(v)| \in [b'_v, b''_v]$ for all $v \in V_L$,
- $|N_{V_R}(v)| \in [c'_v, c''_v]$ for all $v \in V_R$,
- $|N_{V_L}(v)| \in [d'_v, d''_v]$ for all $v \in V_R$.

The problem generalizes d-Cut, by setting $[a'_v, a''_v] = [c'_v, c''_v] = [0, n]$, i.e., "don't care", and setting $[b'_v, b''_v] = [d'_v, d''_v] = [0, d]$, i.e., the required degree constraint.

The problem also generalizes (α, β)-Domination, for intervals $\alpha = [\alpha', \alpha'']$ and $\beta = [\beta', \beta'']$, by setting $[b'_v, b''_v] = [c'_v, c''_v] = [0, n]$, i.e., "don't care", and setting $[a'_v, a''_v] = [\alpha', \alpha'']$ and $[d'_v, d''_v] = [\beta', \beta'']$, i.e., the required degree constraint.

Algorithm. We now describe our solution for Interval-Constrained Cut, which is very similar to the earlier one (only slightly more complicated, since the problem definition involves 8 inequalities instead of 2).

Again, we choose an arbitrary subset V_A of V of size $\lfloor n/2 \rfloor$ and let $V_B = V \setminus V_A$, denoting $V_A = \{v_1, \ldots, v_{\lfloor n/2 \rfloor}\}$, $V_B = \{v_{\lfloor n/2 \rfloor + 1}, \ldots, v_n\}$.

We encode every proper bipartition (S, R) of V_A as a vector q_S and every proper bipartition (S', R') as a vector $p_{S'}$, where both vectors have dimension $8n$. (Bipartitions where one part is empty are handled separately, in the same way as in Section 2.1.) Additionally, we encode the problem constraints as a vector r, also of dimension $8n$. The encoding ensures that q_S dominates $p_{S'} + r$ if and only if $(S \cup S', V \setminus (S \cup S'))$ is a feasible solution.

The entries of vectors $q = q_S$, $p = p_{S'}$, r are indexed as q_i^k, p_i^k, r_i^k for $i \in \{1, \ldots, n\}$ and $k \in \{1, \ldots, 8\}$, ordered lexicographically according to the index (k, i).

Intuitively, the entries form 8 groups, corresponding to the 8 inequalities of the interval constraints in the problem statement, and $q_i^k \geq p_i^k + r_i^k$ verifies whether the k-th inequality holds for vertex v_i.

The encoding is as follows. We start with r, which is the simplest to state. The entries r_i^k are, for all $i = 1, \ldots, n$:

r_i^1	r_i^2	r_i^3	r_i^4	r_i^5	r_i^6	r_i^7	r_i^8
a'_i	$-a''_i$	b'_i	$-b''_i$	c'_i	$-c''_i$	d'_i	$-d''_i$

We next describe the entries q_i^k of q_S and the entries p_i^k of $p_{S'}$. Recall that (S, R) is a bipartition of V_A and (S', R') is a bipartition of V_B. For all $i = 1, \ldots, n$:

$v_i \in$	q_i^1	q_i^2	q_i^3	q_i^4	q_i^5	q_i^6	q_i^7	q_i^8
S	$\lvert N_S(v_i)\rvert$	$-\lvert N_S(v_i)\rvert$	$\lvert N_R(v_i)\rvert$	$-\lvert N_R(v_i)\rvert$	$2n$	$2n$	$2n$	$2n$
R	$2n$	$2n$	$2n$	$2n$	$\lvert N_R(v_i)\rvert$	$-\lvert N_R(v_i)\rvert$	$\lvert N_S(v_i)\rvert$	$-\lvert N_S(v_i)\rvert$
V_B	$\lvert N_S(v_i)\rvert$	$-\lvert N_S(v_i)\rvert$	$\lvert N_R(v_i)\rvert$	$-\lvert N_R(v_i)\rvert$	$\lvert N_R(v_i)\rvert$	$-\lvert N_R(v_i)\rvert$	$\lvert N_S(v_i)\rvert$	$-\lvert N_S(v_i)\rvert$

The three rows of the table correspond to the cases where v_i is in S, R, or V_B, showing the value to which q_i^k is set. The 8 columns distinguish the entries needed for verifying the 8 inequalities (i.e., the index k). Notice that if $v_i \in S$ or $v_i \in R$, then the placement of v_i in V_L or V_R is determined and only 4 of the 8 inequalities in the definition are applicable to v_i. For these cases we set q_i^k to the relevant degree of v_i (with plus sign where we have a lower bound, and minus sign where we have an upper bound). For the inequalities that do not apply to v_i, we set q_i^k to a sufficiently large value of $2n$ which ensures that on the given (k, i) coordinate q dominates $p + r$, as vertex v_i trivially satisfies the condition k.

On the other hand, if $v_i \in V_B$, then the placement of v_i within the cut (V_L, V_R) is not yet determined, in this case we account for all degrees, preparing for both cases.

The encoding of $p = p_{S'}$ is symmetric. For all $i = 1, \ldots, n$:

$v_i \in$	p_i^1	p_i^2	p_i^3	p_i^4	p_i^5	p_i^6	p_i^7	p_i^8
S'	$-\lvert N_{S'}(v_i)\rvert$	$\lvert N_{S'}(v_i)\rvert$	$-\lvert N_{R'}(v_i)\rvert$	$\lvert N_{R'}(v_i)\rvert$	$-2n$	$-2n$	$-2n$	$-2n$
R'	$-2n$	$-2n$	$-2n$	$-2n$	$-\lvert N_{R'}(v_i)\rvert$	$\lvert N_{R'}(v_i)\rvert$	$-\lvert N_{S'}(v_i)\rvert$	$\lvert N_{S'}(v_i)\rvert$
V_A	$-\lvert N_{S'}(v_i)\rvert$	$\lvert N_{S'}(v_i)\rvert$	$-\lvert N_{R'}(v_i)\rvert$	$\lvert N_{R'}(v_i)\rvert$	$-\lvert N_{R'}(v_i)\rvert$	$\lvert N_{R'}(v_i)\rvert$	$-\lvert N_{S'}(v_i)\rvert$	$\lvert N_{S'}(v_i)\rvert$

We then store all vectors $p_{S'} + r$ in the data structure and execute orthogonal dominance queries for all q_S vectors. A running time of $O((2^{1-\varepsilon_c/2})^n)$ follows similarly to the previous section, with $c = 16$, since the dimension is $8n = 16 \log_2 N$.

Correctness. We need to verify that there is a feasible solution to the Interval-Constrained Cut problem if and only if there is a q_S vector that dominates some $p_{S'} + r$ vector.

Suppose first that a feasible solution (V_L, V_R) exists and let $S = V_A \cap V_L$ and $S' = V_B \cap V_L$. We show that $q_S \geq p_{S'} + r$, so the algorithm correctly finds the solution.

We verify this dominance relation on the entries q_i^1, p_i^1, r_i^1; the calculations for the cases $k = 2, \ldots, 8$ are entirely analogous and thus omitted.

If $v_i \in R$ or $v_i \in R'$ then either $q_i^1 = 2n$ or $p_i^1 = -2n$, and in both cases $q_i^1 \geq p_i^1 + r_i^1$, since $r_i^1 = a'_i \leq n$. Thus, the inequality holds.

If $v_i \in S$ or if $v_i \in S'$, then $q_i^1 = |N_S(v_i)|$ and $p_i^1 = -|N_{S'}(v_i)|$. Thus $q_i^1 \geq p_i^1 + r_i^1$ is equivalent to $|N_S(v_i)| + |N_{S'}(v_i)| \geq a'_i$. Since the left side equals $|N_{V_L}(v_i)|$, the inequality follows from the feasibility of (V_L, V_R).

Conversely, suppose that the algorithm identifies vectors q_S and $p_{S'}$ for which $q_S \geq p_{S'} + r$ holds. In particular, if $v_i \in S \cup S'$, then $q_i^1 \geq p_i^1 + r_i^1$, which amounts to $|N_S(v_i)| + |N_{S'}(v_i)| \geq a'_i$, yielding $|N_{S \cup S'}(v_i)| \geq a'_i$. This means that a partition (V_L, V_R) with $V_L = S \cup S'$ satisfies

the first inequality of the problem statement. If $v_i \notin S \cup S'$, then the first inequality does not apply to v_i, and thus trivially holds. The remaining inequalities follow analogously from the cases $k = 2, \ldots, 8$. Thus, a feasible solution $(S \cup S', V \setminus (S \cup S'))$ exists.

Remarks. If only the d-Cut problem is being solved, then one can encode the partitions with only 2 entries per vertex instead of 8, similarly to Internal Partition, yielding a (small) saving in runtime. An additional optimization that we omitted is to notice when some partial cuts (S, R) and (S', R') already violate the degree upper bounds; in such cases the corresponding vectors need not be stored, resp., queried.

2.3 Extensions

So far we have described how to solve the decision problem, i.e., deciding whether a cut with the given constraints exists. Constructing an actual feasible cut is easy, as the data structure can return for a query vector q_S a single data vector $p_{S'}$ that has led to the positive answer without any overhead. With minor bookkeeping, then S and S' are identified, and the bipartition $(S \cup S', V \setminus (S \cup S'))$ is constructed.

Chan's data structure returns the *number* of data vectors dominated by the query vector. Adding up all these counts yields the total number of solutions without overcounting (notice that every solution is uniquely identified by its intersection with the partition (V_A, V_B) chosen by the algorithm). Note that we must also add the solutions found in the special cases when one of S, S', R, R' is empty.

Finally, if we only look for solutions of a given size, say $|V_L| = t$, then we can encode the size of partial cuts ($|S|$ and $|S'|$) and use two additional dimensions to enforce the inequalities $|S| + |S'| \leq t$ and $|S| + |S'| \geq t$. This does not affect the stated runtimes. If we wish to minimize or maximize the size $|V_L| = t$ for which a solution exists, then we can repeat the procedure for $t = 1, \ldots, n-1$ and choose the optimum, with a factor n overhead, which is negligible in our regime.

3 Obtaining a base constant

In this section, for concreteness, we derive a constant value for the base of the running time, without attempting to significantly optimize it.

This results from the analysis of the dominance range searching data structure stated in Lemma 2. We refer to the *online* implementation by Chan described and analyzed in [7, § 2.1]. While the online aspect of the data structure is not strictly needed in our application, the implementation is relatively simple (using a recursive k-d-tree-like approach) and in particular it does not rely on algebraic techniques. While Chan also describes deterministic, offline designs with stronger asymptotic guarantees, they rely on more complicated techniques, and exact constants are more difficult to derive for them (although their running times are also clearly of the form given in Lemma 2).

Chan upper bounds the cost of a query as $e^{\gamma d} \cdot N^{1-\varepsilon} \cdot (bd \log N)^{O(1)}$. The parameter b is set as $b = (c/\delta) \log (c/\delta)$, where $\delta \in (0, 1)$ is a user-chosen parameter, and log is the base 2 logarithm.

Recall that in our application $N = 2^{n/2}$ and $d = c \log N$, where $c = 16$. Thus, the last factor $(bd \log N)^{O(1)}$ can be upper bounded by a polynomial in n, and thus omitted (polynomial factors are absorbed, if we slightly increase the base of the exponential).

As for the remaining parameters, Chan sets in the analysis $\gamma = 8b\alpha$, where $\alpha = \frac{1}{b^4}$, and finally, $\varepsilon = \frac{1}{6b \log \frac{1}{\alpha}} = \frac{1}{24b \log b}$.

Thus, (after ignoring a polynomial factor, as mentioned), the cost of N queries is at most:

$$N^{2-\varepsilon} \cdot e^{\frac{8}{b^3} c \log N} = N^{2-\frac{1}{24b \log b}} \cdot e^{\frac{4cn}{b^3}}.$$

We now plug in $c = 16$ and $N = 2^{n/2}$ and choose $\delta = 0.1$, from which $1171 < b < 1172$ follows.

For the first factor we get an upper bound of 1.999997583^n and for the second factor an upper bound of 1.00000003986^n, making their product less than 1.9999977^n.

It remains to bound the preprocessing cost, i.e., the time needed to build the data structure that stores N vectors. This is given by Chan [7, § 2.1] as $N^{1+O(\delta)}$ multiplied by a factor which resolves to the form $n^{O(\log n)}$. While this is a *quasi-polynomial* factor, it can still be absorbed by the exponential by a slight rounding up of the exponential base, we thus omit this factor as well.

The crucial part is the constant hidden in the term $O(\delta)$ in the exponent. One can observe in the analysis [7, § 2.1] that the term $N^{1+O(\delta)}$ arises as $N \cdot b^{O(d/b)}$. The $O()$-notation is used to suppress constant factors in two steps of the analysis. We will make these explicit, stating the bound as $N \cdot b^{\alpha_1 \cdot \alpha_2 \cdot (d/b)}$ for constants $\alpha_1, \alpha_2 > 1$ (our notation).

For our earlier choices of N, b, d, the quantity is upper bounded as $2^{n/2} \cdot 1.0495^{n \cdot \alpha_1 \cdot \alpha_2}$. It remains to resolve the constants α_1, α_2.

One of them, α_1, captures a factor of $\sum_i 1/b^i$, absorbed in the $O()$-notation in one step of the analysis. For our choice of b, this geometric sum can be upper bounded as $\alpha_1 \leq \frac{b}{b-1} < 1.00085$. The other constant, α_2, arises from upper bounding $\binom{d}{\lfloor d/b \rfloor}$ as $b^{O(d/b)}$. We replace this estimate by the explicit upper bound $b^{\alpha_2 \cdot (d/b)}$. This follows from the well-known inequality $\binom{n}{k} \leq (\frac{en}{k})^k$, and since $b > e$, the constant $\alpha_2 = 2$ suffices for the inequality to hold.

Putting things together, we obtain a runtime of at most $2^{n/2} \cdot 1.0495^{n \cdot \alpha_1 \cdot \alpha_2} < 1.558^n$, which is within our stated bounds.

4 Conclusion

In this paper we gave an algorithm that solves a family of constrained cut problems, combining the split and list technique with a sophisticated geometric data structure that allows orthogonal range queries on degree vectors. Our method can also solve, with minor adaptation, the following vector-based generalization of Subset Sum in similar $(2-\varepsilon)^n$ running time: given a set of n vectors of dimension linear in n, find a subset of vectors whose sum is within a target box t.

Our overall approach is conceptually very simple. One may complain that this simplicity is illusory, since the complexity is all hidden inside the data structure; to which we would respond: *precisely, that is the point of the method.* In all fairness, one could attempt to "unroll" the data structure implementation to see the algorithm in more elementary steps. We instead propose a different question: can we replace the orthogonal range search structure by different kinds of data structures, to extend *split and list* to further algorithmic problems?

The space usage of Chan's data structure is, with careful optimization, near-linear, i.e., of the form $N^{1+\delta}$ where $N = 2^{n/2}$ and $\delta > 0$. In case of Subset Sum, an original space usage of $2^{n/2}$ has subsequently been reduced [28] to $2^{n/4}$ (with a recent small further improvement [26]). Can similar space improvements, or a finer time-space-tradeoff (again, similarly to Subset Sum) be obtained for the problems considered in this paper?

Abstract

The classical *rank aggregation* problem seeks to combine a set X of n permutations into a single representative "consensus" permutation. In this paper, we investigate two fundamental rank aggregation tasks under the well-studied *Ulam metric*: computing a *median* permutation (which minimizes the sum of Ulam distances to X) and computing a *center* permutation (which minimizes the maximum Ulam distance to X) in two settings.

Continuous Setting: In the continuous setting, the median/center is allowed to be any permutation. It is known that computing a center in the Ulam metric is NP-hard and we add to this by showing that computing a median is NP-hard as well via a simple reduction from the Max-Cut problem. While this result may not be unexpected, it had remained elusive until now and confirms a speculation by Chakraborty, Das, and Krauthgamer [SODA '21].

Discrete Setting: In the discrete setting, the median/center must be a permutation from the input set. We fully resolve the fine-grained complexity of the discrete median and discrete center problems under the Ulam metric, proving that the naive $\widetilde{O}(n^2L)$-time algorithm (where L is the length of the permutation) is conditionally optimal. This resolves an open problem raised by Abboud, Bateni, Cohen-Addad, Karthik C. S., and Seddighin [APPROX '23]. Our reductions are inspired by the known fine-grained lower bounds for similarity measures, but we face and overcome several new highly technical challenges.

1 Introduction

Suppose that n judges each rank the performances of L competitors. Given these rankings, how can the judges agree on a single consensus ranking? This fundamental question lies at the heart of a class of tasks known as *rank aggregation*, which has applications across various fields, including social choice theory [11], bioinformatics [37], information retrieval [29], machine learning [38], and recommendation systems [41], among others. Formally, the judges' rankings can be represented as a set of n permutations $X \subseteq \mathcal{S}_L$. Then, for an appropriate metric $d(\cdot,\cdot)$ on the space of permutations $\mathcal{S}_L$, the two most prominent rank aggregation tasks are to compute a *median* permutation π_M which minimizes $\sum_{\pi\in X} d(\pi_M,\pi)$ [33, 49, 50, 23], or a *center* permutation π_C which minimizes $\max_{\pi\in X} d(\pi_C,\pi)$ [8, 10, 43].

Among the metrics studied in this context, two stand out. The first one is the classic *Kendall's tau distance* which measures the number of disagreeing pairs between two permutations, i.e., the number of pairs (i,j) for which one ranking orders i before j while the other orders j before i. Kendall's tau distance is well-motivated as it satisfies several desirable properties beyond the scope of this paper (e.g., neutrality, consistency, and the extended Condorcet property [33, 47]), and is also well-understood from a computational point-of-view [23, 24]. For example, it is known that computing the median or center of just *four* permutations is already NP-hard [23, 10]. Several approximation algorithms have also been proposed for this metric [5, 46], culminating in a PTAS [34, 42] for approximating the median under Kendall's tau metric.

The other key metric is the *Ulam distance* which measures the minimum number of relocation operations required to turn one permutation π into another permutation π' – i.e., the minimum number of competitors whose ranks have to be adjusted in π so that it agrees with π'. This metric offers a simpler and more practical alternative to Kendall's tau metric for rank aggregation tasks [20, 16, 19, 18]. Perhaps more importantly, the Ulam metric is intimately linked to the more general *edit metric* on arbitrary strings, which enjoys countless applications in computational biology [28, 42], specifically in the context of DNA storage systems [27, 44], and beyond [35, 39]. Despite the significance of Ulam rank aggregation problems and the extensive research dedicated to them [8, 16, 19, 18], some basic questions remain unanswered. This is the starting point of our paper.

1.1 Question 1: Polynomial-Time Algorithms for Ulam Median?

The first basic question is whether polynomial-time algorithms exist for exactly computing the center and median permutations under the Ulam metric. For almost all string metrics, including the aforementioned Kendall's tau metric but also metrics beyond permutations such as the Hamming metric [26, 36, 4] or the edit metric [22, 40], median and center problems are well-known and easily-proven to be NP-hard.[1] Quite surprisingly, while it is known that computing an Ulam center is NP-hard [8], the complexity of computing an Ulam median has remained an open question. This is not due to a lack of interest – despite the absence of an NP-hardness proof, Chakraborty, Das, and Krauthgamer have already initiated the study of approximation algorithms for the Ulam median problem [16, 17], achieving a 1.999-factor approximation in polynomial time. Our first contribution is that we finally provide this missing hardness proof:

▶ **Theorem 1.** *The median problem is NP-hard in the Ulam metric.*

[1] A notable exception is the Hamming median problem that can trivially be solved in polynomial time by a coordinate-wise plurality vote.

1.2 Question 2: Fine-Grained Complexity of Discrete Ulam Center and Median?

How can we circumvent this new lower bound? There are two typical approaches. The first is to resort to approximation algorithms as was done in [16, 17]. But there is a commonly-studied second option for aggregation and clustering type problems: to restrict the solution space to *only the input set of permutations* X and compute the best median or center from it.[2] The best median or center from the input set X is typically referred to as the *discrete median* or the *discrete center*, respectively, of X. (In the same spirit, we will occasionally refer to the unrestricted median and center, discussed in the previous subsection, as the *continuous median* and *continuous center*, respectively.) Besides being a natural polynomial-time rank aggregation task, computing discrete medians or centers has two other motivations. First, it is easy to see that computing a discrete median/center yields a 2-approximation of the (continuous) median/center problems. In fact, a key observation in [16] is that a discrete median often provides a $(2-\varepsilon)$-approximation for the (continuous) median, particularly in practical DNA storage system instances where distances tend to be large. Second, the discrete median and center problems have gained significant attraction for the easier Hamming metric [2, 4] and harder edit metric [2], often leading to matching upper and lower bounds. Studying the Ulam metric therefore serves as an interesting intermediate problem capturing some – but not all – of the hardness of the edit metric.

Driven by these motivations, we study the *fine-grained complexity* of the discrete median and discrete center problems with respect to the Ulam distance. That is, we aim to pinpoint their *precise* polynomial run times.

Discrete Ulam Center

The trivial algorithm for computing a discrete center is to explicitly compute the Ulam distance $d_U(\pi, \pi')$ for all pairs of permutations $\pi, \pi' \in X$. We can then easily select the permutation $\pi_C \in X$ minimizing $\max_{\pi \in X} d_U(\pi_C, \pi)$. As the Ulam distance between two length-L permutations can be computed in near-linear time[3] $\widetilde{O}(L)$ using the well-known patience sorting algorithm [6], the total time is $\widetilde{O}(n^2 L)$.

We prove that this simple algorithm is *optimal*, up to subpolynomial factors and conditioned on a plausible assumption from fine-grained complexity:

▶ **Theorem 2.** *Let $\varepsilon > 0$ and $\alpha > 0$. There is no algorithm running in time $O((n^2 L)^{1-\varepsilon})$ that solves the discrete center problem in the Ulam metric for n permutations of length $L = \Theta(n^\alpha)$, unless the Quantified Strong Exponential Time Hypothesis fails.*

The Quantified Strong Exponential Time Hypothesis (QSETH) is a plausible generalization of the by-now well-established Strong Exponential Time Hypothesis (SETH), postulating that the CNF-SAT problem cannot be solved faster than brute-force search even when only some variables are existentially quantified and others are universally quantified (see Section 3.1 for the formal treatment) [12]. This hypothesis has already proven useful for conditional lower bounds for a wide array of problems [12, 3, 2]. Besides, we remark that it is impossible to obtain SETH-based lower bounds for the discrete center problem unless the *Nondeterministic* Strong Exponential Time Hypothesis [15] is false (see Section 5.1).

[2] Or alternatively, the best median/center among the permutations in another given set $Y \subseteq \mathcal{S}_L$; this is typically referred to as the *bichromatic* discrete center/median problem, or as center/median problem with *facilities* in the theory of clustering. All of our results also apply to these bichromatic variants.

[3] We write $\widetilde{O}(T) = T(\log T)^{O(1)}$ to suppress polylogarithmic factors.

We emphasize that these lower bounds applies to the full range of n versus L, as long as L is at least polynomial in n. In the case when L is very small, $\omega(\log n) < L < n^{o(1)}$, previous work by Abboud, Bateni, Cohen-Addad, Karthik C. S. and Seddighin already established a matching conditional lower bound of $n^{2-o(1)}$ [2].

It is interesting to compare Theorem 2 with the state of the art for discrete center problems in the Hamming metric (say, over a constant-size alphabet) and the edit metric. For concreteness, consider the case $L = \Theta(n)$ (i.e., the input consists of n strings/permutations of length roughly n). Then, on the one hand, the discrete center problem in the Hamming metric can be solved in time $O(n^\omega)$ [2, 4], where $\omega < 2.3714$ is the exponent of matrix multiplication [7]. On the other hand, the discrete center problem in the edit metric cannot be solved in time $n^{4-\Omega(1)}$ unless QSETH fails [2]. Therefore, remarkably, Theorem 2 indeed places the discrete center problem in the Ulam metric as a problem of *intermediate* complexity $n^{3\pm o(1)}$. This answers an explicit open question posed by Abboud, Bateni, Cohen-Addad, Karthik C. S., and Seddighin [2].

Discrete Ulam Median

The trivial algorithm for the discrete median problem is exactly the same as for the center problem: First compute all pairwise distances $d_U(\pi, \pi')$, then select the permutation π_M minimizing $\sum_{\pi \in X} d_U(\pi_M, \pi)$. It also runs in time $\widetilde{O}(n^2 L)$. So perhaps one could also hope that a matching lower bound follows from our Theorem 2. Unfortunately, this turns out to be true only for a restricted subproblem.[4] Nevertheless, with considerable technical overhead we manage to prove essentially the same *matching* lower bound:

▶ **Theorem 3.** *Let $\varepsilon > 0$ and $\alpha \geq 1$. There is no algorithm running in time $O((n^2 L)^{1-\varepsilon})$ that solves the discrete median in the Ulam metric for n permutations of length $L = \Theta(n^\alpha)$, unless the SETH fails.*

In comparison to Theorem 2, Theorem 3 has the advantage that it conditions on the *weaker* assumption SETH (thus constituting a *stronger* lower bound). However, the applicable range of parameters is more restricted ($\alpha \geq 1$ forces the permutations to have length $\Omega(n)$).

2 Proof Overview

In this section, we provide the proof overviews of Theorems 1, 2, and 3. We avoid some technicalities to highlight the core ideas – for instance, some subpolynomial factors have been dropped. Complete proofs can be found in Sections 4, 5, and 6, respectively.

2.1 NP-Hardness for Continuous Median in the Ulam Metric

In this section, we provide a high-level sketch of our NP-hardness proof for the continuous median problem in the Ulam metric. Our starting point is the Max-Cut problem[5]. Given a Max-Cut instance $G = (V, E)$ where $V = [n]$, our goal is to construct a set of permutations of length $O(n)$ such that the median of these permutations encodes the cut in G of maximum size.

[4] Namely, the *bichromatic* discrete median problem mentioned in Footnote 2.

[5] Recall that the Max-Cut problem is, given an undirected graph $G = (V, E)$ to compute a vertex partition $V = A \sqcup B$ maximizing the number of edges from A to B.

To achieve this, we first set up a natural correspondence between cuts in G and permutations of length $O(n)$. However, since there are many more permutations than cuts, not all permutations will represent valid cuts. To ensure that only relevant permutations are considered, we construct two special permutations:

$$\pi^L = 1 \circ 2 \circ \cdots \circ (n-1) \circ n \circ X_1 \circ X_2,$$
$$\pi^R = X_1 \circ n \circ (n-1) \circ \cdots \circ 2 \circ 1 \circ X_2,$$

for some fixed long permutations X_1, X_2. The simple key insight is that any median of π^L and π^R has the following form: it starts with some subset $A \subseteq [n]$ of the symbols in *increasing* order, followed by X_1, followed by the symbols in $[n] \setminus A$ in *decreasing* order, finally followed by X_2. Thus, medians of π^L, π^R will naturally encode cuts of the form $(A, [n] \setminus A)$ in G.

To further enforce that the median represents a *maximum* cut, we include additional permutations in our instance. Specifically, for each edge $e \in E$, we include two permutations, π_e^1 and π_e^2, which reward picking solutions that correspond to partitions that cut e. This ensures that the final median permutation encodes a maximum cut of G. The precise construction and formal analysis of these edge-cutting permutations π_e^1, π_e^2 is detailed in Section 4.

2.2 Fine-Grained Lower Bound for Discrete Center in the Ulam Metric

Our proof of the lower bound for the discrete center problem in the Ulam metric relies on two key components. The first is a reduction from the Orthogonal Vectors (OV) problem to the problem of computing the Ulam distance between two permutations. Specifically, we seek a pair of functions that, given two sets of binary vectors as inputs, independently output two permutations whose Ulam distance is small if and only if there exists an orthogonal pair of vectors in the input sets. This falls into a well-established framework in the fine-grained complexity literature [9, 13, 1]: Given two sets of roughly L binary vectors, one constructs "coordinate gadgets", "vector gadgets", and "OR-gadgets" to produce a pair of length-L strings whose edit distance encodes the existence of an orthogonal pair.

Clearly such a reduction cannot exist for the Ulam distance under SETH. The Ulam distance between two permutations can be computed in near-linear time by a simple reduction to the longest increasing subsequence problem [45], and thus, if there were a way to transform sets of $O(L)$ many vectors into permutations of length L such that the existence of an orthogonal pair in the sets could be determined via an Ulam distance computation of these permutations, then that would imply a near-linear time algorithm for OV, falsifying SETH! In light of this observation, we start with $O(\sqrt{L})$ vectors in the OV instance. The constructions of the coordinate and vector gadgets are similar to the edit distance reduction. However, during the construction of the OR-gadgets, there is a quadratic blowup resulting in length L permutations with the desired properties. A detailed construction of these gadgets can be found in Section 5.

The second component in our proof is a reduction from a problem called $\exists\forall\exists$-Orthogonal Vectors. In this problem, we are given four sets A, B, C, E of binary vectors and we have to decide if there exists $a \in A$, such that for all $b \in B$, there exist $c \in C, e \in E$ such that a, b, c, e are orthogonal[6]. If $|A| = |B| = n$ and $|C| = |E| = \sqrt{L}$, then this problem has a

[6] We say that vectors $a, b, c, e \in \{0,1\}^d$ are *orthogonal* if $\sum_{i \in [d]} a[i]b[i]c[i]e[i] = 0$.

$O((n^2L)^{1-\Omega(1)})$ lower bound under the Quantified Strong Exponential Time Hypothesis. Given such sets A, B, C, E, we proceed as follows. First, for each $a \in A$, we construct the set V_a of $\sqrt{L}$ vectors by taking the pointwise product of a with all $\sqrt{L}$ vectors in C. There will be n such sets V_a, one for each choice of $a \in A$. Similarly, for each $b \in B$, we construct the set W_b of $\sqrt{L}$ vectors by taking the pointwise product of b with all $\sqrt{L}$ vectors in C. We then run the OV to Ulam distance reduction from before on these sets to obtain two sets of n-many permutations of length L. Finally, we show that there exists a permutation in the first set with small Ulam distance to every permutation in the second set if and only if the starting $\exists\forall\exists\exists$-OV instance is a YES-instance.

To go from these two sets to the final discrete center instance, we append additional symbols to each permutation and introduce a new permutation that is far from every permutation in the second set. This ensures that the center indeed comes from the first set completing the reduction. We defer the details to Section 5.

2.3 Fine-Grained Lower Bound for Discrete Median in the Ulam Metric

Our lower bound proof for the discrete median problem follows a similar initial approach as our proof for the center lower bound, with only one difference: instead of starting with an $\exists\forall\exists\exists$-OV instance, we begin with a $\exists\exists\exists\exists$-OV (also known as 4-OV) instance. Given this 4-OV instance, we retrace the same steps to construct two sets, X and Y, each containing n permutations of length L. As in the center proof, we show that there exists a permutation in X whose total Ulam distance to all elements in Y is small if and only if the original 4-OV instance is a YES-instance.

However, going from these two sets to the standard single-set version of the discrete median problem is technically very challenging. In fact, such challenges were addressed in the past in the context of the closest pair problem [21, 32], and more generally identified as the task of *reversing color coding* [14], typically requiring extremal combinatorial objects which are then composed with the input in a black-box manner.

In this paper, we transform the bichromatic instance to a monochromatic one, in multiple steps but in a white-box manner using the structure of the input instance. The first key observation is that all pairwise Ulam distances within X can be computed much faster than the naive $O(n^2L)$ time bound, specifically, in $O(n^2\sqrt{L})$ time. This speedup is possible because the permutations in X are not arbitrary but outputs formed during our OV to Ulam distance reduction. Thus, in $O(n^2\sqrt{L})$ time, we can compute the total Ulam distance of each $x \in X$ to all other elements in X.

Once these n distance sums are computed, we initiate a *balancing* procedure. This procedure iteratively appends additional symbols to each permutation in $X \cup Y$ such that:

- For every permutation in X, the sum of its Ulam distances to all other elements in X becomes equal.
- The relative Ulam distances between permutations across the sets remain unchanged.
- For every permutation in Y, the sum of its Ulam distances to all other elements in Y becomes very large.

We show that this balancing procedure can be performed efficiently without significantly increasing the permutation lengths. Finally, we include all modified permutations into a single set, and output that as our final discrete median instance. The details turn out to be quite involved, and we direct the reader to Section 6 for further details.

3 Preliminaries

Sets, Strings and Permutations

For a positive integer n, let $[n]$ denote the set $\{1, 2, \ldots, n\}$. We denote by $\mathcal{S}_n$ the set of all permutations over $[n]$. Throughout the paper, we treat any permutation $s \in \mathcal{S}_n$ as a string over the alphabet $[n]$ with no repeating symbols, and we write $s := s[1]s[2]\ldots s[n]$. Given k strings $s_1, s_2, \ldots, s_k$ over some alphabet, we denote by $\bigcirc_{i\in[k]} s_i$ the concatenated string $s_1 s_2 \ldots s_k$. We will often require strings that can be obtained by adding some fixed "offset" to each symbol of some other canonical string[7]. For every nonnegative integer k and string of length n, we let $\Delta_k(s) := (s[1]+k)(s[2]+k)\ldots(s[n]+k)$. In other words, $\Delta_k(s)$ is the string obtained by adding k to each symbol of s. We will also often require strings that are obtained by restricting some string to some sub-alphabet. Given any string s over the alphabet Σ and any sub-alphabet $\Sigma' \subseteq \Sigma$, we denote by $s|_{\Sigma'}$ to be string obtained from s by deleting all symbols that are not in Σ'. Given $a, b \in \{0,1\}^d$, we write $\langle a, b\rangle$ for the inner product of a and b, i.e., $\langle a, b\rangle = \sum_{i\in[d]} a[i]b[i]$. We further write $a \odot b$ for the pointwise product a and b, i.e., $a \odot b \in \{0,1\}^d$ is the vector satisfying $(a \odot b)[i] = a[i]b[i]$ for all $i \in [d]$.

Ulam Distances and Common Subsequences

The Hamming distance between two equal-length strings x and y, denoted by $d_H(x, y)$, is the number of locations where x and y have different symbols. Let $\pi := \pi[1]\pi[2]\ldots\pi[n] \in \mathcal{S}_n$ be a permutation and $i, j \in [n]$ be distinct positions. A *symbol relocation* operation from position j to position i in π constitutes of deleting the j^{th} symbol of π and reinserting it at position i. More formally, if $\widetilde{\pi} \in \mathcal{S}_n$ is the permutation obtained after applying a symbol relocation from position j to position i in π, then:

$$\widetilde{\pi} := \begin{cases} \pi[1]\pi[2]\ldots\pi[j-1]\pi[j+1]\cdots\pi[i-1]\pi[j]\pi[i]\pi[i+1]\cdots\pi[n], & \text{if } j < i, \\ \pi[1]\pi[2]\cdots\pi[i-1]\pi[j]\pi[i]\pi[i+1]\cdots\pi[j-1]\pi[j+1]\cdots\pi[n], & \text{if } j > i. \end{cases}$$

Given $\pi, \pi' \in \mathcal{S}_n$, the Ulam distance between π and π', denoted by $d_U(\pi, \pi')$, is the minimum number of symbol relocation operations required to transform π into π'. We will further denote by $\mathsf{LCS}(x, y)$ the length of a longest common subsequence of two strings x and y. We will frequently use the following fact throughout the paper, which relates the Ulam distance between two permutations to the length of their longest common subsequence.

▶ **Fact 4** ([6]). *For every $\pi, \pi' \in \mathcal{S}_n$, we have $d_U(\pi, \pi') = n - \mathsf{LCS}(\pi, \pi')$.*

3.1 Hardness Assumptions

Our results are conditional on several hardness assumptions and hypotheses, which we list in this section. The first one is the Strong Exponential Time Hypothesis, which is a standard assumption in the theory of fine-grained complexity.

▶ **Hypothesis 5** (Strong Exponential Time Hypothesis (SETH)). *For all $\varepsilon > 0$, there exists $q \geq 3$ such that no algorithm running in time $O(2^{(1-\varepsilon)n})$ can solve the q-SAT problem on n variables.*

[7] Here we are treating the symbols of a string as integers themselves.

More specifically, for one of our lower bounds, we will need the following corollary of SETH, which we dub Unbalanced 4-OVH.

▶ **Hypothesis 6** (Unbalanced 4-OVH). *For all $\varepsilon > 0$, no algorithm can, given sets $A, B, C, E \subseteq \{0,1\}^d$ with $|A| = n$, $|B|, |C|, |E| = n^{\Theta(1)}$ and $\omega(\log n) < d < n^{o(1)}$, determine if there exists $a \in A$, $b \in B$, $c \in C$, $e \in E$ such that $\sum_{i \in [d]} a[i]b[i]c[i]e[i] = 0$ in time $O((|A||B||C||E|)^{1-\varepsilon})$.*

It is well-known that SETH in conjunction with the sparsification lemma [30] implies Unbalanced 4-OVH [48]. We will also make use of the following strengthening of SETH.

▶ **Hypothesis 7** (∃∀∃SETH). *For all $\varepsilon > 0$ and $0 < \alpha < \beta < 1$, there exists $q \geq 3$, such that given a q-CNF formula ϕ over the variables $x_1, x_2, \ldots, x_n$, no algorithm running in time $O(2^{(1-\varepsilon)n})$ can determine if the following is true:*

$$\exists x_1, \ldots, x_{\lceil \alpha n \rceil} \forall x_{\lceil \alpha n \rceil + 1}, \ldots, x_{\lceil \beta n \rceil} \exists x_{\lceil \beta n \rceil + 1}, \ldots, x_n \ \phi(x_1, x_2, \ldots, x_n).$$

We note that ∃∀∃SETH is a special case of the Quantified SETH proposed by Bringmann and Chaudhury [12] – a hypothesis about the complexity of deciding quantified q-CNF formulas with a constant number of quantifier blocks where each block contains some constant fraction of the variables. We do not formally define Quantified SETH in all of its generality since we only require three quantfier alternations. In fact, the specific hardness assumption we need is the following which is implied by ∃∀∃SETH.

▶ **Hypothesis 8** (Unbalanced ∃∀∃∃OVH). *For all $\varepsilon > 0$, no algorithm can, given sets $A, B, C, E \subseteq \{0,1\}^d$ with $|A| = n$, $|B|, |C|, |E| = n^{\Theta(1)}$ and $\omega(\log n) < d < n^{o(1)}$, determine if there exists $a \in A$ such that for all $b \in B$, there exist $c \in C, e \in E$ such that $\sum_{i \in [d]} a[i]b[i]c[i]e[i] = 0$ in time $O((|A||B||C||E|)^{1-\varepsilon})$.*

4 NP-Hardness of Continuous Median in the Ulam Metric

In this section, we prove Theorem 1. Before we do so, we first formally define the continuous median problem in the Ulam metric.

Continuous Ulam Median	
Input:	A set $S \subseteq \mathcal{S}_n$ of permutations and an integer d.
Question:	Is there a permutation $\pi^* \in S_n$ such that $\sum_{\pi \in S} d_U(\pi, \pi^*) \leq d$?

The main result of this section is the following. All missing proofs in this section can be found in the full version of this paper [25].

▶ **Theorem 9.** *Continuous Ulam Median is NP-hard.*

Proof. We will reduce from the Max Cut problem, which is NP-hard [31]. Let $G = (V, E)$ be a Max Cut instance with $V = [n]$. From G, we will construct a Continuous Ulam Median instance $S \subseteq \mathcal{S}_N$ consisting of permutations of length $N := 3n + 2$. On a high level, our construction will work as follows. We will first construct many copies of two special permutations that will force every median of S to take on a very specific structure. All permutations of this structure will naturally encode cuts of the vertex set V. Then for each edge e in G, we will construct permutations that reward choosing a median that "cuts" e. Thus, we will end up with a set of permutations whose overall median will encode the maximum cut of G. Details follow.

To describe our construction, it will be convenient to define the following two strings, both of length $(n+1)$:

$$X_1 := (n+1) \circ (n+2) \circ \cdots \circ (2n+1),$$
$$X_2 := (2n+2) \circ (2n+3) \circ \cdots \circ (3n+2).$$

Next, we define the two special permutations $\pi^L, \pi^R \in \mathcal{S}_N$ alluded to earlier:

$$\pi^L := 1 \circ 2 \circ \cdots \circ (n-1) \circ n \circ X_1 \circ X_2,$$
$$\pi^R := X_1 \circ n \circ (n-1) \circ \cdots \circ 2 \circ 1 \circ X_2.$$

We make the observation that every median of the set $\{\pi^L, \pi^R\}$ naturally encodes a cut of the vertex set V.

▶ **Definition 10.** *For a nonnegative integer $r \leq n$, let $A = \{a_1, a_2, \ldots, a_r\}$ and $B = \{b_1, b_2, \ldots, b_{n-r}\}$ be sets such that $A \sqcup B = [n]$, $a_1 < a_2 < \cdots < a_r$ and $b_1 > b_2 > \cdots > b_{n-r}$. Define $\pi^{A,B} \in \mathcal{S}_N$ as:*

$$\pi^{A,B} := a_1 \circ a_2 \circ \cdots \circ a_r \circ X_1 \circ b_1 \circ b_2 \circ \cdots \circ b_{n-r} \circ X_2.$$

Furthermore, define $\mathcal{S}_N^* \subseteq \mathcal{S}_N$ as:

$$\mathcal{S}_N^* := \{\pi \in \mathcal{S}_N : \pi = \pi^{A,B} \text{ for some pair of sets } A, B \text{ with } A \sqcup B = [n]\}.$$

Clearly, permutations in $\mathcal{S}_N^*$ naturally encode cuts of $[n]$. We will first show that every permutation in $\mathcal{S}_N^*$ has the same sum of Ulam distances to π^L and π^R.

▶ **Lemma 11.** *For every $\pi \in \mathcal{S}_N^*$, $d_U(\pi, \pi^L) + d_U(\pi, \pi^R) = n$.*

Next, we show that any permutation that is not in $\mathcal{S}_N^*$ has strictly larger sum of Ulam distances to π^L and π^R.

▶ **Lemma 12.** *Let $\pi \notin \mathcal{S}_N^*$. Then $d_U(\pi, \pi^L) + d_U(\pi, \pi^R) \geq n+1$.*

The final pieces in our construction are the "edge gadgets", which we now define. For each edge $e = \{i, j\} \in E$, where $i < j$, define the following two strings:

$$\pi_e^1 = j \circ i \circ X_1 \circ X_2 \circ 1 \circ 2 \circ \cdots \circ (i-1) \circ (i+1) \circ \cdots \circ (j-1) \circ (j+1) \circ \cdots \circ n,$$
$$\pi_e^2 = X_1 \circ i \circ j \circ X_2 \circ 1 \circ 2 \circ \cdots \circ (i-1) \circ (i+1) \circ \cdots \circ (j-1) \circ (j+1) \circ \cdots \circ n.$$

The role of the edge gadgets associated with an edge e is to reward choosing partitions of the vertices that cut e. This is formalized in the following lemma.

▶ **Lemma 13.** *Let $\pi \in \mathcal{S}_N^*$ such that $\pi = \pi^{A,B}$ with $A \sqcup B = [n]$ and $e \in E$. Then we have the following:*

$$d_U(\pi_e^1, \pi) + d_U(\pi_e^2, \pi) = \begin{cases} 2n-2, & \text{if } e \text{ is cut by the partition } (A,B), \\ 2n-1, & \text{otherwise.} \end{cases}$$

Now let $S_E = \{\pi_e^1 : e \in E\} \cup \{\pi_e^2 : e \in E\}$ and S_{aux} be the set consisting of $t := |E|(2n-1)$ copies of π^L and π^R. Our final Continuous Ulam Median instance will be the multiset

$$S := S_E \cup S_{\text{aux}}.$$

We now show that G has a cut of size at least k if and only if the median of S has cost at most k', where $k' = |E|(2n-1) - k + tn$. For the completeness case, assume there exist sets A, B with $A \sqcup B = n$ such that the partition (A, B) cuts at least k edges in G. Denote by $E(A, B)$ the set of all edges cut by the partition (A, B). Now consider the permutation $\pi^{A,B} \in \mathcal{S}_n$ and note that:

$$\begin{aligned}
\sum_{\pi \in S} d_U(\pi^{A,B}, \pi) &= \sum_{\pi \in S_E} d_U(\pi^{A,B}, \pi) + \sum_{\pi \in S_{\text{aux}}} d_U(\pi^{A,B}, \pi) \\
&= \left(\sum_{e \in E} (d_U(\pi^{A,B}, \pi_e^1) + d_U(\pi^{A,B}, \pi_e^2)) \right) + t(d_U(\pi^{A,B}, \pi^L) + d_U(\pi^{A,B}, \pi^R)) \\
&= \left(\sum_{e \in E(A,B)} (d_U(\pi^{A,B}, \pi_e^1) + d_U(\pi^{A,B}, \pi_e^2)) \right) \\
&\qquad + \left(\sum_{e \notin E(A,B)} (d_U(\pi^{A,B}, \pi_e^1) + d_U(\pi^{A,B}, \pi_e^2)) \right) + tn \\
&= (|E(A,B)|(2n-2) + (|E| - |E(A,B)|)(2n-1)) + tn \\
&= |E|(2n-1) - |E(A,B)| + tn \leq |E|(2n-1) - k + tn.
\end{aligned}$$

For the soundness case, assume that there exists $\pi^* \in \mathcal{S}_N$ whose median cost to S is at most k'. We can further assume that $\pi^* \in \mathcal{S}_N^*$ since otherwise, every $\widetilde{\pi} \in \mathcal{S}_N^*$ will have a median cost that is at most that of π^*. Indeed, assume that $\pi^* \notin \mathcal{S}_N^*$ and fix any $\widetilde{\pi} \in \mathcal{S}_N^*$. We have:

$$\begin{aligned}
\sum_{\pi \in S} d_U(\pi^*, \pi) &= \sum_{\pi \in S_{\text{aux}}} d_U(\pi^*, \pi) + \sum_{\pi \in S_E} d_U(\pi^*, \pi) \\
&\geq t(n+1) + 0 = tn + t \\
&= tn + |E|(2n-1) \geq tn + \sum_{\pi \in S_E} d_U(\widetilde{\pi}, \pi) \\
&= \sum_{\pi \in S_{\text{aux}}} d_U(\widetilde{\pi}, \pi) + \sum_{\pi \in S_E} d_U(\widetilde{\pi}, \pi) = \sum_{\pi \in S} d_U(\widetilde{\pi}, \pi).
\end{aligned}$$

Thus, the assumption that $\pi^* \in \mathcal{S}_N^*$ is without loss of generality. Then, we have $\pi^* = \pi^{A,B}$ for sets A, B with $A \sqcup B = [n]$. We claim that the partition (A, B) cuts at least k edges in G. Indeed, since $\sum_{\pi \in S_{\text{aux}}} d_U(\pi^*, \pi) = tn$, we have $\sum_{\pi \in S_E} d_U(\pi^*, \pi) \leq k' - tn = |E|(2n-1) - k = k(2n-2) + (|E| - k)(2n-1)$. Then, by Lemma 13 the partition (A, B) cuts at least k edges. ◀

▶ Remark 14. Although our NP-hardness reduction produces multisets instead of sets, it is not to hard to turn them into sets by appending a unique permutation to each permutation without affecting the structure of the solution. See [25, Appendix B] for details.

5 Fine-Grained Complexity of Discrete Center in the Ulam Metric

In this section, we prove Theorem 2. We first formally define the discrete center problem in the Ulam metric.

The main result of this section is the following. All missing proofs in this section can be found in the full version of the paper [25].

Discrete Ulam Center	
Input:	A set $S \subseteq \mathcal{S}_L$ of permutations such that $\lvert S\rvert = n$ and an integer τ.
Question:	Is there a permutation $\pi^* \in S$ such that $\max_{\pi \in S} d_U(\pi, \pi^*) \leq \tau$?

▶ **Theorem 15.** *Let $\varepsilon > 0$ and $\alpha > 0$. There is no algorithm running in time $O((n^2L)^{1-\varepsilon})$ that solves the Discrete Ulam Center problem for n permutations of length $L = \Theta(n^\alpha)$, unless $\exists\forall\exists$SETH fails.*

The key step in the proof of Theorem 15 is a reduction from Orthogonal Vectors to Ulam Distance, i.e., to construct a pair of functions that, given a set of n binary vectors of length d each as input, outputs, independently of each other, a pair of permutations whose Ulam distance is small if and only if there exists an orthogonal pair of vectors in the input sets.

▶ **Theorem 16.** *There exists a pair of functions f and g such that for all sets $A, B \subseteq \{0,1\}^d$ with $\lvert A\rvert = \lvert B\rvert = n$, the following holds.*

- *$f(A), g(B) \in \mathcal{S}_{(5d-1)n^2}$, i.e., both f and g output permutations of length $(5d-1)n^2$.*
- *If there exists $(a,b) \in A \times B$ such that $\langle a, b\rangle = 0$, then the Ulam distance between $f(A)$ and $g(B)$ is at most $3n^2d - 1$. Otherwise, the Ulam distance between $f(A)$ and $g(B)$ is exactly $3n^2d$.*
- *Both f and g are computable in time $O(n^2d)$.*

Equipped with Theorem 16, Theorem 15 follows in a straightforward manner. For details, the reader is referred to [25].

5.1 The Need for Quantifiers

Our lower bound for Discrete Ulam Center is based on a plausible generalization of the Strong Exponential Time Hypothesis, namely $\exists\forall\exists$SETH. One could ask if we could get a similar lower bound under the weaker but more standard SETH instead. We remark that this is impossible unless the Nondeterministic Strong Exponential Time Hypothesis (NSETH) [15] is false. This is because Discrete Ulam Center can be solved in (co-)nondeterministic time $\widetilde{O}(nL)$ with the following simple algorithm. We first guess the center π_C and compute $d^* := \max_{\pi \in X} d_U(\pi_C, \pi)$. Then for each permutation π, we guess the furthest permutation $\pi' \in X$ and verify that $d_U(\pi, \pi') \geq d^*$, thereby certifying that our guess π_C is optimal. In light of this algorithm, a $O((n^2L)^{1-\Omega(1)})$ fine-grained lower bound based on SETH would contradict NSETH.

6 Fine-Grained Complexity of Discrete Median in the Ulam Metric

In this section, we prove a tight fine-grained lower bound for the Discrete Ulam Median problem conditioned on SETH. We first give a formal statement of the problem.

Discrete Ulam Median	
Input:	A set $S \subseteq \mathcal{S}_L$ of permutations such that $\lvert S\rvert = n$ and an integer τ.
Question:	Is there a permutation $\pi^* \in S$ such that $\sum_{\pi \in S} d_U(\pi, \pi^*) \leq \tau$?

This section is organized as follows. In Section 6.1, we start with a simple lower bound for the *bichromatic* version of the problem that essentially follows from the proof for the Discrete Ulam Center problem from before. Going from the bichromatic version to the standard monochromatic version defined above is presented in Section 6.2. This step is technically very involved: we show that any set of n permutations can be *balanced* in such a way that the sum of Ulam distances from each permutation to all the others is (approximately) *equal* (see Theorem 19).

6.1 Hardness for Bichromatic Instances

In this subsection, we give a fine-grained lower bound for the Bichromatic Discrete Ulam Median problem. In this problem, we given *two* sets X, Y of permutations and an integer τ, and the goal is to determine if there exists $x \in X$ such that $\sum_{y \in Y} d_U(x, y) \leq \tau$.

▶ **Theorem 17.** *Let $\varepsilon > 0$ and $\alpha > 0$. There is no algorithm running in time $O((n^2 L)^{1-\varepsilon})$ that solves the Bichromatic Discrete Ulam Median problem for n permutations of length $L = \Theta(n^\alpha)$, unless the SETH fails.*

Proof. The proof is almost identical to the first half of the proof of Theorem 15. The only difference is the starting problem, which is 4-OV (i.e., $\exists\exists\exists\exists$OV) instead of $\exists\forall\exists\exists$OV. Given a 4-OV instance $A, B, C, E \subseteq \{0,1\}^d$ where $|A| = |B| = n$, $|C| = |E| = m = n^{\Theta(1)}$ and $\omega(\log n) < d < n^{o(1)}$, we retrace the proof of Theorem 15 and construct the sets X and Y. Finally, we set $\tau := 3m^2nd - 1$. Once again, by Theorem 16, it is not hard to see that there exists $x \in X$ such that $\sum_{y \in Y} d_U(x, y) \leq \tau$ if and only if the starting 4-OV instance is a YES-instance. The conclusion then follows from Unbalanced 4-OVH. ◀

6.2 Hardness for Monochromatic Instances

Finally, in this subsection, we provide a fine-grained lower bound for the Monochromatic Discrete Ulam Median problem. To do so, we need the following technical results (which is one of our main contributions), whose proofs can be found in the full version of the paper [25].

▶ **Lemma 18** (Embedding the Hamming Metric on Small Alphabets). *Let $a_1, \ldots, a_n \in \{0,1,2\}^L$. In time $O(nL)$ we can construct permutations $\pi_1, \ldots, \pi_n \in \mathcal{S}_{3L}$ such that $d_H(a_i, a_j) = d_U(\pi_i, \pi_j)$ for all $i, j \in [n]$.*

▶ **Theorem 19** (Full Balancing). *Let n and L be integers such that n is divisible by 4 and let $k_1, \ldots, k_n \in [O(nL)]$. Given $k_1, \ldots, k_n$, in time $\widetilde{O}(n^2 + nL)$ we can construct permutations $\pi_1, \ldots, \pi_n, \tau \in \mathcal{S}_{\widetilde{O}(n+L)}$ and an integer d with the following two properties:*

- *Writing $d_i = \sum_{j \neq i} d_U(\pi_i, \pi_j)$, it holds that $|(k_i + d_i) - d| \leq 1$ for all $i \in [n]$.*
- *It holds that $d_U(\pi_1, \tau) = \cdots = d_U(\pi_n, \tau)$.*

Using the above theorem, we now prove the following:

▶ **Theorem 20.** *Let $\varepsilon > 0$ and $\alpha \geq 1$. There is no algorithm running in time $O((n^2 L)^{1-\varepsilon})$ that solves the (Monochromatic) Discrete Ulam Median problem for n permutations of length $L = \Theta(n^\alpha)$, unless the SETH fails.*

Proof. We follow the same reduction as in Theorem 17, which, given an initial 4-OV instance produces an instance (X, Y) of Bichromatic Discrete Ulam Median on n permutations of length L. During the reduction, we can set everything up so that $L = \Omega(n)$. Without loss

of generality, we may also assume that n is divisible by 4 by adding some dummy vectors in the initial 4-OV instance if necessary. Let $x_1, \ldots, x_n$ denote the permutations in X and let $y_1, \ldots, y_n$ denote the permutations in Y. As a first preprocessing step, concatenate each permutation x_i (or y_i) two times to itself (using fresh symbols when necessary) so that each permutation becomes of length $3L$ and the median distance $\min_i \sum_j d_U(x_i, y_j)$ becomes a multiple of 3.

We first make the observation that the Ulam distance between any two permutations in X can be computed very quickly – in time that is proportional to the square root of the length of the permutations.

▶ **Observation 21.** *Let $x, x' \in X$. Then $d_U(x, x')$ can be computed in time $O(L^{1/2+o(1)})$.*

Proof. Since $x \in X$, there exist $T = \{t_1, t_2, \ldots, t_m\} \subseteq \{0,1\}^d$ such that $x = f(T) \circ f(T) \circ f(T)$, where f is the function from Theorem 16 and each concatenation is done using a fresh set of symbols. Similarly, there exist $T' = \{t'_1, t'_2, \ldots, t'_m\} \subseteq \{0,1\}^d$ such that $x' = f(T') \circ f(T') \circ f(T')$, where again each concatenation is with a fresh set of symbols.

Therefore, we have $d_U(x, x') = 3m \sum_{i \in [m]} d_H(t_i, t'_i)$. Thus, $d_U(x, x')$ can be found by computing the Hamming distance between two bit strings of length md. Further recall that $L = O(m^2 d)$. Therefore, $md = O(L^{1/2+o(1)})$ and the conclusion follows. ◀

By Observation 21, we can compute in time $O(n^2 L^{1/2+o(1)})$ all pairwise distances $d_U(x_i, x_j)$. Let $k_i := \sum_{j \neq i} d_U(x_i, x_j)$; clearly we have that $k_i \leq 3nL$. Thus, we may apply Theorem 19 to obtain permutations $\pi_1, \ldots, \pi_n, \tau \in \mathcal{S}_{L'}$, where $L' = \widetilde{O}(n + L) = \widetilde{O}(L)$, with

$$|(k_i + \sum_{j \neq i} d_U(\pi_i, \pi_j)) - D| \leq 1$$

for some integer D and for all $i \in [n]$, and with $M := d_U(\pi_1, \tau) = \cdots = d_U(\pi_n, \tau)$.

Additionally, let $K := 10(3L + L')$. Compute some length-$O(K)$ permutations $\mu, \eta_1, \ldots, \eta_n$ such that $d_U(\mu, \eta_i) = K$ and such that $\sum_j d_U(\eta_i, \eta_j) = nK$. For instance, viewing $\mu, \eta_1, \ldots, \eta_n$ as 0-1-strings under the Hamming distance to be embedded by Lemma 18, take μ to be the all-0 string of length $2K$, let half of the strings η_i be the string $0^K 1^K$ and let the other half of the strings η_i be the string $1^K 0^K$.

We are now ready to construct the Monochromatic Discrete Ulam Median instance Z. We include into Z the following $2n$ permutations:[8]

- $x'_i := x_i \, \pi_i \, \mu$ (for $i \in [n]$), and
- $y'_i := y_i \, \tau \, \eta_i$ (for $i \in [n]$).

We claim that this construction is correct in the following sense: (1) All discrete medians of Z are strings x'_i. (2) Whenever x'_i is a discrete median in Z, then x_i is a discrete median in (X, Y). (3) There is some discrete median x_i in (X, Y) such that x'_i is a discrete median in Z. The proofs of all three claims easily follow from the following calculations. On the one hand, the median distance for each x'_i is

[8] As always, we use fresh symbols when necessary to ensure that the resulting strings are permutations.

$$\begin{aligned}\sum_{z\in Z} d_U(x'_i, z) &= \sum_j d_U(x'_i, x'_j) + \sum_j d_U(x'_i, y'_j)\\ &= \sum_j (d_U(x_i, x_j) + d_U(\pi_i, \pi_j) + d_U(\mu, \mu))\\ &\qquad + \sum_j (d_U(x_i, y_j) + d_U(\pi_i, \tau) + d_U(\mu, \eta_i))\\ &= k_i + \sum_j d_U(\pi_i, \pi_j) + \sum_j d_U(x_i, y_j) + nM + nK\\ &= \sum_j d_U(x_i, y_j) + nM + nK + D \pm 1.\end{aligned}$$

On the other hand, the median distance for each y'_i is

$$\sum_{z\in Z} d_U(y'_i, z) = \sum_j d_U(y'_i, x'_j) + \sum_j d_U(y'_i, y'_j) \geq \sum_j d_U(\eta_i, \mu) + \sum_j d_U(\eta_i, \eta_j) = 2nK.$$

Comparing these two terms, and recalling that $\sum_j d_U(x_i, y_j) + nM + D \leq 3nL + nL' + nL' < nK$, it is clear that the median distance of any y'_i is always significantly larger that the median distance of any x'_i proving (1). Recalling further that all median distances $\sum_j d_U(x_i, y_j)$ in the original instance are multiples of 3, the ± 1 term in the first computation becomes irrelevant, completing the proofs of claims (2) and (3).

Finally we comment on the running time. The original reduction, along with the computation of the values k_i takes time $\widetilde{O}(nL + n^2 L^{1/2+o(1)})$. Running Theorem 19 takes time $\widetilde{O}(n^2 + nL)$, and the final instance Z can be implemented in negligible overhead. ◀

Abstract

Algorithms for computing fractional solutions to the quickest transshipment problem have been significantly improved since Hoppe and Tardos first solved the problem in strongly polynomial time. For integral solutions, however, no structural improvements on their algorithm itself have yet been proposed. Runtime improvements are limited to general progress on submodular function minimization (SFM), which is an integral part of Hoppe and Tardos' algorithm. In fact, SFM constitutes the main computational load of the algorithm, as the runtime is blown up by using it within Megiddo's parametric search algorithm. We replace this part of Hoppe and Tardos' algorithm with a more efficient routine that solves only a linear number of SFM and, in contrast to previous techniques, exclusively uses minimum cost flow algorithms within Megiddo's parametric search. Our approach improves the state-of-the-art runtime from $\tilde{\mathcal{O}}(m^4k^{15})$ down to $\tilde{\mathcal{O}}(m^2k^5 + m^4k^2)$[2], where k is the number of terminals and m is the number of arcs.

1 Introduction

Network flows over time, also referred to as dynamic flows, extend classical static network flows by a time component. They provide a powerful tool for modeling real-world problems in traffic engineering, building evacuation, and logistics. Over the last decades, a wide range of optimization problems dealing with flows over time have been studied. The *maximum flow over time problem* was studied in the seminal work of Ford and Fulkerson [3], who showed

that the problem can be solved in polynomial time by a reduction to the static minimum cost flow problem. The *quickest flow problem* asks for the minimum time-horizon T^* such that a provided demand of $D \in \mathbb{N}$ units of flow can be sent from a single source s to a single sink t. While a straightforward approach is to combine an algorithm for maximum flows over time with a parametric search algorithm [2], recent results have shown that cost scaling algorithms for minimum cost flows can be modified in order to efficiently compute quickest flows [7, 10].

The *quickest transshipment problem* generalizes the quickest flow problem by allowing for *supply* and *demand* at multiple *sources* and *sinks*. It is one of the most fundamental problems in the field of network flows over time and, as recently stated by Skutella [14], "arguably the most difficult flow over time problem that can still be solved in polynomial time." As in the quickest flow problem, our goal is to send the required flow from sources to sinks while simultaneously minimizing the time horizon.

Similar to the quickest flow problem, the quickest transshipment problem can be solved by determining the minimum time horizon via parametric search. Using this idea, Hoppe and Tardos [4] showed that the quickest transshipment problem can be solved in strongly polynomial time, that is, their algorithm's runtime is polynomially bounded in the number of nodes n, number of arcs m, and the combined number of sources and sinks k.

Recently, faster algorithms have been developed. Notably, Schlöter, Skutella, and Tran [12] proposed an algorithm with a time complexity of $\tilde{\mathcal{O}}(m^2k^5 + m^3k^3 + m^3n)$. Unfortunately, these performance improvements come at the expense of fractional solutions, which may be undesirable for applications that do not allow flow particles to be disassembled. While some of the results speed up the search for the optimal time horizon, no improvements have yet been proposed for finding integral flows over time. Hence, the state-of-the-art complexity for the integral quickest transshipment problem remains unchanged at $\tilde{\mathcal{O}}(m^4k^{15})$ [12].

Our Contribution

We propose improvements to Hoppe and Tardos' algorithm by replacing two computationally expensive subroutines in which submodular function minimization is combined with Megiddo's parametric search. By doing so, we reduce the state-of-the-art runtime for the integral quickest transshipment problem from $\tilde{\mathcal{O}}(m^4k^{15})$ to $\tilde{\mathcal{O}}(m^2k^5 + m^4k^2)$. This narrows the gap to the fractional quickest transshipment problem, which can be solved in $\tilde{O}(m^2k^5 + m^3k^3 + m^3n)$ time using the algorithm by Schlöter, Skutella, and Tran [12].

2 Preliminaries

Given a directed graph $G = (V, A)$ with vertices V and arcs A, we define a *dynamic network* as a triple $\mathcal{N} = (G, u, \tau)$ with *capacity* $u_a \in \mathbb{N}$ and *transit time* $\tau_a \in \mathbb{N}_0$ for each arc $a \in A(\mathcal{N})$. For a given dynamic network $\mathcal{N}$, the set $V(\mathcal{N})$ denotes the network's nodes, while $A(\mathcal{N})$ refers to the network's arcs. Throughout this paper, we denote the number of nodes $|V(\mathcal{N})|$ by n and the number of arcs $|A(\mathcal{N})|$ by m.

A *flow over time* is a family of functions $f_a \colon [0, T) \to \mathbb{R}_{\geq 0}$, representing the in-flow rates for each arc $a \in A(\mathcal{N})$ for every point in time until the end of the *time horizon* $T \in \mathbb{N}$. The $f_a(\theta)$-many flow units entering arc a at time $\theta \in [0, T)$ arrive at time $\theta + \tau_a$ at the end node of a. While we only require f_a to satisfy weak flow conservation, Hoppe and Tardos' algorithm computes an optimal solution satisfying even the strict flow conservation, meaning that all flow units entering a non-sink node are immediately forwarded via an outgoing arc. We refer the reader to [13] for more details on flows over time.

Note that, in contrast to Hoppe and Tardos [4] who defined a flow over time as a static flow in a time-expanded network, we use a continuous-time model. However, all prerequisites for their algorithm directly translate from the discrete- to continuous-time model as shown in [14], meaning that it can also be implemented for the continuous-time model.

For the *dynamic transshipment problem*, we have a triple $(\mathcal{N}, b, T)$ comprising a dynamic network $\mathcal{N}$, a *balance function* $b\colon V(\mathcal{N}) \to \mathbb{Z}$ with $\sum_{v \in V(\mathcal{N})} b(v) = 0$, and a time horizon T. The balances describe how supply and demand are distributed across the network. A node with positive balance $b(v) > 0$ is a *source*, while a node with negative balance is a *sink*. Let S^+ denote the set of sources, S^- the set of sinks, and $S = S^+ \cup S^-$ the set of *terminals*. A dynamic transshipment instance is *feasible* if there exists a flow over time sending the supply from the sources to the sinks such that all demands are satisfied.

▶ **Definition 1.** *Given a subset of terminals $X \subseteq S$, the* maximum out-flow $o(X)$ out of X *is the value of the maximum flow over time from the sources $S^+ \cap X$ to the sinks $S^- \setminus X$.*

The central feasibility criterion states that the *net balance* $b(X) \coloneqq \sum_{v \in X} b(v)$ must not exceed the maximum out-flow $o(X)$ for every $X \subseteq S$.

▶ **Theorem 2** (Feasibility Criterion [4])**.** *The dynamic transshipment instance $(\mathcal{N}, b, T)$ is feasible if and only if $v(X) \coloneqq o(X) - b(X) \geq 0$ for all $X \subseteq S$.*

We call a set $X \subseteq S$ with $v(X) < 0$ a *violated set*. In order to determine the feasibility of a given dynamic transshipment instance, it suffices to show that no violated set exists. However, while the value of $o(X)$, and thus of $v(X)$, can be computed with the Ford-Fulkerson algorithm for maximum flows over time, avoiding the enumeration of all subsets $X \subseteq S$ is not obvious. Fortunately, we can use the *submodularity* of $o\colon 2^S \to \mathbb{N}_0$ and $v\colon 2^S \to \mathbb{Z}$.

▶ **Definition 3** (Submodular Function)**.** *A function $f\colon 2^S \to \mathbb{R}$ over a finite* ground set S *is a* submodular function *if for all $X, Y \subseteq S$ it holds that*

$$f(X \cup Y) + f(X \cap Y) \leq f(X) + f(Y), \tag{1}$$

or, equivalently, if for all $s \in S$ and $X \subseteq Y \subseteq S \setminus \{s\}$ it holds that

$$f(Y \cup \{s\}) - f(Y) \leq f(X \cup \{s\}) - f(X). \tag{2}$$

Given a submodular function f over S, we call a set $X^* \in \operatorname{argmin}_{X \subseteq S} f(X)$ a *minimizer* of f. It is well-known that the set of minimizers of a submodular function is closed under union and intersection. Therefore, there always exists a *minimal minimizer* and a *maximal minimizer*, which are the intersection and union of all minimizers, respectively.

In the context of *submodular function minimization (SFM)*, a submodular function f is typically provided in form of an *evaluation oracle* with complexity $\mathcal{O}(\mathrm{EO})$. The performance of algorithms is measured in the number of oracle calls required for finding a minimizer. The fastest strongly polynomial algorithm for submodular function minimization is due to Lee, Sidford and Wong [6] with a runtime of $\mathcal{O}(k^3 log^2 k \cdot \mathcal{O}(\mathrm{EO}) + k^4 log^{\mathcal{O}(1)} k)$ for $k = |S|$.

For our purpose, the evaluation oracle computes a maximum out-flow $o(X)$ out of terminals $X \subseteq S$ using the Ford-Fulkerson algorithm for maximum flows over time. To this end, we introduce a super-source s^+ and a super-sink s^- and connect them to sources $s \in S^+ \cap X$ and sinks $t \in S^- \setminus X$, respectively, via infinite-capacity, zero-transit arcs. Then the maximum out-flow $o(X)$ is the value of the maximum flow over time from s^+ to s^-. This value can be computed using a static min-cost flow in $\mathcal{O}(m \log n(m + n \log n))$ or $\tilde{\mathcal{O}}(m^2)$ time via Orlin's algorithm [9]. We abbreviate this runtime as $\mathcal{O}(\mathrm{MCF}(n, m))$.

Consequently, determining whether a dynamic transshipment instance $(\mathcal{N}, b, T)$ is feasible takes $\mathcal{O}(k^3 log^2 k \cdot \mathrm{MCF}(n,m) + k^4 log^{\mathcal{O}(1)} k)$ or $\tilde{\mathcal{O}}(m^2k^3)$ time, where $k = |S|$ is the number of terminals. To improve readability, we denote the time it takes to check if an instance with k terminals, n nodes and m arcs is feasible by $\mathcal{O}(\mathrm{SFM}(k,n,m))$.

The Algorithm by Hoppe and Tardos

The algorithm by Hoppe and Tardos [4] was the first strongly polynomial algorithm computing quickest transshipments and remains the most efficient one for integral solutions. In the following, we assume that the minimum time horizon T^* is provided and focus on the algorithm's segment that computes an integral dynamic transshipment. The algorithm relies on the concept of tight orders.

▶ **Definition 4** (Tight Set and Order). *A set of terminals $X \subseteq S$ is called* tight *if $o(X) = b(X)$ holds. Let $\preceq$ be a total order on S. We call $\preceq$* tight *if $\{t' \in S \mid t' \preceq t\}$ is tight for all $t \in S$.*

The general idea by Hoppe and Tardos is to construct an equivalent dynamic transshipment instance for which a tight order exists.

▶ **Theorem 5** (Reduction to Lex-Max Flows [4]). *Given a dynamic transshipment instance $(\mathcal{N}, b, T)$ with a tight order $\preceq$ over the terminals S, an integral dynamic transshipment satisfying b can be computed as a lex-max flow over time in $\mathcal{O}(k\,\mathrm{MCF}(n,m))$ time.*

We refer to [14] for more details on lex-max flows over time. Although computing the integral flow is quite efficient, transforming $(\mathcal{N}, b, T)$ into an equivalent instance $(\mathcal{N}', b', T)$ with a tight order is computationally demanding. We propose improvements to this transformation in Section 5. Before that, we briefly discuss the approach by Hoppe and Tardos.

First, one adds a new terminal $\check{s}$ with $b(\check{s}) = b(s)$ for every terminal $s \in S$ and then sets $b(s) = 0$. Note that the set of terminals S now only contains the nodes $\check{s}$. By adding infinite-capacity, zero-transit arcs $(\check{s}, s)$ for $\check{s} \in S^+$ and $(s, \check{s})$ for $\check{s} \in S^-$, one ensures that the resulting dynamic transshipment instance is equivalent to the original instance (cf. Figure 1).

To construct an instance admitting a tight order, we iteratively shift supply / demand from terminals $\check{s}$ to new terminals $\hat{s}$. In this paper, we call the $\check{s}$ *drained terminals* and the $\hat{s}$ *filled terminals*. We refer the reader to Hoppe and Tardos [4] and the description in the extended paper [1] for a general overview of the algorithm. We focus on the two subroutines, MaximizeAlpha and MinimizeDelta, which compute the amount of supply / demand that is shifted from $\check{s}$ to $\hat{s}$.

When discussing both subroutines, we assume that a feasible dynamic transshipment instance $(\mathcal{N}, b, T)$ is given, with a set of terminals S consisting of the drained terminals $\check{s}$, added in the first step, and all filled terminals $\hat{s}$ that were introduced in previous iterations. Furthermore, we are given two tight sets $Q \subset R \subseteq S$ and a drained terminal $\check{s} \in R \setminus Q$ satisfying $o(Q \cup \{\check{s}\}) > b(Q \cup \{\check{s}\})$.

Note that the instance $(\mathcal{N}, b, T)$, its set of terminals S as well as Q, R, and $\check{s}$ are the input of our subroutines and vary between iterations. In contrast, every subroutine adds a new filled terminal. However, since both subroutines are discussed in isolation, we simplify the notation by referring to both filled terminals as $\hat{s}$. Throughout this paper, we define $\hat{Q} \coloneqq Q \cup \{\hat{s}\}$ and $\hat{R} \coloneqq R \cup \{\hat{s}\}$. Similar to Hoppe and Tardos, we only discuss the case in which $\check{s}$ is a source, since the treatment of sinks is symmetrical and is sketched in the extended paper [1].

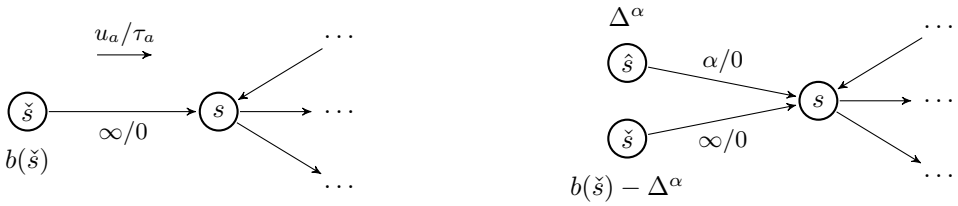

Figure 1 A dynamic transshipment instance $(\mathcal{N}, b, T)$ after initialization with terminal $\check{s}$ (left) and the corresponding α-parametric instance $(\mathcal{N}^\alpha, b^\alpha, T)$ for MaximizeAlpha (right).

Capacity-Parametric Instances

The first subroutine starts with tight sets Q and R and a drained source $\check{s} \in R \setminus Q$ for which $Q \cup \{\check{s}\}$ is not tight. Its aim is to reassign as much supply as possible to a new filled source $\hat{s}$. In doing so, we capacitate the out-flow of $\hat{s}$ such that $\hat{Q}$ is tight and the transformed instance remains feasible.

▶ **Definition 6** (α-Parametric Dynamic Network). *Given a dynamic network $\mathcal{N}$, a drained source $\check{s} \in S^+$ and a parameter $\alpha \in \mathbb{N}_0$, the* α-parametric network $\mathcal{N}^\alpha$ *is constructed by adding a new filled source $\hat{s}$ and connecting it to s via an α-capacity, zero-transit arc $(\hat{s}, s)$.*

Let $o^\alpha \colon 2^{S \cup \{\hat{s}\}} \to \mathbb{N}_0$ be the parametric counterpart of the maximum out-flow as in Definition 1 in the parametric network $\mathcal{N}^\alpha$. Using this notation, we define *α-parametric dynamic transshipment instances* analogously to Hoppe and Tardos [4]. The construction of an α-parametric instance is illustrated in Figure 1.

▶ **Definition 7** (α-Parametric Dynamic Transshipment Instance). *Given a feasible dynamic transshipment instance $(\mathcal{N}, b, T)$, two tight sets of terminals $Q \subset R \subseteq S$, a drained source $\check{s} \in R \setminus Q$ and a parameter $\alpha \in \mathbb{N}_0$, the corresponding* α-parametric dynamic transshipment instance $(\mathcal{N}^\alpha, b^\alpha, T)$ *consists of the following components.*

- *An α-parametric dynamic network $\mathcal{N}^\alpha$ as in Definition 6.*
- *An α-parametric balance function b^α with $b^\alpha(t) = b(t)$ for all terminals $t \in S \setminus \{\check{s}\}$, $b^\alpha(\hat{s}) = \Delta^\alpha$, and $b^\alpha(\check{s}) = b(\check{s}) - \Delta^\alpha$, where $\Delta^\alpha := o^\alpha(\hat{Q}) - o^\alpha(Q)$.*

We call a parameter value $\alpha \in \mathbb{N}_0$ *feasible* if the corresponding α-parametric dynamic transshipment instance $(\mathcal{N}^\alpha, b^\alpha, T)$ is feasible. Determining whether a value α is feasible is equivalent to checking if a *violated* set $X \subseteq S \cup \{\hat{s}\}$ exists. Recall that this can be done by minimizing the parametric submodular function $v^\alpha(X) = o^\alpha(X) - b^\alpha(X)$. A subroutine of the algorithm by Hoppe and Tardos finds a maximum feasible parameter value $\alpha \in \mathbb{N}_0$.

▶ **Definition 8** (MaximizeAlpha). *Given an α-parametric dynamic transshipment instance, find the maximum feasible $\alpha \in \mathbb{N}_0$.*

We denote the maximum feasible parameter value by α^*. Hoppe and Tardos concluded that, given a feasibility oracle for $(\mathcal{N}^\alpha, b^\alpha, T)$ taking $\mathcal{O}(\mathrm{SFM}(k, n, m))$ time, the value α^* can be found in $\mathcal{O}(\log(nU_{\max}) \cdot \mathrm{SFM}(k, n, m))$ time, where $U_{\max} := \max_{a \in A(\mathcal{N})} u_a$. In addition, one can combine Megiddo's parametric search [8] with the combinatorial SFM algorithm by Orlin and Iwata [5] to achieve a strongly polynomial runtime of $\tilde{\mathcal{O}}(m^4 k^{14})$. We mainly improve upon the strongly polynomial approach.

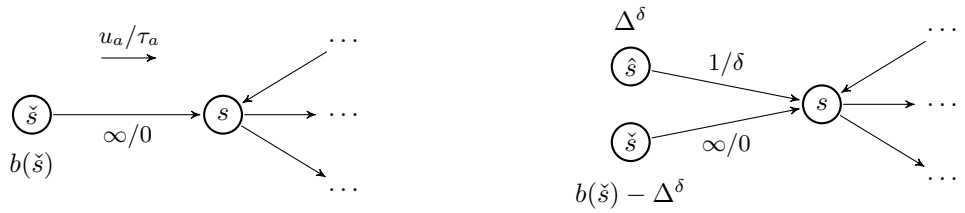

Figure 2 A dynamic transshipment instance $(\mathcal{N}, b, T)$ after initialization with terminal $\check{s}$ (left) and the corresponding δ-parametric instance $(\mathcal{N}^\delta, b^\delta, T)$ for MinimizeDelta (right).

Transit-Parametric Instances

The second subroutine is closely related to MaximizeAlpha. Again, we start with tight sets Q and R and a drained source $\check{s} \in R \setminus Q$ for which $Q \cup \{\check{s}\}$ is not tight. The aim is to reassign as much supply as possible to a new filled source $\hat{s}$. In doing so, we set the transit time for the flow out of $\hat{s}$ such that $\hat{Q}$ is tight and the transformed instance remains feasible.

▶ **Definition 9** (δ-Parametric Dynamic Network)**.** *Given a dynamic network $\mathcal{N}$, a drained source $\check{s} \in S^+$ and a parameter $\delta \in \mathbb{N}_0$, the* δ-parametric network $\mathcal{N}^\delta$ *is constructed by adding a terminal $\hat{s}$ and connecting it to s via a unit-capacity, δ-transit arc $(\hat{s}, s)$.*

Analogously to o^α, we denote the maximum out-flow of a subset of terminals $X \subset S \cup \{\hat{s}\}$ by $o^\delta(X)$. Next, we combine this parametric variant of our dynamic network with a parametric balance function to form a *δ-parametric dynamic transshipment instance* (cf. Figure 2).

▶ **Definition 10** (δ-Parametric Dynamic Transshipment Instance)**.** *Given a feasible dynamic transshipment instance $(\mathcal{N}, b, T)$, two tight sets of terminals $Q \subset R \subseteq S$, a drained source $\check{s} \in R \setminus Q$ and a parameter $\delta \in \mathbb{N}_0$, a* δ-parametric dynamic transshipment instance $(\mathcal{N}^\delta, b^\delta, T)$ *consists of the following components.*

- *A δ-parametric dynamic network $\mathcal{N}^\delta$ as given in Definition 9.*
- *A δ-parametric balance function b^δ with $b^\delta(t) = b(t)$ for all terminals $t \in S \setminus \{\check{s}\}$, $b^\delta(\hat{s}) = \Delta^\delta$, and $b^\delta(\check{s}) = b(\check{s}) - \Delta^\delta$, where $\Delta^\delta := o^\delta(\hat{Q}) - o^\delta(Q)$.*

Again, a parameter value $\delta \in \mathbb{N}_0$ is *feasible* if the corresponding parametric dynamic transshipment instance $(\mathcal{N}^\delta, b^\delta, T)$ is feasible. This can be checked by minimizing the parametric submodular function $v^\delta(X) = o^\delta(X) - b^\delta(X)$. Again, we call a set $X \subseteq S$ with $v^\delta(X) < 0$ *violated*. This yields the following parametric search problem.

▶ **Definition 11** (MinimizeDelta)**.** *Given a δ-parametric dynamic transshipment instance, find the minimum feasible $\delta \in \mathbb{N}_0$.*

Again, δ^* denotes the minimum feasible parameter value. Hoppe and Tardos showed that the optimal value δ^* can be found in $\mathcal{O}(\log(T) \cdot \mathrm{SFM}(k, n, m))$ time, or in strongly polynomial time of $\tilde{\mathcal{O}}(m^4k^{14})$ using the parametric search of Megiddo [8].

The algorithm by Hoppe and Tardos performs a total of k iterations, each of which calls both subroutines MaximizeAlpha and MinimizeDelta once. Therefore, the current version of the algorithm by Hoppe and Tardos takes $\mathcal{O}\left(k \cdot \log(nTU_{\max}) \cdot \mathrm{SFM}(k, n, m)\right)$ time if both subroutines are implemented with a binary search, while Megiddo's parametric search results in a runtime of $\tilde{\mathcal{O}}(m^4k^{15})$. In the following sections, we improve the runtime of each iteration by introducing better parametric search algorithms for both subroutines.

3 Restricting the Domains of Violated Sets

Both problems MaximizeAlpha and MinimizeDelta introduced in the previous section rely on minimizing submodular functions to determine whether a parameter value is feasible. Even with state-of-the-art algorithms for SFM, this remains a computationally expensive subroutine that scales poorly with the number of terminals in the ground set.

We show that, if our parametric instance is infeasible, there always exists a violated set $X \subseteq S \cup \{\hat{s}\}$ satisfying $\hat{Q} \subset X \subset \hat{R}$, which allows us to restrict the ground sets of our parametric submodular functions v^α and v^δ. This provides a practical improvement and establishes the foundation for the following sections.

▶ **Lemma 12.** *Let $X \subseteq S \cup \{\hat{s}\}$ be a violated set for an α-parametric dynamic transshipment instance with respect to a drained source $\check{s}$. Then $\hat{s} \in X$ and $\check{s} \notin X$. The same applies to δ-parametric dynamic transshipment instances.*

Proof. We only prove the statement for α-parametric instances, as the reasoning is analogous for δ-parametric instances. Let $X \subseteq S \cup \{\hat{s}, \check{s}\}$ be an arbitrary subset of terminals. Given that we assume the transshipment instance to be feasible, we have $v(X) \geq 0$. Remember that the maximum out-flow $o^\alpha(X)$ is the value of a maximum flow over time from a super-source s^+ to a super-sink s^-, where infinite-capacity, zero-transit arcs are used to connect s^+ to every source in $S^+ \cap X$ and to connect every sink in $S^- \setminus X$ to s^-. Using this definition, we derive the following observations regarding $o(X)$:

O1 If X contains neither $\hat{s}$ nor $\check{s}$, then maximum out-flow $o^\alpha(X)$ coincides with the out-flow $o(X)$ in the original instance.

O2 If X contains $\check{s}$, then all flow traveling from s^+ to s can bypass the α-capacity arc $(\hat{s}, s)$ and move along the infinite-capacity arcs $(s^+, \check{s})$ and $(\check{s}, s)$ instead. As a consequence, we have $o^\alpha(X) = o(X)$.

We refer the reader back to Figure 1 for a visual intuition. Combining these observations with the parametric balances $b^\alpha(\hat{s}) = \Delta^\alpha$ and $b^\alpha(\check{s}) = b(\check{s}) - \Delta^\alpha$, we prove Lemma 12 by considering the following three complementary cases.

(I) If $\hat{s} \in X$ and $\check{s} \in X$, then it follows that

$$b^\alpha(X) = b^\alpha(X \setminus \{\hat{s}, \check{s}\}) + b^\alpha(\hat{s}) + b^\alpha(\check{s}) \overset{\text{Def. of } b^\alpha}{=} b^\alpha(X \setminus \{\hat{s}, \check{s}\}) + b(\check{s}) = b(X \setminus \{\hat{s}\}) = b(X).$$

Together with Observation 2 we obtain $v^\alpha(X) = v(X) \geq 0$, meaning that X cannot be a violated set.

(II) If $\hat{s} \notin X$ and $\check{s} \in X$, then it follows that $b^\alpha(X) = b(X) - \Delta^\alpha < b(X)$, which, together with Observation 2, implies that X cannot be a violated set since $v^\alpha(X) \geq v(X) \geq 0$.

(III) If $\hat{s} \notin X$ and $\check{s} \notin X$, then $b^\alpha(X) = b(X)$ and therefore X cannot be a violated set as it follows from Observation 1 that $v^\alpha(X) = o^\alpha(X) - b^\alpha(X) = o(X) - b(X) = v(X) \geq 0$.

Hence, X can only be a violated set of $(\mathcal{N}^\alpha, b^\alpha, T)$ if $\hat{s} \in X$ and $\check{s} \notin X$. ◀

Hoppe and Tardos [4] proved the property from Lemma 12 for the special case of the infeasible parameter value $\delta^* - 1$ and used it to show that there exists a set X satisfying $\hat{Q} \subset X \subset \hat{R}$ which is violated for $\delta^* - 1$ and tight for δ^*. We employ similar arguments to show that this also holds for all infeasible $\alpha, \delta \in \mathbb{N}_0$.

▶ **Lemma 13.** *Let $\alpha \in \mathbb{N}_0$ be an infeasible parameter value for MaximizeAlpha. Then there is a minimizer X of v^α with $\hat{Q} \subset X \subset \hat{R}$. Analogously, let $\delta \in \mathbb{N}_0$ be an infeasible parameter value for MinimizeDelta. Then there is a minimizer X of v^δ with $\hat{Q} \subset X \subset \hat{R}$.*

Proof. We only prove the statement for MaximizeAlpha, as the proof for MinimizeDelta is analogous. Let X^* be an arbitrary minimizer of v^α with $v^\alpha(X) < 0$. It follows from Lemma 12 that $\hat{s} \in X^*$ and $\check{s} \notin X^*$. Next, we show that the set $X \coloneqq Q \cup (X^* \cap \hat{R})$ is also a minimizer of v^α. For this, we analyze the tightness of the sets Q, $\hat{Q}$, and $\hat{R}$:

- Q was chosen to be a tight set for $(\mathcal{N}, b, T)$. This also does not change in the parametric instance as $\hat{s}, \check{s} \notin Q$ and hence $v^\alpha(Q) = v(Q) = 0$.
- $\hat{Q}$ is tight, since $b^\alpha(\hat{Q}) = b^\alpha(Q) + \Delta^\alpha \overset{Q \text{ tight}}{=} o^\alpha(Q) + o^\alpha(\hat{Q}) - o^\alpha(Q) = o^\alpha(\hat{Q})$.
- $\hat{R}$ is tight because R is tight and $\hat{s}, \check{s} \in \hat{R}$ directly imply $o^\alpha(\hat{R}) = o(R) = b(R) = b^\alpha(\hat{R})$.

Having shown that Q and $\hat{R}$ are tight sets, we study how tight sets and minimizers of v^α behave under union and intersection. For this purpose, let $Y \in \{Q, \hat{R}\}$. It follows from submodularity of v^α that

$$v^\alpha(X^* \cup Y) + v^\alpha(X^* \cap Y) \leq v^\alpha(X^*) + v^\alpha(Y) = v^\alpha(X^*) < 0. \tag{3}$$

Note that both summands on the left hand side are non-positive, since otherwise one of them would be smaller than the minimum value $v^\alpha(X^*)$. Hence, either both summands are negative, or one is equal to zero while the other equals the minimum value of v^α. In other words, exactly one of the following properties must hold:

(1) Both $X^* \cup Y$ and $X^* \cap Y$ are violated sets of v^α.
(2) Either $X^* \cup Y$ or $X^* \cap Y$ is a minimizer, while the other set is tight.

We apply this case distinction to the cases where $Y = Q$ and $Y = \hat{R}$:

- Let $Y = \hat{R}$, then Lemma 12 states that a violated set cannot contain $\check{s}$, implying that $v^\alpha(X^* \cup \hat{R}) \geq 0$ since $\check{s} \in \hat{R}$. This means that $X^* \cap \hat{R}$ is a minimizer of v^α.
- Consider $Y = Q$ and the minimizer $X^* \cap \hat{R}$. We rule out $Q \cap (X^* \cap \hat{R}) = Q \cap X^*$ as a violated set since $\hat{s} \notin Q \cap X^*$. Therefore, $Q \cup (X^* \cap \hat{R})$ is a minimizer.

Finally, observe that the minimizer $X = Q \cup (X^* \cap \hat{R})$ not only satisfies $\hat{Q} \subseteq X \subseteq \hat{R}$ because $\hat{s} \in X^* \cap \hat{R}$ but also $\hat{Q} \subset X \subset \hat{R}$ since $\hat{Q}$ and $\hat{R}$ are tight. ◀

Lemma 13 allows us to determine feasibility of a parameter value by minimizing the *restricted functions* $\tilde{v}^\alpha \colon 2^{\hat{R} \setminus \hat{Q}} \to \mathbb{Z}$ and $\tilde{v}^\delta \colon 2^{\hat{R} \setminus \hat{Q}} \to \mathbb{Z}$ with $\tilde{v}^\alpha(X) \coloneqq v^\alpha(\hat{Q} \cup X)$ and $\tilde{v}^\delta(X) \coloneqq v^\delta(\hat{Q} \cup X)$. For future use, we define the functions $\tilde{o}^\alpha$, $\tilde{o}^\delta$, $\tilde{b}^\alpha$, and $\tilde{b}^\delta$ analogously.

This brings us to the main result in this section.

▶ **Corollary 14.** *A parameter value $\alpha \in \mathbb{N}_0$ is feasible for* MaximizeAlpha *if and only if $\tilde{v}^\alpha(X) \geq 0$ for every $X \subseteq \hat{R} \setminus \hat{Q}$. Analogously, a parameter value $\delta \in \mathbb{N}_0$ is feasible for* MinimizeDelta *if and only if $\tilde{v}^\delta(X) \geq 0$ for every $X \subseteq \hat{R} \setminus \hat{Q}$.*

The obvious advantage of this result is the reduction of the domain of the submodular functions of interest to $\hat{R} \setminus \hat{Q}$. Although we have $R = S$ and $Q = \emptyset$ at the beginning, the difference becomes smaller over the course of Hoppe and Tardos' algorithm, until both sets are eventually equal. This yields a significant practical speed-up in later iterations of the algorithm. Moreover, the reduction brings further practical and theoretical advantages, which we discuss in the following section.

4 Strong Map Sequences

We concluded the previous section with a useful restriction of our submodular functions v^α and v^δ to sets X with $\hat{Q} \subset X \subset \hat{R}$, while maintaining the guarantee that our parametric instance is feasible if and only if the minimizer of our restricted function is not violated. Building on this, we show that both restricted functions satisfy the *strong map property* (also known as *decreasing differences property*).

▶ **Definition 15** (Strong Map Property [11]). *Let $f_1, f_2 \colon 2^E \to \mathbb{R}$ be two submodular functions defined over the same finite ground set E. We write $f_1 \sqsupset f_2$, or $f_2 \sqsubset f_1$, if $X \subseteq Y \subseteq E$ implies*

$$f_1(Y) - f_1(X) \leq f_2(Y) - f_2(X).$$

The relation is called a strong map. *Submodular functions $f_1, f_2, \ldots, f_k$ form a* strong map sequence *if $f_1 \sqsupset f_2 \sqsupset \cdots \sqsupset f_k$.*

Recall that the minimizers of submodular functions are closed under union and intersection, meaning that there exists a unique minimal and maximal minimizer for every submodular function. A result by Topkis [15] relates the minimal and maximal minimizers of functions that form strong map sequences.

▶ **Lemma 16** (Minimizers for Strong Map Sequences [11]). *Let $f_1, f_2 \colon 2^E \to \mathbb{R}$ be two submodular functions over the same ground set E with $f_1 \sqsubset f_2$. Denote by X_1^{min} and X_1^{max} the minimal and maximal minimizer of f_1, respectively, while X_2^{min} and X_2^{max} are the minimal and maximal minimizer of f_2, respectively. Then $X_1^{min} \subseteq X_2^{min}$ and $X_1^{max} \subseteq X_2^{max}$.*

Lemma 16 already gives an intuition for how the strong map property can be used for the parametric search problems MaximizeAlpha and MinimizeDelta: each choice of α or δ gives us a new submodular function, and, if these functions form strong map sequences, the strong map property implies that we can only encounter at most $|S|$ distinct minimal minimizers for a monotonic sequence of parameter values.

Unfortunately, neither v^α nor v^δ satisfy the strong map property as is[2]. However, this changes when considering the restricted functions $\tilde{v}^\alpha$ and $\tilde{v}^\delta$ defined in Section 3. Recall that these functions are defined over the ground set $\hat{R} \setminus \hat{Q}$, and that their definition ensures that $\hat{s}$ is implicitly added, while $\check{s}$ is excluded.

▶ **Lemma 17.** *Let $0 \leq \alpha \leq \alpha'$. Then $\tilde{v}^\alpha \sqsubset \tilde{v}^{\alpha'}$.*

Proof. Our argument is structured as follows: We first prove that $\tilde{o}^\alpha \sqsubset \tilde{o}^{\alpha+1}$ holds for all $\alpha \in \mathbb{N}_0$ and then use this result to prove that $\tilde{v}^\alpha$ also forms a strong map sequence with $\tilde{v}^\alpha \sqsubset \tilde{v}^{\alpha+1}$. The general claim $\tilde{v}^\alpha \sqsubset \tilde{v}^{\alpha'}$ then immediately follows by transitivity of $\leq$.

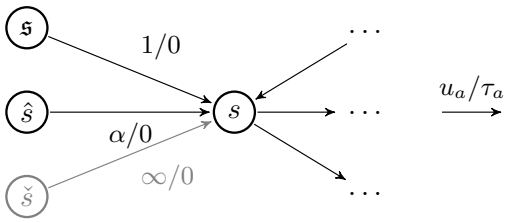

Figure 3 The auxiliary network $\mathfrak{N}$ for MaximizeAlpha.

Let $\alpha \in \mathbb{N}_0$ be arbitrary but fixed. We construct an auxiliary network $\mathfrak{N}$ with nodes $V(\mathfrak{N}) \coloneqq V(\mathcal{N}^\alpha) \cup \{\mathfrak{s}\}$ and arcs $A(\mathfrak{N}) \coloneqq A(\mathcal{N}^\alpha) \cup \{\mathfrak{a} \coloneqq (\mathfrak{s}, s)\}$, where s is the source that was replaced by $\check{s}$ in the first phase of the algorithm. For the new arc, we set $u_\mathfrak{a} = 1$ and $\tau_\mathfrak{a} = 0$. An example network for a given source $\hat{s}$ is depicted in Figure 3.

[2] In nontrivial cases, the nested sets $\emptyset$, $\{\hat{s}\}$, and $\{\hat{s}, \check{s}\}$ satisfy $o^{\alpha+1}(\{\hat{s}\}) - o^{\alpha+1}(\emptyset) > o^\alpha(\{\hat{s}\}) - o^\alpha(\emptyset)$ and $o^{\alpha+1}(\{\hat{s}, \check{s}\}) - o^{\alpha+1}(\{\hat{s}\}) < o^\alpha(\{\hat{s}, \check{s}\}) - o^\alpha(\{\hat{s}\})$. The same holds for o^δ. Consequently, our proofs for Lemma 17 and Lemma 18 fail for the general functions v^α and v^δ.

Let $\mathfrak{o}(X)$ be the max out-flow function for network $\mathfrak{N}$ restricted to the domain $\hat{R} \setminus \hat{Q} \cup \{\mathfrak{s}\}$. Notice how adding $\mathfrak{s}$ to a set of terminals $X \subseteq \hat{R} \setminus \hat{Q} \cup \{\mathfrak{s}\}$ with $\hat{s} \in X$ and $\check{s} \notin X$ is equivalent to increasing α by one, as flow cannot bypass the arcs $(\mathfrak{s}, s)$ and $(\hat{s}, s)$ through $(\check{s}, s)$. Formally, it holds for every set X with $X \subseteq \hat{R} \setminus \hat{Q}$ that

1. $\mathfrak{o}(X) = \tilde{o}^{\alpha}(X)$, and
2. $\mathfrak{o}(X \cup \{\mathfrak{s}\}) = \tilde{o}^{\alpha+1}(X)$.

Clearly, the function $\mathfrak{o}$ is also submodular. Hence, given two sets $X \subseteq Y \subset \hat{R} \setminus \hat{Q}$, the definition of submodularity in Equation (2) can be restated as

$$\mathfrak{o}(Y \cup \{\mathfrak{s}\}) - \mathfrak{o}(X \cup \{\mathfrak{s}\}) \leq \mathfrak{o}(Y) - \mathfrak{o}(X). \tag{4}$$

Combining Equation (4) with all our previous observations, it follows that the sets X and Y satisfy

$$\begin{aligned} \tilde{o}^{\alpha+1}(Y) - \tilde{o}^{\alpha+1}(X) &\overset{\text{Obs. } 2}{=} \mathfrak{o}(Y \cup \{\mathfrak{s}\}) - \mathfrak{o}(X \cup \{\mathfrak{s}\}) \\ &\overset{\text{Eq. (4)}}{\leq} \mathfrak{o}(Y) - \mathfrak{o}(X) \\ &\overset{\text{Obs. } 1}{=} \tilde{o}^{\alpha}(Y) - \tilde{o}^{\alpha}(X). \end{aligned}$$

Hence, we have shown that $\tilde{o}^{\alpha} \sqsubset \tilde{o}^{\alpha+1}$ holds for every parameter value α. Finally, recall our definition of $\tilde{v}^{\alpha}$ as $\tilde{v}^{\alpha}(X) = \tilde{o}^{\alpha}(X) - \tilde{b}^{\alpha}(X)$ for any $X \subseteq \hat{R} \setminus \hat{Q}$. Due to the strong map property of $\tilde{o}^{\alpha}$, we get for all $X \subseteq Y \subseteq \hat{R} \setminus \hat{Q}$ that

$$\begin{aligned} \tilde{v}^{\alpha+1}(Y) - \tilde{v}^{\alpha}(Y) &= \tilde{o}^{\alpha+1}(Y) - \tilde{o}^{\alpha}(Y) + \tilde{b}^{\alpha}(Y) - \tilde{b}^{\alpha+1}(Y) \\ &= \tilde{o}^{\alpha+1}(Y) - \tilde{o}^{\alpha}(Y) + \Delta^{\alpha} - \Delta^{\alpha+1} \\ &\leq \tilde{o}^{\alpha+1}(X) - \tilde{o}^{\alpha}(X) + \Delta^{\alpha} - \Delta^{\alpha+1} \\ &= \tilde{o}^{\alpha+1}(X) - \tilde{o}^{\alpha}(X) + \tilde{b}^{\alpha}(X) - \tilde{b}^{\alpha+1}(X) \\ &= \tilde{v}^{\alpha+1}(X) - \tilde{v}^{\alpha}(X), \end{aligned}$$

therefore proving that $\tilde{v}^{\alpha} \sqsubset \tilde{v}^{\alpha+1}$. Thus, by transitivity of $\leq$, our claim $\tilde{v}^{\alpha} \sqsubset \tilde{v}^{\alpha'}$ holds. ◀

Next, we utilize a similar argument to prove that $\tilde{v}^{\delta}$ forms a strong map sequence. Here, we rely on our specific definition of the δ-parametric network $\mathcal{N}^{\delta}$.

▶ **Lemma 18.** *Let $0 \leq \delta' \leq \delta$. Then $\tilde{v}^{\delta} \sqsubset \tilde{v}^{\delta'}$.*

Proof. The general approach is identical to the proof of Theorem 17. That is, we show that $\tilde{o}^{\delta}$ forms a strong map sequence with $\tilde{o}^{\delta-1} \sqsupset \tilde{o}^{\delta}$ for $\delta \geq 1$. Afterwards, we transfer this result to $\tilde{v}^{\delta-1}$ and $\tilde{v}^{\delta}$. The general claim then directly follows from the transitivity of $\leq$.

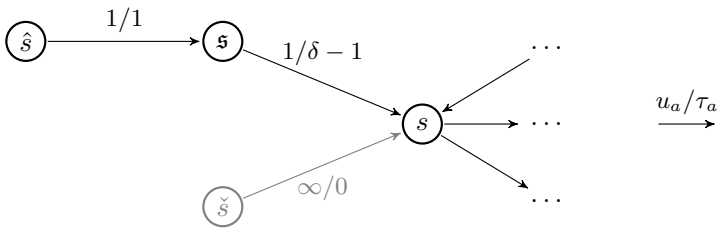

Figure 4 The auxiliary network $\mathfrak{N}$ for MinimizeDelta.

Again, let $\delta \in \mathbb{N}$ be arbitrary but fixed. We construct an auxiliary network $\mathfrak{N}$ with nodes $V(\mathfrak{N}) \coloneqq V(\mathcal{N}^\delta) \cup \{\mathfrak{s}\}$ and arcs $A(\mathfrak{N}) \coloneqq (A(\mathcal{N}^\delta) \setminus \{(\hat{s}, s)\}) \cup \{\mathfrak{a} \coloneqq (\mathfrak{s}, s), \hat{a} \coloneqq (\hat{s}, \mathfrak{s})\}$, s is the source that was replaced by $\check{s}$ in the first step of the algorithm. Additionally, let $u_{\hat{a}} = u_{\mathfrak{a}} = 1$, $\tau_{\mathfrak{a}} = \delta - 1$ and $\tau_{\hat{a}} = 1$. An example for a source $\hat{s}$ is given in Figure 4.

Again, $\mathfrak{o}(X)$ denotes the maximum out-flow function for this network restricted to the domain $\hat{R} \setminus \hat{Q} \cup \{\mathfrak{s}\}$. In this construction, we have replaced the arc $(\hat{s}, s)$ by a path consisting of arcs $(\hat{s}, \mathfrak{s})$ and $(\mathfrak{s}, s)$ with a combined transit time of δ. As a consequence, the maximum out-flow $\mathfrak{o}(X)$ remains unchanged for sets $X \subseteq \hat{R} \setminus \hat{Q}$. If $\mathfrak{s} \in X$ and $\hat{s} \in X$, on the other hand, both sources compete for access to the arc $(\mathfrak{s}, s)$. Then, the flow out of X is maximized by sending all flow from $\mathfrak{s}$. Formally, it holds for every set $X \subseteq \hat{R} \setminus \hat{Q}$ that

1. $\mathfrak{o}(X) = \tilde{o}^\delta(X)$, and
2. $\mathfrak{o}(X \cup \{\mathfrak{s}\}) = \tilde{o}^{\delta-1}(X)$

These observations plus the second definition of submodularity from Equation (2) imply for all sets $X \subseteq Y \subseteq \hat{R} \setminus \hat{Q}$ that

$$\begin{aligned}\tilde{o}^{\delta-1}(Y) - \tilde{o}^{\delta-1}(X) &\overset{\text{Obs. } 2}{=} \mathfrak{o}(Y \cup \{\mathfrak{s}\}) - \mathfrak{o}(X \cup \{\mathfrak{s}\}) \\ &\overset{\text{Eq. (2)}}{\leq} \mathfrak{o}(Y) - \mathfrak{o}(X) \\ &\overset{\text{Obs. } 1}{=} \tilde{o}^\delta(Y) - \tilde{o}^\delta(X).\end{aligned}$$

Therefore, the function $\tilde{o}^\delta$ forms a strong map sequence with $\tilde{o}^{\delta-1} \sqsupset \tilde{o}^\delta$. Finally, by the same arguments as in the proof of Lemma 17, the parametric function $\tilde{v}^\delta$ forms a strong map sequence with $\tilde{v}^\delta \sqsupset \tilde{v}^{\delta'}$ as claimed. ◀

In the following section, we use the strong map property and the resulting nested sequences of minimizers to construct new parametric search algorithms for v^α and v^δ .

5 An Improved Parametric Search

In this section, we adapt Schlöter's [11] parametric search algorithm for the single-source or single-sink quickest transshipment problem to MaximizeAlpha and MinimizeDelta. We start by showing that $\tilde{v}^\alpha$ and $\tilde{v}^\delta$ are monotonic in their respective parameters.

▶ **Lemma 19.** *Given a set of terminals $X \subseteq \hat{R} \setminus \hat{Q}$, both maps $\alpha \mapsto \tilde{v}^\alpha(X)$ and $\delta \mapsto \tilde{v}^\delta(X)$ are monotonic in the parameters α and δ, respectively. That is, we have $\tilde{v}^\alpha(X) \geq \tilde{v}^{\alpha+1}(X)$ and $\tilde{v}^\delta(X) \leq \tilde{v}^{\delta+1}(X)$ for all $\alpha, \delta \in \mathbb{N}_0$.*

Proof. Let $\alpha, \delta \in \mathbb{N}_0$ be arbitrary but fixed parameter values. We set $Z \coloneqq X \cup \hat{Q}$ and decompose $\tilde{v}^\alpha(X)$ (and, analogously, $\tilde{v}^\delta(X)$) as

$$\begin{aligned}\tilde{v}^\alpha(X) &= \tilde{o}^\alpha(X) - \tilde{b}^\alpha(X) \\ &= \tilde{o}^\alpha(X) - \big(b(Z \setminus \{\hat{s}\}) + \Delta^\alpha\big) \\ &\overset{\text{Def. } 7}{=} \tilde{o}^\alpha(X) - \big(b(Z \setminus \{\hat{s}\}) + o^\alpha(\hat{Q}) - o^\alpha(Q)\big) \\ &= \tilde{o}^\alpha(X) - \big(b(Z \setminus \{\hat{s}\}) + \tilde{o}^\alpha(\emptyset) - o^\alpha(Q)\big) \\ &= \tilde{o}^\alpha(X) - \tilde{o}^\alpha(\emptyset) + \big(o^\alpha(Q) - b(Z \setminus \{\hat{s}\})\big).\end{aligned} \tag{5}$$

Observe that we can treat the term $o^\alpha(Q) - b(Z \setminus \{\hat{s}\})$ as constant: since $\hat{s}, \check{s} \notin Q$, the out-flow $o^\alpha(Q)$ is identical for all $\alpha \in \mathbb{N}_0$ (or $\delta \in \mathbb{N}_0$). Similarly, the value of $b(Z \setminus \{\hat{s}\})$ does not depend on α or δ.

We now prove monotonicity using this simplification. For MaximizeAlpha, the monotonicity $\tilde{v}^\alpha(X) \geq \tilde{v}^{\alpha+1}(X)$ holds if and only if $\tilde{o}^\alpha(X) - \tilde{o}^\alpha(\emptyset) \geq \tilde{o}^{\alpha+1}(X) - \tilde{o}^{\alpha+1}(\emptyset)$ is true, which follows directly from the strong map property $\tilde{o}^\alpha \sqsubset \tilde{o}^{\alpha+1}$ shown in the proof of Lemma 17. Similarly, replacing α with δ in Equation (5), it follows from $\tilde{o}^\delta \sqsupset \tilde{o}^{\delta+1}$ that $\tilde{o}^\delta(X) - \tilde{o}^\delta(\emptyset) \geq \tilde{o}^{\delta+1}(X) - \tilde{o}^{\delta+1}(\emptyset)$ and thus $\tilde{v}^\delta(X) \leq \tilde{v}^{\delta+1}(X)$ holds. ◀

The monotonicity and strong map property of $\tilde{v}^\alpha$ and $\tilde{v}^\delta$ allow us to introduce new parametric search algorithms for MaximizeAlpha (cf. Algorithm 1) and MinimizeDelta (cf. Algorithm 2). In their core, they follow a rather simple approach similar to algorithms by Schlöter, Skutella, and Tran [12, 11]: we start with an infeasible parameter value α_1 or δ_1 and a corresponding minimizer X_1 of $\tilde{v}^{\alpha_1}$ or $\tilde{v}^{\delta_1}$. Possible initial values are $\alpha_1 \coloneqq \alpha_{\max} = nU_{\max}$ and $\delta_1 \coloneqq 0$ [4]. Next, we alternate between two steps *jump* and *check* until the current minimizer X_i is no longer violated. In the *jump* step, we compute the largest parameter value α_{i+1} or the smallest parameter value δ_{i+1} such that the previous minimizer X_i is no longer violated. Note that this step is, in essence, an integral parametric min-cost flow problem with one parametrized arc. Afterwards, the *check* step finds a minimizer X_{i+1} for the new value α_{i+1} and δ_{i+1}.

In the check step, we use the results of the previous sections in order to restrict the search for minimizers to $X_{i+1} \subset X_i$. We will show in the following that this restriction is actually feasible. Note that the restriction not only reduces the search space in each iteration to $|X_i|$ terminals, but also limits MaximizeAlpha and MinimizeDelta to at most $|S|$ iterations, since the length of the chain $X_1 \supset X_2 \supset \dots$ is limited by $|\hat{R} \setminus \hat{Q}| \leq |S|$.

▶ **Theorem 20.** *Algorithm 1 computes the maximum feasible $\alpha^* \in \mathbb{N}_0$ for MaximizeAlpha; Algorithm 2 computes the minimum feasible $\delta^* \in \mathbb{N}_0$ for MinimizeDelta. Both algorithms terminate after at most $|S|$ iterations of the while loop.*

Proof. We first show by induction that if α_i is infeasible, then there exists a minimizer X_i of $\tilde{v}^{\alpha_i}$ with $X_i \subset X_{i-1}$, where $X_0 = \hat{R} \setminus \hat{Q}$.

By definition, X_1 is a minimizer of $\tilde{v}^{\alpha_1}$. Let α_i and α_{i+1} be infeasible, and assume that X_i is a minimizer of $\tilde{v}^{\alpha_i}$. We have $\alpha_{i+1} < \alpha_i$, since otherwise $\tilde{v}^{\alpha_{i+1}}(X_i) \overset{\text{Lem. 19}}{\leq} \tilde{v}^{\alpha_i}(X_i) < 0$ contradicts the choice of α_{i+1} as feasible for X_i. Together with Lemma 17, this implies the relation $\tilde{v}^{\alpha_i} \sqsupset \tilde{v}^{\alpha_{i+1}}$. Therefore, we have $X_{i+1}^{\min} \subseteq X_i^{\min} \subseteq X_i$ due to Lemma 16, with $X_j^{\min}$ being the minimal minimizer of $\tilde{v}^{\alpha_j}$ for $j \in \{i, i+1\}$. Since α_{i+1} is infeasible with $\tilde{v}^{\alpha_{i+1}}(X_{i+1}^{\min}) < 0$, and, by definition, $\tilde{v}^{\alpha_{i+1}}(X_i) \geq 0$, we even have $X_{i+1}^{\min} \subset X_i$. Hence, $X_{i+1}^{\min}$ is a feasible choice for X_{i+1} in Algorithm 1.

Algorithm 1 Parametric Search for MaximizeAlpha.

Data: Tight sets $\hat{Q} \subset \hat{R} \subseteq S \cup \{\hat{s}\}$, submodular function $\tilde{v}^\alpha \colon 2^{\hat{R} \setminus \hat{Q}} \to \mathbb{Z}$, infeasible upper bound $\alpha_{\max}$
Result: Maximum feasible $\alpha \in \mathbb{N}_0$

```
α_1 ← α_max, X_1 ← Minimizer of ṽ^{α_1}
i ← 1
while ṽ^{α_i}(X_i) < 0 do
    α_{i+1} ← Maximum α ≥ 0 with ṽ^α(X_i) ≥ 0        ▷ Jump step
    X_{i+1} ← Minimizer X ⊂ X_i of ṽ^{α_{i+1}}       ▷ Check step
    i ← i + 1
end
return α_i
```

Algorithm 2 Parametric Search for MinimizeDelta.

Data: Tight sets $\hat{Q} \subset \hat{R} \subseteq S \cup \{\hat{s}\}$, submodular function $\tilde{v}^\delta \colon 2^{\hat{R}\setminus\hat{Q}} \to \mathbb{Z}$
Result: Minimum feasible $\delta \in \mathbb{N}$
$\delta_1 \leftarrow 0$, $X_1 \leftarrow$ Minimizer of $\tilde{v}^{\delta_1}$
$i \leftarrow 1$
while $\tilde{v}^{\delta_i}(X_i) < 0$ **do**
  $\delta_{i+1} \leftarrow$ Minimum $\delta \geq 0$ with $\tilde{v}^{\delta}(X_i) \geq 0$ ▷ Jump step
  $X_{i+1} \leftarrow$ Minimizer $X \subset X_i$ of $\tilde{v}^{\delta_{i+1}}$ ▷ Check step
  $i \leftarrow i + 1$
end
return δ_i

Recall that Algorithm 1 terminates after at most $|S|$ iterations. Let α_{i^*} be the value returned by the algorithm, and let X_{i^*} be the minimizer generated in the final iteration i^*. If α_{i^*} were not feasible, then X_{i^*} would be a minimizer with $v^{\alpha_{i^*}}(X_{i^*}) < 0$. However, since the algorithm terminates, it follows that α_{i^*} is feasible.

To see that α_{i^*} is maximum, recall that $\alpha_1 = \alpha_{\max}$ is infeasible, and thus the jump step is executed at least once. By construction in the jump, the value α_{i^*} is maximum such that the previous minimizer X_{i^*-1} is no longer violated. Hence, for any $\alpha > \alpha_{i^*}$, we have $v^{\alpha}(X_{i^*-1}) < 0$, so α is infeasible. Therefore, α_{i^*} is the optimal solution to MaximizeAlpha.

The proof for Algorithm 2 is analogous. ◀

The remainder of the section is devoted to the runtime analysis. Our main improvement is due to the upper bound $k = |S|$ on the number of iterations the algorithms execute.

▶ **Theorem 21.** *Algorithm 1 can be implemented to solve MaximizeAlpha in strongly polynomial time of $\mathcal{O}(k[\mathrm{SFM}(k,n,m) + \mathrm{MCF}(n,m)^2])$ and in weakly polynomial time of $\mathcal{O}(k[\mathrm{SFM}(k,n,m) + \log(nU_{max}) \cdot \mathrm{MCF}(n,m)])$.*

Proof. The runtime is determined by the two main steps performed in each iteration:

- Jump can be implemented using Megiddo's parametric search [8] or binary search over the range $[0, nU_{\max}]$ in conjunction with a minimum cost flow algorithm. The former results in a runtime of $\mathcal{O}(\mathrm{MCF}(n,m)^2)$, the latter in $\mathcal{O}(\log(nU_{\max}) \cdot \mathrm{MCF}(n,m))$.
- Check minimizes the submodular function v^α on the restricted domain. In the worst case, this takes $\mathcal{O}(\mathrm{SFM}(k,n,m))$ time.

Together with the upper bound of k on the iterations of the while loop, the final runtime is $\mathcal{O}(k[\mathrm{SFM}(k,n,m) + \mathrm{MCF}(n,m)^2])$ or $\mathcal{O}(k[\mathrm{SFM}(k,n,m) + \log(nU_{\max}) \cdot \mathrm{MCF}(n,m)])$. ◀

We obtain an analogous runtime for Algorithm 2.

▶ **Theorem 22.** *Algorithm 2 can be implemented to solve MinimizeDelta in strongly polynomial time of $\mathcal{O}(k[\mathrm{SFM}(k,n,m) + \mathrm{MCF}(n,m)^2])$ and in weakly polynomial time of $\mathcal{O}(k[\mathrm{SFM}(k,n,m) + \log(T) \cdot \mathrm{MCF}(n,m)])$.*

Proof. The proof is analogous to that of Theorem 21. The binary search for the minimum feasible value of δ is done on the range $[0, T]$, which yields the different logarithmic term. ◀

We conclude this section with an improved runtime for computing integral dynamic transshipments compared to the state-of-the-art runtime of $\tilde{\mathcal{O}}(m^4k^{15})$.

▶ **Theorem 23.** *Given a dynamic transshipment instance $(\mathcal{N}, b, T)$, an integral quickest transshipment can be computed in $\tilde{\mathcal{O}}(m^2k^5 + m^4k^2)$ time.*

Proof. Hoppe and Tardos [4] already proved that their algorithm for dynamic transshipment terminates after $\mathcal{O}(k)$ iterations, each of which consists of one call of Algorithms 1 and 2. Given the strongly polynomial runtime of $\mathcal{O}\big(k(\mathrm{SFM}(k,n,m) + \mathrm{MCF}(n,m)^2)\big)$ for both subroutines, we obtain a worst-case complexity of $\mathcal{O}(k^2(\mathrm{SFM}(k,n,m) + \mathrm{MCF}(n,m)^2))$.

Suppressing the polylogarithmic terms, we have a time complexity of $\tilde{\mathcal{O}}(m^2k^3)$ for $\mathcal{O}(\mathrm{SFM}(k,n,m))$ and of $\tilde{\mathcal{O}}(m^2)$ for $\mathcal{O}(\mathrm{MCF}(n,m))$. Overall, we obtain an improved runtime of $\tilde{\mathcal{O}}(m^2k^5 + m^4k^3)$ time for the integral dynamic transshipment problem.

In order to compute a quickest transshipment, we have to determine the minimum time horizon first. This can be done by the method by Schlöter, Skutella, and Tran [12] in $\tilde{\mathcal{O}}(m^2k^5 + m^3k^3 + m^3n)$ time. This runtime is dominated by that of our algorithm for computing the corresponding transshipment: since we assume that the network is connected, we have $m \geq n \geq k$, and thus $\tilde{\mathcal{O}}(m^3n) \subset \tilde{\mathcal{O}}(m^4)$ and $\tilde{\mathcal{O}}(m^3k^3) \subset \tilde{\mathcal{O}}(m^4k^2)$. Overall, the time required to compute a quickest integral transshipment is

$$\tilde{\mathcal{O}}\big((m^2k^5 + m^3k^3 + m^3n) + (m^2k^5 + m^4k^2)\big) = \tilde{\mathcal{O}}(m^2k^5 + m^4k^2 + m^4) = \tilde{\mathcal{O}}(m^2k^5 + m^4k^2),$$

which shows Theorem 23. ◀

6 Conclusion and Outlook

In this paper, we propose an improved version of the algorithm by Hoppe and Tardos for the integral quickest transshipment problem. Our approach is based on more efficient parametric search algorithms using the strong map property and yields a substantial reduction of the runtime from $\tilde{\mathcal{O}}(m^4k^{15})$ to $\tilde{\mathcal{O}}(m^2k^5 + m^4k^2)$.

Our findings open room for ensuing research. In particular, the restrictions of submodular functions to suitable domains introduced in this paper may provide even better bounds on the runtime for our algorithms. Furthermore, we see potential improvements to the jump steps in Algorithms 1 and 2 that are currently based on Megiddo's parametric search and contribute a factor of $\tilde{\mathcal{O}}(m^4)$ to the runtime. This factor constitutes the remaining gap in runtime between the integral and the fractional quickest transshipment problem. In order to close this gap, future studies may focus on adapting parametric minimum cost flow algorithms akin to the algorithms by Lin and Jaillet [7] and Saho and Shigeno [10].

Bootstrapping Dynamic APSP via Sparsification

Abstract

We give a simple algorithm for the dynamic approximate All-Pairs Shortest Paths (APSP) problem. Given a graph $G = (V, E, \boldsymbol{l})$ with polynomially bounded edge lengths, our data structure processes $|E|$ edge insertions and deletions in total time $|E|^{1+o(1)}$ and provides query access to $|E|^{o(1)}$-approximate distances in time $\widetilde{O}(1)$ per query.

We produce a data structure that mimics Thorup-Zwick distance oracles [17], but is dynamic and deterministic. Our algorithm selects a small number of pivot vertices. Then, for every other vertex, it reduces distance computation to maintaining distances to a small neighborhood around that vertex and to the nearest pivot. We maintain distances between pivots efficiently by representing them in a smaller graph and recursing. We maintain these smaller graphs by (a) reducing vertex count using the dynamic distance-preserving core graphs of Kyng-Meierhans-Probst Gutenberg [16] in a black-box manner and (b) reducing edge-count using a dynamic spanner akin to Chen-Kyng-Liu-Meierhans-Probst Gutenberg [6]. Our dynamic spanner internally uses an APSP data structure. Choosing a large enough size reduction factor in the first step allows us to simultaneously bootstrap a spanner and a dynamic APSP data structure. Notably, our approach does not need expander graphs, an otherwise ubiquitous tool in derandomization.

1 Introduction

The dynamic *All-Pairs Shortest Paths* (APSP) problem asks to maintain query access to pairwise distances for a dynamic graph $G = (V, E)$. Recently, the setting of maintaining crude distance estimates at low computational cost has received significant attention [15, 5, 11, 9, 8, 2, 12, 13] culminating in deterministic algorithms with sub-polynomial update and query time for graphs receiving both edge insertions and deletions [10, 16, 14]. In contrast to other deterministic approaches, [16] allows efficient *implicit* access to approximate shortest paths via a small collection of dynamic trees. This is crucial for applications to decremental single source shortest paths and incremental minimum cost flows [6].

All existing dynamic approximate APSP data structures that work against adaptive adversaries are highly complex [10, 16, 14].

The algorithm [16] establishes the following *Thorup-Zwick-distance oracle*-inspired framework: To maintain approximate APSP in the graph, we select a small (dynamic) set of pivot vertices. For every other vertex, we can reduce distance computation to (a) computing distances in a small neighborhood around the vertex and (b) computing the distance to the nearest pivot vertex. Then, [16] maintains a smaller graph where distances between the pivot vertices can be computed, and recursively maintains these with the same approach. To maintain this smaller graph, [16] designs a dynamic vertex sparsification procedure and performs edge sparsification using the dynamic spanner of [7, 4]. This spanner internally relies on complex data structures for decremental APSP on expanders [9] and uses expander embedding techniques in a non-trivial way. We will use the overall dynamic Thorup-Zwick approach of [16], and we will maintain a small graph for computing distances between pivots in a simpler way.

A key ingredient for us is a new, more powerful fully-dynamic spanner from [6]. This spanner requires both dynamic APSP and expander embedding techniques to maintain. In this work, we observe that this spanner can be simplified so that it only requires dynamic APSP to maintain. Thus, given a dynamic APSP data structure, we can maintain a fully-dynamic spanner. But, [16] also showed that given a fully-dynamic spanner, we can obtain dynamic APSP. This presents a striking opportunity: we can simultaneously bootstrap a dynamic APSP data structure and spanner. This gives our main result, a dynamic approximate APSP data structure.

▶ **Theorem 1.** *For a graph $G = (V, E, \boldsymbol{l})$ with polynomially bounded integral edge lengths $\boldsymbol{l} \in \mathbb{R}^E_{>0}$ undergoing up to m edge updates (insertions and deletions), there is an algorithm with total update time $m^{1+o(1)}$ that maintains query access to approximate distances $\widetilde{\text{dist}}(u, v)$ such that*

$$\text{dist}(u, v) \leq \widetilde{\text{dist}}(u, v) \leq m^{o(1)} \cdot \text{dist}(u, v).$$

The query time is $\widetilde{O}(1)$.

While we present our theorem in the setting of processing m updates in time $m^{1+o(1)}$ to simplify the presentation, we believe that this algorithm can be extended directly to the worst-case update time setting of [16]. Furthermore, the witness paths can be implicitly represented as forest paths as in [16], which enables the cheap flow maintenance via dynamic tree data structures necessary for applications.

1.1 Roadmap

We first define the necessary preliminaries in Section 2. Then, we present a simplified version of our algorithm as a warm-up in Section 3. Afterwards, we present our bootstrapped algorithm based on the KMG-vertex sparsifier [16] and a dynamic spanner in Section 4.

2 Preliminaries

2.1 Graph Notation

We use $G = (V, E, \boldsymbol{l})$ to refer to a graph G with vertex set V, edge set E and length vector $\boldsymbol{l} \in \mathbb{R}^E_{\geq 1}$. We will restrict our attention to polynomially bounded integral lengths, and will denote their upper bound by L.

2.2 Paths, Distances and Balls

For two vertices u, v, we let $\pi^G_{u,v}$ denote the shortest path from u to v in G (lowest sum of edge lengths). Furthermore, we let $\text{dist}_G(u, v)$ be the length of said path.

We let $B_G(u, v) \stackrel{\text{def}}{=} \{w : \text{dist}(u, w) < \text{dist}(u, v)\}$ and $\overline{B}_G(u, v) \stackrel{\text{def}}{=} \{w : \text{dist}(u, w) \leq \text{dist}(u, v)\}$. Then, for a set $A \subseteq V$ we let $B_G(u, A) \stackrel{\text{def}}{=} \bigcup_{a\in A} B_G(u, a)$ and $\overline{B}_G(u, A) \stackrel{\text{def}}{=} \bigcup_{a\in A} \overline{B}_G(u, a)$ respectively.

Finally, we define the neighborhood of a vertex u as $\mathcal{N}(u) \stackrel{\text{def}}{=} \{v : (u, v) \in E\} \cup \{u\}$ and of a set $A \subseteq V$ as $\mathcal{N}(A) \stackrel{\text{def}}{=} \bigcup_{a\in A} \mathcal{N}(a)$. For a vertex v, we let $E_G(v) \stackrel{\text{def}}{=} \{(v, u) : u \in \mathcal{N}(v)\} \subseteq E(G)$.

When it is clear from the context, we sometimes omit the subscript/superscript G.

▶ **Definition 2** (Spanner). *Given a graph $G = (V, E, \boldsymbol{l})$, we say that a subgraph $H \subseteq G$ is an α-spanner of G if for any $u, v \in V$ we have $\text{dist}_G(u, v) \leq \text{dist}_H(u, v) \leq \alpha \cdot \text{dist}_G(u, v)$.*

2.3 Dynamic Graphs

Vertex splits are a crucial operation in our algorithms. They arise since we contract graph components and represent them as vertices. When such a component needs to be divided, this naturally corresponds to a vertex split defined as follows.

▶ **Definition 3** (Vertex Split). *For a graph $G = (V, E, \boldsymbol{l})$, a vertex split takes a vertex $v \in V$ and a set $U \subseteq \mathcal{N}(v)$, and replaces the vertex v with two vertices v', v'' such that $\mathcal{N}(v') = U$ and $\mathcal{N}(v'') = \mathcal{N}(v) \setminus U$.*

▶ **Definition 4** (Master Nodes). *Initially, each $v \in V(G^{(0)})$ is associated with a unique master node $\text{master}(v) = \{v\}$. Then, at any time t, if some $v \in V(G^{(t)})$ is split into v' and v'', we set $\text{master}(v') = \text{master}(v'') = \{v\} \cup \text{master}(v)$.*

We can also define our notion of fully-dynamic graphs, which includes vertex splits as an operation.

▶ **Definition 5** (Fully-Dynamic Graph). *A fully-dynamic graph is a graph undergoing edge insertions/deletions, vertex splits and isolated vertex insertions.*

Whenever we disallow vertex splits, we refer to edge-dynamic graphs instead.

▶ **Definition 6** (Edge-Dynamic Graph). *An edge-dynamic graph is a graph undergoing edge insertions/deletions and isolated vertex insertions.*

2.4 Dynamic Objects and Recourse

For a dynamic object $(F(t))_{t\in[T]}$ defined on an index set $[T] = \{1, \ldots, T\}$, we refer to $F^{(T')} \stackrel{\text{def}}{=} (F(t))_{t\in[T']}$ as the full sequence up to time T'. We can then apply functions $g(\cdot)$ that operate on sequences to $F^{(T')}$, e.g. $g(F^{(T')})$. This is for example very useful to keep track of how an object changes over time. By providing a difference function $\triangle(F(t), F(t-1))$ for a dynamic object F, one may define the recourse as the sum of differences $\left\|F^{(t)}\right\|_{\rightarrow} \stackrel{\text{def}}{=} \sum_{i=0}^{t-1} \triangle(F(i+1), F(i))$.

For functions f that operate on a static object G instead of on a sequence, we overload the notation by saying $f(G^{(t)})$ is simply f applied to the last object in the sequence, that is, $f(G^{(t)}) = f(G(t))$. For example, $\deg_{\max}(G^{(t)})$ is defined to be the maximum degree of the graph G at time t.

Whenever we make a statements about a dynamic object F without making reference to a specific time t, we implicitly mean that the statement holds at all times. For example, $\|H\|_{\to} \leq \|G\|_{\to}$ formally means for all $t : \left\|H^{(t)}\right\|_{\to} \leq \left\|G^{(t)}\right\|_{\to}$. Meanwhile, $|E(H)| \leq |E(G)|$ formally means for all $t : |E(H^{(t)})| \leq |E(G^{(t)})|$, and by our convention for applying functions of static objects to a dynamic object, we have that $|E(H^{(t)})| \leq |E(G^{(t)})|$ means $|E(H(t))| \leq |E(G(t))|$.

The time scales we use are fine-grained as we will consider multiple dynamic objects that change more frequently than the input graph G does. We will choose an index set for the dynamic sequence which is fine-grained enough to capture changes to all the objects relevant to a given proof.

A dynamic object H might not change in a time span in which another object F changes multiple times. In this case, to have sequences that are indexed by the same set, we simply pad the sequence of H with the same object, so that both dynamic objects would share the same index set T.

For fully-dynamic graphs G, we let $\triangle(G(t), G(t-1))$ denote the number of edge insertions, edge deletions, vertex splits and isolated vertex insertions that happened between $G(t)$ and $G(t-1)$. Note that generally, vertex splits cannot be implemented in constant time, and thus recourse bounds are not directly relevant to bounding running time. Nevertheless, this convention for measuring recourse is useful, as it is tailored precisely to the type of recourse bounds we prove.

We can store anything that occurs at various times throughout our algorithm in a dynamic object and define what recourse means for it. For example, we will repeatedly call a procedure ReduceDegree(X). If at time t we call the function with input $X(t)$, we might want to track the quantity $\sum_{t' \leq t} |X(t')|$, so we simply let R_X be the dynamic object such that $R_X(t) = \sum_{t' \leq t} |X(t')|$. By defining the difference $\triangle(R_X(t), R_X(t-1)) = R_X(t) - R_X(t-1)$, we can find out how much the value changed during two points in time. A statement such as $\|H\|_{\to} \leq \|G\|_{\to} + \|R_X\|_{\to}$ then means that at any time t (suitably fine-grained), the total amount of changes that H underwent are not more than the amount of G, plus some extra number of updates determined by the calls to ReduceDegree$(\cdot)$ made up to that time.

By viewing the run-time of dynamic algorithm as evolving over a sequence of updates and thinking of it as a dynamic object, we also give meaning to the statement, say, that an algorithm runs in time $n + \gamma \|G\|_{\to}$.

2.5 Dynamic APSP

We introduce APSP data structures for edge-dynamic graphs.

▶ **Definition 7** (Dynamic APSP). *For an edge-dynamic graph $G = (V, E, \boldsymbol{l})$, a γ-approximate β-query APSP data structure supports the following operations.*

- AddEdge(u, v) / RemoveEdge(u, v)*: Add/Remove edge (u, v) from/to G.*
- Dist(u, v)*: Returns in time β a distance estimate $\widetilde{\text{dist}}(u, v)$ such that at all times*

$$\text{dist}_G(u, v) \leq \widetilde{\text{dist}}(u, v) \leq \gamma \cdot \text{dist}_G(u, v).$$

- Path(u, v)*: Returns a uv-path P in G of length $|P| \leq$ Dist(u, v) in time $\beta \cdot |P|$.*

Given an APSP data structure, we let $APSP(|E|, \Delta, u)$ denote the total run time of initialization and u calls to AddEdge and RemoveEdge on an edge-dynamic graph with $\deg_{\max}(G) \leq \Delta$ and $|E|$ initial edges.

We sometimes also call γ the (worst-case) stretch of the data structure.

2.6 Degree Reduction Through Binary Search Trees

Given an *edge-dynamic* graph G, we can maintain in time $\widetilde{O}(1) \cdot \|G\|_{\to}$ another edge-dynamic graph G' in which we replace vertices by Binary Search Trees with one leaf node per edge of the vertex in the original graph. It is immediate that if we can find shortest paths in G', we can translate them into shortest paths in G. The advantage of this technique is that while $|E(G')| = O(|E(G)|)$, $|V(G')| = O(|E(G)|)$ and $\|G'\|_{\to} = \widetilde{O}(\|G\|_{\to})$, we have $\deg_{\max}(G') \leq 3$.

3 Warm up: Low-Recourse Thorup-Zwick'05

Before we describe our algorithm, we turn our attention to a much more modest goal that still showcases the main ideas used in our full construction: maintaining a relaxed version of Thorup-Zwick pivots [17] in a fully-dynamic graph with low recourse. This allows us to do away with the careful controlling of maximum degrees in intermediate graphs, which is the root cause of most of the technicalities when making the construction computationally efficient. Furthermore, we do not need to bootstrap our data structure in this setting.

3.1 Pivot Hierarchies

We first introduce pivot hierarchies.

▶ **Definition 8** (Pivot Hierarchy). *For a graph $G = (V, E, \boldsymbol{l})$, we let a pivot hierarchy of depth Λ and cluster size γ be*

- *a collection of vertex sets $\mathcal{C} = A_0, \ldots, A_\Lambda$ with $A_i \subseteq V$ for all i, $A_0 = V$ and $|A_\Lambda| = 1$,*
- *pivot maps $p_i : A_i \to A_{i+1}$ for all $0 \leq i < \Lambda$ and*
- *cluster maps $C_i : A_i \to 2^{A_i}$ for all $0 \leq i < \Lambda$ such that for all $u \in A_i$ $|C_i(u)| \leq \gamma$ and $u \in C_i(u)$.*

Pivot maps should be thought of as mapping vertices to smaller and smaller sets of representatives, and the cluster maps should be thought of as small neighborhoods of pivots for which (approximate) distances are stored. In classical Thorup-Zwick, the cluster $C_i(v)$ consists of all vertices in A_i that are closer to v than $p_i(v)$. In our algorithms, these balls become somewhat distorted due to sparsification. We then define the approximate distances maintained by the hierarchy.

▶ **Definition 9** (Distances). *For a pivot hierarchy of depth Λ, we define $\widetilde{\operatorname{dist}}^{(\Lambda)}(u, v) \stackrel{\text{def}}{=} 0$ for $u, v \in A_\Lambda$ and*

$$\widetilde{\operatorname{dist}}^{(i)}(u, v) \stackrel{\text{def}}{=} \begin{cases} \operatorname{dist}_G(u, v) & \text{if } u \in C_i(v) \\ \operatorname{dist}_G(u, p_i(u)) + \widetilde{\operatorname{dist}}^{(i+1)}(p_i(u), p_i(v)) + \operatorname{dist}_G(p_i(v), v) & \text{otherwise} \end{cases}.$$

We let $\widetilde{\operatorname{dist}}(u, v) \stackrel{\text{def}}{=} \widetilde{\operatorname{dist}}^{(0)}(u, v)$ for $u, v \in V$ and call a pivot hierarchy α distance preserving if $\widetilde{\operatorname{dist}}(u, v) \leq \alpha \cdot \operatorname{dist}_G(u, v)$ for all $u, v \in V$.

We note that efficient distance queries can be implemented as long as the distances within clusters and the distances to pivots are efficiently maintained. In this warm up, we only focus on maintaining the collection $\mathcal{C}$ with low recourse. However, our full algorithm will maintain this additional information.

Formally, the goal of this warm-up section is to prove the following theorem.

▶ **Theorem 10.** *For an edge-dynamic graph $G = (V, E)$ with $n = |V|$ vertices, a $\sqrt{\log n}$-depth $n^{o(1)}$-cluster size pivot hierarchy can be maintained in polynomial time per update with total recourse $\|\mathcal{C}\|_{\to} \leq n^{o(1)} \cdot \|G\|_{\to}$ on the pivot sets.*

We emphasize that this theorem is not particularly useful, as it comes without meaningful guarantees on the update time, and one could just use Dijkstras algorithm to obtain exact distances in this regime. Even the recourse guarantee is also of limited use, as we do not control the recourse of the pivot maps or the cluster maps of the pivot hierarchy. Nevertheless, our algorithm for proving this theorem is instructive and closely mirrors our final dynamic APSP algorithm.

The illustrative algorithm for maintaining pivot hierarchies repeatedly decreases the vertex count via low-recourse core graphs, and the edge count via a low-recourse spanner. We present these two pieces separately.

3.2 Low-Recourse KMG-vertex sparsifier

In this section, we state a theorem about maintaining a KMG-vertex sparsifier with low recourse [16]. Although their algorithm only works for edge-dynamic graphs, it can be extended to fully-dynamic graphs rather straightforwardly in the recourse setting. Recall that we count a vertex split as a single operation when defining the recourse of a fully-dynamic graph.

▶ **Definition 11** (Vertex Sparsifier)**.** *Given $G = (V, E, \boldsymbol{l})$ and $A \subseteq V$, we call a graph $\widetilde{G}$ with vertex set $V(\widetilde{G}) \supseteq A$ a β-approximate vertex sparsifier of G with respect to the set A if for every two vertices $u, v \in V(\widetilde{G})$ we have $\operatorname{dist}_G(u, v) \leq \operatorname{dist}_{\widetilde{G}}(u, v)$ and if $u, v \in A$ we further have $\operatorname{dist}_{\widetilde{G}}(u, v) \leq \beta \cdot \operatorname{dist}_G(u, v)$.*

▶ Remark 12. We always associate a map from $V(\widetilde{G})$ to V with a vertex sparsifier, where multiple vertices in $V(\widetilde{G})$ might map to the same vertex in V. This clarifies what we mean with $\operatorname{dist}_G(u, v) \leq \operatorname{dist}_{\widetilde{G}}(u, v)$ and $\operatorname{dist}_{\widetilde{G}}(u, v) \leq \beta \cdot \operatorname{dist}_G(u, v)$ in Definition 11. When we apply multiple vertex sparsifiers to a graph G, we refer to recursively applying this map as mapping vertices back to G.

▶ **Theorem 13** (See Theorem 3.1 in [16])**.** *Consider a size reduction parameter $k > 1$ and a fully-dynamic graph G with lengths in $[1, L]$. Then, there is a deterministic algorithm that explicitly maintains,*

1. *a monotonically growing pivot set $A \subseteq V(G)$ and pivot function $p : V \to A$, such that $|A| \leq n/k + 2\|G\|_{\to}$ and $|C(u)| \leq \widetilde{O}(k)$ for all $u \in V$ where $C(u) = \{v \in V : \operatorname{dist}_G(u, v) < \operatorname{dist}_G(u, p(u))\}$.*
2. *a fully-dynamic graph $\widetilde{G}$, such that $\widetilde{G}$ is a γ_{VS}-approximate vertex sparsifier of G with respect to A. We have that the initial graph $\widetilde{G}^{(0)}$ has at most $m \cdot \gamma_{VS}$ edges and $\gamma_{VS} \cdot m/k$ vertices, where $\gamma_{VS} = \widetilde{O}(1)$. The following properties hold:*
   a. *$\widetilde{G}$ has lengths $\boldsymbol{l}_{\widetilde{G}}$ in $[1, nL]$, and*
   b. *given any edge $e = (u, v) \in \widetilde{G}$, there exists a uv-path P in G with $l_G(P) \leq l_{\widetilde{G}}(e)$.*
   c. *$\left\|\widetilde{G}\right\|_{\to} \leq \gamma_{VS} \cdot (\|G\|_{\to} + m)$ and $\left\|D_{\widetilde{G}}\right\|_{\to} \leq \gamma_{VS} \cdot \|G\|_{\to}$ where $D_{\widetilde{G}}$ is the dynamic object containing the decremental operations (deletions and vertex splits) on $\widetilde{G}$.*

The algorithm runs in polynomial time.

3.3 Low-Recourse Dynamic Spanner

In this section, we describe a simple algorithm for maintaining a spanner H of a fully-dynamic graph G with remarkably low recourse. The construction is based on the greedy spanner of [1]. The low-recourse property of a variant of this algorithm has been observed in [3].

▶ **Theorem 14** (Dynamic Spanner). *There exists a data structure that given a fully-dynamic graph $G = (V, E, \boldsymbol{l})$ with polynomially bounded edge lengths, maintains a fully-dynamic $O(\log |V|)$-spanner H of G such that $|E(H)| \leq \gamma_{DS} \cdot |V(H)|$ and $\|H\|_{\rightarrow} \leq \gamma_{DS} \cdot (\|D_G\|_{\rightarrow} + |V|)$ for $\gamma_{DS} \in \widetilde{O}(1)$, where D_G is a dynamic object that contains all decremental updates to G (deletions and vertex splits).*

H can be maintained in polynomial time per update.

Proof. We assume unit lengths via maintaining separate spanners for length ranges $[2^i, 2^{i+1})$ and returning the direct product of the appropriately scaled spanners. Furthermore, we let $|V^{(0)}| = n$ and re-start after n decremental updates.

Then, there can be at most n vertex splits and therefore G contains at most $2n$ vertices before re-starting. We initialize $H^{(0)}$ to the greedy spanner of $G^{(0)}$, i.e. we consider the edges $(u, v) \in E(G^{(0)})$ in arbitrary order and add them to $E(H^{(0)})$ if $\text{dist}_{H^{(0)}}(u, v) > 2 \log 2n$. This ensure that the graph $H^{(0)}$ is a $O(\log |V|)$-spanner of $G^{(0)}$, and $|E^{(0)}| \leq O(n)$ directly follows from the fact that a girth $2 \log |V| + 1$ graph contains at most $O(|V|)$ edges.[1]

Whenever G is updated, we perform the corresponding operation on H in case of edge deletions and vertex splits such that $H \subseteq G$. Then, we iteratively check for every edge $(u, v) \in E(G) \setminus E(H)$ if $\text{dist}_H(u, v) > 2 \log 2n$ and insert the edges for which the condition is true. In particular, for the insertion of an edge (u, v), this corresponds to inserting the edge whenever $\text{dist}_H(u, v) > 2 \log 2n$.

Clearly H is an $O(\log n)$ spanner of G throughout because every edge is stretched by at most $2 \log 2n$. Furthermore, vertex splits and edge deletions only increase the girth of H, and therefore H contains at most $O(n)$ edges throughout. Finally, the total recourse bound $\|H\|_{\rightarrow} \leq O(n)$ follows until the data structure is re-started because an edge only leaves the graph H when it is deleted.

To conclude, it suffices to observe that the total number of restarts is bounded by $\|D_G\|_{\rightarrow} / n$ and there are $O(\log n)$ data structures in total, so $\gamma_{\text{DS}} = O(\log n)$. ◀

3.4 Low-Recourse Pivot Hierarchies via Iterated Sparsification

Given the low-recourse vertex and edge sparsification routines described above, we are ready to give the algorithm for Theorem 10.

Our algorithm consists of layers $0, \ldots, \Lambda - 1$ where $\Lambda = \sqrt{\log n}$.[2] Each layer consists of two graphs G_i and H_i, where $H_i \subseteq G_i$. We let $G_0 = G$. Then we obtain H_i from G_i and G_i from H_{i-1} as follows:

1. G_i is the output of the vertex sparsifier from Theorem 13 on the graph H_{i-1} for size reduction parameter $k \stackrel{\text{def}}{=} 2^{\sqrt{\log n}}$. For simplicity, we assume that k is an integer without loss of generality.
2. H_i is the dynamic spanner from Theorem 14 on the graph G_i.

[1] In [1] this folklore bound was already used to obtain a spanner.

[2] We remark that our full algorithm uses a much more drastic size reduction to enable bootstrapping, which results in only $O(\log^{\epsilon} \log n)$ layers for some small constant $\epsilon < 1$. This is necessary because the stretch is powered every time we recurse.

Whenever an update to G occurs, we pass the updates up the hierarchy until we reach the first layer j that has recieved more than $\gamma_{DS}^j \gamma_{VS}^j 2^{\Lambda-j}$ since it was initialized. Then, we re-initialize all the layers $j, \ldots, \Lambda$ via the steps described above. Notice in particular that the recourse of each layer is much smaller than the size reduction, leading to manageable recourse over all.

We let the sets A_i be the vertex sets of the graphs G_i mapped back to G, and we let A_Λ contain an arbitrary vertex r in $A_{\Lambda-1}$ (also mapped back to G). Furthermore, we let the pivot map $p_i(\cdot)$ be the pivot function maintained by the data structure from Theorem 13 at layer $i+1$ for $i = 0, \ldots, \Lambda-1$, and the cluster map C_i is the cluster map from vertex sparsifier data structure at layer $i+1$. Finally, we define the cluster map $C_\Lambda(v) \stackrel{\text{def}}{=} A_\Lambda$ and pivot map $p_\Lambda(v)$ for every vertex $v \in A_\Lambda$.

Proof of Theorem 10. We first bound the sizes and recourse of the sets $A_0, \ldots, A_\Lambda$ by induction. The recourse of the set A_0 and the recourse of G_0 is $\|G\|_\to$ by definition, and the recourse of H_0 is at most $\gamma_{\text{DS}}\big(\|G\|_\to + |V|\big)$.

We then observe that recourse caused by non-decremental updates on G_i can be ignored because they do not show up in the recourse of the subsequent spanner H_i by Theorem 14. The recourse of the decremental updates to G_i is $\gamma_{VS} \cdot \|H_{i-1}\|_\to$. The recourse of H_i is $\|H_i\|_\to \leq \gamma_{DS}(\|D_{G_i}\|_\to + |V(G_i)|)$. Therefore, t updates to G cause at most $O(t \cdot \gamma_{VS}^i \gamma_{DS}^i)$ vertices to be added to G_i. Since we re-start every layer i after $\gamma_{DS}^i \gamma_{VS}^i 2^{\Lambda-i}$ updates have arrived and the total amount of updates that reach layer i is $\gamma_{VS}^i \gamma_{DS}^i n$, the total recourse of the layer is $O(2^\Lambda \cdot n \cdot \gamma_{VS}^{i+1} \gamma_{DS}^{i+1})$ and the total recourse of all the sets is at most $O(k \cdot \gamma_{VS}^{\Lambda+1} \gamma_{DS}^{\Lambda+1} \cdot n \cdot \Lambda)$ by Theorem 13 and Theorem 14.

Then, we show that the final set $A_{\Lambda-1}$ is of small enough size for bounding the size of the clusters $C_{\Lambda-1}(\cdot)$. By the recourse bound above, there are at most $n^{o(1)} n / k^{\Lambda-i+1}$ updates to a level before it gets rebuilt. Therefore, the size of level $\Lambda-1$ is at most $n^{o(1)}$ at all times. The bound on the other cluster sizes directly follows from Theorem 13 and the description of our algorithm.

It remains to show that the distance estimates $\widetilde{\text{dist}}$ are good. To do so, we first notice that for every $u, v \in A_i$ we have $\text{dist}_G(u,v) \leq \text{dist}_{G_i}(u,v) \leq n^{o(1)} \text{dist}_G(u,v)$ since each layer only loses $\widetilde{O}(1)$ in distance approximation by Theorem 13 and Theorem 14 and there are $\Lambda = \sqrt{\log n}$ levels. Then, the distance approximation follows by induction since the length of the detour to the pivots can lose at most a poly-logarithmic factor per level because the pivot is closer in the graph G_i and $\text{dist}_G(u,v) \leq \text{dist}_{G_i}(u,v) \leq n^{o(1)} \cdot \text{dist}_G(u,v)$.[3] ◀

4 The Algorithm

We solve the APSP problem on a large graph G using a pivot hierarchy obtained by iterated vertex and edge sparsification, just like in the warm up in Section 3. Again, we will select a set of pivots for the first level of a pivot hierarchy, and perform edge and vertex sparsification to represent the distances between the pivots using a smaller dynamic graph, and then recurse on this graph. The main difference to the previous section is that (a) we want to bootstrap dynamic APSP along the way and (b) we want to develop and use a computationally efficient spanner. This spanner creates a few technical complications. In particular, to make the spanner efficient, we need all our graphs to have somewhat bounded maximum degree.

[3] The bounds on the detour are analogous to [17] after taking into account the extra distortion of the distances in G_i as compared to the original graph G. This extra distortion causes the sub-polynomial overhead.

4.1 Vertex sparsification

First, our algorithm reduces the APSP problem to a graph $\widetilde{G}$ with significantly fewer vertices using the KMG-vertex sparsifier (See Section 4.3). When compared to the low-recourse version presented in Section 3, our vertex sparsifier has an additional routine called ReduceDegree$(\cdot)$ which forces some of the vertices in the vertex sparsifier to be split and therefore have smaller degree. We further elaborate this point in the section below.

The vertex sparsification algorithm is presented in Section 4.3.

4.2 Edge sparsification

Although $\widetilde{G}$ is supported on a much smaller vertex set, it may still contain most of the edges from G. To achieve a proper size reduction, we additionally employ edge sparsification on top of the vertex sparsifier $\widetilde{G}$.

There are two key differences between the warm up and the efficient spanner algorithm.

- To quickly check for detours in the spanner, the efficient algorithm recursively uses APSP datastructures on small instances (See Section 4.4).
- To efficiently maintain the dynamic spanners, it is crucial that the degree of the graph remains bounded. Although we can assume that the degree of the initial graph G is bounded by a constant, repeatedly sparsifying the graph could seriously increase its maximum degree. Fortunately, our dynamic spanner guarantees that the average degree after edge sparsification is low. However, the same cannot be achieved for the maximum degree, which becomes apparent when trying to sparsify a star graph.
  To remedy this issue, we use that the underlying graph has bounded degree and call the ReduceDegree$(\cdot)$ routine of the KMG-vertex sparsifier to reduce the degree of high-degree vertices in the spanner. This operation can lead to changes in $\widetilde{G}$ and its spanner, but we show that repeatedly splitting vertices with high degree in the spanner quickly converges because the progress of splits is larger than the recourse they cause to the spanner.

The edge sparsification algorithm is presented in Section 4.4.

4.3 Pivots and Vertex Sparsification

We use the KMG-vertex sparsifier algorithm [16], which is based on dynamic core graphs, which in turn are based on static low-stretch spanning trees.

We first introduce certified pivots. These are mapping vertices that get sparsified away to vertices in $\widetilde{G}$, and certify the distance for vertices that are closer to each other than to their respective pivots.

▶ **Definition 15** (Certified Pivot). *Consider a graph $G = (V, E)$ with edge lengths $\boldsymbol{l}$ and a set $A \subseteq V$. We say that a function $p : V \to A$ is a pivot function for A, if for all $v \in V$, we have that $p(v)$ is the nearest vertex in A (ties broken arbitrarily but consistently).*

Additionally, we say that p is a certified pivot function if for all vertices $v \in V$, for all $u \in B_G(v, p(v)) \cup \{p(v)\}$ we have computed the exact (u, v) shortest paths and distances.

To motivate Definition 15, we show that pivots can be used to approximate the distance between sparsified vertices whenever their exact distance isn't stored already.

▷ Claim 16. Consider a graph $G = (V, E, l)$ with pivot set A and corresponding pivot function p. Then for any $u, v \in V$, if $v \notin B_G(u, p(u))$, we have $\mathrm{dist}_G(p(u), p(v)) \leq 4 \cdot \mathrm{dist}_G(u, v)$.

Proof. By $v \notin B_G(u, p(u))$ we directly obtain $\text{dist}_G(u, p(u)) \leq \text{dist}_G(u, v)$ and since $p(v)$ is (one of) the neareast vertices to v in A, we have $\text{dist}_G(v, p(v)) \leq \text{dist}_G(v, p(u)) \leq \text{dist}_G(v, u) + \text{dist}_G(u, p(u)) \leq 2\,\text{dist}_G(u, v)$ as well. By using the triangle inequality we get $\text{dist}_G(p(u), p(v)) \leq \text{dist}_G(p(u), u) + \text{dist}_G(u, v) + \text{dist}_G(v, p(v)) \leq 4\,\text{dist}_G(u, v)$. ◁

Next, we state a version of the KMG-vertex sparsifier [16], which is based on dynamic core graphs. We refer the reader to the full version of our article for a more detailed discussion of their vertex sparsifier.

The following theorem should be thought of as an efficient analog to Theorem 13 with the extra operation ReduceDegree(·). As mentioned at the start of this section, this routine comes into play when the spanner produces a high-degree vertex down the line.

▶ **Theorem 17** (KMG-vertex sparsifier, See Theorem 3.1 in [16])**.** *Consider a size reduction parameter $k > 1$ and an edge-dynamic graph G, with $\deg_{\max}(G) \leq \Delta$ and lengths in $[1, L]$. Then, there is a deterministic algorithm that explicitly maintains,*

1. *a monotonically growing pivot set $A \subseteq V(G)$ and certified pivot function $p : A \to V$, such that $|A| \leq n/k + 2\,\|G\|_{\to}$.*
2. *a fully-dynamic graph $\widetilde{G}$, such that $\widetilde{G}$ is a γ_{VS}-approximate vertex sparsifier of G with respect to A. We have that $\widetilde{G}^{(0)}$ has at most $m \cdot \gamma_{VS}$ edges and $\gamma_{VS} \cdot m/k$ vertices, where $\gamma_{VS} = \widetilde{O}(1)$. The following properties hold:*
   - **a.** *$\deg_{\max}(\widetilde{G}) \leq \Delta \cdot \gamma_{VS} \cdot k$, and $\widetilde{G}$ has lengths $\boldsymbol{l}_{\widetilde{G}}$ in $[1, nL]$, and*
   - **b.** *given any edge $e = (u, v) \in \widetilde{G}$, the algorithm can return a uv-path P in G with $l_G(P) \leq l_{\widetilde{G}}(e)$ in time $O(|P|)$.*
   - **c.** *a procedure ReduceDegree(E', z), where $E' \subseteq \{e \in E(\widetilde{G}) : v \in e\}$ for some $v \in V(\widetilde{G})$, and z is a positive integer. It updates the graph $\widetilde{G}$, performing at most $\gamma_{VS} \cdot |E'|/z$ vertex splits, such that afterwards any vertex $v' \in V(\widetilde{G})$ with $v \in \text{master}(v')$ is adjacent to at most $z \cdot \Delta$ edges in E'. This procedure runs in time at most $\gamma_{VS} \cdot k \cdot |E'|$.*
   - **d.** *If R_V is the dynamic object containing the total number of vertex splits performed by ReduceDegree, then $\left\|\widetilde{G}\right\|_{\to} \leq \gamma_{VS} \cdot \|G\|_{\to} + \|R_V\|_{\to}$.*

The algorithm runs in time $m \cdot \gamma_{VS} \Delta k^4 + \|G\|_{\to} \cdot \gamma_{VS} k^4 \Delta$.

4.4 Edge Sparsification

We state our main dynamic spanner theorem whose proof is deferred to the full version of our article. The theorem assumes access to a $\gamma_{apxAPSP}$-approximate, $\widetilde{O}(1)$-query APSP data structure (See Definition 7.)

▶ **Theorem 18** (Dynamic Spanner)**.** *There exists a data structure that given a fully-dynamic graph G with unit lengths and $|V(G^{(0)})| = n$, $\|G\|_{\to} \leq n$ and a parameter $1 \leq K \leq O(\log^{1/3} n)$, maintains a fully-dynamic $\gamma_l^{O(K)}$-spanner S of G such that $|E(S)| \leq \gamma_{ES} \cdot n$ and $\|S\|_{\to} \leq \gamma_{ES} \cdot \|G\|_{\to}$, where $\gamma_l = \widetilde{O}(\gamma_{apxAPSP})$ and $\gamma_{ES} = \widetilde{O}(n^{1/K})$. It runs in time $n \deg_{\max}(G^{(0)}) \gamma_{ES} \gamma_l^{O(K^2)} + APSP(\gamma_{ES} n, 3, \gamma_{ES} n)$.*

▶ Remark 19. We can directly extend Theorem 18 to graphs with edge lengths in $[1, L]$ by bucketing edges in the intervals $[2^i, 2^{i+1})$ for $i = 1, \ldots, O(\log L)$.

Note also that as at all times H is a subgraph of G, it does not undergo more vertex splits and isolated vertex insertions than G, i.e., all extra updates to maintain H are edge insertions/deletions.

4.5 Bootstrapping via Edge and Vertex Sparsification

We are given an edge-dynamic graph G on initially n vertices and m edges, that at all times has maximum degree at most Δ. Applying Theorem 17 to G reduces the problem to finding short paths in $\widetilde{G}$, a graph of $\widetilde{O}(m/k)$ vertices. Although the number of vertices significantly decreases, the graph still contains up to $\widetilde{O}(m)$ edges, preventing efficient recursion. To address this, we apply Theorem 18 on $\widetilde{G}$ to produce a graph H on $\gamma \cdot m/k$ vertices *and* edges, where γ crucially depends only on the parameter K of Theorem 18.

Note that the APSP data structure that Theorem 18 requires also only needs to run on a graph of at most $\gamma \cdot m/k$ vertices and edges, so by choosing a large enough size reduction factor k, the problem size reduces by a factor of γ/k, while the approximation factor increases from $\gamma_{apxAPSP<m}$ to $\widetilde{O}(\gamma_{apxAPSP<m})^{O(K)}$.[4] Balancing both parameters k and K allows us to bootstrap an APSP data structure with the guarantees from Theorem 1.

While H is sparse, it might still have high maximum degree, preventing efficient recursion. The sparsity still implies, however, that there cannot be too many high degree vertices. Hence, we carefully perform a few vertex splits in $\widetilde{G}$ by leveraging the ReduceDegree$(\cdot)$ functionality from Theorem 17 to enforce that H also has small maximum degree.

Algorithm 1 initDynamicAPSP().

1 Maintain $\widetilde{G}$ from Theorem 17.
2 Let H be the graph maintained by applying Theorem 18 to graph $\widetilde{G}$ with parameter K.
`/* Here` $\gamma_{degConstr}$ `is a constant fixed later. */`
3 **while** $\exists v \in V(H)$ *with* $\deg_H(v) > 8\gamma_{degConstr} \cdot \Delta$ **do**
4 | ReduceDegree$(E_H(v), \gamma_{degConstr})$.
5 Initialize and maintain a recursive dynamic APSP data structure on H.

The recursive APSP instance that is running on H expects an edge-dynamic graph, while the spanner from Theorem 18 is fully-dynamic. To circumvent this issue, we simulate the vertex splits by suitable edge insertions/removals and vertex insertions. As the maximum degree of H gets controlled during the while loops, this simulation can lead to at most an extra factor of $O(\gamma_{degConstr} \cdot \Delta)$ in the number of updates.

Algorithm 2 MaintainDynamicAPSP(G, t).

1 Update $\widetilde{G}$ and H accordingly.
2 **while** $\exists v \in V(H)$ *with* $\deg_H(v) > 8\gamma_{degConstr} \cdot \Delta$ **do**
3 | ReduceDegree$(E_H(v), \gamma_{degConstr})$.
4 | Update H accordingly.
5 Forward all updates made to H to the recursive dynamic APSP datastructure that runs on H by simulating the vertex splits accordingly

When queried for the distance between two vertices u and v, our algorithm checks if the certified pivot function stores the distance, and if this is not the case it recursively asks the smaller instance DynamicAPSP$_H$ for the distance between $p(u)$ and $p(v)$ in H.

[4] We only have a valid size reduction if also $\gamma \cdot m/k < n$. We will see that this is indeed the case as we can assume that initially $m = O(n)$.

Algorithm 3 $\textsc{Dist}(u, v)$.

```
if v ∈ B_G(u, A) then
    return dist(u, v)
else
    return dist(u, p(u)) + DynamicAPSP_H.Dist(p(u), p(v)) + dist(p(v), v)
```

4.6 Analysis

We first show that the while loops in Algorithm 1 and Algorithm 2 terminate sufficiently fast. This is the most crucial claim for the analysis.

▷ Claim 20. If R_V is the dynamic object counting the total number of vertex splits performed by ReduceDegree() in Algorithm 1 and Algorithm 2, then $\|R_V\|_{\to} \leq 2\gamma_{VS}(m/k + \|G\|_{\to})$. In particular, the while loops always terminate and immediately thereafter H has maximum degree at most $8\gamma_{degConstr} \cdot \Delta$. The total runtime of all calls to ReduceDegree() is $6\gamma_{VS}^2\gamma_{ES}(m + k\|G\|_{\to})$.

Proof. For tracking progress achieved by vertex splits, we introduce the following potential function

$$\Phi(H) \stackrel{\text{def}}{=} \sum_{v \in V(H)} \max\{\deg_H(v) - \Delta \cdot \gamma_{degConstr}, 0\}.$$

Let t be the time before we enter the while loop in Algorithm 1. Then by Theorem 17 we have that $|V(\widetilde{G}^{(t)})| \leq \gamma_{VS}m/k$ and thus by Theorem 18, we have that $|E(H^{(t)})| \leq \gamma_{VS}\gamma_{ES}m/k$.

By the Handshake-Lemma, $\Phi(H^{(t)}) \leq 2|E(H^{(t)})| \leq 2 \cdot \gamma_{ES} \cdot \gamma_{VS} \cdot m/k$. Note that whenever an update is made to H, the potential can increase by at most 2. This is as edge deletions and vertex splits can only decrease it, and an edge insertion can increase it by at most 2.

Let R_E be the dynamic object counting the number of edges that were passed to ReduceDegree, and note that if $\textsc{ReduceDegree}(E', \gamma_{degConstr})$ is called, we have $|E'| > 8\gamma_{degConstr} \cdot \Delta$ by the while loop condition.

By the properties of ReduceDegree() in Theorem 17, we have that $\|R_V\|_{\to} \leq \gamma_{VS}/\gamma_{degConstr} \cdot \|R_E\|_{\to}$, and that none of the vertices v' that result from the splits to v will be adjacent to more than $\gamma_{degConstr} \cdot \Delta$ of the edges in E'. So if we just forwarded these splits to H, we would have $\deg_H(v') \leq \gamma_{degConstr} \cdot \Delta$, and the potential decreases by at least $7/8 \cdot |E'|$.

However, forwarding these vertex splits to H, Theorem 18 will cause further updates to H to maintain the spanner. Fortunately by Item 2d of Theorem 17 we know that $\|H\|_{\to} \leq \gamma_{ES} \cdot \left\|\widetilde{G}\right\|_{\to} \leq \gamma_{ES} \cdot \gamma_{VS} \cdot \|G\|_{\to} + \gamma_{ES} \cdot \|R_V\|_{\to}$. Let $\gamma = \gamma_{ES} \cdot \gamma_{VS}$. Putting everything together we show that the potential decreases as follows.

$$\begin{aligned}\Phi(H) &\leq 2\gamma m/k - \frac{7}{8}\|R_E\|_{\to} + 2\|H\|_{\to} \leq 2\gamma m/k - \frac{7}{8}\|R_E\|_{\to} + 2\gamma\|G\|_{\to} + 2\gamma_{ES}\|R_V\|_{\to} \\ &\leq 2\gamma m/k - \frac{7}{8}\|R_E\|_{\to} + 2\gamma\|G\|_{\to} + \frac{2\gamma_{ES}\gamma_{VS}}{\gamma_{degConstr}}\|R_E\|_{\to}.\end{aligned}$$

Thus, choosing $\gamma_{degConstr} = \lceil 4\gamma_{VS}\gamma_{ES} \rceil$, we get $\Phi(H) \leq 2\gamma m/k - \frac{3}{8}\|R_E\|_{\to} + 2\gamma\|G\|_{\to}$. As $0 \leq \Phi(H)$, this directly implies that $\|R_E\|_{\to} \leq 6\gamma_{ES}\gamma_{VS}(m/k + \|G\|_{\to})$. Remembering that $\|R_V\|_{\to} \leq \frac{\gamma_{VS}}{\gamma_{degConstr}}\|R_E\|_{\to}$ then yields the bound on $\|R_V\|_{\to}$.

Since the total runtime is given by $\gamma_{VS} \cdot k \cdot \|R_E\|_{\to}$, this bound follows directly. ◁

We then show a bound on the total runtime of our dynamic APSP algorithm in terms of costs for smaller instances, setting us up for our final recursion.

To do so, assume the recursive APSP instance that is running on H and used in Theorem 18 is a $\gamma_{apxAPSP<m}$-approximate, $\widetilde{O}(1)$-query APSP. Let $\gamma_l = \widetilde{O}(\gamma_{apxAPSP<m})$ be the stretch parameter from Theorem 18.

▶ **Theorem 21.** *The total combined runtime of Algorithm 1 and Algorithm 2 over a sequence of up to m/k updates is $m \cdot \gamma_{RC} \cdot \gamma_l^{O(K^2)} \Delta k^4 + APSP(\gamma_{RC} m/k, \gamma_{RC}\Delta, \gamma_{RC}\Delta m/k)$ for some $\gamma_{RC} = \widetilde{O}(m^{3/K})$.*

Proof. We first show that for at most m/k updates, initializing and maintaining H is efficient. Note that by the previous claim, we can bound the total costs incurred in the while loops by $6\gamma_{VS}^2\gamma_{ES}(m + k\|G\|_{\to}) \leq 12\gamma_{VS}^2\gamma_{ES}m$. The total costs of initializing and maintaining $\widetilde{G}$ are $2m \cdot \gamma_{VS}\Delta k^4$ by Theorem 17. Finally, by the previous lemma $\|\widetilde{G}\| \leq \gamma_{VS}\|G\|_{\to} + \|R_V\|_{\to} \leq 3\gamma_{VS}\|G\|_{\to} + 2\gamma_{VS}m/k \leq 4\gamma_{VS}m/k$, so that we can further bound the runtime of Theorem 18 by $\gamma_{VS}^2\gamma_{ES}n\Delta k\gamma_l^{O(K^2)} + APSP(\gamma_{ES} \cdot n, 3, \gamma_{ES} \cdot n)$. Note that here we also crucially used that by Theorem 17, $\Delta_{\max}(\widetilde{G}) \leq k\gamma_{VS}\Delta$.

It remains to consider the APSP data structure that we have to run on H. First note that by the gurantees of Theorem 17 and Theorem 18, initially $|E(H)| \leq \gamma_{VS}\gamma_{ES}m/k$. Secondly, note that as $\|\widetilde{G}\| \leq 4\gamma_{VS}m/k$, we in particular have $\|H\|_{\to} \leq 4\gamma_{ES}\gamma_{VS}m/k$. However, as H is vertex dynamic, we also have to simulate all the vertex splits occuring in H, which can lead to up to $8\gamma_{degConstr}\Delta$ extra updates per split. Hence the total amount of updates that the APSP data structure receives are up to $O(\gamma_{VS}^2\gamma_{ES}^2 m/k)$. By the while loop conditions, we do know that the maximum degree of the graph is always bounded by $8\gamma_{degConstr}\Delta$. Therefore, the total runtime bound follows. ◀

We show that the stretch does not increase too much as the size of the graph increases.

▷ Claim 22. Algorithm 1 provides a worst case stretch of $\widetilde{O}(\gamma_{apxAPSP<m})^{O(K)}$.

Proof. If $v \in B_G(u, A)$ there is nothing to show as then by Theorem 17 we have already pre-computed the exact distance between u and v.

But if $v \notin B_G(u, A)$, then by Claim 16, we have that $\text{dist}_G(p(u), p(v)) \leq 4 \cdot \text{dist}_G(u, v)$. As $p(u), p(v) \in A$, we have $\text{dist}_H(p(u), p(v)) \leq \gamma_l^{O(K)} \cdot \text{dist}_{\widetilde{G}}(p(u), p(v)) \leq \gamma_l^{O(K)} \cdot \gamma_{VS} \cdot \text{dist}_G(p(u), p(v)) = \widetilde{O}(1) \cdot (\widetilde{O}(1) \cdot \gamma_{apxAPSP})^{O(K)} \cdot \text{dist}_G(p(u), p(v)) = \widetilde{O}(\gamma_{apxAPSP})^{O(K)} \cdot \text{dist}_G(p(u), p(v))$. ◁

▶ Remark 23. We can directly extend this to receive a procedure $\textsc{Path}(u, v)$ that provides a u-v path P with $|P| \leq \widetilde{O}(\gamma_{apxAPSP<m})^{O(K)} \cdot \text{dist}_G(u, v)$ and runs in time $\widetilde{O}(|P|)$. This is because Theorem 17 also explicitly stores exact shortest paths between vertices u and their pivots $p(u)$.

In order to prove Theorem 1, we need to carefully assemble the previous insights, which we defer to the full version of our article.

A Deterministic Partition Tree and Applications

Haitao Wang
Kahlert School of Computing, University of Utah, Salt Lake City, UT, USA

Abstract

In this paper, we present a deterministic variant of Chan's randomized partition tree [Discret. Comput. Geom., 2012]. This result leads to numerous applications. In particular, for d-dimensional simplex range counting (for any constant $d \geq 2$), we construct a data structure using $O(n)$ space and $O(n^{1+\epsilon})$ preprocessing time, such that each query can be answered in $o(n^{1-1/d})$ time (specifically, $O(n^{1-1/d}/\log^{\Omega(1)} n)$ time), thereby breaking an $\Omega(n^{1-1/d})$ lower bound known for the semigroup setting. Notably, our approach does not rely on any bit-packing techniques. We also obtain deterministic improvements for several other classical problems, including simplex range stabbing counting and reporting, segment intersection detection, counting and reporting, ray-shooting among segments, and more. Similar to Chan's original randomized partition tree, we expect that additional applications will emerge in the future, especially in situations where deterministic results are preferred.

Acknowledgements We would like to thank Timothy Chan for the discussions on derandomizing his partition tree.

1 Introduction

Simplex range searching is a fundamental problem in computational geometry. Given a set P of n points in the d-dimensional space $\mathbb{R}^d$ for a constant $d \geq 2$, the goal is to build a data structure so that points of P inside a query simplex can be found efficiently. The problem has been extensively studied (see [1, 2, 19] for some excellent surveys). For solving the problem with small space (e.g., near linear), one powerful technique is *partition trees*, e.g., [7, 14, 16–18, 23–25]. In particular, using a partition tree Matoušek [17] built a data structure of $O(n)$ space in $O(n \log n)$ time and each simplex range query can be answered in $O(n^{1-1/d} \log^{O(1)} n)$ time. Subsequently Matoušek [18] gave another more complicated data structure of $O(n)$ space with $O(n^{1+\epsilon})$ preprocessing time and $O(n^{1-1/d})$ query time; throughout the paper let ϵ be an arbitrarily small positive constant. Chazelle [10] proved that $\Omega(n^{1-1/d}/\log n)$ (and $\Omega(\sqrt{n})$ for $d = 2$) is a lower bound on the query time for an $O(n)$-space data structure; it is widely believed that the $\log n$ factor is an artifact of the proof. Although the result of [18] seems to achieve optimal query time with linear space, it is not quite satisfactory. One reason is that partition trees are often used as backbone for designing multi-level data structures and certain properties of the result of [18] makes this challenging, e.g., it has a special root of $O(n^{1/d} \log n)$ degree whose children may have overlapping cells and it does not guarantee the optimal crossing number except at the bottom most level of the tree. To address these issues, Chan [7] proposed a randomized partition tree of $O(n)$ space that can be built in $O(n \log n)$ expected time and the query time is bounded by $O(n^{1-1/d})$ w.h.p. Comparing to Matoušek's work [18], Chan's result has many nice properties, e.g.,

each node has $O(1)$ children, crossing number is optimal (with w.h.p) at almost all layers (except the top few layers), and children's cells at each node are pairwise disjoint. These properties make Chan's partition tree quite amenable to multi-level data structures [7–9].

Simplex range searching has several versions: (1) Counting: compute the number of points of P inside the query simplex Δ; (2) reporting: report all points of P inside Δ; (3) semigroup query (which generalizes the counting query): compute the sum of the weights of the points of P inside Δ, assuming that each point of P is assigned a weight from a semigroup. The above results [7, 17, 18] are applicable to semigroup queries and can also be modified to solve range reporting with an additive term k in the query time, where k is the output size. In particular, Chazelle's lower bound [10] is for the semigroup setting.

Since Chan's partition tree is randomized, for those who need deterministic algorithms, Matoušek's partition trees [17, 18] are still the main resort. In this paper, we "partially" derandomize Chan's partition tree and obtain a deterministic tool, especially for designing multi-level data structures. More specifically, our partition tree is similar to Chan's (e.g., $O(n)$ space, optimal crossing number at all levels except the top few levels, disjointness of children's cells of each node); however, the degree of each node is logarithmic instead of constant (that is why we used "partially" above). Albeit this drawback, our tree is still powerful enough to have many applications, as discussed below.

Simplex range counting. For simplex range counting, we construct a data structure of $O(n)$ space that can answer each query in $O(n^{1-1/d}/\log^{\Omega(1)} n)$ time. Note that this does not violate Chazelle's lower bound [10] as it is for the more general semigroup queries. The preprocessing time is $O(n^{1+\epsilon})$. To achieve the result, we construct our partition tree so that each leaf has $O(\log^{\tau} n)$ points of P for an arbitrarily small constant $\tau > 0$. Because this number is small, we can afford to preprocess all leaves in $O(n)$ time by considering all possible configurations for queries; in this way, each query on a single leaf v can be answered in $O(\log\log n)$ time. While this kind of technique may not be quite surprising, it has never been used in simplex range searching, perhaps because previous work has been focusing on the semigroup queries while this technique does not work in that setting. Note that our above result is also applicable to simplex range emptiness queries.

It should be noted that very recently Chan and Zheng [9] obtained similar randomized results (i.e., $O(n)$ words of space and $o(n^{1-1/d})$ query time w.h.p.) for other data structures and also mentioned a possibility of achieving such result for simplex range counting. One difference is that their technique uses bit-packing by assuming each word has $\Omega(\log n)$ bits (note that the $\log n$-bit word RAM is also a conventional computational model), while ours does not use bit-packing. In addition, their result is randomized while ours is deterministic.

Simplex range stabbing. Given a set of n simplices in $\mathbb{R}^d$, the *simplex range stabbing counting problem* is to build a data structure to compute the number of simplices containing a query point. Using Chan's partition tree, Chan and Zheng [9] built a randomized data structure of $O(n\log\log n)$ space (or $O(n)$ words of space using the bit-packing tricks) in $O(n\log n)$ expected preprocessing time and the query time is $O(n^{1-1/d})$ w.h.p. Using our new deterministic partition tree, we build a deterministic data structure of $O(n\log\log n)$ space in $O(n^{1+\epsilon})$ preprocessing time and the query time is $O(n^{1-1/d}/\log^{\Omega(1)} n)$. Previously, the best deterministic results [17, 18] have $O(n^{1+\epsilon})$ preprocessing time, $O(n\log^{O(1)} n)$ space, and $O(n^{1-1/d}\log^{O(1)} n)$ query time; or $O(n2^{\sqrt{\log n}})$ preprocessing time and space, and $n^{1-1/d}\cdot 2^{O(\sqrt{\log n})}$ query time. For the *reporting problem* (i.e., report all simplices containing a query point), the randomized data structure of [9] has the same performance as above except that the query time becomes $O(k + n^{1-1/d})$ w.h.p., where k is the output size. We also obtain the same deterministic result as above with $O(k + n^{1-1/d}/\log^{\Omega(1)} n)$ query time.

Segment intersection searching. Given a set of n (possibly intersecting) line segments in the plane, the *segment intersection counting problem* is to build a data structure to compute the number of segments intersecting a query segment. Chan and Zhen [9] built a randomized data structure of $O(n \log\log n)$ space (which again can be reduced to $O(n)$ words of space if bit-packing tricks are allowed) in $O(n \log n)$ expected preprocessing time and the query time is $O(\sqrt{n})$ w.h.p. Using our new deterministic partition tree, we build a deterministic data structure of $O(n \log\log n)$ space in $O(n^{1+\epsilon})$ preprocessing time and the query time is $O(\sqrt{n}/\log^{\Omega(1)} n)$. The previously best deterministic result [6] built a data structure of $O(n \log^2 n)$ space in $O(n^{3/2})$ time that can answer each query in $O(\sqrt{n} \log n)$ time.

For the *reporting problem* (i.e., report all segments intersecting a query segment), the randomized data structure of [9] has the same performance as above except that the query time becomes $O(k + \sqrt{n})$ w.h.p., where k is the output size. We also obtain the same deterministic result as above with $O(k + \sqrt{n}/\log^{\Omega(1)} n)$ query time.

Segment intersection detection. Given n (possibly intersecting) line segments in the plane, we wish to build a data structure to decide whether a query line intersects any segment [12,22]. The previous deterministic result [22] builds an $O(n)$-space data structure in $O(n^{3/2})$ time, with $O(\sqrt{n} \log n)$ query time. Using our new partition tree, we build an $O(n)$-space data structure with $O(\sqrt{n}/\log^{\Omega(1)} n)$ query time and $O(n^{1+\epsilon})$ preprocessing time.

Ray-shooting among non-intersecting segments. Given n non-intersecting line segments in the plane, we wish to build a data structure to find the first segment hit by a query ray [3,6,20]. The previous best deterministic result [22] builds an $O(n)$-space data structure in $O(n^{3/2})$ time, with $O(\sqrt{n} \log n)$ query time. With our partition tree, we build an $O(n)$-space data structure with $O(\sqrt{n}/\log^{\Omega(1)} n)$ query time and $O(n^{1+\epsilon})$ preprocessing time.

If the segments are allowed to intersect, then the problem has also been studied [3, 4, 6, 7, 9, 12, 15, 20, 22]. The previously best deterministic result [22] builds an $O(n \log n)$-space data structure in $O(n^{3/2})$ time and each query can be answered in $O(\sqrt{n} \log n)$ time.

Outline. After introducing notation in Section 2, we present our partition tree in Section 3. The simplex range counting problem is treated in Section 4. The simplex range stabbing and the segment intersection searching problems are discussed in Section 5. We solve the segment intersection detection and the ray-shooting problems in Sections 6 and 7, respectively. Due to the space limit, many proofs and details are omitted but can be found in the full paper.

2 Preliminaries

Let H be a set of n hyperplanes in $\mathbb{R}^d$. We use $\mathcal{A}(H)$ to denote the arrangement of H, which can be computed in $O(n^d)$ time [13]. For a compact region $R \in \mathbb{R}^d$, we use H_R to denote the subset of hyperplanes of H that intersect the relative interior of R but does not contain R (we also say that these hyperplanes *cross* R). A *cutting* for H is a collection Ξ of closed cells (each of which is a simplex, possibly unbounded) with disjoint interiors, which together cover the entire space $\mathbb{R}^d$ [11,18]. The *size* of Ξ is the number of cells of Ξ. For a parameter r with $1 \le r \le n$, a $(1/r)$-*cutting* for H is a cutting Ξ satisfying $|H_\sigma| \le n/r$ for every cell $\sigma \in \Xi$.

For any $1 \le r \le n$, a $(1/r)$-cutting of size $O(r^d)$ for H can be computed in $O(nr^{d-1})$ time [11]. We further have Lemma 1 (similar results were mentioned before [5, 7, 21]). Throughout the paper, β always refers to the one in the lemma.

▶ **Lemma 1.** (Cutting Lemma) *Let H be a set of n hyperplanes and Δ a simplex in $\mathbb{R}^d$. For any $1 \le r \le n$, we can compute a $(1/r)$-cutting of $O(K \cdot (r/n)^d + r^{d-1+\beta})$ cells for H whose union is Δ in $O(K \cdot (r/n)^{d-1} + nr^{d-2+\beta})$ time, where K is the number of vertices of $\mathcal{A}(H)$ inside Δ and β is an arbitrarily small positive constant.*

Proof. We apply Chazelle's algorithm [11] but only on the region inside Δ (i.e., starting with $C_0 = \Delta$ following the notation of [11]). A detailed analysis for the 2D case is given in [21, Appendix A]. Below we sketch how to modify the analysis in [11] accordingly by following the notation there.

The analysis follows the same approach except that we use K to replace $\binom{n}{d}$ in the formula $\sum_{s \in C_{k-1}} v(H_{|s}; s) \le \binom{n}{d}$ in [11, Page 153]. As such, the subsequent formula becomes

$$|C_k| \le c \left(\frac{r_0^k \log r_0}{n} \right)^d \cdot K + c r_0^{d-1} (\log r_0)^d |C_{k-1}|.$$

Then, one can prove by induction that $|C_k| \le r_0^{d(k+1)} \cdot K/n^d + r_0^{(k+1)\cdot(d-1+\beta)}$, for an arbitrarily small constant $\beta > 0$. Therefore, the total number of cells of the cutting inside Δ is as stated in the lemma.

For the time analysis, following the same formula $\sum_{0 \le k \le \lceil \log_{r_0} r \rceil} \frac{n}{r_0^k} |C_k|$ in [11, Page 153] and using the above inequality for $|C_k|$, we can derive the time complexity as stated in the lemma. ◀

3 Deterministic partition tree

In this section, we present our deterministic partition tree. The following lemma "partially" derandomizes Chan's partition refinement theorem (i.e., Theorem 3.1 [7]).

▶ **Lemma 2.** *Let P be a set of n points and H a set of m hyperplanes in $\mathbb{R}^d$. Suppose there are t interior-disjoint cells whose union covers P, such that each cell contains at most $2n/t$ points of P and each hyperplane crosses at most κ cells. Then, for any $b \ge 4$, we can divide every cell into $O(b)$ disjoint subcells each containing at most $2n/(bt)$ points of P, for a total of at most bt subcells, so that the total number of subcells crossed by any hyperplane in H is bounded by*

$$O((b \cdot t)^{1-1/d} + b^{1-1/(d-1+\beta)} \cdot \kappa \cdot \log t + b \cdot \log m). \tag{1}$$

Remark. Comparing to Chan's partition refinement theorem, there is an extra $\log t$ in the second term of (1). As will be seen next, due to this extra factor, we have to make each node of our partition tree have logarithmically many children instead of constant. That is why we said before that we "partially" derandomized Chan's result.

3.1 Proving Lemma 2

This subsection is devoted to the proof of Lemma 2.

Let S denote the set of all t given cells in Lemma 2. Let H' be a multiset containing C copies of each hyperplane in H, for a parameter C that is a sufficiently large power of b (so that all future multiplicities are integers; the actual value of C is not important). For any multiset H'' of H, the *size* of H'', denoted by $|H''|$, is the sum of the multiplicities of the hyperplanes in H''. For a cell Δ, let $N_\Delta(H'')$ denote the number of vertices of the

arrangement $\mathcal{A}(H'')$ of H'' inside Δ, counting multiplicities (note that the multiplicity of a vertex is the product of the multiplicities of its defining hyperplanes); let $H''(\Delta)$ denote the (multi)-subset of hyperplanes of H'' crossing Δ.

We process the t cells of S iteratively one by one. The order they will be processed is carefully chosen (in contrast, a random order is used in the proof of [7], which is a major difference between our proof and that in [7]). We will assign indices to the cells following the reverse order they are processed. Suppose we have processed $t-i$ cells, which have been assigned indices and denoted by $\Delta_t, \Delta_{t-1}, \ldots, \Delta_{i+1}$. In the next iteration, we will find a cell among the unprocessed cells of S and process it (and the cell will be assigned index i as Δ_i). Suppose we now have a multiset H_i after cell Δ_{i+1} is processed (initially let $H_{t+1} = H'$). Let S_i denote the subset of unprocessed cells of S. Hence, $|S_i| = i$.

For each cell $\Delta \in S_i$, define

$$A_\Delta = \left(\frac{N_\Delta(H_i)}{b}\right)^{1/d}, \quad B_\Delta = \frac{|H_i(\Delta)|}{b^{1/(d-1+\beta)}}.$$

Define S_{i1} as the subset of cells $\Delta \in S_i$ with $A_\Delta \geq B_\Delta$. Let $S_{i2} = S \setminus S_{i1}$. If $|S_{i1}| \geq i/2$, then we define Δ_i as the cell Δ of S_{i1} that minimizes the value A_Δ; otherwise define Δ_i as the cell Δ of S_{i2} that minimizes B_Δ. Note that the above way of defining Δ_i is a key difference from Chan's approach [7], where Δ_i is chosen from S_i randomly. We now process Δ_i in the following three steps (which is similar to Chan's approach).

1. Construct a $(1/r_i)$-cutting for H_i inside Δ_i with
$$r_i = c \cdot \min\left\{|H_i(\Delta_i)| \cdot \left(\frac{b}{N_{\Delta_i}(H_i)}\right)^{1/d}, b^{1/(d-1+\beta)}\right\},$$
for some constant c. By the cutting lemma, the number of subcells inside Δ_i is $O(N_{\Delta_i}(H_i) \cdot (r_i/|H_i(\Delta_i)|)^d + r_i^{d-1+\beta})$, which can be made at most $b/4$ for a sufficiently small c.
2. We further subdivide each subcell of Δ_i (e.g., using vertical cuts) so that each subcell contains at most $2n/(tb)$ points of P. The number of extra cuts is $O(b)$ as Δ_i contains at most $2n/t$ points of P. The total number of extra cuts for processing all t cells of S is at most $\frac{n}{2n/(tb)} + t = bt/2 + t$, and thus the total number of subcells after processing all t cells is at most $bt/4 + bt/2 + t = 3bt/4 + t$, which is at most bt for $b \geq 4$.
3. For each distinct hyperplane $h \in H_i$, multiply the multiplicity of h in H_i by $(1+1/b)^{\lambda_i(h)}$, where $\lambda_i(h)$ is the number of subcells of Δ_i crossed by h. Let H_{i-1} be the resulting multiset after this.

To prove Lemma 2, it remains to prove Bound (1).

In the third step, since each of the $O(b)$ subcells of Δ_i is crossed by at most $|H_i(\Delta_i)|/r_i$ hyperplanes of H_i, we have $\sum_{h \in H_i} \lambda_i(h) = O(b \cdot |H_i(\Delta_i)|/r_i)$. Since $\lambda_i(h) = O(b)$, we have

$$|H_{i-1}| = \sum_{h \in H_i} (1+1/b)^{\lambda_i(h)} = \sum_{h \in H_i} (1 + O(\frac{\lambda_i(h)}{b})) = |H_i| + \sum_{h \in H_i} O(\frac{\lambda_i(h))}{b}).$$

We thus obtain

$$|H_{i-1}| - |H_i| = O(\frac{1}{b} \cdot \sum_{h \in H_i} \lambda_i(h)) = O(|H_i(\Delta_i)|/r_i) = O(\alpha_i) \cdot |H_i|, \text{ where}$$

$$\alpha_i = \frac{|H_i(\Delta_i)|}{r_i \cdot |H_i|} = O\left(\frac{1}{|H_i|} \cdot \max\left\{\left(\frac{N_{\Delta_i}(H_i)}{b}\right)^{1/d}, \frac{|H_i(\Delta_i)|}{b^{1/(d-1+\beta)}}\right\}\right)$$
$$= O\left(\frac{1}{|H_i|} \cdot \max\{A_{\Delta_i}, B_{\Delta_i}\}\right).$$

After all t cells of S are processed, we have a multiset H_0. Recall that $H_{t+1} = H'$ and $|H'| = C \cdot m$. According to the above analysis, we have

$$|H_0| = |H_{t+1}| \cdot \Pi_{i=1}^{t}(1 + O(\alpha_i)) \leq C \cdot m \cdot \exp\left(O(\sum_{i=1}^{t} \alpha_i)\right). \tag{2}$$

The following lemma gives an upper bound for $\sum_{i=1}^{t} \alpha_i$.

▶ **Lemma 3.** $\sum_{i=1}^{t} \alpha_i = O\left(\frac{t^{1-1/d}}{b^{1/d}} + \frac{\kappa \cdot \log t}{b^{1/(d-1+\beta)}}\right)$.

By Lemma 3 and (2), we have

$$|H_0| \leq C \cdot m \cdot \exp\left(O\left(\frac{t^{1-1/d}}{b^{1/d}} + \frac{\kappa \cdot \log t}{b^{1/(d-1+\beta)}}\right)\right). \tag{3}$$

For any hyperplane $h \in H$, let $\lambda(h)$ be the total number of subcells crossed by h. Our goal is to prove that $\lambda(h)$ is bounded by (1). By the way H_0 is produced, we have $C \cdot (1+1/b)^{\lambda(h)} \leq |H_0|$. Hence,

$$\lambda(h) \leq \log_{1+1/b} \frac{|H_0|}{C} = O(b \cdot \log \frac{|H_0|}{C}) = O(b \log m + (bt)^{1-1/d} + b^{1-1/(d-1+\beta)} \cdot \kappa \cdot \log t).$$

This proves Lemma 2.

3.2 Constructing the partition tree

Using Lemma 2, we can construct a partition tree in the following theorem.

▶ **Theorem 4.** (Hierarchical Partition Theorem) *Given a set P of n points in $\mathbb{R}^d$ and a parameter r with $r_0 \leq r \leq n$ for a sufficiently large constant r_0, for $b = \log^{\rho} r$ for a sufficiently large constant $\rho > 0$, there exists a sequence $\Pi_0, \Pi_1, \ldots, \Pi_{k+1}$ with $k = \lfloor \log_b r \rfloor$ and $b' = \lceil r/b^k \rceil$, where each Π_i is a collection of disjoint simplicial cells (i.e., each cell is a simplex) whose union covers P with the following properties:*

1. *Π_0 has only one cell that is $\mathbb{R}^d$ and the number of cells of Π_i is $O(b' \cdot b^{i-1})$ for $i \geq 1$ (in particular, Π_{k+1} has $O(r)$ cells; the total number of cells in all collections is also $O(r)$).*
2. *Each cell of Π_i contains at least one point and at most $2n/(b' \cdot b^{i-1})$ points of P for all $i \geq 0$ (in particular, each cell of Π_{k+1} contains at most $2n/r$ points).*
3. *Each cell in Π_{i+1} is contained in a single cell of Π_i.*
4. *Each cell of Π_i contains $O(b)$ cells of Π_{i+1} for $i \geq 1$ and the cell of Π_0 contains $O(b')$ cells of Π_1.*
5. *Any hyperplane crosses at most $O((b' \cdot b^{i-1})^{1-1/d} + \log^{O(1)} n)$ cells of Π_i for all $i \geq 1$.*

All collections of cells can be constructed in $O(n^{d^2} \cdot (r^{2-2/d} + \log^{O(1)} n))$ time.

Proof. We only sketch the proof here. The details can be found in the full paper.

Let H be a set of $m = n^{O(1)}$ hyperplanes in $\mathbb{R}^d$. We can prove the following *critical lemma*: With respect to H, one can construct a sequence $\Pi_0, \Pi_1, \ldots, \Pi_{k+1}$ as stated in the theorem with the same properties except that Property (5) only works for any hyperplane in H; also, the construction time is bounded by $O(m^d \cdot (r^{2-2/d} + \log^{O(1)} n) + n \log n + r^{3-1/d} + r^2 \cdot \log^{O(1)} n + m \cdot r^{3-2/d})$.

To prove the above lemma, we first assume that r is a power of b. Then, $r = b^k$ and $b' = 1$. We apply Lemma 2 with H to construct the collections Π'_t iteratively for $t = 1, b, b^2, \ldots$ until $b^k = r$. More specifically, Π'_1 consists of a single cell that is $\mathbb{R}^d$, and Π'_{bt} is obtained by applying Lemma 2 on all cells of Π'_t. We then let $\Pi_0 = \Pi_1 = \Pi'_1$ and $\Pi_i = \Pi'_{b^{i-1}}$. By

Lemma 2, the properties (1)-(4) hold. The proof for Property (5) as well as the case where r is not a power of b are given in the full paper. The algorithm implementation for constructing all collections of cells is also presented in the full paper.

The above critical lemma only guarantees the crossing numbers for the hyperplanes in H. To make it work for any hyperplane in $\mathbb{R}^d$, we resort to the following lemma, which was known before, e.g., [7].

▶ **Lemma 5.** (Test Set Lemma [7]) *For a set P of n points in $\mathbb{R}^d$, we can compute in $O(n^d)$ time a set H (called* test set*) of $O(n^d)$ hyperplanes with the following property: for any set of cells each containing at least one point of P, if κ is the maximum number of cells crossed by any hyperplane of H, then the maximum number of cells crossed by any hyperplane is $O(\kappa)$.*

Now to prove Theorem 4, we just apply the above critical lemma with H as the test set given in Lemma 5, which can be computed in $O(n^d)$ time. Since $m = O(n^d)$ and $r \leq n$, we obtain the theorem from the above critical lemma. ◀

The collections of cells of Theorem 4 naturally form a tree structure, called a *hierarchical partition tree*, in which each node corresponds to a cell. Specifically, the only cell in Π_0 is the root. Cells of Π_{k+1} are the leaves. If a cell $\Delta \in \Pi_i$ contains another cell $\Delta' \in \Pi_{i+1}$, then Δ is the parent of Δ' and Δ' is a child of Δ. As such, each node of the tree has $O(b)$ children (the root has $O(b')$ children). Although the construction time of Theorem 4 is large, it can usually be reduced (e.g., to $O(n^{1+\epsilon})$ time) in applications by constructing an "upper" partition tree using other techniques (e.g., [17]) and then processing the leaves (each containing a small number of points) using Theorem 4, as will be demonstrated in the subsequent sections.

4 Simplex range counting

Given a set P of n points in $\mathbb{R}^d$, we wish to construct a data structure so that the number of points of P inside a query simplex can be quickly computed. If we set $r = n$ in Theorem 4, we can have a data structure of $O(n)$ space and $O(b \cdot n^{1-1/d})$ query time, which is not $O(n^{1-1/d})$ as $b = \Theta(\log n)$. In the following, we reduce the query time to $O(n^{1-1/d}/\log^{\Omega(1)} n)$.

For a region R in the plane, let $P(R)$ denote the subset of points of P in R.

Setting $r = n/b^{2d/(d-1)}$ with $b = \log^{\rho} n$, we apply Theorem 4 to obtain a partition tree T with collections Π_i, $0 \leq i \leq k+1$. The total number of cells is $O(r)$. For each cell Δ, we store $|P(\Delta)|$. By Theorem 4, each cell in Π_{k+1} contains $O(n/r) = O(b^{2d/(d-1)}) = O(\log^{2d\rho/(d-1)} n)$ points of P. The runtime to construct T is $O(n^{d^2+2})$.

Given a query simplex σ, starting from the root of T, for each cell Δ of T, if Δ is contained in σ, then we add $|P(\Delta)|$ to a total count. If Δ is completely outside σ, then we ignore it. Otherwise, a bounding halfplane of σ must cross Δ and we proceed on all children of Δ unless Δ is a leaf. In this way, we obtain a set V of $O(r^{1-1/d})$ leaf cells that are crossed by the bounding halfplanes of σ. The runtime is $O((r/b)^{1-1/d} \cdot b)$, which is $O(r^{1-1/d} \cdot b^{1/d})$.

We now build the data structure recursively on the points in $P(\Delta)$ for each leaf cell Δ of T. If $Q(n)$ is the query time, we have the following recurrence relation:

$$Q(n) = O(r^{1-1/d} \cdot b^{1/d}) + O(r^{1-1/d}) \cdot Q_1(n/r), \tag{4}$$

where $Q_1(\cdot)$ is the query time for each leaf cell Δ, which contains $O(n/r)$ points of P.

To solve $Q_1(n/r)$, we preprocess $P(\Delta)$ for each leaf cell $\Delta \in T$ recursively as above by using different parameters. Specifically, let $n_1 = |P(\Delta)|$, which is $O(n/r)$. Let $\tau > 0$ be an arbitrarily small constant to be set later. Setting $r_1 = n_1/\log^{\tau} n$ with $b_1 = \log^{\rho} n_1$, we

apply Theorem 4 to construct a partition tree $T(\Delta)$ in $O(n_1^{d^2+2})$ time. The total time for constructing $T(\Delta)$ for all leaf cells Δ of T is bounded by $O(n^{d^2+2})$. Using $T(\Delta)$ to handle queries on $P(\Delta)$ and following the same analysis as above, we obtain

$$Q_1(n_1) = O(r_1^{1-1/d} \cdot b_1^{1/d}) + O(r_1^{1-1/d}) \cdot Q_2(n_1/r_1), \tag{5}$$

where $Q_2(\cdot)$ is the query time for each leaf of $T(\Delta)$, which contains $O(n_1/r_1)$ points of P.

Combining (4) and (5) leads to (see the full paper for the detailed proof):

$$\begin{aligned} Q(n) &= O(r^{1-1/d} \cdot b^{1/d}) + O(r^{1-1/d}) \cdot Q_1(n/r) \\ &= O(r^{1-1/d} \cdot b^{1/d}) + O(r^{1-1/d} \cdot r_1^{1-1/d} \cdot b_1^{1/d}) + O(r^{1-1/d} \cdot r_1^{1-1/d}) \cdot Q_2(n_1/r_1) \\ &= O\left(\frac{n^{1-1/d}}{\log^{\Omega(1)} n}\right) + O\left(\left(\frac{n}{t}\right)^{1-1/d}\right) \cdot Q_2(t), \text{ where } t = \log^{\tau} n. \end{aligned} \tag{6}$$

In summary, the above first builds a partition tree T and then builds a partition tree $T(\Delta)$ for each leaf Δ of T (so there are two recursive steps but with different parameters). For notational convenience, we still use T to refer to the entire tree (by attaching $T(\Delta)$ for all leaves Δ), which has $O(n/t)$ leaves, each containing $O(t)$ points. The total space is bounded by $O(n)$ since there are only two recursive steps. In Section 4.1, by using the property that t is very small, we show that after $O(n)$ space and $O(n \log n)$ time preprocessing, each simplex range counting query on any leaf cell of T can be answered in $O(\log t)$ time (i.e., $Q_2(t) = O(\log t)$, which is $O(\log \log n)$; we consider the query on each leaf cell a *subproblem*). As such, we obtain that $Q(n) = O(n^{1-1/d}/\log^{\Omega(1)} n)$. The total preprocessing time is $O(n^{d^2+2})$, dominated by the time for constructing T. We thus have the following result.

▶ **Lemma 6.** *Given a set P of n points in $\mathbb{R}^d$, there is a data structure of $O(n)$ space that can compute the number of points of P in any query simplex in $O(n^{1-1/d}/\log^{\Omega(1)} n)$ time. The data structure can be built in $O(n^{d^2+2})$ time.*

We will reduce the preprocessing time to $O(n^{1+\epsilon})$ in Section 4.2.

4.1 Solving the subproblems

We first consider halfspace queries and then extend the techniques to the simplex case.

A basic data structure. Let A be a set of t points in $\mathbb{R}^d$. We first build a straightforward data structure (called a *basic data structure*) of $O(t^d)$ space in $O(t^{d+1})$ time that can answer each halfspace range counting query on A in $O(\log t)$ time.

Let H be the set of dual hyperplanes of A. We compute the arrangement $\mathcal{A}$ of H in $O(t^d)$ time and space [13]. We then build a point location data structure on $\mathcal{A}$, which can be done in $O(t^d)$ time and supports $O(\log t)$-time point location queries [11]. In addition, for each face f of $\mathcal{A}$, we compute the number of hyperplanes above f (resp., below f) and store these two numbers at f, e.g., by checking every hyperplane of A. This finishes our preprocessing, which can be easily done in $O(t^{d+1})$ time and $O(t^d)$ space. The preprocessing time can be reduced to $O(t^d)$, e.g., by taking an Eulerian tour of the dual graph of the arrangement.

Given a query halfspace σ, the goal is to compute the number of points of A inside σ. Without loss of generality, we assume that σ is an upper halfspace. Then, it is equivalent to computing the number of hyperplanes of H below p, where p is the dual point of the bounding hyperplane of σ. Using the point location data structure, we find the face f of $\mathcal{A}$ that contains p; f stores the number of hyperplanes of H below it and we return that number as our answer to the query. The query time is thus $O(\log t)$.

Handling halfspace queries. Next, we show that after $O(n \log n)$ time and $O(n)$ space preprorcessing we can answer each halfspace range counting query in $O(\log t)$ time on $P(\Delta)$ for each leaf cell Δ of our partition tree T.

We build an algebraic decision tree T_D for the arrangement construction algorithm [13] on a set of t hyperplanes in $\mathbb{R}^d$ so that each node of T_D corresponds to a comparison in the algorithm. The height of T_D is $O(t^d)$ and T_D has $2^{O(t^d)}$ leaves. Each leaf v of T_D corresponds to a "configuration" of t hyperplanes in the following sense. Let A be a set of t hyperplanes with indices $1, 2, \ldots, t$. Following T_D in a top-down manner, we can reach a leaf v such that all comparisons of the nodes in the path of T_D from the root to v are consistent with A; we say that A has the same configuration as v. Let A and B are two sets of t hyperplanes each. Let $\mathcal{A}_A$ and $\mathcal{A}_B$ be the arrangements of A and B, respectively. If the configurations of A and B are both the same as a leaf v of T_D, then there is a one-to-one correspondence between faces of $\mathcal{A}_A$ and faces of $\mathcal{A}_B$ such that if a face f of $\mathcal{A}_A$ corresponds to a face f' of $\mathcal{A}_B$, then the i-th hyperplane of A is above f if and only if the i-th hyperplane of B is above f'.

By the above observation, we do the following preprocessing. For each leaf v of T_D, let A_v be a set of t hyperplanes whose configuration corresponds to v (note that the sets A_v's for all leaves v can be constructed in $t^d \cdot 2^{O(t^d)}$ time by following T_D, which basically enumuerates all possible configurations for the arrangements of a set of t hyperplanes). We construct the above basic data structure on A_v, denoted by $\mathcal{D}_v$. Doing this for all leaves of T_D takes $t^d \cdot 2^{O(t^d)}$ time and space, which is $O(n)$ since $t = \log^\tau n$ if we choose a small enough τ.

For each leaf cell Δ of T, recall $|P(\Delta)| \leq t$ (if $|P(\Delta)| < t$, we add $t - |P(\Delta)|$ dummy points to $P(\Delta)$ so that $P(\Delta)$ has exactly t points). Let $H(\Delta)$ be the set of dual hyperplanes of the points of $P(\Delta)$. We arbitrarily assign indices to the hyperplanes of $H(\Delta)$. Following T_D, we find the leaf v of T_D that has the same configuration as $H(\Delta)$, which can be done in time linear in the height of T_D, i.e., $O(t^d)$; we associate v with Δ. Since T has $O(n/t)$ leaves, doing this for all leaves of T takes $O(n/t \cdot t^d)$ time, which is $O(n \log n)$ if τ is small enough.

Given a query halfspace σ, suppose we want to compute the number of points of $P(\Delta)$ inside σ for a leaf cell Δ of T. This can be done in $O(\log t)$ time as follows. Let v be the leaf of T_D associated with Δ. Let p be the dual point of the bounding hyperplane of σ. Without loss of generality, we assume that σ is an upper halfspace. Hence it is equivalent to finding the number of hyperplanes of $H(\Delta)$ below p. We apply the point location query algorithm using the data structure $\mathcal{D}_v$ with p, but whenever the algorithm attempts to use the i-th hyperplane of A_v to make a comparison, we use the i-th hyperplane of $H(\Delta)$ instead. The point location algorithm will eventually return a face, which stores the number of hyperplanes below it; we return that number as our answer to the query of σ.

Handling simplex queries. We can easily extend the above idea to simplex queries, by using a multilevel data structure. The details are given in the full paper. In summary, with $O(n)$ space and $O(n \log n)$ time preprocessing, a simplex range counting query on $P(\Delta)$ for any leaf cell Δ of T can be answered in $O(\log t)$ time.

4.2 Reducing the preprocessing time

We now reduce the preprocessing time of Lemma 6 to $O(n^{1+\epsilon})$. The idea is to build an "upper partition tree" of $O(1)$ depth using Matoušek's method [17] so that each leaf has $O(n^\delta)$ points of P for a small constant $\delta > 0$ and then construct our data structure in Lemma 6 on each leaf (which form the "lower" part of the partition tree). The details are given below.

A *simplicial partition* for P is a collection $\Pi = \{(P_1, \sigma_1), (P_2, \sigma_2), \ldots, (P_m, \sigma_m)\}$, where the P_i's are pairwise disjoint subsets forming a partition of P, and each σ_i is a simplex containing all points of P_i. The subsets P_i's are called the *classes* and the simplices σ_i's are called *cells*, which may overlap. The *crossing number* of Π is the maximum number of cells crossed by any hyperplane. The following result is from [17].

▶ **Lemma 7.** ([17]) *For a set P of n points in $\mathbb{R}^d$ and a parameter $r \leq n^{\epsilon'}$ for any constant $\epsilon' < 1$, a simplicial partition $\Pi = \{(P_1, \sigma_1), (P_2, \sigma_2), \ldots, (P_{O(r)}, \sigma_{O(r)})\}$ whose classes satisfy $|P_i| \leq n/r$ and whose crossing number is $O(r^{1-1/d})$ can be constructed in $O(n \log r)$ time.*

We build a partition tree T by Lemma 7 recursively, until we obtain a partition of P into subsets of sizes $O(n^\delta)$ for a small enough constant $\delta > 0$ to be fixed later, which form the leaves of T. Each inner node v of T corresponds to a subset P_v of P as well as a simplicial partition Π_v of P_v, which form the children of v. At each child u of v, we store the cell σ_u of Π_v containing P_u and also store the cardinality $|P_u|$. The simplicial partition Π_v is constructed using Lemma 7 with $r = n^{(1-\delta)/k}$ for a constant integer k to be fixed later, i.e., every internal node of T has $O(r)$ children. If we recurse k times, i.e., the depth of T is k, then the subset size of each leaf of T is $O(n^\delta)$. Hence, the number of leaves of T is $O(r^k)$. Next, for each leaf v of T, we construct the data structure of Lemma 6 on P_v, denoted by $\mathcal{D}_v$, in $O(|P_v|^{d^2+2})$ time. Since $|P_v| = O(n^\delta)$, we can make δ small enough so that the total time of Lemma 6 on all leaves of T is $O(n^{1+\epsilon})$. This finishes the preprocessing, which takes $O(n^{1+\epsilon})$ time. The space of the data structure is $O(n)$ since the depth of T is $O(1)$.

Given a query simplex σ, starting from the root of T, for each node v, we check whether σ contains the cell σ_v. If yes, we add $|P_v|$ to the total count. Otherwise, if the boundary of σ crosses σ_v, we proceed to the children of v. In this way, we reach a set V of leaves v of T whose cells σ_v are crossed by the bounding hyperplanes of σ. Since the number of leaves of T is $O(r^k)$ and the depth of T is k, which is a constant, the size of V is $O(r^{k\cdot(1-1/d)})$. If $Q(m)$ is the query time for a subset of size m, then we have the following recurrence

$$Q(m) = O(r) + O(r^{1-1/d}) \cdot Q(m/r), \text{ where } r = n^{(1-\delta)/k} \text{ with } n \text{ as the global input size.}$$

Starting with $m = n$ and recursing k times (using the same r) gives us

$$Q(n) = O(r^{(k-1)\cdot(1-1/d)+1}) + O(r^{k\cdot(1-1/d)}) \cdot Q(n/r^k).$$

Using $r = n^{(1-\delta)/k}$, by setting k to a constant integer larger than $(1/\delta - 1)/(d-1)$, we have

$$Q(n) = O(n^{1-1/d-\delta'}) + O(r^{k\cdot(1-1/d)}) \cdot Q(n/r^k), \tag{7}$$

for another small constant $\delta' > 0$.

Finally, for each leaf node $v \in V$ (i.e., those subproblems $Q(n/r^k)$ in (7)), we use the data structure $\mathcal{D}_v$ to compute the number of points of P_v in σ, in $O(|P_v|^{1-1/d}/\log^{\Omega(1)}|P_v|)$ time by Lemma 6, which is $O((n/r^k)^{1-1/d}/\log^{\Omega(1)} n)$ as $|P_v| = O(n/r^k)$. Plugging this into (7) gives us $Q(n) = O(n^{1-1/d}/\log^{\Omega(1)} n)$. We thus conclude as follows.

▶ **Theorem 8.** *Given a set of n points in $\mathbb{R}^d$, there is a data structure of $O(n)$ space that can compute the number of points in any query simplex in $O(n^{1-1/d}/\log^{\Omega(1)} n)$ time. The data structure can be built in $O(n^{1+\epsilon})$ time for any $\epsilon > 0$.*

5 Simplex range stabbing and segment intersection searching

Given a set S of n simplices in $\mathbb{R}^d$, the problem is to construct a data structure to compute the number of simplices that contain a query point (we also say that those simplices are *stabbed* by the query point). In their data structure, Chan and Zheng [9] utilized a randomized hierarchical partition. We follow their approach and instead use our deterministic hierarchical

partition in Theorem 4. Extra effort needs to be taken because the degree of the partition tree in [7] is $O(1)$ while ours is logarithmic. In the following, we first briefly review Chan and Zheng's approach [9] and then discuss how to make changes.

A review of Chan and Zheng's randomized approach [9]. Each simplex is bounded by $d+1$ hyperplanes. A point p stabs a simplex s if p is in the "correct" side of every bounding hyperplane of s (to simplify the discussion, we assume these are lower halfplanes). In the dual space, this is equivalent to having the dual hyperplane of p above the dual point of each bounding hyperplane of s. Therefore, we have the following problem in the dual space. Given a set S^* of n $(d+1)$-tuples of points in $\mathbb{R}^d$, we wish to construct a data structure to compute the number of tuples whose points are all below a query hyperplane p^*. We can solve the problem using a multi-level data structure as follows.

Let P be the set of the $(d+1)$-th points of all tuples of S^*. Apply the simplicial partition of Lemma 7 to P to obtain a partition $\Pi = \{(P_i, \sigma_i)\}$, with a parameter r to be fixed later. Given a query hyperplane p^*, for every cell σ_i of Π that is crossed by p^*, we recurse on the subset of tuples whose $(d+1)$-th points are in P_i (i.e., apply Lemma 7 on P_i recursively). For each cell σ_i completely below p^*, we recurse on the subset of tuples whose $(d+1)$-th points are in P_i but as a level-d problem (the original problem is a level-$(d+1)$ problem; the recurrence stops at a level-0 problem in which we only need to return the size of the subset). As analyzed in [7], choosing $r = n^\epsilon$ with n as the global input size (i.e., value r is fixed for all levels of the recursion and this makes the recursion depth $O(1)$) can obtain an $O(n)$ space data structure with $O(n^{1-1/d+\epsilon})$ query time, for any $\epsilon > 0$. The preprocessing time is $O(n \log n)$. We summarize this (deterministic) result in the lemma below.

▶ **Lemma 9.** ([9]) *Given a set of n simplices in $\mathbb{R}^d$, one can build a data structure of $O(n)$ space in $O(n \log n)$ time so that the number of simplices containing a query point can be computed in $O(n^{1-1/d+\epsilon})$ time, for any $\epsilon > 0$.*

To improve the query time, Chan and Zheng [9] reduced the problem to a special case where the first d points in each tuple of S^* all lie in $\mathbb{R}^{d-1}$ (equivalently, in the primal setting all but one bounding halfplanes of each input simplex are parallel to the d-th axis). As such, we can reduce some subproblems in the recurrence to the $(d-1)$-dimensional problem and then solve these subproblems by Lemma 9 (where d becomes $d-1$). If $Q(n)$ (resp., $Q'(n)$) is the query time for the problem in $\mathbb{R}^d$ (resp., $\mathbb{R}^{d-1}$), then we have the following recurrence:

$$Q(n) = O(r^{1-1/d}) \cdot Q(n/r) + O(r) \cdot Q'(n/r). \tag{8}$$

By Lemma 9, $Q'(n) = O(n^{1-1/(d-1)+\epsilon})$. If we choose $r = n^\delta$ for a small constant $\delta > 0$, the recursion depth is $O(\log \log n)$ and thus the space is $O(n \log \log n)$. The query time is $O(n^{1-1/d} \log^{O(1)} n)$ due to a constant-factor blowup. To improve the query time to $O(n^{1-1/d})$, a randomized hierarchical partition was used in [9] to replace all recursive simplicial partitions in the preprocessing algorithm for Lemma 9. Here to achieve a deterministic result, we instead use our deterministic hierarchical partition in Theorem 4, as follows.

Our deterministic result. With $r = n/b^c$ for a sufficiently large constant c and $b = \log^\rho n$, we apply Theorem 4 to P to obtain a partition tree T consisting of Π_j, $0 \le j \le k+1$. By Theorem 4, Π_j has $O(b' \cdot b^{j-1})$ cells and each cell has at most $2n/(b' \cdot b^{j-1})$ points of P. We define a sequence of numbers $t_0 < t_1 < \cdots < t_l$ as follows. For each i, $0 \le i \le l$, define $t_i = b' \cdot b^{j_i - 1}$ (and thus $|\Pi_{j_i}| = O(t_i)$), with $j_0 = 1$ and

$$j_i = \left\lceil \log_b \frac{r^{1-(1-\epsilon)^i}}{b'} \right\rceil + 1, \quad 1 \le i \le l,$$

where l is the smallest integer so that $r/b < b' \cdot b^{j_l-1}$. Hence, $l = O(\log\log r)$, which is $O(\log\log n)$. Note that $b' \cdot b^{j_l-1} \leq r$ always holds. By definition, $t_0 = b'$ and t_i is equal to $r^{1-(1-\epsilon)^i}$ within a factor of b for $i \geq 1$.

We replace the recursive partitions in the preprocessing algorithm of Lemma 9 with this sequence of partitions of T: $\Pi_0, \Pi_{j_0}, \Pi_{j_1}, \ldots, \Pi_{j_l}$. As $l = O(\log\log n)$, the space of the data structure is still $O(n\log\log n)$. The cells of the last partition Π_{j_l} will be further preprocessed later. The following lemma analyzes the query time.

▶ **Lemma 10.** *The query time excluding the time spent on the cells of Π_{j_l} is bounded by $O(b \cdot r^{1-1/d} \cdot (n/r)^{1-1/(d-1)+\epsilon})$.*

Lemma 10 leads to the following.

▶ **Corollary 11.** *For a sufficiently large constant c, the query time excluding the time spent on the cells of Π_{j_l} is bounded by $O(n^{1-1/d}/b)$.*

Proof. By Lemma 10, it suffices to show that $b \cdot r^{1-1/d} \cdot (n/r)^{1-1/(d-1)+\epsilon} = O(n^{1-1/d}/b)$, which is equivalent to $b^2 \cdot (n/r)^{1-1/(d-1)+\epsilon} = O((n/r)^{1-1/d})$. This in turn is equivalent to $b^2 = O((n/r)^{1/(d-1)-1/d-\epsilon})$, which holds for a sufficiently large c since $n/r = b^c$. ◀

Preprocessing cells of Π_{j_l}. Recall that Π_{j_l} has $O(b' \cdot b^{t_l-1})$ cells each containing $2n/(b' \cdot b^{t_l-1})$ points of P, and $r/b < b' \cdot b^{t_l-1} \leq r$. Let $r' = b' \cdot b^{t_l-1}$. By Corollary 11, we obtain the following recurrence on the query time $Q(n)$: $Q(n) = O(n^{1-1/d}/b) + O(r'^{1-1/d}) \cdot Q_1(n/r')$, where $Q_1(n/r')$ is the query time for each subproblem of size $O(n/r')$ since each cell of Π_{j_l} contains $O(n/r')$ points of P. As $b = \log^{\rho} n$ and $r/b < r' \leq r$, we can write

$$Q(n) = O(n^{1-1/d}/\log^{\Omega(1)} n) + O((n/n_1)^{1-1/d}) \cdot Q_1(n_1), \tag{9}$$

with $n_1 = \log^{\Theta(1)} n$.

For notational convenience, let T refer to the sequence of partitions $\Pi_0, \Pi_{j_0}, \Pi_{j_1}, \ldots, \Pi_{j_l}$, and cells of Π_{j_l} form the leaves of T.

To solve $Q_1(n_1)$ in (9), we preprocess $P(\Delta)$ for each leaf cell $\Delta \in T$ recursively as above by using different parameters. Specifically, let $\tau > 0$ be an arbitrarily small constant to be set later. Setting $r_1 = n_1/\log^{\tau} n$, we apply Theorem 4 to construct a partition tree $T(\Delta)$ with $b_1 = \log^{\rho} n_1$ in $O(n_1^{d^2+2})$ time. As above (using the new parameters r_1 and b_1), we only use a subset of partitions of $T(\Delta)$ in our query data structure. For notational convenience, we use $T(\Delta)$ to refer to those partitions. The total time for constructing $T(\Delta)$ for all leaves $\Delta \in T$ is bounded by $O(n^{d^2+2})$ and the total space is still $O(n\log\log n)$.

With the same analysis as Lemma 10, we can obtain that the query time on $T(\Delta)$ excluding the time spent on the leaf cells of $T(\Delta)$ is $O(b_1 \cdot r_1^{1-1/d} \cdot (n_1/r_1)^{1-1/(d-1)+\epsilon})$. Define r_1' with respect to r_1 in the same way as above for r' with respect to r, i.e., $T(\Delta)$ has $O(r_1')$ leaf cells and each cell contains $O(n_1/r_1')$ points of P. As above, $r_1/b_1 < r_1' \leq r_1$ holds. Consequently, we obtain $Q_1(n) = O(b_1 \cdot r_1^{1-1/d} \cdot (n_1/r_1)^{1-1/(d-1)+\epsilon}) + O(r_1'^{1-1/d}) \cdot Q_2(n_1/r_1')$, where $Q_2(n_1/r_1')$ is the query time for each leaf cell of $T(\Delta)$. Let $t = n_1/r_1'$. We have

$$Q_1(n) = O(b_1 \cdot r_1^{1-1/d} \cdot (n_1/r_1)^{1-1/(d-1)+\epsilon}) + O((n_1/t)^{1-1/d}) \cdot Q_2(t). \tag{10}$$

Combining (9) and (10) leads to:

$$Q(n) = O\left(\frac{n^{1-1/d}}{\log^{\Omega(1)} n}\right) + O\left(\left(\frac{n}{t}\right)^{1-1/d}\right) \cdot Q_2(t). \tag{11}$$

Since $t = n_1/r'_1$ and $r_1/b_1 < r'_1 \leq r_1$, we have $n/t = n/n_1 \cdot r'_1 \leq n/n_1 \cdot r_1 = n/\log^{\tau} n$. Therefore, we further obtain from the above

$$\begin{aligned} Q(n) &= O\left(\frac{n^{1-1/d}}{\log^{\Omega(1)} n}\right) + O\left(\left(\frac{n}{\log^{\tau} n}\right)^{1-1/d}\right) \cdot Q_2(t) \\ &= O\left(\frac{n^{1-1/d}}{\log^{\Omega(1)} n}\right) + O\left(\frac{n^{1-1/d}}{\log^{\Omega(1)} n}\right) \cdot Q_2(t). \end{aligned} \tag{12}$$

Since $t = n_1/r'_1$ and $r_1/b_1 < r'_1 \leq r_1$, we have $t \leq n_1/r_1 \cdot b_1 = O(\log^{\tau} n \cdot \log^{\rho} \log n)$. Therefore, we can write $t = O(\log^{\tau'} n)$ for another arbitrarily small constant τ'.

In summary, the above first builds a partition tree T and then builds partition trees $T(\Delta)$ for all leaf cells Δ of T (using different parameters). For notational convenience, we still use T to refer to the entire tree (i.e., attaching all leaf trees $T(\Delta)$ to T), which has $O(n/t)$ leaves, each containing $O(t)$ points. The space is bounded by $O(n \log\log n)$ and the total preprocessing time is $O(n^{d^2+2})$. Since t is tiny, we show in the full paper that after additional $O(n \log n)$ time and $O(n)$ space preprocessing, each query on any leaf cell of T can be answered in $O(\log t)$ time (i.e., $Q_2(t) = O(\log\log n)$). Consequently, the query time is bounded by $O(n^{1-1/d}/\log^{\Omega(1)} n)$. We can reduce the preprocessing time to $O(n^{1+\epsilon})$ using idea similar to Section 4.2 (i.e., build an "upper partition tree" of O(1) depth on top using simplicial partitions [17]). We conclude with the following theorem.

▶ **Theorem 12.** *Given a set of n simplices in $\mathbb{R}^d$, one can build a data structure of $O(n \log\log n)$ space so that the number of simplices containing a query point can be computed in $O(n^{1-1/d}/\log^{\Omega(1)} n)$ time. The preprocessing time is $O(n^{1+\epsilon})$ for any $\epsilon > 0$.*

5.1 Other related problems

As studied in [9], some related problems (as stated in the following two theorems) can be solved by similar techniques. For each problem, we basically follow the same high-level algorithmic framework as [9] but use our deterministic partition tree instead of the randomized one in [7]; this is very similar to the above simplex stabbing counting problem, so we omit these details. For each problem, however, we still need to come up with a method to answer queries in $O(\log t)$ time for subproblems of small sizes $t = \log^{\tau} n$ (for an arbitrarily small constant $\tau > 0$) and these are discussed in the full paper.

▶ **Theorem 13.** *Given a set of simplices in $\mathbb{R}^d$, one can build a data structure of $O(n \log\log n)$ space so that the simplices containing a query point can be reported in $O(n^{1-1/d}/\log^{\Omega(1)} n + k)$ time, where k is the output size. The preprocessing time is $O(n^{1+\epsilon})$ for any $\epsilon > 0$.*

▶ **Theorem 14.** *Given a set of n segments in the plane, one can build a data structure of $O(n \log\log n)$ space so that the number of segments intersecting a query segment can be computed in $O(\sqrt{n}/\log^{\Omega(1)} n)$ time (these segments can be reported in additional $O(k)$ time, where k is the output size). The preprocessing time is $O(n^{1+\epsilon})$ for any $\epsilon > 0$.*

6 Segment intersection detection

Let S be a set of n line segments in $\mathbb{R}^2$. We wish to build a data structure to decide whether a query line intersects any segment of S. The problem can be solved by Theorem 14. This section presents a new method that only needs $O(n)$ space while the query time is the same.

Let P be the set of $2n$ endpoints of the segments of S. With $r = 4n/b^3$ and $b = \log^\rho n$, we apply Theorem 4 to P to obtain a partition tree T consisting of collections Π_i, $0 \le i \le k+1$. By Theorem 4, the total number of cells is $O(r)$, each cell in Π_{k+1} contains at most $4n/r = \log^{3\rho} n$ points of P, and the runtime to construct T is $O(n^6)$. For each node $v \in T$, let $\Delta(v)$ denote the corresponding cell of v, which is a triangle in $\mathbb{R}^2$.

The following is a result from the previous work [22] for a special case of the problem. We will use the result as a subroutine in our approach.

▶ **Lemma 15.** ([22]) *If all segments of S intersect a given line segment, then one can build a data structure of $O(n)$ space in $O(n \log n)$ time so that whether a query line intersects any segment of S can be determined in $O(\log n)$ time.*

We store the segments of S in the partition tree T as follows (the idea is similar to [22]). For each segment $s \in S$, starting from the root, for each node v whose cell $\Delta(v)$ contains s (which is true initially when v is the root), if v is a leaf, then we store s at v (let S_v denote the set of all such segments stored at v). Otherwise, we check every child of v. If v has a child u whose cell $\Delta(u)$ contains s, then we proceed on u. Otherwise, for each child u, if $\Delta(u)$ contains an endpoint of s, then since $\Delta(u)$ does not contain s, s must intersect an edge e of $\Delta(u)$; we store s at e (let S_e denote the set of segments stored at e); note that since s has two endpoints, there are two such edges e but it suffices to store s in one such edge. This finishes the algorithm for storing s, which takes $O(b \log n)$ time. Because s is stored at either a leaf or a cell edge, the total space for storing all segments is $O(n)$. The time is $O(nb \log n)$.

Next, for each edge e of each cell of T, since all segments of S_e intersect e, we preprocess S_e using Lemma 15. Doing this for all cell edges e of T takes $O(n \log n)$ time and $O(n)$ space. For those segments stored in S_v for all leaves v, we will preprocess them into a data structure $\mathcal{D}_v$. Before discussing $\mathcal{D}_v$, we describe the query algorithm and analyze the time complexity.

Given a query line ℓ, starting from the root of T, for each node v, assume that ℓ intersects the boundary of $\Delta(v)$, which is true initially when v is the root. If v is a leaf, then we call the data structure $\mathcal{D}_v$ to check whether ℓ intersects a segment of S_v. Otherwise, for each child u of v, for each edge e of $\Delta(u)$, we apply the query algorithm of Lemma 15 to check whether ℓ intersects a segment of S_e; further, if ℓ crosses $\Delta(u)$, then we proceed on u. The following lemma justifies the correctness of the query algorithm.

▶ **Lemma 16.** *The query algorithm works correctly.*

Proof. If the query algorithm detects an intersection, then it is obviously true that ℓ intersects a segment of S. On the other hand, suppose ℓ intersects a segment s, say, at a point p. We argue that the query algorithm must detect an intersection. Indeed, according to our query algorithm, all nodes u of T whose cells $\Delta(u)$ are crossed by ℓ will be processed. If s is stored at a leaf v, then s is contained in $\Delta(v)$. Since ℓ intersects s, ℓ must cross $\Delta(v)$, and thus v must be processed and the data structure $\mathcal{D}_v$ will detect an intersection between ℓ and S_v.

If s is not stored at a leaf, then there must exist an internal node v such that $s \in \Delta(v)$ and s is not in $\Delta(u)$ for any child u of v. According to our preprocessing algorithm, s must be stored in $S_{e'}$ for an edge e' of some cell $\Delta(u)$ of a child u of v. Since $p \in s \subseteq \Delta(v)$ and $p \in \ell$, ℓ must cross $\Delta(v)$. Therefore, our query algorithm will process v by applying the query algorithm of Lemma 15 on S_e for every edge e of every child cell of v. When it is applied to $S_{e'}$, the intersection will be detected. ◀

We now analyze the query time. Recall that T has $O(r)$ leaves. By Theorem 4, the total number internal nodes of T whose cell boundaries are crossed by ℓ is $O(\sqrt{r/b})$, and for each such node, we need to call the query algorithm of Lemma 15 $O(b)$ times and each call

takes $O(\log n)$ time. As such, the query time other than the time spent on calling $\mathcal{D}_v$ for those leaves v whose cell boundaries are crossed by ℓ (let V be the set of all such cells) is $O(\sqrt{r/b} \cdot b \cdot \log n) = O(\sqrt{n}/b \cdot \log n) = O(\sqrt{n}/\log^{\rho-1} n)$ since $r = 4n/b^3$ and $b = \log^\rho n$. By Theorem 4, $|V| = O(\sqrt{r}) = O(\sqrt{n/\log^{3\rho} n})$ and $|S_v| \leq 4n/r = \log^{3\rho} n$ for each leaf v of T.

Let $Q(n)$ be the query time. Following the above analysis, we obtain the following

$$Q(n) = O(\sqrt{rb} \cdot \log n) + O(\sqrt{r}) \cdot Q_1(n/r), \tag{13}$$

where $Q_1(\cdot)$ is the query time for each leaf $v \in V$, whose cell contains $O(n/r)$ points of P.

To solve $Q_1(n/r)$, we recursively process S_v for each leaf cell v of T as above by using different parameters. Specifically, let n_1 be the number of endpoints of S_v; hence $n_1 = O(n/r) = O(\log^{3\rho} n)$. Let $\tau > 0$ be an arbitrarily small constant to be set later. Setting $r_1 = n_1/\log^\tau n$, we apply Theorem 4 to construct a partition tree $T(v)$ with $b_1 = \log^\rho n_1$ in $O(n_1^6)$ time. The total time for constructing $T(\Delta)$ for all leaf cells Δ of T is thus bounded by $O(n^6)$. Using $T(v)$ to handle queries on S_v and following the above analysis, we obtain

$$Q(n_1) = O(\sqrt{r_1 b_1} \cdot \log n_1) + O(\sqrt{r_1}) \cdot Q_2(n_1/r_1), \tag{14}$$

where $Q_2(\cdot)$ is the query time for each leaf cell of $T(v)$, which contains $O(n_1/r_1)$ points of P.

Combining (13) and (14) leads to:

$$Q(n) = O\left(\frac{\sqrt{n}}{\log^{\Omega(1)} n}\right) + O\left(\sqrt{\frac{n}{t}}\right) \cdot Q_2(t), \text{ where } t = \log^\tau n. \tag{15}$$

In summary, the above first builds a partition tree T and then builds partition trees $T(v)$ for all leaves v of T (using different parameters). For notational convenience, we use T to refer to the entire tree (by attaching all trees $T(v)$ to T), which has $O(n/t)$ leaves, each containing $O(t)$ points. The space is bounded by $O(n)$. As t is small, with $O(n \log n)$ additional time and $O(n)$ space preprocessing, each subproblem $Q(t)$ in (15) can be solved in $O(\log t)$ time. This makes the total query time $Q(n)$ bounded by $O(\sqrt{n}/\log^{\Omega(1)} n)$. We can also reduce the preprocesing time to $O(n^{1+\epsilon})$. See the full paper for the details.

▶ **Theorem 17.** *Given a set of n segments in the plane, there is a data structure of $O(n)$ space that can determine whether a query line intersects any segment in $O(\sqrt{n}/\log^{\Omega(1)} n)$ time. The data structure can be built in $O(n^{1+\epsilon})$ time for any $\epsilon > 0$.*

7 Ray-shooting among non-intersecting segments

Let S be a set of n line segments in the plane such that no two segments intersect. The problem is to build a data structure to compute the first segment hit by a query ray.

The following is a result from the previous work [22] for a special case of the problem. We will use it as a subroutine in our approach.

▶ **Lemma 18.** ([22]) *If all segments of S intersect a given line segment, then one can build a data structure of $O(n)$ space in $O(n \log n)$ time so that a ray-shooting query can be answered in $O(\log n)$ time.*

We build the partition tree T and store S in T in a way similar to the segment intersection detection problem in Section 6 except that we use Lemma 18 to preprocess S_e for each cell edge e of T. In addition, for each leaf v of T, we will build a data structure $\mathcal{D}_v$ on S_v.

Given a query ray ρ, starting from the root of T, for each node v, assume that ρ intersects the boundary of $\Delta(v)$, which is true initially when v is the root. If v is a leaf, then we use the data structure $\mathcal{D}_v$ to find the first segment of S_v hit by ρ as our candidate solution segment. Otherwise, for each child u of v, for each edge e of $\Delta(u)$, apply the query algorithm of Lemma 18 to find the first ray of S_e hit by ρ as a candidate; further, if ρ crosses $\Delta(u)$, then we proceed on u. Finally, among all candidate segments, we return the one whose intersection with ρ is closest to the origin of ρ. The correctness follows a similar argument as Lemma 16.

As in Section 6, for each leaf v of T, we construct the data structure $\mathcal{D}_v$ by preprocessing S_v recursively once. The query time analysis follows exactly the same method as in Section 6 since the query time of Lemma 18 is the same as that of Lemma 15, and thus we can also obtain the recurrence (15) with the same value of t. As t is small, with additional $O(n \log n)$ time and $O(n)$ space preprocessing, each subproblem $Q(t)$ in (15) can be solved in $O(\log t)$ time. This makes the total query time $Q(n)$ bounded by $O(\sqrt{n}/\log^{\Omega(1)} n)$. We thus have the following result.

▶ **Lemma 19.** *Given a set of n segments in the plane, there is a data structure of $O(n)$ space that can compute the first segment hit by a query ray in $O(\sqrt{n}/\log^{\Omega(1)} n)$ time. The data structure can be built in $O(n^6)$ time.*

As before, we can reduce the preprocesing time to $O(n^{1+\epsilon})$. See the full paper for the details.

▶ **Theorem 20.** *Given a set of n segments in the plane, there is a data structure of $O(n)$ space that can compute the first segment hit by a query ray in $O(\sqrt{n}/\log^{\Omega(1)} n)$ time. The data structure can be built in $O(n^{1+\epsilon})$ time for any $\epsilon > 0$.*

Smoothed Analysis of Online Metric Problems

Abstract

We study three classical online problems – k-server, k-taxi, and chasing size k sets – through a lens of smoothed analysis. Our setting allows request locations to be adversarial up to small perturbations, interpolating between worst-case and average-case models. Specifically, we show that if the metric space is contained in a ball in any normed space and requests are drawn from distributions whose density functions are upper bounded by $1/\sigma$ times the uniform density over the ball, then all three problems admit polylog(k/σ)-competitive algorithms. Our approach is simple: it reduces smoothed instances to fully adversarial instances on finite metrics and leverages existing algorithms in a black-box manner. We also provide a lower bound showing that no algorithm can achieve a competitive ratio sub-polylogarithmic in k/σ, matching our upper bounds up to the exponent of the polylogarithm. In contrast, the best known competitive ratios for these problems in the fully adversarial setting are $2k-1$, ∞ and $\Theta(k^2)$, respectively.

1 Introduction

In online algorithms, an algorithm has to make decisions online while the input is being revealed, without knowledge of the future input. Traditionally, the majority of research in the field has analyzed problems in the worst-case regime, in terms of the *competitive ratio*, i.e., the largest possible ratio between the algorithm's performance and the optimum in hindsight. This perspective enables clean mathematical models and robust guarantees for algorithms that are satisfied regardless of the input they face. However, worst-case instances are often degenerate and unlikely to occur in practice. Tuning algorithms against such pathological scenarios can lead to worst-case-like performance even when actual inputs are much more favorable.

Moreover, the guarantees that can be achieved even under the most pessimistic assumptions are often weak by necessity. While tight competitive ratio bounds can appeal theoretically, algorithms are unlikely to be adopted in practice if the best promise is that they perform at most some large (e.g., polynomial or exponential) factor worse than optimal. Worse yet, for some problems such as the k-taxi problem, no finite bound on the competitive ratio is currently known for general metric spaces of infinitely many points, even if their diameter is bounded.

The research community generally understands the limitations of worst-case analysis, and there have been many demands for and an increased interest in beyond-worst-case analysis in recent years [46]. A major success story of beyond-worst-case analysis has been Spielman and Teng's smoothed analysis [48], spectacularly explaining why the simplex algorithm for linear problems performs well in practice despite its exponential worst-case running time. They show that perturbing any instance by small Gaussian noise yields an instance which the simplex algorithm solves in expected polynomial time. By varying the size of the random perturbations, smoothed analysis allows to interpolate between worst-case and average-case settings. Other examples of smoothed analysis of the running time of offline problems include k-means [3, 2], TSP [23, 41, 24], local max-cut [1] and more general local search problems [29]. We refer to [46] for more background.

In the context of online problems, prior smoothed analysis has focused mostly on regret minimization in online learning [45, 33, 20, 37, 44, 35, 36, 7, 34, 22] and online discrepancy minimization [36, 4, 5]. In contrast, understanding is much more limited about the smoothed complexity of more dynamic online problems which are typically analyzed through their competitive ratio (rather than regret). The only examples we are aware of are the work of [6], which conduct smoothed competitive analysis of the multi-level feedback algorithm for non-clairvoyant scheduling, and [47], who analyze the work function algorithm for metrical task systems when cost function values are randomly perturbed.

Smoothed Competitive Analysis in Metric Spaces. Here, we initiate smoothed competitive analysis of online problems in metric spaces with randomly perturbed request locations. To do so, we study three classical online problems: namely, the *k-server* problem [40], its generalization the *k-taxi* problem [27, 18], and *chasing small sets* [17] (also known as metrical service systems, and equivalent to layered graph traversal [43, 26]). In these problems, the goal is to minimize movement in a metric space while serving a sequence of requests. In the k-server problem, the algorithm controls k servers and each request is a location that one of the servers must move to. The k-taxi problem generalizes this to the case where each request is a pair of locations, modelling the pick-up and drop-off location of a ride request. In chasing small sets, there is a single server, and each request is a set of up to k points that the server must move to.

On general metric spaces, the best known competitive ratio is $\Theta(k)$ for the k-server problem [38] and $\Theta(k^2)$ for chasing small sets [11]. For the k-taxi problem, the situation is even worse and it is not even known whether any finite competitive ratio can be achieved, even for $k = 4$ servers on a line metric. Better bounds exist only in special cases such as *finite* metrics of n points or bounded aspect ratio Δ, where the k-server problem admits competitive ratios of $O(\log n \log^2 k)$ and $O(\log \Delta \log^3 k)$ [14], and the k-taxi problem an $O(\log^3 \Delta \log^2(nk\Delta))$-competitive algorithm [32]. However, since n and Δ can be infinite in general, these bounds provide no improvement even in seemingly simple metrics such as the line metric or $[0, 1]^2$ with some norm.

We argue that smoothed analysis is a realistic model for these problems. For example, a customer's pick-up location in taxi apps is often determined through somewhat inaccurate GPS or by placing a pin on a map by hand, and even if an address is specified this usually does not correspond to an exact point but rather a small area on a map. Even in cases where exact precision in response to arriving requests is important, the way that inputs are generated is rarely fully adversarial and may be subject to noise. If smoothed analysis can drastically improve the competitive ratio of these problems, we believe that algorithms achieving these improved guarantees have a much higher chance of being adopted in practice than pessimistic worst-case methods.

We consider the setting where the metric space M is a bounded diameter subset of some normed space (and therefore contained in some ball B_M). For each time step, an adversary can choose a distribution from which the next request is drawn, subject to the constraint that the density functions of points appearing in the requests are upper bounded by $1/\sigma$ times the density of the uniform distribution over B_M. Thus, as $\sigma \to 0$, this converges to the classical worst-case setting, whereas $\sigma = 1$ means that request locations are drawn uniformly from $M = B_M$. Small values of σ can model, for example, request locations that are slightly perturbed in a small ball around the worst-case locations.

For all three problems, we obtain $\mathrm{polylog}(k/\sigma)$-competitive algorithms in this setting via simple reductions to the adversarial setting in finite metrics. Thus, for σ polynomial in k we obtain an exponential improvement over the known worst-case guarantees for k-server and chasing small sets, and an infinite improvement for the k-taxi problem. Our algorithms require no knowledge about σ (except for the k-taxi problem, where a non-zero lower bound on σ is requied), and beyond these smoothed bounds they still also achieve the known worst-case guarantees (where they exist, i.e., for k-server and chasing small sets).

Further Related Work. The k-server problem and an easier version of the k-taxi problem was previously studied under a stochastic setting different from smoothed analysis by Dehgani et al. [21]. They consider the case where each request is drawn independently from some distribution, and these distributions are known to the algorithm. For this setting, they give an approximation algorithm for the line and finite metrics that is competitive against the best *online* algorithm for the instance. In contrast, we do not assume knowledge of the distributions, and compare against the best offline algorithm for the input.

Several online problems have been studied in a stochastic setting where requests are drawn i.i.d. from some distribution, see e.g. [28, 30, 31]. This differs from our setting, as we do not require distributions to be identical or independent.

Another beyond-worst-case model that has received significant interest in recent years is the learning-augmented paradigm [39, 42], where an algorithm's input is augmented with additional predictions about future input or best behavior.

The k-server problem, introduced in [40], is considered one of the most fundamental problems in online algorithms and is often called the "holy grail of competitive analysis". For deterministic algorithms the $\Theta(k)$ bound is known to be tight [40, 38] up to a constant factor, and the k-server conjecture states that it is exactly k. For randomized algorithms, the aforementioned improvements for the special cases of finite metrics and bounded aspect ratios are known [14]. The randomized k-server conjecture, positing an $O(\log k)$-competitive algorithm for general metrics, was recently refuted in [12]. The k-taxi problem is known to be at least exponentially harder than the k-server problem at least for deterministic algorithms, with an $\Omega(2^k)$ lower bound and no known upper bound for general metrics [18]. For chasing small sets, the deterministic competitive ratio is known to lie in $O(k2^k) \cap \Omega(2^k)$ [26, 16], and the randomized competitive ratio is $\Theta(k^2)$ [11, 12].

Chasing small sets is a special case of the metrical task systems (MTS) problem [9]. In MTS, each request consists of a cost function, and the algorithm which moves the single server incurs both the "service cost" as well as the movement cost. Chasing small sets corresponds to MTS with request cost functions restricted to set-membership indicator functions. The k-server problem is also a special case of MTS, though not in the same metric space but rather the metric space of configurations.

1.1 Preliminaries

All the problems we consider are defined over a metric space (M, d). The input revealed online is a sequence of requests $r_1, r_2, \ldots, r_T$, each of which must be served immediately as specified below.

k-Server. The algorithm controls the movement of k servers located at points in M. Each request is a point $r_t \in M$, and must be served by moving one of the servers to r_t. The cost of the algorithm is defined as the total distance travelled by all servers.

k-Taxi. The algorithm controls the movement of k taxis located at points in M. Each request is a pair of points $r_t = (a_t, b_t) \in M^2$, representing the start and destination of a ride request. To serve it, the algorithm must choose a taxi and move it first to a_t and then to b_t. The cost is defined as the total distance of "empty runs" (i.e., distance travelled except for the travels from a_t to b_t).

Chasing Small Sets. The algorithm controls the movement of a single server located in M. Each request is a subset $r_t \subset M$ of cardinality at most k. To serve it, the algorithm must move the server to one of the points in r_t. The cost incurred by the algorithm is the total distance travelled.

Smooth Instances. Throughout this paper, we assume that the metric space M is a subset of $\mathbb{R}^m$ and the metric d is induced by a norm, i.e., $d(x, y) = \|x - y\|$ for all $x, y \in M$, where $\|\cdot\|$ is an arbitrary norm. We assume that M has bounded diameter, and denote by B_M a (closed) ball of smallest radius containing M, and by R_M its radius.

We consider the variant of the problems described above where each request r_t is drawn from some probability distribution D_t. These distributions need not be independent, i.e., the distribution D_t (and whether it exists or the sequence stops earlier) can be chosen by the adversary after the realizations of $r_1, \ldots, r_{t-1}$ have been determined (however, without knowledge of any random choices made by the online algorithm). For the k-server problem, D_t is a distribution over M, for the k-taxi over M^2 and for chasing small sets over M^{k_t} for some $k_t \le k$. We denote by D_{ti} the corresponding marginal distributions, where $i = 1$ for k-server, $i \in \{1, 2\}$ for k-taxi and $i \in [k_t]$ for chasing small sets.

In the absence of any restrictions on the probability distribution, this problem setting is equivalent to the familiar worst-case setting, as the adversary can choose a (degenerate) distribution that places all probability mass on the worst-case request sequence. Thus, we impose the following smoothness assumption:

▶ **Definition 1.** *Let $\sigma \in (0, 1]$. An instance is σ-smooth if for each marginal distribution D_{ti}, the probability of any measurable set $S \subseteq M$ is at most a factor $1/\sigma$ larger than under the uniform distribution over B_M.*

Equivalently, this means that the density function of each marginal distribution is upper bounded by $1/(\sigma \cdot \mathrm{vol}(B_M))$. The case $\sigma = 1$ corresponds to uniformly distributed requests, whereas $\sigma \to 0$ captures the classical worst-case setting.

Competitive Ratio in the Smoothed Model. For a (possibly randomized) algorithm A, we denote its expected cost on an instance I by $\mathrm{cost}(A, I)$. Denote by opt the offline algorithm that achieves the lowest possible cost on any instance. In the classical (worst-case) setting, an online algorithm is said to be c-competitive if

$$\mathrm{cost}(A, I) \le c \cdot \mathrm{cost}(\mathrm{opt}, I) + \alpha, \tag{1}$$

for all possible instances I, where α is a constant independent of I. We say that A is c-competitive on σ-smooth instances if inequality (1) holds when I is sampled as a σ-smooth instance and both sides of the inequality are replaced by their expectation over the randomness in I. We allow opt to serve the actual realization of the instance optimally, i.e., knowing the outcome of the random sampling process of I in advance. Of course, any competitive algorithm in this setting is also competitive if opt has to make its choices before knowing the outcomes of the future sampling process of I.

We will usually drop I from the notation when it is understood from the context.

η-Nets. An *η-net* of a metric space M is a subset $N \subseteq M$ satisfying the following properties:

- N is η-dense in M: For all $x \in M$ there exists $y \in N$ such that $d(x, y) \leq \eta$.
- N is η-separated: For all $x, y \in N$ it holds that $d(x, y) > \eta$.

Aspect Ratio. The aspect ratio of a metric space is the ratio between the largest and smallest non-zero distance.

1.2 Our Results

We obtain polylog(k/σ)-competitive algorithms for all three problems we consider, as summarized in the following theorems. By known algorithm combination techniques, our algorithms for k-server and chasing small sets still also achieve the same robustness guarantees as classical worst-case algorithms.

▶ **Theorem 2** (k-Server). *There exists an $O(\min\{k, \log(k/\sigma)\cdot\log^2 k\})$-competitive randomized algorithm for k-server on σ-smooth instances, even if σ is unknown.*

▶ **Theorem 3** (k-Taxi). *There exists an $O(\log^5(k/\sigma))$-competitive randomized algorithm for k-taxi on σ-smooth instances, provided a non-zero lower bound on σ is known.*

▶ **Theorem 4** (Chasing Small Sets). *There exists an $O(\min\{k^2, \log^2(k/\sigma)\})$-competitive randomized algorithm for chasing small sets on σ-smooth instances, even if σ is unknown.*

We complement our upper bounds with the following lower bound, ruling out algorithms with a sub-polylogarithmic dependence on k/σ.

▶ **Theorem 5** (Lower Bound). *For any $c < 1/2$, there is no $O(\log^c(k/\sigma))$-competitive randomized algorithm for general σ-smooth instances of k-server, k-taxi, or chasing small sets when the metric space is a ball in $O(\log k)$-dimensional ℓ_∞-space, even if all distributions D_t are identical and independent.*

1.3 Organization

All our algorithms are based on the same framework, as explained in the next section. The upper bound proofs are completed by separate arguments for bounding the offline cost for the three problems in Section 3. The polylogarithmic lower bound (Theorem 5) is proved in Section 4.

2 Basic Construction

To describe our algorithm, let us assume initially that σ is known. Later we will show how to drop this assumption.

For some suitable $\eta > 0$, we choose a finite η-net N of the metric space M. For each $x \in M$, we pick some point $y \in N$ satisfying $d(x, y) \leq \eta$ and call it the *projection of x onto N*, denoted by $\pi(x) = y$ (making an arbitrary choice in case there are several options). Similarly, for a request r_t we denote by $\pi(r_t)$ the projection of r_t, where each point in r_t is replaced by its projection. As the request sequence $r_1, r_2, \ldots, r_T$ in M is revealed, we simulate some online algorithm A_N that operates on finite metrics to serve the request sequence $\pi(r_1), \pi(r_2), \ldots, \pi(r_T)$ in metric space (N, d). Our online algorithm A_M for the original problem on M follows the configurations of A_N at all times, except for an additional movement from $\pi(r_t)$ to r_t and back at time t, to make sure A_M serves the original request sequence. (For example, for a taxi request (a_t, b_t), algorithm A_M first moves the same taxi as A_N to the point $\pi(a_t)$, then pays at most η to move from $\pi(a_t)$ to a_t; from here, it serves the ride request, which changes the taxi's location from a_t to b_t (at no cost); finally, it moves from b_t to $\pi(b_t)$ for another cost of at most η, restoring the invariant that A_M is in the same configuration as A_N.) Thus, the cost of A_M exceeds the cost A_N by at most 2η per request, and the total cost of A_M is at most $2\eta \cdot T + \eta \cdot k$ larger for a sequence of T requests, with the additional cost ηk for projecting the initial configuration onto N. (In the case of chasing small sets, the $\eta \cdot k$ term can also be replaced by η.)

2.1 Reduction to Worst-Case Setting

Our analysis is based on the observation that the smoothing model forces the offline optimal algorithm to incur a sufficiently large movement cost. In particular, we have:

▶ **Proposition 6.** *For σ-smooth instances of k-server, k-taxi, and chasing small sets, the offline optimal cost is at least $\Omega\left(R_M \cdot \left(\frac{\sigma}{\mathrm{poly}(k)}\right)^{1/m}\right)$ amortized per request in expectation, where $\mathrm{poly}(k) = O(k)$ for k-server and k-taxi and $\mathrm{poly}(k) = O(k^2)$ for chasing small sets.*

More precise statements for the respective problems along with a proof of Proposition 6 are given in Section 3.

If η is within a constant factor of the bound in Proposition 6 and algorithm A_N is c_N-competitive for the worst-case (non-smoothed) problem in N, then we can show that algorithm A_M described above is $O(c_N)$-competitive for the smoothed problem in M:

▶ **Lemma 7.** *If A_N is c_N-competitive in metric space (N, d), then algorithm A_M is $O(c_N)$-competitive on instances in M whose optimal offline cost is at least $\Omega(\eta)$ amortized per request.*

Proof. Denote by opt_M and opt_N, respectively, an optimal offline algorithm for the instance in M and the projected instance in N. By assumption

$$\mathrm{cost}(A_N) \leq c_N \cdot \mathrm{cost}(\mathrm{opt}_N) + \alpha \tag{2}$$

for some constant α. Denote by T the number of requests and by $\mathbb{E}[T]$ its expectation[1]. As argued above,

$$\mathrm{cost}(A_M) \leq \mathrm{cost}(A_N) + 2\eta \cdot \mathbb{E}[T] + \eta \cdot k, \tag{3}$$

[1] T may be random as the adversary can choose the stopping point depending on the realizations of earlier requests.

with the additional cost due to movement between $\pi(r_t)$ and r_t at each time. By a similar argument,

$$\text{cost}(\text{opt}_N) \leq \text{cost}(\text{opt}_M) + 2\eta \cdot \mathbb{E}[T], \tag{4}$$

as a possible offline algorithm to service the requests $\pi(r_1), \pi(r_2), \ldots, \pi(r_T)$ in N is to always be in the configuration of opt_M projected onto N, incurring at most an additional cost 2η per request by the triangle inequality (noting that, without loss of generality, opt_M moves at most one server/taxi per time step). Combining inequalities (2), (3) and (4) gives

$$\text{cost}(A_M) \leq c_N \cdot \text{cost}(\text{opt}_M) + (c_N + 1) \cdot 2\eta \cdot \mathbb{E}[T] + \eta \cdot k + \alpha.$$

Next, we make use of the assumption that the optimal offline cost is at least $\Omega(\eta)$ amortized per request in expectation, i.e., $\text{cost}(\text{opt}_M) \geq \Omega(\eta) \cdot \mathbb{E}[T] - \beta$ for some constant β. Substituting this into the previous inequality gives

$$\text{cost}(A_M) \leq O(c_N) \cdot \text{cost}(\text{opt}_M) + \eta \cdot k + \alpha + O(\beta \cdot c_N),$$

and the lemma follows since the additive term $\eta \cdot k + \alpha + O(\beta \cdot c_N)$ is a constant independent of the request sequence. ◀

2.2 Size of the Net N

Lemma 7 allows us to reduce smoothed instances on M to non-smooth instances on N, provided the offline optimal cost is at least $\Omega(\eta)$ per request. For each of the problems we consider, by known results for finite metric spaces, the competitive ratio c_N can be expressed as a function of the number of points in N and possibly the aspect ratio Δ of N. Specifically, for k-server, the (best known) competitive ratio in n-point metric spaces is $O(\log^2 k \cdot \log n)$ [14, 15], for k-taxi it is $O(\log^3 \Delta \cdot \log^2(nk\Delta))$ [32], and for chasing small sets (which is a special case of metrical task systems) it is $O(\log^2 n)$ [13, 19].

Thus, it remains to choose η (i) large enough to obtain an appropriate value for the cardinality and aspect ratio of N and (ii) small enough to ensure the lower bound in Proposition 6 becomes $\Omega(\eta)$.

The following lemma provides the desired relationship between the parameter η and the number of points in N.

▶ **Lemma 8.** *For each $\eta \in (0, R_M]$, there exists an η-net N of M of size $|N| \leq \left(\frac{3R_M}{\eta}\right)^m$.*

Proof. The proof is similar to [25, Claim 2.6]. We initialize N as a singleton set containing an arbitrary point from M; then as long as there exists a point $x \in M$ such that $d(x, y) > \eta$ for all $y \in N$, we add x to N. By construction, N is an η-net. Moreover, the balls of radius $\eta/2$ centered at the points in N are disjoint and contained in a ball of radius $R_M + \eta/2$ (namely, the ball obtained by extending the radius of B_M by $\eta/2$). The ratio between the volume of a ball of radius $\eta/2$ and the ball of radius $R_M + \eta/2$ is $\left(\frac{\eta/2}{R_M+\eta/2}\right)^m$. Thus, there can be at most $\left(\frac{R_M+\eta/2}{\eta/2}\right)^m \leq \left(\frac{3R_M}{\eta}\right)^m$ disjoint balls. ◀

2.3 Putting it all Together

We now combine the above statements to prove the following statement.

▶ **Proposition 9.** *For known σ, there exists a randomized online algorithm whose competitive ratio on σ-smooth instances is $O(\log(k/\sigma) \cdot \log^2 k)$ for k-server, $O(\log^5(k/\sigma))$ for k-taxi and $O(\log^2(k/\sigma))$ for chasing small sets.*

Proof. Let $\eta = 3R_M \cdot \left(\frac{\sigma}{\text{poly}(k)}\right)^{1/m}$, where $\text{poly}(k)$ is the function from Proposition 6. Then A_M is $O(c_N)$-competitive by Proposition 6 and Lemma 7. If $\eta > R_M$, then N can be chosen as the singleton containing only the center of the ball B_M, which trivially yields $c_N = 1$ and the theorems. Otherwise, by Lemma 8 the size of the η-net N is

$$n := |N| \leq \frac{\text{poly}(k)}{\sigma},$$

and since the diameter of M is at most $2R_M$, the aspect ratio of N is

$$\Delta \leq \frac{2R_M}{\eta} = \frac{2}{3}\left(\frac{\text{poly}(k)}{\sigma}\right)^{1/m}.$$

Thus, since $c_N = O(\log^2 k \cdot \log n)$ for k-server [14, 15], $c_N = O(\log^3 \Delta \cdot \log^2(nk\Delta))$ for k-taxi [32], and $c_N = O(\log^2 n)$ for metrical task system [13, 19], and chasing small sets is a special case of metrical task systems (in the same metric space), the result follows. ◀

We note that the competitive ratio for k-taxi could actually be improved by a factor $1/\min\{m, \log(k/\sigma)\}^3$. (Note that the $\log \Delta$ term stands for a quantity that is at least 1, so the improvement is not greater.) This would typically only yield a constant factor improvement though, considering practical applications of the k-taxi problem usually having a small dimension of at most 3.

2.4 Unknown σ and Robustness

If σ is unknown, and to achieve the robustness bounds in our main theorems, the idea is to simulate in parallel several instances of the above algorithm for different values of σ as well as a worst-case algorithm, and combine them using the technique of Blum and Burch [8].

▶ **Theorem 10** (Blum and Burch [8])**.** *Given $\epsilon > 0$ and ℓ online algorithms $A_1, \ldots, A_\ell$ for a problem that can be formulated as a metrical task system of diameter* diam*, there exists an online algorithm whose expected cost is at most*

$$(1+\epsilon) \cdot \min_{i \in [\ell]} \text{cost}(A_i) + O\left(\frac{\text{diam} \cdot \log \ell}{\epsilon}\right).$$

Chasing Small Sets. Since chasing small sets in a metric space (M, d) is a metrical task system in the same metric space, we can invoke the above theorem with $\epsilon = 1$, $\ell = \lceil \log_2 k \rceil + 1$ and using as A_i for $i = 1, \ldots, \ell - 1$ our algorithm with smoothness parameter $\sigma_i = 2^{-2^i}$, and as A_ℓ the $\Theta(k^2)$-competitive algorithm from [11] for chasing small sets in the fully adversarial setting.

Since $\text{diam} \leq 2R_M$, the additive term in Theorem 10 is a constant independent of the request sequence. Thus, the resulting algorithm achieves, up to a factor $1 + \epsilon \leq 2$, the same competitive ratio as the best of the algorithms A_i. If the true smoothness parameter $\sigma < 2^{-(\ell-1)} \leq 2^{-k}$, then $O(\min\{k^2, \log^2(k/\sigma)\})$-competitiveness follows since the minimum is attained by k^2. Otherwise, there exists i such that $\sigma_i \leq \sigma \leq \sqrt{\sigma_i}$. Since any σ-smooth instance is also σ_i-smooth, we achieve competitive ratio $O(\log^2(k/\sigma_i)) = O(\log^2(k/\sigma))$. This yields Theorem 4.

***k*-Server.** For the k-server problem (Theorem 2), the same argument works since k-server can be modelled as a metrical task system in the space of server configurations (whose diameter is k times the diameter of the original metric space). The only difference is that the algorithm A_ℓ for general metrics in the fully adversarial setting has competitive ratio $\Theta(k)$ [38].

***k*-Taxi.** It is not known how to model the k-taxi problem as a metrical task system, due to configuration changes that incur no cost.[2] Nonetheless, the proof of Theorem 10 in [8] extends to this setting without any change, so we can still apply the same combination method also to the k-taxi problem. However, since no competitive algorithm for the k-taxi problem on general metrics in the fully adversarial setting is known, we require a lower bound on σ to ensure that the number of combined algorithms is finite.

3 Bounding Offline Cost

3.1 *k*-Server

▶ **Lemma 11.** *For σ-smooth instances of the k-server problem, the optimal offline algorithm pays an expected cost of at least*

$$\mathrm{cost}(\mathrm{opt}_M) \geq \frac{R_M}{8} \cdot \left(\frac{\sigma}{8k}\right)^{1/m} \cdot \mathbb{E}[T] - c,$$

where $c > 0$ is a constant independent of the request sequence.

Proof. Let $\delta > 0$. Consider a subsequence $r_{t+1}, r_{t+2}, \ldots, r_{t+4k}$ of $4k$ consecutive requests. For $i = 0, \ldots, 4k$, we denote by S_i a δ-separated subset of $\{r_{t+1}, r_{t+2}, \ldots, r_{t+i}\}$, constructed as follows: $S_0 = \emptyset$, and for $i \geq 1$,

$$S_i = \begin{cases} S_{i-1} \cup \{r_{t+i}\} & \text{if } S_{i-1} \cup \{r_{t+i}\} \text{ is } \delta\text{-separated} \\ S_{i-1} & \text{otherwise.} \end{cases}$$

Note that $S_i = S_{i-1}$ if and only if r_{t+i} belongs to a ball of radius δ centered at a point in S_{i-1}. The volume of each such ball is at most a $\left(\frac{\delta}{R_M}\right)^m$ fraction of the volume of B_M, and thus its probability under D_{t+i} is at most $\left(\frac{\delta}{R_M}\right)^m / \sigma$. Hence, since there are at most $4k$ such balls of radius δ, the probability that $S_i = S_{i-1}$ is bounded as

$$P\left(S_i = S_{i-1}\right) \leq \frac{4k}{\sigma} \left(\frac{\delta}{R_M}\right)^m.$$

We now choose $\delta = R_M \cdot \left(\frac{\sigma}{8k}\right)^{1/m}$, so that the right hand side becomes $1/2$. In other words, in each step, another point is added to S_i with probability at least $1/2$. Thus, after $4k$ steps we have $|S_{4k}| \geq 2k$ with probability at least $1/2$. If this is the case, then any offline algorithm must pay at least $k \cdot \delta$ to serve these requests, regardless of the configuration it starts at: Indeed, at most k of the requests in S_{4k} can be served by a server that previously served no other request from S_{4k}. For the remaining $|S_{4k}| - k \geq k$ requests, the serving server must have moved at least distance δ since the previous time it served a request from S_{4k}, since

[2] Though it belongs to the more general class of metrical task systems with transformation [10].

S_{4k} is δ-separated. Thus, any subsequence of $4k$ consecutive requests contributes $k \cdot \delta/2$ to the expected optimal cost. Over a sequence of T requests, this leads to an expected optimal cost of

$$\begin{aligned}\operatorname{cost}(\operatorname{opt}_M) &\geq \mathbb{E}\left[\left\lfloor \frac{T}{4k} \right\rfloor\right] \cdot \frac{k \cdot \delta}{2} \\ &\geq \frac{\mathbb{E}[T] \cdot \delta}{8} - \frac{k \cdot \delta}{2} \\ &= \frac{\mathbb{E}[T] \cdot R_M \cdot \left(\frac{\sigma}{8k}\right)^{1/m}}{8} - \frac{k \cdot R_M \cdot \left(\frac{\sigma}{8k}\right)^{1/m}}{2}\end{aligned}$$

◀

3.2 k-Taxi

▶ **Lemma 12.** *For σ-smooth instances of the k-taxi problem, the optimal offline algorithm pays an expected cost of at least*

$$\operatorname{cost}(\operatorname{opt}_M) \geq \frac{R_M}{8} \cdot \left(\frac{\sigma}{8k}\right)^{1/m} \cdot \mathbb{E}[T] - c,$$

where $c > 0$ is a constant independent of the request sequence.

Proof. We proceed similarly to the proof of Lemma 11, except in the construction of S_i we add a request $r_{t+i} = (a_{t+i}, b_{t+i})$ if its start location a_{t+i} is more than distance δ from the destinations of *all* the requests $r_{t+1}, \ldots, r_{t+i-1}$:

$$S_i = \begin{cases} S_{i-1} \cup \{r_{t+i}\} & \text{if } d(b_{t+j}, a_{t+i}) > \delta \text{ for all } j = 1, \ldots, i-1 \\ S_{i-1} & \text{otherwise.} \end{cases}$$

Again,

$$P\left(S_i = S_{i-1}\right) \leq \frac{4k}{\sigma}\left(\frac{\delta}{R_M}\right)^m$$

as $S_i = S_{i-1}$ requires a_{t+i} to fall in one of at most $4k$ balls of radius δ. As before, the same choice of δ yields $|S_{4k}| \geq 2k$ with probability at least $1/2$. If this is the case, then any offline algorithm must pay at least $k \cdot \delta$ to serve these requests: At least $|S_{4k}| - k \geq k$ of the requests in S_{4k} are served by a taxi that also served a previous request since time $t+1$, incurring cost at least δ by definition of S_{4k}. The lemma is then concluded in an identical fashion to the proof of Lemma 11. ◀

3.3 Chasing Small Sets

▶ **Lemma 13.** *In σ-smoothed instances of chasing small sets, the optimal offline algorithm pays an expected cost of at least*

$$\operatorname{cost}(\operatorname{opt}_M) \geq \frac{R_M}{2} \cdot \left(\frac{\sigma}{2k^2}\right)^{1/m} \cdot \mathbb{E}[T].$$

Proof. Let $\delta > 0$. Consider two consecutive request sets r_{t-1} and r_t. The probability that the ith point in r_{t-1} is within distance δ from the jth point in r_t is at most $\frac{1}{\sigma}\left(\frac{\delta}{R_M}\right)^m$. Thus, by a union bound over the at most k^2 pairs of points in $r_{t-1} \times r_t$, the probability that some point in r_{t-1} is within distance δ from some point in r_t is at most $\frac{k^2}{\sigma}\left(\frac{\delta}{R_M}\right)^m$. Otherwise, with probability at least $1 - \frac{k^2}{\sigma}\left(\frac{\delta}{R_M}\right)^m$, any offline algorithm must pay at least δ at time t to move from r_{t-1} to r_t. Choosing $\delta = R_M \cdot \left(\frac{\sigma}{2k^2}\right)^{1/m}$, we see that the probability is at least $1/2$. Thus, the expected offline cost is at least $\frac{\delta}{2} = \frac{R_M}{2} \cdot \left(\frac{\sigma}{2k^2}\right)^{1/m}$ per time step. ◀

4 Lower Bound

Complementing our upper bounds, we now prove a polylog(k/σ) lower bound for the three problems, i.e., that no algorithm can achieve a competitive ratio of $O(\log^c(k/\sigma))$ for any $c < 1/2$ (Theorem 5).

Our proof is based on the classical $\Omega(\log k)$ lower bound for k-server and MTS on $(k+1)$-point uniform metrics, in which each request location is drawn uniformly at random from the $k+1$ points [9]. As σ-smooth instances require distributions with infinite support, we intend to simulate this by substituting each of the $k+1$ points by a small neighborhood in normed space. We describe the construction for k-server first, and then explain how to adapt it to k-taxi and chasing small sets.

4.1 k-Server

We first recall the $\Omega(\log k)$ lower bound from [9]:[3] The underlying metric space is a uniform metric of $k+1$ points (i.e., all pairwise distances are 1) and each request is drawn uniformly at random from the $k+1$ points. Thus, an online algorithm must move at each time step with probability $1/(k+1)$, paying $T/(k+1)$ in expectation for a request sequence of length T. In contrast, an offline algorithm can, whenever a request arrives at the (unique) location not covered by a server, take the server from the location whose next request is furthest in the future. Thus, it need not move again until each of the k other locations is requested again at least once. By a standard coupon collector argument, it takes $\frac{k+1}{k} + \frac{k+1}{k-1} + \cdots + \frac{k+1}{1} = \Theta(k \log k)$ steps in expectation for each of the k other locations to be requested again, so the algorithm only needs to move roughly once every $\Theta(k \log k)$ steps. For a sequence of T requests, this leads to an optimal offline cost of $O\left(\frac{T}{k \log k} + 1\right)$ (see [9] for details). The ratio between the online cost $T/(k+1)$ and offline cost $O\left(\frac{T}{k \log k} + 1\right)$ yields the known $\Omega(\log k)$ lower bound for uniform metrics.

To simulate this in the smoothed setting, let $m = \lceil \log_2(k+1) \rceil$ and take as metric space the hypercube $[0,1]^m$ with ℓ_∞ distance, which is a ball in ℓ_∞^m. Let V be a fixed set of some $k+1$ vertices of this hypercube (i.e., with integer coordinates). Let $\epsilon = \frac{1}{2k \log_2 k} \leq \frac{1}{4}$. We say two points are *near* each other if their distance is at most ϵ. Otherwise, they are *far*. Let P be the set of points in $[0,1]^m$ that are near some vertex in V. Consider the instance where each request is drawn uniformly at random from P.

For the online algorithm, each request incurs cost at least $\Omega(1/k)$ in expectation, since with probability at least $\frac{1}{k+1}$ the request arrives near a vertex v whereas all online algorithm servers are near vertices in $V \setminus \{v\}$. For the offline algorithm, if each request arrived at the nearby vertex in V instead of its actual location in P, then the instance would be precisely the aforementioned instance on a $(k+1)$-point uniform metric, with an offline cost of $O\left(\frac{T}{k \log k} + 1\right)$ for T requests. The fact requests arrive *near* vertices instead of *at* vertices only increases the offline cost by at most ϵ per request, as the distance between any two points near the same vertex is at most ϵ. By choice of ϵ, this still leads to an offline cost of $O\left(\frac{T}{k \log k} + 1\right)$, and a competitive ratio lower bound of $\Omega(\log k)$.

It remains to express the lower bound in terms of k/σ. The overall hypercube $[0,1]^m$ has a volume of 1, whereas the set P has a volume of $(k+1)\epsilon^m$. Thus, $\sigma = \frac{1}{(k+1)\epsilon^m} = 2^{-\Theta(\log^2 k)}$, and $k/\sigma = 2^{\Theta(\log^2 k)}$. Hence, the lower bound can be written as $\Omega(\log^{1/2}(k/\sigma))$.

[3] The presentation in [9] is for MTS. We describe it here in the language of k-server.

4.2 k-Taxi

The construction is similar, but requests need to be pairs of two points (a, b). For each request, we sample a as above, and if a is near a vertex v, then we sample b uniformly at random from the points near v as well. This ensures that an offline algorithm can keep its taxis near k distinct vertices. The only difference in calculations is that σ is larger by a factor $k + 1$ as request destinations are sampled from distributions supported on points near a single vertex, but the asymptotic bound $\sigma = 2^{-\Theta(\log^2 k)}$ is unaffected by this.

4.3 Chasing Small Sets

We again use a similar construction. Each request set contains k points in P, sampled uniformly at random subject to the constraint that the points are near k distinct vertices of V. Thus, for each request set there is one vertex in V that is far from it. The online cost is still $\Omega(1/k)$ per request in expectation, as with probability at least $1/(k + 1)$ the request set contains no point near the algorithm's server. The offline cost is also bounded as before, as whenever it is far from all points in the request set, it can first move to the vertex for which it will happen furthest in the future that it is far from all points in the request set; additionally, it pays at most ϵ per request to move to a nearby point in the request set. The lower bound $\Omega(\log^{1/2}(k/\sigma))$ follows in the same way.

Abstract

Let $A = (a_{ij})$ be an $m \times n$ matrix whose elements lie in an arbitrary field $\mathbb{F}$, and let G be the bipartite graph with vertex set $\{v_1, \ldots, v_m\} \cup \{w_1, \ldots, w_n\}$ such that vertices v_i and w_j are adjacent if and only if $a_{ij} \neq 0$. We introduce an algorithm that finds an $m \times n$ matrix U in row echelon form and a permutation matrix Q of order n, such that AQ is row equivalent to U. If a tree decomposition $\mathcal{T}$ of G of width k and size $O(k(m+n))$ is part of the input, then Q and the columns of U that contain a pivot can be computed in time $O(k^2(m+n))$. Among other things, this allows us to compute the rank and the determinant of A in time $O(k^2(m+n))$. It also allows us to decide in time $O(k^2(m+n))$ whether the linear system $Ax = b$ has a solution and to compute a solution of the linear system in case it exists.

1 Introduction

Reducing a matrix to a desired form or decomposing a matrix into a product of matrices with a given structure are basic operations in linear algebra. Problems involving triangular matrices and matrices in row echelon form are often easy to solve, and a large number of tasks may be accomplished by first reducing a general matrix into a matrix of this form. To be precise, a matrix $A = (a_{ij})$ is in *row echelon form* if all rows consisting entirely of zeros are at the bottom, and the following holds for the remaining rows. If i is a nonzero row, its *pivot* is the element $a_{ij} \neq 0$ with least j. If rows $i_1 < i_2$ have pivots in columns j_1 and j_2, respectively, then $j_1 < j_2$.

A basic result in linear algebra states that every matrix can be transformed into a matrix in row echelon form by a sequence of three types of row operations, known as *elementary row operations*. In this paper, we shall refer to two of these types: a type I elementary row operation on a matrix involves interchanging two rows. A type II elementary row operation involves adding a multiple of a row to another row. We say that A and B are *row equivalent* if A can be transformed into B by a sequence of elementary row operations. The process of

© Martin Fürer, Carlos Hoppen, and Vilmar Trevisan;

reducing a matrix to row echelon form by elementary row operations is known as Gaussian elimination. The standard school algorithm reduces an arbitrary $m \times n$ input matrix A with entries in a field $\mathbb{F}$ to row echelon form in $O(mn \min\{m, n\})$ field operations. However, it can be faster if more is known about the structure of A. For instance, if A is sparse, its structure can be exploited if we find a *pivoting scheme* (also known as *elimination ordering*) that minimizes the *fill-in*, defined as the set of matrix positions that were initially 0, but became nonzero at some point during the computation. It is worth noting that sparse matrices often occur for some structural reason, such as small treewidth. Gaussian elimination cannot be used efficiently on random sparse matrices with any elimination order, as we would expect such matrices to quickly get dense as the algorithm progresses. We should mention that other strategies can be used to exploit the sparsity of the input matrix, see for instance the work of Peng and Vempala [12].

Much of the early focus has been on the question of characterizing the graphs corresponding to matrices with a perfect elimination order, meaning that there is a pivot strategy for Gaussian elimination without any fill-in. Parter [11] has assigned a graph to a matrix A with an edge $\{i, j\}$ if a_{ij} or a_{ji} are non-zero. He has then shown that there is a perfect elimination order if the graph is a tree. As became customary afterwards, he chooses all pivots in the diagonal and makes the strong assumption that all diagonal elements of the matrix are non-zero and remain so during the computation, usually referred to as not having any accidental cancellation.

Obviously, this assumption simplifies Gaussian elimination enormously. It is justified because it is true for symmetric positive definite matrices, which are the most important special class of matrices for systems of linear equations. However, one would like to see more widely applicable methods.

Rose [16] shows that Parter's result can be extended to all triangulated graphs (also known as chordal graphs). Rose, Tarjan, and Lueker [18] show that a graph has a perfect elimination order if and only if the graph is triangulated. In this case, they find a perfect elimination order in $O(|V| + |E|)$ time. Rose and Tarjan [17] efficiently find a perfect elimination order in a directed graph if one exists, and show that finding a minimal elimination ordering (minimizing the fill-in) is NP-hard. A directed graph describes the non-zero off-diagonal entries in an $n \times n$ matrix, where Gaussian elimination is done by choosing pivots in the diagonal under the assumption that there will never be a 0 in the diagonal.

The perfect elimination question is more complicated for the case of asymmetric $m \times n$ matrices A, where any nonzero pivot is allowed. Any $m \times n$ matrix $A = (a_{ij})$ may be naturally associated with a bipartite graph G with vertex set $\{v_1, \ldots, v_m\} \cup \{w_1, \ldots, w_n\}$ such that vertices v_i and w_j are adjacent if and only if $a_{ij} \neq 0$. We say that G is the *underlying bipartite graph* of A. This allows us to employ structural decompositions of graph theory to deal with the nonzero entries of A in an efficient way. Different from the symmetric case with pivots restricted to the diagonal, there is no nice characterization known for the bipartite graphs with perfect elimination order when arbitrary pivots are allowed. Nevertheless, a very large class is given by the *chordal bipartite* graphs defined by Golumbic and Goss [7]. These graphs are not chordal, as obviously only forests are bipartite and chordal. Still, chordal bipartite graphs are characterized similarly to chordal graphs. For chordal graphs, the defining property is that every cycle of length at least 4 has a chord, while chordal bipartite graphs are defined by the requirement that every cycle of length at least 6 has a chord. Golumbic and Goss [7] have shown that chordal bipartite graphs have a perfect elimination order.

They are not the only bipartite graphs with a perfect elimination order, but the only ones where one can always pick any simplicial edge (definition follows) as a pivot [7]. An edge $\{u, v\}$ is simplicial if the union of the neighborhoods of u and v induces a complete bipartite graph. It is easy to see that a bipartite graph G has a perfect elimination order if there exists an ordering of a matching $\{(u_1, v_1), (u_2, v_2), \ldots, (u_p, v_p)\}$ in G such that (u_i, v_i) is simplicial in the subgraph $G[V \setminus \{u_1, v_1, u_2, v_2, u_{i-1}, v_{i-1}\}]$ for $i \in \{1, \ldots, p\}$.

Radhakrishnan, Hunt, and Stearns [13] do Gaussian elimination for symmetric matrices with a given tree decomposition of width k in time $O(k^2 n)$. As has been common, they implicitly assume that the diagonal is non-zero and there is no accidental cancellation. Naturally, given today's familiarity with algorithms based on tree decompositions, it would now be an easy exercise to design such an algorithm when pivots can always be selected in the diagonal.

Only in recent years has there finally been some progress towards the difficult problem of efficient Gaussian elimination for matrices of small treewidth without the simplifying assumption that pivots can always be chosen in the diagonal. Fomin et al. [5] have shown a Gaussian elimination algorithm running in time $O(p^2 n)$ where p is the lesser known tree-partition width parameter or the pathwidth. The tree-partition width of a graph can be arbitrarily large already for graphs of constant treewidth, unless the maximum degree is bounded [19]. However, Fomin et al. [5] still obtained an $O(k^3 n)$ algorithm for treewidth k. We should also refer to the work of Dong, Lee, and Ye [4], whose main result implies an $O(k^2 n)$ algorithm for the solution of a linear system $Ax = b$ such that the matrix $A \in \mathbb{R}^{m \times n}$ is full-rank (actually, their result is about the solution of a linear program).

Naturally, the longstanding main goal is an $O(k^2 n)$ Gaussian elimination algorithm for treewidth k without restrictive assumptions. This would provide a smooth transition to the school algorithm when k approaches n. It would also achieve the same running time bound for the general case as for the easy case of non-zero diagonal and no accidental cancellation. It actually seems that the $O(k^2 n)$ goal has not been explicitly formulated until recently [5], maybe because it had not seemed achievable. However, when this goal has been obtained by simple algorithms under very strong assumptions, the question whether these assumptions (that convenient entries are nonzero and thus can be used as pivots) are necessary must have been obvious.

We make substantial progress in this direction by devising the algorithm `Fast Gaussian Elimination`. Given an $m \times n$ matrix A over a field $\mathbb{F}$ with underlying bipartite graph G, and given a tree decomposition $\mathcal{T}$ of G of width k and size $O(k(m + n))$, it produces a matrix U in row echelon form that is row equivalent to A. The entries of the columns of U that contain a pivot (and therefore generate a space of dimension $\operatorname{rank}(A)$) are fully computed in time $O(k^2 n)$. The entries of the remaining columns of U are described implicitly as linear combinations of at most k other columns, and may be computed explicitly in time $O(km(n - \operatorname{rank}(A)))$. In particular, this algorithm allows us to compute the rank and the determinant of A in time $O(k^2(m + n))$. It also allows us to decide in time $O(k^2(m + n))$ whether the linear system $Ax = b$ has a solution, and to compute a solution of the linear system in case it exists. Our main result is stated more formally below.

▶ **Theorem 1.** *Let A be an $m \times n$ matrix over a field $\mathbb{F}$, let G be its underlying bipartite graph, and let $\mathcal{T}$ be a tree decomposition of G of width k and size $O(k(m + n))$. Algorithm `Fast Gaussian Elimination` produces an $m \times n$ matrix U in row echelon form, and a permutation matrix Q of order n with the property that AQ is row equivalent to U. The permutation matrix Q, and the columns of U that contain a pivot may be computed with $O(k^2(m + n))$ field operations. The full matrix U may be computed with $O(km(n - \operatorname{rank}(A)))$ additional field operations.*

We actually also compute a permutation matrix P of order m such that U is the row echelon form that would be obtained from PAQ by the most standard algorithm (adding multiples of earlier rows to later rows).

Our algorithm is not based on the $O(k^3n)$ algorithm of Fomin et al. [5], as it uses standard tree decompositions in a natural way, and does not rely on the somewhat obscure notion of tree-partition width. Even though our algorithm removes the decades old severe restriction to pivoting in the main diagonal, the main idea of our Gaussian elimination algorithm is quite simple. The tree decomposition provides an elimination order for rows (equations) and columns (variables). This order sequentially hands out permissions to rows and columns to be eliminated. However, when a row i receives a green light to be processed, it is only processed immediately if it contains a variable that has already received a green light. Otherwise, this row is put into a buffer to be delayed until one of its variables x_j also has a green light. Then a_{ij} is chosen as a pivot. Likewise, when a variable receives a green light then, if needed, its column is put into a buffer until some row containing this variable has a green light.

As was the case in Fomin et al. [5] we use a *nice tree decomposition* of the underlying bipartite graph G as defined by Kloks [9]. However, to deal with 0's at intended pivot locations, we create temporary buffers for rows and columns that allow us to delay the selection of pivots as discussed above. As is typical for algorithms based on tree decompositions, row operations are actually performed on small submatrices of the input matrices. For simplicity, the algorithm does not manipulate the large given matrix. Instead, these small submatrices, called boxes, are maintained separately. The small submatrices in this paper include additional information to keep track of the rows and columns that lie in the temporary buffer, which allows us to make headway towards the output matrix in row echelon form even when accidental cancellations occur. It is crucial to perform so-called bookkeeping operations that ensure that the temporary buffers remain small during the entire application of the buffer.

The paper is organized as follows. The algorithm is described in Section 2, where we also discuss its correctness. The running time is analyzed in Section 3. We should mention that, to achieve this running time, we need to keep track of the field operations in a global way, rather than adding the contributions of the worst-case scenarios at each step. Together, these two sections establish Theorem 1. We provide several consequences of our result in Section 4.

2 The Algorithm

We now describe the algorithm `Fast Gaussian Elimination`. We start with the definition of a tree decomposition, which we now state. Let $G = (V, E)$ be a ν-vertex graph, with the standard assumption that $V = [\nu] = \{1, \ldots, \nu\}$. A *tree decomposition* of a graph G is a tree $\mathcal{T}$ with *nodes* $\{1, \ldots, r\}$, where each node t is associated with a *bag* $B_t \subseteq V$, satisfying the following properties: (1) $\bigcup_{t=1}^{r} B_t = V$; (2) For every edge $\{v, w\} \in E$, there exists B_t containing v and w; (3) For any $v \in V$, the subgraph of $\mathcal{T}$ induced by the nodes whose bags contain v is connected. The *width* of the tree decomposition $\mathcal{T}$ is defined as $\max_t (|B_t| - 1)$ and the *treewidth* $\mathrm{tw}(G)$ of graph G is the smallest k such that G has a tree decomposition of width k. Tree decompositions were popularized by the seminal work of Robertson and Seymour [14, 15], but other definitions that are similar or even equivalent have appeared in earlier work, see [1, 8]. As mentioned in the introduction, we use the concept of *nice tree decomposition* introduced by Kloks [9], which is a rooted tree decomposition $\mathcal{T}$ of a graph G such that all nodes are of one of the following types:

(a) **(Leaf)** The node t is a leaf of $\mathcal{T}$;
(b) **(Introduce)** The node t introduces vertex v, that is, it has a single child s, $v \notin B_s$ and $B_t = B_s \cup \{v\}$.
(c) **(Forget)** The node t forgets vertex v, that is, t has a single child s, $v \notin B_t$ and $B_s = B_t \cup \{v\}$;
(d) **(Join)** The node t is a join, that is, it has two children s and s', and $B_t = B_s = B_{s'}$.

We further assume that the bag associated with the root is empty. This is easy to accomplish, as any tree decomposition $\mathcal{T}$ that satisfies (a)-(d), but does not satisfy this additional requirement, may be turned into a nice tree decomposition with empty root bag by appending a path of length at most $k+1$ to the root of $\mathcal{T}$, where all nodes have type forget. Having a root with an empty bag ensures that each vertex of $G = (V, E)$ is associated with exactly one forget node that forgets it. Moreover, it ensures that, for any $v \in V$, the node of $\mathcal{T}$ that is closest to the root among all t such that $v \in B_t$ is the child of the node that forgets v. Despite the additional structure, a nice tree decomposition may be efficiently derived from an arbitrary tree decomposition. More precisely, Kloks [9, Lemma 13.1.2] has shown that, if G is a graph of order ν and we are given an arbitrary tree decomposition of G with width k and r nodes, it is possible to turn it into a nice tree decomposition of G with at most 4ν nodes and width at most k in time $O(k(\nu + r))$. Regarding the computation of a tree decomposition, Bodlaender's theorem [2] provides an optimal tree decomposition in linear time when the treewidth k is a constant. Bodlaender et al. [3] and Korhonen [10] compute faster constant factor approximations in linear time. Thus, for bounded k, there is no need to assume a tree decomposition is given, since both the tree decomposition and the Gaussian elimination are then computed in time $O(n)$. However, the constants hidden in the O-notation grow quickly with k.

We are now ready to describe the algorithm. Let A be an $m \times n$ matrix with entries in a field $\mathbb{F}$ and let $G = (V, E)$ be the underlying bipartite graph with vertex set $V = \{v_1, \ldots, v_m\} \cup \{w_1, \ldots, w_n\}$ associated with it. We wish to find an $m \times m$ permutation matrix P, an $n \times n$ permutation matrix Q and an $m \times n$ matrix U in row echelon form such that PAQ is row equivalent to U in a direct way. We shall operate on a nice tree decomposition $\mathcal{T}$ of G with node set $[r]$ and width k rather than on the matrix A itself. The algorithm `Fast Gaussian Elimination` works bottom-up on the rooted tree $\mathcal{T}$, that is, it only processes a node t after its children have been processed. Each node t except the root produces a data structure known as a *box* and transmits it to its parent. A box is a matrix A_t with $O(k)$ rows and columns. It may be recorded as a triple of matrices (M_t, N_t, J_t) whose rows and columns are labeled by distinct elements of $\{v_1, \ldots, v_m\}$ and $\{w_1, \ldots, w_n\}$, respectively, associating rows and columns of the boxes with rows and columns of the original matrix. We may view it as

$$A_t = \begin{array}{|c|c|} \hline \mathbf{0}_{m_t \times n_t} & M_t \\ \hline N_t & J_t \\ \hline \end{array}, \tag{1}$$

where J_t is an $r_t \times c_t$ matrix whose rows and columns are labeled by the elements in B_t, the bag associated with node t. Here r_t is the number of row vertices (i.e., vertices v_i) in B_t and c_t is the number of column vertices (i.e., vertices w_j) in B_t. The matrices M_t and N_t have dimensions $m_t \times c_t$ and $r_t \times n_t$, respectively, where $m_t < 2c_t$ and $n_t < 2r_t$. Observe

that some of these matrices can be degenerated, in the sense that $m_t = 0$, $n_t = 0$, $c_t = 0$ or $r_t = 0$. In a case where $m_t = 0$, $n_t = 2$, $c_t = 2$ and $r_t = 3$, for instance, the box A_t is 3×4 matrix, M_t is a matrix with no rows and two empty columns, and both N_t and J_t are 3×2 matrices. We should note that a similar data structure, also called a box, has been exploited in the context of computing a diagonal matrix that is congruent to a given symmetric matrix using a tree decomposition of its underlying graph [6].

It will also be useful to assign a *canonical ordering* to the rows and columns of the input matrix. We assume that they are ranked according to the order in which their Forget nodes appear in some topological ordering (e.g., obtained by a post-order traversal of $\mathcal{T}$), that is, v_1 is the first vertex that is forgotten among all vertices that represent rows, v_2 is the second, and so on. The same applies to $w_1, \ldots, w_n$.

We start with an intuition about the meaning of the boxes and about how the algorithm works. Recall that the nodes of the nice tree decomposition $\mathcal{T}$ are ordered bottom-up as $1 \ldots, r$, where r is the root and $B_r = \emptyset$. At each node $t \in V(\mathcal{T})$, the algorithm initializes box A_t (if t is a leaf) or produces a new box A_t based on its bag B_t and on the boxes transmitted by its children. While producing the box A_t, the algorithm may access entries a_{ij} of the input matrix such that both i and j are associated with vertices in B_t. The box A_t is then transmitted to its parent, except if t is the root of $\mathcal{T}$. We call this *processing* node t.

It is also useful to keep in mind that the algorithm performs two types of elementary row operations, which we call *authentic operations* and *bookkeeping operations*. The former are operations that can be performed in the full matrix A in order to reach row echelon form. The latter are operations that are only performed on the boxes as a way to limit their sizes, but which do not have full matrix counterparts. The effect of processing nodes may be viewed as a sequence of $m \times n$ matrices

$$\tilde{A}_0 = A, \tilde{A}_1, \ldots, \tilde{A}_r = U, \tag{2}$$

where U is in row echelon form and $\tilde{A}_t$ is obtained from $\tilde{A}_{t-1}$ by performing the authentic elementary row operations that have been performed while node t is processed. We should mention that this sequence of row equivalent matrices is a simplification of what actually happens, but that it could be achieved if an oracle gave us the proper ordering of rows and columns of A. In reality, the proper orderings are also computed by the algorithm while the nodes are processed, leading to the permutation matrices P and Q mentioned in the statement of Theorem 1.

To achieve the complexity stated in Theorem 1, row operations cannot be actually performed on $m \times n$ matrices, but are instead performed only in the (smaller) boxes. It is useful to think that any row or column of the input matrix A, say row i, is initially *untouched* and changes to a *regular* row when the vertex v_i associated with it appears in the bag of a node of the branch[1] of the tree decomposition rooted at t. When v_i is removed from the bag (at the node that forgets it in the nice tree decomposition), either row i is assigned a pivot in some column j, in which case row i is classified as *processed* (column j is also classified as processed), or row i becomes a *buffer* row, meaning that it has been given the green light for a pivot, but that the decision of assigning a pivot has been deferred to a later step because no column has received a green light. In the process of keeping the size of the box bounded, the algorithm may decide that it is impossible or unnecessary to assign a pivot to a buffer row or to a buffer column, in which case the status of the row or column also

[1] We use "branch" to refer to the subtree induced by all descendants of a node.

changes to *processed*. We observe that the classification of each row and column is defined independently for disjoint branches of the tree decomposition, and an important feature of the algorithm is that these independent classifications can be made compatible when two branches are merged (which happens at join nodes).

This finally gets us to the meaning of a box $A_t = (M_t, N_t, J_t)$ at node t. The rows and columns of the matrix J_t are precisely the regular rows and columns of the branch $\mathcal{T}_t$ of $\mathcal{T}$ rooted at node t. In other words, these are the rows and columns corresponding to the vertices in the bag B_t. Moreover, each entry ij of J_t records the *net change* to the original entry a_{ij} due to row operations performed while processing nodes in $\mathcal{T}_t$. The matrix M_t records the entries ij of the matrix $\tilde{A}_t$ defined in (2) in the case where i is a buffer row (with respect to $\mathcal{T}_t$) and j is a regular column. Analogously, N_t records the entries ij of $\tilde{A}_t$ in the case where i is a regular row and j is a buffer column. This reveals another important feature of the algorithm: The entries of the full $m \times n$ matrix associated with regular rows and regular columns can easily be modified in parallel by computations in disjoint branches, as the algorithm does not capture their exact values while processing a single branch. The boxes just store the net changes to the values due to operations in this branch. However, this does not happen for buffer rows and buffer columns, for which exact values are recorded in the box. The top left corner of A_t in (1) shows that, if i is a buffer row and j is a buffer column, the entry ij in $\tilde{A}_t$ is equal to zero. This is consistent with the idea that the algorithm selects a new pivot whenever there are a buffer row i and a buffer column j for which the element ij is nonzero, as both the row and the column had already been given the green light as possible rows and columns for a pivot. So, if row i and column j are in the buffer at the end of step t, then the entry ij must be 0.

While producing the boxes, the algorithm may select pivots for the output matrix U, it may identify zero rows that cannot contain a pivot and it may identify columns that are linear combinations[2] of other columns, and therefore cannot contain pivots together with the other columns. The status of these rows and columns changes to processed, which means that information about them is recorded by global variables, while they are removed from the box.

After this description, we come back to a matrix $\tilde{A}_t$ in (2), depicted in Figure 1[3]. The top left entries lie in processed rows and processed columns that contain pivots. These entries are not modified later in the algorithm. The bottom rows are (processed) zero rows that have been produced while limiting the size of the set of buffer rows (it is indeed impossible to find a pivot in such a row), while the rightmost columns are (processed) columns that have been identified as linear combinations of other columns (except for possible entries in rows whose pivot had already been computed when this column was processed). As a consequence, it is unnecessary to assign a pivot to them. Moreover, while the actual values in the rightmost columns may be modified in later steps of the algorithm, we need not keep track of them, as each such column may be computed as a linear combination of (a known set of) $O(k)$ columns with smaller index at the end of the algorithm. The central submatrix represents entries in the buffer, and in regular or untouched rows and columns. Some of them lie in the box where computations are actually performed in a given step.

Before giving a formal description of every step of the algorithm, we briefly describe what is done at a node of each type. A node of type leaf merely initializes a box with regular rows or columns, while a node of type introduce simply adds a new regular row or column to the

[2] Actually, they are not necessarily linear combinations of the other columns with respect to the entire matrix, but they are linear combinations with respect to a submatrix as depicted in Figure 1.

[3] The authors thank Elizandro Max Borba for the figure.

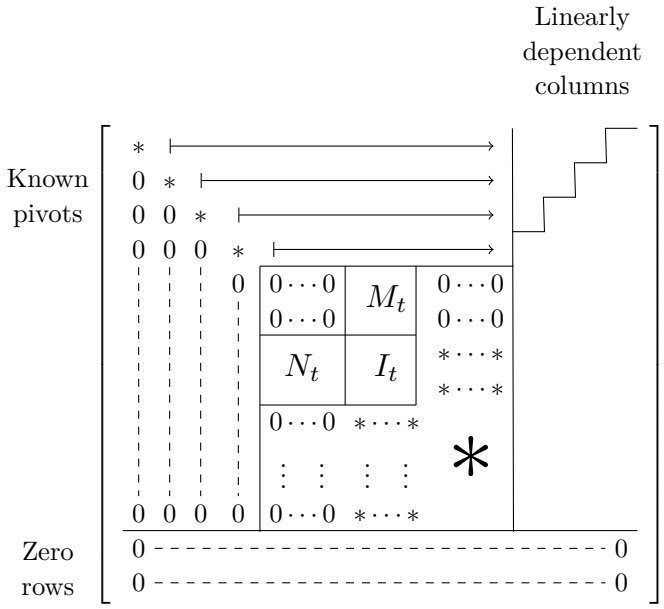

Figure 1 A description of an intermediate matrix in the Gaussian elimination process.

box transmitted by its child. Nodes of type join combine the information that is passed on by two different branches of the decomposition, which have been processed independently of each other. Let A_j and A_ℓ denote the boxes produces by the children of t. A new matrix M_t is produced by stacking the matrix M_j on top of M_ℓ, and a new matrix N_t is produced by juxtaposing N_j to the left of N_ℓ. Such matrices M_t and N_t may become too large, so that row operations are performed to remove some rows and/or columns from the buffer. Producing J_t also requires merging J_j and J_ℓ , as the regular rows and columns are the same. Being able to easily merge the matrices transmitted by the children is the reason why the rows and columns are considered with the canonical ordering mentioned above.

Nodes of type forget concentrate most of the action. Recall that each row i of A is associated with a vertex v_i of G, which in turn is associated with the unique Forget node of $\mathcal{T}$ that forgets v_i. Analogously, each column j of A is associated with a vertex w_j of G and the unique Forget node of $\mathcal{T}$ that forgets w_j. Assume that the algorithm is processing a Forget node t, which means that it received a box A_s of its child s. Further assume that node t forgets a vertex v_i corresponding to row i. This means that the algorithm singles out this row as a candidate for having a pivot. In the box A_s, it checks whether there is a column j that has already been singled out for a possible pivot, but which has no pivot so far. These are precisely the columns of N_s. If such a column exists, it checks whether the entry ij in N_s nonzero. If this is also satisfied, the algorithm performs operations to create a pivot in row i and column j, and they are both removed from the box. If one of the conditions fails, row i is removed from J_s and added to M_t, which contains rows singled out for a pivot, but which have no pivot so far. Furthermore, if the condition on the maximum number of rows of M_t fails after the addition of this new row, the algorithm acts to remove some rows from the buffer.

Analogously, if node t forgets vertex w_j corresponding to column j, it first checks whether there are rows that have been singled out for pivots, but have not been used, namely the rows of M_s. It then looks for one such row i for which the entry ij is nonzero. If such a row

exists, the algorithm performs operations to create a pivot in row i and column j, and they are both removed from the box. If one of the conditions fails, column j is removed from J_s and added to N_t, which contains columns singled out for a pivot, but which have no pivot so far. If the condition on the number of columns of N_t fails after the addition of this new column, the algorithm acts to remove some columns from the buffer.

A high level description of the algorithm may be found in Figure 2. Note that, in this descriptiom, we have five global variables: the number ρ of pivots already computed, two vectors $\mathbf{u}$ and $\mathbf{p}$ of length m and two vectors $\mathbf{w}$ and $\mathbf{q}$ of length n. Initially, these are zero vectors. At the end of the algorithm, vector $\mathbf{u}$ allows us reconstruct the rows of the output matrix U, while vectors $\mathbf{p}$ and $\mathbf{q}$ encode the permutations that generate P and Q, respectively. As we discussed, the algorithm may also find columns of A that are linear combinations of other columns and remove them from boxes. When this happens, the linear combination that produces it is recorded in the vector $\mathbf{w}$, so that the values of entries of U in these columns can also be recovered at the end of the algorithm.

```

Figure 2 High level description of the algorithm `Fast Gaussian Elimination`. The entries of matrix U and the permutations leading to P and Q are constructed stepwise during the `ForgetBox` and `JoinBox` operations.

In the remainder of this section, we shall describe each operation in detail. To simplify our discussion, for a node t, we say that buffer rows and buffer columns have type 1, while regular rows and regular columns have type 2.

Leaf Box

When a node is a leaf corresponding to a bag B_t, then we apply procedure `Leaf Box`. This procedure simply initializes a box A_t where $m_t = 0$, $n_t = 0$, and J_t is a zero matrix of dimension $r_t \times c_t$ whose rows and columns are labeled by the elements of B_t, which contains r_t row vertices and c_t column vertices. No elementary row operations are performed.

Introduce Box

When a node t introduces a vertex u, its bag satisfies $B_t = B_s \cup \{u\}$, where B_s (which does not contain u) is the bag of its child s. The input of `Introduce Box` is the vertex u that has been introduced and the box A_s transmitted by its child. The box A_t is obtained by the

insertion of a new type 2 row or column labeled u whose elements are all zero[4], taking care to insert it in the correct order (with respect to the canonical order of rows and columns of J_t. More precisely, if u is a row vertex v_i, this means that N_t and J_t are obtained from N_s and J_s, respectively, by the addition of a zero row, while $M_t = M_s$. It is clear that $n_t = n_s < 2r_s < 2(r_s + 1) = 2r_t$. Similarly, if v is a column vertex w_j, the addition of this column means that M_t and J_t are obtained from M_s and J_s, respectively, by the addition of a zero column, while $N_t = N_s$. It is clear that $m_t = m_s < 2c_s < 2(c_s + 1) = 2c_t$. No elementary row operations are performed.

Join Box

Let t be a node of type Join and let A_s and $A_{s'}$ be the boxes transmitted by its children, where $s < s' < t$. By the definition of box, A_s and $A_{s'}$ have the same rows and columns of type 2, that is, J_s and $J_{s'}$ have the same dimension and have rows and columns labeled by the same elements (in the same order). Moreover, because vertices of type 1 have been forgotten in their respective branches, the labels of the rows of M_s and $M_{s'}$ are all different, as are the labels of the columns of N_s and $N_{s'}$. The `JoinBox` operation first creates a matrix A_t^* whose rows and columns are labeled by the union of the labels of A_s and $A_{s'}$ with the structure below.

$$A_t^* = \begin{array}{|c|c|c|} \hline \mathbf{0}_{m_s \times n_s} & \mathbf{0}_{m_s \times n_{s'}} & M_s \\ \hline \mathbf{0}_{m_{s'} \times n_s} & \mathbf{0}_{m_{s'} \times n_{s'}} & M_{s'} \\ \hline N_s & N_{s'} & J_t^* \\ \hline \end{array}. \tag{3}$$

Here $J_t^* = J_s + J_{s'}$ has order $r_t \times c_t$ and records the net change of the entries of the original matrix because of row operations in the two branches that are being merged at this step. Let M_t^* be the $(m_s + m_{s'}) \times c_t$ matrix obtained by stacking M_s on top of $M_{s'}$[5]. Let N_t^* be the $r_t \times (n_s + n_{s'})$ matrix obtained by placing N_s to the left of $N_{s'}$.

If $m_s + m_{s'} < 2c_t$, define $M_t = M_t^*$. Otherwise $m_s + m_{s'} \geq 2c_t$. Apply Gaussian elimination to M_t^* until we get a matrix $\tilde{M}_t$ in row echelon form. Here, we can use a standard algorithm for dense matrices that takes $O(c_t^3)$ operations, as M_t^* has c_t columns and at most $4c_t - 2$ rows. Since $m_s + m_{s'} \geq 2c_t$, this process ends with at least c_t zero rows. The matrix M_t is obtained from $\tilde{M}_t$ by removing all the zero rows, and by reordering the rows so that they remain in the original ordering of M_t^*. Assume that the zero rows are labeled by the vertices $v_{i_1}, \ldots, v_{i_\ell}$. The algorithm updates the permutation vector $\mathbf{p}$ by assigning the values $i_1, \ldots, i_\ell$ to the last ℓ components of $\mathbf{p}$ with value 0, which means that the ℓ zero rows of M_t^* become the top zero rows in the description of Figure 1. Given that the new box is defined based on the matrix that has been modified, the type II row operations used for Gaussian elimination are authentic row operations. Given that the order of the rows has been preserved, type I row operations are bookkeeping operations (we observe that the labels of the rows used for authentic row operations will always refer to the original input matrix to account for the fact that row interchanging is not actually performed)[6].

Similarly, if $n_s + n_{s'} < 2r_t$, define $N_t = N_t^*$. Otherwise, make an auxiliary copy of N_t^* and apply Gaussian elimination on it until we get a matrix $\tilde{N}_t$ in row echelon form. As above, we can use a standard algorithm for dense matrices that takes $O(r_t^3)$ operations. There is

[4] The added row or column may actually be empty if a new row vertex is introduced, but $c_s = 0$ and $n_s = 0$, or a new column vertex is introduced, but $r_s = 0$ and $m_s = 0$.

[5] Alternatively, to preserve the canonical ordering of rows, we could merge the two matrices M_s and M'_s in a way that preserves the canonical ordering. However, this does not affect the final result.

[6] The algorithm could be easily adapted to a version where row interchanges are also authentic row operations, but this makes the analysis slightly more involved.

a set S_t of at most r_t columns that form a basis of the column space of N_t^* (precisely the columns of N_t^* with pivots in $\tilde{N}_t$). The matrix N_t is obtained from N_t^* by removing the columns that are not in S_t, form which there are at least $n_s + n_{s'} - r_t \geq r_t$.

▶ Remark 2. We emphasize that N_t is defined in terms of N_t^* rather than $\tilde{N}_t$ in this case, which means that the row operations performed to obtain $\tilde{N}_t$ are *not* performed in the full matrix while producing the sequence (2), but are instead auxiliary operations to find a basis of the column space of N_t^* and to write the remaining columns as linear combinations of the columns in this basis. This is crucial. If we consider the effect of the row operations in the full matrix, while the nonzero entries of the rows corresponding to M_t in the full matrix lie entirely within M_t (except perhaps for entries in columns that are linear combinations of other columns), there may be nonzero entries in the rows corresponding to N_t that lie outside the box A_t. Indeed, the rows of N_t are regular rows, so that they may even be processed in parallel by different branches of the tree decomposition. Adding multiples of them to other rows might affect entries that are not being monitored at this step. This is why the operations performed to turn a copy of N_t^* to row echelon form must be bookkeeping operations.

Coming back to the description of the algorithm, assume that $w_{j_1}, \ldots, w_{j_\ell}$ are the labels of the columns of N_t^* with no pivot in $\tilde{N}_t$, so that they are linear combinations of the remaining columns of $\tilde{N}_t$. The algorithm updates the permutation vector $\mathbf{q}$ by assigning the values $j_1, \ldots, j_\ell$ to the last ℓ components of $\mathbf{q}$ with value 0, which may be seen as moving these columns to the right (see Figure 1). Moreover, the corresponding entries of the vector $\mathbf{w}$ record information about the linear combinations. For each column w_{j_i}, this information consists of the indices of the columns that produce the linear combination, the coefficients of this linear combination, and the number of pivots ρ at this step of the algorithm (as the linear combinations are with respect to the part of the column that does not include rows for which pivots have been assigned.)

Forget Box

Assume that t forgets vertex v and let s be its child, so that $B_t = B_s \setminus \{v\}$. This procedure uses A_s to produce a new box A_t where the row or column associated with v gets a pivot (and is therefore removed from the box) or changes to type 1.

Assume first that $v = v_i$ for a row i. Consider the matrix A_t^* given by[7]

$$A_t^* = \begin{array}{|c|c|} \hline \mathbf{0}_{m_s \times n_s} & M_t^* \\ \hline N_t^* & J_t^* \\ \hline \mathbf{x}_i & \mathbf{y}_i \\ \hline \end{array}, \tag{4}$$

where $M_t^* = M_s$, $\mathbf{x}_i$ is row v_i of N_s, N_t^* is obtained from N_s by removing row $\mathbf{x}_i$, J_t^* is obtained from J_s by removing row v_i, and $\mathbf{y}_i$ is obtained from row v_i of J_s by adding the entry a_{ij} of the input matrix to the entry corresponding to each column w_j.

[7] Representing the row associated with v_i as the last row is helpful for visualizing the operations, but this need not be part of an implementation.

If $\mathbf{x}_i$ is empty or zero, the algorithm sets $J_t = J_t^*$, and adds $\mathbf{y}_i$ to M_t^* as the new bottom row to produce M_t^{**}. If M_t^{**} has at most $2c_t - 1$ rows, the algorithm calls this matrix M_t and concludes the step. Intuitively, this means that row v_i is a new buffer row. Otherwise M_t^{**} has $2c_t$ rows. The algorithm turns this matrix into a matrix $\tilde{M}_t$ in row echelon form and removes $\ell \geq c_t$ zero rows of $\tilde{M}_t$ to produce M_t, as was done in `Join Box`. As a byproduct of these authentic row operations, the algorithm updates $\mathbf{p}$. Similarly, if $n_s < 2r_t$, we set $N_t = N_t^*$. However, because $r_t = r_s - 1$ and the number of columns of N_t^* is n_s, it may be that $n_s \geq 2r_t$. If this happens, as was the case for `Join Box`, the algorithm performs bookkeeping operations to define N_t, and update $\mathbf{q}$ and $\mathbf{w}$.

If $\mathbf{x}_i$ is nonempty and nonzero, the algorithm selects the first nonzero entry of $\mathbf{x}_i$, suppose that it is in column w_j. It then performs row operations in A_t^* in order to eliminate all the other nonzero elements in column w_j (note that these elements are necessarily in rows of type 2, so that only rows in N_t^* and J_t^* are modified). The algorithm defines $\mathbf{p}(\rho) = i$ and $\mathbf{q}(\rho) = j$, while $\mathbf{u}(\rho)$ records information about the nonzero entries of the vector $[\mathbf{x}_i\ \mathbf{y}_i]$, namely the labels j of the nonzero columns of the vector $[\mathbf{x}_i\ \mathbf{y}_i]$ and the actual values of the nonzero entries. The algorithm then adds one to the value of ρ. Matrix J_t is assigned this modified J_t^*, matrix M_t is defined as M_t^*. Moreover, column j is removed from N_t^* to produce N_t^{**}. The row operations performed up to this point are authentic. If the number of columns in N_t^{**} is less than $2r_t$ (note that $r_t = r_s - 1$ and that N_t^{**} has $n_s - 1$ columns), N_t is set to be N_t^{**}. Otherwise, $n_t = 2r_t$ and the algorithm performs bookkeeping operations as in `Join Box` to define N_t, and update $\mathbf{q}$ and $\mathbf{w}$.

Next assume that $v = w_j$ for a column j. Consider the matrix A_t^* given by

$$A_t^* = \left[\begin{array}{ccc} \mathbf{0}_{m_s \times n_s} & M_t^* & \mathbf{c}_j \\ \hline N_t^* & J_t^* & \mathbf{d}_j \end{array}\right], \tag{5}$$

where $N_t^* = N_s$, M_t^* is obtained from M_s by removing column w_j, $\mathbf{c}_j$ is column w_j of M_s, J_t^* is obtained from J_s by removing column w_j and $\mathbf{d}_j$ is obtained from column w_j of J_s by adding the entry a_{ij} (of the input matrix) to the entry corresponding to each row v_i.

If $\mathbf{c}_j$ is empty or zero, the algorithm sets $J_t = J_t^*$ and adds $\mathbf{d}_j$ as a new column of to N_t^* to produce N_t^{**}. If N_t^{**} has fewer than $2r_t$ columns, the algorithm calls this matrix N_t and concludes the step. Otherwise N_t^{**} has $2r_t$ columns and the algorithm defines N_t with bookkeeping operations as was done in `Join Box` (this leads to changes in $\mathbf{q}$ and $\mathbf{w}$). Similarly, if $m_s < 2c_t$, we set $M_t = M_t^*$. However, because $c_t = c_s - 1$ and the number of rows of M_t^* is m_s, it may be that $m_s \geq 2c_t$. If this happens, the algorithm turns M_t^* into a matrix $\tilde{M}_t$ in row echelon form and removes the $\ell \geq c_t$ zero rows of $\tilde{M}_t$ to produce M_t, as was done above (this leads to changes in $\mathbf{p}$). These operations are authentic.

If $\mathbf{c}_j$ is nonempty and nonzero, the algorithm selects the first nonzero entry of $\mathbf{c}_j$, suppose that it is in row i (of type 1). Let c_{ij} be this nonzero entry and let $\mathbf{x}_i$ be row i in M_t^*. The algorithm then performs authentic row operations in A_t^* using row i to eliminate all the other nonzero elements in column j (note that only rows in M_t^* and J_t^* are modified). It then removes row i from M_t^* to produce M_t^{**}. As in the case of rows, the algorithm defines $\mathbf{p}(\rho) = i$ and $\mathbf{q}(\rho) = j$, while $\mathbf{u}(\rho)$ records the nonzero entries of $[\mathbf{x}_i, \mathbf{y}_i]$. It then updates ρ to $\rho + 1$. If the number of columns rows of M_t^{**} is less than $2c_t = 2c_s - 2$, M_t is set to be M_t^{**}. Otherwise, the algorithm turns M_t^{**} into a matrix $\tilde{M}_t$ in row echelon form with authentic operations and removes $\ell \geq c_t$ zero rows of $\tilde{M}_t$ to produce M_t, as was done in `Join Box` (this leads to changes in $\mathbf{p}$)). Matrix N_t is defined as N_t^*.

3 Running time of the algorithm

In this section, we find an upper bound on the number of operation required to produce matrices P, Q and U as in the statement of Theorem 1 using algorithm `Fast Gaussian Elimination`. If the algorithm is given a tree decomposition $\mathcal{T}$ with r nodes and width k of the underlying graph G of matrix M, it first computes a nice tree decomposition $\mathcal{T}'$ of the same width k with fewer than $4(m+n)$ nodes in time $O(k(r+m+n))$ as discussed above. As it turns out, the number of nodes of each type in $\mathcal{T}'$ is at most $m+n$.

We consider the number of operations performed at each type of node. `Leaf Box` initializes a matrix in $r_t \times c_t = O(k^2)$ trivial steps. `Introduce Box` uses $O(k)$ steps to create a row or column filled with zeros.

For `Join Box` and `Forget Box`, the main cost comes from row operations. As each row has size at most $n_t + c_t \leq 2r_t + c_t \leq 2(r_t + c_t) \leq 2k + 2$, each such row operation requires $O(k)$ additions and multiplications. Regarding `Forget Box`, when vertex v_i associated with a row i or vertex w_j associated with a column j is forgotten, either a new type 1 row or column is created, or a new pivot is found. If the latter happens, the algorithm performs at most $m_t + r_t - 1 = O(k)$ row operations, where each row has size at most $O(k)$, leading to $O(k^2)$ field operations. Additionally, the algorithm may perform row operations to keep M_t or N_t of the right size, just as in `Join Box` (see below). If a new type 1 row or column is created, the algorithm just inserts the new row in M_t or the new column in N_t, possibly performing row operations to keep M_t or N_t of the right size, just as in `Join Box`.

It remains to account for the row operations performed to keep matrices M_t and N_t of the right size. Recall that, every time row operations of this type are necessary to produce M_t, we start with a matrix of dimension $m^* \times c_t$, where $m^* \geq 2c_t$ and we create at least $m^* - c_t \geq c_t$ zero rows. These rows become processed. For N_t, we start with a matrix of dimension $r_t \times n^*$, where $n^* \geq 2r_t$ and we identify at least $n^* - r_t \geq r_t$ columns that are linear combinations of other columns. Again, the columns become processed. We shall keep track of the overall number of field operations performed at these steps by "charging" the rows and columns processed at this step, that is, if f field operations are performed and ℓ rows are processed, each of the ℓ rows is charged with f/ℓ operations. Because of the dimensions of the matrices, getting them to row echelon form takes $O(m^{*2}c_t)$ and $O(n^* r_t^2)$ field operations, respectively. In particular, each row can be charged at most $O(m^* c_t) = O(k^2)$ and each column can be charged at most $O(r_t^2) = O(k^2)$. Since any row or column may be processed at most once in this way, the overall number of field operations that the algorithm performs to keep matrices M_t or N_t of the right size is $O((m+n)k^2))$.

Overall, the number of operations taken by the algorithm to produce the vectors $\mathbf{p}$ and $\mathbf{q}$, in addition to vectors $\mathbf{u}(i)$ and $\mathbf{w}(j)$ for every $i \leq \rho = \operatorname{rank}(A)$ and every $j > \rho$ is $O(k(|\mathcal{T}| + m + n) + k^2(m+n))$.

We now consider the decomposition $U_t = P_t \tilde{A}_t Q_t$. The matrices P and Q are defined using $\mathbf{p}$ and $\mathbf{q}$ with no additional field operations. Indeed, $P = (p_{ij})$ is the permutation matrix such that $p_{\mathbf{p}(i)i} = 1$ for $1 \leq i \leq m$, while $Q = (q_{ij})$ is the permutation matrix such that $q_{\mathbf{q}(i)i} = 1$ for $1 \leq i \leq n$.

For U, the entries may be computed in two ways. They are either obtained from a vector $\mathbf{u}(i)$ with no additional computation, or they are obtained as a linear combination of $O(k)$ earlier values using coefficients recorded in $\mathbf{w}(j)$, which requires $O(k)$ sums and products. The number of operations performed to obtain entries of the second type is at most

$$\sum_{\ell=\operatorname{rank}(A)+1}^{n} (m - \gamma_\ell)O(k) = O((n - \operatorname{rank}(A))km). \tag{6}$$

This concludes the analysis.

4 Consequences of Theorem 1

We conclude the paper with the statement of results that are immediate consequences of Theorem 1.

▶ **Corollary 3.** *If A is an $m \times n$ matrix whose bipartite graph is given with a tree decomposition of width k with $O(m+n)$ nodes and b is a column vector of length n, then using $O(k^2(m+n))$ time and arithmetic operations, it can be decided whether the system of linear equations $Ax = b$ has a solution, and if so, then such a solution can be produced.*

Proof. To get one solution of the system of linear equations $Ax = b$, the algorithm to transform A into row echelon form is augmented by doing all row operations on the right hand side as well. If one ever gets a zero row on the left hand side together with a non-zero value on the right hand side, then the system has no solutions. Otherwise, with the left hand side in row echelon form, a solution is obtained by back-substitution. Hereby, all variables that correspond to columns that have been identified as linearly dependent during the algorithm, or just have no pivot, are set to 0. ◀

▶ **Corollary 4.** *The following hold if A is an $m \times n$ matrix whose bipartite graph is given with a tree decomposition of width k with $O(n)$ nodes:*

(a) *The rank of A can be computed using $O(k^2(m+n))$ time and arithmetic operations.*

(b) *For $m = n$, the determinant of A can be computed using $O(k^2 n)$ time and arithmetic operations.*

Proof. The rank is just the number of non-zero rows of the output matrix U. If one of the columns is a linear combination of previous columns, the determinant is zero. Otherwise, the determinant is just the product of the signs of the permutation matrices P and Q with the product of the diagonal elements of the equivalent matrix in row echelon form. ◀

▶ **Corollary 5.** *For a graph given with a tree decomposition of width k with $O(n)$ nodes, the size of a maximum matching can be computed using $O(k^2 n)$ time and arithmetic operations by a randomized algorithm with with one-sided error that is correct with probability at least $1 - 1/n^c$ for an arbitrary constant. In case of an error, the algorithm reports a suboptimal value.*

Proof. This follows from Theorem 1.4 of Fomin et al. [5] by replacing their $O(k^3 n)$ rank algorithm by our $O(k^2 n)$ rank algorithm. ◀
