Hardness of Computation of Quantum Invariants on 3-Manifolds with Restricted Topology

Abstract

Quantum invariants in low-dimensional topology offer a wide variety of valuable invariants about knots and 3-manifolds, presented by explicit formulas that are readily computable. Their computational complexity has been actively studied and is tightly connected to topological quantum computing. In this article, we prove that for any 3-manifold quantum invariant in the Reshetikhin-Turaev model, there is a deterministic polynomial time algorithm that, given as input an arbitrary closed 3-manifold M, outputs a closed 3-manifold M' with the same quantum invariant, such that M' is hyperbolic, contains no low genus embedded incompressible surface, and is presented by a strongly irreducible Heegaard diagram. Our construction relies on properties of Heegaard splittings and the Hempel distance. At the level of computational complexity, this proves that the hardness of computing a given quantum invariant of 3-manifolds is preserved even when severely restricting the topology and the combinatorics of the input. This positively answers a question raised by Samperton [44].

Funding This work has been partially supported by the ANR project ANR-20-CE48-0007 (AlgoKnot) and the project ANR-15-IDEX-0001 (UCA JEDI). It has also been supported by the French government, through the France 2030 investment plan managed by the Agence Nationale de la Recherche, as part of the "UCA DS4H" project, reference ANR-17-EURE-0004.

Acknowledgements We are grateful to Lukas Woike, Alex He, and Nicolas Nisse for helpful discussions on Vafa's theorem, triangulations of Heegaard splittings, and general complexity theory, respectively. We also thank the anonymous reviewers for their thoughtful comments and constructive feedback, which greatly contributed to improving the clarity, rigor, and quality of this paper.

1 Introduction

Quantum invariants are topological invariants defined using tools from physics, explicitly, from topological quantum field theories (TQFTs). These invariants have become of interest for modeling phenomena in condensed matter physics [5, 19], topological quantum computing [29], and experimental mathematics [14, 38], where many deep conjectures remain open. Thanks to their diversity and discriminating power to distinguish between non-equivalent topologies, they have also played an important role in the constitution of censuses of knots and 3-manifolds [12]. The invariants are constructed from the data of a fixed algebraic object, called a *modular category*, and a topological support, and take the form of a partition function, whose value depends solely on the topological type of the support and not on its combinatorial

presentation. Generally, quantum invariants are defined for presentations of either knots or 3-manifolds, although there are types of invariants, such as the Reshetikhin-Turaev, whose definitions naturally encompass both objects.

The complexity of the exact and approximate computation of these invariants has attracted much interest, particularly in connection with quantum complexity classes. Most non-trivial quantum invariants turn out to be #P-hard to compute and, sometimes, even #P-hard to approximate [3, 20, 30] within reasonable precision. This is the case of the Jones polynomial for knots [20, 30] and the Turaev-Viro invariant of 3-manifolds associated with the Fibonacci category [3, 20]. On the positive side, polynomial time *quantum* algorithms exist for computing weak forms of approximations [2, 4, 20] and efficient *parameterized* algorithms have been designed [11, 13, 34, 36, 39] leading to polynomial time algorithms on certain families of instances. For the latter, the topology of the input knot or 3-manifold plays a central role in measuring the computational complexity of the problem, either directly with running times depending strongly on some topological parameter [15, 39], or indirectly where *simple topologies* guarantee the existence of simple combinatorial representations [23, 25, 37] that can be, in turn, algorithmically exploited.

There are other instances, however, where the hardness of computing the invariants is preserved even if the topology and combinatorics of the input are restricted. In [30], Kuperberg shows that, for certain quantum invariants that are *hard to approximate* on *links*, the hardness is preserved when restricted to *knots*. In a follow-up work, Samperton [44] proves that if computing a quantum invariant is hard for all input diagrams of any knot, then the computation remains hard when restricting the input to *hyperbolic* knots given by diagrams with a minimal number of crossings. In this article, we follow a similar path to both [30] and [44], this time for quantum invariants of 3-manifolds, by proving the hardness of computing invariants of irreducible presentations and hyperbolic manifolds.

We follow the strategy of Samperton [44], which consists of using Vafa's theorem [54] to efficiently complicate the topological structure of the input without changing the invariant. Nonetheless, while Samperton's process involves adding extra crossings to the knot diagrams, we increase the *Hempel distance* of a *Heegaard diagram* of some 3-manifold. Although there exists an extensive catalog of algorithms to increase Hempel distances [17, 22, 26, 28, 33, 42, 56], to the best of our knowledge, our work is the first to 1. explicitly compute the involved complexities, ensuring polynomial time; and, 2. keep some 3-manifold invariant constant throughout the process.

The main result is expressed in Theorem 1, whose precise statement can be found in Section 4. Here and throughout the paper, we denote by Σ_g the *closed surface of genus* g (unique up to homeomorphism) with some fixed orientation and assume $g \geq 2$. When referring to a general compact surface, potentially with boundary, we use Σ.

▶ **Theorem 1.** *Let $\mathcal{C}$ be a modular category and M a closed 3-manifold represented by a Heegaard diagram $(\Sigma_g, \alpha, \beta)$ of complexity m. There is a deterministic algorithm that constructs, in time $O(\mathrm{poly}(m, g))$ and uniformly on the choice of $\mathcal{C}$, a strongly irreducible Heegaard diagram $(\Sigma_{g+1}, \alpha', \beta')$ representing a hyperbolic 3-manifold M' that shares with M the Reshetikhin-Turaev invariant over $\mathcal{C}$. Moreover, for a fixed choice of $k \in \mathbb{N}$, M' has no embedded orientable and incompressible surface of genus at most $2k$.*

▶ Remark 2. Hyperbolicity has historically been used as both a simplifying structure and an intermediate step for algorithms on 3-manifold, see for example [31, 50]. Similarly to [44] for knots, our result proves that hyperbolicity is of no help for the computational complexity of the quantum invariant. On the other hand, when producing hard instances of 3-manifolds in computational topology – e.g., in complexity reduction [1, 6] or the construction of

combinatorially involved manifolds [24] – it is common to produce *Haken* 3-manifolds with low genus incompressible surfaces (generally, tori). It is an important open question to understand the hardness of computation for non-Haken 3-manifolds. Our result shows that the computational complexity of quantum invariants is preserved even when getting rid of low-genus incompressible surfaces.

The paper is divided into four parts: a review of background material (Section 2), the demonstration of some auxiliary algorithms (Section 3), the proof our main result (Section 4), and some illustration of its computational consequences for the hardness of computing quantum invariants (Section 5). Due to the conference's constraints, some of the demonstrations were omitted from this current article, but can be found in the extended version of the paper[1].

2 Background material

In the following review, we assume acquaintance with the basic ideas from geometric topology, such as boundaries, compactness, homeomorphisms, (free) homotopies, isotopies, and manifolds. For these topics, we refer the reader to [49] and [51]. Moreover, we shall use, without properly defining, some well-known concepts belonging to the theories of curves and surfaces, which can be found in [18].

2.1 Curves in surfaces

An *arc* in a surface Σ is the image of a proper embedding of the interval in Σ (i.e., its endpoints lie both on $\partial\Sigma$). Similarly, a *simple closed curve* is the image of a proper embedding $S^1 \hookrightarrow \Sigma$. We will often refer to a simple closed curve by only *closed curve* or just *curve*. A *multicurve* is a finite collection of disjoint properly embedded simple curves in Σ. We denote by $\#\gamma$ its number of connected components. Whenever possible, we distinguish simple curves from multicurves by using Greek letters to represent the latter.

A curve in the surface will be called *essential* if not homotopic to a point (or, equivalently, if it does not bound a disk on the surface), a puncture, or a boundary component. A multicurve is essential if all its components are essential. Unless otherwise stated, all curves and multicurves will be assumed essential.

We will often be interested not in a curve s, but in the equivalence classes of s up to *isotopies* in Σ_g, $[s]$. Being essential is preserved under isotopies, so we naturally extend the definition of essential curves to their isotopy classes. For two curves s, t in some surface Σ, their *geometric intersection number* is defined as the minimal number of their intersection points up to isotopy, that is $i(s,t) = \min\{|s' \cap t'| : s' \in [s], t' \in [t]\}$. Two curves in a surface Σ_g are isotopic if and only if they are (free) homotopic [18].

The *curve graph* of a closed surface Σ_g, $C(\Sigma_g)$, is the graph whose vertices are isotopy classes of essential curves and any two vertices $[s]$ and $[t]$ are connected by an edge if and only if $i(s,t) = 0$. The usual graph distance d defines a metric on the vertices of $C(\Sigma_g)$ that is interpreted as $d([s],[t]) = n$ implying the existence a sequence of essential curves $r_0, r_1, \ldots, r_n$ with $r_0 \in [s]$, $r_n \in [t]$, and $r_i \cap r_{i+1} = \emptyset$ for $0 \leq i < n$. The definitions related to the curve graph can be naturally extended to curves by identifying the elements of an isotopy class to the same vertex; in particular, $d(r,s) = 0$ is equivalent to r and s being isotopic.

[1] Available at `https://arxiv.org/abs/2503.02814`.

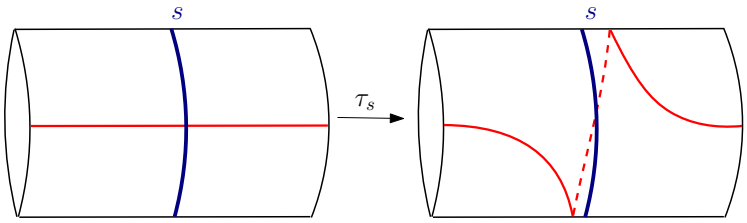

Figure 1 Illustration of the action of a Dehn twist about a curve s (blue) on some curve transversal to it (red). The homeomorphism is only different from the identity on a regular neighborhood of s.

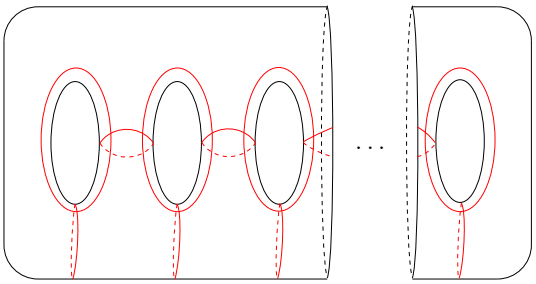

Figure 2 Diagram representing the Lickorish curves in a closed surface $\Sigma_g, g \geq 2$.

We recall that for each surface Σ_g, its *mapping class group*, $\mathrm{Mod}(\Sigma_g)$, is the group of orientation-preserving homeomorphisms $\Sigma_g \to \Sigma_g$ up to isotopies. Its canonical action on the surface conserves the geometric intersection number between curves [18], therefore acting isometrically on $(C(\Sigma_g), d)$ by the induced map $\phi \cdot [s] = \phi_*([s])$. The mapping class groups always contain the (isotopy classes of) *Dehn twists*, homeomorphisms $\tau_s : \Sigma_g \to \Sigma_g$ defined by cutting off a local neighborhood of the (multi)curve s of Σ_g and gluing it back with a 2π counterclockwise twist, determined by the orientation of the surface (Figure 1). In particular, for each $g \geq 2$, $\mathrm{Mod}(\Sigma_g)$ is generated as a group by (isotopy classes of) Dehn twists about the $3g-1$ recursively defined *Lickorish curves* in Σ_g (Figure 2) [32]. We can, consequently, always assume that an element of $\mathrm{Mod}(\Sigma_g)$ is of form $\phi = \tau_{s_r}^{n_r} \circ \cdots \circ \tau_{s_1}^{n_1}$, where $n_i \in \mathbb{Z}$ and s_i are Lickorish curves for $1 \leq i \leq r$.

2.2 Curves on handlebodies and Heegaard splittings

An essential multicurve $\gamma \subset C(\Sigma_g)$ is a *(full) system* if no two components are isotopic to each other and $\Sigma_g - \gamma$ is a union of $\#\gamma - g + 1$ punctured spheres (here the minus sign indicates cutting the surface along γ). The minimum number of connected components that a full system may have is g, in which case $\Sigma_g - \gamma$ is a $2g$-punctured sphere and γ is called a *minimum* system. On the other extreme, a system γ is *maximum* or a *pants decomposition* when $\#\gamma = 3g-3$ and $\Sigma_g - \gamma$ is the union of $2g-2$ thrice punctured spheres, also known as *pairs of pants* (see Figure 4). When every connected component of a system γ is isotopic to a connected component of another system γ', we say that γ is *contained* in γ' and denote that by $\gamma \subseteq \gamma'$. A minimum system γ can always be extended to a pants decomposition $\rho \supseteq \gamma$, see Theorem 16.

The genus g *handlebody* defined for a full system γ in the surface Σ_g is the 3-manifold

$$V_\gamma = \Sigma_g \times [0,1] \cup_{\gamma \times \{0\}} \text{2-handles} \cup \text{3-handles}$$

built by attaching the 2-handles along the curves γ in $\Sigma \times \{0\}$ and then filling any resulting S^2 boundary component with 3-handles. By construction $\partial V_\gamma = \Sigma_g$. Because the curves in

the system γ are assumed to be essential, each of its components will bound (non-trivial) compression disks in V_γ: they will be *meridians* of the handlebody. There are, however, many other meridians in V_γ, as it will be implied by the following definition.

▶ **Definition 3** (Disk graph and equivalent systems). *Let V_γ be a handlebody constructed over Σ_g. Then the disk graph of V_γ, K_γ, is the subgraph of $C(\Sigma_g)$ whose vertices represent (isotopy classes of) meridians of V_γ. We say that two full systems, γ and γ', (potentially with $\#\gamma \neq \#\gamma'$) are equivalent if $\gamma' \subset K_\gamma$ and $\gamma \subset K_{\gamma'}$.*

Note that γ is equivalent to γ' if and only if they define the same handlebody. In particular, if $\gamma \subset \rho$, γ and ρ are equivalent.

In a seminal work, Hempel [22] studied the metric d of the disk graph canonically inherited from $C(\Sigma_g)$. This inspires the next definition. Here and throughout, whenever $A, B \subset C(\Sigma)$ and r is a curve in Σ, we let $d(r, A) = \min\{d(r, s) : s \in A\}$ and $d(A, B) = \min\{d(s, t) : s \in A, t \in B\}$. We assume a curve s on a handlebody V_γ to be fully contained in ∂V_γ.

▶ **Definition 4** (Diskbusting curves). *An essential curve s on a handlebody V_γ is said to be diskbusting if $d(s, K_\gamma) \geq 2$, that is, if s intersects all meridians of V_γ.*

[52] provides a combinatorial condition to verify if a curve on a handlebody is diskbusting, which we quote using the language of [56]. Before, however, we will need a definition.

▶ **Definition 5** (Seams and seamed curves). *An arc in a pair of pants P is called a* seam *if it has endpoints on two distinct components of ∂P. A curve s in a surface Σ_g with a pants decomposition ρ is said to be* seamed *for ρ if, for every component P of $\Sigma_g - \rho$, $s \cap P$ has at least one copy of each of the three types (up to isotopy) of seams in P.*

▶ **Theorem 6** (Theorems 1 of [52], Theorem 4.11 of [56]). *Let s be a curve on the handlebody V_γ. Then s is diskbusting in V_γ if and only if there is a pants decomposition ρ equivalent to γ such that s is seamed for ρ.*

A closed 3-manifold M is said to have a *Heegaard splitting* if it is the union of two handlebodies intersecting only at their common boundary. It is well-known [45] that there exists, for every closed 3-manifold M, a tuple $(\Sigma_g, \alpha, \beta)$ called a *Heegaard diagram (of genus g)*, where α and β are two full systems with the same cardinality in Σ_g, and a Heegaard splitting $M = V_\alpha \cup_{\Sigma_g} V_\beta$. Note, on the other hand, that neither the Heegaard diagram nor the splitting is unique: for example, isotopies to α or β yield the same splitting, whereas given a diagram $(\Sigma_g, \alpha, \beta)$, one can define another splitting for the same manifold, this time of diagram $(\Sigma_{g+1}, \alpha \cup \{c\}, \beta \cup \{c'\})$, where c and c' are curves with $i(c, c') = 1$ fully contained in the extra handle. This last process, known as *stabilization*, is topologically equivalent to directly summing a copy of S^3 to the original manifold M.

Some properties of 3-manifolds can be read straight-up from their Heegaard splittings. For example, a splitting $(\Sigma_g, \alpha, \beta)$ is called *irreducible* if V_α and V_β do not share a meridian. Haken's lemma [49, Theorem 6.3.5] implies that reducible closed 3-manifolds cannot have irreducible Heegaard splittings. Similarly, a splitting $(\Sigma_g, \alpha, \beta)$ is *strongly irreducible* if there are no two essential disjoint curves a and b in Σ_g such that a is a meridian of V_α and b is a meridian of V_β. Every strongly irreducible splitting is irreducible, but the converse is not true (Haken manifolds provide a list of counterexamples [49]).

Given two handlebodies V_α and V_β, we define their *Hempel distance* by $d(K_\alpha, K_\beta)$. In [22], Hempel argued that this distance could be seen as a measure of the complexity of a Heegaard splitting $V_\alpha \sqcup_{\Sigma_g} V_\beta$, which is translated into the following theorem, whose proof (a simple application of results by others) can be found in the full version of the paper.

▶ **Theorem 7.** *Let $(\Sigma_g, \alpha, \beta)$ be a Heegaard diagram of distance $d(K_\alpha, K_\beta) = k$. Then*
- *$k \geq 1$ if and only if $(\Sigma_g, \alpha, \beta)$ is irreducible;*
- *$k \geq 2$ if and only if $(\Sigma_g, \alpha, \beta)$ is strongly irreducible;*
- *if $k \geq 3$, then M is hyperbolic;*
- *M has no orientable and incompressible embedded surface of genus smaller than $2k$.*

▶ Remark 8. Scharlemann and Tomova [48] proved that, if $V_{\alpha'} \cup_{\Sigma_{g'}} V_{\beta'}$ is Heegaard splitting of genus smaller than $k/2$, then $V_\alpha \cup_{\Sigma_g} V_\beta$ is *isotopic* to $V_{\alpha'} \cup_{\Sigma_{g'}} V_{\beta'}$, potentially after finitely many stabilizations. In particular, if $k > 2g + 2$, the splitting is of minimum genus. Unfortunately, as we will see in the proof of Theorem 1, our algorithm is not polynomial time as function of k, which means that it does not imply an efficient reduction to a minimal genus splitting for every input.

Our proof of Theorem 1 will mainly consist of increasing the Hempel distance so that the hypotheses of Theorem 7 are satisfied. For such, we will extensively use the next two theorems due to Yoshizawa.

▶ **Theorem 9** (Theorem 5.8 of [56])**.** *Consider the full systems of curves α and β in Σ_g and $n = \max\{1, d(K_\alpha, K_\beta)\}$. Let $d_i = d(K_i, s)$ for $i = \alpha, \beta$, assume $d_i \geq 2$ and $d_\alpha + d_\beta - 2 > n$. Then, for any $k \in \mathbb{Z}^+$,*

$$\min(k, d_\alpha + d_\beta - 2) \leq d(K_\alpha, K_{\tau_s^{k+n+2}(\beta)}) \leq d_\alpha + d_\beta. \tag{1}$$

▶ **Theorem 10** (Theorem 6.2 of [56])**.** *Let $\gamma = \{c_1, \ldots, c_g\}$ be full in Σ_g and ρ a pants decomposition containing γ. Suppose s is seamed for ρ and define the multicurve $\tau_s^2(\gamma)$ of components $d_1, \ldots, d_g$. Then $d(K_\gamma, \tau_{d_g}^2 \circ \cdots \circ \tau_{d_1}^2(c_1)) \geq 3$.*

2.3 Quantum invariants for 3-manifolds

We will not review the technical construction of TQFTs here, referring the interested reader to [53]. For our purposes, it is enough to know that, for a fixed choice of modular category $\mathcal{C}$ (again, refer to [53] for the definition), the TQFT associates to every closed 3-manifold M a complex scalar known as its *Reshetikhin-Turaev* (RT) invariant. The RT invariant can be given as a function of a Heegaard diagram $(\Sigma_g, \alpha, \beta)$ of M and is denoted by $\langle M \rangle_{\mathcal{C}}^{RT}$ or $\langle (\Sigma_g, \alpha, \beta) \rangle_{\mathcal{C}}^{RT}$, depending on whether we want to emphasize the manifold or the diagram.

The algebraic structure imposed by the modular category sets some constraints on the quantum invariants. The next theorem, for example, is already somewhat folklore in the literature (see [41]) since it implies that non-homeomorphic 3-manifolds may share RT invariants. It can be deduced from Theorem 5.1 of [16] and [43, 53].

▶ **Theorem 11** (Vafa's theorem for 3-manifold TQFTs)**.** *Let $\mathcal{C}$ be a modular category. Then there is an $N \in \mathbb{Z}^+$, depending only on $\mathcal{C}$, such that, for all $k \in \mathbb{Z}$ and every curve s in Σ_g, $\langle (\Sigma_g, \alpha, \beta) \rangle_{\mathcal{C}}^{RT} = \langle (\Sigma_g, \alpha, \tau_s^{kN}(\beta)) \rangle_{\mathcal{C}}^{RT}$.*

For a fixed modular category, we call the integer N the category's *Vafa's constant*.

2.4 Relevant data structure

An embedded graph $G = (V, E)$ in a surface Σ defines a *cellular complex* for Σ if $\Sigma - G$ is a union of open disks, which we call *faces*. Note that this implies that any boundary component of Σ fully lies within some set of edges in E. The *dual graph* of G is another graph embedded in Σ defined by assigning a vertex to each face of $\Sigma - G$ and an edge between the vertices

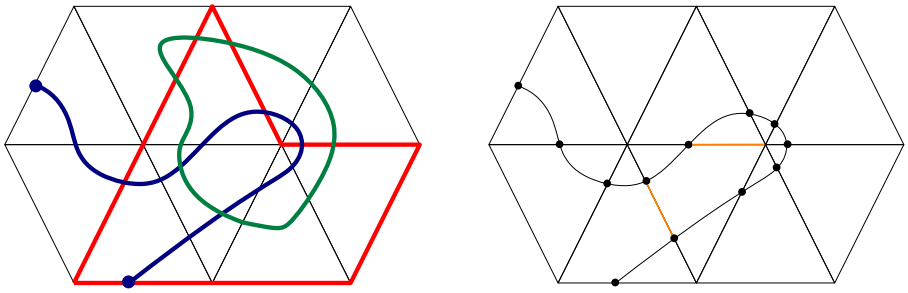

Figure 3 A triangulation of the disk with a curve represented by edge list (red), a standard curve (green), and a normal arc (blue).

if and only if the corresponding faces are separated by an edge in E. As a data structure, we represent a cellular embedding by the lists of faces, their incident edges, and vertices, allowing us to reconstruct Σ by gluing the appropriate pieces. Using this structure, one can compute the dual graph of the cellular embedding in linear time on the number of faces.

A *(generalized) triangulation* $T = (V, E)$ *of a surface* Σ is a cellular complex where all faces are bounded by exactly 3 edges. We denote the number of triangles in a triangulation by $|T|$; note that $|T| = O(|E|)$. We will most often consider *oriented triangulations* by giving an orientation to each triangle consistent with the orientation of the surface; we orient a triangle by imposing an order to its vertices as in the right-hand rule. We say that a triangulation T' of a surface Σ is a *subtriangulation* of another triangulation T of Σ, denoting $T \leq T'$, if the graph of T is embedded on T' (i.e., each vertex of T is a vertex of T' and each edge of T is a union of edges in T'). 'If T and T' are oriented, we also require the induced order of the vertices to be the same. Every face of T' is naturally contained in a face of T.

Using a triangulation $T = (V, E)$ of a surface Σ, we can describe an arc, curve, or multicurve s in Σ lying fully within the edges E by the list of the edges in $E \cap s$ (the red curve in Figure 3). We will call this list an *edge list representation* of the curve s, denote it by $E_T(s)$, and say that the number of edges in $E \cap s$ is the *edge complexity*, $\|E_T(s)\|$. We can always assume that $\|E_T(s)\| \leq |T|$.

For any fixed triangulation T of the surface Σ, there are always, however, isotopy classes of curves in Σ not representable as a subset of edges of T. To deal with this hindrance, we say, for a fixed oriented triangulation $T = (V, E)$ of the surface Σ, that a curve s is *standard* (to T) if it intersects T only transversely and at edges (green curve of Figure 3). If s is standard, we may represent it as an *intersection word* $I_T(s)$, taking E as an alphabet and traversing s along some arbitrary direction and, whenever we meet an edge $e \in E$, we append e to $I_T(s)$ if e is crossed according to the orientation of Σ and e^{-1} otherwise. While the edge representation is well-defined at the curve level, intersection words are defined only up to isotopies inside the triangulation's faces. Furthermore, isotopy classes of $I_T(s)$ are closed under cyclic permutations and taking inverses. The *complexity of an intersection word* $I_T(s)$, $\|I_T(s)\|$, is its length (i.e., the number of edges of T intersected by s, counted with multiplicity). If γ is a multicurve, we let $I_T(\gamma)$ be the set of $\#\gamma$ intersection words representing each component. Similarly, the complexity of a Heegaard diagram $(\Sigma_g, \alpha, \beta)$, where α and β are standard multicurves, equals $\|I_T(\alpha)\| + \|I_T(\beta)\|$. Standard arcs are treated accordingly.

A standard curve, multicurve or arc s is *normal* if no intersection word $I_T(s)$ contains a substring of form ee^{-1} or $e^{-1}e$ where $e \in E$ (the blue curve in Figure 3). When normal, the intersections of s and the faces of the triangulation are arcs connecting distinct edges

of each triangle, which we call *fundamental arcs*. Normal curves are more convenient for tracing than their more general standard counterparts (refer to Proposition 14); moreover, any standard curve s can be made normal in time $O(\|I_T(s)\|)$, see the proof of Theorem 15.

▶ Remark 12. When a curve is normal for a triangulation, its isotopy class is fixed by the number of times it intersects each labeled edge of E [46], meaning that it can be described through a vector in $\mathbb{N}^{|E|}$ called the curve's *normal coordinates* [8, 9, 46, 47], but whose introduction is unnecessary to the results of Section 4.

3 Algorithms for curves in surfaces and handlebodies

3.1 Converting between representations of curves

In Section 2.4, we saw two representations of curves in a surface: edge lists and intersection words. While some topological operations such as cutting along a curve are easier to implement using edge list representations (one needs only to delete the edges crossing $E_T(s)$ from the dual graph of T to cut along s), others, such as doing Dehn twists (Theorem 15) are more suited to curves intersecting the triangulation transversely. Therefore, it will be convenient to have procedures to convert from one representation to the other.

First, we describe an algorithm to transform curves represented by edge lists into intersection words. For an edge list $E_T(s)$ not in a boundary of an oriented surface Σ, there are two choices of normal curves isotopic to s created by slightly displacing it either to the left or to the right of the edges (with respect to the orientation of Σ and some arbitrary orientation of s); we call them *twins born from* s. Given a choice of twin for s, say left, one can compute its intersection word by traversing s and appending the letters representing adjacent edges coming from the left side of the triangulation graph when embedded in Σ. If, however, s lies either partially or fully on the boundary of Σ, we can only consistently displace it to one side, which can be determined in time $O(\|E_T(s)\|)$. This algorithm does not change the triangulation. For convenience, we state this argument as the following proposition.

▶ **Proposition 13.** *Suppose $E_T(s)$ is an edge list representation of an arc, curve, or multicurve s in Σ. Then there is an algorithm to compute an intersection word $I_T(s)$ of complexity $O(|T|)$ in time $O(|T|)$.*

The next result, whose proof is in the paper's full version, describes an algorithm for the other direction, that is, for going from an intersection word to an edge list representation.

▶ **Proposition 14.** *Suppose that s is a normal arc, curve, or multicurve to some triangulation T, with $\|I_T(s)\| = m$. Then, there exists an algorithm that constructs, in time $O(m + |T|)$, a new triangulation $T' \geq T$ of size $O(m + |T|)$ with s in the edges of T'.*

3.2 Basic operations on curves, handlebodies, and Heegaard splittings

Before proceeding with the main results, we will establish algorithms for some basic operations. The first of these is only a minor modification of [47], whereas the second, in the context of curves in surfaces, is mostly due to [55, Theorem 7.1]. The proofs of both theorems are in the paper's full version.

▶ **Theorem 15.** *Suppose t and s are normal (multi)curves for some fixed triangulation T of Σ_g, given through intersection words $I_T(s)$ and $I_T(t)$ with $m = \max\{\|I_T(s)\|, \|I_T(t)\|\}$. Then an intersection word for $\tau_s^k(t)$ for all $k \in \mathbb{Z}$, with $\|I_T(\tau_s^k(t))\| \leq |k|m^3$, can be computed in time $O(|k|m^3)$.*

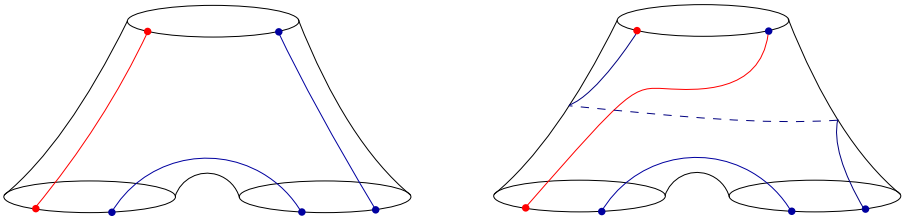

Figure 4 Left: the three types of seams, up to isotopy, on a pair of pants. Two connected components (a red and a blue one) of the multicurve σ are highlighted. Right: a surgery to connect the two distinct components.

▶ **Theorem 16.** *Suppose γ is a minimal system of edge curves in Σ_g. Then one can compute, in time $O(g|T|)$, a triangulation $T' \geq T$ of size $O(m|T|)$ and a pants decomposition ρ in the edges of T', with $\|E_{T'}(\rho)\| = O(g|T|)$, such that ρ contains γ.*

▶ **Theorem 17.** *Suppose γ is a normal minimal system in Σ_g with respect to a triangulation T, with $\|I_T(\gamma)\| = m$. Then there is an algorithm that outputs, in time $O((m + |T|)g^2)$, a disksbuting curve s for the disk graph K_γ, which is normal to T and is represented by intersection word of complexity $O(g|T|)$.*

Proof. Use Proposition 14 to get an edge list representation of γ in a new triangulation T' of complexity $O(m + |T|)$ and then Theorem 16 for an equivalent pants decomposition $\rho \supseteq \gamma$ of complexity $O(g|T'|)$ as an edge list in another triangulation T'' of Σ_g. We will construct a multicurve σ, seamed for the pants decomposition ρ, intersecting each component twice.

For each component r of ρ, select two edges contained in $E_T(r)$ to be points of intersection with σ. For every connected component P of $\Sigma_g - \rho$ (i.e., P is a pair of pants), we connect each intersection point of a boundary component of P to other intersection points in the two other components of ∂P. To avoid self-intersections of σ, we separately draw in each pair of pants a seam at a time, using breadth-first search in the dual graph, recording the intersection words, and changing the dual graph so that no seam can cross a previously traced seam (see the proof of Theorem 16). Even though we change the dual graph, making it more complicated at each drawing of a seam, because the seams are local within pairs of pants, each application of breadth-first search considers only $O(|T''|)$ nodes and edges. At the end of the process, we have a multicurve σ that, although seamed for the pants decomposition ρ, may have up to $g + 1$ connected components. It therefore remains to modify σ so it has just a single component.

Whenever there are still disconnected components in σ, there exists a pair of pants intersected by at least two distinct components of σ, refer to Figure 4. We can then do the surgery on the right side of Figure 4 to connect the two components. Using breadth-first, this takes a total time of $O(g|T''|)$ and yields a connected curve s of intersection word $I_{T''}(s)$. Because, by construction, s is seamed for each pair of pants from $\Sigma_g - \rho$, by Theorem 6, s is diskbusting for γ. Finally, we compute an intersection word of s with respect to T in time $O(|T''|)$ by deleting the edges in $T''\backslash T$. Note that s is already normal for T as, by construction, s is standard to $T'' \geq T' \geq T$ and, since all paths are shortest, no cyclic reductions are possible. ◀

The proof of the following (slightly technical) result is also carried in the paper's extended version.

▶ **Lemma 18.** *Suppose $(\Sigma_g, \alpha, \beta)$ is a Heegaard diagram, with α and β given as intersection words in a triangulation T of Σ_g, where we $m = \max\{\|I_T(\alpha)\|, \|I_T(\beta)\|\}$. One can find, in time $O(m)$, a triangulation T' and new multicurves α', β' which represent a stabilization $(\Sigma_{g+1}, \alpha', \beta')$ of the original diagram, with $O(|T'|) = O(|T|)$ and $\|I_{T'}(\alpha')\|, \|I_{T'}(\beta')\| = O(m)$.*

4 Restricting the topology of 3-manifolds

Given a Heegaard diagram $(\Sigma_g, \alpha, \beta)$ and a fixed $k \in \mathbb{Z}^+$, the algorithm of Theorem 1 uses Theorems 9 and 11 to construct a new diagram $(\Sigma_{g+1}, \alpha, \tau_s^n(\beta))$ with Hempel distance at least k, without altering the associated RT-invariant in the process, where n is some integer multiple of the associated Vafa's constant and s is a curve distant enough from both K_α and K_β. The main challenge of the algorithm comes, however, from building such a curve s. We address the problem by first computing, through Proposition 20, two curves, say s_α and s_β, of distance at least k from K_α and K_β, respectively. We then use these two curves in Proposition 22 to construct a single curve s, whose distances to K_α and K_β satisfy the hypotheses of Theorem 9.

We establish Proposition 20 incrementally, first using Theorem 17 to find a curve s diskbusting to K_γ, increasing $d(K_\gamma, s)$ to at least 3 using Lemma 19, and finally making the distance bigger than k.

▶ **Lemma 19.** *Let γ be a minimal system in Σ_g, normal to a triangulation T of Σ_g, and given by an intersection word $I_T(\gamma)$ with $\|I_T(\gamma)\| = m$. One can compute, in time $O((gm|T|)^9)$, an intersection word of a normal curve s', of complexity $O((gm|T|)^9)$, with $d(K_\gamma, s) \geq 3$.*

This result is simply an application of Theorem 17 followed by Theorem 10; the details are carried out in the extended version.

▶ **Proposition 20.** *Let γ be a minimal system in Σ_g, normal with respect to some triangulation T. Then, for a fixed $3 \leq k \in \mathbb{Z}^+$, one can compute, in time $c_2^{O(k^{c_1})} \log k$, where $c_1 = \log 3$ and $c_2 = O(gm|T|k)$, the intersection word of a curve s, normal to T and of complexity $c_1^{O(k^{c_2})}$, for which $d(K_\gamma, s) > k$.*

Proof. Start using Lemma 19 to find an intersection word of a curve s_0 with $d(K_\gamma, s_0) \geq 3$. If $k = 3$ we are done, so assume otherwise. Define $M = \|I_T(s_0)\|$; recall that $M = O((gm|T|)^9)$. Let c be any connected component of γ and recursively define $s_{i+1} = \tau_{s_i}^{k_i+3}(c)$, where $k_i = 2^{i+1} + 2$. We claim that, for any $\ell \in \mathbb{Z}^+$, $d(K_\gamma, s_\ell) \geq k_{\ell-1}$. We prove this inducting on ℓ: for $\ell = 1$, $k_0 = 4$ and, by Theorem 9 with $\alpha = \beta = \gamma$ and $n = \min\{d(K_\gamma, K_\gamma), 1\} = 1$, we have that

$$d(K_\gamma, s_1) = d(K_\gamma, \tau_{s_0}^{k_0+n+2}(c)) \geq d(K_\gamma, K_{\tau_{s_0}^{k_0+n+2}(\gamma)}) \geq 4.$$

Now assume $d(K_\gamma, s_\ell) \geq 2^\ell + 2$. Again, by Theorem 9,

$$d(K_\gamma, s_{\ell+1}) = d(K_\gamma, \tau_{s_\ell}^{k_\ell+3}(c)) \geq d(K_\gamma, K_{\tau_{s_\ell}^{k_\ell+3}(\gamma)}) \geq 2d(K_\gamma, s_\ell) - 2 \geq 2(2^\ell + 2) - 2 = 2^{\ell+1} + 2,$$

so, by induction, $d(K_\gamma, s_\ell) \geq k_{\ell-1}$. Setting the total number of iterations at $\ell = \lceil \log(k-2) \rceil$ and $s = s_\ell$, we have that $d(K_\gamma, s) \geq k$.

We now estimate the total computational time and the output's complexity of the algorithm. First, we note that, by Theorem 15, $\|I_T(s_{i+1})\| \leq (k_i + 3)\|I_T(s_i)\|^3$. Recursively, this gives

$$\begin{aligned}
\|I_T(s)\| &\leq M^{3^\ell}(k_0+3)^{3^{\ell-1}}(k_1+3)^{3^{\ell-2}}\dots(k_{\ell-1}+3)\\
&\leq M^{3^\ell}(2^1+5)^{3^{\ell-1}}(2^2+5)^{3^{\ell-2}}\dots(2^\ell+5)\\
&\leq M^{3^\ell}(2^\ell+5)^{3^{\ell-1}}(2^\ell+5)^{3^{\ell-2}}\dots(2^\ell+5)\\
&\leq M^{3^\ell}(2^\ell+5)^{3^{\ell-1}+3^{\ell-2}+\dots+3^0}\\
&\leq M^{3^\ell}(2^\ell+5)^{\frac{1}{2}\times(3^\ell-1)}\\
&\leq M^{3^{\log(k-2)+2}}(2^{\log(k-2)+2}+5)^{\frac{1}{2}\times(3^{\log(k-2)+2}-1)}\\
&\leq M^{9\times 3^{\log(k-2)}}(4k-3)^{9/2\times 3^{\log(k-2)}}\\
&\leq M^{9(k-2)^{\log 3}}(4k)^{5(k-2)^{\log 3}}\\
&\leq M^{9k^{c_1}}(4k)^{5k^{c_1}}
\end{aligned}$$

where we used the geometric series in the fifth line, $\lceil \log(k-2)\rceil \leq \log(k-2)+2$ in the sixth line, the relation $a^{\log b} = 2^{\log a \log b} = b^{\log a}$ for any real $a, b > 1$ in the eighth line, and $c_1 = \log 3$ in the last line. The time complexity for computing $I_T(s)$ can be (very coarsely) estimated at $O(\ell \times (k_{\ell-1}+3)\|I_T(s_{\ell-1})\|^3) = O(\log k \times \|I_T(s)\|) = O((gm|T|)^{81k^{c_1}}(4k)^{5k^{c_1}}\log k)$ by noting that $\|I_T(s_i)\| \leq \|I_T(s_{\ell-1})\|$ and $k_i \leq k_{\ell-1} = k$ for all $1 \leq i \leq n$. ◀

We now show Proposition 22, starting with the following technical lemma, whose proof (a simple application of the triangle inequality) is carried out in the paper's full version.

▶ **Lemma 21.** *Consider some full systems γ and γ' in the surface Σ_g with $d(K_\gamma, K_{\gamma'}) \geq 4$ and a curve s with $d(K_\gamma, s) < 2$. Then $d(K_{\gamma'}, s) \geq 2$.*

▶ **Proposition 22.** *Fix an integer $k \geq 4$. Consider some minimal systems α and β in the surface Σ_g for which $d(K_\alpha, K_\beta) = 0$. Then there is a curve s and some full minimal system β' (potentially $\beta' = \beta$) in Σ_g such that*

$$\min_{i=\alpha,\beta'}\{d(K_i,s)\} \geq 2,\ \max_{i=\alpha,\beta'}\{d(K_i,s)\} \geq k, d(K_\alpha,s)+d(K_{\beta'},s)-2 > n,$$
$$\text{and } \langle(\Sigma_g,\beta)\rangle_{\mathcal{C}}^{RT} = \langle(\Sigma_g,\beta')\rangle_{\mathcal{C}}^{RT}, \tag{2}$$

where $n = \min\{d(K_\alpha, K_{\beta'}), 1\}$. Moreover, if $m = \max\{\|I_T(\alpha)\|, \|I_T(\beta)\|\}$, then $I_T(s)$ and $I_T(\beta')$ will have complexity $Nkc_2^{O(k^{c_1})}$ and are computed in similar time for any choice of Vafa's constant $N \in \mathbb{Z}^+$, where $c_1 = \log 3$ and $c_2 = O(gm|T|k)$.

Proof. We use Proposition 20 to find two curves, s_α and s_β, such that $d(K_\alpha, s_\alpha)$ and $d(K_\beta, s_\beta)$ are larger than k. Note that if s_α is diskbusting in K_β, we are done, as we can let $s = s_\alpha$, $\beta' = \beta$, and

$$d(K_\alpha, s) \geq k,\ d(K_{\beta'}, s) = d(K_\beta, s_\alpha) \geq 2, \text{ and } d(K_\alpha, s) + d(K_{\beta'}, s) - 2 > 1.$$

Therefore, assume $d(K_\beta, s_\alpha) < 2$.

By applying Theorem 15, we compute an intersection word for $\widetilde{\beta} = \tau_{s_\beta}^{N(k+3)}(\beta)$. Note that $\|I_T(\widetilde{\beta})\| = O(Nk\|I_T(s_\beta)\|^3) = O(Nk(gm|T|)^{243k^{c_1}}(4k)^{15k^{c_1}})$ and, by Theorem 9, $d(K_\beta, K_{\beta'}) \geq k$. Moreover, because β' was constructed by applying a power of Dehn twists multiple of N to β, by Theorem 11, $\langle(\Sigma_g,\beta)\rangle_{\mathcal{C}}^{RT} = \langle(\Sigma_g,\beta')\rangle_{\mathcal{C}}^{RT}$.

Pick any component $\widetilde{b}$ of $\widetilde{\beta}$. If $\widetilde{b}$ is diskbusting for K_α, then $s = \widetilde{b}$ and $\beta' = \beta$ have the desired properties. In particular, notice that

$$d(K_\alpha, s) \geq 2,\ \ d(K_{\beta'}, s) \geq d(K_\beta, K_{\widetilde{\beta}}) \geq k, \text{ and } d(K_\alpha, s) + d(K_{\beta'}, s) - 2 > 1.$$

If, however, $\widetilde{b}$ is not diskbusting for K_α, it means that $d(K_\alpha, K_{\widetilde{\beta}}) \leq d(K_\alpha, \widetilde{b}) < 2$. Letting $s = s_\alpha$ and $\beta' = \widetilde{\beta}$ gives

$$d(K_\alpha, s) \geq k, \;\; d(K_{\beta'}, s) \geq 2, \text{ and } d(K_\alpha, s) + d(K_{\beta'}, s) - 2 \geq k \geq 3 > d(K_\alpha, K_{\beta'}),$$

where the second inequality comes from $d(K_\beta, s_\alpha) < 2$ and $d(K_\beta, K_{\widetilde{\beta}}) \geq k \geq 4$ applied to Lemma 21. ◀

We can, once again, combine the above result with Theorem 9 to prove our main reduction.

▶ **Theorem 1.** *Let $(\Sigma_g, \alpha, \beta)$ be a Heegaard diagram of a closed 3-manifold M of complexity m to a triangulation T of Σ_g. Choose a modular category $\mathcal{C}$ with Vafa's constant N and fix an integer $k \geq 4$. Then there is a set of three Heegaard diagrams, computed in time $O_k(\text{poly}(g, m, |T|, N))$ (of degree depending on k), representing manifolds with RT invariant over $\mathcal{C}$ equal to $\langle M \rangle_{\mathcal{C}}^{RT}$, one of them guaranteed to be hyperbolic and with no embedded incompressible orientable surface of genus at most $2k$.*

Proof. We start by using Lemma 18 to compute a stabilized splitting $(\Sigma_{g+1}, \alpha', \beta')$; note that $d(K_{\alpha'}, K_{\beta'}) = 0$. Construct two curves s_α and s_β as in the proof of Proposition 22. Let $\beta_1 = \beta'$ and $s_1 = s_\alpha$.

We proceed as in the proof of Proposition 22, computing an intersection word of a new minimal system $\widetilde{\beta} = \tau_{s_\beta}^{N(k+3)}(\beta')$ and defining $\beta_2 = \beta'$ and $\beta_3 = \widetilde{\beta}$, s_2 as any component of $\widetilde{\beta}$, and $s_3 = s_\alpha$. By Proposition 20, for at least one $1 \leq j \leq 3$

$$\min_{i=\alpha',\beta^j} \{d(K_i, s_j)\} \geq 2, \max_{i=\alpha',\beta^j} \{d(K_i, s_j)\} \geq k, d(K_{\alpha'}, s_j) + d(K_{\beta_j}, s_j) - 2 > n$$

where $n = \max\{d(K_{\alpha'}, K_{\beta_j}), 1\}$. Applying, once again, Theorems 15 and 9, we conclude that one of the splittings $(\Sigma_g, \alpha', \tau_{s_j}^{N(k+3)}(\beta_j))$ has a Hempel distance of, at least, k and an intersection word for $\tau_{s_j}^{N(k+3)}(\beta_j)$ can be found in time $O(Nk(\max\{\|I_T(\beta_j)\|, \|I_T(s_j)\|\})^3)$ $= O(N^4 k^4 (gm|T|)^{729k^{c_1}} (4k)^{45k^{c_1}})$. Theorem 7 finishes the proof. ◀

5 Computational reduction for quantum invariants

Theorem 1 gives a polynomial time algorithm to change a general closed 3-manifold into another manifold with very restricted topology without altering the RT invariant in the process. Therefore, the problems of either exactly computing or approximating the invariant of general 3-manifolds *reduce*, in a Cook-Turing sense, to the problems of exactly computing or approximating the invariant when the manifolds are assumed to have the properties of Theorem 1. Ultimately, this means that the *hardness of computation* is not altered in this restricted topology scenario.

We illustrate this reduction by showing that *value-distinguishing* approximations of the Reshetikhin–Turaev and the Turaev-Viro invariants are #P-hard, even for manifolds with the properties of Theorem 1, when we take $\mathcal{C}$ to be the category of representations of the quantum group $SO_r(3)$, for some prime $r \geq 5$ (in this case, one can use $N = 4r$ for Vafa's constant). We note that, by a value-distinguishing approximation, we mean the ability to determine whether the approximated quantity $c \in \mathbb{R}^+$ is $a > c$ or $b < c$ for any fixed $0 < a < b$ where we assume, as a premise, one of the two to hold. In particular, multiplicative approximations are value-distinguishing, although other less restrictive schemes also are [30].

5.1 Reshetikhin–Turaev invariant

For every Heegaard diagram $(\Sigma_g, \alpha, \beta)$, there is an orientation-preserving homeomorphism $\phi : \Sigma_g \to \Sigma_g$ such that $\beta = \phi(\alpha)$ [18, 56]. A lthough not unique, this map is well-defined on $\text{Mod}(\Sigma_g)$, so it can be described by a word on Lickorish generators. We do not differentiate between the notation of the homomorphism ϕ from its equivalence class in $\text{Mod}(\Sigma_g)$.

▶ **Theorem 23** ([3, 20]). *Consider the problem $\mathcal{P}$ of determining a value-distinguishing approximation of the $SO_r(3)$-RT invariant, $r \geq 5$ prime, of a manifold M, represented through a Heegaard splitting described by a word $\phi \in \text{Mod}(\Sigma_g)$ for some known $g \geq 2$. Then $\mathcal{P}$ is #P-hard in the sense of a Cook-Turing reduction.*

Before applying Theorem 1 to this result, we need to find an algorithm to convert the pair (Σ_g, ϕ) into a proper Heegaard diagram (Σ_g, β). This cannot be done through brute force computing $\beta = \phi(\alpha)$, since, as we saw in the proof of Proposition 20, it can lead to exponential bottlenecks. We fix the problem with the following lemma at the cost of potentially increasing the value of g. The proof of the next, as well as all other results of this section (except for Corollary 25), is found in the paper's full version.

▶ **Lemma 24.** *Consider a Heegaard splitting described by a word $\phi \in \text{Mod}(\Sigma_g)$ for some known $g \geq 2$. Then it is possible to compute, in time $O(\text{poly}(g, \phi))$, a Heegaard diagram $(\Sigma_{g'}, \beta)$ representing the same manifold, with β normal to a triangulation T of $\Sigma_{g'}$.*

▶ **Corollary 25.** *Fix a prime $r \geq 5$. Consider the problem $\mathcal{P}$ of, given a Heegaard diagram (Σ_g, β) of a closed 3-manifold M, returning a value-distinguishing approximation of its $SO_r(3)$-RT invariant if M has the properties of Theorem 1, otherwise remaining silent. Then $\mathcal{P}$ is #P-hard in the sense of a Cook-Turing reduction.*

Proof. Let $\mathcal{O}$ be an oracle machine that solves $\mathcal{P}$ and consider the problem $\mathcal{P}'$ of finding a value-distinguishing approximation of a general Heegaard splitting given as a pair (Σ_g, ϕ) for $\phi \in \text{Mod}(\Sigma_g)$. We will show that $\mathcal{O}$ solves P' with only a polynomial overhead. Because $\mathcal{O}$ solves $\mathcal{P}$ and, by Theorem 23, $\mathcal{P}'$ is #P-hard, then so is $\mathcal{P}$.

Let (Σ_g, ϕ) encode a Heegaard splitting of a manifold M, not necessarily with the properties of Theorem 1. Using Lemma 24, we transform (Σ_g, ϕ) into a Heegaard diagram $(\Sigma_{g'}, \beta)$ in polynomial time. Then apply the algorithm of Theorem 1 to this diagram, returning three new diagrams as output. We run the oracle $\mathcal{O}$ in parallel to these three diagrams, stopping the program whenever it halts for one of them. In the end, this gives, in polynomial time, a value-distinguishing approximation of $\langle M \rangle^{RT}_{SO_r(3)}$, concluding the proof. ◀

▶ Remark 26. We note that the sort of reduction assumed by the statement of Corollary 25 is related to what is often called in the complexity literature by a *semi-decision problem*, that is, an oracle that cannot return an incorrect answer, but may not halt for some inputs. Although weaker than the more common approach in which we assume that $\mathcal{P}$ *can* give incorrect approximation of the invariant if the input does not have the expected properties, this sort of oracle has also already been discussed for algorithm on 3-manifolds, e.g. see the Definition 1.3 in [35].

5.2 Turaev-Viro invariant

A compact 3-manifold can also be combinatorially described by a set of tetrahedra $\mathcal{T}$, together with rules on how to glue their triangular faces [10, 40]. This description is called a *triangulation of the 3-manifold*, but it should not be confused with triangulations of surfaces. Nonetheless, if M has a boundary, $\mathcal{T}$ naturally defines a (surface) triangulation for ∂M. For each $g \geq 1$, there exists a one-vertex triangulation of the handlebody of genus g [27].

The Turaev-Viro invariant (TV) is another quantum invariant for closed 3-manifolds. It is defined for spherical categories (which include modular categories) and is computed directly from a triangulation [7]. The Turaev-Walker theorem [53] states that, given a manifold M, $|\langle M\rangle_{\mathcal{C}}^{RT}|^2 = \langle M\rangle_{\mathcal{C}}^{TV}$, provided $\mathcal{C}$ is a modular category. We show that an approximation of the $SO_r(3)$-TV invariant can be used to compute an approximation of $SO_r(3)$-RT [3]. For such, we use the next theorem due to [21].

▶ **Theorem 27.** *Suppose β is a normal minimal system with respect to a one-vertex triangulation of the standard embedding of the genus g handlebody in $\mathbb{R}^3$, with $\|I_T(\beta)\| = m$. There is an algorithm to compute, in time* $\mathrm{poly}(m, g)$*, a triangulation of the 3-manifold of Heegaard diagram (Σ_g, β).*

▶ **Corollary 28.** *Fix a prime $r \geq 5$. Consider the problem $\mathcal{P}$ of, given a triangulation of a closed 3-manifold M, returning a value-distinguishing approximation of its $SO_r(3)$-TV invariant if M has the properties of Theorem 1, otherwise remaining silent. Then $\mathcal{P}$ is #P-hard in the sense of Cook-Turing reduction.*

Tight Guarantees for Cut-Relative Survivable Network Design via a Decomposition Technique

Abstract

In the classical *survivable-network-design problem* (SNDP), we are given an undirected graph $G = (V, E)$, non-negative edge costs, and some k tuples (s_i, t_i, r_i), where $s_i, t_i \in V$ and $r_i \in \mathbb{Z}_+$. The objective is to find a minimum-cost subset $H \subseteq E$ such that each s_i-t_i pair remains connected even after the failure of any $r_i - 1$ edges. It is well-known that SNDP can be equivalently modeled using a weakly-supermodular *cut-requirement function* f, where the objective is to find the minimum-cost subset of edges that picks at least $f(S)$ edges across every cut $S \subseteq V$.

Recently, motivated by fault-tolerance in graph spanners, Dinitz, Koranteng, and Kortsartz proposed a variant of SNDP that enforces a *relative* level of fault tolerance with respect to G. Even if a feasible SNDP-solution may not exist due to G lacking the required fault-tolerance, the goal is to find a solution H that is at least as fault-tolerant as G itself. They formalize the latter condition in terms of paths and fault-sets, which gives rise to *path-relative* SNDP (which they call relative SNDP). Along these lines, we introduce a new model of relative network design, called *cut-relative* SNDP (CR-SNDP), where the goal is to select a minimum-cost subset of edges that satisfies the given (weakly-supermodular) cut-requirement function to the maximum extent possible, i.e., by picking $\min\{f(S), |\delta_G(S)|\}$ edges across every cut $S \subseteq V$.

Unlike SNDP, the cut-relative and path-relative versions of SNDP are not equivalent. The resulting cut-requirement function for CR-SNDP (as also path-relative SNDP) is not weakly supermodular, and extreme-point solutions to the natural LP-relaxation need not correspond to a laminar family of tight cut constraints. Consequently, standard techniques cannot be used directly to design approximation algorithms for this problem. We develop a *novel decomposition technique* to circumvent this difficulty and use it to give a *tight* 2*-approximation algorithm for* CR-SNDP. We also show some new hardness results for these relative-SNDP problems.

1 Introduction

In the classical *survivable-network-design problem* (SNDP), we are given an undirected graph $G = (V, E)$, non-negative edge costs $\{c_e\}_{e \in E}$, and some k source-sink pairs $s_i, t_i \in V$ with requirements $r_i \in \mathbb{Z}_+$, for $i = 1, \ldots, k$. The goal is to find a minimum-cost set $H \subseteq E$ of edges such that there are at least r_i edge-disjoint s_i-t_i paths in H, for all $i \in [k]$. We overload notation and use H to denote both the edge-set, and the corresponding subgraph of G.

SNDP imposes an absolute level of fault-tolerance in a solution subgraph H, by ensuring that for any bounded-size *fault-set* $F \subseteq E$ of edges that may fail, the graph $H - F$ retains some connectivity properties. More precisely, due to Menger's theorem, or the max-flow min-cut theorem, the feasibility condition on H can be stated equivalently as follows. For every $i \in [k]$, and every fault-set $F \subseteq E$ with $|F| < r_i$:

(S1) (Path-version) there is an s_i-t_i path in $H - F$;

(S2) (Cut-version) for every s_i-t_i cut $S \subseteq V$ (i.e., $|S \cap \{s_i, t_i\}| = 1$), we have $\delta_{H-F}(S) \neq \emptyset$, where $\delta_{H-F}(S) := \delta(S) \cap (H - F)$.

Recently, motivated by work on fault-tolerance in graph spanners, Dinitz, Koranteng, and Kortsartz [8], proposed a variant of SNDP that aims to impose a *relative* level of fault-tolerance with respect to the graph G. The idea is that even if the SNDP instance in infeasible, because G itself does not possess the required level of fault-tolerance, one should not have to completely abandon the goal of fault-tolerance: it is still meaningful and reasonable to seek a solution that is "as fault-tolerant as G", and in this sense is fault-tolerant relative to G.

To formalize this, it is useful to consider the definition of SNDP in terms of fault-sets. Roughly speaking, we would like to capture that H is a feasible solution if

$$\text{for every fault-set } F \text{ (valid for SNDP)}, \quad H - F \text{ and } G - F \text{ have similar connectivity.} \quad (*)$$

To elaborate, in SNDP, if there is *even one* fault-set F' under which $G - F'$ fails to have the required connectivity, i.e., $|F'| < r_i$ and $F' \supseteq \delta_G(S)$ for some s_i-t_i cut S, then "all bets are off"; we declare that the instance in infeasible. But declaring infeasibility here feels unsatisfactory because we allow one specific "problematic" fault-set F' to block us from obtaining any kind of fault-tolerance. In contrast, (*) aims to provide a *per-fault-set guarantee*, by asking for a solution H that functions as well as G in terms of connectivity under the failure of any fault-set F (considered for SNDP). We can formalize "$H - F$ and $G - F$ have similar connectivity" in two ways, via paths or cuts, and this gives rise to the following two problem definitions.

▶ **Definition 1.1.** *Let* $\big(G = (V, E), \{c_e\}_{e \in E}, \{s_i, t_i, r_i\}_{i \in [k]}\big)$ *be an* SNDP *instance.*

(R1) Path-relative SNDP*: $H \subseteq E$ is a feasible solution if for every $i \in [k]$ and $F \subseteq E$ with $|F| < r_i$, $G - F$ has an s_i-t_i path $\implies$ $H - F$ has an s_i-t_i path.*

(R2) Cut-relative SNDP *(CR-SNDP): $H \subseteq E$ is a feasible solution if for every $i \in [k]$ and $F \subseteq E$ with $|F| < r_i$, for every s_i-t_i cut S, $\delta_{G-F}(S) \neq \emptyset \implies \delta_{H-F}(S) \neq \emptyset$.*

The goal in both problems is to find a minimum-cost feasible solution.

Perhaps surprisingly, path-relative SNDP and cut-relative SNDP are *not equivalent*, even when the SNDP instance involves a single s-t pair. It is not hard to show that if H is feasible for CR-SNDP, it is also feasible for path-relative SNDP[1] but the converse fails to hold; see Section 7 for an example.

Path-relative SNDP was defined by Dinitz et al. [8], who referred to this problem simply as relative SNDP. They considered (among other problems) the path-relative version of k-edge connected subgraph (k-ECSS), which is the special case of SNDP where we have an s_i-t_i pair with $r_i = k$ for every pair of nodes. (In this case, the path-relative and cut-relative versions do turn out to be equivalent [8].) They called the resulting path-relative problem, *k-edge*

[1] Fix any $i \in [k]$ and $F \subseteq E$ with $|F| < r_i$. If $G - F$ has an s_i-t_i path, then $\delta_{G-F}(S) \neq \emptyset$ for every s_i-t_i cut. So since H is feasible for cut-relative SNDP, we have $\delta_{H-F}(S) \neq \emptyset$ for every s_i-t_i cut, which implies that $H - F$ has an s_i-t_i path.

fault-tolerant subgraph (k-EFTS), and observed that the feasibility condition for k-EFTS can be equivalently stated as: H is feasible iff $|\delta_H(S)| \geq g(S) := \min\{k, |\delta_G(S)|\}$ for all $S \subseteq V$. The function $g : 2^V \mapsto \mathbb{Z}$ is called a *cut-requirement function*, as it stipulates the (minimum) number of edges across any cut in any feasible solution. Cut-requirement functions constitute a very versatile framework for specifying network-design problems, where given a cut-requirement function $f : 2^V \mapsto \mathbb{Z}$, the corresponding *$f$-network-design problem* (f-NDP), also called the *f-connectivity problem*, is to find a minimum-cost set $H \subseteq E$ such that $|\delta_H(S)| \geq f(S)$ for all $S \subseteq V$. For instance, it is easy to see that SNDP corresponds to f-NDP for the cut-requirement function f^{SNDP}, defined by $f^{\mathsf{SNDP}}(S) := \max\{r_i : |S \cap \{s_i, t_i\}| = 1\}$ (and k-ECSS is $f^{k\text{-ECSS}}$-NDP where $f^{k\text{-ECSS}}(S) := k$ for all $\emptyset \neq S \subsetneq V$); various other network-design problems, such as the T-join problem, point-to-point connection problem etc., can be modeled using suitable cut-requirement functions (see, e.g., [10, 11]).

Cut-relative SNDP is a problem that we introduce in this paper. Its formulation in terms of cuts is the problem one obtains when we replace $f^{k\text{-ECSS}}$ in the cut-based formulation of k-EFTS by the cut-requirement function f^{SNDP} for (general) SNDP: that is, (similar to k-EFTS), we can say that $H \subseteq E$ is feasible for CR-SNDP iff $|\delta_H(S)| \geq g^{\text{CR-SNDP}}(S) := \min\{f^{\mathsf{SNDP}}(S), |\delta_G(S)|\}$ for all $S \subseteq V$ (we show this easy equivalence in Section 2); in other words, CR-SNDP corresponds to $g^{\text{CR-SNDP}}$-NDP. To gain some intuition for cut-relative SNDP, and contrast it with path-relative SNDP, consider SNDP with a single s-t pair and requirement r, for simplicity. A feasible solution H to path-relative SNDP offers a per-fault-set guarantee as encapsulated by (R1). But, for a given fault-set F with $|F| < r$, we get a weak fault-tolerance guarantee in terms of s-t cuts: if $\delta_{G-F}(S) = \emptyset$ for *even one* s-t cut S then there is no requirement on H for this fault-set F. Cut-relative SNDP offers a per-fault-set *and per-cut guarantee*, since for (every F with $|F| < r$ and) every s-t cut S, we require that $\delta_{H-F}(S) \neq \emptyset$ if $\delta_{G-F}(S) \neq \emptyset$.

Along the lines of CR-SNDP, we can easily extend the cut-relative model to capture, more broadly, the cut-relative version of any network-design problem specified by a cut-requirement function: given a cut-requirement function f, in the corresponding *cut-relative f-network-design problem* (CR-f-NDP), we seek a min-cost $H \subseteq E$ such that $|\delta_H(S)| \geq g^{\text{CR-}f\text{-NDP}}(S) := \min\{f(S), |\delta_G(S)|\}$ for all $S \subseteq V$; that is, we seek to satisfy the cut-requirement function f to the maximum extent possible. We refer to f as the *base cut-requirement function*, to distinguish it from the cut-requirement function $g^{\text{CR-}f\text{-NDP}}$ that defines CR-f-NDP.

Modeling power. We arrived at CR-f-NDP, which can be seen as a fault-tolerant cut-covering problem, as a technically natural extension of k-EFTS. We show below that CR-f-NDP offers a surprising amount of modeling power, and, in particular, allows one to capture stronger forms of relative fault-tolerance compared to k-EFTS. In k-EFTS, there is a sharp relative-fault-tolerance threshold at k: if H is feasible, then $G - F$ and $H - F$ have the same components whenever $|F| < k$, but there are no guarantees for larger fault-sets. With CR-f-NDP, one can capture a weaker guarantee also for other fault-sets, which allows for a more *graceful degradation* of relative fault-tolerance as $|F|$ increases.

▶ **Example 1.2.** One way of modeling graceful relative-fault-tolerance degradation is as follows: given a *non-increasing function* $\tau : \mathbb{Z}_+ \mapsto \mathbb{Z}_+$, we seek a min-cost subgraph H such that for *every* fault-set F, $G - F$ and $H - F$ have exactly the same components with at most $\tau(|F|)$ nodes. If G models a communication network where connected nodes can communicate with each other, then this yields the desirable guarantee that, *post-faults*, if a node can communicate with more than $\tau(|F|)$ nodes in G then the same holds for H; if

this number is at most $\tau(|F|)$, then post-faults, it can communicate with the same nodes in G and H. Note that if $\tau(k-1) \geq n = |V|$, then H is feasible for k-EFTS; by adding more "levels" to τ, we can obtain fault-tolerance guarantees for larger fault-sets.

In Section 3, we show that this problem can be modeled as CR-f-NDP with the weakly-supermodular function $f = f^{\mathsf{grace}}$, where $f^{\mathsf{grace}}(S) := \min\{\ell : \tau(\ell) < |S|\}$, for $S \neq \emptyset$.

▶ **Example 1.3.** Generalizing Example 1.2 substantially, suppose along with τ, we have a *monotone* function $\pi : 2^V \mapsto \mathbb{R}_+$, i.e., $\pi(T) \leq \pi(S)$ if $T \subseteq S$. We now seek a subgraph H such that for every fault-set F and $S \subseteq V$ with $\pi(S) \leq \tau(|F|)$, we have that S is (the node-set of) a component of $G - F$ iff it is a component of $H - F$. Similar to Example 1.2, we can model this as CR-f-NDP by defining $f(S) := \min\{\ell : \tau(\ell) < \pi(S)\}$, for $S \neq \emptyset$ (Theorem 3.2).

This setup yields fault-tolerance degradation depending on monotone properties of components other than just their size, which creates a rich space of problems. For example, suppose $\pi(S) = \max_{u,v \in S} \min_{u\text{-}v \text{ paths } P \text{ in } G} |P|$ is the weak-diameter of S. Setting $\tau(\ell) = n$ if $\ell < k$, and some $t < n$ for larger ℓ, we seek a k-EFTS solution H such that for $F \subseteq E$ with $|F| \geq k$, $G - F$ and $H - F$ have the same components of weak-diameter at most t.

1.1 Our contributions

We introduce cut-relative network-design problems and develop strong approximation guarantees for these problems. *We obtain an approximation guarantee of* 2 *for cut-relative* SNDP, which, notably, matches the best-known approximation factor for SNDP. Our guarantee applies more generally to CR-f-NDP, whenever the base cut-requirement function f satisfies certain properties and the natural LP-relaxation of the problem ($\text{CRLP}_{f,G}$) can be solved efficiently. Our guarantee is relative to the optimal value of this LP, *and is tight in that it matches the integrality gap of this LP.*

We also show that even in the simplest SNDP setting with only one s-t pair (wherein SNDP is polytime solvable), cut-relative SNDP and path-relative SNDP capture k-ECSS as a special case, and are thus APX-hard (Section 6). Previously, even NP-hardness of path-relative SNDP in the s-t case (which is studied by [8, 9]) was not known.

Technical contributions and overview. Technically, our main contribution is to show that we can obtain such a strong guarantee *despite the fact that the cut-requirement function defining cut-relative network-design (i.e., $g^{\text{CR-}f\text{-NDP}}$) is not weakly supermodular*, which is the key property that drives the 2-approximation algorithm for SNDP. To elaborate, there is a celebrated 2-approximation algorithm for SNDP due to Jain [15] based on iterative rounding. This *crucially* exploits the fact that the underlying cut-requirement function f^{SNDP} is *weakly supermodular*: for any two node-sets $A, B \subseteq V$, we have:

$$f^{\mathsf{SNDP}}(A)+f^{\mathsf{SNDP}}(B) \leq \max\{f^{\mathsf{SNDP}}(A\cap B)+f^{\mathsf{SNDP}}(A\cup B),\ f^{\mathsf{SNDP}}(A-B)+f^{\mathsf{SNDP}}(B-A)\}.$$

This property allows one to argue that given an LP-solution x, any two *tight* sets that cross – i.e., sets A, B for which $x(S) = f^{\mathsf{SNDP}}(S)$ holds for $S \in \{A, B\}$ and $A \cap B, A - B, B - A$ are all non-empty – can be "uncrossed", and thereby an extreme-point solution $\widehat{x}$ to the LP can be defined via a *laminar family* of tight cut constraints. By a laminar family, we mean that any two sets A, B in the family satisfy $A \cap B = \emptyset$ or $A \subseteq B$, and uncrossing two crossing tight sets means that they can be replaced by an equivalent laminar family of tight sets. Jain's seminal contribution was to show that given such a laminar family defining an extreme point, there always exists an edge e for which $\widehat{x}_e \geq \frac{1}{2}$; picking such an edge and iterating then yields the 2-approximation. This technique of uncrossing tight cut-constraints to obtain a laminar

family of tight cut-constraints has proved to be quite versatile, becoming a staple technique that has been leveraged to obtain strong guarantees in various network-design settings such as, most notably, network-design problems with degree constraints [13, 17, 19, 5, 4, 16]. More generally, this technique of uncrossing to obtain a structured family of tight constraints has been utilized for various combinatorial-optimization problems; see, e.g., [18].

As mentioned earlier, the main complication with CR-f-NDP is that the underlying cut-requirement function $g^{\text{CR-}f\text{-NDP}}$ is usually *not* weakly-supermodular, even if the base cut-requirement function f is. In particular, the cut-requirement function $g^{\text{CR-SNDP}}$ defining cut-relative SNDP is not weakly-supermodular. This difficulty was also noted by Dinitz et al. [8] when they considered k-edge fault-tolerant subgraph (k-EFTS, or path- or cut-relative k-ECSS in our terminology). For this special case, they identify a notion called local weak-supermodularity that is satisfied by the cut-requirement function $\min\{k, |\delta_G(S)\}$ for k-EFTS, and observed that Jain's machinery can be used as is if this property holds; that is, one can uncross tight sets to obtain a laminar family, and hence obtain a 2-approximation for k-EFTS proceeding as in Jain's algorithm for SNDP.

However, for general CR-SNDP, such an approach breaks down, because, as we show in Section 2.1, one can construct quite simple CR-SNDP instances where an (optimal) extreme point *cannot be defined by any laminar family of tight cut constraints*. In particular, this implies that the cut-requirement function $g^{\text{CR-}f\text{-NDP}}$ is (in general) not locally weakly-supermodular (even when f is weakly-supermodular); moreover, it does not satisfy any property that allows for the uncrossing of tight sets. The upshot here is that the standard technique of uncrossing tight sets to obtain a laminar family does not work, and one needs new ideas to deal with cut-relative network design.

The chief technical novelty of our work is to show how to overcome the impediment posed by the lack of any such nice structural property for $g^{\text{CR-}f\text{-NDP}}$, via a novel *decomposition technique* that allows one to *reduce* cut-relative f-NDP with a weakly supermodular *base cut-requirement function* to (standard) f-NDP with (different) weakly supermodular cut-requirement functions (see Theorem 4.1).

We introduce a little notation to describe this. Let CR-(h, D)-NDP denote CR-f-NDP on graph D with base cut-requirement function h. For $S \subseteq V$, define its *deficiency* to be $f(S) - |\delta_G(S)|$; we say that S is a *small cut* if its deficiency is positive (i.e., $|\delta_G(S)| < f(S)$). We use $G[S]$ to denote the subgraph induced by S. Let $\overline{S}$ denote $V - S$.

Assume that the underlying base cut-requirement function f is weakly supermodular (as is the case with SNDP). Observe first that if there is no small cut then CR-f-NDP is the same as f-NDP. Our key technical insight is that, otherwise, we can utilize a novel splitting operation to simplify our problem. We show (see Theorem 4.5) that if we pick a small cut $A \subseteq V$ with *maximum deficiency*, then one can define suitable weakly-supermodular functions $f_A : 2^A \mapsto \mathbb{Z}$ and $f_{\overline{A}} : 2^{\overline{A}} \mapsto \mathbb{Z}$ such that *any solution to the original* CR-f-NDP*-instance yields solutions to* CR-$(f_A, G[A])$-NDP *and* CR-$(f_{\overline{A}}, G[\overline{A}])$-NDP*, and vice-versa.* The intuition here is as follows. Since A is a small cut, any feasible CR-f-NDP solution must include all edges in $\delta_G(A)$. The functions f_A and $f_{\overline{A}}$ are essentially the restrictions of f to A and $\overline{A}$ respectively, taking this into account. Consequently, moving to CR-$(f_A, G[A])$-NDP and CR-$(f_{\overline{A}}, G[\overline{A}])$-NDP does not really impact the constraints for cuts that do not cross A; but we do eliminate the constraints for crossing cuts. This is the simplification that we obtain via the splitting operation, and one needs to argue that this does not hurt feasibility; that is, the constraints for such cuts are still satisfied when we take $\delta_G(A)$ along with the CR-$(f_A, G[A])$-NDP and CR-$(f_{\overline{A}}, G[\overline{A}])$-NDP solutions. Here we exploit the weak-supermodularity of f, which implies that the deficiency

function $\mathrm{def}(S) := f(S) - |\delta_G(S)|$ is also weakly supermodular. One can use this, and the fact that A has maximum deficiency, to bound the deficiency of any crossing set T in terms of the deficiency of non-crossing sets, and hence show that the cut-constraint for T is satisfied.

By recursively applying the above splitting operation to A and $\overline{A}$, we end up with a partition $V_1, \ldots, V_k$ of V and weakly-supermodular functions $f_i : 2^{V_i} \mapsto \mathbb{Z}$ for all $i \in [k]$ such that, for each $i \in [k]$, the graph $G[V_i]$ contains no small cut with respect to f_i. It follows that solving f_i-NDP on the graph $G[V_i]$ for all $i \in [k]$ yields a solution to the original CR-f-NDP instance (Theorem 4.1).

While we can obtain this decomposition efficiently, assuming that one has suitable algorithmic primitives involving the base cut-requirement function f (shown in the full version), in fact we only need this decomposition in the *analysis*: in order to obtain the stated LP-relative 2-approximation algorithm, we only need to be able to find an extreme-point optimal solution to the natural LP-relaxation ($\mathrm{CRLP}_{f,G}$) for CR-f-NDP (also after fixing some variables to 1). This is because the translation between CR-f-NDP-solutions for G, and f_i-NDP-solutions on $G[V_i]$ for all $i \in [k]$, also applies to *fractional solutions*, and implies that any extreme-point solution to ($\mathrm{CRLP}_{f,G}$) yields extreme-point solutions to the LP-relaxations of f_i-NDP on $G[V_i]$ for all $i \in [k]$ (parts (b) and (c) of Theorem 4.1); hence, by Jain's result, we can always find some fractional edge of value at least $\frac{1}{2}$, round its value to 1, and iterate. For SNDP, we can find an extreme-point optimal solution efficiently because we argue that one can devise an efficient separation oracle for ($\mathrm{CRLP}_{f,G}$) (Lemma 2.3). This yields a 2-approximation algorithm for CR-SNDP, and more generally CR-f-NDP, whenever f is weakly supermodular and ($\mathrm{CRLP}_{f,G}$) can be solved efficiently (see Algorithm CRNDP-Alg in Section 5).

Other related work. Network design is a fairly broad research topic, with a vast amount of literature. We limit ourselves to the work that is most closely connected to our work.

As mentioned earlier, path-relative SNDP was introduced by Dinitz et al. [8]. In addition to k-EFTS, which is the path-relative version of k-ECSS, they study the path-relative versions of two other special cases of SNDP, for which they developed constant-factor approximation algorithms: (1) SNDP with $r_i \leq 2$ for all i; (2) one s_i-t_i pair with $r_i \leq 3$. Both results were subsequently extended by [9] who gave a 2-approximation for SNDP with $r_i \leq 3$ for all i, and a $2^{O(k^2)}$-approximation when there is one s_i-t_i pair with $r_i = k$. The only result known for general path-relative SNDP is due to [7], who (among other results) devise an $O(k^2 \log^2 n \log\log n)$-approximation algorithm with $n^{O(k)}$ running time. As noted earlier, on the hardness side, prior to our work, it was not known if the setting with one s_i-t_i pair is even *NP*-hard.

An influential paper by Goemans and Williamson [10] (see also the survey [11]), which built upon the work of [1] for the Steiner forest problem, developed the primal-dual method for network-design problems. Their work also popularized the use of cut-requirement functions to specify network-design problems, by showing how this framework can be used to capture a slew of problems, and how their primal-dual framework leads to a 2-approximation algorithm for $\{0,1\}$-cut-requirement functions satisfying some properties. This work was extended to handle general integer-valued cut-requirement functions, which captures SNDP, in [20, 12], which led to an $O(\log \max_i r_i)$-approximation for SNDP. The seminal work of Jain [15] later improved this to a 2-approximation, and in doing so, introduced the powerful technique of *iterative rounding*. Later work of [17, 19] on degree-bounded network design added another ingredient to iterative rounding, namely iteratively dropping some constraints. This paradigm of *iterative rounding and relaxation* has proved to be an extremely versatile and powerful tool in developing algorithms (and structural results) for network-design problems, and more generally in combinatorial optimization; see [18] for an extensive study.

Iterative rounding and relaxation derives its power from the fact that an extreme-point solution to an LP-relaxation of the problem can be defined using a structured family of tight constraints, such as, often a laminar family of cut constraints in the case of network-design problems. As noted earlier, this key property does not hold for cut-relative SNDP (and path-relative SNDP). Recently, various works have considered network-design problems that give rise to cut constraints that are less structured and not quite uncrossable; see [2, 3, 6] and the references therein. Our work can be seen as furthering this research direction.

2 Preliminaries and notation

Recall that we are given an undirected graph $G = (V, E)$ with nonnegative edge costs $\{c_e\}_{e \in E}$. For a subset $S \subseteq V$ and subset $Z \subseteq E$, which we will interchangeably view as the subgraph (V, Z) of G, we use $\delta_Z(S)$ to denote $\delta_G(S) \cap Z$, i.e., the edges of Z on the boundary of S. Recall that $\overline{S}$ denotes $V - S$, and $G[S]$ denotes the subgraph induced by S. A cut-requirement function on G is a function $f : 2^V \mapsto \mathbb{Z}$. (We allow $f(S)$ to be negative chiefly for notational simplicity; this does not affect anything, as we will only examine sets for which $f(S) \geq 0$.) Recall the following network-design problems.

- *f-network-design problem* (f-NDP): find a min-cost edge-set H such that $|\delta_H(S)| \geq f(S)$ for all $S \subseteq V$.
- *Cut-relative network-design problem* (CR-f-NDP): find a min-cost edge-set H such that $|\delta_H(S)| \geq g^{\text{CR-}f\text{-NDP}}(S) := \min\{f(S), |\delta_G(S)|\}$ for all $S \subseteq V$. This corresponds to $g^{\text{CR-}f\text{-NDP}}$-NDP. We call f the base cut-requirement function.
- *Survivable network design problem* (SNDP) is a special case of f-NDP. The input also specifies k tuples $\{(s_i, t_i, r_i)\}_{i \in [k]}$, where $s_i, t_i \in V$ and $r_i \in \mathbb{Z}_+$ for all $i \in [k]$. Defining $f^{\text{SNDP}}(S) := \max\{r_i : |S \cap \{s_i, t_i\}| = 1\}$ for all $S \subseteq V$, we obtain that SNDP is the f^{SNDP}-network-design problem.
- *Cut-relative* SNDP (CR-SNDP): The input here is the same as in SNDP. In Definition 1.1 (R2), CR-SNDP was defined as: find a min-cost $H \subseteq E$ such that for every $i \in [k]$, every $F \subseteq E$ with $|F| < r_i$, and every s_i-t_i cut S, we have $\delta_{H-F}(S) \neq \emptyset$ whenever $\delta_{G-F}(S) \neq \emptyset$. Later in Section 1, we stated that this can be equivalently formulated as CR-f-NDP with base cut-requirement function f^{SNDP}. We now justify this statement.
  Suppose that H is feasible under (R2) but $|\delta_H(S)| < \min\{f^{\text{SNDP}}(S), |\delta_G(S)|\}$ for some $S \subseteq V$. Suppose $f^{\text{SNDP}}(S) = r_i$. Then taking $F = \delta_H(S)$, we have $|F| < r_i$, $\delta_{G-F}(S) \neq \emptyset$, but $\delta_{H-F}(S) = \emptyset$, yielding a contradiction. So H is feasible for CR-f^{SNDP}-NDP. Conversely, suppose H is feasible for CR-f^{SNDP}-NDP. Consider any $i \in [k]$, any $F \subseteq E$ with $|F| < r_i$, and any s_i-t_i cut S with $\delta_{G-F}(S) \neq \emptyset$. Then, $|\delta_F(S)| < \min\{r_i, |\delta_G(S)|\} \leq \min\{f(S), |\delta_G(S)|\} \leq |\delta_H(S)|$; so $\delta_{H-F}(S) \neq \emptyset$, showing that H satisfies (R2).

We will consider network-design problems defined on various graphs and with various cut-requirement functions. Given a graph $D = (V_D, E_D)$ and cut-requirement function $h : 2^{V_D} \mapsto \mathbb{Z}$, we use (h, D)-NDP to denote f-NDP on the graph D with cut-requirement function h, and CR-(h, D)-NDP to denote CR-f-NDP on the graph D with base cut-requirement function h.

Properties of cut-requirement functions. Let $f : 2^V \mapsto \mathbb{R}$. We say that f is *weakly supermodular* if for any two node-sets $A, B \subseteq V$, we have $f(A) + f(B) \leq \max\{f(A \cap B) + f(A \cup B), f(A - B) + f(B - A)\}$. We say that f is *symmetric* if $f(S) = f(V - S)$ for all $S \subseteq V$, and is *normalized* if $f(\emptyset) = f(V) = 0$.

Since we are working on undirected graphs, we can always replace any cut-requirement function f by its symmetric, normalized version f^{sym}, where $f^{\mathsf{sym}}(S) := \max\{f(S), f(V-S)\}$ for all $\emptyset \neq S \subsetneq V$ and $f^{\mathsf{sym}}(\emptyset) = f^{\mathsf{sym}}(V) := 0$, without changing the resulting network-design problem(s), i.e., we have f-NDP $\equiv f^{\mathsf{sym}}$-NDP and CR-f-NDP $\equiv$ CR-f^{sym}-NDP.

Lemma 2.1 shows that weak-supermodularity is preserved under various operations. This will be quite useful in the analysis of our decomposition technique. Part a of the lemma shows that weak supermodularity is preserved under symmetrization and normalization, so for any f-NDP or CR-f-NDP instance involving a weakly-supermodular base cut-requirement function f, we may assume that f is symmetric and normalized.

All omitted proofs and details can be found in the full version of the paper.

▶ **Lemma 2.1.** *Let $f : 2^V \mapsto \mathbb{R}$ be weakly supermodular. Then*

(a) *f^{sym} is weakly supermodular.*

(b) *Let $w \in \mathbb{R}^E_+$. Define $g_1(S) := f(S) - w\big(\delta_G(S)\big)$ for all $S \subseteq V$. Then g_1 is weakly supermodular, and g_1 is symmetric if f is symmetric. In particular, for any $Z \subseteq E$, the function $f(S) - |\delta_Z(S)|$ is weakly supermodular, and is symmetric if f is symmetric.*

(c) *Let $X \subseteq V$, and $\mathcal{C}$ be a collection of subsets of $V - X$ closed under taking set intersections, unions, differences, and complements with respect to $V - X$, i.e., if $S \in \mathcal{C}$ then $V - X - S \in \mathcal{C}$, and $S, T \in \mathcal{C}$ implies that $\{S \cap T, S \cup T, S - T, T - S\} \subseteq \mathcal{C}$.*

Define the projection of f onto X with respect to $\mathcal{C}$ *as the function $g_2 : 2^X \mapsto \mathbb{R}$ given by $g_2(\emptyset) = g_2(X) := 0$, and $g_2(S) := \max_{T \in \mathcal{C}} f(S \cup T)$ for all $\emptyset \neq S \subsetneq X$. If f is symmetric, then g_2 is weakly supermodular and symmetric.*

Proof. Part (a) follows from a simple case analysis; part (b) follows because $w\big(\delta_G(S)\big)$ is symmetric, submodular. We focus on proving part (c). Essentially, the closure properties of $\mathcal{C}$ enable us to transfer the weak-supermodularity of f to the function g_2.

We first argue that g_2 is symmetric. If $A \in \{\emptyset, X\}$, we have $g_2(A) = g_2(X - A)$ by definition. Otherwise, if $g_2(A) = f(A \cup T_A)$, we have $f(A \cup T_A) = f\big(V - (A \cup T_A)\big) = f\big((X - A) \cup (V - X - T_A)\big) \leq g_2(X - A)$ where the last inequality follows since $V - X - T_A \in \mathcal{C}$. We also have $g_2(X - A) \leq g_2(A)$ by the same type of reasoning, and so $g_2(A) = g_2(X - A)$ for all $A \subseteq X$.

Now we show that g_2 is weakly supermodular. Consider $A, B \subseteq X$. If any of the sets $A - B, B - A, A \cap B, X - (A \cup B)$ are empty, then $g_2(A) + g_2(B) = g_2(A \cap B) + g_2(A \cup B)$ or $g_2(A) + g_2(B) = g_2(A - B) + g_2(B - A)$. The former holds when $A - B$ or $B - A$ is empty; the latter holds when $A \cap B$ or $X - (A \cup B)$ is empty, where we also utilize the fact that g_2 is symmetric. So assume otherwise. Then, for every $S \in \{A, B, A \cap B, A \cup B, A - B, B - A\}$, we have $g_2(S) = \max_{T \in \mathcal{C}} f(S \cup T)$.

Let $g_2(A) = f(A \cup T_A)$ and $g_2(B) = f(B \cup T_B)$, where $T_A, T_B \in \mathcal{C}$. Let $A' = A \cup T_A$ and $B' = B \cup T_B$. For any $S \in \{A' \cap B', A' \cup B', A' - B', B' - A'\}$, we can write $S = (S \cap X) \cup T$, where $T \in \mathcal{C}$ due to the closure properties of $\mathcal{C}$. It follows that $g_2(S \cap X) \geq f(S)$ for all $S \in \{A' \cap B', A' \cup B', A' - B', B' - A'\}$. So if $f(A') + f(B') \leq f(A' \cap B') + f(A' \cup B')$, we obtain that $g_2(A) + g_2(B) \leq g_2(A \cap B) + g_2(A \cup B)$, and if $f(A') + f(B') \leq f(A' - B') + f(B' - A')$, we obtain that $g_2(A) + g_{@}(B) \leq g_2(A - B) + g_2(B - A)$. ◀

The intuition behind the projection operation is as follows. Suppose f is a cut-requirement function and we know that no edges are picked from $E_G(V - X) \cup \delta_G(X)$. Then, roughly speaking, $g_2(S)$ captures the constraints that arise on $S \subseteq X$ due to f and $\mathcal{C}$.

2.1 LP-relaxation for CR-f-NDP

We consider the following natural LP-relaxation for CR-f-NDP. From now on, we assume that the cut-requirement function $f : 2^V \mapsto \mathbb{Z}$ is weakly supermodular, symmetric, and normalized. Given $\alpha \in \mathbb{R}^E$ and $F \subseteq E$, let $\alpha(F)$ denote $\sum_{e \in F} \alpha_e$.

$$\min \quad \sum_{e \in E} c_e x_e \tag{CRLP$_{f,G}$}$$

$$\text{s.t.} \quad x\big(\delta_G(S)\big) \geq \min\big\{f(S), |\delta_G(S)|\big\} \qquad \forall S \subseteq V \tag{1}$$

$$0 \leq x_e \leq 1 \qquad \forall e \in E. \tag{2}$$

The LP-relaxation for f-NDP is similar, with the cut-constraints taking the simpler form $x\big(\delta_G(S)\big) \geq f(S)$ for all $S \subseteq V$. We denote this LP by (NDP$_{f,G}$). Our algorithm is based on iterative rounding, where we iteratively fix some x_e variables to 1. Suppose that we have fixed $x_e = 1$ for all $e \in Z_1$. Then, in that iteration, we are considering the residual problem on the subgraph $G' = (V, E' = E - Z_1)$, which leads to the following variant of (CRLP$_{f,G}$):

$$\min \quad \sum_{e \in E'} c_e x_e \tag{P'}$$

$$\text{s.t.} \quad x\big(\delta_{G'}(S)\big) \geq \min\big\{f(S), |\delta_G(S)|\big\} - |\delta_{Z_1}(S)| \qquad \forall S \subseteq V \tag{3}$$

$$0 \leq x_e \leq 1 \qquad \forall e \in E'.$$

Defining $f'(S) = f(S) - |\delta_{Z_1}(S)|$ for all $S \subseteq V$, we can rephrase constraints (3) as $x\big(\delta_{G'}(S)\big) \geq \min\big\{f'(S), |\delta_{G'}(S)|\big\}$ for all $S \subseteq V$. Since f' is weakly supermodular, symmetric (Lemma 2.1 (b)), and normalized, (P') is of the same form as (CRLP$_{f,G}$): we have (P') $\equiv$ (CRLP$_{f',G'}$). This will be convenient for iterative rounding, as the residual problem is of the same form as the original problem. (CRLP$_{f,G}$) and (P') involve an exponential number of constraints, but using the ellipsoid method, we can find an extreme-point optimal solution provided we have a separation oracle for them. Recall that a separation oracle is a procedure that given a candidate point determines if it is feasible, or returns a violated inequality. Observe that a separation oracle for (CRLP$_{f,G}$) also yields a separation oracle for (P'), since (P') is simply (CRLP$_{f,G}$) after fixing some variables to 1.

▶ **Fact 2.2** (Ellipsoid method [14]). *Given a polytime separation oracle for* (CRLP$_{f,G}$)*, one can find an extreme-point optimal solution to LPs* (CRLP$_{f,G}$) *and* (P') *in polytime.*

For CR-SNDP, i.e., when $f = f^{\mathsf{SNDP}}$, a polytime separation oracle for (CRLP$_{f,G}$) can be obtained using min-cut computations. This was shown by [8] for path-relative k-ECSS, which is equivalent to cut-relative k-ECSS; refining their ideas yields a separation oracle for (CRLP$_{f,G}$) for general SNDP.

▶ **Lemma 2.3.** *When $f = f^{\mathsf{SNDP}}$, there is a polytime separation oracle for* (CRLP$_{f,G}$)*. Hence, one can obtain extreme-point optimal solutions to* (CRLP$_{f,G}$) *and* (P') *in polytime.*

Proof. The second statement follows from Fact 2.2. Let $(s_i, t_i, r_i)_{i \in [k]}$ be the k tuples defining the SNDP instance, which recall leads to the cut-requirement function $f^{\mathsf{SNDP}}(S) := \max\{r_i : |S \cap \{s_i, t_i\}| = 1\}$ for all $S \subseteq V$. Say that $S \subseteq V$ is a small cut if $f^{\mathsf{SNDP}}(S) > |\delta_G(S)|$, and it is a small cut for i if $|S \cap \{s_i, t_i\}| = 1$ and $r_i > |\delta_G(S)|$. Note that if $e \in \delta_G(S)$ for any small cut S, then we must have $x_e = 1$ in any feasible solution.

Now we can equivalently phrase the constraints of (CRLP$_{f,G}$) as follows: for any edge $a = uv \in E$, we must have $x_a = 1$ or, for every $i \in [k]$, the minimum s_i-t_i cut also separating u and v under the $\{x_e\}_{e \in E}$-capacities should have capacity at least r_i. So to detect if x is

a feasible solution, we simply need to consider every edge $a = uv$ with $x_a < 1$ and every $i \in [k]$, and find the minimum s_i-t_i cut also separating u and v under the $\{x_e\}_{e \in E}$ capacities. If an s_i-t_i cut separates u, v, then u lies on the s_i-side and v lies on the t_i-side, or the other way around. So to find the minimum s_i-t_i cut also separating u and v, we find the minimum $\{s_i, u\}$-$\{t_i, v\}$ cut – by which we mean the minimum s_i-t_i cut where s_i, u are on the same side, and t_i, v are on the other side–and the minimum $\{s_i, v\}$-$\{t_i, u\}$-cut and take the one with smaller capacity. ◀

Extreme-point solution to $(\mathrm{CRLP}_{f,G})$ not defined by a laminar family

We show that for the CR-SNDP instance shown in Fig. 1, the extreme-point solution $\widehat{x}$ shown in the figure, cannot be expressed as the solution to *any laminar family of tight cut constraints* (1) (along with tight edge constraints (2)). The SNDP instance is s-t 2-edge connectivity: that is, the base cut-requirement function is given by $f(S) = 2$ if S is an s-t cut, and $f(S) = 0$ otherwise.

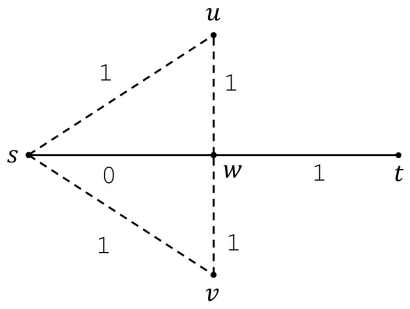

Figure 1 CR-SNDP instance, and an extreme-point solution $\widehat{x}$ to $(\mathrm{CRLP}_{f,G})$. The solid edges have $\widehat{x}_e = 1$ and the dashed edges have $\widehat{x}_e = 0.5$, so $\widehat{x}_e = 0.5$ for $e \in \{su, uw, sv, vw\}$ and $\widehat{x}_e = 1$ for $e \in \{sw, wt\}$.

Note that the only small cut above containing s is $S = \{s, u, v, w\}$. One can verify by inspection that $\widehat{x}$ is feasible. It is not hard to see that $\widehat{x}$ is the unique solution to the following set of equations, which come from constraints that are tight at $\widehat{x}$.

$$x\big(\delta(S)\big) = 2 \qquad \forall S \in \big\{\{s\}, \{s, u, v\}, \{s, u, w\}, \{s, v, w\}\big\}, \tag{4}$$

$$x_e = 1 \qquad \forall e \in \{sw, wt\}. \tag{5}$$

This shows that $\widehat{x}$ is an extreme-point solution to $(\mathrm{CRLP}_{f,G})$. With edge costs $c_{sw} = 0$ and $c_e = 1$ for all other edges, $\widehat{x}$ is also an optimal solution. The constraints $x\big(\delta(S)\big) \geq 2$ for all $S \in \big\{\{s\}, \{s, u, v\}, \{s, u, w\}, \{s, v, w\}\big\}$ imply that (since $x_e \leq 1$ for all e)

$$x_{su} + x_{sv} \geq 1, \quad x\big(\delta(u)\big) \geq 1, \quad x\big(\delta(v)\big) \geq 1, \quad x_{uw} + x_{vw} \geq 1.$$

Adding these constraints, we obtain that $x_{su} + x_{sv} + x_{uv} + x_{vw} \geq 2$. Therefore, the cost of any feasible solution is at least 3, and we have $c^T \widehat{x} = 3$.

$\widehat{x}$ cannot be defined via a laminar family. We now argue that $\widehat{x}$ cannot be defined by any laminar family of tight cut constraints and tight edge constraints. Note that any tight cut constraint corresponds to an s-t cut. So a laminar family $\mathcal{L}$ of tight cut constraints consists of a union of two chains $\mathcal{L}_1 \cup \mathcal{L}_2$, where a chain is a nested collection of sets: $\mathcal{L}_1$

comprising sets containing s but not t, and $\mathcal{L}_2$ comprising sets containing t but not s. Then $\mathcal{L}' = \mathcal{L}_1 \cup \{V - S : S \in \mathcal{L}_2\}$ is also a laminar family, yielding the same cut-constraints as $\mathcal{L}$, and and all sets in $\mathcal{L}'$contain s but not t. So we only need to consider laminar families of tight cut constraints corresponding to a chain of sets containing s and not t.

A simple argument now rules out the existence of any such chain that can uniquely define $\widehat{x}$ along with the tight edge constraints (5). Any such chain of sets $\mathcal{C}$ is obtained by ordering the elements u, v, w, and taking sets of the form $\{s\} \cup T$, where T is some prefix (including the empty prefix) of this ordered sequence; so $\mathcal{C}$ contains at most 4 sets. Since $\widehat{x}$ has 4 fractional edges, $E' = \{su, sv, uw, vw\}$, it must be that $\{\chi^{\delta_{E'}(S)}\}_{S \in \mathcal{C}}$ contains 4 linearly independent vectors. So $\mathcal{C}$ contains exactly 4 sets, and in particular the set $\{s, u, v, w\}$, and all vectors in $\{\chi^{\delta_{E'}(S)}\}_{S \in \mathcal{C}}$ are linearly independent. This yields a contradiction, since $\chi^{\delta_{E'}(\{s,u,v,w\})} = \vec{0}$.

3 Modeling power of CR-f-NDP

We prove that the CR-f-NDP Examples 1.2 and 1.3 listed under "Modeling power" in Section 1 model the stated problems. Recall that in both examples, we have a non-increasing function $\tau : \mathbb{Z}_+ \mapsto \mathbb{Z}_+$.

▶ **Theorem 3.1.** *Consider the base cut-requirement function f^{grace} in Example 1.2, where $f^{\text{grace}}(S) := \min\{\ell : \tau(\ell) < |S|\}$, for $S \neq \emptyset$.*

(a) *The function f^{grace} is weakly-supermodular.*

(b) *H is feasible for CR-f^{grace}-NDP iff for every fault-set $F \subseteq E$, and every $S \subseteq V$ with $|S| \leq \tau(|F|)$, S is (the node-set of) a component of $G - F$ iff it is a component of $H - F$.*

Proof. The function f^{grace} is *downwards-monotone*: if $\emptyset \neq T \subseteq S$, then $f^{\text{grace}}(T) \geq f^{\text{grace}}(S)$. This follows from the definition, since τ is a non-increasing function. Weak-supermodularity of f^{grace} is now immediate since we have $f^{\text{grace}}(A) + f^{\text{grace}}(B) \leq f^{\text{grace}}(A - B) + f^{\text{grace}}(B - A)$, if $A - B, B - A \neq \emptyset$, and otherwise $f^{\text{grace}}(A) + f^{\text{grace}}(B) = f^{\text{grace}}(A \cap B) + f^{\text{grace}}(A \cup B)$.

Note that f^{grace} is not symmetric or normalized, but as indicated by Lemma 2.1, we can consider CR-f-NDP with the symmetric, normalized version of f^{grace} as the base cut-requirement function, without changing the problem.

To prove the feasibility characterization in part (b), we note that the function f^{grace} is constructed so that for any $S \subseteq V$ and $F \subseteq E$, we have $|S| \leq \tau(|F|)$ iff $f^{\text{grace}}(S) > |F|$, so that $|\delta_H(S)| \geq f^{\text{grace}}(S)$ implies that S is not a component of $H - F$. Suppose H is such that $|\delta_H(S)| \geq \min\{f^{\text{grace}}(S), |\delta_G(S)|\}$ for all $S \subseteq V$. Consider any fault-set $F \subseteq E$ and any $S \subseteq V$ such that $|S| \leq \tau(|F|)$. By the above, if S is a component of $H - F$, then $|\delta_H(S)| < f^{\text{grace}}(S)$, and so S must also be a component of $G - F$. But this also implies that if S is a component of $G - F$, then it is a component of $H - F$; otherwise, there is some $A \subsetneq S$ that is a component of $H - F$ with $|A| < |S| \leq \tau(|F|)$, and so A must be a component of $G - F$, which is not the case.

Conversely, suppose that for every $F \subseteq E$, and $S \subseteq V$ with $|S| \leq \tau(|F|)$, we have that S is a component of $G - F$ iff it is a component of $H - F$. If $|\delta_H(S)| < \min\{f^{\text{grace}}(S), |\delta_G(S)|\}$ for some $S \subseteq V$, then take $F = \delta_H(S)$. Since $f^{\text{grace}}(S) > |F|$, we have $|S| \leq \tau(|F|)$. But S is a component of $H - F$ and not $G - F$, which yields a contradiction. ◀

▶ **Theorem 3.2.** *Let $\pi : 2^V \mapsto \mathbb{R}_+$ be a monotone function, i.e., $\pi(T) \leq \pi(S)$ if $T \subseteq S$, as in Example 1.3. Consider CR-f-NDP, where the base cut-requirement function f is given by $f(S) := \min\{\ell : \tau(\ell) < \pi(S)\}$, for all $S \neq \emptyset$. Then*

(a) *f is weakly-supermodular;*

(b) *H is feasible for* CR-f-NDP *iff for every fault-set $F \subseteq E$, and every $S \subseteq V$ with $\pi(S) \leq \tau(|F|)$, S is (the node-set of) a component of $G - F$ iff it is a component of $H - F$.*

Proof. We mimic the proof of Theorem 3.1. Since π is monotone, we obtain that f is downwards-monotone, and hence weakly-supermodular.

For part (b), similar to before, we have that $\pi(S) \leq \tau(|F|)$ iff $f(S) > |F|$. Suppose H is feasible for CR-f-NDP. Consider any fault-set $F \subseteq E$ and any $S \subseteq V$ be such that $\pi(S) \leq \tau(|F|)$. By the above, $f(S) > |F|$, so if S is a component of $H - F$, then it must also be a component of $G - F$. Again, this also implies that if S is a component of $G - F$, then it is a component of $H - F$: otherwise, there is some $A \subsetneq S$ that is a component of $H - F$, and $\pi(A) \leq \pi(S) \leq \tau(|F|)$, which means that A is a component of $G - F$.

Conversely, suppose that for every $F \subseteq E$, and $S \subseteq V$ with $\pi(S) \leq \tau(|F|)$, we have that S is a component of $G - F$ iff it is a component of $H - F$. If $|\delta_H(S)| < \min\{f(S), |\delta_G(S)|\}$ for some $S \subseteq V$, then take $F = \delta_H(S)$. Since $f(S) > |F|$, we have $\pi(S) \leq \tau(|F|)$. But S is a component of $H - F$ and not $G - F$, which yields a contradiction. ◀

Our intent with Examples 1.2 and 1.3 is to illustrate that CR-f-NDP can be used to model some interesting problems. The choice of the τ and/or π functions can of course impact our ability to solve the LP-relaxation (CRLP$_{f,G}$) efficiently.

4 Structure of feasible CR-f-NDP solutions: a decomposition result

We now prove our decomposition result, showing that CR-f-NDP can be reduced to f-NDP with suitably-defined weakly-supermodular cut-requirement functions. Recall that the base cut-requirement function f is weakly supermodular (and symmetric, normalized), but the cut-requirement function $g^{\text{CR-}f\text{-NDP}}$ underlying CR-f-NDP need not be. Given $x \in \mathbb{R}^E$ and $S \subseteq V$, we use x^S to denote the restriction of x to edges in S, i.e., the vector $(x_e)_{e \in E(S)} \in \mathbb{R}^{E(S)}$.

▶ **Theorem 4.1 (Decomposition result).** *There is a partition $V_1, V_2, \ldots, V_k$ of V and weakly-supermodular, symmetric, and normalized functions $f_i : 2^{V_i} \mapsto \mathbb{Z}$ such that the following hold.*

(a) *$F \subseteq E$ is a feasible solution to* CR-(f, G)-NDP *iff $F \supseteq \delta_G(V_i)$ and $F(V_i)$ is a feasible solution to* $(f_i, G[V_i])$-NDP *for all $i \in [k]$.*

(b) *$x \in \mathbb{R}^E$ is feasible to* (CRLP$_{f,G}$) *iff for all $i \in [k]$, we have $x_e = 1$ for all $e \in \delta_G(V_i)$, and x^{V_i} is feasible to* (NDP$_{f_i, G[V_i]}$).

(c) *x is an extreme-point solution to* (CRLP$_{f,G}$) *iff for all $i \in [k]$, we have $x_e = 1$ for all $e \in \delta_G(V_i)$, and x^{V_i} is an extreme-point solution to* (NDP$_{f_i, G[V_i]}$).

Before delving into the proof of Theorem 4.1, we state the following immediate corollary of Theorem 4.1 (c), which directly leads to a 2-approximation algorithm for CR-f-NDP whenever (CRLP$_{f,G}$) can be solved efficiently.

▶ **Corollary 4.2.** *Let $\widehat{x}$ be an extreme-point solution to* (CRLP$_{f,G}$). *There exists some $e \in E$ for which $\widehat{x}_e \geq 1/2$.*

Proof. By Theorem 4.1 (c), there is a partition of V and f-NDP-instances defined on each part such that $\widehat{x}$ induces an extreme-point solution in each f-NDP-instance. By Jain's result, this implies that in each of these instances, there is some edge e with $\widehat{x}_e \geq 1/2$. ◀

The rest of this section is devoted to the proof of Theorem 4.1. For a set $S \subseteq V$, define its *deficiency* $\mathrm{def}(S) := f(S) - |\delta_G(S)|$. We use $\mathrm{def}_{f,G}(S)$ (or $\mathrm{def}_{f,E}(S)$) when we want to make the cut-requirement function and graph (or edge-set) explicit. By Lemma 2.1 (b), $\mathrm{def}(S)$ is weakly supermodular; also, it is symmetric (and normalized). We say that S is a *small cut* (or more explicitly a *small-(f,G)-cut*) if $\mathrm{def}(S) > 0$. Clearly, if there is no small cut, then CR-f-NDP becomes equivalent to f-NDP. Our chief insight and key structural result is that if there is a small cut, then we can simplify the CR-f-NDP instance and move to smaller CR-f-NDP instances, by "splitting" the instance along a suitable small cut (Theorem 4.5). By repeating this operation, we eventually obtain an instance with no small cuts, which leads to Theorem 4.1. The splitting operation relies on the following modification of f.

▶ **Definition 4.3.** *Let $\emptyset \neq S \subsetneq V$. Recall that $\overline{S} := V - S$. Let $Z = \delta_G(S)$. Define the function $f_S : 2^S \mapsto \mathbb{Z}$, which we call the* restriction of f to S, *as follows.*

$$f_S(T) = \begin{cases} 0; & \text{if } T = \emptyset \text{ or } T = S \\ \max\{f(T) - |\delta_Z(T)|, f(T \cup \overline{S}) - |\delta_Z(T \cup \overline{S})|\} & \text{otherwise} \end{cases} \qquad \forall T \subseteq S.$$

The intuition here is that for $T \subseteq S$, $f_S(T)$ is a lower bound on the residual requirement that needs to be met from $\delta_{G[S]}(T)$ given that we pick all edges of Z. Note that since f and $|\delta_Z(.)|$ are symmetric, $f(T \cup \overline{S}) - |\delta_Z(T \cup \overline{S})| = f(S - T) - |\delta_Z(S - T)|$, and so f_S is the symmetric, normalized version of of the residual requirement function $f - |\delta_Z(\cdot)|$.

In the splitting operation, we pick a small cut A of *maximum* deficiency, and move to CR-f-NDP instances on the smaller graphs $G[A]$, and $G[\overline{A}]$ obtained by restricting f to A, and restricting f to $\overline{A}$ respectively (Theorem 4.5). Lemma 4.4 states some basic properties of the restriction of f. Part (b) will be quite useful in proving that the splitting operation maintains feasibility, and part (a) allows us to repeat the splitting operation on the smaller instances. For a set $S \subseteq V$, and set $F \subseteq E$ of edges, we use $F(S)$ to denote the edges of F with both ends in S.

▶ **Lemma 4.4.** *Let $\emptyset \neq S \subsetneq V$. Let f_S be the restriction of f to S. Let $\delta_G(S) \subseteq F \subseteq E$.*

(a) *f_S is weakly supermodular, symmetric, and normalized.*

(b) *Let $\emptyset \neq T \subsetneq S$. Then, $\mathrm{def}_{f_S,F(S)}(T) = \max\{\mathrm{def}_{f,F}(T), \mathrm{def}_{f,F}(T \cup \overline{S})\}$.*

Proof. Let $Z = \delta_G(S)$. Define $f' : 2^V \mapsto \mathbb{R}$ by $f'(T) := f(T) - |\delta_Z(T)|$. Then, f' is weakly supermodular and symmetric (Lemma 2.1 (b)).

For part (a), we can proceed in two ways. As noted earlier, f_S is the symmetric, normalized version f', so part (a) follows from Lemma 2.1 (a). Alternatively, observe that f_S is the projection of f' onto S with respect to $\mathcal{C} := \{\emptyset, \overline{S}\}$, which is closed under set intersections, unions, differences, and complements with respect to $V - S$. So by Lemma 2.1 (c), we obtain that f_S is weakly supermodular and symmetric. Also, f_S is normalized by definition.

For part (b), the stated equality follows by simply plugging in f_S, and noting that for $Y \in \{T, T \cup \overline{S}\}$, we have $|\delta_F(Y)| = |\delta_{F(S)}(T)| + |\delta_Z(Y)|$. ◀

▶ **Theorem 4.5** (Splitting along a small cut)**.** *Suppose that there is some small cut. Let $A \subseteq V$ be a maximum-deficiency cut. Note that $\mathrm{def}(A) > 0$ and $\emptyset \neq A \subsetneq V$.*

(a) *$F \subseteq E$ is a feasible solution to* CR-(f,G)-NDP *iff $F \supseteq \delta_G(A)$, $F(A)$ is a feasible solution to* CR-$(f_A, G[A])$-NDP*, and $F(\overline{A})$ is a feasible solution to* CR-$(f_{\overline{A}}, G[\overline{A}])$-NDP*.*

(b) *$x \in \mathbb{R}^E_+$ is feasible to $(\mathrm{CRLP}_{f,G})$ iff $x_e = 1$ for all $e \in \delta_G(A)$, x^A is feasible to $(\mathrm{CRLP}_{f_A,G[A]})$, and $x^{\overline{A}}$ is feasible to $(\mathrm{CRLP}_{f_{\overline{A}},G[\overline{A}]})$.*

Proof. Part (a) can be seen as the special case of part (b), where x is integral. We prove part (a) here, as the proof is somewhat (notational) simpler. For notational simplicity, let $(f_1, G_1, F_1) = \big(f_A, G[A], F(A)\big)$ and $(f_2, G_2, F_2) = \big(f_{\overline{A}}, G[\overline{A}], F(\overline{A})\big)$. Let $Z = \delta_G(A)$.

The "only if" direction follows easily from the definition of the restriction of f. Let F be feasible to CR-(f, G)-NDP. Since A is a small cut, we must have $F \supseteq Z$. Consider any $\emptyset \neq T \subsetneq A$. Since F is feasible, we have $|\delta_F(T)| \geq \min\big\{f(T), |\delta_G(T)|\big\}$, which implies that $|\delta_{F_1}(T)| \geq \min\big\{f(T) - |\delta_Z(T)|, |\delta_{G_1}(T)|\big\}$. Similarly, we have $|\delta_F(T \cup \overline{A})| \geq \min\big\{f(T \cup \overline{A}), |\delta_G(T \cup \overline{A})|\big\}$, so $|\delta_{F_1}(T)| \geq \min\big\{f(T \cup \overline{A}) - |\delta_Z(T \cup \overline{A})|, |\delta_{G_1}(T)|\big\}$. Combining the inequalities, and using the definition of restriction, we obtain that $|\delta_{F_1}(T)| \geq \min\big\{f_1(T), |\delta_{G_1}(T)|\big\}$. Since T was arbitrary, this shows that F_1 is feasible to CR-(f_1, G_1)-NDP.

A symmetric argument shows that F_2 is a feasible solution to CR-(f_2, G_2)-NDP.

Conversely, suppose that $F \supseteq \delta_G(A)$, $F_1 = F(A)$ is a feasible solution to CR-(f_1, G_1)-NDP, and $F_2 = F(\overline{A})$ is a feasible solution to CR-(f_2, G_2)-NDP. Recall that $Z = \delta_G(A)$. Consider any $\emptyset \neq T \subsetneq V$. Lemma 4.4 (b) can be used to readily argue that if $T \subseteq A$ or $T \subseteq \overline{A}$, then the constraint for set T in CR-(f, G)-NDP is satisfied. We show this for $T \subseteq A$; a symmetric argument applies for $T \subseteq \overline{A}$. If T is a small-(f_1, G_1)-cut, then $F_1 \supseteq \delta_{G_1}(T)$. Since $F \supseteq Z$, this implies that $F \supseteq \delta_G(T)$. Otherwise, we have $\mathrm{def}_{f_1,F_1}(T) \leq 0$, so by Lemma 4.4 (b), we have that $\mathrm{def}_{f,F}(T) \leq \mathrm{def}_{f_1,F_1}(T) \leq 0$. Thus, we always have $|\delta_F(T)| \geq \min\big\{f(T), |\delta_G(T)|\big\}$.

Now consider T such that $T \cap A, T \cap \overline{A} \neq \emptyset$. We exploit the weak supermodularity of $\mathrm{def}_{f,F}$, and that A has maximum deficiency, to bound $\mathrm{def}_{f,F}(T)$ in terms of the deficiency of sets that do not cross A, and thus show that the constraint for T is satisfied. We have

$$\mathrm{def}_{f,F}(T) + \mathrm{def}_{f,F}(A) \leq \mathrm{def}_{f,F}(T \cap A) + \mathrm{def}_{f,F}(T \cup A) = \mathrm{def}_{f,F}(T \cap A) + \mathrm{def}_{f,F}(\overline{A} - T) \quad \text{or}$$
$$\mathrm{def}_{f,F}(T) + \mathrm{def}_{f,F}(A) \leq \mathrm{def}_{f,F}(A - T) + \mathrm{def}_{f,F}(T - A)$$

where in the first inequality we also use the fact that $\mathrm{def}_{f,F}$ is symmetric. In both cases, we have $\mathrm{def}_{f,F}(T) + \mathrm{def}_{f,F}(A) \leq \mathrm{def}_{f,F}(X) + \mathrm{def}_{f,F}(Y)$ where $X \subseteq A$, $Y \subseteq \overline{A}$ and $\delta_G(T) \subseteq \delta_G(X) \cup \delta_G(Y) \cup Z$. As shown previously, for $S \in \{X, Y\}$, we have $|\delta_F(S)| \geq \min\big\{f(S), |\delta_G(S)|\big\}$, or equivalently, $\mathrm{def}_{f,F}(S) \leq \max\big\{0, \mathrm{def}_{f,G}(S)\big\}$. Note that $\mathrm{def}_{f,F}(A) = \mathrm{def}_{f,G}(A) > 0$ since $F \supseteq \delta_G(A)$. Since A is a maximum-deficiency small cut, this also implies that $\mathrm{def}_{f,F}(A) \geq \mathrm{def}_{f,F}(S)$ for $S \in \{X, Y\}$: we have $\mathrm{def}_{f,F}(S) \leq \max\big\{0, \mathrm{def}_{f,G}(S)\big\} \leq \max\big\{0, \mathrm{def}_{f,G}(A)\big\} = \mathrm{def}_{f,F}(A)$.

If both X and Y are small-(f, G)-cuts, then we are done since then we have that $F \supseteq \delta_G(X) \cup \delta_G(Y) \cup Z \supseteq \delta_G(T)$. Otherwise, since $\mathrm{def}_{f,F}(A) \geq \max\big\{\mathrm{def}_{f,F}(X), \mathrm{def}_{f,F}(Y)\big\}$, we have $\mathrm{def}_{f,F}(T) \leq \min\big\{\mathrm{def}_{f,F}(X), \mathrm{def}_{f,F}(Y)\big\} \leq 0$, since at least one of X, Y is not a small-(f, G)-cut. ◀

Proof of Theorem 4.1. Parts (a) and (b) follow easily by induction on the number of nodes, using parts (a) and (b) of Theorem 4.5. Consider part (a). The base case is when there is no small-(f, G)-cut, in which case, we have $V_1 = V$, and $f_1 = f$. Otherwise, let $A = \mathrm{argmax}_{S \subseteq V} \mathrm{def}_{f,G}(S)$. Since f_A and $f_{\overline{A}}$ are weakly-supermodular, we can recurse and induct on CR-$(f_A, G[A])$-NDP and CR-$(f_{\overline{A}}, G[\overline{A}])$-NDP instances, both of which have fewer nodes, to obtain partitions of A and $\overline{A}$; we combine these to obtain $V_1, \ldots, V_k$. Theorem 4.5 (a) and the induction hypothesis then readily yield part (a) here. The only thing to note is that since the induction hypothesis yields $F \supseteq \delta_{G[A]}(V_i)$ for a part $V_i \subseteq A$, and $F \supseteq \delta_G(A)$ by Theorem 4.5 (a), we have $F \supseteq \delta_G(V_i)$. Similarly, $F \supseteq \delta_G(V_i)$ for any part $V_i \subseteq \overline{A}$.

Part (b) follows similarly from Theorem 4.5 (b). Part (c) follows from part (b), because it is not hard to see, using part (b), that any convex combination of feasible solutions to (CRLP$_{f,G}$) yields a convex combination of feasible (NDP$_{f_i, G[V_i]}$)-solutions, and vice versa. ◀

One may wonder if the $(f_i, G[V_i])$-NDP-instances in the decomposition of Theorem 4.1 can be specified more directly or succinctly. In the full version, we prove some properties of the decomposition given by its proof, which as a *consequence*, enable one to do so. But we need our splitting approach to argue why this succinct description fulfills the properties in Theorem 4.1. The properties we establish also imply that the decomposition in Theorem 4.1 can be computed efficiently given suitable algorithmic access to the base cut-requirement function f.

5 Algorithmic implication: LP-relative 2-approximation algorithm

We now exploit the decomposition result stated in Theorem 4.1, and Corollary 4.2, to obtain a 2-approximation algorithm. We assume that we have a separation oracle for $(\text{CRLP}_{f,G})$, which implies that we can efficiently find an extreme-point optimal solution to $(\text{CRLP}_{f,G})$ and any LP that arises in a subsequent iteration after fixing some x_e variables to 1 (Fact 2.2).

Algorithm 1 CRNDP-Alg.

The input is $\big(G = (V, E), \{c_e \geq 0\}, f : 2^V \mapsto \mathbb{Z}\big)$, where f is weakly-supermodular (and symmetric, normalized). We assume there is a separation oracle for $(\text{CRLP}_{f,G})$.

A1. Initialize $F \leftarrow \emptyset$, $G' = (V, E') \leftarrow G$, and $f' \leftarrow f$.

A2. While F is not a feasible solution (which can be detected using the separation oracle), repeat:

A2.1 Find an extreme-point optimal solution $\widehat{x}$ to $(\text{CRLP}_{f',G'})$.

A2.2 Let $Z_1 = \{e \in E' : \widehat{x}_e \geq 1/2\}$. Update $F \leftarrow F \cup Z_1$, $E' \leftarrow E' - Z_1$, and $f'(S) = f'(S) - |\delta_{Z_1}(S)|$ for all $S \subseteq V$.

A3. Return F.

▶ Remark 5.1. The collection of small cuts *does not change across iterations*; that is, S is a small-(f, G)-cut iff it is a small-(f', G')-cut in some other iteration. This is because, for any $S \subseteq V$, we change $|\delta_{G'}(S)|$ and $f'(S)$ by the same amount in every iteration. In the first iteration, we have $\widehat{x}_e = 1$ for every $e \in \delta_G(S)$ and every small cut S, and so $\delta_{G'}(S) = \emptyset$ in any subsequent iteration. So we do not have any constraints for small cuts in subsequent iterations, and this causes problems with uncrossing tight constraints. Nevertheless, we are able to argue, due to our decomposition result, that there is always some edge with $\widehat{x}_e \geq 1/2$.

▶ **Theorem 5.2.** *Let OPT denote the optimal value of $(\text{CRLP}_{f,G})$. Algorithm* CRNDP-Alg *returns a feasible* CR-f-NDP*-solution $F \subseteq E$ such that $c(F) \leq 2 \cdot OPT$.*

Proof. By Corollary 4.2, at least one edge gets added to F in every iteration, so the algorithm terminates in at most $|E|$ iterations. The cost bound follows by induction on the number of iterations to termination. The base case is trivial. Suppose $F = Z_1 \cup F'$, where F' is the solution found in subsequent iterations for the instance CR-(f', G')-NDP. Let OPT' be the optimal solution to $(\text{CRLP}_{G',f'})$. Then, by induction, we have $c(F_1) \leq 2 \cdot OPT'$ and $OPT' \leq \sum_{e \in E'} c_e \widehat{x}_e$, since $(\widehat{x}_e)_{e \in E'}$ is a feasible solution to $(\text{CRLP}_{f',G'})$. We also have $c(Z_1) \leq 2 \cdot \sum_{e \in Z_1} c_e \widehat{x}_e$. Therefore, $c(F) \leq 2c^T \widehat{x} = 2 \cdot OPT$. ◀

Since $(\text{CRLP}_{f^{\text{SNDP}},G})$ admits a polytime separation oracle (Lemma 2.3), we obtain the following result as a corollary.

▶ **Theorem 5.3.** *There is a 2-approximation algorithm for* CR-SNDP.

6 Hardness result

We now show that cut-relative SNDP and path-relative SNDP are APX-hard, even when the base SNDP instance involves only one s-t pair, by showing that the k-edge connected subgraph (k-ECSS) problem can be cast as a special case of these problems. (This hints at the surprising amount of modeling power of {cut, path}- relative SNDP.) Previously, even NP-hardness of path-relative SNDP in the s-t case was not known.

Let $\big(G = (V, E), \{c_e\}_{e \in E}\big)$ be an instance of k-ECSS. We may assume that G is at least k-edge connected, i.e., $|\delta_G(S)| \geq k$ for all $\emptyset \neq S \subsetneq V$, as otherwise there is no feasible solution (and this can be efficiently detected).

Consider the following path-relative SNDP instance. We add a source s and sink t, and edges sv, vt of cost 0, for all $v \in V$. Let $G' = (V', E')$ denote this graph. The base-SNDP instance asks for $(k+n)$-edge connectivity between s and t, where $n = |V|$. That is, the base cut-requirement function f is given by $f(S') = k + n$ if $S' \subseteq V'$ is an s-t cut, and $f(S') = 0$ otherwise. We show that path-relative SNDP and cut-relative SNDP are actually equivalent in this case, and that they encode k-ECSS on the graph G.

▶ **Theorem 6.1.** *$H \subseteq E'$ is a feasible solution to the above {cut, path}-relative* SNDP *instance $\iff$ $H \supseteq \delta_{G'}(s) \cup \delta_{G'}(t)$ and $H(V)$ is a feasible k-*ECSS*-solution for G. Hence, this {cut,path}-relative* SNDP *instance is the same as k-*ECSS *on the graph G.*

Proof. Recall that we are assuming that G is (at least) k-edge connected. The following observation will be handy. The only small cuts in G' are $\{s\}$ and $\{t\}$ (and their complements). For any other s-t cut $S' \subseteq V'$, taking $S = S' \cap V$, we have that $\emptyset \neq S \subsetneq V$. So we have $|\delta_{G'}(S')| = |\delta_G(S)| + |S| + |V - S| \geq k + n$.

$\Leftarrow$ direction. We argue that H is feasible for cut-relative SNDP, which also implies that it is feasible for path-relative SNDP. Clearly, H covers both small cuts. For any other s-t cut $S' \subseteq V'$, taking $S = S' \cap V$, we have $|\delta_H(S')| \geq |\delta_{H(V)}(S)| + |S| + |V - S| \geq k + n$, since $H(V)$ is a feasible k-ECSS-solution for G.

$\Rightarrow$ direction. Suppose that H is feasible for path-relative SNDP. If there is some edge $sv \notin H$, then consider the fault-set $F = \delta_{G'}(s) - \{sv\}$. Then $H - F$ clearly has no s-t path, since $\delta_{H-F}(s) = \emptyset$. But $G' - F$ has an s-t path sv, vt. So we must have $H \supseteq \delta_{G'}(s)$. A similar argument shows that $H \supseteq \delta_{G'}(t)$.

We next argue that $|\delta_H(S')| \geq n + k$ for every s-t cut S' for which $\emptyset \neq S := S' \cap V \subsetneq V$. This is equivalent to showing that $|\delta_{H(V)}(S)| \geq k$, since $|\delta_H(S') \cap \delta_{G'}(s)| + |\delta_H(S') \cap \delta_{G'}(t)| = n$. Assume that $s \in S'$ without loss of generality. Suppose $|\delta_{H(V)}(S)| < k$. Since $|\delta_G(S)| \geq k$, there is some edge $uv \in \delta_G(S) - \delta_{H(V)}(S)$. Suppose $u \in S$. Consider the fault-set $F = \delta_{H(V)}(S) \cup \{sw : w \in V - S\} \cup \{wt : w \in S\}$. Then $|F| < k + n$ and $H - F$ has no s-t path, since we have constructed F to ensure that $\delta_{H-F}(S') = \emptyset$. However, $G - F$ has an s-t path: su, uv, vt. This contradicts that H is feasible for path-relative SNDP.

So we have shown both that $H(V)$ is feasible k-ECSS solution for G, and that H is feasible for cut-relative SNDP.

Since the cost of the edges in $E' - E$ is 0, the above {cut, path}-relative SNDP instance is exactly the same as k-ECSS on the graph G. ◀

7 Non-equivalence of path-relative SNDP and cut-relative SNDP

We consider the same graph and base SNDP instance as in Fig. 1. The graph is reproduced below for convenience, and recall that the base cut-requirement function models s-t 2-edge connectivity: so $f(S) = 2$ if S is an s-t cut, and $f(S) = 0$ otherwise.

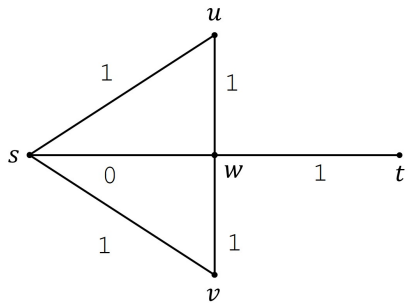

Figure 2 An instance where path-relative SNDP and cut-relative SNDP are not equivalent. The number labeling an edge gives the cost of the edge.

A feasible solution to path-relative SNDP is given by the edge-set $H_1 = \{su, uw, sw, wt\}$, which has cost 3. (This is in fact an optimal solution to path-relative SNDP.)

However, H_1 *is not feasible for cut-relative* SNDP. This is because, we require $\delta_H(\{s, u, w\}) \geq \min\{2, 3\} = 2$ in any feasible CR-SNDP solution H. Moreover, one can infer that any feasible CR-SNDP-solution must include all but one of the edges from $\{su, uw, sw, sv, vw\}$. This is because for any $F \subseteq \{su, uw, sw, sv, vw\}$ with $|F| = 2$, one can verify that there is an s-t cut S such that $|\delta_G(S)| = 3$ and $F \subseteq \delta_G(S)$; so $|\delta_{G-F}(S)| \leq 1$, which implies that there is no feasible solution that excludes F. A feasible CR-SNDP-solution must also include the edge wt, so the optimal value for cut-relative SNDP is 4.

While cut-relative SNDP and path-relative SNDP are not in general equivalent, they are closely related. Dinitz et al. [9] showed (see Lemma A.1 in [9]) that one can give a cut-based formulation for path-relative SNDP, where H is feasible iff $|\delta_H(S)| \geq \min\{f(S), |\delta_G(S)|\}$ for every $S \subseteq V$ *such that* $G[S]$ *and* $G[V' - S]$ *are connected graphs*, where $V' \subseteq V$ is the vertex-set of the component containing S. That is, we require the cut-constraints of CR-SNDP to hold for a suitable collection of node-sets (as opposed to all node-sets in CR-SNDP). This immediately implies that CR-SNDP and path-relative SNDP are equivalent when the underlying graph is a (capacitated) complete graph. Also, as mentioned earlier, path-relative k-ECSS and cut-relative k-ECSS are equivalent [8].

Going Beyond Surfaces in Diameter Approximation

Michał Włodarczyk
University of Warsaw, Poland

Abstract

Calculating the diameter of an undirected graph requires quadratic running time under the Strong Exponential Time Hypothesis and this barrier works even against any approximation better than 3/2. For planar graphs with positive edge weights, there are known $(1+\varepsilon)$-approximation algorithms with running time $\mathsf{poly}(1/\varepsilon, \log n) \cdot n$. However, these algorithms rely on shortest path separators and this technique falls short to yield efficient algorithms beyond graphs of bounded genus.

In this work we depart from embedding-based arguments and obtain diameter approximations relying on VC set systems and the local treewidth property. We present two orthogonal extensions of the planar case by giving $(1+\varepsilon)$-approximation algorithms with the following running times:

- $\mathcal{O}_h((1/\varepsilon)^{\mathcal{O}(h)} \cdot n \log^2 n)$-time algorithm for graphs excluding an apex graph of size h as a minor,
- $\mathcal{O}_d((1/\varepsilon)^{\mathcal{O}(d)} \cdot n \log^2 n)$-time algorithm for the class of d-apex graphs.

As a stepping stone, we obtain efficient $(1+\varepsilon)$-approximate distance oracles for graphs excluding an apex graph of size h as a minor. Our oracle has preprocessing time $\mathcal{O}_h((1/\varepsilon)^8 \cdot n \log n \log W)$ and query time $\mathcal{O}_h((1/\varepsilon)^2 \cdot \log n \log W)$, where W is the metric stretch. Such oracles have been so far only known for bounded genus graphs. All our algorithms are deterministic.

1 Introduction

The diameter of a graph G, denoted $\mathsf{diam}(G)$, is the largest distance between a pair of its vertices in the shortest path metric. We assume that each edge is assigned some real positive weight, and the length of a path is the sum of its weights. The obvious way to calculate $\mathsf{diam}(G)$ is to check the distances for all vertex pairs, but this inevitably requires quadratic time. This trivial approach is essentially optimal because already unweighted graphs of diameter 2 or 3 cannot be distinguished in time $\mathcal{O}(m^{1.99})$ under the Strong Exponential Time Hypothesis [49] (see [2] for hardness in sparse graphs). On the other hand, truly subquadratic algorithms to compute diameter are available in planar graphs [10, 34] and graph classes excluding a minor [26, 42, 46]. Still, the best algorithm for planar graphs runs in time[1] $\tilde{\mathcal{O}}(n^{5/3})$ [34], which is far from linear.

The absence of fast algorithms calculating the diameter exactly led the researchers to seek fast approximation algorithms. Weimann and Yuster [55] gave the first almost-linear $(1+\varepsilon)$-approximation for planar diameter, running in time $\tilde{\mathcal{O}}(2^{\mathcal{O}(1/\varepsilon)} \cdot n)$. This was improved to randomized time $\tilde{\mathcal{O}}((1/\varepsilon)^5 \cdot n)$ by Chan and Skrepetos [12] (see also [18]). Li and Parter [47] gave a deterministic algorithm of this type, as well as a distributed algorithm with a small number of rounds. Observe that each of these can be used to recognize unweighted planar

[1] The variable n refers to the number of vertices in a graph but all the considered graph classes are sparse so the number of edges is $\mathcal{O}(n)$. The $\tilde{\mathcal{O}}$-notation hides factors polylogarithmic in n. We refer to the dependence $\tilde{\mathcal{O}}(n)$ as *almost-linear*.

graphs of diameter D, simply by setting $\varepsilon = 1/(2D)$. There are also specialized algorithms for this task by Eppstein [28], with running time $2^{\mathcal{O}(D \log D)} \cdot n$, and by Abboud, Mozes, and Weimann [1], with running time $\tilde{\mathcal{O}}(D^2 \cdot n)$.

Shortest path separators. An area that is technique-wise related is the design of approximate distance oracles. After a preprocessing step, we would like to quickly estimate any (u, v)-distance within factor $(1 + \varepsilon)$. Thorup [53] exploited the fact that planar graphs admit balanced separators consisting of two shortest paths to give an oracle with preprocessing time $\mathcal{O}((1/\varepsilon)^2 \cdot n \log^3 n)$, space $\mathcal{O}((1/\varepsilon) \cdot n \log n)$, and query time $\mathcal{O}(1/\varepsilon)$. The shortest path separators constitute a crucial ingredient of all the three aforementioned algorithms for estimating planar diameter as well.

Abraham and Gavoille [3] presented a generalization of shortest path separators to graph classes excluding a minor and extended Thorup's oracle to such classes. However, their separators no longer enjoy such a nice structure. The main caveat is that already in a single balanced separator one might need to use paths P_1, P_2 such that P_2 is a shortest path only in $G - P_1$. Hence P_2 may be much longer than $\mathsf{diam}(G)$, which is easily seen to be unavoidable already in the class of apex graphs[2], and it is unclear how to exploit such a separator for diameter computation. The second issue is that finding the separator requires highly superlinear time, which burdens the preprocessing time of the oracle. Almost-linear preprocessing time is currently available only for graphs of bounded genus [40] and for unit disk graphs [13]. The lack of well-structured balanced separators beyond surface-embeddable graphs seems to have limited the development of efficient metric-related algorithms so far.

Beyond surface embedding. There are two directions of generalizing the topological graph classes. First, one can pick $\mathcal{O}(1)$ faces in the surface embedding of a graph and replace them with certain graphs of pathwidth $\mathcal{O}(1)$, which are called the *vortices*. Second, one can insert a set of $\mathcal{O}(1)$ vertices, called the *apices*, and connect them possibly to anyone. The structural theorem of Robertson and Seymour [48] states that for any graph H, all the graphs excluding H as a minor can be constructed from graphs embeddable in some fixed surface using these two operations and by taking a clique-sum of them.

When the excluded minor H is an apex graph, this description can be slightly restricted [25]. What is important to us, apex-minor-free graphs enjoy the *local treewidth property*: their treewidth is bounded in terms of the (unweighted) diameter and this relation is known to be linear [24]. Note that the diameter of an edge-weighted graph cannot be related to treewidth by any means because the diameter can be reduced by scaling the weights, while the topological structure of the graph remains the same. Nevertheless, we will see that the local treewidth property is still useful in the considered setting.

The main message of this work is that the local treewidth property can be used instead of shortest path separators for the sake of approximating diameter and radius, as well as for efficient construction of distance oracles. We first employ it to tackle apex-minor-free graphs but we also show that its usefulness is not limited to such graph classes.

Additive core-sets. Suppose we have a list of vertices $S = (s_0, s_1, \ldots, s_{k-1})$ in G and we want to (approximately) learn all the distance patterns, between a vertex v and all of S. Chan and Skrepetos [12] employed Cabellos's technique of abstract Voronoi diagrams [10] to

[2] G is called an *apex graph* if G can be made planar by removal of a single vertex.

build a data structure to browse such distance patterns in the case when G is planar and S lie on a single face. However, this technique relies heavily on the embedding of the graph.

A more versatile argument was given by Li and Parter [47] in order to approximate planar diameter in a distributed regime. Following their convention, a subset $U' \subseteq U$ is called a *δ-additive core-set* of U if for every $u \in U$ there exists $u' \in U'$ such that for each $i \in [0, k)$ we have $|d(u, s_i) - d(u', s_i)| \leq \delta$. When $\delta = \varepsilon \cdot \mathsf{diam}(G)$, a trivial rounding argument yields a δ-additive core-set of size $(1/\varepsilon)^k$. Remarkably, the dependence on k can be in fact removed from the exponent [47]. This theorem relies on a bound on the VC dimension of a certain set system and this argument carries over to any minor-free graph class [46]. A direct consequence of these theorems reads as follows. (Here K_h stands for the h-vertex clique.)

▶ **Lemma 1** (Corollary of [46, Theorem 1.3]). *Let G be an edge-weighted K_h-minor-free graph G, $S = (s_0, \ldots, s_{k-1}) \in V(G)^k$, $U \subseteq V(G)$, and $\varepsilon > 0$. Then U admits an $(\varepsilon \cdot \mathsf{diam}(G))$-additive core-set (with respect to S) of size $\mathcal{O}(k^{h-1} \cdot (1/\varepsilon)^h)$.*

For the sake of completeness, we provide a proof in Section 2. The local treewidth property will allow us to apply this lemma for $k = \mathsf{poly}(1/\varepsilon)$ to efficiently compress information about distances in large subgraphs.

1.1 Our contribution

A crucial property of a separator S consisting of $\mathcal{O}(1)$ shortest paths is that S can be covered by $\mathcal{O}(1/\varepsilon)$ subgraphs of strong[3] diameter $\varepsilon \cdot \mathsf{diam}(G)$. Then the interaction between the two sides of S can be channeled through $\mathcal{O}(1/\varepsilon)$ *portals* on S when small distance distortion is allowed. We show that balanced separators of this kind exist and can be efficiently found in any class excluding an apex minor. Specifically, we construct a clustering of an apex-minor-free graph into pieces of small strong diameter such that the graph obtained by contracting each cluster has bounded treewidth. We use this construction to estimate the eccentricity $\mathsf{ecc}_G(v)$ of every vertex v, that is, $\max_{u \in V(G)} d_G(v, u)$.

▶ **Theorem 2.** *Let H be an apex graph of size h. There is an algorithm that, given an edge-weighted H-minor-free graph G and $\varepsilon > 0$, runs in time $\mathcal{O}_h((1/\varepsilon)^{3h+2} \cdot n \log^2 n)$ and estimates eccentricity of each vertex vertex $v \in V(G)$ within additive error $\varepsilon \cdot \mathsf{diam}(G)$. Moreover, for each $v \in V(G)$ the algorithm outputs vertex v' for which $d_G(v, v') \geq \mathsf{ecc}_G(v) - \varepsilon \cdot \mathsf{diam}(G)$.*

As a corollary, we get $(1 + \varepsilon)$-approximation for both diameter and radius, which are respectively the largest and the smallest eccentricity.

To employ the additive core-sets in the proof of Theorem 2, we first need to precompute approximate distances for $\mathcal{O}((1/\varepsilon)^2 \cdot n \log n)$ pairs of vertices. To this end, we design a distance oracle with preprocessing and query times tailored to our needs. Similar oracles are available for minor-free graphs [3, 16, 40] but their preprocessing times are far from linear. An oracle with additive error $\varepsilon \cdot \mathsf{diam}(G)$ suffices for the proof of Theorem 2 but we can improve it to multiplicative error by taking into account the metric stretch, i.e., the ratio between the largest and smallest positive distances.

▶ **Theorem 3.** *Let H be an apex graph. Given an edge-weighted H-minor-free graph G of metric stretch W and $\varepsilon > 0$, one can build an $(1 + \varepsilon)$-approximate distance oracle with preprocessing time $\mathcal{O}_H((1/\varepsilon)^8 \cdot n \log n \log W)$ and query time $\mathcal{O}_H((1/\varepsilon)^2 \cdot \log n \log W)$.*

[3] A subgraph H of G has *strong diameter* D if every pair of vertices $u, v \in V(H)$ can be connected by a path in H of length at most D. For comparison, *weak diameter* refers to distances measured in G.

The simplest case not covered by Theorem 2 is of course given by the class of apex graphs. This class no longer enjoys the local treewidth property. Moreover, some problems which are easy on planar graphs become much harder after insertion of a single apex [5, 11]. Note that removing just a single vertex can increase the diameter significantly and so our clustering technique cannot be directly applied to decompose such a graph.

We give a stronger theorem that in particular covers the apex graphs. As a consequence of Robertson and Seymour's structural theorem, for every graph K there exists an apex graph H and a constant c, such that every K-minor-free graph can be constructed via a clique-sum from graphs $G_1, \ldots, G_\ell$ with the following property: each G_i becomes H-minor-free after deletion of c vertices [23, Theorem VI.1]. We extend Theorem 2 to such graphs, assuming that the deletion set is known.

▶ **Theorem 4.** *Let $h, c \in \mathbb{N}$ and $\mathcal{H}$ be a graph class excluding an apex graph of size h. There is an algorithm that, given an edge-weighted graph G, $\varepsilon > 0$, and a set $A \subseteq V(G)$ of size c, for which $G - A \in \mathcal{H}$, runs in time $\mathcal{O}_{h+c}((1/\varepsilon)^\alpha \cdot n \log^2 n)$, where $\alpha = \mathcal{O}((h+1)(c+1))$, and estimates $\mathsf{diam}(G)$ within factor $(1+\varepsilon)$.*

Unlike the apex-minor-free case, this time we do not estimate eccentricities because Theorem 4 involves a certain "irrelevant vertex rule" that only preserves the diameter (approximately). The assumption that the set A is given in the input can be dropped for the class $\mathcal{H}$ of planar graphs, i.e., when the input is a d-apex graph. In this case, one can find the set A in time $2^{\mathcal{O}(d \log d)} \cdot n$ [37], which leads to the following unconditional statement.

▶ **Corollary 5.** *There is an $\mathcal{O}_d((1/\varepsilon)^{\mathcal{O}(d)} \cdot n \log^2 n)$-time algorithm that estimates the diameter of an edge-weighted d-apex graph within factor $(1+\varepsilon)$.*

This result can be regarded as a generalization of the planar case in a direction that is orthogonal to Theorem 2. Unfortunately, when the class $\mathcal{H}$ excludes an arbitrary apex graph H, we do not know whether one can drop the assumption about the set A being provided. Indeed, the fastest parameterized algorithm to find set A for which $G - A$ is H-minor-free (where H is some apex graph) requires quadratic time [50]. We discuss the perspective of handling more general graph classes in Section 6.

1.2 Related Work

Apart from the ones used in this work, there are more VC set systems considered in the context of minor-free graph metrics [7, 8, 21, 22, 26, 39]. Some other approaches to such metrics are based on a decomposition into low-diameter subgraphs, including the classic KPR theorem [41]. Our low-diameter clustering scheme bears resemblance to the *shortcut partitions* [14, 15, 16] which provide even stronger guarantees but it is not known how to construct them in almost-linear time. The related *buffered cop decompositions* [16] yield cluster graphs of bounded weak coloring numbers [6]. These in turn are connected to *sparse covers* [4, 9, 29], however there the low-diameter subgraphs need not to be disjoint.

An alternative way to represent a metric by a bounded treewidth graph is a *metric embedding*. For example, an edge-weighted planar graph G can be embedded into a metric given by a graph of treewidth $f(\varepsilon)$ so that the additive distortion is $\varepsilon \cdot \mathsf{diam}(G)$ [32]. The function f can be estimated as $f(\varepsilon) = \mathcal{O}(\varepsilon^{-4})$ [14]. For apex-minor-free graphs, the current best treewidth bound is $f(\varepsilon) = 2^{\mathcal{O}(1/\varepsilon)}$ [16]. In the latter case, we again do not know if such an embedding can be computed in almost-linear time. See also [23, 30] for metric embeddings of minor-free graphs and a variant with multiplicative distortion.

For more advances in diameter computation, see [13, 17, 27], and for recent developments in planar distance oracles, see [18, 19, 33, 35, 44].

1.3 Organization of the Paper

We begin with Section 2 including preliminaries on VC set systems and additive core-sets. The following three sections contain the main technical lemmas. Sections 3 and 4 culminate with the proof of Theorem 2 while Section 5 contains the crucial lemma for Theorem 4. The formal proofs of Theorems 3 and 4 can be found in the full version of the article. The full version also contains the proofs of the statements marked with (★).

2 Preliminaries

All our statements concern undirected graphs with real positive edge weights. In an unweighted graph, each weight is set to one.

▶ **Definition 6** (Treewidth). *A* tree decomposition *of a graph G is a pair (T, χ) where T is a tree, and $\chi\colon V(T) \to 2^{V(G)}$ is a function, such that:*
1. *for each $v \in V(G)$ the nodes $\{t \mid v \in \chi(t)\}$ form a non-empty connected subtree of T,*
2. *for each edge $uv \in E(G)$ there is a node $t \in V(T)$ with $\{u, v\} \subseteq \chi(t)$.*

The width *of (T, χ) is defined as $\max_{t \in V(T)} |\chi(t)| - 1$. The* treewidth *of a graph G (denoted $\mathsf{tw}(G)$) is the minimal width a tree decomposition of G.*

VC dimension. A set system is a collection $\mathcal{F}$ of subsets of some set U. We say that a subset $Y \subseteq A$ is *shattered* by $\mathcal{F}$ if $\{Y \cap S\colon S \in \mathcal{F}\} = 2^Y$, that is, every subset of Y is an intersection of Y with some $S \in \mathcal{F}$. The VC dimension of a set system is the size of the largest shattered subset. The notion of VC dimension was introduced by Vapnik and Chervonenkis [54]. What is important to us, a set system of bounded VC dimension cannot be too large.

▶ **Lemma 7** (Sauer–Shelah Lemma [51]). *Let $\mathcal{F}$ be a set system of VC dimension d over a set of size m. Then $|\mathcal{F}| = \mathcal{O}(m^d)$.*

2.1 Additive core-sets

For a vector $\mathbf{x} \in \mathbb{R}^{\mathbf{k}}$ its ℓ_∞-norm is defined as $\ell_\infty(\mathbf{x}) = \max_{i=1}^{k} |x_i|$.

▶ **Definition 8** ([47]). *For a sequence of vertices $S = (s_0, \ldots, s_{k-1})$ from G we define the* distance tuple *of v with respect to S as $\Phi_S(v) = (d_G(v, s_0), \ldots, d_G(v, s_{k-1}))$.*

For a vertex set V, a subset $V' \subseteq V$ is called a δ-additive core-set *with respect to S if for every $v \in V$ there exists $v' \in V'$ such that $\ell_\infty(\Phi_S(v) - \Phi_S(v')) \leq \delta$.*

We will take advantage of the bound on VC dimension of certain set systems related to a graph metric. Le and Wulff-Nilsen [46] considered a slight modification of the set systems introduced by Li and Parter [47], and so they denoted them by $\widehat{\mathcal{LP}}$.

▶ **Definition 9** ([46]). *Let G be an edge-weighted graph, S be a k-tuple of vertices from G, and $M \subseteq \mathbb{R}$. For $v \in V(G)$ we define:*

$$\hat{X}_v = \{(i, \Delta)\colon i \in [1, k-1],\ \Delta \in M,\ d_G(v, s_i) - d_G(v, s_0) \leq \Delta\}.$$

Let $\widehat{\mathcal{LP}}_{G,M}(S) = \{\hat{X}_v\colon v \in V(G)\}$ be a collection of subsets of the ground set $[k-1] \times M$.

▶ **Theorem 10** ([46, Theorem 1.3]). *Let G be an edge-weighted K_h-minor free graph and S, M be as in Definition 9. Then $\widehat{\mathcal{LP}}_{G,M}(S)$ has VC dimension at most $h - 1$.*

We adapt the construction of additive core-sets from [47] to rely on the set system $\widehat{\mathcal{LP}}$.

▶ **Lemma 1** (Corollary of [46, Theorem 1.3]). *Let G be an edge-weighted K_h-minor-free graph G, $S = (s_0, \ldots, s_{k-1}) \in V(G)^k$, $U \subseteq V(G)$, and $\varepsilon > 0$. Then U admits an $(\varepsilon \cdot \mathsf{diam}(G))$-additive core-set (with respect to S) of size $\mathcal{O}(k^{h-1} \cdot (1/\varepsilon)^h)$.*

Proof. Let $D = \mathsf{diam}(G)$, $\delta = \varepsilon \cdot D/2$, and $z = \lceil 2/\varepsilon \rceil$. Next, we choose $M = \{j \cdot \delta \colon j \in [-z, z]\}$. We will extend Definition 9 slightly. For vertices u, v we define $d'(u, v)$ as the largest integer j for which $j \cdot \delta \leq d_G(u, v)$. Note that $d'(u, v)$ is always bounded by z. For a vertex v let $\hat{X}_v^\circ$ be the pair $(d'(v, s_0), \hat{X}_v)$. By Theorem 10 and Lemma 7, the family $\{\hat{X}_v \colon v \in V(G)\}$ has size $\mathcal{O}\left(((k-1) \cdot |M|)^{h-1}\right) = \mathcal{O}\left((k/\varepsilon)^{h-1}\right)$. It follows that the family $\{\hat{X}_v^\circ \colon v \in V(G)\}$ has $\mathcal{O}\left(k^{h-1}\varepsilon^{-h}\right)$ elements.

We construct U' by picking for each $X \in \{\hat{X}_v^\circ \colon v \in V(G)\}$ an arbitrary vertex $v \in U$ with $\hat{X}_v^\circ = X$. Then $|U'| = \mathcal{O}\left(k^{h-1}\varepsilon^{-h}\right)$. To show that U' is an (εD)-additive core-set, pick $u \in U$. We need to prove that there exists $u' \in U'$ such that $\ell_\infty(\Phi_S(u) - \Phi_S(u')) \leq \varepsilon D$. By construction, there is $u' \in U'$ for which $\hat{X}_u^\circ = \hat{X}_{u'}^\circ$. Now we need to argue that for each $i \in [0, k-1]$ it holds that $|d_G(u, s_i) - d_G(u', s_i)| \leq \varepsilon D$.

The simplest case is for $i = 0$. As $d'(u, s_0) = d'(u', s_0)$, there is an integer j such that both $d_G(u, s_0)$, $d_G(u', s_0)$ belong to the interval $[j \cdot \delta, (j+1) \cdot \delta)$. Hence $|d_G(u, s_0) - d_G(u', s_0)| \leq \delta = \varepsilon D/2$.

Now consider $i \geq 1$. Let j be the largest integer (possibly negative) for which $d_G(u, s_i) - d_G(u, s_0) \leq j \cdot \delta$. We define j' analogously with respect to u'. Note that $j, j' \in [-z, z]$. Because $\hat{X}_u = \hat{X}_{u'}$ it must be $j = j'$. By the same argument as before, the numbers $x = d_G(u, s_i) - d_G(u, s_0)$, $y = d_G(u', s_i) - d_G(u', s_0)$ differ by at most δ. Finally, since $|d_G(u, s_0) - d_G(u', s_0)| \leq \delta$ we obtain that $|d_G(u, s_i) - d_G(u', s_i)| \leq 2\delta = \varepsilon D$. ◀

In our setting we will only know approximations of the distances from S. We show that this suffices to construct an additive core-set.

▶ **Lemma 11.** *Let G be an edge-weighted K_h-minor-free graph G, $S = (s_0, \ldots, s_{k-1}) \in V(G)^k$, and $U \subseteq V(G)$. Let δ be given and denote $\varepsilon = \delta/\mathsf{diam}(G)$. Next, suppose that for each $v \in U$ we are given $\mathbf{y}_v \in \mathbb{R}^k$ that satisfies $\ell_\infty(\mathbf{y}_v - \Phi_S(v)) \leq \delta$. Then in time $\mathcal{O}((k/\varepsilon)^h \cdot |U|)$ we can compute a (5δ)-additive core-set of U of size $\mathcal{O}\left(k^{h-1}\varepsilon^{-h}\right)$.*

Proof. We first describe the algorithm, which is a simple greedy construction of a 3δ-cover in a metric space. Initialize $\hat{U} = \emptyset$ and iterate over $v \in U$ in any fixed order. When processing v, check if $\hat{U}$ contains u for which $\ell_\infty(\mathbf{y}_v - \mathbf{y}_u) \leq 3\delta$. If there is no such element, add v to $\hat{U}$.

First we show that every vector in $\{\mathbf{y}_v \colon v \in U\}$ is within distance 3δ in the ℓ_∞ metric from the set $\{\mathbf{y}_v \colon v \in \hat{U}\}$. Suppose otherwise and let $v \in U$ be a vertex whose vector $\mathbf{y}_v$ is further than 3δ from this set. In particular, this means that $\ell_\infty(\mathbf{y}_v - \mathbf{y}_u) > 3\delta$ for each u considered before v. So v must have been added to $\hat{U}$ at this point; a contradiction.

Now we argue that $\hat{U}$ is a (5δ)-additive core-set. For each $u \in U$ we know that there exists $v \in \hat{U}$ such that $\ell_\infty(\mathbf{y}_v - \mathbf{y}_u) \leq 3\delta$. Next, by assumption $\ell_\infty(\mathbf{y}_u - \Phi_S(u)) \leq \delta$ and likewise for v. Then by the triangle inequality we get $\ell_\infty(\Phi_S(v) - \Phi_S(u)) \leq 5\delta$, as intended.

Next, we bound the size $\hat{U}$. By construction, for each $u, v \in \hat{U}$ we have $\ell_\infty(\mathbf{y}_v - \mathbf{y}_u) > 3\delta$. We apply the triangle inequality again to get $\ell_\infty(\Phi_S(v) - \Phi_S(u)) > \delta$. By applying Lemma 1 for $\varepsilon' = \varepsilon/2$ we obtain $U' \subseteq U$ so that the $(\delta/2)$-radius balls (in the ℓ_∞ metric) centered at $\{\Phi_S(v) \colon v \in U'\}$ cover the set $\{\Phi_S(v) \colon v \in U\}$. Each such ball has diameter δ so it can contain at most one element from the set $\{\Phi_S(v) \colon v \in \hat{U}\}$. This implies $|\hat{U}| \leq |U'|$ and so the size bound follows from Lemma 1.

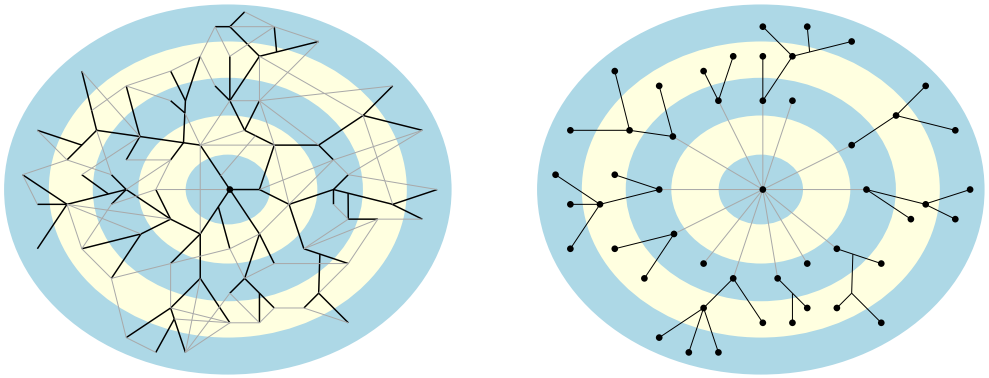

Figure 1 Construction of the clustering in Lemma 14. Left: The black edges form a shortest-path tree T rooted at r. The alternating background colors represented the layers. Each connected subgraph of T contained within a single layer forms a cluster. Right: An argument that $G_{\mathcal{C}}^{I}$ has bounded treewidth for $I = \{2, 3, 4\}$. For simplicity, the edges not originating from T are omitted. After contracting the layers 0 and 1 into a single vertex, we obtain a graph of (unweighted) diameter at most 6. Since this graph is apex-minor-free, we can use the local treewidth property.

Finally, we analyze the running time. When inspecting a vertex $u \in U$ we need to compute distances in $\mathbb{R}^k$ between $\mathbf{x}_u$ and the vectors of all the vertices already placed in the core-set. This requires at most $k \cdot |\hat{U}|$ operations and so the running time bound follows from the bound on $|\hat{U}|$. ◀

3 Low Radius Clustering

We begin with summoning the local treewidth property of apex-minor-free graphs.

▶ **Lemma 12** ([24]). *For every apex graph H, there exists a constant c such that for every unweighted H-minor-free graph G it holds that $\mathsf{tw}(G) \leq c \cdot \mathsf{diam}(G)$.*

Our first tool is a clustering of a graph into induced subgraphs of small strong diameter.

▶ **Definition 13.** *For an edge-weighted graph G, we define a* δ-radius clustering *of G as a collection of pairs $(C_i, c_i)_{i=1}^{\ell}$ with the following properties.*

1. *$(C_i)_{i=1}^{\ell}$ forms a partition of $V(G)$.*
2. *For each $i \in [\ell]$ it holds that $G[C_i]$ is connected, $c_i \in C_i$, and each $v \in C_i$ is within distance δ from c_i in $G[C_i]$.*

For $\mathcal{C} = (C_i, c_i)_{i=1}^{\ell}$ we denote by $G_{\mathcal{C}}$ the cluster graph *obtained from G by contracting each C_i into a single vertex. The vertex c_i is called the* center *of the i-th cluster.*

Note that each cluster in a δ-radius clustering has strong diameter at most 2δ. As our first goal, we aim to construct a δ-radius clustering, for $\delta = \varepsilon \cdot \mathsf{diam}(G)$, whose cluster graph has treewidth $\mathcal{O}(1/\varepsilon)$. Secondly, even when δ is chosen to be much smaller $\mathsf{diam}(G)$ we would like to put vertices u, v, satisfying $d_G(u, v) = \mathcal{O}(\delta)$, into "nearby" clusters.

For a graph G, a *layering* is simply a function $\mathsf{layer} \colon V(G) \to \mathbb{N}$. When such a function is clear from the context, for $I \subseteq \mathbb{N}$ we denote by G^I the subgraph of G induced by the vertices v with $\mathsf{layer}(v) \in I$. Given a clustering $\mathcal{C}$ of G and a layering of $G_{\mathcal{C}}$, we naturally extend it to a layering of G.

▶ **Lemma 14 (★).** *Let H be an apex graph. Given a connected edge-weighted n-vertex H-minor-free graph G and $\delta > 0$, we can in time $\mathcal{O}(n \log n)$ find a δ-radius clustering $\mathcal{C}$ of G and a layering function* $\mathsf{layer}\colon V(G_{\mathcal{C}}) \to \mathbb{N}$ *such that the following hold.*

1. *For an interval $I \subseteq \mathbb{N}$ of size p, the graph $G_{\mathcal{C}}^I$ has treewidth $\mathcal{O}_H(p)$.*
2. *The treewidth of $G_{\mathcal{C}}$ is bounded by $\mathcal{O}_H(\mathsf{diam}(G)/\delta)$.*
3. *For each $u, v \in V(G)$ and $p \in \mathbb{N}$ satisfying $d_G(u,v) \leq \delta \cdot p$, it holds that $|\mathsf{layer}(u) - \mathsf{layer}(v)| \leq p$. In this case, there is an interval $I \subseteq \mathbb{N}$ depending only on $(\mathsf{layer}(u), \mathsf{layer}(v), p)$, such that $|I| \leq 2p+1$ and the (u,v)-distance is the same in G and G^I.*

The proof constructs the layering by analyzing a shortest-path tree T rooted at an arbitrary vertex r. Then the j-th layer corresponds to vertices whose distance from r belongs to $[j \cdot \delta,\ j \cdot \delta + \delta)$. The clustering $\mathcal{C}$ is obtained by contracting all the edges in T connecting vertices sharing the same layer.

Clearly, each root-to-leaf path in T traverses at most $\mathsf{diam}(G)/\delta$ layers, which bounds the (unweighted) diameter of $G_{\mathcal{C}}$. Since $G_{\mathcal{C}}$ is a contraction of G, it is H-minor-free as well and we can take advantage of the local treewidth property. A similar argument yields Item 1 while Item 3 follows from the triangle inequality.

Lemma 12 only guarantees that $\mathsf{tw}(G_{\mathcal{C}})$ can be bounded in terms of ε, without providing an efficient way to construct a tree decomposition. Moreover, the known algorithms for computing optimal (or $\mathcal{O}(1)$-approximate) tree decomposition require time exponential in treewidth, whereas we aim at polynomial dependence on ε. Luckily, there is one algorithm available that suits our needs, with a bit worse width guarantee.

While several algorithms rely on dynamic programming over a tree decomposition to compute the diameter exactly [2, 28, 36], we cannot afford such an strategy due to prohibitive error accumulation. Instead, we will turn the decomposition into a balanced one, again by increasing its width slightly, and use it to build our data structures.

▶ **Lemma 15.** *There is an algorithm that, given a graph G of treewidth at most k, runs in time $\mathcal{O}(k^7 \cdot n \log n)$ and outputs a binary rooted tree decomposition of G of width $\mathcal{O}(k^2)$, depth $\mathcal{O}(\log n)$, and size $\mathcal{O}(n)$.*

Proof. First, in time $\mathcal{O}(k^7 \cdot n \log n)$ one can compute a tree decomposition (T, χ) of G of width $k' = \mathcal{O}(k^2)$ [31]. By a standard argument, we can modify (T, χ) to have size $\mathcal{O}(n)$. Next, we turn (T, χ) into a binary rooted tree decomposition of depth $\mathcal{O}(\log n)$ and width at most $4k' + 3$ in time $\mathcal{O}(n)$ [20]. This also preserves the bound $|V(T)| = \mathcal{O}(n)$. ◀

4 Processing a Tree Decomposition

We will need an argument to reroute paths to go through a center c_i of some cluster C_i.

▶ **Lemma 16.** *Let G be an edge-weighted graph, $u, v, w \in V(G)$, and let C be a vertex set contained in the δ-radius ball around w. Suppose there is a shortest (u,v)-path P in G that intersects C. Then $d_G(u,w) + d_G(w,v) \leq d_G(u,v) + 2\delta$.*

Proof. Orient the path P from u to v and define u', v' as the first and the last vertices from C appearing on P. Since u', v' lie on a shortest (u,v)-path, we have $d_G(u,u') + d_G(v',v) \leq d_G(u,v)$. Next, it holds that each of $d_G(w,u')$, $d_G(w,v')$ is at most δ. Hence $d_G(u,w) \leq d_G(u,u') + \delta$ and $d_G(w,v) \leq d_G(v',v) + \delta$, which yields the desired inequality. ◀

We will now show how, using a tree decomposition of the cluster graph of width $\mathcal{O}((1/\varepsilon)^2)$, to construct a distance oracle and estimate eccentricities. We give a unified proof for both statements because the constructed oracle is directly applied to obtain the second result. The presented algorithm is arguably simpler than the recursive schemes based on shortest path separators since in the analysis we only need to manage $\mathcal{O}(1)$ rounding errors, rather than $\mathcal{O}(\log n)$. We no longer need to assume that the excluded minor is an apex graph and this will allow us later to apply Theorem 17 in a more general setting.

▶ **Theorem 17.** *Suppose we are given an edge-weighted n-vertex K_h-minor-free graph G, $\delta > 0$, a δ-radius clustering $\mathcal{C}$ of G, and a binary rooted tree decomposition (T, χ) of $G_{\mathcal{C}}$ of width w, depth $\mathcal{O}(\log n)$, and size $\mathcal{O}(n)$.*

1. *In time $\mathcal{O}_h(w \cdot n \log n)$ we can build a data structure that, when queried for $u, v \in V(G)$, outputs $x \in [d_G(u,v),\, d_G(u,v) + 2 \cdot \delta]$ in time $\mathcal{O}(w \cdot \log n)$.*
2. *Assume additionally that G is connected and let $\tau = \mathsf{diam}(G)/\delta$. In time $\mathcal{O}_h(w^{h+1} \cdot \tau^h \cdot n \log^2 n)$ we can compute eccentricity of each vertex $v \in V(G)$ within additive error $16 \cdot \delta$. Moreover, within the same time we can also output a vertex $u \in V(G)$ for which $d_G(v,u) \geq \mathsf{ecc}_G(v) - 16 \cdot \delta$.*

Let us clarify that the parameter τ does not have to be given and it only appears in the analysis. However, we can always assume that the diameter is known within factor 2 after computing any eccentricity.

Proof. We begin with some notation that will be used throughout the proof. We will use variables u, v to denote vertices of G and variables i, j to index the set of clusters. For a cluster $i \in \mathcal{C}$, let $\mathsf{loc}(i)$ denote the node $t \in V(T)$ that is closest to the root among those satisfying $i \in \chi(t)$. We naturally extend this notation to vertices of G: all vertices $v \in C_i$ receive $\mathsf{loc}(v) = \mathsf{loc}(i)$. This mapping can be computed for all clusters and vertices in linear time by scanning T top-down.

For $t \in V(T)$ let $U_t \subseteq \mathcal{C}$ denote the set of clusters $i \in \mathcal{C}$ for which $\mathsf{loc}(i)$ lies in the subtree of T rooted at t, inclusively. Next, let $V_t = \bigcup_{i \in U_t} C_i$.

▷ Claim 18. It holds that $\sum_{t \in V(T)} |V_t| = \mathcal{O}(n \log n)$, and all the sets V_t can be computed in total time $\mathcal{O}(n \log n)$.

Proof. For each $i \in \mathcal{C}$ the nodes t satisfying $i \in U_t$ must be lie on the $\mathsf{loc}(i)$-to-root path in T and so there are $\mathcal{O}(\log n)$ of them. Hence each $i \in \mathcal{C}$ contributes $\mathcal{O}(|C_i| \cdot \log n)$ to the sum $\sum_{t \in V(T)} |V_t|$, which yields the upper bound as $\mathcal{C}$ is a partition of $|V(G)|$. This argument leads directly to an algorithm computing the sets V_t. ◁

Distance oracle. Consider $t \in V(T)$, $i \in \mathcal{C}$, and $v \in V(G)$. We call (t, i, v) a *valid triple* when $t = \mathsf{loc}(i)$ and $v \in V_t$. For fixed $t \in V(T)$, the number of valid triples in which t appears is at most $(w+1) \cdot |V_t|$, and so by Claim 18 the number of valid triples is $\mathcal{O}(w \cdot n \log n)$.

Recall that for $i \in \mathcal{C}$ the vertex $c_i \in C_i$ is the center of cluster i. We will populate table $\mathsf{inner\text{-}dist}$ indexed by valid triples, so that $\mathsf{inner\text{-}dist}[t, i, v]$ will store the exact (v, c_i)-distance within the graph $G[V_t]$. If there is no such path, we set $\mathsf{inner\text{-}dist}[t, i, v] = \infty$.

▷ Claim 19. We can compute $\mathsf{inner\text{-}dist}[t, i, v]$ for all valid triples in total time $\mathcal{O}_h(w \cdot n \log n)$.

Proof. Consider $t \in V(T)$. For each $i \in \mathcal{C}$ with $\log(i) = t$, we compute all distances from c_i in $G[V_t]$ using the linear single-source shortest path algorithm for K_h-minor-free graphs [52]. The total running time, over all $t \in V(T)$, is proportional to the number of valid triples. ◁

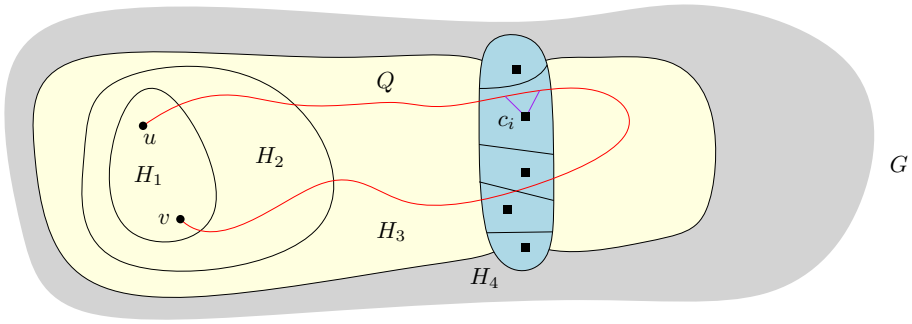

Figure 2 Illustration to Claim 20. By inspecting the nodes $t \in V(T)$ that are ancestral to both $\mathsf{loc}(u), \mathsf{loc}(v)$, we obtain a family of subgraphs $H_1 \subset H_2 \subset H_3 \subset H_4 \subset H_5 = G$, induced by the sets V_t. Here, H_4 is the smallest among them that accommodates the shortest (u, v)-path Q. This path must intersect some cluster C_i for which $\mathsf{loc}(i) = t$, where $G[V_t] = H_4$, as otherwise it would be contained in H_3. Hence the (u, v)-distance in H_4 is the same as in G and we can stretch Q within H_4 to go through c_i using Lemma 16.

We now argue that information gathered in table inner-dist is sufficient to retrieve all distances in G, up to small additive error. This is the only place where we rely on the fact that each cluster has small *strong* diameter.

▷ Claim 20. For each $u, v \in V(G)$ there exist $t \in V(T)$ and $i \in \mathcal{C}$ such that:
1. (t, i, u) and (t, i, v) are valid triples,
2. $\mathsf{inner\text{-}dist}[t, i, u] + \mathsf{inner\text{-}dist}[t, i, v] \leq d_G(u, v) + 2\delta$.

Proof. Let Q be a shortest (u, v)-path in G. Next, let $\mathcal{C}_Q \subseteq \mathcal{C}$ denote the set of clusters intersected by Q and let $T_Q \subseteq V(T)$ be the set of nodes in which $\mathcal{C}_Q$ appear, i.e., $T_Q = \chi^{-1}(\mathcal{C}_Q)$. Since $G_{\mathcal{C}}$ is a contraction of G, the subgraph $G_{\mathcal{C}}[\mathcal{C}_Q]$ is connected. Consequently, T_Q induces a connected subtree of T. Let $t \in T_Q$ be the node that is closest to the root among T_Q. Note that $t = \mathsf{loc}(i)$ for some $i \in \mathcal{C}_Q$.

We claim that the pair (t, i) satisfies the requested conditions. Note that for each $j \in \mathcal{C}_Q$ the node $\mathsf{loc}(j)$ lies in the subtree of T rooted at t. Hence $\mathcal{C}_Q \subseteq U_t$ and so $V(Q) \subseteq V_t$. In particular, we obtain that $u, v \in V_t$ so (t, i, u), (t, i, v) are valid triples (Item 1).

Since Q is a shortest (u, v)-path and $V(Q) \subseteq V_t$, we infer that the (u, v)-distance in $G[V_t]$ equals their distance in G. Now we apply Lemma 16 to the graph $H = G[V_t]$ and $C = C_i$, $w = c_i$. Because $i \in \mathcal{C}_Q$, we know that Q intersects C_i. It is crucial that all C_i-vertices are within distance δ from c_i when considering distances within $G[C_i]$ (Definition 13(2)), not just in G. As $C_i \subseteq V_t$, this property carries over to the graph H. Lemma 16 implies that $d_H(u, c_i) + d_H(c_i, v) \leq d_H(u, v) + 2\delta$. We have $\mathsf{inner\text{-}dist}(t, i, u) = d_H(u, c_i)$, $\mathsf{inner\text{-}dist}(t, i, v) = d_H(c_i, v)$, and $d_H(u, v) = d_G(u, v)$, which yields Item 2. ◁

▷ Claim 21 (Oracle). Let $u, v \in V(G)$ be given. Using the table inner-dist we can output $x \in [d_G(u, v), d_G(u, v) + 2\delta]$ in time $\mathcal{O}(w \cdot \log n)$.

Proof. We iterate over all pairs $t \in V(T)$, $i \in \mathcal{C}$ for which (t, i, u) and (t, i, v) are valid triples. There are only $\mathcal{O}(\log n)$ candidates for t just because (t, i, u) is a valid triple and so t must lie on the $\mathsf{loc}(u)$-to-root path. For each such t there are clearly at most $w + 1$ candidates for i.

We return x equal to the minimum value of $\mathsf{inner\text{-}dist}[t, i, u] + \mathsf{inner\text{-}dist}[t, i, v]$ taken over all such pairs (t, i). For each (t, i) the considered sum is either ∞ or it equals the length of some (u, v)-walk in $G[V_t]$. This implies that $x \geq d_G(u, v)$. The inequality $x \leq d_G(u, v) + 2\delta$ follows from Claim 20. ◁

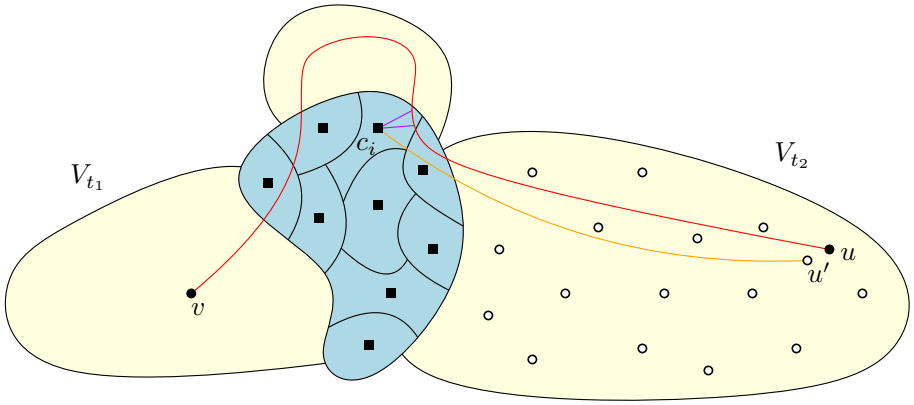

Figure 3 Illustration to Claim 23. The blue area corresponds to the union of clusters C_i over $i \in \chi(t)$. For any $v \in V_{t_1}$, $u \in V_{t_2}$ the shortest (v,u)-path (red) must traverse some C_i so by Lemma 16 there is a slightly longer path that goes through c_i (purple). The hollow discs represent the additive core-set of V_{t_2} with respect to the centers from $\chi(t)$. This core-set contains a vertex u' which is comparable to u with respect to distances from $\{c_i : i \in \chi(t)\}$ (e.g., the orange path). Hence u' can simulate u for the task of estimating the eccentricity of v.

Claims 19 and 21 yield the additive distance oracle (Item 1). Now we move on to a proof sketch of Item 2, whose complete proof can be found in the full version of the paper.

Eccentricities. For a non-root $t \in V(T)$ we refer to its parent in T as $\mathsf{parent}(t)$. For $u, v \in V(G)$ let $\mathsf{apx\text{-}dist}(u,v)$ denote the value returned by the oracle from Claim 21 when queried for the pair u, v. This is a well-defined function because the oracle is deterministic. Recall the concept of an additive core-set from Lemma 1 and that $\tau = \mathsf{diam}(G)/\delta$.

▷ Claim 22 (★). In total time $\mathcal{O}\left((w \cdot \tau)^h \cdot n + w^2 \cdot n \log^2 n\right)$ we can compute for each non-root $t \in V(T)$ a subset $V'_t \subseteq V_t$ of size $\mathcal{O}\left(w^{h-1}\tau^h\right)$ that is a $(10 \cdot \delta)$-additive core-set of V_t with respect to $\chi(\mathsf{parent}(t))$.

The total number of distances we care about is $(w+1) \cdot \sum_{t \in V(T)} |V_t| = \mathcal{O}(w \cdot n \log n)$. Each of them can be estimated using the oracle in time $\mathcal{O}(w \log n)$. We would like to use those numbers to compute the additive core-sets, however a priori the bound from Lemma 1 might not hold for approximate distances. Nevertheless, we prove that a greedy procedure still constructs a small core-set, even after perturbation of distances. A similar issue is handled in [47] via randomization but we can afford a simpler argument because our strategy allows us to first query the oracle for all the distances between V_t and $\chi(\mathsf{parent}(t))$.

In the next claim, we argue that the core-sets suffice to estimate the maximal distance between v and u, where v is fixed and u is quantified over all vertices from some subtree. There are three sources of accuracy loss: relying on the additive core-set, on the approximate distance oracle, and stretching the paths along a center from $\chi(t)$ (Lemma 16).

▷ Claim 23 (★). Consider $t \in V(T)$ with children t_1, t_2. Let $v \in V_{t_1}$ and $V' \subseteq V_{t_2}$ be a ρ-additive core-set with respect to $\chi(t)$. Let $y = \max d_G(v,u)$ over all $u \in V_{t_2}$, and x be defined as follows:

$$x = \max_{u \in V'} \min_{i \in \chi(t)} \left(\mathsf{apx\text{-}dist}(v, c_i) + \mathsf{apx\text{-}dist}(c_i, u)\right).$$

Then $|x - y| \leq \rho + 6 \cdot \delta$. Furthermore, the vertex $u^* \in V'$ realizing x satisfies $d_G(v, u^*) \geq y - \rho - 6 \cdot \delta$.

We now use the additive core-sets to estimate the eccentricity of a vertex. Essentially, we apply Claim 23 for each choice of the lowest common ancestor of v, u; hence $\mathcal{O}(\log n)$ times.

▷ Claim 24 (★). For a given vertex $v \in V(G)$ we can compute its eccentricity within additive error $16 \cdot \delta$ in time $\mathcal{O}\left(w^{h+1} \cdot \tau^h \cdot \log^2 n\right)$. Within the same time, we can output a vertex u for which $d_G(v,u) \geq \mathsf{ecc}_G(v) - 16 \cdot \delta$.

Theorem 17(2) follows by applying Claim 24 to each vertex. ◀

▶ **Theorem 2.** *Let H be an apex graph of size h. There is an algorithm that, given an edge-weighted H-minor-free graph G and $\varepsilon > 0$, runs in time $\mathcal{O}_h((1/\varepsilon)^{3h+2} \cdot n \log^2 n)$ and estimates eccentricity of each vertex vertex $v \in V(G)$ within additive error $\varepsilon \cdot \mathsf{diam}(G)$. Moreover, for each $v \in V(G)$ the algorithm outputs vertex v' for which $d_G(v,v') \geq \mathsf{ecc}_G(v) - \varepsilon \cdot \mathsf{diam}(G)$.*

Proof. One can assume that G is connected as otherwise the diameter is ∞. We compute the eccentricity D of an arbitrary vertex v: this can be done in linear time [52]. The diameter of G must be contained in $[D, 2D]$. We apply Lemma 14 for $\delta = \varepsilon D/16$ in time $\mathcal{O}(n \log n)$; let $\mathcal{C}$ denote the obtained δ-radius clustering. Next, let $\tau = \mathsf{diam}(G)/\delta$; note that $\tau = \mathcal{O}(1/\varepsilon)$. By Lemma 14(2) we know that $\mathsf{tw}(G_{\mathcal{C}}) = \mathcal{O}_h(1/\varepsilon)$. We use Lemma 15 to build a binary tree decomposition of $\mathsf{tw}(G_{\mathcal{C}})$ of width $w = \mathcal{O}_h(\varepsilon^{-2})$, depth $\mathcal{O}(\log n)$ and size $\mathcal{O}(n)$; this takes time $\mathcal{O}_h(\varepsilon^{-7} \cdot n \log n)$. Now we can take advantage of Theorem 17(2) to compute the eccentricities of all vertices within additive error $16 \cdot \delta \leq \varepsilon \cdot \mathsf{diam}(G)$, together with vertices that realize these distance approximately. This takes time $\mathcal{O}_h(w^{h+1} \cdot \tau^h \cdot n \log^2 n) = \mathcal{O}_h((1/\varepsilon)^{3h+2} \cdot n \log^2 n)$. Finally, observe that h is greater than 1 in any non-trivial instance so $7 < 3h + 2$ and so the time needed to compute the tree decomposition is negligible. ◀

In the full version of the article we show how to replace additive error in the distance oracle with multiplicative one, which yields Theorem 3.

5 Handling Apices

We move on to the proof of Theorem 4, extending the diameter approximation to graphs G with an apex set A, for which $G - A$ is apex-minor-free. We do not formulate an analogous theorem generalizing the distance oracle because it is trivial. To see this, first precompute all the distances from each $w \in A$ and then, given u, v, return the minimum of their distance in $G - A$ and $\min_{w \in A} d(u,w) + d(w,v)$. The first scenario can be readily handled with the same data structure as in Theorem 3.

The reason why we cannot apply the same reduction for diameter computation is that $\mathsf{diam}(G - A)$ might be huge compared to $\mathsf{diam}(G)$. Hence we lose the relation between the diameter and radii of clusters (governing the additive error), crucial to bound the treewidth of the cluster graph. As a remedy, we will first preprocess the graph $G - A$ to chop it into connected components of bounded diameter.

▶ **Lemma 25.** *Let H be a fixed graph and $c \in \mathbb{N}$. Let G be a connected edge-weighted n-vertex connected graph, $A \subseteq V(G)$ be such that $G - A$ is H-minor-free and $|A| = c$, and $D \in \mathbb{R}$ satisfy $2D \geq \mathsf{diam}(G)$. There is an algorithm that, given the above and $\varepsilon > 0$, runs in time $\mathcal{O}_{H,c}((1/\varepsilon)^c \cdot n)$ and either correctly reports that $\mathsf{diam}(G) > D$ or outputs a connected edge-weighted n-vertex graph G' and $A' \subseteq V(G')$ of size c, with the following guarantees.*

1. *$G' - A'$ is H-minor-free.*
2. *$\mathsf{diam}(G') \geq \mathsf{diam}(G)$.*
3. *If $\mathsf{diam}(G) \leq D$ then $\mathsf{diam}(G') \leq (1+\varepsilon) \cdot D$.*
4. *Each connected component of $G' - A'$ has strong diameter at most $8 \cdot (2/\varepsilon)^c \cdot D$.*

Proof. First of all, we remove all edges with weight larger then $2D$ as they cannot contribute to any shortest path. Observe that G is K_h-minor-free for $h = |V(H)| + c$. We compute shortest paths from each vertex $w \in A$ using the linear SSSP algorithm for minor-free graphs [52]. If any computed distance is greater than D, we can terminate the algorithm. Otherwise for each $w \in A$, $v \in V(G)$, we insert the wv-edge with weight $d_G(w, v)$ or update the weight if the edge is already present. This preserves all the pairwise distances in G and does not affect the graph $G - A$. We will keep the variable G to refer to the modified graph. The performed modification ensures the following property.

▷ Claim 26. Let $u, v \in V(G)$ and suppose that there is a shortest (u, v)-path in G that intersects A. Then there is a shortest (u, v)-path with one internal vertex that belongs to A.

For $u, v \in V(G)$ let $d'(u, v)$ denote the largest integer j for which $j \cdot \varepsilon D/2 \leq d_G(u, v)$. For $v \in V(G) \setminus A$ we define its *signature* as $S_v = (d'(v, a_1), \ldots, d'(v, a_c))$ where $(a_1, \ldots, a_c)$ is some fixed ordering of A. Let $\mathcal{S} = \{S_v \colon v \in V(G) \setminus A\}$. Since we have not terminated the algorithm in the first step, each $d'(v, a_i)$ is most $\lfloor 2/\varepsilon \rfloor$ and so $|\mathcal{S}| \leq (2/\varepsilon)^c$.

We say that a pair $S_1, S_2 \in \mathcal{S}$ is *relevant* if for each $i \in [c]$ we have $S_1[i] + S_2[i] > 2/\varepsilon$. We also call $S \in \mathcal{S}$ relevant if it appears in at least one relevant pair.

▷ Claim 27. Let $u, v \in V(G) \setminus A$ be such that (S_u, S_v) is a relevant pair. Then there is no (u, v)-path of length $\leq D$ that goes through A.

Proof. If there was such a path then $d_G(u, w) + d_G(w, v) \leq D$ for some $w \in A$. But for each $w \in A$ we have $d_G(u, w) + d_G(w, v) \geq (\varepsilon D/2) \cdot (d'(u, w) + d'(w, v)) > D$. ◁

▷ Claim 28. Let $u, v \in V(G) \setminus A$ be such that $S_u = S_v$ and S_u is relevant. If $d_{G-A}(u, v) > 2D$ then $\mathsf{diam}(G) > D$.

Proof. Suppose that $\mathsf{diam}(G) \leq D$. Since S_u is relevant, there exists $z \in V(G) \setminus A$ such that (S_u, S_z) is a relevant pair. Due to Claim 27, the shortest (u, z)-path avoids A so $d_{G-A}(u, z) \leq D$. By the same argument $d_{G-A}(v, z) \leq D$ and the claim follows from the triangle inequality. ◁

For each relevant $S \in \mathcal{S}$ let us choose an arbitrary v with $S_v = S$; we denote the set of chosen vertices as B. Clearly $|B| \leq |\mathcal{S}| \leq (2/\varepsilon)^c$. For each $b \in B$ we compute all the distances from b in $G - A$ in linear time and check whether there is any $v \in V(G) \setminus A$ with $S_v = S_b$ and $d_{G-A}(b, v) > 2D$. If so, then by Claim 28 we can again terminate the algorithm.

▷ Claim 29. Suppose that the algorithm has not been terminated and let $Z \subseteq V(G) \setminus A$ be the set of vertices z satisfying $d_{G-A}(z, b) > 3D$ for all $b \in B$. Next, let $F \subseteq E(G - A)$ be the set of edges from $G - A$ with at least one endpoint in Z. Suppose that $\mathsf{diam}(G) \leq D$. Then $\mathsf{diam}(G \setminus F) \leq (1 + \varepsilon) \cdot D$.

Proof. Consider $u, v \in V(G)$ and let P be a shortest (u, v)-path in G. By assumption, P is not longer than D. We need to show that there is a (u, v)-path of length $\leq (1 + \varepsilon) \cdot D$ that avoids F. If P intersects A then by Claim 26 we can assume that P consists only of edges incident to A (at most two). Then clearly P avoids F.

Suppose now that $V(P) \cap A = \emptyset$ and that P uses some edge from F. Then there is $z \in V(P) \cap Z$ whose distance in $G - A$ to each of u, v is at most D. We claim that S_u, S_v are irrelevant. Assume w.l.o.g. that S_u is relevant and let $b \in B$ be the chosen vertex with $S_u = S_b$. We have $d_{G-A}(u, b) \leq 2D$ as otherwise we would have terminated the algorithm due to Claim 28. But $d_{G-A}(u, z) \leq D$ so $d_{G-A}(z, b) \leq 3D$. This contradicts the property used to define Z.

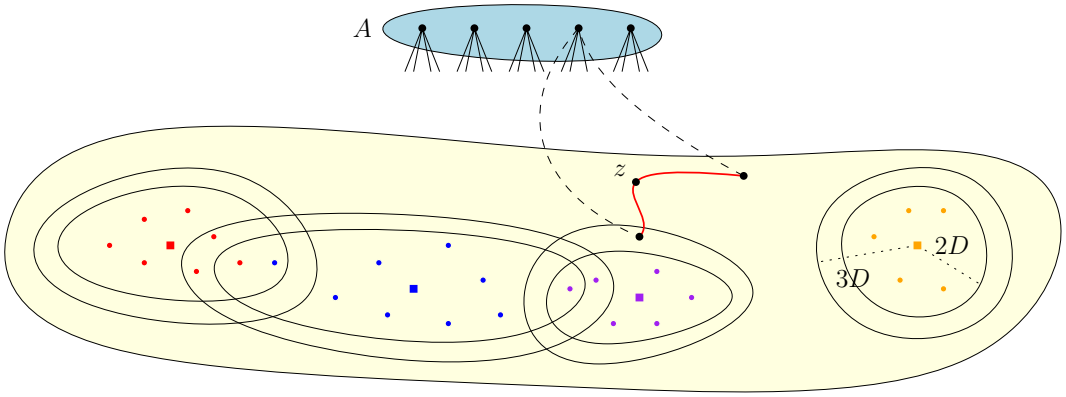

Figure 4 Illustration to Claim 29. The set B of representatives for relevant signatures is given by the squares. By Claim 28, every vertex sharing the same signature as $b \in B$ (represented by the same color) must lie in the $2D$-radius ball around b in $G - A$. If z is outside all $3D$-radius balls, then every path in $G - A$ of length $\leq D$ traversing z must connect vertices u, v for which (S_u, S_v) is an irrelevant pair. For such pairs, there must be an almost shortest path traversing A.

We established that S_u, S_v are irrelevant, so the pair (S_u, S_v) is also irrelevant. By definition, this means that there is $w \in A$ such that $d'(u, w) + d'(w, v) \leq 2/\varepsilon$. We have $d_G(u, w) \leq (\varepsilon D/2) \cdot (d'(u, w) + 1)$ and likewise for the pair (v, w). We estimate

$$d_G(u, w) + d_G(w, v) \leq (\varepsilon D/2) \cdot (d'(u, w) + d'(w, v) + 2) \leq D + (\varepsilon D/2) \cdot 2 = (1 + \varepsilon) \cdot D.$$

Hence the path (u, w, v) is sufficiently short and it avoids F. The claim follows. ◁

We showed that removing all edges from F is safe for approximating the diameter of G. It remains to prove that this operation splits $G - A$ into pieces of bounded strong diameter.

▷ Claim 30. Let $C \subseteq V(G) \setminus A$ be a set of vertices inducing a connected component of $(G - A) \setminus F$. Then $\mathsf{diam}(G[C]) \leq 8 \cdot (2/\varepsilon)^c \cdot D$.

Proof. For $b \in B$ let C_b be the set of vertices within distance $3D$ from b in $G - A$. Observe that C is either a single vertex from Z or a union of C_b for $b \in B'$ for some $B' \subseteq B$. In the first case the diameter is 0 so let us focus on the second case.

Let $u, v \in C$ and P be a shortest (u, v)-path in $G[C]$. Then $u \in C_{b_1}$ for some $b_1 \in B'$. Let v_1 be the farthest vertex on P (counting from u) that belongs to C_{b_1}. The (u, v_1)-distance in $G[C]$ is at most their distance in $G[C_{b_1}]$ so $d_P(u, v_1) \leq 6D$ as P is a shortest path. Next, take u_2 to be the next vertex on P after v_1 and pick $b_2 \in B$ satisfying $u_2 \in C_{b_2}$. Analogously as before, we find the vertex $v_2 \in C_{b_2}$ that is farthest on P and continue this process. By construction, every vertex $b \in B'$ appears at most once as b_i so this splits P into at most $|B'|$ subpaths of length $\leq 6D$. Also for each i the edge between v_i and u_{i+1} has weight at most $2D$ because we have removed all the heavier edges at the very beginning. The claim follows from $|B'| \leq |B| \leq (2/\varepsilon)^c$. ◁

We check that $G' = G \setminus F$ and $A' = A$ satisfy all the points of the lemma. First, $G' - A$ is a subgraph of $G - A$ so it remains H-minor-free. Next, removing edges can only increase the diameter so $\mathsf{diam}(G') \geq \mathsf{diam}(G)$ while the second inequality follows from Claim 29. The diameter bound for components of $G' - A'$ has been given in Claim 30. Finally, the sets Z and F can be identified in time $\mathcal{O}_H(|B| \cdot n) = \mathcal{O}_{H,c}((1/\varepsilon)^c \cdot n)$. ◀

We briefly explain how Lemma 25 leads to Theorem 4. Given $D \in [\mathsf{diam}(G), 2 \cdot \mathsf{diam}(G)]$ we want to learn that $\mathsf{diam}(G) > D$ or that $\mathsf{diam}(G) \leq (1+\varepsilon) \cdot D$. Let (G', A') be the output given by Lemma 25 and $\delta = \Theta(\varepsilon D)$. Each connected component G^i of $G' - A'$ satisfies $\mathsf{diam}(G^i) = \mathcal{O}((1/\varepsilon)^c \cdot D)$. We apply Lemma 14 to get a δ-radius clustering $\mathcal{C}^i$ of G^i so that the treewidth of the cluster graph $G^i_{\mathcal{C}^i}$ is $\mathcal{O}(\mathsf{diam}(G^i)/\delta) = \mathcal{O}((1/\varepsilon)^{c+1})$. We combine those to get a δ-radius clustering $\mathcal{C}'$ of G' by assigning each $w \in A'$ a singleton cluster.

Using Lemma 15 we can compute a balanced tree decomposition of $G'_{\mathcal{C}'}$ of width $w = \mathcal{O}((1/\varepsilon)^{2(c+1)})$. It can be now processed with Theorem 17(2): in time $\mathcal{O}(w^{h+1}(1/\varepsilon)^h \cdot n \log^2 n)$ we can estimate $\mathsf{diam}(G')$ within additive error $16 \cdot \delta = \Theta(\varepsilon D)$. If this value is too large, we learn that $\mathsf{diam}(G') > (1+\varepsilon) \cdot D$, implying $\mathsf{diam}(G) > D$. Otherwise we infer that $\mathsf{diam}(G) \leq \mathsf{diam}(G') \leq (1+\varepsilon) \cdot D$. Repeating this procedure for different D allows us to estimate $\mathsf{diam}(G)$ within multiplicative error $(1+\varepsilon)$. The details can be found in the full version of the article.

6 Conclusion and Open Problems

We have presented almost-linear algorithms approximating diameter that bypass topological arguments and work way beyond surface-embeddable graphs. A natural next step would be to generalize these results further, to all graph classes excluding a minor. The reason why we could not extend Corollary 5 to all cases covered in Theorem 4 is that we need to know the deletion set to the apex-minor-free class. The best known algorithm finding such a set requires quadratic time [50]. To apply the same strategy for the general case of H-minor-free graphs, one would need to compute some form of the Robertson and Seymour's decomposition, which seems an even harder task. However, recent advances in minor testing [43] suggest that this may be possible in time $\mathcal{O}_H(n^{1+o(1)})$ (see the section "Outlook" there). We have not attempted to generalize Theorem 4 to work on such decompositions because (1) this would require a tedious analysis of a balanced tree decomposition of the clique-sum decomposition, and (2) this strategy currently seems hopeless to achieve running time $\mathcal{O}_H(\mathsf{poly}(1/\varepsilon, \log n) \cdot n)$. Is there an alternative approach that would work without the decomposition at hand?

Another question is whether one can improve the dependence on n to $\mathcal{O}(n \log n)$ or even $\mathcal{O}(n)$? The current running time bound follows from the fact that we need to precompute $\Omega(n \log n)$ distances and each oracle call requires time $\Omega(\log n)$. Can this be improved? For example, for planar metrics there exist distance oracles with constant query time (for constant ε) albeit with preprocessing time $\Omega(n \log^3 n)$ [12, 45].

When it comes to the dependence on ε, our running time is burdened by the fact that for k-treewidth graphs we compute a tree decomposition of width $\mathcal{O}(k^2)$. Unfortunately, all the known almost-linear $\mathcal{O}(1)$-approximation algorithms for treewidth require time exponential in k. Since we rely on a construction from [31] that works for general graphs, it is tempting to improve the width guarantee therein when the input graph is H-minor-free. Again, this is doable in planar graphs [38].

Abstract

We show that, for every fixed positive integers r and k, Max-Weight List r-Colorable Induced Subgraph admits a polynomial-time algorithm on kP_3-free graphs. This problem is a common generalization of Max-Weight Independent Set, Odd Cycle Transversal and List r-Coloring, among others. Our result has several consequences.

First, it implies that, for every fixed $r \geq 5$, assuming $\mathsf{P} \neq \mathsf{NP}$, Max-Weight List r-Colorable Induced Subgraph is polynomial-time solvable on H-free graphs if and only if H is an induced subgraph of either kP_3 or $P_5 + kP_1$, for some $k \geq 1$. Second, it makes considerable progress toward a complexity dichotomy for Odd Cycle Transversal on H-free graphs, allowing to answer a question of Agrawal, Lima, Lokshtanov, Rzążewski, Saurabh, and Sharma [ACM Trans. Algorithms 2025]. Third, it gives a short and self-contained proof of the known result of Chudnovsky, Hajebi, and Spirkl [Combinatorica 2024] that List r-Coloring on kP_3-free graphs is polynomial-time solvable for every fixed r and k.

We also consider two natural distance-d generalizations of Max-Weight Independent Set and List r-Coloring and provide polynomial-time algorithms on kP_3-free graphs for every fixed integers r, k, and $d \geq 6$.

1 Introduction

A fundamental class of graph optimization problems consists in finding a maximum-weight induced subgraph satisfying a certain fixed property Π. Lewis and Yannakakis [12] showed that, whenever this fixed property Π is nontrivial and hereditary, the corresponding problem is NP-hard. In this paper, we investigate the case where Π is the property of being list r-colorable, leading to a meta-problem called Max-Weight List r-Colorable Induced Subgraph. In order to properly define this problem, we first require some definitions.

Let $G = (V, E)$ be a finite simple graph. A *coloring* of G is a mapping $\phi\colon V \to \{1, 2, \ldots\}$ that gives each vertex $u \in V$ a *color* $\phi(u)$ in such a way that, for every two adjacent vertices u and v in G, we have that $\phi(u) \neq \phi(v)$. For $r \geq 1$, a coloring ϕ of G is an *r-coloring* if $\phi(u) \in \{1, \ldots, r\}$ for every $u \in V$, and a graph is *r-colorable* if it admits an r-coloring. For $r \geq 1$, an *r-list assignment* of G is a function $L\colon V \to 2^{\{1,\ldots,r\}}$ that assigns each vertex $u \in V$ a *list* $L(u) \subseteq \{1, \ldots, r\}$ of admissible colors for u. A coloring ϕ of G *respects* L if $\phi(u) \in L(u)$ for every $u \in V$. We are finally ready to define Max-Weight List r-Colorable Induced Subgraph, where r is a fixed positive integer.

Max-Weight List r-Colorable Induced Subgraph

Input: A graph G equipped with a weight function $w\colon V(G) \to \mathbb{Q}_+$, and an r-list assignment L of G.
Task: Find a subset $F \subseteq V(G)$ such that:
1. The induced subgraph $G[F]$ admits a coloring that respects L, and
2. The weight $w(F) = \sum_{v \in F} w(v)$ is maximum subject to the condition above.

Max-Weight List r-Colorable Induced Subgraph is a common generalization of several well-known and deeply investigated NP-hard problems, as we explain next. Max-Weight List r-Colorable Induced Subgraph generalizes List r-Coloring and hence r-Coloring as well, which are known to be NP-hard for all $r > 2$ [11]. Recall that, for a fixed $r \geq 1$, List r-Coloring is the problem to decide whether a given graph G with an r-list assignment L admits a coloring that respects L. By setting $L(u) = \{1, \ldots, r\}$ for every $u \in V(G)$, we obtain r-Coloring. Note also that, for $r_1 \leq r_2$, List r_1-Coloring is a special case of List r_2-Coloring.

Several other NP-hard problems are special cases of Max-Weight List r-Colorable Induced Subgraph for specific values of r. For example, for $r = 1$, Max-Weight List r-Colorable Induced Subgraph is equivalent to Max-Weight Independent Set, which is the problem of finding a maximum-weight subset of pairwise non-adjacent vertices of an input graph G. For $r = 2$, Max-Weight List r-Colorable Induced Subgraph generalizes the problem of finding a maximum-weight induced bipartite subgraph of an input graph G which, by complementation, is equivalent to finding a minimum-weight subset of vertices intersecting all odd cycles in G. The latter is the well-known Odd Cycle Transversal.

Given the hardness of Max-Weight List r-Colorable Induced Subgraph, it is natural to investigate whether the problem becomes tractable for restricted classes of inputs. The framework of hereditary graph classes (i.e., graph classes closed under vertex deletion) is particularly well suited for this type of research, where the ultimate goal is to obtain complexity dichotomies telling us for which hereditary graph classes the problem at hand can or cannot be solved efficiently (under the standard complexity assumption that P $\neq$ NP).

We recall some relevant definitions. A graph G is *H-free*, for some graph H, if it contains no induced subgraph isomorphic to H. For a set of graphs $\{H_1, \ldots, H_p\}$, a graph is *$(H_1, \ldots, H_p)$-free* if it is H_i-free for every $i \in \{1, \ldots, p\}$. The *disjoint union* $G + H$ of graphs G and H is the graph with vertex set $V(G) \cup V(H)$ and edge set $E(G) \cup E(H)$. We denote the disjoint union of k copies of G by kG and let P_s denote the chordless path on s vertices.

It is known that, for $r = 2$, Max-Weight List r-Colorable Induced Subgraph admits no polynomial-time algorithm on H-free graphs unless H is a *linear forest* (i.e., a disjoint union of paths). Indeed, Chiarelli et al. [3] showed that its special case Odd Cycle Transversal is NP-hard on H-free graphs if H contains a cycle or a claw (the claw is the 4-vertex star). In recent years, considerable work has been done toward classifying the

complexity of Odd Cycle Transversal (and its generalizations) on graphs forbidding an induced linear forest. In Theorem 1, we collect known results for Odd Cycle Transversal and its two generalizations Max-Weight r-Colorable Induced Subgraph and Max-Weight List r-Colorable Induced Subgraph on H-free graphs, where H is a linear forest. The problems are listed in increasing order of generality. In particular, an NP-hardness result for a certain problem implies NP-hardness for a more general problem. Note also that the hardness results hold even in the unweighted setting.

▶ **Theorem 1.** *The following hold:*

(i) *Odd Cycle Transversal on H-free graphs can be solved in polynomial time if*
- $H = P_5$ (Agrawal et al. [1]), *or*
- $H = kP_2$ *for all* $k \in \mathbb{N}$ (Chiarelli et al. [3]), *or*
- $H = P_3 + kP_1$ *for all* $k \in \mathbb{N}$ (Dabrowski et al. [7]),

and remains NP-hard if
- $H = (P_6, P_5 + P_2)$ (Dabrowski et al. [7]).

(ii) *Max-Weight r-Colorable Induced Subgraph on H-free graphs can be solved in polynomial time if*
- $H = P_5 + kP_1$ *for all* $k \in \mathbb{N}$ (Henderson et al. [10]),

and remains NP-hard if
- $H = (P_6, P_5 + P_2)$ *for* $r = 2$, *or*
- $H = 2P_4$ *for all* $r \geq 5$ (Hajebi et al. [9]).

(iii) *Max-Weight List r-Colorable Induced Subgraph on H-free graphs can be solved in polynomial time if*
- $H = P_5$ (Lokshtanov et al. [13]),
- $H = P_5 + kP_1$ *for all* $k \in \mathbb{N}$ (Henderson et al. [10]),

and remains NP-hard if
- $H = (P_6, P_5 + P_2)$ *for* $r \geq 2$, *or*
- $H = P_4 + P_2$ *for all* $r \geq 5$ (Couturier et al. [6]).

Recently, Chudnovsky et al. [4] obtained the following complete complexity dichotomy for List r-Coloring when $r \geq 5$. Assuming $\mathsf{P} \neq \mathsf{NP}$, List r-Coloring ($r \geq 5$) can be solved in polynomial time on H-free graphs if and only if H is an induced subgraph of either kP_3 or $P_5 + kP_1$, for some $k \in \mathbb{N}$. Their main result toward this was showing that List r-Coloring ($r \geq 1$) can be solved in polynomial time on kP_3-free graphs, for any $k \in \mathbb{N}$, and this was obtained building on a very technical result of Hajebi et al. [9, Theorem 5.1].

Motivated by the quest for a complexity dichotomy, Agrawal et al. [1] posed very recently as an open problem to classify the computational complexity of Odd Cycle Transversal on $(P_3 + P_2)$-free graphs, the unique minimal open case stemming from Theorem 1.

It should also be mentioned that classifying the complexity of Max-Weight Independent Set on H-free graphs when H is a linear forest is a notorious open problem in algorithmic graph theory (see [5] for the state of the art). Note however that Max-Weight Independent Set substantially differs from Odd Cycle Transversal on H-free graphs, in the sense that it is polynomial-time solvable on claw-free graphs.

In this paper, we also consider the distance-d generalizations of Max-Weight Independent Set and List r-Coloring, defined as follows. For $d \geq 2$, a *distance-d independent set* of a graph G is a set of vertices of G pairwise at distance at least d in G. For fixed $d \geq 2$, Max-Weight Distance-d Independent Set (also known as d-Scattered Set) is the problem to find a maximum-weight distance-d independent set of an input graph G.

Trivially, for every fixed $d \geq 2$, Max-Weight Distance-d Independent Set is easy on P_{d+1}-free graphs, and the following hardness results are known.

▶ **Theorem 2.** *The following hold for Distance-d Independent Set on H-free graphs:*
- **(i)** *It is* NP*-hard if H contains $2P_{(d+1)/2}$, for every fixed odd $d \geq 3$* (Eto et al. [8])*;*
- **(ii)** *Assuming ETH, it admits no $2^{o(|V(H)|+|E(H)|)}$-time algorithm if H contains a cycle or a claw, for every fixed $d \geq 3$* (Bacsó et al. [2])*.*

For $d \geq 2$, a (d, r)-*coloring* of a graph G is an assignment of colors to the vertices of G using at most r colors such that no two distinct vertices at distance less than d receive the same color. Thus, a $(2, r)$-coloring is nothing but an r-coloring. Similarly as above, for fixed $d \geq 2$ and $r \geq 1$, we define (d, r)-Coloring as the problem of determining whether a given graph G has a (d, r)-coloring. List (d, r)-Coloring is defined similarly but we require in addition that every vertex u must receive a color from some given list $L(u) \subseteq \{1, \ldots, r\}$.

Sharp [18] provided the following complexity dichotomy: For fixed $d \geq 3$, (d, r)-Coloring is polynomial-time solvable for $r \leq \lfloor 3d/2 \rfloor$ and NP-hard for $r > \lfloor 3d/2 \rfloor$.

Our results. We prove three main algorithmic results for kP_3-free graphs. The first result, proven in Section 3, concerns Max-Weight List r-Colorable Induced Subgraph.

▶ **Theorem 3.** *Let $r \geq 1$ be a fixed integer. For every $k \in \mathbb{N}$, Max-Weight List r-Colorable Induced Subgraph can be solved in polynomial time on kP_3-free graphs.*

Theorem 3 has several interesting consequences. First, it immediately implies that Odd Cycle Transversal can be solved in polynomial time on kP_3-free graphs, for every $k \in \mathbb{N}$, thus solving a generalized version of the aforementioned open problem of Agrawal et al. [1]. Our result for Odd Cycle Transversal also complements the polynomial-time algorithms for Feedback Vertex Set and Even Cycle Transversal on kP_3-free graphs of Paesani et al. [16]. Second, Theorem 3 generalizes the recent result of Chudnovsky et al. [4] that List r-Coloring can be solved in polynomial time on kP_3-free graphs for every $r, k \in \mathbb{N}$. Although partially inspired by their approach, as we explain below, our proof of the more general Theorem 3 has the advantage of being considerably shorter and self-contained.

Theorem 3 also makes considerable progress toward a complete complexity dichotomy for Max-Weight List r-Colorable Induced Subgraph and Odd Cycle Transversal on H-free graphs. Indeed, paired with the recent result of [10], it *completely* settles the complexity of Max-Weight List r-Colorable Induced Subgraph on H-free graphs for $r \geq 5$ (see Theorem 1 and the discussion preceding it):

▶ **Theorem 4.** *Let $r \geq 5$ be a fixed integer. Assuming* P $\neq$ NP*, Max-Weight List r-Colorable Induced Subgraph on H-free graphs is polynomial-time solvable if and only if H is an induced subgraph of either kP_3 or $P_5 + kP_1$, for some $k \geq 1$.*

Moreover, paired with the results of [3, 7, 10] mentioned above, Theorem 3 leaves the case $H = k_4P_4 + k_3P_3 + k_2P_2 + k_1P_1$, with $k_4 \geq 1$ and $k_4 + k_3 \geq 2$, as the only remaining open case toward a complete complexity dichotomy for Odd Cycle Transversal on H-free graphs.

We then consider the distance-d generalizations of Max-Weight Independent Set and List r-Coloring, for $d \geq 6$, and prove the following two results.

▶ **Theorem 5.** *Let $d \geq 6$ be a fixed integer. For every $k \in \mathbb{N}$, Max-Weight Distance-d Independent Set can be solved in polynomial time on kP_3-free graphs.*

▶ **Theorem 6.** *Let $d \geq 6$ and $r \geq 1$ be fixed integers. For every $k \in \mathbb{N}$, List (d, r)-Coloring can be solved in polynomial time on kP_3-free graphs.*

Paired with the aforementioned result of Eto et al. [8], Theorem 5 completely settles the computational complexity of Max-Weight Distance-d Independent Set on kP_3-free graphs, except for the *only* remaining open case $d = 4$.

Technical overview. We now explain our approach toward Theorem 3, which combines ideas from [14, 15] and [4]. It is instructive to first consider the special case of Odd Cycle Transversal (by complementation, Max-Weight 2-Colorable Induced Subgraph) on kP_2-free graphs, where a very simple algorithm can be obtained. Indeed, kP_2-free graphs have polynomially many (inclusion-wise) maximal independent sets, and these can be enumerated in polynomial time. Consequently, a maximum-weight induced bipartite subgraph can be found by exhaustively enumerating all pairs of maximal independent sets [3]. However, it is easily seen that even P_3-free graphs (i.e., graphs whose connected components are cliques) do not have polynomially many maximal independent sets. But it turns out that a weaker property is enough for our purposes: Admitting a polynomial family of "well-behaved" vertex sets such that every maximal independent set is contained in one of these sets. In our case, "well-behaved" means inducing a P_3-free subgraph. The intuition is that, given such a family, we can efficiently guess the color classes, each of which will be a disjoint union of cliques, and then match vertices to the possible color classes.

The following key notion, which we dub amiable family, was first introduced by Lozin and Mosca [15]. For a graph G, a family $\mathcal{S} \subseteq 2^{V(G)}$ of subsets of $V(G)$ is an *amiable family* if it satisfies the following two properties:

- Each member of $\mathcal{S}$ induces a P_3-free subgraph in G;
- Each (inclusion-wise) maximal independent set of G is contained in some member of $\mathcal{S}$.

Lozin and Mosca [15] showed that, when $k = 2$, every kP_3-free graph G admits an amiable family of size polynomial in $|V(G)|$ and which can be computed in polynomial time. Later, Lozin [14] observed how such property in fact holds for every $k \geq 2$ (see Lemma 8 for a formal statement). Given an amiable family $\mathcal{S}$ of polynomial size of a kP_3-free graph G, we would like to exhaustively solve Max-Weight List r-Colorable Induced Subgraph on every possible r-tuple consisting of members of $\mathcal{S}$. More precisely, let $(S_1, \ldots, S_r) \in \mathcal{S}^r$ be an r-tuple of members of $\mathcal{S}$. We would like to find a maximum-weight induced subgraph of $G[\bigcup_{i\in[r]} S_i]$ which admits an r-coloring respecting the given r-list assignment and such that, for $i = 1, \ldots, r$, all vertices colored i are contained in S_i. To do this, we then extend an idea of Chudnovsky et al. [4] as follows. We reduce our problem to that of finding a maximum-weight matching in an auxiliary bipartite graph where one partition class Y consists of $\bigcup_{i\in[r]} S_i$, the other class X consists of the connected components of the subgraphs $G[S_i]$, for $i = 1, \ldots, r$, and there is an edge between $y \in Y$ and $x \in X$ if and only if y belongs to the connected component x. Since each weighted matching problem can be solved in polynomial time using the Hungarian method (see, e.g., [17, Theorem 17.3]) and we build $|\mathcal{S}|^r$ auxiliary problems, which is a polynomial in $|V(G)|$, a solution to Max-Weight List r-Colorable Induced Subgraph can be found in polynomial time.

In order to prove Theorems 5 and 6, we consider the following distance-d generalization of the notion of amiable family. For a graph G, a family $\mathcal{S} \subseteq 2^{V(G)}$ of subsets of $V(G)$ is a *distance-d amiable family* if it satisfies the following properties:

- Each member of $\mathcal{S}$ induces a P_3-free subgraph in G;
- For each $S \in \mathcal{S}$, the connected components of $G[S]$ are pairwise at distance at least d in G;
- Each (inclusion-wise) maximal distance-d independent set of G is contained in some member of $\mathcal{S}$.

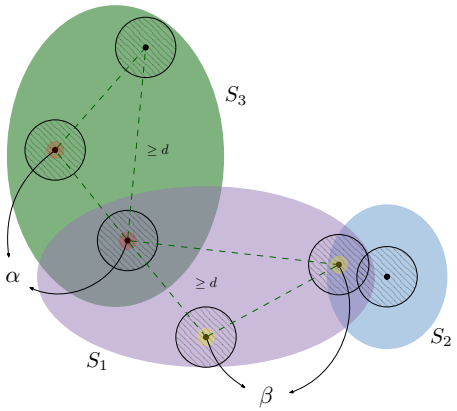

Figure 1 Visualization for distance-d amiable family $\mathcal{S} = \{S_1, S_2, S_3\}$. Circles represent cliques and α, β are maximal distance-d independent sets. Dashed lines depict paths of lengths at least d.

Clearly, a distance-2 amiable family is nothing but an amiable family. Our main technical contribution is the following Lemma 7, proven in Section 4. Although the algorithm for Lemma 7 is inspired by the case $d = 2$ and hence by the work of Lozin and Mosca [15], its proof of correctness is much more involved and requires genuinely new ideas.

▶ **Lemma 7.** *Let $d \geq 6$ be a fixed integer. For every $k \in \mathbb{N}$, every kP_3-free graph admits a distance-d amiable family of size $|V(G)|^{O(k)}$, which can be computed in time $|V(G)|^{O(k)}$.*

Equipped with Lemma 7, we immediately obtain Theorem 5. Indeed, in order to solve Max-Weight Distance-d Independent Set on a kP_3-free graph G, we simply find in polynomial time a distance-d amiable family $\mathcal{S}$ of G as above and, for each member $S \in \mathcal{S}$, find a max-weight independent set in the P_3-free graph $G[S]$. The latter can be clearly done in polynomial time, thus proving Theorem 5. The proof of Theorem 6 is similar to that of Theorem 3, the only difference being the use of a distance-d amiable family for $d \geq 6$, and hence omitted.

A remark about our approach, which combines ideas of Lozin and Mosca [14, 15] and Chudnovsky et al. [4], is in place. The proof of Chudnovsky et al. [4] that List r-Coloring ($r \geq 1$) is polynomial-time solvable on kP_3-free graphs generalizes the earlier result of Hajebi et al. [9] that List 5-Coloring is polynomial-time solvable on kP_3-free graphs, by replacing the second step in the proof of Hajebi et al. (see [9, Theorem 4.3]) with a significantly simpler argument (the aforementioned reduction to a bipartite matching problem) that, in addition, works for all $r \in \mathbb{N}$. However, their result still relies on the very technical first step of Hajebi et al. (see [9, Theorem 5.1]). Our approach can be viewed as a step further in the direction of simplifying and generalizing, as exemplified by our Theorems 3 and 6, which extend in different ways the main result of Chudnovsky et al. [4] by means of an arguably elegant and self-contained proof.

Proofs of statements marked with "$\star$" are omitted due to space constraints.

2 Preliminaries

We denote the set of positive integers by $\mathbb{N}$. For every $n \in \mathbb{N}$, we let $[n] := \{1, \ldots, n\}$. Given a set A, we denote by A^r the set of all ordered r-tuples of elements of A, i.e., $A^r = \{(a_1, \ldots, a_r) : a_i \in A \text{ for } i = 1, \ldots, r\}$.

All graphs in our paper are finite and simple. The *empty graph* is the graph with no vertices. Let now G be a graph. For $X \subseteq V(G)$, we denote the subgraph of G *induced* by X as $G[X]$, that is $G[X] = (X, \{uv : u, v \in X \text{ and } uv \in E(G)\})$. We use $N_G(X)$ to denote the neighbors in $V \setminus X$ of vertices in X. For disjoint sets $X, Y \subseteq V(G)$, we say that X is *complete* to Y if every vertex in X is adjacent to every vertex in Y, and X is *anticomplete* to Y if there are no edges between X and Y. For a subset $X \subseteq V(G)$, the *anti-neighborhood* of X, denoted by $\mathcal{A}(X)$, is the subset of vertices in $V(G) \setminus X$ which are anticomplete to X. With a slight abuse of notation, if $X = \{v_1, \ldots, v_i\}$, we denote $\mathcal{A}(X) = \mathcal{A}(\{v_1, \ldots, v_i\})$ by $\mathcal{A}(v_1, \ldots, v_i)$. Given two subsets $X, Y \subseteq V(G)$, an X, Y*-path* in G is a path in G which has one end in X, the other end in Y, and whose inner vertices belong to neither X nor Y. For vertices $u, v \in V(G)$, we denote by $d_G(u, v)$ the distance between u and v in G, i.e., the length of a shortest u, v-path in G. If no such path exists, we let $d_G(u, v) = \infty$. Moreover, for $d \in \mathbb{N}$, we let $N_G^{\geq d}(v) = \{u \in V(G) : d_G(v, u) \geq d\}$ and $N_G^{\leq d}(v) = \{u \in V(G) \setminus \{v\} : d_G(v, u) \leq d\}$. Given two subsets $X, Y \subseteq V(G)$, the *distance* between X and Y in G is the quantity $d_G(X, Y) = \min_{x \in X, y \in Y} d_G(x, y)$, i.e., the length of a shortest path in G between a vertex in X and a vertex in Y. Given $u \in V(G)$ and $Q \subseteq V(G)$, we say that u is connected to Q in G if there exists a u, Q-path in G (possibly of length 0).

A *clique* of a graph is a set of pairwise adjacent vertices and an *independent set* is a set of pairwise non-adjacent vertices. A *matching* of a graph is a set of pairwise non-adjacent edges. A *connected component* of G is a maximal connected subgraph of G. For convenience, we will often view a connected component as its vertex set rather than the subgraph itself. For this reason, we will say for example that "a connected component is a clique" rather than "a connected component is a complete subgraph". Throughout the paper, we will repeatedly make use of the fact that every connected component of a P_3-free graph is a clique.

3 The proof of Theorem 3

In this section we prove Theorem 3. As mentioned in the introduction, the first step is to obtain a polynomial-time algorithm for finding an amiable family (necessarily of polynomial size) of a kP_3-free graph. The second step consists then in reducing Max-Weight List r-Colorable Induced Subgraph to polynomially many auxiliary weighted matching problems. We do this in Lemma 9. We finally combine these two steps and prove Theorem 3.

▶ **Lemma 8** ($\star$). *For every $k \in \mathbb{N}$, every kP_3-free graph G admits an amiable family of size $|V(G)|^{O(k)}$, which can be computed in time $|V(G)|^{O(k)}$.*

▶ **Lemma 9.** *Let $r \geq 1$ and $d \geq 2$ be fixed integers. Let G be a graph with weight function $w \colon V(G) \to \mathbb{Q}_+$, L an r-list assignment of G, and $\mathcal{S}$ a distance-d amiable family of G. Given an r-tuple $(S_1, \ldots, S_r) \in \mathcal{S}^r$, there exists an $O(((r+1)|V(G)|)^3)$-time algorithm that finds a maximum-weight induced subgraph H of $G[\bigcup_{i \in [r]} S_i]$ which admits a (d, r)-coloring $\phi \colon V(H) \to [r]$ satisfying the following:*

1. *For every $v \in V(H)$, $\phi(v) \in L(v)$;*
2. *For every $i \in [r]$, $\{v \in V(H) \colon \phi(v) = i\} \subseteq S_i$.*

Proof. Consider an r-tuple $(S_1, \ldots, S_r) \in \mathcal{S}^r$. For every $i \in [r]$, let c_i be the number of connected components of $G[S_i]$ and let $S_i^1, \ldots, S_i^{c_i}$ be an arbitrary ordering of the connected components of $G[S_i]$. By definition of distance-d amiable family, each such connected component of $G[S_i]$ is a clique and any two of them are pairwise at distance at least d in G.

The first step of our algorithm consists in preprocessing the graph $G[\bigcup_{i\in[r]} S_i]$ as follows. For every $i \in [r]$, if there exists a vertex $v \in S_i$ such that $i \notin L(v)$, then we remove v from S_i, that is, we set $S_i = S_i \setminus \{v\}$. Observe that this preprocessing is safe. Indeed, if H is an induced subgraph of $G[\bigcup_{i\in[r]} S_i]$ for which there exists a (d,r)-coloring ϕ satisfying both 1 and 2, then surely $\phi(v) \neq i$ if $v \in V(H)$.

We next show that finding such an induced subgraph of $G[\bigcup_{i\in[r]} S_i]$ of maximum weight boils down to finding a maximum-weight matching in an auxiliary weighted bipartite graph B constructed as follows. The graph B has bipartition $X \cup Y$ and edge set $E(B)$, where

$$X = \left\{x_{S_i^j} : i \in [r], j \in [c_i]\right\},\ Y = \left\{y_v : v \in \bigcup_{i\in[r]} S_i\right\} \text{ and } E(B) = \bigcup_{i=1}^{r}\bigcup_{j=1}^{c_i}\left\{y_v x_{S_i^j} : v \in S_i^j\right\}.$$

Moreover, for each $v \in \bigcup_{i\in[r]} S_i$, every edge of B incident to y_v is assigned the weight $w(v)$. Note that $|V(B)| = |\bigcup_{i\in[r]} S_i| + \sum_{i\in[r]} c_i \leq |V(G)| + r|V(G)| = (r+1)|V(G)|$.

▷ Claim 10 (⋆). Let $m \in \mathbb{Q}_+$. The graph $G[\bigcup_{i\in[r]} S_i]$ has an induced subgraph H with $w(V(H)) = m$ and which admits a (d,r)-coloring satisfying both 1 and 2 if and only if B has a matching of weight m.

Now, by Claim 10, our problem reduces to finding a maximum-weight matching in the bipartite graph B, which can be done in $O(|V(B)|^3)$-time using the Hungarian method (see [17, Theorem 17.3]). Since $|V(B)| \leq (r+1)|V(G)|$, this completes the proof of Lemma 9. ◀

We can finally sketch the proof of Theorem 3.

Proof of Theorem 3. Given a kP_3-free graph G and an r-list assignment L of G, the following algorithm outputs, in polynomial time, an induced subgraph H of G admitting a coloring that respects L and such that H is of maximum weight among all such subgraphs of G.

1. Compute an amiable family $\mathcal{S}$ of G of size $|V(G)|^{O(k)}$.
2. For each r-tuple $(S_1, \ldots, S_r) \in \mathcal{S}^r$, find a maximum-weight induced subgraph H of $G[\bigcup_{i\in[r]} S_i]$ which admits a coloring $\phi\colon V(H) \to [r]$ satisfying 1 and 2 of Lemma 9.
3. Among all induced subgraphs computed in Step 2, output one of maximum weight. ◀

4 Distance-d amiable families: The proof of Lemma 7

In this section we prove Lemma 7, which is used for the proof of Theorem 6. To make our inductive proof of Lemma 7 work, we show in fact something more general, which requires the following definition. Given a graph G and a subset $F \subseteq V(G)$, a subset $S \subseteq V(G)$ is *F-avoiding* if $S \cap F = \varnothing$. By extension, a family $\mathcal{S} \subseteq 2^{V(G)}$ is *F-avoiding* if each member of $\mathcal{S}$ is F-avoiding. For a graph G, a family $\mathcal{S} \subseteq 2^{V(G)}$ of subsets of $V(G)$ is an *F-avoiding distance-d amiable family* if it satisfies the following properties:

- $\mathcal{S}$ is F-avoiding;
- Each member of $\mathcal{S}$ induces a P_3-free subgraph in G;
- For each $S \in \mathcal{S}$, the connected components of $G[S]$ are pairwise at distance at least d in G;
- Each (inclusion-wise) maximal F-avoiding distance-d independent set of G is contained in some member of $\mathcal{S}$.

Note that a distance-d amiable family of G is nothing but an F-avoiding distance-d amiable family of G for $F = \varnothing$. As we shall see, our proof of Lemma 7 in fact shows that, for every kP_3-free graph G and every $F \subseteq V(G)$, the graph G admits an F-avoiding distance-d amiable family of size $|V(G)|^{O(k)}$ and which can be computed in time $|V(G)|^{O(k)}$.

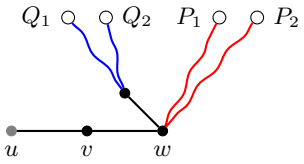

Figure 2 The case $d \leq 5$ (paths in blue are of length $d-3$, those in red, $d-2$).

Before formally proving Lemma 7, let us discuss why our approach fails for $3 \leq d \leq 5$ (recall however that the failure for $d \in \{3,5\}$ is to be expected given the hardness results in Theorem 2). The algorithm for computing a distance-d amiable family is, in essence, similar to the one for computing an amiable family (so $d=2$): it enumerates all P_3's uvw in the graph, "guesses" which vertex in the path is in the independent set and recursively calls the algorithm on (roughly) the anti-neighborhood of $\{u,v,w\}$, which is $(k-1)P_3$-free. The main difference (and difficulty) is in ensuring that the family computed recursively satisfies the distance requirement: the connected components of each member in this family could in principle be closer in the original graph. Consider, for instance, the case where u is picked in the independent set, and there are four connected components Q_1, Q_2, P_1, P_2 in a member of the recursively computed family with shortest paths between Q_1 and Q_2, and P_1 and P_2 as shown in Figure 2. Then, for $d \leq 5$, Q_1 and Q_2 can end up at a distance less than d, while P_1 and P_2 are at a distance at least d. Since there is a priori no way of "distinguishing" these two cases, we have to take d "large enough". The precise argument appears in the proof of Lemma 7 (Claim 12). We finally restate Lemma 7.

▶ **Lemma 7.** *Let $d \geq 6$ be a fixed integer. For every $k \in \mathbb{N}$, every kP_3-free graph admits a distance-d amiable family of size $|V(G)|^{O(k)}$, which can be computed in time $|V(G)|^{O(k)}$.*

Proof of Lemma 7. To prove the lemma, we provide, for every $d \geq 6$ and every $k \geq 1$, an algorithm Λ_k^d which takes as input a kP_3-free graph G, together with an arbitrary ordering of $V(G)$, and a subset $F \subseteq V(G)$, and outputs an F-avoiding distance-d amiable family $\Lambda_k^d(G,F)$ of G. The pseudo-code of the algorithm is given in Algorithm 1. Note that, if the input graph G is the empty graph, Λ_k^d correctly outputs $\Lambda_k^d(G) = \{\varnothing\}$.

In the following, we prove three claims (Claims 11–13) which altogether show that, for every $d \geq 6$ and every $k \geq 1$, if G is a kP_3-free graph and $F \subseteq V(G)$, then the family $\Lambda_k^d(G,F)$ is indeed an F-avoiding distance-d amiable family. We will then show that $\Lambda_k^d(G,F)$ has size $|V(G)|^{O(k)}$ and that the algorithm Λ_k^d has running time $|V(G)|^{O(k)}$. Taking $F = \varnothing$, will prove the lemma.

Given a graph G on n vertices and an ordering $v_1, \ldots, v_n$ of $V(G)$, we let $G_i = G[\{v_1, \ldots, v_i\}]$. Moreover, an induced path in G with vertex set $\{x_1, x_2, \ldots, x_\ell\}$ and edge set $\{x_1x_2, x_2x_3, \ldots x_{\ell-1}x_\ell\}$ is denoted by listing its vertices in the natural order $x_1x_2 \cdots x_\ell$.

▷ Claim 11 (⋆). For every $d \geq 6$ and every $k \geq 1$, if G is a kP_3-free graph and $F \subseteq V(G)$, then $\Lambda_k^d(G,F)$ is F-avoiding.

▷ Claim 12. For every $d \geq 6$ and $k \geq 1$, if G is a kP_3-free graph, $F \subseteq V(G)$, and $S \in \Lambda_k^d(G,F)$, then $G[S]$ is P_3-free and its connected components are pairwise at distance at least d in G.

Proof of Claim 12. For fixed $d \geq 6$, we proceed by induction on k. The statement holds for $k=1$, since for every P_3-free graph G and every $F \subseteq V(G)$, $\Lambda_1^d(G) = \{V(G) \setminus F\}$. Suppose now that $k > 1$ and that the statement holds for $k-1$. Let G be an n-vertex kP_3-free

Algorithm 1 Λ_k^d.

Input: A kP_3-free graph G, an arbitrary ordering $v_1, \ldots, v_n$ of $V(G)$, and a subset $F \subseteq V(G)$.
Output: An F-avoiding distance-d amiable family of G.

1: Initialize $\mathcal{S} = \{\varnothing\}$.
2: **for** $i = 1, \ldots, n$ **do**
3: **if** $v_i \notin F$ **then**
4: **for** every member $S \in \mathcal{S}$ **do**
5: **if** $G[S \cup \{v_i\}]$ is P_3-free and its connected components are pairwise at distance at least d in G **then**
6: Set $S = S \cup \{v_i\}$.
7: **for** every induced P_3 uvw in G_i such that $u \notin F$ **do**
8: Compute $\mathcal{C} := \Lambda_{k-1}^d(G[N_G^{\geq 4}(u)], (F \cap N_G^{\geq 4}(u)) \cup (N_G^{\geq 4}(u) \cap N_G^{\leq d-1}(u)))$.
9: **for** every $C \in \mathcal{C}$ **do**
10: Set $\mathcal{S} = \mathcal{S} \cup \{C \cup \{u\}\}$.
11: **for** every induced P_3 uvw in G_i such that $v \notin F$ **do**
12: Compute $\mathcal{C} := \Lambda_{k-1}^d(G[N_G^{\geq 4}(v)], (F \cap N_G^{\geq 4}(v)) \cup (N_G^{\geq 4}(v) \cap N_G^{\leq d-1}(v)))$.
13: **for** every $C \in \mathcal{C}$ **do**
14: Set $\mathcal{S} = \mathcal{S} \cup \{C \cup \{v\}\}$.
15: **return** $\Lambda_k^d(G, F) := \mathcal{S}$.

graph and let $F \subseteq V(G)$ as in input. For every $i \in [n]$, let $\mathcal{S}^i$ be the state of the family $\mathcal{S}$ at the end of the i-th iteration of the main loop. We show by induction on i that each member of $\mathcal{S}^i$ induces a P_3-free subgraph of G whose connected components are pairwise at distance at least d in G. The case $i = 1$ trivially holds, since either $v_1 \in F$ in which case $\mathcal{S}^1 = \{\varnothing\}$, or $v_1 \notin F$ in which case $\mathcal{S}^1 = \{\{v_1\}\}$. Thus, suppose that $i > 1$ and that the statement holds for $i - 1$.

Consider $S \in \mathcal{S}^i$. If $S \in \mathcal{S}^{i-1}$ then, by the induction hypothesis, $G[S]$ is P_3-free and its connected components are pairwise at distance at least d in G. Thus, we may assume that $S \notin \mathcal{S}^{i-1}$. This implies that S is added to $\mathcal{S}^i$ in one of the three inner loops during the i-th iteration of the main loop. If S is added in line 6 as an extension of a member of $\mathcal{S}^{i-1}$, then the statement holds by construction. Suppose next that S is added to $\mathcal{S}^i$ in line 10. Hence, there exist an induced P_3 uvw in G_i such that $u \notin F$ and a set $C \in \Lambda_{k-1}^d(G[N_G^{\geq 4}(u)], (F \cap N_G^{\geq 4}(u)) \cup (N_G^{\geq 4}(u) \cap N_G^{\leq d-1}(u)))$ such that $S = C \cup \{u\}$. Observe now that since G is kP_3-free and $(N_G(v) \cup N_G(w)) \cap N_G^{\geq 4}(u) = \varnothing$, the graph $G[N_G^{\geq 4}(u)]$ is $(k-1)P_3$-free, and thus, by the induction hypothesis on $k - 1$, every member of $\Lambda_{k-1}^d(G[N_G^{\geq 4}(u)], (F \cap N_G^{\geq 4}(u)) \cup (N_G^{\geq 4}(u) \cap N_G^{\leq d-1}(u)))$ induces a P_3-free subgraph of G whose connected components are pairwise at distance at least d in $G[N_G^{\geq 4}(u)]$. We claim that then, the connected components of $G[C]$ are in fact pairwise at distance at least d in G. Suppose, to the contrary, that there exist two connected components Q_1 and Q_2 of $G[C]$ such that $d_G(Q_1, Q_2) \leq d - 1$. Since the distance in $G[N_G^{\geq 4}(u)]$ between Q_1 and Q_2 is at least d, every shortest path in G from Q_1 to Q_2 contains at least one vertex of $V(G) \setminus N_G^{\geq 4}(u)$; let P be such a shortest path and let $x \in V(G) \setminus N_G^{\geq 4}(u)$ be an arbitrary vertex on P. Clearly, $d_G(u, x) \leq 3$. Now, by Claim 11, $C \cap ((F \cap N_G^{\geq 4}(u)) \cup (N_G^{\geq 4}(u) \cap N_G^{\leq d-1}(u))) = \varnothing$ which implies, in particular, that $C \subseteq N_G^{\geq d}(u)$. It follows that for $j \in [2]$,

$$d \leq d_G(u, Q_j) \leq d_G(u, x) + d_G(x, Q_j) \leq 3 + d_G(x, Q_j) \text{ and thus,}$$
$$d_G(Q_1, Q_2) = d_G(Q_1, x) + d_G(x, Q_2) \geq 2(d - 3).$$

Since, by assumption, $d_G(Q_1, Q_2) \leq d-1$, we conclude that $2(d-3) \leq d-1$, that is, $d \leq 5$, a contradiction. Thus, the connected components of $G[C]$ are pairwise at distance at least d in G. Since $C \subseteq N_G^{\geq d}(u)$, as previously observed, and $G[C]$ is P_3-free, it follows that $S = C \cup \{u\}$ induces a P_3-free graph whose connected components are pairwise at distance at least d in G. We conclude similarly in the case where S is added to $\mathcal{S}^i$ in line 14. ◁

▷ Claim 13. For every $d \geq 6$ and $k \geq 1$, if G is a kP_3-free graph and $F \subseteq V(G)$, then every F-avoiding distance-d independent set of G is contained in a member of $\Lambda_k^d(G, F)$.

Proof of Claim 13. For fixed $d \geq 6$, we proceed by induction on k. The statement clearly holds for $k = 1$, since for every P_3-free graph G and every $F \subseteq V(G)$, $\Lambda_1^d(G, F) = \{V(G) \setminus F\}$. Suppose now that $k > 1$ and that the statement holds for $k-1$. Let G be a kP_3-free graph and let $F \subseteq V(G)$ as in input. For every $i \in [n]$, let $\mathcal{S}^i$ be the state of the family $\mathcal{S}$ at the end of the i-th iteration of the main loop. Furthermore, given a distance-d independent set I of G such that $I \subseteq V(G_i)$, we say that I is *G_i-compatible* if for every $u \in I$ and every connected component Q of G_i such that u is connected to Q in G, there exists a shortest u, Q-path $P_{u,Q}$ in G such that $N_G^{\leq 2}(u) \cap V(P_{u,Q}) \subseteq V(G_i)$. We now show, by induction on i, that for every G_i-compatible F-avoiding distance-d independent set I of G such that $I \subseteq V(G_i)$, there exists $S \in \mathcal{S}^i$ such that $I \subseteq S$. Note that this is enough to prove our statement for k, since any F-avoiding distance-d independent set of $G = G_n$ is surely G_n-compatible.

The base case $i = 1$ trivially holds, since either $v_1 \in F$ and $\mathcal{S}^1 = \{\varnothing\}$ in which case $\varnothing$ is the only G_1-compatible F-avoiding distance-d independent of G_1, or $v_1 \notin F$ and $\mathcal{S}^1 = \{\{v_1\}\}$ in which case $\{v_1\}$ is the only maximal G_1-compatible F-avoiding distance-d independent set of G_1. Thus, suppose that $i > 1$ and that the statement holds for $i-1$.

Consider a G_i-compatible F-avoiding distance-d independent set I of G such that $I \subseteq V(G_i)$. If $I \subseteq V(G_{i-1})$ and I is G_{i-1}-compatible then, by the induction hypothesis, there exists $S \in \mathcal{S}^{i-1}$ such that $I \subseteq S$. Observe now that, by construction, there then exists $S' \in \mathcal{S}^i$ such that $S \subseteq S'$ and hence $I \subseteq S'$. Thus, assume that this does not hold. This implies that either $I \not\subseteq V(G_{i-1})$, or $I \subseteq V(G_{i-1})$ but I is not G_{i-1}-compatible. We distinguish these two cases and argue that we can always find $S \in \mathcal{S}^i$ such that $I \subseteq S$.

Case 1. $I \not\subseteq V(G_{i-1})$.
Hence, $v_i \in I$. Since I is F-avoiding, $v_i \notin F$. We claim that $I \setminus \{v_i\}$ is G_{i-1}-compatible. Indeed, since I is G_i-compatible, for every $u \in I \setminus \{v_i\}$ and every connected component Q of G_i such that u is connected to Q in G, there exists a shortest u, Q-path $P_{u,Q}$ in G such that $N_G^{\leq 2}(u) \cap V(P_{u,Q}) \subseteq V(G_i)$. But v_i is at distance at least $d \geq 6$ from u in G and so $v_i \notin (N_G^{\leq 2}(u) \cap V(P_{u,Q}))$, that is, $N_G^{\leq 2}(u) \cap V(P_{u,Q}) \subseteq V(G_{i-1})$ which proves our claim. By the induction hypothesis, there exists $S \in \mathcal{S}^{i-1}$ such that $I \setminus \{v_i\} \subseteq S$. If $G[S \cup \{v_i\}]$ is P_3-free and its connected components are pairwise at distance at least d in G, then $S \cup \{v_i\} \in \mathcal{S}^i$ by construction (cf. line 6) and $I \subseteq S \cup \{v_i\}$. Thus, we may assume that this does not hold. Hence, either $G[S \cup \{v_i\}]$ contains at least one induced P_3, or $G[S \cup \{v_i\}]$ is P_3-free but at least two of its connected components are at distance strictly less than d in G.

Case 1.1. $G[S \cup \{v_i\}]$ contains at least one induced P_3.
By Claim 12, $G[S]$ is P_3-free and thus, any induced P_3 in $G[S \cup \{v_i\}]$ must contain v_i. We distinguish two cases. Suppose first that there exist a connected component Q of $G[S]$ and a vertex $u \in Q$ such that v_i is adjacent to u but not complete to Q, say $w \in Q$ is nonadjacent to v_i. Note that at some point during the i-th iteration of the main loop, the induced P_3 v_iuw is considered in the second inner loop, since $v_i \notin F$. Furthermore, since G is kP_3-free and $(N_G(u) \cup N_G(w)) \cap N_G^{\geq 4}(v_i) = \varnothing$, the graph $G[N_G^{\geq 4}(v_i)]$ is $(k-1)P_3$-free. Thus, by the induction hypothesis on $k-1$ and since $I \setminus \{v_i\} \subseteq N_G^{\geq d}(v_i) \setminus F$, there exists

$C \in \Lambda^d_{k-1}(G[N^{\geq 4}_G(v_i)], (F \cap N^{\geq 4}_G(v_i)) \cup (N^{\geq 4}_G(v_i) \cap N^{\leq d-1}_G(v_i)))$ such that $I \setminus \{v_i\} \subseteq C$. But then, $C \cup \{v_i\} \in \mathcal{S}^i$ and $I \subseteq C \cup \{v_i\}$. The case where, for every connected component Q of $G[S]$ the vertex v_i is either complete or anticomplete to Q, is handled similarly.

Case 1.2. $G[S \cup \{v_i\}]$ is P_3-free but at least two of its connected components are at distance strictly less than d in G.

By Claim 12, the connected components of $G[S]$ are pairwise at distance at least d in G and so there must exist a connected component Q of $G[S \cup \{v_i\}]$ at distance strictly less than d in G to the connected component of $G[S \cup \{v_i\}]$ containing v_i. Now, since v_i is connected to Q in G and $v_i \in I$, the assumption that I is G_i-compatible implies that there exists a shortest v_i, Q-path $P_{v_i,Q}$ in G such that $N^{\leq 2}_G(v_i) \cap V(P_{v_i,Q}) \subseteq V(G_i)$. Let $u_1, u_2 \in V(G_i)$ be the two vertices on $P_{v_i,Q}$ at distance one and two, respectively, from v_i. Note that at some point during the i-th iteration of the main loop, the induced P_3 $v_iu_1u_2$ is considered in the second inner loop, since $v_i \notin F$. Moreover, since G is kP_3-free and $(N_G(u_1) \cup N_G(u_2)) \cap N^{\geq 4}_G(v_i) = \varnothing$, the graph $G[N^{\geq 4}_G(v_i)]$ is $(k-1)P_3$-free. Thus, by the induction hypothesis on $k-1$ and since $I \subseteq N^{\geq d}_G(v_i) \setminus F$, there exists $C \in \Lambda^d_{k-1}(G[N^{\geq 4}_G(v_i)], (F \cap N^{\geq 4}_G(v_i)) \cup (N^{\geq 4}_G(v_i) \cap N^{\leq d-1}_G(v_i)))$ such that $I \setminus \{v_i\} \subseteq C$. But then, $C \cup \{v_i\} \in \mathcal{S}^i$ and $I \subseteq C \cup \{v_i\}$.

Case 2. $I \subseteq V(G_{i-1})$ but I is not G_{i-1}-compatible.

Hence, there must exist $u \in I$ and a connected component Q of G_i to which u is connected in G such that $v_i \in N^{\leq 2}_G(u) \cap V(P_{u,Q})$, where $P_{u,Q}$ is a shortest path in G from u to Q given by the G_i-compatibility of I. Let $u_1, u_2 \in V(G_i)$ be the vertices on $P_{u,Q}$ at distance one and two, respectively, from u. Note that at some point during the i-th iteration of the main loop, the induced P_3 uu_1u_2 is considered in the second inner loop, since $v_i \notin F$. Moreover, since G is kP_3-free and $(N_G(u_1) \cup N_G(u_2)) \cap N^{\geq 4}_G(u) = \varnothing$, the graph $G[N^{\geq 4}_G(u)]$ is $(k-1)P_3$-free. Thus, by the induction hypothesis on $k-1$ and since $I \subseteq N^{\geq d}_G(u) \setminus F$, there exists $C \in \Lambda^d_{k-1}(G[N^{\geq 4}_G(u)], (F \cap N^{\geq 4}_G(u)) \cup (N^{\geq 4}_G(u) \cap N^{\leq d-1}_G(u)))$ such that $I \setminus \{u\} \subseteq C$. But then, $C \cup \{u\} \in \mathcal{S}^i$ and $I \subseteq C \cup \{u\}$.

Since in all cases we found $S \in \mathcal{S}^i$ with $I \subseteq S$, this concludes the proof of Claim 13. ◁

It follows now from Claims 11–13 that, for every $d \geq 6$ and every $k \geq 1$, if G is a kP_3-free graph and $F \subseteq V(G)$, then the family $\Lambda^d_k(G, F)$ is indeed an F-avoiding distance-d amiable family. It remains to show that $\Lambda^d_k(G, F)$ has size at most $|V(G)|^{O(k)}$ and that the running time of the algorithm Λ^d_k is $|V(G)|^{O(k)}$. To this end, let

$$f_d(n, k) = \max\{|\Lambda^d_k(G, F)| : |V(G)| \leq n,\ F \subseteq V(G) \text{ and } G \text{ is } kP_3\text{-free}\}.$$

Clearly, $f_d(n, 1) = 1$ for every $n \in \mathbb{N}$. We claim that, for every $n \in \mathbb{N}$ and $k > 1$, $f_d(n, k) \leq 2n^4 \cdot f_d(n, k-1)$. Indeed, for every n-vertex kP_3-free graph G and every $F \subseteq V(G)$, a member of $\Lambda^d_k(G, F)$ can only be created during an i-th iteration of the main loop (for some $i \in [n]$) in one of the inner loops from an induced P_3 of G_i and some set resulting from a call to Λ^d_{k-1}. Since for each $i \in [n]$ there are at most i^3 such copies of P_3 in G_i, at most $2i^3 \cdot f_d(n, k-1)$ new members are added in the i-th iteration of the main loop. It follows that $f_d(n, k) \leq \sum_{i \in [n]} 2i^3 \cdot f_d(n, k-1) \leq 2n^4 \cdot f_d(n, k-1)$ and thus $f_d(n, k) \leq 2^{k-1} n^{4(k-1)}$.

Similarly, for every $d \geq 6$ and every $n, k \in \mathbb{N}$, if $T_d(n, k)$ denotes the running time of the algorithm Λ^d_k on an n-vertex kP_3-free graph, then clearly $T_d(n, 1) = O(n)$. Furthermore, we obtain the following recurrence for $T_d(n, k)$, where we use the fact that checking if an n-vertex graph is P_3-free can be done in $O(n^3)$ time and determining if the connected components of an n-vertex graph are pairwise at distance at least d can be done in $O(n^3)$ time (using an all-pair-shortest-path algorithm):

$$T_d(n, k) \leq cn \cdot (f_d(n, k) \cdot n^3 + 2n^3 \cdot (T_d(n, k-1) + f_d(n, k-1))) \leq 2cn^4 \cdot T_d(n, k-1) + O(n^{4k}),$$

for some constant $c > 0$. We conclude that $T_d(n, k) \leq n^{O(k)}$. ◀

Abstract

We present an efficient algorithm for the min-max correlation clustering problem. The input is a complete graph where edges are labeled as either positive $(+)$ or negative $(-)$, and the objective is to find a clustering that minimizes the ℓ_∞-norm of the disagreement vector over all vertices.

We address this problem with an efficient $(3+\epsilon)$-approximation algorithm that runs in nearly linear time, $\tilde{O}(|E^+|)$, where $|E^+|$ denotes the number of positive edges. This improves upon the previous best-known approximation guarantee of 4 by Heidrich, Irmai, and Andres [37], whose algorithm runs in $O(|V|^2 + |V|D^2)$ time, where $|V|$ is the number of nodes and D is the maximum degree in the graph (V, E^+).

Furthermore, we extend our algorithm to the massively parallel computation (MPC) model and the semi-streaming model. In the MPC model, our algorithm runs on machines with memory sublinear in the number of nodes and takes $O(1)$ rounds. In the streaming model, our algorithm requires only $\tilde{O}(|V|)$ space, where $|V|$ is the number of vertices in the graph.

Our algorithms are purely combinatorial. They are based on a novel structural observation about the optimal min-max instance, which enables the construction of a $(3+\epsilon)$-approximation algorithm using $O(|E^+|)$ neighborhood similarity queries. By leveraging random projection, we further show these queries can be computed in nearly linear time.

1 Introduction

In the correlation clustering problem, we are given a complete graph where each edge is labeled as either "+" or "-". A "+" edge indicates that the two vertices are *similar*, while a "-" edge indicates they are *dissimilar*. For any partition of the graph, an edge is considered to be in disagreement if it is a negative edge and its endpoints belong to the same cluster, or if it is a positive edge and its endpoints belong to different clusters. It is typical to assume that the input graph is $G^+ = (V, E^+)$, where E^+ is the set of positive edges, and to obtain time bounds in terms of properties of G^+, such as $m = |E^+|$ and D, the maximum degree of G^+. This is because, in many practical applications, the number of positive edges is often much smaller than the number of negative edges [23].

Given a clustering (partition), the disagreement $\rho(v)$ for any node v is defined as the number of edges incident to v that are in disagreement with respect to the clustering. The goal of the correlation clustering problem is to find a clustering that minimizes an objective function capturing the disagreement of edges.

Puleo and Milenkovic [41] introduced the objective of minimizing the ℓ_p-norm of the disagreements over the vertices, which is defined as $\left(\sum_{v\in V}\rho(v)^p\right)^{1/p}$. This objective generalizes the correlation clustering problem proposed by Bansal, Blum, and Chawla [8], which corresponds to the case $p = 1$, where the goal is to minimize the total number of disagreements. Significant progress has been made on the ℓ_1-norm objective [21, 3, 22, 27, 26], Cao, Cohen-Addad, Lee, Li, Newman, and Vogl [14] present a 1.437-approximate algorithm for ℓ_1-norm objective. For the case $p = \infty$, it corresponds to the min-max correlation clustering problem, where the goal is to minimize the maximum disagreements over all vertices. While the $p = 1$ case captures scenarios in which minimizing overall disagreements is desired, the $p = \infty$ case caters to situations where the quality of every individual needs to be ensured – for example, in community detection problems where no "antagonists" are allowed, with an antagonist referring to an individual whose properties are inconsistent with those of too many other members.

Compared to the $p = 1$ case where significant progress has been made, the $p = \infty$ case remains relatively unexplored. Puleo and Milenkovic [41] proposed an algorithm that achieves a 48-approximation ratio. Their approach uses the standard metric linear programming formulation followed by a rounding algorithm. Later, Charikar, Gupta, and Schwartz [20] improved this result to a 7-approximation using the same framework, and Kalhan, Makarychev, and Zhou [39] further reduced it to a 5-approximation. Davies, Moseley, and Newman [29] designed a combinatorial algorithm that achieves a 40-approximation ratio with a runtime of $O(n^2 \log n)$, where $n = |V|$ is the number of vertices in the graph. The best known approximation ratio to date is 4, achieved by Heidrich, Irmai, and Andres [37], who also used a combinatorial approach with a runtime of $O(n^2 + nD^2)$, where D is the maximum degree of the G^+.

Concerning efficiency, the ultimate goal of an efficient algorithm is to achieve a running time that is nearly linear in $m = |E^+|$. However, none of the aforementioned algorithms has yet achieved such a goal. Recently, Cao, Li, and Ye [16] proposed an nearly linear-time algorithm that achieves a 63.3-approximation ratio. While their algorithm is fast, the approximation ratio is far from optimal. This naturally leads to the question:

> Can we design a nearly linear algorithm for min-max correlation clustering with a small approximation ratio?

We give a nearly linear algorithm for the problem that achieves a $(3+\epsilon)$-approximation. Moreover, it can be made exactly 3-factor approximation with additional running time.

▶ **Theorem 1.** *Let $G = (V, E^+)$ be a min-max correlation clustering instance, $\epsilon > 0$ be a small constant, and* OPT *be the value of the optimal solution. There exist:*

1. *A randomized $O(m \log^2 n/\epsilon^2)$-time algorithm that outputs a clustering $\mathcal{C}$ with* $\mathrm{obj}(\mathcal{C}) \le (3+\epsilon)\cdot \mathrm{OPT}$ *w.h.p.*[1]
2. *A deterministic $O(mD \log n)$-time sequential algorithm that outputs a clustering $\mathcal{C}$ with* $\mathrm{obj}(\mathcal{C}) \le 3 \cdot \mathrm{OPT}$*, where D is the maximum degree of $G^+ = (V, E^+)$.*

[1] *With high probability*, which refers to with probability at least $1 - 1/n^c$ for a sufficiently large constant c.

1.1 Semi-Streaming and MPC Settings

For large graphs, it can be infeasible to store the graph G entirely on a single machine and then compute the solution. A substantial body of research has focused on massively parallel computation (MPC) algorithms for the $p = 1$ case [10, 40, 31, 11, 25, 7, 12, 15, 28]. Very recently, Cao, Cohen-Addad, Lee, Li, Lolck, Newman, Thorup, Vogl, Yan, and Zhang [13] gave an $O(1)$-round MPC algorithm that achieves a $(1.437 + \epsilon)$-approximation ratio.

Moreover, several constant-round semi-streaming algorithms with $n \operatorname{polylog} n$ space complexity have been developed [23, 2, 25, 9]. The first single-pass semi-streaming algorithm was given by Ahn, Cormode, Guha, McGregor, and Wirth [2], and it was later improved by multiple works [7, 9, 18, 28]. Very recently, a breakthrough result of Assadi, Khanna, and Putterman [5] showed that it is possible to obtain a $(\alpha_{\text{best}} + o(1))$-approximation in a single pass using $n \operatorname{polylog} n$ space, where α_{best} denotes the best approximation ratio achievable by polynomial-time sequential algorithms. Currently, it is known that $\alpha_{\text{best}} \leq 1.437$ [14].

In contrast, less work in such directions have been done for the $p = \infty$ setting. For the MPC setting, the only known work is by Cao, Ye, and Li [16], who proposed an algorithm that achieves a 63.3-approximation ratio in $O(\log^3 n)$ rounds and another algorithm that achieves a 360-approximation ratio in $O(1)$ rounds. For the semi-streaming setting, to our knowledge, we are not aware of any existing work on semi-streaming algorithms. Most of the aforementioned streaming algorithms for $p = 1$ were specifically tailored for this case, and the sparsification technique of [5] does not seem to generalize obviously to other values of p.

In addition to our sequential algorithm, we give a constant-round MPC algorithm and a single-pass semi-streaming algorithm that achieve a $(3 + \epsilon)$-approximation for the problem:

▶ **Theorem 2.** *Let $G = (V, E^+)$ be a min-max correlation clustering instance, $\epsilon > 0$ be a small constant, and* OPT *be the value of the optimal solution. In the following models, there exist randomized algorithms that output a clustering $\mathcal{C}$ with* $\text{obj}(\mathcal{C}) \leq (3 + \epsilon) \cdot \text{OPT}$ *w.h.p.:*

1. *(MPC model) An $O(1)$-round algorithm using $O(n^\delta)$ memory per machine and total memory $O(m \log n / \epsilon^2)$ for any constant $0 < \delta < 1$.*
2. *(Semi-streaming model) A single-pass streaming algorithm that uses $O(n \log n / \epsilon^2)$ space.*

1.2 Technical Overview

Better Approximation. Our first main technical contribution is a newly achieved approximation factor of 3. Given a guess for the optimal objective value ϕ, if $OPT \leq \phi$, [37] observed that if the neighborhoods of u and v share at least 2ϕ elements, then they must belong to the same cluster in the optimal solution. Similarly, if neighborhoods of u and v differ by more than 2ϕ elements, then they must belong to different clusters in the optimal solution.

Furthermore, they observed that these properties can be used to determine the clusters for vertices of degrees at least 4ϕ. Specifically, if $d(x) \geq 4\phi$, then for every other vertex y, either $|N[x] \cap N[y]| \geq 2\phi$ or $|N[x] \Delta N[y]| \geq 2\phi$. Here, $N[x] = N(x) \cup \{x\}$ represents the closed neighborhood of vertex x. The remaining vertices can then be placed in singleton clusters, as the disagreements per vertex will be upper bounded by their degrees, 4ϕ. Therefore, a clustering of disagreements upper bounded by 4ϕ can be constructed, resulting in a 4-approximation algorithm.

To achieve a 3-approximation, we first observe that if two vertices x and y have degrees greater than 3ϕ, then it is also the case either $|N[x] \cap N[y]| \geq 2\phi$ or $|N[x] \Delta N[y]| \geq 2\phi$ holds. In other words, whether x and y belong to the same cluster is uniquely determined in the optimal solution. Therefore, the clustering induced on the high-degree vertices (vertices with $d > 3\phi$) is uniquely determined.

Now the question lies in the placement of the low-degree vertices, that is, vertices with degrees upper-bounded by 3ϕ. It is unclear whether they should be placed in singleton clusters, as it is possible that they need to be included in the same cluster with certain high-degree vertices. Otherwise, the disagreements associated with the high-degree vertices could become too large.

We show that the low-degree vertices can be placed in the high-degree clusters to achieve a maximum disagreements of 3ϕ, provided $OPT \leq \phi$. A key structural result we show is that if a low-degree vertex w belongs to some cluster C in an optimal solution, then no vertex v outside C can have similar neighborhood with w, i.e., $|N[v] \Delta N[w]| \leq 2\phi$. Using this structural result, we show the following algorithm constructs a clustering with maximum disagreement upper bounded by 3ϕ (presented slightly differently here than in the main body for the sake of intuition):

1. Form clusters for high-degree vertices based on whether $|N[u] \Delta N[v]| \leq 2\phi$ for all high-degree vertices u, v (abort if any inconsistency occurs). 2. Choose an arbitrary vertex u in each cluster and have it send proposal messages to low-degree neighboring vertices whose neighborhoods are similar to u. 3. For each low-degree vertex that receives at least one proposal, pick one arbitrary proposal and join the cluster containing the vertex that sent it. 4. Place all low-degree vertices that do not receive a proposal into singleton clusters.

Efficient Implementations. The remaining question is how such an algorithm can be implemented efficiently, particularly in time (and total memory) nearly linear in $|E^+|$. A main technical challenge lies in Step 1. To implement it within the aforementioned time bound, we can only afford to conduct similarity tests (i.e. to test whether $|N[u] \Delta N[v]| \leq 2\phi$) for $O(|E^+|)$ times. However, it is possible for two vertices that are endpoints of a negative edge to have similar neighborhoods and thus need to be placed in the same cluster to achieve a good clustering.

Using the structural result, we further show that two high-degree vertices u and v are in the same cluster in the optimal solution if and only if there are at least $\phi + 1$ disjoint paths of length 2 connecting u and v in E_{sim}, where $E_{\text{sim}} \subseteq E^+$ consists of all the edges in E^+ whose endpoints have similar neighborhoods. This property enables us to develop efficient algorithms for the sublinear MPC model and the sequential model.

The remaining question lies in how to find E_{sim} efficiently. To this end, for each vertex u, we treat its neighborhood set $N[u]$ as a point in an n-dimensional space. Then, we apply the (discrete) random projection technique [1] developed for the Johnson-Lindenstrauss transform [38] to reduce the dimension to $O(\log n/\epsilon^2)$ while preserving the ℓ_2 distance (up to a $(1 \pm \epsilon)$ factor) between the points. For 0/1 vectors, the square of the ℓ_2 distance is exactly the symmetric difference. Since the dimension is $O(\log n/\epsilon^2)$, it takes $O(\log n/\epsilon^2)$ time to compute the difference. To our knowledge, this is the first time that random projection techniques have been applied to computing efficient solutions for correlation clustering and problems alike. This may be of independent interest, as neighborhood similarity is known to be used in various tools such as *almost-clique decompositions* [36, 19, 33, 34, 32, 4, 30, 6, 24, 7].

Single-Pass Semi-Streaming. While the above techniques are sufficient for getting our MPC and sequential algorithms, the single-pass semi-streaming algorithm introduces additional technical difficulties. The main difficulty for a single-pass semi-streaming to work here lies in Step 2, where an arbitrarily chosen high-degree vertex in each cluster proposes to its neighbors who have similar neighborhoods. For convenience, we call the chosen high-degree vertices *pivots* here.

To be able to do this, we need to memorize the neighbors of all the chosen vertices using $n\,\mathrm{polylog}(n)$ space. Suppose that $\mathrm{OPT} \le \phi$, it can be shown that each cluster in the optimal clustering containing at least one low-degree vertex has size of $\Theta(\phi)$. As a result, any vertex from these clusters has degree at most $O(\phi)$. Since we pick a pivot per cluster, $O(\phi \cdot (n/\phi))$ is the space we need to store the neighbors of the pivots.

However, we do not know beforehand how the clusters of high-degree vertices look like, so the pivots cannot be chosen at the beginning of the stream. Without knowing what the pivots are beforehand, it is difficult to store their neighbors in the same pass.

As a result, we sample each vertex (both high-degree and low-degree vertices) independently with probability $O(\log n/d(v))$ so that w.h.p. each cluster in the optimal clustering has $O(\log n)$ sampled vertices. Then we store the neighbors of all the sampled vertices. This poses another problem: low-degree vertices may be chosen as pivots. However, a low-degree vertex is exempted from our structural result – using it as a pivot may steal vertices from other clusters in an optimal clustering.

To resolve this, we do the following. For each sampled vertex y, we first try to recover the high-degree portion L of the cluster containing y in the optimal solution. We construct a candidate set $\mathrm{Cand}(L)$ that contains vertices that would not be added to other clusters. When using y as a pivot, we restrict it to consider only the intersection with the candidate set, $N[y] \cap \mathrm{Cand}(L)$ to ensure that it does not steal vertices from other clusters.

Roughly speaking, the candidate set $\mathrm{Cand}(L)$ contains all the low-degree vertices that have similar neighborhood with every vertex in L but have different neighborhood with every vertex in any other cluster L' (as a result, $\mathrm{Cand}(L) \cap \mathrm{Cand}(L') = \varnothing$). We show such a modification does not affect the approximation ratio. Furthermore, since the candidate sets are defined based on similarity of neighborhoods, they can be constructed by the aforementioned dimension reduction technique, which takes $O(n \log n/\epsilon^2)$ space.

2 Preliminaries

▶ **Definition 3.** *Given $u \in G^+ = (V, E^+)$, let $N(u)$ denote the neighbors of $u \in G^+$. Define $N[u] = N(u) \cup \{u\}$. $d(u) = |N(u)|$ is the number of neighbors of $u \in G^+$. We use $N_H(u)$,$N_H[u]$ and $d_H(u)$ to denote the the corresponding quantities in graph H when $H \neq G^+$.*

▶ **Definition 4.** *Let A and B be sets. The symmetric difference between A and B, $A\Delta B$, is defined as $A\Delta B = (A \setminus B) \cup (B \setminus A)$.*

In general, we say A and B are similar if $|A\Delta B|$ is small.

▶ **Lemma 5** (Triangle Inequality [35])**.** *Let A, B, C be sets. Then: $|A\Delta C| \le |A\Delta B| + |B\Delta C|$.*

▶ **Definition 6.** *Given any clustering $\mathcal{C}$ and any vertex u, $\mathcal{C}_u$ is defined to be the cluster of $\mathcal{C}$ containing u.*

▶ **Definition 7.** *Given clustering $\mathcal{C}$, define $\rho_{\mathcal{C}}(x)$ as the number of disagreements incident to vertex x. More precisely:*

$$\rho_{\mathcal{C}}(x) = |\mathcal{C}_x \setminus N[x]| + |N[x] \setminus \mathcal{C}_x| = |N[x]\Delta\mathcal{C}_x| = |N(x) \,\Delta\, \mathcal{C}_x| - 1$$

▶ **Definition 8.** *Given a clustering $\mathcal{C}$, the objective value of $\mathcal{C}$, $\mathrm{obj}(\mathcal{C}) = \max_u \rho_{\mathcal{C}}(u)$, is defined as the maximum incident disagreements over every vertex.*

The MPC Model. In the MPC model, computation proceeds in synchronous parallel *rounds* across multiple machines. Each machine has memory S. At the beginning of the computation, data is arbitrarily partitioned across the machines. During each round, machines process data locally, exchange messages with other machines, and send or receive messages of total size S. The efficiency of an algorithm in this model is measured by the number of rounds required for the algorithm to terminate and the size S of the memory available to each machine.

In this paper, we focus on the most practical and challenging regime, also known as the *strictly sublinear regime*, where each machine has $S = O(n^{\delta})$ local memory. Here, n represents the number of vertices, and $0 < \delta < 1$ is an arbitrary constant. Under this assumption, the input assigned to each machine and the messages exchanged during any round are of size $O(n^{\delta})$.

The Semi-Streaming Model. In the semi-streaming model, the input is a stream of edges in E^{+}. We are allowed to use $n \operatorname{polylog} n$ space, where the space complexity is the number of words used and a word consists of $O(\log n)$ bits. A solution is expected to be output at the end of the stream.

3 Algorithm

▶ **Definition 9.** *For any $0 \le \eta < 1$, an η-similarity query $\Delta_\eta(u, v, t)$ returns:*

$$\Delta_\eta(u,v,t) = \begin{cases} 0, & \text{if } |N[u] \Delta N[v]| > (1+\eta)t. \\ 0 \text{ or } 1, & \text{if } t < |N[u] \Delta N[v]| \le (1+\eta)t. \\ 1, & \text{if } |N[u] \Delta N[v]| \le t. \end{cases}$$

▶ **Definition 10.** *(Shorthand for η-similarity query) For readability, we use $|N[u] \Delta N[v]| \le_\eta t$ to denote that an η-similarity query $\Delta_\eta(u, v, t)$ has been conducted and returned 1. We use $|N[u] \Delta N[v]| \not\le_\eta t$ to denote that the query $\Delta_\eta(u, v, t)$ returned 0.*

The parameter η was introduced to accommodate the error induced by an approximate test of whether $|N[u] \Delta N[v]| \le 2\phi$. For the sake of simplicity, we urge the readers to assume $\eta = 0$ when reading for the first time. When $\eta = 0$, $|N[u] \Delta N[v]| \le_\eta 2\phi$ if and only if $|N[u] \Delta N[v]| \le 2\phi$.

▶ **Definition 11.** *Define $V_{\text{low}} \leftarrow \{w \in V \mid d(w) \le (3+\eta)\phi\}$ and $V_{\text{high}} \leftarrow V \setminus V_{\text{low}}$, where we call the vertices in V_{low} and V_{high} as low-degree and high-degree vertices, respectively.*

Algorithm Description. Algorithm 1 takes two parameters ϕ and $0 \le \eta < 1$, where ϕ is a guess on the upper bound of OPT and η is an error control parameter. The goal of the algorithm is to output a solution of value $(3+\eta)\phi$ provided OPT $\le \phi$. Note that we use η instead of ϵ here to indicate that it can be set to zero (at the cost of computing the more expensive exact neighborhood similarity).

The algorithm works as follows: first, we form a clustering of high-degree vertices $\mathcal{L}$ based on the similarity between the neighborhood of vertices. If two high-degree vertices u and v have similar neighborhood (i.e. $N[u] \Delta N[v] \le_\eta 2\phi$) then they will be placed in the same cluster.

Once the high-degree clusters are formed, we go through each cluster $L_i \in \mathcal{L}$. For each L_i, we pick an arbitrary pivot $u_i \in L_i$. For each neighbor w of u_i that remains unclustered (i.e. in V_i), we include it in $R(u_i)$ if w and u_i have similar neighborhoods (i.e. $N[w] \Delta N[u_i] \le_\eta 2\phi$). Then we set our cluster C_i to be $L_i \cup R(u_i)$. Then we update the unclustered vertices to be $V_{i+1} = V_i \setminus R(u_i)$.

Algorithm 1 ClusterPhi($G^+ = (V, E^+), \phi, \eta$).
Input: A graph G^+ and parameters ϕ and $0 \le \eta < 1$.
Output: A clustering $\mathcal{C}$ with $\mathrm{obj}(\mathcal{C}) \le (3+\eta)\phi$ or "OPT > ϕ"

function ClusterPhi($G^+ = (V, E^+), \phi, \eta$)
  $V_{\text{low}} \leftarrow \{w \mid d(w) \le (3+\eta)\phi\}, V_{\text{high}} \leftarrow V \setminus V_{\text{low}}$
  for $u, v \in V_{high}$ **do** ▷ uv not necessarily in E^+.
    if $|N[u] \Delta N[v]| \le_\eta 2\phi$ **then**
      $E' \leftarrow E' \cup \{uv\}$.
    end if
  end for
  $V_1 = V_{\text{low}}$
  Let $\mathcal{L} = \{L_i\}_{i=1}^{|\mathcal{L}|}$ be the partition formed by the connected components in (V_{high}, E').
  for i from 1 to $|\mathcal{L}|$ **do**
    Choose any node $u_i \in L_i$.
    Compute $R(u_i) = \{w \in V_i \cap N(u_i) \mid |N[w] \Delta N[u_i]| \le_{\eta/2} 2\phi\}$
    $C_i \leftarrow L_i \cup R(u_i)$
    $V_{i+1} \leftarrow V_i \setminus R(u_i)$
  end for
  Let $\mathcal{C} = \{C_i\}_{i=1}^{|\mathcal{L}|} \cup \bigcup_{v \in V_{|\mathcal{L}|+1}} \{\{v\}\}$
  if for some i there exists $u \in C_i$ such that $\rho_{\mathcal{C}}(u) > (3+\eta)\phi$ **then**
    return "OPT > ϕ"
  else
    return $\mathcal{C}$.
  end if
end function

Once we went through every L_i, there might be still some unclustered low-degree vertices (i.e. those in $V_{|\mathcal{L}|+1}$). For each such vertex, we put it in a singleton cluster. Then, we check if the clustering we have obtained has an objective value at most $(3+\eta)\phi$ or not. If it does, then we are done. If not, we conclude that OPT > ϕ, so we would need to set our guess of ϕ larger.

▶ **Theorem 12.** *Suppose that* OPT $\le \phi$*, Algorithm 1 outputs a clustering* $\mathcal{C}$ *with* $\mathrm{obj}(\mathcal{C}) \le (3+\eta)\phi$.

Proof. Let $\mathcal{C}^*$ be an optimal solution so $\mathrm{obj}(\mathcal{C}^*) \le \phi$. In the next subsections, we show the following:

1. (High-Degree Nodes Clustering). For any $u \in V_{\text{high}}$, $\mathcal{L}_u \cap V_{\text{high}} = \mathcal{C}^*_u \cap V_{\text{high}}$.
2. (No Stealing on Low-Degree Nodes). For each $i \in [1, |\mathcal{L}|]$, let C_i^* be the cluster in $\mathcal{C}^*$ such that $L_i \cap V_{\text{high}} = C_i^* \cap V_{\text{high}}$. We have $C_i^* \cap V_i = C_i^* \cap V_{\text{low}}$. That is, those low-degree vertices in C_i^* are not taken by other clusters C_j for $j < i$.
3. (Low-Degree Nodes Inclusion). For any $i \in [1, |\mathcal{L}|]$, $C_i^* \cap N(u_i) \subseteq C_i$.
4. (Closeness). For any $i \in [1, |\mathcal{L}|]$, $|N[u_i] \Delta C_i| \le \phi$ and $|C_i^* \Delta C_i| \le \phi$.

Once we have shown the above, we can see that $\mathrm{obj}(\mathcal{C}) \le (3+\eta)\phi$ as follows. Consider a component C_i of $\mathcal{C}$. If C_i is a singleton $\{v\}$ with $d(v) \le (3+\eta)\phi$, then obviously, $\rho_{\mathcal{C}}(v) \le (3+\eta)\phi$. Otherwise, C_i contains some vertex x with $d(x) > (3+\eta)\phi$. By Item 1, there must exist C_i^* such that $C_i \cap V_{\text{high}} = C_i^* \cap V_{\text{high}}$.

Let v be any vertex in C_i. We will show that $\rho_{\mathcal{C}}(v) \le 3\phi$. Suppose that $v \in C_i^* \cap C_i$, we have:

$$\begin{aligned}\rho_{\mathcal{C}}(v) = |N[v] \Delta C_i| &\le |N[v] \Delta C_i^*| + |C_i^* \Delta C_i| && \text{by Lemma 5}\\ &= \rho_{\mathcal{C}^*}(v) + |C_i^* \Delta C_i| \le \phi + \phi = 2\phi\end{aligned}$$

Otherwise, if $v \notin C_i^* \cap C_i$ then it must be the case that $v \in C_i \setminus C_i^*$. In such a case, v must be a vertex in $R(u_i)$ added to C_i in Line 12 to Line 13. This implies $|N[v] \Delta N[u_i]| \le_{\eta/2} 2\phi$ and thus $|N[v] \Delta N[u_i]| \le (1 + \eta/2) \cdot 2\phi$. Therefore:

$$\begin{aligned}\rho_{\mathcal{C}}(v) = |N[v] \Delta C_i| &\le |N[v] \Delta N[u_i]| + |N[u_i] \Delta C_i| && \text{by Lemma 5}\\ &\le (1 + \eta/2) \cdot 2\phi + \phi = (3 + \eta)\phi\end{aligned}$$

◀

▶ Remark 13. To get a $(3 + \epsilon)$-approximation algorithm, $O(\log n)$ calls of Algorithm 1 are sufficient, as we can perform a binary search on ϕ in the range of $[0, n]$ with $\eta = \epsilon$ and take the solution output by the algorithm with the smallest ϕ. For a 3-approximation algorithm, it can also be achieved within $O(\log n)$ calls of Algorithm 1 by setting $\eta = 0$.

We prove each of the four items in the proof in the following subsections. Note that the no-stealing property of low-degree vertices (Theorem 17 in Section 3.2) is the main structural result, which not only leads to a guarantee on the approximation ratio, but it is also crucial in the design of efficient algorithms in the subsequent sections.

3.1 High-Degree Nodes Clustering

Recall that ϕ is our guess of the upper bound of the optimal solution. In this subsection, we show if ϕ is indeed such an upper bound, then there is a unique way to form clustering on high-degree nodes in the optimal solution. Our algorithm clusters the high-degree nodes using the unique way. The following two lemmas are observed by [37].

▶ **Lemma 14.** *Suppose that $|N[x] \cap N[y]| > t$. If there is a clustering $\mathcal{C}'$ such that x and y are in different clusters, then* $\mathrm{obj}(\mathcal{C}') > t/2$.

Proof.

$$t < |N[x] \cap N[y]| \le |N[x] \cap N[y] \setminus \mathcal{C}'_y| + |N[x] \cap N[y] \setminus \mathcal{C}'_x| \le \rho_{\mathcal{C}'}(y) + \rho_{\mathcal{C}'}(x)$$

Therefore, $\mathrm{obj}(\mathcal{C}') \ge \max(\rho_{\mathcal{C}'}(x), \rho_{\mathcal{C}'}(y)) \ge (\rho_{\mathcal{C}'}(x) + \rho_{\mathcal{C}'}(y))/2 > t/2$. ◀

▶ **Lemma 15.** *Suppose that $|N[x] \Delta N[y]| > t$. If there is a clustering $\mathcal{C}'$ such that x and y are in the same clusters, then* $\mathrm{obj}(\mathcal{C}') > t/2$.

Proof. Let C be the cluster containing x and y. By Lemma 5, we have:

$$t < |N[x] \Delta N[y]| \le |N[x] \Delta C| + |N[y] \Delta C| = \rho_{\mathcal{C}'}(x) + \rho_{\mathcal{C}'}(y)$$

Therefore, $\mathrm{obj}(\mathcal{C}') \ge \max(\rho_{\mathcal{C}'}(x), \rho_{\mathcal{C}'}(y)) \ge (\rho_{\mathcal{C}'}(x) + \rho_{\mathcal{C}'}(y))/2 > t/2$. ◀

▶ **Lemma 16.** *Let $\mathcal{C}^*$ be a clustering with* $\mathrm{obj}(\mathcal{C}^*) \le \phi$. *For any $u \in V_{\mathrm{high}}$, $\mathcal{L}_u \cap V_{\mathrm{high}} = \mathcal{C}_u^* \cap V_{\mathrm{high}}$.*

Proof. Suppose on the contrary that $\mathcal{L}_u \cap V_{\text{high}} \neq \mathcal{C}^*_u \cap V_{\text{high}}$. Then there exists some node x such that $x \in (\mathcal{L}_u \cap V_{\text{high}}) \Delta (\mathcal{C}^*_u \cap V_{\text{high}})$.

Suppose that there exists a node x such that $x \in \mathcal{L}_u \cap V_{\text{high}}$ but $x \notin \mathcal{C}^*_u \cap V_{\text{high}}$. Then there must exist $y \in \mathcal{C}^*_u$ such that $(x, y) \in E'$. This implies $|N[x] \Delta N[y]| \leq_\eta 2\phi$ and so $|N[x] \Delta N[y]| \leq (1+\eta)2\phi$. Therefore,

$$\begin{aligned} |N[x] \cap N[y]| &= (d(x) + 1 + d(y) + 1 - |N[x] \Delta N[y]|)/2 \\ &> ((3+\eta)\phi + 1 + (3+\eta)\phi + 1 - (1+\eta)2\phi)/2 \\ &= (6\phi + 2 - 2\phi)/2 = 2\phi + 1 \end{aligned}$$

By Lemma 14, $\text{obj}(\mathcal{C}^*) > \phi$, a contradiction.

Otherwise, it must be the case that $x \in \mathcal{C}^*_u \cap V_{\text{high}}$ but $x \notin \mathcal{L}_u \cap V_{\text{high}}$. In this case, there exists $y \in \mathcal{C}^*_u$ such that $(x, y) \notin E'$. This implies that $|N[x] \Delta N[y]| \not\leq_\eta 2\phi$, which in turns implies $|N[x] \Delta N[y]| > 2\phi$. By Lemma 15, $\text{obj}(\mathcal{C}^*) > \phi$, a contradiction. ◀

3.2 No Stealing on Low-Degree Nodes

In the algorithm, low-degree nodes (i.e. nodes with degree at most $(3+\eta)\phi$) are added to the clusters formed by high-degree nodes iteratively. In this subsection, we show that if a low-degree node degree node y belongs to C^*_i for some i, then it will not be included in C_j for $j < i$. This implies that $y \in V_i$, the candidate set of vertices to be added C_i. Then in the next subsection, we show that it will be added to C_i.

▶ **Theorem 17.** *Let $\mathcal{C}^*$ be a clustering with obj$(\mathcal{C}^*) \leq \phi$. Let u and v be vertices of degree greater than $(3+\eta)\phi$ where $\mathcal{C}^*_u \neq \mathcal{C}^*_v$, and w be a vertex with $d(w) \leq (3+\eta)\phi$. If $w \in \mathcal{C}^*_u$ then $|N[v] \Delta N[w]| > (1+\eta)2\phi$ and so $|N[v] \Delta N[w]| \not\leq_\eta 2\phi$.*

A representative case that illustrates the intuition of why the theorem holds is when $|N[u] \cap N[v] \cap N[w]| \leq \phi$, i.e. the three sets have small intersections. Since they have small intersection, together with the fact that u and v have degrees greater than $(3+\eta)\phi$, it cannot be the case that both the symmetric differences $N[u] \Delta N[w]$ and $N[v] \Delta N[w]$ are small, as illustrated in Figure 1. We will refer the case that $|N[u] \cap N[v] \cap N[w]| \leq \phi$ as the *easy case*.

When the three sets have a large intersection, with a more sophisticated argument on the relations among $N[u], N[v]$, and $N[w]$, it can also be shown that $N[w]$ and $N[u]$ will not intersect a lot. We will refer to the case that $|N[u] \cap N[v] \cap N[w]| > \phi$ as *the hard case*.

3.2.1 The easy case

We will first show the theorem for the easy case as follows.

▶ **Lemma 18.** *Let $\mathcal{C}^*$ be a clustering with obj$(\mathcal{C}^*) \leq \phi$. Let u and v be vertices of degree greater than $(3+\eta)\phi$ where $\mathcal{C}^*_u \neq \mathcal{C}^*_v$, and w be a vertex with $d(w) \leq (3+\eta)\phi$. If $w \in \mathcal{C}^*_u$ and $|N[v] \cap N[u] \cap N[w]| \leq \phi$, then $|N[v] \Delta N[w]| > (1+\eta)2\phi$ and so $|N[v] \Delta N[w]| \not\leq_\eta 2\phi$.*

Proof. We will show that $|N[v] \Delta N[w]| + |N[u] \Delta N[w]|$ is greater than $(1+\eta)4\phi$. Figure 1 gives a high level illustration of why this should be true. To show this formally, first note that:

$$\begin{aligned} &|N[v] \cap N[w] \cap N[u]| + |N[w] \setminus N[u]| + |N[v] \setminus N[w]| \\ &\geq |N[v] \cap N[w] \cap N[u]| + |(N[v] \cap N[w]) \setminus N[u]| + |N[v] \setminus N[w]| \\ &= |N[v] \cap N[w]| + |N[v] \setminus N[w]| = |N[v]| \end{aligned}$$

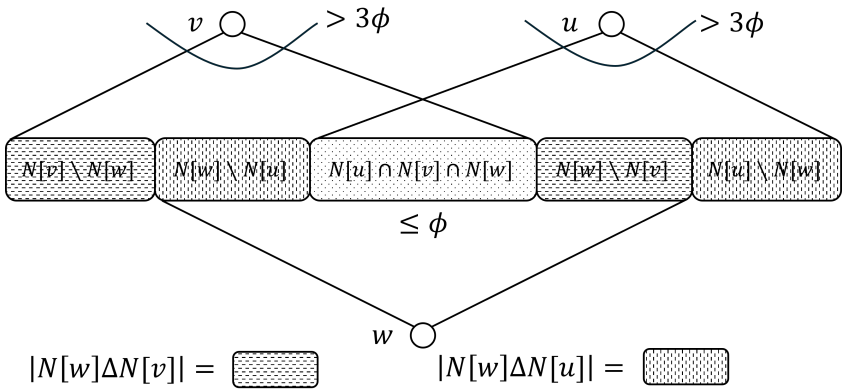

Figure 1 A pictorial illustration of the proof of Lemma 18 when $\eta = 0$. It shows that if $N[u] \cap N[v] \cap N[w]$ is small, then either $N[w]\Delta N[v]$ or $N[w]\Delta N[u]$ has to be large, since $|N[u]|$ and $|N[v]|$ are more than 3ϕ.

Re-arranging, we have:

$$\begin{aligned} |N[w] \setminus N[u]| + |N[v] \setminus N[w]| &\geq |N[v]| - |N[v] \cap N[w] \cap N[u]| \\ &> (3+\eta)\phi - \phi = (2+\eta)\phi \end{aligned} \tag{1}$$

By the same reasoning, we have

$$|N[w] \setminus N[v]| + |N[u] \setminus N[w]| > (2+\eta)\phi \tag{2}$$

Now consider the following:

$$\begin{aligned} &|N[v]\Delta N[w]| + |N[u]\Delta N[w]| \\ &= |N[v] \setminus N[w]| + |N[w] \setminus N[v]| + |N[u] \setminus N[w]| + |N[w] \setminus N[u]| \\ &> (2+\eta)\phi + (2+\eta)\phi \qquad \text{by (1) and (2)} \\ &= (4+2\eta)\phi \end{aligned}$$

Therefore, assume to the contrary that $|N[v]\Delta N[w]| \leq_\eta 2\phi$ and so $|N[v]\Delta N[w]| \leq (1+\eta)2\phi$. Then, it must be the case that $|N[u]\Delta N[w]| > (4+2\eta)\phi - |N[v]\Delta N[w]| \geq 2\phi$. By the fact that $w \in \mathcal{C}_v^*$ and Lemma 15, $\text{obj}(\mathcal{C}^*) > \phi$, a contradiction. ◀

3.2.2 The hard case

Now we consider the case where $|N[w] \cap N[u] \cap N[v]| > \phi$. To illustrate the idea of proof, suppose that $|N[w] \cap N[u] \cap N[v]| = \phi + t$ for some $t > 0$. If we follow the same argument as Lemma 18, we would only be able to show that $|N[w]\Delta N[v]| + |N[w]\Delta N[u]| > (4+2\eta)\phi - 2t$ as opposed to $(4+2\eta)\phi$.

However, if this is the case, we can show that $|N[w]\Delta N[u]| \leq 2(\phi - t)$, as stated in Lemma 19. This would make $|N[w]\Delta N[v]| > (1+\eta)2\phi$.

The high-level idea of the proof of Lemma 19 is illustrated in Figure 2. First, we observe that at most ϕ vertices in $|N[u] \cap N[v] \cap N[w]|$ can be contained in $\mathcal{C}_u^*$; otherwise the vertex v would have disagreements greater than ϕ. This implies the contribution of disagreement from $N[u] \cap N[w]$ to u (and to w) is already at least t. If the symmetric difference $|N[u]\Delta N[w]|$ is too large, i.e. larger than $2(\phi - t)$, then it would force the disagreements of either u or w to be too large.

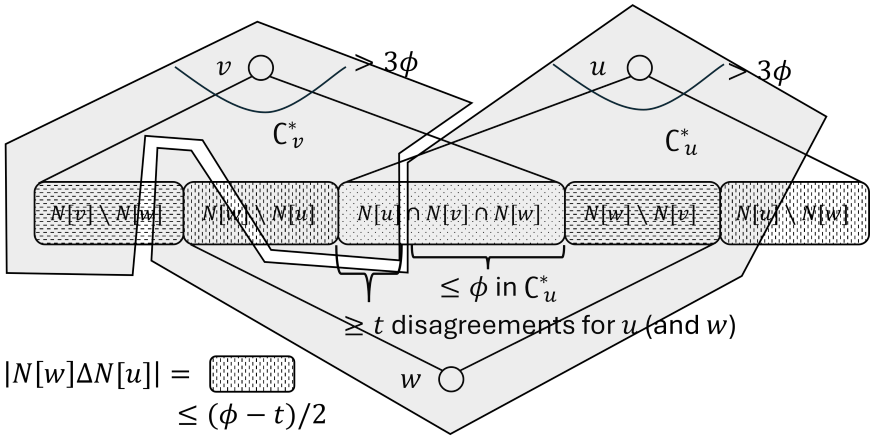

Figure 2 A pictorial illustration of the proof of Lemma 19 when $\eta = 0$. This means that $N[u] \cap N[v] \cap N[w]$ must contribute at least t disagreements to both u and v. Additionally, each element in $|N[u]\Delta N[w]|$ contributes a disagreement to at least one of u or w, so $|N[u]\Delta N[w]|$ cannot exceed $(\phi - t)/2$; otherwise, the disagreement of u or w would exceed ϕ.

▶ **Lemma 19.** *Let $\mathcal{C}^*$ be a clustering with $obj(\mathcal{C}^*) \leq \phi$. Let u and v be vertices of degree greater than $(3+\eta)\phi$ where $\mathcal{C}^*_u \neq \mathcal{C}^*_v$, and $w \in \mathcal{C}^*_u$ be a vertex with $d(w) \leq (3+\eta)\phi$. Suppose that $|N[w] \cap N[v] \cap N[u]| = \phi + t$ for some $t > 0$. Then, $|N[w]\Delta N[u]| \leq 2(\phi - t)$.*

Proof. Let $S = N[w] \cap N[v] \cap N[u]$. First we claim that at most ϕ vertices in S can be in $\mathcal{C}^*_u$. This in turns implies that vertices in S contributes at least t disagreements to vertex u and vertex w. To see why this holds, suppose to the contrary that $|S \cap \mathcal{C}^*_u| > \phi$. Since $S \subseteq N[v]$ and $\mathcal{C}^*_v \neq \mathcal{C}^*_u$, it must be the case that $\rho_{\mathcal{C}^*}(v) \geq |N[v] \setminus C^*_v| \geq |S \setminus C^*_v| \geq |S \cap \mathcal{C}^*_u| > \phi$, a contradiction. Therefore, we conclude that:

$$|S \setminus \mathcal{C}^*_u| \geq t \tag{3}$$

Now note that the disagreements of u and w are at least:

$$\rho_{\mathcal{C}^*}(u) \geq |S \setminus \mathcal{C}^*_u| + |(N[w] \setminus N[u]) \cap \mathcal{C}^*_u| + |(N[u] \setminus N[w]) \setminus \mathcal{C}^*_u|$$
$$\rho_{\mathcal{C}^*}(w) \geq |S \setminus \mathcal{C}^*_u| + |(N[u] \setminus N[w]) \cap \mathcal{C}^*_u| + |(N[w] \setminus N[u]) \setminus \mathcal{C}^*_u|$$

Using the fact $\rho_{\mathcal{C}^*}(u), \rho_{\mathcal{C}^*}(w) \leq \phi$ and summing up the above two inequalities, we have:

$$\begin{aligned}
2\phi &\geq \rho_{\mathcal{C}^*}(u) + \rho_{\mathcal{C}^*}(w) \\
&\geq 2|S \setminus \mathcal{C}^*_u| + |(N[w] \setminus N[u]) \cap \mathcal{C}^*_u| + |(N[u] \setminus N[w]) \setminus \mathcal{C}^*_u| + \\
&\qquad |(N[u] \setminus N[w]) \cap \mathcal{C}^*_u| + |(N[w] \setminus N[u]) \setminus \mathcal{C}^*_u| \\
&= 2|S \setminus \mathcal{C}^*_u| + |(N[w]\Delta N[u]) \cap \mathcal{C}^*_u| + |(N[u]\Delta N[w]) \setminus \mathcal{C}^*_u| \\
&= 2|S \setminus \mathcal{C}^*_u| + |(N[w]\Delta N[u])| \\
&\geq 2t + |(N[w]\Delta N[u])|
\end{aligned}$$

Therefore, $|N[w]\Delta N[v]| \leq 2(\phi - t)$. ◀

▶ **Lemma 20.** *Let $\mathcal{C}^*$ be a clustering with $obj(\mathcal{C}^*) \leq \phi$. Let u and v be vertices of degree greater than $(3+\eta)\phi$ where $\mathcal{C}^*_u \neq \mathcal{C}^*_v$, and w be a vertex with $deg(w) \leq (3+\eta)\phi$. If $w \in \mathcal{C}^*_u$ and $|N[v] \cap N[u] \cap N[w]| > \phi$, then $|N[v]\Delta N[w]| > (1+\eta)2\phi$ and so $|N[v]\Delta N[w]| \not\leq_\eta 2\phi$.*

Proof. By (1) in the proof of Lemma 18, we have:

$$\begin{aligned}|N[w] \setminus N[u]| + |N[v] \setminus N[w]| &\geq |N[v]| - |N[v] \cap N[w] \cap N[u]| \\ &> (3+\eta)\phi - (\phi + t) = (2+\eta)\phi - t \\ |N[w] \setminus N[v]| + |N[u] \setminus N[w]| &\geq |N[u]| - |N[v] \cap N[w] \cap N[u]| \\ &> (3+\eta)\phi - (\phi + t) = (2+\eta)\phi - t\end{aligned}$$

Therefore,

$$\begin{aligned}|N[v] \Delta N[w]| + |N[u] \Delta N[w]| &= |N[v] \setminus N[w]| + |N[w] \setminus N[v]| \\ &\quad + |N[u] \setminus N[w]| + |N[u] \setminus N[w]| \\ &> (4+2\eta)\phi - 2t\end{aligned}$$

By Lemma 19, we have $|N[u] \Delta N[w]| \geq 2(\phi - t)$, therefore:

$$|N[v] \Delta N[w]| > (4+2\eta)\phi - 2t - 2(\phi - t) = (1+\eta)2\phi$$

Hence, $|N[v] \Delta N[w]| \not\leq_\eta 2\phi$. ◀

Lemma 18 and Lemma 20 complete the proof of Theorem 17. Theorem 17 immediately implies the following:

▶ **Corollary 21.** *Let C_i^* be the cluster in $\mathcal{C}^*$ such that $L_i \cap V_{\text{high}} = C_i^* \cap V_{\text{high}}$. For any i, $C_i^* \cap V_i = C_i^* \cap V_{\text{low}}$.*

3.3 Low-Degree Nodes Inclusion

Here, we show that all the vertices in $\mathcal{C}_i^*$ have similar neighborhoods with u_i. As a result, if they are neighbors of u_i, they will be added to C_i.

▶ **Lemma 22.** *Let C_i^* be the cluster in $\mathcal{C}^*$ such that $L_i \cap V_{\text{high}} = C_i^* \cap V_{\text{high}}$. For any i, $C_i^* \cap N(u_i) \subseteq C_i$.*

Proof. If $w \in C_i^* \cap V_{\text{high}}$, then $w \in C_i$ because $C_i = L_i \cup R(u_i)$ and $L_i \cap V_{\text{high}} = C_i^* \cap V_{\text{high}}$ by Lemma 16. Now it remains to consider the case $w \in C_i^* \cap V_{\text{low}} \cap N(u_i)$. It suffices for us to show that $w \in R(u_i)$, where $R(u_i) = \{w \in V_i \cap N(u_i) \mid |N[w] \Delta N[u_i]| \leq_\eta 2\phi\}$, as $R(u_i)$ will be added to C_i.

By Corollary 21, we have $w \in C_i^* \cap V_i \cap N(u_i)$, which means w is not going to be stolen by other clusters. To show that $w \in C_i$, now it suffices to show that $|N[w] \Delta N[u_i]| \leq_\eta 2\phi$ always holds. This is indeed true, because:

$$\begin{aligned}|N[w] \Delta N[u_i]| &\leq |N[w] \Delta C_i^*| + |C_i^* \Delta N[u_i]| && \text{by Lemma 5} \\ &\leq \phi + \phi \leq 2\phi && u_i, w \in C_i^*, \rho_{\mathcal{C}^*}(w), \rho_{\mathcal{C}^*}(u_i) \leq \phi\end{aligned}$$ ◀

3.4 Closeness

In the following, we will show that the cluster we constructed C_i will be similar to C_i^* and $N[u_i]$. Intuitively, this holds because the low-degree part of C_i will be sandwiched between the low-degree part of $C_i^* \cap N[u_i]$ and $N[u_i]$, i.e. $C_i^* \cap N[u_i] \cap V_{\text{low}} \subseteq C_i \cap V_{\text{low}} \subseteq N[u_i] \cap V_{\text{low}}$. Also, we know that $N[u_i]$ and C_i^* are close (i.e. $|N[u_i] \Delta C_i^*| \leq \phi$), so somehow C_i cannot be too far away from C_i^* and $N[u_i]$. Note that the high-degree parts of C_i and C_i^* coincide.

▶ **Lemma 23.** *Let C_i^* be the cluster in $\mathcal{C}^*$ such that $L_i \cap V_{\text{high}} = C_i^* \cap V_{\text{high}}$. For any i, $|N[u_i] \Delta C_i| \leq \phi$ and $|C_i^* \Delta C_i| \leq \phi$.*

Proof. We first show that $|N[u_i] \Delta C_i| \leq \phi$.

$$\begin{aligned}
|V_{\text{low}} \cap (N[u_i] \Delta C_i)| &= |V_{\text{low}} \cap (N[u_i] \setminus C_i)| && (V_{\text{low}} \cap C_i) \subseteq N[u_i] \\
&\leq |V_{\text{low}} \cap (N[u_i] \setminus C_i^*)| && \text{by Lemma 22} \\
&\leq |V_{\text{low}} \cap (N[u_i] \Delta C_i^*)| && (4)
\end{aligned}$$

Moreover, since $C_i^* \cap V_{\text{high}} = C_i \cap V_{\text{high}}$, it must be the case that

$$|(N[u_i] \Delta C_i) \cap V_{\text{high}}| = |(N[u_i] \Delta C_i^*) \cap V_{\text{high}}| \quad (5)$$

Therefore,

$$\begin{aligned}
&|N[u_i] \Delta C_i| \\
&= |(N[u_i] \Delta C_i) \cap V_{\text{low}}| + |(N[u_i] \Delta C_i) \cap V_{\text{high}}| \\
&\leq |(N[u_i] \Delta C_i^*) \cap V_{\text{low}}| + |(N[u_i] \Delta C_i^*) \cap V_{\text{high}}| && \text{by (4) and (5)} \\
&= |N[u_i] \Delta C_i^*| \leq \phi && u_i \in C_i^* \text{ and } \rho_{C^*}(u_i) \leq \phi
\end{aligned}$$

Now we show that $|C_i^* \Delta C_i| \leq \phi$.

$$\begin{aligned}
&|C_i^* \Delta C_i| \\
&= |V_{\text{low}} \cap (C_i^* \Delta C_i)| && C_i^* \cap V_{\text{high}} = C_i \cap V_{\text{high}} \\
&= |V_{\text{low}} \cap (C_i^* \setminus C_i)| + |V_{\text{low}} \cap (C_i \setminus C_i^*)| \\
&= |V_{\text{low}} \cap (C_i^* \cap N[u_i] \setminus C_i)| + |V_{\text{low}} \cap (C_i^* \setminus N[u_i] \setminus C_i)| \\
&\qquad + |V_{\text{low}} \cap (C_i \setminus C_i^*)| \\
&= |V_{\text{low}} \cap (C_i^* \cap N[u_i] \setminus C_i)| + |V_{\text{low}} \cap (C_i^* \setminus N[u_i])| \\
&\qquad + |V_{\text{low}} \cap (C_i \setminus C_i^*)| && V_{\text{low}} \cap C_i \subseteq V_{\text{low}} \cap N[u_i] \\
&= |V_{\text{low}} \cap (C_i^* \setminus N[u_i])| + |V_{\text{low}} \cap (C_i \setminus C_i^*)| && C_i^* \cap N[u_i] \subseteq C_i \\
&\leq |V_{\text{low}} \cap (C_i^* \setminus N[u_i])| + |V_{\text{low}} \cap (N[u_i] \setminus C_i^*)| && V_{\text{low}} \cap C_i \subseteq V_{\text{low}} \cap N[u_i] \\
&= |V_{\text{low}} \cap (C_i^* \Delta N[u_i])| \leq |C_i^* \Delta N[u_i]| \leq \phi
\end{aligned}$$

◀

4 Efficient Algorithms for the Sequential and MPC Models

To make the algorithm efficient in the sequential and MPC settings, we need to address several challenges. First, we need to compute the graph E' for high-degree nodes. Second, we need to be able to conduct approximate neighborhood similarity queries efficiently. We will address these issues one by one.

4.1 Computing the Clustering for High-Degree Nodes

In this section, we show that although E' may be significantly larger than E^+, it is sufficient to make only $O(|E^+|) = O(m)$ neighborhood similarity queries to identify the high-degree clusters. Algorithm 2 describes how to form a clustering $\mathcal{F}$ for high-degree vertices by conducting $O(m)$ similarity queries.

Algorithm 2 HighDegreeClustering$(G^+ = (V, E^+), \phi, \eta)$.
Input: A graph G^+, a parameter ϕ, a parameter $0 \le \eta < 1$.
Output: A clustering $\mathcal{F} = \{L_i\}_{i=1}^{|\mathcal{L}|}$ of V_{high} such that $\mathcal{F} = \mathcal{L}$.

1: **function** HighDegreeClustering$(G^+ = (V, E^+), \phi, \eta)$
2: Let $G_{\text{sim}} = (V, E_{\text{sim}})$, where $E_{\text{sim}} = \{uv \in E^+ \mid |N[u] \Delta N[v]| \le_\eta 2\phi\}$.
3: Assign each vertex V with an unique ID, $\text{ID}(v)$.
4: Every vertex $v \in V$ sets $\min(v) \leftarrow \min_{x \in N_{G_{\text{sim}}}[v] \cap V_{\text{high}}} \text{ID}(x)$
5: Every vertex $v \in V$ sends a token of value $\min(v)$ to the neighbor of v in G_{sim}.
6: If a vertex $v \in V_{\text{high}}$ receives at least $\phi + 1$ tokens of the same value, set $cluster(v)$ to be the minimum such value.
7: Let $\mathcal{F}$ be a clustering where each cluster is formed by vertices with the same $cluster$ values.
8: **end function**

Algorithm Description. In Algorithm 2, we first perform $O(m)$ neighborhood queries to construct $G_{\text{sim}} = (V, E_{\text{sim}})$, where $E_{\text{sim}} \subseteq E^+$ consists of those endpoints who have similar neighborhoods. Then we assign every vertex u with a unique identifier, $\text{ID}(u)$. By sending the ID of every high-degree vertex to its neighbors in G_{sim}, every vertex u can learn ID of the high-degree vertex with the smallest ID in its closed neighborhood in G_{sim} (Line 4) and then set $\min(u)$ to be such an ID. Now, every vertex u (including low-degree vertices) sends a token with value $\min(u)$ to all the neighbors of u in G_{sim}. Then, if a vertex u recieved at least $\phi + 1$ tokens of the same value, it will set its cluster ID, $cluster(u)$, to be the minimum value that occurs at least $\phi + 1$ times. Finally, we assign all high-degree vertices with the same cluster ID to be in the same cluster.

In Lemma 24, we show that if OPT $\le \phi$, then the output $\mathcal{F}$ is exactly $\mathcal{L}$. The proof is based on showing that if two high-degree vertices u, v are in the same cluster in $\mathcal{C}^*$, then there will be at least $\phi + 1$ disjoint paths of length two in G_{sim}.

▶ **Lemma 24.** *efficienthighdeg Suppose that* OPT $\le \phi$. *Algorithm 2 outputs a clustering* $\mathcal{F}$ *such that* $\mathcal{F} = \mathcal{L}$.

Proof. Let $\mathcal{C}^*$ be a clustering with $\text{obj}(\mathcal{C}^*) \le \phi$. Let u be a vertex in V_{high}. Let u_* be the vertex with the minimum ID in $\mathcal{L}_u$. We will show that

1. Every vertex $x \in \mathcal{L}_u \cap V_{\text{high}}$ will receive at least $\phi + 1$ tokens of values $\text{ID}(u_*)$ in Line 6.
2. In addition, if x received at least $\phi + 1$ tokens of value T, then $T \ge \text{ID}(u_*)$.

Once these two points are established, every vertex $x \in \mathcal{L}_u \cap V_{\text{high}}$ will be assigned $\texttt{cluster}(x) = \text{ID}(u_*)$. Consequently, this ensures that $\mathcal{F}_u = \mathcal{L}_u$. Now we start with the first point, since $x, u_* \in \mathcal{C}^*_u$, $|N[u_*] \Delta N[x]| \le 2\phi$; for otherwise $\text{obj}(\mathcal{C}^*) > \phi$ by Lemma 15. This implies:

$$\begin{aligned} |N[u_*] \cap N[x]| &= (|N[x]| + |N[u_*]| - |N[u_*] \Delta N[x]|)/2 \\ &\ge (3\phi + 2 + 3\phi + 2 - 2\phi)/2 = 2\phi + 2 \end{aligned}$$

Also, since $u_* \in \mathcal{C}^*_u$ and by definition of $\rho_{\mathcal{C}^*}(u_*)$, we have:

$$\phi \ge \rho_{\mathcal{C}^*}(u_*) \ge |N[u_*]| - |(\mathcal{C}^*_u \cap N[u_*])| \tag{6}$$

Therefore,

$$\begin{aligned}|(\mathcal{C}_u^* \cap N[u_*]) \cap N[x]| &= |N[x] \cap N[u_*]| - |N[x] \cap (N[u_*] \setminus (\mathcal{C}_u^* \cap N[u_*]))| \\ &\geq |N[x] \cap N[u_*]| - |N[u_*] \setminus (\mathcal{C}_u^* \cap N[u_*])| \\ &\geq (2\phi + 2) - \phi \qquad \text{by (6)} \\ &\geq \phi + 2\end{aligned}$$

Hence:

$$|(\mathcal{C}_u^* \cap N[u_*]) \cap N(x)| \geq |(\mathcal{C}_u^* \cap N[u_*]) \cap N[x]| - 1 \geq \phi + 1$$

Note that all vertices in $(\mathcal{C}_u^* \cap N[u_*])$ must have their $\min(\cdot)$ values equal to $\mathrm{ID}(u_*)$. This is because if $v \in (\mathcal{C}_u^* \cap N[u_*])$ and $v \in V_{\text{high}}$, then $(N_{G_{\text{sim}}}(v) \cap V_{\text{high}}) \subseteq \mathcal{C}_u^*$. If $v \in (\mathcal{C}_u^* \cap N[u_*])$ and $v \notin V_{\text{high}}$, then it must be the case that $v \in N_{G_{\text{sim}}}(u_*)$. Moreover, $N_{G_{\text{sim}}}[v] \cap V_{\text{high}}$ cannot contain any cluster nodes outside $\mathcal{C}_u^*$ by Theorem 17. Thus, $\min(v) = \mathrm{ID}(u_*)$. This implies x will receive at least $\phi + 1$ tokens with value $\mathrm{ID}(u_*)$.

Next we show that if there is a value T such that x receives from at least $\phi + 1$ tokens, then $T \geq \mathrm{ID}(u_*)$. Suppose to the contrary that $T < \mathrm{ID}(u_*)$. First note that if $v \in N(x)$ has $\min(v) = T$, then it cannot be the case that $v \in V_{\text{high}}$. Otherwise, u_*, v, and a vertex whose ID is T, would all be in $\mathcal{C}_u^*$, which contradict with the fact $\mathrm{ID}(u_*)$ is the smallest ID in $\mathcal{L}_u = \mathcal{C}_u^* \cap V_{\text{high}}$. Therefore, it must be the case that vertices $v \in N(x)$ with $\min(v) = T$ are all in V_{low}.

Now note that if $v \in \mathcal{C}_u^*$ then by Theorem 17, v can only be connected to vertices in $\mathcal{C}_u^*$ in G_{sim}. In this case, $\min(v) \geq \mathrm{ID}(u_*)$ so $\min(v) \neq T$ by the assumption of $\mathrm{ID}(u_*)$. So the only possibility for v to have $\min(v) = T$ is when $v \notin \mathcal{C}_u^*$. However, as $\rho_{\mathcal{C}^*}(x) \leq \phi$, there are at most ϕ neighbors of x not in $\mathcal{C}_x^*$. This implies x will receive less than $\phi + 1$ tokens whose value equals to T. ◀

4.2 Approximate Neighborhood Similarity Testing by Random Projection

We show that for $0 < \eta < 1$, w.h.p. the queries $\Delta_\eta(x, y, 2\phi)$ for all $xy \in E^+$ can be answered in $O(m \log n/\eta^2)$ time and thus G_{sim} can be constructed in $O(m \log n/\eta^2)$ time.

▶ **Definition 25.** *Given a vertex x, let $\vec{N}[x] \subseteq \{0,1\}^n$ denote the characteristic vector of $N[x]$.*

▶ **Lemma 26.** *Given $\epsilon > 0$, let $k = C \cdot (\log n/\epsilon^2)$ for some large enough constant $C > 0$. Let A be a $k \times n$ matrix where each entry is drawn from $\{-1, +1\}$ uniformly at random. W.h.p. for every two vertices x and y, we have:*

$$(1-\epsilon) \cdot |N[x] \Delta N[y]| \leq ||A \cdot \vec{N}[x] - A \cdot \vec{N}[y]||_2^2/k \leq (1+\epsilon) \cdot |N[x] \Delta N[y]|$$

Proof. By the Johnson-Lindenstrauss lemma [1, 38], w.h.p. for every x and y, we have:

$$(1-\epsilon) \cdot ||\vec{N}[x] - \vec{N}[y]||_2^2 \leq ||A \cdot \vec{N}[x] - A \cdot \vec{N}[y]||_2^2/k \leq (1+\epsilon) \cdot ||\vec{N}[x] - \vec{N}[y]||_2^2$$

The lemma follows by observing that $|N[x] \Delta N[y]| = ||\vec{N}[x] - \vec{N}[y]||_2^2$. ◀

▶ **Lemma 27.** *Let $\epsilon = \Theta(\eta)$ be such that $(1+\eta) = (1+\epsilon)/(1-\epsilon)$, $k = O(\log n/\epsilon^2)$, and set:*

$$\Delta_\eta(x, y, t) = \begin{cases} 0 & \text{if } ||A \cdot \vec{N}[x] - A \cdot \vec{N}[y]||_2^2/((1+\epsilon)k) > t \\ 1 & \text{otherwise} \end{cases}$$

W.h.p. the above implementation returns a correct answer for $\Delta_\eta(x, y, t)$.

Proof. It suffices to show that if $|N[x]\Delta N[y]| \leq t$ then w.h.p. we will set $\Delta_\eta(x, y, t)$ to be 0 and if $|N[x]\Delta N[y]| > (1+\eta)t$, then w.h.p. we will set $\Delta_\eta(x, y, t)$ to be 1.

If $|N[x]\Delta N[y]| \leq t$, then w.h.p.

$$||A \cdot \vec{N}[x] - A \cdot \vec{N}[y]||_2^2/((1+\epsilon)k) \leq |N[x]\Delta N[y]| \leq t$$

Thus, $\Delta_\eta(x, y, t)$ returns 1.

On the other hand, if $|N[x]\Delta N[y]| > (1+\eta)t$ then w.h.p.

$$||A \cdot \vec{N}[x] - A \cdot \vec{N}[y]||_2^2/((1+\epsilon)k) \geq \frac{1-\epsilon}{1+\epsilon} \cdot (|N[x]\Delta N[y]|) > \frac{1-\epsilon}{1+\epsilon}(1+\eta) \cdot t = t$$

Thus, $\Delta_\eta(x, y, t)$ returns 0. ◀

We have presented the key ingredients that lead to efficient sequential and MPC algorithms. The details of their implementations are presented in the full version [17]. For the semi-streaming algorithm, different challenges arise. The necessary modifications and details are also included in the full version.

(Multivariate) k-SUM as Barrier to Succinct Computation

Abstract

How does the time complexity of a problem change when the input is given *succinctly* rather than explicitly? We study this question for several geometric problems defined on a set X of N points in $\mathbb{Z}^d$. As succinct representation, we choose a sumset (or Minkowski sum) representation: Instead of receiving X explicitly, we are given sets A, B of n points that define X as $A + B = \{a + b \mid a \in A, b \in B\}$.

We investigate the fine-grained complexity of this succinct version for several $\tilde{O}(N)$-time computable geometric primitives. Remarkably, we can tie their complexity tightly to the complexity of corresponding k-SUM problems. Specifically, we introduce as All-ints 3-SUM(n, n, k) the following multivariate, multi-output variant of 3-SUM: given sets A, B of size n and set C of size k, determine for all $c \in C$ whether there are $a \in A$ and $b \in B$ with $a + b = c$. We obtain the following results:

1. Succinct closest L_∞-pair requires time $N^{1-o(1)}$ under the 3-SUM hypothesis, while succinct furthest L_∞-pair can be solved in time $\tilde{O}(n)$.
2. Succinct bichromatic closest L_∞-Pair requires time $N^{1-o(1)}$ iff the 4-SUM hypothesis holds.
3. The following problems are fine-grained equivalent to All-ints 3-SUM(n, n, k): succinct skyline computation in 2D with output size k and succinct batched orthogonal range search with k given ranges. This establishes conditionally tight $\tilde{O}(\min\{nk, N\})$-time algorithms for these problems. We obtain further connections with All-ints 3-SUM(n, n, k) for succinctly computing independent sets in unit interval graphs.

Thus, (Multivariate) k-SUM problems precisely capture the barrier for enabling sumset-succinct computation for various geometric primitives.

1 Introduction

Consider an algorithmic problem on an input set X of N points in $\mathbb{Z}^d$. How does the time complexity of the problem change when the input is given *succinctly* rather than explicitly? In this paper, we investigate this question when the succinct representation of X is chosen as a *sumset* (or *Minkowski sum*) representation $X = A + B \coloneqq \{a + b \mid a \in A, b \in B\}$.

Our motivation is threefold:

1. **Complexity on structured input:** How does the time complexity of the problem change when we are supplied with structural information about the input? As a case in point, this question has received considerable interest for the fundamental task of sorting. Indeed, the well-known Sorting $A + B$ problem studied by Fredman [20], and originally posed by Berlekamp[1], asks to determine whether we can compute, given A, B with $|A| = |B| = n$, the sorted order of $A + B$ in time $o(n^2 \log n)$. Since the succinct representation gives a large partial order essentially for free – simply presort A, B in time $O(n \log n)$ –, this question essentially boils to whether or not a partial solution structure helps significantly in determining the full output. The Sorting $A + B$ problem has several connections to problems in computational geometry such as polygon containment, computing the Minkowski sum of orthogonal polygons and minimizing the Hausdorff distance under translation for two segment sets, as described by the works of Barequet and Har-Peled [6], and Barrera [7].
   Another example that has received considerable attention is the *Pareto Sum* problem (see, e.g., [27, 24]), which asks to compute the skyline of $X = A + B$ (see Section 4 for a formal definition). It is only natural to ask analogous questions for other numerical/geometric problems. In particular, a succinct sumset representation reveals additive structure of the problem, which may or may not simplify the algorithmic task considerably.
2. **Algorithmic applications (sumset-compressed computational geometry):** Let $T(N)$ denote the optimal running time for solving a problem of interest on an input set of N points in $\mathbb{Z}^d$. For favorable inputs, it may be possible to find *much smaller* sets A, B with $X = A + B$ – in principle compressions to size $O(\sqrt{N})$ are possible. If we were able to solve the problem of interest in time $O(T(|A| + |B|))$ rather than $T(|X|)$ (aka *decompress-and-solve* running time), we could obtain significantly faster algorithms that reduce the running time from $T(N)$ to $O(T(\sqrt{N}))$. In fact, even small asymptotic improvements over $T(N)$ might be algorithmically interesting.
3. ***k*-SUM as precise barrier for succinct computations:** Our setup offers another perspective on the k-SUM problem. Specifically, for various problems, we shall prove that refuting a corresponding k-SUM hypothesis is *equivalent* to solving the sumset-succinct version of the problem faster than via decompress-and-solve. That is, despite its simple definition (asking a very basic question about sumsets), the k-SUM problem captures much more general primitives on succinct inputs. We believe that this yields valuable insights into the true expressiveness of k-SUM and the plausibility of the corresponding hardness hypothesis.

1.1 Our setup

For any algorithmic problem g defined on an input set $X \subseteq \mathbb{Z}^d$, we consider the following sumset-succinct version as *succinct-g*:

[1] In the literature, the name Sorting $X + Y$ is more common. However, throughout our paper X will denote the explicit input and $A + B$ its succinct representation.

Problem g		**Problem** succinct-g	
Input:	$X \subseteq \mathbb{Z}^d$ possibly additional inputs z	**Input:**	$A, B \subseteq \mathbb{Z}^d$ possibly additional inputs z
Output:	$g(X, z)$	**Output:**	$g(X, z)$ where $X = A + B$

As a convention, we set $N := |X|$, $n := |A|$ and $m := |B|$. For ease of presentation, we will generally assume that $n = m$, but our results can be adapted to the general case. Throughout the paper, we will assume that all input numbers are chosen from a polynomial range, i.e., $X \subseteq \{N^c, \ldots, N^c\}^d$ for some arbitrarily large constant c.

Let us consider a few (near-)linear time solvable problems g. We observe that their succinct versions may have very different time complexities:

A succintly easy problem: Selection

Consider the problem Selection: Given $X \subseteq \mathbb{Z}$ and $1 \leq k \leq N$, return the k-th largest element in X. Selection is well known to be solvable in time $O(N)$; see [8, 15]. Its succinct version succinct-Selection has received considerable attention as well [30, 29, 28, 19] and can be solved significantly faster than decompress-and-solve, specifically, in time $\tilde{O}(n)$.[2]

A succinctly hard problem: Skyline computation

Consider the problem of skyline computation (aka non-dominance filtering or Pareto front computation), see, e.g. [32, 14, 22]: Given $X \subseteq \mathbb{Z}^d$, compute the set Z of non-dominated points, i.e., all $x \in X$ for which there is no $x' \in X$ with $x' \neq x$ and $x \leq x'$ component-wise. This problem can be solved in near-linear time $\tilde{O}(N)$, see, e.g., [32]. Its succinct version is known as Pareto Sum and naturally occurs in several multi-objective optimization algorithms, see Hespe et al. [27]. Notably, a conditional lower bound of $N^{1-o(1)}$ that holds when the output size is $\Theta(\sqrt{N})$ has been proven under the $(\min, +)$-convolution hypothesis [21] and the 3-SUM hypothesis [24]. We shall investigate this problem in much more detail below.

On reductions to k-SUM

The 3-SUM problem[3] is one of the first problems used for conditional lower bounds. Initially introduced to explain various quadratic-time barriers observed in computational geometry [23], it has since been used to show quadratic-time hardness for a wealth of problems from various fields [41, 35, 5, 34, 13]. Its generalization, the k-SUM problem[4], has led to further conditional lower bounds beyond quadratic-time solvable problems [18, 4, 1, 2]. For a more comprehensive overview, we refer to the survey of Williams [43].

An important aspect of our investigations is that we establish *fine-grained equivalences* with k-SUM problems, which requires the somewhat unusual direction of reducing certain problems *to* k-SUM. Conveniently, we may exploit for this task a recent completeness theorem [24]: This work introduces general classes of problems which can be reduced to k-SUM, thereby simplifying the arguments needed to reduce sumset-related

[2] The authors consider a slight variant in which $A + B$ is viewed as a multiset (or $|A + B| = |A| \cdot |B|$).
[3] Given sets A, B, C do there exist $a \in A, b \in B, c \in C$ s.t $a + b + c = 0$.
[4] The k-SUM problem asks, given sets $A_1, \ldots, A_k$ of n numbers, whether there exist $a_1 \in A_1, \ldots, a_k \in A_k$ such that $\sum_{i=1}^{k} a_i = 0$. The k-SUM hypothesis states that for no $\epsilon > 0$ there exists a $O(n^{\lceil k/2 \rceil - \epsilon})$ time algorithm that solves k-SUM.

problems to k-SUM. Specifically, we shall need the existential fragment of the class $\mathsf{FOP}_{\mathbb{Z}}$: It consists of problems whose inputs are sets $A_1 \subseteq \mathbb{Z}^{d_1}, \ldots, A_k \subseteq \mathbb{Z}^{d_k}$, and free variables $t_1 \ldots t_\ell \in \mathbb{Z}$, and the task is to determine whether there exist $a_1 \in A_1 \ldots a_k \in A_k$ such that $\varphi(a_1[1], \ldots, a_1[d_1], \ldots, a_k[1], \ldots, a_k[d_k], t_1 \ldots, t_\ell)$ holds, where φ is a fixed, but arbitrary linear arithmetic formula over the vector entries of $a_1 \ldots a_k$ and the free variables. (In particular, the dimensions $d_1, \ldots, d_k$ are constant.) Each such problem is near-linear time reducible to k-SUM. We will frequently argue in our reductions that subtasks can be expressed as an existential $\mathsf{FOP}_{\mathbb{Z}}$ formula and exploit the completeness theorem.

Further related work

The authors in [9] explored connections of the $X + Y$ sorting problem with the $(\min, +)$-convolution problem. Other works consider the fine-grained complexity of other notions of succinct inputs, such as representing sequences succinctly as grammar-based compressions [2, 1], or succinctly defined graphs using the notion of factored graphs [25].

1.2 Our results

We investigate the succinct versions of many well-studied geometric primitives solvable in near-linear time. While some turn out to be easy, many others can be tightly connected to the k-SUM problem. In fact, we believe our results may serve as template to classify further problems according to their succinct complexity.

Some succinctly easy problems

For context, we observe that there is a large number of non-trivial geometric primitives (beyond selection) for which fast succinct computation is indeed possible.

As perhaps most prominent and well-known example, consider the convex hull problem: Given $A, B \subseteq \mathbb{Z}^2$, compute the convex hull $\mathsf{conv}(X)$ of $X = A + B$. By a folklore identity, $\mathsf{conv}(A + B) = \mathsf{conv}(A) + \mathsf{conv}(B)$, with complexity $|\mathsf{conv}(A)| + |\mathsf{conv}(B)|$. This yields $\tilde{O}(n)$-time algorithms for succinctly computing convex hulls, see also [17]. This fact leads us to the following general observation.

▶ **Observation 1.** *If we can compute $g(X)$ by a $T(m)$-time algorithm that receives as input only the convex hull of X of size m, then succinct-$g(X)$ can be solved in time $\tilde{O}(T(n))$.*

While the observation is simple, it leads to an interesting class of problems which can be solved in near-linear time in the size of the sumset compression. Some examples of problems which can be efficiently solved using only the convex hull of the input are the diameter of points, the maximum bounding box, the distance between two convex hulls and many more, described by Shamos in [36]. All these problems can be solved with a known technique originally introduced by Shamos [37, 36], which has subsequently been coined *rotating calipers* and further explored by Toussaint [39].

On Closest vs. Furthest Pair

Consider the problem Closest L_∞-Pair: Given $X \subseteq \mathbb{Z}^d$, determine $\min_{x_1, x_2 \in X, x_1 \neq x_2} \|x_1 - x_2\|_\infty$. Its natural maximization analogue is Furthest L_∞-Pair: Given $X \subseteq \mathbb{Z}^d$, determine $\max_{x_1, x_2 \in X} \|x_1 - x_2\|_\infty$. Both problems are solvable in near-linear time $\tilde{O}(N)$ whenever d is constant [22, 10].

However, we observe that the succinct versions differ substantially in their time complexity: Succinct-Furthest L_∞-Pair can be solved in time $\tilde{O}(n)$, while for succinct-Closest L_∞-Pair we obtain a 3-SUM-based lower bound of $N^{1-o(1)}$ already in 1D, using the fact that the EqDist problem is 3-SUM-hard [6]; see the full version of the paper.

Naturally, we may also consider the bichromatic case of the Closest L_∞-Pair problem: Given $X, Y \subseteq \mathbb{Z}^d$, determine $\min_{x\in X, y\in Y} \|x-y\|_\infty$. Here, the natural succinct version receives sets $A, B, C, D \subseteq \mathbb{Z}^d$ as inputs, and the task is to solve the problem for $X = A + B$ and $Y = C + D$. We prove that this succinct-Bichromatic L_∞-Pair problem is *fine-grained equivalent* to 4-SUM. The reduction to 4-SUM follows from observing that the decision problem can be formulated as an existential $\mathsf{FOP}_\mathbb{Z}$ formula, which can be reduced to 4-SUM [24]. It remains an interesting question whether the *monochromatic* succinct Closest-L_∞-Pair is fine-grained equivalent to 3-SUM (our results place it between 3-SUM and 4-SUM). For further fine-grained complexity results on Closest and Furthest Pair in higher dimensions; see e.g., [42] and [31].

Multivariate 3-SUM

The remaining problems that we study will exhibit a tight connection to a multivariate version of the 3-SUM problem. Specifically, we introduce the following problem:

▶ **Definition 2** (All-ints 3-SUM(n, n, k))**.** *Given sets $A, B \subseteq \mathbb{Z}$ of size n, and a set $C \subseteq \mathbb{Z}$ of size k. Determine for each c in C if there exists $(a, b) \in A \times B$ with $a + b = c$.*

It is easy to see that this problem can be solved in time $\tilde{O}(\min\{kn, n^2 + k\})$: The $O(kn)$ bound follows by solving, for each $c \in C$, the corresponding 2-SUM problem of detecting $a \in A, b \in B$ with $a + b = c$, which is well-known to be solvable in time $O(n)$. The $\tilde{O}(n^2 + k)$ upper bound follows from computing $A+B$ explicitly, and solving the corresponding dictionary problem for each $c \in C$. This time bound turns out to be conditionally tight; see Section 3: For any $k = \Theta(n^\alpha)$ with $0 < \alpha \leq 1$, we show using standard techniques that this problem cannot be solved in time $O((nk)^{1-\epsilon})$ with $\epsilon > 0$ unless the 3-SUM hypothesis is false. Note that this establishes a conditionally tight answer for all k: If $k = \Theta(n^\alpha)$ with $\alpha > 1$, then we obtain a $n^{2-o(1)}$ conditional lower bound via padding, and a $\Omega(k)$ lower bound follows from the input size of the problem.

Perhaps surprisingly, this problem naturally captures the precise fine-grained complexity of various succinct geometric primitives. Note that when $k = n$, All-ints 3-SUM(n, n, k) is well known to be subquadratic equivalent to 3-SUM [40], but a fine-grained equivalence for $k = \Theta(n^\alpha)$ with $\alpha < 1$ does not appear to follow from standard techniques. We will thus make use of a slight generalization of the completeness theorem for existential $\mathsf{FOP}_\mathbb{Z}$ formulas, which is implicit in [24]. Consider the following problems: Given $A \subseteq \mathbb{Z}^{d_1}, B \subseteq \mathbb{Z}^{d_2}, C \subseteq \mathbb{Z}^{d_3}$ of sizes n, n and k, respectively, compute for each $c \in C$, whether there exist $a \in A, b \in B$ such that a linear arithmetic formula $\varphi(a[1], \ldots, a[d_1], b[1], \ldots, b[d_2], c[1], \ldots, c[d_3])$ over the entries in the vectors a, b, c holds. For every linear arithmetic formula φ, we can reduce this problem to $\tilde{O}(1)$ instances of All-ints 3-SUM(n, n, k). A standalone proof of this fact can be found in the full version of the paper.

Succint orthogonal range queries

Consider a *batched* (or *offline*) version of answering orthogonal range queries over X, which we call Batched Orthogonal Range Searching: Given $X \subseteq \mathbb{Z}^d$ and orthogonal ranges $r_1, \ldots, r_k$, determine for each $j = 1, \ldots, k$ whether $X \cap r_j$ is empty. This problem can be solved in

time $\tilde{O}(N+k)$ for constant d, see, e.g. [12]. We observe that succinct-Batched Orthogonal Range Searching is fine-grained equivalent to All-ints 3-SUM(n,n,k). To reduce from All-ints 3-SUM(n,n,k), use A,B as succinct input sets for a 1-dimensional instance of succinct-Batched Orthogonal Range Searching and for $C=\{c_1,\ldots,c_k\}$ choose $r_i=[c_i,c_i]$. The other direction follows from observing that we may represent the succinct Orthogonal Range Searching problem as a suitable All-ints-$\mathsf{FOP}_{\mathbb{Z}}$ formula. The details can be found in the full version of the paper.

Succinct skyline (Pareto Sum)

Recall the prominent geometric problem of skyline computation (aka non-dominance filtering or maxima of point sets computation), see, e.g. [32, 14, 22]: Given $X\subseteq\mathbb{Z}^d$, compute the set Z of non-dominated points, i.e., all $x\in X$ for which there is no $x'\in X$ with $x'\neq x$ and $x\leq x'$ component-wise. This (explicit) problem can be solved in time $O(N\log k)$ [32], where $k=|Z|$ denotes the output size. For $d=2$, Hespe et al. show how to compute its succinct variant, the Pareto Sum, in time $O(n\log n+kn)$. We prove that computing all k non-dominated points of $X=A+B$ is fine-grained equivalent to All-ints 3-SUM(n,n,k).

Starting point of our reduction from All-ints 3-SUM(n,n,k) to the Pareto Sum is the subquadratic reduction from 3-SUM to Pareto Sum given in [24], which uses Conv3-SUM as an intermediate step. Notably, however, our multivariate setting poses a perhaps unexpected challenge: The standard reductions from 3-SUM to Conv3-SUM [35, 11] do not readily transfer to a multivariate setting. Instead, we introduce a variant of Conv3-SUM that we call All-ints-MixedConv3-SUM(n,n,k)[5]:

▶ **Definition 3** (All-ints-MixedConv3-SUM). *Given sequences $A[0],\ldots,A[k-1]$ and $B[0],\ldots,B[k-1]$, where each set $A[i],B[j]$ is a* set *of $O(n/k)$ integers, and a sequence of integers $C[0],\ldots,C[k-1]$, determine for each $0\leq i<k$ whether there exists some j and elements $a\in A[j],b\in B[i-j]$ such that $a+b=C[i]$.*

This problem can easily be solved in time $O(kn)$. We carefully adapt the reduction from 3-SUM to convolution 3-SUM given in [11] to reduce All-ints 3-SUM(n,n,k) to All-ints-MixedConv3-SUM(n,n,k). As a further technical challenge, our approach requires an equivalence between the problem of computing the complete Pareto Sum and computing the Pareto Sum inside a given query range. Specifically, in our lower bound, we need to allow as query ranges quadrants of the form $[x,\infty)\times[y,\infty)$; with this choice, even for sets A,B with a Pareto Sum as large as $\Omega(n^2)$ one may still give a query range with arbitrary small outputsize k, e.g., $k=O(1)$. Interestingly, using an involved construction detailed in Section 4.1, we show that this problem reduces to its specical case of computing the complete Pareto set under the promise that its size is $k+O(1)$. As a by-product, this also shows that for any $n\in\mathbb{N}$, there exist sets A,B of size n of incomparable vectors in $\mathbb{Z}^2$ with a Pareto Sum of constant size, which does not appear to have been proven before. After showing this equivalence, we reduce All-ints-MixedConv3-SUM to Pareto Sum, reminiscent of the reduction from Convolution 3-SUM to Pareto Sum in [24].

The reverse reduction from Pareto Sum to All-ints 3-SUM(n,n,k) is also technically interesting: while Hespe et al. [27] show how to compute each of the k output points successively in $\tilde{O}(n)$ time per point, unfortunately, we cannot follow this approach in our reduction (calling an All-ints 3-SUM(n,n,k)-oracle $\Omega(k)$ times would trivially exceed $\tilde{O}(kn)$

[5] The definition appears related in spirit (but different) to Factored 3-SUM defined in [16].

running time). Instead, we aim to identify the k output points essentially simultaneously. To this end, we perform a divide-and-conquer approach. We maintain a set of already identified Pareto Sum points S, as well as a list of up to k *active* x-intervals – an interval is deemed active if it contains at least one (unidentified) point of the Pareto Sum. At each level of the recursion, we split all active intervals into two halves. The key observation is the following: Given S and an arbitrary list of intervals $I_1, \ldots, I_s$, we can compute for each I_j whether it contains a point in the Pareto Sum (but not already in S) using only $\tilde{O}(1)$ All-ints $\mathsf{FOP}_{\mathbb{Z}}$ (n, n, s) queries, which in turn can be reduced to $\tilde{O}(1)$ All-ints 3-SUM(n, n, k) instances. After $O(\log n)$ levels of the recursion, each interval consists of at most a single integer, and can be resolved fully. The details can be found in Section 4.

Succinct independent set in unit interval graphs

Consider the maximum independent set problem (MIS) in unit interval graphs: Given a set of (open) unit intervals $\mathcal{I}$ in $\mathbb{Z}$, compute a maximum independent set S^*, i.e., a pairwise non-intersecting subset of intervals maximizing its size. A simple greedy algorithm is well known to solve the problem in time $O(n \log n)$, see, e.g. [26]. Taking the output size $k = |S^*|$ into account, this can be slightly improved to time $O(n \log k)$, see [38].

For studying its connection with All-ints 3-SUM(n, n, k), the technical work spent for the equivalence to Pareto Sum pays off: On the lower bound side, we establish a fine-grained reduction from All-ints 3-SUM(n, n, k) to succinct-MIS in unit interval graphs using a similar approach as for the Pareto Sum. In particular, we may reduce immediately from All-ints MixedConv3-SUM(n, n, k), and transfer conceptually similar arguments to the MIS setting.

On the upper bound side, we are not quite able to establish the reverse reduction. However, we show how to reduce computing a *maximal* independent set to All-ints 3-SUM(n, n, k), again exploiting careful parallel binary searches in a divide-and-conquer approach. It remains an interesting open problem to reduce the MIS problem in unit interval graphs to All-ints 3-SUM(n, n, k). The details can be found in the full version of the paper.

Summary

For the problems equivalent to All-ints 3-SUM(n, n, k), our results show that improving over decompress-and-solve running time $N^{1\pm o(1)}$ is possible whenever the output size k is small enough, specifically $k = O(N^{1/2-\epsilon}) = O(n^{1-\epsilon})$ for some $\epsilon > 0$. We refer to Figure 1 for an overview of the reductions shown. In the full version of the paper, we provide a table which summarizes runtimes for various problems, when defined succinctly and explicitly.

2 Preliminaries

We make use of basic tools in fine-grained complexity, for a comprehensive overview; see the survey [43]. For our purposes, the basic notion of *fine-grained reduction* is as follows. Consider problems P_1, P_2, with presumed time complexities T_1,T_2, we say there is a fine-grained reduction from P_1 to P_2 if for all $\epsilon > 0$ there exists $\delta > 0$ and an algorithm A solving P_1 with oracle access to P_2 such that if all calls to P_2 are replaced by an $O(T_2(n)^{1-\epsilon})$-time algorithm, then A runs in time $O(T_1(n)^{1-\delta})$. We say problems P_1, P_2 are fine-grained equivalent if there exist fine-grained reductions from P_1 to P_2 and P_2 to P_1. Throughout the paper, M will always denote a large number which we set as follows: With $A, B, C \subseteq \mathbb{Z}^d$, we let $M := 10 \cdot \max\{\|a\|_1 + \|b\|_1 + \|c\|_1 : a \in A, b \in B, c \in C\}$.

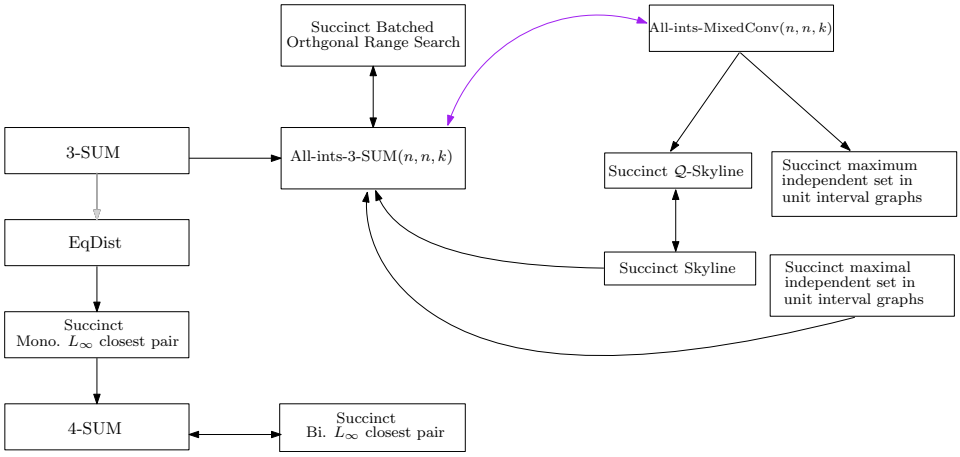

Figure 1 The above figure gives an overview of our most important results. The black arrows, denote the reductions, we have shown. The single gray arrow (reduction) from 3-SUM to the problem EqDist has been shown by Barequet and Har-Peled [6]. Furthermore, the violet arrow i.e the equivalence between All-ints 3-SUM(n, n, k) and All-intsMixedConv(n, n, k), holds only for the case, when $k \in \Theta(n^\alpha)$, where $\alpha \in (0, 1]$.

3 Multivariate 3-SUM variants

Let us recall two central problems for our results.

▶ **Definition 4** (All-ints 3-SUM(n, n, k))**.** *Given sets A, B of size n, and a set C of size k. Determine for each c in C if there exists $(a, b) \in A \times B$ with $a + b = c$.*

▶ **Definition 5** (All-ints-MixedConv3-SUM(n, n, k))**.** *Given sequences of sets $A[0] \dots A[k-1]$ and $B[0] \dots B[k-1]$ of size $O(n/k)$, and a sequence of integers $C[0], \dots, C[k-1]$, determine for every $C[i]$ if there exists an element $a \in A[j]$ and an element $b \in B[i-j]$ such that $a + b = C[i]$.*

In order to show an equivalence between All-ints 3-SUM(n, n, k) and All-ints-MixedConv3-SUM, we make use of a family of hash functions $h : [U] \to [m]$ defined by $h(x) := x \bmod p$ over a uniform random prime p selected in $[m/2, m)$. These hash functions satisfy the following properties.

- almost-linearity, that is $h(x + y) = h(x) + h(y)$ or $h(x + y) = h(x) + h(y) - p$.
- $O(\log(U))$-universality, that is $\Pr_{h \in \mathcal{H}}[h(x) = h(y)] = O(\frac{\log(U)}{m})$.

Throughout, we assume that $A, B, C \subseteq [U]$ with $U = O(n^3)$ which can be achieved using a standard universe reduction. Furthermore, the above hash functions exhibit the following additional property.

▶ **Lemma 6** (Overfull buckets [11])**.** *Let $\mathcal{H}$ be a family of d-universal hash functions $[U] \to [m]$. Furthermore, let $h \in \mathcal{H}$ be chosen randomly. Let S be a set of n integers in $[U]$. We call x bad iff the number of elements equal to $h(x)$ (excluding x) exceeds a parameter t. The expected number of bad elements x in S is at most $\frac{dn}{m} \cdot \frac{1}{t} \cdot n$.*

We adapt the approach of Chan and He [11] (originally used to show a deterministic reduction from Convolution 3-SUM to 3-SUM) to show the following.

▶ **Lemma 7.** *Let $k = \Theta(n^\alpha)$, where $\alpha \in (0, 1]$. If we can solve All-ints-MixedConv3-SUM in time $O((nk)^{1-\epsilon})$ for some $\epsilon > 0$, then we can solve All-ints 3-SUM(n, n, k) in time $O((nk)^{1-\epsilon'})$ for some $\epsilon' > 0$.*

Proof. We reduce from All-ints 3-SUM(n, n, k). Let p be a prime number chosen from $[m/2, m)$ where $m = \frac{dk}{R}$ with $d = O(\log(U)) = O(\log(n))$ and R to be chosen later. Let $h(x) := x \bmod p$ and $C'[i] := \{c \in C : h(c) = i\}$, $A'[i] := \{a \in A : h(a) = i\}$, $B'[i] := \{b \in B : h(b) = i\}$. We call elements in $c \in C$ bad if $|C'[i]| > t$ where $i = h(c)$. Furthermore, we call elements $a \in A$ bad if $|A'[i]| > t \cdot n/m$ where $i = h(a)$. Similarly, we call elements $b \in B$ bad if $|B'[i]| > t \cdot n/m$ where $i = h(b)$.

The expected number of bad elements in C is $O\left(\frac{dk}{\frac{dk}{R}} \cdot \frac{1}{t}\right) \cdot k = O\left(\frac{Rk}{t}\right)$. The expected number of bad elements in A and B is $O\left(\frac{dn}{m} \cdot \frac{1}{\frac{n}{m} \cdot t} \cdot n\right) = O\left(\frac{nd}{t}\right)$.

By making use of Markov's inequality for the sets A, B, C separately, the probability that the number of bad A, B and C elements exceed 4 times its expectation is at most $1/4$ each. Thus by applying the union bound, there exists a hash function h, represented by some suitable prime p, where the number of bad elements for each set A, B, C is bounded by at most 4 times the number of expected bad elements.

We find such a hash function by going naively through all $O(m/\log(m))$ primes $p \in [m/2, m)$. The primes can be generated in time $\tilde{O}(m)$ by the sieve of Eratosthenes, and computing the bucket sizes takes time $O(m/\log(m)) \cdot O(n) = \tilde{O}(\frac{dkn}{R})$.

We proceed now as follows: For the bad elements in C, we perform a bruteforce 2-SUM algorithm, which needs time $O(n)$. There are at most $O(\frac{Rk}{t})$ many bad elements, thus this takes time $O(\frac{Rkn}{t})$.

For the bad elements in A and B, we also perform a simple bruteforce algorithm, which needs time $O(k)$, resulting in a runtime $O(k \cdot \frac{nd}{t}) = \tilde{O}(\frac{nk}{t})$.

For the remaining good elements in C, which occur at most t times, we proceed as follows: For each possible candidate in $[t]$, we perform an All-ints-MixedConv3-SUM instance for both cases of the almost-additiveness. For this, we get a runtime of $\tilde{O}(t \cdot (n \cdot \frac{k}{R})^{1-\epsilon})$. Concluding, we get a total runtime of

$$\tilde{O}\left(\frac{kn}{R}\right) + O\left(\frac{Rkn}{t}\right) + \tilde{O}\left(\frac{nk}{t}\right) + \tilde{O}\left(t \cdot (n \cdot \frac{k}{R})^{1-\epsilon}\right).$$

By setting $t = R^2$, we equate the first two terms, reducing to a runtime of:

$$\tilde{O}\left(\frac{kn}{R}\right) + \tilde{O}\left(\frac{nk}{R^2}\right) + \tilde{O}\left(R^2 \cdot \left(n \cdot \frac{k}{R}\right)^{1-\epsilon}\right),$$

which is bounded by $\tilde{O}\left(\frac{kn}{R}\right) + \tilde{O}\left(R^{1+\epsilon} \cdot (n \cdot k)^{1-\epsilon}\right)$. We balance the expression by setting $R = (nk)^{\epsilon/(2+\epsilon)}$, resulting in the final runtime $\tilde{O}((nk)^{1-\epsilon'})$, for an $\epsilon' > 0$. We remove the polylog factors by choosing an ϵ^* such that $0 < \epsilon^* < \epsilon'$, and get the desired runtime $O((nk)^{1-\epsilon^*})$. ◀

The reverse reduction is simpler and follows the standard reduction from convolution 3-SUM to 3-SUM.

▶ **Lemma 8.** *Let $k = \Theta(n^\alpha)$, where $\alpha \in (0, 1]$. If All-ints 3-SUM(n, n, k) can be solved in time $T(n, k)$, then we can solve All-ints MixedConv3-SUM(n, n, k) in time $O(T(n, k))$.*

Proof. We first convert the All-intsMixed-Conv3-SUM (n, n, k) problem into an All-ints 3-SUM (n, n, k) problem. Consider the newly created sets A', B', C', and a large number M as follows:

$$A' := \{a + iM : i \in \{0, \dots, k-1\} \wedge a \in A[i]\}$$
$$B' := \{b + iM : i \in \{0, \dots, k-1\} \wedge b \in B[i]\}$$
$$C' := \{c[i] + iM : i \in \{0, \dots, k-1\}\}$$

Due to the large choice of M it holds that there exist $a' \in A', b' \in B', c' \in C'$ such that $a' + b' = c'$ iff there exists $i, j, k \in \{0, \dots, k-1\}$ such that $i + j = k$ and there exists $a \in A[i], b \in B[j]$ such that $a + b = C[k]$. ◀

▶ **Lemma 9** (All-ints $\mathsf{FOP}_{\mathbb{Z}}$ queries [24]). *Let $A_1 \subseteq \mathbb{Z}^{d_1}, A_2 \subseteq \mathbb{Z}^{d_2}, A_3 \subseteq \mathbb{Z}^{d_3}$, with $|A_1| = k, |A_2| = |A_3| = n$, and $\varphi(a_1, a_2, a_3)$ be a quantifier free linear arithmetic formula. If we can solve All-ints 3-SUM(n, n, k) in time $T(n, k)$, then we can determine for each $a_1 \in A_1$, whether there exist $a_2 \in A_2, a_3 \in A_3$ such that $\varphi(a_1, a_2, a_3)$ is satisfied in time $\tilde{O}(T(n, k))$.*

The details can be found in the full version of the paper. We conclude with a simple 3-SUM lower bound for All-ints 3-SUM(n, n, k).

▶ **Lemma 10.** *Let $k = \Theta(n^\alpha)$ for $\alpha \in (0, 1]$. If we can solve All-ints 3-SUM (n, n, k) in time $O((nk)^{1-\epsilon})$ for some $\epsilon > 0$, then the 3-SUM hypothesis fails.*

Proof. We reduce from 3-SUM and separate the set C into $O(n/k)$ sets of size $O(k)$. We perform then $O(n/k)$ instances of All-ints 3-SUM(n, n, k) that run in time $O(n/n^\alpha) \cdot O((n \cdot n^\alpha)^{1-\epsilon}) = O(n^{2-\epsilon'})$ for some $\epsilon' > 0$. ◀

4 Output sensitive Skyline

We recall the two variants of the Pareto Sum problem.

▶ **Definition 11** (Succinct Skyline/Pareto Sum). *Given a succinctly defined set $X = A + B \subseteq \mathbb{Z}^2$, the skyline (aka Pareto front) of X consists of all non-dominated vectors in X. More formally compute the following set: $\mathsf{PS}(A, B) := \{x \in X : \text{There is no } x' \in X \setminus \{x\} : x \leq x'\}$, where we denote the output size by $k := |\mathsf{PS}(A, B)|$.*

▶ **Definition 12** ($\mathcal{Q}$-Succinct Skyline/$\mathcal{Q}$-Pareto Sum). *Given a succinctly defined set $X = A + B \subseteq \mathbb{Z}^2$, and a quadrant $\mathcal{Q} = [\alpha_1, \infty) \times [\alpha_2, \infty)$ the skyline (aka Pareto front) of X consists of all non-dominated vectors in X inside $\mathcal{Q}$. More formally compute the following set: $\mathsf{PS}_{\mathcal{Q}}(A, B) := \{x \in X = A + B : x \in \mathcal{Q} \text{ and there is no } x' \in X \setminus \{x\} : x \leq x'\}$, where again we denote the output size by $k := |\mathsf{PS}_{\mathcal{Q}}(A, B)|$.*

In the following section, we show that the above problems are fine-grained equivalent, which will be necessary to show the fine-grained equivalence between the Pareto Sum problem and All-ints 3-SUM(n, n, k).

4.1 On the equivalence of succinct skyline and $\mathcal{Q}-$succinct skyline

▶ **Theorem 13.** *If we can compute the Pareto Sum in time $T(n, k)$, then the $\mathcal{Q}$-Pareto Sum of an instance $A, B, \mathcal{Q}$ with $|A| = |B| = n$ and output size k can be computed in time $\mathcal{O}(T(n, k))$.*

Proof. Assume the quadrant to be given in the form $\mathcal{Q} = [L.x, \infty) \times [L.y, \infty)$. The goal is to construct a Pareto Sum instance where only Pareto points $c \in A + B$ with $c[0] \geq L.x$ and $c[1] \geq L.y$ are part of the output. The reduction consists of the following steps:

- Step 1: Transform the point coordinates in A, B such that the minimum coordinate value is at least 1 and adapt $L.x$ and $L.y$ accordingly. Define M larger than the largest possible point coordinate in $A + B$ and set $A' := A \cup A^+$ and $B' = B \cup B^+$ where $A^+ = \{(-5M + L.x, 7M), (-3M + L.x, 5M), (9M, -7M), (11M, -9M)\}$ and $B^+ = \{(-5M, 7M), (-M, 3M), (3M, -M)\}$.
- Step 2: Transform the point coordinates in A' and B' such that the minimum coordinate values are again at least 1 and adjust $L.y$ accordingly. Let M' be larger than the new maximum coordinate of any point in $A' + B'$. Augment A' with points A^{++} and B' with points B^{++}, which are derived from A^+, B^+ by swapping their x- and y-coordinates, respectively, and replacing M by M' and $L.x$ by (the transformed) $L.y$.
- Step 3: Compute the Pareto Sum C' of A', B'.
- Step 4: Delete all points with coordinates smaller than 1 or larger than M' from C', transform the coordinates of the remaining points in C' by reversing the transformations applied in Step 4, delete again elements with coordinate values smaller than 1 or larger than M and finally transform the coordinates once more by reversing the transformation applied in Step 2.

Applying the steps 1 and 2 takes time $\mathcal{O}(n)$ each. Step 3 takes time $T(\max\{|A'|, |B'|\}, |C'|)$ with $\max\{|A'|, |B'|\} = n+8$. Step 4 takes time in $\mathcal{O}(|C'|)$. Below, we argue that the returned result is correct and that $|C'| \in \mathcal{O}(k)$.

After the coordinate transformation in Step 1, the elements in A and B have coordinates in $\{1, \ldots, M-1\}$. Figure 2 illustrates the impact of adding A^+ and B^+ to A and B, respectively. Firstly, we observe that all elements $c = a + b$ with $a \in A^+$ or $b \in B^+$ – except for $A_2^+ + B_3^+$ – have either $c[0] < M$ or $c[1] < M$. Accordingly, none of these elements can dominate any element in $A + B$ as their maximum coordinate is bounded by M. The point $A_2^+ + B_3^+ = (L, 4M)$, however, dominates all points in $A + B$ with an x-coordinate of at most $L.x$. These points are all outside of $\mathcal{Q}$ based on our definition of $L.x$. Next, we observe that only 12 points $c = a + b$ with $a \notin A$ or $b \notin B$ are non-dominated, see again Figure 2. For cells having a colored point in Figure 2 we argue in the following that they dominate the corresponding colored ranges by comparing the x- and y-coordinates of the dominating point to the x- and y-coordinates of the dominated range.

- $A_1^+ + B_3^+ = (-2M + L, 6M)$ dominates $A_2^+ + B$ (yellow) since $-2M + L > -3M + L + 1$ and $-2M + L > -2M + L - 1$ for the x-coordinates and for the y-coordinates $6M > 6M - 1$ and $6M > 5M + 1$.
- $A_2^+ + B_2^+ = (-4M + L, 8M)$ dominates two ranges, namely $A_1^+ + B$ and $A + B_1^+$ (orange). The former is dominated since $-4M + L > -5M + L - 1$ and $-4M + L > -4M + L - 1$ hold for the x-coordinates and $8M > 8M - 1$ and $8M > 7M + 1$ for the y-coordinates. For the latter range we conclude that $-4M + L > -5M + 1$ and $-4M + L > -4M - 1$ for the x-coordinates and $8M > 8M - 1$ and $8M > 7M + 1$ for the y-coordinates.
- $A_2^+ + B_3^+ = (L, 4M)$ dominates $A + B_2^+$ (purple) since $L > -M + 1$ and $L > -1$ for the x-coordinates and $4M > 4M - 1$ and $4M > 3M + 1$ for the y-coordinates.
- $A_3^+ + B_1^+ = (4M, 0)$ dominates $A + B_3^+$ (light green) since $4M > 3M + 1$ and $4M > 4M - 1$ for the x-coordinates and $0 > -1$ and $0 > -M + 1$ for the y-coordinates.
- $A_3^+ + B_3^+ = (12M, -8M)$ dominates $A_4^+ + B$ (turquoise) since $12M > 11M + 1$ and $12M > 12M - 1$ for the x-coordinates and $-8M > -8M - 1$ and $-8M > -9M + 1$ for the y-coordinates.

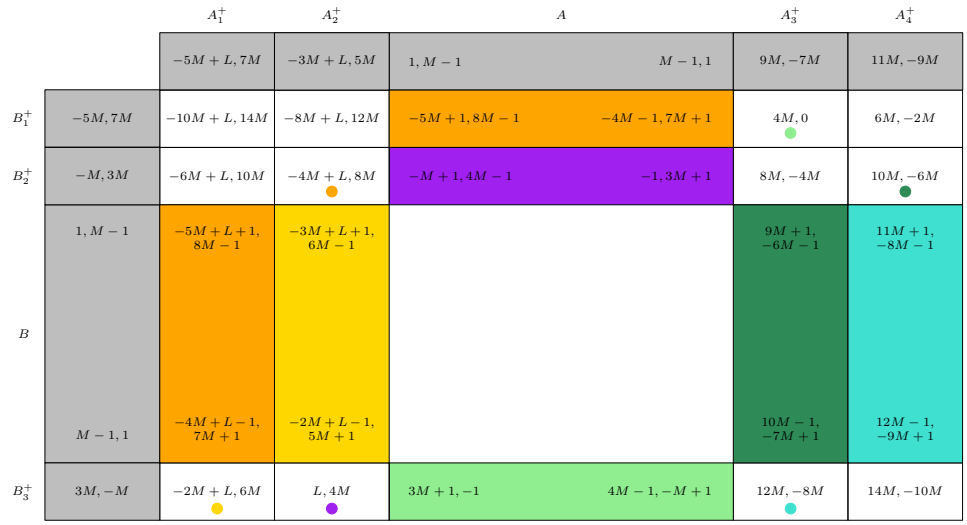

Figure 2 $\mathcal{Q}$-Pareto Sum instance augmented with A^+, B^+. The colored regions are dominated by the element in the cell with the dot of matching color. L refers to $L.x$. By definition, we have $L \leq M$.

- $A_4^+ + B_2^+ = (10M, -6M)$ dominates $A_3^+ + B$ (dark green) since $10M > 9M + 1$ and $10M > 10M - 1$ for the x-coordinates and $-6M > -6M - 1$ and $-6M > -7M + 1$ for the y-coordinates.

Step 2 repeats the very same process of coordinate transformation and augmentation, now with the goal to introduce a filter for the points with a y-coordinate smaller than $L.y$. The arguments from above apply again. Therefore, computing the Pareto Sum on A', B' in Step 3 results in C' of size at most $k + 24$. Thus, the filtering and back transformation in Step 4 takes time in $\mathcal{O}(k)$. Summing up over all steps, the running time is in $\mathcal{O}(n + k + T(n, k)) = \mathcal{O}(T(n, k))$.

After completing Step 4, C' is guaranteed to contain all points of the $\mathcal{Q}$-Pareto Sum C of A, B that are strictly inside $\mathcal{Q}$, as the points with an x-coordinate of at most $L.x$ and a y-coordinate of at most $L.y$ are dominated by the newly introduced elements in the augmented sumset, and Pareto points that result from the augmentation steps are filtered. ◀

We remark that the reduction in the other direction is trivial. Given an instance A, B of Pareto Sum, we can construct an instance of $\mathcal{Q}$-Pareto Sum with the same solution by enclosing all points in $A+B$ inside a large quadrant i.e $\mathcal{Q} = [-M, \infty) \times [-M, \infty)$. Accordingly, these two problems are fine-grained equivalent.

Moreover, our reduction technique can be leveraged to show that there are arbitrarily large Pareto Sum instances, where A and B consist of incomparable vectors, for which the output size k is constant. In prior work, it was only shown that for an instance with $|A| = 2$ and $|B| = 5$ an output size $k = 4 < \max(|A|, |B|)$ is possible [33]. But the question whether there exist sets A, B with $|A|, |B| = n$ and a Pareto Sum of size $k \in o(n)$ has been open. Given any Pareto Sum instance, we can define $L.x$ as the maximum x coordinate of any Pareto point in $A + B$. Using the augmentation described in Step 2 in the proof of Theorem 13, all Pareto points of $A + B$ will be dominated and only 12 new Pareto points will be introduced. Thus, we get the following corollary.

▶ **Corollary 14.** *For any $n \in \mathbb{N}$, there exist sets A, B of incomparable vectors with $|A| = |B| = n$ and output size of the Pareto Sum $k \in \mathcal{O}(1)$.*

4.2 A lower bound from All-ints 3-SUM(n, n, k)

▶ **Lemma 15.** *If we can compute the output-sensitive $\mathcal{Q}$-Pareto Sum of size $k = \Theta(n^\alpha)$ for $\alpha \in (0, 1]$ for sets A, B in time $O(T(n, k))$, then we can solve All-ints MixedConv3-SUM(n, n, k) in time $O(T(n, k))$.*

Proof. Consider an All-ints MixedConv3-SUM(n, n, k) instance given by array of sets $A[0, \ldots, k-1], B[0, \ldots, k-1]$ of size $O(n/k)$, and the array $C[0, \ldots, k-1]$. Let $A' := \{a + 100iM : i \in \{0, \ldots, k-1\} \wedge a \in A[i]\}$, $B' := \{b + 100iM : i \in \{0, \ldots, k-1\} \wedge b \in B[i]\}$ $C' := \{C[i] + 100iM : i \in \{0, \ldots, k-1\}\}$. It is clear that the newly constructed sets A', B' are of size at most n and the set C' of size at most k. Let $t := 2M$, and by the above construction, it holds that for an index $i \in \{0, \ldots, k-1\}$ there does not exist a $j \in \{0, \ldots, k-1\}$, where $j \leq i$ and $a \in A[j], b \in B[i-j]$ such that $a+b = C[i]$ if and only if for all $a' \in A', b' \in B'$ there exists $c' \in C'$, where one of the following two inequalities holds: $c' + 1 \leq a' + b' \leq c' + 1 + t$ or $c' - t - 1 \leq a' + b' \leq c' - 1$. Let us create the following set of the left side of the inequalities observed, that is $\tilde{C} := \bigcup_{c \in C'} \{c' + 1, c' - t - 1\}$.

We will construct the following sets in $\mathbb{Z}^2$, in order to integrate both above inequalities in a Pareto Sum problem.

$$A^* := \left\{ \begin{pmatrix} a \\ -a \end{pmatrix} : a \in A' \right\}, B^* := \left\{ \begin{pmatrix} b \\ -b \end{pmatrix} : b \in B' \right\}, C^* := \left\{ \begin{pmatrix} c + t \\ -c \end{pmatrix} : c \in \tilde{C} \right\}$$

We perform an output sensitive $\mathcal{Q}$-Pareto Sum computation on the following sets, with a quadrant $\mathcal{Q}$, which we determine in a bit.

$$H = A^* \cup \left(C^* + \left\{ \begin{pmatrix} 1000kM \\ -1000kM \end{pmatrix} \right\} \right), G = B^* \cup \left\{ \begin{pmatrix} -1000kM \\ 1000kM \end{pmatrix} \right\}$$

The sumset $H + G$ then consists of the following sumsets:

$$A^* + B^*,\ A^* + \left\{ \begin{pmatrix} -1000kM \\ 1000kM \end{pmatrix} \right\},\ C^* + B^* + \left\{ \begin{pmatrix} 1000kM \\ -1000kM \end{pmatrix} \right\},\ C^*.$$

We set the quadrant $\mathcal{Q} = [\min_{c \in C^*} c[0], \infty) \times [\min_{c \in C^*} c[1], \infty)$, thus forcing the output-sensitive $\mathcal{Q}$-Pareto Sum to ignore everything besides the points in $A^* + B^*$ and C^*.

Let us first argue that the points in C^* need to be part of the output-sensitive skyline. We argue based on the indices $i \in \{0, \ldots, k-1\}$, which separate the points in $A^* + B^*$ and C^* into clusters of points. For each $i, j \in \{0, \ldots, k-1\}$ the points in $A^* + B^*$ are of the form $\begin{pmatrix} a + 100iM + b + 100jM \\ -a - b - 100iM - 100jM \end{pmatrix} = \begin{pmatrix} (a+b) + (i+j)100M \\ -(a + b + (i+j)100M) \end{pmatrix}$. For each $i \in \{0, \ldots, k-1\}$ the two points originally induced by index i, now in C^* are of the form $\tilde{c}_i^1 := \begin{pmatrix} c[i] + 100iM + 1 + t \\ -(c[i] + 100iM + 1) \end{pmatrix}, \tilde{c}_i^2 := \begin{pmatrix} c[i] + 100iM - t - 1 + t \\ -(c[i] + 100iM - t - 1) \end{pmatrix} = \begin{pmatrix} c[i] + 100iM - 1 \\ -(c[i] + 100iM - t - 1) \end{pmatrix}$. For each $i \in \{0, \ldots, k-1\}$, we now observe the points which are included in the Pareto Sum. Clearly, the Pareto front, will contain $\tilde{c}_i^1$ as it is the point with the largest x-coordinate among the points landing at the cluster of points induced by index i. Furthermore, the point $\tilde{c}_i^2 = \begin{pmatrix} c[i] + 100iM - 1 \\ -(c[i] + 100iM - t - 1) \end{pmatrix}$ is contained in the Pareto Sum as it is the point with the highest y-coordinate among the points landing at the cluster of points induced by index i. Let us prove the following claim.

▷ Claim 16. The Pareto front of the cluster of points induced by index i will contain precisely the points $\{\tilde{c}_i^1, \tilde{c}_i^2\}$ if and only if there is no $j \in \{0, \ldots, k-1\}$ such that there exists an $a \in A[j]$ and $b \in B[i-j]$ with $a + b = C[i]$.

Proof. As argued before the points $\{\tilde{c}_i^1, \tilde{c}_i^2\}$, will always be in the Pareto Sum induced by index i. Assume there exists an index j such that there exists an $a \in A[j]$ and $b \in B[i-j]$ such that $a + b = C[i]$, then in the sumset $A^* + B^*$ there will be a point γ_i of the form:

$$\gamma_i = \begin{pmatrix} a + 100jM + b + 100(i-j)M \\ -(a + 100jM + b + 100(i-j)M) \end{pmatrix} = \begin{pmatrix} c[i] + 100iM \\ -(c[i] + 100iM) \end{pmatrix}.$$

The point $\tilde{c}_i^1 = \begin{pmatrix} c[i] + 100iM + 1 + t \\ -(c[i] + 100iM + 1) \end{pmatrix}$ does not dominate γ_i because of the y-coordinate. Furthermore, the point $\tilde{c}_i^2 = \begin{pmatrix} c[i] + 100iM - 1 \\ -(c[i] + 100iM - t - 1) \end{pmatrix}$ does not dominate γ_i because of the x-coordinate. Lastly, it is easy to see that the only points not dominated by $\tilde{c}_i^1$ or $\tilde{c}_i^2$ in the cluster of points induced by index i need to be of the form γ_i. Concluding, the Pareto front of the cluster of points induced by index i will contain precisely the points $\{\tilde{c}_i^1, \tilde{c}_i^2, \gamma_i\}$ if and only if there exists a $j \in \{0, \ldots, k-1\}$ and $a \in A[j]$ and $b \in B[i-j]$ with $a + b = C[i]$. ◁

After having proven the claim, it remains to scan through the Pareto Sum and identify whether the Pareto front induced by each index i consists of two points, concluding the reduction from All-ints MixedConv3-SUM(n, n, k). Lastly, notice that the size of the Pareto front evaluated is at most $O(k)$. ◀

By a simple padding argument we can now show the following lower bound.

▶ **Lemma 17.** *Let $\epsilon > 0$. There is no output-sensitive algorithm to compute the Pareto Sum of sets A, B of size n in time $O(n^{2-\epsilon})$ with guaranteed output size $\Theta(n^\alpha)$, where $1 \leq \alpha < 2$ and $k := n^\alpha$, unless All-ints 3-SUM(n, n, k) can be solved in time $O(n^{2-\epsilon'})$ for an $\epsilon' > 0$.*

Proof. Case $\alpha \leq 1$ is shown in Lemma 15, by making use of the fine-grained equivalence between All-ints 3-SUM(n, n, k) and All-ints-MixedConv-3-SUM(n, n, k).

We reduce from the case $\alpha = 1$, let $\beta = \alpha - 1$. We construct an artificial blowup of the Pareto Sum output set of size n^β. To this end, take a subset of B' of size n^β from the set B. Let the vectors in B' be numbered arbitrarily $b_1, \ldots, b_m$. Construct the following set:

$$\bar{B} := B \cup \underbrace{\bigcup_{i=1}^{m} \left\{ b_i + \begin{pmatrix} i \cdot M \\ -i \cdot M \end{pmatrix} \right\}}_{:=\tilde{B}}.$$

The Pareto Sum C will now consist of the original Pareto Sum of size n combined, with $A + \tilde{B}$ of size $n^{1+\beta}$. This holds due to the fact that all vectors in $A + \tilde{B}$ are incomparable to each other, and incomparable to the vectors $A + B$, due to the shift chosen for each vector. ◀

Let us now make use of the 3-SUM hardness of All-ints 3-SUM(n, n, k) to show the following lower bound, by a simple combination of Lemma 15 and Lemma 17.

▶ **Theorem 18.** *Let $k = \Theta(n^\alpha)$, where $\alpha \in (0, 2)$. There is no algorithm to solve output sensitive Pareto Sum of output size k, in time $O(\min\{n^2, nk\}^{1-\epsilon})$ for an $\epsilon > 0$, unless the 3-SUM hypothesis fails.*

Proof. We perform a simple case distinction depending on α, if $0 < \alpha \leq 1$ we apply Lemma 15 together with the fine-grained equivalence between All-ints 3-SUM(n, n, k) and All-ints MixedConv-3-SUM(n, n, k). In the case of $1 < \alpha < 2$, we similarly apply Lemma 17 together with the fact that All-ints 3-SUM(n, n, k) is 3-SUM hard. ◀

4.3 A reduction to All-ints 3-SUM(n, n, k)

▶ **Lemma 19.** *Given sets $A, B \subseteq \mathbb{Z}^2$ of size n and closed intervals $I_1 = [\alpha_1, \omega_1], \ldots, I_k = [\alpha_k, \omega_k]$. We can compute for all intervals I_j the highest point in $A + B$ with x-coordinate in I_j in time $\tilde{O}(T(n, k))$ if All-ints 3-SUM(n, n, k) can be solved in time $T(n, k)$.*

Proof. We consider a parallel binary search approach. Let $\gamma_1, \ldots, \gamma_k, \in [-M, M]$ and $C := \{(\alpha_i, \omega_i, \gamma_i) : i \in \{1, \ldots, k\}\}$. An application of All-ints$\mathsf{FOP}_{\mathbb{Z}}$ query to the set C on the formula

$$\exists a \in A \exists b \in B \exists c \in C : c[0] \leq a[0] + b[0] \wedge a[0] + b[0] \leq c[1] \wedge a[1] + b[1] \geq c[2],$$

gives us an answer for each interval I_j, where $j \in \{1, \ldots, k\}$, whether there exist points $a \in A, b \in B$ such that the x-coordinate of $a + b$ lies on the interval I_j and the y-coordinate of $a + b$ is higher than γ_j. By appropriately changing the value of γ_j, for each interval and constructing a new formula in a logarithmic number of steps, we can find the height y_j^* of the highest point in each interval I_j via a parallel binary search.

We now continue computing the x-coordinate of the highest point for each interval, which we can also compute by a binary search. Consider $\delta_1, \ldots, \delta_k$, where $\delta_i = \lfloor (\omega_i + \alpha_i)/2 \rfloor$ and construct the following set $C' = \{(\alpha_i, \omega_i, \delta_i, y_i^*) : i \in \{1, \ldots, k\}\}$. An application of All-ints $\mathsf{FOP}_{\mathbb{Z}}$ query to the set C' of the formula

$$\exists a \in A \exists b \in B \exists c' \in C' : c[0] \leq a[0]+b[0] \wedge a[0]+b[0] \leq c[1] \wedge a[0]+b[0] \geq c[2] \wedge a[1]+b[1] = c[3]$$

gives us an answer for each Interval I_j, whether there exists $a \in A, b \in B$ such that the x-coordinate of $a + b$ lies on or to the right of δ_j and the y-coordinate of $a + b$ is precisely the y-coordinate of the highest point in the interval I_j.

Thus, by appropriately changing the value of δ_i for each interval and constructing a new formula, in a logarithmic number of steps, we can find a corresponding x-coordinate to the highest y-coordinate in each interval via a parallel binary search. Notice that we can choose to binary search in such a way as to find for each interval the rightmost point, which equals the highest y-coordinate. Lastly, we can also deduce if there is no point $a + b$ inside an interval at all.

For the runtime notice that a parallel binary search on an All-ints $\mathsf{FOP}_{\mathbb{Z}}$ query runs in time $\tilde{O}(T(n, k)) \cdot O(\log U) = \tilde{O}(T(n, k))$ by Lemma 9, where $U \in O(poly(n))$ denotes the size of the universe. ◀

▶ **Theorem 20.** *If we can solve All-ints 3-SUM(n, n, k) in time $T(n, k)$, then we can compute an output sensitive Pareto Sum in time $\tilde{O}(T(n, k))$.*

Proof. We perform a divide and conquer approach, where we keep a collection of disjoint intervals $\mathcal{I}$, with the invariant that every interval $I \in \mathcal{I}$ contains at least one point the Pareto front of $A + B$ whose x-coordinate lies in I. Furthermore, keep a set S which stores the points of the skyline of $A + B$.

Start with the set of intervals given by one interval concluding the x-coordinate of all points, $\mathcal{I} := \{I_1 = [-M, M]\}$. We now state the general procedure.

Firstly, compute the highest points inside all intervals in $\mathcal{I}$ by an application of Lemma 19. In the beginning we directly, store this point in the set S as it must be part of the Pareto front of $A + B$.

Now, for each interval $I_j = [\alpha, \omega]$ in $\mathcal{I}$, we create two intervals $I_j^{(1)} := [\alpha, m-1]$ and $I_j^{(2)} := [m, \omega]$, where $m = \lfloor(\alpha+\omega)/2\rfloor$ is the middle x-coordinate of the interval I_j. Perform a call on Lemma 19 with A, B and the set of intervals $\mathcal{I}' := \{I_1^{(1)}, I_1^{(2)} \ldots, I_l^{(1)}, I_l^{(2)}\}$, to compute the highest points of the non-empty intervals. In the case of several highest points in an interval, Lemma 19 computes the rightmost highest point. We can now deduce for each of the intervals in $\mathcal{I}'$ if it contains at least one point in the Pareto front of $A+B$. Clearly if the interval is empty, we can disregard it and keep the non-empty half. Assume for I_j, we have that $I_j^{(1)}$ and $I_j^{(2)}$ are both non-empty, with the highest points being s_1 and s_2 respectively. If s_2 dominates the point s_1, we can disregard the interval $I_j^{(1)}$, as it can not be part of the Pareto front of $A+B$, any further subdivision of $I_j^{(1)}$ would create only more dominated points by monotonicity. Otherwise, we know $s_1[0] < s_2[0]$ and $s_1[1] > s_2[1]$. Let d_1 and d_2, be the rightmost highest points of the intervals $[m, M]$ and $[\omega+1, M]$ respectively, which can be computed by a call to Lemma 19 for all non-empty intervals $I_1^{(1)}, I_1^{(2)} \ldots, I_l^{(1)}, I_l^{(2)}$. We will keep the interval $I_j^{(1)}$ (store s_1 in S) iff d_1 does not dominate s_1, and will keep the interval $I_j^{(2)}$ (and store s_2 in S) iff the point d_2 does not dominate s_2. Continue recursively, with the set of non-disregarded intervals $\mathcal{I}'$, and the stored Pareto front points S, where we terminate the recursion and return the set S when all intervals in $\mathcal{I}$ are of length 1.

For the correctness, we remark that the invariant holds that every interval in $\mathcal{I}$ holds at least one point in the Pareto front. For the runtime, notice that the length of the intervals is halved in every recursion step. Finally, we have a recursion depth of at most $\log_2 U$, where $U \in O(poly(n))$ denotes the size of the universe, and in each recursion, we perform a call to Lemma 19 with at most $4k$ intervals (including the computation of d_1 and d_2). Thus, we get a final runtime of $\tilde{O}(T(n,k))$. ◀

5 Conclusion

We conclude with some open questions. It appears difficult to reduce All-ints 3-SUM(n,n,k) to 3-SUM when $k \ll n$, which would lead to a fine-grained equivalence between the problems. A first step might be to investigate if All-ints 3-SUM(n,n,k) admits an efficient self-reduction. Furthermore, it remains to classify further problems into being succinctly-easy or succinctly-equivalent to variants of k-SUM. Finally, it is interesting to study good representations of arbitrary sets X as sumsets $A+B$. In recent work [3], it was shown that determining perfect representability is NP-hard. However, perhaps we can efficiently compute approximate representations of sumsets, which may even lead to efficient (approximation) algorithms for explicit versions of various geometric primitives.

Abstract

Covering and partitioning the edges of a graph into cliques are classical problems at the intersection of combinatorial optimization and graph theory, having been studied through a range of algorithmic and complexity-theoretic lenses. Despite the well-known fixed-parameter tractability of these problems when parameterized by the total number of cliques, such a parameterization often fails to be meaningful for sparse graphs. In many real-world instances, on the other hand, the minimum number of cliques in an edge cover or partition can be very close to the size of a maximum independent set $\alpha(G)$.

Motivated by this observation, we investigate *above-α* parameterizations of the edge clique cover and partition problems. Concretely, we introduce and study Edge Clique Cover Above Independent Set (ECC/α) and Edge Clique Partition Above Independent Set (ECP/α), where the goal is to cover or partition all edges of a graph using at most $\alpha(G) + k$ cliques, and k is the parameter. Our main results reveal a distinct complexity landscape for the two variants. We show that ECP/α is fixed-parameter tractable, whereas ECC/α is NP-complete for all $k \geq 2$, yet can be solved in polynomial time for $k \in \{0, 1\}$. These findings highlight intriguing differences between the two problems when viewed through the lens of parameterization above a natural lower bound.

Finally, we demonstrate that ECC/α becomes fixed-parameter tractable when parameterized by $k + \omega(G)$, where $\omega(G)$ is the size of a maximum clique of the graph G. This result is particularly relevant for sparse graphs, in which ω is typically small. For H-minor free graphs, we design a subexponential algorithm of running time $f(H)^{\sqrt{k}} \cdot n^{\mathcal{O}(1)}$.

1 Introduction

Covering and partitioning the edges of a graph into cliques are fundamental combinatorial problems that lie at the intersection of combinatorial optimization, graph theory, and complexity theory. In the Edge Clique Cover (ECC) problem one seeks to cover all edges of a graph with as few cliques as possible, while in Edge Clique Partition (ECP) the same objective is pursued under the additional constraint that each edge must lie in exactly one of the chosen cliques. Both problems were extensively studied from various algorithmic perspectives (See Section 1.2 for an overview), in particular from parameterized algorithms.

ECC and ECP are known to be fixed-parameter tractable (FPT) when parameterized by the number of cliques in the cover or partition [24, 40]. While this parameterization is meaningful for dense graphs, it becomes less relevant for sparse graphs (e.g., graphs with bounded maximum degree or planar graphs), where the size of a clique cover or partition usually scales proportionally with the number of vertices. In such cases, a brute-force algorithm that guesses all possible partitions already runs in FPT time under this parameter choice.

These observations naturally lead us to explore a different parameterization – one that captures a lower bound on the size of the cover or partition. In particular, for any graph G without isolated vertices, an edge clique cover or partition must contain at least $\alpha(G)$ cliques, where $\alpha(G)$ denotes the size of a maximum independent set of G. Empirical studies of ECC (see, e.g., [29, Table 3]) indicate that in many real-world instances, after suitable preprocessing, the number of cliques in the cover is *very* close to $\alpha(G)$. This observation motivates us to investigate ECC and ECP in the setting of parameterization *above* α. Concretely, we initiate the study of the following parameterized problems.

Edge Clique Partition Above Independent Set (ECP/α) parameterized by k

Input:	A graph G without isolated vertices, an integer $k \geq 0$.
Task:	Find an edge clique partition of G with at most $\alpha(G) + k$ cliques.

Edge Clique Cover Above Independent Set (ECC/α) parameterized by k

Input:	A graph G without isolated vertices, an integer $k \geq 0$.
Task:	Find an edge clique cover of G with at most $\alpha(G) + k$ cliques.

While ECC and ECP are both FPT when parameterized by the number of cliques, their above-guarantee variants – ECC/α and ECP/α– exhibit notably different and intriguing behaviors.

1.1 Our Results

Our first result establishes parameterized complexity of Edge Clique Partition Above Independent Set (ECP/α). It is worth to note that the running time of our algorithm matches the best known running time of the algorithm for ECP [18]. Moreover, as we show, any improvement in the running time for ECP would improve the running time in our theorem too.

▶ **Theorem 1.** *ECP/α can be solved in $2^{\mathcal{O}(k^{3/2}\log k)} \cdot n^{\mathcal{O}(1)}$ time.*

We underline that the input of ECP/α (or ECC/α) does not contain the value of $\alpha(G)$. Interestingly, while computing the maximum independent set is well-known to be intractable, we show in Lemma 12 that, given an instance (G, k) of ECP/α, in $2^{\mathcal{O}(k^{3/2}\log k)} \cdot n^{\mathcal{O}(1)}$ time

we can either compute $\alpha(G)$ or conclude that (G, k) is a no-instance. This algorithm is used as a subroutine in Theorem 1 and, in fact, our algorithm for ECP/α either outputs an edge clique cover of size at most $\alpha(G) + k$ together with $\alpha(G)$ or correctly reports a no-instance.

While both ECP and ECC are FPT when parameterized by the number of cliques in the solution, their above-guarantee variants exhibit drastically different behaviors. The following theorem shows that for every fixed integer $k \geq 2$, deciding whether a graph can be covered by at most $\alpha(G) + k$ cliques is NP-complete even on prefect graphs for which the independence number can be computed in polynomial time [26]. Consequently, this places ECC/α in the class of Para-NP-complete problems.

▶ **Theorem 2.** *For every $k \geq 2$, ECC/α is NP-complete. Furthermore, the hardness holds even on perfect graphs.*

The condition in Theorem 2 concerning k is tight: for $k < 2$, the problem is solvable in polynomial time. Taken together, Theorems 2 and 3 establish a dichotomy result on the complexity of ECC/α for all values of k.

▶ **Theorem 3.** *ECC/α admits polynomial-time algorithms for $k \in \{0, 1\}$.*

Despite the intractability of ECC/α on general graphs, for certain classes of sparse graphs it is possible to design FPT algorithms. We summarize these findings in the following theorem. Here and further, the statements whose proof are omitted in this extended abstract are labeled ($\star$). The proofs can be found in the full version of this paper [21].

▶ **Theorem 4 ($\star$).** *ECC/α admits parameterized algorithms with the following running times:*

- $4^{\binom{\omega}{2} \cdot k} \cdot n^{\mathcal{O}(1)}$ *on graphs with clique number ω,*
- $2.081^{(d-1)k} \cdot n^{\mathcal{O}(1)}$ *on graphs of degeneracy $d \geq 3$,*
- $1.619^k \cdot n^{\mathcal{O}(1)}$ *on 2-degenerate graphs,*
- $f(H)^{\sqrt{k}} \cdot n^{\mathcal{O}(1)}$ *on H-minor-free graphs.*

Neither of ω, d, H should be given to the corresponding algorithm explicitly.

Complementing this result, we observe that, under the Exponential Time Hypothesis, the dependency on k cannot be improved in neither of the algorithms; additionally, the dependency on d is almost optimal. We refer the reader to the full version of this paper [21] for proper formal discussion.

1.2 Related Work

ECC and ECP are classical combinatorial problems [16, 28, 37, 46], whose origins can be traced back to fundamental questions posed by Boole in 1868 [7]. Over time, these problems have been studied under various names, including Covering by Cliques (Problem GT17) and Intersection Graph Basis (Problem GT59) in Garey and Johnson's compendium [23], as well as Keyword Conflict [34].

From a practical standpoint, ECC and ECP arise in diverse application areas such as computational geometry [2], applied statistics [25, 43], networks [27], compiler optimization [44], or bioinformatics [19]. Due to their broad importance, both ECC and ECP have been investigated from multiple perspectives, including approximation algorithms and inapproximability bounds [3, 38], heuristics [4, 25, 34, 36, 43, 44], and polynomial-time solutions for special graph classes [8, 23, 30, 31, 32, 39, 42].

Moreover, the relation between the smallest edge clique cover and the maximum independent set plays another important role in practical applications. On large instances, it may be infeasible to compute the optimal edge clique cover, and only heuristical methods

could be applied within a reasonable timeframe. Finding a suffiently large independent set serves then as a certificate for the quality of the solution, in terms of the size of the edge clique cover: If, say, there is only a 1% difference between the found independent set and clique cover, then the smallest clique cover is also bound to lie in this small interval. As observed by Hevia et al. [29], this phenomenon occurs frequently on real-world instances. Simultaneously, this certifies that the difference between the smallest edge clique cover and the largest independent set is also small on these instances.

Both ECC and ECP are known to be NP-complete even in restricted graph classes [42, 9, 30]. In particular, ECC remains NP-complete and even when the input graph is planar [9] or has bounded degree [30]. Furthermore, Lund and Yannakakis [38] showed that ECC is not approximable within a factor of n^{ε} (for some $\varepsilon > 0$) unless P=NP.

In particular, a significant amount of work in the algorithms engineering community is devoted to the studies of ECC on sparse graphs, whose independence number is large. For example, Abdullah and Hossain [1], and Conte, Grossi, and Marino [11] studied ECC on d-degenerate graphs. Blanchette, Kim, and Vetta in [6] obtained an PTAS for ECC on planar graphs as well as an FPT algorithm parameterized by the treewidth of a graph.

Within the realm of parameterized complexity, a natural parameterization is by the number of cliques k. Gramm et al. [24] pioneered this direction by presenting simple reduction rules that produce a kernel of size at most 2^k, making it one of the earliest examples of kernelization techniques described in textbooks [12, 22, 41]. Later, Cygan, Pilipczuk, and Pilipczuk [13] showed that there is no algorithm solving ECC in time $2^{2^{o(k)}} \cdot n^{\mathcal{O}(1)}$ unless the Exponential Time Hypothesis (ETH) fails.

Mujuni and Rosamond [40] established that ECP is FPT when parameterized by k, the number of cliques in the solution. Feldmann, Issac, and Rai [18] improved the running time to $2^{k^{3/2}\log k} \cdot n^{\mathcal{O}(1)}$. Fleischer and Wu [20] devised an algorithm for planar graphs running in $2^{\mathcal{O}(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$, and for graphs of degeneracy d they achieved $2^{dk} \cdot k \cdot n^{\mathcal{O}(1)}$ running time.

1.3 Organization of the Paper

In Section 2, we introduce basic notions and provide auxiliary results. Section 3 contains the proof of Theorem 1. In Section 4, we show the dichotomy for ECC/α on general graphs, proving Theorems 2 and 3. Finally, in Section 5, we give algorithmic results and establish computational lower bounds for ECC/α on sparse graph classes, as stated in Theorem 4. Due to the space restrictions, we omit proofs of some of the results. Several parts of Section 5 are also omitted. The omitted proofs and parts can be found in the full version of this paper [21].

2 Definitions and Preliminaries

Graphs. In this paper, we consider simple undirected graphs and refer to the textbook by Diestel [15] for notions that are not defined here. We use $V(G)$ and $E(G)$ to denote the set of vertices and the set of edges of G, respectively. We use n and m to denote the number of vertices and edges in G, respectively, unless this creates confusion. For a vertex subset $X \subseteq V(G)$, we use $G[X]$ to denote the subgraph of G induced by the vertices of X and $G - X$ to denote $G[V(G) \setminus X]$. For a vertex $v \in V(G)$, we write $N_G(v) = \{u \in V(G) \mid uv \in E(G)\}$ to denote the *open neighborhood* of v, and we use $N_G[v] = N_G(v) \cup \{v\}$ for the *closed neighborhood*. For $X \subseteq V(G)$, $N_G(X) = \left(\bigcup_{v \in X} N_G(v)\right) \setminus X$ and $N_G[X] = \bigcup_{v \in X} N_G[v]$. We denote by $d_G(v) = |N_G(v)|$ the *degree* of a vertex v; a vertex of degree zero is *isolated*. The minimum degree is denoted by $\delta(G)$. A graph G is *d-degenerate* for an integer $d \geq 0$ if

$\delta(H) \leq d$ for any subgraph H of G. By $\mathrm{dg}(G)$ we denote the degeneracy of G, i.e. minimum d for which G is d-degenerate. A graph H is a *minor* of G if the graph isomorphic to H can be obtained from G by vertex/edge deletions and edge contractions. A graph G is *H-minor-free* if H is not a minor of G. A set of pairwise adjacent vertices is called a *clique*, and a set of pairwise non-adjacent vertices is *independent*. The maximum size of an independent set in G is denoted by $\alpha(G)$, and the maximum size of a clique in G is denoted by $\omega(G)$. A vertex $v \in V(G)$ is said to be *simplicial* if $N_G[v]$ is a clique, and we say that a clique K is *simplicial* if K equals $N_G[v]$ for a simplicial vertex v. An edge $uv \in E(G)$ is *covered* by a clique K if $u, v \in K$. A set $\mathcal{K}$ of cliques is a *vertex clique cover* if for every $v \in V(G)$, there is $K \in \mathcal{K}$ such that $v \in K$. We say that $\mathcal{K}$ is an *edge clique cover* if for every $uv \in E(G)$, there is $K \in \mathcal{K}$ with $u, v \in K$, and $\mathcal{K}$ is an *edge clique partition* if $\mathcal{K}$ is an edge clique cover such that any two cliques in $\mathcal{K}$ has at most one common vertex. We use $\mathrm{ecc}(G)$ and $\mathrm{ecp}(G)$ to denote the minimum size of an edge clique cover and partition of G, respectively.

Parameterized Complexity. We refer to the textbook by Cygan et al. [12] for an introduction to the area. We remind that a *parameterized problem* is a language $L \subseteq \Sigma^* \times \mathbb{N}$ where Σ^* is a set of strings over a finite alphabet Σ. An input of a parameterized problem is a pair (x, k) where x is a string over Σ and $k \in \mathbb{N}$ is a *parameter*. A parameterized problem is *fixed-parameter tractable* (or FPT) if it can be solved in $f(k) \cdot |x|^{\mathcal{O}(1)}$ time for some computable function f. The complexity class FPT contains all fixed-parameter tractable parameterized problems. We use the *Exponential Time Hypothesis* (ETH) of Impagliazzo, Paturi, and Zane [33] to obtain conditional computational lower bounds. Under ETH, there is a positive real δ such that 3-Satisfiability (3-SAT) with n variables and m clauses cannot be solved in $2^{\delta n} \cdot (n+m)^{\mathcal{O}(1)}$ time; in particular, 3-SAT cannon be solved in time subexponential in n.

We need the following auxiliary results about edge clique covers and independent sets. First, we observe that $\alpha(G)$ gives a lower bound for $\mathrm{ecc}(G)$ and $\mathrm{ecp}(G)$.

▶ **Observation 5** ($\star$). *For a graph G without isolated vertices $\alpha(G) \leq \mathrm{ecc}(G) \leq \mathrm{ecp}(G)$.*

Notice that the absence of isolated vertices is crucial for the lower bound of $\mathrm{ecc}(G)$ and $\mathrm{ecp}(G)$. We also remark that that excluding isolated vertices is essential for our algorithmic results for ECP/α and ECP/α.

▶ **Observation 6** ($\star$). *For any graph class $\mathcal{G}$ closed under adding pendent neighbors and isolated vertices such that ECP (ECC) is* NP*-complete on $\mathcal{G}$, it is* NP*-complete to decide whether a graph $G \in \mathcal{G}$ given together with its maximum independent set has an edge clique partition (cover) of size at most $\alpha(G)$.*

The following lemma plays the most fundamental role for ECC/α and ECP/α.

▶ **Lemma 7.** *Let G be a graph without isolated vertices, and let $\mathcal{C}$ be an edge clique cover (partition) of G of size at most $\alpha(G) + k$ for an integer $k \geq 0$. Then*

(i) *at most k vertices of any maximum independent set are non-simplicial,*

(ii) *at most $2k$ cliques of $\mathcal{C}$ are non-simplicial.*

Proof. As an edge clique partition is an edge clique cover, it is sufficient to show the claim when $\mathcal{C}$ is an edge clique cover of size at most $\alpha(G)+k$. Let X be a maximum independent set of G. Clearly, any clique of G contains at most one vertex of X by independence. Because G has no isolated vertices, each vertex $v \in X$ is included in at least one clique of $\mathcal{C}$. Furthermore, v is simplicial if v is included in a single clique of $\mathcal{C}$. Since $|\mathcal{C}| \leq \alpha(G) + k$, we obtain that at least $\alpha(G) - k$ vertices of X are contained in exactly one clique of $\mathcal{C}$. Therefore, at least

$\alpha(G) - k$ vertices of X are simplicial, and at least $\alpha(G) - k$ cliques of $\mathcal{C}$ are simplicial. This means that at most k vertices of X are non-simplicial and proves (i). To show (ii), note that because at least $\alpha(G) - k$ cliques of $\mathcal{C}$ are simplicial, at most $2k$ cliques could be non-simplicial. This concludes the proof. ◀

In particular, this lemma implies that ECC/α and ECP/α are trivial for $k = 0$.

▶ **Observation 8** ($\star$). *ECC/α and ECP/α can be solved in polynomial time for $k = 0$.*

We use Lemma 7 to argue that for graphs admitting an edge clique cover of bounded size, we can compute $\alpha(G)$.

▶ **Lemma 9** ($\star$). *Let G be a graph and let $\mathcal{C}$ be an edge clique cover (partition) of G of size at most k. Then $\alpha(G)$ can be computed in $\mathcal{O}(2^k \cdot k^2 n)$ time.*

We remark that our algorithm from Lemma 9 can be easily modified to output an independent set of maximum size.

3 Clique Partition above Independent Set

In this section, we prove Theorem 1. For this, we need several auxiliary results. We start with the classical result of de Bruijn and Erdős from 1948 [14].

▶ **Proposition 10** (de Brujin and Erdős [14]). *For any $n \geq 3$, an edge clique partition of K_n into cliques of size at most $n - 1$ contains at least n cliques.*

To solve ECP/α, we use as a black box an algorithm for ECP parameterized by the number of cliques in a solution. The state-of-the-art FPT algorithm was given by Feldmann, Issac, and Rai [18].

▶ **Proposition 11** (Feldmann, Issac, Rai [18]). *ECP can be solved in $2^{\mathcal{O}(k^{3/2}\log k)} \cdot n^{\mathcal{O}(1)}$ time where k is the maximum number of cliques in a solution. Furthermore, the algorithm outputs an edge clique partition of size at most k if it exists.*

Next, we show that combining Lemma 7, Lemma 9, and Proposition 11, we can compute $\alpha(G)$ for graphs admitting an edge clique partition of size at most $\alpha(G) + k$.

▶ **Lemma 12.** *There is an algorithm with running time $2^{\mathcal{O}(k^{3/2}\log k)} \cdot n^{\mathcal{O}(1)}$ that, given an instance (G, k) of ECP/α, either computes $\alpha(G)$ or correctly reports that (G, k) is a no-instance of ECP/α.*

Proof. Let G be a graph without isolated vertices. We compute the set $\mathcal{S}$ of all simplicial cliques and select a simplicial vertex in each simplicial clique. Denote by X the obtained set of simplicial vertices. It is well-known that G has a maximum independent set U such that $X \subseteq U$. This implies that $\alpha(G) = \alpha(H) + |\mathcal{S}|$ where $H = G[W]$ for $W = V(G) \setminus \bigcup_{S\in\mathcal{S}} S$. If G admits an edge clique partition of size at most $\alpha(G) + k$ then, by Lemma 7, at most $2k$ cliques of the partition are non-simplicial. Notice that the edges of H can be covered only by non-simplicial cliques. Therefore, H should have an edge clique partition of size at most $2k$. We apply the algorithm from Proposition 11 to H and check in $2^{\mathcal{O}(k^{3/2}\log k)} \cdot n^{\mathcal{O}(1)}$ time whether H has an edge clique partition of size at most $k' = 2k$. If the algorithm reports that such a partition does not exist then we conclude that (G, k) is a no-instance of ECP/α. Otherwise, the algorithm outputs an edge clique partition $\mathcal{C}$ of size at most $2k$. Given this partition, we use the algorithm from Lemma 9 to compute $\alpha(H)$ in $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ time. Then

we output $\alpha(G) = \alpha(H) + |\mathcal{S}|$. Because simplicial cliques can be found in polynomial time, for example, by the algorithm of Kloks, Kratsch, and Müller [35], the overall running time is $2^{\mathcal{O}(k^{3/2}\log k)} \cdot n^{\mathcal{O}(1)}$. This concludes the proof. ◀

By the following claim, which is proved by making use of Proposition 10, we show that all cliques of size at least $6k+1$ that belong to any solution to an instance of ECP/α can be found in polynomial time.

▶ **Lemma 13** ($\star$). *There is a polynomial algorithm that, given an instance (G,k) of ECP/α for $k \geq 1$, either outputs a set $\mathcal{K}$ of cliques of G such that*

- **(i)** *each clique $C \in \mathcal{K}$ is included in any edge clique partition of G of size at most $\alpha(G)+k$,*
- **(ii)** *for every edge clique partition $\mathcal{C}$ of G of size at most $\alpha(G)+k$ and any clique $C \in \mathcal{C}$ of size at least $6k+1$, $C \in \mathcal{K}$,*
- **(iii)** *for any two distinct cliques $C_1, C_2 \in \mathcal{K}$, $|C_1 \cap C_2| \leq 1$,*

or correctly concludes that (G,k) is a no-instance.

Now we are ready to show Theorem 1 which we restate.

▶ **Theorem 1.** *ECP/α can be solved in $2^{\mathcal{O}(k^{3/2}\log k)} \cdot n^{\mathcal{O}(1)}$ time.*

Proof. Let (G,k) be an instance of ECP/α. As pointed out in Observation 8, the problem is trivial if $k=0$. Hence, we assume that $k \geq 1$. First, we call the algorithm from Lemma 12 for (G,k). The algorithm either computes $\alpha(G)$ or correctly reposts that (G,k) is a no-instance of ECP/α. If we obtain a no-instance, we report it and stop. We assume from now on that this is not the case, and the value $\alpha(G)$ is known to us.

In the following step, we construct a partial solution $\mathcal{K}$ using the algorithm from Lemma 13. This algorithm works in polynomial time and either outputs a set $\mathcal{K}$ of cliques of G such that

- **(i)** each clique $C \in \mathcal{K}$ is included in any edge clique partition of G of size at most $\alpha(G)+k$,
- **(ii)** for every edge clique partition $\mathcal{C}$ of G of size at most $\alpha(G)+k$ and any clique $C \in \mathcal{C}$ of size at least $6k+1$, $C \in \mathcal{K}$,
- **(iii)** for any two distinct cliques $C_1, C_2 \in \mathcal{K}$, $|C_1 \cap C_2| \leq 1$,

or correctly concludes that (G,k) is a no-instance. If the algorithm returns that (G,k) is a no-instance then we return the answer and stop. We also conclude that (G,k) is a no-instance if $|\mathcal{K}| > \alpha(G)+k$. From now on, we assume that $\mathcal{K}$ is a set of cliques that are included in any edge clique partition of size at most $\alpha(G)+k$ such that any two distinct cliques of $\mathcal{K}$ do not cover the same edge.

Next, we list all distinct simplicial cliques of G and denote by $\mathcal{S}$ the set of simplicial cliques. We say that a clique $S \in \mathcal{S}$ is *broken* in a (potential) solution to (G,k), if S is not included in the edge clique partition. Notice that if S is a broken simplicial clique, then at least two distinct non-simplicial cliques should be used to cover the edges incident to the corresponding simplicial vertex. By Lemma 7, any edge clique partition of size at most $\alpha(G)+k$ can include at most $2k$ non-simplicial cliques. Thus, for any solution, the number of broken simplicial cliques should not exceed k. Our algorithm identifies the set $\mathcal{B}$ of broken cliques in a solution.

We initialize $\mathcal{B}$ using the following branching algorithm. Consider the auxiliary graph H whose nodes are simplicial cliques. Two distinct nodes $S_1, S_2 \in \mathcal{S}$ are adjacent in H if and only if $|S_1 \cap S_2| \geq 2$. Observe that if $|S_1 \cap S_2| \geq 2$ then either S_1 or S_2 should be broken in a solution. Thus, the set of broken cliques in any solution should be a vertex cover of H of size at most k. We can decide in $\mathcal{O}(2^k \cdot n)$ time whether H has a vertex cover of size at most k and, moreover, we can list all inclusion minimal vertex covers using the standard recursive branching algorithm for Vertex Cover (see [12]). If H has no vertex cover of

size at most k, we report that (G,k) is a no-instance of ECP/α and stop. Assume that this is not the case. Then we obtain the list $\mathcal{L}$ of all inclusion minimal vertex covers of H of size at most k. Notice that $|\mathcal{L}| \leq 2^k$. Then if (G,k) admits an edge clique partition of size at most $\alpha(G)+k$, there is $L \in \mathcal{L}$ such that $L \subseteq \mathcal{B}$ – the set of broken cliques in $\mathcal{C}$. To initialize $\mathcal{B}$, we branch on all possible choices of $L \in \mathcal{L}$ and set $\mathcal{B} := L$. If we find a solution for some choice of L, we output it and stop. Otherwise, if we fail to find an edge clique partition of size at most $\alpha(G)+k$ for any initial selection of $\mathcal{B}$, we report that (G,k) is a no-instance of ECP/α.

From now on, we assume that the initial choice of $\mathcal{B}$ is fixed from one of at most 2^k choices given by $\mathcal{L}$. We update $\mathcal{B}$ by adding cliques that get broken because of the cliques in the partial solution. Notice that if $S \notin \mathcal{K}$ is a simplicial clique covering the same edge as one of the cliques in the partial solution, then S has to be broken. This implies the correctness of the following step:

- For every simplicial clique $S \notin \mathcal{B} \cup \mathcal{K}$ such that $|S \cap K| \geq 2$ for some $K \in \mathcal{K}$, set $\mathcal{B} := \mathcal{B} \cup \{S\}$.
- If $|\mathcal{B}| > k+1$ then stop and discard the current choice of L.

Assume that the algorithm does not stop in this step. We call the set $\mathcal{B}$ obtained in this step a *base set of broken cliques*.

We say that a simplicial clique S is *free* if $S \notin \mathcal{B} \cup \mathcal{K}$, and we use $\mathcal{F}$ to denote the set of free cliques. Lemma 13 and the construction of $\mathcal{B}$ imply the following property.

▷ Claim 14. For any two distinct cliques $S_1, S_2 \in \mathcal{F} \cup \mathcal{K}$, $|S_1 \cap S_2| \leq 1$.

This means that no edge of G is covered by two cliques of $\mathcal{F} \cup \mathcal{K}$. In the final step of our algorithm, we try to extend $\mathcal{F} \cup \mathcal{K}$ to an edge clique partition of G of size at most $\alpha(G)+k$. If we fail, then we recurse by including one of the free cliques to the set of broken cliques. Formally, we use the subroutine Extend$(\mathcal{F},\mathcal{B})$ in Algorithm 1 which either finds a solution extending $\mathcal{K}$, such that all cliques in $\mathcal{B}$ are broken, or discards the current choice of $\mathcal{F}$ and $\mathcal{B}$.

The description of the algorithm is finished. To argue correctness, observe that in each recursive call of the algorithm, we increase the size of $\mathcal{B}$ and stop if $|\mathcal{B}| > k$ in line 2. This means that Extend$(\mathcal{F},\mathcal{B})$ is finite. If this subroutine outputs a set of cliques $\mathcal{C}^*$ then it is a valid edge partition of G. First, because of Claim 14, no two cliques intersect. Second, the cover $\mathcal{C}$, constructed by the algorithm from Proposition 11 in line 5, outputs an edge clique partition for the edges which are not covered by the cliques of $\mathcal{F} \cup \mathcal{K}$. Since we verify that $|\mathcal{C}^*| \leq \alpha(G)+k$ in line 7, if the algorithm outputs some $\mathcal{C}^*$ then it is a valid solution to (G,k). Thus, we have to show that if (G,k) is a yes-instance of ECP/α, then the algorithm necessarily finds a solution. For this, we show the following claim.

▷ Claim 15 ($\star$). Suppose that G has an edge clique partition of size at most $\alpha(G)+k$ such that all simplicial cliques in $\mathcal{B}$ are broken. Suppose also that $\mathcal{B}$ contains the base set of broken cliques, and let $\mathcal{F}$ be the set of simplicial cliques S such that $S \notin \mathcal{B} \cup \mathcal{K}$. Then Extend$(\mathcal{F},\mathcal{B})$ outputs a solution to (G,k).

To complete the correctness proof, observe that if (G,k) is a yes-instance of ECP/α then there is $L \in \mathcal{L}$ such that every clique of L is broken in a solution. Then for the base set of broken cliques $\mathcal{B}$ constructed for L, each clique of $\mathcal{B}$ should be broken. By Claim 15, Extend$(\mathcal{F},\mathcal{B})$ called for this $\mathcal{B}$ and the corresponding set of free cliques $\mathcal{F}$ should output an edge clique partition of size at most $\alpha(G)+k$. This completes the correctness proof.

We conclude the proof with a claim explaining the running time bound.

Algorithm 1 EXTEND$(\mathcal{F}, \mathcal{B})$.

Input: $\mathcal{F}$, $\mathcal{B}$
Result: An edge clique cover of G or No
begin
  if $|\mathcal{B}| > k$ **then return** No and quit;
  construct the graph Q with the edge set $R = \{uv \in E(G) \mid$ there is no clique $K \in \mathcal{F} \cup \mathcal{K}$ s.t. $u, v \in K\}$, whose vertex set is the set of the endpoints of the edges of R; note that R is the set of edges which are not covered by $\mathcal{F} \cup \mathcal{K}$;
  if $|V(Q)| > 12k^2$ **then return** No and quit;
  use the algorithm from Proposition 11 to find an edge clique partition $\mathcal{C}$ of Q of minimum size $k' \leq 2k$ if such a partition exists;
  if *the algorithm returns* $\mathcal{C}$ **then**
    if $|\mathcal{C}^*| \leq \alpha(G) + k$ *for* $\mathcal{C}^* = \mathcal{C} \cup \mathcal{F} \cup \mathcal{K}$ **then return** $\mathcal{C}^*$ and quit;
  end
  foreach $uv \in E(G)$ *such that* $u, v \in V(Q)$ *and there is* $F \in \mathcal{F}$ *with* $u, v \in F$ **do**
    if *a call to* EXTEND$(\mathcal{F} \setminus \{F\}, \mathcal{B} \cup \{F\})$ *returns a solution* $\mathcal{C}^*$ **then**
      return $\mathcal{C}^*$ and quit;
    end
  end
  return No
end

▷ Claim 16 (⋆). The algorithm runs in $2^{\mathcal{O}(k^{3/2} \log k)} \cdot n^{\mathcal{O}(1)}$ time.

The proof is complete. ◀

In the conclusion of this section, we remark that the algorithm of Proposition 11 is a bottleneck for the running time of our algorithm for ECP/α. More precisely, given an algorithm solving ECP in time $f(k) \cdot n^{\mathcal{O}(1)}$, the running time of our algorithm is $k^{\mathcal{O}(k)} f(2k) \cdot n^{\mathcal{O}(1)}$. Furthermore, consider the graph G' obtained from a graph G by adding a pendent neighbor to each vertex of G. Since $\mathrm{ecp}(G') = \alpha(G') + \mathrm{ecp}(G)$, a faster algorithm for ECP/α would improve the algorithm of Proposition 11.

4 Clique Cover above Independent Set

In this section, we establish the dichotomy result for ECC/α by showing Theorem 2 and Theorem 3. For this, we need some auxiliary results about relations of EDGE CLIQUE COVER ABOVE INDEPENDENT SET with other problems which will be useful also in Section 5. Therefore, we put them in a separate subsection.

4.1 Reductions between ECC/α, Annotated ECC, and k-Coloring

Following Orlin [42], we consider the generalization of ECC where the aim is to cover a subset of edges.

Annotated Edge Clique Cover (Annotated ECC) parameterized by k

Input:	A graph G, an edge set $B \subseteq E(G)$, an integer k.
Task:	Find k cliques in G, such that each edge in B belongs to at least one clique.

Recall that $\mathrm{ecc}(G)$ denotes the size of the smallest edge clique cover of G. Similarly, in the context of Annotated ECC, for a graph G and a subset of its edges $B \subseteq E(G)$, we denote by $\mathrm{aecc}_B(G)$ the size of the smallest collection of cliques in G that cover all edges in B.

▶ **Lemma 17** (⋆). *ECC/α admits an* FPT*-Turing-reduction to Annotated ECC, where an instance (G, k) is reduced to at most $2k$ instances (G', R', k') such that G' is an induced subgraph of G and $k' \leq 2k$. The reduction works in time $4^k \cdot n^{\mathcal{O}(1)}$.*

The running time of Lemma 17 is dominated by computing the maximum independent set in an induced subgraph, and the reduction can be performed more efficiently on certain graph classes, where instead of Lemma 9 one can compute the independent set directly with a faster algorithm. To accomodate for this, we state the following corollary of Lemma 17.

▶ **Corollary 18** (⋆). *Let $\mathcal{G}$ be a hereditary graph class. ECC/α admits an* FPT*-reduction to Annotated ECC, where an instance (G, k) with $G \in \mathcal{G}$ is reduced to at most $2k$ instances (G', R', k') such that G' is an induced subgraph of G and $k' \leq 2k$. If it can be determined in time $f(k) \cdot n^{\mathcal{O}(1)}$ whether a graph in $\mathcal{G}$ has an independent set of size k, then the reduction admits the same running time bound.*

Next, we show that Annotated ECC can be, in turn, reduced to the k-Coloring problem. We note that the reduction is almost the same as the standard conversion from ECC to Vertex Clique Cover, as introduced by Kou, Stockmeyer and Wong [36].

▶ **Lemma 19** (⋆). *Annotated ECC is polynomial-time reducible to k-Coloring on a graph with $|B|$ vertices.*

As k-Coloring is polynomial-time solvable when $k \leq 2$, we immediately get the following corollary.

▶ **Corollary 20.** *Annotated ECC is polynomial-time solvable for $k \leq 2$.*

We note that a polynomial-time reduction from k-Coloring or Vertex Clique Cover to Annotated ECC follows immediately from a reduction to ECC.

4.2 Dichotomy for ECC/α

In this subsection, we prove that ECC/α is Para-NP-complete when parameterized by k. More precisely, we show that the problem is NP-complete for every $k \geq 2$ on instances where the graph is perfect without isolated vertices. We complement this result by proving that for $k = 0$ or 1, the problem is in P. We start with obtaining the following result for Annotated ECC. The arguments are similar to the arguments of Orlin [42].

▶ **Lemma 21** (⋆). *Annotated ECC is* NP*-complete on co-bipartite graphs for every $k \geq 3$. Furthermore, the hardness holds for the case when B is a perfect matching between the bipartition sets.*

We use Lemma 21 to prove Theorem 2. We restate it here.

▶ **Theorem 2.** *For every $k \geq 2$, ECC/α is* NP*-complete. Furthermore, the hardness holds even on perfect graphs.*

Proof. We use Lemma 21 and reduce from Annotated ECC.

Let (G, B, k) be an instance of Annotated ECC where G is an n-vertex co-bipartite graph for $n \geq 2$. We also assume that B is a perfect matching in G, that is, each vertex of G is incident to an edge of B. We set $R = E(G) \setminus B$ and construct the graph G' as follows.

- Construct a copy of G.
- Construct a vertex v and make it adjacent to each vertex of G.
- For each vertex $x \in V(G)$, construct a vertex u_x and make it adjacent to x.
- For every edge $e = xy \in R$, construct a vertex w_e and make it adjacent to x and y.

Because G is a co-bipartite graph with at least two vertices that has a perfect matching, G has no isolated vertices. Then the construction implies that the same holds for G'. Notice that G' is a perfect graph. To see this, we use the perfect graph theorem [10]. Trivially, a vertex of degree one does not belong to any odd hole or antihole. For any vertex w_e for $e \in R$, w_e does not belong to any odd hole because the neighbors of w_e are adjacent, and w_e does not belong to any antihole with at least 7 vertices because the degree of w_e is two. Since the graph obtained from the co-bipartite graph G by adding the universal vertex v is co-bipartite, this graph is perfect. This immediately implies that G' is perfect.

Consider the set $I = \{v\} \cup \{u_x \mid x \in V(G)\} \cup \{w_e \mid e \in R\}$. By the construction of G', I is an independent set of size $|R| + n + 1$. We claim that I is a maximum independent set. To see this, note that the vertices of $I' = \{u_x \mid x \in V(G)\} \cup \{w_e \mid e \in R\}$ are simplicial. Therefore, there is a maximum independent set of G' containing I'. Since v is the unique vertex nonadjacent to the vertices of I', we obtain that the size of I is maximum. Thus, $\alpha(G') = |R| + n + 1$.

We set $k' = k - 1$ and claim the following.

▷ Claim 22 (⋆). (G, B, k) is a yes-instance of Annotated ECC if and only if (G', k') is a yes-instance of ECC/α.

This concludes the proof of the theorem. ◀

As a corollary of Lemma 19 and Corollary 20, we obtain that when $k = 0$ or $k = 1$, ECC/α can be solved in polynomial time. Thus, combining Theorem 2 and Theorem 3, we get the computational complexity dichotomy for the problem with respect to k.

▶ **Theorem 3.** *ECC/α admits polynomial-time algorithms for $k \in \{0, 1\}$.*

Proof. Given an instance (G, k) of ECC/α for $k \leq 1$, the algorithm from Lemma 17 in polynomial time reduces the problem to solving at most two instances (G', B, k') of Annotated ECC where $k' \leq 2$. Then we apply the algorithm from Corollary 20 to the obtained instances and solve the problem in polynomial time. ◀

Using the result of Orlin [42] about the NP-completeness of the Edge Biclique Cover problem, it is easy to see that ECC is NP-complete on co-bipartite graphs. This result immediately implies that ECC/α is NP-complete on co-bipartite graphs. We provide the proof for completeness in [21].

▶ **Observation 23** (⋆). *ECC/α is* NP*-complete on co-bipartite graphs.*

Because ECC/α is NP-complete on co-bipartite graphs, we have that for every integer $p \geq 2$, NP-complete on graphs G with $\alpha(G) \leq p$. It is trivial to see that if $\alpha(G) = 1$ then G is a complete graph and, therefore, the edges of G can be covered by a single clique.

Theorem 2 and Observation 23 imply that ECC/α is Para-NP-hard when parameterized by either k or the independence number. Because ECC is FPT when parameterized by the number of cliques in a solution [24], it is straightforward to make the following observation.

▶ **Observation 24.** *ECC/α is* FPT *when parameterized by both k and the independence number of the input graph.*

5 Covering Sparse Graphs

In this section, we design FPT algorithms for ECC/α for several well-studied graph classes, where ECC or Independent Set remain NP-complete. We build on Lemma 17 (and Corollary 18), that allow us to transform parameterized algorithms for Annotated ECC (and Independent Set) on a graph class $\mathcal{G}$, into parameterized algorithms for ECC/α on $\mathcal{G}$. The only requirement for $\mathcal{G}$ is being closed under deletion of simplicial vertices.

In the first two subsections of this section, we give parameterized algorithms for Annotated ECC on K_r-free, d-degenerate and H-minor-free graphs. In the third subsection, we combine these algorithms into corresponding algorithms for ECC/α, proving Theorem 4. Finally, we complement these results with lower bounds based on the Exponential Time Hypothesis.

5.1 Bounded Clique Number

Annotated ECC on K_r-free graphs can alternatively be seen as Annotated ECC parameterized by $k+\omega$, where ω is the maximum clique size in G. Naturally, we cannot have more than $\binom{\omega}{2} \cdot k$ edges in B in a yes-instance of Annotated ECC, which hints that Annotated ECC should be FPT with respect to $k + \omega$. There is, however, a crucial obstacle: computing ω is NP-hard and W[1]-hard when parameterized by ω.

Fortunately, independent sets of size more than k in G will guarantee that (G, B, k) is a no-instance. This allows us to use the classical Ramsey's theorem [45] to either conclude that the instance is negative or to find ω. Formally, we use the following algorithmic result that is derived from the Ramsey number upper bound given by Erdős and Szekeres [17].

▶ **Proposition 25** (Adaptation of a proof by Erdős and Szekeres [17])**.** *There is a polynomial-time algorithm that, given n-vertex graph G and two integers p, q such that $n \geq \binom{p+q-2}{p-1}$, finds either a clique of size p or an independent set of size q in G.*

We are ready to prove that Annotated ECC is FPT with respect to $k + \omega$.

▶ **Lemma 26.** *Annotated ECC is fixed-parameter tractable with respect to the combined parameter $k + \omega$. The running time of the corresponding algorithm is $2^{\binom{\omega}{2} \cdot k} \cdot n^{\mathcal{O}(1)}$. The value of ω needs not to be given in the input.*

Proof. We present an algorithm that finds a solution to the given instance (G, B, k) of Annotated ECC. We assume that G, B are not empty, as otherwise the instance is trivial. If $k \leq 2$, we use the algorithm of Corollary 20 as a subroutine to solve the instance in polynomial time. We explain how the algorithm deals with the general case $k \geq 3$ in several steps below.

Triangle-free check. The algorithm first checks whether G is triangle-free, that is, $\omega > 2$. This is performed in polynomial time. If G has $\omega = 2$, then no two edges can belong to the same clique in G, so optimal cover of edges in B consists of $|B|$ cliques. Hence, if G turns out to be triangle-free, then the algorithm reports that (G, B, k) is a yes-instance if $|B| \leq k$ and no-instance otherwise.

Clique or independent set. If there is a vertex $v \in V(G)$ without incident edges in B, then there exists an optimal solution where none of the cliques contain v. The algorithm removes all such vertices from G. Now any solution to (G, B, k) should contain each vertex of G in at least one of the cliques. The algorithm then finds the largest r such that $n \geq \binom{k+r-1}{k}$ and $n < \binom{k+r}{k}$. Substituting r and $k+1$ in Proposition 25, the algorithm finds either an independent set of size $k+1$ in G or a clique of size r in G in polynomial time. An independent set of size $k+1$ guarantees that (G, B, k) is a no-instance, as it is impossible to cover each vertex of G by using at most k cliques. With this outcome, our algorithm reports a no-instance and stops. In the complementary case, we have that $\omega \geq r$ and $n < \binom{k+\omega}{k}$.

Computing ω. For an integer $p \geq 3$, $\omega < p$ can be verified in time $\mathcal{O}(p^2 \cdot n^p)$. As the next step, the algorithm computes the exact value of ω by performing these checks iteratively for consecutive integer values starting from $\max\{4, r+1\}$ up to $\omega + 1$. This routine takes $n^{\omega+\mathcal{O}(1)}$ running time. To give an upper bound on the running time in terms of k and ω, we need the following claim.

▷ Claim 27 (⋆). If a, b are positive integers with $a, b \geq 3$, then $\binom{a+b}{b} \leq 2^{\frac{ab}{2}}$.

By substituting $k, \omega \geq 3$ in Claim 27, we obtain

$$n^{\omega-1} < \binom{k+\omega}{\omega}^{\omega-1} < \left(2^{\frac{k\omega}{2}}\right)^{\omega-1} = 2^{\binom{\omega}{2}\cdot k}.$$

Hence, it takes time $2^{\binom{\omega}{2}\cdot k} \cdot n^{\mathcal{O}(1)}$ for the algorithm to compute the exact value of ω.

Solution via set cover. No clique in G can cover more than $\binom{\omega}{2}$ edges in B. Thus, if $|B| > \binom{\omega}{2} \cdot k$, the algorithm reports correctly that (G, B, k) is a no-instance. Otherwise, the algorithm reduces (G, B, k) to an instance $(B, \mathcal{F}, k)$ of Set Cover. In this instance, B is treated as the universe set. Subset family $\mathcal{F}$ consists of subsets of B, and a subset $B' \subset B$ belongs to $\mathcal{F}$ if and only if all edges of B' belong simultaneously to the same clique in G. Clearly, (G, B, k) is a yes-instance if and only if B can be covered by at most k sets from $\mathcal{F}$, i.e. $(B, \mathcal{F}, k)$ is a yes-instance of Set Cover.

The Set Cover instance is constructed in time $2^{|B|} \cdot n^{\mathcal{O}(1)}$ by the algorithm. Using the celebrated subset convolution algorithm for Set Cover due to Björklund, Husfeldt and Koivisto [5] as a subroutine, our algorithm finally decides $(B, \mathcal{F}, k)$ within the same $2^{|B|} \cdot n^{\mathcal{O}(1)}$ running time bound. The overall running time is therefore dominated by $2^{\binom{\omega}{2}\cdot k} \cdot n^{\mathcal{O}(1)}$. ◀

Consequent parts of Section 5 are omitted and can be found in the full version of the paper [21].

Near-Optimal Vertex Fault-Tolerant Labels for Steiner Connectivity

Koustav Bhanja

Abstract

We present a compact labeling scheme for determining whether a designated set of terminals in a graph remains connected after any f (or less) vertex failures occur. An *f-FT Steiner connectivity labeling scheme* for an n-vertex graph $G = (V, E)$ with terminal set $U \subseteq V$ provides labels to the vertices of G, such that given only the labels of any subset $F \subseteq V$ with $|F| \leq f$, one can determine if U remains connected in $G - F$. The main complexity measure is the maximum label length.

The special case $U = V$ of global connectivity has been recently studied by Jiang, Parter, and Petruschka [33], who provided labels of $n^{1-1/f} \cdot \text{poly}(f, \log n)$ bits. This is near-optimal (up to $\text{poly}(f, \log n)$ factors) by a lower bound of Long, Pettie and Saranurak [37]. Our scheme achieves labels of $|U|^{1-1/f} \cdot \text{poly}(f, \log n)$ for general $U \subseteq V$, which is near-optimal for any given size $|U|$ of the terminal set. To handle terminal sets, our approach differs from [33]. We use a well-structured Steiner tree for U produced by a decomposition theorem of Duan and Pettie [24], and bypass the need for Nagamochi-Ibaraki sparsification [40].

1 Introduction

Labeling schemes are distributed graph data structures with many applications in graph algorithms and distributed computing. The goal is to assign the vertices (and/or edges) of the graph with succinct yet informative labels, so that queries of interest can be answered from only the labels of the query arguments, without any access to the graph or to any other centralized storage. The main complexity measure is the *label length*, which is the maximum number of bits stored in a single label; construction and query time are secondary measures. Diverse types of labeling have been studied, with notable examples being adjacency [14, 15, 34, 4, 7], ancestry and least common ancestors in trees [1, 6], exact or approximate distances [46, 26, 5, 12, 27], and pairwise edge- or vertex-connectivity [35, 30, 31, 44].

The error-prone nature of many real-life networks has further motivated researchers to consider labeling schemes designed to support events of failures in the graph. Courcelle and Twig [19] were the first to explicitly define and study *fault-tolerant (FT)* (a.k.a *forbidden set*) labeling schemes, where the goal is to answer queries subject to the failure (i.e., deletion) of a set F of vertices or edges in the graph. Here, the set F is part of the query arguments, so the labels assigned to F are available to the query algorithm. Usually, $|F|$ is assumed to be bounded by some integer parameter $f \geq 1$ (this is abbreviated to the f-FT model). A lot of the works on FT labeling studied special graph families, such as planar or bounded doubling-dimension graphs [19, 18, 2, 3, 8, 13]. In this work, we consider a general n-vertex (undirected) graph $G = (V, E)$ and focus on connectivity-related f-FT labeling schemes.

s-t connectivity. The "s-t variant" of this problem has been extensively studied in recent years. Here, a query consists of a triplet (s, t, F), and it is required to determine if s, t are connected in $G - F$. The study of f-FT s-t connectivity labeling was initiated by Dory and Parter [23] with subsequent works in [32, 41, 42, 37], rendering it reasonably well-understood by now: it is known to admit very succinct labels of only $\text{poly}(f, \log n)$ bits, either with edge failures or with vertex failures; we refer to [37] for a detailed presentation of the state-of-the-art bounds.

Global connectivity. Parter, Petruschka and Pettie [42] have proposed the "global connectivity" variant, where the query consists only of F, and it is required to determine if $G-F$ is a connected graph. Unlike with s-t connectivity, the global variant turns out to behave very differently with edge failures ($F \subseteq E$) or with vertex failures ($F \subseteq V$). Essentially all known labeling schemes for the s-t connectivity variant under edge failures [23, 32, 37] also solve the global variant en route, hence the latter also admits succinct $\text{poly}(f, \log n)$-bit labels. However, in case of vertex failures, it was shown in [42] that polynomial dependency in f is impossible, and their lower bound was improved to $\Omega(n^{1-1/f}/f)$ by Long, Pettie and Saranurak [37]. Very recently, Jiang, Parter and Petruschka [33] gave a nearly matching upper bound by providing a construction of f-FT global connectivity labels of $n^{1-1/f} \cdot \text{poly}(f, \log n)$ bits, essentially settling the problem.

Steiner connectivity. In this work, we study the natural generalization of the problem to *Steiner connectivity*. In this variant, the graph $G = (V, E)$ comes with a (fixed) subset of designated vertices $U \subseteq V$ called *terminals*. Given a query $F \subseteq V \cup E$ of up to f faulty vertices/edges, it is required to report if F is a *U-Steiner cut* in G, i.e., if there is a pair of disconnected terminals in $G - F$. Note that U is fixed and not a part of the query, so we only get to see the labels of F.[1] We call this variant *f-FT Steiner connectivity labeling scheme*.

We first note that the lower bound for the global connectivity variant of [37] immediately yields a lower bound for the Steiner setting as well:[2]

▶ **Theorem 1** ([37]). *Any f-FT Steiner connectivity labeling schemes for n-vertex graphs with k terminals must have label length of $\Omega(k^{1-1/f}/f)$ bits (in the worst case).*

Our technical contribution is providing a nearly matching upper bound which is optimal up to $\text{poly}(f, \log n)$ factors, hence generalizing the result of [33] (recovered when $U = V$):

[1] If we also get the labels of U, we can just use the $\text{poly}(f, \log n)$-bit labels of the s-t variant, and apply $|U| - 1$ pairwise connectivity queries (between one terminal in U to all the others) in $G - F$.

[2] Construct the lower bound instance of [37] on k vertices set as terminals, and add $n - k$ isolated vertices.

▶ **Theorem 2.** *For every n-vertex graph $G = (V, E)$ with terminal set $U \subseteq V$ and $f \geq 1$, there is an f-FT Steiner connectivity labeling scheme for (G, U) with labels of $|U|^{1-1/f} \cdot \text{poly}(f, \log n)$ bits. The labels are computed deterministically in polynomial time.*

The f-FT Steiner connectivity labeling scheme of Theorem 2 supports any query $F \subseteq V \cup E$ of vertices and edges with $|F| \leq f$. However, the challenge lies entirely in the case of vertex failures, i.e., $F \subseteq V$: proving Theorem 2 for this case implies also the general case. Indeed, we can construct a new instance (G', U) where G' is obtained from G by splitting each edge e of G by a new middle v_e, so the failure of e in G is equivalent to the failure of v_e in G' (in terms of affect on connectivity between original vertices).

As for the case of only edge failures $F \subseteq E$, much like in the global connectivity variant, it behaves very differently and admits labels of $\text{poly}(f, \log n)$ bits, implicit by known constructions of f-FT connectivity labels for pairwise connectivity queries (the standard s-t variant in the literature). Specifically, both the labels of [23] based on linear graph sketches and its derandomized version in [32] are straightforward to augment to answer Steiner connectivity queries,[3] and other constructions in [23, 37] seem plausibly amenable to such augmentations as well. In light of the discussions above, in the rest of the paper we will only consider the case of vertex failures, i.e., queries are of the form $F \subseteq V$ with $|F| \leq f$.

Related work: Steiner variants. We mention that providing "Steiner generalizations" that interpolate between the two extreme scenarios of the terminal set ($|U| = n$ and $|U| = 2$) is a common objective in various algorithmic and graph-theoretic problems, such as computing Steiner mincut [22, 17, 29, 20], data structures for Steiner mincuts [21, 22, 9] and minimum+1 Steiner cuts [11], sensitivity oracles for Steiner mincuts [10, 11], Steiner connectivity augmentation and splitting-off [16] and construction of cactus graphs for compactly storing and characterizing Steiner mincuts [22, 29].

Related work: connectivity oracles. FT connectivity labeling schemes can be seen as distributed versions of *connectivity oracles under failures*, which are centralized data structures designed to answer the same kind of queries. These have been extensively studied especially in the s-t variant, with both edge faults [43, 24, 28] and vertex faults [24, 47, 38, 45, 36, 39]. Much like with labeling schemes, in the global variant of connectivity oracles, vertex failures require much larger complexity than edge failures, as was first observed by Long and Saranurak [38]. Very recently, Jiang, Parter and Petruschka [33] provided almost-optimal oracles for global connectivity under vertex failures, and their approach seems plausible to extend also to the Steiner variant.

1.1 Our Approach

While our scheme of Theorem 2 and its formal analysis are not complicated, the intuitions behind them might seem illusive. In this section we aim to clarify these. We first introduce a warm-up suboptimal labeling scheme for the Steiner case, then survey the solution of [33] for the global variant, and finally explain how we "glue together" ideas from both to get our solution. For notational convenience, we use here $\tilde{O}(\cdot)$ to hide $\text{poly}(f, \log n)$ factors.

[3] These are based on fixing some spanning tree T for G, and reconnecting the connected components of $T - F$ to obtain those of $G - F$. Augment the label of each tree edge with the number of terminals in the subtree below it. Then we can invoke a similar strategy to the sketch computation in [23, 32] to determine the number of terminals in each component of $T - F$, and hence also of $G - F$.

A basic building block are the previously-introduced f-FT labels for the s-t connectivity variant, with length $\tilde{O}(1)$ bits [42, 37]. Their construction is highly complicated, but we use them as a black-box. Let $\ell(\cdot)$ denote these labels, and $L(\cdot)$ the labels that we construct; each $L(\cdot)$-label will store many $\ell(\cdot)$-labels.

Warm-up: using degree classification. To gain intuition, we first sketch a *suboptimal* construction based on a strategy introduced in [41]. Assume first $U = V$. Choose an arbitrary spanning tree T in G. Let r be some degree threshold. Let B be the set of vertices with T-degree $\geq r$ (high-deg), and $V - B$ be the rest (low-deg). For a low-deg $x \in V - B$, let $L(x)$ store $\{\ell(x)\} \cup \{\ell(y) \mid y \text{ is } T\text{-neighbor of } x\}$. This handles the following queries:

- **(all-low-deg)** If $F \subseteq V - B$, use the $\ell(\cdot)$-labels to check pairwise connectivity between all T-neighbors of F; one observes that F is a cut in G iff we find some disconnected pair.

To handle the remaining queries where $F \cap B \neq \emptyset$, we use recursion. For each $x \in V$ let $L(x)$ store, for every $y \in B$, x's label *to handle* $f - 1$ *faults in* $G - \{y\}$ (recursively). Then,

- **(one-high-deg)** If there is some $y \in F \cap B$, we answer the query $F - \{y\}$ in $G - y$.

Let b_f denote the resulting label length. As $|B| = O(n/r)$, we get $b_f = \tilde{O}(r + (n/r) \cdot b_{f-1})$. Optimizing r and solving the recurrence (with base case $b_1 = 1$) yields $b_f = \tilde{O}(n^{1-1/2^{f-1}})$.

Generalizing to the Steiner variant with arbitrary terminals $U \subseteq V$ is rather smooth. Essentially, one takes T as a *minimal Steiner tree* that connects all terminals U. Then high-deg vertices in T are only $|B| \leq O(|U|/r)$, which eventually results in $\tilde{O}(|U|^{1-1/2^{f-1}})$-bit labels. The details are provided in the full version of the paper.

Existing solution: the global case. As previously mentioned, Jiang, Parter and Petruschka [33] gave near-optimal labels for the f-FT global connectivity variant, i.e., the case $U = V$. Roughly speaking, they also use a high/low-deg partition B and $V - B$ (with threshold r), but divide queries F in a dual manner to the warm-up above: **(all-high-deg)** $F \subseteq B$, or **(one-low-deg)** $F \cap (V - B) \neq \emptyset$. The high/low-deg partition is w.r.t. to degrees in G, not in a spanning tree. To enable this, they use *Nagamochi-Ibaraki sparsification* [40], yielding a subgraph H of G with $\tilde{O}(n)$ edges such that $G - F$ and $H - F$ have the same connected components, for every $F \subseteq V$, $|F| \leq f$. So w.l.o.g., G has only $m = \tilde{O}(n)$ edges.

To see the broad strokes, we explain their solution in the special case that G is f-vertex-connected. As [33] observe, in this case, if the query F is indeed a cut, then every $x \in F$ is adjacent to every connected component of $G - F$. Thus, for a low-deg $x \in V - B$, one lets $L(x)$ store $\{\ell(y) \mid (x, y) \in E\}$, and answers a query with $x \in F$ by looking for a pair of neighbors disconnected in $G - F$. Note that this argument crucially hinges on the fact that these are all of x's neighbors in the (sparsified) graph G, and not in a spanning tree. To handle queries $F \subseteq B$, one observes that a high-deg $x \in B$ can participate in at most $O(|B|^{f-1})$ such queries, and simply writes the answers to these inside $L(x)$. As $|B| \leq O(m/r)$, the label length is $\tilde{O}(r + (m/r)^{f-1})$. Setting $r = m^{1-1/f}$ gives $\tilde{O}(m^{1-1/f}) = \tilde{O}(n^{1-1/f})$.

Our new solution: the Steiner case. The main issue that prevents extending the solution of [33] to the Steiner case with arbitrary terminals $U \subseteq V$ lies in the sparsification step. Intuitively, to get $\tilde{O}(|U|^{1-1/f})$ label length, we would like to have $\tilde{O}(|U|)$ edges in the sparsified subgraph H, but then preserving connected components under faults is clearly impossible: $|U|$ can be much smaller than $|V|$, so such H cannot even be connected. To tackle this, one may wish to construct other meaningful sparsifiers for Steiner connectivity under faults. This seems to be a challenging task, as even a plausible definition is non-trivial.

Instead, we take a different route and combine the "best-of-both-worlds": we use a Steiner tree for high/low-deg partition as in the warm-up, but (roughly speaking) divide queries F to *all-high-deg* or *one-low-deg* as in [33]. Thus, even in the global case $U = V$, our approach yields a near-optimal scheme which is different than that of [33].

On a high level, the key is not using just any (minimal) Steiner tree T, but one where high-degree vertices B admit a lot of structure, by using a powerful graph decomposition of Duan and Pettie [24]. While it still holds that $|B| \leq O(|U|/r)$, the additional structure is that after deleting B from G, the remaining forest $T - B$ is still a Steiner forest for $U - B$ (i.e., connected terminals in $G - B$ are also connected in $T - B$). The main technical part of our solution lies in a structural analysis that studies the interplay between the (known-in-advance) $G - B$ and $T - B$, and the terminals in the graph $G - F$ defined by a given query F (this is mostly reflected in the correctness proof, specifically Claim 10). Essentially, this extra structure lets us design labels where it is enough for low-deg vertices to be defined w.r.t. the tree, and store the $\ell(\cdot)$-labels of only their tree neighbors.

2 Preliminaries

Throughout the paper, $G = (V, E)$ is an undirected graph with n vertices, $U \subseteq V$ is a designated terminal set in G, and $f \geq 1$ is an integer parameter.

For $K, W \subseteq V$, we say that K *separates* W if there exist two vertices $w, w' \in W - K$ that are disconnected in $G - K$. A vertex set $F \subseteq V$ is called *a cut* in G if it separates V, and a *Steiner cut* if it separates the terminals U.

To shorten statements of theorems, lemmas, etc., we always use the term "algorithm" to mean a deterministic polynomial-time algorithm.

3 Basic Tools

As mentioned in Section 1.1, the most basic tool, which we use as a black box, is the succinct f-FT labels for s-t connectivity:

▶ **Theorem 3** ([37]). *There is an algorithm that outputs an $O(f^4 \log^{7.5}(n))$-bit label $\ell(v)$ to every $v \in V$ with the following property:*

For every $F \subseteq V$ with $|F| \leq f$ and $s, t \in V$, one can determine if s, t are connected in $G - F$, by only inspecting the $\ell(\cdot)$-labels of $F \cup \{s, t\}$.

As explained in Section 1.1, our labels $L(\cdot)$ of Theorem 2 store many $\ell(\cdot)$ labels, and to answer a query F, we make many s-t connectivity queries in $G - F$ using these $\ell(\cdot)$-labels. Suppose that during the query algorithm, we found in this way a pair s, t which is disconnected in $G - F$. Then clearly F is a cut in G, but we still cannot determine that is a *Steiner cut*, as one of s, t might lie in a connected component of $G - F$ without any terminals. We now present a simple tool that augments Theorem 3 to help us detect this situation.

▶ **Lemma 4.** *There is an algorithm that outputs an $O(f^4 \log^{7.5})$-bit label $\bar{\ell}(v)$ to every $v \in V$ with the following property:*

For every $F \subseteq V$ with $|F| \leq f$ and $x \in V$, one can determine there exists some $u \in U$ such that x, u are connected in $G - F$, by only inspecting the $\bar{\ell}(\cdot)$-labels of $F \cup \{x\}$.

Proof. Construct an auxiliary graph G' from G by adding a new vertex z and adding an edge (z, u) for every terminal $u \in U$. Let $\ell'(\cdot)$ be the labels computed by the algorithm of Theorem 3 on G', and define $\bar{\ell}(v) := (\ell'(v), \ell'(z))$. Now, let $F \subseteq V$ with $|F| \leq f$ and

$x \in V$. Note that there exists some $u \in U$ which is connected to x in $G - F$ iff x, z are connected in $G' - F$. The $\bar{\ell}(\cdot)$-labels of $F \cup \{x\}$ contain all $\ell'(\cdot)$-labels of $F \cup \{x, z\}$, so we can use them to determine if the latter condition holds. ◀

4 The Labeling Scheme: Proof of Theorem 2

In this section, we prove our main Theorem 2, giving f-FT Steiner connectivity labels of $|U|^{1-1/f} \cdot \text{poly}(f, \log n)$ bits. Recall that, as discussed in the introduction, we only need to consider up to f vertex failures, i.e., queries $F \subseteq V$ with $|F| \leq f$.

Subset labels. We first introduce a somewhat technical lemma. Roughly speaking, in terms of the high-level intuition of Section 1.1, it serves to treat the *all-high-degree* case. The idea is to store explicit information for some relatively small collection of vertex-subsets (of "high-deg vertices", see Section 1.1), such we have the information on $K \subseteq F$, we can determine if K itself already separates $U - F$, which implies that F is a Steiner cut.

▶ **Lemma 5.** *There is an algorithm that given any $K \subseteq V$, outputs a* subset label $\hat{\ell}(K)$ *of $O(f \log n)$ bits with the following property:*

For every $F \subseteq V$ with $|F| \leq f$, one can determine if K separates $U - F$, by only inspecting $\hat{\ell}(K)$ and the names/identifiers of the vertices in F.

Proof. Let $C_1, \ldots, C_p$ be the connected components of $G - K$ that contain some terminal, and denote $U_i = C_i \cap U$, where w.l.o.g. $|U_1| \leq \cdots \leq |U_p|$. Our goal is that given $\hat{\ell}(K)$ and any $F \subseteq V$, $|F| \leq f$, we can decide if at least two sets in $\{U_i - F \mid 1 \leq i \leq p\}$ are non-empty.

Suppose there exists some q such that $\sum_{i=1}^{q} |U_i| > f$ and $\sum_{i=q+1}^{p} |U_i| > f$. Then for every $F \subseteq V$ with $|F| \leq f$ there is one non-empty set in $\{U_i - F \mid i \leq q\}$ and another in $\{U_i - F \mid i \geq q+1\}$. Thus, we just indicate this situation in $\hat{\ell}(K)$ and always answer YES.

Assume now that no such q exists.

- If $|U_p| > f$: Then $\sum_{i=1}^{p-1} |U_i| < f$, and we let $\hat{\ell}(K)$ store $U_1, \ldots, U_{p-1}$ (and indicate that $|U_p| > f$). This suffices as for every $F \subseteq V$ with $|F| \leq f$ we know that $U_p - F \neq \emptyset$, so we only need to decide if $\{U_i - F \mid 1 \leq i \leq p-1\}$ has a non-empty set.
- If $|U_p| \leq f$: We assert that the sum $\sum_{i=1}^{p} |U_i|$ is at most $3f$. Indeed, if it is more than f, let q be maximal such that $\sum_{i=q+1}^{p} |U_i| > f$. Then $\sum_{i=1}^{q} |U_i| \leq f$, $\sum_{i=q+2}^{p} |U_i| \leq f$ (by maximality), and $|U_{q+1}| \leq |U_p| \leq f$. Thus, we just let $\hat{\ell}(K)$ store all of $U_1, \ldots, U_p$. ◀

The Duan-Pettie Decomposition. Our label construction crucially relies on a graph decomposition algorithm of Duan-Pettie [24] (as explained in Section 1.1). This algorithm is a recursive version of the Fürer-Raghavachari [25] algorithm for finding a Steiner tree with smallest possible maximum degree, up to $+1$ error. The Duan-Pettie decomposition utilizes the structural properties of the Fürer-Raghavachari tree (rather than its strong approximation guarantee). In the following, a *Steiner forest* means a forest in the graph where each pair of connected terminals (in the graph) is also connected in the forest.

▶ **Theorem 6** ([24]). *Let $r \geq 3$ be a* degree threshold. *There is an algorithm* $\mathsf{Decomp}(G, U, r)$ *that outputs a pair (T, B) such that the following hold:*

1. *T is a Steiner forest for U in G, and $T - B$ is a Steiner forest for $U - B$ in $G - B$.*
2. *The maximum degree in the forest $T - B$ is at most r.*
3. *$|B| < |U|/(r-2)$ and $|B \cap U| < |U|/(r-1)$.*

The running time of $\mathsf{Decomp}(G, U, r)$ *is $O(|U| m \log |U|)$.*

In the following we assume that $f \geq 2$, as Theorem 2 is trivial when $f = 1$: the label of vertex x just stores a single bit indicating whether $\{x\}$ is a Steiner cut.

Labeling. Our first step is to invoke $\mathsf{Decomp}(G, U, r := |U|^{1-1/f} + 2)$ of Theorem 6; let (T, B) be the output. For every $x \in V$, we choose an arbitrary terminal $u_x \in U$ such that x, u_x are connected in $G - B$ (where $u_x := \perp$, i.e., a null value, if there is no such terminal). Next, we construct the $\ell(\cdot)$-labels and $\bar{\ell}(\cdot)$-labels of Theorem 3 and Lemma 4; for every $v \in V$, define $\ell^*(v) := (v, \ell(v), \bar{\ell}(v))$. Finally, the $L(\cdot)$ labels are constructed as follows:

Algorithm 1 Creating the label $L(x)$ of a $x \in V$.

1: **store** $\ell^*(x)$
2: **store** $\ell^*(u_x)$ (or $\perp$ if $u_x = \perp$)
3: **store** $\{\ell^*(b) \mid b \in B\}$
4: **store** $\hat{\ell}(K = \emptyset)$ of Lemma 5 (i.e., applying this lemma with $K = \emptyset$)
5: **if** $x \notin B$ **then**
6: **store** $\{\ell^*(y) \mid (x, y)$ is an edge of $T - B\}$
7: **else** ▷ $x \in B$
8: **for** every $K \subseteq B$ s.t. $x \in K$ and $|K| \leq f$ **do**
9: **store** K along with $\hat{\ell}(K)$ of Lemma 5

The label length analysis is rather straightforward, given in detail in the following claim.

▷ Claim 7. Each label $L(x)$ generated by Algorithm 1 has $|U|^{1-1/f} \cdot \mathrm{poly}(f, \log n)$ bits, and takes polynomial time to compute.

Proof. By Theorem 3, Lemma 4 and Lemma 5 each $\ell^*(\cdot)$-label or $\hat{\ell}(\cdot)$-label consists of $\mathrm{poly}(f, \log n)$ bits, so we show that only $O(|U|^{1-1/f})$ such labels are stored in $L(x)$. The first four lines only store $O(|B|)$ such labels, and $|B| \leq |U|/(r-2) = |U|^{1/f}$ by the properties of $\mathsf{Decomp}(G, U, r)$ in Theorem 6). As we assume $f \geq 2$, $|U|^{1/f} \leq |U|^{1-1/f}$, so this is within budget. If $x \notin B$, then, line 6 stores $\ell^*(y)$ for each neighbor y of x in $T - B$, which are at most $r = O(|U|^{1-1/f})$ again by Theorem 6. Next suppose $x \in B$. The number of sets $K \subseteq B$ s.t. $x \in K$ and $|K| \leq f$ can be bounded by

$$\sum_{k=0}^{f-1} \binom{|B|-1}{k} \leq 1 + \sum_{k=1}^{f-1} \left(\frac{|B| \cdot e}{k}\right)^k \leq 1 + |B|^{f-1} \cdot \sum_{k=1}^{f-1} \left(\frac{e}{k}\right)^k \leq O(|U|^{1-1/f})$$

(we used $\binom{n}{k} \leq (n/k)^k$ for $1 \leq k \leq n$, $\sum_{k=1}^{\infty} (e/k)^k$ is convergent, and $|B| \leq |U|^{1/f}$). Thus, lines 8 and 9 store $O(|U|^{1-1/f})$ $\hat{\ell}(\cdot)$-labels.

Note that constructing the $\ell^*(\cdot)$ labels for all vertices takes polynomial time by Theorem 3 and Lemma 4. Also, we only need to construct $\hat{\ell}(K)$ labels for sets $K \subseteq B$ such that $x \in B$ and $|K| \leq f$ (or such that $K = \emptyset$), and there are only $O(|U|^{1-1/f})$ such sets K by the arguments above; constructing each $\hat{\ell}(K)$ takes polynomial time by Lemma 5. ◁

▶ Remark 8. The subset labels of Lemma 5 are trivial to construct with $O(f^2 \log n)$ bits: with notations from the proof, choose arbitrary $f+1$ sets among $U_1, \ldots, U_p$ (or all if $p \leq f$), take $f+1$ terminals from each chosen U_i (or all if $|U_i| \leq f$). We've included the more efficient version to demonstrate that the $\mathrm{poly}(f, \log n)$ factors in Claim 7 come from the f-FT labels of the s-t variant (Theorem 3). These have an $\Omega(f + \log n)$-bit lower bound bits [42], so even if the latter is matched, the contribution of the subset labels is lightweight.

Query algorithm. The pseudo-code for the query algorithm is given in the following Algorithm 2, designed to return *YES* if the query F is a Steiner cut, and *NO* otherwise.

Algorithm 2 Answering a query $F \subseteq V$, $|F| \leq f$ from the labels $\{L(x) \mid x \in F\}$.

1: let $K := F \cap B$
2: **if** K separates $U - F$ in G **then return** *YES*
3: let $S := \{v \in V - F \mid \ell^*(v)$ is stored in $L(x)$ of some $x \in F\}$
4: let $W := \{w \in S \mid \exists u \in U$ s.t. u, w are connected in $G - F\}$
5: **if** $W \neq \emptyset$ **then**
6: choose an arbitrary $w^* \in W$
7: **for** every $w \in W - \{w^*\}$ **do**
8: **if** w^*, w are disconnected in $G - F$ **then return** *YES*
9: **return** *NO*

We now provide the implementation details:

- Line 2 is executed using $\hat{\ell}(K)$ of Lemma 5 (and the names of the vertices in F, given in their labels). If $K = F \cap B$ is non-empty, we can find $\hat{\ell}(K)$ in the label $L(x)$ of some $x \in F \cap B$. Otherwise, $\hat{\ell}(K)$ is stored in $L(x)$ for every $x \in F$.
- Line 4 is executed by using the $\bar{\ell}(\cdot)$-labels of the vertices in $S \cup F$ (which appear in their $\ell^*(\cdot)$-labels). For every $w \in S$, we use $\bar{\ell}(w)$ and $\{\bar{\ell}(x) \mid x \in F\}$ to decide if w is connected to some $u \in U$ in $G - F$, which is possible by Lemma 4.
- Line 8 is executed using the $\ell(\cdot)$-labels of w^*, w and F (which appear in their $\ell^*(\cdot)$-labels), which enable to determine if w^*, w are connected in $G - F$ by Theorem 3.

Correctness. We need to show that *YES* is returned if and only if F is a Steiner cut, namely F separates U in G. The soundness direction ('only if') is trivial:

▷ Claim 9. If the query algorithm (Algorithm 2) returns *YES* then F is a Steiner cut in G.

Proof. If *YES* was returned in line 2, then F has a subset K which separates two terminals in $U - F$, so these are also separated by F. Thus, F is a Steiner cut.

Otherwise, *YES* was returned in line 8, so there are $w^*, w \in W$ disconnected in $G - F$. By definition of W (line 4 of Algorithm 1), there exists terminals $u^*, u \in U$ such that u^*, w^* and u, w are connected pairs in $G - F$. Thus, u^*, u are two terminals disconnected in $G - F$, so F is a Steiner cut. ◁

Next, we address the completeness ('if') direction:

▷ Claim 10. If F is a Steiner cut in G, then the query algorithm (Algorithm 2) returns *YES*.

Proof. Let us first consider the trivial case when $K = F \cap B$ separates $U - F$ in G. Then Algorithm 2 returns *YES* in line 2 as needed. Henceforth, we assume that F satisfies the following property:

(P1) $F \cap B$ does not separate $U - F$ in G.

Note that given Property (P1), the only possible place where Algorithm 2 can return *YES* is in line 8, so we aim to show that this is indeed the case. We will crucially use Property (P1) later on in the proof.

Let $u, u' \in U$ be two terminals disconnected in $G - F$, which exists as F is a Steiner cut. We will show there exists $w, w' \in W$ such that (i) u, w are connected in $G - F$ and (ii) u', w' are connected in $G - F$. Let us argue why this suffices to complete the proof. First, this

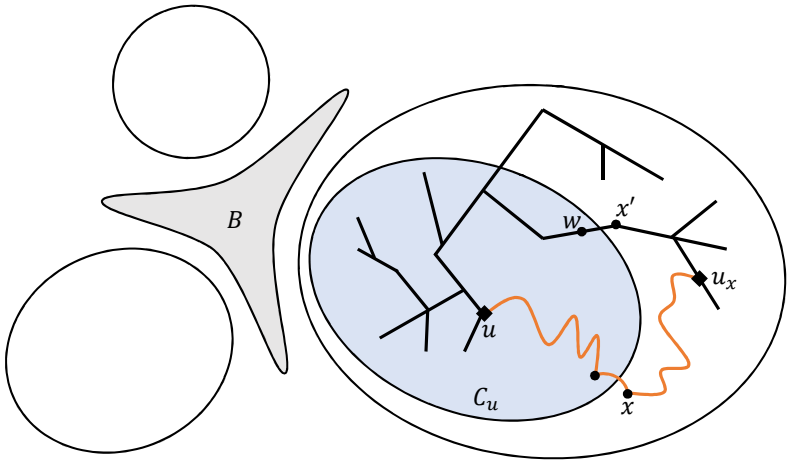

Figure 1 Illustrating the proof of Claim 10. Given (P1) and (P2), the connected component C_u of u in $G - F$ is fully contained in some connected component of $G - B$, and C_u has some neighbor $x \in F$ within this bigger component. Thus, both u and the chosen terminal u_x for x are connected to x in this component. The forest $T - B$ contains a tree that connects *all terminals* in this component, so it must connect u and u_x. If $u_x \notin C_u$ (as shown in the figure), then the tree must contain a vertex $w \in C_u$ which is a neighbor of some $x' \in F$ in $T - B$, and so $w \in S$. Otherwise, $u_x \in C_u \cap S$. In either case, we find some vertex in $C_u \cap S$ as required.

clearly implies that $W \neq \emptyset$. Second, one of w, w' must be disconnected from w^* in $G - F$, as otherwise w, w' would be connected in $G - F$, so by (i) and (ii) we get that u, u' are also connected in $G - F$, but this is a contradiction. Therefore, line 8 of Algorithm 2, when executed with either w or w' must return *YES* as required.

We thus focus on showing the existence of $w \in W$ which is connected to u in $G - F$ (and the proof for w' and u' is symmetric). Let C_u be the connected component of u in $G - F$. Recall the definitions of S and its subset W from lines 3 and 4 of Algorithm 2. Note that every vertex $w \in C_u \cap S$ is automatically in W, since it belongs to S and is connected to the terminal u in $G - F$. So, our goal is simply to show that $C_u \cap S \neq \emptyset$, or in other words, that the $\ell^*(\cdot)$-label of some vertex in C_u is stored in some $L(x)$ of $x \in F$.

Again, there is a trivial case: if $C_u \cap B \neq \emptyset$ then we are done, because $\{\ell^*(b) \mid b \in B\}$ is stored in every $L(x)$ of $x \in F$ (line 3 of Algorithm 1), so $B \subseteq S$. Thus, we assume that:

(P2) The connected component C_u of u in $G - F$ does not intersect B.

In fact, the inclusion of the $\ell^*(\cdot)$-labels of B in every label $L(x)$ is precisely aimed at enforcing Property (P2).

Our next step is to "capitalize on" properties (P1), (P2), and the important property that $T - B$ is a Steiner forest for $U - B$ in $G - B$ (guaranteed by Theorem 6). Consider the set $N_G(C_u)$ of all vertices outside C_u that are adjacent to C_u in G. Note that, as C_u is a connected component in $G - F$, we have $N_G(C_u) \subseteq F$. Observe that $N_G(C_u)$ separates $U - F$ in G, as $u, u' \in U - F$ with $u \in C_u$ and $u' \notin C_u$. Thus, by Property (P1), it must be that $N_G(C_u) \not\subseteq F \cap B$. Hence, there exists some $x \in N_G(C_u) \cap (F - B)$. Now, using Property (P2), we see that all vertices in $C_u \cup \{x\}$ are connected in $G - B$, so u is connected to x in $G - B$. Recall that the terminal $u_x \in U$ is also (by definition) connected to x in $G - B$. (Note that u_x exists since x is connected to the terminal u in $G - B$.) Hence, u, u_x are connected in $G - B$, and thus also in $T - B$. This is the crux for finishing the proof in the following argument. See Figure 1 for an illustration.

Observe that $u_x \in S$, since $\ell^*(u_x)$ is stored in $L(x)$ (line 2 of Algorithm 1). So, if u, u_x are connected in $G - F$, then $u_x \in C_u \cap S$ and we are done. Otherwise, the path in $T - B$ between u and u_x must go through F. Let $x' \in F$ be the vertex closest to u on this path, and let w be its neighbor in the direction of u on the path. (It might be that $x' = x$.) Then the subpath between u and w avoids F, so $w \in C_u$. Also, $x' \notin B$ and (x', w) is an edge of $T - B$, hence $\ell^*(w)$ is stored in $L(x')$ (line 6 of Algorithm 1), so $w \in S$. Namely, we have shown that $C_u \cap S \neq \emptyset$, and the proof is concluded. ◁

Theorem 2 follows immediately from the combination of Claim 7, Claim 9 and Claim 10.

Abstract

The edit distance $\mathsf{ed}(X, Y)$ of two strings $X, Y \in \Sigma^*$ is the minimum number of character edits (insertions, deletions, and substitutions) needed to transform X into Y. Its weighted counterpart $\mathsf{ed}^w(X, Y)$ minimizes the total cost of edits, where the costs of individual edits, depending on the edit type and the characters involved, are specified using a function w, normalized so that each edit costs at least one. The textbook dynamic-programming procedure, given strings $X, Y \in \Sigma^{\le n}$ and oracle access to w, computes $\mathsf{ed}^w(X, Y)$ in $\mathcal{O}(n^2)$ time. Nevertheless, one can achieve better running times if the computed distance, denoted k, is small: $\mathcal{O}(n + k^2)$ for unit weights [Landau and Vishkin; JCSS'88] and $\widetilde{\mathcal{O}}(n + \sqrt{nk^3})$[1] for arbitrary weights [Cassis, Kociumaka, Wellnitz; FOCS'23].

In this paper, we study the dynamic version of the weighted edit distance problem, where the goal is to maintain $\mathsf{ed}^w(X, Y)$ for strings $X, Y \in \Sigma^{\le n}$ that change over time, with each update specified as an edit in X or Y. Very recently, Gorbachev and Kociumaka [STOC'25] showed that the *unweighted* distance $\mathsf{ed}(X, Y)$ can be maintained in $\widetilde{\mathcal{O}}(k)$ time per update after $\widetilde{\mathcal{O}}(n + k^2)$-time preprocessing; here, k denotes the *current* value of $\mathsf{ed}(X, Y)$. Their algorithm generalizes to small integer weights, but the underlying approach is incompatible with large weights.

Our main result is a dynamic algorithm that maintains $\mathsf{ed}^w(X, Y)$ in $\widetilde{\mathcal{O}}(k^{3-\gamma})$ time per update after $\widetilde{\mathcal{O}}(nk^\gamma)$-time preprocessing. Here, $\gamma \in [0, 1]$ is a real trade-off parameter and $k \ge 1$ is an integer threshold *fixed* at preprocessing time, with ∞ returned whenever $\mathsf{ed}^w(X, Y) > k$. We complement our algorithm with conditional lower bounds showing fine-grained optimality of our trade-off for $\gamma \in [0.5, 1)$ and justifying our choice to fix k.

We also generalize our solution to a much more robust setting while preserving the fine-grained optimal trade-off. Our full algorithm maintains $X \in \Sigma^{\le n}$ subject not only to character edits but also substring deletions and copy-pastes, each supported in $\widetilde{\mathcal{O}}(k^2)$ time. Instead of dynamically maintaining Y, it answers queries that, given any string Y specified through a sequence of $\mathcal{O}(k)$ arbitrary edits transforming X into Y, in $\widetilde{\mathcal{O}}(k^{3-\gamma})$ time compute $\mathsf{ed}^w(X, Y)$ or report that $\mathsf{ed}^w(X, Y) > k$.

1 Introduction

Among the most fundamental string processing problems is the task of deciding whether two strings are similar to each other. A classic measure of string (dis)similarity is the *edit distance*, also known as the *Levenshtein distance* [22]. The (unit-cost) edit distance $\mathsf{ed}(X, Y)$ of two strings X and Y is defined as the minimum number of character edits (insertions, deletions, and substitutions) needed to transform X into Y. In typical use cases, edits model naturally occurring modifications, such as typographical errors in natural-language texts or mutations in biological sequences. Some of these changes occur more frequently than others, which motivated introducing *weighted edit distance* already in the 1970s [33]. In this setting, each edit has a cost that may depend on its type and the characters involved (but nothing else), and the goal is to minimize the total cost of edits rather than their quantity. The costs of individual edits can be specified through a weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, where $\overline{\Sigma} = \Sigma \cup \{\varepsilon\}$ denotes the alphabet extended with a symbol ε representing the lack of a character. For $a, b \in \Sigma$, the cost of inserting b is $w(\varepsilon, b)$, the cost of deleting a is $w(a, \varepsilon)$, and the cost of substituting a for b is $w(a, b)$. (Note that the cost of an edit is independent of the position of the edited character in the string.) Consistently with previous works, we assume that w is normalized: $w(a, b) \geq 1$ and $w(a, a) = 0$ hold for every distinct $a, b \in \overline{\Sigma}$. The unweighted edit distance constitutes the special case when $w(a, b) = 1$ holds for $a \neq b$.

The textbook dynamic-programming algorithm [32, 25, 26, 33] takes $\mathcal{O}(n^2)$ time to compute the edit distance of two strings of length at most n, and some of its original formulations incorporate weights [26, 33, 27]. Unfortunately, there is little hope for much faster solutions: for any constant $\delta > 0$, an $\mathcal{O}(n^{2-\delta})$-time algorithm would violate the Orthogonal Vectors Hypothesis [1, 7, 2, 5], and hence the Strong Exponential Time Hypothesis [16, 17]. The lower bound holds already for unit weights and many other fixed weight functions [7].

Bounded Edit Distance. On the positive side, the quadratic running time can be improved when the computed distance is small. For unweighted edit distance, the algorithm by Landau and Vishkin [21], building upon the ideas of [30, 24], computes $k := \mathsf{ed}(X, Y)$ in $\mathcal{O}(n + k^2)$ time for any two strings $X, Y \in \Sigma^{\leq n}$. This running time is fine-grained optimal: for any $\delta > 0$, a hypothetical $\mathcal{O}(n + k^{2-\delta})$-time algorithm, even restricted to instances satisfying $k = \Theta(n^\kappa)$ for some constant $\kappa \in (0.5, 1]$, would violate the Orthogonal Vectors Hypothesis.

As far as the bounded *weighted* edit distance problem is concerned, a simple optimization by Ukkonen [30] improves the quadratic time complexity of the classic dynamic-programming algorithm to $\mathcal{O}(nk)$, where $k := \mathsf{ed}^w(X, Y)$. Recently, Das, Gilbert, Hajiaghayi, Kociumaka, and Saha [12] developed an $\mathcal{O}(n + k^5)$-time solution and, soon afterwards, Cassis, Kociumaka, and Wellnitz [8] presented an $\widetilde{\mathcal{O}}(n + \sqrt{nk^3})$-time algorithm. Due to the necessity to read the entire input, the latter running time is optimal for $k \leq \sqrt[3]{n}$. More surprisingly, there is a tight conditional lower bound for $\sqrt{n} \leq k \leq n$ [8], valid already for edit costs in the real interval $[1, 2]$. For any constants $\kappa \in [0.5, 1]$ and $\delta > 0$, an $\mathcal{O}(\sqrt{nk^{3-\delta}})$-time algorithm restricted to instances satisfying $k = \Theta(n^\kappa)$ would violate the All-Pairs Shortest Paths Hypothesis [31]. The optimal complexity remains unknown for $\sqrt[3]{n} < k < \sqrt{n}$, where the upper bound is $\widetilde{\mathcal{O}}(\sqrt{nk^3})$, yet the lower-bound construction allows for an $\widetilde{\mathcal{O}}(n + k^{2.5})$-time algorithm.

Dynamic Edit Distance. Over the last decades, the edit distance problem has been studied in numerous variants, including the dynamic ones, where the input strings change over time. The most popular dynamic (weighed) edit distance formulation is the following one [9, 15].

▶ **Problem 1.1** (Dynamic Weighted Edit Distance). *Given an integer n and oracle access to a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, maintain strings $X, Y \in \Sigma^{\leq n}$ subject to updates (character edits in X and Y) and report $\mathsf{ed}^w(X,Y)$ after each update.*[2]

The time complexity of Problem 1.1 is already well understood if it is measured solely in terms of the string length n. In case of unit weights, the algorithm of Charalampopoulos, Kociumaka, and Mozes [9] (building upon the techniques by Tiskin [28]) is characterized by $\widetilde{\mathcal{O}}(n)$ update time and $\mathcal{O}(n^2)$ preprocessing time; any polynomial-factor improvement would violate the lower bound for the static edit distance problem. As far as arbitrary weights are concerned, the approach presented in [9, Section 4] achieves $\widetilde{\mathcal{O}}(n\sqrt{n})$ update time after $\widetilde{\mathcal{O}}(n^2)$-time preprocessing, and there is a matching fine-grained lower bound [8, Section 6] conditioned on the All-Pairs Shortest Paths Hypothesis.

In this work, we aim to understand Problem 1.1 for small distances:

How fast can one dynamically maintain $\mathsf{ed}^w(X,Y)$ when this value is small?

Very recently, Gorbachev and Kociumaka [15] settled the parameterized complexity of Problem 1.1 in the *unweighted* case. Their solution achieves $\widetilde{\mathcal{O}}(n+k^2)$ preprocessing time and $\widetilde{\mathcal{O}}(k)$ update time; improving either complexity by a polynomial factor, even for instances satisfying $k = \Theta(n^\kappa)$ for some $\kappa \in (0,1]$, would violate the Orthogonal Vectors Hypothesis.

Interestingly, the approach of [15] builds upon the static procedure for bounded *weighted* edit distance [8] and, as a result, the dynamic algorithm seamlessly supports *small integer* weights, achieving $\mathcal{O}(W^2k)$ update time for edit costs in $[1..W]$. Unfortunately, [15] does not provide any improvements for arbitrary weights; in that case, the results of [8] yield a solution to Problem 1.1 with $\widetilde{\mathcal{O}}(n)$ preprocessing time and $\widetilde{\mathcal{O}}(\min(k^3, \sqrt{nk^3}))$ update time. This is far from satisfactory: for $k \geq \sqrt[3]{n}$, the algorithm simply recomputes $\mathsf{ed}^w(X,Y)$ from scratch after every update, and for $k < \sqrt[3]{n}$, it does not store (and reuse) anything beyond a dynamic data structure for checking the equality between fragments of X and Y.

Our Results: Lower Bounds

The reason why the approach of [15] is incompatible with large weights, e.g., $W = \Omega(k)$, is that their presence allows a single update to drastically change $\mathsf{ed}^w(X,Y)$. Our first result strengthens the lower bound of [8] and shows that the $\widetilde{\mathcal{O}}(n+\sqrt{nk^3})$-time static algorithm is fine-grained optimal already for instances that can be transformed from a pair of equal strings using four edits. The ideas behind the following theorem are presented in Section 5.

▶ **Theorem 1.2.** *Let $\kappa \in [0.5, 1]$ and $\delta > 0$ be real parameters. Assuming the APSP Hypothesis, there is no algorithm that, given two strings $X, Y \in \Sigma^{\leq n}$ satisfying $\mathsf{ed}(X,Y) \leq 4$, a threshold $k \leq n^\kappa$, and oracle access to a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, in time $\mathcal{O}(n^{0.5+1.5\kappa-\delta})$ decides whether $\mathsf{ed}^w(X,Y) \leq k$.*

As a simple corollary, we conclude that significantly improving upon the naïve update time of $\widetilde{\mathcal{O}}(\sqrt{nk^3})$ for $\sqrt{n} \leq k \leq n$ requires large preprocessing time.

▶ **Corollary 1.3.** *Suppose that Problem 1.1 admits a solution with preprocessing time $T_P(n, \mathsf{ed}^w(X,Y))$ and update time $T_U(n, \mathsf{ed}^w(X,Y))$ for some non-decreasing functions T_P and T_U. If $T_P(n,0) = \mathcal{O}(n^{0.5+1.5\kappa-\delta})$ and $T_U(n, n^\kappa) = \mathcal{O}(n^{0.5+1.5\kappa-\delta})$ hold for some real parameters $\kappa \in [0.5, 1]$ and $\delta > 0$, then the APSP Hypothesis fails.*

[2] For clarity, the introduction focuses on the version of the problem where the value $\mathsf{ed}^w(X,Y)$ is reported after every update. In Theorem 1.7, we address a more general setting where queries may occur less frequently, allowing us to distinguish between update time and query time.

Proof idea. For an instance (X, Y) of the static problem of Theorem 1.2, we initialize the dynamic algorithm with (X, X) and transform one copy of X into Y using four updates. ◀

As discussed in the full version of the paper [6], instead of initializing the dynamic algorithm with (X, X), we can initialize it with a pair of empty strings and gradually transform this instance to (X, X) using $\mathcal{O}(n)$ updates while keeping the weighted edit distance between 0 and 2 at all times. Hence, as long as the preprocessing of $(\varepsilon, \varepsilon)$ takes $n^{\mathcal{O}(1)}$ time and is not allowed to access the entire weight function (e.g., weights are revealed online when an update introduces a fresh character for the first time) , we can replace $T_P(n, 0) = \mathcal{O}(n^{0.5+1.5\kappa-\delta})$ with $T_U(n, 2) = \mathcal{O}(n^{1.5\kappa-0.5-\delta})$ in the statement of Corollary 1.3.

Overall, we conclude that, in order to support updates with relatively large distances faster than naively (i.e., by computing $\mathsf{ed}^w(X, Y)$ from scratch using a static algorithm), one needs to pay a lot for both preprocessing and updates while $\mathsf{ed}^w(X, Y)$ is still very small. In particular, we should decide in advance how large distances need to be supported efficiently. This justifies a simplified variant of Problem 1.1, where the parameter k is fixed at preprocessing time. Here, instead of $\mathsf{ed}^w(X, Y)$, the algorithm reports the following quantity:

$$\mathsf{ed}^w_{\leq k}(X, Y) = \begin{cases} \mathsf{ed}^w(X, Y) & \text{if } \mathsf{ed}^w(X, Y) \leq k, \\ \infty & \text{otherwise.} \end{cases}$$

▶ **Problem 1.4** (Dynamic Weighted Edit Distance with Fixed Threshold)**.** *Given integers $1 \leq k \leq n$ and oracle access to a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, maintain strings $X, Y \in \Sigma^{\leq n}$ subject to updates (character edits in X and Y) and report $\mathsf{ed}^w_{\leq k}(X, Y)$ upon each update.*

Corollary 1.3 can be rephrased in terms of Problem 1.4, but its major limitation is that it only applies to $k \geq \sqrt{n}$. To overcome this issue, we compose multiple hard instances from Theorem 1.2. This results in the following theorem, discussed in Section 5.

▶ **Theorem 1.5.** *Suppose that Problem 1.4 admits a solution with preprocessing time $T_P(n, k)$ and update time $T_U(n, k)$ for some non-decreasing functions T_P and T_U. If $T_P(n, n^\kappa) = \widetilde{\mathcal{O}}(n^{1+\kappa\cdot\gamma})$ and $T_U(n, n^\kappa) = \mathcal{O}(n^{\kappa\cdot(3-\gamma)-\delta})$ hold for some parameters $\gamma \in [0.5, 1)$, $\kappa \in (0, 1/(3-2\gamma)]$, and $\delta > 0$, then the APSP Hypothesis fails.*

Theorem 1.5 indicates that (conditioned on the APSP Hypothesis and up to subpolynomial-factor improvements), for a dynamic algorithm with preprocessing time $\widetilde{\mathcal{O}}(nk^\gamma)$ for $\gamma \in [0.5, 1)$, the best possible update time is $\widetilde{\mathcal{O}}(k^{3-\gamma})$. The lower bound does not extend to $\kappa > 1/(3-2\gamma)$; precisely then, the $\widetilde{\mathcal{O}}(\sqrt{nk^3})$-time static algorithm improves upon the $\widetilde{\mathcal{O}}(k^{3-\gamma})$ update time.

Our Results: Algorithms

Our main positive result is an algorithm that achieves the fine-grained-optimal trade-off.

▶ **Theorem 1.6.** *There exists an algorithm that, initialized with an extra real parameter $\gamma \in [0, 1]$, solves Problem 1.4 with preprocessing time $\widetilde{\mathcal{O}}(nk^\gamma)$ and update time $\widetilde{\mathcal{O}}(k^{3-\gamma})$.*

As a warm-up, in Section 3, we prove Theorem 1.6 for $\gamma = 1$. Similarly to [15], the main challenge is that updates can make X and Y slide with respect to each other. If we interleave insertions at the end of Y and deletions at the beginning of Y, then, after $\Omega(k)$ updates, for every character $X[i]$, the fragment $Y[i-k..i+k]$ containing the plausible matches of $X[i]$ changes completely. The approach of [15] was to restart the algorithm every $\Theta(k)$ updates.

Our preprocessing time is too large for this, so we resort to a trick originating from dynamic edit distance approximation [20]: we maintain a data structure for aligning X with itself. Instead of storing Y, we show how to compute $\mathsf{ed}^w_{\le k}(X,Y)$ for any string Y specified using $\mathcal{O}(k)$ edits (of arbitrary costs) transforming X into Y. To find such edits in the original setting of Problem 1.4, one can use a dynamic *unweighted* edit distance algorithm. Already the folklore approach, based on [21, 23], with $\widetilde{\mathcal{O}}(k^2)$ time per update is sufficiently fast.

In Section 4, we discuss how to generalize our dynamic algorithm to arbitrary $\gamma \in [0,1]$. This is our most difficult result – it requires combining the techniques of [8] and their subsequent adaptations in [15] with several new ideas, including a novel *shifted* variant of self-edit distance. We derive Theorem 1.6 as a straightforward corollary of the following result, which demonstrates that the same fine-grained optimal trade-off can be achieved in a much more robust setting compared to the one presented in Problem 1.4.

▶ **Theorem 1.7.** *There is a dynamic algorithm that, initialized with a real parameter $\gamma \in [0,1]$, integers $1 \le k \le n$, and $\mathcal{O}(1)$-time oracle access to a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\ge 0}$, maintains a string $X \in \Sigma^{\le n}$ and, after $\widetilde{\mathcal{O}}(nk^\gamma)$-time preprocessing, supports the following operations (updates and queries):*

- *Apply a character edit, substring deletion, or copy-paste to X in $\widetilde{\mathcal{O}}(k^2)$ time.*
- *Given u edits transforming X into a string Y, compute $\mathsf{ed}^w_{\le k}(X,Y)$ in $\widetilde{\mathcal{O}}(u + k^{3-\gamma})$ time.*

We remark that our query algorithm for $\gamma = 1$ extends a subroutine of [11], where the string X is static. In [11], this result is used for approximate pattern matching with respect to weighted edit distance. If the pattern is far from periodic, which is arguably true in most natural instances, the trade-off of Theorem 1.7 yields a faster pattern matching algorithm.

Open Problems

Recall that Theorem 1.5 proves fine-grained optimality of Theorem 1.6 only for $\gamma \in [0.5, 1)$. The omission of $\gamma \in [0, 0.5)$ stems from a gap between algorithms and lower bounds for the underlying static problem. Hence, we reiterate the open question of [8] asking for the complexity of computing $\mathsf{ed}^w(X,Y)$ when $\sqrt[3]{n} < \mathsf{ed}^w(X,Y) < \sqrt{n}$. Since our lower bounds arise from Theorem 1.2, it might be instructive to first try designing faster algorithms for the case of $\mathsf{ed}(X,Y) \le 4$. Before this succeeds, one cannot hope for faster dynamic algorithms.

Wider gaps in our understanding of Problem 1.4 remain in the regime of large preprocessing time. It is open to determine the optimal update time for $\gamma = 1$ and to decide whether $\gamma > 1$ can be beneficial. As far as $\gamma = 1$ is concerned, we believe that [9, Section 4] can be used to obtain $\widetilde{\mathcal{O}}(k\sqrt{n})$ update time, which improves upon Theorem 1.6 for $k \ge \sqrt{n}$. Moreover, by monotonicity, the lower bound of [8, Section 6] excludes update times of the form $\mathcal{O}(k^{1.5-\delta})$.

Finally, we remark that all our lower bounds exploit the fact that $\mathsf{ed}^w(X,Y)$ can change a lot as a result of a single update. It would be interesting to see what can be achieved if the weights are small (but fractional) or when the update time is parameterized by the change in $\mathsf{ed}^w(X,Y)$. In these cases, we hope for non-trivial applications of the approach of [15].

2 Preliminaries[3]

A string $X \in \Sigma^n$ is a sequence of $|X| := n$ characters over an alphabet Σ. We denote the set of all strings over Σ by Σ^*, we use ε to represent the empty string, and we write $\Sigma^+ := \Sigma^* \setminus \{\varepsilon\}$. For a *position* $i \in [0..n)$, we say that $X[i]$ is the i-th character of X. We

[3] In this section, we partially follow the narration of [8, 15].

say that a string X occurs as a *substring* of a string Y, if there exist indices $i, j \in [0..|Y|]$ satisfying $i \leq j$ such that $X = Y[i] \cdots Y[j-1]$. The occurrence of X in Y specified by i and j is a *fragment* of Y denoted by $Y[i..j)$, $Y[i..j-1]$, $Y(i-1..j-1]$, or $Y(i-1..j)$.

Weighted Edit Distances and Alignment Graphs

Given an alphabet Σ, we set $\overline{\Sigma} \coloneqq \Sigma \cup \{\varepsilon\}$. We call w a *normalized weight function* if $w\colon \overline{\Sigma} \times \overline{\Sigma} \to \mathbb{R}_{\geq 1} \cup \{0\}$ and, for $a, b \in \overline{\Sigma}$, we have $w(a,b) = 0$ if and only if $a = b$. Note that w does not need to satisfy the triangle inequality nor does w need to be symmetric.

We interpret weighted edit distances of strings as distances in alignment graphs.

▶ **Definition 2.1** (Alignment Graph, [8]). *For strings $X, Y \in \Sigma^*$ and a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, we define the* alignment graph $\mathsf{AG}^w(X,Y)$ *to be a weighted directed graph with vertices $[0..|X|] \times [0..|Y|]$ and the following edges:*

- *a horizontal edge $(x,y) \to (x+1,y)$ of cost $w(X[x],\varepsilon)$ representing a deletion of $X[x]$, for every $(x,y) \in [0..|X|) \times [0..|Y|]$,*
- *a vertical edge $(x,y) \to (x,y+1)$ of cost $w(\varepsilon,Y[y])$ representing an insertion of $Y[y]$, for every $(x,y) \in [0..|X|] \times [0..|Y|)$, and*
- *a diagonal edge $(x,y) \to (x+1,y+1)$ of cost $w(X[x],Y[y])$ representing a substitution of $X[x]$ into $Y[y]$ or, if $X[x] = Y[y]$, a match of $X[x]$ with $Y[y]$, for every $(x,y) \in [0..|X|) \times [0..|Y|)$.*

We visualize the graph $\mathsf{AG}^w(X,Y)$ as a grid graph with $|X|+1$ columns and $|Y|+1$ rows, where $(0,0)$ and $(|X|,|Y|)$ are the top-left and bottom-right vertices, respectively.

Alignments between fragments of X and Y can be interpreted as paths in $\mathsf{AG}^w(X,Y)$.

▶ **Definition 2.2** (Alignment). *Consider strings $X, Y \in \Sigma^*$ and a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$. An* alignment $\mathcal{A}$ *of $X[x..x')$ onto $Y[y..y')$, denoted $\mathcal{A}\colon X[x..x') \rightsquigarrow Y[y..y')$, is a path from (x,y) to (x',y') in $\mathsf{AG}^w(X,Y)$, often interpreted as a sequence of vertices. The* cost *of $\mathcal{A}$, denoted by $\mathsf{ed}^w_{\mathcal{A}}(X[x..x'),Y[y..y'))$, is the total cost of edges belonging to $\mathcal{A}$.*

The *weighted edit distance* of strings $X, Y \in \Sigma^*$ with respect to a weight function w is $\mathsf{ed}^w(X,Y) \coloneqq \min \mathsf{ed}^w_{\mathcal{A}}(X,Y)$ where the minimum is taken over all alignments $\mathcal{A}$ of X onto Y. An alignment $\mathcal{A}$ of X onto Y is *w-optimal* if $\mathsf{ed}^w_{\mathcal{A}}(X,Y) = \mathsf{ed}^w(X,Y)$.

We say that an alignment $\mathcal{A}$ of X onto Y aligns fragments $X[x..x')$ and $Y[y..y')$ if $(x,y),(x',y') \in \mathcal{A}$. In this case, we also denote the cost of the *induced alignment* (the subpath of $\mathcal{A}$ from (x,y) to (x',y')) by $\mathsf{ed}^w_{\mathcal{A}}(X[x..x'),Y[y..y'))$.

A normalized weight function satisfying $w(a,b) = 1$ for distinct $a, b \in \overline{\Sigma}$ gives the *unweighted* edit distance (Levenshtein distance [22]). In this case, we drop the superscript w.

▶ **Definition 2.3** (Augmented Alignment Graph, [15]). *For strings $X, Y \in \Sigma^*$ and a weight function $w\colon \overline{\Sigma}^2 \to [0, W]$, the* augmented alignment graph $\overline{\mathsf{AG}}^w(X,Y)$ *is obtained from $\mathsf{AG}^w(X,Y)$ by adding, for every edge of $\mathsf{AG}^w(X,Y)$, a back edge of weight $W+1$.*[4]

The following fact shows several properties of $\overline{\mathsf{AG}}^w(X,Y)$. Importantly, $\mathsf{ed}^w(X[x..x'),Y[y..y'))$ is the distance from (x,y) to (x',y') in $\overline{\mathsf{AG}}^w(X,Y)$.

[4] These edges ensure that $\overline{\mathsf{AG}}^w(X,Y)$ is strongly connected, and thus the distance matrices used throughout this work are Monge matrices (see Definition 2.11) rather than so-called partial Monge matrices.

▶ **Fact 2.4** ([15, Lemma 5.2]). *Consider strings $X, Y \in \Sigma^*$ and a weight function $w\colon \overline{\Sigma}^2 \to [0, W]$. Every two vertices (x, y) and (x', y') of the graph $\overline{\mathsf{AG}}^w(X, Y)$ satisfy the following properties:*

Monotonicity. *Every shortest path from (x, y) to (x', y') in $\overline{\mathsf{AG}}^w(X, Y)$ is (weakly) monotone in both coordinates.*

Distance preservation. *If $x \le x'$ and $y \le y'$, then*

$$\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}((x, y), (x', y')) = \mathsf{dist}_{\mathsf{AG}^w(X,Y)}((x, y), (x', y')).$$

Path irrelevance. *If ($x \le x'$ and $y \ge y'$) or ($x \ge x'$ and $y \le y'$), then every path from (x, y) to (x', y') in $\overline{\mathsf{AG}}^w(X, Y)$ monotone in both coordinates is a shortest path between these two vertices.*

Consistently with many edit-distance algorithms, we will often compute not only the distance from $(0, 0)$ to $(|X|, |Y|)$ in $\overline{\mathsf{AG}}^w(X, Y)$ but the entire *boundary distance matrix* $\mathsf{BM}^w(X, Y)$ that stores the distances from every *input* vertex on the top-left boundary to every *output* vertex on the bottom-right boundary of the graph $\overline{\mathsf{AG}}^w(X, Y)$.

▶ **Definition 2.5** (Input and Output Vertices of an Alignment Graph, [15, Definition 5.5]). *Let $X, Y \in \Sigma^*$ be two strings and $w\colon \overline{\Sigma}^2 \to [0, W]$ be a weight function. Furthermore, for fragments $X[x..x')$ and $Y[y..y')$, let $R = [x..x'] \times [y..y']$ be the corresponding* rectangle *in $\overline{\mathsf{AG}}^w(X, Y)$. We define the* input vertices *of R as the sequence of vertices of $\overline{\mathsf{AG}}^w(X, Y)$ on the left and top boundary of R in the clockwise order. Analogously, we define the* output vertices *of R as a sequence of vertices of $\overline{\mathsf{AG}}^w(X, Y)$ on the bottom and right boundary of R in the counterclockwise order. Furthermore, the input and output vertices of $X \times Y$ are the corresponding boundary vertices of the whole graph $\overline{\mathsf{AG}}^w(X, Y)$.*

▶ **Definition 2.6** (Boundary Distance Matrix, [15, Definition 5.6]). *Let $X, Y \in \Sigma^*$ be two strings and $w\colon \overline{\Sigma}^2 \to [0, W]$ be a weight function. The* **b**oundary distance **m**atrix *$\mathsf{BM}^w(X, Y)$ of X and Y with respect to w is a matrix M of size $(|X|+|Y|+1) \times (|X|+|Y|+1)$, where $M_{i,j}$ is the distance from the i-th input vertex to the j-th output vertex of $X \times Y$ in $\overline{\mathsf{AG}}^w(X, Y)$.*

The following fact captures the simple dynamic programming algorithm for bounded weighted edit distance.

▶ **Fact 2.7** ([15, Fact 3.3]). *Given strings $X, Y \in \Sigma^*$, an integer $k \ge 1$, and $\mathcal{O}(1)$-time oracle access to a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\ge 0}$, the value $\mathsf{ed}^w_{\le k}(X, Y)$ can be computed in $\mathcal{O}(\min(|X| + 1, |Y| + 1) \cdot \min(k, |X| + |Y| + 1))$ time. Furthermore, if $\mathsf{ed}^w(X, Y) \le k$, the algorithm returns a w-optimal alignment of X onto Y.*

The proof of Fact 2.7 relies on the fact that a path of length k can visit only a limited area of the alignment graph $\mathsf{AG}^w(X, Y)$. This property can be formalized as follows:

▶ **Fact 2.8** ([15, Lemma 5.3]). *Let $X, Y \in \Sigma^*$ be two strings, k be an integer, and $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\ge 0}$ be a normalized weight function. Consider a path P of cost at most k connecting (x, y) to (x', y') in $\overline{\mathsf{AG}}^w(X, Y)$. All vertices $(x^*, y^*) \in P$ satisfy $|(x - y) - (x^* - y^*)| \le k$ and $|(x' - y') - (x^* - y^*)| \le k$.*

The *breakpoint representation* of an alignment $\mathcal{A} = (x_t, y_t)_{t=0}^m$ of X onto Y is the subsequence of $\mathcal{A}$ consisting of pairs (x_t, y_t) such that $t \in \{0, m\}$ or $\mathcal{A}$ does not match $X[x_t]$ with $Y[y_t]$. Note that the size of the breakpoint representation is at most $2 + \mathsf{ed}_{\mathcal{A}}(X, Y)$ and that it can be used to retrieve the entire alignment and its cost: for any two consecutive

elements $(x', y'), (x, y)$ of the breakpoint representation, it suffices to add $(x - \delta, y - \delta)$ for $\delta \in (0..\max(x - x', y - y'))$. We will also talk of *breakpoint representations* of paths in $\overline{\mathsf{AG}}^w(X, Y)$ that are weakly monotone in both coordinates. If such a path starts in (x, y) and ends in (x', y') with $x \leq x'$ and $y \leq y'$, then the breakpoint representation of such a path is identical to the breakpoint representation of the corresponding alignment. Otherwise, if $x > x'$ or $y > y'$, we call the breakpoint representation of such a path a sequence of all its vertices; recall that all edges in such a path have strictly positive weights.

Planar Graphs, the Monge Property, and Min-Plus Matrix Multiplication

As alignment graphs are planar, we can use the following tool of Klein.

▶ **Fact 2.9** (Klein [19]). *Given a directed planar graph G of size n with non-negative edge weights, we can construct in $\mathcal{O}(n \log n)$ time a data structure that, given two vertices $u, v \in V(G)$ at least one of which lies on the outer face of G, computes the distance $\mathsf{dist}_G(u, v)$ in $\mathcal{O}(\log n)$ time. Moreover, the data structure can report the shortest $u \rightsquigarrow v$ path P in $\mathcal{O}(|P| \log\log \Delta(G))$ time, where $\Delta(G)$ is the maximum degree of G.*

The following lemma specifies a straightforward variation of Klein's algorithm tailored for path reconstruction in alignment graphs.

▶ **Lemma 2.10.** *Given strings $X, Y \in \Sigma^+$ and $\mathcal{O}(1)$-time access to a normalized weight function $w\colon \overline{\Sigma}^2 \to [0, W]$, we can construct in $\mathcal{O}(|X| \cdot |Y| \log^2(|X| + |Y|))$ time a data structure that, given two vertices $u, v \in \overline{\mathsf{AG}}^w(X, Y)$ at least one of which lies on the outer face of $\overline{\mathsf{AG}}^w(X, Y)$, computes the distance $\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, v)$ in $\mathcal{O}(\log(|X| + |Y|))$ time. Moreover, the breakpoint representation of a shortest $u \rightsquigarrow v$ path can be constructed in $\mathcal{O}((1 + \mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, v)) \log^2(|X| + |Y|))$ time.*

Proof. The data structure we build is recursive. We first build the data structure of Klein's algorithm (Fact 2.9) for $\overline{\mathsf{AG}}^w(X, Y)$, and then if $|X| > 1$, recurse onto $(X[0..\lfloor |X|/2 \rfloor), Y)$ and $(X[\lfloor |X|/2 \rfloor..|X|), Y)$. Preprocessing costs $\mathcal{O}(|X| \cdot |Y| \log^2(|X| + |Y|))$ time. For distance queries, the top-level instance of Klein's algorithm is sufficient. It remains to answer path reconstruction queries. We reconstruct the shortest $u \rightsquigarrow v$ path recursively. First, in $\mathcal{O}(\log(|X| + |Y|))$ time we query $\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, v)$. If the distance is 0, we return the breakpoint representation of the trivial shortest $u \rightsquigarrow v$ path. Otherwise, we make further recursive calls. If u and v both lie in $X[0..\lfloor |X|/2 \rfloor) \times Y$ or both lie in $X[\lfloor |X|/2 \rfloor..|X|) \times Y$, by the monotonicity property of Fact 2.4 we can recurse onto the corresponding small recursive data structure instance. Otherwise, every $u \rightsquigarrow v$ path contains a vertex (x, y) with $x = \lfloor |X|/2 \rfloor$. Furthermore, due to Fact 2.8, there are $\mathcal{O}(\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, v))$ possible values for y. In $\mathcal{O}(\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, v) \log(|X| + |Y|))$ time we query $\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, (x, y))$ and $\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}((x, y), v)$ using the smaller recursive data structure instances and find some y satisfying $\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, v) = \mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, (x, y)) + \mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}((x, y), v)$. We then recursively find the breakpoint representations of the optimal $u \rightsquigarrow (x, y)$ path and the optimal $(x, y) \rightsquigarrow v$ path in the smaller recursive data structure instances. There are $\mathcal{O}(\log(|X| + 1))$ recursive levels, on each one of them our total work is $\mathcal{O}((1+\mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, v)) \log(|X|+|Y|))$; thus, the total time complexity is $\mathcal{O}((1 + \mathsf{dist}_{\overline{\mathsf{AG}}^w(X,Y)}(u, v)) \log^2(|X| + |Y|))$. ◀

As discussed in [13, Section 2.3] and [15, Fact 3.7 and Section 5.1], the planarity of alignment graphs implies that the $\mathsf{BM}^w(X, Y)$ matrices satisfy the following *Monge property*:

▶ **Definition 2.11** (Monge Matrix). *A matrix A of size $p \times q$ is a* Monge *matrix if, for all $i \in [0..p - 1)$ and $j \in [0..q - 1)$, we have $A_{i,j} + A_{i+1,j+1} \leq A_{i,j+1} + A_{i+1,j}$.*

In the context of distance matrices, concatenating paths corresponds to the min-plus product of matrices; this operation preserves Monge property and can be evaluated fast.

▶ **Fact 2.12** (Min-Plus Matrix Product, SMAWK Algorithm [3], [29, Theorem 2]). *Let A and B be matrices of size $p \times q$ and $q \times r$, respectively. Their* min-plus product *is a matrix $A \otimes B \coloneqq C$ of size $p \times r$ such that $C_{i,k} = \min_j A_{i,j} + B_{j,k}$ for all $i \in [0..p)$ and $k \in [0..r)$.*

If A and B are Monge matrices, then C is also a Monge matrix. Moreover, C can be constructed in $\mathcal{O}(pr + \min(pq, qr))$ time assuming $\mathcal{O}(1)$-time random access to A and B.

3 $\widetilde{\mathcal{O}}(k^2)$-Time Updates after $\widetilde{\mathcal{O}}(nk)$-Time Preprocessing

In this section, we present a dynamic algorithm that maintains $\mathsf{ed}^w_{\le k}(X, Z)$ for two dynamic strings $X, Z \in \Sigma^{\le n}$ with $\widetilde{\mathcal{O}}(nk)$ preprocessing time and $\widetilde{\mathcal{O}}(k^2)$ update time. As all vertical and horizontal edges cost at least 1, the relevant part of the graph $\overline{\mathsf{AG}}^w(X, Z)$ has size $\mathcal{O}(nk)$ (i.e., a band of width $\Theta(k)$ around the main diagonal), and thus we can afford to preprocess this part of $\overline{\mathsf{AG}}^w(X, Z)$. Nevertheless, the curse of dynamic algorithms for bounded weighted edit distance is that, after $\Theta(k)$ updates (e.g., $\Theta(k)$ character deletions from the end of Z and $\Theta(k)$ character insertions at the beginning of Z), the preprocessed part of the original graph $\overline{\mathsf{AG}}^w(X, Z)$ can be completely disjoint from the relevant part of the updated graph $\overline{\mathsf{AG}}^w(X, Z)$, which renders the original preprocessing useless. To counteract this challenge, we use the idea from [20]: we dynamically maintain information about $\overline{\mathsf{AG}}^w(X, X)$ instead of $\overline{\mathsf{AG}}^w(X, Z)$. Every update to X now affects both dimensions of $\overline{\mathsf{AG}}^w(X, X)$, so the relevant part of the graph does not shift anymore, and hence our preprocessing does not expire. Tasked with computing $\mathsf{ed}^w_{\le k}(X, Z)$ upon a query, we rely on the fact that, unless $\mathsf{ed}^w_{\le k}(X, Z) = \infty$, the graph $\overline{\mathsf{AG}}^w(X, Z)$ is similar to $\overline{\mathsf{AG}}^w(X, X)$.

Consistently with the previous works [8, 15], we cover the relevant part of $\overline{\mathsf{AG}}^w(X, X)$ with $m = \mathcal{O}(n/k)$ rectangular subgraphs G_i of size $\Theta(k) \times \Theta(k)$ each; see Figure 1. We preprocess each subgraph in $\widetilde{\mathcal{O}}(k^2)$ time. A single update to X alters a constant number of subgraphs G_i, so we can repeat the preprocessing for such subgraphs in $\widetilde{\mathcal{O}}(k^2)$ time. The string Z does not affect any subgraph G_i; we only store it in a dynamic strings data structure supporting efficient substring equality queries for the concatenation $X \cdot Z$.

Let V_i for $i \in [1..m)$ be the set of vertices in the intersection of G_i and G_{i+1}; see Figure 1. Furthermore, let $V_0 \coloneqq \{(0, 0)\}$ and $V_m \coloneqq \{(|X|, |X|)\}$. Let G be the union of all graphs G_i. Let $D_{i,j}$ for $i, j \in [0..m]$ with $i < j$ denote the matrix of pairwise distances from V_i to V_j in G. Note that $D_{a,c} = D_{a,b} \otimes D_{b,c}$ holds for all $a, b, c \in [0..m]$ with $a < b < c$.

Upon a query for $\mathsf{ed}^w(X, Z)$, we note that only $\mathcal{O}(\mathsf{ed}(X, Z))$ subgraphs G_i in $\overline{\mathsf{AG}}^w(X, X)$ differ from the corresponding subgraphs in $\overline{\mathsf{AG}}^w(X, Z)$. (If $\mathsf{ed}(X, Z) > k$, then $\mathsf{ed}^w_{\le k}(X, Z) = \infty$, so we can assume that $\mathsf{ed}(X, Z) \le k$.) We call such subgraphs *affected*. Let G'_i, V'_i, and $D'_{i,j}$ be the analogs of G_i, V_i, and $D_{i,j}$ in $\overline{\mathsf{AG}}^w(X, Z)$. Note that if $\mathsf{ed}^w(X, Z) \le k$, then $\mathsf{ed}^w(X, Z)$ is the only entry of the matrix $D'_{0,m}$. Furthermore, we have $D'_{0,m} = D'_{0,1} \otimes \cdots \otimes D'_{m-1,m}$. We compute this product from left to right. For unaffected subgraphs G_i, we have $D'_{i-1,i} = D_{i-1,i}$, and we can use precomputed information about $\overline{\mathsf{AG}}^w(X, X)$. To multiply by $D'_{i-1,i}$ for affected subgraphs G_i, we use the following lemma, the proof of which can be found in the full version of the paper [6].

▶ **Lemma 3.1** (Generalization of [11, Claim 4.2]). *Let $X, Y \in \Sigma^+$ be nonempty strings and $w\colon \overline{\Sigma}^2 \to [0, W]$ be a weight function. Given $\mathcal{O}(1)$-time oracle access to w, the strings X and Y can be preprocessed in $\mathcal{O}(|X| \cdot |Y| \log^2(|X| + |Y|))$ time so that, given a string $Y' \in \Sigma^*$ and a vector v of size $|X| + |Y'| + 1$, the row $v^T \otimes \mathsf{BM}^w(X, Y')$ can be computed in*

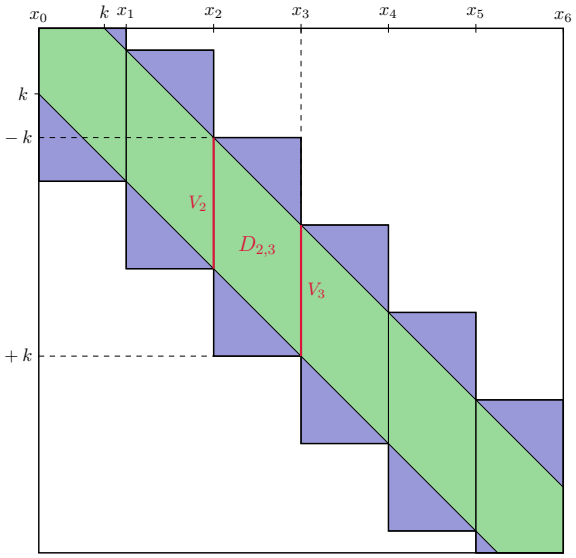

Figure 1 The decomposition of the alignment graph of X onto X into subgraphs G_i of size $\Theta(k) \times \Theta(k)$ that cover the whole stripe of width $\Theta(k)$ around the main diagonal. Each matrix $D_{i,i+1}$ represents the pairwise distances from V_i to V_{i+1}.

$\mathcal{O}((\mathsf{ed}(Y, Y') + 1) \cdot (|X| + |Y|) \log(|X| + |Y|))$ *time. Furthermore, given an input vertex* a *and an output vertex* b *of* $X \times Y'$*, the shortest path from* a *to* b *in* $\overline{\mathsf{AG}}^w(X, Y')$ *can be computed in the same time complexity.*

There are $\mathsf{ed}(X, Z)$ edits that transform $\overline{\mathsf{AG}}^w(X, X)$ into $\overline{\mathsf{AG}}^w(X, Z)$, and each edit affects a constant number of subgraphs G_i. Therefore, applying Lemma 3.1 for all affected subgraphs takes time $\widetilde{\mathcal{O}}(k^2)$ in total. Between two consecutive affected subgraphs G_i and G_j, we have $D'_{i,j-1} = D_{i,j-1}$, and thus it is sufficient to store some range composition data structure over $(D_{i,i+1})_{i=0}^{m-1}$ to quickly propagate between subsequent affected subgraphs.

As the information we maintain dynamically regards $\overline{\mathsf{AG}}^w(X, X)$ and does not involve the string Z, we may generalize the problem we are solving. All we need upon a query is an alignment of X onto Z of *unweighted* cost at most k. Such an alignment can be obtained, for example, from a dynamic bounded unweighted edit distance algorithm [15] in $\widetilde{\mathcal{O}}(k)$ time per update. Alternatively, it is sufficient to have $\widetilde{\mathcal{O}}(1)$-time equality tests between fragments of X and Z. In this case, we can run the classical Landau–Vishkin [21] algorithm from scratch after every update in $\widetilde{\mathcal{O}}(k^2)$ time to either get an optimal unweighted alignment or learn that $\mathsf{ed}^w(X, Z) \geq \mathsf{ed}(X, Z) > k$. Efficient fragment equality tests are possible in a large variety of settings [10] including the dynamic setting [23, 4, 14, 18], so we will not focus on any specific implementation. Instead, we assume that the string Z is already given as a sequence of $u \leq k$ edits of an unweighted alignment transforming X into Z, and our task is to find a w-optimal alignment. We are now ready to formulate the main theorem of this section.

▶ **Theorem 3.2.** *There is a dynamic data structure that, given a string* $X \in \Sigma^*$*, a threshold* $k \geq 1$*, and* $\mathcal{O}(1)$*-time oracle access to a normalized weight function* $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$*, can be initialized in* $\mathcal{O}((|X| + 1)k \log^2(|X| + 2))$ *time and allows for the following operations:*

- *Apply a character edit to* X *in* $\mathcal{O}(k^2 \log^2(|X| + 2))$ *time.*
- *Given* $u \leq k$ *edits transforming* X *into a string* $Z \in \Sigma^*$*, compute* $\mathsf{ed}^w_{\leq k}(X, Z)$ *in* $\mathcal{O}(k \cdot (u + \log(|X| + 2)) \cdot \log(|X| + 2))$ *time. Furthermore, if* $\mathsf{ed}^w(X, Z) \leq k$*, the algorithm returns the breakpoint representation of a* w*-optimal alignment of* X *onto* Z*.*

Proof Sketch. At the initialization phase, we decompose $\overline{\mathsf{AG}}^w(X,X)$ into subgraphs G_i and, for each subgraph G_i, initialize the algorithm of Lemma 3.1 and compute $D_{i-1,i}$ using Lemma 2.10. We also build a dynamic range composition data structure over $(D_{i,i+1})_{i=0}^{m-1}$, implemented as a self-balancing binary tree. Given a range $[a..b)$, in $\mathcal{O}(\log n)$ time, this data structure returns (pointers to) $\ell = \mathcal{O}(\log n)$ matrices $S_1, \ldots, S_\ell$ such that $D_{a,b} = S_1 \otimes \cdots \otimes S_\ell$.

When an update to X comes, it affects a constant number of subgraphs G_i, which we locally adjust and recompute the initialization for in $\widetilde{\mathcal{O}}(k^2)$ time.

Upon a query, we are tasked with computing $D'_{0,1} \otimes \cdots \otimes D'_{m-1,m}$. We locate the $\mathcal{O}(u)$ affected subgraphs G_i and process them one-by-one. We use Lemma 3.1 to multiply the currently computed row $v^T = D'_{0,1} \otimes \cdots \otimes D'_{i-2,i-1}$ by $D'_{i-1,i}$. The algorithm then uses the range composition data structure over $(D_{i,i+1})_{i=0}^{m-1}$ to obtain $\ell = \mathcal{O}(\log n)$ matrices $S_1, \ldots, S_\ell$ that correspond to the segment of matrices between the current affected subgraph G_i and the next affected subgraph G_j. We use SMAWK algorithm (Fact 2.12) to multiply v^T by matrices $S_1, \ldots, S_\ell$. After processing all the matrices, we obtain $D'_{0,1} \otimes \cdots \otimes D'_{m-1,m}$, the only entry of which is equal to $\mathsf{ed}^w(X,Z)$ if $\mathsf{ed}^w_{\le k}(X,Z) \neq \infty$. The applications of Lemma 3.1 work in $\mathcal{O}(ku \log n)$ time in total. Each of the $\mathcal{O}(u)$ blocks of unaffected subgraphs is treated by invoking SMAWK algorithm (Fact 2.12) $\mathcal{O}(\log n)$ times for a total of $\mathcal{O}(ku \log n)$ time.

See the full version of the paper [6] for a formal proof including the alignment reconstruction procedure. ◀

We complete this section with a simple corollary improving the query time if $\mathsf{ed}^w(X,Z) \ll k$.

▶ **Corollary 3.3.** *There is a dynamic data structure that, given a string $X \in \Sigma^*$, a threshold $k \ge 1$, and $\mathcal{O}(1)$-time oracle access to a normalized weight function $w\colon \Sigma^2 \to \mathbb{R}_{\ge 0}$ can be initialized in $\mathcal{O}((|X|+1)k\log^2(|X|+2))$ time and allows for the following operations:*

- *Apply a character edit to X in $\mathcal{O}(k^2\log^2(|X|+2))$ time.*
- *Given $u \le k$ edits transforming X into a string $Z \in \Sigma^*$, compute $\mathsf{ed}^w_{\le k}(X,Z)$ in $\mathcal{O}(1 + (u+d)\cdot(u+\log(|X|+2))\cdot\log(|X|+2))$ time, where $d := \min(\mathsf{ed}^w(X,Z), k)$. Furthermore, if $\mathsf{ed}^w(X,Z) \le k$, the algorithm returns the breakpoint representation of a w-optimal alignment of X onto Z.*

Proof. We maintain the data structures of Theorem 3.2 for thresholds $1, 2, 4, \ldots, 2^{\lceil \log k \rceil}$. Upon a query, we query the data structures for subsequent thresholds starting from $2^{\lceil \log u \rceil}$ until we get a positive result or reach $2^{\lceil \log k \rceil}$. ◀

As discussed earlier, in a variety of settings, upon a query, in $\widetilde{\mathcal{O}}(k^2)$ time we can compute an optimal unweighted alignment of X onto Z or learn that $\mathsf{ed}^w(X,Z) \ge \mathsf{ed}(X,Z) > k$. Therefore, we may assume that whenever Corollary 3.3 is queried, we have $u = \mathsf{ed}(X,Z) \le k$. In this case, the query time complexity can be rewritten as $\mathcal{O}(1 + \min(\mathsf{ed}^w(X,Z), k) \cdot (\mathsf{ed}(X,Z) + \log(|X|+2)) \cdot \log(|X|+2))$.

Due to the robustness of the setting of Corollary 3.3, there are many problems beyond dynamic weighted edit distance that can be solved using Corollary 3.3. For example, given strings $X, Y_0, \ldots, Y_{m-1} \in \Sigma^{\le n}$, we can find $\mathsf{ed}^w_{\le k}(X, Y_i)$ for all $i \in [0..m)$ in $\widetilde{\mathcal{O}}(nm+nk+mk^2)$ time, compared to $\widetilde{\mathcal{O}}(m \cdot (n + \sqrt{nk^3}))$ time arising from m applications of the optimal static algorithm [8].

4 Trade-Off Algorithm: Technical Overview

In the full version of the paper [6], we generalize the result of Theorem 3.2 in two ways. First, we extend the set of updates the string X supports from character edits to *block edits*, which include substring deletions and copy-pastes. More importantly, rather than having $\widetilde{\mathcal{O}}(nk)$

preprocessing time and $\widetilde{\mathcal{O}}(k^2)$ query time, we allow for a complete trade-off matching the lower bound of Theorem 1.5, i.e., $\widetilde{\mathcal{O}}(nk^\gamma)$ preprocessing and $\widetilde{\mathcal{O}}(k^{3-\gamma})$ update time for any $\gamma \in [0,1]$.

A major challenge for $\gamma < 1$ is that we cannot preprocess the whole width-$\Theta(k)$ band around the main diagonal of $\overline{\mathsf{AG}}^w(X,X)$. In the proof of Theorem 3.2, we cover the band with $\Theta(k)\times\Theta(k)$-sized subgraphs G_i and preprocess each of them in $\widetilde{\mathcal{O}}(k^2)$ time for a total of $\widetilde{\mathcal{O}}(nk)$. To achieve $\widetilde{\mathcal{O}}(nk^\gamma)$-time preprocessing, we are forced to instead use $\Theta(k^{2-\gamma})\times\Theta(k^{2-\gamma})$-sized subgraphs G_i and still spend just $\widetilde{\mathcal{O}}(k^2)$ preprocessing time per subgraph.

To remedy the shortage of preprocessing time, we use the ideas behind the recent static algorithms [8, 15]. At the expense of a logarithmic-factor slowdown, they allow us to answer queries only for "repetitive" fragments of X rather than the whole X. More precisely, we are tasked to answer queries involving fragments $\hat{X}$ of X satisfying $\mathsf{self\text{-}ed}(\hat{X}) \le k$, where the *self-edit distance* $\mathsf{self\text{-}ed}(\hat{X})$ is the minimum unweighted cost of an alignment of $\hat{X}$ onto itself that does not match any character of $\hat{X}$ with itself. We can use this to our advantage: the subgraphs G_i corresponding to more "repetitive" fragments X_i allow for more thorough preprocessing in $\widetilde{\mathcal{O}}(k^2)$ time since we can reuse some computations. On the other hand, upon a query, we can afford to spend more time on subgraphs G_i with less "repetitive" fragments X_i as their number is limited due to $\mathsf{self\text{-}ed}(\hat{X}) \le k$.

This approach requires the repetitiveness measure to be super-additive: $\sum_i \mathsf{self\text{-}ed}(X_i) \le \mathsf{self\text{-}ed}(\hat{X})$. Unfortunately, self-edit distance is sub-additive: $\sum_i \mathsf{self\text{-}ed}(X_i) \ge \mathsf{self\text{-}ed}(\hat{X})$. To circumvent this issue, we introduce a better-suited notion of repetitiveness we call *k-shifted self-edit distance* $\mathsf{self\text{-}ed}^k(\hat{X})$: a relaxed version of $\mathsf{self\text{-}ed}(\hat{X})$ allowed to delete up to k first characters of $\hat{X}$ and insert up to k last characters of $\hat{X}$ for free. In contrast to self-edit distance, the k-shifted variant $\mathsf{self\text{-}ed}^k$ satisfies $\sum_i \mathsf{self\text{-}ed}^k(X_i) \le \mathsf{self\text{-}ed}(\hat{X})$ if $\mathsf{self\text{-}ed}(\hat{X}) \le k$.

By using the value of $\mathsf{self\text{-}ed}^k(X_i)$ to determine the level of preprocessing performed on G_i, upon a query, similarly to Theorem 3.2, we have $\mathcal{O}(k)$ "interesting" subgraphs G_i (subgraphs that are either affected by the input edits or satisfy $\mathsf{self\text{-}ed}^k(X_i) > 0$) that we process one-by-one in time $\widetilde{\mathcal{O}}((u_i + \mathsf{self\text{-}ed}^k(X_i))\cdot k^{2-\gamma})$ each using a generalization of Lemma 3.1. The super-additivity property of $\mathsf{self\text{-}ed}^k$ guarantees that this sums up to a total of $\widetilde{\mathcal{O}}(k^{3-\gamma})$. The remaining subgraphs G_i are not affected by the input edits and satisfy $\mathsf{self\text{-}ed}^k(X_i) = 0$, which means that X_i has a period of at most k. For such subgraphs G_i, we can afford the complete preprocessing and, upon a query, processing such subgraphs in chunks in $\widetilde{\mathcal{O}}(k^2)$ time in total precisely as in the proof of Theorem 3.2. Furthermore, similarly to Theorem 3.2, all the information the data structure stores is either local or cumulative, and thus block edits can be supported straightforwardly. This rather simple high-level approach runs into several low-level technical complications that are discussed in detail in the full version of the paper [6].

5 Lower Bounds: Technical Overview

As discussed in Section 1, our conditional lower bounds stem from the following result:

▶ **Theorem 1.2.** *Let $\kappa \in [0.5, 1]$ and $\delta > 0$ be real parameters. Assuming the APSP Hypothesis, there is no algorithm that, given two strings $X, Y \in \Sigma^{\le n}$ satisfying $\mathsf{ed}(X,Y) \le 4$, a threshold $k \le n^\kappa$, and oracle access to a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\ge 0}$, in time $\mathcal{O}(n^{0.5+1.5\kappa-\delta})$ decides whether $\mathsf{ed}^w(X,Y) \le k$.*

The reduction provided in [8] is insufficient because the instances it produces satisfy $\mathsf{ed}(X,Y) = \Theta(k)$ rather than $\mathsf{ed}(X,Y) \le 4$. Still, we reuse hardness of the following problem:

▶ **Problem 5.1** (Batched Weighted Edit Distance [8]). *Given a* batch *of strings* $X_1, \ldots, X_m \in \Sigma^x$*, a string* $Y \in \Sigma^y$*, a threshold* $k \in \mathbb{R}_{\geq 0}$*, and oracle access to a weight function* $w : \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$*, decide if* $\min_{i=1}^{m} \mathsf{ed}^w(X_i, Y) \leq k$.

The hard instances of Problem 5.1, which cannot be solved in $\mathcal{O}(x^{2-\delta}\sqrt{m})$ time for any $\delta > 0$ assuming the APSP Hypothesis, satisfy many technical properties, including $h := \max_{i=1}^{m-1} \mathsf{hd}(X_i, X_{i+1}) = \mathcal{O}(x/m)$, where $\mathsf{hd}(X_i, X_{i+1})$ is the Hamming distance, i.e., the number of positions in which X_i differs from X_{i+1}.

The approach of [8, Section 7] is to construct strings $\bar{X}$ and $\bar{Y}$ that take the following form if we ignore some extra gadgets: $\bar{X} = X_1 Y X_2 \cdots X_{m-1} Y X_m$ and $\bar{Y} = X_0^{\perp} Y X_1^{\perp} \cdots X_{m-1}^{\perp} Y X_m^{\perp}$, where $X_i^{\perp} \in \Sigma^x$ is chosen so that $\mathsf{ed}^w(X_i^{\perp}, X_{i-1}) = \mathsf{ed}^w(X_i^{\perp}, X_i) = h$. The ignored gadgets let us focus on alignments $\mathcal{A}_i : \bar{X} \rightsquigarrow \bar{Y}$ that satisfy the following properties for $i \in [1..m]$:

- the fragment X_i is aligned with the copy of Y in $\bar{Y}$ located between $X_{i-1}^{\perp}$ and $X_i^{\perp}$;
- the $m-1$ copies of Y in $\bar{X}$ are matched with the remaining $m-1$ copies of Y in $\bar{Y}$;
- all the characters within the fragments $X_{i-1}^{\perp}$ and $X_i^{\perp}$ of $\bar{Y}$ are inserted;
- for $j \neq i$, the fragment X_j is aligned with $X_{j-1}^{\perp}$ if $j < i$ and with $X_j^{\perp}$ if $j > i$.

This ensures that the cost of $\mathcal{A}_i$ is equal to a baseline cost (independent of i) plus $\mathsf{ed}^w(X_i, Y)$.

Our reduction uses three types of "X gadgets": X_i, $X_i^{\perp}$, and $X_i^{\top}$, with the latter two playing similar roles. We also introduce a new symbol \$ that is extremely expensive to delete, insert, or substitute with any other symbol. Modulo some extra gadgets, our strings are of the following form:

$$\tilde{X} = X_0^{\top} Y X_0^{\perp} Y \$ \bigodot_{i=1}^{m-1} \Big(X_i Y X_i^{\top} Y X_i^{\perp} Y \Big) X_m Y X_m^{\top} Y X_m^{\perp} \$,$$

$$\tilde{Y} = \$ X_0^{\top} Y X_0^{\perp} Y \bigodot_{i=1}^{m-1} \Big(X_i Y X_i^{\top} Y X_i^{\perp} Y \Big) X_m Y X_m^{\top} \$ Y X_m^{\perp}.$$

Notice that removing the two \$ symbols from $\tilde{X}$ or from $\tilde{Y}$ results in the same string, so we have $\mathsf{ed}(\tilde{X}, \tilde{Y}) \leq 4$. Due to the expensive cost for editing a \$, any optimal alignment must match the two \$ symbols in $\tilde{X}$ with the two \$ symbols in $\tilde{Y}$, deleting a prefix of $\tilde{X}$ and a suffix of $\tilde{Y}$ for some predictable cost. Thus, we can focus our analysis on $\mathsf{ed}^w(\hat{X}, \hat{Y})$, where

$$\hat{X} = X_1 Y X_1^{\top} Y X_1^{\perp} Y \cdots X_m Y X_m^{\top} Y X_m^{\perp} \quad \text{and} \quad \hat{Y} = X_0^{\top} Y X_0^{\perp} Y X_1 Y \cdots X_{m-1}^{\perp} Y X_m Y X_m^{\top}.$$

Observe that both $\hat{X}$ and $\hat{Y}$ consists of "X gadgets" interleaved with Y, and that $\hat{Y}$ contains one more copy of Y and one more "X gadget". Analogously to [8], the ignored extra gadgets let us focus on the alignments $\mathcal{A}_i : \hat{X} \rightsquigarrow \hat{Y}$ satisfying the following properties for $i \in [1..m]$:

- the fragment X_i in $\hat{X}$ is aligned with the copy of Y in $\hat{Y}$ located between $X_{i-1}^{\perp}$ and $X_{i-1}^{\top}$;
- the $3m-1$ copies of Y in $\hat{X}$ are matched with the remaining $3m-1$ copies of Y in $\hat{Y}$;
- all characters within the fragments $X_{i-1}^{\perp}$ and $X_{i-1}^{\top}$ of $\hat{Y}$ are inserted;
- the remaining "X gadgets" in $\hat{X}$ are aligned with the remaining "X gadgets" in $\hat{Y}$.

To perfectly mimic [8], we should ensure that all the "X gadgets" that we can possibly align are at weighted edit distance h. We only managed to construct $X_i^{\perp}$ and $X_i^{\top}$ so that:

- $\mathsf{ed}^w(X_i, X_{i-1}^{\top}) = \mathsf{ed}^w(X_i, X_{i-1}^{\perp}) = \mathsf{ed}^w(X_i^{\top}, X_i) = \mathsf{ed}^w(X_i^{\perp}, X_i) = 2h$, and
- $\mathsf{ed}^w(X_i^{\top}, X_{i-1}^{\perp}) = \mathsf{ed}^w(X_i^{\perp}, X_i^{\top}) = 4h$.

Although we have two different distances between the relevant pairs of "X gadgets", it is easy to see the number of pairs of either type is constant across all the alignments $\mathcal{A}_i$. This is sufficient to guarantee that the cost of $\mathcal{A}_i$ is equal to some baseline cost plus $\mathsf{ed}^w(X_i, Y)$. Moreover, as in [8], the costs of alignments $\mathcal{A}_i$ is $\mathcal{O}(x + mh) = \mathcal{O}(x)$ and, if we denote $n := |\tilde{X}| = |\tilde{Y}|$, then the lower bound derived from the lower bound for Problem 5.1 excludes running times of the form $\mathcal{O}(x^{2-\delta}\sqrt{m}) = \mathcal{O}(x^{2-\delta}\sqrt{n/x}) = \mathcal{O}(\sqrt{nx^{3-2\delta}})$.

Lower Bounds for Dynamic Weighed Edit Distance

From Theorem 1.2 we derive two dynamic lower bounds, each justifying a different limitation of our algorithm given in Theorem 1.6. Our first lower bound, formalized in the following lemma and proved in the full version of the paper [6], concerns our choice to fix a threshold k at the preprocessing phase. If, instead, we aimed for time complexities depending on the current value of $\mathsf{ed}^w(X,Y)$, then, for sufficiently large values of $\mathsf{ed}^w(X,Y)$, we could not achieve update times improving upon the static algorithm.

▶ **Lemma 5.2.** *Consider the following dynamic problem: Given an integer $n \geq 1$ and $\mathcal{O}(1)$-time oracle access to a normalized weight function $w\colon \overline{\Sigma}^2 \to \mathbb{R}_{\geq 0}$, maintain two initially empty strings $X, Y \in \Sigma^{\leq n}$ that throughout the lifetime of the algorithm satisfy $\mathsf{ed}(X,Y) \leq 4$ subject to updates (character edits) and output $\mathsf{ed}^w(X,Y)$ after every update. Suppose that there is an algorithm that solves this problem with $T_P(n)$ preprocessing and $T_U(n, \mathsf{ed}^w(X,Y))$ update time, where T_U is non-decreasing. If $T_P(n) = \mathcal{O}(n^{0.5+1.5\kappa-\delta})$, $T_U(n,2) = \mathcal{O}(n^{1.5\kappa-0.5-\delta})$, and $T_U(n,n^\kappa) = \mathcal{O}(n^{0.5+1.5\kappa-\delta})$ hold for some real parameters $\kappa \in [0.5,1]$ and $\delta > 0$, then the APSP Hypothesis fails.*

Our second dynamic lower bound justifies the specific trade-off between the preprocessing and update time in Theorem 1.6. In simple words, we prove that, with preprocessing time $\widetilde{\mathcal{O}}(nk^\gamma)$ for $\gamma \in [0.5,1)$, the best possible update time is $\mathcal{O}(k^{3-\gamma-o(1)})$. For that, we note that Theorem 1.2 is based on a reduction from the Negative Triangle problem, which is *self-reducible*: solving m instances of bounded weighted edit distance from Theorem 1.2 is hence, in general, m times harder than solving a single instance. Given such m instances $(X_0,Y_0),\ldots,(X_{m-1},Y_{m-1})$, we initialize a dynamic algorithm with a pair of equal strings $\hat{X} = \hat{Y} = \bigodot_{i=0}^{m-1}(X_i \cdot \dagger)$, where $\dagger$ is an auxiliary symbol that is very expensive to edit. For $i \in [0..m)$, in $\mathsf{ed}(X_i,Y_i) = \mathcal{O}(1)$ updates, we can transform the fragment X_i of $\hat{Y}$ into Y_i and retrieve $\mathsf{ed}^w_{\leq k}(\hat{X},\hat{Y}) = \mathsf{ed}^w_{\leq k}(X_i,Y_i)$. By applying and reverting these updates for every $i \in [0..m)$, we can thus find $\mathsf{ed}^w_{\leq k}(X_i,Y_i)$ for all i. If we pick $m \coloneqq n/k^{3-2\gamma-2\delta}$ for an arbitrary small constant $\delta > 0$, then the static lower bound requires $m \cdot (\sqrt{(n/m)k^3})^{1-o(1)} \geq (nk^{\gamma+\delta})^{1-o(1)}$ total time. Our preprocessing time is asymptotically smaller, so, among $\mathcal{O}(m)$ updates, some must take $\Omega((\sqrt{(n/m)k^3})^{1-o(1)}) = \Omega(k^{3-\gamma-\delta-o(1)})$ time. See the full version of the paper [6] for a formal proof.

Max-Distance Sparsification for Diversification and Clustering

Soh Kumabe
CyberAgent, Tokyo, Japan

Abstract

Let $\mathcal{D}$ be a set family that is the solution domain of some combinatorial problem. The *max-min diversification problem on* $\mathcal{D}$ is the problem to select k sets from $\mathcal{D}$ such that the Hamming distance between any two selected sets is at least d. FPT algorithms parameterized by $k + \ell$, where $\ell = \max_{D \in \mathcal{D}} |D|$, and $k + d$ have been actively studied recently for several specific domains.

This paper provides unified algorithmic frameworks to solve this problem. Specifically, for each parameterization $k + \ell$ and $k + d$, we provide an FPT oracle algorithm for the max-min diversification problem using oracles related to $\mathcal{D}$. We then demonstrate that our frameworks provide the first FPT algorithms on several new domains $\mathcal{D}$, including the domain of t-linear matroid intersection, almost 2-SAT, minimum edge s, t-flows, vertex sets of s, t-mincut, vertex sets of edge bipartization, and Steiner trees. We also demonstrate that our frameworks generalize most of the existing domain-specific tractability results.

Our main technical breakthrough is introducing the notion of *max-distance sparsifier* of $\mathcal{D}$, a domain on which the max-min diversification problem is equivalent to the same problem on the original domain $\mathcal{D}$. The core of our framework is to design FPT oracle algorithms that construct a constant-size max-distance sparsifier of $\mathcal{D}$. Using max-distance sparsifiers, we provide FPT algorithms for the max-min and max-sum diversification problems on $\mathcal{D}$, as well as k-center and k-sum-of-radii clustering problems on $\mathcal{D}$, which are also natural problems in the context of diversification and have their own interests.

1 Introduction

1.1 Background and Motivation

The procedure for approaching real-world problems with optimization algorithms involves formulating the real-world motivations as mathematical problems and then solving them. However, real-world problems are complex, and the idea of a "good" solution cannot always be correctly formulated. The paradigm of *diversification*, introduced by Baste et al. [8] and Baste et al. [7], is a "formulation of the unformulatable problems", which formulates *diversity measures* for a set of multiple solutions, rather than attempting to formulate the "goodness" of a single solution. By computing a set of solutions that maximize this measure, the algorithm provides effective options to evaluators who have the correct criteria for judging the "goodness" of a solution.

Let U be a finite set, $k \in \mathbb{Z}_{\geq 1}$ and $d \in \mathbb{Z}_{\geq 0}$. Let $\mathcal{D} \subseteq 2^U$ be the feasible domain of some combinatorial problem. The following problem frameworks, defined by two types of diversity measures, have been studied extensively.

Max-Min Diversification Problem on $\mathcal{D}$: Does there exist a k-tuple $(D_1, \ldots, D_k) \in \mathcal{D}^k$ of sets in $\mathcal{D}$ such that $\min_{1 \leq i < j \leq k} |D_i \triangle D_j| \geq d$?[1]

Max-Sum Diversification Problem on $\mathcal{D}$: Does there exist a k-tuple $(D_1, \ldots, D_k) \in \mathcal{D}^k$ of sets in $\mathcal{D}$ such that $\sum_{1 \leq i < j \leq k} |D_i \triangle D_j| \geq d$?

These problems ensure diversity by aiming to output solutions that are as dissimilar as possible in terms of Hamming distance.

Parameterized algorithms for diversification problems have been actively studied. Particularly, FPT algorithms for the max-min diversification problems parameterized by $k + \ell$, where $\ell = \max_{D \in \mathcal{D}} |D|$ [7, 8, 22, 26, 31], as well as by $k + d$ [17, 21, 22, 23, 24, 29], have been the focus of research. Since assuming $d \leq 2\ell$ does not lose generality in the max-min diversification problem, the latter addresses a more general situation than the former. Since the max-sum diversification problem is empirically more tractable than the max-min diversification problem, for some time hereafter, we will restrict our discussion to the max-min diversification problem.

This research provides general algorithmic frameworks for FPT algorithms solving max-min (and max-sum) diversification problems for both parameterizations $k + \ell$ and $k + d$. Our frameworks are very general and can be applied to all domains [5, 6, 7, 8, 17, 21, 22, 23, 25, 26, 31] for which FPT algorithms parameterized by $k + \ell$ and $k + d$ are currently known for the case that diversity measure is defined using an unweighted Hamming distance. Moreover, our frameworks further provide the first algorithms for several domains where such algorithms were previously unknown.

Our main technical breakthrough is introducing a notion of *max-distance sparsifier* as an intermediate step, which, for the max-min diversification problem, essentially works as a *core-set* [2]. The formal definition is given in Section 1.3. The critical fact is that, when $\mathcal{K}$ is a max-distance sparsifier of $\mathcal{D}$, the max-min diversification problem on $\mathcal{D}$ is equivalent to the same problem on $\mathcal{K}$. Our framework constructs a constant-size max-distance sparsifier $\mathcal{K}$ of $\mathcal{D}$ using the oracles on $\mathcal{D}$, enabling us to solve the max-min diversification problems on $\mathcal{D}$ by brute-force search on $\mathcal{K}$.

The power of max-distance sparsification is not limited to solving diversification problems. Specifically, the following *k-center* [27] and *k-sum-of-radii clustering problems on $\mathcal{D}$* [11] can also be solved via max-distance sparsification.

***k*-Center Clustering Problem on $\mathcal{D}$:** Does there exist a k-tuple of subsets $(D_1, \ldots, D_k) \in \mathcal{D}^k$ such that for all $D \in \mathcal{D}$, there exists an $i \in \{1, \ldots, k\}$ satisfying $|D_i \triangle D| \leq d$?

***k*-Sum-of-Radii Clustering Problem on $\mathcal{D}$:** Does there exist a k-tuple of subsets $(D_1, \ldots, D_k) \in \mathcal{D}^k$ and a k-tuple of non-negative integers $(d_1, \ldots, d_k) \in \mathbb{Z}^k_{\geq 0}$ with $\sum_{i \in \{1, \ldots, k\}} d_i \leq d$ such that for all $D \in \mathcal{D}$, there exists an $i \in \{1, \ldots, k\}$ satisfying $|D_i \triangle D| \leq d_i$?

When $\mathcal{D}$ is an explicitly given set of points, parameterized algorithms for these problems have been extensively studied in the area of clustering [3, 4, 12, 15, 16, 20, 28]. Furthermore, approximation algorithms for the *relational k-means* [13, 19, 30] and *relational k-center* [1] problems are investigated, which are the k-means and k-center clustering problem defined on

[1] We define $Z_1 \triangle Z_2 := (Z_1 \setminus Z_2) \cup (Z_2 \setminus Z_1)$.

a point set represented as a *join* of given relational databases. Their setting is similar to ours as the point set are implicitly given and its size can be exponential. This research adds several new combinatorial domains to the literature on clustering problems on implicitly given domains, and also introduces a parameterized view. These problems are also natural in the context of diversification, since in real situations, the concept of diversity often means that the extracted elements cover the entire space comprehensively rather than being mutually dissimilar. This motivation is formulated by clustering problems, which extract a list of sets in $\mathcal{D}$ such that for each set in $\mathcal{D}$, there is an extracted set near to it.

1.2 Our Results

This paper consists of two parts. In the first part, we design general frameworks for solving diversification and clustering problems. In the second part, we apply our frameworks to several specific domains $\mathcal{D}$. Table 1 shows a list of domains on which our frameworks provide the first or an improved algorithm for the max-min diversification problem.

1.2.1 The Frameworks

We define the following $(-1,1)$-*optimization oracle on* $\mathcal{D}$ and the *exact extension oracle on* $\mathcal{D}$.

> **$(-1,1)$-Optimization Oracle on $\mathcal{D}$:** Let U be a finite set, $\mathcal{D} \subseteq 2^U$, and $w \in \{-1,1\}^U$ be a weight vector. Return a set $D \in \mathcal{D}$ that maximizes $\sum_{e \in D} w_e$.

> **Exact Extension Oracle on $\mathcal{D}$:** Let U be a finite set, $r \in \mathbb{Z}_{\geq 0}$, $\mathcal{D} \subseteq 2^U$, and $C \in \mathcal{D}$. Let $X, Y \subseteq U$ be two disjoint subsets of U. If there exists a set $D \in \mathcal{D}$ such that $|D \triangle C| = r$, $X \subseteq D$, and $Y \cap D = \emptyset$, return one such set. If no such set exists, return $\perp$.

When $C = \emptyset$ and $X = \emptyset$, we specifically call the exact extension oracle on $\mathcal{D}$ the *exact empty extension oracle on* $\mathcal{D}$.

> **Exact Empty Extension Oracle on $\mathcal{D}$:** Let U be a finite set, $r \in \mathbb{Z}_{\geq 0}$, $\mathcal{D} \subseteq 2^U$, and $Y \subseteq U$. If there exists a set $D \in \mathcal{D}$ such that $|D| = r$ and $Y \cap D = \emptyset$, return one such set. If no such set exists, return $\perp$.

Let $\mathcal{P}_{\mathcal{D}}$ be the max-min/max-sum diversification problem or the k-center/k-sum-of-radii clustering problem on $\mathcal{D}$. Our main result is FPT algorithms for solving $\mathcal{P}_{\mathcal{D}}$ using these oracles. We construct frameworks for both types of parameterizations, $k + \ell$ and $k + d$. The result for the parameterization by $k + \ell$ is as follows.

▶ **Theorem 1.** *There exists an oracle algorithm solving $\mathcal{P}_{\mathcal{D}}$ using the exact empty extension oracle on $\mathcal{D}$, where the number of oracle calls and time complexity are both FPT parameterized by $k + \ell$ and for each call of an oracle, r and $|Y|$ are bounded by constants that depend only on $k + \ell$.*

The result for the parameterization by $k + d$ is as follows.

▶ **Theorem 2.** *There exists a randomized oracle algorithm solving $\mathcal{P}_{\mathcal{D}}$ using the $(-1,1)$-optimization oracle on $\mathcal{D}$ and the exact extension oracle on $\mathcal{D}$, where the number of oracle calls and time complexity are both FPT parameterized by $k + d$ and for each call of the exact extension oracle, $r + |X| + |Y|$ are bounded by constants that depend only on $k + d$.*

Table 1 List of new results for the max-min diversification problem obtained by our frameworks. The first column represents the domain $\mathcal{D}$. The second column represents parameterization. For the formal definition of each domain, see the full version.

Domain	Parameter
t-Linear Matroid Intersection	$k+\ell+t$
Almost 2-SAT	$k+\ell$
Independent Set on Certain Graphs	$k+\ell$
Min Edge s,t-Flow	$k+d$
Steiner Tree	$k+d+\lvert T\rvert$
Vertex Set of Min s,t-Cut	$k+d$
Vertex Set of Edge Bipartization	$k+d+s$

1.2.2 Applications of Theorem 1

On most domains $\mathcal{D}$, the exact empty extension oracle can be designed by almost the same way as an algorithm to extract a single solution from $\mathcal{D}$. For example, consider the case where $\mathcal{D}$ is the *ℓ-path domain*, i.e., a domain of sets of edges on paths of length ℓ. In this case, the exact empty extension oracle on $\mathcal{D}$ is equivalent to the problem of finding an ℓ-path in the graph obtained by removing all edges in Y from the input. Combining Theorem 1 with this empirical fact, we can claim that, for most domains $\mathcal{D}$, the diversification and clustering problems parameterized by $k+\ell$ on $\mathcal{D}$ are as easy as determining the non-emptiness of $\mathcal{D}$.

To demonstrate that Theorem 1 yields existing tractability results, we design the oracles for the domains of the vertex cover [7, 8], t-hitting set [7], feedback vertex set [7], and common independent set of two matroids [17, 22]. We also apply our framework on new domains, t-represented linear matroid intersection, almost 2-SAT, and independent set on *subgraph-closed IS-FPT* graph classes. Here, a graph class is *subgraph-closed IS-FPT* if it is closed under taking subgraphs and the problem of finding independent set of size ℓ is FPT parameterized by ℓ. The following theorem summarizes our results, where the precise definitions of each domain are given in the full version.

▶ **Theorem 3.** *Let $\mathcal{D}$ be the domain of vertex covers, t-hitting sets, feedback vertex sets, t-represented linear matroid intersections, almost 2-SATs, or independent sets on subgraph-closed IS-FPT graph classes. Then, max-min and max-sum diversification problems and k-center and k-sum-of-radii clustering problems admit an FPT algorithm, where the parameterization is $k+\ell$ except for the t-hitting set and t-represented linear matroid intersection, which are parameterized by $k+\ell+t$.*

Theorem 1 also generalizes existing frameworks for diversification. Baste et al. [8] provided an algorithmic framework for diversification using a *loss-less kernel* [9, 10], which, roughly speaking, is a kernel that completely preserves the information of the solution space. Since loss-less kernels are known for very limited domains, their framework requires very strong assumptions. Our framework has broader applicability than theirs because it relies on a weaker oracle, as the exact empty extension oracle can be constructed using a loss-less kernel. Hanaka et al. [26] developed a color-coding-based framework for diversification. The oracle they use can be regarded as the exact empty extension oracle with an additional colorfulness constraint. Our framework again has broader applicability than theirs because our oracle can be constructed using theirs. Moreover, our framework also treats clustering problems, which these two do not.

1.2.3 Applications of Theorem 2

FPT algorithms for the max-min diversification problems on $\mathcal{D}$ parameterized by $k+d$ are known for the cases where $\mathcal{D}$ is the family of matroid bases [17, 22], perfect matchings [22], and shortest paths [23]. The result for the perfect matchings is later extended to the matchings of specified size, not necessarily perfect [17]. Additionally, for the cases where $\mathcal{D}$ is the family of interval schedulings [26] and the longest common subsequences of an absolute constant number of strings [31], FPT algorithms parameterized by $k+\ell$ are known. Both of these two can be generalized to the domain of dynamic programming problems, which we define in the full version. Furthermore, the problem of finding a pair of a branching and an in-branching such that the Hamming distance between them is at least d is investigated as the name of *d-distinct branchings problem* [5, 6, 25], which admits FPT algorithm parameterized by d. This problem can naturally be extended to the case that selects k_1 branchings and k_2 in-branching, rather than one each. We give FPT algorithms parameterized by $k+d$ for all those problems, where $k=k_1+k_2$ for the extended version of d-distinct branchings problem. We also give FPT algorithms on domains of minimum edge s,t-flows, Steiner trees, vertex sets of s,t-mincut, and vertex sets of edge bipartization, which are domains where no FPT algorithm for the max-min diversification problem is previously known. Remark that the domain of shortest paths [23] is the special case of the minimum edge s,t-flow domain and the minimum Steiner tree domain. The following theorem summarizes our results, where the precise definitions of each domain are given in the full version.

▶ **Theorem 4.** *Let $\mathcal{D}$ be the domain of matroid bases, branchings, matchings of specified size, minimum edge s,t-flows, minimum Steiner trees, vertex sets of s,t-mincut, vertex sets of edge bipartization, and dynamic programming problems. Then, max-min and max-sum diversification problems and k-center and k-sum-of-radii clustering problems admit an FPT algorithm, where the parameterization is $k+d$ except for the Steiner tree, which is parameterized by $k+d+|T|$ for the terminal set T, and edge bipartization, which is parameterized by $k+\ell+s$, where s is the minimum number of edges to be removed to make the given graph bipartite. Furthermore, the extended version of d-distinct branching problem also admits FPT algorithm parameterized by $k+d$.*

Eiben et al. [17] provided a technique called *determinantal sieving*, which is a general tool to give and speed up parameterized algorithms, including that for diversification problems. Particularly, they provided a framework to solve the diversification problem by using an oracle that, roughly speaking, counts the number of solutions modulo 2. Using their framework, they improved the running times of FPT algorithms for max-min diversification problems on matchings and matroid bases, as well as the d-distinct branchings problem. Although not stated explicitly, their framework seems to yield FPT algorithms parameterized by $k+d$ when $\mathcal{D}$ is the dynamic programming domain, thereby improving the parameterizations in the results of [26] and [31], respectively, as well as the extended version of d-distinct branchings problems. We are not sure whether our framework generalizes theirs, that is, whether our oracle can be constructed using their oracle. However, we strongly believe that our framework has broader applicability because their framework assumes counting oracles, which is often hard even modulo 2. In contrast, our framework uses optimization-type oracles, which are generally more tractable than counting. Indeed, our framework provides an FPT algorithm with the same parameterization for every domain which they explicitly considered. Moreover, we do not think their framework can give an FPT algorithm for the max-min diversification problem on the domains of minimum edge s,t-flows, vertex sets of minimum s,t-cut, and vertex sets of edge bipartization. Furthermore, our framework can be applied not only to diversification problems but also to clustering problems.

1.3 Framework Overview

In this section, we provide an overview of the entire flow of our frameworks. Our frameworks first construct max-distance sparsifiers using the corresponding oracles and then solve diversification and clustering problems using them.

1.3.1 From d-Limited k-Max-Distance Sparsifier to Diversification and Clustering

We begin by defining the max-distance sparsifiers. The key for Theorem 1 is designing the following *k-max-distance sparsifier of $\mathcal{D}$*.

▶ **Definition 5** (k-max-distance sparsifier)**.** *Let $k \in \mathbb{Z}_{\geq 1}$. Let U be a finite set and $\mathcal{D}, \mathcal{F} \subseteq 2^U$. We say that $\mathcal{K} \subseteq \mathcal{D}$ is a* k-max-distance sparsifier of $\mathcal{D}$ with respect to $\mathcal{F}$ *if for any $(F_1, \ldots, F_k) \in \mathcal{F}^k$ and $(z_1, \ldots, z_k) \in \mathbb{Z}^k_{\geq 0}$, the two conditions*

- *There exists $D \in \mathcal{D}$ such that for each $i \in \{1, \ldots, k\}$, $|F_i \triangle D| \geq z_i$.*
- *There exists $K \in \mathcal{K}$ such that for each $i \in \{1, \ldots, k\}$, $|F_i \triangle K| \geq z_i$.*

are equivalent. Unless specifically noted, when we write k-max-distance sparsifier of $\mathcal{D}$*, we mean the case where $\mathcal{D} = \mathcal{F}$.*

Similarly, the key for Theorem 2 is designing the following *d-limited k-max-distance sparsifier of $\mathcal{D}$*.

▶ **Definition 6** (d-limited k-max-distance sparsifier)**.** *Let $k \in \mathbb{Z}_{\geq 1}$ and $d \in \mathbb{Z}_{\geq 0}$. Let U be a finite set and $\mathcal{D}, \mathcal{F} \subseteq 2^U$. We say that $\mathcal{K} \subseteq \mathcal{D}$ is a* d-limited k-max-distance sparsifier of $\mathcal{D}$ with respect to $\mathcal{F}$ *if for any $(F_1, \ldots, F_k) \in \mathcal{F}^k$ and $(z_1, \ldots, z_k) \in \{0, \ldots, d\}^k$, the two conditions*

- *There exists $D \in \mathcal{D}$ such that for each $i \in \{1, \ldots, k\}$, $|F_i \triangle D| \geq z_i$.*
- *There exists $K \in \mathcal{K}$ such that for each $i \in \{1, \ldots, k\}$, $|F_i \triangle K| \geq z_i$.*

are equivalent. Unless specifically noted, when we write d-limited k-max-distance sparsifier of $\mathcal{D}$*, we mean the case where $\mathcal{D} = \mathcal{F}$.*

The difference between the two sparsifiers is that the domain of $(z_1, \ldots, z_k)$ is $\mathbb{Z}^k_{\geq 0}$ in the former case, while it is $\{0, \ldots, d\}^k$ in the latter. By definition, any k-max-distance sparsifier is also a d-limited k-max-distance sparsifier for any $d \in \mathbb{Z}_{\geq 0}$. We can prove that given a d-limited $(k-1)$-max-distance sparsifier of $\mathcal{D}$ with size bounded by a constant that depends only on $k+d$, we can construct FPT algorithms parameterized by $k+d$ for the max-min/max-sum diversification problems on $\mathcal{D}$. Similarly, we can prove that given a $(d+1)$-limited k-max-distance sparsifier of $\mathcal{D}$ with size bounded by a constant that depends only on $k+d$, we can construct FPT algorithms parameterized by $k+d$ for the k-center/k-sum-of-radii clustering problems on $\mathcal{D}$. Therefore, to prove Theorems 1 and 2, it suffices to construct FPT oracle algorithms for designing k-max-distance sparsifiers and d-limited k-max-distance sparsifiers, respectively.

1.3.2 Computing k-Max-Distance Sparsifier

The remaining task towards Theorem 1 is to provide an FPT algorithm parameterized by $k+\ell$ that constructs a k-max-distance sparsifier of $\mathcal{D}$ with size bounded by a constant that depends only on $k+\ell$. The key lemma toward this is that, if $\mathcal{K}$ contains a sufficiently large *sunflower* (see Section 3 for the definition) consisting of sets of the same size, then we can safely remove one of them from $\mathcal{K}$ while preserving the property that $\mathcal{K}$ is a k-max-distance

sparsifier (actually, for the sake of simplifying the framework, we prove a slightly stronger statement). Starting with $\mathcal{K} = \mathcal{D}$ and exhaustively removing such sets leads to a $\mathcal{K}$ that is still a k-max-distance sparsifier of $\mathcal{D}$, and by using the well-known sunflower lemma (Lemma 13), its size is bounded by a constant.

However, this observation is still not sufficient to obtain an FPT algorithm. The reason is that $\mathcal{D}$ generally has exponential size, and removing sets one by one would require an exponential number of steps. Instead, our algorithm starts with $\mathcal{K} = \emptyset$ and exhaustively adds sets of $\mathcal{D}$ to $\mathcal{K}$ until $\mathcal{K}$ becomes a k-max-distance sparsifier. In this way, the number of steps is bounded by a constant. The remaining task is to choose a set to be added at each step. For this task, we design an FPT algorithm using constant number of calls of the exact empty extension oracle.

1.3.3 Computing d-Limited k-Max-Distance Sparsifier

The algorithm in the previous section alone is insufficient to prove Theorem 2 since ℓ is unbounded and the sunflower-lemma-based bound for the number of steps cannot be used. Our algorithm divides $\mathcal{D}$ into at most k clusters, computes a d-limited k-max-distance sparsifier for each cluster, and outputs their union. Let $p > 2d$ be a constant that depends only on $k + d$. We first find $\mathcal{C} \subseteq \mathcal{D}$ satisfying the following properties: (i) $|\mathcal{C}| \leq k$, (ii) for all distinct $C, C' \in \mathcal{C}$, $|C \triangle C'| > 2d$, and (iii) for all $D \in \mathcal{D}$, there exists $C \in \mathcal{C}$ such that $|D \triangle C| \leq p$. If such a family does not exist, a trivial d-limited k-max-distance sparsifier of $\mathcal{D}$ will be found, and we output it and terminate.

We provide an algorithm for computing $\mathcal{C}$. Our algorithm starts with $\mathcal{C} = \emptyset$ and exhaustively adds sets in $\mathcal{D}$ to $\mathcal{C}$ until $\mathcal{C}$ satisfies the above conditions or its size exceeds k. To choose the elements to be added, we randomly sample $w \in \{-1, 1\}^U$ and call a $(-1, 1)$-optimization oracle. We can prove for sufficiently large constant p that if there exists $D \in \mathcal{D}$ such that $|D \triangle C| > p$ for any $C \in \mathcal{C}$, with a constant probability, the $(-1, 1)$-optimization oracle will find a $D \in \mathcal{D}$ such that $|D \triangle C| > 2d$ for any $C \in \mathcal{C}$. Thus, if $\mathcal{C}$ does not meet the conditions, by calling the $(-1, 1)$-optimization oracle a sufficient number of times, we can find a set to add to $\mathcal{C}$ with high probability.

Here, we provide an algorithm for computing a d-limited k-max-distance sparsifier of $\mathcal{D}$ using $\mathcal{C}$. For each cluster $\mathcal{D}_C := \{D \in \mathcal{D} \colon |D \triangle C| \leq p\}$, let $\mathcal{D}^*_C := \{D \triangle C \colon D \in \mathcal{D}_C\}$. The algorithm computes a k-max-distance sparsifier of each $\mathcal{D}^*_C$ and outputs their union. For technical reasons, we actually compute a slightly more general object, but we will not delve into the details here. Since each $\mathcal{D}^*_C$ consists only of sets whose size is at most p, the k-max-distance sparsifier of $\mathcal{D}^*_C$ can be constructed using the algorithm in Section 1.3.2. The exact empty extension oracle on $\mathcal{D}^*_C$ corresponds to the exact extension oracle on $\mathcal{D}$.

Here, we note the difference between our framework and that used by Fomin et al. [22] and Funayama et al. [23] to provide FPT algorithms for the max-min diversification problem on $\mathcal{D}$ when $\mathcal{D}$ is the family of perfect matchings and shortest paths, respectively. Their algorithms also start by dividing $\mathcal{D}$ into clusters. However, their algorithms perform stricter clustering than ours. Specifically, in their clustering, clusters $\mathcal{D}_C$ corresponding to different $C \in \mathcal{C}$ must be well-separated. In contrast, we allow clusters to overlap. This simplifies the clustering step compared to their approach at the cost of a more challenging task afterward. We resolve this more challenging task by introducing and designing the d-limited k-max-distance sparsifier.

1.4 Organization

The rest of this paper is organized as follows. In Section 2, we provide FPT algorithms for solving diversification and clustering problems on $\mathcal{D}$ using a constant-size d-limited k-max-distance sparsifier of $\mathcal{D}$. In Section 3, we prove Theorem 1 by providing an FPT oracle algorithm parameterized by $k + \ell$ that computes a constant-size k-max-distance sparsifier of $\mathcal{D}$. In Section 4, we prove Theorem 2 by providing an FPT oracle algorithm parameterized by $k + d$ that computes a constant-size d-limited k-max-distance sparsifier of $\mathcal{D}$. The discussion in Section 4 internally uses the results from Section 3. In the full version, we apply the results of Theorems 1 and 2 to several domains $\mathcal{D}$ to obtain FPT algorithms for diversification and clustering problems. The full version also contains further related work and the proofs of the lemmas marked with an asterisk.

2 From Sparsifier to Diversification and Clustering

In this section, we provide FPT algorithms for diversification and clustering problems using a d-limited k-max-distance sparsifier of constant size.

2.1 Diversification

Let U be a finite set, $d \in \mathbb{Z}_{\geq 0}$, $k \in \mathbb{Z}_{\geq 1}$, and $\mathcal{D} \subseteq 2^U$. For diversification problems, we have the following.

▶ **Lemma 7.** *Let $\mathcal{K} \subseteq \mathcal{D}$ be a d-limited $(k-1)$-max-distance sparsifier of $\mathcal{D}$ and $(D_1, \ldots, D_k) \in \mathcal{D}^k$. Then, there is a k-tuple $(K_1, \ldots, K_k) \in \mathcal{K}^k$ such that $\min(d, |D_i \triangle D_j|) \leq \min(d, |K_i \triangle K_j|)$ holds for all $1 \leq i < j \leq k$. Particularly, if there exists a solution to the max-min/max-sum diversification problem on $\mathcal{D}$, then there exists a solution consisting only of sets in $\mathcal{K}$.*

Proof. Assume $(D_1, \ldots, D_k) \in \mathcal{D}^k \backslash \mathcal{K}^k$ and let $i \in \{1, \ldots, k\}$ be an index such that $D_i \notin \mathcal{K}$. It is sufficient to prove that there is a set $K_i \in \mathcal{K}$ such that $\min(d, |D_i \triangle D_j|) \leq \min(d, |K_i \triangle D_j|)$ holds for all $j \in \{1, \ldots, k\} \setminus \{i\}$. For $j \in \{1, \ldots, k\} \setminus \{i\}$, let $z_j := \min(d, |D_i \triangle D_j|)$. Since $\mathcal{K}$ is a d-limited $(k-1)$-max-distance sparsifier of $\mathcal{D}$, there exists $K_i \in \mathcal{K}$ such that $\min(d, |K_i \triangle D_j|) \geq \min(d, z_j) = \min(d, |D_i \triangle D_j|)$ holds for all $j \in \{1, \ldots, k\} \setminus \{i\}$. ◀

Considering an algorithm that exhaustively searches for a subfamily of $\mathcal{K}$ of size k, we can state the following.

▶ **Lemma 8.** *Assume there exists an FPT algorithm parameterized by $k + d$ to compute a d-limited $(k-1)$-max-distance sparsifier of $\mathcal{D}$ with size bounded by a constant that depends only on $k + d$. Then, there exists an FPT algorithm parameterized by $k + d$ for the max-min/max-sum diversification problem on $\mathcal{D}$.*

We note that, under the slightly stronger assumption, the discussion in this section can directly be extended to the case where the sets $D_1, \ldots, D_k$ are taken from different domains. Specifically, let $\mathcal{D}_1, \ldots, \mathcal{D}_k \subseteq 2^U$ and assume $(k-1)$-max-distance sparsifiers $\mathcal{K}_1, \ldots, \mathcal{K}_k$ of these domains with respect to 2^U are computed. Then, we can determine whether there exists a k-tuple $(D_1, \ldots, D_k) \in \mathcal{D}_1 \times \cdots \times \mathcal{D}_k$ such that $\min_{1 \leq i < j \leq k} |D_i \triangle D_j| \geq d$ (or $\sum_{1 \leq i < j \leq k} |D_i \triangle D_j| \geq d$) by exhaustive search on $\mathcal{K}_1 \times \cdots \times \mathcal{K}_k$.

2.2 Clustering

Let U be a finite set, $d \in \mathbb{Z}_{\geq 0}$, $k \in \mathbb{Z}_{\geq 1}$, and $\mathcal{D} \subseteq 2^U$. Here, we provide an FPT algorithm for the k-center and k-sum-of-radii clustering problems using a $(d+1)$-limited k-max-distance sparsifier $\mathcal{K}$ of $\mathcal{D}$. For $Z \subseteq U$ and $r \in \mathbb{Z}_{\geq 0}$, the *ball* of radius r centered at Z is defined as $\mathcal{B}(Z, r) := \{Z' \subseteq U : |Z \triangle Z'| \leq r\}$. The algorithm first guesses a partition of $\mathcal{K}$ into k clusters $\mathcal{K}_1, \ldots, \mathcal{K}_k$. Since $|\mathcal{K}|$ is constant, the cost of this guess is constant. Then, for each $i \in \{1, \ldots, k\}$, the algorithm computes the minimum radius r_i such that there is a set $D_i \in \mathcal{D}$ satisfying $\mathcal{K}_i \subseteq \mathcal{B}(D_i, r_i)$. If $r_i > d$, the algorithm asserts it instead of computing the specific value of r_i. The k-center clustering problem and k-sum-of-radii clustering problem on $\mathcal{D}$ are solved by checking whether the maximum and sum, respectively, of the r_is is at most d. We show the correctness of this algorithm by proving the following.

▶ **Lemma 9.** *Let $(D_1, \ldots, D_k) \in \mathcal{D}^k$ and $(r_1, \ldots, r_k) \in \{0, \ldots, d\}^k$. Assume $\mathcal{K}_i \subseteq \mathcal{B}(D_i, r_i)$ holds for all $i \in \{1, \ldots, k\}$. Then, for all $D \in \mathcal{D}$, there is an index $i \in \{1, \ldots, k\}$ such that $D \in \mathcal{B}(D_i, r_i)$.*

Proof. Assume the contrary. Then, there is a set $D \in \mathcal{D}$ such that for all $i \in \{1, \ldots, k\}$, $|D_i \triangle D| \geq r_i + 1$. Since $\mathcal{K}$ is a $(d+1)$-limited k-max-distance sparsifier of $\mathcal{D}$, there is a set $K \in \mathcal{K}$ such that for all $i \in \{1, \ldots, k\}$, $|D_i \triangle K| \geq r_i + 1$. Hence, $K \notin \mathcal{K}_i$ for all $i \in \{1, \ldots, k\}$, contradicting the fact that $(\mathcal{K}_1, \ldots, \mathcal{K}_k)$ is a partition of $\mathcal{K}$. ◀

We now provide an algorithm to decide whether there exists $D \in \mathcal{D}$ with $\mathcal{K}_i \subseteq \mathcal{B}(D, r_i)$ for each $i \in \{1, \ldots, k\}$ and $r_i \in \{0, \ldots, d\}$. If the domain $\mathcal{D}$ is 2^U, this problem is equivalent to the *closest string problem* on binary strings, for which a textbook FPT algorithm parameterized by $d + |\mathcal{K}_i|$ is known [14]. Our algorithm is a modified version of this. An element $e \in U$ is *bad* if there exist both $K \in \mathcal{K}_i$ with $e \in K$ and $K \in \mathcal{K}_i$ with $e \notin K$. The following lemma is fundamental.

▶ **Lemma 10** ([14])**.** *If there are more than $d|\mathcal{K}_i|$ bad elements, no $D \in \mathcal{D}$ satisfies $\mathcal{K}_i \subseteq \mathcal{B}(D, d)$.*

Let B be the set of bad elements, and assume $|B| \leq d|\mathcal{K}_i|$. The algorithm first guesses $B' \subseteq B$. The cost of this guess is $2^{d|\mathcal{K}_i|}$. Then, it determines whether there exists $D \in \mathcal{D}$ such that $D \cap B = B'$ and $\mathcal{K}_i \subseteq \mathcal{B}(D, r_i)$. Let $K^* = \operatorname{argmax}_{K \in \mathcal{K}_i} |(K \cap B) \triangle B'|$. Then, we can claim the following.

▶ **Lemma 11.** *For $D \in \mathcal{D}$ such that $D \cap B = B'$, $\max_{K \in \mathcal{K}_i} |K \triangle D| = |K^* \triangle D|$.*

Proof. Let $K \in \mathcal{K}_i$. Then, $|K \triangle D| = |(K \cap B) \triangle (D \cap B)| + |(K \setminus B) \triangle (D \setminus B)|$. From the definition of B, the value of $|(K \setminus B) \triangle (D \setminus B)|$ is equal among all $K \in \mathcal{K}_i$. Thus, the maximum value of $|K \triangle D|$ for $K \in \mathcal{K}_i$ is achieved by the set K that maximizes $|(K \cap B) \triangle (D \cap B)| = |(K \cap B) \triangle B'|$. ◀

Now, it is sufficient to solve the problem of determining whether there exists $D \in \mathcal{D}$ such that $D \cap B = B'$ and $|K^* \triangle D| \leq r_i$. This corresponds to the exact extension oracle on $\mathcal{D}$ with $r = r_i$, $X = B'$, $Y = B \setminus B'$, and $C = K^*$. Therefore, we can claim the following:

▶ **Lemma 12.** *Assume there exists an FPT algorithm parameterized by $k + d$ that computes a $(d+1)$-limited k-max-distance sparsifier of $\mathcal{D}$ with size bounded by a constant that depends only on $k + d$, and the exact extension oracle on $\mathcal{D}$ whose time complexity is FPT parameterized by $r + |X| + |Y|$. Then, there exists an FPT algorithm parameterized by $k + d$ for the k-center/k-sum-of-radii clustering problem on $\mathcal{D}$.*

Algorithm 1 k-max-distance sparsification of $\mathcal{D}$.

```
Procedure KSparsify(k, r)
    Input: k ∈ Z_{≥1}, r ∈ Z_{≥0}
    Let K := ∅;
    while true do
        Let R := ⋃_{K∈K} K, f := false;
        for ℓ' ∈ {0, ..., l} do
            Let 𝔖 be the family of all sunflowers S ⊆ K such that |S| = kr + 1 and
              each S ∈ S satisfies |S| = ℓ';
            for Y ⊆ R that intersects with all K ∈ K with |K| = ℓ' and the cores of all
              sunflowers of 𝔖 do
                Let D = ExactEmptyExtension(ℓ', Y);
                if D ≠ ⊥ and f = false then
                    Add D to K and f := true;
        if f = false then
            break;
    return K;
```

3 Framework for k-Max-Distance Sparification

In this section, we complete the proof of Theorem 1 by providing an FPT algorithm that uses the exact empty extension oracle on $\mathcal{D}$ to obtain a k-max-distance sparsifier of $\mathcal{D}$. For further use, we show a slightly more extended result. Let $r \in \mathbb{Z}_{\geq 0}$. We construct a k-max-distance sparsifier of $\mathcal{D}$ with respect to $\mathcal{B}(\emptyset, r)$ for $r \geq \ell$. Since $\mathcal{D} \subseteq \mathcal{B}(\emptyset, \ell) \subseteq \mathcal{B}(\emptyset, r)$ for $r \geq \ell$, this is also a k-max-distance sparsifier of $\mathcal{D}$ (with respect to $\mathcal{D}$). A set family $\mathcal{S} := \{S_1, \ldots, S_t\}$ is called a *sunflower* if there exists a set called *core* C such that for any $1 \leq i < j \leq t$, $S_i \cap S_j = C$. The following is well-known.

▶ **Lemma 13** (Sunflower Lemma [14, 18]). *Let U be a finite set, $\ell, t \in \mathbb{Z}_{\geq 0}$, and $\mathcal{K} \subseteq 2^U$ be a family consisting only of sets of size at most ℓ. If $|\mathcal{K}| > \ell!(t-1)^\ell$, then $\mathcal{K}$ contains a sunflower of size t.*

For $t \in \mathbb{Z}_{\geq 0}$, $\mathcal{T} \subseteq 2^U$, and $Z \in 2^U \setminus \mathcal{T}$, a sunflower $\mathcal{S} \subseteq \mathcal{T}$ is a *(Z,t)-sunflower of $\mathcal{T}$* if it satisfies the following three conditions.

- $|\mathcal{S}| = t$,
- For each $S \in \mathcal{S}$, $|S| = |Z|$, and
- The core of $\mathcal{S}$ is a subset of Z.

The following lemma is the core of our framework.

▶ **Lemma 14 (*).** *Let U be a finite set, $\mathcal{D} \subseteq 2^U$, and $\mathcal{K} \subseteq \mathcal{D}$ be a k-max-distance sparsifier of $\mathcal{D}$ with respect to $\mathcal{B}(\emptyset, r)$. Let $Z \in \mathcal{K}$ and assume there is a $(Z, kr+1)$-sunflower $\mathcal{S}$ of $\mathcal{K} \setminus \{Z\}$. Then, $\mathcal{K} \setminus \{Z\}$ is also a k-max-distance sparsifier of $\mathcal{D}$ with respect to $\mathcal{B}(\emptyset, r)$.*

Our algorithm is given in Algorithm 1, where ExactEmptyExtension(ℓ', Y) represents the exact empty extension oracle on $\mathcal{D}$ with arguments ℓ' and Y. The algorithm starts with $\mathcal{K} := \emptyset$ and repeatedly adds $Z \in \mathcal{D} \setminus \mathcal{K}$ such that there is no $(Z, kr+1)$-sunflower of $\mathcal{K}$ to $\mathcal{K}$. The following lemma shows this algorithm stops after a constant number of iterations.

▶ **Lemma 15** (*). *The number of iterations of the loop starting from line 3 in Algorithm 1, as well as the size of the output family, is at most* $(\ell+1)!(kr+1)^\ell$.

In particular, at each step of the algorithm, since $|R| \leq |\mathcal{K}|l \leq (\ell+1)!(kr+1)^\ell \ell$, the size of Y chosen in line 7 is bounded by a constant. The time complexity is bounded as follows.

▶ **Lemma 16** (*). *Algorithm 1 makes at most* $2^{2^{O(\ell \log(klr))}}$ *calls of* ExactEmptyExtension$(\cdot)$ *and has a time complexity of* $2^{2^{O(\ell \log(klr))}}$.

The correctness of the algorithm is shown as follows.

▶ **Lemma 17** (*). *Algorithm 1 outputs a k-max-distance sparsifier of $\mathcal{D}$ with respect to $\mathcal{B}(\emptyset, r)$.*

4 Framework for d-Limited k-Max-Distance Sparsification

4.1 Overall Flow

In this section, we complete the proof of Theorem 2 by providing FPT algorithm that uses the $(-1,1)$-optimization oracle and the exact extension oracle on $\mathcal{D}$ to obtain a d-limited k-max-distance sparsifier of $\mathcal{D}$. Actually, for further applications, we construct the slightly more general object of d-limited k-max-distance sparsifier of $\mathcal{D}$ with respect to 2^U, not with respect to $\mathcal{D}$ itself. Our framework consists of two steps. Let $p \in \mathbb{Z}_{\geq 0}$ be an integer with $2d < p$. The first step achieves one of the following.

- Find a set $\mathcal{C} \subseteq \mathcal{D}$ with size at most k such that $\mathcal{D} \subseteq \bigcup_{C\in\mathcal{C}} \mathcal{B}(C,p)$.
- Find a set $\mathcal{C} \subseteq \mathcal{D}$ of size $k+1$ such that $|C \triangle C'| > 2d$ holds for any distinct $C, C' \in \mathcal{C}$.

We do this by using the following *approximate far set oracle*, which will be designed in Section 4.2.

> **Approximate Far Set Oracle:** Let U be a finite set, $d \in \mathbb{Z}_{\geq 0}$, $\mathcal{D} \subseteq 2^U$, and $\mathcal{C} \subseteq \mathcal{D}$. The approximate far set oracle returns one of the following.
> - A set of $\mathcal{D}$ that does not belong to $\bigcup_{C\in\mathcal{C}} \mathcal{B}(C, 2d)$.
> - $\perp$. This option can be chosen only when $\mathcal{D} \subseteq \bigcup_{C\in\mathcal{C}} \mathcal{B}(C,p)$.

Starting with $\mathcal{C} := \emptyset$, we repeat the following steps. If the approximate far set oracle returns $\perp$, terminate the loop. Otherwise, add the element found by the oracle to $\mathcal{C}$. If the oracle returns $\perp$ within k iterations, the first condition is achieved. If not, the set $\mathcal{C}$ after $k+1$ iterations satisfies the second condition. In the latter case, the following lemma shows that $\mathcal{C}$ is a d-limited k-max-distance sparsifier.

▶ **Lemma 18** (*). *Let $r \in \mathbb{Z}_{\geq 0}$. Let $\mathcal{C}$ be a subset of $\mathcal{D}$ of size $k+1$ such that for any distinct $C, C' \in \mathcal{C}$, $|C \triangle C'| \geq 2d$. Then, $\mathcal{C}$ is a d-limited k-max-distance sparsifier of $\mathcal{D}$ with respect to 2^U.*

Now, we assume the first condition. Let $\mathcal{C}$ be a subset of $\mathcal{D}$ of size at most k such that $\mathcal{D} \subseteq \bigcup_{C\in\mathcal{C}} \mathcal{B}(C,p)$. The second step involves constructing a d-limited k-max-distance sparsifier of $\mathcal{D}_C := \mathcal{D} \cap \mathcal{B}(C,p)$ with respect to $\mathcal{B}(C, p+d)$ for each $C \in \mathcal{C}$. We prove that the union of all such d-limited k-max-distance sparsifiers obtained in this manner is a d-limited k-max-distance sparsifier of $\mathcal{D}$ with respect to 2^U.

▶ **Lemma 19** (*). *Assume $\mathcal{D} = \bigcup_{C\in\mathcal{C}} \mathcal{D}_C$. For each $C \in \mathcal{C}$, let $\mathcal{K}_C \subseteq \mathcal{D}_C$ be a d-limited k-max-distance sparsifier of $\mathcal{D}_C$ with respect to $\mathcal{B}(C, p+d)$. Then, $\mathcal{K} := \bigcup_{C\in\mathcal{C}} \mathcal{K}_C$ is a d-limited k-max-distance sparsifier of $\mathcal{D}$ with respect to 2^U.*

Next, we reduce the computation of d-limited k-max-distance sparsifiers to the computation of k-max-distance sparsifiers of families consisting of constant-size sets, which was discussed in Section 3. For $C \in \mathcal{C}$, let $\mathcal{D}^*_C := \{D \triangle C \mid D \in \mathcal{D}_C\}$. By the definition of $\mathcal{D}_C$, we have $\mathcal{D}^*_C \subseteq \mathcal{B}(\emptyset, p)$. The following holds.

▶ **Lemma 20 (*).** *Let $C \in \mathcal{C}$. A subset $\mathcal{K}_C \subseteq \mathcal{D}_C$ is a d-limited k-max-distance sparsifier of $\mathcal{D}_C$ with respect to $\mathcal{B}(C, p+d)$ if and only if $\mathcal{K}^*_C := \{K \triangle C \mid K \in \mathcal{K}_C\}$ is a d-limited k-max-distance sparsifier of $\mathcal{D}^*_C$ with respect to $\mathcal{B}(\emptyset, p+d)$.*

If $\mathcal{K}^*_C$ is a k-max-distance sparsifier of $\mathcal{D}^*_C$ with respect to $\mathcal{B}(\emptyset, p+d)$, then it is also a d-limited k-max-distance sparsifier of $\mathcal{D}^*_C$ with respect to $\mathcal{B}(\emptyset, p+d)$ for any $d \in \mathbb{Z}_{\geq 0}$. Therefore, a d-limited k-max-distance sparsifier $\mathcal{K}$ of $\mathcal{D}$ with respect to $\mathcal{B}(C, p+d)$ can be computed as

$$\mathcal{K} := \bigcup_{C \in \mathcal{C}} \{K^* \triangle C \colon K^* \in \mathcal{K}^*_C\}.$$

From the discussion in Section 3, $\mathcal{K}^*_C$ can be obtained by calling the exact empty extension oracle on $\mathcal{D}^*_C$ a constant number of times that depends on k, $\ell = p$, and $r = p + d$. The exact empty extension oracle for $\mathcal{D}^*_C$ is equivalent to the exact extension oracle on $\mathcal{D}_C$ when the inputs C, X, Y are taken to be $C, Y \cap C, Y \setminus C$, respectively. Therefore, $\mathcal{K}^*_C$ can be obtained by calling the exact extension oracle on $\mathcal{D}_C$ a constant number of times that depends only on k and p.

4.2 Designing the Approximate Far Set Oracle

Here, we design a randomized algorithm parameterized by $|\mathcal{C}|$ and d for the approximate far set oracle. Our algorithm repeats the following sufficient number of times: It selects a weight vector $w \in \{-1, 1\}^U$ uniformly at random and finds a set $D \in \mathcal{D}$ that maximizes $w(D) := \sum_{e \in D} w_e$. If the found D does not belong to $\bigcup_{C \in \mathcal{C}} \mathcal{B}(C, 2d)$, it outputs this D and terminates. If no such D is found after a sufficient number of iterations, it returns $\perp$. We now prove the correctness of the algorithm. We can claim the following.

▶ **Lemma 21 (*).** *Assume $\max_{D \in \mathcal{D}} w(D) > \max_{C \in \mathcal{C}} w(C) + 2d$. Then, the D that attains the maximum on the left-hand side does not belong to $\bigcup_{C \in \mathcal{C}} \mathcal{B}(C, 2d)$.*

The following lemma is the core of the analysis.

▶ **Lemma 22 (*).** *Assume $p \geq (4d+2)^2 \cdot 2^{k-1}$ and $|\mathcal{C}| \leq k$. Let $D \in \mathcal{D}$ and assume $D \notin \bigcup_{C \in \mathcal{C}} \mathcal{B}(C, p)$. Then,*

$$\Pr\left[w(D) > \max_{C \in \mathcal{C}} w(C) + 2d\right] \geq 2^{-2^{O(k)}}.$$

By repeating the sampling of w a sufficient number of times, we can state the following.

▶ **Lemma 23.** *Let $\epsilon > 0$, $\mathcal{D}, \mathcal{C} \subseteq 2^U$, $k \in \mathbb{Z}_{\geq 1}$, and $d \in \mathbb{Z}_{\geq 0}$. Assume $|\mathcal{C}| \leq k$. Then, there exists a randomized algorithm that runs in time $2^{2^{O(k)}} \log \epsilon^{-1}$ and satisfies the following.*

- *If there exists $D \in \mathcal{D}$ such that $D \notin \bigcup_{C \in \mathcal{C}} \mathcal{B}(C, (4d+2)^2 \cdot 2^k)$, the algorithm returns a set $D' \in \mathcal{D}$ satisfying $D' \notin \bigcup_{C \in \mathcal{C}} \mathcal{B}(C, 2d)$ with probability at least $1 - \epsilon$.*
- *If not, the algorithm returns either $\perp$ or a set $D' \in \mathcal{D}$ satisfying $D' \notin \bigcup_{C \in \mathcal{C}} \mathcal{B}(C, 2d)$.*

Combining Lemma 23 with the results from Sections 3 and 4.1, we have the following.

▶ **Lemma 24 (*).** *Let $\epsilon > 0$, $\mathcal{D} \subseteq 2^U$, $k \in \mathbb{Z}_{\geq 1}$, and $d \in \mathbb{Z}_{\geq 0}$. Then, there exists a randomized algorithm that, with probability $1-\epsilon$, computes a d-limited k-max-distance sparsifier of $\mathcal{D}$ with respect to 2^U with size at most $2^{2^{O(k+\log d)}}$ in time $\left(2^{2^{2^{O(k+\log d)}}} + 2^{2^{O(k)}} \log \epsilon^{-1}\right) poly(|U|)$. It uses at most $2^{2^{O(k)}} \log \epsilon^{-1}$ calls to the $(-1,1)$-optimization oracle on $\mathcal{D}$ and at most $2^{2^{2^{O(k+\log d)}}}$ calls to the exact extension oracle on $\mathcal{D}$ such that $r \leq (4d+2)^2 2^{k-1}$ and $|X|, |Y| \leq 2^{2^{O(k+\log d)}}$.*

Abstract

The suffix array contains the lexicographical order of all suffixes of a text. It is one of the most well-studied text indices with applications in bioinformatics, compression, and pattern matching. The main bottleneck of distributed-memory suffix array construction algorithms is their memory requirements. Even careful implementations require 30×–60× the input size as working memory. We present a scalable and lightweight distributed-memory adaptation of the difference cover (DCX) suffix array construction algorithm. Our approach relies on novel bucketing and random chunk redistribution techniques which reduce our memory requirement to 20×–26× the input size for medium-sized inputs and to 14×–15× for large-sized inputs. Regarding running time, we achieve speedups of up to 5× over current state-of-the-art distributed suffix array construction algorithms.

1 Introduction

The suffix array [30, 22] is one of the most studied text indices. Given a text T of length n, its suffix array SA contains a permutation of the integers $1, \ldots, n$ such that the corresponding suffixes appear in lexicographical order. More concretely, SA[i] is the starting position of the i-th smallest suffix of T, or equivalently, we have $T[\mathrm{SA}[i]..n] \leq T[\mathrm{SA}[j]..n]$ for any $1 \leq i \leq j \leq n$. To compute the suffix array, we have to (implicitly) sort all suffixes of the text. Therefore, the task of constructing the suffix array is sometimes referred to as suffix sorting. Suffix arrays can be constructed in linear time requiring only constant working space in addition to the space for the suffix array [23, 29].

Suffix arrays have numerous applications in pattern matching and text compression [34]. They are a very powerful full-text index and are used as a space-efficient replacement [1] of the suffix tree, which is considered to be one of the most powerful full-text indices. Furthermore, suffix arrays can be used to compute the Burrows-Wheeler transform [12], which is the backbone of many compressed full-text indices [17, 21].

One problem when considering texts as input is that the amount of textual data to be processed is ever-increasing with no sign of slowing down. For example, the English Wikipedia contains around 60 million pages and grows by around 2.5 million pages each year.[1] A snapshot of all public source code repositories on GitHub requires more than 21 TB to store.[2] Furthermore, the capability to sequence genomic data is increasing exponentially, due to technical advances [37]. All these examples show the importance of scalable algorithms for the analysis of textual information many of which use the suffix array as a building block.

In this paper, we consider distributed-memory suffix sorting. Here, we can utilize many processing elements (PEs) that are connected via a network, e.g., high-performance clusters or cloud computing. In this setting, the main obstacle when computing suffix arrays is the immense amount of working memory required by the current state-of-the-art algorithms. Even carefully engineered implementations require around 30×–60× the input size as working space [19, 20]. Additionally, there is a significant space-time trade-off. The memory-efficient algorithms tend to be slower. We thus ask the question:

Is there a scaling, fast, and *memory-efficient suffix array construction algorithm in distributed memory?*

Summary of our Contributions. We answer this question positively by providing a scalable, fast, *and* space-efficient distributed-memory suffix array construction algorithm (SACA), using a bucketing approach in conjunction with a randomized (chunk-based) redistribution scheme for load balancing with provable performance guarantees. Our algorithm is the fastest (on all inputs but one) distributed-memory suffix array construction algorithm on up to 12 288 cores and requires only 20×–26× the input size as working space. As a side result of independent interest, we improve the load balancing for a distributed prefix-doubling algorithm, enhancing its performance significantly. This might be of interest for future work, as prefix doubling algorithms can more easily be extended to also compute the longest common prefix (LCP) array, another important data structure for text processing.

Paper Outline. First, in Section 2, we introduce some basic concepts required for suffix array construction and distributed-memory algorithms. Next, in Section 3, we discuss previous work on suffix array construction. In Section 4, we present the main result of this paper.

We start with a description of the distributed-memory variant of the DCX [26] suffix array construction algorithm in Section 4.2. In Section 4.2.1, we demonstrate how a previously developed technique for space-efficient string sorting [31, 28] can be applied to the DCX suffix sorting to obtain a more lightweight algorithm. Subsequently, in Section 4.2.2, we introduce a *randomized chunking scheme* to provide provable load-balancing guarantees for our space-efficient (suffix) sorting approach, followed by a brief analysis of the overall algorithm in Section 4.2.3. Finally, an experimental evaluation of our highly-engineered implementation using MPI is presented in Section 5, followed by a conclusion in Section 6.

2 Preliminaries

We assume a distributed-memory machine model consisting of p processing elements (PEs) allowing single-ported point-to-point communication. The cost of exchanging a message of h *machine words* between any two PEs is $\alpha + \beta h$, where α accounts for the message start-up overhead and β quantifies the time to exchange one machine word. Let h be the maximum number of words a PE sends or receives, then collective operations like *broadcast, prefix sum, (all-)reduce, and (all-)gather* can be implemented in time $\mathcal{O}(\alpha \log p + \beta h)$ [35]. An alltoall exchange using direct messaging is possible in $\mathcal{O}(\alpha p + \beta h)$ [35].

The input to our algorithms is a text T consisting of $n-1$ characters over an alphabet Σ. By $T[i]$, we denote the i-th character of T for $0 \leq i < n-1$. We assume $T[n-1]$ to be a sentinel character $\$ \notin \Sigma$ with $\$ < z$ for all $z \in \Sigma$. The i-th suffix of T, $s_i = T[i, n)$, is the substring starting at the i-th character of T. Due to the sentinel element all suffixes are prefix-free. The *suffix array* SA contains the lexicographical ordering of all suffixes of T. More precisely, SA is an array of length n with $\mathrm{SA}[i]$ containing the index of the i-th smallest suffix of T. A length-l- (or simply l)-prefix of a suffix with starting position i is the substring $T[i, l)$.

In our distributed setting, we assume that each PE i holds a subarray T_i of T as input such that T is the concatenation of all local input arrays T_i, i.e., $T = T_0 \circ \ldots \circ T_{p-1}$. Furthermore, we assume the input to be well-balanced, i.e., $|T_i| = \Theta(n/p)$. For our DCX algorithm, we assume a suitable padding of up to X sentinel characters at the end of the text.

3 Related Work

There has been extensive research on the construction of suffix arrays in the sequential, external-memory, shared-memory parallel, and (to a somewhat lesser extent) in the distributed-memory setting. All suffix array construction algorithms are based on three general algorithmic techniques: *prefix doubling*, *induced copying*, and *recursion* or combinations thereof. In the following, we give a brief overview of these techniques. For a more comprehensive overview, we refer to the most recent surveys [7, 9].

Prefix-Doubling. In algorithms based on prefix doubling, the suffixes are iteratively sorted by their length-h prefix starting with $h = 1$. Now, all suffixes that share a common h-prefix are said to be in the same h-group and have an h-rank corresponding to the number of suffixes in lexicographically smaller h-groups. By sorting all suffixes based on their h-group, we can compute the corresponding suffix array SA_h. Note that this suffix array does not necessarily have to be unique, as the order of suffixes within an h-group is not unique. If for some h, all h-groups contain only a single suffix, we have $\mathrm{SA}_h = \mathrm{SA}$. Therefore, the idea is to increase h until all h-ranks are unique. To this end, during each iteration, the length of the

considered prefixes is doubled. Fortunately, we do not have to compare the prefixes explicitly. Instead, during iteration $i > 0$, for a suffix s_j starting at index j, the rank of its length-h prefix can be inferred from the pair of ranks $(\text{rank}_{h/2}[j], \text{rank}_{h/2}[j + h/2])$ computed in the previous iterations for the suffixes s_j and $s_{j+h/2}$. This yields the correct result as comparing two suffixes s_i and s_j by their length-h prefix can be achieved by (a) comparing their first $h/2$ characters and – if they tie – (b) comparing the following $h/2$ characters, which in turn is equivalent to lexicographically comparing the ranks of the corresponding $h/2$-prefixes. Using the overlap of suffixes in a text, prefix-doubling boils down to at most $\mathcal{O}(\log n)$ rounds in which n pairs of integers have to be sorted. Thus, this approach has an overall complexity in $\mathcal{O}(n \log n)$ in the sequential setting, when using integer sorting algorithms. The first suffix array construction algorithm [30] is based on prefix-doubling. In the sequential setting, this approach has not received much attention, due to its non-linear running time. However, in distributed memory, the fastest currently known suffix array construction algorithm is based on prefix doubling [20].

Induced-Copying. Induced-copying algorithms sort a (small) subset of suffixes and then *induce* the order of all other suffixes using the subset of sorted suffixes. First, all suffixes are classified using one of two [25, 33] classification schemes. Next, all suffixes necessary for inducing the order of the remaining suffixes are sorted directly. Then, the properties of the classification allow us to induce the order of the remaining suffixes based on their class, starting characters, and preceding or succeeding directly sorted suffix. The inducing part of these algorithms usually consists of just two scans of the text, where for each position only one or two characters have to be compared. Combined with a recursive approach, induced copying algorithms can compute the suffix array in linear time requiring only constant working space in addition to the space for the suffix array [23, 29]. This combination is also very successful, as it is used by the fastest sequential suffix array construction algorithms [4, 18, 24, 32]. Interestingly, there is only one linear-time suffix array construction algorithm based on induced copying that does not also rely on recursion [5]. In distributed memory, induced copying algorithms are space-efficient [19].

Recursive Algorithms. The third and final technique is to use recursion to solve subproblems of ever decreasing sizes. Here, the general idea is to partition the input into multiple different (potentially overlapping) substrings. A subset of these substrings can then be sorted using an integer sorting algorithm (in linear time). If all substrings are unique, we can compute a suffix array together with the remaining suffixes not yet sorted. Otherwise, we recurse on the non-unique ranks of the substrings as new input. We then use the suffix array from the recursive problem to compute the unique ranks from the original subset of substrings. The first linear-time suffix array construction algorithm is purely based on recursion [26]. This algorithm is also the foundation of the distributed-memory suffix array construction algorithm presented in this paper. It already has been considered in distributed memory [6, 10]. However, all implementations are direct adaptations of the sequential algorithm to distributed memory.

4 A Space-Efficient Variant of Distributed DCX

In this section, we describe the general idea of the sequential DC3 algorithm [26]. Then, we give a canonical transformation of the sequential DC3 algorithm to a distributed-memory algorithm. Here, we also consider the more general form – the DCX algorithm. Finally, we discuss how to optimize this canonical transformation into a scaling, fast, and memory-efficient distributed suffix array construction algorithm.

4.1 The Sequential DCX Algorithm

The *skew* or **D**ifference **C**over 3 algorithm (DC3) – and its generalization DCX – is a recursive suffix array construction algorithm that exhibits linear running time (in the sequential setting). As our main contribution is a fast and lightweight distributed variant of the algorithm, we now briefly discuss its key ideas, beginning with the eponymous concept of a *difference cover*.

Let X be a positive integer. A subset $D_X \subseteq \{0, \ldots, X-1\}$ is a difference cover modulo X if for every $r \in \{0, \ldots, X-1\}$ there are $i, j \in D_X$ such that $i - j \bmod X = r$. Put differently, D_X *covers* the set $\{0, \ldots, X-1\}$ in the sense that we have $\{0, \ldots, X-1\} = \{i - j \bmod X \mid i, j \in D_X\}$.

A key property of a difference cover modulo X, on which the DCX algorithm relies, is that for all $i, j \in \mathbb{N}$, there is a $0 \leq l < X$ such that $(i+l) \bmod X \in D_X$ and $(j+l) \bmod X \in D_X$. $X = 3$ is the smallest X for which a non-trivial difference cover exists, with $D_3 = \{1, 2\}$.

DCX Algorithm. We now discuss the main steps of the DCX algorithm. It starts by classifying the suffixes s_j of a given text T into different sets, based on their starting position j. Suffixes with index $(j \bmod X) \in D_X$ constitute the *(difference cover) sample* S_{D_X}.

For now, assume that we know a relative ordering of the suffixes in S_{D_X} within the text. Since D_X is a difference cover, for *any* two suffixes s_i and s_j, there is an $l < X$ such that s_{i+l} and s_{j+l} are in S_{D_X} for which we already know a relative ordering. Hence, for comparing s_i and s_j, it is sufficient to compare the l-prefixes of s_i and s_j, using the ranks of s_{i+l} and s_{j+l} to break ties. That is, we compare tuples $(T[i, i+l), \text{rank}[i+l])$ and $(T[j, j+l), \text{rank}[j+l])$. For $X = 3$, this rank-*inducing* can be achieved using linear-time integer sorting.

It remains to discuss how the relative ordering of the sample suffixes can be obtained. We start by sorting the X-prefixes of the sample suffixes. If they are unique, we are already done, as we can take their rank for the ordering. Otherwise, we replace the sample suffixes j with the rank of their X-prefix and reorder them by $(j \bmod X, j \operatorname{div} X)$. This results in an auxiliary text T' that contains the renamed difference cover sample suffixes in original text order within each equivalence class in D_X. We can now recursively apply the algorithm to this text T', yielding a suffix array SA'. From SA' we can retrieve a relative ordering of the sample suffixes with regard to the original text T.

For DC3, the number of sample suffixes is $\leq 2/3n$. As all other operations can be achieved with work linear in the size of the input, the overall complexity of the algorithm is in $\mathcal{O}(n)$.

4.2 The Distributed DCX Algorithm

Our distributed suffix array construction is a simple and practical distributed variant of the DCX algorithm for $X \geq 3$. Algorithm 1 shows a high-level pseudocode for the algorithm.

We now discuss the algorithm in some more detail. The input to the algorithm on PE i is the local chunk T_i of the input text T.

1. **Sort the Difference Cover Sample.** In the first phase of the algorithm, we select, on each PE i, the difference cover (DC) sample suffixes starting at (global) positions j with $(j \bmod X) \in D_X$. As in the sequential setting, we want to compute unique ranks of these suffixes first. For that, we first globally sort the X-prefixes of all DC sample suffixes. If all of them are unique, this already constitutes the relative ordering of the sample suffixes within the final suffix array. This rank information can then be used to compare any two suffixes s_i and s_j (see Section 4.1) and we continue with step three. Otherwise, we have to recurse on the sample suffixes as described in the following step two of the algorithm.

Algorithm 1 High-level overview of a simple distributed variant of the DCX algorithm.

Input: Text T_i on PE i.
Output: Local part of distributed suffix array of T.

1 $o_i = \texttt{PrefixSum}(|T_i|)$ `// global text index offset`
2 $C_i = \langle 0 \leq j < |T_i| \mid (j + o_i \bmod X) \in D_X \rangle$ `// DC sample positions`
3 $S_i = \langle (\underbrace{T_i[j, j+X)}_{X\text{-prefix}}, \underbrace{j + o_i}_{\text{global idx}}) \mid j + o_i \in C_i \rangle$ `// (X-prefix,idx) of DC samples`
4 globally **sort** S_i by first entry
5 **if** *all first entries of S are unique* **then**
6 $\quad R_i = \langle (\texttt{rank}(t, S), j) \mid t = (\text{prefix}, j) \in S_i \rangle$ `// unique ranks of DC samples`
7 **else**
8 $\quad P_i = \langle (\texttt{rank}(t, S), j) \mid t = (\text{prefix}, j) \in S_i \rangle$ `// replace X-prefix with rank`
9 $\quad$ globally **sort** P_i by $(j \bmod X, j \operatorname{div} X)$
10 $\quad SA'_i \leftarrow$ recursively call DCX on $T'_i = \langle r \mid (r, j) \in P_i \rangle$
11 $\quad R_i = \langle (j, \underbrace{\texttt{mapback}(SA[j])}_{\text{restore idx of DC samples in } T}) \mid 0 \leq j < |SA'_i| \rangle$
12 globally **sort** R_i by second component `// bring R_i in text order`
`// construct (X-prefix, <ranks>) tuples for all suffixes`
13 $S_i = \langle (\underbrace{T_i[j, \ldots, j+X)}_{X\text{-prefix}}, \underbrace{R_i[\texttt{next}(j,\ 1)], \ldots, R_i[\texttt{next}(j,\ v)]}_{\text{ranks of DC samples following } j}, \underbrace{j + o_i}_{\text{global idx}})) \mid 0 \leq j < |T_i| \rangle$
14 globally **sort** S_i by appropriate comparison function (see [26])
15 output last entry of S_i as suffix array SA_i

2. **Compute Unique Ranks Recursively.** If the ranks are not already unique, we locally create an array P_i by replacing each entry $(X-\text{prefix}, j)$ of S_i with $(\text{rank}[j], j)$. The distributed array $S = \bigcup S_i$ contains the DC sample suffixes sorted by their X-prefix. The rank$[j]$ of the j-th sample suffix is the global rank of its X-prefix within S. Equal prefixes obtain the same rank. Since S is sorted, the ranks can be computed by a prefix sum. Afterwards, we globally sort P_i by $(j \bmod X, j \operatorname{div} X)$. This rearranges the newly renamed sample suffixes in their original order by respecting the equivalence class of their starting index within D_X. We then recursively call the DCX algorithm on the text T'_i where T'_i contains the new names of the sample suffixes from P_i dropping the index. From the suffix array SA' of T', we can determine the rank of each sample suffix j using the `mapback` function which maps the index of a DC sample in T' back to its original position in T. Due to the construction of T', the unique ranks of the DC sample suffixes within T' also yield a relative ordering of the DC sample suffixes in T [26].
3. **Sort All Suffixes.** Now, we construct for each suffix s_j in T a tuple containing: (1) the X-prefixes of the suffix, (2) the previously computed ranks of the following $|D_X|$ DC samples after s_j in text order, and (3) its global index j within T. Globally sorting theses tuples using the previously discussed comparison function for suffixes s_i, s_j yields the suffix array of the original text T.

Existing distributed DC$\{3, 7, 13\}$ implementations [27, 6] broadly follow this straightforward adaptation of the algorithm to the distributed setting. However, this approach is not space-efficient. Materializing the X-prefixes of the suffixes for the final sorting step results in a memory blow-up proportional to X compared to the actual input. Consequently, sorting suffixes on distributed machines using DCX with large X is not feasible due to the limited main memory, even though DCX with $X > 3$ shows better performance on many real-world inputs [19]. We propose a technique to overcome this problem in the following Section 4.2.1.

4.2.1 Bucketing

In the sequential or shared-memory parallel setting, X-prefixes of suffixes can be sorted space-efficiently as each such element e can be represented as a pointer to the starting position of the suffix within the input text. This space-efficient sorting, however, is no longer possible in distributed memory. If we want to globally sort a distributed array of suffix-prefixes, we have to fully materialize and exchange them – resulting in a memory blow-up of at least a factor X. A simple idea to prevent this blow-up is to use a partitioning strategy which divides the elements of the distributed array into multiple buckets using splitter elements and processes only one bucket at a time.

We now describe a generalization of a bucketing technique for space-efficient sorting which has been previously proposed for scalable distributed string sorting [31, 28].

Whenever a distributed array of elements with a space-efficient representation has to be globally sorted, we first determine $q+1$ global splitter elements $s_0, s_1, \ldots s_q$ with $s_0 = -\infty$ and $s_q = \infty$. We then locally partition the array into q buckets, such that element e with $s_k < e \leq s_{k+1}$ is placed in bucket k. We then execute q global sorting steps. In each step k, we materialize and communicate the elements from bucket k using a distributed sorting algorithm. Assuming that the splitters are chosen such that the global number of elements in each bucket is n/q and the elements within each bucket are equally distributed among the PEs (see Section 4.2.2 how this can be ensured), we only have to materialize $n/(pq)$ elements per bucket and PE instead of n/p elements per PE when using only one sorting phase.

By choosing q proportional to the memory blow-up caused by materializing an element, we can keep the overall memory consumption of this sorting approach in $\mathcal{O}(n/p)$.

4.2.2 Load-Balanced Bucketing via Random Chunk Redistribution

The global number of elements per bucket can be balanced by judiciously choosing the splitter elements, e.g., by regular or random sampling, or even using multi-sequence selection [36, 2]. However, the number of elements per PE within a bucket can vary greatly depending on the input. Assume an input which is already globally sorted with $q < p$ buckets. In this setting, all n/p elements located on the first PE have to be materialized when processing the first bucket. This results in memory blow-up and poor load-balancing across the PEs. Increasing the number of buckets q can only address the memory consumption issue but does not help with load-balancing.

A standard technique to resolve this kind of problem is a random redistribution of the elements to be sorted. However, this is not directly possible for elements which are stored in a space-efficient manner as in our case. We propose to solve this problem by randomly redistributing not single prefixes of suffixes but whole chunks of the input text before sorting. To be more precise, we partition T into consecutive chunks C_j of size c, i.e., $T = C_0 \circ \ldots \circ C_{n/c-1}$. For the sake of simplicity, we assume chunks to be aligned with PE boundaries. Each chunk is then sent to a random PE.

▶ **Theorem 1** (Random Chunk Redistribution). *When redistributing chunks of size c uniformly at random across p PEs, with $q < p$ buckets each containing n/q elements, the expected number of elements from a single bucket received by a PE is $n/(pq)$.*

Furthermore, the probability that any PE receives $2n/(pq)$ or more elements from the same bucket is at most $1/p^\gamma$ for $n \geq 8c(\gamma+2)pq\ln(p)/3$ and $\gamma > 0$.

Proof. Let Y_i^k denote the number of elements belonging to bucket k which are assigned to PE i. In the following, we will determine the expected value of Y_i^k and show that $\mathbb{P}[Y_i^k \geq 2\mathbb{E}[Y_i^k]]$ is small. This will then be used to derive the above-stated bounds.

Let c_j^k be the number of elements belonging to bucket k in chunk j. For the sake of simplicity, we assume all buckets to be of equal size, thus, $\sum_{j=0}^{n/c-1} c_j^k = n/q$. We define

$$X_{j,i}^k = \begin{cases} c_j^k & \text{if chunk } j \text{ is assigned to PE } i \\ 0 & \text{otherwise,} \end{cases}$$

for chunk j with $0 \leq j < n/c$, PE i with $0 \leq i < p$, and bucket k with $0 \leq k < q$. Thus, the random variable $X_{j,i}^k$ indicates the number of elements from bucket k received by PE i if chunk j is assigned to this PE. Hence, we can express Y_i^k as the sum over all $X_{j,i}^k$, i.e., $Y_i^k = \sum_{j=0}^{n/c-1} X_{j,i}^k$. As all chunks are assigned uniformly at random and there are p PEs, we furthermore have $\mathbb{E}[X_{j,i}^k] = c_j^k/p$. By the linearity of expectation, we can derive the expected value of Y_i^k as

$$\mathbb{E}[Y_i^k] = \mathbb{E}\left[\sum_{j=0}^{n/c-1} X_{j,i}^k\right] = \sum_{j=0}^{n/c-1} \mathbb{E}[X_{j,i}^k] = \sum_{j=0}^{n/c-1} \frac{c_j^k}{p} = \frac{n}{pq}.$$

For each bucket k, we now bound the probability $\mathbb{P}[Y_i^k \geq 2n/(pq)]$ that PE i receives two times its expected number of elements or more. We have

$$\mathbb{P}\left[Y_i^k \geq \frac{2n}{pq}\right] = \mathbb{P}\left[\sum_{j=0}^{n/c-1} X_{j,i}^k \geq \frac{2n}{pq}\right] = \mathbb{P}\left[\sum_{j=0}^{n/c-1} X_{j,i}^k - \mathbb{E}[X_{j,i}^k] \geq \frac{n}{pq}\right].$$

As the value of $X_{i,j}^k$ is bounded by the chunk size c, the Bernstein inequality [11, Theorem 2.10, Corollary 2.11] yields the following bound

$$\mathbb{P}\left[\sum_{j=0}^{n/c-1} X_{j,i}^k - \mathbb{E}[X_{j,i}^k] \geq \frac{n}{pq}\right] \leq \exp\left(-\frac{\left(\frac{n}{pq}\right)^2}{2\left(\sum_{j=0}^{n/c-1} \mathbb{E}[(X_{j,i}^k)^2] + \frac{cn}{3pq}\right)}\right). \tag{1}$$

Since we find $\mathbb{E}[(X_{j,i}^k)^2] = (c_j^k)^2/p$, it follows that

$$\sum_{j=0}^{n/c-1} \mathbb{E}[(X_{j,i}^k)^2] = \sum_{j=0}^{n/c-1} (c_j^k)^2/p \leq \frac{1}{p} \sum_{j=0}^{n/(qc)-1} c^2 = \frac{cn}{pq},$$

as the sum of the squares of a set of elements $0 \leq a_i \leq c$ with $\sum_i a_i = b$ and b divisible by c is maximized if they are distributed as unevenly as possible, i.e., $a_i = c$ for b/c elements and 0 for all others. We can use this estimation for an upper bound on the right-hand side of (1)

$$\exp\left(-\frac{\left(\frac{n}{pq}\right)^2}{2\left(\sum_{j=0}^{n/c-1} \mathbb{E}[(X_{j,i}^k)^2] + \frac{cn}{3pq}\right)}\right) \leq \exp\left(-\frac{\left(\frac{n}{pq}\right)^2}{2\left(\frac{cn}{pq} + \frac{cn}{3pq}\right)}\right) = \exp\left(-\frac{3n}{8pqc}\right). \tag{2}$$

Combining these estimations, we obtain the bound

$$\mathbb{P}\left[Y_i^k \geq \frac{2n}{pq}\right] \leq \exp\left(-\frac{3n}{8pqc}\right) \leq \exp\left(-(\gamma+2)\ln p\right) = \frac{1}{p^{\gamma+2}}$$

for $n \geq 8pqc\ln(p)(\gamma+2)/3$. Using the union-bound argument yields the following estimation

$$\mathbb{P}\left[\bigcup Y_i^k \geq 2\frac{n}{pq}\right] \leq \sum_{i=0}^{p-1}\sum_{k=0}^{q-1} \mathbb{P}[Y_i^k \geq 2\frac{n}{pq}] \leq \sum_{i=0}^{p-1}\sum_{k=0}^{q-1} \frac{1}{p^{\gamma+2}} \leq \frac{1}{p^\gamma}.$$

Hence, we obtain $\frac{1}{p^\gamma}$ as an upper bound on the probability that any PE receives more than two times the expected number of elements $n/(pq)$ for any bucket when assuming $q \leq p$. ◀

Theorem 1 shows that combining a random chunk redistribution with the bucketing approach yields a space-efficient solution to the sorting problems occurring within our distributed variant of the DCX algorithm.

Within the DCX algorithm – depending on the actual step – we do not only redistribute chunks of the text but also corresponding rank entries and some bookkeeping information like the global index of a chunk. Furthermore, we require each chunk to have an *overlap* of X characters to ensure that an X-prefix for each element within a chunk can be constructed without communication. By choosing $c \geq X$, one can assure that the total size of a chunk remains in $\mathcal{O}(c)$. The redistribution can be achieved in time $\mathcal{O}(\alpha p + \beta n/p)$ as each PE sends and receives at most $\mathcal{O}(n/p)$ elements assuming the conditions of Theorem 1 are met.

4.2.3 Overall Analysis

We now briefly outline the running time of our algorithm using bucketing in conjunction with random chunk redistribution. All steps outside the recursion of distributed DCX are either global sorting steps, alltoall exchanges or local work linear in the size of the text per PE (see Algorithm 1). Additionally, we perform a constant number of allreduce and prefix sum operations, whose running time is dominated by the alltoall exchanges.

First, we consider the sorting steps. Assume that we want to sort a distributed array of m elements of type e with $\mathcal{O}(m/p)$ elements per PE, each of size $\mathcal{O}(e_s)$ while comparing any two elements takes time $\mathcal{O}(e_c)$. To facilitate the analysis, we assume a distributed (k-level) sorting routine with a running time

$$\mathrm{T}_{\text{sort}}(m,p,k) = \mathcal{O}\left(\underbrace{e_c \frac{m}{p}\log m}_{\text{local work}} + \underbrace{\alpha k \sqrt[k]{p}}_{\text{start-up latency}} + \underbrace{\beta k e_s \frac{m}{p}}_{\text{communication costs}}\right)$$

which also balances the output, i.e., after sorting, each PE holds $\Theta(m/p)$ elements.[3] A sorting step with $q < p$ buckets and random chunk redistribution can then be realized in time

$$\begin{aligned}\widetilde{\mathrm{T}}_{\text{sort}}(m,p,q,k) &= q\mathrm{T}_{\text{sort}}(\mathcal{O}(m/q),p,k) + \mathcal{O}\left(\alpha p + \beta\frac{m}{p}\right)\\ &= \mathcal{O}\left(\underbrace{e_c \frac{m}{p}\log m}_{\text{local work}} + \underbrace{\alpha(p + qk\sqrt[k]{p})}_{\text{start-up latency}} + \underbrace{\beta k e_s \frac{m}{p}}_{\text{communication costs}}\right)\end{aligned}$$

with probability $\geq 1 - 1/p^\gamma$ for any fixed $\gamma > 0$ and sufficiently large m, increasing only the latency term due to q sorting steps and an additional alltoall exchange. Note that the time required for the computation of the bucket splitters and subsequent classification is dominated by the running time mentioned above when using regular sampling with $\Theta(q)$ samples per PE and the distributed (k-level) sorting routine.

In this setting, we see that all sorting steps (and the alltoall exchanges) in DCX are dominated by the final sorting of all suffixes, where we have $e_s = \mathcal{O}(X \log\sigma + \sqrt{X}\log n)$[4] and $e_c = \mathcal{O}(X)$. Due to the geometric decrease of the input size within the recursion, we

[3] Note that for example the running time of adaptive multi-level sample sort (AMS) [2, Theorem 3] using k levels of indirection comes close to this. AMS also balances the output.

[4] Within the recursive calls, we have $e_s = \mathcal{O}(X \log n)$ as the alphabet size is now $\mathcal{O}(n)$. However, as the problem size also decreases by a factor $\Theta(\sqrt{X})$ [13, 26], this increase in alphabet size can be accounted for by the $\mathcal{O}(\sqrt{X}\log n)$ term in e_s of the first level.

reach an overall problem size of $\mathcal{O}(n/p)$ after $\mathcal{O}(\log p)$ iterations. Gathering all remaining data on a single PE and applying the sequential DCX algorithm yields the running time stated in Theorem 2.

▶ **Theorem 2.** *Using a distributed sorting routine with the above-stated properties, our lightweight distributed DCX algorithm has a running time*

$$DCX(n,p) = \mathcal{O}\left(\underbrace{X\frac{n}{p}\log n}_{\text{local work}} + \underbrace{\alpha \log(p)(p + qk\sqrt[k]{p})}_{\text{start-up latency}} + \underbrace{\beta X\frac{n}{p}\left(\log(\sigma) + \frac{\log n}{\sqrt{X}}\right)}_{\text{communication costs}}\right)$$

with probability $\geq 1 - 1/p^{\gamma}$ *for any fixed* $\gamma > 0$ *and sufficiently large* n.

4.2.4 Further Optimizations

In addition to the techniques described above, we also utilize discarding and packing, two techniques commonly used in distributed- and external-memory SACAs.

Discarding. After sorting the X-prefixes of the sample suffixes, we have to recursively apply the DCX algorithm (or any other suffix sorting algorithm) to a smaller subproblem if there are duplicate ranks. However, in order to obtain overall unique ranks for the sample suffixes, we do not have to recurse on all of them but can discard suffixes whose ranks are already unique after initial sorting. This *discarding* technique has been used in the external-memory setting [15] but has not been explored for distributed memory yet.

Packing. Packing is an optimization for small-sized (integer) alphabets proposed for distributed memory prefix-doubling by Flick et al. [20]. Assume $b = \lceil \log \sigma \rceil < B$, where B is the size of one machine word. Instead of using one machine word per character, we can pack up to B/b characters into one word and exchange/sort them at once.

5 Experimental Evaluation

For our extensive evaluation, we use up to 256 compute nodes (12 288 cores) of SuperMUC-NG where each node is equipped with one Intel Skylake Xeon Platinum 8174 processor with 48 cores and 96GB of main memory.[5] The internal interconnect is a fast OmniPath network with 100 Gbit/s.

We compare the following algorithms. See Table 1 for an overview.

ℓDCX. Our implementation of the lightweight distributed DCX algorithm described above. In the experiments, we use $X = 39$. In preliminary experiments, we found this value to provide the best trade-off between reduction ratio and running time per level. We use the bucketing technique for sorting the DC samples and also for the final sorting of all suffixes. For sorting the DC samples, we use 16 buckets in the first two levels of recursion. For the final merging, we use 64 buckets in the first two levels and 16 in a third level. In later levels of recursion, the remaining number of suffixes is small enough so that all elements can

[5] We also conducted preliminary experiments on the HoreKa supercomputer. As the results obtained there are in line with our findings from SuperMUC-NG presented here, we omit them.

be sorted at once. Bucket splitters are determined by centrally sorting a random sample of 2×10^4 elements and then drawing the splitters equidistantly from the sorted sample elements. Additionally, we employ our randomized redistribution of chunks with 10^4 chunks per PE. We use AMS-sort by Axtmann et al. [2, 3] as our distributed sorting routine. Due to the large number of single sorting steps, we require a low-latency sorting algorithm (at least for large PE configurations). Therefore, we use AMS with two levels as a default. As the discarding optimization has certain overheads, we only apply it when the reduction ratio is more than 0.7. Furthermore, we use 40-bit integers for storing rank information to reduce the memory footprint.

PSAC [20]. We explore two different original configurations. PSAC is the standard (more memory-efficient) configuration performing prefix-doubling as described in Section 3. Once the ratio of suffixes with non-unique h-prefix falls below $n/10$, it switches to another algorithm which tries to avoid global sorting steps as much as possible but has a somewhat higher memory consumption. This approach sorts each non-unique range of suffixes with identical h-prefix independently by splitting the PEs into different groups and can be regarded as a kind of discarding. The configuration PSAC$^+$ runs this second algorithm immediately. Additionally, we implemented a 40-bit integer version of their algorithm as well as a version which uses AMS for distributed sorting. Due to the small performance benefit of using AMS, we do not include these variants in the plots.

dPD [19]. This algorithm also relies on distributed prefix doubling with discarding, i.e., it does not continue sorting suffixes whose h-prefix is already unique. In contrast to PSAC$^+$, dPD redistributes the remaining non-unique suffixes across all PEs and keeps using a global sorting routine. dPD uses 40-bit integers.

The original sorting algorithm within dPD gathers suffixes with identical h-prefix on the same PE. While this facilitates the rank computation for the next prefix-doubling round, it introduces severe load-balancing problems in case of many identical h-prefixes. We provide an improved version of this algorithm, where identical h-ranks may span multiple consecutive PEs. In combination with AMS as a sorting subroutine, this yields a much more scalable algorithm with a substantially improved load-balancing. We refer to this new variant as dPD* (dPD^{*,1} and dPD^{*,2} indicates the usage of one- or two-level AMS sort).

B-DC$_X$ [6]. A straightforward adaptation of the sequential DCX algorithm to the distributed-memory setting for $X = \{3, 7, 13\}$. The implementation is limited to inputs of size 4 GB due to the internal usage of 32-bit integers.

Other Algorithms. There also exists a lightweight distributed suffix sorting algorithm based on induced copying [19]. Unfortunately, we were not able to run this algorithm successfully on our system. It also suffers from the same load-balancing issues as dPD. While this algorithm exhibits a relatively low memory blow-up factor of around 30 on up to 1 280 cores, the running-time of the algorithm is reported to be always slower than or on par with the default configuration of PSAC or the non-load-balanced dPD.

There also exists prefix-doubling and DC3/DC7 implementations [10] in the distributed external-memory BigData framework *Thrill* [8]. Although the framework supports MPI, their focus is on non-MPI data center clusters. We were not able to execute their algorithms on more than one compute node because Thrill relies on external local disk storage, which

Table 1 Overview of algorithms used in this experimental evaluation. All algorithms, except for libsais are distributed-memory algorithms.

Name	Brief Description	Reference
ℓDCX	Our main contribution described in Section 4	[here]
PSAC	Prefix doubling w/o discarding, last 10 % are sorted with PSAC$^+$	[20]
PSAC$^+$	Prefix doubling, each h-group is sorted independently (discarding-like)	[20]
PSAC$_{40}$	Same as PSAC but using 40-bit integers	[here]
PSAC$^+_{40}$	Same as PSAC$^+$ but using 40-bit integers	[here]
dPD	Prefix doubling w/ discarding, 40-bit integers, and PE-local ranks	[19]
dPD^{*,1}	Same as dPD but w/o PE-local ranks and using AMS with one level	[here]
dPD^{*,2}	Same as dPD but w/o PE-local ranks and using AMS with two levels	[here]
B-DC$_X$	Basic MPI implementation of DCX for $X = \{3, 7, 13\}$	[6]
libsais	Fastest sequential and shared-memory suffix sorting algorithm	[24]

is very limited on our cluster. On a single compute node (48 cores), their algorithms were more than a factor of two slower than ℓDCX on all data sets but DNA-Rep. Here, their DC7 implementation is only a factor of 1.8 slower than our algorithm.

Recently and independently, Ferguson also started working on a variant of a distributed-memory difference cover algorithm using a similar bucketing approach, implemented in the Chapel parallel programming language [16]. Their algorithm does not use random chunk redistribution and other optimizations present in our implementation. Preliminary comparisons executed by Ferguson on a low-latency Cray supercomputer demonstrated that our implementation was approximately twice as fast on a DNA dataset. In preliminary experiments on our system – which has higher communication latency – Ferguson's implementation exhibited less favorable scaling behavior. Additionally, it requires around 20×–80× the input size as working memory. Therefore, it is not included in our evaluation.

In addition to the above-mentioned distributed-memory algorithms, we also compared our algorithm to the currently fastest and highly-engineered sequential and shared-memory parallel suffix sorting implementation libsais [24].

General Settings and Data Sets. All algorithms are implemented in C++ (C for libsais) and compiled with `GCC 12.2.0` with optimization flags `-O3` and `-march=native`. We use IntelMPI 2021.11 for interprocess communication. Additionally, our DCX implementation uses the zero-overhead MPI bindings KaMPIng [40]. Reported times are the average of at least three runs. We generally observed only very low variations in running time.

We use inputs from the five data sets given in Table 2 with different characteristics regarding the alphabet size σ and the longest common prefix (LCP) distribution.

5.1 Weak-Scaling Experiments

Figure 1 shows the running times of weak-scaling experiments with 20 MB of text data per PE (960 MB per compute node). In Figure 2, we present the corresponding memory blow-up, i.e., the maximum peak memory aggregated over each compute node divided by the total input size on a compute node. We read the maximum *resident set size (rss)* of each MPI process to obtain these values.

Table 2 Data sets used in our evaluation. Statistics consider the first 50 GB of each data set.

Name	Brief Description	σ	avg. LCP	max LCP
CC [14]	Websites crawled by Common Crawl Project	243	$1{,}04 \times 10^4$	$1{,}84 \times 10^6$
Wiki [41]	XML data sets of Wikipedia	213	396.07	$1{,}58 \times 10^6$
Prot [39]	Protein data from *Universal Protein Resource*	26	179.31	$3{,}43 \times 10^4$
DNA [38]	DNA Data from *1000 Genomes Project*	4	25.15	$3{,}57 \times 10^3$
DNA-Rep	Concatenate first MB of DNA 245 760×	4	$2{,}50 \times 10^{10}$	$5{,}00 \times 10^{10}$

We see that ℓDCX is the fastest (distributed) algorithm on CC on all evaluated numbers of PEs. Compared to the previous algorithms, we achieve speedups of up to 4.3, while being at least 1.6× more memory-efficient. The improved prefix-doubling algorithm dPD* performs better, especially when using AMS with two levels (dPD^{*,2}). However, ℓDCX is still about a factor of 1.6 faster. A similar trend can be seen for Wiki, although less pronounced, with speedups of 3.2 and 1.2 on 256 nodes, respectively. This is due to the lower LCP values of Wiki compared to the CC data set. The prefix-doubling algorithms require fewer iterations and therefore perform better. This becomes even more evident for DNA and Prot, as these data sets have even lower LCP values. Additionally, the smaller alphabet size of these texts makes the packing optimization more effective. These factors explain the lower running time of all algorithms on these data sets. On DNA, our improved dPD* is fastest on 256 compute nodes and outperforms ℓDCX by a factor of 1.2.

Due to the repetitive nature of DNA-Rep, the data set has very high average LCP values and therefore is a particularly hard instance for prefix-doubling algorithms. Consequently, these algorithms were not able to terminate within the time limit for all PE configurations (or even crashed on some configurations). Our ℓDCX algorithm is, due to its algorithmic properties, largely insensitive to this input characteristic and shows a very good scaling behavior even on this hard input instance with speedups of up to 5.5 over its competitors.

The DC$\{3, 7, 13\}$ implementation by Bingmann (B-DC$_X$) does not scale well.[6] However, at least the DC$\{7, 13\}$ variants have competitive running times for CC and Wiki on up to two compute nodes. Nonetheless, their memory consumption reveals a key problem of a straightforward adaptation of DCX to distributed memory. Although using 32-bit integers internally, DC3 exhibits a blow-up of $\approx 50\times$ while DC7 and DC13 have a blow-up of $\geq 60\times$ and $\approx 80\times$, respectively.

The running times for the shared-memory parallel variant of libsais (using all 48 cores of one compute node) are given for the input of all p cores. We see that libsais is faster than ℓDCX when using only one compute node. This is not surprising as libsais leverages native OpenMP parallelization while our implementation of DCX uses interprocess-communication via MPI even when running on only one compute node. But from only two compute nodes on (4 compute nodes for DNA-Rep) ℓDCX clearly surpasses libsais effectively utilizing the additional cores. We cannot run libsais on inputs larger than $8 \times 48 \times 20$ MB due to the limited main memory of 96 GB per compute node.

Overall, our lightweight distributed DCX algorithm shows a very good scaling behavior and is either fastest or competitive with our improved version of prefix-doubling with discarding, which is fastest on the remaining inputs (again at least for large PE configurations).

[6] While the scaling behavior of the implementation could certainly be improved, we chose not to do so as our engineered space-efficient ℓDCX algorithm already supersedes it in terms of implementation.

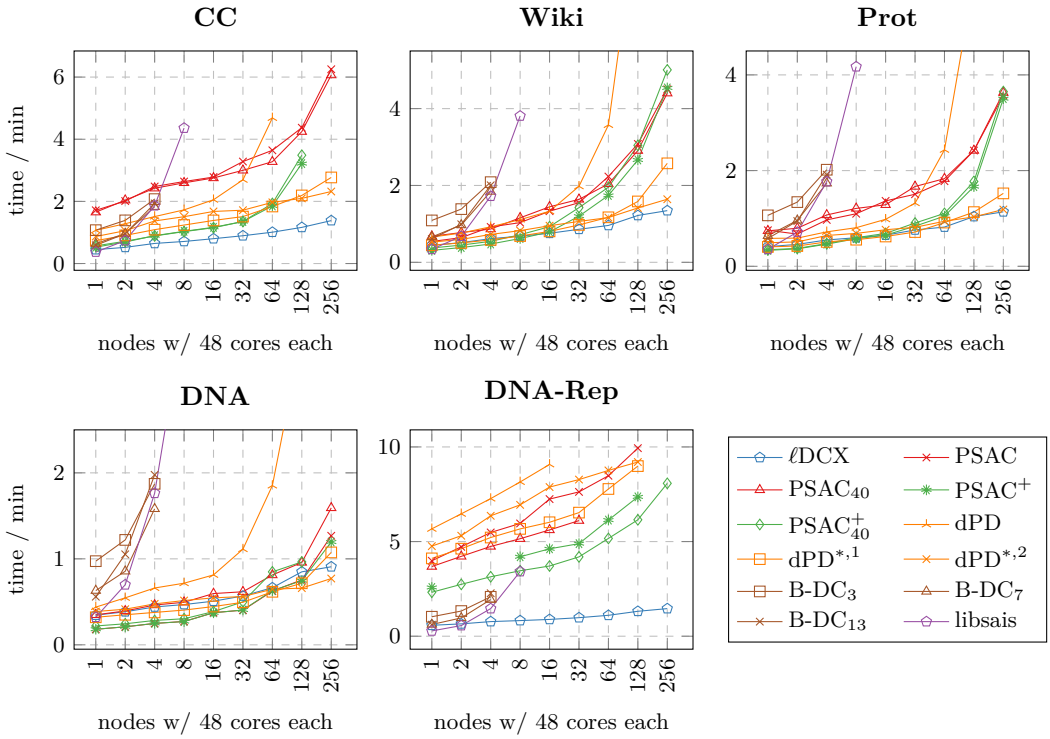

Figure 1 Running time in minutes of the suffix array construction algorithms in our weak-scaling experiments with 20 MB per PE. Missing data points are due to time limits or crashes.

Regarding the memory consumption (Figure 2), we see that ℓDCX is clearly the most memory-efficient one of all evaluated distributed algorithms due to the bucketing with randomized chunk redistribution approach. We see a slight increase in memory consumption for larger PE configurations which we assume to be caused by external factors such as the internal buffer allocation strategy of the MPI implementation and the release policy of memory allocators as we could not detect a significant increase in bucket imbalances.

5.2 Breakdown Experiments

Figure 3 shows the result of a breakdown test, where we run the algorithms on 16 compute nodes (768 cores) and increase the input size per PE until the algorithms can no longer finish due to memory limitations. We start the experiment with 20 MB (15.36 GB in total). The standard PSAC variants using 64-bit integers can handle up to 30 MB (at least for DNA). The 40-bit variants as well as the different variants of dPD can handle up to 40 MB of text per PE. Our ℓDCX implementation is, as expected, far more memory-efficient and can handle up to 130 MB of input per PE (6.24 GB per compute node). With inputs size larger than 100 MB per PE, the maximum memory consumption of ℓDCX is only between 14× to 15× the input size. We attribute this to fixed-size memory overheads of the MPI runtime becoming less important with increasing input size. These values come close to the theoretically expected memory consumption of our implementation.

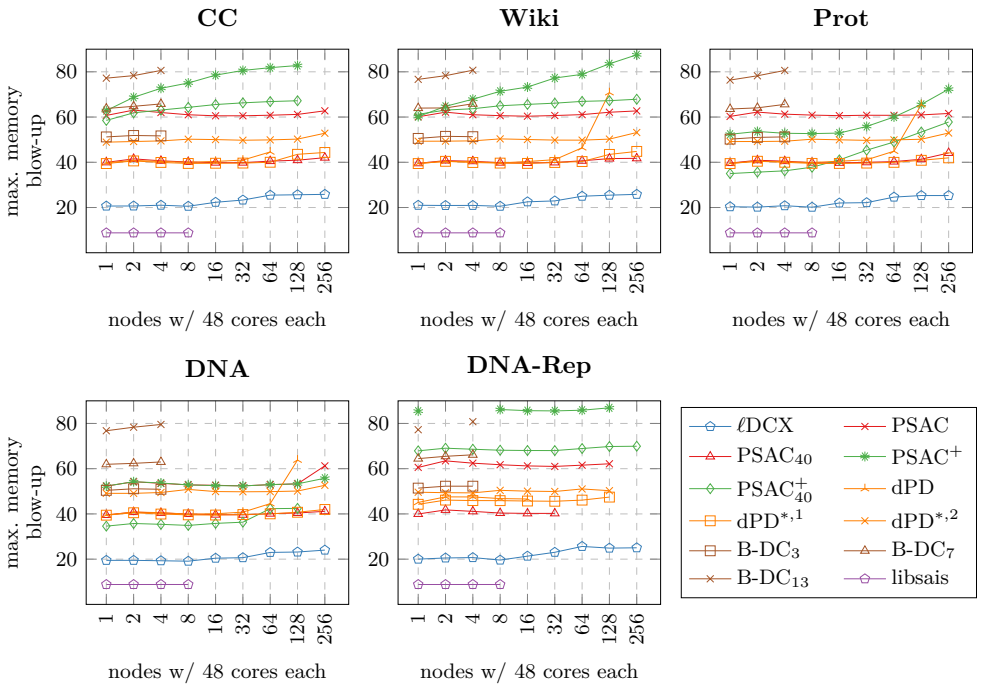

Figure 2 Memory blow-up of the suffix array construction algorithms in our weak-scaling experiments with 20 MB per PE.

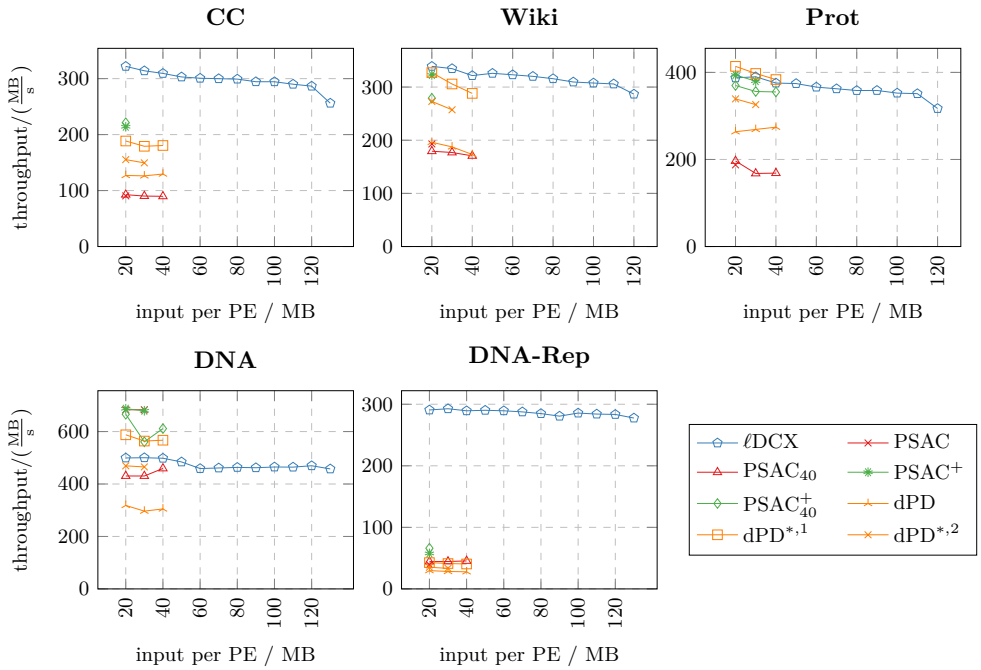

Figure 3 Breakdown test on 16 compute nodes (768 cores) with increasing input size.

6 Conclusion and Future Work

In this work, we present a fast and lightweight distributed variant of the DCX suffix sorting algorithm. We rely on a bucketing scheme for space-efficient distributed sorting to reduce the algorithm's memory consumption and combine it with a load-balancing approach based on random chunk redistribution. In our extensive experimental evaluation, we show that our algorithm is up to 5× faster than previous distributed suffix sorting algorithms while being substantially more memory-efficient. For future work, we plan to extend our bucketing and random chunk redistribution approach to other models of computing such as the distributed external-memory model and distributed multi-GPU architectures.

The Support of Bin Packing Is Exponential

Abstract

Consider the classical Bin Packing problem with d different item sizes s_i and amounts of items a_i. The support of a Bin Packing solution is the number of differently filled bins. In this work, we show that the lower bound on the support of this problem is $2^{\Omega(d)}$. Our lower bound matches the upper bound of 2^d given by Eisenbrand and Shmonin [Oper.Research Letters '06] up to a constant factor. This result has direct implications for the time complexity of several Bin Packing algorithms, such as Goemans and Rothvoss [SODA '14], Jansen and Klein [SODA '17] and Jansen and Solis-Oba [IPCO '10].

To achieve our main result, we develop a technique to aggregate equality constrained ILPs with many constraints into an equivalent ILP with one constraint. Our technique contrasts existing aggregation techniques as we manage to integrate upper bounds on variables into the resulting constraint. We believe this technique can be useful for solving general ILPs or the d-dimensional knapsack problem.

1 Introduction

In their seminal work [8] Eisenbrand and Shmonin inspect integer conic combinations $b \in \mathbb{Z}^d$ of a finite set of integer vectors $X \subset \mathbb{Z}^d$. They provide upper bounds on the size of the smallest subset $X^* \subseteq X$ such that b is an integer conic combination of elements in X^*. This can be interpreted in the context of integer programming. Integer Programs (IPs) are composed of a matrix $A \in \mathbb{Z}^{d \times n}$, an (optional) cost vector $c \in \mathbb{Z}^n$, a target vector $b \in \mathbb{Z}^d$ and a solution vector $x \in \mathbb{Z}^n$. The goal is to compute the solution vector satisfying $Ax = b$ while minimizing the value $c^T x$. In this context, the set of integer vectors correspond to the columns of A and the size of the smaller subset X^* is the number of non-zero entries (the *support*) in the solution vector. More precisely, they show that for any polytope $P \subseteq \mathbb{R}^d$ and any integral vector $x \in \mathbb{Z}_{\geq 0}^{|P \cap \mathbb{Z}^d|}$ of multiplicities there exists a $x^* \in \mathbb{Z}_{\geq 0}^{|P \cap \mathbb{Z}^d|}$ such that $|\text{supp}(x^*)| \leq 2^d$ and $\sum_{p \in P \cap \mathbb{Z}^d} x_p \cdot p = \sum_{p \in P \cap \mathbb{Z}^d} x_p^* \cdot p$. They achieve this through a sophisticated exchange argument, transforming a solution with a large support into one with a bounded support. They show a second bound of $O(d \log(d\Delta))$, where $\Delta = ||A||_\infty$ is the largest number in the matrix A, in a similar fashion. These celebrated result have found application in a variety of applications. These include classical problems of computer science like scheduling on identical and uniform machines (using the second bound) [15, 19] and bin packing problem (using the first bound) [13, 18, 20].

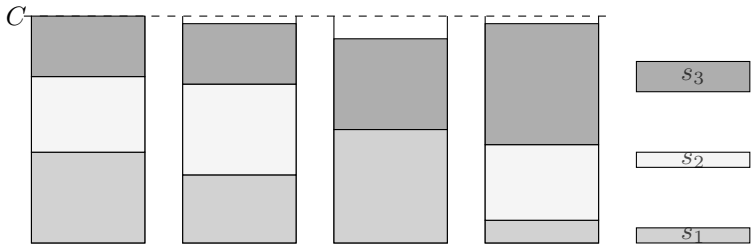

Figure 1 An illustration of the Bin Packing problem with three item types, four bins and capacity C. Colors indicate item types. Each bin has a unique *configuration*, i.e., combination of items, assigned to it. Only the leftmost bin is completely filled. The sizes of each item type are shown on the right.

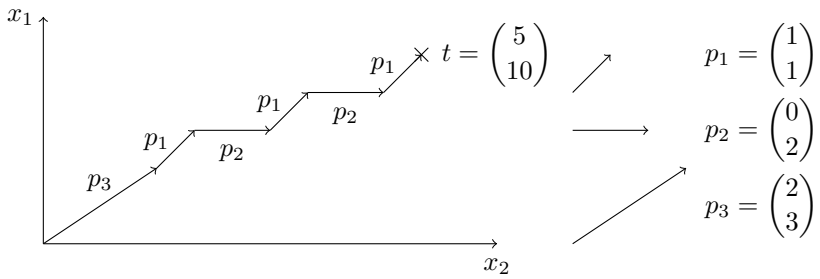

Figure 2 An illustration of the Cone and Polytope Intersection problem with three points $p_i \in P$ and the target $t \in Q$. The values of each vector are given. A possible solution is shown.

Improvements on the first bound would have direct implications for the time complexity of several algorithms. Consider the high-multiplicity Bin Packing (BP) problem with bin size C: We are given item sizes $s_1, \dots s_d \in [0, C]$, and multiplicities $a_i \in \mathbb{Z}_{\geq 0}, i \in [d]$. The task is to find the minimum number $B \in \mathbb{N}$ such that all items can be packed into B bins of size C. See Figure 1 for an illustration. For this problem, Jansen and Solis-Oba [20] give an additive approximation algorithm with guarantee OPT+1. The time complexity of their algorithm is $d^{O(d2^d)} \cdot 2^{O(8^d)} \cdot \text{poly}(enc)$, where $\text{poly}(enc)$ represents a polynomial in the input. In their paper, they ask whether the support bound by Eisenbrand and Shmonin can be improved to be polynomial in d. Consequently, this would reduce the dependency on d in the algorithm to be singly-exponential, i.e., result in a running time of $2^{\text{poly}(d)} \cdot \text{poly}(enc)$.

Following this result, Goemans and Rothvoss [13] provide an algorithm running in time $\text{enc}(s, a, C)^{2^{O(d)}}$. Here, $\text{enc}(s, a, C)$ denotes the bitsize of encoding the size vector s, the multiplicity vector a and the bin capacity C in binary. The time complexity of this algorithm would also be improved by a smaller support bound. For example, a polynomial support $\text{poly}(d)$ in d directly improves their running time to $\text{enc}(s, a, C)^{\text{poly}(d)}$. They achieve this result by solving a more general problem, the Cone and Polytope Intersection (CAPI) problem. Here, we are given two polytopes $P, Q \subseteq \mathbb{R}^d$, where P is bounded. The task is to decide whether there is a point in Q that can be expressed as a non-negative integer combination of integer points in P. Goemans and Rothvoss show that this problem captures the essence of high-multiplicity BP. They reduce BP to CAPI by setting the integer points in $P = \{\binom{x}{1} \in \mathbb{R}^{d+1}_{\geq 0} | s^T x \leq C\}$ to every possible configuration, i.e., combinations of items that fit in a single bin. They set $Q = \binom{a}{B}$ to be the point that corresponds to all items being taken. The final entry in P and Q is used to count the number of used bins B.

Jansen and Klein extend the work of Goemans and Rothvoss in [18]. They give an algorithm for bin packing that depends on the number V_I of vertices in the underlying knapsack polytope of a single bin. Their algorithm has a running time of $|V_I|^{2^{O(d)}}\text{enc}(s,a,C)^{O(1)}$. Thus, it improves upon Goemans and Rothvoss' result when V_I is small. However, it does not improve upon the result by Goemans and Rothvoss in the general sense, as the bound on V_I is $\Omega(\text{enc}(s,a,C))^d$ as given by Hayes and Larman [14].

All three of these results could be improved with a polynomial (in d) support bound for BP. However, our result shows that there is no polynomial support bound in d for bin packing, and thus answers the question posed by Jansen and Solis-Oba negatively. Goemans and Rothvoss made first strides in this direction in [13], where they show that the bound given by Eisenbrand and Shmonin is tight for polytopes, i.e., there is an exponential support when reaching a target with only column vectors or linear combinations of them. They construct a set of column vectors X with dimension d and $|X| = 2^{d-1}$. Define the polytope $P = conv(X)$, where $conv(X)$ is the convex hull of X. They then define $t = \sum_{x\in X} x$ and show that you can only reach t by taking every element of X exactly once. This shows a lower bound on the support of $2^{d-1} = 2^{\Omega(d)}$. However, their bound does not admit a knapsack constraint and can therefore not be applied to the bin packing problem directly. This is because the columns in the bin packing ILP originate from a knapsack constraint that determines the feasible packings of a single bin.

With so many different problems gaining important information from support bounds, it should come as no surprise that there are other bounds on the support of integer programs with different parameterizations. Berndt, Brinkop, Jansen, Mnich and Stamm show that the support is also bounded by $d \cdot (\log(3||A||_1) + \sqrt{\log(||A||_1)})$ [3]. They complement this result by showing a lower bound on the size of the support of $d \cdot (\lfloor \log(||A||_1 \rfloor + 1)$. Aliev, de Loera, Oertel and O'Neill [2] give two support bounds for linear diophantine equations of $r(A) + \lfloor \log(H(A)) \rfloor$, where $r(A)$ is the column rank of the matrix A and $H(A)$ is the determinant of the span of the $r(A)$-dimensional sublattice of $\mathbb{Z}^n$ formed by all integer points in the linear subspace spanned by the columns of A, i.e., $H(A) = \det(\text{span}_{\mathbb{R}}(A) \cap \mathbb{Z}^n)$. Their second bound is $\lfloor 2d \log(2\sqrt{d}\Delta) \rfloor$. Aliev, De Loera, Eisenbrand, Oertel and Weismantel [1] show the bound of $\lfloor 2d \log(2\sqrt{d}\Delta) \rfloor$ for general ILPs.

The main tool we use in the following is *aggregation.* Aggregation is a powerful tool that transforms an ILP with multiple constraints into a single constraint. Research into this technique began in the 70's, resulting in several different aggregation methods, see e.g. [4, 5, 9, 11, 12, 21, 22, 23, 24]. Elmaghraby and Wig [9] iteratively combine two equations into a single one. Applying this technique repeatedly yields a single constraint. Another approach is given by Padberg [22]. Instead of combining two equations iteratively, he aggregates all equations at the same time.

Our approach is based on the techniques by Padberg [22]. Our aggregation techniques also aggregate all constraints in a single step. However, we manage to include the upper bounds of the variables inside the resulting knapsack constraints, where Padbergs method leaves them outside the constraint. We believe that this type of aggregation can find application in different contexts, such as d-dimensional knapsack problems or general ILPs with d constraints. Here, the aggregation may yield faster algorithms, especially when one manages to reduce the size of the coefficients. This may be done by using techniques by Frank and Tardos [10], Eisenbrand, Hunkenschröder, Klein, Koutecký Levin and Onn [7] or Jansen, Kahler and Zwanger [16].

On the negative side, it is known that aggregation is not feasible for a set of inequalities, as was proven by Chvátal and Hammer [6]. They provide a simple two-line ILP that cannot be aggregated.

1.1 Our Contribution

In this work, we continue research into the support of Bin Packing solutions. We show that a set of points of Cone and Polytope Intersection can be embedded inside a knapsack polytope of dimension $O(d)$. Using this polytope, we show that the support of the high-multiplicity BP problem is exponential, requiring at least $2^{\Omega(d)}$ many different configurations in an optimum solution. This yields our main result, Theorem 1:

▶ **Theorem 1.** *There exists a high-multiplicity Bin Packing instance of dimension d such that the solution-vector x (a vector of configurations) contains at least $2^{\Omega(d)}$ non-zero entries, i.e., $|supp(x)| \in 2^{\Omega(d)}$.*

With this result, we answer an open question posed by Jansen and Solis-Oba in [20]. They provide an algorithm for the cutting stock problem. The running time of this algorithm could be improved to be singly-exponential if the support of bin packing is not exponential. However, our result answers this question negatively. In a similar vein, our result shows that the algorithm by Goemans and Rothvoss [13] can not be directly improved. The same holds for the algorithm by Jansen and Klein [17].

A major tool to achieve this result is the aggregation of multiple constraints without upper bounds on the variables into a single constraint. To the best of our knowledge, this type of constraint-aggregation has not been done before. Contrasting prior results, our method of aggregation manages to include upper bounds inside the constraints instead of copying them from the original problem. This technique is given in Section 3.

Overview

Here, we give a brief overview of the structure of the document and the structure of our main proof. We begin, in Section 3, by developing a technique with which we can aggregate an ILP containing only d equalities into one containing only a single equality. Next, in Section 4.1 we adapt an idea originally given by Goemans and Rothvoss in [13] to construct a polytope P of dimension $d' + 1$ and generate a target vector t. We provide an alternative proof to [13] that shows we require $2^d - 1$ points in P to reach t. Next, in Section 4.2, we construct an equality ILP with $O(d)$ constraints. Each constraint later defines an item size of the BP problem. We show that there are $2^d - 1$ feasible solutions to this ILP, with each solution x having the first $d + 1$ entries as vectors in P, i.e., there is one solution to the ILP for each vector in P. These solutions are the $2^d - 1$ configurations X^* of the BP problem. Then, we aggregate this ILP using the technique in Section 3. This yields an equality ILP with one row. We transform this into a knapsack constraint with right hand side C. Denote the set of all configurations with total size at most C as X. This constraint is then used to define the capacity of a bin in the BP problem. The total number of items of each type is given as the sum of all configurations in X^*. To place all these items in the optimal $2^d - 1$ bins, we know, by Section 4.1, that need to take every configuration in X^* exactly once. Taking any configuration in $X \setminus X^*$ would require at least one additional bin. This proves Theorem 1.

2 Preliminaries

For a positive integer n, we define $[n] \coloneqq \{1, 2, \ldots, n\}$ and $[n]_0 \coloneqq \{0, 1, \ldots, n\}$. A vector that contains a certain value in all entries is stylized, e.g. the zero vector 0_d is written as $\mathbb{0}_d$. We omit the dimension d if it is apparent from the context. The support of a d-dimensional vector v is the set of its indices with a non-zero entry. It is denoted by $\text{supp}(v) \coloneqq \{i \in [d] \mid v_i \neq 0\}$. We define the size of the support with $s(v) \coloneqq |\text{supp}(v)|$.

▶ **Definition 2** (Bin Packing). *Given is a set of d different item types with sizes $s_i \in (0, C]$ and amounts $a_i \in \mathbb{Z}_{\geq 0}$. Given a number $B \in \mathbb{Z}_{\geq 0}$, the goal is to decide whether all items can be assigned to one of B bins, while all bins are filled to at most C.*

A powerful tool to model countless optimization problems is that of integer programming.

▶ **Definition 3** (Integer Programming). *An integer linear program (ILP) is composed of a matrix $A \in \mathbb{Z}^{d \times n}$, an (optional) cost vector $c \in \mathbb{Z}^n$, a target vector $b \in \mathbb{Z}^d$ and a solution vector $x \in \mathbb{Z}^n_{\geq 0}$. The goal is to compute a solution vector satisfying $Ax = b$ while minimizing the value $c^T x$.*

Such integer programs can be used to express high-multiplicity Bin Packing. These are often referred to as *configuration ILPs*. A configuration is a feasible assignment $x \in \mathbb{Z}^d_{\geq 0}$ of items into a bin, i.e., one with total size at most $s^T x \leq C$. Denote the set of all feasible configurations as $\mathcal{C}$, and set $n := |\mathcal{C}|$. Set $c = \mathbb{1}_n$ and let each column of A represent a configuration, where row i corresponds to item type i. Finally set the right hand side $b := a$, i.e., the vector representing the total number of items of each size in the instance.

A useful tool that we use is the classical knapsack problem.

▶ **Definition 4** (Unbounded Knapsack). *Given a set I of n items each defined by a profit $p_i \in \mathbb{R}_{\geq 0}$ and a weight $w_i \in \mathbb{Z}_{\geq 1}$, along with a knapsack of capacity $C \in \mathbb{Z}_{\geq 1}$. Find a solution vector $x \in \mathbb{Z}^n_{\geq 0}$ such that $\sum_{i=0}^n w_i x_i \leq C$ and $\sum_{i=0}^n p_i x_i$ is maximal. We call $\sum_{i=0}^n w_i x_i = C$ the equality Knapsack constraint to the corresponding problem.*

Following this definition, we call the set of all solutions fulfilling $x_i \geq 0$, $\forall i \in [n]$ and $\sum_{i=0}^n w_i x_i \leq C$ the Knapsack Polytope.

3 Aggregation of an ILP

In this section, we show how to transform an ILP with multiple equality constraints into a single knapsack constraint. The novel aspect of our technique is that we also include the external upper bounds of the variables in the aggregation.

Consider an ILP of the form $\min\{c^T x \mid Ax = b, x \in \mathbb{Z}^n_{\geq 0}, x \leq u\}$ with $A = (a_{ij})_{i \in [d], j \in [n]} \in \mathbb{Z}^{d \times n}, c \in \mathbb{Z}^n, u \in \mathbb{Z}^n_{\geq 0}$ and $b \in \mathbb{Z}^d$ and let $\Delta := \|A\|_\infty$ be the largest absolute value in A.

For each variable $x_j, j \in [n]$, we define the following constraint: $x_j + s_j = u_j$, where $s_j \in \mathbb{Z}_{\geq 0}$ is a slack variable. This simulates the upper bound $x_j \leq u_j$. Define $U := \sum_{j=1}^n u_j$ as the overall upper bound on the sum of all variables. For this, add the constraint:

$$\sum_{i=j}^{n} (x_j + s_j) + s_{n+1} = U, \tag{1}$$

with $s_{n+1} \in \mathbb{Z}_{\geq 0}$ as a slack variable. Note that bounding the sum of variables by the sum of their upper bounds does not change the solution.

This results in a new ILP $A' \begin{pmatrix} x \\ s \end{pmatrix} = (b,\ u,\ U)$, where

$$A' := \begin{pmatrix} A & 0_{dn} & 0 \\ I_n & I_n & 0 \\ \mathbb{1}_n & \mathbb{1}_n & 1 \end{pmatrix} \in \mathbb{Z}^{(d+n+1) \times (2n+1)}.$$

Next, we use the bound U to define a large integer M, which we then use to aggregate the constraints.

$$\begin{aligned} M &:= \Delta U + \max(\|b\|_\infty, \|u\|_\infty) + \Delta + 2 \\ &> \Delta U + \max(\|b\|_\infty, \|u\|_\infty). \end{aligned} \tag{2}$$

By giving the upper-bound constraint (1) the largest weight M^{d+n}, we ensure that it may never be broken and thus, keeps the sum of the variables in its range. Multiplying both sides of the equations with $1, M, M^2, \ldots, M^{d+n}$ generates the following ILP where all variables have to be non-negative integers.

$$\begin{aligned} \textstyle\sum_{j=1}^{n} a_{1j}x_j &= b_1 \\ M\textstyle\sum_{j=1}^{n} a_{2j}x_j &= Mb_2 \\ &\vdots \\ M^{d-1}\textstyle\sum_{j=1}^{n} a_{mj}x_j &= M^{d-1}b_m \\ M^d(x_1 + s_1) &= M^d u_1 \\ &\vdots \\ M^{d+n-1}(x_n + s_n) &= M^{d+n-1}u_n \\ M^{d+n}(\textstyle\sum_{j=1}^{n}(x_j + s_j) + s_{n+1}) &= M^{d+n}U \\ x_j &\in \mathbb{Z}_{\geq 0} \quad \forall j \in [n] \\ s_j &\in \mathbb{Z}_{\geq 0} \quad \forall j \in [n+1] \end{aligned} \tag{3}$$

These constraints can also be formulated as $A' \begin{pmatrix} x \\ s \end{pmatrix} = (b,\ u,\ U)$, where

$$A' := \begin{pmatrix} A & 0_{dn} & 0 \\ I_n & I_n & 0 \\ \mathbb{1}_n & \mathbb{1}_n & 1 \end{pmatrix} \in \mathbb{Z}^{(d+n+1)\times(2n+1)}$$

An intuitive view of the aggregation technique is that the resulting single constraints solution is a base M number, where M is a large integer. There, the smallest digit represents the solution of the first constraint, the second constraints solution is represented by the second smallest digit and so on.

Next, we show that this ILP can be aggregated into a single equality knapsack constraint by proving that their solutions are identical. The proof is presented in the full version.

▶ **Lemma 5** (✂). *The vector* $\texttt{sol} = (x,\ s)^T \in \mathbb{Z}_{\geq 0}^{2n+1}$ *is a feasible integer solution to* (3) *if and only if* `sol` *is an integer solution to the following equation:*

$$\begin{aligned} \sum_{i=1}^{d}\big(M^{i-1}\sum_{j=1}^{n}(a_{ij}x_j)\big) + \sum_{j=1}^{n}\big(M^{d+j-1}(x_j + s_j)\big) + M^{d+n}\big(\sum_{j=1}^{n}(x_j + s_j) + s_{n+1}\big) \\ = \sum_{i=1}^{d}(M^{i-1}b_i) + \sum_{j=1}^{n}\big(M^{d+j-1}u_j\big) + M^{d+n}U \end{aligned} \tag{4}$$

4 Bounding the Support for Bin Packing

Assume we are given a knapsack polytope P of dimension $d' + 1$. Also assume that there exists a Bin Packing instance $\mathcal{I}$ with just one unique integer solution $x \in \mathbb{Z}_{\geq 0}^{d}$, $d = O(d')$ to the configIP and the $d' + 1$-dimensional integer points in P are equal to the first $d' + 1$

dimensions of the configurations. If we now require k different points in P to represent a vector t as a conic integer combination then x has at least k non-zero entries, which means that we need at least k different configurations in the Bin Packing solution. If now k is exponential in d', we have shown that there exists an exponential lower bound on the support of the Bin Packing problem, i.e., Theorem 1.

4.1 The support of closed polytopes

In this section, we give a knapsack polytope P of dimension $d+1$ and show that there exists a vector $t \in \mathbb{Z}^{d+1}$ such that we need at least $2^d - 1$ points in P to represent t as a conic integer combination. We adapt a construction pioneered by Goemans and Rothvoss in [13] and set

$$\begin{aligned} X &= \{\mathbb{0}\} \cup \{(x_1, \dots, x_d, (4k)^{\sum_{i=0}^{d-1} 2^i x_i}) \mid x_i \in \{0,1\} \forall i \in [d]\} \setminus \{(0, \dots, 0, 1)\}\} \\ &= \{a_0, a_1, \dots, a_k\} \end{aligned} \tag{5}$$

with $k = 2^d - 1$ and define $P := \text{conv}(X)$. E.g. for $d = 2$, we have

$$X = \left\{ \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 \\ 0 \\ 4k \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \\ (4k)^2 \end{pmatrix}, \begin{pmatrix} 1 \\ 1 \\ (4k)^3 \end{pmatrix} \right\}.$$

Assume that the elements in X are sorted according to their length, i.e., $\|a_0\|_\infty = 0$ and $\|a_i\|_\infty = (4k)^i$ for all $i \in [k]$. Then the following lemma proves the goal of this section.

▶ **Lemma 6.** *Set $t = \sum_{i=0}^{k} a_i$. The conic combination $t = \sum_{i=1}^{k} a_i$ is unique (except for arbitrarily adding a_0). This implies that we need all $2^d - 1$ points in P exactly once to represent t as a conic integer combination.*

Proof. Each integer conic combination that represents t and includes $\mathbb{0}$ can be transformed into an integer conic combination of less points by removing $\mathbb{0}$. Therefore, we can assume that $\mathbb{0}$ is not part of the conic combination.

Now considering P, the only integer points in P are the elements in X, i.e., $P \cap \mathbb{Z}^{d+1} = X$. This holds due to the first d coordinates. For all $\mu_i \in (0,1)$ with $\sum_i \mu_i = 1$ it holds that $\mu_i \cdot 0 + \mu_j \cdot 1 \notin \mathbb{Z}$ and for each pair of vectors $(a_i, a_j) \in X$ with $i \neq j$, there is at least one coordinate ℓ, where with $a_i(\ell) = 0$ and $a_j(\ell) = 1$ or $a_i(\ell) = 1$ and $a_j(\ell) = 0$. Thus, there can not be any integer points other than X in $P \cap \mathbb{Z}^{d+1}$.

Now consider an arbitrary integer conic combination $\sum_{i=1}^{k} \mu_i a_i = t = \begin{pmatrix} 2^{d-1} \\ \vdots \\ 2^{d-1} \\ \sum_{i=1}^{k} (4k)^i \end{pmatrix}$.

Since $t_1 = \dots = t_{d-1} = 2^{d-1}$ and we do not include $\mathbb{0}$, we can not take a single vector more than $2^{d-1} \leq k$ times. Furthermore, we can not take more than dk vectors total, as each vector except $\mathbb{0}$ has an entry in at least one of the d dimensions, and each entry can only sum up to k. This leaves us with the following:

$$0 \leq \sum_{i=1}^{k} \mu_i \leq d \cdot 2^{d-1} \leq dk, \quad \text{and}$$
$$\mu_i \leq 2^{d-1} \leq k \quad \forall i \in [k]$$

i.e., that at most dk vectors can be summed up to reach t and each vector is taken $\leq k$ times.

We now show that $\mu_i = 1$ for all $i \in [k]$ is the only solution to $t = \sum_{i=1}^{k} \mu_i a_i$. First, observe that $t_{d+1} = \sum_{i=1}^{k} (4k)^i < 2(4k)^k$ holds. Therefore, we have $\mu_k < 2$. Next, observe that $k(4k)^{x-1} < (4k)^x - (4k)^{x-1} \Leftrightarrow (k+1)(4k)^{x-1} < (4k)^x$ holds for all $x \in \mathbb{Z}_{\geq 1}$ because $(k+1) < 4k$. Because of this, even after adding the maximum possible k copies of the $k-1$-th item, we have that $t_{d+1} - k(4k)^{k-1} > (4k)^{k-1}$. We can only compensate this difference by adding smaller items. Here, we can apply the argument iteratively, as we can only add k copies of column $(k-2)$ to sum up to a value $> (4k)^{k-1}$. Thus, $\sum_{i=1}^{k-1} k(4k)^i < (4k)^k$ holds. Therefore, we can not sum up to $(4k)^k$ without the last item and $\mu_k > 0$ directly follows. Taking $\mu_k < 2$ and $\mu_k > 0$ together, we have $\mu_k = 1$. Because of $\mu_k = 1$, we have $t_{d+1} = \sum_{i=1}^{k} -1(4k)^i$, and we only need to consider $\mu_i, i \in [k-1]$. Then, this argument can be applied iteratively, yielding $\mu_i = 1$ for all $i \in [k]$. ◀

By Lemma 6, we have shown that we require $2^d - 1$ different points in P to represent a vector t as a conic integer combination. In the following we build the bridge to Bin Packing and prove that there exists a Bin Packing instance where the first $d+1$ dimensions of the solution vector of its configIP equals the integer points in P. In total, our Bin Packing instance has $O(d)$ dimensions which then with Lemma 6 implies the exponential lower bound of Bin Packing and therefore Theorem 1.

4.2 Construction of the ILP

In this section, we now aim to construct an ILP with equality constraints, where the first $d+1$ coordinates in its solution vectors are unique and form the following set:

$$\{(x_0^{\texttt{bin}}, \dots, x_{d-1}^{\texttt{bin}}, \gamma^{\sum_{\ell=0}^{d-1} 2^\ell x_\ell^{\texttt{bin}}}) \mid x_\ell^{\texttt{bin}} \in \{0,1\} \forall \ell \in [d-1]_0\} \setminus \{(0, \dots, 0, 1)\}\}. \tag{6}$$

Note that this is exactly the set X of points in P in the prior section without $a_0 = \mathbb{0}$ and where $\gamma = 4k$ and that the solution vectors form the configurations in the configIP.

Also note that the last coordinate is of the form γ^i for some $i \in \mathbb{Z}_{\geq 1}$ and the first d coordinates are the binary encoding of i. We first define a variable $r(d)$, which we use to construct a set of constraints that is only feasible if $r(d) = \gamma^i$ holds for some $i \in \mathbb{Z}_{\geq 1}$. Additionally, a certain set of variables in the constraints matches the points in Equation (6). In second part of this section, we use the aggregation presented in Section 3 to transform these constraints into a single knapsack constraint. We provide a proof that the knapsack constraint is indeed equivalent to the proposed set of constraints (i.e., both allow the same set of solutions) and requires $O(d)$ many variables. With this equivalence, we then have that the first $d+1$ dimensions of the configurations in the configIP form the set Equation (6). In combination with the Lemma 6, this then implies that there exists an exponential lower bound on the support of the Bin Packing problem.

Next, assume that we are given a dimension $d \in \mathbb{Z}_{\geq 1}$ and a base $\gamma \in \mathbb{Z}_{\geq 2}$. We introduce a set of constraints with $O(d)$ variables which has exactly $2^d - 1$ integer solutions. For each $i \in [2^d - 1]$, the variable $r(d)$ of the solution vector is forced to take the value γ^i. Additionally, the variables $x^{\texttt{bin}}(\ell) \in \{0,1\}, \ell \in [d-1]_0$ match the binary encoding of i, i.e., $i = \sum_{\ell=0}^{d-1} 2^\ell x^{\texttt{bin}}(\ell)$.

For a brief overview, our constraints behave as follows. First, the value $r(d)$ is some integer in the interval $[2, \gamma^{2^d-1}]$. Let us assume that $r(d) = \gamma^i$ for some i. Later, we show that we only allow those integers that equal γ^i where i is a positive integer. Next, for each $\ell = d-1, \dots, 0$, we introduce the variable $y(\ell)$ that helps us to correctly determine the bit $x^{\texttt{bin}}(\ell)$ of the binary encoding. We also introduce the variable $z(\ell)$ that helps us to determine

the $r(\ell)$ which will then be used recursively. For a more detailed version of the procedure of converting a decimal number $i \in \mathbb{Z}_{\geq 1}$ to binary, we refer to Algorithm 1. Note that the number we aim to convert is in the exponent of γ.

Algorithm 1 Decimal to Binary.

Input: Dimension $d \in \mathbb{Z}_{\geq 1}$; Base $\gamma \in \mathbb{Z}_{\geq 2}$; Exponent $i \in \mathbb{Z}_{\geq 1}$
Output: Binary encoding $x^{\texttt{bin}}$ of i

Set $r(d) \coloneqq \gamma^i$ with $i \in \mathbb{Z}_{\geq 1}$ and $\gamma^i \leq \gamma^{2^d-1}$.
for $\ell = d-1, \dots, 0$ **do**
  if $r(\ell+1) \geq \gamma^{2^\ell}$ **then**
    Record a 1 in position ℓ, i.e., $x^{\texttt{bin}}(\ell) \coloneqq 1$.
    Subtract 2^ℓ from the current exponent, i.e., $r(\ell) \coloneqq \frac{r(\ell+1)}{\gamma^{2^\ell}}$.
  else
    Record a 0 in position ℓ, i.e., $x^{\texttt{bin}}(\ell) \coloneqq 0$.
    Do not change the current exponent, i.e., $r(\ell) \coloneqq r(\ell+1)$.
return the vector $x^{\texttt{bin}}(\ell), \ell \in [d-1]_0$

The following set of constraints simulates this algorithm. Let α be some integer number larger than 3. Later, α represents the total number of constraints. Each set of constraints $\texttt{C}_{\ell,k}, k \in [13]$ is defined for all $\ell \in [d-1]_0$. They simulate the algorithm above. Additionally, $\texttt{C}_{\alpha-2}$ bounds $r(d)$, i.e., ensures its binary encoding has at most d bits. $\texttt{C}_0$ guarantees that in the end, there is no remainder left. This constraint is also needed to guarantee that the exponent i is integer (Lemma 12). Also, we do not want to allow $i = 0$, respectively $x^{\texttt{bin}}(\ell) \neq 0$. That is done by $\texttt{C}_{\alpha-3}$. Thus, in total, we have $13d + 3$ constraints.

▶ **Constraints 1.** *For each $\ell \in [d-1]_0$, we have the following set of constraints:*

$$
\begin{aligned}
y(\ell) &\geq 0 && (C_{\ell,1})\\
y(\ell) &\leq (r(\ell+1)/\gamma^{2^\ell}) + 1/(\gamma^{2^\ell}+1) && (C_{\ell,2})\\
y(\ell) &\geq (r(\ell+1)/\gamma^{2^\ell}) - (\gamma^{2^\ell}-1)/\gamma^{2^\ell} && (C_{\ell,3})\\
x^{bin}(\ell) &\geq 0 && (C_{\ell,4})\\
x^{bin}(\ell) &\leq 1 && (C_{\ell,5})\\
x^{bin}(\ell) &\leq y(\ell) && (C_{\ell,6})\\
y(\ell) &\leq (\gamma^{2^\ell}+1)x^{bin}(\ell) && (C_{\ell,7})\\
r(\ell) &\geq 0 && (C_{\ell,8})\\
(\gamma^{2^\ell}-1)z(\ell) + r(\ell) &= r(\ell+1) && (C_{\ell,9})\\
z(\ell) &\geq 0 && (C_{\ell,10})\\
z(\ell) &\geq -\gamma^{2^\ell} + \gamma^{2^\ell}x^{bin}(\ell) + r(\ell) && (C_{\ell,11})\\
z(\ell) &\leq \gamma^{2^\ell}x^{bin}(\ell) && (C_{\ell,12})\\
z(\ell) &\leq r(\ell) && (C_{\ell,13})
\end{aligned}
$$

Also, we add the additional constraints $C_0, C_{\alpha-3}$ and $C_{\alpha-2}$

$$
\begin{aligned}
r(0) &= 1 && (C_0)\\
r(d) &\geq 2 && (C_{\alpha-3})\\
r(d) &\leq \gamma^{2^d-1} && (C_{\alpha-2})
\end{aligned}
$$

All of the constraints are necessary to ensure that $r(d)$ takes some value of the form $\gamma^i, i \in \mathbb{Z}_{\geq 1}$, while $x^{\texttt{bin}}$ is the binary encoding of i. Moreover, the constraints forbid any other assignment of $r(d)$ and $x^{\texttt{bin}}$. All other variables are forced to take a specific value based on i. In the full version, we give an example that we cannot omit the variables $z(\ell)$, as that would allow other solutions with $r(d) = \gamma^i, i \in \mathbb{Z}_{\geq 1}$.

For easier understanding, we now present an example.

▶ **Example 7.** Let $\gamma \in \mathbb{Z}_{\geq 2}$ and set $d := 3$. Then, for $i \in [7]$, we get the following values for the variables.

i	1	2	3	4	5	6	7
$r(3)$	γ^1	γ^2	γ^3	γ^4	γ^5	γ^6	γ^7
$y(2)$	0	0	0	1	γ^1	γ^2	γ^3
$y(1)$	0	1	γ^1	0	0	1	γ^1
$y(0)$	1	0	1	0	1	0	1
$x^{\mathtt{bin}}(2)$	0	0	0	1	1	1	1
$x^{\mathtt{bin}}(1)$	0	1	1	0	0	1	1
$x^{\mathtt{bin}}(0)$	1	0	1	0	1	0	1
$r(2)$	γ^1	γ^2	γ^3	$\gamma^{4-4} = 1$	$\gamma^{5-4} = \gamma^1$	$\gamma^{6-4} = \gamma^2$	$\gamma^{7-4} = \gamma^3$
$r(1)$	γ^1	$\gamma^{2-2} = 1$	$\gamma^{3-2} = \gamma^1$	1	γ^1	$\gamma^{2-2} = 1$	$\gamma^{3-2} = \gamma^1$
$r(0)$	$\gamma^{1-1} = 1$	1	$\gamma^{1-1} = 1$	1	$\gamma^{1-1} = 1$	1	$\gamma^{1-1} = 1$
$z(2)$	0	0	0	1	γ^1	γ^2	γ^3
$z(1)$	0	1	γ^1	0	0	1	γ^1
$z(0)$	1	0	1	0	1	0	1

Now, we state properties for the variables $y(\ell), x^{\mathtt{bin}}(\ell), r(\ell), z(\ell)$ based on the value of $r(\ell+1)$. After that, we prove that the vector $x^{\mathtt{bin}}$ is indeed the binary encoding of i.

$\mathtt{C}_{\ell,1}, \mathtt{C}_{\ell,4}, \mathtt{C}_{\ell,8}$ and $\mathtt{C}_{\ell,10}$ are lower bounds of the variables $y(\ell), x^{\mathtt{bin}}(\ell), r(\ell)$ and $z(\ell)$. We omit these constraints later on by restricting all variables of the constructed ILP to be non-negative.

$\mathtt{C}_{\ell,1}$ to $\mathtt{C}_{\ell,3}$ ensure that the currently most significant bit is assigned correctly. As the values of $y(\ell)$ are assigned from the most significant bit to the least significant bit, this ensures the correctness of the binary encoding. More specifically, we have the following property.

▶ **Observation 8.** *Constraints $\mathtt{C}_{\ell,1}$ to $\mathtt{C}_{\ell,3}$ imply*

$$y(\ell) \begin{cases} = 0, & \text{if } r(\ell+1) < \gamma^{2^\ell} \\ \geq 1 & \text{if } r(\ell+1) \geq \gamma^{2^\ell} \end{cases}$$

Proof. We show this by analyzing the cases separately:

Case 1: Assume $r(\ell+1) < \gamma^{2^\ell}$. $\mathtt{C}_{\ell,2}$ states $y(\ell) \leq {}^{r(\ell+1)}/_{\gamma^{2^\ell}} + {}^{1}/_{(\gamma^{2^\ell}+1)}$. With the assumption and the fact that $r(\ell+1)$ is integer, we get $y(\ell) \leq {}^{(\gamma^{2^\ell}-1)}/_{\gamma^{2^\ell}} + {}^{1}/_{(\gamma^{2^\ell}+1)}$. Now, ${}^{1}/_{(\gamma^{2^\ell}+1)} < {}^{1}/_{\gamma^{2^\ell}}$ implies $y(\ell) < {}^{\gamma^{2^\ell}}/_{\gamma^{2^\ell}} = 1$. Since $y(\ell)$ is also restricted to integer values we get $y(\ell) = 0$ with $\mathtt{C}_{\ell,1}$. Now, we only need to show that the other constraint is also fulfilled for $y(\ell) = 0$. For $\mathtt{C}_{\ell,3}$ we get $0 = y(\ell) \geq {}^{r(\ell+1)}/_{\gamma^{2^\ell}} - {}^{(\gamma^{2^\ell}-1)}/_{\gamma^{2^\ell}}$, since $r(\ell+1) \leq \gamma^{2^\ell} - 1$ which completes this part of the proof.

Case 2: Assume $r(\ell+1) \geq \gamma^{2^\ell}$. $\mathtt{C}_{\ell,3}$ states $y(\ell) \geq {}^{r(\ell+1)}/_{\gamma^{2^\ell}} - {}^{(\gamma^{2^\ell}-1)}/_{\gamma^{2^\ell}}$. With the assumption, we get $y(\ell) \geq 1 - {}^{(\gamma^{2^\ell}-1)}/_{\gamma^{2^\ell}} > 0$. Since $y(\ell)$ is restricted to integer values we get $y(\ell) \geq 1$. Now, we only need to show that the other constraints are also fulfilled for $y(\ell)$. This clearly holds for $\mathtt{C}_{\ell,1}$. For $\mathtt{C}_{\ell,2}$ we get $1 \leq y(\ell) \leq {}^{r(\ell+1)}/_{\gamma^{2^\ell}} + {}^{1}/_{(\gamma^{2^\ell}+1)}$, since ${}^{r(\ell+1)}/_{\gamma^{2^\ell}} \geq 1$ and ${}^{1}/_{(\gamma^{2^\ell}+1)} \leq 1$. This finalizes the proof. ◀

In particular, we have that the value of $y(\ell) = \lfloor {}^{r(\ell+1)}/_{\gamma^{2^\ell}} + {}^{1}/_{(\gamma^{2^\ell}+1)} \rfloor$ is unique for given $r(\ell+1)$. This is due to the fact that the feasible interval (given by $\mathtt{C}_{\ell,2}$ and $\mathtt{C}_{\ell,3)}$) is of size $1 - {}^{1}/_{\gamma^{2^\ell}} \leq {}^{1}/_{(\gamma^{2^\ell}+1)} + {}^{(\gamma^{2^\ell}-1)}/_{\gamma^{2^\ell}} < 1$. The second inequality implies that there exists at most one integer value in the interval. The first inequality in combination with the fact that $r(\ell+1)$ is integer, we also have that there must exist an integer value in the interval.

Now, we are able to show that the $x^{\mathtt{bin}}(\ell), \ell \in [d-1]_0$ matches the binary encoding of i. $\mathtt{C}_{\ell,6}$ ensures that $x^{\mathtt{bin}}(\ell) = 0$ if $y(\ell) = 0$, while $\mathtt{C}_{\ell,7}$ provides that $x^{\mathtt{bin}}(\ell) > 0$ if $y(\ell) > 0$. Taken together with $\mathtt{C}_{\ell,5}$ and the fact that $x^{\mathtt{bin}}(\ell)$ is integer, we observe the following.

▶ **Observation 9.** *Constraints $\mathtt{C}_{\ell,1}$ to $\mathtt{C}_{\ell,7}$ imply*

$$x^{\mathtt{bin}}(\ell) = \begin{cases} 0, & \text{if } r(\ell+1) < \gamma^{2^\ell} \\ 1, & \text{if } r(\ell+1) \geq \gamma^{2^\ell} \end{cases}$$

Proof. We show this by again separately analyzing the cases:

Case 1: Assume $r(\ell+1) < \gamma^{2^\ell}$. With Observation 8, we know $y(\ell) = 0$. $\mathtt{C}_{\ell,6}$ now implies $x^{\mathtt{bin}}(\ell) = 0$. This also fulfills $\mathtt{C}_{\ell,4}, \mathtt{C}_{\ell,5}$ and $\mathtt{C}_{\ell,7}$.

Case 2: Assume $r(\ell+1) \geq \gamma^{2^\ell}$. Observation 8 and $\mathtt{C}_{\ell,7}$ now imply $x^{\mathtt{bin}}(\ell) \geq 1$. With $\mathtt{C}_{\ell,5}$ we get $x^{\mathtt{bin}}(\ell) = 1$. This also fulfills $\mathtt{C}_{\ell,4}$ and $\mathtt{C}_{\ell,6}$ and finalizes the proof.

Note that this also upper bounds the value of $y(\ell)$. Since $x^{\mathtt{bin}}(\ell) \leq 1$, $\mathtt{C}_{\ell,7}$ implies $y(\ell) \leq \gamma^{2^\ell} + 1$. ◀

And finally, $\mathtt{C}_{\ell,10}$ to $\mathtt{C}_{\ell,13}$ represent the remainder calculation and ensure that the constraints can be used recursively. More concretely, we have the following behavior.

▶ **Observation 10 (✂).** *Constraints $\mathtt{C}_{\ell,8}$ to $\mathtt{C}_{\ell,13}$ imply*

$$r(\ell) = \begin{cases} r(\ell+1), & \text{if } r(\ell+1) < \gamma^{2^\ell} \\ {}^{r(\ell+1)}/_{\gamma^{2^\ell}}, & \text{if } r(\ell+1) \geq \gamma^{2^\ell} \end{cases}$$

Also, for each $\ell \in [d]_0$, the remainder is bounded by $r(\ell) \leq \gamma^{2^\ell} - 1$.

Proof Outline. We prove this statement via case distinction and induction over ℓ. Due to space concerns the proof can be found in the full version. ◀

Now, we prove that if the Constraints 1 are feasible, then $r(d)$ is of the form $\gamma^i, i \in \mathbb{Z}_{\geq 1}$ and $x^{\mathtt{bin}}$ is the binary encoding of i. We also show that the constraints do not permit any other integer solutions.

▶ **Lemma 11.** *Let $d \in \mathbb{Z}_{\geq 1}$ and $\gamma \in \mathbb{Z}_{\geq 2}$. If there exists an $i \in \mathbb{Z}_{\geq 1}$ such that $r(d) = \gamma^i, i \in \mathbb{Z}_{\geq 1}$, with $\gamma^i \leq \gamma^{2^d-1}$, then $x^{\mathtt{bin}}$ is the binary encoding of i.*

Proof. Assume, there exists an $i \in \mathbb{Z}_{\geq 1}$ such that $r(d) = \gamma^i$ and $\gamma^i \leq \gamma^{2^d-1}$. We prove that $x^{\mathtt{bin}}$ is the binary encoding of i by induction over $\ell = d-1, \ldots, 0$.

Base Case: By the assumption $r(d) = \gamma^i$, we have that $r(d)$ is correctly set.

Inductive Step: Let $\ell \in [d-1]$ and assume that $r(\ell)$ is the correct remainder in the ℓ-th iteration. Following the procedure described at the beginning of this section, we know that $x^{\mathtt{bin}}(\ell-1)$ is required to be 1 if $r(\ell) \geq \gamma^{2^{\ell-1}}$ and 0 otherwise. This property holds due to Observations 8 and 9. By Observation 10, we know that the next remainder $r(\ell-1)$ is correctly set to ${}^{r(\ell)}/_{\gamma^{2^{\ell-1}}}$ if $r(\ell) \geq \gamma^{2^{\ell-1}}$ and to $r(\ell)$ otherwise. ◀

Now, we know that $x^{\texttt{bin}}$ is the binary encoding of i, if there exists $i \in \mathbb{Z}_{\geq 1}$ with $\gamma^i \leq \gamma^{2^d-1}$ and $r(d) = \gamma^i$. To finalize that the constraints fulfill the desired property, we need to show that the constraints are infeasible for any other value of $r(d)$.

▶ **Lemma 12.** *Let $d \in \mathbb{Z}_{\geq 1}$ and $\gamma \in \mathbb{Z}_{\geq 2}$. If $r(d) = \gamma^i$ for some $i \notin \mathbb{Z}_{\geq 1}$ holds, then the Constraints 1 are infeasible.*

Proof. Assume $r(d) = \gamma^i$ for some $i \notin \mathbb{Z}_{\geq 1}$. Note that we can formulate any integer number k in the form $\gamma^{\log k / \log \gamma}$. The proof is split into different cases. For each case, we lead the constraints to a contradiction.

Case 1: First, we show that the set of constraints is infeasible when i is negative. Let $d \in \mathbb{Z}_{\geq 1}$ and $\gamma \in \mathbb{Z}_{\geq 2}$. Set $j \coloneqq -i$. By the assumption, we have $r(d) = \gamma^i = 1/\gamma^j$. This contradicts the constraint that $r(d)$ is required to be integer.

Case 2: We now show that the set of constraints is infeasible when i is not integer. Let $\gamma \in \mathbb{Z}_{\geq 2}$ and $i \notin \mathbb{Z}_{\geq 0}$. Again set $r(d) = \gamma^i$. We now show by induction that the exponent $p(\ell)$ of γ is not integer for all $\ell \in [d]$. This then leads to a contradiction. This contradiction appears either at the additional constraint $r(0) = 1$ or already at constraint $\mathtt{C}_{k,9}$ for some $k \in [d-1]_0$.

Base Case: By definition of i in this case, i is not integer and with the assumption $r(d) = \gamma^i = \gamma^{p(d)}$ we get $i = p(d)$ and therefore $p(d)$ is not integer. Note that the assumption that the value $\gamma^{p(d)}$ is assigned to the variable $r(d)$ implies that $\gamma^{p(d)}$ must be integer.

Inductive Step: Let $\ell \in [d]$ and assume $p(\ell)$ is not integer and $r(\ell) = \gamma^{p(\ell)}$ is integer. Now we can meet the following two cases. Either, $r(\ell) < \gamma^{2^{\ell-1}}$ or $r(\ell) \geq \gamma^{2^{\ell-1}}$. In the first case, Observation 10 gives $r(\ell-1) = r(\ell)$ which directly implies $p(\ell-1) = p(\ell)$. Thus, $p(\ell-1)$ is not integer and $r(\ell-1)$ is integer. In the second case, with Observation 10 we get $r(\ell-1) = r(\ell)/\gamma^{2^{\ell-1}} = \gamma^{p(\ell)}/\gamma^{2^{\ell-1}} = \gamma^{p(\ell)-2^{\ell-1}}$. Since $p(\ell)$ is not integer and $2^{\ell-1}$ is integer, we get that $p(\ell-1) = p(\ell) - 2^{\ell-1}$ is not integer. If now $r(\ell-1) = \gamma^{p(\ell-1)}$ is integer, we repeat the inductive step. However, if $r(\ell-1) = \gamma^{p(\ell-1)}$ is not integer, there is no feasible integer assignment for $r(\ell-1)$ as $\mathtt{C}_{\ell,9}$ is an equality constraint.

If $r(\ell)$ is integer for all $\ell \in [d]$, we get that $p(0)$ is not integer. This implies $r(0) = \gamma^{p(0)}$. This is a contradiction to $r(0) = 1$.

Case 3: The only case left is $\gamma^i = 1$, i.e., $i = 0$. Again, by the assumption, we get $r(d) = \gamma^i = 1$ which directly contradicts $\mathtt{C}_{\alpha-3}$ which states $r(d) \geq 2$. ◀

Thus, we have shown that the Constraints 1 are feasible if and only if variable $r(d)$ takes a value of the form γ^i for given $\gamma \in \mathbb{Z}_{\geq 2}$ and positive integer i (Lemma 12). Additionally, $x^{\texttt{bin}}$ matches the binary encoding of i, i.e., it holds that $i = \sum_{\ell=0}^{d-1} 2^\ell x^{\texttt{bin}}(\ell)$ (Lemma 11).

The attentive reader might have noticed that in Example 7 the values of $y(\ell)$ and $z(\ell)$ match for all values of i and ℓ. In the full version, we show that we can not simply replace $z(\ell)$ with $y(\ell)$ in $\mathtt{C}_{\ell,9}$.

4.3 Aggregation of the Constraints

Before we can aggregate the constraints into a single knapsack constraint, we need to transform the inequalities into equations such that we achieve an ILP of the form considered in Section 3. We can do that by introducing slack variables. Also, we omit the lower bounds $\mathtt{C}_{\ell,1}, \mathtt{C}_{\ell,4}, \mathtt{C}_{\ell,8}$ and $\mathtt{C}_{\ell,10}$ by restricting all variables to only take non-negative values. This results in the following new set of constraints:

▶ **Constraints 2.**

$$\begin{aligned}
r(0) &= 1 && \\
(\gamma^{2^{\ell+1}}+\gamma^{2^\ell})y(\ell)-(\gamma^{2^\ell}+1)r(\ell+1)+s_1(\ell) &= \gamma^{2^\ell} && \forall \ell \in [d-1]_0\\
-\gamma^{2^\ell}y(\ell)+r(\ell+1)+s_2(\ell) &= \gamma^{2^\ell}-1 && \forall \ell \in [d-1]_0\\
x^{\texttt{bin}}(\ell)+s_3(\ell) &= 1 && \forall \ell \in [d-1]_0\\
x^{\texttt{bin}}(\ell)-y(\ell)+s_4(\ell) &= 0 && \forall \ell \in [d-1]_0\\
y(\ell)-(\gamma^{2^\ell}+1)x^{\texttt{bin}}(\ell)+s_5(\ell) &= 0 && \forall \ell \in [d-1]_0\\
(\gamma^{2^\ell}-1)z(\ell)+r(\ell)-r(\ell+1) &= 0 && \forall \ell \in [d-1]_0\\
\gamma^{2^\ell}x^{\texttt{bin}}(\ell)-z(\ell)+r(\ell)+s_7(\ell) &= \gamma^{2^\ell} && \forall \ell \in [d-1]_0\\
-\gamma^{2^\ell}x^{\texttt{bin}}(\ell)+z(\ell)+s_8(\ell) &= 0 && \forall \ell \in [d-1]_0\\
z(\ell)-r(\ell)+s_9(\ell) &= 0 && \forall \ell \in [d-1]_0\\
r(d)-s_{\alpha-3} &= 2 && \\
r(d)+s_{\alpha-2} &= \gamma^{2^d-1} &&
\end{aligned}$$

Now, we add the upper bounds of the variables. With Observation 10, we have $r(\ell) \leq \gamma^{2^\ell}-1$. In combination with Observation 8, we get $y(\ell) \leq \lfloor (\gamma^{2^{\ell+1}}-1)/\gamma^{2^\ell} + 1/(\gamma^{2^\ell}+1) \rfloor \leq \gamma^{2^\ell}$. $x^{\texttt{bin}}(\ell)$ is bounded by 1 due to $\texttt{C}_{\ell,5}$ and it holds that $z(\ell) \leq \min(\gamma^{2^\ell}, \gamma^{2^\ell}-1) = \gamma^{2^\ell}-1$ by $\texttt{C}_{\ell,12}$ and $\texttt{C}_{\ell,13}$. The slack variables are bounded by the coefficients, the variables and the right-hand-side of their constraint. For instance, since $\gamma^{2^\ell}x^{\texttt{bin}}(\ell)-z(\ell)+r(\ell)+s_7(\ell)=\gamma^{2^\ell}$, we have $s_7(\ell)=\gamma^{2^\ell}-\gamma^{2^\ell}x^{\texttt{bin}}(\ell)+z(\ell)-r(\ell)$. With $x^{\texttt{bin}}(\ell)\geq 0$, $r(\ell)\geq 0$ and the bound on $z(\ell)$, this implies $s_7(\ell) \leq \gamma^{2^\ell}+\gamma^{2^\ell}-1 = 2\gamma^{2^\ell}-1$.

Now, as done in Section 3, we define U to be the sum of the upper bounds of all variables (including slacks) and introduce the constraint which restricts the sum of all variables by U. Let $v \coloneqq \sum_{\ell=0}^{d-1}(y(\ell)+z(\ell)+r(\ell)+\sum_{j=1}^{9}(s_j(\ell)))+r(d)+s_{\alpha-3}+s_{\alpha-2}$ be the sum of all variables. Thus, our additional constraint is $v+s_\alpha = U$. Setting $M \coloneqq 2\gamma^{2^d}\cdot U + \gamma^{2^d-1}+2\gamma^{2^d}+2$ and multiplying the ILP with the vector $(1, M, M^2, \ldots, M^{\alpha-1})$ results in an ILP of the form (3) which is equivalent to the Constraints 2.

Lemma 5 now implies that vector $\texttt{sol} = (x^{\texttt{bin}}, y, z, r, s)^T \in \mathbb{Z}_{\geq 0}^{12d+4}$ is a feasible solution to Constraints 2 if and only if $\texttt{sol}$ is a solution to

$$\begin{aligned}
r(0)+\textstyle\sum_{\ell=0}^{d-1}\Big(& M^{9\ell+1}\big((\gamma^{2^{\ell+1}}+\gamma^{2^\ell})y(\ell)-(\gamma^{2^\ell}+1)r(\ell+1)+s_1(\ell)\big)\\
&+M^{9\ell+2}\big(-\gamma^{2^\ell}y(\ell)+r(\ell+1)+s_2(\ell)\big)\\
&+M^{9\ell+3}\big(x^{\texttt{bin}}(\ell)+s_3(\ell)\big)\\
&+M^{9\ell+4}\big(x^{\texttt{bin}}(\ell)-y(\ell)+s_4(\ell)\big)\\
&+M^{9\ell+5}\big(y(\ell)-(\gamma^{2^\ell}+1)x^{\texttt{bin}}(\ell)+s_5(\ell)\big)\\
&+M^{9\ell+6}\big((\gamma^{2^\ell}-1)z(\ell)+r(\ell)-r(\ell+1)\big)\\
&+M^{9\ell+7}\big(\gamma^{2^\ell}x^{\texttt{bin}}(\ell)-z(\ell)+r(\ell)+s_7(\ell)\big)\\
&+M^{9\ell+8}\big(-\gamma^{2^\ell}x^{\texttt{bin}}(\ell)+z(\ell)+s_8(\ell)\big)\\
&+M^{9\ell+9}\big(z(\ell)-r(\ell)+s_9(\ell)\big)\Big)\\
&+M^{\alpha-3}\big(r(d)-s_{\alpha-3}\big)\\
&+M^{\alpha-2}(r(d)+s_{\alpha-2})\\
&+M^{\alpha-1}(v+s_\alpha)\\
&=1+\textstyle\sum_{\ell=1}^{d-1}\Big(M^{9\ell+1}\gamma^{2^\ell}+M^{9\ell+2}(\gamma^{2^\ell}-1)+M^{9\ell+3}+M^{9\ell+7}\gamma^{2^\ell}\Big)\\
&\quad +M^{\alpha-3}\cdot 2+M^{\alpha-2}\gamma^{2^d-1}+M^{\alpha-1}U.
\end{aligned} \tag{7}$$

This equation can be transformed into an unbounded knapsack constraint by grouping coefficients such that each variable only occurs once. These coefficients then define the item size vector s. For example, the sizes of the item $x^{\texttt{bin}}(\ell), \ell \in [d-1]_0$ is $s_{x^{\texttt{bin}}(\ell)} = M^{9\ell+3} + M^{9\ell+4} + M^{9\ell+7} \cdot \gamma^{2^\ell} - M^{9\ell+8} \cdot \gamma^{2^\ell}$. To complete the transformation, set the lower bound of each variable to 0 and exchange the equality into $\leq$, i.e., the sum of item sizes and multiplicites is at most the right hand side. Denote the polytope as $P = \{x \in \mathbb{R}^d | x_i, s^T x \leq C\}$. All feasible configurations are then integer points in P, i.e., $p \in P \cap \mathbb{Z}^d$.

4.4 Main proof

With this, we are ready to prove our main theorem.

▶ **Theorem 1.** *There exists a high-multiplicity* Bin Packing *instance of dimension d such that the solution-vector x (a vector of configurations) contains at least $2^{\Omega(d)}$ non-zero entries, i.e., $|supp(x)| \in 2^{\Omega(d)}$.*

Proof. Let $d' \in \mathbb{Z}_{\geq 0}$. The dimension of the Bin Packing instance has dimension d, i.e., number of different item sizes, $d = 12d' + 4$. Denote the capacity of a single bin as C and set the sizes according to (7), and denote them as the size vector s. Set C to be the right hand side of the knapsack constraint (7). Define the knapsack polytope $P = \{x \in \mathbb{R}^d | x_i, s^T x \leq C\}$. Let X be the set of all solutions in $P \cap \mathbb{Z}^d$, i.e., with total size less than or equal to C. Define $X^* = \{x \in X | s^T x = A\}$ to be the set of all solutions with size exactly C. See Figure 3 for an illustration. Thus, X is the set of all feasible configurations. By the definition of the knapsack constraint and Lemma 12, we know that $|X^*| = 2^{d'} - 1 =: k$, as (7) has exactly one solution for every possible combination of $x^{\texttt{bin}}(\ell), \ell \in [d-1]_0$ with $x^{\texttt{bin}}(\ell) \in \{0, 1\}$. Define the total amount of items y as the sum of all configurations, i.e., $y = \sum_{x \in X^*} x$. Thus, the total size of all items to be placed is $y^T \cdot s = kC$.

Clearly, the optimal solution to this Bin Packing instance uses exactly k bins. One possible solution is to take each configuration in X^* exactly once. In the following we show that this is the only solution using elements in X and using exactly k bins. Now, define the projection $\pi : x \to (x^{\texttt{bin}}(0), \dots x^{\texttt{bin}}(d'-1), r(d'))$. This projection reduces every configuration to just the binary encoding and the value $r(d')$. It holds that $\pi(y) = \begin{pmatrix} 2^{d-1} \\ \vdots \\ 2^{d-1} \\ \sum_{i=1}^{k} (4k)^i \end{pmatrix}$. Recall that we set $\gamma = 4k$. We can not consider configurations in $X \setminus X^*$ as they have size $< C$. As the total size of the right hand size is exactly kC taking one of these configurations while still using k bins would require another bin to be filled $> C$, which is infeasible due to (7). Thus, there are no other feasible configurations, as only those of the form (after applying π) exactly like in Lemma 6, i.e., those in X^*, have size exactly C. Thus, when applying the projection π, we have met the conditions of applying Lemma 6 and know that the only optimal solution takes each of the k vectors exactly once.

Therefore, after removing the projection, the only optimal solution to the Bin Packing instance uses every configuration in X^* exactly once, and therefore we have $|\text{supp}(x)| = k = 2^{d'} - 1$. As we have $d = 12d' + 4$ we have $|\text{supp}(x)| \in 2^{\Omega(d)}$. ◀

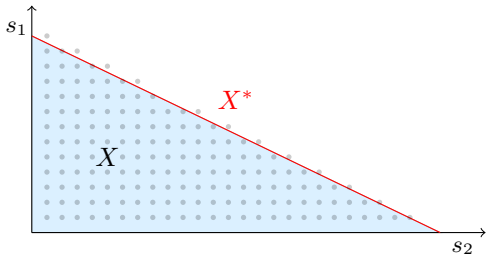

Figure 3 A 2-dimensional example of the knapsack constraint with item types s_1, s_2. The shaded area denotes the knapsack polytope P. The points resemble integer points and show all feasible configurations. Integer points in the shaded region are the configurations in the set X. Integer points on the red line form the set X^* of configurations. Only configurations in X^* fill the knapsack constraint with equality.

Efficient Top-Down Updates in AVL Trees

Vincent Jugé
LIGM, CNRS, Univ Gustave Eiffel, Marne-la-vallée, France
IRIF, Université Paris-Cité & CNRS, France

Abstract

Since AVL trees were invented in 1962, two major open questions about rebalancing operations, which found positive answers in other balanced binary search trees, were left open: can these operations be performed top-down (with a fixed look-ahead), and can they use an amortised constant number of write operations per update? We propose an algorithm that solves both questions positively.

1 Introduction

Balanced search trees are among the most fundamental and basic data structures in computer science. Their formidable story started with the invention of AVL trees by Adel'son-Vel'skii and Landis [1] in 1962, who proposed a data structure and a maintenance algorithm thanks to which the insertion, deletion and research of an element in a linearly ordered set of size n was feasible in time $\mathcal{O}(\log(n))$.

AVL trees are binary search trees in which each node x maintains some form of *balance*: the heights of its children differ from each other by at most 1. Satisfying this property at each node ensures that the tree is of height $\mathcal{O}(\log(n))$. The number of comparisons required to search an element in a binary search tree being linear in the height of the tree, it is thus logarithmic in n.

However, for instance, inserting a node into the sub-tree rooted at the left child of our node x may increase the height of that sub-tree, damaging the balance of x. Thus, the challenge of maintenance algorithms consists in efficiently modifying the parenthood relations inside the tree in order to ensure that each node remains balanced.

Unfortunately, in spite of their excellent worst-case height, AVL trees suffer from updating algorithms that are significantly less efficient than those of other balanced binary search tree structures such as weight-balanced trees [9], red-black trees [4], half-balanced trees [11], splay trees [12] or, more recently, weak AVL trees [5]. Indeed, as illustrated in Table 1, they have two shortcomings, from which almost all other algorithms are exempt:

- starting from an empty tree, performing n updates in a row may trigger $\Theta(n\log(n))$ rotations [2] or, more generally, write operations, which may also consist in modifying the balance of a node without changing the tree structure;
- updates following an insertion or deletion must be performed in a bottom-up fashion; the inventors of weak AVL trees even said, in [5, p. 23], that "Top-down insertion or deletion with fixed look-ahead in an AVL tree is problematic. (We do not know of an algorithm; we think there is none.)"

Requiring only $\Theta(1)$ amortised write operations per update instead of $\Theta(\log(n))$ would clearly improve the efficiency of AVL trees. As mentioned in [4, 5], being able to use top-down algorithms is also important, because requiring a bottom-up pass is costly: either it forces each node to maintain a link toward its parent, or it must be performed *via* recursive calls or

Table 1 Amortised number of rewrite operations per update with n nodes, and existence of top-down update algorithms. Next to each piece of information are indicated references where it is proved.

Tree family	Amortised write cost/update	Top-down update algorithm
AVL (state of the art)	$\Theta(\log(n))$ [2]	no
AVL (this article)	$\Theta(1)$	yes
Weight-balanced	$\Theta(1)$ [3]	yes [7, 8]
Red-black	$\Theta(1)$ [4]	yes [4]
Half-balanced	$\Theta(1)$ [11]	for insertions [10]
Splay	$\Theta(\log(n))$ [12]	yes [12]
Weak AVL	$\Theta(1)$ [5]	yes [5]

storing visited nodes in a stack. This second approach is even more expensive in distributed settings, because each process should lock the entire branch it is visiting, preventing any update from starting before the previous update has ended.

A way of circumventing these deficiencies of AVL trees is to use weak AVL trees instead [5]. By having less demanding balance criteria, this variant of AVL offers update algorithms that require $\mathcal{O}(1)$ rotations in the worst case, and $\mathcal{O}(1)$ amortised write operations (which may include updating information on the balance of nodes) per update. Furthermore, these algorithms can be made top-down, with the following exception, which is common to all binary search tree data structures: instead of deleting an internal node x, we must delete a node y whose key immediately precedes or follows the key of x, an approach called Hibbard deletion [6], and then replace the key of x by that of y. In AVL trees, y must be a leaf or the parent of a leaf, which reduces the problem of node deletion to that of leaf deletion, up to to keeping a pointer on an internal node we may wish to delete.

In this article, we prove that top-down insertion and deletion with fixed look-ahead in an AVL tree *is* feasible; having a look-ahead of d means that the algorithm, when it reads or writes information at a node x, is forbidden to later read or write informations at nodes that do not descend from the d^{th} ancestor of x. At the same time, this can also be write-efficient, thus bridging a gap of theoretical importance: it was somewhat unsettling to observe that this seminal balanced tree structure was also the one for which no efficient algorithms had been found, thus leading specialists in this field to conjecture that such algorithms did not exist.

We proceed step-by-step: in Section 2, we briefly present textbook algorithms for updating AVL trees; in Section 3, we propose a bottom-up algorithm that requires $\mathcal{O}(1)$ amortised write operations per update; finally, in Section 4, we propose a top-down algorithm that requires $\mathcal{O}(1)$ amortised write operations per update. Note that, unlike algorithms for AVL trees or some other structures (e.g., red-black trees), a given update may require these algorithms to perform $\Theta(\log(n))$ rotations: our efficiency criterion is based on the amortised number of write operations (and, in particular, rotations) only, not on the maximal number of such operations that a single update may require.

Both algorithms have flavours similar to those used when designing weak AVL trees [5]: they rely on making sure that "transient" rebalancing operations decrease some integer-valued potential and, for the top-down algorithm, on being able to start and stop long enough yet finite sequences of such transient operations. This illustrates the usefulness of the approach used to design these algorithms, and also suggests that additional results similar

to [5, Theorem 7.4] should also be valid here. The main difficulties, however, reside first in designing a suitable notion of potential, and then in managing to start and stop these sequences of transient operations; this task is easy when dealing with insertions only, and quite challenging when taking deletions into account.

2 State-of-the-art

2.1 Preliminaries

A *binary search tree* is an ordered rooted tree $\mathcal{T}$ in which each tree node x has one *key* $\mathsf{key}(x)$, one *left child* x_1 and one *right child* x_2, which can be *tree nodes* or *null nodes*; null nodes represent the empty tree and have no key nor children, and tree nodes whose two children are null nodes are called *leaves*. By definition, the *descendants* of x consist of x, its children x_1 and x_2, and all their descendants (if they are tree nodes); these descendants form a sub-tree of $\mathcal{T}$ rooted at x and denoted by $\mathcal{T}(x)$, and x is one of their *ancestors*.

Node keys are pairwise distinct, and must belong to a linearly ordered set. For each tree node y that descends from x, we have $\mathsf{key}(y) < \mathsf{key}(x)$ if y belongs to $\mathcal{T}(x_1)$, and $\mathsf{key}(y) > \mathsf{key}(x)$ if y belongs to $\mathcal{T}(x_2)$. Moreover, the *height* of x is the length (i.e., the number of parent-child edges) of the longest downward path starting from x and ending in a leaf; it is denoted by $\mathsf{h}(x)$. By convention, each null node has height -1.

A binary search tree is an AVL tree when the height difference $\mathsf{h}(x_1) - \mathsf{h}(x_2)$ belongs to the set $\{-1, 0, 1\}$ for all tree nodes x. This ensures that an AVL tree with n nodes is of height $\mathcal{O}(\log(n))$.

Here, we follow the presentation of [5] and assume that AVL tree structures are implemented by assigning a *rank* $\mathsf{r}(x)$ to each tree node x. This rank is our current estimation of the height $\mathsf{h}(x)$, which may be slightly invalid if, say, some leaf was inserted way below x, and we did not yet have the time to update information about the height of x. Hence, we should control the rank differences $\mathsf{r}(x) - \mathsf{r}(x_i)$ for each node x. Focusing on these differences, we say that x_i is an ℓ-child if $\mathsf{r}(x) - \mathsf{r}(x_i) = \ell$, and that x is an $\{\ell, \ell'\}$-node if its children are ℓ- and ℓ'-children.

In practice, these ranks are rarely stored directly in AVL implementations: instead, each node x contains either (i) the difference $\mathsf{r}(x_2) - \mathsf{r}(x_1)$ between the ranks of its children x_1 and x_2, or (ii) the difference $\mathsf{r}(p) - \mathsf{r}(x)$ between the rank of its parent p and its own rank. In what follows, we will disregard these implementation details, and pretend that we stored node ranks in clear; adapting our algorithm to let it fit the frameworks (i) or (ii) is easy.

Since binary search trees represented ordered sets, the three main operations they must support are searching, inserting, and deleting an element. Searching an element is easy: when searching a key k in a non-empty tree $\mathcal{T}(x)$, we compare k with $\mathsf{key}(x)$; then, we keep searching k in $\mathcal{T}(x_1)$ if $k < \mathsf{key}(x)$, or in $\mathcal{T}(x_2)$ if $k > \mathsf{key}(x)$, or we declare that k was found if $k = \mathsf{key}(x)$; whereas, when searching k in an empty tree, we must declare that k was nowhere to be found.

Inserting or deleting an element is substantially more difficult, because it requires altering the structure of the tree: this may change its height and even damage the balance of some tree nodes. As a result, the relation $\mathsf{r}(x) = \max\{\mathsf{r}(x_1), \mathsf{r}(x_2)\} + 1$ might fail for one node x, or one rank difference $\mathsf{r}(x_1) - \mathsf{r}(x_2)$ might no longer belong to the set $\{-1, 0, 1\}$. The purpose of bottom-up rebalancing algorithms is precisely to eliminate this anomaly, either directly, or by "propagating it upward", i.e., making it concern a strict ancestor of x, with rank larger than $\mathsf{r}(x)$.

2.2 Tree cuts and cut rebalancing

A *cut* of a tree $\mathcal{T}$ is a list $(x^1, x^2, \dots, x^\ell)$ of nodes of $\mathcal{T}$ that are pairwise incomparable for the ancestorship relation (i.e., the sub-trees $\mathcal{T}(x^i)$ are pairwise disjoint), ordered from left to right, and which is maximal for inclusion.

Let x denote the root of $\mathcal{T}$. When the nodes $x^1, x^2, \dots, x^\ell$ have ranks $\mathsf{r}(x) - \delta^1$, $\mathsf{r}(x) - \delta^2, \dots,$ $\mathsf{r}(x) - \delta^\ell$, the *profile* of the associated cut is defined as the integer tuple $\boldsymbol{\delta} = (\delta^1, \delta^2, \dots, \delta^\ell)$. Accordingly, we say that a node x has profile $\boldsymbol{\delta}$ when $\mathcal{T}(x)$ contains a tree cut of profile $\boldsymbol{\delta}$. When the order of the integers $\delta^1, \delta^2, \dots, \delta^\ell$ is irrelevant, we may also say that x has profile $\{\delta^1, \delta^2, \dots, \delta^\ell\}$, just writing a multiset of integers: this just means that there exists a permutation σ of $\{1, 2, \dots, \ell\}$ such that x has profile $(\delta^{\sigma(1)}, \delta^{\sigma(2)}, \dots, \delta^{\sigma(\ell)})$. In particular, an $\{\ell, \ell'\}$-node is simply a node with profile $\{\ell, \ell'\}$.

Below, we may modify the structure of a tree $\mathcal{T}$, thus generalising so-called *rotations*: starting from a cut $(x^1, x^2, \dots, x^\ell)$ of $\mathcal{T}$, let $a^1, a^2, \dots, a^{\ell-1}$ be the strict ancestors of the cut nodes x^i, listed from left to right. We assign a new pair of children to each node a^i, and decide that the new root should be some node a^j, as long as the graph we obtain is a binary search tree rooted at a^j; nodes a^j are said to be *affected* by the cut rebalancing. While doing so, (i) we must never modify the structure or rank of any of the sub-trees $\mathcal{T}(x^i)$, and (ii) node ranks of nodes a^i are reassigned to make sure that each node a^i is a $\{1, 1\}$- or a $\{1, 2\}$-node in the resulting tree. Such an operation is called a *cut rebalancing*, and is easy to describe diagrammatically, like in Figure 1 below; cut nodes and their ancestors will typically be denoted with capital letters, from left to right.

2.3 Textbook bottom-up algorithm

Inserting a key may create a *zero-edge*, i.e., an edge between a parent x and its child x_i such that $\mathsf{r}(x) = \mathsf{r}(x_i)$; in that case, the integer $\mathsf{r}(x) = \mathsf{r}(x_i)$ is called the *rank* of the zero-edge. A zero-edge is created when x is a leaf below which we wish to insert the key k, because some child x_i of x, which used to be null, becomes a leaf.

Similarly, deleting a key may create a $\{2, 2\}$- or $\{1, 3\}$-node, which we call a *four-node*; this happens if x is a $\{1, 2\}$-node one of whose children is a leaf containing the key k we wish to delete, because that leaf will be transformed into a null node.

Zero-edges are dealt with as follows, and as illustrated in Figure 1. Up to using a left-right symmetry, and without loss of generality, we assume that $\mathsf{r}(x_1) \geqslant \mathsf{r}(x_2)$, i.e., that both $\mathsf{r}(x)$ and $\mathsf{r}(x_1)$ are equal to the rank r of the zero-edge:

1. If $\mathsf{r}(x_{11}) = \mathsf{r}(x_{12}) = \mathsf{r} - 1$ and $\mathsf{r}(x_2) = \mathsf{r} - 2$ (row 1, left), the cut (x_{11}, x_{12}, x_2) has profile $(1, 1, 2)$. Let A, C and E denote the cut nodes x_{11}, x_{12} and x_2, and let B and D denote their ancestors x_1 and x. We rebalance $\mathcal{T}(x)$ by letting D become the parent of C and E, and B become the parent of A and D, thus obtaining a tree with root B. This cut rebalancing is a *simple rotation*.
2. If $\mathsf{r}(x_{11}) = \mathsf{r} - 1$ and $\mathsf{r}(x_{12}) = \mathsf{r}(x_2) = \mathsf{r} - 2$ (row 1, right), we perform the same rotation; however, the resulting ranks differ.
3. If $\mathsf{r}(x_{12}) = \mathsf{r} - 1$ and $\mathsf{r}(x_{11}) = \mathsf{r}(x_2) = \mathsf{r} - 2$ (row 2, left), the cut $(x_{11}, x_{121}, x_{122}, x_2)$ is to be rebalanced. Let A, C, E and G denote the cut nodes x_{11}, x_{121}, x_{122} and x_2, and let B, D and F denote their ancestors x_1, x_{12} and x. We rebalance $\mathcal{T}(x)$ by giving these seven nodes the shape of a complete binary tree: B becomes the parent of A and C, F becomes the parent of E and G, and D becomes the parent of B and F, as well as the root of the resulting tree. This is a *double rotation*.
4. If $\mathsf{r}(x_2) = 1$ (row 2, right), we rebalance $\mathcal{T}(x)$ by not changing its structure, but simply increasing the rank of its root x. This is a *promotion*.

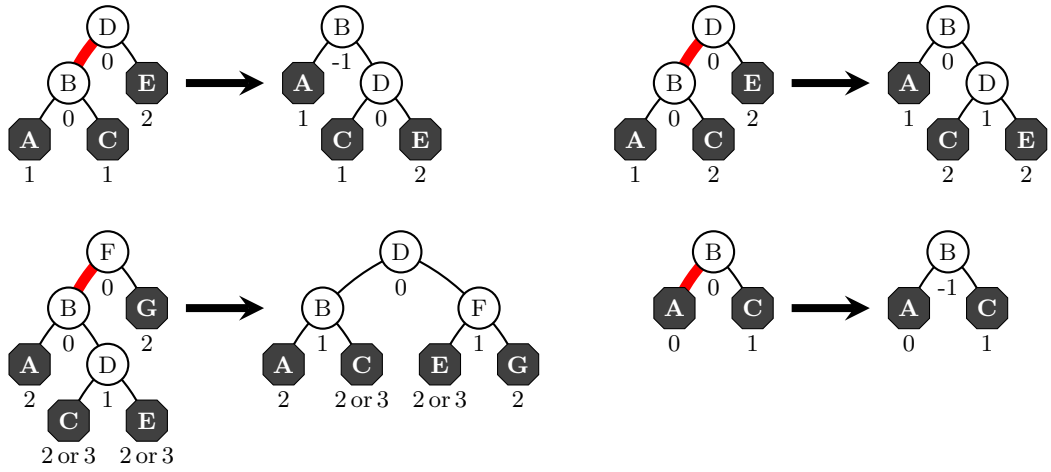

Figure 1 Eliminating or propagating upward a (thick, red-painted) zero-edge of rank r through cut rebalancings. Black octagons represent cut nodes, at which are rooted sub-trees whose structure and ranks will not change. White circles represent their ancestors. Once the rebalancing operation has taken place, the rank of a node is defined as the smallest integer larger than the ranks of its children. Below each node z is written the rank difference $\mathsf{r} - \mathsf{r}(z)$; when two rank differences δ and δ' are possible, we just write "δ or δ'". These notations will be used in all subsequent diagrams.

Doing so, whenever we face a zero-edge e of rank r, we will either eliminate it at once, or replace it by a new zero-edge e' of rank $\mathsf{r}+1$, placed just above where e' used to be. Consequently, if inserting a key creates a zero-edge, we will simply propagate that zero-edge upward until it disappears.

Likewise, four-nodes are dealt with as follows, and as illustrated in Figure 2. Up to using a left-right symmetry, we assume that $\mathsf{r}(x_1) \geqslant \mathsf{r}(x_2)$:

5. If $\mathsf{r}(x_{11}) = \mathsf{r}(x_{12}) = \mathsf{r}-2$ and $\mathsf{r}(x_2) = \mathsf{r}-3$ (row 1, left), we perform a simple rotation.
6. If $\mathsf{r}(x_{11}) = \mathsf{r}-2$ and $\mathsf{r}(x_{12}) = \mathsf{r}(x_2) = \mathsf{r}-3$ (row 1, right), we perform the same rotation; the resulting ranks differ.
7. If $\mathsf{r}(x_{12}) = \mathsf{r}-2$ and $\mathsf{r}(x_{11}) = \mathsf{r}(x_2) = \mathsf{r}-3$ (row 2, left), we perform a double rotation.
8. If $\mathsf{r}(x_2) = \mathsf{r}-2$ (row 2, right), we decrease the rank of its root x; this is a *demotion*.

Cut rebalancing operations 5 to 7 are the same as operations 1 to 3 for eliminating zero-edges, except that the ranks of x_1, x_2 and their descendants were all shifted down by one. In all eight cases, these operations result either in eliminating the four-node x or in making the (former) parent of x our new four-node.

3 Efficient bottom-up updates

3.1 Overview and complexity analysis

The textbook algorithm presented in Section 2.3 aims at eliminating or propagating upward zero-edges and four-nodes. Thus, each insertion or deletion update consists in (i) finding the location at which we want to create or delete a tree leaf, (ii) observe that we may have created a zero-edge or four-node, (iii) moving this anomaly upward, until (iv) we eliminate it once and for all. Step (i) requires no write operation on the tree structure, and steps (ii) and (iv) occur once per update. However, step (iii) may require arbitrarily many write operations per update.

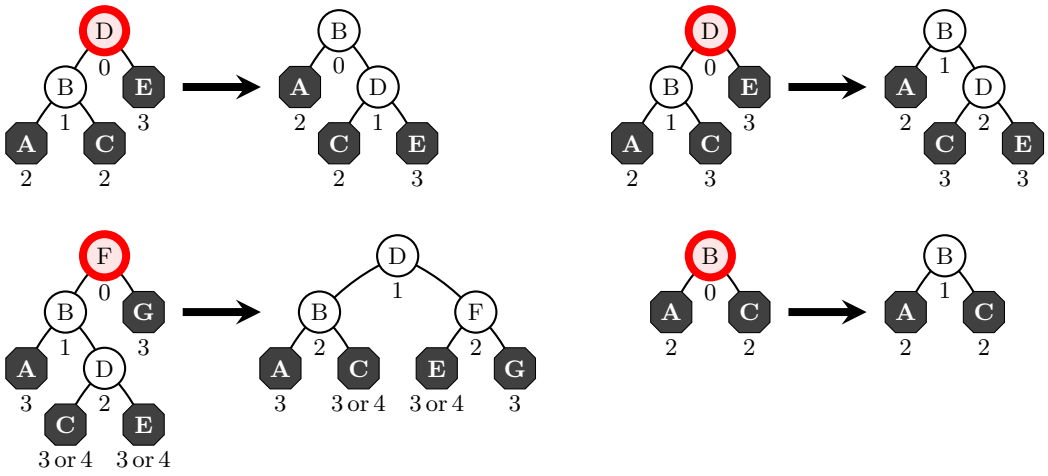

Figure 2 Eliminating or increasing the rank of a (thick, red-painted) four-node.

Hence, cut rebalancing operations of cases 1 to 8 are called *terminal* if they result in eliminating the anomaly (thus being a part of step (iv)), and *transient* if they just propagate it upward (thus being a part of step (iii)): transient operations are operations 1 and 4 when x used to be a 1-child, and operations 6 to 8 when x had a parent that used to be a $\{1,2\}$-node. We should prove that updating n times an initially empty AVL tree triggers $\mathcal{O}(n)$ transient operations.

With the textbook algorithm, the statement we wish to prove is invalid, as was shown in [2]. Consequently, we will tweak the operations performed in cases 1 to 8, aiming at making them terminal whenever possible.

The complexity proof of the resulting algorithm is based on *potential* techniques. In our case, we define the *potential* of a a tree $\mathcal{T}$ as the the number of $\{1,2\}$-nodes, plus twice the number of *full* nodes it contains, where full nodes are defined as follows.

In absence of zero-edges, a node x is called *full* when x and its two children x_1 and x_2 are $\{1,1\}$-nodes, and at least one of its grand-children x_{12} and x_{21} is a $\{1,1\}$-node. In other words, a node is full when it has profile $(2,3,3,2,2)$ or, symmetrically, $(2,2,3,3,2)$. When zero-edges are (temporarily) allowed, a node x may also be considered full if x is a $\{0,1\}$-node whose 1-child is a $\{1,1\}$-node; or if x is a $\{1,1\}$-node, x_1 and x_2 are $\{0,1\}$- and/or $\{1,1\}$-nodes, and one of x_{12} and x_{21} is a 0-child or a null, a $\{0,1\}$- or a $\{1,1\}$-node.

As we will prove:

1. each update or write operation modifies the neighbourhood (parenthood relations and/or rank) of a constant number of nodes, thus increasing the tree potential by at most a constant;
2. each transient operation aimed at eliminating a zero-edge of rank $\mathsf{r} \geqslant 4$ destroys one full node and creates one $\{1,2\}$-node, thus decreasing the tree potential;
3. each transient operation triggered by a deletion decreases the number of $\{1,2\}$-nodes, and does not increase the number of full nodes, also decreasing the tree potential.

Statement 1 will be immediate, and thus we will focus on proving statement 2 in Section 3.3 (this will be Lemma 3), and statement 3 in Section 3.4 (this will be Lemma 4). Once all three statements are proved, we will finally be able to derive the following result.

▶ **Theorem 1.** *The updating algorithm that we present in Sections 3.3 (for insertions) and 3.4 (for deletions) performs $\mathcal{O}(1)$ amortised write operations per update.*

Proof. Starting from an empty tree, let n insertion or deletion updates be performed. Let us keep track of the variations of tree potential while these updates are performed. There exists a constant K such that each update requires:

1. inserting or deleting a leaf, an operation that increases the potential by at most K;
2. eliminating at most four zero-edges of rank $\mathsf{r} \leqslant 3$, each of which increases the potential by at most K;
3. performing a certain number of transient operations, each of which decreases the potential by at least one;
4. performing at most one terminal operation, which increases the potential by at most K.

Hence, if T transient operations were performed in total, the potential increased by at most $6n\mathsf{K} - \mathsf{T}$. It started with the value 0, and ended with a non-negative value, which shows that $\mathsf{T} \leqslant 6n\mathsf{K}$. Therefore, in total, these n updates required performing no more than $\mathcal{O}(n) + \mathcal{O}(\mathsf{T}) \subseteq \mathcal{O}(n)$ write operations. ◀

3.2 Cut promotions and demotions

Some cut profiles, such as the ones that charaterise full nodes, allow rebalancing trees to either increase or decrease their rank. More precisely, if we are lucky enough, a tree $\mathcal{T}$ with rank r and profile $\boldsymbol{\delta}$ will always admit a cut, whose profile does not need to be $\boldsymbol{\delta}$, that can be rebalanced to obtain a tree $\mathcal{T}'$ of rank $\mathsf{r}' = \mathsf{r} + \varepsilon$, where $\varepsilon = \pm 1$ is an integer of our choice. This cut rebalancing operation is called a *cut promotion* when $\varepsilon = 1$, and a *cut demotion* when $\varepsilon = -1$.

Some profiles ensure that a cut promotion or demotion can be performed, as outlined by the following result.

▶ **Lemma 2.** *Trees with a full root can always be subject to a cut promotion; the root of the resulting tree is a $\{1,2\}$-node. By contrast, trees with profile $\{3,3,3,4,4\}$ can always be subject to a cut demotion; the root of the resulting tree is a $\{1,1\}$-node.*

Proof. The recipe given in Figure 3 (row 1) shows how to apply a cut promotion to a tree whose root is full. Hence, let us focus on applying a cut demotion on a tree $\mathcal{T}$ that admits a cut $(x^1, x^2, x^3, x^4, x^5)$ with profile $\{3,3,3,4,4\}$.

Replacing the three nodes x^i with rank $\mathsf{r}-3$ by their children gives an 8-node cut, whose nodes all have rank $\mathsf{r}-4$ or $\mathsf{r}-5$, at least five of these nodes having rank $\mathsf{r}-4$. These 8 nodes and their 7 ancestors can be reshaped to form a 15-node complete binary tree $\mathcal{T}'$ of height 3, whose nodes at height h must have rank $\mathsf{r}-5+h$ or $\mathsf{r}-4+h$. Moreover, among the four leaves (y^1, y^2, y^3, y^4), at least one has rank $\mathsf{r}-4$, which proves that the root x' of $\mathcal{T}'$ has a left child x'_1 of rank $\mathsf{r}-1$; similarly, its right child has rank $\mathsf{r}-2$, and x' is a $\{1,1\}$-node of rank $\mathsf{r}-1$. This is illustrated in Figure 3 (row 2). ◀

In general, when cut-rebalancing a k-node cut transforms a sub-tree $\mathcal{T}(x)$ into a tree $\mathcal{T}'$ with root x' and rank $\mathsf{r}(x)-1$, $\mathsf{r}(x)$ or $\mathsf{r}(x)+1$, the tree potential increases by no more than $2k+4$. Indeed, $k-1$ cut ancestors were affected, possibly becoming $\{1,2\}$-nodes or full nodes; the parent of x, whose child is now x', might also become a $\{1,2\}$-node or a full node; and the grand-parent and great-grand-parent of x might become full nodes. Hence, cut promotions increase the tree potential by 14 or less, and cut demotions increase this potential by 20 or less.

These two kinds of cut promotions and demotions will be used in Sections 3.3 and 3.4. Another kind of cut rebalancing operation, called *saving*, will be introduced in Section 4.3, only being useful for designing efficient top-down updating algorithms.

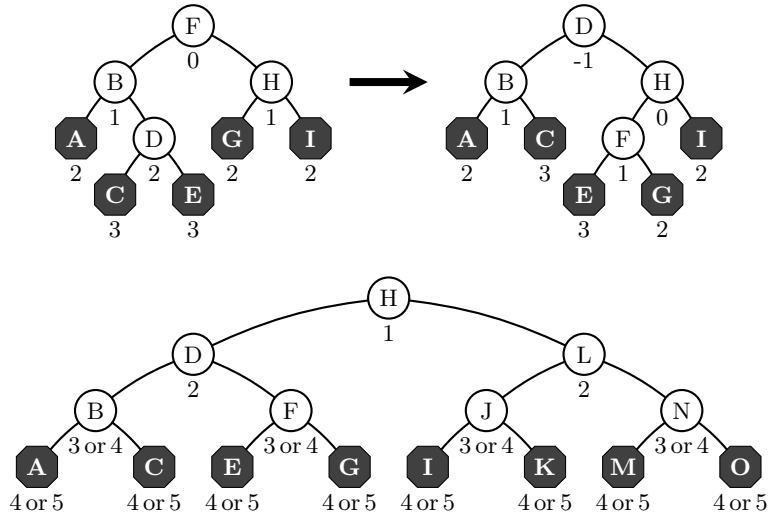

Figure 3 Row 1: Applying a cut promotion to a tree whose root is full. Row 2: 15-node complete binary tree whose root has profile $\{1, 1\}$ and rank $\mathsf{r} - 1$, which results from applying a cut demotion to a tree with profile $\{3, 3, 3, 4, 4\}$.

3.3 Insertion

Let us modify the textbook insertion algorithm to make some transient operations, which should occur in cases 1 and 4 of page 4, terminal operations. In particular, all transient operations in our variant are already transient in the textbook algorithm.

Case 1 is easy to take care of. Indeed, let us say that a node x is *weak* when x is either a leaf or a $\{1, 2\}$-node whose 1-child is also weak. An immediate induction proves that, when using the textbook algorithm, the lower end of a zero-edge is always weak. This proves, in particular, the well-known fact that case 1 is actually spurious, since it features a zero-edge whose lower end is a $\{1, 1\}$-node.

It remains to take care of case 4, which we subdivide into two sub-cases. First, we promote x like in the textbook algorithm, thus obtaining a tree $\mathcal{T}'$ of rank $\mathsf{r} + 1$. Then,

4. a) if x_2 is a $\{1, 1\}$-node, we do nothing more: we just performed a node promotion;

b) if x_2 is a $\{1, 2\}$-node, let us recall that x_1 is weak, which gives it the profile $\{2, 2, 3\}$, whereas x_2 has profile $\{1, 2\}$; hence, $\mathcal{T}'$ has profile $\{3, 3, 3, 4, 4\}$, and a cut demotion transforms $\mathcal{T}'$ into a tree $\mathcal{T}''$ of rank r again: we just performed a terminal operation.

▶ **Lemma 3.** *Each transient operation aimed at eliminating a zero-edge of rank* $\mathsf{r} \geqslant 4$ *destroys one full node and creates one* $\{1, 2\}$*-node, thus decreasing the tree potential.*

Proof. We just saw that the only transient case is case 4a, on the condition that x was a 1-child.

If the parent $x^{(1)}$ of x is full after x was promoted, it must now be a $\{0, 1\}$-node whose other child is a $\{1, 1\}$-child. Hence, before promoting x, its parent $x^{(1)}$ was already a $\{1, 1\}$-node whose children were a $\{0, 1\}$-and a $\{1, 1\}$-node, its child x having two children x_1 and x_2 that were a 0-child and a $\{1, 1\}$-node. This means that $x^{(1)}$ was already full.

Similarly, if the grand-parent $x^{(2)}$ of x is full after x was promoted, it must now be a $\{1, 1\}$-node whose children are a $\{1, 0\}$-node (the node $x^{(1)}$) and a $\{1, 1\}$-node (the sibling of $x^{(1)}$), one of it grand-children $x^{(2)}_{12}$ or $x^{(2)}_{21}$, say y, being a 0-child or a $\{1, 1\}$-node. Before promoting x, the node $x^{(1)}$ was already a $\{1, 1\}$-node, and either $y = x$, in which case y

was already a $\{0,1\}$-node, or $y \neq x$, in which case y was already a $\{1,1\}$-node. This means that $x^{(2)}$ was already full.

Finally, promoting x, in case it used to be a 1-child, does not make any other ancestor of x a full node. Hence, our transient operation transformed a full node into a $\{1,2\}$-node, and did not create any other full node or $\{1,2\}$-node: as a result, it decreased the tree potential by one. ◀

3.4 Deletion

Similarly, we wish to transform as many transient operations, which occur in cases 6 to 8 of the textbook textbook algorithm, into terminal operations.

The rotations and demotion performed in these cases transform a tree $\mathcal{T}(x)$ of rank r rooted at a four-node x into a tree $\mathcal{T}'$ of rank $\mathsf{r}-1$ whose root x' is a $\{1,1\}$-node. If x' is full, performing a cut promotion on $\mathcal{T}'$ results in another tree $\mathcal{T}''$ of rank r; similarly, if some child x'_i of x' is full, performing a cut promotion on $\mathcal{T}'(x'_i)$ and increasing the rank of x' by 1 also transforms $\mathcal{T}'$ into another tree $\mathcal{T}''$ of rank r; and if both children of x' are full, x' is also full, a case we already took care of. In all cases, this two-step transformation of $\mathcal{T}(x)$ into $\mathcal{T}''$ is a terminal operation.

If, however, neither x' nor its children is full, the rotation or demotion we performed in case 6, 7 or 8 did not create any full node. Indeed, replacing $\mathcal{T}(x)$ by a tree of smaller rank did not make any ancestor of x a full node. The only other nodes whose rank or induced sub-tree was changed are x' and its children, which we precisely assumed are not full either. In that case, our operation is transient if the parent of x, say y, was a $\{1,2\}$-node, and became a four-node.

▶ **Lemma 4.** *Each transient operation triggered by a deletion decreases the number of* $\{1,2\}$*-nodes, and does not increase the number of full nodes, also decreasing the tree potential.*

Proof. We just proved that transient operations are those where y was a $\{1,2\}$-node and neither its new child x' nor the children of x' became full. Hence, we did not create any full node, and it suffices to check, on a case-by-case basis, that the number of $\{1,2\}$-nodes decreased:

- **i)** in case 6, we destroyed two $\{1,2\}$-nodes ($\mathsf{B} = x_1$ and y);
- **ii)** in case 7, we destroyed at least two $\{1,2\}$-nodes ($\mathsf{B} = x_1$ and y) to create at most one $\{1,2\}$-node ($\mathsf{B} = x'_1$ or $\mathsf{F} = x'_2$, in case D used to be a $\{1,2\}$-node);
- **iii)** in case 8, we destroyed one $\{1,2\}$-node (y). ◀

4 Top-down updates

4.1 Overview and complexity analysis

Our top-down algorithms for inserting a key k in a tall enough AVL tree $\mathcal{T}$ and for deleting k from $\mathcal{T}$ follow the same general ideas, which were already successfully applied to weak AVL trees [5]. We will discover, in a top-down manner, the branch $x^0, x^1, \ldots$ below which k should be inserted or deleted, where x^0 is the root of $\mathcal{T}$ and each node x^{i+1} is a child of the previous node x^i. Using a $\mathcal{O}(1)$ look-ahead, and after discovering the first $\mathcal{O}(1)$ nodes on that branch, we must already decide what to do.

If we are lucky enough, we found a node x^i, for some integer $i \geqslant 1$, that is deemed *safe*: propagating a zero-edge (during insertions) or four-node (during deletions) that we would have planted along our branch far enough below x^i will stop when meeting x^i. When such a

node x^i exists among the top few nodes of the branch, we say that $\mathcal{T}$ was *friendly*; indeed, we should simply focus on updating the tree $\mathcal{T}(x^i)$, whose rank is smaller than $\mathcal{T}$ itself, and which will be transformed into a new tree of the same rank.

This fortunate case suggests focusing only on updating trees whose root is safe. Hence, if $\mathcal{T}$ has an unsafe root, a preliminary step will consist in transforming $\mathcal{T}$ into a tree whose root is safe, which we will then update; all subsequent (recursively called) updates will be performed on trees whose root is safe.

If, however, $\mathcal{T}$ has a safe root but is unfriendly, we will choose a deep enough node, say x^ℓ, and transform the sub-tree $\mathcal{T}(x^\ell)$ into a tree $\mathcal{T}'$ whose root is safe, while promoting it (during insertions) or demoting it (during deletions). This transformation will create a zero-edge or a four-node that will be propagated upward and whose propagation will stop when meeting the safe root x; afterward, it just remains to update $\mathcal{T}'$.

Once implemented, these ideas lead to a bottom-up updating algorithm, whose amortised complexity we study now.

▶ **Theorem 5.** *The updating algorithm whose skeleton we just presented, and whose details are presented in Sections 4.2 (for insertions) and 4.3 (for deletions) performs $\mathcal{O}(1)$ amortised write operations per update.*

Proof. Like for Theorem 1, we start from an empty tree, perform n insertion or deletion updates, and keep track of the variations of tree potential while these updates are performed. There is a large enough constant K such that each update requires:

1. optionally, making the tree root safe, which increases the tree potential by at most K;
2. identifying some safe nodes; this requires no write operation and does not change the tree potential;
3. operating on trees small height, i.e., whose height is smaller than a constant $h_{\min}$; this requires performing a constant number of write operations, and increases the tree potential by a at most K;
4. performing a certain number of batches, each of which consists in (i) cut-demoting a node to make it safe and make its ancestor a four-node; (ii) optionally, performing a cut rebalancing for ensuring that some node will stop propagating four-nodes; (iii) $\ell - \mathcal{O}(1)$ transient operations; and (iv) one "terminal" operation where the four-node stop being propagated.

In each batch, steps (i), (ii) and (iv) increase the tree potential by no more than a constant, and each transient operation decreases the tree potential. Thus, each batch decreases the tree potential by $\ell - \mathcal{O}(1)$, i.e., by no more than $\mathsf{L} - \ell$, where L is a constant; it also requires performing $\mathcal{O}(\ell+1)$ write operations. In particular, if $\ell \geqslant \mathsf{L}+1$, and if T batches of operations were performed in total, the potential increased by at most $n\mathsf{K} - \mathsf{T}$; of course, making sure that $\ell \geqslant \mathsf{L}+1$ means that we will need to determine a suitable constant L.

The tree potential started with the value 0, and ended with a non-negative value, which shows that $\mathsf{T} \leqslant 2n\mathsf{K}$. Therefore, in total, these n updates required performing no more than $\mathcal{O}(n) + \mathsf{T} \times \mathcal{O}(\mathsf{L}+1) \subseteq \mathcal{O}(n)$ write operations. ◀

Hence, it remains to:

1. define our notions of safe nodes, both for insertions and for deletions;
2. prove that trees rooted at an unsafe node can be cut promoted to make their root safe, during insertions;
3. prove that trees rooted at an unsafe node can be cut demoted to make their root safe, during deletions;

4. compute the constants hidden in the $\mathcal{O}(1)$ notations above, in order to effectively compute a constant ℓ for which batches decrease the tree potential.

Below, we will prove that choosing $\ell = 48$ during insertions, and $\ell = 126$ during deletions is enough for our purposes: each batch will decrease the tree potential by at least 1, and other operations will increase the tree potential by $\mathcal{O}(\ell)$ per update. These values of ℓ are grossly sub-optimal: for example, choosing $\ell = 15$ during insertions, and $\ell = 20$ during deletions would be enough; computing these better values, although not intrinsically difficult, involves lengthy case-by-case studies that we chose to avoid here.

4.2 Insertion

Below, we say that a node x is *insertion-safe* (or simply *safe*, when the context is clear) when (i) $\mathsf{r}(x) = 1$ and x is a $\{1, 2\}$-node, or (ii) $\mathsf{r}(x) \geqslant 2$ and x is not full. We showed in Section 3.2 that each tree rooted at a full node, i.e., each tree $\mathcal{T}$ of rank $\mathsf{r} \geqslant 2$ whose root is unsafe, can be subject to a cut promotion, resulting in a tree $\mathcal{T}'$ of rank $\mathsf{r} + 1$ whose root is a $\{1, 2\}$-node, thus being safe.

This makes following the recipe of Section 4.1 easy once the desired integer ℓ is chosen. First, if $\mathsf{r}(\mathcal{T}) \leqslant \ell + 2$, just use the bottom-up algorithm of Section 3.3, which may result in a tree $\mathcal{T}'$ of rank $\mathsf{r}(\mathcal{T}') = \mathsf{r}(\mathcal{T}) + 1$ only in case $\mathcal{T}$ was rooted at an unsafe node. Otherwise, $\mathsf{r}(\mathcal{T}) \geqslant \ell + 3$, and:

1. if $\mathcal{T}$ is rooted at an unsafe node, cut-promote it, thus obtaining a tree $\mathcal{T}'$ of rank $\mathsf{r}(\mathcal{T}') \geqslant \ell + 4$ whose root is safe;
2. if $\mathcal{T}$ is friendly, let $i \leqslant \ell$ be the least positive integer for which x^i is safe: we simply focus on inserting the key k in $\mathcal{T}(x^i)$;
3. if $\mathcal{T}$ is unfriendly, the first nodes $x^1, \dots$ on our branch are all unsafe; thus, they are $\{1, 1\}$-nodes, and the branch contains at least ℓ nodes, with the guarantee that $\mathsf{r}(x^\ell) \geqslant \mathsf{r}(\mathcal{T}) - (\ell + 1) \geqslant 2$, so that all nodes $x^1, \dots, x^\ell$ are full; hence we cut-promote $\mathcal{T}(x^\ell)$ and promote all nodes $x^1, \dots, x^{\ell-1}$, thereby creating a zero-edge between x^0 and x^1, which we eliminate by using the cut rebalancing prescribed in Section 3.3.

▶ **Lemma 6.** *Step 3 consists in a batch operation that decreases the tree potential by $\ell - 47$ or more.*

Proof. It suffices to decompose step 3 in atomic operations:

- **i)** a cut promotion, which increases the tree potential by 14 or less;
- **ii)** replacing each of the $\ell - 1$ full nodes $x^1, \dots, x^{\ell-1}$ by a $\{1, 2\}$-node, which decreases the tree potential by $\ell - 1$;
- **iii)** eliminating a zero-edge through a terminal cut rebalancing performed on a cut with 2 to 4 nodes, and optionally followed by a cut demotion; this increases the tree potential by 32 or less. ◀

4.3 Deletion

We will now characterise *deletion-safe* (or simply *safe*, when the context is clear) nodes: a node x should be safe when they can stop propagating four-nodes. There will be three families of safe nodes: (i) *surely safe* nodes, which stop propagating four-nodes even when using the textbook deletion algorithm, (ii) *barely safe* nodes, which are some of the nodes that can be transformed to create surely safe nodes in their close vicinity, and (iii) *simply safe* nodes, which stop propagating four-nodes when using the algorithm of Section 3.4.

Surely safe nodes are the nodes x of rank $\mathsf{r}(x) \geqslant 1$ with profile $(1,1)$, or rank $\mathsf{r}(x) \geqslant 2$ and profile $(2,2,2)$. Indeed, if some child x_i of x is to be replaced by a node of smaller rank, either (i) x had profile $(1,1)$, in which case its new profile is simply $\{1,2\}$, or (ii) x had profiles $\{1,2\}$ and $(2,2,2)$, in which case x_i was the 2-child of x (because the 1-child of x had profile $(1,1)$), and we fall in case 5 of the bottom-up algorithm.

Detecting other kinds of safe nodes is more challenging; in particular, whether a node x is safe may depend on which descendants of x are to be replaced by nodes of smaller rank. More precisely, let $x = x^\ell$ be a node that belongs to the branch $x^0, x^1, \ldots$ below which the key k will be deleted, and let $z = x^{\ell+4}$.

▶ **Lemma 7.** *Each tree $\mathcal{T}$ can be subject to a cut rebalancing, called* cut saving*, that yields a tree $\mathcal{T}'$ of rank $\mathsf{r}(\mathcal{T})$ or $\mathsf{r}(\mathcal{T})-1$ in which z has a surely safe ancestor. This cut saving increases the tree potential by no more than* 38*.*

Proof. Let x be the root of $\mathcal{T}$. If x is surely safe already, there is nothing to do. Hence, we assume that x has profiles $\{1,2\}$ and $\{2,2,3\}$. Replacing its descendants of rank $\mathsf{r}(x)-2$ by their children gives a cut $(\mathsf{A},\mathsf{C},\mathsf{E},\mathsf{G},\mathsf{I})$ with profile $\{3,3,3,3,3\}$, $\{3,3,3,3,4\}$ or $\{3,3,3,4,4\}$.

In the first case, the children of x must have profiles $(1,1)$ and $(2,2,2)$, and once again, there is nothing to do. In the third case, cut-demoting $\mathcal{T}(x)$ transforms it into a tree $\mathcal{T}'$ of rank $\mathsf{r}(x)-1$ whose root is a $\{1,1\}$-node.

It remains to treat the second case. Let y be the node of rank $\mathsf{r}(x)-4$ in the cut $(\mathsf{A},\mathsf{C},\mathsf{E},\mathsf{G},\mathsf{I})$, and let B, D, F and H be the cut ancestors. By symmetry, we assume that y coincides with A, C or E; if $y = \mathsf{E}$, that z descends from E, G or I; and if $y = \mathsf{E}$ and z descends from E, there are no more $\{1,2\}$-nodes among A and C than among G and I. Then, we distinguish ten cases; the tree $\mathcal{T}'$ will be of rank $\mathsf{r}(x)$ in cases 1 to 8, and $\mathsf{r}(x)-1$ in cases 9 and 10:

1. If (i) $y = \mathsf{A}$ or $y = \mathsf{C}$ and (iii) z descends from E, G or I, we rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_1$); this makes F a surely safe ancestor of z.
2. If (i) $y = \mathsf{A}$, (ii) C is a $\{1,1\}$-node and (iii) z descends from A or C, we rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_1$); this makes B a surely safe ancestor of z.
3. If (i) $y = \mathsf{A}$, (ii) E is a $\{1,1\}$-node (whereas C is not), and (iii) z descends from A or C, we rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_2$); this makes C a surely safe ancestor of z.
4. If (i) $y = \mathsf{C}$, (ii) A is a $\{1,1\}$-node, and (iii) z descends from A or C, we rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_1$); this makes B a surely safe ancestor of z.
5. If (i) $y = \mathsf{C}$, (ii) E is a $\{1,1\}$-node (whereas A is not), and (iii) z descends from A or C, we rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_4$); this makes B a surely safe ancestor of z.
6. If (i) $y = \mathsf{E}$ and (iii) z descends from G or I, we rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_5$); this makes H a surely safe ancestor of z.
7. If (i) $y = \mathsf{E}$, (ii) C is a $\{1,1\}$-node, and (iii) z descends from E, we rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_5$); this makes D a surely safe ancestor of z.
8. If (i) $y = \mathsf{E}$, (ii) A is a $\{1,1\}$-node (whereas C is not), and (iii) z descends from E, we rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_6$); this makes F a surely safe ancestor of z.
9. If (i) $y = \mathsf{A}$ or $y = \mathsf{C}$, (ii) all of A, C and E coincide with y or are $\{1,2\}$-nodes, and (iii) z descends from A or C, we first rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_3$). The sub-tree $\mathcal{T}_3(\mathsf{D})$ has profile $\{3,3,3,4,4\}$ and we cut-demote it, before demoting the node F itself; this yields a tree of rank $\mathsf{r}(x)$-1 whose root F is a $\{1,1\}$-node.
10. If (i) $y = \mathsf{E}$, (ii) all of A, C, G and I are $\{1,2\}$-nodes, and (iii) z descends from E, we first rebalance $\mathcal{T}(x)$ as shown in Figure 4 (tree $\mathcal{T}_5$). The sub-tree $\mathcal{T}_5(\mathsf{B})$ has profile $\{3,3,3,4,4\}$ and we cut-demote it, before demoting the node F itself; this yields a tree of rank $\mathsf{r}(x)$-1 whose root F is a $\{1,1\}$-node.

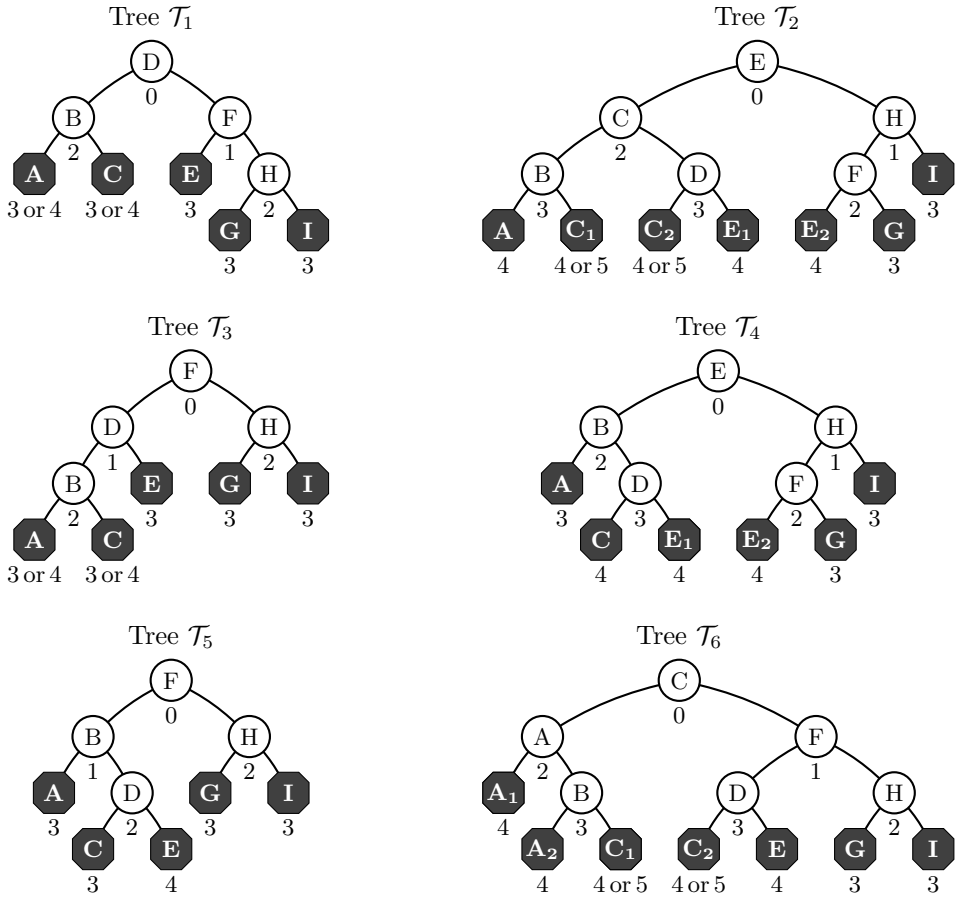

Figure 4 Trees the saving procedure may result in, or use as intermediate step (in cases 9 and 10).

All cases consist in performing a cut rebalancing operation on a cut with at most 7 nodes, optionally followed by a cut demotion. Hence, the saving operation increases the tree potential by no more than 38. ◀

We can now present two additional notions of safety. First, a node x is said to be *barely safe* when the cut saving transforms $\mathcal{T}(x)$ into a tree $\mathcal{T}'(x')$ of rank $\mathsf{r}(x)$. Second, as already mentioned, a node is said to be *simply safe* if its stops propagating four-nodes. Fortunately, deciding whether a node is simply safe is easy, as outlined by the following result.

▶ **Lemma 8.** *Being simply safe depends on local criteria only.*

Proof. Provided that the node $x = x^\ell$ is not surely safe, and if the node $t = x^{\ell+1}$ has just been replaced by a node of smaller rank, the textbook algorithm must now replace $\mathcal{T}(x)$ by a tree $\mathcal{T}'$ whose root x' is a $\{1,1\}$-node with rank $\mathsf{r}(x') = \mathsf{r}(x) - 1$. Furthermore, as can be seen in Figure 2, at least one of its children x'_1 and x'_2 will also be a $\{1,1\}$-node. Hence, we say that x is *m-strong* when the child x'_m is a $\{1,1\}$-node.

Being 1- or 2-strong depends on local criteria only. Indeed, the node x is 1-strong when:

- t coincides with x_1, and x has profile $(1,2)$, $(2,3,2)$, $(2,3,3,3)$ or $(2,3,4,3)$; or
- t coincides with x_2, and x has profile $(3,3,1)$, $(3,3,3,2)$ or $(3,3,4,2)$.

Hence, being 1-strong is a purely local criterion and, symmetrically, so is being 2-strong.

Then, knowing whether t is 1-strong and/or 2-strong allows checking whether x itself is safe, based on other local criteria. For instance, when t coincides with x_2, the node x is safe when it has profile $(1,1)$ or $(2,2,2)$, or in the following cases:

6. $\mathsf{r}(x_{11}) = \mathsf{r}(x_2) = \mathsf{r}-2$ and $\mathsf{r}(x_{12}) = \mathsf{r}-3$, and
  a) x has profile $(3,4,4,3,2)$, $(3,3,4,4,2)$ or $(2,4,5,5,2)$, or
  b) x has profile $(2,4,4,2)$ and x_2 is 1-strong;

7. $\mathsf{r}(x_{11}) = \mathsf{r}-3$ and $\mathsf{r}(x_{12}) = \mathsf{r}(x_2) = \mathsf{r}-2$, and
  a) x has profile $(3,4,4,3,2)$, $(3,3,4,4,2)$, $(4,5,5,4,4,3,2)$, $(4,5,5,4,4,4,2)$, $(4,4,5,5,4,3,2)$, $(4,4,5,5,4,4,2)$, $(3,3,4,5,5,2)$ or $(3,4,4,5,5,2)$, or
  b) x has profile $(3,3,4,4,2)$ or $(3,4,4,4,2)$ and x_2 is 1-strong;

8. $\mathsf{r}(x_1) = \mathsf{r}-2$ and $\mathsf{r}(x_2) = \mathsf{r}-1$, and
  a) x has profile $(3,4,4,1)$, or
  b) x has profile $(3,3,1)$ and x_2 is 1-strong.

These cases were listed by simply enumerating all conditions that could leaf to creating a full node while cut-rebalancing a tree in cases 6 to 8. Hence, some of them are redundant; for instance, in case 7a, if x has profile $(3,3,4,5,5,2)$, it must also have had profile $(3,3,4,4,2)$, which was sufficient for flagging it as safe. Symmetric characterisations exist when t coincides with the left child x_1 of the node x. ◀

Safe nodes and the above saving procedure allow us to implement the recipe succinctly described in Section 4.1. If $\mathcal{T}$ is of rank $\mathsf{r}(\mathcal{T}) \leqslant 2\ell+4$ and its root is barely safe, first use the saving procedure to let a surely safe node appear on the branch below which k will be deleted, and then use the bottom-up algorithm of Section 3.4; this will result in a tree $\mathcal{T}'$ of rank $\mathsf{r}(\mathcal{T}') = \mathsf{r}(\mathcal{T})$. Otherwise, if $\mathcal{T}$ is of rank $\mathsf{r}(\mathcal{T}) \leqslant 2\ell+4$ and its root is *not* barely safe, directly use the bottom-up algorithm of Section 3.4. It may result in a tree $\mathcal{T}'$ of rank $\mathsf{r}(\mathcal{T}') = \mathsf{r}(\mathcal{T}) - 1$ only when $\mathcal{T}$ was rooted at an unsafe node.

We focus now on trees $\mathcal{T}$ of rank $\mathsf{r}(\mathcal{T}) \geqslant 2\ell+5$:

1. If $\mathcal{T}$ is rooted at an unsafe node, the saving procedure transforms it into a tree $\mathcal{T}'$ of rank $\mathsf{r}(\mathcal{T}') \geqslant 2\ell+4$ whose root is safe.

2. If $\mathcal{T}$ is friendly, let $i \leqslant \ell$ be the least positive integer for which x^i is safe: we simply focus on inserting the key k in $\mathcal{T}(x^i)$.

3. If $\mathcal{T}$ is unfriendly, we first consider two sub-cases: if the root x^0 of $\mathcal{T}$ is surely or simply safe, we set $\alpha = x^0$; otherwise, applying the saving algorithm to $\mathcal{T}$ results, without altering the sub-tree $\mathcal{T}(x^4)$, in a tree $\mathcal{T}'$ of rank $\mathsf{r}(\mathcal{T})$ in which x^4 has a surely safe ancestor, the least of which we call α. Then, observing that $\mathsf{r}(x^\ell) \geqslant \mathsf{r}(x) - 2\ell \geqslant 4$, we apply the saving procedure to the sub-tree $\mathcal{T}(x^\ell)$, which makes $x^{\ell-1}$ a four-node. We propagate once this four-node by using the textbook deletion algorithm, i.e., we do not cut-promote full-nodes that might result from using the textbook algorithm; then, we keep propagating our four-node using the algorithm from Section 3.4, a propagation that will stop only when reaching the node α, at which point the four-node is eliminated.

▶ **Lemma 9.** *Step 3 consists in a batch operation that decreases the tree potential by $\ell - 125$ or more.*

Proof. Like for Lemma 4, it suffices to decompose step 3 in atomic operations:

i) optionally, using the saving procedure (cases 1 to 8) on $\mathcal{T}$, which increases the tree potential by no more than 38;

ii) cut-demoting $\mathcal{T}(x^\ell)$ or using the saving procedure (case 9 or 10) on $\mathcal{T}(x^\ell)$, which increases the tree potential by no more than 38;

iii) propagating once the four-node by using the textbook deletion algorithm on $\mathcal{T}(x^{\ell-1})$: this consists in rebalancing a cut with at most 4 nodes, thus increasing the tree potential by no more than 12;

iv) propagating the four-node by using the algorithm of Section 3.4 on nodes $x^{\ell-2}, \dots, x^4$, and stopping just before one meets the surely safe ancestor α of x^4; there are at least $\ell-5$ such propagations, hence the tree potential decreases by at least $\ell - 5$;

v) eliminating the four-node by using the algorithm of Section 3.4 on α; this consists in rebalancing a cut with at most 4 nodes, then possibly performing a cut promotion, and even a node promotion afterward; these three phases, two of which are optional, increase the tree potential by at most 12, 14, and 6, respectively. ◀

Abstract

We present algorithms for the online minimum hitting set problem in geometric range spaces: Given a set P of n points in the plane and a sequence of geometric objects that arrive one-by-one, we need to maintain a hitting set at all times. For disks of radii in the interval $[1, M]$, we present an $O(\log M \log n)$-competitive algorithm. This result generalizes from disks to positive homothets of any convex body in the plane with scaling factors in the interval $[1, M]$. As a main technical tool, we reduce the problem to the online hitting set problem for a finite subset of integer points and bottomless rectangles. Specifically, for a given $N > 1$, we present an $O(\log N)$-competitive algorithm for the variant where P is a subset of an $N \times N$ section of the integer lattice, and the geometric objects are bottomless rectangles.

1 Introduction

In the general form of the *Hitting Set* problem, we are given a point set P and a collection of subsets $\mathcal{C} = \{S_1, \ldots, S_m\}$, and we need to find a subset $H \subset P$ (**hitting set**) of minimal size such that every set $S_i \in \mathcal{C}$ contains some point in H. In the ***Online*** *Hitting Set* problem, the set P is known in advance, but the subsets $S_1, S_2, \ldots$ in $\mathcal{C}$ arrive one at a time (without advance knowledge). We need to maintain a hitting set $H_i \subseteq P$ for the first i sets $\{S_1, \ldots, S_i\}$ such that $H_i \subseteq H_{i+1}$ for all $i \geq 1$ (that is, we can add new points to the hitting set, but we cannot delete any point). The study of the *Online Hitting Set* problem (which is dual to the *Online Set Cover* problem) was initiated by Alon et al. [2]. They designed a deterministic algorithm with competitive ratio $O(\log |P| \log |\mathcal{C}|)$ and obtained almost matching lower bound of $\Omega\left(\frac{\log |P| \log |\mathcal{C}|}{\log\log |P| + \log\log |\mathcal{C}|}\right)$.

Geometric Hitting Set. In the **geometric** *Hitting Set* problem, we have $P \subseteq \mathbb{R}^d$ for some constant dimension d, and the sets in $\mathcal{C}$ are geometric objects of some type: for example, balls, unit balls, simplices, axis-aligned cubes, or hyper-rectangles. Depending on whether P is finite or infinite, there are different versions of the problem. In this paper, we consider P to be a finite set of points in $\mathbb{R}^2$.

Related Previous Work. When P is finite, Even and Smorodinsky [12] initiated the study of the geometric online *Hitting Set* problem for various geometric objects. They established an optimal competitive ratio of $\Theta(\log |P|)$ when the objects are intervals in $\mathbb{R}$, or half-planes or congruent disks in the plane. Later, Khan et al. [14] investigated this problem for a finite set of integer points $P \subseteq [0, N)^2 \cap \mathbb{Z}^2$ and a collection $\mathcal{C}$ of axis-aligned squares $S \subseteq [0, N)^2$ with integer coordinates for $N > 0$. They developed an $O(\log N)$-competitive algorithm for this variant. They also established a randomized lower bound of $\Omega(\log |P|)$, where $P \subset \mathbb{R}^2$ consists of finitely many points and $\mathcal{C}$ consists of translates of an axis-aligned square. Recently, De et al. [6] considered the variant when P is set of n points in $\mathbb{R}^2$ and $\mathcal{C}$ consists of homothetic copies of a regular k-gon (for $k \geq 4$) with scaling factors in the interval $[1, M]$, and designed an $O(k^2 \log M \log n)$-competitive randomized algorithm. Even though a disk can be approximated by a regular k-gon as $k \to \infty$, this does not imply any competitive algorithm for disks with radii in the interval $[1, M]$.

Our results and Technical Contribution. We study the *Online Hitting Set* problem when P is set of n points in $\mathbb{R}^2$. Table 1 summarizes the existing results and the results of the current paper.

Table 1 Summary of known and new results for the geometric *Online Hitting Set* problem where $|P| = n$ is finite. (#) indicates randomized results. Our results are listed in the last three lines.

Points	Objects	Lower Bound	Upper Bound
$P \subset \mathbb{R}$	Intervals in $\mathbb{R}$	$\Omega(\log n)$ [12]	$O(\log n)$ [12]
$P \subset \mathbb{R}^2$	Half-planes and translates of a disk in $\mathbb{R}^2$	$\Omega(\log n)$ [12]	$O(\log n)$ [12]
$P \subseteq [0, N)^2 \cap \mathbb{Z}^2$	Axis-aligned squares in $[0, N)^2 \cap \mathbb{Z}^2$ with integer coordinates	$\Omega(\log n)$ [14] (#)	$O(\log N)$ [14]
$P \subset \mathbb{R}$	Homothetic copies of a regular k-gon ($k \geq 4$) with scaling factors in the interval $[1, M]$	$\Omega(\log n)$ [14] (#)	$O(k^2 \log M \log n)$ [6] (#)
$P \subseteq [0, N)^2 \cap \mathbb{Z}^2$	Bottomless rectangles (for definition, see Section 2.1)	$\Omega(\log n)$ [12]	$O(\log N)$ [Theorem 1]
$P \subset \mathbb{R}^2$	Disks having radii in the interval $[1, M]$	$\Omega(\log n)$ [12]	$O(\log M \log n)$ [Theorem 12]
$P \subset \mathbb{R}^2$	Positive homothets of an arbitrary convex body in $\mathbb{R}^2$ with scaling factors in the interval $[1, M]$	$\Omega(\log n)$ [14] (#)	$O(\log M \log n)$ [Theorem 14]

We now present our contributions and briefly discuss the technical ideas involved.

Bottomless Rectangles in $[0, N]^2$. We present an $O(\log N)$-competitive deterministic algorithm for the geometric *Online Hitting Set* problem, where $P \subset [0, N)^2 \cap \mathbb{Z}^2$, and $\mathcal{C}$ is a sequence of bottomless rectangles of the form $[a, b) \times [0, c)$ arriving one by one (Theorem 1 in Section 2). When a bottomless rectangle $[a, b) \times [0, c)$ arrives, our algorithm chooses hitting points guided by the **canonical partition** of the interval $[a, b]$ (see Section 2 for a definition). For each point p in an offline optimum, this structured canonical partition ensures that $O(\log N)$ points are sufficient to hit all the incoming rectangles in $[0, N]^2 \cap \mathbb{Z}^2$ that are hit by p. We prove that our algorithm is $O(\log N)$-competitive for a broader class of objects– sets $S \subset [a, b) \times \mathbb{R}$ with **lowest-point property** (see Section 2.2 for a definition).

Disks with Radii in $[1, M]$. Our main result is a deterministic $O(\log M \log n)$-competitive *Online Hitting Set* algorithm for an arbitrary set P of n points in the plane, and a sequence of disks of radii in the interval $[1, M]$ (Theorem 12 in Section 4). Previously, an $O(\log n)$-competitive algorithm was known only for congruent disks [12]. In particular, our result is the first $O(\log n)$-competitive algorithm that works for disks of radii in the interval $[1, 1+\varepsilon]$ for any constant $\varepsilon > 0$ (Corollary 13).

However, a finite set of disks in the plane do not necessarily have the lowest-point property. We reduce the problem to objects with the lowest-point property in two steps. First, we consider a restricted version, the **line-separated setting** (Section 3), where the centers of disks in $\mathcal{C}$ lie on one side of a line (w.l.o.g., the x- or y-axis), while P lies on the other side. We use the concept of **disk hull** for a point set (introduced by Dumitrescu et al. [10]), which generalizes the notion of convex hulls and α-hulls. Among other important properties, the boundary of the disk hull is monotone w.r.t. the separating line. Using these properties, we reduce the *Hitting Set* problem in the line-separated setting to objects with the lowest-point property, and obtain an $O(\log n)$-competitive algorithm in the line-separated setting (Theorem 9 in Section 3).

In general, there is no restriction on the location of the points in P and the centers of disks. We reduce the general problem to the line-separated setting as follows: We partition the disks of radii in the interval $[1, M]$ into $O(\log M)$ layers, ensuring that the ratio of radii of disks in each layer is bounded by at most 2. For each layer, our algorithm maintains a tiling of the plane into axis-aligned squares such that (a) any disk of a given layer contains the entire tile that contains the disk center, and (b) each disk intersects only $O(1)$ tiles. Our algorithm simultaneously runs several invocations of the line-separating algorithm (one for each directed grid line). When a disk arrives, our algorithm inserts it into all relevant invocations of the line-separating algorithms; we show that only $O(1)$ invocations are relevant. In the competitive analysis, we show that for each point p in an offline optimum solution, our algorithm uses $O(\log n)$ hitting points for the disks in each layer that contain p. Since there are $O(\log M)$ layers, our algorithm is $O(\log M \log n)$-competitive.

Homothets of a Convex Body with Diameters in $[1, M]$. We generalize our main result from disks to positive homothets of any convex body in the plane, where the radii in the interval $[1, M]$ are replaced by scaling factors in the interval $[1, M]$ (Theorem 14 in Section 5). Our online algorithm is based on a two-stage approach, similar to the case of disks, and it is $O(\log M \log n)$-competitive. The key technical difficulty arises from the geometric differences between a disk and a general convex body. It is easy to extend the concept of a disk hull to hulls for homothetic convex bodies. However, unlike for disks, the boundary of the hull is not necessarily x- or y-monotone: We show that it is monotone w.r.t. some carefully chosen directions. To generalize a layered decomposition of axis-parallel lines, we need **two** directions in which the hull is monotone, the two directions must be far apart (in the space of directions), to create a tiling with properties (a) and (b) above. We call a pair of directions satisfying these requirements a **good pair** of directions. We use a careful geometric argument, which heavily relies on convexity, a suitable affine transformation, and the variational method (i.e., the intermediate value theorem) to prove that every convex body in the plane admits a good pair of directions.

1.1 Further Related Work

When the point set P is infinite, one may further distinguish between the **continuous** setting where $P = \mathbb{R}^d$ (also known as the **piercing problem**) and the **discrete** setting where P is a discrete subset of $\mathbb{R}^d$ (for example, $P = \mathbb{Z}^d$).

Continuous Setting. In the geometric setting, the duality between the *Hitting Set* problem and the *Set Cover* problem only holds when the objects are translates of a convex body [5, Theorem 2]. Hence the results obtained for the *Set Cover* problem for translates of a convex body also hold for the *Hitting Set* problem. Charikar et al. [3] studied the *Online Set Cover* problem for translates of a ball. They proposed an algorithm with a competitive ratio $O(2^d d \log d)$. They also proved $\Omega(\log d / \log\log\log d)$ as the deterministic lower bound of the competitive ratio for this problem. Dumitrescu et al. [9] improved the bounds on the competitive ratio for translates of a ball, establishing an upper bound of $O(1.321^d)$ and a lower bound of $\Omega(d+1)$. For translates of a centrally symmetric convex body, they proved that the competitive ratio of every deterministic algorithm is at least $I(s)$, where $I(s)$ is the illumination number of the object s[1]. For translates of an axis-aligned hypercube in $\mathbb{R}^d$, Dumitrescu and Tóth [11] proved that the competitive ratio of any deterministic algorithm for *Online Set Cover* is at least 2^d. Later, De et al. [5] studied the *Online Hitting Set* problem for α-fat objects in $\mathbb{R}^d$ with diameters in $[1, M]$ and designed a deterministic algorithm with competitive ratio $O\left((2+\frac{2}{\alpha})^d \log M\right)$. For hitting axis-aligned homothetic hypercubes with side lengths in $[1, M]$, they gave a deterministic algorithm with competitive ratio at most $3^d\lceil \log_2 M\rceil + 2^d$. They also proved a $\Omega(d \log M + 2^d)$ lower bound for the problem of hitting homothetic hypercubes in $\mathbb{R}^d$, with side lengths in the interval $[1, M]$.

Discrete Setting. De and Singh [7, 8] studied a variant of this problem where $P = \mathbb{Z}^d$ and $\mathcal{C}$ consists of translates of a ball or an axis-aligned hypercube in $\mathbb{R}^d$. For translates of an axis-aligned hypercube, they showed that there is a randomized algorithm with an expected competitive ratio of $O(d^2)$ and also proved that every deterministic algorithm has a competitive ratio of at least $d+1$. For translates of a ball in $\mathbb{R}^d$, they proposed a deterministic algorithm having a competitive ratio of $O(d^4)$ and proved that every deterministic algorithm has a competitive ratio of at least $d+1$, for $d \leq 3$. Recently, Alefkhani et al. [1] considered the variant where $P = (0, N)^d \cap \mathbb{Z}^d$ and $\mathcal{C}$ is a family of α-fat objects in $(0, N)^d$, for some constant $\alpha > 0$. They proposed a deterministic algorithm with a competitive ratio of at most $(\frac{4}{\alpha}+1)^{2d} \log N$, and proved that the competitive ratio of every deterministic algorithm is $\Omega\left(\frac{\log N}{1+\log \alpha}\right)$. Very recently, De et al. [6] improved both the upper and lower bounds of Alefkhani et al. [1]. They considered the case where $P = \mathbb{Z}^d$ and $\mathcal{C}$ is a family of α-fat objects having diameters in $[1, M]$, for some constant $\alpha > 0$. They proposed a deterministic algorithm with competitive ratio $O((\frac{2}{\alpha})^d \log M)$, and established that the competitive ratio of any randomized algorithm is $\Omega(d \log M)$.

2 Bottomless Rectangles and Integer Points

We present an $O(\log N)$-competitive algorithm for the *Online Hitting Set* problem where P is a subset of an $N \times N$ section of the integer lattice, and the objects are *bottomless rectangles* (Section 2.1); and then generalize the algorithm for the same point set but with objects that have the *lowest-point property* (Section 2.2).

[1] The **illumination number** of an object s, denoted by $I(s)$, is the minimum number of smaller homothetic copies of s (λs, where $\lambda \in (0, 1)$) whose union contains s.

2.1 Bottomless Rectangles

In this section we present an $O(\log N)$-competitive algorithm for the *Online Hitting Set* problem where P is a subset of the integer lattice with nonnegative coordinates less than N, that is, $P \subset [0, N)^2 \cap \mathbb{Z}^2$; and the objects are bottomless rectangles. **Bottomless rectangles** are of the form $r_i = [a_i, b_i) \times [0, c_i)$, where $0 \le a_i < b_i \le N$ and $0 \le c_i \le N$. Note that there are only $O(N^3)$ combinatorially different rectangles w.r.t. P, so the general result by Alon et al. [2] gives an algorithm for the online hitting set with competitive ratio $O(\log^2 N)$. In this section, we present an $O(\log N)$-competitive algorithm, which is the best possible (a matching lower bound follows from the lower bound for the *Online Hitting Set* problem for intervals in one-dimension [12]).

Preliminaries. We need some preparation before we can present the algorithm. We may assume w.l.o.g. that N is a power of 2, and every bottomless rectangle $r_i = [a_i, b_i) \times [0, c_i)$ is given with integer parameters a_i, b_i, and c_i. An interval I is **canonical** if it is of the form $I = \big[q2^j, (q+1)2^j\big)$ for some integers $q, j \ge 0$. For a canonical interval $I = \big[q2^j, (q+1)2^j\big)$, we also define the **left neighbor** $L(I) = \big[(q-1)2^j, q2^j\big)$ and the **right neighbor** $R(I) = \big[(q+1)2^j, (q+2)2^j\big)$. For every canonical interval I, if $(I \times [0, N)) \cap P \neq \emptyset$, then let $p(I)$ denote a **lowest-point** in $(I \times [0, N)) \cap P \neq \emptyset$ (that is, a point with minimum y-coordinate; ties are broken arbitrarily). If $(I \times [0, N)) \cap P = \emptyset$, then $p(I)$ is undefined.

For every interval $[a, b)$ with nonnegative integer endpoints, we define a **canonical partition**, i.e., a partition of $[a, b)$ into canonical intervals. This partition is standard – we walk through some of the technical details because we need them for our algorithm and its analysis. Let $j \ge 0$ be the largest integer such that $q2^j \in (a, b)$, for some $q \in \mathbb{Z}$. (Note that $q \in \mathbb{Z}$ is unique. Indeed, suppose that q is not unique, say $q2^j, (q+1)2^j \in (a, b)$. Since q or $q+1$ is even, then $q/2$ or $(q+1)/2$ is an integer. Now, we have $\frac{q}{2}2^{j+1}$ or $\frac{q+1}{2}\,2^{j+1} \in (a, b)$, which contradicts the maximality of j.) We call the integer $s_{[a,b)} := q2^j$ the **splitting point** of $[a, b)$. We can partition a given interval $[a, b)$ into canonical intervals as follows. If $[a, b)$ is not canonical, find its splitting point $s = s_{[a,b)}$, partition it into two intervals $[a, b) = [a, s) \cup [s, b)$, and recurse on $[a, s)$ and $[s, b)$. For example, the splitting point of interval $[5, 11)$ is 8, and its canonical partition is $[5, 11) = [5, 6) \cup [6, 8) \cup [8, 10) \cup [10, 11)$; see Figure 1a) for an illustration.

Note also that in the canonical partition of $[a, s)$ (resp., $[s, b)$), there is at most one interval of each size, where the possible sizes are powers of 2 between 1 and $s - a$ (resp., $b - s$). Specifically, if I is in the canonical partition of $[a, s)$, then its left neighbor $L(I)$ is not contained in $[a, b)$, consequently $a \in \overline{L(I)}$, where $\overline{L(I)}$ is the closure of $L(I)$. Similarly, if I is in the canonical partition of $[s, b)$, then $b \in R(I)$.

Online algorithm ALG for bottomless rectangles. We can now present our online algorithm. We maintain a hitting set $H_i \subseteq P$, which is initially empty: $H_0 = \emptyset$. When the i-th bottomless rectangle $r_i = [a_i, b_i) \times [0, c_i)$ arrives, initialize $H_i := H_{i-1}$. If $r_i \cap H_i \neq \emptyset$, then do not add any new points to H_i. Otherwise, we may assume that $r_i \cap H_i = \emptyset$. Compute the splitting point s_i of $[a_i, b_i)$, and the canonical partitions $\mathcal{A}_i$ and $\mathcal{B}_i$ of $[a_i, s_i)$ and $[s_i, b_i)$, respectively. If $([a_i, s_i) \times [0, c_i)) \cap P \neq \emptyset$, then find the largest canonical interval $I \in \mathcal{A}_i$ such that $p(I) \in r_i$, and put $H_i := H_i \cup \{p(I)\}$. Similarly, if $([s_i, b_i) \times [0, c_i)) \cap P \neq \emptyset$, then find the largest interval $I \in \mathcal{B}_i$ such that $p(I) \in r_i$, and put $H_i := H_i \cup \{p(I)\}$. Overall, we add at most two new points to H_i in step i.

Competitive analysis. We now prove that ALG is $O(\log N)$-competitive.

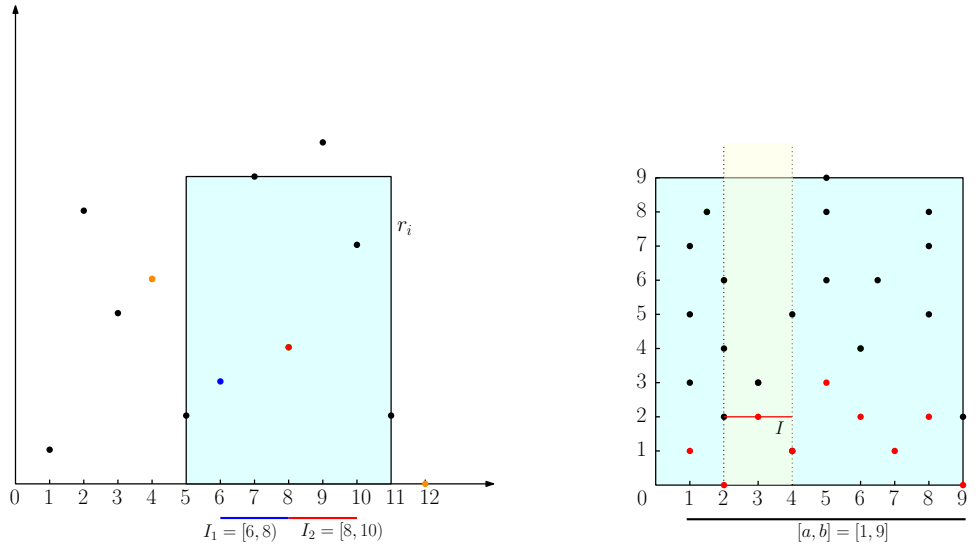

Figure 1 (a) When the ith bottomless rectangle $r_i = [5, 11) \times [0, c_i)$ arrives, suppose that the hitting set H_i contains the orange points, and $r_i \cap H_i = \emptyset$. The splitting point of $[5, 11)$ is 8, with canonical partitions $\mathcal{A}_i = [5, 6) \cup [6, 8)$ and $\mathcal{B}_i = [8, 10) \cup [10, 11)$, respectively. Here, $I_1 = [6, 8) \subset \mathcal{A}_i$ and $I_2 = [8, 10) \subset \mathcal{B}_i$ are the largest canonical intervals in $\mathcal{A}_i$ and $\mathcal{B}_i$, respectively. The blue (resp., red) point is the lowest-point in $I_1 \times [0, N) \cap P$ (resp., $I_2 \times [0, N) \cap P$). We add both points to H_i. (b) The black and red colored points denote the set P, while the red colored points denote the set S. The yellow strip denotes $I \times \mathbb{R}$.

▶ **Theorem 1.** *For the Online Hitting Set problem for a point set $P \subseteq [0, N)^2 \cap \mathbb{Z}^2$ and a sequence of bottomless rectangles, the online algorithm ALG has competitive ratio $O(\log N)$.*

Proof. Let $\mathcal{C}$ be a sequence of bottomless rectangles. Let H and OPT be the hitting set returned by the online algorithm ALG and an (offline) minimum hitting set of $\mathcal{C}$, respectively. For a point $p \in$ OPT, let $\mathcal{C}_p$ be the subsequence of bottomless rectangles that contain p. It is enough to show that for every $p \in$ OPT, our algorithm adds $O(\log N)$ points to H in response to the objects in $\mathcal{C}_p$.

Let $p \in$ OPT, with coordinates $p = (p_x, p_y)$; and let $r_1, \ldots, r_m$ be a sequence of bottomless rectangles in $\mathcal{C}_p$ for which our algorithm adds new points to the hitting set. We show that $m = O(\log N)$. We can distinguish between two types of rectangles $r_i = [a_i, b_i) \times [0, c_i)$ depending on whether the x-coordinate p_x of p is on the left or right of the splitting point s_i of $[a_i, b_i)$: namely, $p_x < s_i$ or $s_i \leq p_x$. We analyze the two types separately (the two cases are analogous).

Assume w.l.o.g. that $p_x < s_i$ for $i = 1, \ldots, m$. This means that $p \in [a_i, s_i) \times [0, c_i)$, and so ALG adds the hitting point $p(I)$ for exactly one interval $I \in \mathcal{A}_i$. Suppose that the algorithm adds the hitting point $p(I)$ for $I \in \mathcal{A}_i$. Then I is the largest (hence rightmost) canonical interval in $\mathcal{A}_i$ such that $(I \times [0, c_i)) \cap P \neq \emptyset$. Recall that $a_i \in \overline{L(I)}$, where $L(I)$ is the left neighbor of the canonical interval I. This implies that $p_x \in L(I) \cup I$. That is, either I or its left neighbor $L(I)$ contains p_x. Note that p_x is contained in $\log N$ canonical intervals (one for each possible size), and each of these canonical intervals has a unique right neighbor. Consequently, I is one of at most $2 \log N$ canonical intervals under the assumption that $p_x < s_i$ for all $i = 1, \ldots, m$. This proves that $m \leq 4 \log N$. ◀

2.2 Objects with the lowest-point property

In this section, we generalize Theorem 1 to a broader class of objects. Similarly to Section 2.1, let $P \subseteq [0, N)^2 \cap \mathbb{Z}^2$. For a set $S \subseteq P$, the span of S, denoted $\text{span}(S)$ is the smallest interval $[a, b)$ with integer endpoints $a, b \in \mathbb{Z}$ such that $S \subset [a, b) \times \mathbb{R}$. An object $S \subseteq P$ has the **lowest-point property** if for every point $s = (s_x, s_y)$ in S and every interval $I \subset \text{span}(S)$ that contains s_x, the object S contains all points in $P \cap (I \times \mathbb{R})$ with the minimum y-coordinates. For an illustration of set S see Figure 1b. Note, in particular, that every bottomless rectangle $r_i = [a_i, b_i) \times [0, c_i)$ has the lowest-point property: Indeed, if $s_x \in I \subset [a_i, b_i)$, then $I \times [0, s_y] \subset r_i$.

Our online hitting set algorithm and its analysis readily generalize when the objects have the lowest-point property. Let $\mathcal{C} = (S_1, \ldots, S_m)$ be a sequence of objects with the lowest-point property.

Online algorithm ALG_0 for objects with the lowest-point property. We maintain a hitting set $H_i \subseteq P$, which is initially empty: $H_0 = \emptyset$. When set S_i arrives, initialize $H_i := H_{i-1}$. If $S_i \cap H_i \neq \emptyset$, then do not add any new points to H_i. Suppose that $S_i \cap H_i = \emptyset$. Let $[a_i, b_i) = \text{span}(S_i)$. Compute the splitting point s_i of $[a_i, b_i)$, and the canonical partitions $\mathcal{A}_i$ and $\mathcal{B}_i$ of $[a_i, s_i)$ and $[s_i, b_i)$, respectively. If $([a_i, s_i) \times \mathbb{R}) \cap S_i \cap P \neq \emptyset$, then find the largest interval $I \in \mathcal{A}_i$ such that $p(I) \in S_i$, and put $H_i := H_i \cup \{p(I)\}$. Similarly, if $([s_i, b_i) \times \mathbb{R}) \cap S_i \cap P \neq \emptyset$, then find the largest interval $I \in \mathcal{B}_i$ such that $p(I) \in S_i$, and put $H_i := H_i \cup \{p(I)\}$. Overall, we add at most two new points to H_i in step i.

Correctness and competitive analysis. When ALG_0 adds a points $p(I)$ to H_i in step i, the lowest-point property ensures that $p(I) \in S_i$. Therefore, ALG_0 maintains that H_i is a hitting set for $\{S_1, \ldots, S_i\}$, proving the correctness of ALG_0. We now show that ALG_0 is $O(\log N)$-competitive.

▶ **Theorem 2.** *For the Online Hitting Set problem for a point set $P \subset [0, N]^2 \cap \mathbb{Z}^2$ and a sequence $\mathcal{C} = (S_1, \ldots, S_m)$ of objects with the lowest-point property, algorithm ALG_0 has competitive ratio $O(\log N)$.*

Proof. Let $\mathcal{C}$ be a sequence of objects with the lowest-point property. Let H and OPT be the hitting set returned by the online algorithm ALG_0 and an (offline) minimum hitting set of $\mathcal{C}$, respectively. For each $p \in \mathsf{OPT}$, let $\mathcal{C}_p$ the subsequence of sets in $\mathcal{C}$ that contain p. It is enough to show that for every $p \in \mathsf{OPT}$, our algorithm adds $O(\log N)$ points to H in response to the objects in $\mathcal{C}_p$.

Let $p \in \mathsf{OPT}$, with coordinates $p = (p_x, p_y)$; and let $S_1, \ldots, S_m$ be a sequence of sets in $\mathcal{C}_p$ for which our algorithm adds new points to the hitting set. We show that $m = O(\log N)$. We can distinguish between two types of sets S_i depending on whether the x-coordinate p_x of p is to the left or right of the splitting point s_i: namely, $p_x < s_i$ or $s_i \leq p_x$. We analyze the two types separately (the two cases are analogous).

Assume w.l.o.g. that $p_x < s_i$ for $i = 1, \ldots, m$. This means that $p \in [a_i, s_i) \times \mathbb{R}$, and so ALG adds the hitting point $p(I)$ for exactly one interval $I \in \mathcal{A}_i$. Suppose that the algorithm adds the hitting point $p(I)$ for $I \in \mathcal{A}_i$. Then I is the largest (hence rightmost) canonical interval in $\mathcal{A}_i$ such that $(I \times \mathbb{R}) \cap P \neq \emptyset$. Recall that $a_i \in \overline{L(I)}$, where $L(I)$ is the left neighbor of the canonical interval I. This implies that $p_x \in L(I) \cup I$. That is, either I or its left neighbor $L(I)$ contains p_x. Note that p_x is contained in $\log N$ canonical intervals (one for each possible size), and each of these canonical intervals has a unique right neighbor. Consequently, I is one of at most $2 \log N$ canonical intervals under the assumption that $p_x < s_i$ for all $i = 1, \ldots, m$. This proves that $m \leq 4 \log N$. ◀

3 Disks in the Plane: Separated Setting

In this section, we consider the *Online Hitting Set* problem in the plane, where P is a finite set above the x-axis (given in advance); and $\mathcal{C}$ consists of disks of arbitrary radii with centers located on or below the x-axis (arriving one-by-one). Note that the disks in $\mathcal{C}$ do not necessarily have the lowest-point property; see Figure 2.

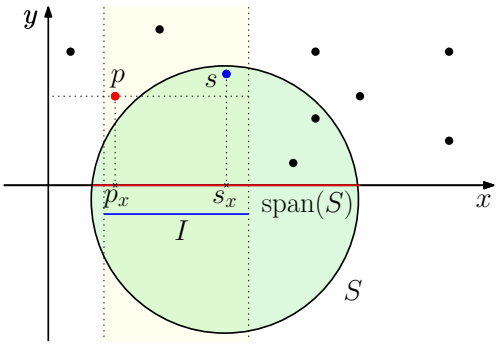

Figure 2 Disk S with center below the x-axis does not have the lowest-point property: We have $s \in S$, and the interval $I \subset \text{span}(S)$ contains s_x, but S does not contain the point $p \in P$ with minimum y-coordinate in the strip $I \times \mathbb{R}$.

Disk hulls for a point set w.r.t. disks and its properties. The unit disk hull of a point set was introduced by Dumitrescu et al. [10] as an analogue of the convex hull. Recall that the convex hull $\text{conv}(P)$ of a point set $P \subset \mathbb{R}^2$ is the smallest convex set in the plane that contains P. Equivalently, it is the intersection of all closed half-planes that contain P; it can be computed by the classical "rotating calipers" algorithm, where we continuously rotate a line ℓ around P while P remains in one closed half-plane bounded by ℓ. Intuitively, we obtain the unit disk hull of P by rolling a unit disk, with center on or below the x-axis, around P. We generalize this notion to disks of any fixed radius $t > 0$.

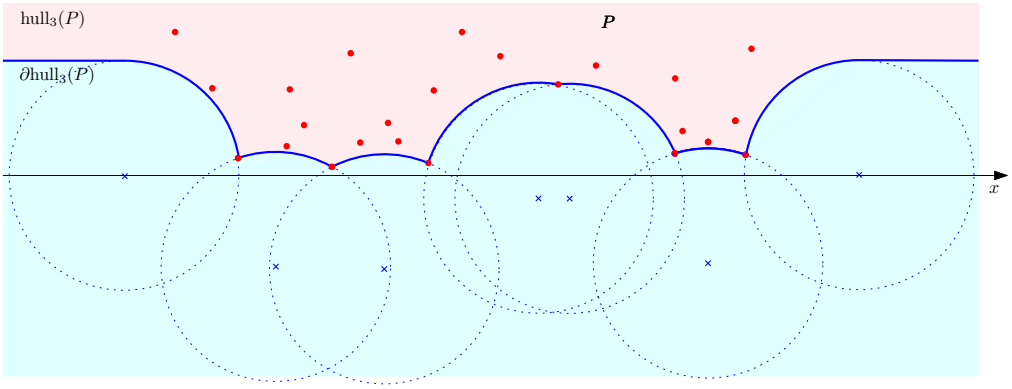

Figure 3 A point set P (red) and region $\text{hull}_3(P)$ (pink). The boundary $\partial\text{hull}_3(P)$ is composed of horizontal lines and circular arcs.

▶ **Definition 3.** *Let $P \subset \mathbb{R}^2$ be a finite set of points above the x-axis and let $t > 0$. Let $\mathcal{D}_t$ be the set of all disks of radius t with centers on or below the x-axis. Let $M_t(P)$ be the union of all disks $D \in \mathcal{D}_t$ such that $P \cap \text{int}(D) = \emptyset$. Now, we define the* ***t-hull*** *of P as $\text{hull}_t(P) = \mathbb{R}^2 \setminus \text{int}(M_t(P))$. The boundary of $\text{hull}_t(P)$ is denoted by $\partial\text{hull}_t(P)$; for an illustration see Figure 3.*

Dumitrescu et al. [10, Lemma 4] proved that $\partial\text{hull}_t(P)$ is x-monotone[2] for any $t > 0$, and established other properties, which were used by Conroy and Tóth [4], as well.

▶ **Lemma 4** (Dumitrescu et al. [10]). *For a finite set $P \subset \mathbb{R}^2$ above the x-axis and $t > 0$, the following holds:*

1. *$\partial\text{hull}_t(P)$ lies above the x-axis;*
2. *every vertical line intersects $\partial\text{hull}_t(P)$ in one point, thus $\partial\text{hull}_t(P)$ is an x-monotone curve;*
3. *for every disk $D \in \mathcal{D}_t$, the intersection $D \cap (\partial\text{hull}_t(P))$ is connected (possibly empty);*
4. *for every disk $D \in \mathcal{D}_t$, if $P \cap D \neq \emptyset$, then $P \cap D$ contains a point in $\partial\text{hull}_t(P)$.*

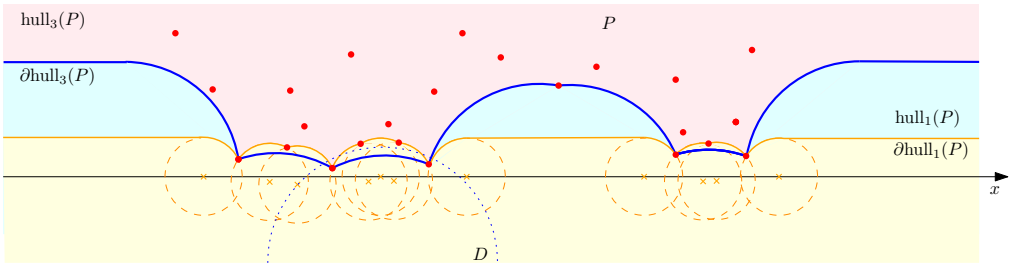

Figure 4 A point set P (red), hull$_3(P)$ (pink), and hull$_1(P)$ (light blue or pink). A disk $D \in \mathcal{D}_3$ of radius 3 (dotted blue), where the intersection $D \cap (\partial\text{hull}_1(P))$ has two components.

Since we consider the case of disks with bounded radii, for our purposes, we need to compare two disk hulls for the same point set P w.r.t. different radii; see Figure 4. We start with an easy observation.

▶ **Lemma 5.** *Let γ_1 and γ_2 be circular arcs lying entirely above the x-axis, such that γ_1 and γ_2 are arcs of circles C_1 and C_2, resp., of radii r_1 and r_2, with centers on or below the x-axis.*

1. *Then both γ_1 and γ_2 are x-monotone and concave curves.*
2. *Furthermore, if points $p_1, p_2 \in \mathbb{R}^2$ are contained in both γ_1 and γ_2, and $r_1 < r_2$, then γ_1 lies above γ_2 (i.e., for every vertical line L that separates p_1 and p_2, point $\gamma_1 \cap L$ lies above point $\gamma_2 \cap L$).*

Proof. (1) For every $i \in \{1, 2\}$, the center of C_i is below the x-axis, and so the leftmost and rightmost points of C_1 are also below the x-axis. The leftmost and rightmost points partition C_i into two halfcircles, one above the center and one below the center. Both halfcircles are x-monotone: The lower halfcircle is convex curve and the upper halfcircle is concave. Since γ_i lies entirely above the x-axis, it is contained in the upper halfcirlce, which is x-monotone and concave.
(2) The locus of centers of circles that contain both p_1 and p_2 is the orthogonal bisector of the line segment p_1p_2, that we denote by $(p_1p_2)^\perp$. Note that p_1p_2 is not vertical (or else $(p_1p_2)^\perp$ would be a horizontal line above the x-axis, and the centers of C_1 and C_2 would also be above the x-axis). As the center a circle containing p_1 and p_2 continuously moves from the center of C_1 down to $y = -\infty$, the circular arc between p_1 and p_2 deforms continuously from γ_1 to the line segment p_1p_2. Since γ_1 concave, it lies above the segment p_1p_2. Since $r_1 < r_2$, the arc γ_2 lies between the arc γ_1 and the segment p_1 and p_2. Consequently, then γ_2 lies below γ_1, as claimed. ◀

[2] A curve in the plane is x-monotone if every vertical line intersects it at most once.

▶ **Lemma 6.** *For every finite set $P \subset \mathbb{R}^2$ above the x-axis, the following holds:*

1. *If $0 < s < t$, then for every disk $D \in \mathcal{D}_s$ of radius s, the intersection $D \cap (\partial\text{hull}_t(P))$ is connected (possibly empty).*
2. *Suppose that $p \in P$ lies on the curve $\partial\text{hull}_t(P)$ for some $t > 0$. Then there is a radius $r_p \in (0, t)$ such that p is also on $\partial\text{hull}_s(P)$ for all $s \in [r_p, t]$, but p is below $\partial\text{hull}_s(P)$ for all $s \in [0, r_p)$.*

Proof. (1) Let $D \in \mathcal{D}_s$. Suppose, to the contrary, that the intersection $D \cap (\partial\text{hull}_t(P))$ has two or more components. By Lemma 4(2), the x-coordinates of the components form disjoint intervals, and the components have a natural left-to-right ordering. Let q_1 be the rightmost point in the first component, and let q_2 be the leftmost point in the second component. Clearly $q_1, q_2 \in \partial D$. Let q' be an arbitrary point in $\partial\text{hull}(A)$ between q_1 and q_2. Then q' lies on the boundary of some disk D' of radius t whose center is below the x-axis, and whose interior is disjoint from P. In particular, neither q_1 nor q_2 is in the interior of D'. Since the center of D' is below the x-axis, $\partial D'$ contains two interior-disjoint circular arcs between q and the x-axis; and both arcs must cross ∂D. We have found two intersection points $p_1, p_2 \in \partial D \cap \partial D'$ above the x-axis. Furthermore, between p_1 and p_2, the circular arc ∂D lies above the circular arc $\partial D'$, contradicting Lemma 5(2). This completes the proof of Property 1.
(2) Consider a point $p \in P$ that lies on the curve $\partial\text{hull}_t(P)$ for some $t > 0$. Then there exists a disk $D \in \mathcal{D}_t$ of radius t centered at some point c below the x-axis such that $p \in \partial D$. Let c_1 be the intersection point of the x-axis the line cp, and c_2 the orthogonal projection of p to the x-axis. We describe two continuous motions, where the disk D continuously changes while p is in the circle ∂D and there is no point in P in the interior of D: First, a central dilation from center p continuously moves D to a disk D_1 centered at c_1. Second, the center of D moves from c_1 towards c_2 continuously until its center reaches c_2 or a point c_3 where ∂D contains both p and another point $p' \in P$. Let r_p be radius of D at that time. The continuous motion shows that $p \in \partial\text{hull}_s(P)$ for all $s \in [r_p, t]$, but it is not in $\partial\text{hull}_s(P)$ for all $s < r_p$. ◀

Note that Lemma 6(1) is not symmetric for $s < t$: For a disk $D \in \mathcal{D}_t$ of radius t, the intersection $D \cap (\partial\text{hull}_s(P))$ is not necessarily connected; see Figure 4 for an example.

Reduction. We can reduce the *Online Hitting Set* problem for a finite set $P \subset \mathbb{R}^2$ and disks of bounded radii in the separated setting, to the *Online Hitting Set* problem for a finite subset of integer points and objects with the lowest-point property. We achieve the reduction in two steps:
(1) We choose a subset $Q \subseteq P$ of points that are relevant for a hitting set (Lemma 7); and
(2) we map the points in P into a set of integer points $P' \subset [0, n]^2 \cap \mathbb{Z}^2$ (Lemma 8).

For a finite point set P in the plane above the x-axis, let $Q = Q(P)$ be the set of points $p \in P$ such that $p \in \partial\text{hull}_t(P)$ for some $t > 0$.

▶ **Lemma 7.** *For a finite point set P in the plane above the x-axis, $Q = Q(P)$ has the following property: For every disk D centered below the x-axis, if $D \cap P \neq \emptyset$, then $D \cap Q \neq \emptyset$.*

Proof. Let D be a disk of radius $t > 0$ centered below the x-axis. By Lemma 4(4), $D \cap P$ contains a point in $\partial\text{hull}_t(P)$. By the definition of Q, this point is in Q. ◀

We may assume that the points in P have distinct x-coordinates (if two or more points in P have the same x-coordinate, w.l.o.g. a minimum hitting set would contain only the point with the smallest y-coordinate). Sort P by increasing x-coordinates such that $P = \{p_0, \ldots, p_{n-1}\}$.

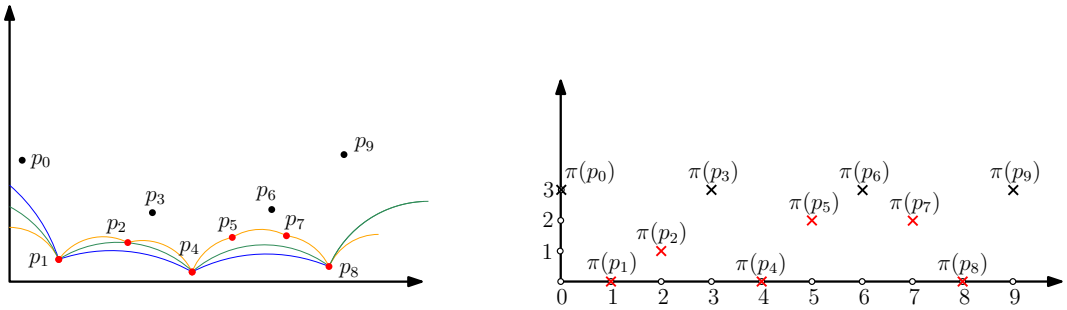

Figure 5 Description of the function π. Left: $\partial\text{hull}_1(P)$ is orange, $\partial\text{hull}_2(P)$ is green, and $\partial\text{hull}_3(P)$ is blue. Right: The grid points $\pi(p_0), \ldots, \pi(p_9)$ corresponding to $p_0, \ldots, p_9$.

For every point $q \in Q$, let $t(q) > 0$ be the maximum radius such that $q \in \partial\text{hull}_{t(q)}(P)$. Consider the set of radii $T = \{t(q) : q \in Q\}$. Sort the radii in T in decreasing order as $t_0 > t_1 > \ldots > t_{|T|-1}$. We can now define the function $\pi : P \to [0, n)^2 \cap \mathbb{Z}^2$. For every $p_i \in Q$, let $\pi(p_i) = (i, j)$ if and only if $t(p_i) = t_j$, that is, the first coordinate of $\pi(p_i)$ corresponds to the index i of p_i (the x-order of all points in Q), and the second coordinate of $\pi(p_i)$ corresponds to index j of the radius $t_j = t(p_i)$. For every $p_i \in P \setminus Q$, let $\pi(p_i) = (i, |T|)$; see Figure 5 for an illustration. Finally, let $P' = \pi(P) = \{\pi(p_i) : p_i \in P\}$ and $Q' = \pi(Q) = \{\pi(p_i) : p_i \in Q\}$. Note that the points in $P' \setminus Q'$ lie above all points in Q'. Since π is injective, then it is a bijection between P and P'. Note also that $|T| \leq |Q| \leq |P| = n$, consequently $P' \subset [0, n]^2 \cap \mathbb{Z}^2$.

▶ **Lemma 8.** *For a set P of n points in the plane above the x-axis and for every disk D centered below the x-axis, the set $\pi(D \cap P)$ has the lowest-point property.*

Proof. Let D be a disk centered below the x-axis. We rephrase the lowest-point property in terms of $D \cap P$. Recall that the points in P are sorted by x-coordinates. Suppose that $s = (s_x, s_y)$ is in $D \cap P$ and $s_x \in I \subset \text{span}(D \cap P)$. Consider the point sets $P(I) := \{p = (p_x, p_y) \in D \cap P : p_x \in I\}$. By Lemma 7, we know that $D \cap Q \neq \emptyset$; let t be the largest radius in T such that $Q(I) \cap \partial\text{hull}_t(P) \neq \emptyset$. We need to show that D contains all points in $P(I) \cap \partial\text{hull}_t(P)$.

Let q_{left} and $q_{\text{right}} \in P(I)$, resp., be the leftmost and rightmost points in $P(I) \cap Q$; and let L_{left} and L_{right} be the vertical lines through q_{left} and q_{right}. By the definition of Q, we have $q_{\text{left}} \in \partial\text{hull}_{t(q_{\text{left}})}(P)$ and $q_{\text{right}} \in \partial\text{hull}_{t(q_{\text{right}})}(P)$, and $t \geq \max\{t(q_{\text{left}}), t(q_{\text{right}})\}$ by the definition of t. Consequently, the intersection point $\ell := L_{\text{left}} \cap \partial\text{hull}_t(P)$ lies at or below q_{left}, the intersection point $r := L_{\text{right}} \cap \partial\text{hull}_t(P)$ lies at or below q_{right}. Since $q_{\text{left}}, q_{\text{right}} \in D$, then D contains both ℓ and r. We know that $\partial\text{hull}_t(P)$ is an x-monotone curve by Lemma 4(2), and $D \cap \partial\text{hull}_t(P)$ is connected by Lemma 6(2). Since D contains both ℓ and r, then D contains the sub-curve of $\partial\text{hull}_t(P)$ between r and ℓ. Since all points in $P(I)$ are between the vertical lines L_{left} and L_{right}, then D contains all points in $P(I) \cap \partial\text{hull}_t(P)$, as required. ◀

Online algorithm for disks in the separated setting. We can now complete the reduction.

▶ **Theorem 9.** *For the Online Hitting Set problem for a set $P \subset \mathbb{R}^2$ of n points above the x-axis and disks centered below the x-axis, there is an $O(\log n)$-competitive algorithm.*

Proof. We are given a set $P \subset \mathbb{R}^2$ of n points above the x-axis, and we receive a sequence $\mathcal{C} = (D_1, \ldots, D_m)$ of disks centered on or below the x-axis in an online fashion. Let $\mathsf{OPT} \subseteq P$ be a minimum hitting set for $\mathcal{C}$.

Initially, we compute the set $P' \subset [0,n]^2 \cap \mathbb{Z}^2$ as defined above Lemma 8. When a disk D_i arrives, we compute the set $S_i = \pi(D_i \cap P)$, which has the lowest-point property by Lemma 8. The bijection π maps OPT to a set $\mathsf{OPT}' = \pi(\mathsf{OPT}) \subseteq P'$, where $|\mathsf{OPT}| = |\mathsf{OPT}'|$. Here, OPT' is a hitting set for the sets $\mathcal{C}' = (S_1, \ldots, S_m)$.

We run the online algorithm ALG_0 described in Section 2.2 for the point set P' and the sequence $\mathcal{C}'$ of sets. By Theorem 1, ALG returns a hitting set $H' \subseteq P'$ of size $|\mathsf{OPT}'| \cdot O(\log n)$. By Lemma 7, $H = \pi^{-1}(H') \subset P$ is a hitting set for $\mathcal{C}$, and its size is bounded by $|H| = |H'| \leq |\mathsf{OPT}'| \cdot O(\log n) = |\mathsf{OPT}| \cdot O(\log n)$, as required. ◀

4 Disks of Bounded Radii: General Setting

In this section, we consider the *Online Hitting Set* problem, where P is a finite set (given in advance) in the plane; and the objects are disks with radii in the interval $[1, M)$, where $M > 1$ is a constant.

Distinguishing layers of disks, according to their radii. We partition the disks of radii in the interval $[1, M)$ into $\lfloor \log M \rfloor + 1$ layers as follows: for each $j \in \{0, 1, \ldots, \lfloor \log M \rfloor\}$, let **layer** L_j be the set of disks of radii in the interval $[2^j, 2^{j+1})$. The index of each layer L_j is denoted by j.

Tiling of the plane for each layer index j. For every $j \in \{0, 1, \ldots, \lfloor \log M \rfloor\}$, let $\Lambda_j = \{\alpha_1 \mathbf{v}_1 + \alpha_2 \mathbf{v}_2 : (\alpha_1, \alpha_2) \in \mathbb{Z}^2\}$ be a two-dimensional lattice spanned by vectors $\mathbf{v}_1 = 2^{j-1/2}\mathbf{e}_1$ and $\mathbf{v}_2 = 2^{j-1/2}\mathbf{e}_2$, where $\mathbf{e}_1 = (1,0)$ and $\mathbf{e}_2 = (0,1)$ are the standard basis vectors. Let $\tau_j = \left[0, 2^{j-1/2}\right]^2$ be a square of side length $2^{j-1/2}$ with lower-left corner at the origin. Translates of τ_j (**tiles**), with translation vectors in the lattice Λ_j, form the **tiling** $\mathcal{T}_j$. Let $\mathcal{L}_j$ denote the set of axis-parallel lines spanned by the sides of the tiles in $\mathcal{T}_j$.

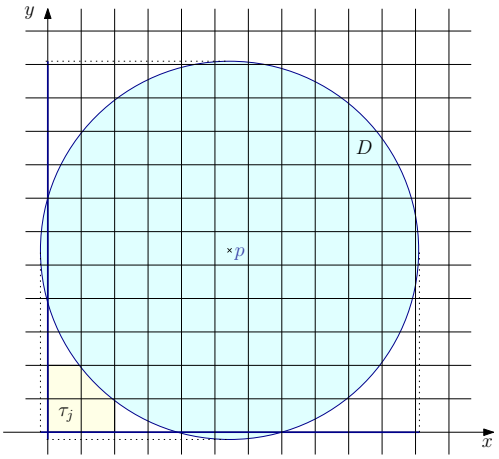

Figure 6 A section of the tiling $\mathcal{T}_j$, the tile τ_j of side length $2^{j-1/2}$, and a disk D of radius 2^{j+2}.

We observe two key properties of the construction of layers and the tilings.

▶ **Observation 10.** *For every $j \in \{0, 1, \ldots, \lfloor \log M \rfloor\}$, if $\sigma \in L_j$ and the center of σ is in a tile $\tau \in \mathcal{T}_j$, then $\tau \subset \sigma$; see Figure 6.*

Proof. Since $\sigma \in L_j$, the radius of the disk σ is in at least 2^j. The tile τ is a translate of $\tau_j = [0, 2^{j-1/2}]^2$, and so its diameter is $\sqrt{2} \cdot 2^{j-1/2} = 2^j$. If the center c of σ is in S, then every $p \in \tau$ is within distance 2^j from c, which implies that $\tau \subset \sigma$. ◀

▶ **Observation 11.** *For every $j \in \{0, 1, \ldots, \lfloor \log M \rfloor\}$, every disk D of radius at most 2^{j+2} intersects at most 24 lines in $\mathcal{L}_j$: at most 12 horizontal and 12 vertical lines.*

Proof. Let D be a disk of radius 2^{j+2}; see Figure 6. The orthogonal projection of D to the x-axis (resp., y-axis) is an interval of length at most 2^{j+3}. Since the distance between any two consecutive vertical (resp., horizontal) lines in $\mathcal{L}_j$ is $2^{j-1/2}$, then D intersects at most $\lceil 2^{j+3}/2^{j-1/2} \rceil = \lceil 2^{7/2} \rceil = 12$ horizontal and at most 12 vertical lines in $\mathcal{L}_j$. ◀

Subproblem for a directed line L. For a directed line L, we denote by L^- and L^+ the closed half-plane on the left and right of L, respectively. Given a directed line L and the input $(P, \mathcal{C})$ of the *Online Hitting Set* problem, where P is a set of points, and $\mathcal{C}$ is a sequence of disks in the plane, we define a subproblem $(P_L, \mathcal{C}_L)$ as follows: Let $P_L = P \cap L^-$, and let $\mathcal{C}_L$ be the subsequence of disks $\sigma_i \in \mathcal{C}$ such that the center of σ_i is in L^+ and σ_i contains at least one point in P_L. Now for each subproblem $(P_L, \mathcal{C}_L)$, we can run the online algorithm ALG_0 described in Theorem 9, which was developed for the separated setting in Section 3. Let $\mathsf{ALG}_0(L)$ denote the online algorithm, where we run the online algorithm ALG_0 on the subproblem $(P_L, \mathcal{C}_L)$.

Online algorithm. We can now present our online algorithm ALG. In the current algorithm, we use the online algorithm $\mathsf{ALG}_0(L)$ as a subroutine. For each $j \in \mathbb{N} \cup \{0\}$, let layer L_j be the set of disks of radii in the interval $[2^j, 2^{j+1})$. The algorithm maintains a hitting set $H \subseteq P$ for the disks presented so far. Upon the arrival of a new disk σ with radius r, if it is already hit by a point in H, then do nothing. Otherwise, proceed as follows.

- First, find the layer L_j, where $j = \lfloor \log r \rfloor$, in which σ belongs.
- Find the tile $\tau \in \mathcal{T}_j$ that contains the center of σ.
  - If $P \cap \tau \neq \emptyset$, then choose an arbitrary point $p \in P \cap \tau$ and add it to H.
  - Otherwise, for every line $L \in \mathcal{L}_j$ that intersects σ, direct L such that L^+ contains the center of σ, feed the disk σ to the online algorithm $\mathsf{ALG}_0(L)$, and add any new hitting point chosen by $\mathsf{ALG}_0(L)$ to H.

Competitive analysis. We now prove that ALG is $O(\log M \log n)$-competitive.

▶ **Theorem 12.** *For the Online Hitting Set problem for a set P of n points in the plane and a sequence $\mathcal{C} = (\sigma_1, \ldots, \sigma_m)$ of disks of radii in the interval $[1, M]$, the online algorithm ALG has competitive ratio $O(\log M \log n)$.*

Proof. Let $\mathcal{C}$ be a sequence of disks. For each $j \in \{0, 1, \ldots, \lfloor \log M \rfloor\}$, let $\mathcal{C}^j$ be the collection of disks in $\mathcal{C}$ with radii in the interval $\left[2^j, 2^{j+1}\right)$. Let H and OPT, resp., be the hitting set returned by the online algorithm ALG and an (offline) minimum hitting set for $\mathcal{C}$. For every point $p \in \mathsf{OPT}$, let $\mathcal{C}_p$ be the set of disks in $\mathcal{C}$ containing p. For each $j \in \{0, 1, \ldots, \lfloor \log M \rfloor\}$, let $\mathcal{C}_p^j$ be the set of disks in $\mathcal{C}^j$ containing p, i.e., $\mathcal{C}_p^j = \mathcal{C}^j \cap \mathcal{C}_p$. Let $H_p^j \subseteq H$ be the set of points that ALG adds to H in response to hit objects in $\mathcal{C}_p^j$. It is enough to show that for every $j \in \{0, 1, \ldots, \lfloor \log M \rfloor\}$ and $p \in \mathsf{OPT}$, we have $|H_p^j| \leq O(\log n)$.

Let τ be the tile in $\mathcal{T}_j$ that contains p, and let ${\mathcal{C}'}_p^j \subseteq \mathcal{C}_p^j$ be the subset of disks whose centers are located in τ. To hit the first disk $\sigma \in {\mathcal{C}'}_p^j$, our algorithm adds a point from $P \cap \tau$ to H. By Observation 10, any point in $P \cap \tau$ hits σ, as well as any subsequent disks in ${\mathcal{C}'}_p^j$. Our algorithm adds at most 1 point to H to hit all the disks in ${\mathcal{C}'}_p^j$.

It remains to bound the number of points our algorithm adds for disks in $\mathcal{C}_p^j \setminus \mathcal{C}'^j_p$. Notice that a disk D_0 centered at p of radius 2^{j+1} contains all the centers of the disks in $\mathcal{C}_p^j \setminus \mathcal{C}'^j_p$. By the triangle inequality, a disk D centered at p of radius 2^{j+2} contains all disks in $\mathcal{C}_p^j \setminus \mathcal{C}'^j_p$. For any disk $\sigma \in \mathcal{C}_p^j \setminus \mathcal{C}'^j_p$, our algorithm uses algorithm $\mathsf{ALG}_0(L)$ for a line $L \in \mathcal{L}_j$, directed such that L^+ contains the center of σ. According to Observation 11, the disk D intersects at most 24 lines in $\mathcal{L}_j$. However, depending on the location of the center of σ, each line may be used in either direction for $\mathsf{ALG}_0(L)$. As a result, for all disks in $\mathcal{C}_p^j \setminus \mathcal{C}'^j_p$, algorithm $\mathsf{ALG}_0(L)$ is called with at most 48 directed lines L.

For each directed line L, the online algorithm $\mathsf{ALG}_0(L)$ maintains a hitting set $H(L)$ for the disks fed into this algorithm. For the point p, let $H_p^j(L)$ denote the set of points that algorithm $\mathsf{ALG}_0(L)$ adds to $H(L)$ in response to a disk in $\mathcal{C}_p^j \setminus \mathcal{C}'^j_p$ that it receives as input. By Theorem 9, we have $|H_p^j(L)| \leq O(\log |\mathcal{C}_p^j \setminus \mathcal{C}'^j_p|) \leq O(\log n)$ for every directed line L. This yields $|H_p^j| \leq 1 + 48 \cdot O(\log n) = O(\log n)$, as required.

By construction, we have $H = \bigcup_{j=0}^{\lfloor \log M \rfloor} \bigcup_{p \in \mathsf{OPT}} H_p^j$. We have shown that $|H_p^j| = O(\log n)$, for all $j \in \{0, 1, \ldots, \lfloor \log M \rfloor\}$ and $p \in \mathsf{OPT}$. Consequently, we obtain $|H| \leq \sum_{j=0}^{\lfloor \log M \rfloor} \sum_{p \in \mathsf{OPT}} O(\log n) = (\lfloor \log M \rfloor + 1)\, |\mathsf{OPT}|\, O(\log n) = O(\log M \log n)|\mathsf{OPT}|$. ◀

For disks of radii in $[1, 1+\varepsilon]$ where $\varepsilon > 0$ is constant, Theorem 12 implies the following.

▶ **Corollary 13.** *For the Online Hitting Set problem for a set P of n points in the plane and a sequence $\mathcal{C} = (\sigma_1, \ldots, \sigma_m)$ of disks of radii in the interval $[1, 1+\varepsilon]$, where $\varepsilon > 0$ is a constant, the online algorithm ALG is $O(\log n)$-competitive.*

5 Generalization to Positive Homothets of a Convex Body

In this section, we generalize Theorem 12 for positive homothets of an arbitrary convex body C in the plane. A set $C \subset \mathbb{R}^2$ is a **convex body** if it is convex and has a nonempty interior; and it is **centrally symmetric** (w.r.t. the origin) if $C = -C$, where $-C = \{-p : p \in C\}$.

The key components of our $O(\log n)$-competitive algorithm for disks of comparable sizes were an $O(\log n)$-competitive online algorithm in the line-separated setting and a grid tiling that allowed a reduction to the line-separated setting. Specifically, Observation 10 and Observation 11 formulate the two essential properties of a tiling: If a center of disk σ lies in a tile τ, then $\tau \subset \sigma$ (Observation 10); and every disk intersects $O(1)$ grid lines (Observation 11).

We state the main result of this section here. For a detailed explanation and the complete proof, please refer to the full version of the paper.

▶ **Theorem 14 (⋆).** *Given any convex body $\sigma \subset \mathbb{R}^2$ and a parameter $M \geq 1$, there is an online algorithm with a competitive ratio of $O(\log M \log n)$ for the Online Hitting Set problem for a set P of n points in the plane and a sequence $\mathcal{C} = (\sigma_1, \ldots, \sigma_m)$ of positive homothets $\sigma_i = a_i\sigma + b_i$, where $a_i \in [1, M]$.*

For positive homothets of a convex object with scaling factor in $[1, 1+\varepsilon]$, where $\varepsilon > 0$ is a constant, Theorem 14, implies the following.

▶ **Corollary 15.** *Given any convex body $\sigma \subset \mathbb{R}^2$ and constant $\varepsilon > 0$, there is an online algorithm of competitive ratio $O(\log n)$ for the Online Hitting Set problem for a set P of n points in the plane and a sequence $\mathcal{C} = (\sigma_1, \ldots, \sigma_m)$ of positive homothets $\sigma_i = a_i\sigma + b_i$, where $a_i \in [1, 1+\varepsilon]$.*

A good pair of lines. The key technical tool for the proof of Theorem 14 is Definition 16. Given a convex body C, we first consider an inscribed triangle of the maximum area (see [13]). We then apply an area-preserving (unary) affine transformation to transform C so that this inscribed triangle of the maximum area becomes an equilateral triangle. (This is similar to mapping the minimum enclosing ellipse of C into a circle, or assuming that C is "fat" after a suitable affine transformation.) We may further assume, by scaling, that the inscribed circle of this triangle has a unit diameter.

▶ **Definition 16.** *Let C be a convex body in the plane such that an inscribed triangle of the maximum area is an equilateral triangle T_{in}, and the circle inscribed in T_{in} is a circle of a unit diameter. A pair of lines $\{\ell_1, \ell_2\}$ is a* ***good pair for C*** *if they satisfy the following properties:*

1. *The angle between the two lines is bounded from below by $\angle(\ell_1, \ell_2) \geq \pi/15$.*
2. *For $i \in \{1, 2\}$, there exist points $p_i, q_i \in \partial C$ such that the two lines tangent to C parallel to ℓ_i contain p_i and q_i, respectively; furthermore, C contains the disk $B(x, \frac{1}{50})$ of diameter $\frac{1}{25}$ centered at the intersection point $x = p_1q_1 \cap p_2q_2$.*

In the full version, we prove that every convex body C specified in Definition 16 admits a good pair of lines, which can be computed in polynomial time if C is a convex polygon. No attempts were made to optimize the constants $\pi/15$ and $\frac{1}{50}$ in Definition 16.

6 Conclusions and Open Problems

We revisited the *Online Hitting Set* problem for a set of n points in the plane and geometric objects that arrive in an online fashion, such as disks or homothets of a convex body of comparable sizes, or bottomless rectangles in the plane. In all these cases, we designed $O(\log n)$-competitive online algorithms, which is the best possible. It remains an open problem whether our results generalize to 3- or higher dimensions. In fact, no $O(\log n)$-competitive algorithm is currently known for simple geometric objects in 3-space, for example, a set of n points and a sequence of unit balls in $\mathbb{R}^3$; or a set of n points $P \subset [0, n)^3 \cap \mathbb{Z}^3$ and a sequence of axis-aligned cubes in $\mathbb{R}^3$.

Our results provide further evidence that there may exist $O(\log n)$-competitive algorithms for the *Online Hitting Set* problem for n points in $\mathbb{R}^d$ and any sequence of objects $\mathcal{C}$ of bounded VC-dimension – an open problem raised by Even and Smorodinsky [12]; see also [14]. This problem remains open: The current best lower and upper bounds are $\Omega(\log n)$ and $O(\log^2 n)$ [2]. No better bounds are known even in some of the most common geometric range spaces, for example, when P is a subset of the grid $[0, n)^2 \cap \mathbb{Z}^2$ and $\mathcal{C}$ is a sequence of axis-aligned rectangles in the plane; or when P is a set of n points in the plane, and $\mathcal{C}$ is a sequence of disks of arbitrary radii.

Abstract

Quantum k-minimum finding is a fundamental subroutine with numerous applications in combinatorial problems and machine learning. Previous approaches typically assume oracle access to exact function values, making it challenging to integrate this subroutine with other quantum algorithms. In this paper, we propose an (almost) optimal quantum k-minimum finding algorithm that works with approximate values for all $k \geq 1$, extending a result of van Apeldoorn, Gilyén, Gribling, and de Wolf (FOCS 2017) for $k = 1$. As practical applications, we present efficient quantum algorithms for identifying the k smallest expectation values among multiple observables and for determining the k lowest ground state energies of a Hamiltonian with a known eigenbasis.

1 Introduction

Quantum minimum finding was initially proposed in [14], with a direct but clever use of Grover search [19]. They showed that given quantum query access to n unordered elements (with exact values), one can find the smallest one with an optimal quantum query complexity $\Theta(\sqrt{n})$, which quadratically outperforms any classical algorithms. As a generalization, quantum k-minimum finding was later developed in [13], which finds the k smallest elements from n elements with an optimal quantum query complexity $\Theta(\sqrt{nk})$. Quantum k-minimum finding for exact values turns out to have various applications in different fields, e.g., minimum spanning tree and strong connectivity in graph theory [13], clustering [3, 27] and k-nearest neighbor [43] in machine learning (see also [37, 7]), and pattern matching [34] and other string problems [42, 4, 24] in stringology.

The traditional quantum (k-)minimum finding works when the elements are comparable by their exact values. However, it does not apply to the numerical case, where the values of the elements can be computed by (stochastic) numerical methods. Notably, this case often appears in practice, especially when the values of the elements are estimated by quantum subroutines such as quantum phase estimation [25, 31] and amplitude estimation [9]. A typical example is the quantum SDP (semi-definite program) solver proposed in [40, 8, 39], where the ground energy of a Hamiltonian is found by a quantum minimum finding over approximate quantum phases. To facilitate the discussion of the numerical scenarios and the composability of quantum k-minimum finding, we introduce an abstract type of quantum oracle for numerical inputs, called *approximate oracle*. In an approximate oracle, each query returns a *superposition* of approximate values of the queried element to high precision and with high success probability (see Definition 5 for the formal definition). This is a very general definition which meets the requirement for all known situations where quantum k-minimum finding is used as a subroutine. A key question is then

How to solve quantum k-minimum finding problem with an approximate oracle?

This question is not only of theoretical interest, but also holds significant practical value. The solution turns out to be more subtle as one may initially expect. To address this problem clearly, we propose two (weak and strong) definitions of approximate minimum index sets as characterizations of the required output in k-minimum finding algorithms, naturally generalizing the requirement of the approximate minimum finding problem. We give almost optimal quantum algorithms for computing these sets with $\widetilde{O}(\sqrt{nk})$ queries to the approximate oracle. Finally, we showcase two applications of our algorithms: identifying the k smallest expectation values and determining the k lowest ground state energies of a Hamiltonian.

1.1 Approximate Oracles and Approximate Minimum Index Sets

Before presenting our main results, we define the concept of approximate oracle, explain why the standard algorithm for quantum k-minimum finding fail in this case, and define the concept of approximate minimum index set as an appropriate output.

1.1.1 Approximate Oracles

In the standard setting of quantum (k-)minimum finding (see [14, 13]), an *exact oracle* for the input data is assumed, which always returns the *exact function value* for each query. The assumption of an exact oracle is reasonable in the case where the input data is previously known or is produced by deterministic algorithms. However, it fails to describe the situation where the input data is generated by randomized or quantum numerical algorithms.

Generally speaking, for a randomized numerical algorithm that estimates a real number x, its output is a random variable X, such that the distance between X and x is no more than ε with probability at least $1-\delta$. We will call ε the precision parameter and δ the error parameter from now on. If the values are estimated using quantum algorithms, a general situation is that the estimated values are stored in a quantum state in superposition. Hence, it is natural to consider the following definition of *approximate oracles*. An (ε, δ)-approximate oracle for the input x_i's is a quantum unitary operator that with probability at least $1-\delta$, outputs a quantum state which is a *superposition* of estimated values for x_i within ε distance upon querying i. The formal definition of approximate oracle can be found in Definition 5. This input model works well with two widely-used quantum procedures for quantum numerical computations, namely phase estimation and amplitude estimation.

There are other input unitary oracle models, such as the bounded-error oracle [21, 42], and untrustworthy oracle [32]. We summarize their properties in the following table, with a detailed discussion in Section 3.1.

Table 1 Different Unitary Oracle Models for Minimum Finding.

	Allows Error	Considers Precision	Complexity of Min Finding
Exact oracle [13]	×	×	$O(\sqrt{n})$
Bounded-error oracle [42]	✓	×	$\widetilde{O}(\sqrt{n})$
Untrustworthy oracle [32]	✓	✓	$\widetilde{O}(\sqrt{n(1+\Delta)})^a$
Approximate oracle	✓	✓	$\widetilde{O}(\sqrt{n})$

[a] Δ is the upper bound on the number of elements within any interval of unit length.

1.1.2 Approximate Minimum Index Set

When discussing the k-minimum finding problem, it is important to define what conditions of the output, which we call the approximate minimum index set, need to satisfy. For reason to be clear later, we will consider both the weak and strong approximate minimum index sets.

As a warm-up, let us consider what we can learn from the randomized numerical algorithms. Suppose that there are n elements $x_1, x_2, \ldots, x_n$, and for each $j \in [n]$, a random result X_j is generated by a randomized numerical algorithm, that is ε-close to the actual value x_j with probability at least $1 - \delta$. With this as the input oracle, it may be impossible for us to find out the k smallest elements in extreme cases, for example, when all elements are ε-close to each other. As a compromise, we seek an approximate solution instead.

For the minimum finding problem, the authors of [40] implicitly gave a characterization of the *approximate minimum index*, namely an index j whose value x_j is ε-close to the true minimum value. This characterization, however, could be interpreted and generalized in various different ways when k-minimum finding is considered.

Weak Approximate Minimum Index Set. One way to understand the approximate minimum index is that the solution we find are *entry-wise* ε-close to the ideal solution. Generalizing this idea to the k-minimum case, we propose the definition of the *weak approximate minimum index set*, which requires the approximate solution to be entry-wise ε-close to the k minima (see Definition 11 for a formal definition).

Strong Approximate Minimum Index Set. The other way to interpret the approximate minimum is to regard it as an ε-approximate version of a *global* condition. To be more precise, the minimum has the property that it is no more than all other elements; and the approximate minimum index requires this condition to hold within at most ε-error. Generalizing this idea to the k-minimum case, we propose the definition of the *strong approximate minimum index set*, which requires the approximate solution to be bounded by the other values whose indices are not in the set within at most ε-error (see Definition 13 for a formal definition).

Relationships between the two definitions. To the best of our knowledge, neither of the above definitions has been proposed for $k \geq 2$, and their relationships are not well understood before. Although the above definitions are equivalent for $k = 1$, this equivalence does not

hold for larger k anymore. In the paper, we show that a strong approximate minimum index set must be a weak one, but not vice versa (see Section 4 for more details). We also note that, in certain scenarios, a strong (k, ε)-approximate minimum index set is needed and a weak one does not suffice (see Remark 2 for more details).

1.2 Main Results

Given an approximate oracle as an input, we design *almost optimal* quantum algorithms for k-minimum finding, based on the concepts of weak and strong approximate minimum index sets.

▶ **Theorem 1** (Quantum Approximate k-minimum Finding, informal version of Theorem 17 and Theorem 18). *Suppose V is an (ε, δ)-approximate oracle for a vector $v \in \mathbb{R}^n$, where $\delta > 0$ is sufficiently small, and suppose k is the desired number of minimal indices.*

- *Weak Approximate Minimum Index Set Finding: There is a quantum algorithm that, with high probability, outputs a weak $(k, 2\varepsilon)$-approximate minimum index set S for v, using $\widetilde{O}(\sqrt{nk})$ queries to V.*
- *Strong Approximate Minimum Index Set Finding: There is a quantum algorithm that, with high probability, outputs a strong $(k, 7\varepsilon)$-approximate minimum index set S for v, using $\widetilde{O}(\sqrt{nk})$ queries to V.*

Actually, a weak approximate minimum index set is not necessarily a strong one (see Example 15). This is because the weak approximate minimum index set focuses on entry-wise approximation while the strong one considers the global property that small values should not be ignored. The need of strong approximate minimum index sets exists in quantum machine learning. For example, in [15], a strong approximate minimum index set is required; in case the approximate minimum index set is weak, their key intermediate conclusion [15, Proposition D.12] no longer holds. Due to the well-known $\Omega(\sqrt{nk})$ bound of quantum k-minimum finding [13], and the exact oracle being a special case of the approximate oracle, our algorithms for approximate k-minimum finding achieves almost optimal query complexity for this problem.

The assumption that δ needs to be sufficiently small is not critical in applications. In fact, by applying the median trick to the approximate oracle, similar to techniques used in phase estimation and amplitude estimation [30], the failure probability could be reduced with an extra logarithmic overhead if it is smaller than $1/3$.

1.3 Techniques

The algorithm for finding a weak minimum index set serves as the basis of the algorithm for finding a strong index set, although the techniques used in designing these algorithms are quite different. We now present the techniques for both algorithms separately.

To design a quantum algorithm for finding the weak approximate minimum index set, we first observe an important property of the weak approximate minimum index set which we call *error-tolerant incrementability* (Proposition 12). This property allows us to add an "approximately" $(k+1)$ smallest entry to a weak (k, ε)-approximate minimum index set and form a weak $(k+1, \varepsilon)$-approximate minimum index set. It serves as the key property in demonstrating weak approximate minimum index set finding (see the full version, specially [16, Theorem A.1]), and enables us to solve the weak k-minimum finding problem by repeatedly applying the quantum approximate minimum finding with an approximate oracle [40, 11]. We can therefore mimic the way how the quantum k-minimum finding [13] can be solved using

original quantum minimum finding [14]. To be more concrete, our algorithm (Algorithm 1) works as follows: in the j-th iteration of the k runs, the algorithm finds an element not selected yet with value (approximately) no greater than the $(k-j+1)$-th element. While this approach may seem adaptable to more general cases, it turns out that it can only return a *weak* approximate minimum index set, since strong approximate minimum index sets do not exhibit the error-tolerant incrementability property.

Nevertheless, we still manage to design a quantum algorithm for finding a strong approximate minimum index set with several additional new ideas. The key insight is that the algorithm for finding a weak approximate minimum index set could be used to estimate the value of the k-th smallest element approximately. Thus, we could set a threshold u which is slightly smaller than the value of the k-th smallest element. The threshold u can be understood as a filter, capturing small elements that must not be ignored. Having obtained the threshold u, we focus on all estimates with value lower than u (including those estimates whose corresponding elements are larger than u), and then sample (at most) $\widetilde{O}(k)$ indices. From these, we can find k indices that form a *strong* approximate minimum index set.

More specifically, we begin with a quantum state $|\Phi\rangle = \frac{1}{\sqrt{n}}\sum_{j=1}^{n}|j\rangle|\Lambda_j\rangle$, where $|\Lambda_j\rangle = \sum_\nu \alpha_{j,\nu}|\nu\rangle$ is a superposition of all possible estimates of the j-th element. If we focus on the register containing the estimate values ν, then we can write $|\Phi\rangle = \sum_\nu |S_\nu\rangle|\nu\rangle$, where $|S_\nu\rangle$ is a superposition of indices. If we now condition on whether ν is lower than the threshold u, the quantum state can be written as $|\Phi\rangle = |\Phi_{\le u}\rangle + |\Phi_{>u}\rangle$, where $|\Phi_{\le u}\rangle = \sum_{\nu\le u}|S_\nu\rangle|\nu\rangle$. By quantum amplitude amplification [9], we can sample one index from $|\Phi_{\le u}\rangle$ by using $O(1/\||\Phi_{\le u}\rangle\|)$ queries to the unitary oracle that prepares $|\Phi\rangle$. Using an argument similar to the coupon collector's problem, we prove that sampling sufficiently many (precisely, $\Theta(n\||\Phi_{\le u}\rangle\|^2)$) times will collect all the "small" elements with high probability. Finally, we use simple post-processing to find a strong approximate minimum index set (see Section 6 for more details).

1.4 Applications

Our algorithms for finding approximate minimum index sets can be applied to several practical scenarios, some of which are formally discussed in Section 7.

Approximate k minima in multiple expectations. Given purified access to n quantum states $\{\rho_j\}_{j=1}^n$, and block-encoding access (see Definition 4) to n observables $\{O_j\}_{j=1}^n$, the task is to approximately find the k minimal values among expectations $\mathrm{tr}(O_j\rho_j)$. The expectation $\mathrm{tr}(O\rho)$ of an observable O with respect to a quantum state ρ can be estimated, for example, by the Hadamard test [2] or quantum measurements. The problem has been considered in the literature in various situations where, in most of the cases, the same quantum state are used for different observables. These include quantum SDP solvers [8, 40, 39], shadow tomography [22, 1, 10] and multiple expectation estimation [23]. By our quantum approximate k-minimum finding with amplitude estimation, we can find an ε-approximate of the k minimal expectations in $\widetilde{O}(\sqrt{nk}/\varepsilon)$ time.

Approximate k ground state energies. Given block-encoding access to a Hamiltonian with the known eigenbasis, our algorithm can be used to find an ε-approximate of the k ground state energies in $\widetilde{O}(\sqrt{nk}/\varepsilon)$ time, which could be seen as a generalization of the approximate ground state energy finding [40].

In the special case when the Hamiltonian is diagonal (i.e., with the computational basis as its eigenbasis), our quantum algorithm for approximate k-minimum finding can be used in quantum multi-Gibbs sampling [15]. See Remark 2 for a more detailed discussion.

▶ Remark 2. For the special case where the approximate oracle is implemented by quantum amplitude estimation, a quantum k-minimum finding was claimed in [15]. However, an error in their Theorem C.3 was found due to their incorrect error-reduction of consistent quantum amplitude estimation. Nevertheless, using our quantum *strong* approximate k-minimum finding with an approximate oracle, we can fill the gaps in their proof, and their result still holds.

2 Preliminaries

2.1 Notations

For $n \in \mathbb{Z}_+$, we use $[n]$ to denote the set $\{1, 2, \ldots, n\}$, and we set $[0] = \emptyset$ for convenience. $\mathbb{R}^n_{\geq 0}$ stands for the set of n-dimensional vectors with non-negative entries. For sets A and B, we use $A - B$ to denote the set consisting of the elements in A but not in B. We assume the readers are familiar with the basic knowledge of quantum computing (see [31] for a reference). In this paper, when discussing the query complexity of U, we assume having query access to U, $U^\dagger$ and their controlled versions.

2.2 Concepts in Quantum Computing

We use a quantum data structure called QSet to store the found indices in our algorithm. The functionality of this data structure is characterized by the following proposition.[1]

▶ **Proposition 3.** *There is a quantum data structure* QSet *that supports the following operations.*

- *Initialization* QSet.Initialize(n)*: return an instance $\mathcal{S}$ of* QSet*, with a set S initialized to empty set which can store at most n elements.*
- *Add* S.Add(j) *for an $j \in [n]$: insert the element j into the set S.*
- *Hide* S.Hide()*: output a unitary satisfying* S.Hide()$|i\rangle|j\rangle = |i\rangle|2 \times \mathbf{1}_S(i) + j\rangle$ *for any computational basis $|j\rangle$, where $\mathbf{1}_S(\cdot)$ is the indicator function of the set S, i.e, $\mathbf{1}_S(i) = 1$ if $i \in S$, and $\mathbf{1}_S(i) = 0$ if $i \in [n] - S$.*

Block-encoding is a very useful concept in quantum algorithms proposed in [17], and we recall its definition as follows.

▶ **Definition 4** (Block-encoding [17, Definition 24])**.** *Let A be a linear operator acting on an s-qubit Hilbert space. For $\alpha, \varepsilon > 0$ and integer a, we say an $(a+s)$-qubit unitary operator U is an (α, a, ε)-block-encoding of A, if $\|A - \alpha\langle 0|^{\otimes a} U |0\rangle^{\otimes a}\| \leq \varepsilon$.*

When a and ε could be omitted (for instance, $a = O(1)$ and $\varepsilon = 0$, or the values of a and ε have shown up in previous context), we simply call U an α-block-encoding of A.

3 Approximate Oracle

▶ **Definition 5** (Approximate Oracle)**.** *Suppose $v = (v_1, \ldots, v_n) \in \mathbb{R}^n_{\geq 0}$ is an n-dimensional vector with $v_j \in [0, 1]$ for $j \in [n]$. For $\varepsilon \in [0, 1/2)$ and $\delta \in [0, 1/2)$, a unitary V is called an (ε, δ)-approximate oracle for v, if it satisfies $V|i\rangle|j\rangle = |i\rangle|\Lambda_i + j\rangle$ for all $i \in [n]$, where*

[1] If we allow the use of quantum(-read classical-write) random access memory (QRAM) (see [6] for a more detailed discussion), all these operations could be implemented efficiently (i.e., in $\widetilde{O}(1)$ one- and two-qubit gates and QRAM read and write operations).

$$|\Lambda_i + j\rangle = \sqrt{p_i^\varepsilon}|\Lambda_i^\varepsilon + j\rangle + \sqrt{1-p_i^\varepsilon}|\Lambda_i^{\varepsilon\perp} + j\rangle,$$

is a normalized state in a d-dimensional space, $|\Lambda_i^\varepsilon + j\rangle = \sum_{\nu:\,|\nu - v_i|\le\varepsilon} \alpha_\nu^{(i)}|\nu + j\rangle$, $|\Lambda_i^{\varepsilon\perp} + j\rangle$ *is the state orthogonal to* $|\Lambda_i^\varepsilon + j\rangle$*, and* $p_i^\varepsilon \ge 1 - \delta$ *for all* $i \in [n]$.[2]

▶ Remark 6. In simple words, the definition states that V is an (ε, δ)-approximate oracle for v, if for each $i \in [n]$, by querying i, with probability at least $1 - \delta$, V will return (a superposition) of estimated values in $[v_i - \varepsilon, v_i + \varepsilon]$. As an example, such a scenario shows up when the phase estimation procedure is used to estimate the values of v_i.

By using the median trick [30], we have the following proposition stating that the success probability of the approximate oracle can be efficiently amplified.

▶ **Proposition 7** (Failure probability reduction of the approximate oracle)**.** *Suppose* $v \in \mathbb{R}^n$ *is an* n*-dimensional vector and* V *is an* (ε, δ)*-approximate oracle for* v*, for some* $\varepsilon \in (0, 1/2)$ *and* $\delta \in (0, 1/3)$*. Then, for any* $\delta' \in (0, \delta)$*, one can construct an* (ε, δ')*-approximate oracle for* v*, using* $O(\log(\delta/\delta'))$ *queries to* V*.*

3.1 Comparisons of Different Oracles

In this part, we briefly investigate different input oracles considered in previous literature for the quantum minimum finding problem, namely the bounded-error oracle and the untrustworthy oracle.

Bounded-error Oracle. As the name suggests, bounded-error considers the case when only bounded-error access to the input is provided for computation tasks, such as quantum search [21] and quantum minimum finding [42]. This kind of oracle model could return the *correct exact answer* with bounded error (i.e., high probability), while the exact oracle returns the correct exact answer with certainty. Therefore, bounded-error oracle could be seen as a slight generalization of the exact oracle. Their computational powers are close, as the bounded-error oracle can simulate the exact oracle by majority voting with logarithmic repetitions.

Untrustworthy Oracle. The precision issue for the oracle model motivates researchers to consider another oracle model [32], which we call the untrustworthy oracle.[3] The untrustworthy oracle will return the correct comparison result between two elements if they are far away enough; and an unknown, possibly adversary (but deterministic) comparison result, if the distance between them is less than a fixed threshold ε. In this model, quantum minimum finding over n elements could be done in time $\widetilde{O}(\sqrt{n(1+\Delta)})$, where Δ is the upper bound on the number of elements within any interval of length ε. The result shows that, achieving quadratic speedup for the minimum finding in this model may pose strict requirements on the inputs.

[2] We also allow the case where V produces ancillary states, namely $V|i\rangle|j\rangle|0\rangle = |i\rangle|\Lambda_i + j\rangle|\psi_j\rangle$, which will not influence our proofs.

[3] The untrustworthy oracle is originally called "noisy oracle" in [32]. However, we renamed it according to its behavior, to avoid the conflict with the noisy oracle related to physical noises.

We note that our definition of approximate oracle includes exact oracle and bounded-error oracle as special cases. In fact, a bounded-error oracle with bounded-error δ is a $(0, \delta)$-approximate oracle by definition. The approximate oracle model is generally incomparable to the untrustworthy oracle, see Remark 8 for a detailed discussion.

▶ Remark 8. The untrustworthy oracle is incomparable with the approximate oracle. This can be seen from two perspectives. First, the latter cannot simulate the former, because the comparison between close elements by the approximate oracle is always in superposition. Second, the former reveals more information than the latter when comparing two elements x_1, x_2 with distance slightly above the threshold, say $|x_1 - x_2| = 1.1\varepsilon$. In this case, the former returns the correct comparison with certainty, while the latter may not be able to even distinguish the two elements (in extreme cases, the approximate values of the two elements x_1, x_2 can be the same, i.e. $(x_1 + x_2)/2$, with certainty).

There are other types of input oracles that are quantum channels due to imperfect implementations and noise; they were considered in the unstructured search problem in the literature, e.g., [38, 5, 26, 35, 20, 36]. In particular, in [35, 36], it was shown that no quadratic speedup exists in the presence of (constant-rate) depolarizing or dephasing noise after each application of the exact oracle. By contrast, the bounded-error, untrustworthy and approximate oracles are all unitary.

4 Approximate k-Minimum Index Set: Weak and Strong Definitions

The problem of finding the smallest element from a set of n numbers using an oracle that provides an approximate value has been a topic of interest in quantum computation studies, specifically quantum algorithms for optimization tasks [40, 11]. As discussed in Section 3, a natural setup where the values of vector v are prepared involves employing the amplitude estimation procedure with a limited precision parameter ε using V. Given the limitation of the estimation precision, it is reasonable to expect that we could only find an *approximate* minimum value that is $O(\varepsilon)$-close to the true minimum. We also observe that, instead of finding the approximate minimum value, it suffices to find the index of the approximate minimum value. Thus, motivated by prior results (Theorem 50 in [40] and Theorem 2.4 in [11]), we present the following notion of ε-approximate minimum index, which were implicit in those prior works.

▶ **Definition 9** (Approximate Minimum Index)**.** *Let $v = (v_1, v_2, \ldots, v_n) \in \mathbb{R}^n_{\geq 0}$ be an n-dimensional vector. Suppose the coordinates of v are sorted from small to large as*

$$v_{s_1} \leq v_{s_2} \leq v_{s_3} \leq \cdots \leq v_{s_n},$$

then, an ε-approximate minimum index for v is an index $i \in [n]$ satisfying $v_i \leq v_{s_1} + \varepsilon$.

▶ Remark 10. For some v and ε, there may exist multiple indices that are ε-approximate minimum indices of v. For instance, if $v = (1, 1, \ldots, 1) \in \mathbb{R}^n$, then, for any $\varepsilon > 0$ and any $j \in [n]$, j is an ε-approximate minimum index of v by definition.

In simple terms, i is an ε-approximate minimum index for v if $v_i \leq \min_{j\in[n]} v_j + \varepsilon$. Therefore, after identifying an ε-approximate minimum index i, one can use amplitude estimation to obtain an ε-approximate estimate of v_i, which is $O(\varepsilon)$-close to the actual minimum $\min_{j\in[n]} v_j$.

Interestingly, generalizing this concept for finding k smallest elements approximately is challenging. In this section, we introduce two definitions of the approximate k-minimum index set, extending the notion of approximate minimum index in two distinct ways. Furthermore, we explore the relationships between these definitions.

We first propose the definition of weak (k, ε)-approximate minimum index set, which requires that after sorting the elements in the set from small to large, they are entry-wise ε-close to the real minima.

▶ **Definition 11** (Weak Approximate Minimum Index Set). *Let $v = (v_1, v_2, \ldots, v_n) \in \mathbb{R}^n_{\geq 0}$ be an n-dimensional vector. Suppose the coordinates of v are sorted from small to large as $v_{s_1} \leq v_{s_2} \leq v_{s_3} \leq \cdots \leq v_{s_n}$. A set S of size k is called a* weak (k, ε)-approximate minimum index set *for v if there is an enumeration $i_1, i_2, \ldots, i_k$ of elements of S such that $v_{s_j} \leq v_{i_j} \leq v_{s_j} + \varepsilon$ for all $j \in [k]$.*

The following incrementability property plays a crucial role in finding weak approximate minimum index sets. Essentially, it states that from a weak (k, ε)-approximate minimum index set, we can add an index whose value is no more than the $(k+1)$-smallest value plus ε, yielding a weak $(k+1, \varepsilon)$-approximate minimum index set. This is also stated and proved in [16, Proposition A.2] in the full version.

▶ **Proposition 12** (Error-tolerant Incrementability). *Let $v \in \mathbb{R}^n_{\geq 0}$ be an n-dimensional vector, and its coordinates can be sorted as $v_{s_1} \leq v_{s_2} \leq \cdots \leq v_{s_n}$. Suppose S is a weak (k, ε)-approximate minimum index set for a positive integer $k \in [n-1]$ and a positive real ε. Let $a_{k+1} \in [n] - S$ be an index satisfying $v_{a_{k+1}} \leq v_{s_{k+1}} + \varepsilon$. Then, $S \cup \{a_{k+1}\}$ is a weak $(k+1, \varepsilon)$-approximate minimum index set for v.*

Next, we introduce a strong notion of approximate minimum index set, as the weaker version might not be adequate for certain applications. The definition builds upon the following characterization of a k-minimum index set: For a set $S \subseteq [n]$ of size k that constitutes a k-minimum index set, it holds that $v_j \geq v_i$ for every $i \in S$ and $j \in [n] - S$. In other words, the inequality $\max_{i \in S} v_i \leq v_j$ must be satisfied for every $j \in [n] - S$. If we relax these constraints to allow for an epsilon margin of error, we obtain the following definition.

▶ **Definition 13** (Strong Approximate Minimum Index Set). *Let $v = (v_1, v_2, \ldots, v_n) \in \mathbb{R}^n_{\geq 0}$ be an n-dimensional vector. Then, a set $S = \{i_1, i_2, \ldots, i_k\} \subseteq [n]$ of size k is called a* strong (k, ε)-approximate minimum index set *for v, if for all $j \in [n] - S$, we have $\max_{i \in S} v_i \leq v_j + \varepsilon$.*

As the name suggests, a strong (k, ε)-approximate minimum index set is also a weak (k, ε)-approximate minimum index set, and we formally state this proposition as follows, which is also stated and proved in [16, Proposition A.7] in the full version.

▶ **Proposition 14.** *For an n-dimensional vector $v \in \mathbb{R}^n_{\geq 0}$, let $S \subseteq [n]$ with size k be a strong (k, ε)-approximate minimum index set for v. Then, S is also a weak (k, ε)-approximate minimum index set for v.*

However, a weak (k, ε)-approximate minimum index set is not necessarily a strong one. In particular, the strong approximate minimum index set is not error-tolerant incrementable, which is shown in the following example.

▶ **Example 15** (No Error-Tolerant Incrementability for Strong Approximate Minimum Index Set). Consider a 5-dimensional vector $v = (0.1, 0.2, 0.3, 0.4, 0.5)$. Let $\varepsilon = 0.15$. By definition, $\{2\}$ is a strong $(1, \varepsilon)$-approximate minimum index set for v. Also, for the index 3, we know $v_3 = 0.3 \leq v_2 + \varepsilon$. Therefore, by definition, $\{2, 3\}$ is a weak $(2, \varepsilon)$-approximate minimum index set for v. However, since $0.3 > 0.1 + \varepsilon$, $\{2, 3\}$ is *not* a strong $(2, \varepsilon)$-approximate minimum index set for v.

This illustration could be extended to encompass arbitrary values of n and k, demonstrating that for any fixed constant $c \geq 1$, there exists a weak (k, ε)-approximate minimum index set that is not a strong $(k, c\varepsilon)$-approximate minimum index set.

5 Quantum Algorithms for Finding Weak Approximate Minimum Index Sets

In this section, we will develop an approximate version of k-minimum finding that enables us to find a weak (k, ε)-approximate minimum index set, given access to an *approximate oracle*. The technique of generalized minimum finding from [40] is an important subroutine in our algorithm, which could be stated as follows.

▶ **Theorem 16** (Generalized Minimum Finding, [40, Theorem 49]). *Let n be a positive integer, and $\delta \in (0, 1/3)$. Suppose U is an $n \times n$ unitary operator satisfying $U|0\rangle = \sum_{\ell=1}^{n} \sqrt{p_\ell}|\psi_\ell\rangle|x_\ell\rangle$, where $p_\ell \in [0, 1]$, $\sum_{\ell=1}^{n} p_\ell = 1$, $|\psi_\ell\rangle$ are normalized states, and $\{ x_\ell : \ell \in [n] \}$ are distinct real numbers satisfying $x_1 < x_2 < \cdots < x_n$. Let X denote a discrete random variable with $p_\ell = \Pr(X = x_\ell)$, and $M \in (0, 1]$ be a lower bound on the probability $\Pr(X \leq m)$ for some $m \in \mathbb{R}$. Then, there exists a quantum algorithm $\mathsf{FindMin}(U, M, \delta)$ that, with probability at least $1 - \delta$, outputs a state $|\psi_i\rangle|x_i\rangle$ where $x_i \leq m$, using $\widetilde{O}(1/\sqrt{M})$ queries to U.*

Using this theorem, we can establish the following result for finding a weak (k, ε)-approximate minimum index set, extending and generalizing the approximate minimum finding procedure proposed in [40]. To express the algorithm more compactly, let $\mathsf{Uniform}$ be a unitary such that $\mathsf{Uniform}|0\rangle = \frac{1}{\sqrt{n}} \sum_{j=1}^{n} |j\rangle$, which can be implemented by $\widetilde{O}(1)$ one- and two-qubit gates.

Algorithm 1 $\mathsf{FindApproxWeakMin}(V, k, \varepsilon, \delta)$.

Require: An n-dimensional unitary V, $k \in [n]$, $\varepsilon \in (0, 1/2)$, $\delta \in (0, 1)$, with V being an (ε, δ)-approximate oracle of an n-dimensional vector v.
Ensure: A weak (k, ε)-approximate minimum index set S for v.
1: $S \leftarrow \emptyset, \mathcal{S} \leftarrow \mathsf{QSet.Initialize}(n)$.
2: **for** $t = k, \ldots, 1$ **do**
3: $\quad |\psi_\nu\rangle|\nu\rangle \leftarrow \mathsf{FindMin}(\mathcal{S}.\mathsf{Hide}() \cdot V \cdot \mathsf{Uniform}, t/n, \delta/k)$.
4: $\quad$ Perform computational measurement on the state $|\psi_\nu\rangle$, let the result be w_t.
5: $\quad S \leftarrow S \cup \{w_t\}, \mathcal{S}.\mathsf{Add}(w_t)$.
6: **end for**
7: Return set S.

▶ **Theorem 17** (Approximate Weak Minimum Index Set Finding). *Suppose $v = (v_1, \ldots, v_n) \in \mathbb{R}^n_{\geq 0}$ is an n-dimensional vector with $v_j \in [0, 1]$ for $j \in [n]$. For $\varepsilon \in [0, 1/2)$ and $\delta \in [0, 1/2)$, let V be a d-dimensional (ε, δ)-approximate oracle for v, Then, there is a quantum algorithm $\mathsf{FindApproxWeakMin}(V, k, \varepsilon, \delta)$ that, with probability at least $1 - \delta - \widetilde{O}(nd\delta\sqrt{kd})$, outputs a weak $(k, O(\varepsilon))$-approximate minimum index set S for v, using $\widetilde{O}(\sqrt{nk})$ queries to V.*

The proof of this theorem is given in the full version (see [16, Theorem B.4]).

We further note that, the failure probability could be made to $1 - O(\delta)$ by introducing an extra logarithmic multiplicative term in query complexity as Proposition 7 suggests.

6 Quantum Algorithms for Finding Strong Approximate Minimum Index Set

In this section, we present a quantum algorithm, $\mathsf{FindApproxStrongMin}$, which returns a strong approximate minimum index set. This algorithm builds on the method used for finding a weak approximate minimum index set.

The core idea of our algorithm is to first employ the algorithm FindApproxWeakMin for an estimate v_g of the k-th smallest entry of v, and then repeatedly sample from an "amplified" approximate oracle which facilitates querying entries that are approximately less than $v_g - 5\varepsilon$. The algorithm, explicitly given in Algorithm 2 uses two key subroutines $\mathsf{QCount}(V, c, \delta)$ and $\mathsf{AmpSamp}(V, c, \delta)$ where V is an approximate oracle for the vector v, c is a positive number, and $\delta \in [0, 1/2]$. The goal of $\mathsf{QCount}(V, c, \delta)$ is to approximately estimate the amplitude of all indices whose estimated value is no more than c, while the goal of $\mathsf{AmpSamp}(V, c, \delta)$ is to perform amplitude amplification on this state to achieve constant success probability. The formal statements of these procedures can be found in the full version, particularly in [16, Proposition C.3, Proposition C.6].

To describe the algorithm concisely, we use $\mathsf{ApproxQuery}(V, i)$ to denote a single computational measurement result of the state $V|i\rangle|0\rangle$. For an index set $S \subseteq [n]$, $\mathsf{ApproxQuery}(V, S)$ represents the collection of computational measurement outcomes of $V|i\rangle|0\rangle$ for all $i \in S$.

Algorithm 2 $\mathsf{FindApproxStrongMin}(V, k, \varepsilon, \delta)$.

Require: An n-dimensional unitary V, $k \in [n]$, $\varepsilon \in (0, 1/2)$, $\delta, \delta_0 \in (0, 1)$, with V being an (ε, δ_0)-approximate oracle of an n-dimensional vector v.

Ensure: A set S of size k being a strong $(k, O(\varepsilon))$-approximate minimum index set for v.

1: $S_0 \leftarrow \mathsf{FindApproxWeakMin}(V, k, \varepsilon, \delta/10)$.
2: $v' \leftarrow \mathsf{ApproxQuery}(V, S_0)$.
3: $v_g \leftarrow \max_{i \in S_0} v'_i$.
4: $\ell \leftarrow \mathsf{QCount}(U, v_g - 5\varepsilon, \delta/10)$, $R \leftarrow \emptyset$.
5: **for** $t = 1, 2, \ldots, \Theta(\ell \log(k) \log(10/\delta))$ **do**
6: $\quad |\phi\rangle \leftarrow \mathsf{AmpSamp}(V, v_g - 5\varepsilon, \delta/5n\ell)$, measure the first register of the state $|\phi\rangle$ in computational basis, and add the result to the set R.
7: **end for**
8: $\widetilde{v} \leftarrow \mathsf{ApproxQuery}(V, R \cup S_0)$.
9: **return** the index set of the k smallest elements in $\{\, \widetilde{v}_i : i \in R \cup S_0 \,\}$.

The following theorem states the correctness and the time efficiency of this algorithm.

▶ **Theorem 18** (Approximate Strong Minimum Index Set Finding). *Suppose $v = (v_1, \ldots, v_n) \in \mathbb{R}^n_{\geq 0}$ is an n-dimensional vector with $v_j \in [0, 1]$ for $j \in [n]$. For $\varepsilon \in [0, 1/2)$, $\delta \in [0, 1/2)$, and $\delta_0 \in [0, 1/2)$, let V be a d-dimensional (ε, δ_0)-approximate oracle for v, Then, there is a quantum algorithm $\mathsf{FindApproxStrongMin}(V, k, \varepsilon, \delta)$ that, with probability at least $1 - \delta - \widetilde{O}(nd\delta_0\sqrt{kd})$, outputs a strong $(k, O(\varepsilon))$-approximate minimum index set S for v, using $\widetilde{O}(\sqrt{nk})$ queries to V.*

Due to the length limit, we leave a complete proof to Appendix C in [16] in the full version.

7 Applications

7.1 Approximate k-minimum Expectations

As an application of our quantum approximate k-minimum finding algorithms, we address the problem of finding approximate k minima in multiple expectations. This can be directly solved by combining our algorithms with quantum amplitude estimation. The formal statement of the problem is as follows.

▶ **Definition 19** (Approximate k-minimum Expectations). *For a positive integer n, let $\{\rho_i\}_{i=1}^n$ be a set of s-qubit density matrices, and $\{O_i\}_{i=1}^n$ be a set of s-qubit positive semi-definite observables with $\|O_i\| \leq 1$ for $i \in [n]$. Given the unitary U being the purified access to ρ_i, i.e., $U|i\rangle_A|0\rangle_B|0\rangle_C = |i\rangle_A|\rho_i\rangle_{BC}$, such that $\mathrm{tr}_C(|\rho_i\rangle\langle\rho_i|) = \rho_i$, and a unitary $V = \sum_{j\in[n]}|j\rangle\langle j| \otimes V_j$, where V_j is a 1-block-encoding of the observable O_j for each $j \in [n]$. The* approximate k-minimum expectations *problem requires to find a strong (k,ε)-approximate minimum index set for the vector v with coordinates $v_i = \mathrm{tr}(O_i\rho_i)$.*

By leveraging our algorithms for finding strong approximate minimum index sets alongside quantum expectation estimation algorithms, we present the following theorem, which effectively addresses the problem of finding approximate k-minimum expectations.

▶ **Theorem 20.** *For a positive integer n, let $\{\rho_i\}_{i=1}^n$ be a set of s-qubit density matrices with purified access U_ρ, and let $\{O_i\}_{i=1}^n$ be a set of s-qubit positive semi-definite observables with block-encoding access V where $\|O_i\| \leq 1$ for $i \in [n]$. Then, there is a quantum algorithm* FindApproxExpectationMin$(U_\rho, V, k, \varepsilon, \delta)$ *that, with probability at least $1-\delta$, finds a strong (k,ε)-approximate minimum index set for the vector v with coordinates $v_i = \mathrm{tr}(O_i\rho_i)$, using $\widetilde{O}(\sqrt{nk}/\varepsilon)$ queries to U_ρ and V.*

Proof. See [16, Theorem D.5] in the full version. ◀

7.2 Approximate k-ground Energy Problem

We now turn to the approximate k-ground state energy problem, a generalization of the task of approximating the ground state energy of a Hamiltonian. The formal definition of the problem is as follows.

▶ **Definition 21** (Approximate k-ground State Energy). *Let H be a Hamiltonian acting on n-dimensional Hilbert space satisfying $\|H\| \leq \beta$, with a spectral decomposition $H = \sum_{j=1}^n \lambda_j|\varphi_j\rangle\langle\varphi_j|$. Assume that the eigenvalues $\{\lambda_j\}_{j=1}^n$ of H can be sorted as $\lambda_{s_1} \leq \lambda_{s_2} \leq \cdots \leq \lambda_{s_n}$. Let a unitary U_{enc} be an 1-block encoding of H, and U_{basis} be a unitary satisfying $U_{\mathrm{basis}}|j\rangle|0\rangle = |j\rangle|\varphi_j\rangle$. For a positive integer k and a positive real number ε, the* approximate (k,ε)-ground state energy *problem is to find a strong (k,ε)-approximate minimum index set for the vector v with coordinates $v_i = \lambda_i$.*

By integrating our quantum algorithms for finding strong approximate minimum index sets with quantum phase estimation, we present the following theorem that effectively solves the problem of finding approximate k-ground state energy, as also stated and proved in [16, Theorem D.9] in the full version.

▶ **Theorem 22.** *For $k \in \mathbb{N}^+$ and $\varepsilon, \delta \in (0, 1/3)$, there is a quantum algorithm that, with probability at least $1-\delta$, solves the problem defined in Definition 21 using $\widetilde{O}(\beta\sqrt{nk}/\varepsilon)$ queries to U_{enc} and U_{basis}.*

▶ Remark 23. The algorithm described in Theorem 22 can be employed in the case when the Hamiltonian is diagonal (with respect to the computational basis, i.e., $U_{\mathrm{basis}}|j\rangle|0\rangle = |j\rangle|j\rangle$). This scenario aligns precisely with the particular case discussed in Line 2 of Algorithm 2 in [15]. We therefore address the issue noted in Remark 2.

8 Discussion

In this paper, we carefully examined quantum algorithms for k-minimum finding with access to approximate oracles for function values. We introduced two distinct notions of approximate minimum index sets. The weak notion is defined entry-wise and possesses an error-tolerant

incrementability property, which facilitates the design of efficient algorithms. However, this notion may be insufficient for certain applications. To address this, we introduced a stronger notion of approximate minimum index sets and developed algorithms by combining the weak k-minimum finding algorithm with a coupon collector argument. We also discussed two potential applications related to the expectations of observables and the ground energy of Hamiltonians. Several intriguing open problems remain as a result of our work.

- The query complexity of the approximate minimum index set finding problem is not optimal yet. Is it possible to remove the extra logarithmic factors from the query complexity in Theorem 1?
- Can we approximate the k ground state energies of a Hamiltonian without knowing its eigenbasis?
- Can we find more types of input oracles for the minimum finding problem which are reasonable abstractions of practical scenarios? Is it possible to design algorithms for minimum finding using these oracles with optimal query complexity?
- Can we find more applications of quantum approximate k-minimum finding? We believe that our quantum algorithms in Theorem 1 could be applicable in other scenarios.

Abstract

One of the classic problems in online decision-making is the *secretary problem*, where the goal is to hire the best secretary out of n rankable applicants or, in a natural extension, to maximize the probability of selecting the largest number from a sequence arriving in random order. Many works have considered generalizations of this problem where one can accept multiple values subject to a combinatorial constraint. The seminal work of Babaioff, Immorlica, Kempe, and Kleinberg (SODA'07, JACM'18) proposed the *matroid secretary conjecture*, suggesting that there exists an $O(1)$-competitive algorithm for the matroid constraint, and many works since have attempted to obtain algorithms for both general matroids and specific classes of matroids. The ultimate goal of these results is to obtain an e-competitive algorithm, and the *strong matroid secretary conjecture* states that this is possible for general matroids.

One of the most important classes of matroids is the *graphic matroid*, where a set of edges in a graph is deemed independent if it contains no cycle. Given the rich combinatorial structure of graphs, obtaining algorithms for these matroids is often seen as a good first step towards solving the problem for general matroids. For matroid secretary, Babaioff et al. (SODA'07, JACM'18) first studied graphic matroid case and obtained a 16-competitive algorithm. Subsequent works have improved the competitive ratio, most recently to 4 by Soto, Turkieltaub, and Verdugo (SODA'18).

In this paper, we break the 4-competitive barrier for the problem, obtaining a new algorithm with a competitive ratio of 3.95. For the special case of simple graphs (i.e., graphs that do not contain parallel edges) we further improve this to 3.77. Intuitively, solving the problem for simple graphs is easier as they do not contain cycles of length two. A natural question that arises is whether we can obtain a ratio arbitrarily close to e by assuming the graph has a large enough girth.

We answer this question affirmatively, proving that one can obtain a competitive ratio arbitrarily close to e even for constant values of girth, providing further evidence for the strong matroid secretary conjecture. We further show that this bound is tight: for any constant g, one cannot obtain a competitive ratio better than e even if we assume that the input graph has girth at least g. To our knowledge, such a bound was not previously known even for simple graphs.

1 Introduction

In the past two decades there has been a renewed interest in online item selection problems where a sequence of items arrive one by one, revealing their *weight*, and a decision maker needs to irrevocably decide whether or not to accept each item as it arrives. The goal is to maximize the total accepted weight, subject to a feasibility constraint on the chosen items. An algorithm's performance is typically measured by its *competitive ratio*, which compares the algorithm's total weight with the offline optimum – the total weight achievable if all item weights were known in advance. These problems are appealing both from a mathematical perspective, as they are concise models for online decision making, and from an economical perspective, as they have close connection to pricing and auction theory [30, 29, 8, 12].

In the absence of any information about future items, the problem is essentially hopeless as any single item could be significantly heavier than all others, and the decision maker has no way of deciding which it is. As such, most works make distributional assumptions on either the weight of the arriving items, or their arrival order. The former class of problems are generally referred to as *prophet inequalities* while the latter are known as *secretary problems*. Numerous works have studied secretary problems for a large class of combinatorial constraints [38, 19, 34, 33, 20, 44, 46, 23, 31] and objective functions [10, 25], and considered close variants of these problems such as the prophet-secretary problem [22].

Perhaps the most important open question in the area of online decision making is the *matroid secretary problem* posed by the seminal work of Babaioff, Immorlica, Kempe, and Kleinberg (SODA'07,JACM'18) [8, 7]. In the matroid secretary problem, items arrive in a random order, and each item corresponds to an element in a matroid $M = (E, I)$,where E is the set of elements and I is the collection of independent sets in matroid M. Upon arrival, the weight of each item is revealed, and the decision maker must immediately decide whether to accept or reject it. The goal is to maximize the total weight of accepted items, with the constraint that the selected items form an independent set in the matroid. The matroid secretary conjecture [8, 7] states that there exists a constant-competitive ratio algorithm for this problem, and the *strong matroid secretary conjecture* (e.g., see [46]) states that there exists an e-competitive algorithm. Many works have studied the problem for both general matroids and specific cases.

In this paper, we focus on the specific case of graphic matroids. In this case, the arriving items correspond to the edges of a graph and the goal is to accept a set of edges that do not contain a cycle. Solving problems for graphic matroids is often viewed as a promising first step toward addressing arbitrary matroids, as graphs possess rich combinatorial structures and graphic matroids, along with linear matroids, are among the most intuitive examples of non-trivial matroids. Many counterexamples for candidate matroid secretary algorithms are, in fact, graphic matroids [8, 9]. It is common to illustrate the main ideas behind general algorithms by showing their behavior on this specific case [47]. Recent work has also explored whether techniques for graphic matroids can be extended to general matroids [1].

The seminal paper of Babaioff et al. originally studied the graphic matroid secretary problem, obtaining a 16-competitive algorithm for the problem. Babaioff et. al. [6] designed a $3e$-competitive algorithm. The competitive ratio was later improved to $2e$ by Korula and Pal [38] and later to 4 by Soto, Turkieltaub, and Verdugo [46]. Whether or not the ratio can be improved has been open at least since 2018.[1]

1.1 Our results and techniques

In this paper we obtain an algorithm with competitive ratio 3.95 for the problem, breaking the 4-competitive barrier. We further improve this result for the specific case of *simple graphs*, i.e., graphs that do not have parallel edges. Intuitively, simple graphs represent an easier special case as they don't have any cycles of length 2; since the algorithm is forbidden from accepting edges that form a cycle, the lack of 2-cycles gives the algorithm more freedom to accept edges. Our main result is the following theorem.

▶ **Theorem 1.** *There exists a* 3.95*-competitive algorithm for the graphic matroid secretary problem. Furthermore, if the input graph is assumed to be simple, there exists an algorithm with competitive ratio* 3.77*.*

The basic approach for this result is to, at each step, compute a set of outgoing edges such that each node has exactly one outgoing edge. More exactly, at each step we compute a maximum spanning forest, then direct the edges in this forest toward an arbitrary root; each node then has a unique outgoing edge. We then argue that if the algorithm only accepts an edge for whose endpoints it has not previously accepted an outgoing edge, then the algorithm's set of taken edges will always be independent.

Given this, the key aspect of Algorithm 1 that allows it to obtain an improved competitive ratio is a slightly stronger condition used to determine whether an edge is taken. Specifically, while for one endpoint we only demand that we have not taken an outgoing edge, for the other endpoint we demand that we have not even seen an outgoing edge. We can then show an increased probability for the former condition being satisfied for a currently considered edge by using the fact that the latter condition may not be satisfied by a previously seen outgoing edge, causing said edge to not be taken. Algorithm 1 furthermore makes use of random choice in determining which endpoint to apply the stronger condition to, which is crucial for handling the case of duplicate edges. When the input graph is guaranteed to be simple, this random choice is unnecessary – removing this random choice gives our algorithm for simple graphs (see the full version of the paper) which allows us to obtain an even lower competitive ratio.

Motivated by the improvement for simple graphs, we additionally study, for the first time, the landscape of the graphic matroid secretary problem for graphs of high *girth*, where we recall that the girth of a graph is the length of its shortest cycle. We note that the fact that a graph is simple follows from the assumption that girth is at least 3. We show that when the graph has large (but constant) girth, one can obtain a competitive ratio arbitrarily close to e. Formally, we prove the following theorem.

▶ **Theorem 2.** *For any graph G with girth at least g, there exists an $(e + o_g(1))$-competitive algorithm.*

[1] This paper was previously submitted to STOC'25 on November 4, 2024. Independently of our work, on November 18, 2024, Bérczi et al. [11] posted a preprint on arXiv, obtaining a 3.99-competitive algorithm and a 3.71-competitive algorithm for general graphs and simple graphs, respectively.

The result builds on yet another property of the combinatorial structure of the set of outgoing edges introduced in the proof of Theorem 1. We first observe that the fact that every vertex has at most one outgoing edge implies that, in a graph induced by the outgoing edges, each edge belongs to at most one cycle. On the other hand, we prove that if Algorithm 1 were to accept outgoing edges without respecting the graphic matroid independence condition, it would yield a higher acceptance probability of $\frac{1}{e}$ for an edge from the maximum independent set. These observations lead to a natural approach: accepting an outgoing edge only with a certain probability such that, for every cycle of length g, the probabilities of taking each edge of this cycle are equal. Intuitively, as the length of the shortest cycle increases, this probability tends towards $\frac{1}{e}$. We refer the reader to the full version of the paper for more details.

The best competitive ratios we attain over the three algorithms we introduce are listed in Table 1 for girths less than 10.

Table 1 The best competitive ratio we obtain for graphic matroid secretary when the input graph is restricted to have girth at least g for $g < 10$. $g = 2$ corresponds to multigraphs, while $g = 3$ corresponds to simple graphs. As g approaches infinity, the competitive ratio approaches e. See the full version of the paper for the algorithms for simple graphs and high girth graphs.

Girth (g)	Competitive Ratio	Algorithm
2	3.95	Algorithm 1
3	3.77	Simple graph algorithm
4	3.77	Simple graph algorithm
5	3.76	High girth algorithm
6	3.61	High girth algorithm
7	3.50	High girth algorithm
8	3.42	High girth algorithm
9	3.35	High girth algorithm

Perhaps more surprisingly, we show that this is tight: no algorithm can achieve a competitive ratio better than e, even for graphs with high girth. To our knowledge, this lower bound was not previously known even for simple graphs, and our techniques may be of independent interest for related online arrival problems.

▶ **Theorem 3.** *For any $g \in \mathbb{N}$, there does not exist an algorithm for the graphic matroid secretary problem on graphs of girth at least g that obtains competitive ratio less than e.*

The two results fully characterize the landscape of the secretary problem in the high-girth setting, essentially showing that the problem becomes as easy as the single secretary problem in the limit. To prove the lower bound in Theorem 3, we first show that weighted single secretary, also known as a cardinal secretary, is hard "on average" in the following sense. We demonstrate the existence of a finite distribution over the instances of this problem such that even if the adversary samples instances, as opposed to choosing them in a worst-case manner, from that distribution, it is still hard for any algorithm to choose the maximum weight element.

We then construct a high girth bipartite graph based on Ramanujan graphs, where vertices of one bipartition have same degree d. The hard distribution of instances of weighted single secretary of size d can now be sampled independently and embedded on the edges incident to each degree-d vertex on one side of the constructed bipartite graph. Given an algorithm that performs well on this graph, we obtain an algorithm performing well on the original distribution of weighted single secretary by simulating the first algorithm and mimicking the choices that it makes on a single degree-d vertex.

Our construction of the input graph in addition to high-girth Ramanujan graphs uses the probabilistic method. Our construction of the sets of hard weights is based on an extension of a similar argument from an infinite to a finite version of Ramsey theorem. We employ zero-sum games duality argument to show an existence of the final probabilistic distribution over the instances.

2 Related work

Many other derivations and specific cases of the general matroid secretary problem have been given attention over the years. Hajiaghayi, Kleinberg and Parkes [30] had first introduced the *multiple-choice value version* of the problem, aka the uniform matroid secretary problem, in which the goal is to maximize the expected sum of the at most k selected numbers. Kleinberg [36] later presented a tight $(1-O(\sqrt{1/k}))^{-1}$-competitive algorithm for the k uniform secretary resolving an open problem of [30]. Transversal matroids were first considered in [8] who gave $4d$-competitive algorithm, where d is the degree of the transversal matroid. This was improved by Dimitrov and Plaxton [19] who showed a ratio of 16 for all transversal matroids. The optimal ratio of e follows from the e-competitive algorithm for secretarial online weighted bipartite matching problem [35], which generalizes the problem on transversal matroids. For the laminar matroids, a long line of work led to $3\sqrt{3}e$ competitive ratio [32, 33, 41], which was improved to 9.6 in [41], $3\sqrt{3}$ in [46], 4.75 in [31], and 3.26 in [11]. The challenging general class of regular matroids was proven to admit $9e$-competitive algorithm [20].

Other generalizations of the secretary problem such as the submodular variant have been initially studied by the Bateni, Hajiaghayi, and ZadiMoghaddam [10] and Gupta, Roth, Schoenebeck, and Talwar [28]. The connection between the secretary problem and online auction mechanisms has been explored by Kesselheim et al. [34], who give a e-competitive solution to the online bipartite weighted matching problem.

The *prophet secretary* problem is another well-studied variant of the secretary problem, closely related to prophet inequalities. In the *prophet inequality* setting, introduced by Krengel and Sucheston [39, 40], we know the distributions of n arriving items and aim to maximize the ratio of the expectation of the selected item's value to the expectation of the sequence maximum, with a tight competitive ratio of 2. Research connecting prophet inequalities and online auctions, initiated by Hajiaghayi, Kleinberg, and Sandholm [29], led to follow-up studies such as Alaei, Hajiaghayi, and Liaghat's work [3] on the bipartite matching variant of prophet inequality, also achieving a competitive ratio of 2 [3]. Feldman et al. [24] expanded the problem to combinatorial auctions with multiple buyers, achieving the same bound through a posted pricing scheme, and Kleinberg and Weinberg [37] extended this result to matroids with a 2-competitive algorithm. A recent paper explores matroid structures that allow breaking the tight competitive ratio of 2 [4]. Contrary to results presented in this paper, they prove that in the general matroid setting, a high girth is not a sufficient condition while considering k-fold matroid unions suffices.

The prophet secretary model, introduced by Esfandiari, Hajiaghayi, Liaghat, and Monemizadeh [22], assumes a random arrival order and known item distributions. They designed an algorithm achieving a competitive factor of $(\frac{e}{e-1})$, which has proven challenging to improve. However, Azar et al. [5] and Correa et al. [16, 17] improved this bound to $(1-1/e+1/30)^{-1} \approx 1.502$. For the single-item i.i.d. case, Abolhasani et al. [2] achieved a 1.37-competitive ratio, later improved to 1.342 by Correa et al. [14]. Recently, Peng and Tang [43] achieved a 1.379-competitive algorithm for the *free order* case, however finding the tight competitive bound for the general prophet secretary problem remains open.

Last but not least, extensions beyond matroids for the secretary problem have also been studied. For example, Kleinberg and Weinberg [37] provided an $O(p)$-competitive algorithm for the intersection of p matroids, later generalized to polymatroids by Dütting and Kleinberg [21]. Rubinstein [44] and Rubinstein and Singla [45] considered prophet inequalities and secretary problems in arbitrary downward-closed set systems. For such settings, Babaioff et al. [8] proved a lower bound of $\Omega(\log n \log\log n)$, and further studies have explored combinatorial optimization applications [18, 26, 27, 42].

3 Preliminaries

Graph Notation

In this paper, we assume all graphs are undirected, weighted, and may contain multiple edges between the same pair of vertices. Specifically, a graph is defined as a triple $G = (V, E, w : E \to \mathbb{R})$, where V, with $|V| = n$, is the set of vertices; E, with $|E| = m$, is the multiset of edges; and w assigns weights to the edges. We assume graphs do not contain loops (i.e., edges connecting a vertex to itself[2]). Given any vertex $u \in V$, we denote the degree of u by $deg_G(u)$. A graph is called *simple* if there is at most one edge connecting any pair of vertices. For a graph G, we denote g as the *girth* of G, representing the length of its shortest cycle. In graphs with multiple edges, a cycle is defined as any multiset of edges $C = \{(a_1, b_1), \ldots, (a_k, b_k)\}$, for $k \geq 2$, such that $\forall_{1 \leq i \leq k-1}\, b_i = a_{i+1}$ and $b_k = a_1$. For an integer $g \geq 2$, let $\mathcal{G}_g$ denote the set of all graphs with girth at least g. We also denote $[n] = \{1, 2, \ldots, n\}$.

Matroids

A *matroid* $M = (E, I)$ is a combinatorial structure that generalizes independence. It consists of a finite set E and a collection I of independent subsets of E satisfying: (1) the empty set is independent, (2) any subset of an independent set is also independent, and (3) if one independent set is larger than another, an element from the larger set can extend the smaller one while preserving independence. These properties capture the concept of independence, making matroids useful for modeling optimization problems where we seek a maximum-weight or maximum-cardinality independent subset of elements.

A *graphic matroid* $\mathcal{M}(G)$ associated with a graph G has as its elements the edges in the multiset E, and defines independent sets as acyclic subsets of edges (i.e., subgraphs without cycles). The weight of an independent set is the sum of its edge weights.

Problems

Consider a graphic matroid $\mathcal{M}(G)$ associated with a *multigraph* $G = (V, E, w : E \to \mathbb{R})$. In the online secretary problem on graphic matroids, the elements of E are presented to the algorithm in a random order, chosen uniformly from all possible permutations of the multiset E. Elements arrive one at a time, effectively creating m time steps during the algorithm's execution. Upon the arrival of an element, the algorithm must decide whether to accept or reject it, with the constraint that an element can only be accepted if it forms an independent set with the already accepted elements. Decisions are irrevocable.

[2] As explained in the following paragraph, such edges are irrelevant in the context of graphic matroids.

The objective is to design an algorithm that maximizes the expected sum of the weights of the accepted elements, referred to as the algorithm's gain. For an algorithm ALG, we denote its (random) gain by ALG and its expected gain by $\mathbb{E}(ALG)$.

Let OPT denote an independent set with maximum weight in the matroid $\mathcal{M}(G)$. We say an algorithm ALG is α-*competitive* (or has an α competitive ratio, for some $\alpha \geq 1$) for a family of matroids if $\alpha \cdot \mathbb{E}(ALG) \geq W(OPT)$ for all matroids in that family, where $W(OPT)$ is the weight of OPT.

4 Improved bounds for graphic matroid secretary: proof of Theorem 1

In this section, we prove the following theorem, which contains the result from Theorem 1 for general graphs.

▶ **Theorem 4.** *There exists a* 3.95*-competitive algorithm for graphic matroid secretary.*

To prove the theorem, we present an algorithm that attains a competitive ratio less than 3.95 for the graphic matroid secretary problem, surpassing a result of Soto, Turkieltaub, and Verdugo [46] attaining a competitive ratio of 4 that previously stood for six years as the best result achieved for graphic matroid secretary; this algorithm is described in Section 4.1.

To prove Theorem 1 for simple graphs, we consider a slight modification of our algorithm. See the full version of the paper for details.

4.1 Improvement for general graphs

Algorithm 1 New algorithm for graphic matroid secretary.

Let E' be the first m' edges `// set of observed edges`
$A \leftarrow \emptyset$ `// set of accepted edges`
$\forall v \in V$: $seen_outgoing(v) \leftarrow False$
$\forall v \in V$: $taken_outgoing(v) \leftarrow False$
for $t \in \{ m'+1, \ldots, m \}$ **do**
  Let e_t be the edge arriving in time t
  Add e_t to E'
  $T_t^{\text{opt}} \leftarrow$ maximum weighted directed forest on $G[E']$
  $\forall v \in V : outgoing(v) \leftarrow$ the edge directed away from v in T_t^{opt} if it exists
  $\forall v \in V$ such that $outgoing(v) = null : outgoing(v) \leftarrow$ a unique edge in E' not in T_t^{opt}
  if $e_t \in T_t^{\text{opt}}$ **then**
    $e_t \leftarrow (u, v)$ `// where` e_t `is directed from` u `to` v `in` T_t^{opt}
    $(a, b) \leftarrow$ either (u, v) or (v, u) with equal probability
    if $seen_outgoing(a) = False$ *and* $taken_outgoing(b) = False$ **then**
      $taken_outgoing(u) \leftarrow True$
      add e_t to A
    end
  end
  if $outgoing(w) = e_t$ *for some* $w \in V$ **then**
    $seen_outgoing(w) \leftarrow True$
  end
end

The pseudocode of the algorithm is provided in Figure 1. The algorithm consists of two phases. During the first m' steps (where m' depends only on m), edges are only observed without being taken. In later steps, let e be the presented edge. The algorithm computes a maximum spanning forest T_t^{opt} of all edges seen so far. We assume the forest is rooted, where the root for each tree is chosen lexicographically for simplicity; how we choose the root does not affect the algorithm as long as it depends only on the set of the edges already seen and not their order. This forest is directed towards the root, so that every edge is directed and each node has at most one outgoing edge. We additionally compute an array of *outgoing* edges: for each node v, if v has an outgoing edge in T_t^{opt}, then that is its outgoing edge; if it does not, then we choose an arbitrary edge not already assigned to be the outgoing edge of another vertex [3] and declare that to be the outgoing edge from v. Note that said edge does not even have to have v as an endpoint. Also note that crucially, the choice of edges declared to be outgoing for the vertices that need it depends on the set of edges observed so far but not their order.

We only consider e if it is in T_t^{opt}. In this case, it points from some u to some v, and so is the outgoing edge for u. In order to take e, we randomly order u, v as a, b and impose the following constraints on e:

- No edge e' has been taken such that e' was the outgoing edge for b when e' was presented.
- No edge e' has appeared such that e' was the outgoing edge for a when e' was presented.

If e satisfies both constraints then it is taken. Otherwise, the algorithm still notes that e could have been selected for u.

The distinct constraints used for a, b are key – the stronger condition applied to endpoint a allows us to lower bound the probability that an edge is blocked from being taken, which can then be used to show an increased probability that the weaker condition for endpoint b is satisfied for an edge that we would like to be taken. The randomness in ordering u, v into a, b is also essential. To see why, consider the specific example of an edge $e_t \in OPT$ with endpoints u, v that is presented at step t, and consider some step $j < t$. Suppose that T_j^{opt} contains an edge e^u outgoing from u to a third node x and an edge e^v outgoing from v to a fourth node y. We would like to argue that in the case that either e^u or e^v is the edge e_j presented at step j, there is a possibility that some outgoing edge from x or y respectively had already been presented prior to step j, meaning that e^u or e^v could not have been taken.

This means that, for example, if e^u were the edge presented at step j, we would desire that, in the case of edge e_t, $b = u$, and in the case of edge $e_j = e^u$, $a = x$ (and so $b = u$), so that e^u could be blocked by an edge outgoing from x simply being presented, while e_t is then not blocked because e^u was not actually taken. This suggests that we could simply always take $b = u$ and $a = v$, applying the stronger condition to the endpoint which the edge is directed towards.

However, as in general graphs it is possible for multiple edge to have the same endpoints, it is possible that we in fact have $x = v$, in which case an edge outgoing from x would block e_t itself. This is illustrated in the top-left quadrant of Figure 1. Therefore, in order to guarantee an improvement, we crucially allow for the possibility that in the case of edge e_t, $b = v$, and in the case of edge $e_j = e^v$, $a = y$ – if e^u has the same endpoints as e_t, then e^v cannot as T_j^{opt} is a spanning tree, and so y will necessarily be distinct from u, meaning that there is a possibility for e^v to be blocked by an edge outgoing from y while still allowing e_t to be taken. This is illustrated in the bottom-left quadrant of Figure 1.

[3] Note that if m is too small (specifically, if $m' + 1 < n$) then there may not exist sufficiently many edges for this to be possible. However, if this is the case, we can simply mix in "dummy edges" that the algorithm can treat the same as real edges in order to cause $m' + 1$ to be at least n. The details of this mixing in are described in the proof of Theorem 4.

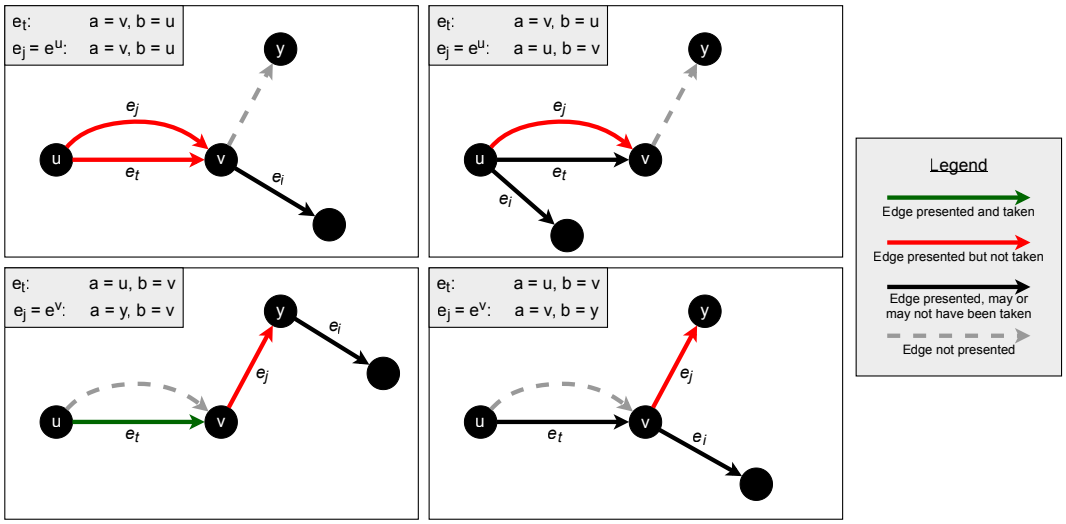

Figure 1 The described "worst-case" example for Algorithm 1. At step t, we are presented with an edge e_t in the optimum solution. e_t may be blocked from being taken due to an earlier step j. We suppose that the outgoing edge e^u from u in T_j^{opt} goes to v while the outgoing edge e^v from v in T_j^{opt} goes to a third vertex y; these are the only possible values of e_j with a potential to block e_t. All of e_t, e^u, e^v are depicted. Additionally depicted is an edge e_i outgoing from the endpoint of e_j selected as b – this edge being presented at step i would block e_j from being taken. Each of the four images depicts one equally likely possibility for the random choice of (a, b) in the case of e_t as well as in the case of e_j, where e_j is assumed to be the edge outgoing from b in T_j^{opt} (as this is the only case relevant for an increased probability arising from e_j not being taken). Only in one case is e_t guaranteed to be taken (assuming steps other than those depicted do not block e_t from being taken).

Analysis

We now proceed with a formal analysis. Due to space constraints, parts of the proof are deferred to the full version of the paper. We first show that any set of edges accepted by Algorithm 1 is independent, meaning that the algorithm is a valid graphic matroid secretary algorithm.

▶ **Lemma 5.** *The set A of accepted edges in Algorithm 1 is always an independent set in the graphic matroid.*

We now proceed to demonstrate that Algorithm 1 has the desired approximation factor for an appropriate choice of m'. We first define quantities f, g, h below that will be crucial for the analysis:

▶ **Definition 6.** *Define $f_{u,S}(i)$ to be the probability that after step i, seen_outgoing$(u) =$ False, given that S is the set of edges that are presented in steps $1, \ldots, i$.*

▶ **Definition 7.** *Define $g_{u,v,S}(i)$ to be the probability that after step i, both seen_outgoing$(u) =$ False and seen_outgoing$(v) =$ False, given that S is the set of edges that are presented in steps $1, \ldots, i$.*

▶ **Definition 8.** *Define $h_{u,v,S}(i)$ to be the probability that after step i, if we take (a, b) to be either (u, v) or (v, u) with equal probability, then seen_outgoing$(a) =$ False and taken_outgoing$(b) =$ False, given that S is the set of edges that are presented in steps $1, \ldots, i$.*

The condition used to define h is the same condition checked to see whether an edge between u and v can be taken.

A key tool for our analysis is the following. Note that for any node u, *seen_outgoing*(u) is set to $True$ when at some step j we observe an edge e such that e is in T_j^{opt} and is directed from u. Importantly, T_j^{opt} depends only on the set of edges presented up to step j and not their order. Therefore, conditioned on the set of edges that appears in steps $1, \ldots, j$, the probability that at step j we are presented with the outgoing edge from u is at most $\frac{1}{j}$ because there is exactly one such edge, and this edge, if it exists, is presented at step i with probability $\frac{1}{i}$.

The above idea is applied in the following lemma:

▶ **Lemma 9.** *For all vertices u, all i from m' to m, and all S with $|S| = i$, $f_{u,S}(i) = \frac{m'}{i}$.*

The next lemma uses the same idea to derive a similar expression for g:

▶ **Lemma 10.** *For all $u, v \in V$ and $i \in [m', m]$, and all S with $|S| = i$, $g_{u,v,S}(i) \geq \frac{m'(m'-1)}{i(i-1)}$.*

We now proceed to lower bound h; we again use the same idea but now additionally take advantage of the stronger condition applied to a in the algorithm to derive a bound for h superior to the one we derived for g by lower bounding the probability that an edge that would have been selected for one of u, v was not actually taken. As the lower bound for h is more complicated, we define its lower bound as an additional function h_δ.

▶ **Definition 11.** *Define $h_\delta(i)$ recursively by $h_\delta(m') = 1$ and $h_\delta(i) = (1 - \frac{2}{i})h_\delta(i-1) + \frac{\delta}{i} \cdot \frac{m'(m'-1)}{(i-1)(i-2)} \left[1 - \frac{m'}{i-1}\right]$.*

We parameterize h by δ as h will reused later with a different value of δ.

▶ **Lemma 12.** *For all vertices u, v, all i from m' to m, and all S with $|S| = i$, $h_{u,v,S}(i) \geq h_{\frac{1}{4}}(i)$.*

As mentioned before, the conditions defining $h_{u,v,S}(i)$ are identical to the conditions for taking an edge given that it is in T_i^{opt}. As any edge in the overall optimum is in T_i^{opt}, lower bounding the probability of such an edge being taken allows us to lower bound the overall approximation factor. This is expressed in the following lemma.

▶ **Lemma 13.** *Let $W(S)$ be the sum of the weights of edges in S, and recall that A is the set of edges accepted by Algorithm 1. Then,*

$$\frac{\mathbb{E}[W(A)]}{W(OPT)} \geq \frac{1}{m} \sum_{t=m'+1}^{m} h_{\frac{1}{4}}(t-1).$$

It now only remains to give a concrete lower bound for $\frac{1}{m}\sum_{t=m'+1}^{m} h_{\frac{1}{4}}(t-1)$. We proceed to derive such a bound in the following lemma.

▶ **Lemma 14.** *If we let $m' = \lfloor \alpha m \rfloor$, then*

$$\lim_{m\to\infty} \frac{1}{m} \sum_{i=m'+1}^{m} h_\delta(i-1) \geq \alpha - \alpha^2 + \delta\alpha^2 \ln \alpha + \frac{\delta}{2}\left(\alpha - \alpha^3\right).$$

Setting $\alpha = 0.4914$, we can show that the above lemma implies Theorem 4. We refer to the full version of the paper for the full proof.

5 Impossibility result for high girth graphs: proof of Theorem 3

In this section, we prove a hardness result for high-girth graphs. We begin by showing that the weighted single secretary problem remains hard even when the instance is drawn from a known distribution, using the Finite Ramsey Theorem and zero-sum game duality. We then reduce this to the weighted graphic matroid secretary problem on large-girth graphs via a construction based on Ramanujan graphs. Specifically, by carefully removing edges using the probabilistic method, we construct bipartite graphs with certain properties and embed hard instances of single secretary into them to obtain similarly hard graphic secretary instances. Due to space constraints, parts of the proofs are deferred to the full version of the paper.

We note that it is crucial that the hardness holds even when the distribution is known in advance, unlike deterministic instances that are only hard when the instance is hidden. This allows us to present multiple instances from the distribution without the algorithm gaining any advantage from earlier ones – since it already knows the distribution fully.

5.1 Hard inputs for single secretary

We first prove that no algorithm for the secretary problem can achieve a competitive ratio better than $1/e$, even if the weights are drawn from a known finite set.

▶ **Theorem 15.** *For any $\varepsilon > 0$ and for any $\rho > 1$, there exists an integer n and a finite set of numbers $W \subset \{1, \rho, \rho^2, \ldots\}$ over which no (randomized) algorithm for the single secretary problem with n items can choose the maximum with probability $\frac{1}{e} + \varepsilon$.*

See the full version of the paper for the proof. The result essentially serves as the starting point of our proof as it provides "hard instances" of the secretary problem which we then carefully embed in graphs of large girth. Correa et al. [15, 13] previously proved this theorem for infinite sets; our proof modifies their technique using the finite version of Ramsey's theorem.

While the generalization to finite sets may seem like a small technical issue, it has important consequences. As we will see, the finite assumption is necessary as it allows us to invoke the Minimax theorem for finite games. This in turn allows us to guarantee that there is a hard distribution over inputs, rather than just a single instance. As we will need to simultaneously embed multiple "independent" hard instances of the single secretary problem to obtain a hard instance of the graphical matroid secretary, this generalization is necessary.

We will now use the Minimax principle and Theorem 15 to prove the following.

▶ **Theorem 16.** *For any $\varepsilon > 0$ and for any $\rho > 1$, there exists an integer n, a finite set $W \subset \{1, \rho, \rho^2, \ldots\}$, and a finite distribution D over all subsets of size n from W with the following property. If a random instance of the secretary problem is drawn from D, for any algorithm, the probability of choosing the maximum element from the random instance is at most $\frac{1}{e} + \varepsilon$, where the probability is over the randomness of the instance and the algorithm.*

5.2 Embedding single secretary in simple graphs

This subsection presents the proof of Theorem 3. We first describe some preliminaries which are used in our analysis.

Preliminaries

It is straightforward to reduce the single secretary problem to the graphic matroid secretary problem when the graph allows for multiple edges. In that case, given the single secretary problem with n adversarial weights, we create a multi-graph with just two vertices u and v

and a set of n parallel edges between u and v, with each edge assigned exactly one of these n adversarial weights. Note, that this multi-graph has girth 2. We will need to work harder to reduce the single secretary problem to the graphic matroid problem on simple graphs, where we will even assume that the simple graph has an arbitrarily large girth.

For said reduction, we define below three different measures of performance of a secretarial algorithm. Given an algorithm $a \in \mathcal{A}$ and an instance I of the matroid secretary problem, we abuse the notation from the previous section and denote by $a(I)$ the set of elements of the matroid output by a on instance I. Let also $opt(I)$ be the optimal solution to the problem on the instance I. Given any subset X of the matroid's elements, we denote by $w(X)$ the sum of the weights of all elements in X.

Let Π be a matroid secretary problem on a matroid which has $n \in \mathbb{N}$ elements. Given a finite set of numbers (weights) $W \subset \mathbb{R}_+$, let D be a probability distribution over the set W^n. We will later on instantiate Π with the single secretary problem and with the graphic matroid secretary problem.

Let $a \in \mathcal{A}$ be a (randomized) algorithm for problem Π. Given an instance I of Π, let $S_a(I)$ be a random variable such that $S_a(I) = 1$ if a outputs the optimal solution on instance I, that is, when $a(I) = opt(I)$; and $S_a(I) = 0$ if $a(I) \neq opt(I)$. Then we have that $\mathbb{E}[S_a(I)] = \Pr[a(I) = opt(I)]$; note that the probability is over the internal randomness of algorithm a and over the randomness in the arrival order of the matroid elements.

For the convenience of this subsection, it will be useful to define an algorithm a as having a performance guarantee $\alpha \leq 1$ of

- type 1 if $\mathbb{E}_{I\sim D}[\mathbb{E}[S_a(I)]] \geq \alpha$.
  That is, the algorithm chooses the optimum with probability at least α in expectation over instances.
- type 2 if $\mathbb{E}_{I\sim D}[w(a(I))/w(opt(I))] \geq \alpha$.
  That is, the expected ratio of the algorithm's weight to the optimum's weight is at least α, where the expectation is over instances, algorithm randomness, and element order.
- type 3 if $\mathbb{E}_{I\sim D}[w(a(I))] \geq \mathbb{E}_{I\sim D}[w(opt(I))] \cdot \alpha$.
  That is, the algorithm's expected weight is at least an α fraction of the expected optimum weight. The first expectation includes all randomness; the second expectation is over instances only.

We next reformulate Theorem 16 in terms of the type 1 performance guarantee.

▶ **Theorem 17.** *For any $\epsilon > 0$, $\rho > 1$, there exists a finite distribution D of instances of weighted single secretary such that no algorithm's type 1 performance guarantee is $\geq \frac{1}{e} + \epsilon$. For any instance I of single secretary in the support of D, any two weights in I differ by at least a factor of ρ.*

We now extend the result of Theorem 17 to the type 2 performance guarantee. This proof will make use of the guarantee depending on ρ provided by Theorem 17 to bound the weight attained by an algorithm when it fails to select the maximum.

▶ **Lemma 18.** *For any $\epsilon > 0$, there exists a finite distribution D of instances of weighted single secretary such that no algorithm's type 2 performance guarantee is $\geq \frac{1}{e} + \epsilon$.*

The following lemma then shows an equivalence in hardness between the type 2 and type 3 performance guarantees. The idea of its proof is to reweight the distribution D by making the probability of each instance being chosen inversely proportional to its optimum weight.

▶ **Lemma 19.** *For any matroid secretary problem Π, there exists a bijection B between finite distributions over instances of Π such that if $D' = B(D)$, then there exists an algorithm with a type 2 performance guarantee of r on D iff there exists one with a type 3 performance guarantee of r on D'.*

We now move to the portion of the proof that extends the hardness of the single secretary problem to the graph setting. As part of this reduction, we first show the following lemma, demonstrating the existence of bipartite graphs of high girth with the key property that one part is both much larger than the other and has high degree. This construction proceeds by applying the probabilistic method to derive a graph with our desired properties by removing edges from a high-girth Ramanujan graph.

▶ **Lemma 20.** *For any $d, g, t \in \mathbb{N}$ with $d \geq 2$, $t \geq 4$, there exist $m, n \in \mathbb{N}$ such that $\frac{n}{m} \geq t$ and there exists a graph G' of girth at least g, whose vertices can be partitioned into sets A and B, such that $|A| = m$, $|B| = n$, all edges are between A and B, and each vertex in B has degree at least d.*

We now apply the graph provided by Lemma 20 to extend the hardness of a distribution of instances of the single secretary problem to hardness of matroid secretary on a high-girth graph. The proof, which is quite technical, is provided in the full version of the paper.

▶ **Lemma 21.** *If there exists a finite distribution D of instances of weighted single secretary such that no algorithm has a type 3 performance guarantee $\geq r$ on D, then for any $\epsilon > 0, g \in \mathbb{N}$ there exists a graph G with girth $\geq g$ and a finite distribution D_G of instances of weighted graph secretary on G such that no algorithm has a type 3 performance guarantee $\geq r + \epsilon$ on D'.*

Combining the above results, we obtain Theorem 3; see the full version of the paper for more details.

Abstract

The reduction of the fragment assembly problem to (variations of) the classical Eulerian trail problem [Pevzner et al., PNAS 2001] has led to remarkable progress in genome assembly. This reduction employs the notion of *de Bruijn graph* $G = (V, E)$ of order k over an alphabet Σ. A single Eulerian trail in G represents a *candidate* genome reconstruction. Bernardini et al. have also introduced the complementary idea in data privacy [ALENEX 2020] based on z-anonymity. Let S be a private string that we would like to release, preventing, however, its full reconstruction. For a privacy threshold $z > 0$, we compute the largest k for which there exist at least z Eulerian trails in the order-k de Bruijn graph of S, and release a string S' obtained via a random Eulerian trail.

The pressing question is: How hard is it to reconstruct a best string from a de Bruijn graph given a function that models domain knowledge? Such a function maps every length-k string to an *interval of positions* where it may occur in the reconstructed string. By the above reduction to de Bruijn graphs, the latter function translates into a function c mapping every edge to an interval where it may occur in an Eulerian trail. This gives rise to the following basic problem on graphs:

Given an instance (G, c), can we efficiently compute an Eulerian trail respecting c?

Hannenhalli et al. [CABIOS 1996] formalized this problem and showed that it is NP-complete. Ben-Dor et al. [J. Comput. Biol. 2002] showed that it is NP-complete, even on de Bruin graphs with $|\Sigma| = 4$. In this work, we settle the lower-bound side of this problem by showing that finding a c-respecting Eulerian trail in de Bruijn graphs over alphabets of size 2 is NP-complete.

We then shift our focus to *parametrization* aiming to capture the quality of our domain knowledge in the complexity. Ben-Dor et al. developed an algorithm to solve the problem on de Bruijn graphs in $\mathcal{O}(m \cdot w^{1.5}4^w)$ time, where $m = |E|$ and w is the *maximum interval length* over all edges in E. Bumpus and Meeks [Algorithmica 2023] later rediscovered the same algorithm on temporal graphs, which highlights the relevance of this problem in other contexts. Our central contribution is showing how combinatorial insights lead to *exponential-time* improvements over the state-of-the-art algorithm. In particular, for the important class of de Bruijn graphs, we develop an algorithm parametrized by $w(\log w + 1)/(k-1)$: for a de Bruijn graph of order k, it runs in $\mathcal{O}(mw \cdot 2^{\frac{w(\log w+1)}{k-1}})$ time. Our result improves on the state of the art by roughly an exponent of $(\log w + 1)/(k-1)$. The existing algorithms have a natural interpretation for string reconstruction: when for each length-k string, we know a small range of positions it must lie in, string reconstruction can be solved in linear time. Our improved algorithm shows that *it is enough when the range of positions is small relative to k.*

We then generalize both the existing and our novel FPT algorithm by allowing the cost at every position of an interval to vary. In this optimization version, our hardness result translates into inapproximability and the FPT algorithms work with a slight extension. Surprisingly, even in this more general setting, we extend the FPT algorithms to count and enumerate the min-cost Eulerian trails. The counting result has direct applications in the data privacy framework of Bernardini et al.

1 Introduction

One of the most important algorithmic tasks in bioinformatics is that of *genome assembly* (or *fragment assembly*) [30, 8, 23, 9]: the process of taking a large number of short DNA fragments and putting them back together to create a representation of the original chromosomes from which the DNA originated. The textbook reduction of the fragment assembly problem to (variations of) the classical Eulerian trail problem [26] has led to remarkable progress in the past three decades. This reduction is based on the notion of *de Bruijn graph* (dBG, in short).

Let $S = S[1] \dots S[|S|] = S[1 \,..\, |S|]$ be a *string* of length $|S|$ over an *alphabet* Σ. We fix a collection $\mathcal{S}$ of strings over Σ and define the *order-k de Bruijn graph* of $\mathcal{S}$ as a directed graph, denoted by $G_{\mathcal{S},k} = (V, E)$, where V is the set of length-$(k-1)$ substrings of the strings in $\mathcal{S}$ and E has an edge (u, v) if and only if $u[1] \cdot v = u \cdot v[k-1]$ and $u[1] \cdot v$ occurs in some string S of $\mathcal{S}$. In applications, we often consider a de Bruijn *multigraph* where the multiplicity of an edge is exactly the total number of these occurrences in the strings in $\mathcal{S}$. Then, a single Eulerian trail in $G_{\mathcal{S},k}$ represents a *candidate* string reconstruction [26]; see Figure 1.

Eulerian trails	String reconstructions
$e_1e_3e_6e_5e_2e_4e_7e_8$	0110011010
$e_1e_3e_7e_2e_4e_6e_5e_8$	0110110010
$e_1e_3e_7e_8e_6e_5e_2e_4$	0110100110
$e_8e_6e_5e_1e_3e_7e_2e_4$	0100110110
$e_8e_7e_1e_3e_6e_5e_2e_4$	0101100110
$e_1e_3e_6e_5e_8e_7e_2e_4$	0110010110

Figure 1 The de Bruijn multigraph $G_{\mathcal{S},k} = (V, E)$ (left), the set of node-distinct Eulerian trails from s to t (middle), and the corresponding set of string reconstructions (right) for the string collection $\mathcal{S} = \mathtt{001}, \mathtt{010}, \mathtt{011}, \mathtt{011}, \mathtt{100}, \mathtt{101}, \mathtt{110}, \mathtt{110}$, over the alphabet $\Sigma = \{\mathtt{0}, \mathtt{1}\}$, and $k = 3$.

Bernardini et al. have introduced the complementary idea in data privacy [4] based on the z-*anonymity* privacy property [27, 29]. Let S be a *private* string that we would like to release for data analysis, preventing, however, its full reconstruction. For a privacy threshold $z > 0$, we compute the largest k for which there exist at least z node-distinct Eulerian trails in the order-k dBG of $\mathcal{S} = \{S\}$, and release a string S' obtained via a random Eulerian trail. In Figure 1, we have 6 node-distinct Eulerian trails (and thus 6 distinct strings) corresponding to $\mathcal{S}$. Under the z-anonymity assumption, one cannot know which of the 6 strings is S unless they can rely on some additional information about S, such as on *domain knowledge*.

The pressing question arising from these applications is thus: How hard is it to reconstruct a best string from $G_{\mathcal{S},k}$ given a function modeling domain knowledge? This function maps every length-k string to an *interval of positions* where it may occur in the reconstructed string. By the above reduction, this translates into a function c mapping every edge to an interval where it may occur in an Eulerian trail, raising the following basic graph problem:

Given an instance (G, c), can we efficiently compute an Eulerian trail respecting c?

Although Hannenhalli et al. [16] formalized this basic problem in the context of dBGs, it has applications in temporal graphs [7, 22, 24] and other networks [11, 31, 20]. We denote it here by diET (see Section 2 for a formal definition). Hannenhalli et al. showed that diET is NP-complete when each node of G has in- and out-degree at most two. Even if their motivating application was fragment assembly and thus based on dBGs, their result was shown on general directed graphs. Ben-Dor et al. [3] then showed that diET is NP-complete, even on dBGs with $|\Sigma| = 4$. We settle the negative landscape by showing the following result:

▶ **Theorem 3 (*).** *The* diET *problem is* NP*-complete, even on de Bruijn graphs with* $|\Sigma| = 2$.

Beyond theoretically interesting, Theorem 3 shows that *in general* it is indeed hard to reconstruct a private (binary) string from a given dBG, thus providing theoretical justification for the privacy framework introduced by Bernardini et al. [4]. Given these negative results, we shift our focus to *parametrization* aiming to capture the quality of our domain knowledge in the complexity. This leads to algorithms that are efficient if the intervals are small [16]: every interval length is bounded by a natural number w, which we term the *interval width*. We denote this parametrized version of diET by diET$[w]$. Hannenhalli et al. [16] showed an algorithm for diET$[w]$ working in $\mathcal{O}(m^{2w+\log(2w)})$ time for any directed graph $G = (V, E)$, with $m = |E|$ and $w = \mathcal{O}(1)$. Ben-Dor et al. [3] developed an algorithm to solve the problem on dBGs in $\mathcal{O}(m \cdot w^{1.5}4^w)$ time, for any w. Bumpus and Meeks [7] later rediscovered the same algorithm on temporal graphs, which highlights the relevance of the diET problem in other contexts. We may thus summarize the state of the art in the following statement.

▶ **Theorem 10** (Theorem 11 of [3], Theorem 7 of [7])**.** *There is an $\mathcal{O}(m \cdot w^{1.5}4^w)$-time algorithm solving the* diET$[w]$ *problem. Therefore,* diET$[w]$ *is in* FPT.

We observe that the state-of-the-art algorithm does not exploit the dBG structure. Our central contribution is developing an algorithm for dBGs parametrized by $w(\log w+1)/(k-1)$:

▶ **Theorem 11.** *Let G be a de Bruijn graph of order k over alphabet Σ, $|\Sigma| = \mathcal{O}(1)$. There is an $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$-time algorithm solving the* diET$[w]$ *problem, where $\lambda := \min(|\Sigma|^{k-1}, 2w-1)$.*

Theorem 11 improves on the state of the art by roughly an exponent of $(\log w+1)/(k-1)$. The existing algorithms [16, 3, 7] all have a natural interpretation for string reconstruction: when for each length-k substring (k-*mer*), we know a small range of positions it must lie in, string reconstruction can be solved in linear time. Theorem 11 shows that *it is enough when*

the range of positions is small relative to the order k of the dBG. In particular, we show that for dBGs it is sufficient if $w \log w/(k-1)$ is relatively small, which significantly extends the practical applicability of our technique. For instance, in bioinformatics, it is standard to use $k = 31$ [21] and then we have $|\Sigma| = 4$ (the size of the DNA alphabet), which implies an exponential speedup by $\sqrt[30]{\cdot}$. Our approach of improving the FPT algorithms for diET based on combinatorial insights into the structure of the instances suggests further research into closely-related problems; e.g., the *Hierarchical Chinese Postman* (HCP) problem [15, 19, 11, 1] and the related *Time-Constrained Chinese Postman* (TCCP) problem [31, 28].

We then generalize the above results by allowing the cost at every position of an interval to vary. We denote this problem here by dicET (see Section 2 for a formal definition). In this setting, our hardness result (Theorem 3) translates into inapproximability.

▶ **Corollary 7 (*).** *If* P $\neq$ NP *there is no constant-factor polynomial-time approximation algorithm for the* dicET *problem, even on de Bruijn graphs with interval cost functions.*

We show that the FPT algorithms underlying both Theorems 10 and 11 also work in the optimization version with an interval cost function, which we denote by dicET$[w]$.

▶ **Corollary 20 (*).** *Given a* dicET$[w]$ *instance, there is an $\mathcal{O}(m \cdot w^{1.5} 4^w)$-time algorithm finding a min-cost Eulerian trail in G. On a de Bruijn graph of order k over alphabet Σ, $|\Sigma| = \mathcal{O}(1)$, we can solve this problem in $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$ time, where $\lambda := \min(|\Sigma|^{k-1}, 2w-1)$.*

Surprisingly, even in this more general setting, we show how to extend our FPT techniques to count the number of min-cost Eulerian trails. We show the following result.

▶ **Theorem 21.** *Given a* dicET$[w]$ *instance, we can count the number of min-cost Eulerian trails in $\mathcal{O}(m \cdot w^{1.5} 4^w)$ time. On a de Bruijn graph of order k over alphabet Σ, $|\Sigma| = \mathcal{O}(1)$, we can solve this problem in $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$ time, where $\lambda := \min(|\Sigma|^{k-1}, 2w-1)$.*

We can also enumerate these trails in the same time as for counting (Theorem 21) plus time that is linear in the size of the output. Notably, all of our algorithmic results translate from directed to undirected graphs with the same complexities. It is easy to verify that none of the proofs depend on the directedness of the graph. For simplicity, we focus our discussion on directed graphs. Particularly our result for counting Eulerian trails in undirected graphs is surprising given that the problem is #P-complete in the standard setting [6]. We also show that most of our algorithmic results generalize to multigraphs. Finally, we show that the undirected version of dicET, which we denote by uicET, is also NP-complete.

Overview of Hardness Techniques. We consider dBGs over alphabets of size two. Unlike [16, 3], this highly structured setting requires intricate techniques to obtain an (elementary) reduction from the directed Hamiltonian path problem [18]. For our instances, we harness the fact that the shortest path between any two nodes in a complete dBG is unique and has a meaningful string interpretation. The structure of the reduction makes it directly translatable to the optimization setting implying inapproximability. Similarly, we reduce the undirected Hamiltonian path problem [18] to finding a min-cost c-respecting Eulerian trail in an undirected graph. This reduction requires a different approach than the directed case to ensure that critical parts of the graph can only be traversed in the desired order. We assign different costs at even and odd time steps to certain edges to achieve that goal.

Overview of Algorithmic Techniques. We apply tools from parametrized algorithms [10] to solve dicET$[w]$ efficiently. Our techniques can be viewed as a careful combination of searching in a well-bounded state space and dynamic programming. We further combine

approaches from graph and string algorithms to enhance the vanilla version of these tools with combinatorial insights into dBGs and obtain exponential-time improvements. The robustness of these tools allows us to generalize our algorithm for the decision version of dicET[w] to both the optimization and the counting versions. The counting result in particular relies on the fact that the state space compactly captures all possible Eulerian trails, by excluding impossible trails at the construction level, and representing the possible ones efficiently.

Other Related Work. Our work is closely related to exploring *temporal graphs* [24, 13, 14, 12, 2, 7, 22]: graphs where every edge is available at an arbitrary subset of the time steps. Most relevant to our work are perhaps the works by Bumpus and Meeks [7] and by Marino and Silva [22]. The former proved that deciding whether a temporal graph has an Eulerian trail is NP-complete even if each edge appears at most r times, for every fixed $r \geq 3$. They also apply similar parametrized tools to interval-membership-width, a temporal graph parameter related to our interval width, but they do not consider directed graphs, costs, or counting. Marino and Silva [22] showed, for undirected graphs, that, if the edges of a temporal graph (G, λ) with lifetime τ are always available during the lifetime, then deciding whether (G, λ) has an Eulerian trail is NP-complete even if $\tau = 2$. They also showed that this problem is in XP when parametrized by $\tau + \mathsf{tw}(G)$, where $\mathsf{tw}(G)$ is the treewidth of G.

Our work is also closely related to the HCP problem [15, 19, 11, 1] (and the related TCCP problem [31, 28]). In HCP, we are given an edge-weighted undirected graph $G = (V, E)$, a partition $\mathcal{P}$ of E into k classes, and a partial order $\prec$ on $\mathcal{P}$, and we are asked to find a least-weight closed walk traversing each edge in E at least once such that each edge e in a class E' is traversed only after all edges in all classes $E'' \prec E'$ are traversed. The main differences to our problem are two: (1) In HCP, there is a partition on the edges and then a partial order between the classes, whereas we have an arbitrary interval per edge; and (2) in HCP, one must traverse each edge at least once, whereas we have to do this exactly once.

Paper Organization. We begin by formalizing diET and dicET in Section 2. We present our hardness and inapproximability results in Section 3. We complement these negative results with positive algorithmic results for diET[w] in Section 4. In Section 5, we extend our algorithms to counting Eulerian trails and discuss the relationship to the data privacy applications. In the full version, we discuss how most of our algorithms extend to multigraphs. *The formal statements, with proofs or details deferred to the full version, are marked with* ⋆.

2 Preliminaries

For $a, b \in \mathbb{N}$, let $[a, b] \coloneqq \{x \in \mathbb{N} \mid a \leq x \leq b\}$, $[a, b) \coloneqq \{x \in \mathbb{N} \mid a \leq x < b\}$, and $[b] \coloneqq [1, b]$. Further let $\mathcal{I}_b \coloneqq \{[i, j] \mid 1 \leq i \leq j \leq b\} \cup \{\{\}\}$ be the set of intervals on $[b]$.

We imagine a trail as "walking" through a graph and thus refer to the ranks of the edges as happening at certain time steps (e.g., the second edge is associated with the time step 2). This vocabulary borrowed from temporal graphs makes the discussion more intuitive.

▶ **Definition 1.** *Let $G = (V, E)$ be a directed or undirected graph with $m = |E|$. We call a function $c\colon E \to \mathcal{I}_m$ an* interval function *for G. We extend this notion to an* interval cost function *where, for each $e \in E$, each time step from the interval $c(e)$ is associated with a cost from $\mathbb{Z}$. As an abuse of notation, we write $c(e, t)$ for this cost. If $t \notin c(e)$, we set $c(e, t) \coloneqq \infty$.*

When the relevant graph $G = (V, E)$ is clear from context, we set $n \coloneqq |V|$ and $m \coloneqq |E|$. We next formalize the main problems in scope on directed graphs.

▶ **Problem.** Eulerian Trails in Digraphs with Interval functions (diET)

Given: Directed graph $G = (V, E)$, interval function $c\colon E \to \mathcal{I}_m$

Decide: Is there an Eulerian trail $P = e_1 \dots e_m$ in G such that for all $t \in [m]$, $t \in c(e_t)$?

Similarly, we consider the version with interval *cost* functions.

▶ **Problem.** Eulerian Trails in Digraphs with Interval Cost functions (dicET)

Given: Directed graph $G = (V, E)$, interval cost function $c\colon E \times [m] \to \mathbb{Z} \cup \{\infty\}$, $c_{\text{budget}} \in \mathbb{N}$

Decide: Is there an Eulerian trail $P = e_1 \dots e_m$ in G such that $\sum_{t=1}^{m} c(e_t, t) \leq c_{\text{budget}}$?

In addition, we consider the uicET problem as the natural *undirected* version of dicET.

Note that in all cases, we allow setting every interval to the whole $[m]$. In the case without costs, this yields the classical Eulerian trail problem [17]. In the case with costs, this yields a min-cost Eulerian trail problem without any interval restrictions, which is a natural special case we will call out when considering it to be particularly relevant. See Figure 2 for an example of a graph with an interval function and the corresponding edge availabilities.

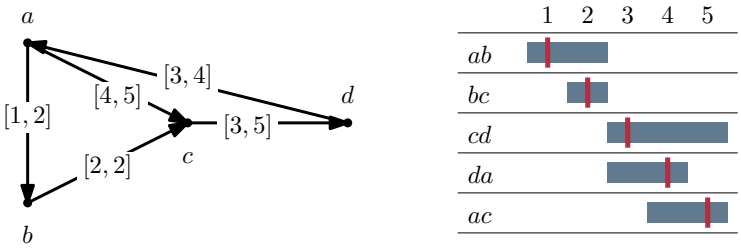

Figure 2 On the left is the input graph G: every edge is labeled with the time steps at which it is available. On the right is a table illustrating the interval every edge is available: *abcdac* is an Eulerian trail; the edge usages corresponding to this trail are indicated with red vertical lines.

The following definition makes our arguments based on an interval function more legible.

▶ **Definition 2.** *We call an edge $e \in E$* available *at $t \in [m]$, if $t \in c(e)$. For a time step $t \in [m]$, we write $E(t)$ to denote the set of edges available at t. Given an interval $T \subseteq [m]$, we similarly write $E(T)$ for the set of edges available at at least one time step from T.*

3 NP-hardness and Inapproximability

In this section, we consider both the directed and undirected case from the hardness perspective. Since in the directed case, dBGs are a particularly relevant application, we give strong results, even when restricting the instances to this graph class. We are the first to show the hardness for alphabets of all sizes (except $|\Sigma| = 1$, where the problem is trivial). In particular, we settle the question for the important case of binary alphabets. In the undirected case, we consider general graphs, which we believe is nonetheless insightful regarding what makes this problem class hard.

We first settle the computational complexity of diET.

▶ **Theorem 3 (*).** *The* diET *problem is* NP*-complete, even on de Bruijn graphs with $|\Sigma| = 2$.*

We reduce from the directed Hamiltonian path problem, which is NP-complete [18]. Let $G = (V, E)$ be the directed graph in which we want to find a Hamiltonian path.

Construction of the dBG. We consider any two-letter alphabet; for example, here we will consider the subset $\Sigma \coloneqq \{\mathtt{A}, \mathtt{T}\}$ of the DNA alphabet. We set $\ell \coloneqq \lceil \log_2(|V|) \rceil$ and construct a diET instance $(G' = (V', E'), c)$ as the complete dBG on the set of nodes each labeled by a string of length $k - 1 = 4\ell + 10$, as well as an interval function c that we will describe later. Note that, by the choice of ℓ and Σ, G' has $|\Sigma|^{k-1} = 2^{4\ell+10} = \mathcal{O}(|V|^4)$ nodes. We will pay special attention to some of the nodes in G', which we assign an interpretation in terms of G.

For each $v \in V$, let $\mathrm{id}_v \in \Sigma^\ell$ be a unique identifier among V. By the choice of ℓ, this numbering is always possible. Similarly, let $\mathrm{id}_{v'} \in \Sigma^{4\ell+10}$ be the string associated with a node $v' \in V'$. With each node $v \in V$, we associate two nodes v'_1 and v'_2 in V' such that:

$$\mathrm{id}_{v'_1} \coloneqq \mathtt{A}^{\ell+3} \cdot \mathtt{T} \cdot \mathrm{id}_v \cdot \mathtt{T} \cdot \mathtt{A}^{\ell+3} \cdot \mathtt{T} \cdot \mathrm{id}_v \cdot \mathtt{T} \text{ and } \mathrm{id}_{v'_2} \coloneqq \mathtt{A}^{\ell+2} \cdot \mathtt{T} \cdot \mathrm{id}_v \cdot \mathtt{T} \cdot \mathtt{A}^{\ell+3} \cdot \mathtt{T} \cdot \mathrm{id}_v \cdot \mathtt{T} \cdot \mathtt{A},$$

where $\mathtt{A}^i$ is the string of i $\mathtt{A}$'s. We use the notation $a \xrightarrow{x} b$ to denote a directed edge ab labeled x, where x is the letter used to obtain b from a in the dBG. We extend this notation to $a \overset{X}{\rightsquigarrow} b$ to denote the path from a to b using string X. Observe that by the choice of the underlying strings, we have an edge $v'_1 \xrightarrow{\mathtt{A}} v'_2$ in the dBG. We call this the *inner edge* for v. With each edge $e = vu \in E$, we associate two nodes e'_1 and e'_2 such that:

$$\mathrm{id}_{e'_1} \coloneqq \mathtt{A}^{\ell+3} \cdot \mathtt{T} \cdot \mathrm{id}_v \cdot \mathtt{T} \cdot \mathtt{A}^{\ell+3} \cdot \mathtt{T} \cdot \mathrm{id}_u \cdot \mathtt{T} \text{ and } \mathrm{id}_{e'_2} \coloneqq \mathtt{A}^{\ell+2} \cdot \mathtt{T} \cdot \mathrm{id}_v \cdot \mathtt{T} \cdot \mathtt{A}^{\ell+3} \cdot \mathtt{T} \cdot \mathrm{id}_u \cdot \mathtt{T} \cdot \mathtt{A}.$$

Again, we have an edge $e'_1 \xrightarrow{\mathtt{A}} e'_2$ in the dBG. We call this the *inner edge* for e. For every other string of length $4\ell + 10$ over Σ a node v' exists in V', but it is not associated with a node $v \in V$ or an edge $e \in E$. See Figure 3 for an illustration of this construction. A crucial property that we will later utilize is that for every pair of nodes $v, u \in V$, such that $vu \in E$, there is a unique shortest path of length $2\ell + 4$ in G' between v'_2 and $(vu)'_1$; this path is associated with the string $\mathtt{A}^{\ell+2} \cdot \mathtt{T} \cdot \mathrm{id}_u \cdot \mathtt{T}$ (see Figure 3). The analogous property holds for $(vu)'_2$ and u'_1: there is a unique shortest path of length $2\ell + 4$ in G' from $(vu)'_2$ to u'_1.

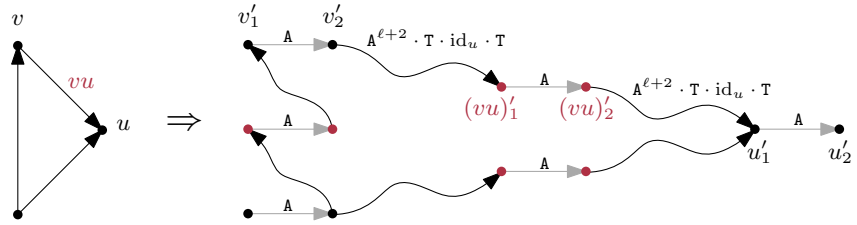

Figure 3 A directed graph G (left) and the corresponding part of graph G' (right). The nodes in G' that correspond to nodes in G are colored black; the nodes in G' that correspond to edges in G are colored red. Inner edges in G' are colored gray and squiggly lines indicate *paths* of length $2\ell + 4$.

It is straightforward to verify that the claimed path (from v'_2 to $(vu)'_1$) exists. To see that this is the shortest possible, notice that $\mathrm{id}_{v'_2}$ contains the substring $\mathtt{A}^{\ell+3}$ starting at position $2\ell + 5$ (i.e., after the first occurrence of $\mathrm{id}_v \cdot \mathtt{T}$). Any one edge on a path to $(vu)'_1$ shifts this substring left by one letter. By the strategic placement of $\mathtt{T}$ around the id parts, the substring $\mathtt{A}^{\ell+3}$ occurs precisely at positions 1 and $2\ell + 6$ in $\mathrm{id}_{(vu)'_1}$. Thus, the closest occurrence of $\mathtt{A}^{\ell+3}$ left of position $2\ell + 6$ in $\mathrm{id}_{(vu)'_1}$ starts at position 1 (i.e., requires a left shift by at least $2\ell + 4$ letters). Therefore, any path from v'_2 to $(vu)'_1$ must contain at least $2\ell + 4$ edges. The argument is analogous for the path from $(vu)'_2$ to u'_1.

Construction of the Interval Function. Let us set $\tau \coloneqq 2n - 1 + 2(n - 1)(2\ell + 4)$. We dub the time steps 1 to τ *early* and all others *late*. The intuition is that the first τ edges on any c-respecting Eulerian trail in G' will correspond to a Hamiltonian path in G. For ease of notation, we set $m' \coloneqq |\Sigma|^k = 2^{4\ell+11}$ to be the number of edges in G'.

For the interval function c, we set $c(v'_1v'_2) \coloneqq [1, \tau]$, for all $v \in V$. For any non-edge $e \notin E$ we set $c(e'_1e'_2) \coloneqq [\tau + 1, m']$. All other edges in G' have the full interval $[m']$. This also holds for all inner edges for the edges in E. Note that with these choices, the inner edges for nodes $v \in V$ are only available early, and for a node pair $v, u \in V$, the edge $(vu)'_1 \to (vu)'_2$ is available early only if $v \to u$ is an edge in E.

▶ **Lemma 4.** *If G has a Hamiltonian path, there is a c-respecting Eulerian trail in (G', c).*

Proof. Let $P = v_1 \dots v_n$ be a Hamiltonian path in G. Then for the Eulerian trail in G', set

$$P'_1 \coloneqq (v_1)'_1 \xrightarrow{\mathtt{A}} (v_1)'_2 \overset{\mathtt{A}^{\ell+2}\cdot\mathtt{T}\cdot\mathrm{id}_{v_2}\cdot\mathtt{T}}{\rightsquigarrow} (v_1v_2)'_1 \xrightarrow{\mathtt{A}} (v_1v_2)'_2 \rightsquigarrow \cdots \rightsquigarrow (v_n)'_1 \xrightarrow{\mathtt{A}} (v_n)'_2.$$

Notice that P'_1 traverses all inner edges for nodes and that P'_1 has length exactly τ. Thus all inner edges for nodes are available by construction at their time steps on P'_1. Similarly, for any $i \in [n-1]$, we have that $v_iv_{i+1} \in E$ since P is a Hamiltonian path in G. Thus, the inner edges for edges are available on P'_1 as well. Finally, all other edges on P'_1 have their $\mathtt{A}^{\ell+3}$ substring in such positions that they do not fall under any of the edge classes whose interval is restricted, thus they are available for the full interval $[m']$. We conclude that P'_1 respects c.

As we want P'_1 to be the prefix of an Eulerian trail, we must ensure that no edge repeats in P'_1. The nodes of types v'_1, v'_2, e'_1, and e'_2 in G', for some $v \in V$ or $e \in E$, each appears at most once on P'_1 by construction, and thus so must their inner edges. Therefore, if there is an edge xy in G', for two nodes x and y, that appears twice on P'_1, it must be on some subpath of type $(v_i)'_2 \overset{\mathtt{A}^{\ell+2}\cdot\mathtt{T}\cdot\mathrm{id}_{v_{i+i}}\cdot\mathtt{T}}{\rightsquigarrow} (v_iv_{i+1})'_1$ (or analogously of the type $(v_iv_{i+1})'_2 \overset{\mathtt{A}^{\ell+2}\cdot\mathtt{T}\cdot\mathrm{id}_{v_{i+1}}\cdot\mathtt{T}}{\rightsquigarrow} (v_{i+1})'_1$) as well as at some other part of P'_1. Let us analyze the string corresponding to node x. As x appears on the path from $(v_i)'_2$ to $(v_iv_{i+1})'_1$, it must have the form $r_1 \cdot \mathtt{A}^{\ell+3} \cdot \mathtt{T} \cdot \mathrm{id}_{v_i} \cdot \mathtt{T} \cdot r_2$, where r_1 is a suffix of $\mathtt{A}^{\ell+2} \cdot \mathtt{T} \cdot \mathrm{id}_{v_i} \cdot \mathtt{T}$ and r_2 is a prefix of $\mathtt{A}^{\ell+3} \cdot \mathtt{T} \cdot \mathrm{id}_{v_{i+1}} \cdot \mathtt{T}$. Consider that therefore the string corresponding to x contains the substring $\mathtt{A}^{\ell+3}\cdot\mathtt{T}\cdot\mathrm{id}_{v_i}\cdot\mathtt{T}$ somewhere in the middle. Since, however, our id's are unique, x may only appear on the subpath corresponding to an out-edge of v_i in G and a Hamiltonian path can only include one out-edge per node. Finally, no edge can repeat within the same such subpath as this is a shortest path. The above discussion contradicts our assumption that xy repeats on P'_1. Therefore, we conclude that all edges on P'_1 are unique.

We are left to show that we can complete P'_1 to traverse every edge of G' exactly once. Observe that since G' is a complete dBG, the in- and out-degree of every node is $|\Sigma| = 2$. Therefore, in $G' - P'_1$ (which we define as G' without the edges in P'_1) the in- and out-degree of every node is the same except for $(v_1)'_1$ (where the out-degree is one less than the in-degree) and for $(v_n)'_2$ (where the out-degree is one more than the in-degree). Also notice that $G' - P'_1$ remains weakly connected (as any strongly connected 2-regular directed graph remains weakly connected if a path is removed). By these properties, there is an Eulerian trail P'_2 in $G' - P'_1$. In particular, it must start at $(v_n)'_2$ and end at $(v_1)'_1$. Hence $P' \coloneqq P'_1P'_2$ is an Eulerian trail in G'. As the time steps of all edges from P'_1 remain the same, that prefix of P' still respects c. For the suffix of P' defined by P'_2, observe that all edges are used at time steps later than τ and that none of the edges are inner edges for nodes. Thus, all edges in the P'_2 part of P' are also available under c. We conclude that P' is an Eulerian trail in (G', c). ◀

Similar ideas allow us to prove the other direction, yielding the following lemma.

▶ **Lemma 5 (*).** *If there is a c-respecting Eulerian trail in G', G has a Hamiltonian path.*

Lemma 4 and Lemma 5 allow us to deduce Theorem 3.

Consequences. The construction we used is quite restrictive in that it uses only two letters to construct the dBG and is within the framework of interval functions without costs. This allows us to deduce the following two corollaries, narrowing down the hardness landscape of the general problem even further. Corollary 6 was first shown by Hannenhalli et al. [16].

▶ **Corollary 6** ([16]). *The* diET *problem remains* NP*-hard even on 2-regular graphs.*

Proof. Notice that the construction for Theorem 3 uses only the letters $\{\mathtt{A}, \mathtt{T}\}$ and thus the complete dBG (over that alphabet) is 2-regular. ◀

Our hardness reduction also directly implies that dicET is NP-hard: we set the costs of every edge to 0 within its interval and to 1 outside its interval. We also set $c_{\text{budget}} := 0$. As our proof of Theorem 3 relies only on distinguishing zero and non-zero cost instances, we deduce the following inapproximability result, which is to the best of our knowledge new.

▶ **Corollary 7** (*). *If* P $\neq$ NP *there is no constant-factor polynomial-time approximation algorithm for the* dicET *problem, even on de Bruijn graphs with interval cost functions.*

Interestingly, the problem remains hard and inapproximable, even when restricting dicET to instances where every interval is the full interval $[m]$ (effectively dropping the interval requirement and only considering edge costs). This reduction simply extends, for each edge, its interval and let all costs outside the original interval be $c_{\text{budget}} + 1$.

Although we can find an Eulerian trail in an undirected graph in linear time by Hierholzer's algorithm [17], counting the number of Eulerian trails in an undirected graph is #P-complete [6]. Given this complexity landscape and our results on directed graphs, it is natural to ask about the complexity of deciding if an Eulerian trail of at most some fixed cost exists. We show that this problem is NP-complete and inapproximable in the full version.

4 FPT by Interval Width

After these strong negative results, it is now natural to ask whether there is a restricted setting in which we can efficiently solve diET. Interval functions (see Definition 1) are a restricted class of functions that are natural to the string reconstruction application. In this setting, it is equally natural to ask if more precise domain knowledge leads to more efficient algorithms. Providing tighter intervals for the time step each edge is to be used reduces the combinatorial complexity as there are fewer valid combinations to consider. This observation also translates to string reconstruction, where we might expect that reconstructing a string is easier when the location of every k-mer is narrowed down to a small interval.

▶ **Definition 8.** *Given a* diET *instance* $((V, E), c)$ *with interval function* c*, we define the instance's* interval width w *as the length of the longest interval of any edge* $e \in E$ *under* c*.*

Interestingly, this concept is closely related to the notion of *interval-membership width* (imw, in short) studied by Bumpus and Meeks in the context of temporal graphs [7]. This notion asks how many edges in the graph are relevant to the decision at a specific time step t by looking at the set of edges which have been available at or before t *and* will also be available at or after t. The imw is the largest size of such a set for any t. In Lemma 9, we show that this parameter is related to the length of the longest interval in our setting (Definition 8). A special case of this observation also underlies the FPT algorithm of Ben-Dor et al [3]. This relates the length of time any single edge is available to the total number of edges relevant at a given time. With this observation, we unveil the equivalence of the algorithms by Bumpus and Meeks and by Ben-Dor et al.

For dBGs of order k, we severely speed up these algorithms by roughly an exponent of $(\log w + 1)/(k-1)$. In fact, we show that on dBGs, the problem is not only in FPT by w, but also by $w \log w/k$; namely, we show that it suffices if w is small compared to k to make the problem tractable. We achieve this by extending the techniques in [3, 7] with the properties of dBGs and their underlying string interpretation. By utilizing a significantly more general setting, Bumpus and Meeks [7] have shown that the algorithm by Ben-Dor et al. [3] applies to a significantly broader graph class than dBGs. We observe that this leaves plenty of dBG-specific structure unexploited to speed up the task. Finally, we show how to extend both the existing and our novel approach to find min-cost Eulerian trails.

Considering Definition 8, the definition of the parametrized problem diET[w] is canonical. We first consider simple graphs, deferring the discussion of multigraphs to the full version.

▶ **Problem.** diET[w]

Parameter:	$w \in \mathbb{N}^+$
Given:	Directed graph $G = (V, E)$, interval function $c\colon E \to \mathcal{I}_m$ with interval width w
Decide:	Is there an Eulerian trail $P = e_1 \dots e_m$ such that for all $t \in [m]$, $t \in c(e_t)$?

The following structural insight (Lemma 9) generalizes [3, Lemma 8] and underpins their algorithm and our reduction to the Bumpus and Meeks version of the FPT algorithm: Since any edge is available only at a bounded number of time steps, a similar bound applies to the set of edges available at an individual time step. This insight implies that there are relatively few choices on which edge to select at a specific time step in an Eulerian trail.

▶ **Lemma 9 (*).** *If (G, c, w) is a YES-instance of* diET[w] *and T is an interval in $[m]$, then $|E(T)| \leq |T| + 2w - 2$.*

In particular, Lemma 9 implies that at any specific time step (i.e., an interval of length 1), there are at most $2w - 1$ edges available. Thus, we have that any graph with interval width w has imw at most $2w - 1$. The condition of this lemma is easy to check in time $\mathcal{O}(mw)$ by testing if the number of edges available at each time step is at most $2w - 1$. If this is not the case for any time step, we deduce that (G, c, w) is a NO-instance for diET[w]. We will henceforth assume that the condition has been checked and deduce the following result.

▶ **Theorem 10** (Theorem 11 of [3], Theorem 7 of [7])**.** *There is an $\mathcal{O}(m \cdot w^{1.5} 4^w)$-time algorithm solving the* diET[w] *problem. Therefore,* diET[w] *is in* FPT*.*

Three remarks are in order regarding the version of this theorem by Bumpus and Meeks [7]. First, note that this rendering of the theorem requires a small modification, as we are interested in any Eulerian trail, not necessarily a cycle. This allows us to slash a factor of w. Second, their algorithm is for undirected graphs, but it naturally translates to directed graphs. Third, their version of the algorithm does not exclude a small number of irrelevant states and is thus slightly slower (by another factor of $\sqrt{w}$) than the version by Ben-Dor et al. For the sake of completeness, we provide a proof with these modifications in the full version.

Specializing the parametrized technique of [3, 7] to dBGs allows us to design an algorithm that achieves a significant speedup. Our improvements rely on exploiting the specific structure in the dBG graph class in which we are particularly interested in finding Eulerian trails.

▶ **Theorem 11.** *Let G be a de Bruijn graph of order k over alphabet Σ, $|\Sigma| = \mathcal{O}(1)$. There is an $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$-time algorithm solving the* diET[w] *problem, where $\lambda := \min(|\Sigma|^{k-1}, 2w-1)$.*

Since λ is defined as a minimum, the algorithm underlying Theorem 11 always runs in time $\mathcal{O}(mw \cdot 2^{\frac{w(\log w+1)}{k-1}})$, as shown by the following lemma.

▶ **Lemma 12.** *For any* $w, k \in \mathbb{N}^+$, $(2w-1)^{\frac{w}{k-1}+1} = \mathcal{O}(w \cdot 2^{\frac{w(\log w+1)}{k-1}})$.

Proof. Note that $(2w-1)^{\frac{w}{k-1}+1} = (2w-1) \cdot (2w-1)^{\frac{w}{k-1}}$. We first bound the exponential term. Then multiplying by $(2w-1)$ gives the claimed upper bound. We have that

$$(2w-1)^{\frac{w}{k-1}} = 2^{\frac{w \log(2w-1)}{k-1}} \leq 2^{\frac{w \log(2w)}{k-1}} = 2^{\frac{w(\log w + \log 2)}{k-1}} = 2^{\frac{w(\log w+1)}{k-1}}.$$ ◀

Notice that the exponential part is higher than for the $\mathcal{O}(mw^{1.5} \cdot 4^w)$-time algorithm only if $w(\log w + 1)/(k-1) > 2w$, that is, if $w = \Omega(4^k)$; but in this case, since λ is defined by the minimum, our new algorithm takes $\mathcal{O}(mw \cdot |\Sigma|^w)$ time. Thus, for alphabets of size at most 4, in the extreme edge case, our new algorithm is at least a $\sqrt{w}$ factor faster than the state of the art. Note that since $n \leq |\Sigma|^{k-1}$, for alphabets of size at most 4, this extreme edge case can only occur if w is linear in n, where by our Theorem 3 the problem is not tractable. Specifically, in that case, the running time of both the state of the art and our novel approach become unrealistic.

We describe how to encode a diET$[w]$ instance $(G = (V, E), c, w)$, where G is a dBG, using an auxiliary directed graph $H = (V', E')$ of size $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$ in which there is a path between the designated source and target nodes if and only if the instance contains a c-respecting Eulerian trail. The graph H consists of a sequence of $m+1$ *layers* of nodes with edges only between consecutive layers. In this model, traversing an edge of H between layers $t-1$ and t means traversing a corresponding edge of G at time step t. We show the construction of graph $H = (V', E')$ and start by defining the construction of the nodes in V'.

The algorithms in [3, 7] rely on enumerating states, where a state is described by a node v of G (this is the end location of the current partial trail), a time step t, and some information about the edges of the partial trail. Both [3] and [7] achieve their FPT runtime by observing that it is unnecessary to encode the entire partial trail; instead, it suffices to consider the last w edges of it. They are even able to show that it is unnecessary to remember the order these edges are used on the trail. Applying Lemma 9 shows that, for each $v \in V$ and $t \in [m]$, it suffices to consider all subsets of a fixed size. These are at most $\binom{2w-1}{w} = \mathcal{O}(4^w/\sqrt{w})$; see the full version. We will use additional structural insights into dBGs to severely reduce the number of states that need to be considered in many relevant cases.

Henceforth, we set $\lambda \coloneqq \min(|\Sigma|^{k-1}, 2w-1)$ as in Theorem 11. For ease of notation, we also set $\ell \coloneqq \lceil \min(w,t)/(k-1) + 1 \rceil$ when t is clear from the context. Intuitively, ℓ is the number of nodes required to uniquely represent a path of length $\min(w,t)$ in G. By id_v we denote the string of length $k-1$ associated with the node $v \in V$.

The Nodes of H. We add a node to V' for every tuple (t, α) such that:

- $t \in [0, m]$ is a time step; and
- $\alpha \in \Sigma^{\min(w,t)+k-1}$ is a string of length $\min(w,t)+k-1$ over Σ, such that, for all $i \in [\ell]$, the node of G corresponding to the substring $\alpha[(i-1)(k-1)+1 \,..\, i(k-1)]$ of α has an incoming edge labeled $\alpha[i(k-1)]$, available at time step $t - w + (i-1)(k-1)$.

In order to avoid edge casing, we say that the incoming-edge requirement is fulfilled vacuously for time step 0: for layers $t \leq w$, we do not require the first encoded node to have an incoming edge. We also add to V' auxiliary source and target nodes, denoted by s and z, respectively.

▶ Remark 13. While this construction appears overtechnical at first glance, by the definition of a dBG $G = (V, E)$, the string α is equivalent to a sequence of nodes $v_\ell, \ldots, v_1 \in V$, such that v_i has an incoming edge labeled $\mathrm{id}_{v_i}[k-1]$ available at time step $t - (i-1) \cdot (k-1)$.

Intuitively, this construction relies on the insight that any path (of length r) in a dBG is fully described by the string (of length $r+k-1$) it generates and that this string in turn is fully described by examining every $(k-1)$-th node on the path.

The Edges of H. For a node (t, α) in V', we now potentially create an outgoing edge for each letter $x \in \Sigma$ to $(t+1, \alpha[2\,..\,|\alpha|] \cdot x)$, essentially deleting the leftmost letter of α and then appending x. However, we add the edge $(t, \alpha) \xrightarrow{x} (t+1, \alpha[2\,..\,|\alpha|] \cdot x)$ to E' only if:

- both the head and tail node exist in V'; and
- $\alpha[|\alpha| - k + 2\,..\,|\alpha|] \cdot x$ (the last $k-1$ letters of α appended with x) does not occur in α.

The first condition ensures that the head and tail nodes fulfill the condition that the encoded nodes have incident edges at the required time steps. The second condition ensures that the edge of G with label x that starts at the node v with $\mathrm{id}_v = \alpha[|\alpha| - k + 2\,..\,|\alpha|]$ is not traversed more than once in the (Eulerian) trail we aim to construct.

We also add an edge from the source node s to all nodes in layer 0 (i.e., all nodes where $t = 0$), and from all nodes in layer m (i.e., all nodes where $t = m$), to the target node z.

See Figure 4 for an illustration of this construction.

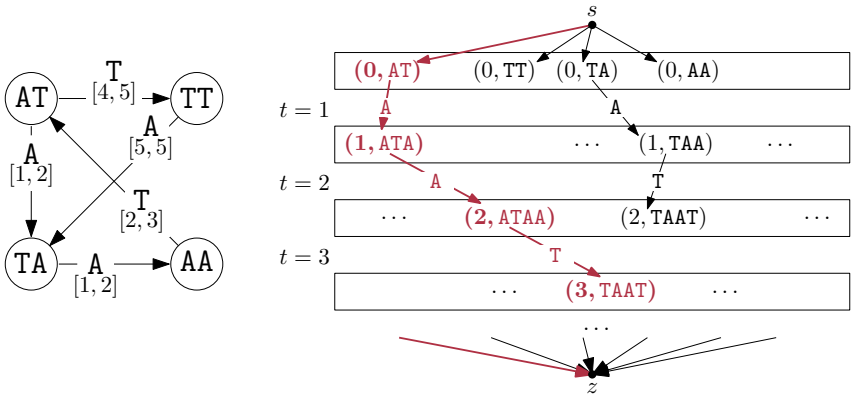

Figure 4 The input de Bruijn graph G (on the left) and the construction of graph H (on the right) for $k = 3$, $|\Sigma| = 2$, $w = 2$, and thus $w + k - 1 = 4$. For instance, for $t = 2$, $\ell = 2$, and $i = 2$, we add node $(t, \alpha) = (2, \texttt{ATAA})$ to layer $t = 2$ in H, because the node of G corresponding to $\alpha[(i-1)(k-1)+1\,..\,i(k-1)] = \texttt{AA}$ has an incoming edge labeled $\alpha[i(k-1)] = \texttt{A}$ available at time step $t - w + (i-1)(k-1) = 2$. A c-respecting Eulerian trail in G is indicated in red in H.

▶ **Lemma 14.** *Graph H has $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$ nodes and $\mathcal{O}(m\,|\Sigma| \cdot \lambda^{\frac{w}{k-1}+1})$ edges, where $\lambda := \min(|\Sigma|^{k-1}, 2w-1)$. Graph H can be constructed in time linear in its maximum size.*

Proof. Firstly, for any layer $t > 0$ in H, there can be at most $|\Sigma|^{w+k-1} = \left(|\Sigma|^{k-1}\right)^{\frac{w}{k-1}+1}$ choices for α. Secondly, by Lemma 9, there are at most $2w-1$ edges available at any time step $t > 0$, thus there can be at most that many nodes with at least one incoming edge available at t. Thus, by Remark 13, there can be at most $(2w-1)^\ell$ such strings α.

By construction, there are precisely n nodes in layer 0. Counting s and z as well and by the choice of λ, there are at most $2 + n + m \cdot \lambda^{\frac{w}{k-1}+1}$ nodes in H. For the edges, observe that every node (except s) has out-degree at most $|\Sigma|$. Node s has out-degree n and node z has in-degree the size of the last layer, that is at most $\lambda^{\frac{w}{k-1}+1}$. This yields the bound on the number of edges. We next discuss how H can be efficiently constructed.

To construct H efficiently, we perform a DFS over its *implicit* representation. For each node (t, α), we store the last letter of α, and associate each incoming edge with the letter it removed from the string in the previous layer to obtain α. The only part that requires a little care is when our DFS is at some node (t, α) and has to decide whether to add an edge with letter $x \in \Sigma$. In such a case, we have to check the condition that the string $\alpha[|\alpha|-k+2\,..\,|\alpha|] \cdot x$ does not occur in α. Instead of storing the entire string α and performing

the pattern matching explicitly, we use a single bit-string of length m during the DFS that maintains the set of w previously used edges (which are equivalent to the strings of length k that can appear in this form). This set can be maintained by correctly flipping the bits corresponding to the edges at the top and at the w-th position in the DFS stack every time the DFS moves forward or backward. In the word RAM model, each edge id is from $[m]$ and so it fits into one machine word. We therefore decide on the existence of each possible edge of H in $\mathcal{O}(1)$ time. To conclude, constructing H takes linear time in its maximum size. ◀

Formalizing the intuition behind the aim of the construction yields the following central lemma. See also Figure 4 that illustrates the properties stated in the lemma.

▶ **Lemma 15 (*).** *For any $t \in [m]$ and $\alpha \in \Sigma^{\min(w,t)+k-1}$, the graph H contains a path from s to the node labeled (t, α) if and only if there exists a trail $W = e_1 \dots e_t$ in G such that:*

1. *every edge from G occurs at most once in W;*
2. *for every $t' \in [t]$, the edge $e_{t'}$ is available at time step t';*
3. *the last w edges of W correspond to α; namely, they start at the node labeled $\alpha[1\,..\,k-1]$ and then follow the edges corresponding to $\alpha[k\,..\,|\alpha|]$.*

From Lemma 15, we can deduce the following crucial property, which both proves the correctness of our algorithm (i.e., Theorem 11) and underpins our extensions.

▶ **Lemma 16 (*).** *Graph H contains an s-to-z path if and only if there exists an Eulerian trail $W = e_1 \dots e_m$ in G, such that for every $i \in [m]$, edge e_i is available at time step i.*

Lemma 14 and Lemma 16 imply Theorem 11. We stress that, by Lemma 14, if we waive the assumption that $|\Sigma| = \mathcal{O}(1)$, we get an algorithm that is slower only by a factor of $|\Sigma|$.

Generalizations. We now discuss how to exploit this construction to solve more general problems. These extensions work analogously on the algorithm underlying Theorem 10 for general directed graphs. As a first extension, we can use these algorithms to report a witness: a c-respecting Eulerian trail in G. The following result makes this precise.

▶ **Corollary 17 (*).** *For any instance (G, c), where c is an interval function with width w, there is an $\mathcal{O}(m \cdot w^{1.5} 4^w)$-time algorithm finding a c-respecting Eulerian trail in G if it exists and correctly deciding non-existence otherwise. On a de Bruijn graph of order k over alphabet Σ, $|\Sigma| = \mathcal{O}(1)$, we can solve this problem in $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$ time, where $\lambda \coloneqq \min(|\Sigma|^{k-1}, 2w-1)$.*

For small $w \log w/(k-1)$ values, the algorithm on dBGs is highly efficient. At first glance, that is unintuitive, as even if for each pair of consecutive positions there are only two available k-mers (edges), there could already be $2^{m/2}$ possible orderings. Yet, our result shows that the additional structure of the graph allows us to efficiently select the correct ordering. The following remark captures the significant improvement over previous works which required w to be tractably small to efficiently solve the string reconstruction problem.

▶ Remark 18. Let $|\Sigma| = \mathcal{O}(1)$. For any $\frac{w \cdot \log w}{k-1} = \mathcal{O}(1)$, the diET$[w]$ problem on dBGs can be solved in $\mathcal{O}(mw)$ time. For any $w = \mathcal{O}(1)$, diET$[w]$ on dBGs can be solved in $\mathcal{O}(m)$ time.

It is important to note that in many practical applications, especially in bioinformatics and data privacy (see Figure 1), the dBGs considered are multigraphs (have parallel edges). For our FPT technique, the analysis above relies on the fact that an edge is uniquely determined by its endpoints, but with some extra care it can be adjusted to extend to multigraphs. We give a full discussion in the full version, but we restate the following main observation here.

▶ **Observation 19.** *If there is a c-respecting Eulerian trail in a de Bruijn multigraph $G = (V, E)$, with $m = |E|$, then there is a c-respecting Eulerian trail $W = e_1 \dots e_m$ such that for any time step t where the edge e_t has a parallel edge e' that is also available at t and appears after e_t on W, we have that* $\max c(e_t) \leq \max c(e')$.

Moreover, as mentioned above, we can generalize our technique to interval cost functions and retain the same running time, for both general directed graphs and for dBGs.

▶ **Corollary 20 (*).** *Given a* dicET$[w]$ *instance, there is an $\mathcal{O}(m \cdot w^{1.5} 4^w)$-time algorithm finding a min-cost Eulerian trail in G. On a de Bruijn graph of order k over alphabet Σ, $|\Sigma| = \mathcal{O}(1)$, we can solve this problem in $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$ time, where $\lambda := \min(|\Sigma|^{k-1}, 2w-1)$.*

Note that in this setting, we can allow an edge to become temporarily unavailable by setting its cost to at least $c_{\text{budget}} + 1$. In such a case, the width of the edge's interval remains the difference between the last and the first time step at which the edge is available.

Corollary 20 directly implies that dicET parametrized by w is in FPT. On dBGs, dicET is also in FPT when parametrized by $w \log w/(k-1)$.

5 Counting Eulerian Trails with Applications in Data Privacy

Our results are of crucial relevance for the data privacy applications presented in [4] and [5]. On the one hand, our hardness results (Theorem 3 and Corollary 7) show that *in general* it is indeed hard to reconstruct a private (binary) string from a given dBG, thus providing theoretical justification for the privacy model introduced in [4]. On the other hand, our algorithmic results (Theorem 11 and Corollary 20) show that, with sufficiently specific domain knowledge, one can reconstruct such a (best) string in linear time. To address this concern, the algorithms of [4, 5] rely on a counting routine to efficiently ensure that the released string has at least κ possible reconstructions. To verify that the κ-anonymity property continues to hold even when reconstruction is aided by domain knowledge, we can directly employ the following result as the counting routine in the main algorithm of [4, 5].

▶ **Theorem 21.** *Given a* dicET$[w]$ *instance, we can count the number of min-cost Eulerian trails in $\mathcal{O}(m \cdot w^{1.5} 4^w)$ time. On a de Bruijn graph of order k over alphabet Σ, $|\Sigma| = \mathcal{O}(1)$, we can solve this problem in $\mathcal{O}(m \cdot \lambda^{\frac{w}{k-1}+1})$ time, where $\lambda := \min(|\Sigma|^{k-1}, 2w-1)$.*

Proof. Observe that by Lemma 16 and Corollary 20, there is a one-to-one correspondence between min-cost s-to-z paths in H and min-cost c-respecting Eulerian trails in G. Thus, we can apply the folklore linear-time shortest-path counting DAG dynamic program [25]. ◀

▶ Remark 22. The algorithm underlying Theorem 21 can be trivially extended to enumerate all such Eulerian trails in additional time that is linear in the size of the output.

Non-Boolean OMv: One More Reason to Believe Lower Bounds for Dynamic Problems

Bingbing Hu
University of California San Diego, La Jolla, CA, USA

Adam Polak
Bocconi University, Milan, Italy

Abstract

Most of the known tight lower bounds for dynamic problems are based on the Online Boolean Matrix-Vector Multiplication (OMv) Hypothesis, which is not as well studied and understood as some more popular hypotheses in fine-grained complexity. It would be desirable to base hardness of dynamic problems on a more believable hypothesis. We propose analogues of the OMv Hypothesis for variants of matrix multiplication that are known to be harder than Boolean product in the offline setting, namely: equality, dominance, min-witness, min-max, and bounded monotone min-plus products. These hypotheses are a priori weaker assumptions than the standard (Boolean) OMv Hypothesis and yet we show that they are actually equivalent to it. This establishes the first such fine-grained equivalence class for dynamic problems.

1 Introduction

The job of a dynamic algorithm is to keep its output up to date whenever its input undergoes a local change, e.g., maintaining a shortest s–t path in a graph while it undergoes vertex deletions. Ideally each such update should take at most a polylogarithmic time, but at the very least it should be faster than it takes to recompute a solution from scratch. Despite great progress in the field, for many dynamic problems that goal is beyond the reach of current algorithmic techniques. Starting from the seminal paper by Pătraşcu [19], we often get to explain this hardness by fine-grained conditional lower bounds.

Most of the known *tight* lower bounds for dynamic problems are based on the OMv Hypothesis [11]. This hypothesis is not as widely studied and as well understood as some other hypotheses in fine-grained complexity, such as SETH, 3SUM Hypothesis, and APSP Hypothesis (see, e.g., [22]). It would be more desirable to base hardness of dynamic problems on these more popular (and hence also more believable) assumptions. Unfortunately, the existing lower bounds conditional on them are often not tight for dynamic problems. It seems likely that these hypotheses are not strong enough to explain the complexity of many dynamic problems. We may need to search for a different approach to the following glaring question:

Can we have tight lower bounds for dynamic problems
based on a hypothesis that is more believable than OMv?

Recall that the OMv Hypothesis is about *Boolean product*; it asserts that computing the Boolean product of two $n \times n$ matrices requires cubic $n^{3-o(1)}$ time if the second matrix is given column by column in an online fashion. In the static (i.e., non-online) setting, Boolean product is arguably the easiest of the many studied variants of matrix multiplication. Indeed, it can be computed in time $O(n^\omega)$, where $\omega < 2.372$ [2] is the (integer) matrix multiplication exponent.[1]

In the static matrix product world, if the $O(n^\omega)$ running time is on the "fast" end of the spectrum, then the min-plus product (related to distance computations in graphs) marks the other end: the fastest known algorithm shaves only a subpolynomial factor over the naive cubic running time [26], and the APSP Hypothesis from fine-grained complexity essentially says that no $n^{3-o(1)}$-time algorithm is possible [23].

There are also numerous variants of matrix multiplication that seem to have an "intermediate" hardness on this spectrum. Examples include min-max product [21, 9], min-witness product [8], equality product (a.k.a. Hamming product [18]), dominance product [17], threshold product [12], plus-max product [20], ℓ_{2p+1} product [13], and many others. The fastest known algorithms for these problems have running times that are functions of the matrix multiplication exponent ω, and they converge to $O(n^{2.5})$ when $\omega = 2$. Although it is still an open problem whether this is necessarily the right complexity for all these problems, there are some partial results in the form of tight fine-grained reductions that suggest it might be the case [13, 15, 24].

1.1 Our contributions

The OMv Hypothesis (and the lower bounds it implies) would be a priori more believable if we could replace in its statement the Boolean product with some other product known to be harder in the static world. For instance, we can define in a similar way the Min-Max-OMv problem using the min-max product: Pre-process a matrix $M \in \mathbb{Z}^{n\times n}$, and then answer (one by one, in an online fashion) n queries, each of them asking, given a vector $v \in \mathbb{Z}^n$, to compute the min-max product of M and v, i.e., the vector $u \in \mathbb{Z}^n$ such that

$$u[i] := \min_{k\in[n]} \max\{M[i,k], v[k]\}.$$

Then we can state a corresponding hypothesis, let us call it the Min-Max-OMv Hypothesis, asserting that the Min-Max-OMv problem cannot be solved in truly subcubic time $O(n^{3-\varepsilon})$, for any $\varepsilon > 0$. This of course brings a question:

Can we still give tight reductions from Min-Max-OMv to those dynamic problems for which there are known reductions from (Boolean-)OMv?

It turns out, yes, we can! Somewhat surprisingly[2], we can even give a tight reduction from Min-Max-OMv to Boolean-OMv. This shows that the Min-Max-OMv Hypothesis and the standard (Boolean-)OMv Hypothesis are actually equivalent. Moreover, the min-max product is not a unique example of this phenomenon. We show more equivalent hypotheses based on several matrix products, which are harder than the Boolean product in the static setting (see Section 2 for the formal definitions).

[1] Moreover, the fastest known "combinatorial" algorithm for the Boolean product [1] does not give a similar improvement for the integer product.

[2] This is perhaps less surprising to those readers who are familiar with how the subcubic algebraic algorithms for the intermediate problems work; see Section 1.2.

▶ **Theorem 1.** *The following problems either all have truly subcubic algorithms or none of them do:*

- *Boolean-OMv;* $(\exists_k M[i,k] \wedge v[k])$
- *∃Equality-OMv;* $(\exists_k M[i,k] = v[k])$
- *∃Dominance-OMv;* $(\exists_k M[i,k] \leqslant v[k])$
- *Min-Witness-OMv;* $(\min\{k \mid M[i,k] \wedge v[k]\})$
- *Min-Max-OMv;* $(\min_k \max\{M[i,k], v[k]\})$
- *Bounded Monotone Min-Plus-OMv.* $(\min_k M[i,k] + v[k])$

For the Bounded Monotone Min-Plus-OMv problem the implied algorithm is randomized.

This conglomeration of equivalent problems can be interpreted as making the OMv Hypothesis more believable, and the conditional lower bounds based on it stronger. We recall two analogous conglomerations: the NP-complete problems and the problems equivalent to the All-Pairs Shortest Paths (APSP) problem under subcubic reductions. One of the reasons behind the great success of the theory of NP-completeness is its structural simplicity: many natural problems are NP-complete, and solving any of them efficiently would solve all of them efficiently, so they are all hard for the same underlying reason. For all the multi-faceted NP-complete problems, researchers from different areas have not managed to find a single efficient algorithm, so it seems very plausible that no such algorithm exists. The fine-grained complexity theory at large does not enjoy a similar simplicity: there are multiple independent hardness assumptions, and the reductions often go only in one way, establishing *hardness* but not *equivalence*. A notable exception[3] is the APSP problem, which is conjectured to require cubic time and there are many other problems equivalent to it via subcubic reductions [23]. No truly subcubic algorithms have been found so far for any of these problems, which strengthens the APSP Hypothesis. Our Theorem 1 establishes another such class of problems equivalent under fine-grained subcubic reductions.

Subcubic algorithms in the cell-probe model. We remark that the above equivalences also hold in the cell-probe model, where the running time is measured solely by the number of memory cell probes, and computation is free of charge. To be more specific, from our proofs it follows that each of the above problems can be solved by solving $t^{O(1)}$ instances of any other of those problems and performing some additional computation that runs in time $O(n^3/t)$, in the word RAM model, where t is a parameter to be chosen. Since any algorithm that runs sequentially in time $O(n^{3-\varepsilon})$ in the word RAM model can access only a truly subcubic number of memory cells, the subcubic equivalence in the cell-probe model follows. Larsen and Williams [14] showed that the OMv Hypothesis is actually *false* in the cell-probe model: Every query can be computed with $O(n^{7/4}w^{-1/2})$ probes, where w is the word size. This means that all the other problems listed above have truly subcubic algorithms in the cell-probe model as well.

1.2 Technical overview

We prove Theorem 1 by a series of fine-grained reductions, depicted in Figure 1. The reductions are inspired by known subcubic algebraic algorithms for the corresponding (static) matrix product problems. Such algorithms have running times that are functions of the (integer) matrix multiplication exponent ω. For example, the fastest known (static) min-max

[3] Another such exception is a class of vector problems equivalent to the Orthogonal Vectors problem [7].

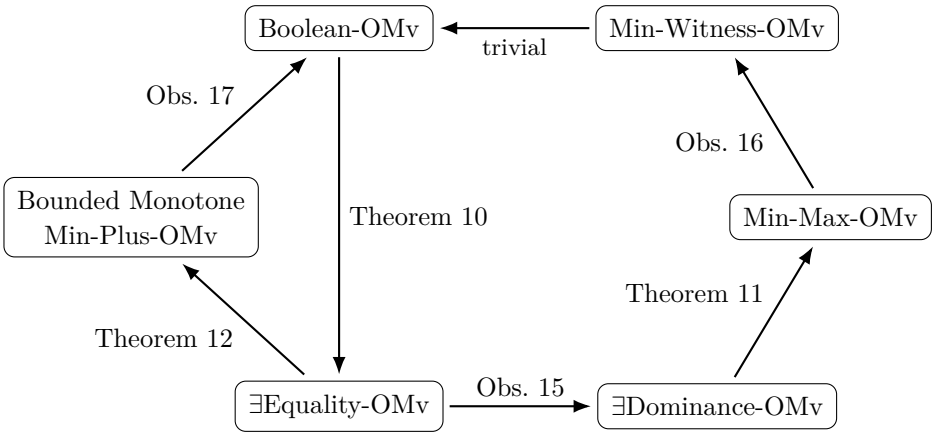

Figure 1 Fine-grained reductions that together prove Theorem 1. An arrow from problem A to problem B means that a subcubic algorithm for A implies a subcubic algorithm for B.

product algorithm [9] runs in time $O(n^{(3+\omega)/2+o(1)})$, which is subcubic for any value of $\omega < 3$. In other words, this algorithm is an implicit subcubic reduction from the (static) min-max product to the (static, integer) matrix multiplication problem. The same is true about all the other intermediate problems we consider in this paper. Our technical contribution is adapting these implicit reductions so that (1) they work in the online setting, and (2) they require only Boolean (and not integer) product.

Detour into static combinatorial algorithms. Before we say a few words about each of the reductions in the paper, let us take a detour from online problems so that we can explicitly state the observation that we already hinted at in the previous paragraph.

▶ **Observation 2.** *The static variants of all the matrix products listed in Theorem 1 are equivalent to each other under subcubic reductions, and the reductions are "combinatorial". That is, if any of the static problems admits a subcubic "combinatorial" algorithm, then all of them do.*

Why is this the case? In one direction, all those non-Boolean products can encode the Boolean product as a special case. In the other direction, all those non-Boolean products admit strongly subcubic algorithms with running times of the form $O(n^{f(\omega)})$ for a function f that happens to satisfy $f(x) < 3$ for every $x < 3$. Therefore, if we could replace in such an algorithm every use of fast algebraic (integer) matrix multiplication with a hypothesized $O(n^{3-\varepsilon})$-time "combinatorial" Boolean matrix multiplication algorithm, we would get a "combinatorial" algorithm for the corresponding non-Boolean product with the running time exponent $f(3-\varepsilon) < 3$. Such a replacement is possible whenever the non-Boolean algorithm does not use (or can be modified not to use) the full counting power of integer matrix multiplication but only checks which output entries are nonzero. This is explicitly the case for some of the non-Boolean products we consider (e.g., the min-witness product [8]). For some others, e.g., the bounded monotone min-plus product [25, 10], such a modification is nontrivial, but still possible.

While this observation is simple and in hindsight not really surprising, we are not aware of it being folklore in the field of fine-grained complexity, so we state it for completeness.

Subcubic reductions and where to find them. In Section 3 we show a subcubic reduction from ∃Equality-OMv to Boolean-OMv (Theorem 10), which can be seen as an adaptation to the online setting of the sparse matrix multiplication algorithm of Yuster and Zwick [27]. Specifically, our algorithm for ∃Equality-OMv handles the $n^{\varepsilon/2}$ most frequently appearing values with the help of $n^{\varepsilon/2}$ Boolean-OMv queries (about indicator vectors of those values). The remaining less frequent values can then be handled with a brute-force approach within the target running time bound.

In Section 4 we show how a subcubic algorithm for ∃Dominance-OMv would yield a subcubic algorithm for Min-Max-OMv (Theorem 11). The proof is inspired by the known (static) min-max product algorithms [21, 9], but it is at the same time simpler, because we do not have to optimize the dependence on ε in the running time of the resulting algorithm. In short, the algorithm splits each row of M into $n^{\varepsilon/2}$ buckets based on the values of the entries, and makes $n^{\varepsilon/2}$ many ∃Dominance-OMv queries in order to establish for each output entry to which bucket of the corresponding row it belongs; then, the algorithm exhaustively searches through the entire bucket.

In Section 5 we show a reduction from Bounded Monotone Min-Plus-OMv to ∃Equality-OMv. On a high level it follows some of the previous (static) algorithms for the bounded monotone min-plus product [25, 10]. However, it also gives a fresh perspective on the problem, because those previously known algorithms use a generalization of the min-witness and bounded (non-monotone) min-plus products (see [25, Theorem 1.2]), while ours deviates from this approach by using the equality product.

In Section 6 we show the remaining reductions (Observations 15, 16, 17). Each of them is either very simple or follows easily from folklore arguments.

1.3 Related work

Bringmann et al. [4] take a different approach at strengthening the OMv Hypothesis. They propose a hypothesis about the complexity of determining if a (nondeterministic) finite automaton accepts a word, and show that this hypothesis implies the OMv Hypothesis. While their new hypothesis is not as well supported as the three main fine-grained complexity hypotheses, it is remarkable that it is a statement about a *static* problem implying a tight lower bound for an online problem.

In a very recent work, Liu [16] shows that OMv is equivalent to the online problem of maintaining a $(1+\epsilon)$-approximate vertex cover in a fully dynamic bipartite graph.

To the best of our knowledge, the only other work that considers a variant of OMv for a non-Boolean product is by Chen et al. [6]. They use an assumption that the Min-Plus-OMv requires cubic time in order to separate partially retroactive from fully retroactive data structures. We note that this assumption seems too strong to be equivalent to the OMv Hypothesis. In particular, any "too simple" reduction from Min-Plus-OMv to Boolean-OMv would morally translate to a subcubic algorithm for the (static) Min-Plus Product problem, refuting the APSP Hypothesis.

1.4 Open problems

In this paper we manage to reduce to Boolean-OMv from OMv variants that *do not involve counting*. We leave it open whether a subcubic algorithm for Boolean-OMv would imply subcubic OMv algorithms for, e.g., the counting variants of the equality and dominance products (i.e., $u[i] := \#\{k \mid M[i,k] = v[k]\}$, and $u[i] := \#\{k \mid M[i,k] \leqslant v[k]\}$, respectively), or at least for the standard integer product ($u[i] := \sum_k M[i,k] \cdot v[k]$).

These open problems relate to the general quest for fine-grained *counting-to-decision* reductions. Chan, Vassilevska Williams, and Xu [5] gave such reductions for the Min-Plus Product, Exact Triangle, and 3SUM problems. Somewhat ironically, their reductions crucially rely on a fast algebraic algorithm for (static) integer matrix multiplication, so it seems unlikely that their techniques could be used to resolve the above open problems, which are about online problems.

2 Preliminaries

2.1 Notation

We use $[n] := \{1, 2, \ldots, n\}$.

2.2 Problems

In this section we formally define all the problems that appear in Theorem 1. Since the definitions are similar to each other, we underline the differences between them.

▶ **Definition 3** (Boolean-OMv). *We are first given for preprocessing a Boolean matrix $M \in \{0,1\}^{n\times n}$, and then we need to answer n queries: In the j-th query, we are given a column vector $v_j \in \{0,1\}^n$, and we have to compute the Boolean product $Mv_j \in \{0,1\}^n$ defined by*

$$(Mv_j)[i] := \begin{cases} 1, & \text{if } \exists_{k\in[n]}\, M[i,k] = 1 \wedge v_j[k] = 1, \\ 0, & \text{otherwise.} \end{cases}$$

We need to answer queries one by one in an online fashion, i.e., we have to output Mv_j before we can receive v_{j+1}.

▶ **Definition 4** (∃Equality-OMv). *We are first given for preprocessing an integer matrix $M \in \mathbb{Z}^{n\times n}$, and then we need to answer n queries: In the j-th query, we are given a column vector $v_j \in \mathbb{Z}^n$, and we have to compute the ∃equality product $M \ominus v_j \in \{0,1\}^n$ defined by*

$$(M \ominus v_j)[i] := \begin{cases} 1, & \text{if } \exists_{k\in[n]}\, M[i,k] = v_j[k], \\ 0, & \text{otherwise.} \end{cases}$$

We need to answer queries one by one in an online fashion, i.e., we have to output $M \ominus v_j$ before we receive v_{j+1}.

▶ **Definition 5** (∃Dominance-OMv). *We are first given for preprocessing an integer matrix $M \in \mathbb{Z}^{n\times n}$, and then we need to answer n queries: In the j-th query, we are given a column vector $v_j \in \mathbb{Z}^n$, and we have to compute the ∃dominance product $M \oslash v_j \in \{0,1\}^n$ defined by*

$$(M \oslash v_j)[i] := \begin{cases} 1, & \text{if } \exists_{k\in[n]}\, M[i,k] \leqslant v_j[k], \\ 0, & \text{otherwise.} \end{cases}$$

We need to answer queries one by one in an online fashion, i.e., we have to output $M \oslash v_j$ before we receive v_{j+1}.

▶ **Definition 6** (Min-Witness-OMv). *We are first given for preprocessing a Boolean matrix $M \in \{0,1\}^{n\times n}$, and then we need to answer n queries: In the j-th query, we are given a column vector $v_j \in \{0,1\}^n$, and we have to compute the min-witness product $M \circledcirc v_j \in ([n] \cup \{\infty\})^n$ defined by*

$$(M \circledcirc v_j)[i] := \min(\{k \in [n] \mid M[i,k] = 1 \wedge v_j[k] = 1\} \cup \{\infty\}).$$

We need to answer queries one by one in an online fashion, i.e., we have to output $M \circledcirc v_j$ before we can receive v_{j+1}.

▶ **Definition 7** (Min-Max-OMv). *We are first given for preprocessing an integer matrix $M \in \mathbb{Z}^{n\times n}$, and then we need to answer n queries: In the j-th query, we are given a column vector $v_j \in \mathbb{Z}^n$, and we have to compute the min-max product $M \circledcirc v_j \in \mathbb{Z}^n$ defined by*

$$(M \circledcirc v_j)[i] := \min_{k\in[n]} \max\{M[i,k], v_j[k]\}.$$

We need to answer queries one by one in an online fashion, i.e., we have to output $M \circledcirc v_j$ before we receive v_{j+1}.

▶ **Definition 8** (Bounded Monotone Min-Plus-OMv). *We are first given for preprocessing an integer matrix $M \in [n]^{n\times n}$, and then we need to answer n queries: In the j-th query, we are given a column vector $v_j \in [n]^n$, and we have to compute the min-plus product $M \oplus v_j \in \mathbb{Z}^n$ defined by*

$$(M \oplus v_j)[i] := \min_{k\in[n]} (M[i,k] + v_j[k]).$$

We need to answer queries one by one in an online fashion, i.e., we have to output $M \oplus v_j$ before we receive v_{j+1}. We are guaranteed that at least one of the following conditions holds:

- *each row of M is nondecreasing, i.e., $M[i,k] \leqslant M[i,k+1]$;*
- *each column of M is nondecreasing, i.e., $M[i,k] \leqslant M[i+1,k]$;*
- *each v_j is nondecreasing, i.e., $v_j[k] \leqslant v_j[k+1]$;*
- *for every k, $v_j[k]$ is a nondecreasing function of j, i.e., $v_j[k] \leqslant v_{j+1}[k]$;*

or it holds with "nondecreasing" replaced by "nonincreasing".

2.3 Hypotheses

Each of the problems defined above admits a naive cubic time algorithm, and for each of them we can conjecture that it is optimal up to subpolynomial factors.

▶ **Definition 9** (*-OMv Hypotheses). *For $x \in \{$Boolean, ∃Equality, ∃Dominance, Min-Witness, Min-Max, Bounded Monotone Min-Plus$\}$, the x-OMv Hypothesis is the statement that there is no algorithm for the x-OMv problem running in time $O(n^{3-\varepsilon})$, for any $\varepsilon > 0$.*

In other words, Theorem 1 says that all the hypotheses stated in Definition 9 are equivalent.

3 Reduction from ∃Equality-OMv to Boolean-OMv

In this section we give a subcubic reduction that can be seen as an easy adaptation to the online setting of the sparse matrix multiplication algorithm of Yuster and Zwick [27].

▶ **Theorem 10.** *If Boolean-OMv can be solved in time $O(n^{3-\varepsilon})$, for some $\varepsilon > 0$, then ∃Equality-OMv can be solved in time $O(n^{3-(\varepsilon/2)})$.*

Proof. Recall that M denotes the input matrix given for preprocessing in the ∃Equality-OMv problem. Let $t := \lceil n^{\varepsilon/2} \rceil$ be a parameter. For every $k \in [n]$ and every $\ell \in [t]$, let $f_k^{(\ell)}$ be the ℓ-th most frequent value appearing in the k-th column of matrix M (if there are less than ℓ distinct values in the column, let $f_k^{(\ell)}$ be some other arbitrary integer). Note that for any value x not in $\{f_k^{(1)}, f_k^{(2)}, \ldots, f_k^{(t)}\}$, x appears in the k-th column of M at most n/t times; we call such values *rare*. In the preprocessing phase, the algorithm prepares t Boolean matrices $M^{(1)}, M^{(2)}, \ldots, M^{(t)} \in \{0,1\}^{n \times n}$ defined as follows:

$$M^{(\ell)}[i,k] := \begin{cases} 1, & \text{if } M[i,k] = f_k^{(\ell)}, \\ 0, & \text{otherwise.} \end{cases}$$

Then, it instantiates the hypothesized Boolean-OMv algorithm for each of these matrices separately. Finally, for each column of M, the algorithm prepares a dictionary mapping each rare value in that column to a list of indices under which that value appears in the column. This ends the preprocessing phase.

Upon receiving a query $v \in \mathbb{Z}^n$, the algorithm first initializes the output vector to all zeros. Then, for every $\ell = 1, \ldots, t$, it creates the vector $v^{(l)}$ defined by

$$v^{(\ell)}[k] := \begin{cases} 1, & \text{if } v[k] = f_k^{(\ell)}, \\ 0, & \text{otherwise,} \end{cases}$$

and computes the Boolean product $M^{(\ell)}v^{(\ell)}$, using the ℓ-th instantiation of the hypothesized Boolean-OMv algorithm. Each such product gets then element-wise OR-ed to the output vector. Finally, for every $k = 1, \ldots, n$, if $v[k]$ is a rare value in the k-th column of matrix M, the algorithm goes through the list of all indices i such that $M[i][k] = v[k]$ (recall that there are at most n/t of them) and for each of them sets the corresponding i-th entry of the output vector to 1.

It is easy to see that whenever the algorithm sets an output entry to 1, it is because of some pair of entries $M[i][k]$ and $v[k]$ that have the same value. Conversely, if some pair of entries $M[i][k]$ and $v[k]$ have the same value, then either it is a frequent value and some $M^{(\ell)}v^{(\ell)}$ contributes a 1, or it is a rare value and gets manually matched.

Let us analyze the running of our ∃Equality-OMv algorithm. There are t instantiations of the hypothesized Boolean-OMv algorithm, which require $O(tn^{3-\varepsilon})$ time in total. Then, going through all rare values takes at most $O(n^2/t)$ time per v_j, and thus $O(n^3/t)$ time for all n queries. This adds up to total time $O(tn^{3-\varepsilon} + n^3/t)$. By choosing $t := \lceil n^{\varepsilon/2} \rceil$ we get the claimed running time $O(n^{3-(\varepsilon/2)})$. ◀

4 Reduction from Min-Max-OMv to ∃Dominance-OMv

In this we show how a subcubic algorithm for ∃Dominance-OMv would yield a subcubic algorithm for Min-Max-OMv. Our proof is inspired by the static min-max product algorithms [21, 9], but it is at the same time simpler, because we do not optimize the dependence on ε in the running time of the resulting algorithm.

▶ **Theorem 11.** *If ∃Dominance-OMv can be solved in time $O(n^{3-\varepsilon})$, for some $\varepsilon > 0$, then Min-Max-OMv can be solved in time $O(n^{3-(\varepsilon/2)})$.*

Proof. Let $t := \lceil n^{\varepsilon/2} \rceil$ be a parameter. For every $i \in [n]$, let R_i be the sorted i-th row of the input matrix M. Consider partitioning each R_i into t *buckets* of consecutive elements, with at most $\lceil n/t \rceil$ elements per bucket. For every $\ell \in [t]$, let $M^{(\ell)} \in (\mathbb{Z} \cup \{\infty\})^{n \times n}$ be the matrix defined as follows:

$$M^{(\ell)}[i,k] := \begin{cases} -M[i,k], & \text{if } M[i,k] \text{ lands in the } \ell\text{-th bucket of } R_i, \\ \infty, & \text{otherwise.} \end{cases}$$

Note that each row of $M^{(\ell)}$ contains $\Theta(n/t)$ finite entries.[4]

In the preprocessing phase, the algorithm instantiates the hypothesised ∃Dominance-OMv algorithm for each of the matrices $M^{(1)}, M^{(2)}, \ldots, M^{(\ell)}$, and also for the matrix M.[5]

Upon receiving a query $v \in \mathbb{Z}^n$, the algorithm proceeds to compute the product $M \circledcirc v$ in two steps. First, for every $i \in [n]$, it computes the minimum $M[i,k]$ such that $M[i,k] \geqslant v[k]$, and stores the results in a column vector u. Second, for every $i \in [n]$, it computes the minimum $v[k]$ such that $v[k] \geqslant M[i,k]$, and stores the results in a column vector w. At the very end the algorithm computes $(M \circledcirc v)[i] = \min\{u[i], w[i]\}$, for every $i \in [n]$.

In order to compute u, the algorithm first asks for the dominance products $M^{(\ell)} \circledgtr (-v)$, for all $\ell \in [t]$. Then, for each $i = 1, \ldots, n$, the algorithm finds the smallest ℓ such that $(M^{(\ell)} \circledgtr (-v))[i] = 1$, which corresponds to finding the first bucket in R_i containing an element *greater*[6] than or equal to the corresponding element in v. Hence, the algorithm can scan the elements in this bucket and pick the smallest one that is larger than or equal to the corresponding element in v; this element is then stored in $u[i]$.

Let us analyze the cost of computing u's over the span of n queries. The t dominance products require time $O(tn^{3-\varepsilon})$ in total. On top of that, for each of the n queries and for each of the n output coordinates, the algorithm scans one bucket of size $\Theta(n/t)$, which takes time $O(n^3/t)$ in total. All together, the algorithm spends time $O(tn^{3-\varepsilon} + n^3/t) = O(n^{3-(\varepsilon/2)})$ on computing u's.

Next, it is almost symmetric to calculate w. The algorithm sorts the entries of v into an ordered list S, and partitions S into t buckets, with at most $\lceil n/t \rceil$ elements per bucket. For each bucket $\ell \in [t]$, the algorithm computes the dominance product $M \circledless v^{(\ell)}$, where $v^{(\ell)} \in (\mathbb{Z} \cup \{-\infty\})^n$ is the column vector such that

$$v^{(\ell)}[k] = \begin{cases} v[k], & \text{if } v[k] \text{ lands in the } \ell\text{-th bucket of } S, \\ -\infty, & \text{otherwise.} \end{cases}$$

Then, for each $i = 1, \ldots, n$, the algorithm looks for the smallest ℓ such that $(M \circledless v^{(\ell)})[i] = 1$, and scans the elements in the ℓ-th bucket looking for the smallest $v[k]$ that is greater than or equal to the corresponding $M[i,k]$. By the same argument as before, computing all w's takes time $O(n^{3-(\varepsilon/2)})$. ◀

[4] If there are multiple entries with the same value, they may land in different buckets.

[5] Formally, the ∃Dominance-OMv algorithm may not accept infinite entries in the input, but we can replace each ∞ with $W + 2$, where W denotes the largest absolute value of any entry in M, and each entry greater than W in any query vector with $W + 1$.

[6] This is because the entries in $M^{(\ell)}$ and $-v$ are negated.

5 Reduction from Bounded Monotone Min-Plus-OMv to ∃Equality-OMv

In this section we show a reduction from Bounded Monotone Min-Plus-OMv to ∃Equality-OMv. We follow the high-level approach of some of the previous static algorithms for the bounded monotone min-plus product [25, 10]. However, we deviate from that approach by using the equality product where the known algorithms use a generalization of the min-witness and bounded (non-monotone) min-plus products (see [25, Theorem 1.2]).

▶ **Theorem 12.** *If ∃Equality-OMv can be solved in time $O(n^{3-\varepsilon})$, for some $\varepsilon > 0$, then Bounded Monotone Min-Plus-OMv can be solved in time $O(n^{3-(\varepsilon/3)} \log n)$ by a randomized algorithm that succeeds with probability*[7] *at least $1 - 1/n$.*

Before we present the algorithm itself let us introduce some notation and prove some preliminary facts. Let $\Delta := \lceil n^{\varepsilon/3} \rceil$ be a parameter. For a fixed query vector $v \in \mathbb{Z}^n$, let

$$u := M \oplus v, \quad \widehat{M} := \lfloor M/\Delta \rfloor, \quad \widehat{v} := \lfloor v/\Delta \rfloor, \quad \text{and} \quad \widehat{u} := \widehat{M} \oplus \widehat{v}.$$

Be mindful that it is *not* necessarily the case that $\widehat{u} = \lfloor u/\Delta \rfloor$. Finally, for every $i \in [n]$, let us define the set of *candidates for* $u[i]$ to be

$$C_i := \left\{ k \in [n] \;\middle|\; \widehat{M}[i,k] + \widehat{v}[k] \in \{\widehat{u}[i], \widehat{u}[i]+1\} \right\}.$$

▶ **Lemma 13.** *It suffices to check only $k \in C_i$ in order to compute $u[i]$, i.e.,*

$$\min_{k \in [n]} M[i,k] + v[k] = \min_{k \in C_i} M[i,k] + v[k].$$

Proof. First, for any pair $(i,j) \in [n] \times [n]$, due to rounding down we have

$$M[i,j] + v[j] - \Delta \cdot (\widehat{M}[i,j] + \widehat{v}[j]) \in [0, 2\Delta).$$

Now, suppose that k is a witness for $u[i]$, and l is a witness for $\widehat{u}[i]$, i.e., $M[i,k] + v[k] = u[i]$, and $\widehat{M}[i,l] + \widehat{v}[l] = \widehat{u}[i]$. We derive that

$$\begin{aligned} \Delta \cdot \widehat{u}[i] + 2\Delta &= \Delta \cdot (\widehat{M}[i,l] + \widehat{v}[l]) + 2\Delta \\ &> M[i,l] + v[l] \\ &\geqslant M[i,k] + v[k] \\ &\geqslant \Delta \cdot (\widehat{M}[i,k] + \widehat{v}[k]). \end{aligned}$$

Therefore, we have $\widehat{M}[i,k] + \widehat{v}[k] < \widehat{u}[i] + 2$. Since the matrix entries all take integer values, we have that if $k \in [n]$ is a witness for $u[i]$, then it must satisfy that $\widehat{M}[i,k] + \widehat{v}[k] \in \{\widehat{u}[i], \widehat{u}[i]+1\}$, i.e., $k \in C_i$. ◀

Now we argue that small sets of candidates can be enumerated efficiently.

▶ **Lemma 14.** *For a fixed query vector $v \in \mathbb{Z}^n$, there is an algorithm that runs in time $O(n^2 \log n/\Delta)$ and lists all elements of all sets C_i such that $|C_i| \leqslant n/\Delta$. In the case that $v_j[k]$ is a (weakly) monotone function of j (i.e., the 4-th case in Definition 8) this running time is amortized over n query vectors.*

[7] Note that the success probability can be amplified to $1 - 1/\operatorname{poly}(n)$ by running in parallel a constant number of copies of the algorithm and taking the majority vote.

Proof. We consider four cases, based on the direction of the monotonicity:

(1) Each column of M is monotone. In this case also the columns of $\widehat{M}$ are monotone, and their entries are bounded by $\lfloor n/\Delta \rfloor$. The algorithm uses a self-balancing binary search tree (BST) to maintain, while i iterates from 1 to n, the set of pairs

$$\big\{(\widehat{M}[i,k] + \widehat{v}[k], k) \;\big|\; k \in [n]\big\}.$$

Computing $\widehat{u}[i]$ is the standard tree operation of querying for the minimum. Moreover, the BST can report the number of elements smaller than a certain value in time $O(\log n)$, and enumerate them in time proportional to that number. This allows the algorithm to determine the size of C_i quickly, and enumerate it if it is small. As i iterates from 1 to n, the algorithm only needs to update the elements where there is an increase (or decrease) from $\widehat{M}[i,k]$ to $\widehat{M}[i+1,k]$. In each column of M there are at most n/Δ such changes, thanks to the boundedness and monotonicity.[8] Therefore the total number of updates over the n iterations is at most n^2/Δ, and each update takes time $O(\log n)$. The time spent on listing elements of C_i (for all i) is $O(n \log n + n^2/\Delta)$.

(2) For each k, $v_j[k]$ is a monotone function of j. This case is very similar to the previous one. The algorithm maintains (over the span of n queries) a separate BST for each i, and uses it to compute $(\widehat{M} \oplus \widehat{v}_j)[i]$ for all j's. When there is an increase (or decrease) from $\widehat{v}_j[k]$ to $\widehat{v}_{j+1}[k]$, the algorithm has to update an element in all n trees, but this happens at most n/Δ times for each k, so n^2/Δ times for all k's. Hence, the total time spent on such updates over the course of n queries is $O(n^3 \log n/\Delta)$, and the amortized time per query is $O(n^2 \log n/\Delta)$.

(3) Each row of M is monotone. Due to the monotonicity, we can think of the i-th row of $\widehat{M}$, for each $i = 1, \ldots, n$, as consisting of $\lfloor n/\Delta \rfloor + 1$ contiguous *blocks* $K_i^{(0)}, K_i^{(1)}, \ldots, K_i^{(\lfloor n/\Delta \rfloor)} \subseteq [n]$ of identical entries, i.e., $\forall_{k \in K_i^{(x)}}\, M[i,k] = x$. Upon receiving a query vector v, the algorithm builds (in linear time) a range minimum query (RMQ) data structure (see, e.g., [3]) in order to compute in constant time the minimum entry of $\widehat{v}$ in each of the $O(n^2/\Delta)$ blocks, i.e., $\widehat{v}[[K_i^{(x)}]] := \min\{\widehat{v}[k] \mid k \in K_i^{(x)}\}$. Adding each of these minima to their corresponding values from $\widehat{M}$ gives a list of candidate values for $\widehat{u}[i]$'s, i.e.,

$$\widehat{u}[i] = \min\big\{0 + \widehat{v}[[K_i^{(0)}]],\; 1 + \widehat{v}[[K_i^{(1)}]],\; \ldots,\; \lfloor n/\Delta \rfloor + \widehat{v}[[K_i^{(\lfloor n/\Delta \rfloor)}]]\big\}.$$

Thus, we already know how to compute $\widehat{u}$ is time $O(n^2/\Delta)$. Now let us explain how to extend this idea to also list elements of all small enough C_i's. For each value that appears in $\widehat{v}$, the algorithm calculates the sorted sequence of indices under which this value appears in $\widehat{v}$. This allows computing in time $O(\log n)$ how many times a given value appears in a given range of indices in $\widehat{v}$; indeed, it boils down to performing two binary searches of the two endpoints of the range in the sequence corresponding to the given value. Furthermore, all these appearances can be enumerated in time proportional to their count. For each block $K_i^{(x)}$ such that $x + \widehat{v}[[K_i^{(x)}]] = \widehat{u}[i]$ the algorithm enumerates all appearances of $\widehat{v}[[K_i^{(x)}]]$ and $\widehat{v}[[K_i^{(x)}]] + 1$ in the range $K_i^{(x)}$ in $\widehat{v}$, and adds them to C_i. If the total size of C_i would exceed n/Δ, the algorithm stops the enumeration and proceeds to the next block. Similarly, for each block such that $x + \widehat{v}[[K_i^{(x)}]] = \widehat{u}[i] + 1$ the algorithm enumerates all appearances of $\widehat{v}[[K_i^{(x)}]]$.

[8] The locations of all such changes can be, e.g., precomputed before processing any query, or computed during each query using binary search in time $O(\log n)$ per each location.

(4) Each v is monotone. This case is symmetric to the previous one. The difference is that now the algorithm splits $\widehat{v}$ into $O(n/\Delta)$ blocks, and prepares an RMQ data structure for each row of $\widehat{M}$. ◀

Now we are ready to present our subcubic algorithm for Bounded Monotone Min-Plus OMv, assuming a subcubic algorithm for ∃Equality-OMv.

Proof of Theorem 12. In the preprocessing, the algorithm samples uniformly and independently at random a set $R \subseteq [n]$ of columns of M, of size $|R| := \lceil 3\Delta \ln n \rceil$. For each $r \in R$, the algorithm prepares an ∃Equality-OMv data structure for matrix $M^{(r)}$ obtained from M by subtracting the r-th column from all the columns, i.e.,

$$M^{(r)}[i,k] := M[i,k] - M[i,r].$$

The algorithm handles each query in two independent steps. The goal of the first step is to compute $u[i]$ for those i that have $|C_i| \leqslant n/\Delta$, and the goal of the second step is to compute $u[i]$ for i with $|C_i| > n/\Delta$.

First step. For each $i \in [n]$, the algorithm either finds out that $|C_i| > n/\Delta$, or lists all elements of C_i and then computes $u[i] = \min_{k \in C_i}(M[i,k] + v[k])$. By Lemma 14, this takes time $O(n^2 \log n/\Delta)$, for all i's in total. The correctness of this step follows from Lemma 13.

Second step. In the second step, the algorithm must compute the remaining $u[i]$'s, i.e., those for which C_i's contain too many elements to be handled in the first step. To this end, for every $r \in R$ and every $\delta \in \{0, 1, \ldots, 3\Delta - 2\}$ the algorithm computes the equality product $M^{(r)} \ominus -(v - v[r] + \delta)$. For every $i \in [n]$, if $(M^{(r)} \ominus -(v - v[r] + \delta))[i]{=}1$, then there must exist $k \in [n]$ such that

$$M[i,k] - M[i,r] = -(v[k] - v[r] + \delta)$$

and hence

$$M[i,k] + v[k] = M[i,r] + v[r] - \delta.$$

The algorithm therefore adds $M[i,r] + v[r] - \delta$ to the list of possible values for $u[i]$, and at the end of the process it sets each $u[i]$ to the minimum over those values.

Analysis of the second step. We now argue that if $R \cap C_i \neq \emptyset$ (which holds with high probability when $|C_i| > n/\Delta$ via a standard hitting set argument, see below), then the algorithm correctly computes $u[i]$ in the second step. Indeed, pick $r \in R \cap C_i$ and let $k \in [n]$ be a witness for $(M \oplus v)[i]$, i.e., $M[i,k]+v[k] = (M \oplus v)[i]$. Let $\delta := (M[i,r]+v[r]) - (M[i,k]+v[k])$. Clearly, $(M^{(r)} \ominus -(v - v[r] + \delta))[i]{=}1$, so it only remains to show that $\delta \in \{0, 1, \ldots, 3\Delta - 2\}$. Obviously, $\delta \geqslant 0$, because k minimizes $M[i,k] + v[k]$. Now let us upper bound the offset δ. Since $r \in C_i$, we have $\widehat{M}[i,r] + \widehat{v}[r] \leqslant \widehat{u}[i] + 1$, and hence

$$M[i,r] + v[r] \;\leqslant\; (\Delta\widehat{M}[i,r] + \Delta - 1) + (\Delta\widehat{v}[r] + \Delta - 1) \;\leqslant\; \Delta\widehat{u}[i] + 3\Delta - 2.$$

Moreover, $\widehat{M}[i,k] + \widehat{v}[k] \geqslant \widehat{u}[i]$, and therefore

$$M[i,k] + v[k] \;\geqslant\; \Delta\widehat{M}[i,k] + \Delta\widehat{v}[k] \;\geqslant\; \Delta\widehat{u}[i].$$

We conclude that $\delta \leqslant (\Delta\widehat{u}[i] + 3\Delta - 2) - \Delta\widehat{u}[i] = 3\Delta - 2$, as required.

It remains to analyze the success probability of the whole algorithm. For a fixed output index $i \in [n]$ such that $|C_i| > n/\Delta$, the probability that the algorithm failed to sample an element r from C_i in all $|R| = \lceil 3\Delta \ln n \rceil$ rounds is at most $(1-1/\Delta)^{3\Delta \ln n} < (1/e)^{3 \ln n} = 1/n^3$. By a union bound over all n output indices for each of the n queries, the algorithm succeeds to correctly compute all n^2 output entries with probability at least $1 - n^2/n^3 = 1 - 1/n$.

Running time. The first step of each query (Lemma 14) takes time $O(n^2 \log n/\Delta)$, summing up to $O(n^3 \log n/\Delta)$ for all n queries. Regarding the second step, for each query the algorithm computes $O(|R|\Delta) = O(\Delta^2 \log n)$ equality matrix-vector products, and over the course of n queries this takes time $O(n^{3-\varepsilon}\Delta^2 \log n)$. The total running time is therefore $O(n^3 \log n/\Delta + n^{3-\varepsilon}\Delta^2 \log n) = O(n^{3-(\varepsilon/3)} \log n)$. ◀

6 Remaining reductions

In this section we state the remaining easy reductions that complete the proof of Theorem 1.

6.1 Reduction from ∃Dominance-OMv to ∃Equality-OMv

▶ **Observation 15.** *If ∃Equality-OMv can be solved in time $T(n)$, then ∃Dominance-OMv can be solved in time $O(T(n) \log n)$.*

Proof. The proof follows a folklore argument, see, e.g., [13]. It uses the fact that, for any two non-negative integers a and b, it holds that $a < b$ if and only if there exists $\ell \geqslant 0$ such that

- the ℓ-th least significant bit of a is 0; and
- the ℓ-th least significant bit of b is 1; and
- a agrees with b on all bits higher than the ℓ-th least significant, i.e., $\lfloor a/2^{\ell+1} \rfloor = \lfloor b/2^{\ell+1} \rfloor$.

Moreover, without loss of generality, all the input numbers are integers between 0 and $n^2 - 1$. Indeed, in the preprocessing, each entry of M can be replaced by its rank in the sorted order of all entries of M; then, during a query, each entry of v can be replaced by the rank of the smallest entry of M greater than or equal to it. Last but not least, $M[i,k] \leqslant v[k]$ if and only if $M[i,k] < v[k] + 1$, because the input numbers are integers. Hence, the algorithm sets, for $\ell = 0, 1, \ldots, \lceil \log(n^2) \rceil$,

$$M^{(\ell)}[i,k] := \begin{cases} \left\lfloor \frac{M[i,k]}{2^{\ell+1}} \right\rfloor, & \text{if the } \ell\text{-th least significant bit of } M[i,k] \text{ is } 0 \\ -1, & \text{otherwise,} \end{cases}$$

$$v^{(\ell)}[k] := \begin{cases} \left\lfloor \frac{v[k]+1}{2^{\ell+1}} \right\rfloor, & \text{if the } \ell\text{-th least significant bit of } v[k]+1 \text{ is } 1 \\ -2, & \text{otherwise,} \end{cases}$$

and uses the fact that $(M \circledcirc v)[i] = 1$ if and only if $\exists_\ell \ (M^{(\ell)} \ominus v^{(\ell)})[i] = 1$. ◀

6.2 Reduction from Min-Witness-OMv to Min-Max-OMv

▶ **Observation 16.** *If Min-Max-OMv can be solved in time $T(n)$, then Min-Witness-OMv can be solved in time $T(n) + O(n^2)$.*

Proof. The proof follows another folklore argument, see, e.g., [15]. The algorithm sets

$$M'[i,k] := \begin{cases} k, & \text{if } M[i,k] = 1 \\ \infty, & \text{otherwise,} \end{cases} \quad \text{and} \quad v'[k] := \begin{cases} k, & \text{if } v[k] = 1 \\ \infty, & \text{otherwise,} \end{cases}$$

and uses the fact $M \circledcirc v = M' \circledcirc v'$. ◀

6.3 Reduction from Boolean-OMv to Bounded Monotone Min-Plus-OMv

▶ **Observation 17.** *If Bounded Monotone Min-Plus-OMv can be solved in time $T(n)$, then Boolean-OMv can be solved in time $T(n) + O(n^2)$.*

Proof. The algorithm sets

$$M'[i,k] := 2 \cdot (i+k) - M[i,k], \quad \text{and} \quad v'_j[k] := 2 \cdot (j-k) - v_j[k],$$

and uses the fact that $(Mv_j)[i] = 1$ if and only if $(M' \oplus v'_j)[i] = 2 \cdot (i+j) - 2$. ◀

We remark that the above reduction produces Min-Plus-OMv instances that are monotone in all four directions simultaneously, while our Bounded Monotone Min-Plus-OMv algorithm of Theorem 12 works already for instances with monotonicity in one (arbitrarily chosen) direction.

Safe Sequences via Dominators in DAGs for Path-Covering Problems

Francisco Sena[1]

Abstract

A *path-covering* problem on a directed acyclic graph (DAG) requires finding a set of source-to-sink paths that cover all the nodes, all the arcs, or subsets thereof, and additionally they are optimal with respect to some function. In this paper we study *safe sequences* of nodes or arcs, namely sequences that appear in some path of every path cover of a DAG.

We show that safe sequences admit a simple characterization via cutnodes. Moreover, we establish a connection between maximal safe sequences and leaf-to-root paths in the source- and sink-dominator trees of the DAG, which may be of independent interest in the extensive literature on dominators. With dominator trees, safe sequences admit an $O(n)$-size representation and a linear-time output-sensitive enumeration algorithm running in time $O(m + o)$, where n and m are the number of nodes and arcs, respectively, and o is the total length of the maximal safe sequences.

We then apply maximal safe sequences to simplify Integer Linear Programs (ILPs) for two path-covering problems, LeastSquares and MinPathError, which are at the core of RNA transcript assembly problems from bioinformatics. On various datasets, maximal safe sequences can be computed in under 0.1 seconds per graph, on average, and ILP solvers whose search space is reduced in this manner exhibit significant speed-ups. For example on graphs with a large width, average speed-ups are in the range $50 - 250\times$ for MinPathError and in the range $80 - 350\times$ for LeastSquares. Optimizing ILPs using safe sequences can thus become a fast building block of practical RNA transcript assembly tools, and more generally, of path-covering problems.

1 Introduction

Data reduction, namely simplifying the input to a problem while maintaining equivalent solutions, has proved extremely successful in solving hard problems in both theory and practice [26]. While the most well-known approach for data reduction is *kernelization* [37, 18], there are also other ways to pre-process the input in order to obtain practical algorithms.

For example, for graph problems where a solution is a set of vertices with certain properties, Bumpus et al. [8] and Jansen and Verhaegh [29] considered the notion of *c-essential vertex* as one belonging to *all* c-approximate solutions to the problem. They showed that for some vertex-subset finding problems (e.g. Vertex Cover) and some values of c, there exist algorithms with an exponential dependency only in the number of *non-c-essential vertices*.

In this paper we pursue a similar data reduction approach, via the notion of *safe partial solution* [52], defined as one "appearing" in all solutions to a problem. For solutions that are sets of paths satisfying certain properties, a *safe path* can be defined as one appearing as a subpath of some path of any solution. Intuitively, safety corresponds to 1-essentiality.

For an NP-hard problem, it is usually intractable also to compute all its safe partial solutions (see e.g. [15]). As such, in this paper we use the following property about safety. Let $\mathcal{S}$ be the (unknown) set of solutions to a problem, and let $\mathcal{S}' \supseteq \mathcal{S}$ be a superset of $\mathcal{S}$ whose safe partial solutions can be computed efficiently. Then, if a partial solution appears in all solutions in $\mathcal{S}'$, it also appears in all solutions in $\mathcal{S}$.

This property was used by Grigorjew et al. [25] when applying safety as a pre-processing step for the Minimum Flow Decomposition (MFD) problem. The MFD problem asks to decompose the flow in a directed acyclic graph (DAG) into a minimum number of weighted source-to-sink paths [4, 53]. As solution superset $\mathcal{S}'$, they considered flow decompositions with any number of paths, whose safe paths can be computed in polynomial time [30, 31, 2]. Instead of simplifying the input graph, they used the safe paths to simplify an integer linear program (ILP) for the MFD problem from [17], thus reducing the search space of the ILP solver. This resulted in speed-ups of up to 200 times on the hardest instances.

In this paper we focus on problems whose input consists of an s-t *DAG*[2] G where the solution superset $\mathcal{S}'$ contains all the sets of paths in G from s to t that together cover all the nodes or arcs of G (or given subsets thereof). We will refer to these objects simply as *path covers*. Note that a flow decomposition is also a path cover of the arcs carrying flow, but path covers generalize many other problems, especially those modeling practical problems from bioinformatics, see Section 1.2. Next, we present the contributions of the paper and further contextualization.

1.1 Optimal enumeration of maximal safe sequences via dominators

Safe sequences as a generalization of safe paths. The notion of a safe *path* has been extensively used to capture *contiguous* safe partial solutions (see e.g. [52, 48, 15, 40, 45, 31, 11]). However, for our purposes contiguity is not necessary, but only the fact that the nodes/arcs in a safe partial solution appear in the same order in some path of every solution. For example, it may be that the only way to reach a node u is via a node v, with some complex subgraph between them. The sequence u, v thus appears in some path of every path cover of the nodes.

[2] By an s-t *directed graph* we mean one with a unique source s and unique sink t such that all nodes are reachable from s and all nodes reach t; if the graph is acyclic, then it is an s-t *DAG*. Path-covering problems on DAGs typically require that paths either start in a source of the graph, or more generally, in a given set of starting nodes, and analogously end in a sink, or in a given set of terminal nodes. However, these start/end nodes can naturally be connected to s and t, and thus we can assume, without loss of generality, that our DAGs are s-t DAGs.

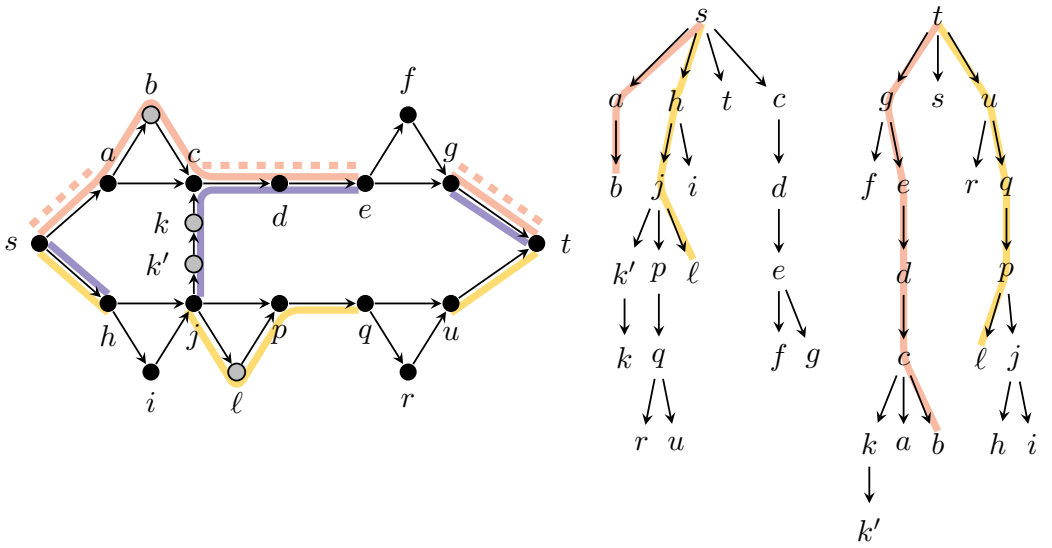

Figure 1 An s-t DAG and its s- and t-dominator trees. Three maximal safe sequences with respect to path covers of the nodes are shown in solid orange, violet, and yellow. Nodes b and ℓ are leaves in both dominator trees, and thus their extension into the orange and yellow sequences, resp., are maximally safe. (The maximal safe sequences obtained by extending nodes f, i and r are not shown.) Note that $k'k$ is a unitary path and that $\mathsf{extension}(k') = \mathsf{extension}(k)$. The dashed orange safe sequence is not maximal and can be obtained by extending a.

We thus define a *safe sequence* with respect to the path covers of a DAG G, either of the nodes or of the arcs, analogously to that of a safe path (see Figure 1 for an example). This notion is inspired by the work of Ma, Zheng and Kingsford [57], who proposed a problem (AND-Quant) and a max-flow-based algorithm deciding when a sequence of arcs appears in some path in every flow decomposition (with any number of paths) of a flow in a DAG. Here, we are particularly interested in characterizing but also in computing *maximal* safe sequences, i.e., safe sequences that are not a proper subsequence of another safe sequence.

Characterization of safe sequences. Assume that the input DAG has n nodes and m arcs. We show that safe sequences admit a simple characterization in terms of cutnodes. A u-v *cutnode* is a node such that all paths from u to v (u-v *paths*) pass through it. We present our results for path covers of the nodes and refer to the extended version for the results for path covers of the arcs. Omitted proofs can be found in the extended version.

▶ **Theorem 1** (Characterization of safe sequences). *Let $G = (N, A)$ be an s-t DAG and X be a sequence of nodes. The following statements are equivalent:*

1. *X is safe for path covers.*
2. *There is a node $u \in N$ such that every s-t path covering u contains X.*
3. *There is a node $v \in N$ such that X is contained in the sequence obtained as the concatenation of the sequences of s-v and v-t cutnodes.*

While outputting the sequences of s and t cutnodes for every node v in the graph can be done in time $O(m)$ per node, different nodes can thus be extended to the same maximal safe sequence, and some extensions may not even be maximal (see Figure 1). The challenge is to characterize those nodes identifying all and only maximal safe sequences, without duplicates.

Linear-time output-sensitive enumeration via dominators. We show that we can identify such nodes in an elegant manner using *dominators*, which is a well-studied concept related to cutnodes (see e.g. the survey [23] for an in-depth contextualization of dominators). In particular, the *s-dominator tree* of an *s-t* DAG (N, A) has node set N, and u is the parent of v iff all paths from s to v pass through u, and moreover there is no node reachable from u (except u itself) whose removal makes v unreachable from u.

The key idea behind our results is to work *also* with the t-dominator tree of G, which is defined in an analogous manner, but considering reachabilities *to* t. By analyzing the interplay between the two trees, we show that the nodes solving this problem (Theorem 9) are those that are *leaves in both* the s- and t-dominator trees, only after overcoming some technicalities arising from unitary paths (see Figure 1, Lemma 4 and Lemma 8). Since dominator tree leaves admit a characterization in terms of in- or out-neighborhoods on DAGs (Lemma 5), this leads to an $O(mn)$-time algorithm outputting all and only maximal safe sequences without duplicates, independently of dominator trees:

▶ **Theorem 2.** *Given an s-t DAG G with n nodes and m arcs, we can compute all and only the maximal safe sequences of G in $O(nm)$-time, without constructing dominator trees.*

To improve this time bound we resort to the fact that dominator trees admit an $O(m+n)$ time construction [6, 7, 20], although so far some of these algorithms do not seem to be practical. See [24, 22, 14] for experimental studies on different dominator tree algorithms. Regardless, any dominator algorithm serves our purposes and its effect on the runtime of our algorithm is clear in the proof of the theorem below.

▶ **Theorem 3** (Enumeration of maximal safe sequences)**.** *Let G be an s-t DAG with n nodes and m arcs. The following hold:*

1. *There is an $O(m + o)$ time algorithm outputting the set of all maximal safe sequences with no duplicates, where o denotes the total length of all the maximal safe sequences.*
2. *There is an $O(n)$-size representation of all the maximal safe sequences of G that can be built in $O(m + n)$ time.*

An analogous result to Theorem 3 can be obtained for path covers where only a given subset $C \subseteq N$ of nodes has to be covered. To achieve that, we have to analyze the dominator trees induced by the dominance relation restricted to C. Moreover, analogous results can be obtained also for path covers of the arcs. The details can be found in the extended version.

1.2 Scaling path-covering ILPs for bioinformatics problems

The motivation of our work comes from bioinformatics, where many NP-hard graph problems related to sequencing data require finding a set of paths in a DAG satisfying certain properties. For example, in the *RNA transcript assembly* problem, we need to recover the RNA transcripts produced in various abundances by a gene, given only smaller fragments (i.e. RNA-seq reads) sequenced from the RNA transcripts. This problem is usually solved by first building an arc-weighted DAG from the fragments, i.e., a *splice graph*. The RNA transcripts correspond to a set of source-to-sink weighted paths in the DAG that "best explain" the arc-weights, under various definitions of optimality, see e.g. [36, 35, 56, 46, 55, 47, 50, 19, 17, 15].

In our work we consider two path-covering problems used for RNA transcript assembly, in which we use safe sequences to fix some variables of the corresponding ILPs. We assume that in every arc uv of the input graph there is an associated positive weight $w(uv)$. We now briefly describe the ILPs.

We selected a classical least-squares model (which we call LeastSquares) that is at the core of several RNA assembly tools e.g. [34, 12, 21, 33, 38, 51]. This minimizes the sum of squared differences between the weight of an arc and the weights of the solution paths passing through the arc. The ILP formulation requires no additional constraints, and the ILP objective function is:[3]

$$\min \sum_{uv \in A} \left(w(uv) - \sum_{i=1}^{k} x_{uvi} w_i \right)^2 . \tag{1}$$

While this model is popular, it has quadratic terms in its objective function, which makes it harder to solve. Therefore, as second model (which we call MinPathError), we chose one that was recently introduced in [16]. Then, for k paths to be a solution to the ILP, we require that the absolute difference between the weight of an arc and the weights of the solution paths passing through the arc must be below the sum of the errors (or slacks) of the paths passing through the arc. Formally, we add the constraint:[4]

$$\left| w(uv) - \sum_{i=1}^{k} x_{uvi} w_i \right| \leq \sum_{i=1}^{k} x_{uvi} \rho_i, \quad \forall uv \in A, \tag{2}$$

with objective function: $\min \sum_{i=1}^{k} \rho_i$. By definition, the solution paths must cover every arc uv, since otherwise the above condition becomes $w(uv) \leq 0$, which contradicts the assumption that w is positive everywhere. See [17] for further details.

On various datasets, maximal safe sequences can be computed in under 0.1 seconds per graph, on average, and such safety-optimized ILPs show significant speed-ups over the original ones. More specifically, on the harder instances of graphs with a large width, average speed-ups are in the range $50 - 250\times$ for MinPathError and in the range $80 - 350\times$ for LeastSquares. As such, our optimizations can become a scalable building block of practical RNA transcript assembly tools, but also of general path-covering problems.

2 Notation and preliminaries

Graphs. In this paper we consider directed graphs, especially directed acyclic graphs (DAGs). For a DAG $G = (N, A)$ with node set N and arc set A, we let $n = |N|$ and $m = |A|$. We denote an arc from u to v as uv and a path p through nodes $v_1, \ldots, v_k$ as $p = v_1 \ldots v_k$. Two paths are considered distinct if they differ in at least one node. The set of *in-neighbors* (*out-neighbors*) of a node v is denoted N_v^- (N_v^+), and its *indegree* (*outdegree*) as d_v^- (d_v^+). For nodes u, v we say that there is a *u-v path* if there is a path whose first node is u and last node is v (we also say that u *reaches* v). An *antichain* is a set of pairwise unreachable nodes. The size of the largest antichain in a DAG is called *width*. Analogously, for arcs uv, xy we say that uv reaches xy if v reaches x. An *arc-antichain* is a set of pairwise unreachable arcs, and the *arc-width* of a DAG is the size of the largest arc-antichain of the graph.

For $X \subseteq N$ we denote a *sequence* X through nodes $u_1, \ldots, u_\ell$ as $X = u_1, \ldots, u_\ell$ if there is a u_i-u_{i+1} path for all $1 \leq i \leq \ell - 1$; in particular, a path is a sequence. We say that X *covers* or *contains* a node v if $v = u_i$ for some $i \in \{1, \ldots, \ell\}$, and we write $u \in X$. If Y is a sequence and each node of X is contained in Y we say that X is a *subsequence* of Y, or that X is *contained* in Y. Since G is a DAG, the nodes of X appear in the same order as in Y.

[3] Note that the terms $x_{uvi} w_i$ are not linear, but can be linearized using a simple technique, see [17, 16].
[4] Note again that the terms $x_{uvi} w_i$ and $x_{uvi} \rho_i$ are not linear, but can be linearized using a simple technique, see [16].

Let $X' = v_1, v_2, \ldots, v_{\ell'}$ be a sequence such that there is a path from the last node u_ℓ of X to v_1. The *concatenation* of X and X' is simply the sequence XX' obtained as X followed by X'. If $u_\ell = v_1$, then the repeated occurrence of v_1 is removed, i.e. $XX' := u_1, \ldots, u_\ell, v_2, \ldots, v_{\ell'}$. We adopt the convention that lowercase letters u, v, w, x, y, z denote nodes and uppercase letters X, Y denote sequences of nodes.

Safety. We define a *path cover* of G to be a set P of s-t paths such that $\forall u \in N\ \exists p \in P : u \in p$; we also say *cover* instead of "s-t path cover of G" when the graph G is clear from the context. Two path covers are distinct if they differ in at least one path. We assume that every node of G lies in some s-t path. We say that a sequence X is *safe* for G if in every path cover P of G it holds that X is a subsequence of some path in P. If X is not safe we say that it is *unsafe*. A sequence X is *maximally safe* if it is not a subsequence of any other safe sequence. We assume that there is always an s-t path containing a given sequence of nodes, otherwise that sequence is vacuously unsafe. Note that imposing the collection of s-t paths of a cover to be minimal with respect to inclusion results in an equivalent definition of safety: any sequence that is safe for path covers is also safe for minimal path covers since every minimal path cover is a path cover; but also, if X is safe for minimal path covers then it is also safe for general path covers, as otherwise we could have a path cover P avoiding X from which arbitrary s-t paths can be removed until P becomes minimal.

Graph compression. We define a *unitary path* as a path where each node has indegree equal to one but the first one, and each node has outdegree equal to one but the last one. For example, in Figure 1, the paths *de* and *pq* are unitary, the path *cde* is maximally unitary. With respect to G, we define the *compressed graph of* G as the graph where every maximal unitary path of G is contracted into a single node. It is a folklore result that compressing a graph can be done in linear time (see e.g. [13, 52]). We state this fact in the next lemma together with an additional property stating that compressed graphs cannot have arcs uv with v the unique out-neighbor of u and u the unique in-neighbor of v, since uv would then be a unitary path.

▶ **Lemma 4.** *Let G be a directed graph with n nodes and m arcs. Then the following hold:*
1. *We can compute the compressed graph of G in $O(n + m)$ time.*
2. *In a compressed graph there is no arc uv such that $N_u^+ = \{v\}$ and $N_v^- = \{u\}$.*

The compression of unitary paths preserves safety: every s-t path in G traversing the unitary path traverses the corresponding node in the compressed graph of G, and every s-t path traversing a node in the compressed graph of G necessarily traverses the unitary path it corresponds to in G. This idea appeared in the context of walk-finding problems in [11].

Cutnodes and dominators. In the dominator literature, the directed graphs on which dominators are computed have a single start node s from which every node is reachable. In some cases, the graphs have instead or additionally a unique sink t which is reached by every node, in which case the dominance relation is referred to as post-dominance (see e.g., [5, 27]). A prominent application of dominators is in the context of program analysis, where s corresponds to the entry point of the program and t to its exit point. Our graphs always have unique abstract nodes s and t, hence, diverging from standard notation, we parameterize the domination relation by s and t. We borrow standard concepts and notation from the literature of dominators, which we describe next.

Let G be an s-t directed graph. A node u is said to *s-dominate* a node v if every s-v path contains u, hence u is an s-v cutnode if and only if u s-dominates v. Every node s- and t-dominates itself. We also say that v *t-dominates* u if every u-t path contains v, which is equivalent to v being a u-t cutnode. We say that u *strictly s-dominates* v if u s-dominates v and $u \neq v$. For $v \neq s$, the *immediate s-dominator* of v is the strict s-dominator of v that is dominated by all the nodes that strictly dominate v, in which case we write $idom_s(v) = u$. The domination relation on G with respect to s can be represented as a rooted tree at s with the same nodes as G, called the *s-dominator tree* of G. In this tree, the parent of every node is its immediate s-dominator, every node is s-dominated by all its ancestors and s-dominates all its descendants and itself. A node is said to be an *s-dominator* if it strictly s-dominates some node. The same terminology will be used for the t-domination relation. We also define a function $dom : N \times \mathbb{N}^+ \to N$ on rooted trees as follows. Let $dom_s(v, k) := idom_s(v)$ when $k = 1$ and $dom_s(v, k) := dom_s(dom_s(v, 1), k - 1)$ when $k > 1$. If k is larger than the number of *strict* dominators of a given node, then it defaults to s (resp. t) in the s-dominator tree (resp. t-dominator tree). Essentially, dom gives the k-th ancestor of a node in a rooted tree, if it is well defined, otherwise it returns the root of the tree. For example, in Figure 1, the immediate s-dominator of b is a ($dom_s(b, 1) = a$) and $dom_t(q, 3) = t$. Node c is a strict t-dominator of the nodes $\{a, b, k, k'\}$. See [23] for an in-depth presentation of dominators.

In DAGs, dominators admit a characterization, which we state in Lemma 5 below. This was first presented by Ochranová [41], but with an incomplete proof. This characterization was also discussed by Alstrupt et al. [6, Sec. 5.1]. To the best of our knowledge, we did not find a complete proof of this characterization in the literature, and hence one can be found in the extended version.

▶ **Lemma 5** (Characterization of node-dominators in DAGs). *Let $G = (N, A)$ be an s-t DAG. A node $u \in N$ is an s-dominator (resp. t-dominator) if and only if there is a node v such that $N_v^- = \{u\}$ (resp. $N_v^+ = \{u\}$).*

3 Safe sequences via dominators

3.1 Characterization of safe sequences

We start by proving Theorem 1.

Proof of Theorem 1. ($1 \Rightarrow 2$) If for every node $u \in N$ there is an s-t path covering u that avoids X, then we can build a path cover by considering for every node u of G an s-t path avoiding X that covers u. This contradicts the safety of X.

($2 \Rightarrow 3$) Since every s-t path covering u contains the sequence of s-u cutnodes followed by the sequence of u-t cutnodes and X is contained in every such path, the implication follows by taking $u = v$.

($3 \Rightarrow 1$) Since X is a subsequence of a sequence containing every s-v and v-t cutnode and v must be covered in every path cover by some s-t path, any of which contains the s- and t-cutnodes of v, it follows that X is safe. ◀

We will heavily use the type of sequence obtained as in point 3 of Theorem 1. As such, we define the *extension* of a node v, $\mathsf{extension}(v)$, as the sequence obtained from the concatenation of the sequence of s-v cutnodes with the sequence of v-t cutnodes. By Theorem 1 every maximal safe sequence is the extension of some node, and so in a DAG with n nodes and m arcs there are at most n maximal safe sequences. Moreover, for any node $v \in N$, $\mathsf{extension}(v)$ can be computed in time $O(m + n)$ by computing the s-v cutnodes

and v-t cutnodes with e.g. the simple algorithm of Cairo et al. [9]. Thus, Theorem 1 implies that we can compute in time $O(nm)$ a set of safe sequences containing every maximal safe sequence of G, by reporting $\mathsf{extension}(v)$ for every node v. However, the reported sequences may not be maximal and the same sequence may be reported multiple times.

Because of the correspondence between cutnodes and dominators explained in Section 2, the extension of a node can also be expressed as suitable paths in dominator trees. We will use this fact in the rest of the paper.

▶ Remark 6. In an s-t DAG G, $\mathsf{extension}(v)$ is the same as the path from s to v in the s-dominator tree of G concatenated with the path from v to t in the t-dominator tree of G.

3.2 Properties of s- and t-dominator trees

We start with a lemma showing an interplay between s-domination and t-domination on general s-t directed graphs.

▶ **Lemma 7.** *Let $G = (N, A)$ be an s-t directed graph, let $u, v \in N$ be nodes, and let $k \in \mathbb{N}^+$. If u is the k-th ancestor of v in the s-dominator tree, then $dom_t(u, k)$ t-dominates v, and v is not a t-dominator of u unless $v = dom_t(u, k)$.*

Proof. Note that $u \neq t$ since u is an s-dominator. Let $w = dom_t(u, k)$ and let $y_1, \ldots, y_{k-1}$ be the nodes between u and v in the s-dominator tree. We can assume $w \neq v$.

Observe that $w \neq y_i$ for all $i \in \{1, \ldots, k-1\}$. Suppose otherwise. Then $w \neq t$ because t is not an s-dominator. Hence, by definition of dom_t, there are $k-1$ nodes $x_1, \ldots, x_{k-1}$ between w and u in the t-dominator tree. Some x_j is not between u and w in the s-dominator tree, and hence there is a u-w path avoiding x_j. Further, since x_j is strictly t-dominated by w there is a w-t path avoiding x_j. Concatenating these paths at w results in a u-t path avoiding x_j, contradicting the fact that x_j t-dominates u.

Suppose now for a contradiction that v is not strictly t-dominated by w. From the point above, there is a u-v path avoiding w. This path concatenated with a v-t path avoiding w gives a u-t path also avoiding w, contradicting the fact that w t-dominates u.

It remains to show that v cannot t-dominate u. Suppose otherwise. Then we have $v = x_i$ for some $i \in \{1, \ldots, k-1\}$, since v is strictly t-dominated by w and t-dominates u. Thus, some y_j is not between v and u in the t-dominator tree, implying that there is a u-v path avoiding y_j. Since y_j is s-dominated by u, there is an s-u path avoiding y_j, which concatenated with the previous path gives an s-v path also avoiding y_j, contradicting the fact that y_j s-dominates v. ◀

Lemma 7 can be interpreted for the special case of $k = 1$ as follows: if u immediately s-dominates v then the immediate t-dominator of u t-dominates v (see Figure 2). Another consequence of this result is that if u is an s-dominator, then at most one node immediately s-dominated by u is in the path from t to u in the dominator tree of t, which must be the immediate t-dominator of u.

Observe now in Figure 1 that c is the immediate s-dominator only of d and that d is the immediate t-dominator only of c, and likewise for d and e, and so $\mathsf{extension}(c) = \mathsf{extension}(d) = \mathsf{extension}(e)$. This redundancy and asymmetry introduced by unitary paths is undesirable in the characterization of maximal safe sequences. This discussion motivates the following result.

▶ **Lemma 8.** *Let $G = (N, A)$ be a compressed s-t DAG and let $u, v \in N$ be distinct nodes. If u immediately s-dominates v and v immediately t-dominates u then u immediately s-dominates some node different from v and v immediately t-dominates some node different from u.*

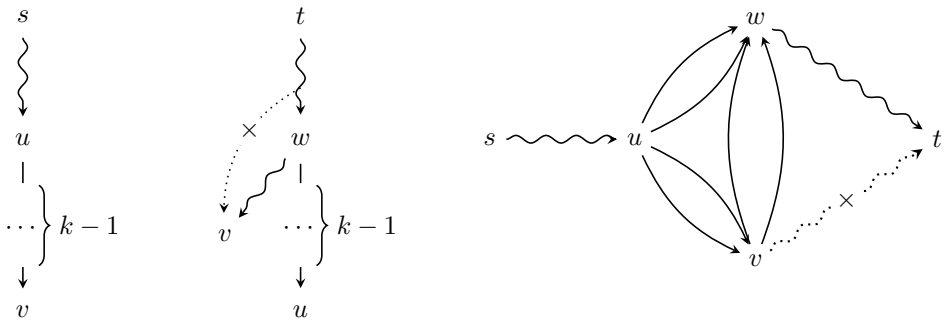

Figure 2 Illustration of the proof of Lemma 7. The two dominator trees discussed in the proof are shown on the left. On the right, an abstract graph for the special case of $k = 1$ is shown; node v cannot reach t without w, without contradicting the fact that $dom_t(u, 1) = w$.

Proof. Assume without loss of generality that u immediately s-dominates only node v.

We claim that $N_v^- = \{u\}$. Suppose otherwise. If N_v^- is empty then $v = s$, and so v is not a t-dominator, a contradiction. So there is an arc wv with $w \neq u$. Since u s-dominates v, it must also s-dominate every in-neighbour of v, namely w. But u immediately s-dominates only v, thus, v must s-dominate w, implying that there is a v-w path. Since $wv \in A$, G contains a cycle, a contradiction.

Since v is a t-dominator, by Lemma 5 there is a node whose unique out-neighbour is v. If this node is u, we contradict the fact that the graph is compressed by Lemma 4. Therefore, v must have at least two distinct in-neighbors, a contradiction. ◀

3.3 Characterization and enumeration of maximal safe sequences

Using Lemmas 7 and 8, we can give a precise characterization of maximal safe sequences.

▶ **Theorem 9** (Characterization of maximal safe sequences)**.** *Let $G = (N, A)$ be a compressed s-t DAG and let $u \in N$ be a node. Then* extension(u) *is a maximal safe sequence if and only if u is a leaf in both the s- and t-dominator trees of G.*

Proof. ($\Leftarrow$) If u is a leaf in both dominator trees then extension(u) is maximal: no other node can be added to this sequence by the equivalence of safe sequences and paths in the dominator trees given by Remark 6 and Theorem 1.

($\Rightarrow$) Suppose that extension(u) is a maximal safe sequence but u is not a leaf in both dominator trees. Without loss of generality suppose that u is not a leaf in the s-dominator tree. Note that $u \neq t$ since u is an s-dominator. Let v be a node immediately s-dominated by u and let w denote the immediate t-dominator of u.

First we argue that there is a node z that is immediately s-dominated by u and that is strictly t-dominated by w. We consider two cases. If $v \neq w$ then we can take $z = v$, because by Lemma 7 for $k = 1$ we can conclude that w t-dominates v, and since $v \neq w$, it strictly t-dominates v. If $v = w$ then we can take $z = v'$, since by Lemma 8 there is a node $v' \neq v$ that is immediately s-dominated by u; applying Lemma 7 to u and v' with $k = 1$, we conclude that w t-dominates v, and since $w = v \neq v$, w strictly t-dominates v'.

Now we show that extension(z) properly contains extension(u). Consider extension(u), which by definition consists of the sequence of s-u cutnodes (call it Y_1) concatenated with the sequence of u-t cutnodes (call it Y_2). In extension(u), by definition, the double occurrence

of u is removed, and thus let Y_2' be the sequence of w-t cutnodes. That is, $\mathsf{extension}(u)$ can be written as Y_1Y_2'. Consider also $\mathsf{extension}(z)$, which can be written analogously as X_1X_2'. Since u is the parent of z in the s-dominator tree, we have that Y_1 is *strictly* contained in X_1, and since z is a proper descendant of w in the t-dominator tree, we have that Y_2' is contained in X_2' (possibly $Y_2' = X_2'$). Therefore, $\mathsf{extension}(u)$ is a proper subsequence of $\mathsf{extension}(z)$, contradicting our assumption that $\mathsf{extension}(u)$ is a maximal safe sequence. ◀

The idea in the above theorem of targeting special nodes or arcs in order to characterize every maximal safe object is a recurring theme in safety problems. For instance, [31, 2] proposed the notion of *representative arc*, [48] proposed that of *core*, and [10] found a special class of walks, coined *macrotigs*, from where every maximal safe walk can be built. Each of these constructs was used in a different safety problem.

While the above characterization uses dominator trees, we can derive an equivalent characterization of dominator-tree leaves just in terms of in- and out-neighborhoods via Lemma 5, since a node is a leaf if and only if it is not a dominator. Computing the extension of every node satisfying such condition leads to a simple $O(mn)$ time algorithm outputting all and only maximal safe sequences, without needing to compute the dominator trees, from which Theorem 2 follows.

Since dominator trees can be built in $O(m+n)$ time (see, e.g., the algorithm by Alstrup et al. [6], Buchsbaum et al. [7]), or Fraczak et al. [20]), we can prove Theorem 3.

Proof of Theorem 3. Let G' be the compressed graph of G. Build the dominator trees of G' and compute all the leaves common to both trees. These three steps take $O(m+n)$ time.

1: For every node that is a leaf in both dominator trees, output $\mathsf{extension}(v)$. By Theorem 9 we find every maximal safe sequence during this process. Further, no duplicate safe sequence is computed since different leaves common to both trees have different extensions. Therefore the algorithm runs in time equal to the length of all the maximal safe sequences plus the time required to build two dominator trees over G', so $O(m+o)$ altogether.

2: With the equivalence given by Theorem 9, we have that every maximal safe sequence is the result of $\mathsf{extension}(v)$ for every node v of G' that is a leaf in both dominator trees. The sequence $\mathsf{extension}(v)$ is encoded in the dominator trees by Remark 6. ◀

4 Experiments

The experiments were performed on an AMD 32-core machine with 512GB RAM. The source code of our project is publicly available on Github[5]. All our algorithms are implemented in Python3, as are the scripts to produce the experimental results. To solve ILPs, we use Gurobi's Python API (version 11) under an academic license. For every graph, we run Gurobi with 4 threads and set up a timeout of 300 seconds in Gurobi's execution time.

Implementation. As described in Section 1.2, we study experimentally the potential of applying safe sequences in two arc-path covering problems, LeastSquares and MinPathError.

We did not use an external algorithm to compute arc-dominator trees because these are mostly tailored for node-dominators. Instead, we compute the immediate s-dominator and t-dominator of all arcs with an $O(m^2)$ time procedure via the algorithm of [9], appropriately handling the reversed graph of G for the immediate s-domination relation. The classical

[5] `https://github.com/algbio/safe-sequences`

algorithm of Aho and Ulman [3] to build dominator trees has the same running time as our procedure. We remark that even with a suboptimal algorithm to compute the dominator trees, our entire safety-preprocessing step takes less than 0.1 seconds on average.

With the dominator trees, we can compute all the maximal safe sequences with respect to arbitrary subsets $C \subseteq A$ of arcs to be covered, all in time proportional to the total length of all the maximal safe sequences, completely analogously to the discussion in Section 3.

The ILPs were optimized as in [25] by fixing x_{uvi} variables to 1 based on the maximal safe sequences of the input DAG, which reduces the search space of the linear program and hence speeds-up the solver. Let $X_1, \ldots, X_t$ be sequences in the input DAG such that: (a) each X_i, $i \in \{1, \ldots, t\}$, must appear in some solution path of the ILP, and (b) there exists no path in the DAG containing two distinct X_i and X_j. In the case that every X_i is a path, Grigorjew et al. [25] noticed that if the two mentioned properties hold, then $X_1, \ldots, X_t$ must appear in t distinct paths of among the k solution paths of the ILP (see the three solid-colored sequences shown in Figure 1 which must appear in different paths of any path cover). As such, without loss of generality, one can set $x_{uvi} = 1$ for each arc uv of X_i, for all $i \in \{1, \ldots, t\}$. When using sequences to set binary variables, we can proceed in a completely analogous manner. To have a large number of binary variables set to 1, we follow the approach of [25]. Namely, for every arc uv, we define its weight as the length of the longest safe sequence containing uv. Then we find a maximum-weight antichain of arcs in the DAG using the min-flow reduction of [39]. Then, for each a_i in the maximum-weight antichain, we consider a longest safe sequence X_i containing a_i to fix variables to 1. Note that a path covering two such sequences X_i and X_j would witness that a_i and a_j cannot be in an antichain. Finally, we set k to the arc-width of the graph and run Gurobi to solve the ILP.

Note that any solution to MinPathError is also a path cover, since each arc weight is positive, and thus the simplified ILP has equivalent optimal solutions. This may not be the case for LeastSquares, since some arcs may not be covered by any solution path. To handle such scenarios we propose using maximal safe sequences for path covers where only a subset C of nodes or arcs can be trusted to appear in any optimal solution. As an illustration of this approach, we perform experiments by choosing the subset C as those arcs whose weight is at least as large as the 25-th percentile of the weights of all arcs, since we can heuristically infer that the solution paths of LeastSquares cover the arcs of large enough weight.

Datasets. We experiment with seven datasets. The first four contain splice graphs with erroneous weights created directly from gene annotation by [16].[6] These were created starting from the well-known dataset of Shao and Kingsford [49], which was also used in several other studies benchmarking the speed of minimum flow decomposition solvers [17, 32, 54]. The original splice graphs were created in [49] from gene annotation from **Human**, **Mouse** and **Zebrafish**. This dataset also contains a set of graphs (**SRR020730**) from human gene annotation, but with flow values coming from a real sequencing sample from the Sequence Read Archive (SRR020730), quantified using the tool Salmon [42]. To mimic splice graphs constructed from real read abundances, [16] added noise to the flow value of each arc, according to a Poisson distribution. The last three datasets contain graphs constructed by a state-of-the-art tool for RNA transcript assembly, IsoQuant [44]. Mouse annotated transcript expression was simulated according to a Gamma distribution that resembles real expression profile [44]. From these expressed transcripts, PacBio reads were simulated using

[6] Available at `https://doi.org/10.5281/zenodo.10775004`

IsoSeqSim [1] and fed to IsoQuant for graph creation (we call this **Mouse PacBio**), and ONT reads were simulated using Trans-Nanosim [28], which was modified to perform a more realistic read truncation (see [44]), and fed to IsoQuant for graph creation (we call this **Mouse ONT**). For the latter one, there is also a simpler version where no read truncation was introduced (**Mouse ONT.tr**). These are available at [43].

Discussion. We group the graphs in each dataset by width (column "w"). For each width-interval we show different metrics, namely the number of graphs "#g", the average number of arcs "avg m" (and the maximum number of arcs in parenthesis), the time taken in seconds by the safety preprocessing step in "prep", the percentage of fixed arc-variables x_{uvi} of the ILP out of all mk variables in "vars", the number of solved instances by the ILP with and without safety in "#solved" (and in parenthesis the average time taken in seconds to solve those instances), and in the column "×" we show the average speedup obtained by advising the linear program with safety. The speed-ups are computed by considering for each graph the ratio between the time taken by the original ILP (or 300 sec. if this timed-out) divided by the time taken by the optimized ILP, and averaging these ratios. In the "prep" and "vars" column, a dash is written only if no instance was solved with safety information. In the remaining columns a dash means not applicable.

In Table 1 we show the experimental results of the safety-optimized ILPs for MinPathError.(As explained before, for this problem it is correct to select $C = A$.) When the width of the graph is small, the speed-ups are also small. However, such graphs are fast to solve without safety in the first place. The challenging cases are the graphs of larger widths and more arcs (indeed, the solver with no safety information performs poorly and it becomes slower as the width increases). The speed-up of the solver significantly increases as the width of the graph increases, becoming more than 200× in some datasets. Moreover, these speed-up are obtained almost for free, in the sense that the time needed to compute safe sequences is negligible for all datasets, i.e. below 0.1 seconds, and often even much faster. We highlight the notable difference between the number of instances solved with no safety and with safety. In Table 2 for LeastSquares we observe the same phenomena, obtaining in some datasets speed-ups of 300× on graphs of larger widths, and solving always more instances with safety than without safety. In the extended version results for $C \subsetneq A$ in the MinPathError and for $C = A$ in the LeastSquares can be found.

PLS-Completeness of String Permutations

Dominik Scheder
TU Chemnitz, Germany

Johannes Tantow
TU Chemnitz, Germany

Abstract

Bitstrings can be permuted via permutations and compared via the lexicographic order. In this paper we study the complexity of finding a minimum of a bitstring via given permutations. As finding a global optimum is known to be NP-complete [1], we study the local optima via the class PLS[8] and show hardness for PLS. Additionally, we show that even for one permutation the global optimization problem is NP-complete and give a formula that has these permutation as its symmetries. This answers an open question inspired from Kołodziejczyk and Thapen [9] and stated at the *SAT and interactions* seminar in Dagstuhl [14].

Acknowledgements We want to thank Neil Thapen for introducing the problem to us.

1 Introduction

Given a string $\mathbf{x} \in \{0,1\}^n$ and a couple of permutations in S_n, we can apply a permutation to $\mathbf{x}$ and obtain a new bit string. What is the lexicographically smallest string we can obtain this way? This problem is known [1] to be NP-hard. What about finding a local minimum, i.e., arriving at a bit string that cannot be further improved by a single application of a permutation? In this paper, we show that this problem is PLS-complete.
To be more formal, we are given a string $\mathbf{x} \in \{0,1\}^n$ and permutations $\pi_1, \dots, \pi_m$ on the set $[n]$. When we view $\mathbf{x}$ as a function $[n] \to \{0,1\}$, the notation $\mathbf{x} \circ \pi$ makes sense and is the string obtained from $\mathbf{x}$ by permuting the coordinates according to π. By $\langle \pi_1, \dots, \pi_m \rangle$ we denote the subgroup of $S_{[n]}$ generated by the π_i. The problem k-Permutation Global Orbit Minimum asks for the $\pi \in \langle \pi_1, \dots, \pi_k \rangle$ such that $\mathbf{x} \circ \pi$ is lexicographically minimal. Babai and Luks [1] showed that this is NP-hard even for $k = 2$. In fact, we will see that it is NP-hard even for $k = 1$, i.e., a single permutation.

k-Permutation Local Orbit Minimum asks for a local minimum. That is, an element $\pi \in \langle \pi_1, \dots, \pi_k \rangle$ such that

$$\mathbf{x} \circ \pi \preceq_{\text{lex}} \mathbf{x} \circ \pi \circ \pi_i \quad \text{for all } 1 \leq i \leq k \ ,$$

i.e., a single application of a permutation π_i cannot further improve the string $\mathbf{x} \circ \pi$.
A local optimum always exists and hence this is an instance of a total search problem. Total search problems where solutions are recognizable in polynomial time form the class TFNP. Total search problems that can be stated as finding a local optimum with respect to a certain *cost function* and a *neighborhood relation* constitute the subclass PLS (polynomial local search). Known hard problems for PLS include finding a pure Nash-equilibrium in a congestion game[4] or finding a locally optimal max cut (LocalMaxCut) [13]. Almost all known PLS-complete problems require quite involved cost functions. Our problem

k-Permutation Local Orbit Minimum has the benefit of using the possibly simplest cost function - the lexicographic ordering. The only other PLS-complete problem using a lexicographic cost function that we know of is FLIP, which asks to minimize the m-bit output of a circuit C, where the solutions are all n-bit inputs and the neighborhood relation is defined by flipping a single bit.

Thus, our result unifies two desirable properties - our PLS-complete problem is very combinatorial in nature (in contrast to FLIP) and uses a very simple cost function (in contrast to LocalMaxCut)

1.1 SAT Solving and Symmetry Breaking

When encoding a combinatorial problem as a CNF formula F (think of "is there a k-Ramsey graph on n vertices?"), the formula will often contain many symmetries. To make the problem easier for SAT solvers, one can take the statement

> *The satisfying assignment α should be a local lexicographical minimum with respect to those symmetries,*

encode it as a CNF formula G and feed $F \wedge G$ to the SAT solver. Clearly, $F \wedge G$ is satisfiable if and only if F is. In case that $F \wedge G$ is unsatisfiable, SAT solvers are often expected to produce a proof of unsatisfiability. A popular proof system used in this context is DRAT [15]. However, it is not known to what extend DRAT can handle symmetry breaking [7], that is, whether a short DRAT-refutation of $F \wedge G$ can be transformed into a short DRAT-refutation of F. In this context, Thapen [14] asked whether there exists a polynomial algorithm that, given a CNF formula F, a handful of symmetries thereof, and a satisfying assignment α, finds a satisfying assignment β that is a local lexicographical minimum with respect to those symmetries. In this paper, we show that this problem is PLS-complete, which is evidence that such a polynomial time algorithm might not exist.

2 Preliminaries

2.1 Total search problems and PLS

The class FNP is the functional correspondent of NP. TFNP $\subset$ FNP is the subset of *total* search problems, i.e., problems that always have a solution. As this is a semantic class, TFNP has no known complete problems, and thus it is usually studied via its subclasses. These subclasses are based on the combinatorial principle that proves the existence of a solution. These principles include the existence of sinks in directed acyclic graphs (PLS)[8], the parity argument for directed and undirected graphs (PPAD, PPA) or the pigeonhole principle (PPP) (all introduced in [11]). Nonetheless, not all problems in TFNP can be categorized in one of the known subclasses, Factoring being a prime example.

By the above characterization, PLS requires finding a sink of a directed acyclic graph G. This would be possible in polynomial time if G was given explicitly. Instead, G is always given implicitly via a circuit that computes the successor list of a given node. To make sure that G is acyclic, we have a second circuit computing a topological ordering, that is, a "cost" function that is strictly decreasing along the edges. A solution to the problem is a sink of G or an edge (u, v) with $\text{cost}(u) \leq \text{cost}(v)$, i.e., violating the decreasing cost condition. This guarantees the totality of the problem.

An alternative definition is the following. For a PLS problem P we have a set of instances I. Each instance $i \in I$ has a set of feasible solutions S (e.g. for the Euclidean traveling salesman problem the solutions are exactly the Hamilton cycles of K_n). Additionally, we require the following polynomial-time computable algorithms (usually given as circuits):

1. an algorithm that decides whether a given s is a feasible solution.
2. an algorithm that computes a starting solution $s \in S$
3. an algorithm that computes for a feasible solution s the neighborhood $N(s)$
4. an algorithm that computes for a solution s the cost $\text{cost}(s)$

A feasible solution s is a *local minimum* if $\text{cost}(s) \leq \text{cost}(s')$ for all $s' \in N(s)$. The definition is given for a minimization problem, but can be also defined in terms of a maximization problem.

We can easily transform this into a directed acyclic graph by keeping only those neighbors in $N(s)$ having strictly smaller cost–or even keeping only the one neighbor $s' \in N(s)$ of minimal cost (breaking ties arbitrarily).

Similar to NP, there is also a hardness structure in PLS. Let P and Q be two problems in PLS. P reduces to Q via a *PLS-reduction* (f, g) for functions f and g such that f maps an instance I from P to an instance $f(I)$ of Q and g maps a solution s of $f(I)$ to a solution $g(I, s)$ of P so that if s is a local minimum in $f(I)$ then also $g(I, s)$ is a local minimum in I. This was defined in [8] and the first natural PLS-complete problem is FLIP. There solutions are n-bit strings, the cost is calculated by a given circuit C and the neighborhood are all n-bit strings with a Hamming distance of 1.

The obvious greedy algorithm to find a solution for a PLS-problem is as follows: Use the given algorithms to compute the start solution and always select the best neighbor until there is no better solution. This solution is called the *standard solution* and the algorithm the *standard algorithm*. For the problem FLIP, finding the standard solution for a given start solution is PSPACE-complete[12, Lemma 4].

Reductions that preserve the PSPACE-completeness are called tight[13]. For this, we consider the transition graph $TG(I)$ of an instance I of the problem P, that has a directed edge from each feasible solution x to all of its neighbors $N(x)$.

A PLS-reduction (f, g) from P to Q is called *tight* if for every instance I of P there exists a set $\mathcal{R}$ of feasible solutions for $f(I)$ such that

1. $\mathcal{R}$ contains all local optima of $f(I)$
2. For every solution s of I it is possible to construct in polynomial time a feasible solution $t \in \mathcal{R}$ such that $g(I, t) = s$
3. If the transition graph of $TG(f(I))$ contains a path from q to q' such that both q and q' are in $\mathcal{R}$ and all other intermediate nodes are not in $\mathcal{R}$, let $p = g(I, q)$ and $p' = g(I, q')$ be the corresponding solutions in P. Then either $p = p'$ or there is an arc from p to p' in $TG(I)$.

An interesting subclass of PLS is CLS that is supposed to capture continuous local search problems. Recently, it was shown that CLS = PLS ∩ PPAD[5].

2.2 Permutation groups

A permutation of a set V is a bijection $\pi : V \to V$. For permutations $\pi_1, \ldots, \pi_k$, we denote by $\langle \pi_1, \ldots, \pi_k \rangle$ the subgroup of S_V generated by the π_i. Checking membership $\pi \in \langle \pi_1, \ldots, \pi_k \rangle$ is non-trivial but can be done in polynomial time [6, Section 1].

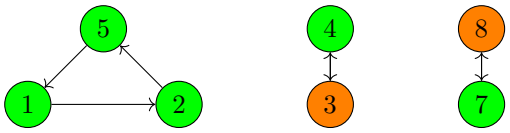

Figure 1 An example of the scenario for one permutation π.

3 Related Work

Many problems are known to be PLS-complete, whose reductions mostly start from FLIP. An influential reduction technique was used by Krentel [10] to show that finding a local minimum of a weighted CNF-formula is PLS-complete. The idea is to have multiple copies of the circuit, so called *test circuits* that precompute the effects of a flip. This idea is pushed further in [13] in order to show that finding a local minimum for weighted positive NAE(not all equal) 3-SAT is PLS-complete, and this is used to show that other problems as finding a LocalMaxCut or finding a stable configurations of Hopfield networks are PLS-complete.

Other direct reductions from FLIP are used in [4] to show that finding a pure Nash equilibrium in an asymmetric network congestion game is PLS-complete and in [3] to show that maximum constraint assignment, a generalization of CNF-SAT, is PLS-complete. These reductions are especially of interest to us as FLIP is to the best of our knowledge the only problem in PLS with lexicographical weights and hence needed for our reduction.

Numerous optimization problems on permutation groups given via generators $\pi_1, \ldots, \pi_k$ are studied in [2]. These include finding a $\pi \in \langle \pi_1, \ldots, \pi_k \rangle$ that minimizes $\Sigma_{i \in V} c(i, \pi(i))$ for some cost function $c : V^2 \to \mathbb{R}$. All these problems are shown to be NP-complete via a reduction from finding a fixed-point free permutation, which is shown to be NP-complete.

Our problem has previously been studied in [1], but there the interest was in *global* optima. This was proven to be NP-hard even for abelian groups.

4 The one permutation problem

We start our investigation by studying the special case that $k = 1$, i.e., we have only one generator π_1 and our subgroup is $\langle \pi_1 \rangle$. In this case one can efficiently find a local optimum[9, Section 8.2]. We show this with a different algorithm again. In contrast, we will show that surprisingly finding a global optimum is NP-complete. To the best of our knowledge, this has only been known for *two* permutations [1].

4.1 Finding a local optimum

The problem is efficiently solvable when $k = 1$, i.e., we are only given a single permutation π. We describe a different way of solving it in contrast to [9]. We can transform π into the cycle notation and annotate each element with the bit that it is mapped to by the string $\mathbf{x} \in \{0, 1\}^n$. We call a cycle *interesting* if $\mathbf{x}$ is non-constant on it. Additionally, we identify each cycle with its smallest member.

Consider the permutation (1 2 5)(3 4)(7 8) and the string 001001 depicted in Figure 1. We color an element green if it is mapped to zero and orange if it is mapped to one by the string. The left cycle is the cycle of 1 and not interesting whereas the other two are which are identified by 3 and 7.

The permutation has no effect on elements on non-interesting cycles. Due to the cost function, lower indices are more costly than higher indices. We look for the interesting cycle that contains the position with the least index among all interesting cycles and let l be the

smallest index on it. There are indices i and $j := \pi(i)$ on this cycle with $x_i = 0$ and $x_j = 1$. Let k be such that $\pi^k(l) = i$. Then $\mathbf{x} \circ \pi^k$ has a 0 at position i but $\mathbf{x} \circ \pi^{k+1}$ has a 1. In other words, $\mathbf{x} \circ \pi^k$ is a local optimum

In example in Figure 1 we have $x = 3$, $j = 4$ and $d = 1$. The local optimal permutation is hence π.

4.2 Finding a global optima

▶ **Theorem 1** ([1]). *2-Permutation Global Orbit Minimum is NP-hard.*

This follows via a reduction from Independent Set where we encode a graph as a bit string, one bit per potential edge, and the permutations basically allow us to move the vertices of the independent set I to the front, generating a large prefix of $\binom{|I|}{2}$ many 0's.

Since 1-Permutation Local Orbit Minimum was so clearly solvable in polynomial time (even by the greedy algorithm), it comes as a surprise that global optimization, even for *one* permutation, is NP-hard:

▶ **Theorem 2.** *1-Permutation Global Orbit Minimum is NP-hard.*

We will define an intermediate NP-complete problem called Disjunctive Chinese Remainder, short DCR. For two numbers $t, m \in \mathbb{N}$ and a set $S \subseteq \mathbb{N}$, we write

$$t \notin S \mod m$$

to state that $t \not\equiv s \mod m$ for all $s \in S$. Now in the DCR decision problem, we are given moduli $m_1, \ldots, m_l$ and sets of "forbidden remainders" $S_1, \ldots, S_l$ with $S_i \subseteq \mathbb{Z}_{m_i} := \{0, 1, \ldots, m_i - 1\}$. All numbers are given in unary and the moduli are not required to be pairwise co-prime. DCR asks for a solution $t \in \mathbb{N}$ of the system

$$t \notin S_i \mod m_i \qquad \forall i = 1, \ldots, l\ .$$

This is clearly in NP: if there is a solution $x \in \mathbb{N}$, then there is one with $0 \leq t \leq \operatorname{lcm}(m_1, m_2, \ldots m_l)$ and thus t has polynomially many bits in binary. Verifying that this t is a solution can now be done by division with remainder.

▶ **Lemma 3.** *DCR is NP-complete.*

Proof. We reduce from 3-Colorability. Given a graph $G = (V, E)$ with $|V| = n$, we let $3 = p_1, p_2, \ldots, p_n$ be the first n prime numbers greater than 2. By the prime number theorem, p_n is polynomial in n, thus the p_i can be found in polynomial time by a brute force search using naive prime number testing.

We let $N = p_1 \cdot p_2 \cdot \cdots \cdot p_n$ and define the following function from $\mathbb{Z}_N$ to 3-colorings of the vertices V: given a number $0 \leq t \leq N - 1$, the corresponding coloring $c_t : V \to \{r, g, b\}$ is defined by

$$c_t(v_i) = \begin{cases} r & \text{if } t \equiv 0 \mod p_i \\ g & \text{if } t \equiv 1 \mod p_i \\ b & \text{else.} \end{cases}$$

By the Chinese Remainder Theorem, this is a surjective function and thus every 3-coloring can be encoded by one single number $0 \leq x \leq N-1$. For an edge $e = \{u, v\}$, we write a constraint that makes sure that u and v receive different colors. For each pair $(a, b) \in \mathbb{Z}_{p_u} \times \mathbb{Z}_{p_v}$ with

$(a,b) = (0,0)$ or $(a,b) = (1,1)$ or $a \geq 2, b \geq 2$, we compute the unique number $c \in \mathbb{Z}_{p_u q_v}$ with $c \equiv a \mod p_u$ and $c \equiv b \mod q_v$. Let S_e be the set of all numbers c thus constructed, set $m_e := p_u \cdot p_v$ and write the constraint

$$x \notin S_e \mod m_e \ . \tag{1}$$

If e is the i^{th} edge of the graph, we set $m_i = p_u p_v$ and $S_i = S_e$. We see that x satisfies (1) if and only if x encodes a properly colors edge e. ◀

▶ **Lemma 4.** *DCR reduces to* 1-Permutation Global Orbit Minimum.

Proof. Given an instance of DCR we set $M = m_1 + m_2 + \cdots + m_l$ and define a permutation π on $[M]$ that has l disjoint cycles, one of length m_i for each i. We label the elements of the i^{th} cycle consecutively with the numbers $0, \ldots, m_i - 1$. We define a bit string $\mathbf{x} \in \{0,1\}^M$ that has exactly one 1 in each cycle, placed on the element that has label 0. The orbit element $\mathbf{x} \circ \pi^t$ still has exactly one 1 in cycle i, but now at the vertex labeled $t \bmod m_i$.

For each cycle i, let F_i be the elements on it whose labels are in the set S_i of forbidden remainders and let $F := F_1 \cup \cdots \cup F_l$. We order the elements of $[M]$ such that the elements of F come first. There exists a solution $t \in \mathbb{N}$ to the DCR instance if and only if the string $\mathbf{x} \circ \pi^t$ has no 1 in any position in F. ◀

5 PLS-Hardness

We now state and prove our main result:

▶ **Theorem 5.** *k-Permutation Local Orbit Minimum is PLS-complete.*

In order to view it as a PLS-problem we have an instance I consisting of the permutations $\pi_1, .., \pi_k$ and the string $s \in \{0,1\}^N$. Solutions are permutations from $\langle \pi_1, \ldots \pi_k \rangle$ as we can efficiently recognize whether permutations are in the group generated by $\pi_1, .., \pi_k$. The start solution is the identity. Neighbors of π are permutations $\pi \circ \pi_i$ for $i \in \{1, \ldots k\}$. The cost of a permutation π is $\sum_{i=1}^{N} s(\pi(i)) 2^{N-i}$, where $s(\pi(i))$ is the digit of the position that i is mapped to by π. All these can be computed in polynomial time, hence the problem is in PLS.

A solution π is cheaper than a solution σ for a string s if there is an integer i such that for all $j < i$ we have that $s(\sigma(j)) = s(\pi(j))$ and $s(\pi(i)) < s(\sigma(i))$ as the cost is a geometric sum.

We can turn the minimization problem into a maximization problem by inverting the string.

5.1 High-level idea

We reduce from the PLS-complete problem FLIP. This problem is especially suitable since it uses a lexicographic cost function, too. Formally FLIP is defined as follows:

▶ **Definition 6.** *An instance of FLIP consists of a circuit C with n inputs and m outputs. Feasible solutions are all input assignments, i.e., the set $\{0,1\}^n$. The cost of a solution $\mathbf{x}$ is the output of $C(\mathbf{x}) \in \{0,1\}^m$. Two solutions are neighbors if they differ in a single bit. The cost function is defined by reading the output as a number in binary; in other words, by the lexicographic order on $\{0,1\}^m$. We are asked to find a solution whose cost is minimal among all its neighbors.*

We use an idea by Krentel[10] and have $n+1$ copies $C_0, C_1, \ldots, C_n$ of the circuit C, where C_0 is fed as an input $\mathbf{x}$ and C_i is fed as an input $\mathbf{x} \oplus \mathbf{e}_i$, i.e., $\mathbf{x}$ with the i-th bit flipped. The setup is depicted in Figure 2.

The permutation group consists of two types of permutations. The first kind π_i^j simulates flipping the output of gate i in circuit j; we allow for gates and hence circuits to be temporarily evaluated incorrectly. The input and output of a gate are not saved anywhere but syntactically built into the permutations and string. An exception is the input and output of the circuit, which we save for later usage. We use some positions as very important control bits to ensure that the correct evaluation is always possible.

The second type of permutation σ_j swaps the circuit 0 with the circuit j and flips the j-th input bit for all other circuits. This simulates a step in the FLIP-problem.

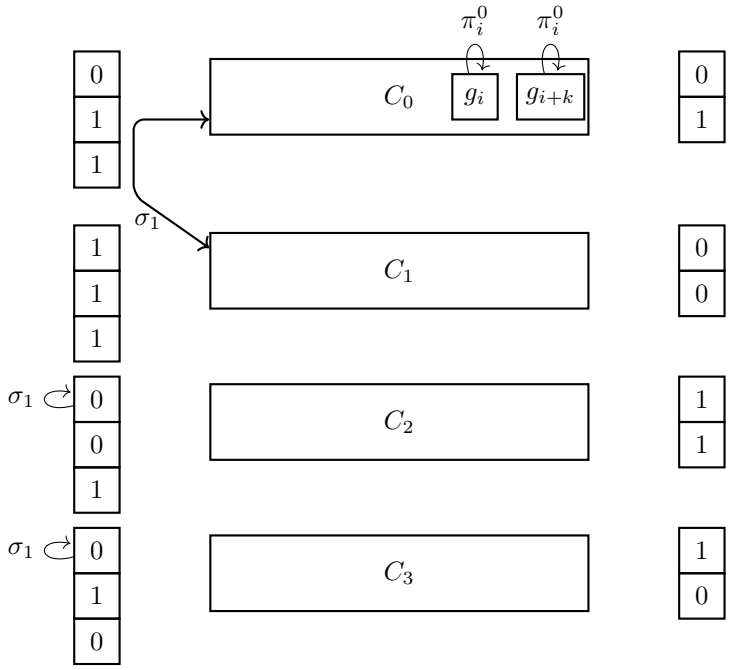

Figure 2 A high level overview of the reduction.

5.2 Definition of the reduction

We assume without loss of generality that the circuit C consists only of NAND-gates. Additionally, we assume that no input is directly passed to an output, i.e. on every path from an input to an output, there is at least one gate.

We will now describe the set V of *positions*, the permutations in S_V, and how strings in $\{0,1\}^V$, called *assignments*, correspond to the circuits $C_0, \ldots, C_n$ computing their values on an input $\mathbf{x}$ and its neighbors $\mathbf{x} \oplus \mathbf{e}_i$. We face two main challenges:

1. We need an operation of the form "flip bit i", but permutations can only permute positions, not flip bits. We solve this by replacing position i by two positions i_0, i_1 and encoding $[y_i = 0]$ by $[y_{i_0} = 0, y_{i_1} = 1]$ and $[y_i = 1]$ by $[y_{i_0} = 1, y_{i_1} = 0]$. Flipping bit i then corresponds to the permutation that swaps i_0 and i_1, i.e., the transposition (i_0, i_1). We call the one-position-per-bit view the *condensed view* and the two-positions-per-bit view the *expanded view*. We will give details in the full version due to space restrictions. For now, we phrase things in the condensed view.

2. Usually, when we flip an input x_i to a circuit C, we imagine the change propagating instantaneously through the circuit C, potentially changing its output. Here, we need to allow for a way for this change to proceed gradually; therefore, we allow gates to be temporarily in an incorrect state.

When we have a position $i \in V$ and an assignment $\mathbf{y} \in \{0,1\}^V$ and $y_i = b$, we sometimes say *i is assigned value b* and sometimes *the label of i is b*.

State of a gate. The *state of a gate* is a triple (x, y, b) where x, y are the two input bits and b is the output bit. If $b = \neg(x \wedge y)$ we call (x, y, b) *correct*, because b is what it is supposed to be: the NAND of x and y; otherwise, we call it *incorrect*. A gate g is represented by a gadget of four positions $g_{00}, g_{01}, g_{10}, g_{11}$, ordered as a 2×2 square, as shown in Figure 3. A state (x, y, b) is encoded as follows: position g_{xy} is labeled b, the three remaining ones are labeled with $\neg b$. Note that not all labelings of the gadget correspond to a gate state, only those where the number of positions labeled 1s is one or three.

▶ **Observation 7.** *The triple (x, y, b) is correct if and only if the position g_{11} in its representation is labeled* 0.

This is the core reason why we use this representation: we can determine correctness of a gate by reading just one bit. This will be important later when defining a cost function: having a 1 at those *control positions* is bad.

Input and output variables. Let $x_i^{(j)}$ be the i-th input variable to the j-th circuit (so $1 \le i \le n$ and $0 \le j \le n$). We introduce one position for each $x_i^{(j)}$. Similarly, let $c_k^{(j)}$ be the k-th output value of the j-th circuit; we introduce one position for each $c_k^{(j)}$.

A central definition is that of a well-behaved assignment. Basically, it formalizes when an assignment encodes the partial evaluation of the inputs by the $n + 1$ circuits.

▶ **Definition 8.** *An assignment $\mathbf{y} \in \{0,1\}^V$ is called* well-behaved *if the following hold:*

- *For each gate g, the four positions $g_{00}, g_{01}, g_{10}, g_{11}$ are the encoding of a gate state $(a_1, a_2, b) \in \{0,1\}^3$.*
- *If the output of a gate g is the l-th input of some gate h, then the corresponding input and output values agree, i.e., if the state of h is (a'_1, a'_2, b') then $b = a'_l$.*
- *If the l-th input of g is an input variable $x_i^{(j)}$, then $x_i^{(j)}$ is assigned the value a_l.*
- *If g is the k-th output gate of circuit j, then its output value b is the same as the label of $c_k^{(j)}$.*
- *The labels of the input values $x_i^{(j)}$ equal $x_i^{(0)}$ if $i \neq j$, and are unequal if $i = j$; in words, if the labels of the input positions of C_0 form a vector $\mathbf{x} \in \{0,1\}^n$, then those of C_j form the vector $\mathbf{x} \oplus e_j$.*

Next, we describe the permutations on the positions. They come in two types: (1) flipping a gate and (2) swapping two circuits.

Flipping a gate. If g is in state (a_1, a_2, b), then flipping g means replacing b by $\neg b$, and for each gate h (in state (a'_1, a'_2, b')) into which g feeds as l-th input, flipping a'_l. Since our permutations do not work on the *state* of a gate but on its representation in the four-position gadget (Figure 3), we work as follows: we flip the labels in all positions of g, i.e., $g_{00}, g_{01}, g_{10}, g_{11}$; if g is the first input of h, we swap positions of h horizontally: swap h_{00} with h_{10} and h_{01} with h_{11}; if g is the second input of h, we perform a vertical swap: h_{00}

with h_{01} and h_{10} with h_{11}. This operation changes the state of g from incorrect to correct (or vice versa) and may also change correctness of h. If g happens to be the k-th output bit of circuit j, then this operation also flips position $c_k^{(j)}$. See Figure 4 for an example of two consecutive gates being flipped. We call this permutation π_g. If g is the i-th gate in circuit j, we may also call it π_i^j. Note that if $\mathbf{y}$ is a well-behaved then $\mathbf{y} \circ \pi_g$ is well-behaved, too.

Swapping two circuits. We want a permutation that simulates flipping the i-th input bit to C, the circuit in the instance of FLIP. We achieve this by swapping C_0 with C_i – that is, swapping every position (input values, values in gate gadgets, output values) in C_0 with its corresponding position in C_i, and simultaneously flipping the i-th input bit $x_i^{(j)}$ for every circuit C_j with $j \in \{1, \dots, n\} \setminus \{i\}$; naturally, if this $x_i^{(j)}$ is the first input to a gate g in C_j, we have to perform the "horizontal swap" at g outlined above, and if it is the second input to g, a "vertical swap" at g. We call this permutation σ_i. Again, if $\mathbf{y}$ is well-behaved then $\mathbf{y} \circ \sigma_i$ is well-behaved, too.

The starting string $\mathbf{y_{start}} \in \{0,1\}^V$. This is the assignment where C_0 has input $\mathbf{0} \in \{0,1\}^n$ and C_i has input $\mathbf{e}_i \in \{0,1\}^n$ and all gates have output 0 (whether correctly or incorrectly). This is certainly well-behaved (or rather, can be made well-behaved by making sure that input to gate h matches output of gate g should they be connected).

We now have a set V of positions, an assignment $\mathbf{y}_{\text{start}} \in \{0,1\}^V$, and a set of permutations-gate-flippers π_g for each gate g and circuit-swappers σ_i for each $i \in [n]$. They generate a subgroup G of S_V. It is clear that the orbit of $\mathbf{y}_{\text{start}}$ under G is the set of well-behaved assignments.

5.3 The cost function

We have promised to use a lexicographic ordering as a cost function. That is, if $\mathbf{y}, \mathbf{y}' \in \{0,1\}^V$ are two assignments, then $\mathbf{y}$ is better than $\mathbf{y}'$ (meaning lower cost) if $\mathbf{y} \prec_{\text{lex}} \mathbf{y}'$. Thus, to define the cost function it suffices to specify an ordering on the positions in V.

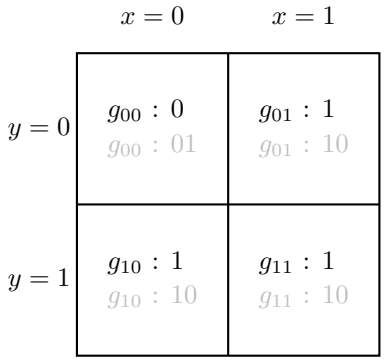
- Positions in C_0 come before positions in C_1 and so on.
- Within a circuit, most important are the control positions g_{11} of the gates, followed by the output gates, followed by all remaining positions.
- Within control positions in the same circuit, the order follows the topological ordering of the circuit, i.e., if g feeds into h, then g's control position comes before h's.

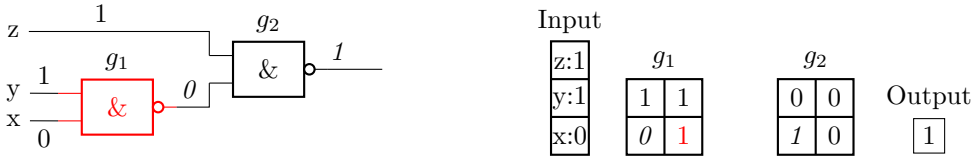
5.4 Proof of Correctness

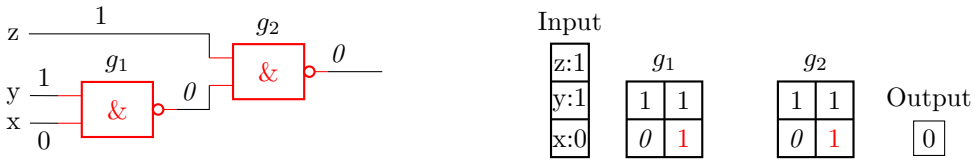
In this section we now prove the correctness and tightness of our reduction. In order to show the correctness we have to show that if $\pi \in G$ is a local optimum of the k-Permutation Local Orbit Minimum instance, i.e., if the assignment $\mathbf{y} := \mathbf{y}_{\text{start}} \circ \pi$ cannot be further improved by applying a π_g or a σ_j, then the input to C_0 encoded in $\mathbf{y}$ corresponds to a local optimum of FLIP.

Well-behaved permutations for a string s and a circuit C are interesting, because they realize the evaluation of the circuit somehow. The only problem is that the gate does not have the correct output in the current permutation with the string s compared to C.

▶ **Lemma 9.** *Let $\mathbf{y}$ be a well-behaved assignment and suppose that $y(g_{11}) = 0$ for every gate – every control position is labeled 0. Then all output positions are mapped to correct results according to C. That is, if $\mathbf{x} \in \{0,1\}^n$ is the vector to which the positions of circuit C_0 are mapped under $\mathbf{y}$, then*







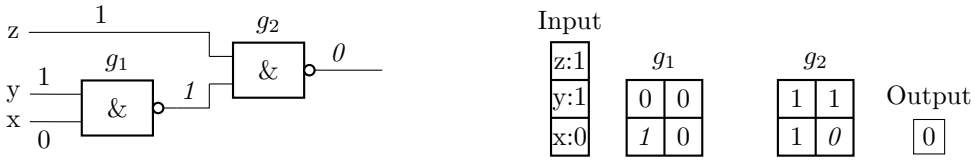


Figure 3 An example gate configuration with the input $x = 0$ and $y = 0$ and the output 0. This is incorrect for a NAND-gate as indicated by the control bit. In light grey we denote the expanded encoding of the positions.

(a) Step 1: Initial state. Gate g_1 is evaluated incorrectly, g_2 correctly. Still, we call this a *well-behaved* state.

(b) Step 2: Application of the permutation π_{g_2} which leads to g_2 being now incorrect as well. This is not a local improvement step. While it minimizes the output, the more expensive control bit of g_2 is now active. Still the relationship between the gate state and the string under the current permutation holds, so this is well-behaved as well.

(c) Step 3: Application of the permutation π_{g_1}. Due to the inversion, g_1 is now correct and the change of its output is reflected in g_2 which is now also correct since the one was swapped out of the control position. This is now a local optima.

Figure 4 Step-by-step evaluation of the circuit and reduction process. Each step shows the circuit state (left) and the reduction state (right). Currently incorrect gates are marked red and the output of a gate is identifiable via italics.

1. *the input positions of C_i are mapped to $\mathbf{x} \oplus \mathbf{e}_i$ (this actually holds for every well-behaved $\mathbf{y}$, control positions being 0 or 1),*
2. *the output positions of C_0 are mapped to $C(\mathbf{x})$;*
3. *the output positions of C_j are mapped to $C(\mathbf{x} \oplus \mathbf{e}_j)$*

Proof. This follows from Observation 7 and induction over the sequence of gates. ◀

The previous lemma tells us that all control positions should be mapped to zero in any local optimum so that all output positions are mapped to the correct output of C given the input. We show that we can always apply a permutation to achieve this.

▶ **Lemma 10.** *Let π be a permutation from G. We consider a gate g_i in the circuit j. The control position of g_i is mapped to position of the form $g^j_{i,k}$ by π*

Proof. This can be proven by induction on the structure of π in the permutation group. Any generator preserves this property as it either does not affect this position at all $\pi^{j'}_{i'}$ for $i \neq i'$ or $j \neq j'$. If both i' and j' are equal to i and j, then the position is simply inverted which preserves this property. Additionally, any permutation σ_j either maps a gate to itself or swaps the gate, so that the claim holds here as well. ◀

▶ **Lemma 11.** *If $\mathbf{y}$ is well-behaved and some control position g_{11} is 1 under $\mathbf{y}$, then $\mathbf{y}$ is not a local optimum.*

Proof. Among all control positions assigned 1, let g_{11} be the highest-ranking (i.e., of smallest index). Now apply π_g, i.e., flip gate g, which inverts the bit by the previous lemma. Under $\mathbf{y} \circ \pi_g$, the control position g_{11} is now correct; successor gates h in the same circuit might now become incorrect, but their control positions have lower rank by our ordering; gates in other circuits are not affected. Thus, $\mathbf{y} \circ \pi_g \prec_{\text{lex}} \mathbf{y}$, and $\mathbf{y}$ is not a local optimum. ◀

▶ **Corollary 12.** *In any local optimum all sub circuits are correctly evaluated.*

The previous lemmas suffice to show the main result.

▶ **Lemma 13.** *Let $\mathbf{y} = \mathbf{y}_{\text{start}} \circ \pi \in \{0,1\}^V$ be a local optimum an instance of* k-Permutation Local Orbit Minimum. *Suppose the input variables of C_0 are mapped to some $\mathbf{x} \in \{0,1\}^n$. Then $\mathbf{x}$ is a local optimum of the FLIP instance.*

Proof. Since $\mathbf{y}$ is well-behaved, the input variables of C_i are mapped to $\mathbf{x} \oplus \mathbf{e}_i$. Since $\mathbf{y}$ is a local minimum, by the corollary, the output values of C_j are in fact mapped to the correct output $C(\mathbf{x} \oplus \mathbf{e}_j)$.

Suppose now that the mapped input is not a local optimum for the FLIP instance. Then there must be neighbor with a better output, i.e., $C(\mathbf{x} \oplus e_j) \prec_{\text{lex}} C(\mathbf{x})$. Now consider $\mathbf{y}' = \mathbf{y} \circ \sigma_j$. Under $\mathbf{y}'$, the control positions of C_0 are all mapped to 0 (because those of C_j were under $\mathbf{y}$); the output of C_0 under $\mathbf{y}'$ is better than under $\mathbf{y}$ because $C(\mathbf{x} \oplus e_j) \prec_{\text{lex}} C(\mathbf{x})$. Control positions in C_i with $i \geq 1$ might now be 1, but their priority is less than that of C_0's output. Thus, $\mathbf{y}'$ is better than $\mathbf{y}$, and $\mathbf{y}$ is not a local optimum. ◀

This concludes the proof of Theorem 5. Every permutation used in the reduction has an order of two, so it is an involution. Still, these permutations do not form a commutative group due to the σ_i permutations. This is to be expected as even finding a global optimum for the lexicographical leader of a string under an abelian permutation group where every element has an order of two is polynomial time solvable[1, Section 3.1].

We additionally note that the reduction is tight and hence finding a local optimal bitstring under permutations via the standard algorithm is PSPACE-complete.

▶ **Theorem 14.** *The given reduction is tight.*

Proof. Let I be an instance of FLIP and (f, g) the previously defined reduction. We use as $\mathcal{R}$ simply the set of all permutations in the group of the generators which necessarily contains all local optima. We can find for any solution s of I in polynomial time a solution π with

$g(I, \pi) = s$ in $\mathcal{R}$ by applying the σ_j permutations to construct the needed input string. This requires applying at most n permutations which can be done in polynomial time. Finally, we see that any path where only the endpoints are in $\mathcal{R}$ must be an edge. If the edge is due to an π_i^j permutation the input does not change and hence both endpoints are mapped to the same solution. If the edge is alternatively due to a σ_j permutation this changes the input in one variable and is hence an edge in $TG(I)$ as it corresponds directly to a flip there. ◀

6 Realizing the permutations in propositional formula

In the problem Locally Minimal Solution we are given a CNF formula F over some variables V, a satisfying assignment $\alpha : V \to \{0, 1\}$, and a list of permutations $\pi_1, \ldots, \pi_k$ on V such that F is invariant under π_i (that is, when applying π_i to each variable occurrence in F, the resulting formula F' is equal to F up to a re-ordering of the clauses and the literals therein). The task now is to find a satisfying assignment β of F that such that $\beta \circ \pi_i \succeq_{\text{lex}} \beta$. This is clearly in PLS: whether F is invariant under the π_i and whether β satisfies F are both easy to check. Note that it is not required that β be in the orbit of α under $\langle \pi_1, \ldots, \pi_k \rangle$.

▶ **Theorem 15.** *Locally Minimal Solution is PLS-complete.*

Proof. We will define a formula F whose satisfying assignments correspond exactly the well-behaved assignments to the positions, as defined in Definition 8. We first describe how to encode one circuit of the total $n + 1$ circuits. We have input variables $x_1, \ldots, x_n$ to the circuit; we introduce one *gate output variable* g_{out} for each gate; and four *gate control variables* $g_{00}, g_{01}, g_{10}, g_{11}$ for the four positions in the square-representation of that gate, as in Figure 3. For each such variable u we introduce its twin $\tilde{u}$ and add $(u \leftrightarrow \neg\tilde{u})$. In other words, the (positive) literal $\tilde{u}$ simulates the negative literal $\bar{u}$. Take a gate g, let u, v be its inputs and w its output. The following formula F_g ensures that the gate control variables g_{ab} are set correctly as required for a well-behaved assignment:

$$
\begin{aligned}
&(u \wedge v \wedge w) \to (\tilde{g}_{00} \wedge \tilde{g}_{01} \wedge \tilde{g}_{10} \wedge g_{11})\\
&(u \wedge v \wedge \tilde{w}) \to (g_{00} \wedge g_{01} \wedge g_{10} \wedge \tilde{g}_{11})\\
&(u \wedge \tilde{v} \wedge w) \to (\tilde{g}_{00} \wedge \tilde{g}_{01} \wedge g_{10} \wedge \tilde{g}_{11})\\
&(u \wedge \tilde{v} \wedge \tilde{w}) \to (g_{00} \wedge g_{01} \wedge \tilde{g}_{10} \wedge g_{11})\\
&(\tilde{u} \wedge v \wedge w) \to (\tilde{g}_{00} \wedge g_{01} \wedge \tilde{g}_{10} \wedge \tilde{g}_{11})\\
&(\tilde{u} \wedge v \wedge \tilde{w}) \to (g_{00} \wedge \tilde{g}_{01} \wedge g_{10} \wedge g_{11})\\
&(\tilde{u} \wedge \tilde{v} \wedge w) \to (g_{00} \wedge \tilde{g}_{01} \wedge \tilde{g}_{10} \wedge \tilde{g}_{11})\\
&(\tilde{u} \wedge \tilde{v} \wedge \tilde{w}) \to (\tilde{g}_{00} \wedge g_{01} \wedge g_{10} \wedge g_{11})
\end{aligned}
$$

F_g can easily be written as a CNF formula. The permutation π_g amounts to flipping the output of gate g and flipping the corresponding inputs at those gates h that g's output feeds into. Thus, π_g is

$$(w\tilde{w})(g_{00}\tilde{g}_{00})(g_{01}\tilde{g}_{01})(g_{10}\tilde{g}_{10})(g_{11}\tilde{g}_{11}) \circ (\text{stuff at successor gates}) \tag{2}$$

F_g is invariant under π_g (even when we write it as a CNF). Next, there is a permutation σ that flips the input u of g. This swaps the two rows of the square representation of g:

$$(\text{stuff at predecessor gates}) \circ (u\tilde{u})(g_{00}g_{10})(\tilde{g}_{00}\tilde{g}_{10})(g_{01}g_{10})(\tilde{g}_{01}\tilde{g}_{11}) \tag{3}$$

If u is the output of some gate h, then σ is π_h and "stuff at predecessor gate" is what we describe in (2); otherwise u is an input variable x_i and "stuff at predecessor gate" does nothing – for now.

This formula describes well-behaved assignments in one of the $n+1$ circuits $C_0, \dots, C_n$. We now create $n+1$ copies of this formula, introducing a fresh version of each variable, so the j^{th} input variable x_j becomes $x_j^{(i)}$ in C_i, and g_{00} becomes $g_{00}^{(i)}$ and so on. We create a formula H to ensure that $x_j^{(i)}$ and $x_j^{(0)}$ differ if and only if $i = j$:

$$H := \bigwedge_{\{i_1,i_2\} \in \binom{\{0,\dots,n\}}{2}} \bigwedge_{j=1}^{n} \left\{ \begin{array}{ll} \left(x_j^{(i_1)} \leftrightarrow x_j^{(i_2)}\right) \wedge \left(\tilde{x}_j^{(i_1)} \leftrightarrow \tilde{x}_j^{(i_2)}\right) & \text{if } j \notin \{i_1, i_2\} \\ \left(x_j^{(i_1)} \leftrightarrow \tilde{x}_j^{(i_2)}\right) \wedge \left(\tilde{x}_j^{(i_1)} \leftrightarrow x_j^{(i_2)}\right) & \text{if } j \in \{i_1, i_2\} \ . \end{array} \right\} \tag{4}$$

The permutation σ_i flipping circuit C_i and C_0 and inverting $x_i^{(i')}$ for all other i' can be written as

$$\begin{aligned} &\left(u_j^{(i)} u_j^{(0)}\right)\left(\tilde{u}_j^{(i)} \tilde{u}_j^{(0)}\right) && \text{(for each input and gate output and control variable } u) \\ \circ &\left(x_i^{(i')} \tilde{x}_i^{(i')}\right) \circ \Big(\text{do (3) at gates having } x_i^{(i')} \text{ as input}\Big) && \text{(for all } i' \in \{1,\dots,n\} \setminus \{i\}) \end{aligned}$$

This forms the final formula $F = H \wedge \bigwedge_{i=0}^{n} \bigwedge_{\text{gate } g} F_g^{(i)}$. Its satisfying assignments correspond exactly to the well-behaved assignments described above and that each π_g and each σ_i is indeed a symmetry of F. The order of the variables is as in the previous proof: of highest priority are the control variables $g_{11}^{(0)}$ (following the topological order of the gates in the circuit); then the output variables of C_0; then to the control variables of the other circuits; then all the rest. It is easy to provide an "initial" satisfying assignment $\alpha \in \mathrm{SAT}(F)$. Finally, if β is some satisfying assignment of F that is locally minimal, i.e., cannot be improved by applying any π_g or σ_i, then β represents a configuration in which all circuits $C_0, \dots, C_n$ are correctly evaluated and no C_i outputs something better than C_0; in other words, a local optimum of FLIP. This shows that Locally Minimal Solution is PLS-complete. ◀

7 Conclusion and open questions

We have shown that the problem is PLS-hard in general and hence a polynomial time algorithm is unlikely unless P=PLS. In the theory of PLS-complete problems we thereby demonstrated another example of a hard problem with lexicographic weights. The used permutations are realistic in the sense that they can occur in an actual CNF formula.

Our above reduction requires polynomially many permutations. There is an efficient algorithm for the case of *one* permutation. What about when we are given a constant number of permutations?

What about if the given permutations form an Abelian group? Is it still PLS-hard to find a local minimum?

The neighborhood of a solution π is in our work defined as $\pi \circ \pi_i$ for some generator π_i. An alternative neighborhood would be $\pi_i \circ \pi$, which would place the generator between the string and the current permutation. While the results of the one permutation case trivially hold again, the hardness proof does not transform to this formulation.

Abstract

We study the token swapping problem, in which we are given a graph with an initial assignment of one distinct token to each vertex, and a final desired assignment (again with one token per vertex). The goal is to find the minimum length sequence of *swaps* of adjacent tokens required to get from the initial to the final assignment.

The token swapping problem is known to be NP-complete. It is also known to have a polynomial-time 4-approximation algorithm. From the hardness-of-approximation side, it is known to be NP-hard to approximate with a ratio better than 1001/1000.

Our main result is an improvement of the approximation ratio of the lower bound: We show that it is NP-hard to approximate with ratio better than 14/13.

We then turn our attention to the *0/1-weighted* version, in which every token has a weight of either 0 or 1, and the cost of a swap is the sum of the weights of the two participating tokens. Unlike standard token swapping, no constant-factor approximation is known for this version, and we provide an explanation. We prove that 0/1-weighted token swapping is NP-hard to approximate with ratio better than $(1-\varepsilon)\ln(n)$ for any constant $\epsilon > 0$.

Lastly, we prove two barrier results for the standard (unweighted) token swapping problem. We show that one cannot beat the current best known approximation ratio of 4 using a large class of algorithms which includes all known algorithms, nor can one beat it using a common analysis framework.

1 Introduction

In the *token swapping* problem [1, 8, 2, 25, 30, 31, 32, 35, 18, 9, 10, 16, 20, 17, 36, 21, 29], we are given an undirected n-vertex graph $G = (V, E)$, n distinct tokens, and two one-to-one assignments of tokens to vertices: a *starting* assignment, and a *target* assignment. A swap along an edge $(u, v) \in E$ switches the locations of the tokens on u and v. The token swapping problem asks how many swaps are needed to arrive at the target configuration from the starting configuration.

The token swapping problem is a fundamental and well-studied problem, and one of the central problems in the area of *reconfiguration* algorithms. It has also found relevance in a number of disparate areas including network engineering [2], robot motion planning [12, 28], and game theory [14]. Token swapping (mainly its parallel variant [3, 6, 12, 17, 37]) also

has an extensively studied application to qubit routing (e.g. [5, 26, 19, 7, 11, 15, 24, 33]). Algorithms and heuristics for the token swapping problem have also undergone experimental evaluation [23, 27].

The token swapping problem is NP-complete [18], even when the underlying graph is a tree [1]. As a result, the research literature has focused on approximation algorithms. Miltzow, Narins, Okamoto, Rote, Thomas, and Uno gave a 4-approximation [18], which remains the best known. For the special case of trees, there is a 2-approximation, which was independently discovered 3 times using different algorithms [2, 32, 35].

From the hardness side, the above work [18] proved that token swapping is APX-hard (on general graphs). Thus, unless P = NP, token swapping does not admit a PTAS, and instead there exists some positive constant c for which there is no c-approximation. Regarding this constant c, they state *"We want to point out that a crude estimate for the constant c in [the NP-hardness result] is $c \approx 1 + 1/1000$. We do not believe that it is worth to compute c exactly. Instead, we hope that future research might find reductions with better constants."* This question is the main focus of our work.

We also consider the *0/1-weighted* version of token swapping, in which each token has a weight of either 0 or 1, and the cost of a swap is the sum of the weights of the two tokens. Despite being studied in prior work [8, 1], there is no known approximation algorithm for 0/1-weighted token swapping with a non-trivial approximation ratio. Furthermore, there is no known separation between 0/1-weighted token swapping and standard token swapping.

See the introductions of [8] and [1] for a more detailed survey of related work, including a sizable body of work on token swapping for a number of special classes of graphs.

1.1 Our Results

Our main result is the first hardness of approximation result for token swapping with an explicit approximation ratio of "reasonable" magnitude. Specifically, we show that it is NP-hard to obtain better than a 14/13-approximation:

▶ **Theorem 1.** *For any constant $\epsilon > 0$, it is NP-hard to approximate token swapping on graphs within a factor of $14/13 - \epsilon$.*

Our result is via a reduction from the label cover problem. We note that our result does not rely on the Unique Games Conjecture, and is instead a gap-preserving reduction from a regime of the label cover problem known to be NP-complete.

For 0/1-weighted token swapping, our next result explains the aforementioned gap in the literature by showing a large separation between the 0/1-weighted and unweighted versions. Specifically, we show that it is NP-hard to obtain better than an $(\ln n)$-approximation for 0/1-weighted token swapping:

▶ **Theorem 2.** *For any constant $\epsilon > 0$, it is NP-hard to approximate weighted token swapping with $\{0, 1\}$ weights on n vertices within a factor of $(1 - \epsilon) \cdot \ln n$.*

Our reduction uses a completely different technique from our main result, and is a much simpler reduction, from the set cover problem. This is notable in comparison to the known reductions in the token swapping literature, which tend to be quite complicated [1, 8, 18, 9].

Our final two results are barrier results regarding the algorithm and analysis techniques that could possibly achieve better than the current best-known approximation ratio of 4 (for standard unweighted token swapping). All known token swapping algorithms have the

natural property of *local optimality*: they never perform a swap that brings *both* tokens farther from their destinations.[1] We show that, strangely, this property must be violated to achieve any approximation ratio better than 4.

▶ **Theorem 3.** *For any $\delta > 0$, there exists a token swapping instance K so that for any locally optimal swap sequence of length k, $(4-\delta) \cdot OPT(K) \leq k$.*

In our second barrier result, we show that a proof technique used by all known analyses of approximation algorithms for token swapping, cannot yield better than a 4-approximation. In particular, all known approximation algorithms for token swapping on general graphs and trees [18, 35, 2] use the following approach to bound the approximation factor. Given a Token Swapping instance K, consider the quantity $total(K) = \sum_{t \in T} \text{dist}(f_1(t), f_2(t))$. We observe that $\frac{1}{2} total(K) \leq OPT(K)$, as each swap moves at most two tokens closer to their destinations. Proofs of correctness for approximation algorithms then show that they yield swap sequences of length at most $c \cdot total(K)$, which implies that the given algorithm is a $2c$-approximation. A natural approach to obtaining a $(4-\epsilon)$-approximation for token swapping on graphs, then, is to show that on any input an algorithm yields a swap sequence of length at most $c \cdot total(K)$, for some $c < 2$. Below, we show that this approach will not work.

▶ **Theorem 4.** *For any $\delta > 0$, there exists a token swapping instance K so that $OPT(K) \geq (2-\delta) \cdot total(K)$.*

The proof is given in the full version.

Lastly, in the full version we provide an alternative algorithm that gives a 4-approximation for token swapping (in addition to the known algorithm [18]). While the algorithm of [18] is an extension of the 2-approximation "happy swap algorithm" for trees [2], our algorithm is an extension of the 2-approximation "cycle algorithm" for trees [35].

1.2 Additional Related Work

Token swapping and its variants have been studied from many angles. Exponential-time algorithms and hardness under the Exponential Time Hypothesis (ETH) were studied in [18]. Parameterized complexity was studied in [9], where the authors show that token swapping is W[1]-hard when the parameter is the number of swaps, and show further hardness under ETH. Token swapping has also been studied on a variety of special classes of graphs including cycles [16], stars [21, 20], brooms [17, 8, 31], complete bipartite graphs [35], complete split graphs [36], and cliques [10] (dating back to Cayley in 1849). *Colored* token swapping has also been studied, where each token has a color and same-colored tokens are indistinguishable [18, 8, 9, 34, 34]. There are also several other models of token movement on graphs such as token sliding, token rotation, and token permutation (see e.g. [28]). See also the introductions of [8] and [1] for more details on the wealth of related work.

[1] We compare the notion of a locally optimal algorithm to that of an *ℓ-straying* algorithm, introduced in prior work on token swapping for *trees* [1]. These two notions are incomparable: a swap sequence can have either property without having the other. However, any algorithm that solves token swapping on general graphs must generate an $\Omega(n)$-straying swap sequence: consider the example of a cycle where each token wants to shift over by 1. For this reason, we do not consider ℓ-straying algorithms for general graphs, and focus instead on locally optimal algorithms.

2 Preliminaries

▶ **Definition 5.** *A* Token Swapping *instance* $K = (G, T, f_1, f_2)$ *consists of a graph* $G = (V, E)$*, a set of tokens* T *where* $|T| = |V|$*, and two one-to-one assignments* $f_1, f_2 : T \to V$*. We call* f_1 *and* f_2 *the* starting *and* target *configurations respectively. A swap along an edge* $(u, v) \in E$ *switches the locations of the tokens on* u *and* v*. The token swapping problem asks how many swaps are needed to arrive at the target configuration from the starting configuration.*

For a token swapping instance K, we denote by $OPT(K)$ the length of the shortest swap sequence. For a vertex v, we denote by $f_1^{-1}(v)$ and $f_2^{-1}(v)$ the tokens that begin and end on v. When a token t lies on the vertex v_1 of the path $p = v_1, v_2, ..., v_k$, we use the phrase *bubbling* t *across* p to denote the sequence of swaps $(v_1, v_2), (v_2, v_3), ..., (v_{k-1}, v_k)$.

We also consider the following weighted variant of Token Swapping:

▶ **Definition 6** (Weighted Token Swapping)**.** *An instance of* Weighted Token Swapping $W = (G, T, w, f_1, f_2)$ *consists of a graph* $G = (V, E)$*, together with a set of tokens* T *of size* $|V|$*. The weight function* $w : T \to \mathbb{R}^{\geq 0}$ *assigns to each token a non-negative real weight. As in standard* Token Swapping*, the one-to-one functions* $f_1, f_2 : T \to V$ *map each token to a unique vertex, giving the starting and target configurations of* W*. The weight of an edge swap is the sum of the weights of the tokens being swapped. The weight of a swap sequence is the sum of the weights of the constitutive edge swaps. The output to* W *is the weight of the lowest-weight swap sequence from the starting to the target configuration.*

3 Hardness for standard token swapping

In this section, we prove Theorem 1.

▶ **Theorem 1.** *For any constant* $\epsilon > 0$*, it is NP-hard to approximate token swapping on graphs within a factor of* $14/13 - \epsilon$*.*

This improves on the lower bound presented in [18], which is roughly 1001/1000. We obtain our lower bound via a gap-preserving reduction from Label-Cover, defined below.

▶ **Definition 7** (Label Cover)**.** *An instance of* Label-Cover $\Phi = (X, Y, E, \Sigma, \Pi)$ *consists of a bipartite graph with vertex set* $X \cup Y$ *and edge set* E*, together with a finite alphabet* Σ*, and a set of constraints* $\Pi = \{\Pi_e : e \in E\}$*. Each constraint is a function* $\Pi_e : \Sigma \to \Sigma$*.*

A labelling of $X \cup Y$ *is a function* $\lambda : X \cup Y \to \Sigma$ *which assigns a label to each vertex. For* $x \in X$*,* $y \in Y$*, a constraint* $\Pi_{(x,y)}$ *is satisfied if* $\Pi_{(x,y)}(\lambda(x)) = \lambda(y)$*.*

We denote by $OPT(\Phi)$ the maximum fraction of constraints in Φ which can be satisfied by any labelling. An instance of the promise problem GapLabel-Cover$_{1,\gamma}(\Sigma)$ consists of a label-cover instance Φ with alphabet Σ, together with the guarantee that either $OPT(\Phi) = 1$ or $OPT(\Phi) < \gamma$. Here, γ is a positive constant close to 0. The following is a seminal result in the theory of hardness of approximation.

▶ **Theorem 8.** *For any constant* $\gamma > 0$*, there exists a sufficiently large constant* $|\Sigma|$ *(dependent only on* γ*) such that* GapLabel-Cover$_{1,\gamma}(\Sigma)$ *is NP-hard.*

Arora and Lund [4] describe a reduction from 3-SAT which, together with Raz's Parallel Repetition Theorem [22], implies that Theorem 8 remains true even on instances where the underlying graph is regular. Moreover, we may take the degree to be at least any arbitrarily

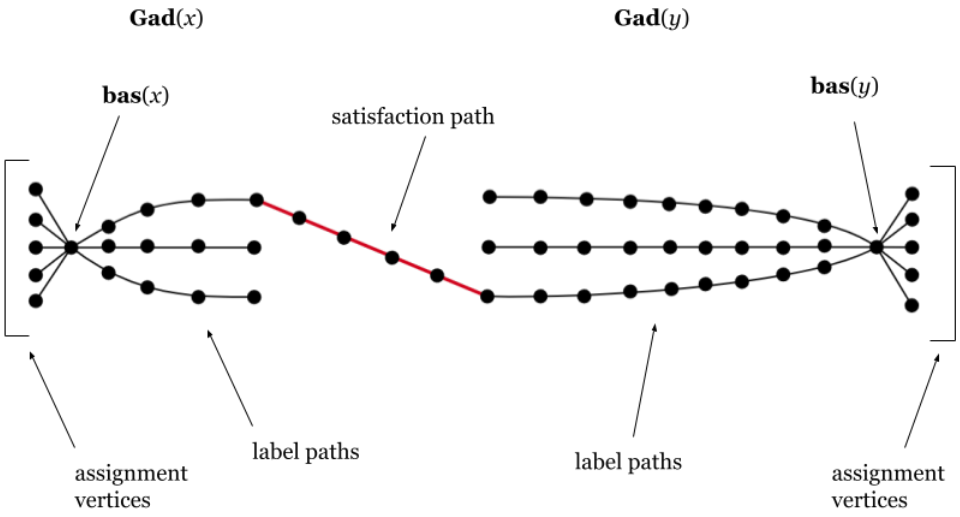

Figure 1 A left and right gadget, joined by a satisfaction path; $d = 5$, $|\Sigma| = 3$.

large constant by creating many copies of our graph $X \cup Y$ and adding a copy of the constraint $\Pi_{(x,y)}$ between every copy of x and every copy of y. Note that in such an instance $|X| = |Y|$. We use a gap-preserving reduction from label-cover to prove Theorem 1.

3.1 Construction

Our reduction maps a label cover instance $\Phi = (X, Y, E, \Sigma, \Pi)$, where the base graph has degree d, to a token swapping instance $K(\Phi) = (G, T, f_1, f_2)$.

We construct G by building a gadget $\mathbf{Gad}(v)$ for each $v \in X \cup Y$ as follows. Our construction for $\mathbf{Gad}(v)$ starts with a base vertex $\mathbf{bas}(v)$. We add d additional vertices adjacent to $\mathbf{bas}(v)$, which we call *assignment vertices* (recall that d is the degree in the label-cover instance). To each assignment vertex in $\mathbf{Gad}(v)$ we identify a unique edge $(v, w) \in E$ (where E is the label cover edge set) incident to v; we call this assignment vertex $\mathbf{asg}(v, w)$. We then create $|\Sigma|$ paths, each with $\mathbf{bas}(v)$ as an endpoint. We call these paths *label paths*. If $v \in X$, then each label path in $\mathbf{Gad}(v)$ contains $d - 1$ edges; if $v \in Y$, then each label path in $\mathbf{Gad}(v)$ contains $2d - 1$ edges. To each label path in $\mathbf{Gad}(v)$ we associate a unique $\sigma \in \Sigma$, and denote this label path by $\mathbf{lab}(v, \sigma)$.

If $v \in X$, then we call $\mathbf{Gad}(v)$ a *left gadget*; otherwise, we call $\mathbf{Gad}(v)$ a *right gadget*. We call an assignment vertex a left (resp. right) assignment vertex if it is in a left (resp. right) gadget. We denote the set of left gadgets by $\mathbf{L}$ and the set of right gadgets by $\mathbf{R}$.

Whenever it is the case that the label pair (σ_x, σ_y) satisfies the constraint $\Pi_{(x,y)}$, we add a path of d edges connecting the endpoint of $\mathbf{lab}(x, \sigma_x)$ opposite $\mathbf{bas}(x)$ with the endpoint of $\mathbf{lab}(y, \sigma_y)$ opposite $\mathbf{bas}(y)$. We call such a path a *satisfaction path*, and denote it by $\mathbf{sat}(x, \sigma_x, y, \sigma_y)$.

This gives our construction for G. An illustration of a left and right gadget connected by a satisfaction path given in Figure 1. We construct f_1 and f_2 as follows. For each $(x, y) \in E$, the tokens on $\mathbf{asg}(x, y)$ and $\mathbf{asg}(y, x)$ wish to swap positions with each other. That is, $f_2(f_1^{-1}(\mathbf{asg}(x, y))) = \mathbf{asg}(y, x)$, and $f_2(f_1^{-1}(\mathbf{asg}(y, x))) = \mathbf{asg}(x, y)$.

We will refer to such a token as an *assignment token*. We will call an assignment token t where $f_1(t)$ is a left (resp. right) assignment vertex a left (resp. right) assignment token. For $t \in T$ that are not assignment tokens, $f_1(t) = f_2(t)$. That is, t does not wish to move from its starting position.

The intuition behind the reduction is as follows: if there is a labelling λ satisfying every constraint in Π, then all the assignment tokens that start in $\mathbf{Gad}(v)$ can move to their destination along the single label path associated with $\lambda(v)$. Then, any assignment token seeking to *enter* $\mathbf{Gad}(v)$ can travel along this path, and will in the process swap with many of the assignment tokens leaving $\mathbf{Gad}(v)$, bringing them closer to their destination. If, on the other hand, no good labelling exists, then having so many efficient swaps becomes impossible.

We prove the following lemma.

▶ **Lemma 9.** *Let $\Phi = (X, Y, \Sigma, \Pi)$ be a label-cover instance whose graph is d-regular. The following two claims hold:*

- *If $OPT(\Phi) = 1$, then $OPT(K(\Phi)) \leq \left(\frac{13}{4}d^2 + d\right)|X \cup Y|$.*
- *If $OPT(\Phi) < \gamma$, then $OPT(K(\Phi)) > \left(\frac{7-\gamma}{2}d^2 - 5d\right)|X \cup Y|$.*

Given a label-cover instance Φ, the token swapping instance $K(\Phi)$ can be computed in polynomial time. We set d to be a large constant and γ a small constant, and the hardness result of Theorem 1 follows from Lemma 9. In Section 3.2, we briefly discuss the proof of the first half of Lemma 9 (completeness), with a proof given in the full version. In Section 3.3, we prove the second half (soundness).

3.2 Completeness

Let Φ be a label-cover instance as defined in Lemma 9 such that $OPT(\Phi) = 1$. We prove the first half of Lemma 9 by providing a swap sequence for $K(\Phi)$ using $(\frac{13}{4}d^2 + d)|X \cup Y|$ swaps. We describe the procedure in detail, and prove the first half of Lemma 9 in the full version.

3.3 Soundness

In this section, we will prove the second half of Lemma 9: if $OPT(\Phi) < \gamma$, then $OPT(K(\Phi)) > \left(\frac{7-\gamma}{2}d^2 - 5d\right)|X \cup Y|$.

Let Φ be a label-cover instance such that $OPT(\Phi) < \gamma$, and let S_{OPT} denote the optimal sequence of swaps on $K(\Phi)$. For a token $t \in T$, consider the subsequence of S_{OPT} in which t is one of the tokens being swapped. This subsequence traces out a walk in G. Consider the path from $f_1(t)$ to $f_2(t)$ obtained by removing all the closed sub-walks from this walk. We denote this path $\mathbf{Swap}(t)$.

We now partition the assignment tokens into two types: *detour tokens* and *non-detour* (assignment) tokens.

▶ **Definition 10** (Detour token)**.** *A token t is a* detour token *if:*

- *$f_1(t)$ is an assignment vertex.*
- ***Swap**(t) has more than $4d$ edges.*

We will refer to all other assignment tokens as *non-detour tokens*. This allows us to introduce the following notation: det_L (resp. det_R) is the number of detour tokens t such that $f_1(t)$ is a left (resp. right) assignment vertex. We will denote by Det the set of detour tokens, and $Ndet$ the set of non-detour tokens.

We obtain lower bounds on two quantities: B_{sat}, the number of swaps occurring within satisfaction paths, and B_{Gad}, the number of swaps occurring within gadgets.

$$B_{sat} \geq (d^2 - 3d)|X \cup Y| + \frac{d}{2}(det_L + det_R) \tag{1}$$

$$B_{Gad} > \left(\frac{5-\gamma}{2}d^2 - 2d\right)|X \cup Y| - \frac{d}{2}(det_L + det_R) \tag{2}$$

Combining these inequalities proves the second half of Lemma 9.

3.3.1 Swaps on satisfaction paths

First, we prove inequality 1.

▶ **Observation 11.** *If t is a detour token, then **Swap**(t) contains at least three satisfaction paths as subpaths.*

Observation 11 follows from the construction of G; any path of length greater than $4d$ with a left assignment vertex and a right assignment vertex as endpoints traverses at least three satisfaction paths. Therefore, we can associate to each detour token t a sequence of at least three satisfaction paths. We refer to the path(s) in this sequence which are not the first or last path as the *intermediate path(s)* of t. Each detour token has at least one intermediate path.

▷ Claim 12. S_{OPT} contains at least $\frac{d}{2}(det_L + det_R)$ swaps where at least one token is a detour token visiting one of its intermediate paths.

Proof. There are $det_L + det_R$ detour tokens, each of which participates in at least d swaps on intermediate paths. Each swap involves at most 2 tokens, hence the bound of $\frac{d}{2}(det_L + det_R)$. ◁

Furthermore, let $ext(t)$ denote the number of swaps that t participates in on satisfaction paths that are not intermediate paths. For $t \in Det$, $ext(t) \geq 2d$. For $t \in Ndet$, $ext(t) \geq d$. Unfortunately, we cannot simply add these quantities together to obtain a lower bound on the number of swaps on satisfaction paths. This is because a swap may be between two different assignment tokens, so adding these quantities would risk double-counting. However, we can obtain an upper-bound on the amount of double-counting that can take place, using the following definition.

▶ **Definition 13** (Efficient satisfaction swap)**.** *A swap between assignment tokens t_1 and t_2 is an* efficient satisfaction swap *if one of the following is the case:*

1. *neither t_1 nor t_2 is a detour token,*
2. *one of t_1 or t_2 is not a detour token, the other is a detour token not on an intermediate path, and the swap is contained in **Swap**(t), where t is the detour token, or*
3. *t_1 and t_2 are detour tokens, neither is on an intermediate path, and the swap is contained in **Swap**(t), where t is t_1 or t_2.*

Let k_{sat} denote the number of efficient satisfaction swaps in S_{OPT}. Combining Definition 13 with Claim 12, we obtain the following inequality:

$$B_{sat} \geq \frac{d}{2}(det_L + det_R) + \sum_{t \in Det} ext(t) + \sum_{t \in Ndet} ext(t) - k_{sat}$$

which implies that

$$B_{sat} \geq \frac{d}{2}\left(det_L + det_R\right) + 2d(det_L + det_R) + d\Big(d|X \cup Y| - (det_L + det_R)\Big) - k_{sat}. \quad (3)$$

We give an upper bound on k_{sat}. We do so by proving individual upper bounds on each of the three types of efficient satisfaction swaps outlined in Definition 13.

Swaps of type 1: *neither t_1 not t_2 is a detour token.* Because the label-cover graph is simple, each edge $(x, y) \in E$ is mapped by our reduction to a unique pair of assignment vertices, those being $\mathbf{asg}(x, y)$ and $\mathbf{asg}(y, x)$. Therefore, any satisfaction path $\mathbf{sat}(x, \sigma_x, y, \sigma_y)$ is traversed by at most two non-detour assignment tokens, those being $f_1^{-1}(\mathbf{asg}(x, y))$ and $f_1^{-1}(\mathbf{asg}(y, x))$. It follows that any non-detour token can swap on a satisfaction path with at most one other non-detour token Because there are $d|X \cup Y| - (det_L + det_R)$ non-detour assignment tokens, we obtain the following upper bound on swaps of type 1:

$$\frac{1}{2}\Big(d|X \cup Y| - (det_L + det_R)\Big).$$

Swaps of type 2: *one of t_1 or t_2 is not a detour token, and the other is a detour token not on an intermediate path.* Again, any satisfaction path $\mathbf{sat}(x, \sigma_x, y, \sigma_y)$ is traversed by at most two non-detour assignment tokens, those being $f_1^{-1}(\mathbf{asg}(x, y))$ and $f_1^{-1}(\mathbf{asg}(y, x))$. A detour token moving across $\mathbf{sat}(x, \sigma_x, y, \sigma_y)$ can swap with only one, depending on the direction in which it is moving. Because each detour token traverses exactly two non-intermediate satisfaction paths, the number of swaps of type 2 is at most:

$$2(det_L + det_R)$$

Swaps of type 3: *t_1 and t_2 are detour tokens, but neither is on an intermediate path.* Each detour token participates in at most a combined $2d$ swaps on the first and last satisfaction paths that it visits. Each of these swaps involves at most 2 such tokens, implying that the number of swaps of type 3 is at most:

$$d(det_L + det_R).$$

Combining these bounds with inequality 3, we are left with the following lower bound on B_{sat}:

$$\begin{aligned}
B_{sat} &\geq \frac{d}{2}\left(det_L + det_R\right) + d\Big(d|X \cup Y| - (det_L + det_R)\Big) + 2d(det_L + det_R) \\
&\quad - \frac{1}{2}\Big(d|X \cup Y| - (det_L + det_R)\Big) - 2(det_L + det_R) - d(det_L + det_R) \\
&= d^2|X \cup Y| + \frac{3d}{2}(det_L + det_R) - \frac{d}{2}|X \cup Y| - \left(d + \frac{5}{2}\right)(det_L + det_R) \\
&= \left(d^2 - \frac{d}{2}\right)|X \cup Y| + \left(\frac{d-5}{2}\right)(det_L + det_R) \\
&\geq \left(d^2 - 3d\right)|X \cup Y| + \frac{d}{2}(det_L + det_R)
\end{aligned}$$

as desired.

3.3.2 Swaps on gadgets

Next, we prove inequality 2:

$$B_{Gad} > \left(\frac{5-\gamma}{2}d^2 - 2d\right)|X \cup Y| - \frac{d}{2}(det_L + det_R).$$

Any assignment token t participates in at least $3d-2$ swaps within label paths: $d-1$ swaps on a left label path and $2d-1$ swaps on a right label path. Moreover, we can identify the two label paths, one in a left gadget and one in a right gadget, which come at either end of $\mathbf{Swap}(t)$. We refer to these paths as the *first* and *last legs* of t. Note that the first leg of t comes in the gadget containing t's start vertex, and the last leg comes in the gadget containing t's target vertex.

A swap which corresponds to an edge in the first leg of one token t_1 and the last leg of another token t_2 we will call an *efficient gadget swap*. Note that such a swap appears in both $\mathbf{Swap}(t_1)$ and $\mathbf{Swap}(t_2)$. We denote the number of efficient gadget swaps in S_{OPT} by k_{Gad}, and we denote the number of efficient gadget swaps occurring within the gadget $\mathbf{Gad}(v)$ by $k_{Gad}(v)$. We observe that

$$B_{Gad} \geq (3d^2 - 2d)|X \cup Y| - k_{Gad} \tag{4}$$

and we seek an upper bound on k_{Gad} accordingly.

To this end, we define the *outflow* of a label path p to be the number of tokens whose first leg is p, and the *inflow* of p to be the number of tokens whose last leg is p. For $\mathbf{Gad}(v) \in \mathbf{L} \cup \mathbf{R}$, we call the label path in $\mathbf{Gad}(v)$ with the maximum outflow (resp. inflow) the *out-dominant* (resp. *in-dominant*) label path of $\mathbf{Gad}(v)$. We denote by $out(\mathbf{Gad}(v))$ (resp. $in(\mathbf{Gad}(v))$) the outflow (resp. inflow) of the out-dominant (resp. in-dominant) label path in $\mathbf{Gad}(v)$. We obtain two inequalities.

▷ Claim 14. For any gadget $\mathbf{Gad}(v)$,
- $k_{Gad}(v) \leq d(out(\mathbf{Gad}(v)))$
- $k_{Gad}(v) \leq d(in(\mathbf{Gad}(v)))$.

Proof. We prove the first inequality. Let $t \in T$ be an assignment token. Suppose $f_2(t)$ is in $\mathbf{Gad}(v)$. Then t participates in at most $out(\mathbf{Gad}(v))$ efficient gadget swaps on $\mathbf{Gad}(v)$, as at most $out(\mathbf{Gad}(v))$ such swaps can occur on the label path taken by t. There are d tokens t where $f_2(t)$ is an assignment vertex in $\mathbf{Gad}(v)$, hence the bound of $d(out(\mathbf{Gad}(v)))$. The proof of the second inequality is symmetric. ◁

▷ Claim 15. If $OPT(\Phi) < \gamma$, then

$$\sum_{x \in X} out(\mathbf{Gad}(x)) + \sum_{y \in Y} in(\mathbf{Gad}(y)) < \left(\frac{1+\gamma}{2}\right) d|X \cup Y| + det_L$$

$$\sum_{x \in X} in(\mathbf{Gad}(x)) + \sum_{y \in Y} out(\mathbf{Gad}(y)) < \left(\frac{1+\gamma}{2}\right) d|X \cup Y| + det_R$$

Proof. We prove the first half of the claim; the proof of the second half is symmetric. Suppose for contradiction the first inequality does not hold. The left side of the inequality counts two quantities: (a) the total outflow from the out-dominant label path of each left gadget, plus (b) the total inflow to the in-dominant label path of each right gadget. Each left assignment token can contribute at most 1 to (a) and at most 1 to (b). Because $d|X \cup Y|$ is the total number of assignment tokens and the graph is regular (so $|X| = |Y|$), there are exactly $(d/2)|X \cup Y|$ left assignment tokens. As a result, even if the maximum number of left assignment tokens are contributing to only one of (a) or (b), at least $\frac{\gamma}{2}(d|X \cup Y|) + det_L$ contribute to both. Therefore, there are at least $\frac{\gamma}{2}(d|X \cup Y|)$ non-detour tokens starting in left gadgets which have an out-dominant label path as a first leg and an in-dominant label path as a last leg. Let t be such a token. Because t is a non-detour token, there is a

satisfaction path between t's first and last legs. By our construction, the constraint in the label cover instance associated with t is satisfied by the labelling corresponding to t's first and last legs. Consider a labelling of Φ which assigns to $x \in X$ the label corresponding to the out-dominant label path of $\mathbf{Gad}(x)$, and to $y \in Y$ the label corresponding to the in-dominant label path of $\mathbf{Gad}(y)$. There are at least $\gamma|E|$ constraints satisfied by this labelling, which is a contradiction. ◁

We average the inequalities in Claim 14 and rearrange some terms to obtain the new bound for any $\mathbf{Gad}(v)$:

$$\frac{k_{Gad}(v)}{d} \leq \frac{out(\mathbf{Gad}(v)) + in(\mathbf{Gad}(v))}{2}$$

and we average the two inequalities in Claim 15 to obtain

$$\sum_{v \in X \cup Y} \frac{out(\mathbf{Gad}(v)) + in(\mathbf{Gad}(v))}{2} < \left(\frac{1+\gamma}{2}\right) d|X \cup Y| + \frac{det_L + det_R}{2}.$$

Combining these bounds, we arrive at the following inequality:

$$\sum_{v \in X \cup Y} \frac{k_{Gad}(v)}{d} < \frac{1+\gamma}{2} d|X \cup Y| + \frac{det_L + det_R}{2}$$

which implies

$$k_{Gad} < \frac{1+\gamma}{2} d^2|X \cup Y| + \frac{d}{2}(det_L + det_R)$$

which, combined with inequality 4:

$$B_{Gad} \geq (3d^2 - 2d)|X \cup Y| - k_{Gad}$$

implies inequality 2:

$$B_{Gad} > \left(\frac{5-\gamma}{2} d^2 - 2d\right)|X \cup Y| - \frac{d}{2}(det_L + det_R).$$

4 Hardness for 0/1-Weighted Token Swapping

We prove the following theorem:

▶ **Theorem 2.** *For any constant $\epsilon > 0$, it is NP-hard to approximate weighted token swapping with $\{0, 1\}$ weights on n vertices within a factor of $(1 - \epsilon) \cdot \ln n$.*

We proceed via a reduction from the Set Cover problem, defined below.

▶ **Definition 16** (Set Cover). *An instance of Set-Cover $\Phi = (U, \{S_i\}_{1 \leq i \leq k})$ consists of a finite universe set U, together with subsets $S_1, ..., S_k \subseteq U$. We seek to find the size of the smallest collection of subsets in $\{S_1, ..., S_k\}$ so that each element of U is in at least one subset.*

Dinur and Steurer [13] prove the following theorem:

▶ **Theorem 17.** *For any constant $\delta > 0$, it is NP-hard to approximate Set Cover within a factor of $(1 - \delta) \cdot \ln(|U| + k)$.*

We give a gap-preserving reduction from Set Cover to Weighted Token Swapping. We describe the reduction in the full version, proving the desired lower-bound.

5 Additional barriers to improved algorithms

In this section, we discuss two barriers to obtaining a $(4-\epsilon)$-approximation for unweighted token swapping on graphs. The first barrier (Theorem 3 is against a broad class of algorithms that encompasses all known approximation algorithms for token swapping. The second barrier (Theorem 4) shows that the technique used to prove approximation factors for existing algorithms cannot be used to prove an approximation factor of $4-\epsilon$ for any $\epsilon > 0$. The proof of Theorem 4 is given in the full version of the paper.

5.1 A barrier against a general class of algorithms

We define the following property for swap sequences on a Token Swapping instance.

▶ **Definition 18** (Local Optimality). *A swap sequence is* locally optimal *if every swap between tokens t_1 and t_2 does not move both t_1 and t_2 further from their destinations.*

All known algorithms for token swapping on trees or on general graphs work by returning the length of a swap sequence that is locally optimal.

▶ **Theorem 3.** *For any $\delta > 0$, there exists a token swapping instance K so that for any locally optimal swap sequence of length k, $(4-\delta) \cdot OPT(K) \leq k$.*

We construct a token swapping instance K as follows. See Figure 2. Let p and q be parameters to be decided later. We can assume p is even. We begin with a cycle C^{out} of length $p \cdot q$. Starting with an arbitrary vertex, we label the vertices $v_0, ..., v_{p \cdot q-1}$ in one direction (say, clockwise) around the cycle. We partition the vertices of C^{out} into p consecutive "segments". For any $0 \leq i \leq p-1$, the vertices $\{v_{iq}, ..., v_{iq+(q-1)}\}$ form the i-th segment. If i is even, we call such a segment an *even segment*; else it is an *odd segment*. For any j so that v_j is in an even segment, the token starting on v_j has target vertex $v_{j+2q} \pmod{pq}$. If v_j is in an odd segment, the token starting on v_j has target vertex $v_{j-2q} \pmod{pq}$. That is, each token in an even segment wants to move to the corresponding vertex in the next even segment in the clockwise direction, while each token in an odd segment wants to move to the next odd segment over in the counter-clockwise direction. For each $0 \leq j \leq pq$, we add a path P_j of $2q-2$ edges between v_j and v_{j+2q}. All the vertices on this path (except the endpoints in C^{out}) wish to stay on their start vertices. We call these paths *inner paths*. We call the vertices in C^{out} *outer vertices*, and all other vertices *inner vertices*. Tokens that begin on outer vertices (which also have destinations on outer vertices) we call *outer tokens*; other tokens are *inner tokens*. Outer tokens with start and target vertices in even segments we will call *even tokens*; other outer tokens we will call *odd tokens*. Note that each outer token begins on a vertex connected to its target vertex by an inner cycle. The outer cycle, together with a single inner cycle, is depicted in Figure 2.

▷ Claim 19. $OPT(K) \leq pq^2$.

Proof. Here is a swap sequence bringing every token to its destination vertex:

1. For $j = 0, ..., pq-1$:
   a. If $f_1^{-1}(v_j)$ is an odd token, bubble it counter-clockwise around C^{out} across q edges.
2. Again, for $j = 0, ..., pq-1$:
   a. If $f_1^{-1}(v_j)$ is an odd token, bubble it counter-clockwise around C^{out} across q edges.

We check that the above swap sequence brings every token to its target vertex. No swap occurs on an edge in an inner cycle, so none of the inner tokens are displaced. Suppose $f^{-1}(v_j)$ (the token starting on v_j) is an odd outer token. It is not difficult to see that when

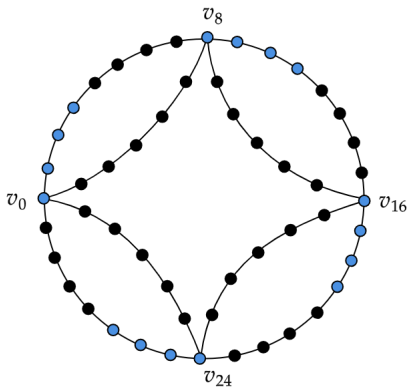

Figure 2 An (incomplete) graph for a token swapping instance where $p = 8$, $q = 4$. The diagram depicts the outer cycle and one inner cycle, but leaves out the remaining inner cycles for legibility. In the outer cycle, vertices in even segments are colored blue, while those in odd segments are colored black. The token starting on v_0 has target v_8, the token starting on v_8 has target v_{16}, the token starting on v_{16} has target v_{24}, and the token starting on v_{24} has target v_0.

$f^{-1}(v_j)$ is bubbled q edges counter-clockwise, it only swaps with even tokens (this is because any odd token from the same segment was already bubbled q edges counter-clockwise during a previous iteration). Thus, each odd token is bubbled counter-clockwise $2q$ times, and each even token is bubbled clockwise $2q$ times. This brings every token to its target node. ◁

▷ Claim 20. Let S be the shortest locally optimal swap sequence bringing every token to its destination, and let k be the length of S. Then $4pq^2 - 5pq - 8q^2 \leq k$.

We observe that for $0 \leq j \leq 2q - 1$, the inner paths $P_j, P_{j+2q}, P_{j+4q}, ..., P_{j+q(p-1)}$ form a cycle, which we will call the j-th *inner cycle*, denoted C^{in}_j. Moreover, every token begins on a vertex in the same inner cycle as its target vertex. Claim 20 will follow from the next two claims.

▷ Claim 21. Let $a, b \in V$ be in the same inner cycle C^{in}_j, and let $P_{a,b}$ be a path from a to b containing at least one edge not in C^{in}_j. Then $\text{dist}(a, b) + 2 \leq |P_{a,b}|$, where $|P_{a,b}|$ is the number of edges in $P_{a,b}$.

Proof. We will prove the claim in two steps. First, we will modify $P_{a,b}$ to obtain a path $P'_{a,b}$ which is the same length as $P_{a,b}$ and which does not contain any edges from inner cycles other than C^{in}_j, but which contains at least one edge from C^{out}. Then, we will show that any path from a to b which contains edges from (and only from) both C^{in}_j and C^{out} has length at least $\text{dist}(a, b) + 2$.

Suppose $P_{a,b}$ contains edges outside of C^{in}_j. If $P_{a,b}$ does not contain edges from a different inner cycle, then we set $P'_{a,b}$ to $P_{a,b}$ and move on to the argument in the next paragraph. Otherwise, $P_{a,b}$ contains an edge e from a different inner cycle. Let ℓ be such that C^{in}_ℓ is the inner cycle containing e. Suppose e is, in particular, the first edge to appear in $P_{a,b}$ which is in an inner cycle other than C^{in}_j. Therefore, e is incident to a vertex $v_{\ell'}$ so that $\ell' \equiv \ell \pmod{2q}$, and e is contained in either $P_{\ell'}$ or $P_{\ell'-2q}$. We can assume by symmetry that e is contained in $P_{\ell'}$. Because $P_{a,b}$ is a shortest path, it is simple. By the construction of the graph then, $P_{a,b}$ contains the entirety of $P_{\ell'}$. Let $v_{j'}$ be the last vertex in C^{in}_j preceding $v_{\ell'}$ in $P_{a,b}$. Because e is incident to an outer vertex, the path between $v_{j'}$ and $v_{\ell'}$ only has edges in C^{out}. The length of the sub-path of $P_{a,b}$ from the appearance of $v_{j'}$ to $v_{\ell'+2q}$ is

then $|\ell' - j'| + 2q - 2$. We replace this sub-path with the following path: the shortest path in C^{in}_j from $v_{j'}$ to $v_{j'+2q}$, then the shortest path in C^{out} from $v_{j'+2q}$ to $v_{\ell'+2q}$. The length of this path is at most $|\ell' - j'| + 2q - 2$, so we have not increased the length of $P_{a,b}$, but we have decreased the number of edges from an inner cycle other than C^{in}_j. We repeat this procedure until we obtain a path $P'_{a,b}$ which does not contain any edges from inner cycles other than C^{in}_j.

We have a simple path $P'_{a,b}$ which contains edges only from C^{in}_j and C^{out}, and at least one edge from C^{out}. Then there exists a consecutive sub-path in $P'_{a,b}$ of edges from C^{out} of length $2q$, as this is the number of edges needed to go from one vertex in C^{in}_j to another while traversing C^{out}. However, this sub-path can be replaced by the sub-path of length $2q - 2$ between its endpoints using only edges from C^{in}_j. Therefore, $\text{dist}(a, b) + 2 \leq |P'_{a,b}| = |P_{a,b}|$. ◁

For a, b in C^{in}_j, and for c not in C^{in}_j which is a neighbor of a, it is the case that $\text{dist}(a, b) < \text{dist}(c, b)$. Otherwise, there would be a path from a to b containing the edge (a, c) of length at most $\text{dist}(a, b) + 1$, even though (a, c) is not in C^{in}_j, which contradicts Claim 21. Because each token starts in the same inner cycle as its target vertex, this implies that any swap across an edge in C^{out} is not locally optimal. We proceed by proving a lower bound on the number of swaps needed to bring all the tokens in C^{in}_j to their target vertex without leaving C^{in}_j.

▷ Claim 22. For any j, the number of swaps needed to bring all of the tokens on C^{in}_j to their target vertices while swapping only along edges in C^{in}_j is greater than $2pq - 5p/2 - 4q$.

Proof. Suppose without loss of generality that v_j is in an even segment; by our construction, all the other outer vertices in C^{in}_j are also in even segments. Moreover, each outer vertex in C^{in}_j begins with a token which wants to move to the closest outer vertex in C^{in}_j in the clockwise direction, of distance $2q - 2$ away. All inner tokens want to stay on their start vertices. Note that C^{in}_j has length $p(q - 1)$, and contains $p/2$ outer vertices.

In a given swap, one token in C^{in}_j is moved clockwise, and the other counter-clockwise. For a token t, let $\mathit{clock}(t)$ be the number of swaps in the optimal swap sequence on C^{in}_j in which t is moved clockwise, and $\mathit{counter}(t)$ the number of times its moved counter-clockwise.

Let t_{in} be an inner token in C^{in}_j. Because t_{in} has the same start and target, $\mathit{clock}(t_{in}) - \mathit{counter}(t_{in}) \equiv 0 \pmod{p(q-1)}$. If t_{out} is an outer vertex in C^{in}_j, then $\mathit{clock}(t_{out}) - \mathit{counter}(t_{out}) \equiv 2q - 2 \pmod{p(q-1)}$. Because each swap moves one token clockwise and one token counter-clockwise, $\sum_{t_{in} \in C^{in}_j} \mathit{clock}(t_{in}) - \mathit{counter}(t_{in}) = 0$. It follows there is a token $t_{counter} \in C^j_{in}$ where $\mathit{counter}(t_{counter}) > \mathit{clock}(t_{counter})$ (else, each token in C^j_{in} would end on its start vertex). By our construction, the distance from $t_{counter}$'s start vertex to its target in the counter-clockwise direction is at least $p(q-1) - 2q + 2$, so $\mathit{counter}(t_{counter}) - \mathit{clock}(t_{counter}) \geq p(q-1) - 2q + 2$.

If there is an additional token $t'_{counter}$ so that $p(q-1) - 2q + 2 \leq \mathit{counter}(t')$, then there are at least $2(p(q-1) - 2q) > 2pq - 5p/2 - 4q$ swaps in the optimal swap sequence, as desired. Otherwise, there are at least $p/2 - 1$ outer tokens in C^{in}_j which are not moved counter-clockwise at least $p(q-1) - 2q$ times. Each is involved in at least $2q - 2$ swaps where it is the token being moved clockwise. Moreover, at most 1 of these swaps is with $t_{counter}$, because if a pair of tokens swap at least twice, then both swaps can be removed to yield an equivalent swap sequence. This results in a total of at least

$$\begin{aligned}(p/2-1)(2q-3) + \mathit{counter}(t_{counter}) &\geq (p/2-1)(2q-3) + p(q-1) - 2q \\ &> 2pq - 5p/2 - 4q\end{aligned}$$

swaps, as desired. ◁

Because there are $2q$ inner cycles, the total number of swaps taken by a sequence with only locally optimal swaps is at least $2q(2pq - 5p/2 - 4q) = 4pq^2 - 5pq - 8q^2$, proving Claim 20. We set p, q to be large enough so that $4pq^2$ overtakes the smaller-order terms, so that for the parameter δ,

$$4 - \delta < (4pq^2 - 5pq - 8q^2)/pq^2 < 4.$$

This proves Theorem 3.

Abstract

We improve the space bound for streaming approximation of Diameter but also of Farthest Neighbor queries, Minimum Enclosing Ball and its Coreset, in high-dimensional Euclidean spaces. In particular, our deterministic streaming algorithms store $\mathcal{O}(\varepsilon^{-2}\log(\frac{1}{\varepsilon}))$ points. This improves by a factor of ε^{-1} the previous space bound of Agarwal and Sharathkumar (SODA 2010), while retaining the state-of-the-art approximation guarantees, such as $\sqrt{2}+\varepsilon$ for Diameter or Farthest Neighbor queries, and also offering a simpler and more complete argument. Moreover, we show that storing $\Omega(\varepsilon^{-1})$ points is necessary for a streaming $(\sqrt{2}+\varepsilon)$-approximation of Farthest Pair and Farthest Neighbor queries.

1 Introduction

In the streaming model, the input data is assumed to be vast and must be processed using limited memory in one or a few passes. Therefore, streaming algorithms "sketch" the input, yielding a small data structure that still accurately preserves desired properties. The research on streaming algorithms has been remarkably fruitful and we now have optimal or near-optimal algorithms for counting distinct elements, frequency moments, quantiles and a plethora of other problems (see [14] for a comprehensive exposition).

We focus on high-dimensional geometric streams, where the input S consists of points in $\mathbb{R}^d$ for d large, a topic of recent interest, e.g., [28, 17, 26, 15, 25, 11, 10, 12, 23]. Extent measures, such as the Diameter or the Minimum Enclosing Ball, are fundamental statistics of a set of points, having a body of work in both streaming and non-streaming settings [2, 22, 19, 3, 8, 7].

In an influential work, Agarwal and Sharathkumar [5] gave a streaming algorithmic framework for several high-dimensional extent problems. Their Blurred Ball Cover data structure maintains a collection of $\mathcal{O}(\frac{1}{\varepsilon^2}\log(\frac{1}{\varepsilon}))$ balls, whose union approximately covers the

input S. It was then used to approximate a number of high-dimensional extent problems. The claim is that each ball is represented by a coreset of $\mathcal{O}(\frac{1}{\varepsilon})$ points of S, for a total space of $\mathcal{O}(\frac{1}{\varepsilon^3}\log(\frac{1}{\varepsilon}))$ points. It appears though that a somewhat higher space bound is needed for the claimed approximations; see Section A.

We give a modified data structure, Guarded Ball Cover, building on [5]. It allows for both a simpler and more complete treatment, and also results in the smaller space bound of $\mathcal{O}(\frac{1}{\varepsilon^2}\log(\frac{1}{\varepsilon}))$ points. The improved space bound extends to all four applications: approximate Farthest Neighbor queries and for maintaining approximate Farthest Pair (providing an estimate for Diameter), Minimum Enclosing Ball, and Coreset for Minimum Enclosing Ball. This is feasible by storing only a single point per ball, along with its center and radius. Correctness arguments are simplified by also storing the first point of S as a proxy for all points deleted later from memory. We retain the approximation guarantees of all four applications, as in [5]: $1.22+\varepsilon$ for Minimum Enclosing Ball and $\sqrt{2}+\varepsilon$ for each of Diameter, Farthest Neighbor Queries, and Coreset for Minimum Enclosing Ball.

We also show that $\Omega(\varepsilon^{-1})$ points need to be stored for a comparable $(\sqrt{2}+\varepsilon)$-approximation of Farthest Neighbor queries and also for maintaining $(\sqrt{2}+\varepsilon)$-approximate Farthest Pair. This applies to a computational model where the algorithm must return an input point upon a query and the space is determined by the number of points stored; crucially, once a point is deleted from memory, it cannot be retrieved.

2 Preliminaries

Let S be a multiset of points in $\mathbb{R}^d$ that arrive sequentially in a stream. Upon arrival, each point $p \in S$ is either stored in memory (and, possibly, deleted later) or irrevocably discarded. We assume one-pass streaming algorithms in the insertion-only setting. By $\varepsilon \in (0,1]$ we denote an error parameter and by $\alpha > 1$ an approximation guarantee.

An extent measure of a set of points computes certain statistics of either this set or a geometric shape enclosing it [2]. Let $\|pq\|$ denote the Euclidean distance between points $p \in \mathbb{R}^d$ and $q \in \mathbb{R}^d$. The *Diameter* is the maximum Euclidean distance between any pair of points in S and the *Farthest Pair* $\mathsf{FP}(S)$ is a pair of points of S having Euclidean distance equal to the Diameter. The *Farthest Neighbor* of a point q is a point p of the largest Euclidean distance from q. An α-farthest-neighbor α-$\mathsf{FN}(q)$ of a query point $q \in \mathbb{R}^d$ is a point $x \in S$ such that for every $p \in S$ it is $\|qp\| \leq \alpha \cdot \|xq\|$.

By $B(c(B), r(B))$ we denote a ball centered at point $c(B)$ with radius $r(B)$. The $(1+\varepsilon)$-expansion of $B(c,r)$ is defined as $B(c,(1+\varepsilon)r)$. The *Minimum Enclosing Ball* $\mathsf{MEB}(S)$ is the ball of minimum radius containing all points of S. A ball B is α-$\mathsf{MEB}(S)$ if $r(B) \leq \alpha r(\mathsf{MEB}(S))$ and each point of S is within Euclidean distance $r(B)$ from $c(B)$.

For a set of points S, a *coreset* is a set $S' \subseteq S$ preserving a geometric property of S [21]. A set $S' \subseteq S$ is α-$\mathsf{coreset}(S)$ for MEB if each point of S is contained in the α-expansion of $\mathsf{MEB}(S')$.

We focus on computing $(\sqrt{2}+\varepsilon)$-$\mathsf{FN}(q)$ for any query $q \in \mathbb{R}^d$ and maintaining $(1.22+\varepsilon)$-$\mathsf{MEB}(S)$, $(\sqrt{2}+\varepsilon)$-$\mathsf{coreset}(S)$ and $(\sqrt{2}+\varepsilon)$-$\mathsf{FP}(S)$; these ratios are the same as in [5].

2.1 Related Work

The streaming algorithm of Gonzalez [20] computes a 2-MEB by storing the first point p_1 of S and its farthest neighbor q; the enclosing ball is simply $B(p_1, \|p_1 q\|)$. Zarrabi-Zadeh and Chan [29] improved the guarantee of α-MEB to $\alpha = 1.5$ by giving a one-pass streaming algorithm that stores one ball. They also gave a lower bound of $\frac{\sqrt{2}+1}{2} \approx 1.207$ for the guarantee of any deterministic algorithm for α-MEB that stores only one ball.

Badŏiu et al. [8] showed that the number of coreset points approximating $(1+\varepsilon)$-MEB(S') for a set S' in $\mathbb{R}^d$ does not depend on d. Improved algorithms were given in [24, 6, 7]; however, these algorithms do not work in a streaming fashion.

Preceding the work of Agarwal and Sharathkumar [4], a simple $(1/\sqrt{3})$-approximate two-pass algorithm for the Diameter was given by Egecioglu and Kalantari [16], working in space $\mathcal{O}(d)$.

Following the conference result of [4] that maintains a $(\frac{1+\sqrt{3}}{2}+\varepsilon)$-MEB$(S)$, Chan and Pathak [9] improved this guarantee to $\alpha = 1.22+\varepsilon$ by employing a detailed analysis to this algorithm. Subsequently, Agarwal and Sharathkumar in their journal paper [5] observed that the guarantee of their algorithm is slightly greater than $\frac{\sqrt{2}+1}{2} \approx 1.207$ by presenting an input for $d = 3$.

On the negative side, any randomized streaming algorithm that maintains α-FP(S), α-MEB(S) or α-coreset(S) with probability at least $2/3$ requires $\Omega(\min\{n, \exp(d^{1/3})\})$ space for certain values of α. These values are $\alpha < \sqrt{2}(1-2/d^{1/3})$ for α-FP(S) and α-coreset(S) and $a < (1+\sqrt{2})(1/2-1/d^{1/3})$ for α-MEB(S), as shown by Agarwal and Sharathkumar [5].

For low d, such as $d = O(1)$ or $d = O(\log\log n)$, the lower bounds do not apply as it is possible to maintain $(1+\varepsilon)$-FP(S) or answer $(1+\varepsilon)$-FN(x) queries in a poly-logarithmic space, using an optimized version of the sampling approach of [18]; this applies also to dynamic streams where points may be deleted. For high-dimensional dynamic streams, the best streaming algorithm follows from asymmetric embedding techniques of Indyk [22] but provides $O(1)$-approximation only at the cost of using space polynomial in n.

3 The Guarded Ball Cover

The Guarded Ball Cover is a collection $\mathcal{B}$ of balls that approximately cover all points of S. We represent each ball of $\mathcal{B}$ by a triplet $B = (c, r, q)$, where c is the center of B (possibly $c \notin S$), r is its radius, and q is a point of S inside B. The point q is referred to as the *guard* of B. Our algorithm maintains a coreset Q that consists of the guard points. We treat the first point $p_1 \in S$ specially by always having $p_1 \in Q$.

Let $(1+\varepsilon)\mathcal{B} = \{(c, (1+\varepsilon)r, q) : (c, r, q) \in \mathcal{B}\}$ be the collection of the $(1+\varepsilon)$-expansions of the balls in $\mathcal{B}$. If the arriving point $p \in S$ belongs to $(1+\varepsilon)\mathcal{B}$, then it is discarded. Otherwise, a new ball is added to $\mathcal{B}$. Finally, all balls of too small radius are removed from $\mathcal{B}$.

As the space bound is our primary measure, we assume an exact MEB algorithm, but a good approximation also suffices, specifically within a factor of $1+\varepsilon^2/16$ (using the algorithm of [6] as a subroutine).

Algorithm 1 Algorithm for processing a new point $p \in S$ (excluding the first point p_1).

1: **if** $p \notin (1+\varepsilon)\mathcal{B}$ **then** ▷ If p is outside of the expansions of all guarded balls
2: $(c, r) \leftarrow$ MEB$(Q \cup \{p\})$ ▷ Compute new MEB
3: $\mathcal{B} \leftarrow \{(c, r, p)\} \cup \{(c', r', p') \in \mathcal{B} : r' \geq \varepsilon^2 r/80\}$ ▷ Add new ball, delete small balls
4: $Q \leftarrow \{p_1\} \cup \bigcup_{(c'', r'', q) \in \mathcal{B}} \{q\}$ ▷ Update coreset

The following lemma holds for every MEB computed in line 2 of Algorithm 1:

▶ **Lemma 1** (Lemma 2.2 in [8]). *If $B = B(c, r)$ is the MEB of a set X of points, then any closed half-space containing c also contains a point of X on the boundary of B.*

To analyze the algorithm, we first observe that deleted balls are "guarded" by p_1.

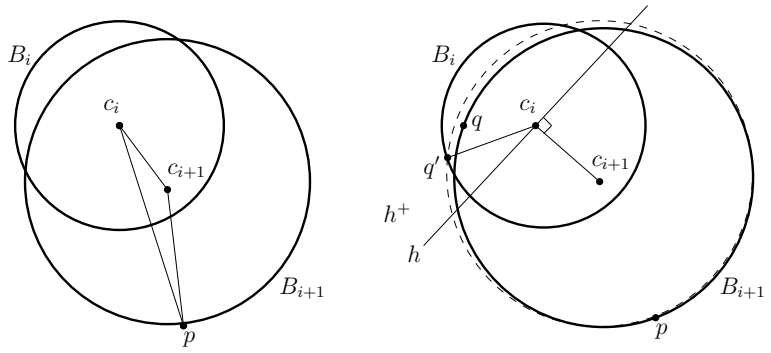

Figure 1 Left: Case $\|c_ic_{i+1}\| \leq 5\varepsilon r_i/6$, Right: Case $\|c_ic_{i+1}\| > 5\varepsilon r_i/6$ of Lemma 3. The ball with dashed boundaries is the MEB of all points, assuming that q' is deleted before B_{i+1} is created.

▶ **Lemma 2.** *Suppose ball B is deleted when a ball of radius r is added to $\mathcal{B}$. Then, B is contained in a ball of radius $\varepsilon^2 r/40$ centered at p_1. Consequently, for any guard point q' that has been deleted up to the current time, it holds that $\|q'p_1\| \leq \varepsilon^2 r/40$.*

Proof. B contains p_1 and when deleted in line 3, it has radius at most $\varepsilon^2 r/80$. Since the guard of B (which is also evicted from memory) is inside B, it is within distance at most $\varepsilon^2 r/40$ from p_1. ◀

The main technical part is to show that the radii of new balls increase exponentially:

▶ **Lemma 3.** *If $B_{i+1} = (c_{i+1}, r_{i+1}, p)$ is added to $\mathcal{B}$ following $B_i = (c_i, r_i, p_i)$, then it holds that $r_{i+1} \geq (1 + \varepsilon^2/8) \cdot r_i$.*

Proof. The proof is similar to that of Lemma 2 in [5] and Claim 2.4 in [8]. We first assume that the exact MEB is computed in line 2 of Algorithm 1. Let Q, $\hat{Q}_D$ be the point sets such that $B_{i+1} = \mathsf{MEB}(Q \cup \{p\})$ and $B_i = \mathsf{MEB}(Q \cup \hat{Q}_D)$, i.e., Q is the coreset just before computing B_{i+1}. Consider two cases:

If $\|c_ic_{i+1}\| \leq 5\varepsilon r_i/6$ then $r_{i+1} \geq \|c_{i+1}p\| \geq \|c_ip\| - \|c_ic_{i+1}\| \geq (1+\varepsilon)r_i - 5\varepsilon r_i/6 \geq (1+\varepsilon^2/6)r_i$ (Figure 1, left), using the triangle inequality and that $p \notin (1+\varepsilon)B_i$ (by line 1).

Otherwise $\|c_ic_{i+1}\| > 5\varepsilon r_i/6$. Then let h be the hyperplane passing through c_i with direction c_ic_{i+1} as its normal and let h^+ be the halfspace bounded by h that does not contain c_{i+1}. There is a point $q' \in (Q \cup \hat{Q}_D) \bigcap h^+$ at Euclidean distance r_i from c_i, by Lemma 1. Then, $\|q'c_{i+1}\| \geq (\|c_ic_{i+1}\|^2 + \|q'c_i\|^2)^{1/2} \geq ((5\varepsilon r_i/6)^2 + r_i^2)^{1/2} \geq (1+\varepsilon^2/4)r_i$ (Figure 1, right), where the first inequality follows from the cosine law. By Lemma 2, there is a point $q \in Q$ such that $\|qq'\| \leq (\varepsilon^2/40)r_i$ (if $q' \in Q$ then $q = q'$, and $q = p_1$ otherwise). Hence, $r_{i+1} \geq \|qc_{i+1}\| \geq \|q'c_{i+1}\| - \|qq'\| \geq (1+\varepsilon^2/5)r_i$.

Finally, if we use a $(1+\varepsilon^2/16)$-approximate MEB, then we still have that $r_{i+1} \geq (1+\varepsilon^2/5)r_i/(1+\varepsilon^2/16) \geq (1+\varepsilon^2/8)r_i$. ◀

Finally, we show that at any time, the $(1+\varepsilon)$-expansion of any deleted ball is contained in the $(1+\varepsilon)$-expansion of each ball created after the deletion of the former ball.

▶ **Lemma 4.** *If ball $\hat{B}$ was deleted then $(1+\varepsilon)\hat{B} \subset (1+\varepsilon)B_i$, for each $B_i \in \mathcal{B}$ created after the deletion of $\hat{B}$.*

Proof. Let $B_i \in \mathcal{B}$. By Lemmas 2 and 3, it is $\hat{B} \subset B(p_1, \varepsilon^2 r(B_i)/40)$; therefore, we have $(1+\varepsilon)\hat{B} \subset B(p_1, \varepsilon r(B_i)/20)$ as $\varepsilon \leq 1$. Since p_1 is in B, it follows that $(1+\varepsilon)\hat{B} \subset (1+\varepsilon/20)B_i$. ◀

Our main result follows from the preceding lemmas:

▶ **Theorem 5.** *$\mathcal{B}$ contains $\mathcal{O}((1/\varepsilon^2)\log(1/\varepsilon))$ balls and $S \subset (1+\varepsilon)\mathcal{B}$.*

Proof. The first claim follows from Lemma 3 and line 3 of Algorithm 1. For the second claim, let $p \in S$. By construction, p is in the $(1+\varepsilon)$-expansion of a ball B that entered $\mathcal{B}$. By Lemma 4, $(1+\varepsilon)B \subset \cup_{B' \in \mathcal{B}}(1+\varepsilon)B'$, whether B was deleted or not. ◀

Differences to the Blurred Ball Cover

The Blurred Ball Cover [5], similarly to the Guarded Ball Cover, initiates the computation of a new ball when an arriving point is not contained in any $(1+\epsilon)$-expansion of a stored ball. The key difference is that in the Blurred Ball Cover, the coreset on the boundary of the new ball, which is returned by the MEB computation and comprises up to $\lceil 1/\epsilon \rceil$ points, is explicitly stored in memory for each ball. (In fact, $\Omega(1/\epsilon^2)$ points may need to be stored for each ball in the Blurred Ball Cover as we discuss in Appendix A.) Coresets belonging to sufficiently small balls are also deleted from the Blurred Ball Cover, though the radius threshold for this deletion is $\approx \varepsilon r$ instead of $\approx \varepsilon^2 r$ in our algorithm. Finally, the first point $p_1 \in S$ is never deleted by the Guarded Ball Cover, contrary to the Blurred Ball Cover which treats p_1 as any other point of S.

Update time

The worst-case update time of our algorithm is $\mathcal{O}(d \cdot \text{poly}(1/\varepsilon))$ when an approximate MEB computation is used [7], which is comparable to that of [5]; the precise update times primarily depend on the MEB computation. (Note that the update times of [5] are also affected by the possible issue mentioned in Appendix A.) We remark that the Blurred Ball Cover of [5] allows for better *amortized* update time as it is possible to perform batched updates, i.e., storing incoming points in a buffer and only running the update procedure when the buffer gets full (see also the second paragraph in Appendix A). This is not possible in our case as we require storing one guard per ball; that is, if we run an update on our sketch with a batch of size C, we may need to store up to C guard points for B_{i+1} if they all end up in the coreset of B_{i+1} (and thus on its boundary).

4 Applications

Farthest Neighbor Queries and Diameter

We largely follow the analysis of [5]. For a query point $x \in \mathbb{R}^d$, the algorithm computes and returns the farthest point in Q: $q' = \arg\max_{q \in Q}\|qx\|$. We show that $\|p'x\| \le (\sqrt{2}+2\varepsilon)\|q'x\|$, where $p' = \arg\max_{p \in S}\|px\|$ is one of the (optimal) farthest points from x.

Let $B_i = (c_i, r_i)$ be the ball in $\mathcal{B}$ of greatest radius that contains p' in its $(1+\varepsilon)$-expansion, which exists by Theorem 5. Applying the triangle inequality, followed by the inequality $x + y \le \sqrt{2(x^2+y^2)}$, we have that

$$\|xp'\| \le \|xc_i\| + \|c_ip'\| \le \|xc_i\| + (1+\varepsilon)r_i \le \sqrt{2}(\|xc_i\|^2 + r_i^2)^{1/2} + \varepsilon r_i \ . \tag{1}$$

By Lemma 1 (for half-space with direction c_ix as normal, c_i on the boundary, and not containing x), when B_i was created, there was a guard z such that: i) $\|zc_i\| = r_i$, ii) $\|xz\| \ge r_i$, and iii) $\angle zc_ix \ge 90°$. By i), iii), and the cosine law, we have

$$\|xz\| \ge (\|xc_i\|^2 + r_i^2)^{1/2} \ . \tag{2}$$

Combining (1) and (2) and using ii), we get that

$$\|xp'\| \leq \sqrt{2}\|xz\| + \varepsilon r_i \leq (\sqrt{2}+\varepsilon)\|xz\| \ . \tag{3}$$

Note that $\|q'x\| \geq r_m/2$, where r_m is the radius of the largest ball in $\mathcal{B}$, as otherwise there is a ball containing Q of radius less than r_m. Also, by Lemma 2, there is a point $w \in Q$ (z or p_1) of distance at most $\varepsilon^2 r_m/80 \leq \varepsilon^2\|q'x\|/40$ from z. By definition of q', $\|wx\| \leq \|q'x\|$. Thus, $\|xz\| \leq \|wx\| + \|wz\| \leq (1+\varepsilon^2/40)\|q'x\|$. Combining this with (3) gives that q' is a $(\sqrt{2}+\varepsilon')$-$\mathsf{FN}(x)$, for $\varepsilon' = 2\varepsilon$.

Finally, for the closely related problem of Diameter (Farthest Pair), we return $\mathsf{FN}(p)$ for each point $p \in S$. If $\bar{p} = \mathsf{FN}(p)$ and $\|p\bar{p}\|$ exceeds the stored value for Diameter, then we replace the old Farthest Pair with the new pair $(p, \bar{p})$.

▶ **Corollary 6.** *For a stream S of points in $\mathbb{R}^d$, the Guarded Ball Cover of $\mathcal{O}((1/\varepsilon)^2 \log(1/\varepsilon))$ stored points answers $(\sqrt{2}+\varepsilon)$-FN(x) for any query $x \in \mathbb{R}^d$, and maintains $(\sqrt{2}+\varepsilon)$-FP(S).*

Minimum Enclosing Ball

The following theorem was shown by Chan and Pathak [9] and improved the guarantee of the approximate MEB algorithm of Agarwal and Sharathkumar to $1.22+\varepsilon$ (see [5], p. 91):

▶ **Theorem 7** (Theorem 1 in [9], Theorem 1 in [27])**.** *Let $K_1, ..., K_u$ be subsets of a point set S in $\mathbb{R}^d$, with $B_i =$ MEB(K_i) such that: i) $r(B_i)$ is increasing over i, and ii) $K_i \subset (1+\varepsilon)B_j$, for each $i < j$. Then, $r(B) \leq (1.22+\varepsilon) \cdot r(MEB(S))$, where $B =$ MEB$(\bigcup_{i=1}^{u} B_i)$.*

In our case, K_i is the coreset on the boundary of the MEB computed in line 2 of Algorithm 1. Therefore, the first requirement of Theorem 7 holds by Lemma 3. The second requirement follows immediately for points in Q and by Lemma 4 for points deleted from Q.

▶ **Corollary 8.** *For a stream S of points in $\mathbb{R}^d$, the Guarded Ball Cover of $\mathcal{O}((1/\varepsilon^2)\log(1/\varepsilon))$ stored points maintains $(1.22+\varepsilon)$-MEB(S).*

Coreset for Minimum Enclosing Ball

We mostly follow the analysis of [5]. Let $B = (c, r_m)$ be the most recently created ball added to $\mathcal{B}$ and let Q be the coreset at the time of computing B, thus $B = \mathsf{MEB}(Q)$. Note that $\mathsf{MEB}(S)$ has radius at least r_m, since B is an MEB of a subset of S. We claim that $(\sqrt{2}+\varepsilon)B$ contains all points in S, which implies that Q forms a $(\sqrt{2}+\varepsilon)$-coreset(S). Namely, we show that each point $y \in S$ has $\|yc\| \leq (\sqrt{2}+\varepsilon')r_m$, for $\varepsilon' = 2\varepsilon$.

Consider a point $y \in S$ that is farthest from c. Let $B_i = (c_i, r_i)$ be a guarded ball that has not been deleted and whose $(1+\varepsilon)$-expansion contains y (B_i is well-defined by Theorem 5). By the triangle inequality and the definition of B_i, $\|yc\| \leq \|cc_i\| + \|yc_i\| \leq \|cc_i\| + (1+\varepsilon)r_i$. Let h be the hyperplane passing through c_i with direction cc_i as normal and let h^+ be the halfspace bounded by h that does not contain c. By Lemma 1 there is a guard g in h^+ with $\|gc_i\| = r_i$, and by the cosine law it is $\|gc\| \geq \sqrt{\|cc_i\|^2 + r_i^2}$. Then (using the inequality $a+b \leq \sqrt{2(a^2+b^2)}$),

$$\frac{\|yc\|}{\|gc\|} \leq \frac{\|cc_i\| + (1+\varepsilon)r_i}{\sqrt{\|cc_i\|^2 + r_i^2}} \leq \frac{\sqrt{2(\|cc_i\|^2 + r_i^2)} + \varepsilon \cdot r_i}{\sqrt{\|cc_i\|^2 + r_i^2}} \leq \sqrt{2} + \varepsilon \ .$$

By Lemma 2, there is a guard $q \in Q$ with $\|qg\| \leq \varepsilon^2 r_m/40$, so by the triangle inequality, $\|gc\| \leq \|qc\| + \|gq\| \leq (1+\varepsilon^2/40)r_m$. Hence, $\|yc\| \leq (\sqrt{2}+\varepsilon)(1+\varepsilon^2/40)r_m \leq (\sqrt{2}+2\varepsilon)r_m$.

▶ **Corollary 9.** *For a stream S of points in $\mathbb{R}^d$, the Guarded Ball Cover of $\mathcal{O}((1/\varepsilon)^2\log(1/\varepsilon))$ stored points maintains $(\sqrt{2}+\varepsilon)$-coreset(S).*

5 Lower Bound for Farthest Pair and Farthest Neighbor Queries

We show that computing a $\sqrt{2}$-approximation (with $\varepsilon = 0$) of Farthest Neighbor queries or Farthest Pair is impossible in the streaming model without returning points outside of S.

This applies to the computational model of "coreset-based algorithms" in which the space bound is counted in the number of input points stored and the algorithm must return an input point upon a query (or two input points for the Farthest Pair); crucially, once a point is deleted from memory, it cannot be retrieved. This model is akin to comparison-based model in sorting or selection, as used in [13] for streaming lower bounds for quantile estimation.

▶ **Theorem 10.** *For any $\varepsilon > 0$ and $d = \Omega(1/\varepsilon)$, any coreset-based randomized streaming algorithm answering approximate Farthest Neighbor queries or maintaining the approximate Farthest Pair in $\mathbb{R}^d$ with multiplicative error $\leq \sqrt{2} + \varepsilon$, has to store $\Omega(1/\varepsilon)$ points.*

Proof. We use the easy direction of Yao's minimax principle and design a distribution over instances (points and Farthest Neighbor queries) so that any deterministic streaming algorithm using space $o(1/\varepsilon)$ will, with high constant probability, answer a $\mathsf{FN}(q)$ query incorrectly, i.e., the point returned on the query q will be more than $(\sqrt{2}+\varepsilon)$-factor closer to q than the farthest point. The same argument applies to Farthest Pair.

Suppose without loss of generality that $2/\varepsilon \in \mathbb{Z}$. We insert $k := 1/(2\varepsilon) + 1$ points of the standard basis, i.e., $\mathbf{e}_i = (0, 0, \ldots, 1, 0, \ldots, 0)$, where the i-th coordinate is 1, for $i = 0, \ldots, k-1$ (the order of insertions does not matter). The random part of the construction is to choose $j \in \{0, \ldots, k-1\}$ uniformly at random and make a Farthest Neighbor query for point $q_j = (2\varepsilon, 2\varepsilon, \ldots, -1, 2\varepsilon, \ldots, 2\varepsilon, 0, \ldots, 0)$, where the coordinate j is -1 and only the first k coordinates are not 0. Clearly, the farthest point from q_j is e_j and their Euclidean distance is $\sqrt{4 + (k-1)\cdot 4\varepsilon^2} = \sqrt{4 + 2\varepsilon}$, using the choice of k.

However, with some constant probability, point e_j is not stored as the algorithm stores $o(1/\varepsilon) = o(d)$ points. Conditioning on the event that e_j is not stored, the algorithm needs to answer the query with a point e_i for $i \neq j$. However, the distance between q_j and e_i with $i \neq j$ is $\sqrt{(1-2\varepsilon)^2 + 1 + (k-2)\cdot 4\varepsilon^2} = \sqrt{2 - 4\varepsilon + (k-1)\cdot 4\varepsilon^2} = \sqrt{2 - 2\varepsilon}$, using the choice of k. Thus, the approximation ratio of the algorithm is at least $\sqrt{(4+2\varepsilon)/(2-2\varepsilon)} > \sqrt{2} + \varepsilon$. ◀

6 Conclusions and Open Problems

We have designed streaming algorithms storing $\mathcal{O}((1/\varepsilon^2)\log(1/\varepsilon))$ points from $\mathbb{R}^d$ that can estimate several extent statistics of the input. All error guarantees are almost optimal, with the only exception of the Minimum Enclosing Ball application, where there exists a small gap between the approximation guarantee of $1.22 + \varepsilon$ and the lower bound converging to $(\sqrt{2}+1)/2 \approx 1.207$ for $d \to \infty$. This is achieved by simplifying (and also fixing) the Blurred Ball Cover from [5] into a "Guarded Ball Cover", where we store $\Theta(1)$ points per ball, compared to $\mathrm{poly}(1/\varepsilon)$ points per ball for the Blurred Ball Cover.

We believe that the space bound can be improved, at least by shaving off the $\log(1/\varepsilon)$ factor. One possible direction for improvement is the use of randomization as both our algorithms and those of [5] are deterministic, while the simple lower bound of $\Omega(1/\varepsilon)$ for "coreset-based" algorithms holds even when randomization is used.

While our algorithms are more space-efficient than that of [5], the amortized update times are somewhat worse, as discussed in Section 3. Thus, we ask if it is possible to optimize the $\mathrm{poly}(d \cdot \varepsilon^{-1})$ amortized update time while retaining the near-quadratic space bound. More importantly, it would be interesting to develop a "fast" streaming algorithm for extent problems, that is, with amortized update time $\mathcal{O}(d \cdot \mathrm{poly}(\log \varepsilon^{-1}))$.

Beyond the streaming setting, an important property of data sketches is mergeability [1], which enables to summarize the input in a parallel or distributed way and then merge the resulting sketches into one summary of the whole dataset. It is open how to design a merge operation for Guarded (or Blurred) Ball covers while retaining the space and approximation guarantees.

A A Note on Lemma 2 in [5]

We report on a possible issue in the proof of Lemma 2 in [5] (a similar issue appears in the conference version [4]). Lemma 2 in [5] states that for any i, $r(B_{i+1}) \geq (1+\varepsilon^2/8) \cdot r(B_i)$, where B_i and B_{i+1} are two consecutive balls of the Blurred Ball Cover. The property that the radii of balls increase geometrically is crucially needed to bound the space requirements.

The proof of Lemma 2 goes as follows: Ball $B_{i+1} = \textsf{APPROX-MEB}(\bigcup_{j \leq i} K_j \cup A), \varepsilon/3)$ is created (K_j is the coreset of B_j and APPROX-MEB is the subroutine of [7] that computes it) because one of the points in a buffer A is not contained in any $(1+\varepsilon)$-expansion of a

ball B_j for $j \leq i$. Define ball B' as the MEB of $\bigcup_{j \leq i} K_j \cup A$. It is subsequently claimed that $r(B_{i+1}) \geq r(B')$, without a proof. However, B' is the MEB of $\bigcup_{j \leq i} K_j \cup A$, while B_{i+1} is an *approximate* MEB for $\bigcup_{j \leq i} K_j \cup A$, namely the $(1 + \varepsilon/3)$-expansion of B_{i+1} contains all these points but a smaller expansion of B_{i+1} may not contain them all.

We observe that this is fixable by computing a tighter MEB approximation $B_{i+1} = \text{APPROX-MEB}(\bigcup_{j \leq i} K_j \cup A), \varepsilon^2/16)$. That, however, may result in a coreset K_{i+1} of size $\Theta(\varepsilon^{-2})$, which (unlike our approach) increases the space bound in [5] from $\mathcal{O}(\varepsilon^{-3} \log(1/\varepsilon))$ to $\mathcal{O}(\varepsilon^{-4} \log(1/\varepsilon))$. We are unaware of a fix that does not affect the space bound or error guarantees.

Improved Dominance Filtering for Unions and Minkowski Sums of Pareto Sets

Abstract

A key task in multi-objective optimization is to compute the *Pareto frontier* (a.k.a. *Pareto subset*) P of a given d-dimensional objective space F; that is, a maximal subset $P \subseteq F$ such that every element in P is *non-dominated* (i.e., it is better in at least one criterion, against any other point) within F. This process, called *dominance-filtering*, often involves handling objective spaces derived from either the *union* or the *Minkowski sum* of two given partial objective spaces which are Pareto sets themselves, and constitutes a major bottleneck in several multi-objective optimization techniques. In this work, we introduce three new data structures, ND$^+$-trees, QND$^+$-trees and TND$^+$-trees, which are designed for efficiently indexing non-dominated objective vectors and performing dominance-checks. We also devise three new algorithms that efficiently filter out dominated objective vectors from the union or the Minkowski sum of two Pareto sets. An extensive experimental evaluation on both synthetically generated and real-world data sets reveals that our new algorithms outperform state-of-art techniques for dominance-filtering of unions and Minkowski sums of Pareto sets, and scale well w.r.t. the number of $d \geq 3$ criteria and the sets' sizes.

1 Introduction

In multiobjective combinatorial optimization (MOCO) problems, given an implicit description (e.g., via linear constraints) of a *solution space* X and the corresponding *objective space* F with d-dimensional ($d \geq 2$) objective-value vectors of all elements in X, the goal is to compute the *Pareto frontier*, or *Pareto subset*: a maximal subset of F whose elements are non-dominated (i.e., they are better in at least one criterion, against any other point) within F. Many algorithms for MOCO problems, especially when having to work with instances of substantial sizes, rely heavily on the *dominance-filtering* subtask, aiming to efficiently combine (the Pareto frontiers of the objective spaces for) partial solution spaces and filtering out all the dominated objective-value vectors. In this work we focus on two special cases of dominance-filtering, in which the merged objective space F is created as

either the *union* $A \cup B$, or the *Minkowski sum*[1] $A \oplus B$ of two Pareto sets A, B. These are the two most frequently used variants by solvers of various MOCO problems, e.g., of *decomposition* techniques for multiobjective integer programming [18], of *Pareto local search* for multiobjective set cover [15], and of *dynamic programming* methods for multiobjective shortest paths (MOSP) [16, 20, 22], multi-objective knapsack [6], multi-objective vehicle routing [19], or multi-objective network design [2, 4]. As manifested in [21], dominance-checking constitutes a major computational burden of most state-of-the-art algorithms for MOSP problems during the identification of new solutions. Hence, the development of efficient data structures and algorithms to handle dominance-filtering in unions and Minkowski sums of Pareto sets is of utmost importance in MOCO problems.

Related Work and Motivation. The literature offers a diverse collection of dominance filtering techniques. For $d = 2$ objectives, some highly efficient algorithms have been developed [9, 12]. For the more challenging case of $d \geq 3$ objectives, some general approaches have been explored [11, 13]. In dynamic settings, where solutions are not known in advance and are revealed gradually, the choice of an indexing data structure plays a crucial role in efficiently updating the Pareto frontier. Several indexing data structures for dominance checking have been proposed in the literature, such as *balanced binary search trees* [17], *ND-trees* [10, 14], and a variant of *k-d trees* [1, 3]. To the best of our knowledge, the most efficient algorithms for dominance-filtering of unions and Minkowski sums of Pareto sets for $d \geq 3$ objectives appear in [13]. These methods utilize *space-partitioning ND-trees* [10, 14], or *divide-and-conquer* strategies. Despite their effectiveness, these methods suffer from an inherent inefficiency that occurs when the input data emerge from real-world scenarios that typically contain *plateaus* (large collections of objective vectors with identical values in one or more dimensions, e.g., tolls in road networks), and/or are correlated (e.g., distance and time in road networks). In such cases, ND-trees turn out to be highly unbalanced, which results in significant time bottlenecks for the elementary operations of removing dominated elements from an ND-tree and of re-balancing the tree.

Our Contribution. This work focuses on dominance-filtering techniques for unions and Minkowski sums of Pareto sets for $d \geq 3$ optimization criteria. As our first contribution, we propose three novel data structures for indexing sets of non-dominated elements, which are custom-tailored to overcome the critical bottlenecks of the algorithms in [13]: (1) **ND$^+$-trees**, which inherit some desirable features of *k-d* trees [1] and ND-trees [10, 14]. (2) **QND$^+$-trees**, which dynamically adapt partitioning techniques when constructing the indexing tree from a given Pareto set, selecting the most suitable splitting method for each case. This ensures a *provably* balanced tree structure, leading to faster dominance-checks while also achieving dimensionality reduction, whenever this is possible. (3) **TND$^+$-trees** which are specially designed for scenarios where large *plateaus* occur that cause severe imbalances, which the TND$^+$-trees mitigate while also achieving dimensionality reduction, whenever this is possible.

Our second contribution concerns three new algorithms for dominance-filtering of unions and/or Minkowski sums of two Pareto sets for $d \geq 3$ optimization criteria: (1) `PlainNDred`, which reduces the problem's dimensionality by lexicographically sorting the elements, and eliminates the need for element removals from the data structure. (2) `PreND`, which constructs

[1] The *Minkowski sum* $A \oplus B$ contains all the component-wise additions of elements in A and B. If $A = \{(3,5,4),(5,2,1)\}$ and $B = \{(2,1,3),(6,3,2)\}$, then $A \oplus B = \{(5,6,7),(9,8,6),(7,3,4),(11,5,3)\}$.

an initial tree from a subset of the Pareto set, thereby reducing the need for frequent re-balancing, and avoids element removals. (3) `SymND`, which exploits symmetry to compute non-dominated objective vectors, also avoiding element removals. `PlainNDred` and `PreND` are applicable to both the union and the Minkowski sum of two Pareto sets. They can also be applied to a single objective space, as pure dominance-checks, to extract its Pareto frontier. `SymND`, on the other hand, is applicable only to the union of two Pareto sets. All three algorithms are compatible with each of the aforementioned data structures.

Our final contribution is an extensive experimental evaluation to assess the performance of our algorithms and data structures. We consider all nine combinations of a filtering algorithm among `PlainNDred`, `PreND`, and `SymND` with an indexing data structure from ND$^+$-trees, QND$^+$-trees, and TND$^+$-trees. We compare them with the state-of-the-art algorithms in [13] for $d \geq 3$ criteria. For our experimental evaluation, we used real-world data sets, synthetic data sets similar to those in [13], and new synthetic data sets specifically designed to resemble features of real-world instances. Our experimental results reveal that our algorithms are very efficient and scale well w.r.t. both the number of criteria d and the set sizes across all data sets. Notably, they achieve speedups up to 5.9× on real-world data sets and up to 13.2× on synthetic data sets against the best-performing algorithms from [13].

2 Preliminaries

Let $[n] = \{1, 2, \ldots, n\}$, $\forall n \in \mathbb{Z}^+$. In the following, small letters denote scalars, boldfaced small letters denote vectors, and capital letters denote sets. For any element or point $\mathbf{p} \in \mathbb{R}^d$, let $\mathbf{p}[i]$ denote the value of its i-th coordinate, for each $i \in [d]$. We consider multi-objective minimization problems with $d \geq 2$ objective functions:

$$\begin{array}{ll} \text{minimize} & \mathbf{f}(\mathbf{x}) = (\ \mathbf{f}(\mathbf{x})[1] = f_1(\mathbf{x}),\ \mathbf{f}(\mathbf{x})[2] = f_2(\mathbf{x}),\ \ldots\ ,\ \mathbf{f}(\mathbf{x})[d] = f_d(\mathbf{x})\ ) \\ \text{s.t.} & \mathbf{x} \in X \end{array}$$

X is the *solution space*, i.e., the set of feasible solutions for the instance at hand. $F = \mathbf{f}(X) = \{\mathbf{p} \in \mathbb{R}^d : \exists \mathbf{x} \in X, \mathbf{p} = \mathbf{f}(\mathbf{x})\}$ is the corresponding *objective space*, with all d-dimensional vectors that appear as *objective-value vectors* for at least one feasible solution from X. We refer to these objective vectors simply as *(data) points* and focus on $F \subseteq \mathbb{R}^d$, since all dominance checks are conducted among the points of F. For $\mathbf{p}, \mathbf{p}' \in \mathbb{R}^d$, we say that $\mathbf{p}$ *dominates* $\mathbf{p}'$, denoted as $\mathbf{p} < \mathbf{p}'$, if $\mathbf{p} \neq \mathbf{p}'$ and $\mathbf{p}[i] \leq \mathbf{p}'[i]$, $\forall i \in [d]$. For $F \subseteq \mathbb{R}^d$, its *Pareto frontier* (*subset* or *skyline*) is the maximal subset $P \subseteq F$ of points which are not dominated by any other point in F. If $P = F$, then F itself is also called a *Pareto set*. For $A, B \subset \mathbb{R}^d$, their *Minkowski sum* is $A \oplus B = \{\mathbf{a} + \mathbf{b} \mid \mathbf{a} \in A, \mathbf{b} \in B\}$. Given two Pareto sets $A, B \subset \mathbb{R}^d$, their *Pareto union* is the Pareto frontier of $A \cup B$, and their *Pareto sum* is the Pareto frontier of $A \oplus B$. Given $F \subset \mathbb{R}^d$, the *dominance-filtering* problem aims at filtering out all points in F which are dominated by other points in F, so as to construct its Pareto frontier.

3 Algorithmic Background

A generic approach for dominance-filtering is to process the points of $F = \{\mathbf{p_1}, \ldots, \mathbf{p_n}\}$ sequentially, and keep updating a subset P, which will eventually be the Pareto frontier of F, as follows. For each new point $\mathbf{p_i} \in F$: Compare $\mathbf{p_i}$ (sequentially) with each point $\mathbf{p_j} \in P$ ($j < i$). If $\mathbf{p_j} < \mathbf{p_i}$ then reject $\mathbf{p_i}$ (it is dominated by some point in P) and proceed with the next point of F. Otherwise, if $\mathbf{p_i} < \mathbf{p_j}$, then remove $\mathbf{p_j}$ from P (it is dominated by $\mathbf{p_i}$); if there is no other point in P to compare with, append $\mathbf{p_i}$ to P; otherwise, proceed with

a comparison of $\mathbf{p_i}$ with the next point in P. The efficiency of the data structure used to maintain the current subset P and perform the previously mentioned dominance-checks is critical for the performance of this incremental approach. A well-suited data structure for this task is the ND-tree [10], which we discuss subsequently.

3.1 ND-trees

An ND-tree is a typical rooted c-ary tree T, in which a distinct node $r = root(T)$, of degree at most c, is the *root node*, all nodes of degree 1 (except possibly for the root) are its *leaf nodes*, and the remaining nodes of degree from 2 up to $c+1$ are its *internal nodes*. The ND-trees are *leaf-oriented*, meaning that all data points are stored exclusively in leaf nodes. Each leaf node can store up to m points. The parameters c and m must satisfy the condition $c \leq m+1$ [14]. Each node v stores a lower-bounding vector $\mathbf{lb_v}$ and an upper-bounding vector $\mathbf{ub_v}$ for all the data points stored in leaves of the subtree T_v of T rooted at v. Specifically, for each point $\mathbf{p}$ stored in T_v, it holds that $\forall i \in [d], \mathbf{lb_v}[i] \leq \mathbf{p}[i] \leq \mathbf{ub_v}[i]$. An example of an ND-tree can be found in Figure 1.

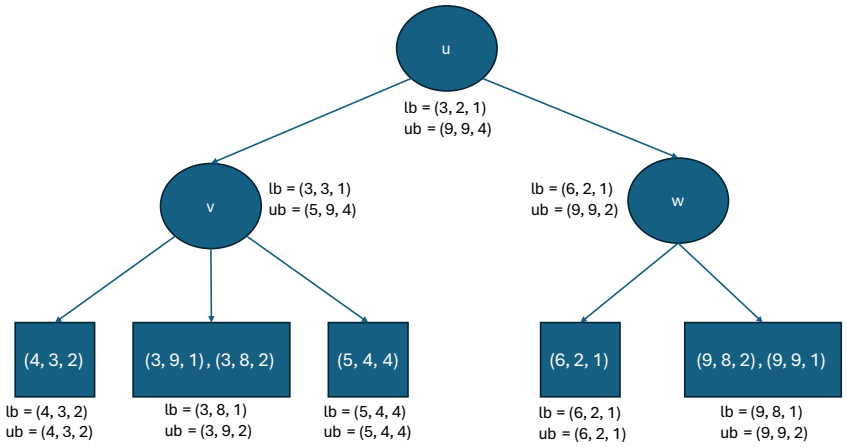

Figure 1 ND-tree containing 3-dimensional points.

The lower and upper-bounding vectors are typically used to determine, as early as possible, if a new data point $\mathbf{p}$ is dominated by any data point already in the tree. For instance, if $\exists i \in [d] : \mathbf{p}[i] < \mathbf{lb_v}[i]$, then $\mathbf{p}$ is not dominated by any data point stored in T_v, and we do not have to explicitly verify this with all of them (of course, it might still be the case that $\mathbf{p}$ dominates some of these data points). If $\mathbf{p} < \mathbf{lb_v}$ then $\mathbf{p}$ dominates all the data points stored in T_v. Finally, if $\mathbf{p} > \mathbf{ub_v}$, then all the data points stored in leaves of T_v dominate $\mathbf{p}$. An ND-tree T supports the following operations.

- `NonDomPrune`$(\mathbf{p}, T)$: This operation effectively utilizes the bounding vectors to perform two tasks, a *dominance-check* for a point $\mathbf{p}$ to decide whether it is dominated by any data point in T, and a *pruning* of T to remove all its data points that are dominated by $\mathbf{p}$. If $\mathbf{p}$ is not dominated by any point in T, `NonDomPrune` returns True; otherwise, it returns False.
- `Insert`$(\mathbf{p}, v)$: This operation inserts a new point $\mathbf{p}$ into a leaf of T_v as follows. If v is a non-leaf node, then a child node w of v is selected with minimum distance from $\mathbf{p}$. The distance of $\mathbf{p}$ from any node u is the Euclidean distance between $\mathbf{p}$ and $\frac{\mathbf{lb_u}+\mathbf{ub_u}}{2}$ (the center of the bounding box containing all data points stored T_u). Consequently, $\mathbf{p}$ is

recursively requested to be inserted in T_w. For a leaf node v, if it stores less than m data points, then $\mathbf{p}$ is simply appended to its list of stored points; otherwise, v is converted into an internal node with c children, and the pending $m+1$ data points are distributed evenly among them. Throughout the insertion process, the bounds of all affected nodes are updated accordingly.

- `SPNDBuild`(P): This operation, introduced in [14], aims to handle situations in which repeated insertions into an ND-tree might eventually lead to an unbalanced tree structure. It takes as input a Pareto set P (e.g., with all the data points stored in an unbalanced ND-tree) and builds from scratch a *perfectly balanced* ND-tree from it, as no pruning is ever required, in which the bounding areas defined by the upper and lower bounds also *are non-overlapping*.

3.2 ND-Tree based Algorithms for Dominance Filtering

The following dominance-filtering algorithms, proposed in [13], are all based on ND-trees and are, to our knowledge, the state-of-the-art techniques for $d \geq 3$ criteria.

- `PlainND`: This algorithm employs `NonDomPrune` and `Insert` to compute either the Pareto union or the Pareto sum of two Pareto sets A and B. It begins with an empty ND-tree T, and processes sequentially the points in F (either $A \cup B$, or $A \oplus B$). For each point $\mathbf{p} \in F$, it calls `NonDomPrune`($\mathbf{p}, T$). If False is returned, $\mathbf{p}$ is discarded. Otherwise, it executes `Insert`($\mathbf{p}, T$) to store $\mathbf{p}$ in T. After having processed all points in F, the points eventually stored in the leaves of T constitute the Pareto frontier of F.
- `PlainSPND`: This algorithm is similar to `PlainND`, but it periodically takes the Pareto set P of data items in the current ND-tree, it then destroys the tree, and consequently calls `SPNDBuild`(P) to create a new, balanced ND-tree. This periodic tree reconstruction can significantly improve the efficiency of intermediate calls to the `NonDomPrune` and `Insert` operations, due to limitations in the imbalance of the evolving ND-tree, while the tree reconstruction cost is amortized among consecutive insertion and pruning operations.
- `PruneSPND`: This algorithm is custom-tailored for computing the Pareto union of two Pareto sets A and B. It exploits the fact that points in A may only be dominated by points in B, and vice versa. Therefore, for the larger of the two sets (say, A) it calls `SPNDBuild`(A) to build a balanced ND-tree T. Subsequently, for each point $\mathbf{p}$ in the smaller set (say, B), it calls `NonDomPrune`($\mathbf{p}, T$) to check if $\mathbf{p}$ is dominated and to remove from T all points dominated by $\mathbf{p}$. If $\mathbf{p}$ is dominated, it is removed from B. After having processed all points in B, T contains all points of A which are not dominated by any point in B, and (eventually) B has only retained those points which are not dominated by any point in A. Their union constitutes the Pareto union.

4 New Data Structures for Dominance-Filtering

We present here our new data structures, ND$^+$-trees, QND$^+$-trees and TND$^+$-trees, designed to boost the efficiency of dominance-filtering. Detailed description of their operations, pseudocode, and the proofs of theorems can be found in the full version of the paper.

4.1 Overview of ND$^+$-trees

An ND$^+$-tree T is a leaf-oriented *binary* tree, with each leaf node storing up to m data points. As in k-d trees [1], every node v is associated with a level-dependent dimension $v.dim = 1 + (v.level \bmod d)$, a subset S_v of data points (to be stored in the leaves of T_v) and

the median value $v.q$ among the coordinates of all the points of S_v in dimension $v.dim$. Each node v also maintains a lower-bounding vector $\mathbf{lb_v}$ (i.e., the coordinate-wise minimum) of all points in S_v, similarly to ND-trees [10]. However, we avoid storing also the upper-bounding vectors, since our experimental evaluation showed that maintaining them is not beneficial for the operations on ND$^+$-trees. Moreover, if v is internal node, then S_v is partitioned in two distinct subsets, one per child of v: the left child gets all points in S_v with $\mathbf{p}[v.dim] < v.q$ and the right child gets all the remaining points of S_v. An example of an ND$^+$-tree is shown in Figure 2. For each ND$^+$-tree T, the following elementary operations are supported:

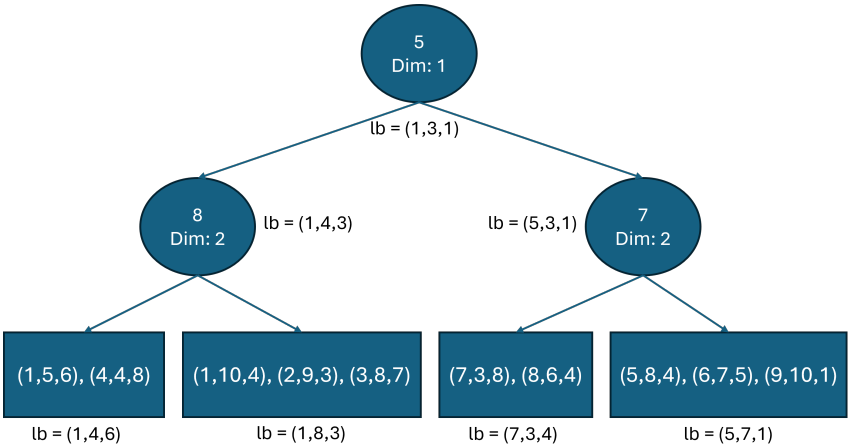

Figure 2 Example of an ND$^+$-tree containing 3-dimensional points with $m = 3$.

- `BuildND`$^+(P, \ell, d)$ constructs an ND$^+$-(sub)tree at level ℓ (an entire tree, when $\ell = 0$) containing all the data points of a Pareto set P.
- `ComputeBoundsND`$^+(r)$ computes the lower-bounding vectors for all nodes of T_r.
- `WidenBoundsND`$^+(v, \mathbf{p})$ updates the lower-bounding vector of node v, if necessary, due to a (previous) addition of a new point $\mathbf{p}$ in T_v.
- `InsertND`$^+(v, \ell, \mathbf{p})$ inserts a new point $\mathbf{p}$ into the subtree T_v rooted at the level-ℓ node v.
- `DominatedND`$^+(v, \ell, \mathbf{p})$ decides whether a new point $\mathbf{p}$ is dominated by any other point in the subtree T_v rooted at the level-ℓ node v.

In the remaining part of this section we provide some theoretical guarantees on the complexities of these elementary operations, when each leaf of the tree stores at most m d-dimensional points, for arbitrary constants $m, d \in O(1)$.

▶ **Theorem 1.** *Given a Pareto set of n points, `BuildND`$^+$ constructs an ND$^+$-tree, with $N = O(n)$ nodes in $O(n \log n)$ time when all splits of a point set produce constant fractions for both parts, and in $O(n^2)$ time otherwise.*

▶ **Theorem 2.** *Given an ND$^+$-tree with N nodes, n points and height h, the following bounds hold for its elementary operations: (i) `ComputeBoundsND`$^+$ takes $O(nmd) = O(n)$ time; (ii) `InsertND`$^+$ takes $O(hd + m) = O(h)$ time; (iii) `DominatedND`$^+$ takes $O(dn) = O(n)$ time.*

4.2 Overview of QND$^+$-trees

For a Pareto set P with its points having *distinct values* per dimension, `BuildND`$^+$ constructs a *balanced* ND$^+$-tree in *quasilinear* time (cf. Theorem 1). However, objective spaces F emerging from real-world scenarios (and their Pareto subsets) rarely adhere to such a strong property. Instead, it is common for large subsets of objective vectors to possess identical

values in certain dimensions, e.g., for tolls in road networks. When a subset of S_v constitutes a large *plateau* around $v.q$ (i.e., those data points have the same value $v.q$ in $v.dim$) for some internal node v, the resulting partition of S_v may be (possibly heavily) uneven. If this pattern occurs frequently at intermediate nodes, then the resulting ND$^+$-tree will be heavily unbalanced, leading to *quadratic* construction time and also *linear* (instead of logarithmic) time for insertion of new points. This may happen even if initially a balanced tree is constructed, due to subsequent insertions of points that constitute a plateau in F.

To tackle these worst-case performances of the ND$^+$-trees, we introduce in this section an alternative data structure, the QND$^+$-trees (*Quartile ND$^+$-trees*). In a nutshell, the QND$^+$-trees are almost identical to the ND$^+$-trees, the only difference being that they perform a more careful bipartition of the data set S_v associated with an internal node v. Specifically, if there is a large plateau (more than one fourth) in dimension $v.dim$ around the splitting value $v.q$, then this plateau is entirely assigned to v's right child, with the remaining points being assigned (irrespectively of their values in dimension $v.dim$) to its left child. Moreover, when checking for dominance-checks in the subtree rooted at v's right child, it is no longer necessary to consider $v.dim$, achieving dimensionality reduction. If no such plateau is discovered in S_v, then the split is done as in an ND$^+$-tree.

We consider the following partitioning strategies: `Median Partitioning (MP)`, also used in ND$^+$-trees, assigns points of S_v with values in $v.dim$ less than $v.q$ to v's left child, and the remaining points of S_v to v's right child; `Quartile Partitioning (QP)` assigns points of S_v with value $v.q$ in dimension $v.dim$ to v's right child, and all other points to v's left child. The following elementary operations are supported for QND$^+$-trees:

- `BuildQND`$^+(P, \ell, d)$ constructs a QND$^+$-tree with the points of Pareto set P, in an analogous manner with `BuildND`$^+(P, \ell, d)$. The only difference is that, before splitting the point set S_v associated to an internal node v, it first computes the quartiles of S_v in dimension $v.dim$ and then applies `QP` when $Q_1 = Q_2$ (this implies that the size of the plateau is at least $|S_v|/4$), and `MP` otherwise. After completing the tree construction, it calls `ComputeBoundsND`$^+$ to compute all the lower bounding vectors.
- `InsertQND`$^+(v, \ell, \mathbf{p})$ inserts a new point $\mathbf{p}$ in T_v, similarly to the corresponding operation on ND$^+$-trees. It first updates $\mathbf{lb_v}$ using `WidenBoundsND`$^+$ and then recursively calls itself for the appropriate child of v (if this is an internal node), depending on the existence (or not) of a plateau in $v.dim$, or else (for a leaf node) it either stores $\mathbf{p}$ in v's data list, otherwise (when there is no free space in v's list) it changes v into an internal node and redistributes evenly all the pending data points among its two children, executing also `ComputeBoundsND`$^+$ to update their lower bounding vectors.
- `DominatedQND`$^+(v, \ell, \mathbf{p}, D)$, an adaptation of `DominatedND`$^+$ on QND$^+$-trees, checks whether a new point $\mathbf{p}$ is dominated by any other point in T_v, taking also into account if there are any dimensions to ignore (due to existence of plateaus) during its recursive calls.

▶ **Theorem 3.** *Given a Pareto set of n points, `BuildQND`$^+$ constructs a QND$^+$-tree with $N = O(n)$ nodes and height $O(\log n + d) = O(\log n)$ in $O(n(\log n + d)) = O(n \log n)$ time.*

▶ **Theorem 4.** *Given a QND$^+$-tree with N nodes and height h, containing n points, then the following time bounds hold for its elementary operations: (i) `InsertQND`$^+$ takes $O(hd) = O(h)$ time; (ii) `DominatedQND`$^+$ takes $O(dn) = O(n)$ time.*

4.3 Overview of TND$^+$-trees

TND$^+$-trees (*Ternary ND$^+$-trees*) are designed to exploit both tree balance and dimensionality reduction due to the existence of plateaus. Contrary to the other trees, TND$^+$-trees are not strictly binary. In particular, whenever a large plateau is discovered within S_v in dimension $v.dim$ of an internal node v, three children are created: The left child is associated with points $\mathbf{p} \in S_v$ with $\mathbf{p}[v.dim] < v.q$, the right child with points $\mathbf{p} \in S_v$ with $\mathbf{p}[v.dim] > v.q$, and the middle child with all the points which constitute the plateau (i.e., $\mathbf{p}[v.dim] = v.q$). Again, for the middle child we also exploit the resulting dimensionality reduction. We will refer to this plateau-based partitioning strategy as a `TriPartitioning (TP)`. If no plateau is detected, then the standard `Median Partitioning (MP)` strategy is applied. The following elementary operations are supported for TND$^+$-trees:

- `BuildTND`$^+(P, \ell, d)$ constructs a TND$^+$-tree for the points of a Pareto set in a fashion analogous to that of `BuildQND`$^+$, applying `(TP)` whenever $Q_1 = Q_2$ or $Q_2 = Q_3$ for the quartiles of S_v in dimension $v.dim$, ensuring that at least 25% of S_v are assigned to the middle child where we also benefit from dimensionality reduction. After completing the tree construction, `ComputeBoundsTND`$^+$ is executed, a slightly modified version of `ComputeBoundsND`$^+$ that also takes into consideration the middle child, to compute the lower-bounding vectors of each node in the tree.
- `InsertTND`$^+(v, \ell, \mathbf{p})$ inserts $\mathbf{p}$ to the TND$^+$-(sub)tree T_v, resembling `InsertQND`$^+$. It first updates v's lower-bounding vector using `WidenBoundsND`$^+$. If v is an internal node, then a recursive call of the method is executed to insert $\mathbf{p}$ to the appropriate child of v, taking also into account whether v possesses a middle child. If v is a leaf node that stores less than m points, then it simply stores $\mathbf{p}$ at v's list of points, otherwise v is converted into an internal node and the $m + 1$ now pending points (including $\mathbf{p}$) are redistributed among its (either two or three, depending on the presence of a plateau) children, using `BuildTND`$^+$. Upon completion, `ComputeBoundsTND`$^+$ is executed to compute the lower bounds of the newly created children.
- `DominatedTND`$^+(v, \ell, \mathbf{p}, D)$ determines whether $\mathbf{p}$ is dominated by any other point in the TND$^+$-(sub)tree T_v.

▶ **Theorem 5.** *Given a Pareto set of n points, `BuildTND`$^+$ constructs an TND$^+$-tree with $N = O(n)$ nodes and height $O(\log n + d) = O(\log n)$ in $O(n(\log n + d)) = O(n \log n)$ time.*

▶ **Theorem 6.** *Given a TND$^+$-tree with n nodes and height h, then the following time bounds hold for its elementary operations: (i) `InsertTND`$^+$ takes $O(hd) = O(h)$ time; (ii) `DominatedTND`$^+$ takes $O(dn) = O(n)$ time.*

4.4 Comparison of the New Data Structures

To illustrate the differences between the three data structures, and to demonstrate how QND$^+$- and TND$^+$-trees produce more balanced structures than ND$^+$-trees in the presence of plateaus, consider building ND$^+$-, QND$^+$-, and TND$^+$-trees from the point set $S = \{(1, 10, 2),\ (2, 9, 6),\ (2, 8, 7),\ (2, 12, 0),\ (2, 7, 8),\ (2, 11, 1),\ (4, 7, 4),\ (5, 7, 3),\ (6, 7, 2),\ (7, 6, 1),\ (8, 6, 0)\}$. Assume that each leaf node can store up to $m = 4$ points.

- **ND$^+$-tree:** Median Partitioning (MP) is first applied in the first dimension, yielding the median value 2. This assigns $(1, 10, 2)$ to the left subtree and all remaining points to the right, giving $L = \{(1, 10, 2)\}$ and $R = \{(7, 6, 1),\ (8, 6, 0),\ (2, 7, 8),\ (4, 7, 4),\ (5, 7, 3),\ (6, 7, 2),\ (2, 8, 7),\ (2, 9, 6),\ (2, 11, 1),\ (2, 12, 0)\}$. MP is then applied to R in the second dimension, with median 7, producing $RL = \{(7, 6, 1),\ (8, 6, 0)\}$ and $RR = \{(2, 12, 0),$

$(2,11,1)$, $(6,7,2)$, $(5,7,3)$, $(4,7,4)$, $(2,9,6)$, $(2,8,7)$, $(2,7,8)\}$. Since RR exceeds the leaf size m, it is split once more using MP in the third dimension, where the median is 4, giving $RRL = \{(2,12,0)$, $(2,11,1)$, $(6,7,2)$, $(5,7,3)\}$ and $RRR = \{(4,7,4)$, $(2,9,6)$, $(2,8,7)$, $(2,7,8)\}$. All resulting subtrees contain at most m points, completing the tree (see Figure 3).

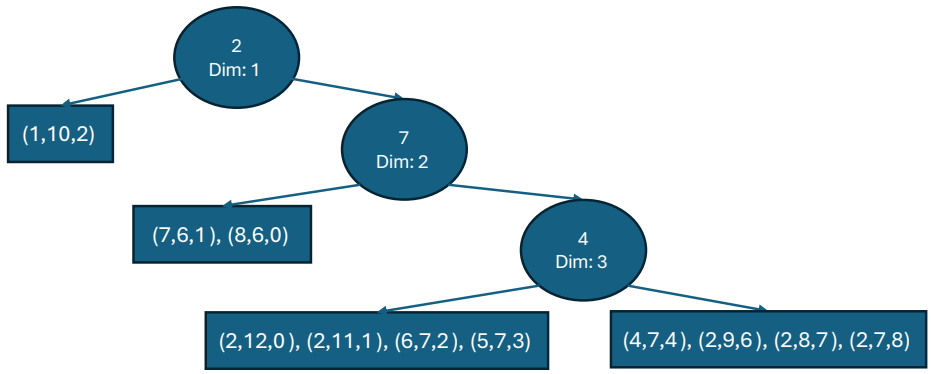

Figure 3 ND$^+$-tree containing 3-dimensional points with $m = 4$.

- **QND$^+$-tree:** Since $Q_1 = Q_2 = 2$ in the first dimension, Quartile Partitioning (QP) is used, yielding $L = \{(7,6,1)$, $(8,6,0)$, $(4,7,4)$, $(5,7,3)$, $(6,7,2)$, $(1,10,2)\}$ and $R = \{(2,7,8)$, $(2,8,7)$, $(2,9,6)$, $(2,11,1)$, $(2,12,0)\}$. In L, $Q_1 = 6 \neq 7 = Q_2$ in the second dimension, so MP is applied, splitting it into $LL = \{(7,6,1)$, $(8,6,0)\}$ and $LR = \{(4,7,4)$, $(5,7,3)$, $(6,7,2)$, $(1,10,2)\}$, both of which satisfy the leaf size constraint. In R, $Q_1 = 8 \neq 9 = Q_2$ in the second dimension, so MP is again applied, giving $RL = \{(2,8,7)$, $(2,7,8)\}$ and $RR = \{(2,9,6)$, $(2,11,1)$, $(2,12,0)\}$, each also within the allowed limit. The tree is thus complete (see Figure 4).

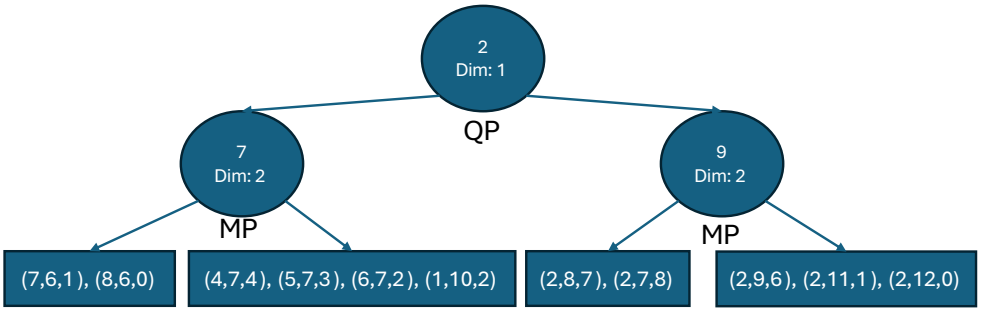

Figure 4 QND$^+$-tree containing 3-dimensional points with $m = 4$.

- **TND$^+$-tree:** $Q_1 = Q_2 = 2$ in the first dimension, so TriPartitioning (TP) is applied, producing $L = \{(1,10,2)\}$, $M = \{(2,7,8)$, $(2,8,7)$, $(2,9,6)$, $(2,11,1)$, $(2,12,0)\}$, and $R = \{(7,6,1)$, $(8,6,0)$, $(4,7,4)$, $(5,7,3)$, $(6,7,2)\}$. L needs no further processing. In M, no plateau is present in the second dimension, so MP is used with median 9, resulting in $ML = \{(2,7,8)$, $(2,8,7)\}$ and $MR = \{(2,9,6)$, $(2,11,1)$, $(2,12,0)\}$. In R, a plateau is found: $Q_2 = 7 = Q_3$, so TP is applied again, yielding $RL = \{(7,6,1)$, $(8,6,0)\}$ and $RM = \{(4,7,4)$, $(5,7,3)$, $(6,7,2)\}$. All resulting subtrees respect the leaf size constraint, completing the tree (see Figure 5).

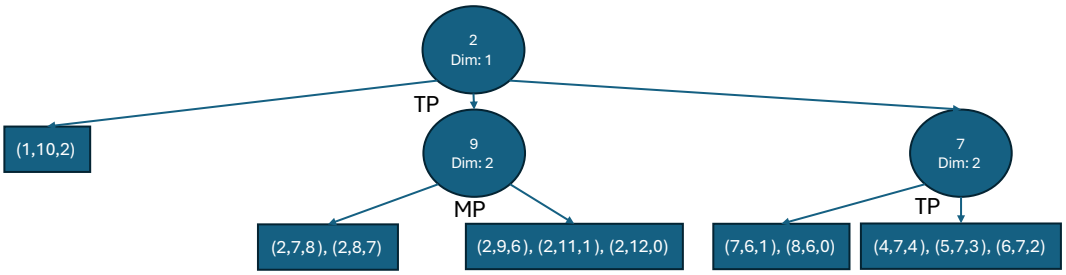

Figure 5 TND$^+$-tree containing 3-dimensional points with $m = 4$.

5 Overview of New Algorithms for Pareto Unions and Sums

We now present our new algorithms for computing Pareto unions or Pareto sums of Pareto sets. These algorithms are designed to work with any of the three data structures of Section 4. For simplicity, all algorithms are presented w.r.t. ND$^+$-trees – details and missing proofs can be found in the full version. In our experimental evaluation (cf. Section 6) we consider all possible combinations of algorithms and data structures.

5.1 PlainNDred

As noted in [13], the main computational burden in `PlainND`, `PlainSPND` and `PruneSPND` is the execution of `NonDomPrune` operations (cf. Section 3). The most demanding task is the removal of all dominated points from the tree, as new points are inserted to it. The main idea behind the `reduced PlainND` algorithm (`PlainNDred` in short) is to avoid this costly *pruning* task of the evolving tree, by ensuring that any point that is inserted to the tree is actually a member of the required Pareto frontier of F. To achieve this, `PlainNDred` first lexicographically sorts F, in quasilinear time. Then, to efficiently manage *dominance-checks*, it processes the data points in that order and uses one of the new indexing structures (ND$^+$-trees in `PlainNDred`, QND$^+$-trees in `PlainQNDred`, and TND$^+$-trees in `PlainTNDred`) to store only the non-dominated ones of F so far. In particular, for each point $\mathbf{p}$ in the lexicographic order, the algorithm must only check if it is dominated by any point in the tree, since $\mathbf{p}$ cannot dominate any of the preceding points in that order, as shown next.

▶ **Lemma 7.** *Let $S = (\mathbf{p_1}, \mathbf{p_2}, \ldots, \mathbf{p_n})$ be a lexicographic order of a set $F \subset \mathbb{R}^d$ of n points. Then the following non-dominance property holds: $\forall 1 \leq i < j \leq n$, $\mathbf{p_j}$ cannot dominate $\mathbf{p_i}$.*

If $\mathbf{p}$ is not dominated by any point already in the tree, the algorithm inserts it. Moreover, *dominance-checks* can safely ignore dimension 1, since $\mathbf{p}[1] \geq \mathbf{q}[1]$ for any point preceding $\mathbf{p}$ in the lexicographic order. Therefore, `PlainNDred` needs only to check the remaining $d-1$ dimensions. As a result, the algorithm builds a tree considering only the last $d-1$ dimensions of the points in F. We denote as $\mathbf{p_{red}}$ the projection of $\mathbf{p}$ on the last $d-1$ dimensions. The following statement demonstrates time complexity of `PlainNDred`.

▶ **Theorem 8.** *For an n-point set F that is either the Minkowski sum or the union of two Pareto sets, the time complexity of `PlainNDred` algorithm is $O(n^2(d-1)) = O(n^2)$.*

Proof. The points of F are first lexicographically sorted, in time $O(n \log n)$. Then, for each point, we perform a dominance-check against the previously processed points that belong to the tree. Each pairwise dominance-check takes time $O(d-1)$ since only the last $d-1$ dimensions matter. Even if all points in F are non-dominated and no pruning occurs, each point is compared to all previously processed points. Therefore, the algorithm makes at most $(d-1)\frac{n(n-1)}{2} \in O((d-1)n^2)$ comparisons, for all dominance-checks. ◀

5.2 PreND

The consecutive insertions into the tree by `PlainNDred` are likely to gradually unbalance it, thereby diminishing the efficiency of subsequent dominance-checks and insertions. To address this challenge, one option would be to periodically rebuild the tree, as is done by `PlainSPND` in [13]. However, building the entire tree from scratch is not a trivial task. To avoid that, we could leverage once more the lexicographic order of the point set $F = (\mathbf{p_1}, \ldots, \mathbf{p_n})$ to compute first an initial subset P of the Pareto frontier, which is then used to construct a *balanced* ND$^+$-tree that will be large enough so that the subsequent insertions of the remaining non-dominated points, again examined in lexicographic order, will not be able to unbalance it severely. This is exactly the main idea of the `presorted ND` algorithm (`PreND` in short).

To compute this subset of the Pareto frontier, we deploy the `ParetoSubset` algorithm. It starts with the initialization of a vector $\mathbf{y}$ of length d, corresponding to the number of dimensions, with each dimension assigned the value ∞, and then makes a single pass over the data points, in lexicographic order, using $\mathbf{y}$ to keep track of the smallest values seen in each dimension, up to the current point $\mathbf{p_i}$. For the next point in order, $\mathbf{p_{i+1}}$, if there exists a dimension $j \in [d]$ such that $\mathbf{p_{i+1}}[j] < \mathbf{y}[j]$, then $\mathbf{p_{i+1}}$ is not dominated by any preceding point. Moreover, due to the lexicographic order, $\mathbf{p_{i+1}}$ cannot be dominated by any subsequent point $\mathbf{p_k} : k \geq i+2$ (cf. Lemma 7). Therefore, $\mathbf{p_{i+1}}$ is certainly a non-dominated point in F and is appended to P, and $\mathbf{y}$ is updated to always keep the smallest value seen so far, per dimension. Otherwise, when $\mathbf{y} \leq \mathbf{p_{i+1}}$, $\mathbf{p_{i+1}}$ is appended to another subset Q, for further examination, during the second processing phase. Note that, since all points are processed in lexicographic order, Q remains lexicographically sorted. Observe also that, for $d = 2$, `ParetoSubset` already computes the entire Pareto frontier of F.

The `PreND` algorithm initially calls `ParetoSubset` to get the sets P and Q. It then calls `BuildND`$^+$ to construct an initial ND$^+$-tree with the points of P. Subsequently, for each point $\mathbf{q} \in Q$, it calls `DominatedND`$^+$ to determine if $\mathbf{q}$ is dominated by any point of the tree. If it is dominated, then it is discarded. Otherwise, it is appended to P and inserted to the ND$^+$-tree by calling `InsertND`$^+$. After having processed all points in Q, P is the required Pareto frontier of F. Note that `PreND` can be used for constructing the Pareto union or the Pareto sum of two Pareto sets, but also for identifying the Pareto frontier of a single set.

▶ **Theorem 9.** *For an n-point set F that is either the Minkowski sum or the union of two Pareto sets, the time complexity of `PreND` is $O(n^2)$.*

Proof. `ParetoSubset` first lexicographically sorts the set of points, in $O(n \log n)$ time. Then, it iterates through all n points and for each point determines in $O(d)$ time whether it belongs to P or Q. Thus, `ParetoSubset` runs in $O(n \log n + nd) = O(n \log n)$ time. Next, an ND$^+$-tree is constructed from the points in P. In the worst case, this step takes $O(n^2)$ time ($O(n \log n)$ for QND$^+$ and TND$^+$-trees). After constructing the tree, for each point in Q, we perform a dominance-check against the points already in the tree. In the worst case, where no pruning occurs and every point is non-dominated, each dominance-check involves comparing the point with all previously processed points. Since the pairwise dominance-checks are executed in time $O(d)$, and we perform this check for at most $\frac{n(n-1)}{2}$ pairs of points, the total time complexity for the dominance-checks is $O(dn^2)$. Hence, the overall time complexity of the `PreND` algorithm is $O(dn^2) = O(n^2)$. ◀

5.3 SymND

Especially for the union of two Pareto sets A, B, recall that points of one set may be dominated only by points of the other set. Thus, applying some sort of symmetric dominance-filtering could be extremely efficient. This is exactly what the `symmetric ND` algorithm (`SymND` in short) does. It constructs first an ND$^+$-tree using the points of A and then executes `DominatedND`$^+$ for each point in B, to remove from B all those points which are dominated by a point in A. Then, it constructs another ND$^+$-tree, using only the remaining points in B, and executes `DominatedND`$^+$ for each point in A, to remove those points which are dominated by a point in B. In the end, both surviving subsets of A and B contain only non-dominated points, and their union constitutes the Pareto union of A and B.

▶ **Theorem 10.** *Given two Pareto sets A and B, the time complexity of `SymND` to compute their Pareto union is $O(|A| \cdot |B|)$.*

Proof. Let $|A| = n_1 \leq |B| = n_2$. Assume also that the size of their Pareto union (to be computed) is k. First, an ND$^+$-tree is constructed using the points of the smaller set A, which takes time $O(dn_1^2)$ in the worst case for ND$^+$-trees, and $O(n_1 \log n_1)$ for QND$^+$ and TND$^+$-trees. Then, for each point in set B, the `DominatedND`$^+$ method is applied. Since there are n_2 points in set B, and each `DominatedND`$^+$ operation takes time $O(dn_1)$ in the worst case (when each point of B is compared to all points in the tree), the total complexity of this step is $O(dn_1n_2)$.

Consequently, we construct a second ND$^+$-tree using the remaining (at most $\hat{n}_2 = \min\{k, n_2\}$) points from set B. This tree construction requires in worst case time $O(d\hat{n}_2^2)$ time for ND$^+$-trees and $O(\hat{n}_2 \log \hat{n}_2)$ for QND$^+$ and TND$^+$-trees. Next, the `DominatedND`$^+$ method is applied for each point in set A, removing any dominated points from A. As there are n_1 points in set A, the total complexity of this second phase is $O(dn_1\hat{n}_2)$. Therefore, the overall time complexity of the `SymND` algorithm is $O(dn_1^2 + dn_1n_2 + d\hat{n}_2^2 + dn_1\hat{n}_2) = O(dn_1(n_2 + \min\{k, n_2\}))$ with ND$^+$-trees and $O(dn_1 \log n_1 + dn_1n_2 + d\hat{n}_2 \log \hat{n}_2 + dn_1\hat{n}_2) = O(dn_1n_2)$ with QND$^+$-trees and TND$^+$-trees. ◀

6 Experimental Evaluation

In our experimental evaluation, we implemented all nine combinations of our proposed indexing data structures and dominance-filtering algorithms. We distinguish each combination with an appropriate naming as follows: For each algorithm, its short name is used to indicate an implementation with ND$^+$-trees, and variants with QND$^+$-trees and TND$^+$-trees are indicated by the appearance in the short name of the substrings "QND" and "TND", respectively. For example, `PlainNDred` indicates the implementation of `reduced PlainND` with ND$^+$-trees, `PreQND` indicates the implementation of `presorted ND` with QND$^+$-trees, and `SymTND` indicates the implementation of `symmetric ND` with TND$^+$-trees.

In addition, we implemented nine algorithms of [13], which constitute, to the best of our knowledge, the state-of-the-art dominance-filtering algorithms for MOCO problems with $d \geq 3$ dimensions. Apart from the algorithms `PlainSPND` and `PruneSPND` which were discussed in Section 3, several more algorithms were provided in [13]: `NonDomDC` explores divide-and-conquer strategies that partition the initial set of solutions into smaller subsets to reduce unnecessary comparisons; `FilterX2` and `FilterSym` are bidirectional filters that are also based on divide-and-conquer techniques; `BatchedSPND` that utilizes SPND-trees; `LimMem` provides a memory-efficient alternative for scenarios where memory availability is limited; finally, `Doubling(Filter)` and `Doubling(Tree)` are adaptations of `FilterSym` and

`PruneSPND`, respectively, which are custom-tailored for Minkowski sums. All implemented algorithms are listed in Table 1, where their applicability on the specific dominance-filtering variant (union and/or Minkowski sum) is also mentioned.

Table 1 Algorithms that were implemented and tested in our experimental evaluation.

6.1 Data Sets

To evaluate the performance of our algorithms, we used both real-world and synthetic data sets. Note that real-world data sets with three or more objectives ($d \geq 3$) are very rare. Since our main goal is to test scalability with dimensionality, we have also used two families of synthetic data sets with up to $d = 10$ objectives: the randomly constructed data sets of [13], and some new, carefully generated synthetic data sets that resemble some crucial features of real-world instances for MOCO problems. Below, we provide a brief overview of all these data sets; more details can be found in the full version of the paper. The **RW** sets are based on the New York City road network [5], and are equipped with two cost metrics: travel time and distance. We extend them to higher dimensions according to well established augmentation techniques: for $d = 3$, we adopted [17] and introduced a third objective which is related to hazardous material transportation [7]. For $d = 5$, we adopted [8] and added a fourth objective which is a random integer from 1 to 100, and a fifth objective which is a random integer from 1 up to the number of graph edges. The **URS** sets were synthetically generated according to the procedure described in [13] (sampling points uniformly in d-dimensional space and then projecting them into the unit sphere to ensure that these are Pareto sets). Apart from these "baseline" RW and URS data sets, we also considered a few extensions towards incorporating some typical features of real-world instances. The **RWP** and **URSP** sets try to model realistic instances with repeated or flat objective values (e.g., tolls for road networks), by introducing plateaus in some objectives of the RW and URS sets, respectively. The **RWC** and **URSC** sets simulate interdependencies between objectives (also encountered quite often in real-world instances), by introducing correlations between some objectives. Finally, the **URSPC** set combines both correlation and plateau features in a single Pareto set. The size of data sets given as input to all algorithms varies from 10K to 1M points, while the number of objectives (dimensions) d varies from 3 to 10 (3, 5 for RW, 5 for RWP and RWC, 4, 6, 8, 10 for URS, URSP, URSC and 5, 6, 8, 10 for URSPC).

6.2 Overview of Experimental Results

We provide here an overview of our experimental results. All details can be found in the full version of the paper.

Comparison with the state-of-the-art. Tables 2 and 3 compare our algorithms with the best-performing algorithms from [13] for the Pareto sum and the Pareto union of two Pareto sets, respectively. We compute the speedup factor per (algorithm, data set) pair, as follows: for each (dimensionality, input size) pair, we identify the fastest algorithm of [13]. We then compute the ratio of its runtime to that of our own algorithm. In the tables we report the minimum and maximum speedups observed across all (dimensionality, input size) pairs.

Table 2 Min and Max speedups for each algorithm for the *Pareto Sum* operation.

Algorithm	RW		RWP		RWC		URS		URSP		URSC		URSPC	
	Min	Max	Min	Max	Min	Max	Min	Max	Min	Max	Min	Max	Min	Max

For Pareto sums (Table 2), `PreND`, `PlainNDred` and their variants exhibit nearly identical performance, consistently outperforming all other algorithms on RW/RWC/RWP, with speedups reaching up to 4.5×. For the synthetic data sets, all our algorithms significantly outperform the algorithms of [13], with `PlainNDred` and its variants achieving the largest speedups, up to 11.8× for URS, 9.2× for URSP, 7.5× for URSC, and 13.2× for URSPC.

For Pareto unions (Table 3), the variants of `PreND` achieve the greatest speedup on RW/RWP/RWC. On URS/URSP, all our algorithms show similar speedup ranges. On URSC/URSPC, the variants of `SymND` emerge as the top performers. Note that, although the variants of `PreND` and `PlainNDred` seem to occasionally be slower than `PruneSPND` on URSC and URSPC, they are faster or identical in average in most cases. `SymND` and it variants outperform `PruneSPND` for all data sets, with speedups of up to 3.9×.

Regarding the three data structures, for the Pareto union of two Pareto sets, QND$^+$-trees and TND$^+$-trees outperform ND$^+$-trees across almost all data sets. However, for the Pareto sum, ND$^+$-trees generally perform better than QND$^+$-trees and TND$^+$-trees on the real-world data sets. In contrast, for the synthetic data sets, QND$^+$-trees are typically the most efficient, followed by TND$^+$-trees, with ND$^+$-trees trailing behind.

Exploring the impact of tree height on algorithmic performances. The balance of a tree is crucial for the performance of our algorithms. When the tree is well-balanced, pruning mechanisms at each level can reduce more efficiently the search space and limit the number

of candidate points that may dominate a new one. To evaluate this in practice, we conducted an experiment using a URSP set A consisting of $n = 100,000$ points, with a plateau of size $n/2$ around the median in a random dimension. We constructed an ND$^+$, a QND$^+$ and a TND$^+$ tree using their `Build` methods on A. For each tree, we computed the average height, the balance indicator $BI = \max(\text{height}) - \min(\text{height})$, and the number of dominance-checks required per point from a second set B when queried against the respective trees.

Table 4 Comparison of the novel data structures, w.r.t. average tree height, balance indicator (BI), and number of dominance-checks, for $100K$ points.

Tree	4 Dimensions			6 Dimensions			8 Dimensions			10 Dimensions		
	Height	BI	Checks	Height	BI	Checks	Height	BI	Checks	Height	BI	Checks
ND$^+$	16	10	56	15	7	243	14	4	511	14	2	537
QND$^+$	13	0	68	13	0	230	13	0	431	13	0	423
TND$^+$	13	1	38	13	1	137	13	1	371	13	1	428

The results, summarized in Table 4, show that QND$^+$ and TND$^+$ trees are consistently more balanced than ND$^+$ trees and also exhibit shorter heights. Although ND$^+$ trees are only slightly taller on average, their significantly higher balance indicator values reveal a more skewed structure. Consequently, except in the case of 4 dimensions, the ND$^+$ trees required more dominance-checks than the other two variants. It is important to note that, as highlighted in our complexity analysis (in the full version of the paper), the worst-case scenario may require a point to be compared against all nodes in the tree. However, the experimental results indicate that in practice, the number of dominance-checks is substantially lower. This highlights the practical efficiency of our tree structures and the effectiveness of their lower-bounding mechanisms.

7 Conclusions and Future Work

We introduced three new data structures and three efficient algorithms for computing the Pareto unions and Pareto sums of Pareto sets, for which we provided a theoretical analysis for their worst-case performances and conducted a thorough experimental evaluation against state-of-art techniques (for $d \geq 3$) from [13], on several real-world and synthetically generated data sets. In all instances and dominance-filtering scenarios all of our algorithms consistently outperformed each algorithm in [13] (except for the case of Pareto unions on URSC and URSPC data sets, in which only `SymND` and its variants outperformed the best algorithm in [13]). Future work will focus on enhancing the performance of `PreND` by developing an alternative method to `ParetoSubset`, so as to precompute larger subsets of the Pareto frontier without significantly increasing computational costs.

Fast and Memory-Efficient BWT Construction of Repetitive Texts Using Lyndon Grammars

Jannik Olbrich
Ulm University, Germany

Abstract

The Burrows-Wheeler Transform (BWT) serves as the basis for many important sequence indexes. On very large datasets (e.g. genomic databases), classical BWT construction algorithms are often infeasible because they usually need to have the entire dataset in main memory. Fortunately, such large datasets are often highly repetitive. It can thus be beneficial to compute the BWT from a compressed representation. We propose an algorithm for computing the BWT via the Lyndon straight-line program, a grammar based on the standard factorization of Lyndon words. Our algorithm can also be used to compute the extended BWT (eBWT) of a multiset of sequences. We empirically evaluate our implementation and find that we can compute the BWT and eBWT of very large datasets faster and/or with less memory than competing methods.

1 Introduction

The *Burrows-Wheeler Transform* (BWT) [13] is one of the most important data structures in sequence analysis and is applied in a wide range of fields from data compression to bioinformatics. It is obtained by assigning the ith symbol of the BWT to the last character of the ith lexicographically smallest conjugate of the input text. The BWT can be computed in linear time and space. The run-length compressed BWT (RLBWT) uses the fact that the number of equal-character runs in the BWT is small compared to the text length when the text is repetitive [13]. Mantaci et al. [32] extended the notion of the BWT to string collections: the *extended* BWT (eBWT) of a string collection consists of the last characters of the strings in $\mathcal{M}$ arranged in infinite periodic order (see Section 2 for definitions).

The BWT serves as the basis of several *self-indexes*, i.e., data structures supporting access to the text as well as pattern matching queries. One of the most successful such indexes is the FM-index [20], which is used e.g. in the important bioinformatics programs BWA [30] and Bowtie [28]. However, the FM-index uses space proportional to the size of the dataset and is thus not applicable for huge datasets that vastly exceed the size of main memory. Such datasets often contain data from thousands or millions of individuals from the same species and are therefore extremely repetitive. The *r-index* [22] is based on the RLBWT and is the first text index of size proportional to the number r of runs in the BWT. It can be constructed in space proportional to r from the RLBWT, which raises the problem of constructing the RLBWT of huge datasets with small working memory. For this reason, various tools have emerged that exploit the repetitiveness of these datasets.

The Lyndon grammar of a text is a straight-line program (SLP), i.e., a context-free grammar in Chomsky normal form that generates a single text, where each symbol corresponds to a node in the Lyndon tree. It was introduced in [25] as the basis for a self-index. In this

paper, we describe a method for efficiently computing several BWT variants of a text or a text collection via the input's Lyndon grammar and show that our method surpasses other tools with respect to time or memory used, especially when using multiple threads.

1.1 Related work

Boucher et al. [11] developed *prefix-free parsing (PFP)*, a dictionary-compression technique that results in a dictionary and parse from which the (RL)BWT can be constructed in space proportional to their total size and in time linear to the size of the dataset. While the dictionary typically grows slowly as the size of the dataset increases, the parse grows linearly with the input size (with a small constant chosen at runtime). Consequently, for extremely large and repetitive datasets, "the parse is more burdensome than the size of the dictionary" [41]. In an effort to remedy this, Oliva et al. [41] developed *recursive prefix-free parsing*, which applies PFP to the parse. PFP has also been used to construct the eBWT [10]. The currently fastest implementation for computing the suffix array SA (and BWT) for general texts is `libsais` and is based on the linear-time *suffix array induced sorting (SAIS)* algorithm [37, 40]. `ropebwt3` uses `libsais` to compute the BWT of chunks of the input and successively merges these BWTs [29]. Díaz-Domínguez and Navarro used grammar compression to maintain the intermediate data in the SAIS algorithm with low main memory usage, resulting in a linear-time semi-external algorithm that computes a variant of the eBWT [14, 17]. Specifically for a collection of sequences where each is similar to a given reference (e.g. human chromosomes), Masillo introduced `CMS-BWT`, which computes the BWT via *matching statistics* [35].

Lyndon words have previously been used in the construction of SA and play an important role in the original eBWT. In [33, 34], a strategy for computing SA was presented where "local suffixes" (i.e., substrings ending at boundaries between Lyndon factors) can be processed separately in each Lyndon factor. Later, Baier effectively generalized the underlying idea by showing that sorting the suffixes by their longest Lyndon prefixes can be used for linear time SA construction [2]. The *bijective* BWT (BBWT) is the eBWT of the text's Lyndon factors [23, 27, 32]. Bonomo et al. showed that it is possible to compute the eBWT via the BBWT and gave an $\mathcal{O}(N \log N / \log\log N)$ construction algorithm based on properties of Lyndon words [8, 9]. Later, Bannai et al. modified the SAIS algorithm to compute the BBWT in linear time [3]. Since publication, Baier's algorithm was improved in terms of time and memory usage [6, 39] and further generalized such that it can be used to compute eBWT and BBWT in linear time [40]. The principles used this generalized algorithm lie at the base of our algorithm for computing the BWT, BBWT and eBWT variants from a Lyndon grammar.

1.2 Our contributions

Let N be the size of a text or text collection, $n_{\max}$ the maximum size of a string in the text collection, and g the size of the Lyndon SLP of the text or text collection. We give two online in-memory algorithms for constructing the Lyndon SLP with $\mathcal{O}(Ng)$ and $\mathcal{O}\big(N \log g + g \log^2 g\big)$ worst-case time complexity, both using $\mathcal{O}(g)$ words of memory. Notably, the text or text collection is streamed from right to left and does not have to reside in main memory. Additionally, we give an expected linear-time algorithm that uses $\mathcal{O}(g + n_{\max})$ words of memory. Furthermore, we give an $\mathcal{O}(g)$ algorithm for sorting the symbols of a Lyndon SLP lexicographically by their generated strings, and an $\mathcal{O}(N)$ algorithm for constructing the (run-length compressed) BWT, BBWT, or eBWT from a Lyndon SLP. We implemented our algorithms and demonstrate empirically that we can construct the BWT, BBWT or eBWT of repetitive texts or text collections faster and/or with less space than competing methods.

2 Preliminaries

For $i, j \in \mathbb{N}_0$ we denote the set $\{k \in \mathbb{N}_0 : i \leq k \leq j\}$ by the interval notations $[i\,..\,j] = [i\,..\,j+1) = (i-1\,..\,j] = (i-1\,..\,j+1)$. For an array A we analogously denote the *subarray* from i to j by $\mathsf{A}[i\,..\,j] = \mathsf{A}[i\,..\,j+1) = \mathsf{A}(i-1\,..\,j] = \mathsf{A}(i-1\,..\,j+1) = \mathsf{A}[i]\mathsf{A}[i+1]\ldots\mathsf{A}[j]$. We use zero-based indexing, i.e., the first entry of the array A is $\mathsf{A}[0]$.

A *string* S of *length* n over an *alphabet* Σ is a sequence of n characters from Σ. We denote the length n of S by $|S|$ and the ith symbol of S by $S[i-1]$, i.e., strings are zero-indexed. In this paper we assume any string S of length n to be over a totally ordered and linearly sortable alphabet (i.e., the characters in S can be sorted in $\mathcal{O}(n)$). Analogous to arrays we denote the *substring* from i to j by $S[i\,..\,j] = S[i\,..\,j+1) = S(i-1\,..\,j] = S(i-1\,..\,j+1) = S[i]S[i+1]\ldots S[j]$. For $j > i$ we let $S[i\,..\,j]$ be the *empty string* ε. For two strings u and v and an integer $k \geq 0$ we let uv be the concatenation of u and v and denote the k-times concatenation of u by u^k. A string S is *primitive* if it is non-periodic, i.e., $S = w^k$ implies $w = S$ and $k = 1$. The *suffix* i of a string S of length n is the substring $S[i\,..\,n)$ and is denoted by $\mathrm{suf}_i(S)$. Similarly, the substring $S[0\,..\,i]$ is a *prefix* of S. A suffix (prefix) is *proper* if $i > 0$ ($i+1 < n$). For two possibly empty strings u and v, uv is a conjugate of vu.

We assume totally ordered alphabets. This induces a total order on strings. Specifically, we say a string S of length n is *lexicographically smaller* than another string T of length m if and only if there is some $\ell \leq \min\{n, m\}$ such that $S[0\,..\,\ell) = T[0\,..\,\ell)$ and either $n = \ell < m$ or $\ell < \min\{n, m\}$ and $S[\ell] < T[\ell]$, and write $S <_{lex} T$ in this case. A non-empty string S is in its *canonical form* if and only if it is lexicographically minimal among its conjugates. If S is additionally strictly lexicographically smaller than all of its other conjugates, S is a *Lyndon word*. Equivalently, S is a Lyndon word if and only if S is lexicographically smaller than all its proper suffixes [18].

In the following, we use `abbabcbcabb` as our running example.

▶ **Theorem 1** (Chen-Fox-Lyndon theorem [15]). *Any non-empty string S has a unique* Lyndon factorization*, that is, there is a unique sequence of Lyndon words (*Lyndon factors*) $v_1 \geq_{lex} \ldots \geq_{lex} v_k$ with $S = v_1 \ldots v_k$.*

The Lyndon factorization of our running example is $\texttt{abbabcbc}, \texttt{abb}$.

▶ **Definition 2** (Standard Factorization [15]). *The* standard factorization *of a Lyndon word w of length $|w| \geq 2$ is the tuple (u, v) where $w = uv$ and v is the longest proper suffix of w that is Lyndon. The standard factorization (u, v) of a Lyndon word w with $|w| \geq 2$ always exists and both u and v are Lyndon.*

The standard factorization of the first Lyndon factor of our running example is $(\texttt{abb}, \texttt{abcbc})$ as `abcbc` is Lyndon and no longer proper suffix is Lyndon.

▶ **Lemma 3** ([40, Lemma 3.20]). *Any Lyndon word w with $|w| \geq 2$ is of the form $w[0]w_{c_1} \cdots w_{c_k}$, where $w_{c_1} \geq_{lex} w_{c_2} \geq_{lex} \ldots \geq_{lex} w_{c_k}$ are the Lyndon factors of $\mathrm{suf}_1(w)$.*

Figure 1 illustrates the following definitions.

▶ **Definition 4** (next smaller suffix array, nss). *Let the* next smaller suffix *array* nss *of a string S be such that $\mathrm{nss}[i] = \min\{j \in (i\,..\,|S|] \mid \mathrm{suf}_j(S) <_{lex} \mathrm{suf}_i(S)\}$.*

▶ **Definition 5** (Infinite Periodic Order). *We write $S <_\omega T$ if and only if the infinite concatenation $S^\infty = SS\ldots$ is lexicographically smaller than the infinite concatenation $T^\infty = TT\ldots$.*

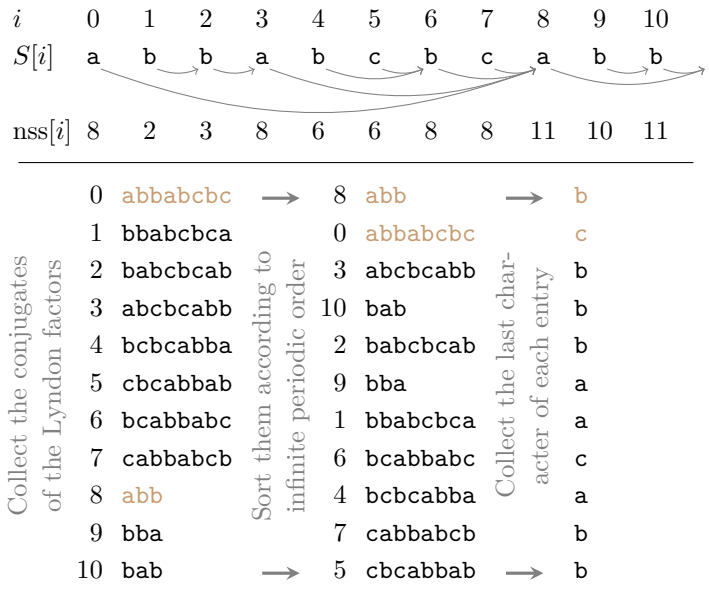

Figure 1 Next smaller suffix array nss (top) and BBWT (bottom) of the running example $S =$ `abbabcbcabb`. Each arrow points from i to nss[i]. Lyndon factors are coloured (■).

For instance, `ab` $<_{lex}$ `aba` $<_{lex}$ `abb` and `abb` $>_{\omega}$ `ab` $>_{\omega}$ `aba` since `abb`$\ldots >_{lex}$ `abab`$\ldots >_{lex}$ `abaab`$\ldots$.

▶ **Definition 6** (Bijective Burrows-Wheeler Transform (BBWT)). *The* bijective Burrows-Wheeler Transform (BBWT) *of a string S is the string obtained by taking the last character of each conjugate of the Lyndon factors of S arranged in infinite periodic order.*

▶ **Definition 7** (Extended Burrows-Wheeler Transform (eBWT)). *The* extended Burrows-Wheeler Transform (eBWT) *of a multiset $\mathcal{M}$ of strings is the string obtained by taking the last character of each conjugate of the strings in $\mathcal{M}$ arranged in infinite periodic order.*

Note that, by definition, the BBWT of a string S is the eBWT of the Lyndon factors of S. Similarly, the eBWT of a multiset $\mathcal{M}$ of strings is the BBWT of the concatenation of the canonical forms of the strings in $\mathcal{M}$ arranged in lexicographically decreasing order [3] (the Lyndon factors of the resulting string are conjugates of the roots of the strings in $\mathcal{M}$).[1]

For a primitive string S, its BWT, the eBWT of $\{S\}$, and the BBWT of the smallest conjugate of S are identical. Consequently, the $-BWT of a string S (i.e., BWT(S\$), where \$ is smaller than all characters in S) commonly computed via the suffix array of S, is identical to BWT(\$$S$) = BBWT(\$$S$) = eBWT($\{$\$$S\}$).

2.1 Lyndon Grammar

▶ **Definition 8** (Lyndon Tree/Forest [4, 25]). *The* Lyndon tree *of a Lyndon word w – denoted by LTree(w) – is the ordered full binary tree defined recursively as follows: If $|w| = 1$, then LTree(w) consists of a single node labelled by w, and if $|w| \geq 2$ and w has the standard factorization (u, v), the root of LTree(w) is labelled by w, the left child of the root is LTree(u), and the right child of the root is LTree(v). For a non-Lyndon word, we let the* Lyndon Forest *be the sequence of Lyndon trees of the Lyndon factors.*

[1] The eBWT was originally defined for sets of primitive strings [32]. This limitation is unnecessary [10, 40].

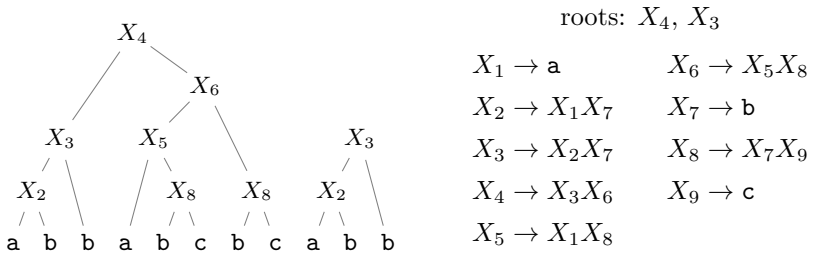

Figure 2 Lyndon Forest (left) and Lyndon SLP (right) for the running example $S = \texttt{abbabcbcabb}$. For clarity, instead of the node labels the corresponding grammar symbols are shown. Note the structural similarity between the Lyndon forest and the arrows indicating nss in Figure 1.

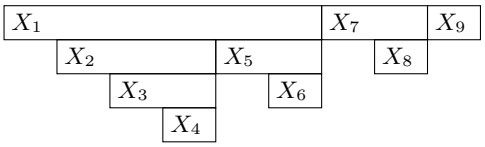
The Lyndon Forest of the running example is shown in Figure 2. Note that the Lyndon Forest of a string S is closely related to the Lyndon array λ of S [25], where $\lambda[i]$ is the length of the longest prefix of $\mathrm{suf}_i(S)$ that is Lyndon (equivalently, $\lambda[i] = \mathrm{nss}[i] - i$ [7], cf. Figure 1). A succinct representation of λ occupies $2|S|$ bits and can be computed in linear time directly from the text [7, 16, 31].

▶ **Definition 9** (Lyndon straight-line program [25]). *A* Lyndon straight-line program *(SLP) is a context-free grammar $\mathcal{G}$ over an alphabet Σ in Chomsky normal form, where $[X_i]$ is a Lyndon word for each symbol X_i and each rule $X_i \to X_aX_b$ is such that the standard factorization of $[X_i]$ is $([X_a], [X_b])$, where $[X_i]$ denotes the unique string generated by X_i. A symbol X_i is called* terminal symbol *if there is a rule of the form $X_i \to c$ ($c \in \Sigma$), and* non-terminal symbol *otherwise. When $r_1, \ldots, r_k$ are the root symbols of $\mathcal{G}$,[2] $\mathcal{G}$ generates $[\mathcal{G}] = [r_1] \ldots [r_k]$, and $[r_1] \geq \cdots \geq [r_k]$ is the Lyndon factorization of $[\mathcal{G}]$. The* size $|\mathcal{G}|$ *of $\mathcal{G}$ is the number of production rules plus the number of start symbols. The* derivation tree *of the SLP $\mathcal{G}$ is a labelled ordered tree where the root node has the children $r_1, \ldots, r_k$. We assume that distinct symbols generate distinct words.*

A Lyndon SLP arises from renaming the nodes of a Lyndon Forest such that two nodes with isomorphic subtrees (i.e., representing the same string) are assigned the same symbol. The Lyndon Forest and Lyndon SLP of our running example can be seen in Figure 2.



Clearly, the size of a Lyndon SLP $\mathcal{G}$ is bounded by $\mathcal{O}(|[\mathcal{G}]|)$. This bound is tight and there is no non-trivial bound in terms of e.g. the number of runs in the BWT, the size γ of the smallest string attractor [26] or the size of the smallest SLP: consider $S = \texttt{a}^{n-1}\texttt{b}$ for $n > 1$. The smallest SLP generating S has size $\mathcal{O}(\log n)$, its BWT has two runs, and the smallest string attractor has size $\gamma = |\{0, n-1\}| = 2$, but every suffix of S is Lyndon and thus the Lyndon SLP generating S has $\Theta(n)$ symbols.

In the following, we assume the set of symbols V of an SLP $\mathcal{G}$ to be numbered consecutively, i.e., $V = \{X_1, \ldots, X_{|V|}\}$.

3 Properties of sorted Lyndon Grammars

Consider a Lyndon grammar $\mathcal{G}$ where the symbols are sorted lexicographically, i.e., $[X_i] <_{lex} [X_j] \iff i < j$. In this section we examine such Lyndon SLPs and find properties that enable sorting any Lyndon SLP lexicographically in linear time (Section 4) and give rise to an online algorithm for constructing Lyndon SLPs (Section 6.3). Note that the grammar shown in Figure 2 is lexicographically sorted.

[2] In slight deviation of the usual definition of SLPs, we allow multiple root/start symbols. The reason for this is that we want to represent arbitrary strings with the Lyndon SLP, not just Lyndon words.

$X_1 \to \mathtt{a}$ $X_7 \to \mathtt{b}$ $X_9 \to \mathtt{c}$
$X_2 \to X_1X_7$ $X_5 \to X_1X_8$ $X_8 \to X_7X_9$
$X_3 \to X_2X_7$ $X_6 \to X_5X_8$
$X_4 \to X_3X_6$

Figure 3 First-symbol forest of the (lex. sorted) Lyndon SLP of the running example (cf. Figure 2).

▶ **Definition 10** (Prefix- and Suffix-symbols). *Define $\mathcal{P}_L(X_i)$ ($\mathcal{P}_R(X_i)$) as the set of symbols occurring on the leftmost (rightmost) path of X_i's derivation tree. More formally, if X_i is a terminal symbol define $\mathcal{P}_L(X_i) = \mathcal{P}_R(X_i) = \{X_i\}$, and if $X_i \to X_aX_b$ is a non-terminal symbol define $\mathcal{P}_L(X_i) = \{X_i\} \cup \mathcal{P}_L(X_a)$ and $\mathcal{P}_R(X_i) = \{X_i\} \cup \mathcal{P}_R(X_b)$. We correspondingly define $\mathcal{P}_L^{-1}(X_i)$ ($\mathcal{P}_R^{-1}(X_i)$) to be the set of symbols on whose leftmost (rightmost) path of the derivation tree X_i occurs, i.e. $\mathcal{P}_L^{-1}(X_i) = \{X_j \mid X_i \in \mathcal{P}_L(X_j)\}$ and $\mathcal{P}_R^{-1}(X_i) = \{X_j \mid X_i \in \mathcal{P}_R(X_j)\}$.*

For example, we have $\mathcal{P}_L(X_6) = \{X_6, X_5, X_1\}$, $\mathcal{P}_R(X_6) = \{X_6, X_8, X_9\}$ and $\mathcal{P}_L^{-1}(X_1) = \{X_1, X_2, X_3, X_4, X_5, X_6\}$ for the grammar shown in Figure 2.

▶ **Definition 11.** *Define $\mathcal{D}(X_i)$ as the set of symbols occurring in X_i's derivation tree. More formally, if X_i is a terminal symbol define $\mathcal{D}(X_i) = \{X_i\}$, and if $X_i \to X_aX_b$ is a non-terminal symbol define $\mathcal{D}(X_i) = \{X_i\} \cup \mathcal{D}(X_a) \cup \mathcal{D}(X_b)$.*

Let $r(X_i)$ be the largest symbol whose derivation tree has X_i on the leftmost path, i.e., $r(X_i) = \max\big(\mathcal{P}_L^{-1}(X_i)\big)$. Similarly, let $l(X_i)$ be the smallest symbol whose derivation tree has X_i on the leftmost path, i.e. $l(X_i) = \min\big(\mathcal{P}_L^{-1}(X_i)\big)$. For example, $l(X_1) = X_1$ and $r(X_1) = X_6$ in the grammar from Figure 2. In the remainder of this section, we show that all symbols X_j in the interval $[l(X_i)\,..\,r(X_i)]$ generate strings with $[X_i]$ as prefix and even satisfy $X_j \in \mathcal{P}_L(X_i)$. This then implies that these intervals form a tree-structure.

▶ **Lemma 12.** *$l(X_i) = X_i$ for all i.*

Proof. For $X_j \in \mathcal{P}_L^{-1}(X_i)$ we have $[X_i] \leq_{lex} [X_j]$ as $[X_i]$ is prefix of $[X_j]$ by definition. ◀

The following lemma follows from basic properties of Lyndon words and the definition of the Lyndon grammar/tree. Its proof is omitted due to space constraints.

▶ **Lemma 13.** *For all $X_j \in [l(X_i)\,..\,r(X_i)]$ it holds $X_i \in \mathcal{P}_L(X_j)$, i.e., X_i occurs on the leftmost path of X_j's derivation tree. Equivalently, $[l(X_i)\,..\,r(X_i)] = \mathcal{P}_L^{-1}(X_i)$.*

▶ **Corollary 14.** *Any two intervals $[l(X_i), r(X_i)]$ and $[l(X_j), r(X_j)]$ either do not intersect or one is fully contained within the other.*

Proof. Let X_i and X_j be different such that $l(X_i) < l(X_j) \leq r(X_i)$ (Lemma 3 implies $l(X_i) \neq l(X_j)$). This implies $X_j \in \mathcal{P}_L(X_i)$ by Lemma 13 and thus $\mathcal{P}_L(X_j) \subset \mathcal{P}_L(X_i)$ and $r(X_j) \leq r(X_i)$. ◀

▶ **Corollary 15.** *The intervals $[l(X_i), r(X_i)]$ induce a forest.*

The following definition defines this forest. An example can be seen in Figure 3.

▶ **Definition 16.** *We say an interval* $[l(X_j), r(X_j)]$ *is* embedded *in an interval* $[l(X_i), r(X_i)]$ *if it is a subinterval of* $[l(X_i), r(X_i)]$*, i.e.* $l(X_i) < l(X_j) \leq r(X_j) \leq r(X_i)$*. If* $[l(X_j), r(X_j)]$ *is embedded in* $[l(X_i), r(X_i)]$ *and there is no interval embedded in* $[l(X_i), r(X_i)]$ *in which* $[l(X_j), r(X_j)]$ *is embedded,* $[l(X_j), r(X_j)]$ *is a* child interval *of* $[l(X_i), r(X_i)]$*.*

The first-symbol forest *is a rooted forest, where each symbol* X_i *of the SLP corresponds to a node* u_i*, and* u_j *is a child of* u_i *if and only if* $[l(X_j), r(X_j)]$ *is a child interval of* $[l(X_i), r(X_i)]$*. Note that the parent of* $X_i \to X_a X_b$ *is* X_a*. Also, the terminal symbols correspond to the roots of the trees in the forest.*

▶ **Lemma 17.** *Let* X_i *be a symbol of a Lyndon SLP. We have* $\mathcal{P}_L(X_i) = \{X_{\ell_0}, \ldots, X_{\ell_k}\}$ *where* $X_{\ell_j} \to X_{\ell_{j-1}} X_{c_j}$ *for all* $j \in [1\,..\,k]$*,* X_{ℓ_0} *is a terminal symbol,* $X_{\ell_k} = X_i$*, and* $[X_{c_1}] \geq \cdots \geq [X_{c_k}]$ *is the Lyndon factorization of* $\mathrm{suf}_1([X_i])$*.*

Proof. Follows immediately from Lemma 3. ◀

4 Lexicographically sorting a Lyndon Grammar

Given a Lyndon SLP $\mathcal{G}$ with roots $r_1, \ldots, r_k$, we want to rename the symbols such that $[X_i] <_{lex} [X_j]$ holds if and only if $i < j$. This is possible in $\mathcal{O}(|\mathcal{G}|)$ using a similar principle to what is used for computing the Lyndon grouping in [2, 40]: consider a symbol X_i. By Lemma 17 and simple properties of Lyndon words, the symbols in $\mathcal{D}(X_i) \setminus \mathcal{P}_L(X_i)$ are lexicographically greater than X_i. Therefore, when considering the symbols in lexicographically decreasing order we can "induce" the position of a symbol $X_i \to X_a X_b$ upon encountering X_b: the symbols in $\mathcal{P}_L^{-1}(X_i)$ must be the lexicographically largest symbols with X_a as prefix symbol that have not yet been induced.

Algorithm 1 shows the procedure. Throughout, $\mathsf{A}[i]$ is either the ith symbol in the lexicographical order or $\perp$, and for each inserted X_i, $\mathsf{G}[i]$ is the index in A of the smallest child of X_i that has been inserted into A (or $r(X_i) + 1$ if no child has been inserted yet). In the first for-loop, all terminal symbols are inserted into A, and in the second for-loop, the remaining symbols are induced. Consequently, after the second for-loop, A contains the lexicographic order of the symbols, and G is (almost) it's inverse, i.e. $\mathsf{G}[\mathsf{A}[i]] = i + 1$.

There are two operations in Algorithm 1 that are not immediately obvious, namely finding $\left|\mathcal{P}_L^{-1}(X_i)\right|$ and iterating over all X_j with $X_j \to X_a X_{\mathsf{A}[i]}$ for a given $\mathsf{A}[i]$. For the first, note that the values $\left|\mathcal{P}_L^{-1}(X_i)\right|$ can be trivially computed in linear-time using the recurrence $\left|\mathcal{P}_L^{-1}(X_a)\right| = 1 + \sum_{X_i \to X_a X_b} \left|\mathcal{P}_L^{-1}(X_i)\right|$. Secondly, iterating efficiently over all X_j with $X_j \to X_a X_{\mathsf{A}[i]}$ can be achieved using a linear-time preprocessing step where we collect for each symbol X_i the symbols which have X_i as second symbol on the right-hand side.

The following theorem follows. Its proof is omitted due to space constraints.

▶ **Theorem 18.** *Algorithm 1 lexicographically sorts a Lyndon SLP in linear time.*

5 BWT construction

In this section, we describe an algorithm that derives the BBWT from the Lyndon SLP. Specifically, combining the second phase of `GSACA` [2, 40] with run-length encoding on the lexicographically sorted Lyndon SLP results in a very efficient algorithm on real data.

The following lemmas and corollary establish a relationship between the lexicographical order of suffixes and the lexicographical order of certain symbols of the Lyndon grammar.

Algorithm 1 Lexicographically sorting a Lyndon SLP.

$(\mathsf{A}, s) \leftarrow (\perp^n, 0)$;
for $X_i \to c$ *with* $c \in \Sigma$ **do** /* in increasing lexicographical order of c */
  $\mathsf{A}[s] \leftarrow i$; /* There are s symbols X with $[X][0] < c$ */
  $s \leftarrow s + \left|\mathcal{P}_L^{-1}(X_i)\right|$; /* There are $\left|\mathcal{P}_L^{-1}(X_i)\right|$ symbols X with $[X][0] = c$ */
  $\mathsf{G}[i] \leftarrow s$; /* X_i is the lex. smallest symbol in $\mathcal{P}_L^{-1}(X_i)$ */
end
for $i = n - 1 \to 0$ **do**
  for $X_j \to X_a X_{\mathsf{A}[i]}$ **do**
    // The symbols in $\mathcal{P}_L^{-1}(X_j)$ must be in $A\big[G[a] - \left|\mathcal{P}_L^{-1}(X_j)\right| .. G[a]\big)$
    $\mathsf{G}[j] \leftarrow \mathsf{G}[a]$;
    $\mathsf{G}[a] \leftarrow \mathsf{G}[a] - \left|\mathcal{P}_L^{-1}(X_j)\right|$;
    $\mathsf{A}[\mathsf{G}[a]] \leftarrow j$; /* X_j is the lex. smallest symbol in $\mathcal{P}_L^{-1}(X_j)$ */
  end
end

▶ **Lemma 19** ([40, Lemma 3.3]). *Let $\mathcal{L}_i$ be the longest prefix of $\mathrm{suf}_i(S)$ that is Lyndon. Then, $\mathcal{L}_i <_{lex} \mathcal{L}_j$ implies $\mathrm{suf}_i(S) <_{lex} \mathrm{suf}_j(S)$.*

▶ **Lemma 20.** *Consider an occurrence of $X_i \to X_a X_b$ at position j in the text S (this implies $S[j\,..\,j + |[X_i]|] = [X_i]$). Then, $[X_b]$ is the longest prefix of $\mathrm{suf}_{j+|[X_a]|}(S)$ that is Lyndon.*

Proof. Follows immediately from the relationship between Lyndon forest and Lyndon grammar [25] and [21, Lemma 15]. ◀

▶ **Corollary 21.** *Consider occurrences of $X_i \to X_a X_b$ at position j and of $X_{i'} \to X_{a'} X_{b'}$ at position j'. It holds $\mathrm{suf}_{j+|[X_a]|}(S) <_{lex} \mathrm{suf}_{j'+|[X_{a'}]|}(S)$ if $[X_b] <_{lex} [X_{b'}]$.*

To see why Corollary 21 is useful, consider a symbol $X_i \to X_a X_b$. Each occurrence of X_i in the derivation tree corresponds to a suffix of the text with prefix $[X_b]$, and each such suffix introduces an occurrence of the last character of $[X_a]$ to the BWT in the SA-interval of $[X_b]$. In our running example (cf. Figure 2), each occurrence of $X_8 \to X_7 X_9$ introduces a b in the SA-interval of $[X_9] = \mathsf{c}$.

In [40], an array $\mathsf{SA}'_\circ$[3] is computed such that $\mathsf{BBWT}[i] = S[\mathsf{SA}'_\circ[i]]$ holds for all i. This array arises from sorting the conjugates of the Lyndon factors of S and replacing each start position of a Lyndon word with the end position of the Lyndon word in S. It was shown that Algorithm 2 correctly computes the array $\mathsf{SA}'_\circ$ in linear time [40].[4] Basically, Lemma 19 implies that the positions in $\mathsf{SA}'_\circ$ are grouped by the longest Lyndon prefixes of the corresponding suffixes. The longest Lyndon prefix of $\mathrm{suf}_i(S)$ is $S[i\,..\,\mathrm{nss}[i])$. Because $\mathrm{suf}_{\mathrm{nss}[i]}(S) <_{lex} \mathrm{suf}_i(S)$ by definition, we can proceed by induction from lexicographically small to large.[5] Consider for instance the suffixes starting with c at indices 5 and 7 in our

[3] $\mathsf{SA}'_\circ$ is essentially the analogue to SA for conjugates of Lyndon factors and the infinite periodic order. A precise definition is omitted because only the relationship between $SA'_\circ$ and BBWT is relevant for this paper.
[4] In [40], Lyndon factors (roots of the Lyndon forest) come after every non-root representing the same Lyndon word. To reflect this, we use $\mathsf{L}[2(i-1)+1]$ if an occurrence of X_i is a root and $\mathsf{L}[2(i-1)]$ otherwise.
[5] There is a slight detail omitted here for clarity and brevity. Namely, that for the BBWT we are concerned with the *next smaller conjugate* of the respective Lyndon factor instead of the next smaller suffix [40].

Algorithm 2 Computing $\mathsf{SA}'_\circ$ from the lexicographically sorted Lyndon grammar [40, Algorithms 2 and 3].

```
(s, SA'_∘, L) ← (n, [], []^n);
for i = k → 1 do /* insert the end positions of the roots r_1, ..., r_k of
 the Lyndon SLP                                                        */
    L[2(r_i − 1) + 1].append(s);
    s ← s − |[X_{r_i}]|;
end
for m = 0 → 2g − 1 do
    foreach i in L[m] do
        SA'_∘.append(i);
        for j with nss[j] = i do
            Find X_k such that [X_k] = S[j .. nss[j]);
            L[2(k − 1)].append(j);
        end
    end
end
```

running example (cf. Figure 2). By Lemma 19, they are in the same "Lyndon group" [2] in the sorted list of suffixes because $\mathtt{c}$ is their longest Lyndon prefix. We have $\mathrm{nss}[5] = 5+|\mathtt{c}| = 6$ and $\mathrm{nss}[7] = 7+|\mathtt{c}| = 8$. When processing these Lyndon groups in lexicographically increasing order, the relative order of suffixes 6 and 8 is known at the point in time when the Lyndon group $\mathtt{c}$ is considered (because they are lexicographically smaller), and can therefore determine the lexicographical order of the suffixes 5 and 7.

We are now going to transform Algorithm 2 such that it outputs the BBWT instead of $\mathsf{SA}'_\circ$ and works without nss and the text indices. First, consider a text index $i \in [0\,..\,N)$ and let u_i be the highest node in the Lyndon forest at position i. (Equivalently, u_i corresponds to the longest Lyndon word starting at i.) Now consider the parent v_i of u_i. By its definition, it is clear that u_i is the right child of v_i. Let w_i be the left child of v_i. We can observe that, starting from w_i, the nodes on the rightmost path (excluding w_i) correspond exactly to the set $\{j \in [0\,..\,i) \mid \mathrm{nss}[j] = i\}$. For instance, in our running example there is a node labelled with $[X_8] = \mathtt{bc}$ at position 6 (cf. Figures 1 and 2). This node is the right child of a node labelled with $[X_6]$, which has a node labelled with $[X_5]$ as left child. There are two nodes on the rightmost path from this latter node, namely one at position 4 labelled with $[X_8] = \mathtt{bc}$ and one at position 5 labelled with $[X_9] = \mathtt{c}$. We consequently have $\mathrm{nss}[4] = \mathrm{nss}[5] = 6$.

Second, for $\mathsf{SA}'_\circ[k] = i$ we have $\mathsf{BBWT}[k] = S[i-1]$ and it follows that $\mathsf{BBWT}[k]$ is the last character of the string corresponding to v_i's left child w_i. Because of these two observations, we can replace the insertion of i in Algorithm 2 with the insertion of w_i. Consequently, we can reformulate Algorithm 2 to Algorithm 3.

▶ **Theorem 22.** *Algorithm 3 correctly computes* BBWT *from the sorted Lyndon SLP in* $\mathcal{O}(N)$ *time.*

Proof. The linear worst-case time complexity trivially follows from the fact that each iteration of the inner loop appends at least one character to BBWT. A proof of correctness is omitted due to space constraints. ◀

Note that runs in a list in L compound: If there is a run of symbol X_i, there is also a run of at least the same length of X_ℓ in X_r for each non-terminal $X_s \in \mathcal{P}_R(X_i)$ with $X_s \to X_\ell X_r$. Thus, Algorithm 3 often requires much fewer than N iterations.

Algorithm 3 Deriving the BBWT from the lexicographically sorted Lyndon grammar.

```
L ← []^{2g};                    /* initialize L[i] as an empty RLE list ∀i ∈ [0..2g) */
for i = 1 → k do A[2(r_i − 1) + 1].append(r_i); /* insert the roots r_1, ..., r_k */
for i = 0 → 2g − 1 do
    for (s, count) in L[i] do
        BBWT.append(last_char[s], count);
        while X_s is a non-terminal do /* walk the rightmost path from X_s */
            Let X_s → X_a X_b;
            A[2(b − 1)].append(a, count);
            s ← b;
        end
    end
end
```

5.1 Computing BWT and eBWT

When the text S is a Lyndon word, the BBWT of S is equal to the original BWT of S [3]. Since the BWT is independent of the rotation of the input and $\$S$ is a Lyndon word, we have $\mathsf{BBWT}(\$S) = \mathsf{BWT}(S\$)$. The latter is the \$-BWT commonly computed via the suffix array. Therefore, we can simply compute the \$-BWT by prepending a sentinel character to the text. Note that this is trivial and can be done after building the Lyndon grammar of S.

The eBWT of a set $\mathcal{S}$ of strings is the same as the BBWT of the string $\mathcal{S}^c$ that arises from arranging the canonical forms of the strings in $\mathcal{S}$ in lexicographically decreasing order [40]. In particular, the Lyndon factors of $\mathcal{S}^c$ are exactly the canonical forms of the input strings (assuming that the input strings are primitive). Note that, in Algorithm 3, sorting the canonical forms of the input strings is done implicitly in the first for-loop.

Note that the Lyndon grammars of the input strings are independent of each other (as long as equal Lyndon words are assigned equal grammar symbols). Therefore, we can also construct their Lyndon grammars independently of each other while using the same dictionary. As a consequence, it is easy to use our algorithms for parallel construction of the Lyndon grammar of a collection of sequences. Although our algorithm for deriving the BWT from the grammar is not parallelized, parallel construction of the Lyndon grammar leads to a substantial reduction in wall-clock-time because it is by far the most time-consuming part of the pipeline (see Section 7).

5.2 Other BWT variants for string collections

Besides the original eBWT, several other BWT variants for string collections have been proposed (see [14] for an overview). Several of the variants are especially suited to be computed with our algorithm, because there the input sequences $\mathcal{S} = \{S_1, \ldots, S_n\}$ can be parsed independently (and in parallel) like for the eBWT: The *dollar*-eBWT $\mathsf{dolEBWT}(\mathcal{S}) = \mathsf{eBWT}(\{S\$ \mid S \in \mathcal{S}\})$, the *multidollar* BWT $\mathsf{mdolBWT}(\mathcal{S}) = \mathsf{BWT}(S_1\$_1 \ldots S_n\$_n)$, and the *concatenated* BWT $\mathsf{concBWT}(\mathcal{S}) = \mathsf{BWT}(S_1\$ \ldots S_n\$\#)$, where $\# < \$$ and $\$_1 < \cdots < \$_n$ are

smaller than all characters in $\mathcal{S}$. This is done by constructing the Lyndon SLP of each S_i (with a shared dictionary) and then applying post-processing steps such that the desired eBWT variant can be derived from the resulting SLP. This is possible because the \$'s separate the input strings in the sense that no Lyndon word starting inside some S_i can contain a \$.

More specifically, for the doleBWT, no post-processing is required and we can just apply our eBWT construction algorithm, except that finding the canonical forms of the strings is trivial because $\mathsf{eBWT}(\{S\$ \mid S \in \mathcal{S}\}) = \mathsf{eBWT}(\{\$S \mid S \in \mathcal{S}\})$ and $\$S$ is a Lyndon word. For the mdolBWT and concBWT, we replace each S_i in $S_1\$_1 \dots S_n\$_n$ and $S_1\$ \dots \$S_n\$\#$, respectively, with the roots of the grammar generating S_i and compute the grammar of a rotation of the resulting string using Algorithm 3: both $\$_1S_2\$_2 \dots S_n\$_nS_1$ and $\#S_1\$ \dots \$S_n\$$ are Lyndon. Therefore, $\mathsf{BWT}(S_1\$_1 \dots S_n\$_n) = \mathsf{BBWT}(\$_1S_2\$_2 \dots S_n\$_nS_1)$ and $\mathsf{BWT}(S_1\$ \dots \$S_n\$\#) = \mathsf{BBWT}(\#S_1\$ \dots \$S_n\$)$ and we can apply our BBWT construction algorithm to these rotations.

Note that all other BWT variants for string collections given in [14] can be simulated with the multidollar BWT by using different relative orders of the separator symbols.

6 Practical Lyndon grammar construction

As shown in [1], the simple folklore algorithm for constructing the Lyndon array can be used to construct the Lyndon forest. With a fitting lookup data structure, we can trivially construct the Lyndon SLP instead. We essentially use Algorithm 4.

Algorithm 4 Prepending $S[i]$ [1].

```
Find c with [X_c] = S[i];                    /*Set c to the symbol generating S[i]*/
while stack is not empty do
    t ← stack.top();
    if [X_t] ≤_lex [X_c] then break;
    else
        stack.pop();
        Find X_c' with X_c' → X_c X_t;
        c ← c';
    end
end
stack.push(c);
```

There are two steps that have to be explained: First, one must be able to compare $[X_t]$ and $[X_c]$ lexicographically, and secondly, one must be able to find $X_{c'}$ with $X_{c'} \to X_cX_t$ (this is also called the *naming function*). For the former, we store for each symbol on the stack a fixed-length prefix of the generated string. In many cases, this is sufficient for determining the lexicographical order. Possibilities to handle the other cases are explained in Sections 6.1, 6.2 and 6.3. The following paragraphs will deal with the naming function.

For the naming function, we use a hash table to find the symbol names. This provides (expected) constant time lookup/insertion.[6] In practice however, N hash table lookups are unnecessarily slow, especially because we assume the input to be repetitive. In particular, having fewer but longer keys is cache friendlier and thus faster on modern computer architectures.

[6] Note that this is also possible in $\mathcal{O}(\log\log g)$ deterministic time with at most $2g + g\log g + o(g\log g))$ bits of memory, where g is the number of symbols of the grammar [42].

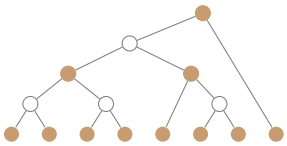


Figure 4 Partial representation of a Lyndon Forest with $n_{thres} = 2$. Heavy nodes are coloured in (■) while light nodes are not.

Specifically, we decrease the number of hash table accesses by partitioning the nodes of the Lyndon forest into *heavy* and *light* nodes and querying a second hash table H for each heavy node. The naming function is then only used when such a query to H does not return an answer. Leaves of the Lyndon forest are considered heavy. An inner node v is considered heavy, if and only if its number of *immediate heavy descendants* (heavy descendants for which only light nodes occur on the path to v) exceeds a fixed constant $n_{thres} > 1$ (see Figure 4).[7]

For a heavy node v of the Lyndon forest we query H with the sequence of immediate heavy descendants $v_1, \ldots, v_k$ of v. This means that we only store heavy nodes on the stack, for a light node we instead store all immediate heavy descendants.

Different occurrences of the same symbol represent the exact same Lyndon tree and therefore correspond to the exact same sequence of immediate heavy descendants. Consequently, if a subtree isomorphic to the subtree rooted at a heavy node has occurred previously, the query to H is sufficient to resolve it. Otherwise, we use the naming function to find the correct symbol and insert the sequence of immediate heavy descendants with it into H.

Note that each heavy node has at most $2n_{thres}$ immediate heavy descendants because it has exactly two children (or zero), each of which is either light (and thus has at most n_{thres} immediate heavy descendants) or heavy itself. This implies that the total memory usage increases by a factor of at most $\mathcal{O}(n_{thres})$.

6.1 Constant time suffix comparisons

Because the Lyndon forest (and thus the Lyndon SLP) is closely related to the Lyndon array, we can use the Lyndon array to decide whether $[X_t] \leq_{lex} [X_c]$ holds in constant time. Specifically, when considering $S[i]$ in Algorithm 3, we have $[X_c] <_{lex} [X_t]$ while $\lambda[i] > |[X_c]|$.

Unfortunately, as far as we know, all linear-time algorithms for constructing the Lyndon array directly from the text need random access to the text [1, 7, 19] and thus the text should reside in main memory.

For a BWT of a real-world string collection $\mathcal{S}$ however, this is typically not a problem because, as noted in Section 5.1, the SLPs of the strings in $\mathcal{S}$ can be computed independently (with a shared dictionary). Consequently, it suffices to have only the string (and its (succinct) Lyndon array) in main memory whose Lyndon SLP is currently computed. This increases the RAM usage by $n_{\max}(\lceil \log_2 |\Sigma| \rceil + 2)$ bits, where $n_{\max}$ is the length of the longest string in $\mathcal{S}$. For real biological data, $n_{\max}$ is generally small compared to the size of the entire input.

6.2 Naïve suffix comparisons using the Lyndon grammar

In this section, we describe a simple method for comparing $[X_t]$ and $[X_c]$ lexicographically which requires constant extra memory and works well in practice. We assume that $a, b < i$ holds for each rule $X_i \to X_a X_b$. This is clearly the case for SLPs constructed with Algorithm 4 if we assign increasing indices to new symbols.

[7] In our experiments, $n_{thres} = 31$.

First note that, because we assign equal Lyndon words to equal symbols, $[X_t] = [X_c]$ if and only if $t = c$. The key to our algorithm is that we find the longest common symbol $X_\ell \in \mathcal{P}_L(X_t) \cap \mathcal{P}_L(X_c)$. Additionally, we determine $X_{t'} \in \mathcal{P}_L(X_t)$ and $X_{c'} \in \mathcal{P}_L(X_c)$ with $X_{t'} \to X_\ell X_r$ and $X_{c'} \to X_\ell X_{r'}$. Note that, by definition, $r \neq r'$ (otherwise, $c' = t'$, contradicting the choice of ℓ) and therefore the lexicographical order of $[X_r]$ and $[X_{r'}]$ is the same as the lexicographical order of $[X_t]$ and $[X_c]$. Formally, $[X_t] <_{lex} [X_c] \iff [X_r] <_{lex} [X_{r'}]$. If such a tuple (ℓ, t', c') does not exist, either $[X_t]$ and $[X_c]$ do not share a non-empty prefix (i.e., $[X_t][0] \neq [X_c][0]$), or one of X_t and X_c is a prefix of the other.

Note that the indices of the elements in $\mathcal{P}_L(X_i)$ have the same relative order as the lengths of the generated strings in the sense that for all $a, b \in \mathcal{P}_L(X_i)$ we have $a < b$ if and only if $|[X_a]| < |[X_b]|$. For this reason, we can proceed with a two-pointer search to find ℓ (and t' and c'). More specifically, assuming that the desired $\ell \in \mathcal{P}_L(X_t) \cap \mathcal{P}_L(X_c)$ exists, we have $\ell \in \mathcal{P}_L(X_a)$ if $|[X_t]| < |[X_c]|$ for $X_c \to X_a X_b$, and vice versa. A concrete implementation is omitted due to space constraints.

Because in each step, at least one of the symbol indices decreases, the time complexity for a comparison is at most linear in the size of the SLP. In fact, because in each step we go from a symbol to one of its children, the time complexity is actually bounded by the *height* of the SLP. This in turn implies a time complexity of $\mathcal{O}(Ng)$ when using Algorithm 4 with the described method for constructing the Lyndon SLP.

Note that this worst-case time complexity is tight, e.g. on the string $a^k b a^k$ ($k \in \mathbb{N}$). However, the Lyndon forests of random strings have expected height proportional to the logarithm of the input size [36] and our approach works very well in practice (see Section 7).

6.3 Construction in $\mathcal{O}\left(N \log g + g \log^2 g\right)$

In this Section, we describe an algorithm that is able to compute the Lyndon grammar online in $\mathcal{O}\left(N \log g + g \log^2 g\right)$ deterministic time from right to left in a streaming fashion using $\mathcal{O}(g)$ words of extra memory.

Basically, this is done by maintaining the grammar's set of symbols $\mathcal{S}$ in an ordered sequence, lexicographically sorted by their respective generated strings. Using e.g. a B-Tree [5], one can then find the rank of any symbol in $\mathcal{O}(\log|\mathcal{S}|)$ time. Thus, determining the lexicographical order of two symbols in $\mathcal{S}$ can also be done in $\mathcal{O}(\log|\mathcal{S}|)$ time. What remains to be shown is how the symbols can be maintained in this sorted arrangement.

As shown in Section 3, a lexicographically sorted Lyndon grammar has a forest-structure (cf. Figure 3). This first-symbol forest can be represented using a *balanced parenthesis sequence (BPS)* of length $2|\mathcal{S}|$ [24], which can be obtained using a depth-first traversal of the first-symbol forest (starting at the roots) by writing an opening parenthesis `'('` when visiting a node for the first time and a closing parenthesis `')'` when all subtrees of a node have been visited [24]. Each parenthesis pair corresponds to a symbol in the grammar, where the ith opening parenthesis corresponds to the ith smallest symbol (by lexicographical order). For a grammar with symbol set $\mathcal{S}$, let this BPS be $\mathcal{B}_\mathcal{S}$. We represent $\mathcal{B}_\mathcal{S}$ as an ordered sequence $\mathcal{T}_\mathcal{S}$, which contains two markers $(_i$ and $)_i$ for each symbol X_i in $\mathcal{S}$, such that the ranks of $(_i$ and $)_i$ are the indices of X_i's opening and closing parenthesis in $\mathcal{B}_\mathcal{S}$, respectively. For instance, the sequence $\mathcal{T}_\mathcal{S}$ for the lexicographically sorted Lyndon grammar of our running example (see Figure 3) would be $(_1(_2(_3(_4)_4)_3)_2(_5(_6)_6)_5)_1(_7(_8)_8)_7(_9)_9$.

Now consider adding a new symbol $X_i \to X_a X_b$, where X_a and X_b are in $\mathcal{T}$ (i.e. $X_i \notin \mathcal{S}$, $X_a, X_b \in \mathcal{S}$). By Lemma 15, the parent of X_i's parenthesis pair in $\mathcal{B}_{\mathcal{S}\cup\{X_i\}}$ must be X_a's parenthesis pair. Therefore, it suffices to determine X_i's lexicographically smallest "sibling" $X_j \to X_a X_c$ ($X_j \in \mathcal{S}$) with $[X_c] >_{lex} [X_b]$; X_i's parenthesis pair must appear immediately

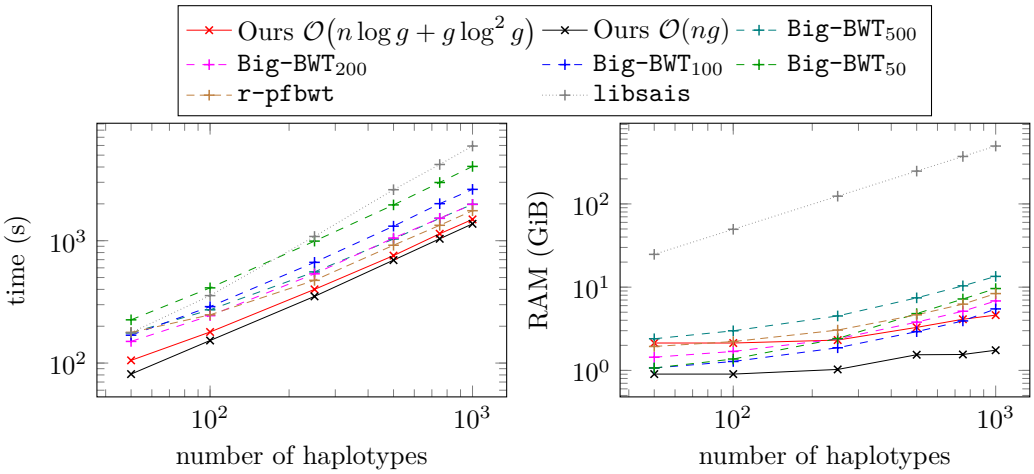

Figure 5 Wall clock time and maximum resident memory of BWT construction algorithms on chromosome 19 sequences. The sequences were concatenated and all programs used only one thread.

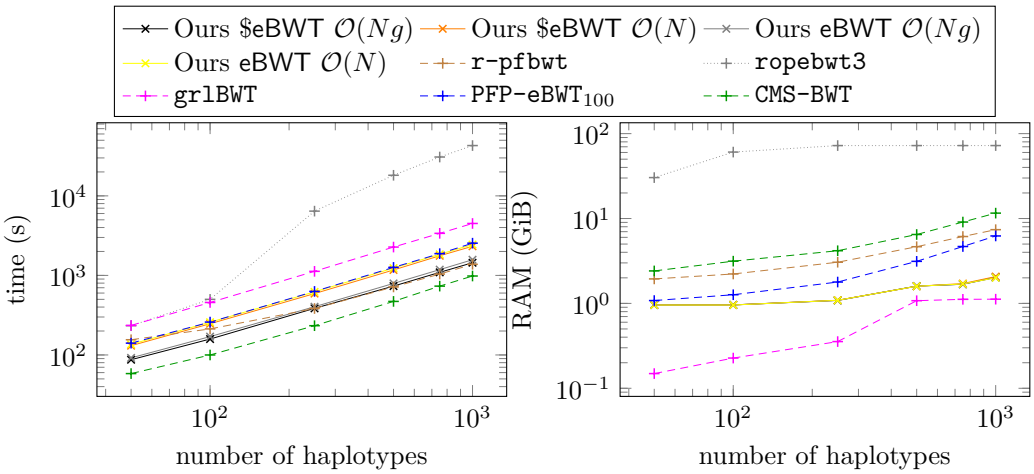

Figure 6 Wall clock time and maximum resident memory of tools for constructing BWT variants for string collection on chromosome 19 sequences. All programs used only one thread.

in front of $(_j$ in $\mathcal{T}_{\mathcal{S}\cup\{X_i\}}$. If there is no such sibling, X_i is (currently) the largest child of X_a and thus X_i's parenthesis pair must be immediately in front of $)_a$ instead. Note that comparing $[X_b]$ and $[X_c]$ is possible in $\mathcal{O}(\log|\mathcal{S}|)$ because both X_b and X_c are in $\mathcal{T}_{\mathcal{S}}$.

In order to be able to find the correct sibling of X_i as described, we additionally maintain for each X_a an ordered sequence $\mathcal{T}_a$ containing the symbols $\mathcal{S}_a = \{X_k \to X_a X_b \mid X_k, X_b \in \mathcal{S}\}$ in lexicographical order. Inserting $X_i \to X_a X_b$ into $\mathcal{T}_a$ can then be accomplished with $\mathcal{O}(\log|\mathcal{S}_a|) \subseteq \mathcal{O}(\log|\mathcal{S}|)$ comparisons, each of which is possible in $\mathcal{O}(\log|\mathcal{S}|)$ via $\mathcal{T}_{\mathcal{S}}$.

In total, we obtain a time complexity of $\mathcal{O}\big(|\mathcal{S}|\log^2|\mathcal{S}|\big)$ for maintaining the grammar's symbols lexicographically sorted, and $\mathcal{O}(N\log|\mathcal{S}|)$ for constructing the Lyndon forest.

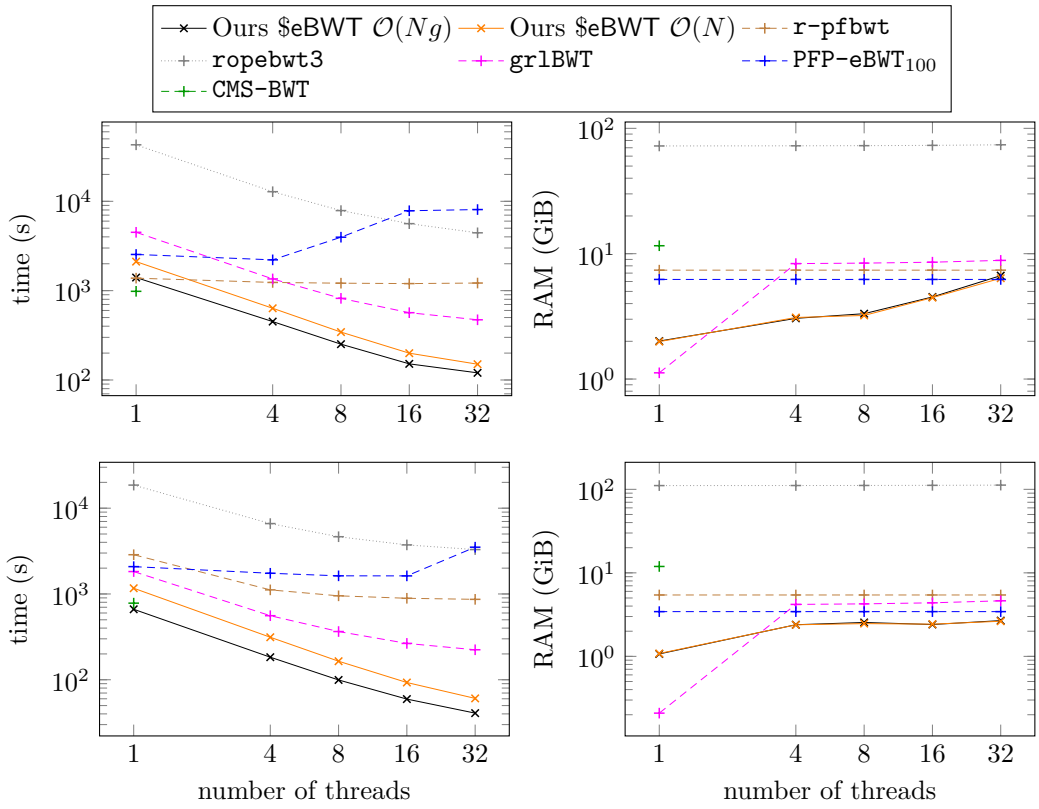

Figure 7 Wall clock time and maximum resident memory of tools for constructing BWT variants on 1000 Chromosome 19 sequences (top) and 10^6 SARS-CoV-2 sequences (bottom) using multiple threads. Note that `CMS-BWT` does not support multithreading. For the SARS-CoV-2 data, `PFP-eBWT` required the `--reads` flag.

7 Experiments

The source code of our implementation is publicly available.[8]

We compare our BWT algorithms for single texts with the programs `Big-BWT`[9] [11] and `r-pfbwt`[10] [41], as well as `libsais`.[11] The latter uses a modified version of the Suffix-Array Induced Sorting (SAIS) algorithm [37] to compute the BWT and, since it is based on the currently fastest SA construction implementation for general real-world data [40], can be viewed as a lower bound for algorithms using the suffix array to compute the BWT.

For the BWT of text collections, we compare with `PFP-eBWT`[12] [10], `r-pfbwt` [41], `ropebwt3`[13] [29], `grlBWT`[14] [17] and `CMS-BWT`[15] [35] (for `CMS-BWT` we used the first sequence in the collection as reference). All tool except the last one support multi-threading. Note

[14] `https://github.com/ddiazdom/grlBWT`, last accessed: 22.04.2025, git hash `f09e7fa`
[15] `https://github.com/fmasillo/cms-bwt`, last accessed: 22.04.2025, git hash `1099d07`. Note that the speed and memory usage of `CMS-BWT` has improved massively since its publication in [35].

that not all of these tools compute the same BWT variant [14]. Also note that all algorithms based on PFP as well as `grlBWT` are semi-external, i.e., write/read some temporary data to/from disk.

As test data, we use up to 1000 human Chromosome 19 haplotypes from [12] ($\approx 6 \cdot 10^{10}$bp) and 10^6 SARS-CoV-2 sequences ($\approx 3 \cdot 10^{10}$bp).[16] All experiments were conducted on a Linux-6.8.0 machine with an Intel Xeon Gold 6338 CPU and 512 GB of RAM. All programs were compiled with GCC 13.3.0. Before each test, the test file was scanned once to ensure it is cached by the kernel. The results can be seen in Figures 5, 6 and 7. The subscripts for the PFP-based algorithms indicate the used modulus.

For our programs, computing the doleBWT using the suffix comparison method from Section 6.2 is generally the fastest. Computing the original eBWT is slightly slower because we need to find the smallest rotation of each input string. In the single-threaded case, for both the 1000 Chromosome 19 haplotypes and 10^6 SARS-CoV-2 sequences, over 98% of the time was spent constructing the grammar (for our fastest algorithm). Using the linear-time algorithm for constructing the Lyndon array from [7] to ensure expected linear time complexity slows our programs down by up to 60%. As expected, the suffix comparison method from Section 6.3 is much slower than our other methods. The increase in memory consumption of our program in the multithreaded case is due to the use of thread-safe hash tables and multiple sequences and stacks residing in main memory.

For the Chromosome 19 collections and a single thread, `CMS-BWT` is the fastest program (at the cost of high memory usage), followed by `r-pfbwt` (for larger cases) and our algorithms. For more threads, our program is always the fastest. Regarding the memory consumption, `grlBWT` uses the least amount of main memory for single-threaded processing, followed by our programs. For the SARS-CoV-2 sequences, our program is the fastest, especially with multiple threads, and for more than one thread also the most memory efficient.

8 Conclusion and Further Work

We described an algorithm to compute the BBWT – and by extension the common \$-BWT and various versions of the eBWT – from the lexicographically sorted Lyndon grammar of a text or text collection. Furthermore, we gave an algorithm that lexicographically sorts a Lyndon grammar and discussed approaches to efficiently compute the Lyndon grammar of a text or text collection. We implemented the described algorithms and found that they outperform other current state-of-the art programs in terms of time or memory consumed (often both).

Abstract

We propose an implementation, using the CGAL library, of an algorithm to compute ε-nets on hyperbolic surfaces proposed by Despré, Lanuel and Teillaud [17]. We describe the data structure, detail the implemented algorithm and report experimental results on hyperbolic surfaces of genus 2. The implementation differs from the cited algorithm on several aspects. In particular, we use a different data structure, based on combinatorial maps, to represent a triangulation of a surface. We explain how to generate fundamental polygons to represent our input hyperbolic surfaces and the arithmetic issues related to the number type of the coordinates of their vertices.

1 Introduction

Hyperbolic surfaces are well studied in mathematics since hyperbolic geometry is the natural geometry on surfaces of genus larger than one [26]. However, there are long standing open problems that could be experimentally investigated like finding the hyperbolic surface of genus 3 with the longest *systole* (i.e., the length of the shortest non-contractible closed geodesic) or the hyperbolic surface of genus 2 with the smallest diameter.

A few computational tools for hyperbolic surfaces have only been available recently. Iordanov and Teillaud [28] introduced a package in CGAL [29] to construct Delaunay triangulations with Bowyer's incremental algorithm [5], only for the Bolza surface, which is the most symmetric surface of genus two. The authors in [12] proposed an implementation of

edge flips to transform any triangulation of a closed hyperbolic surface into the Delaunay triangulation. Their software [13] also generates surfaces of genus 2. The algorithm does not support insertions of new points.

An ε-net (see Section 2.2) is a natural tool to approximate distances on a surface, therefore it helps to address the aforementioned open problems. Our contribution is the implementation[1] of an ε-net algorithm proposed in [17] inspired from Shewchuk's Delaunay refinement [35]. To the best of our knowledge, it is the first implementation for this problem.

There are two candidate data structures to represent a hyperbolic surface in this context: one focuses on a fundamental domain in the universal cover [17] and the other considers the surface as a combinatorial map [12]. We use an enriched version of the data structure implemented in the CGAL package *2D triangulations on hyperbolic surfaces* [13] based on a combinatorial map.

Our implementation is independent from the genus of the surface. However, the only tractable surfaces that we can currently generate have genus two. Indeed, except for the specific case of the Bolza surface mentioned above, which involves algebraic numbers, so far the only surfaces that are reachable by exact computations are a dense subset of the set of surfaces of genus two given by a domain with rational coordinates. As mentioned in [24], even for generalized Bolza surfaces, the representation of fundamental domains with algebraic numbers in genus higher than two is an obstacle to overcome when implementing.

The algorithm iteratively inserts in the triangulation the circumcenter of a *large triangle*, which is a triangle whose circumradius is greater than ε. Even though the coordinates of a circumcenter lie in an algebraic extension of degree two with respect to the coordinates of the vertices of the triangle, our algorithm only constructs points with exact rational coordinates that approximate the circumcenters. Consequently, our algorithm only uses exact rational arithmetic for the construction of the Delaunay triangulation. The final step is to check that the vertices of this triangulation actually form an ε-net in spite of the approximation of inserted circumcenters; this is the only place where we use algebraic numbers of degree 2. As explained in Section 7.1, it is very hard to sample the set of hyperbolic surfaces with a satisfactory distribution in practice. We use the generator introduced by Dubois et al. [12], which samples a dense subset of the set of surfaces of genus 2 and describes them by rational points (Section 5). Quite noticeably, a random hyperbolic surface is likely to have a reasonably long systole, which is actually the case in our experiments, and our final ε-net check is always successful. We observe in [16, Sec 7.3] that for a surface specifically designed to have a very small systole, the final ε-net check may fail, which means that a higher precision on the rational approximation of the circumcenter would be needed.

The key component of the algorithm, alongside the Delaunay flip part, is the point location. To insert a point in a triangulation of the surface, we work in the triangulation lifted in the hyperbolic plane $\mathbb{H}^2$, and determine the lift of a triangle containing the point (Section 2.1). Similar to the Euclidean plane, there are multiple strategies for traversing the triangulation and locate a point [23]. We tested both the straight and the visibility walks, which demonstrate comparable efficiency for our purposes. Theorem 1 ensures that the visibility walk terminates successfully in the context of finite or periodic Delaunay triangulations of $\mathbb{H}^2$.

The paper is organized as follows: We discuss point location strategies in triangulations in $\mathbb{H}^2$ in Section 3. We detail our data structure in Section 4. The generation of input surfaces and the related arithmetic issues are introduced in Section 5. Our implemented algorithm is presented in Section 6. Our experiments are reported in Section 7.

2 Background and Notation

2.1 Hyperbolic Surfaces

We refer the reader to textbooks [9, 2, 7] for more details on topology and hyperbolic surfaces. In this paper, we use the term *hyperbolic surface* for a closed (connected, compact, and without boundary) oriented hyperbolic surface. Such a surface S can be seen as the quotient of the hyperbolic plane $\mathbb{H}^2$ under the action of a discrete subgroup Γ of the group of orientation-preserving isometries of $\mathbb{H}^2$. The surface S is locally isometric to $\mathbb{H}^2$ and thus has constant curvature -1. Note that Hilbert's theorem prevents to isometrically embed $\mathbb{H}^2$ or any hyperbolic surface in $\mathbb{R}^3$, thus all our illustrations will be drawn in the Poincaré disk model. The computation of distances in $\mathbb{H}^2$ will be detailed in Section 6.2. We denote as g the genus of S, that is its number of handles, and σ its systole which is the length of the shortest non-contractible closed geodesic.

The action of Γ on $\mathbb{H}^2$ induces a projection $\rho : \mathbb{H}^2 \mapsto \mathbb{H}^2/\Gamma = S$. For $x \in S$, an element $\widetilde{x} \in \Gamma x := \rho^{-1}(x) \subset \mathbb{H}^2$ is called a *lift* of x. Throughout this paper, objects written with a tilde $\widetilde{\cdot}$ are in $\mathbb{H}^2$ while objects on S are written without.

A *fundamental domain* for S is a connected subset of $\mathbb{H}^2$ containing exactly one lift of every point of S, except on its boundary. The *Dirichlet domain* $\mathcal{D}_{\widetilde{b}}$ of a point $\widetilde{b} \in \mathbb{H}^2$ is defined as the closed Voronoi cell of $\widetilde{b}$ in the Voronoi diagram of the point set $\Gamma\widetilde{b}$. It is a fundamental polygon for S: the interiors of two copies of the domain are disjoint, $\Gamma\mathcal{D}_{\widetilde{b}} = \mathbb{H}^2$, and its boundary is made of geodesic segments called *sides*. To each side s of $\mathcal{D}_{\widetilde{b}}$, there is a unique element $\gamma_s \in \Gamma$, called *side pairing*, such that $\gamma_s(s)$ is also a side. The side pairings generate Γ, so that $\mathcal{D}_{\widetilde{b}}$ and its side pairings determine the metric of the surface.

We work with the *Poincaré disk model* in which $\mathbb{H}^2$ is represented by the open unit disk of $\mathbb{C}$ (Figure 1). The geodesics are either diameters of the disk, or circular arcs orthogonal to the unit circle. Hyperbolic circles are Euclidean circles but their centers do not coincide in general.

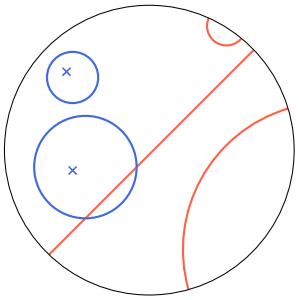

Figure 1 Geodesics (red) and hyperbolic circles (blue) in the Poincaré disk.

For a triangulation T of S, we note $\widetilde{T}$ the infinite periodic triangulation of $\mathbb{H}^2$ whose vertices, edges and faces are all lifts of those of T. Conversely, any vertex, edge or face of $\widetilde{T}$ projects on S as a vertex, edge or face of T. The triangulation T is a *Delaunay triangulation* if $\widetilde{T}$ is a Delaunay triangulation of $\mathbb{H}^2$, that is, no circumcircle of a triangle of $\widetilde{T}$ contains a vertex of $\widetilde{T}$ in its interior.

2.2 ε-Nets

Let us recall definitions [8]. Let (X, d) be a metric space and $\varepsilon > 0$. A subset $P \subset X$ is an *ε-covering* if $d(x, P) \leqslant \varepsilon$ for all $x \in X$, i.e., the closed balls of radius ε centered at points of P cover X. It is an *ε-packing* if $d(p, q) \geqslant \varepsilon$ for all $p \neq q \in P$, that is, the open balls of radius $\varepsilon/2$ centered at points of P are pairwise disjoint. If P is both an ε-covering and an ε-packing, then it is an *ε-net*, also known as an $(\varepsilon, \varepsilon)$-Delone set.

When $\varepsilon < \sigma$, we say that S is *ε-thick*. The number of points in an ε-packing of a hyperbolic surface S is upper-bounded by $16(g-1)\left(1/\varepsilon^2 + 1/\sigma^2\right)$, or $16(g-1)/\varepsilon^2$ for an ε-thick surface [17].

2.3 Original Algorithm

Let us summarize the algorithm [17], from which our implementation derives. The algorithm is inspired by Shewchuk's Delaunay refinement [35]. It starts with a Delaunay triangulation of S with a single vertex b. In a nutshell, as long as there is a large triangle in the triangulation, its circumcenter is inserted and the triangulation is updated (see Figure 2): the triangle in which the circumcenter lies is first split into three new triangles, then the Delaunay property is retrieved using edge flips [30, 18]. The set of vertices of the final Delaunay triangulation is an ε-net of S, and all the intermediate sets of vertices are ε-packings.

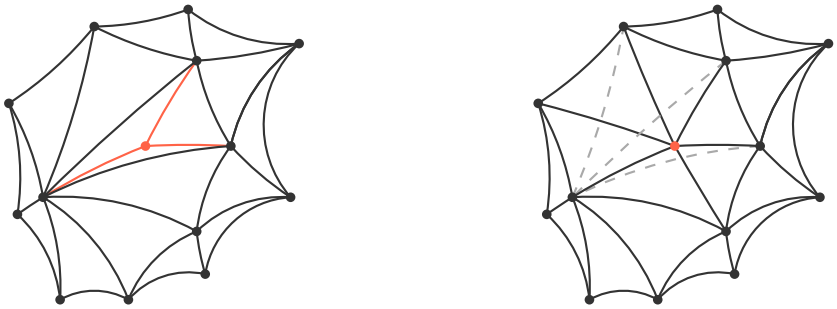

Figure 2 Insertion of a point in a Delaunay triangulation using a flip algorithm.

The algorithm also stores the Dirichlet domain $\mathcal{D}_{\tilde{b}}$ of a lift $\widetilde{b}$ of b together with its side pairings, which can be computed from any fundamental domain for S [14]. The data structure stores the lift in $\mathcal{D}_{\tilde{b}}$ of each vertex of the triangulation (or one of its lifts if it lies on the boundary of $\mathcal{D}_{\tilde{b}}$), and for each triangle, the information needed to retrieve its (at most three) lifts having at least one vertex in $\mathcal{D}_{\tilde{b}}$.

The most crucial step of the algorithm is the location of the circumcenter c_Δ of a triangle Δ in a triangulation of S. To this aim, a lift of c_Δ is located in the lifted triangulation in $\mathbb{H}^2$, as follows. First, the circumcenter $\widetilde{c}_\Delta$ of a lift $\widetilde{\Delta}$ of Δ with at least one vertex in $\mathcal{D}_{\tilde{b}}$ is computed. The point $\widetilde{c}_\Delta$ is a lift of c_Δ that does not necessarily lie in $\mathcal{D}_{\tilde{b}}$. To locate $\widetilde{c}_\Delta$, the algorithm first walks in the tiling $\Gamma\mathcal{D}_{\tilde{b}}$ to find the element $\gamma_c \in \Gamma$ such that $\widetilde{c}_\Delta \in \gamma_c \mathcal{D}_{\tilde{b}}$. The lift $\widetilde{c_b} = \gamma_c^{-1}\widetilde{c}_\Delta$ of c_Δ lying in $\mathcal{D}_{\tilde{b}}$ can then be computed. Second, the triangle in $\mathcal{D}_{\tilde{b}}$ in which $\widetilde{c_b}$ lies is identified by checking, for each triangle, its (at most three) lifts having at least one vertex in $\mathcal{D}_{\tilde{b}}$. It can be shown that the walk in the tiling $\Gamma\mathcal{D}_{\tilde{b}}$ traverses a bounded number of Dirichlet domains. The complexity of the algorithm is bounded by $O\left(N^2\right)$, where N is the number of points in the ε-net.

3 Preliminary Result: Walking in a Triangulation in $\mathbb{H}^2$

As mentioned above, a crucial step of the algorithm relies on finding a triangle containing a given point in a triangulation of $\mathbb{H}^2$ (there is only one such triangle, except for collinear points). There are two classical algorithms in the Euclidean plane: the straight walk and the visibility walk [23], which can be adapted to the hyperbolic plane. Both methods find the triangle containing a query point $\widetilde{q}$ in a triangulation starting from a vertex $\widetilde{p}$ of a triangle $\widetilde{\Delta}$. The *straight walk* visits all triangles along the geodesic segment $\widetilde{pq}$. The algorithm starts by rotating around $\widetilde{p}$ to find a triangle incident to $\widetilde{p}$ that has an edge intersecting the geodesic segment $\widetilde{pq}$. The *visibility walk* consists, for each visited triangle not containing $\widetilde{q}$, of moving to a neighbor through an edge $\widetilde{e}$ if $\widetilde{q}$ and the third vertex of the visited triangle are on different sides of the geodesic line supporting $\widetilde{e}$.

In the Euclidean case, the visibility walk terminates in a Delaunay triangulation [25] but it can loop forever in a non-Delaunay triangulation [11]. The following theorem takes care of the hyperbolic case.

▶ **Theorem 1.** *The visibility walk terminates in a finite or periodic hyperbolic Delaunay triangulation.*

The proof follows the same logic as in the Euclidean case [22] but it requires a new definition of the power of a point with respect to a circle, adapted to the hyperbolic case, which requires to rewrite the details. Due to lack of space, the proof is given in the full version of this article [16, Sec 3].

4 Data Structure

We enrich the data structure of the CGAL package *2D triangulations on hyperbolic surfaces* [13] based on a combinatorial map. A *combinatorial map* is an edge-centered data structure based on *darts*, which are equivalent to half-edges in our setting [31, 10]. A dart can be seen as an oriented edge. In dimension 2, each dart has a pointer β_1 to access the dart of the next edge in the same face, and a pointer β_2 to access the dart of the same edge in the adjacent face, as illustrated in Figure 3. Following β_1 pointers, we obtain all the darts of a given face. Following $\beta_1 \circ \beta_2$ combinations of pointers, we obtain all the darts of a given vertex.

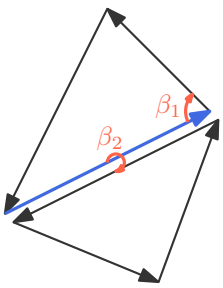

Figure 3 A dart (bold blue) in a 2D combinatorial map, and its pointers.

In the CGAL package *2D triangulations on hyperbolic surfaces* [13], the geometric information of a triangulation T is given as a cross-ratio for each edge, which is associated with darts. The *cross-ratio* of four pairwise distinct points z_1, z_2, z_3, z_4 in the Poincaré disk is defined as $[z_1, z_2, z_3, z_4] = \dfrac{(z_4 - z_2)(z_3 - z_1)}{(z_4 - z_1)(z_3 - z_2)} \in \mathbb{C}$. Let $\widetilde{e} = (\widetilde{p}, \widetilde{r})$ be a lift of an edge e and

$\widetilde{q}, \widetilde{s}$ be the remaining vertices of the lifted triangles incident to $\widetilde{e}$, such that $\widetilde{p}, \widetilde{q}, \widetilde{r}, \widetilde{s}$ are oriented counter-clockwise. The cross-ratio of e in T is $R_T(e) = [\widetilde{p}, \widetilde{q}, \widetilde{r}, \widetilde{s}]$. It is invariant under orientation-preserving isometries, so, the cross-ratio of an edge e can be defined from any of its lifts. The imaginary part of $R_T(e)$ is positive if and only if $\widetilde{s}$ lies in the circumdisk of the triangle $(\widetilde{p}, \widetilde{q}, \widetilde{r})$, i.e., if and only if the edge e is Delaunay flippable.

In addition to cross-ratios, the data structure of [13] contains one anchor, which represents a lift of one triangle in the Poincaré disk. The *anchor* is composed of a dart representing the triangle in the combinatorial map, and of the coordinates of the three vertices $\widetilde{p}, \widetilde{q}, \widetilde{r}$ of a lift of the triangle. The dart corresponds to the edge (p, q). Knowing a lift of a triangle, its neighbors can be retrieved using the cross-ratios of its edges: if $(\widetilde{p}, \widetilde{q}, \widetilde{r})$ and $(\widetilde{p}, \widetilde{r}, \widetilde{s})$ are two triangles in $\mathbb{H}^2$ sharing the edge $(\widetilde{p}, \widetilde{r})$, the coordinates of $\widetilde{s}$ can be deduced from $\widetilde{p}, \widetilde{q}, \widetilde{r}$ and $R_T((p, r))$. The anchor can therefore be used to compute a part of $\widetilde{T}$ one step at a time, for example to draw a lift of each triangle of T.

Our algorithm (see Section 6) performs computations with lifts of triangles at each step, in particular to compute a lift of the circumcenter of a triangle and locate it. To have constant time access to a lift of any triangle, we actually store an anchor for *each* face of the triangulation. The three darts of each triangular face are associated with its anchor.

Note that the set of anchors of all faces of T is not necessarily connected.

Updating the Data Structure

In the ε-net algorithm, the data structure is modified by two operations: splitting a triangle into three new triangles, and flipping an edge.

When splitting a triangle Δ, we know the lift $\widetilde{\Delta} = (\widetilde{p}, \widetilde{q}, \widetilde{r})$ given by its anchor and the point $\widetilde{s}$ to be inserted in $\widetilde{\Delta}$. The darts of Δ are kept and three pairs of darts are created (Figure 4). The pointers β_1 and β_2 of all these darts are set or updated to create the three new triangles in the combinatorial map. We create three new anchors corresponding to the new triangles $(\widetilde{p}, \widetilde{q}, \widetilde{s})$, $(\widetilde{q}, \widetilde{r}, \widetilde{s})$ and $(\widetilde{r}, \widetilde{p}, \widetilde{s})$ and associate them to the darts of their respective triangles. The cross-ratios of the three new edges are computed from the coordinates of $\widetilde{p}, \widetilde{q}, \widetilde{r}$, and $\widetilde{s}$. The cross-ratios of the edges $(p, q), (q, r)$, and (r, p) must be updated. For the edge (p, q), for instance, we use its non-updated cross-ratio and the vertices $\widetilde{p}, \widetilde{q}$ and $\widetilde{r}$ to compute the coordinates of a lift of the third vertex of its neighboring incident triangle. This step is mandatory because the anchor associated with the adjacent triangle in the combinatorial map may store a non-adjacent lift in $\mathbb{H}^2$. The new value of the cross-ratio can then be computed.

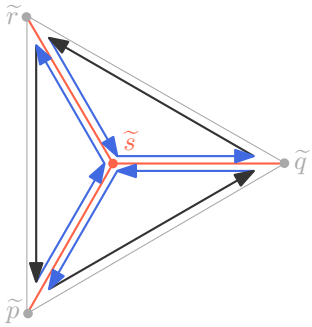

Figure 4 Splitting a triangular face in three in the combinatorial map, new darts are in blue.

To flip an edge, we use the CGAL package [13], which modifies the β_1 pointers and updates the cross-ratios [12]. We still need to update the anchors. To do so, we get the coordinates of the points stored in the anchor of a dart δ of the edge being flipped. We call them $\widetilde{p}, \widetilde{q}, \widetilde{r}$,

in such a way that the edge $(\widetilde{r},\widetilde{p})$ is represented by δ in the combinatorial map. Using the cross-ratio of that edge, we compute the coordinates of $\widetilde{s}$, the third vertex of the other lifted triangle sharing the edge $(\widetilde{r},\widetilde{p})$ (Figure 5). We then create two new anchors corresponding to the lifts of the triangles obtained after the flip, $(\widetilde{q},\widetilde{s},\widetilde{p})$ and $(\widetilde{q},\widetilde{s},\widetilde{r})$ and we associate them to the darts of their respective triangles.

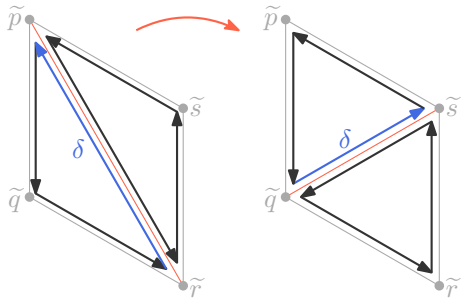

Figure 5 A flip. No darts are added or removed, only adjacencies are modified.

Note that, though these operations remove triangles and create new ones, darts are added but never removed in the data structure.

5 Generation of Input Surfaces

The input of our algorithm is a Delaunay triangulation of a surface with a single vertex. It is constructed from a fundamental domain with all its vertices in $\mathbb{H}^2$ projecting to the same point on the surface. We now explain how to generate such fundamental domains and the arithmetic issues related to the number type of the coordinates of its vertices.

The Teichmüller space $\mathcal{T}_g$, the space of all hyperbolic surfaces of genus g, can be parameterized for instance from a pants decomposition (Fenchel-Nielsen coordinates) [7, § 1.7], its group of isometries (Fricke coordinates) [27, § 2.5], or by a fundamental polygon in $\mathbb{H}^2$ [7, § 6]. Since we aim at computing a triangulation in $\mathbb{H}^2$, starting from a fundamental polygon is the right choice to avoid the use of hyperbolic trigonometric functions. Our algorithm relies on computations of cross-ratios and points in $\mathbb{H}^2$. There is no point in computing with `float` or `double` number types, as this is notoriously unstable.[2] Previous work showed that Delaunay triangulations can be computed on the Bolza surface, represented by a fundamental polygon with very specific algebraic numbers [28, 29]. Even when computing the Delaunay triangulation of points with rational coordinates, the group of the surface leads to algebraic numbers. In practice, algebraic numbers are handled with the CORE library [20] but this approach was shown to fail for generalized Bolza surfaces, already for genus 3 [24].

We now detail a way to generate and compute with generic surfaces of genus 2. Any genus 2 surface has a fundamental domain that is a symmetric octagon centered at the origin [1]. More precisely, three points are first chosen in the upper half of the Poincaré disk. Then a fourth point is computed so that the octagon formed by these four points and the four symmetric points with respect to the origin is a fundamental domain. The Teichmüller space $\mathcal{T}_2$ is thus parameterized by three complex numbers. Restricting to complex numbers with rational real and imaginary parts gives a dense subset of the Teichmüller space $\mathcal{T}_2$ [12]. This means that for any genus 2 surface, we can work on an arbitrary close surface given

[2] `https://www.cgal.org/exact.html`

by a fundamental domain whose vertices have rational coordinates. This allows us to only use exact rational computations for constructing an ε-net (see Section 6.2) and algebraic extensions of degree 2 to check its correctness (see Section 6.4).

A Delaunay triangulation of this octagon is computed as in the CGAL package [13, 12]: the eight vertices of the domain actually project on a same point on the surface, which we denote as b. Triangulating this convex octagon in an arbitrary way gives a triangulation of the surface with one vertex. The next step is to compute the cross-ratios of all edges. Then the Delaunay triangulation is computed using flips. The data structure of the CGAL package [13] is a combinatorial map with a cross-ratio on each edge, and one anchor. To generate the input for our ε-net algorithm, we only have to add an anchor for each face of the triangulation. Since the initial triangulation has only one vertex and six faces, the remaining anchors are computed (and associated with the darts of their respective faces) using cross-ratios, by successively computing lifts of adjacent triangles, as detailed in Section 4.

For higher genus surfaces, a construction of fundamental polygons is described in [36, § 6.11], but unfortunately it is not clearly leading to tractable numbers. We are investigating how polygons with rational coordinates could be generated since in such a case our algorithm will have the same robustness properties as those we illustrate in genus 2.

6 The Implemented Algorithm

The data structure is implemented in `Anchored_hyperbolic_surface_triangulation_2`, a class inherited from the CGAL class `Triangulation_on_hyperbolic_surface_2` [13]. The algorithm to compute an ε-net is implemented in the `epsilon_net(epsilon)` method. It maintains a Delaunay triangulation and iteratively inserts circumcenters of large triangles. We first detail our processing of large triangles aiming at minimizing the number of computations of circumcenters (Section 6.1). We then detail the largeness test, the representation of coordinates of points in $\mathbb{H}^2$ by exact rational numbers and the possible issues of the approximation of circumcenters (Section 6.2). The point location is detailed in Section 6.3. Finally, we explain how to certify that the set of vertices of the output triangulation is an ε-net using exact computation in degree two algebraic extensions (Section 6.4).

6.1 Additional Data Structure

At each step of the algorithm, a large triangle is considered. In the original algorithm, all triangles of the current triangulation are checked until a large one is found. Consequently, all triangles that are not affected by an insertion will be checked again for the next insertion. This choice has no effect on the theoretical complexity of the algorithm, but it is time-consuming in practice. Instead, we maintain a list of triangles to be processed by the algorithm. We ran experiments to guide our choice towards an effective way of maintaining this list. The details of these experiments can be found in [16, App A]. The results show that any attempt to maintain the list using criteria involving circumradii, like storing only large triangles or ordering them according to their circumradius, is highly inefficient.

More precisely, we maintain a list $\mathcal{L}$ of darts representing the triangles to be processed. The only operations on the list are: pop the front dart, and push new darts to the back. Each dart has a mark represented by a Boolean and we maintain the property that each triangle represented in $\mathcal{L}$ has exactly one marked dart; A triangle can have several darts in $\mathcal{L}$, but only one is marked. The computation of a circumradius is *only* performed when a *marked* dart is popped from the front. The list is initialized with one marked dart for each triangle of the input triangulation. Remark that for a reasonable choice of ε, all these triangles are large.

When a dart is popped out from $\mathcal{L}$, if it is marked, we unmark it and the circumradius of the triangle it represents is computed. If the triangle is large, its circumcenter splits the triangle containing it as detailed in Section 4, and one dart is marked and pushed to the back of $\mathcal{L}$ for each of the three new triangles. Darts are added to $\mathcal{L}$ without checking the size of the circumradius of the corresponding triangle and without checking if it is a Delaunay triangle. The Delaunay property is restored using the flip algorithm described in [12] and implemented in [13]. After a flip, in each of the two new triangles, we maintain the property that only one dart is marked. Indeed, such a new triangle may have 0, 1 or 2 marked darts (Figure 6). If it has none, then we mark one and push it to the back of $\mathcal{L}$; if it has two, then we leave them in $\mathcal{L}$ and unmark one; otherwise there is nothing to do.

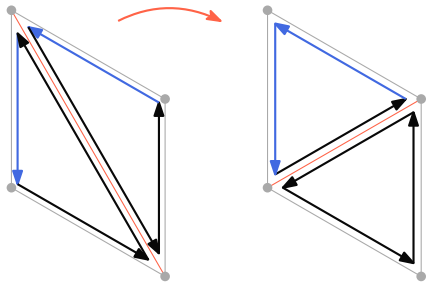

Figure 6 Case when triangles created by a flip have one or two marked darts.

When a non-marked dart is popped out from $\mathcal{L}$, then nothing is done: it means that the triangle it belongs to is represented by another marked dart in $\mathcal{L}$.

The algorithm proceeds with the new front dart until $\mathcal{L}$ is empty. Note that in practice, since darts representing new triangles are always pushed at the end of $\mathcal{L}$, large triangles tend to be close to the front and are processed before triangles with smaller circumradii.

Remark that no element of $\mathcal{L}$ is ever removed from the list, except at the front. As explained in Section 4, when a triangle disappears from the triangulation, its darts stay in the data structure, but their β_1 pointers are modified. So, it can be the case that a dart represented a large triangle when it was inserted in $\mathcal{L}$, but it represents a triangle whose circumradius is not greater than ε when it comes to the front of $\mathcal{L}$.

6.2 Circumcenters and Circumradii

When a marked dart is popped out from $\mathcal{L}$, the circumcenter of a lift of the triangle represented by the dart is first constructed in order to compute its circumradius. The lifted triangle is the one stored in the anchor associated to the dart. The coordinates of a circumcenter of three vertices with rational coordinates are algebraic numbers of degree two [4]. When it is inserted in the triangulation, a circumcenter becomes a vertex. Handling exact circumcenters would thus lead to cascading the algebraic degrees of coordinates, which would result in computations that are known to be impossible to handle in practice.

The coordinates of the circumcenter $\widetilde{c}_\Delta$ of a triangle $\widetilde{\Delta}$ are represented by the type `CGAL::Sqrt_extension`, which handles algebraic numbers of degree two. We do not insert the point $\widetilde{c}_\Delta$ but a rational approximation denoted $\widetilde{c}$. We round each coordinate of $\widetilde{c}_\Delta$ to a double precision number using the `to_double()` method of CGAL and convert it to an exact rational type. More specifically, coordinates of all vertices of our triangulation are represented by the `CGAL::Exact_rational` number type, which is a wrapper for the arbitrary-precision rational type `mpq_t` provided by GMP [21]. All the computations on our data structure are

performed using this `CGAL::Exact_rational` number type for points and cross-ratios. Note that the bitsize of the rationals encoding an inserted point is bounded whereas the bitsize of the rationals encoding a cross-ratio grows when it is updated during a flip.

Let us detail the computation of the largeness test for triangles that we use to avoid as much as possible the use of hyperbolic trigonometric functions. In the Poincaré disk, the distance between two points $\widetilde{u}$ and $\widetilde{v}$ is $d_{\mathbb{H}^2}(\widetilde{u},\widetilde{v}) = \operatorname{arcosh}(1+\lambda(\widetilde{u},\widetilde{v}))$, where $\lambda(\widetilde{u},\widetilde{v}) = \dfrac{2||\widetilde{u}-\widetilde{v}||^2}{(1-||\widetilde{u}||^2)(1-||\widetilde{v}||^2)}$ and $||\cdot||$ is the Euclidean distance. We compute the minimum λ between the approximate circumcenter $\widetilde{c}$ and the three vertices of the anchor. If it is greater than a certified upper bound of $\cosh(\varepsilon)-1$, then we consider the triangle large and insert $\widetilde{c}$ in the triangulation. The certified upper bound on $\cosh(\varepsilon)$ is computed with the Boost interval library [19]. Due to approximations for the computation of $\widetilde{c}$, this process may miss a large triangle and thus does not enforce the ε-covering property. Similarly, even if the point $\widetilde{c}$ that is inserted into the triangulation is at distance at most ε from the vertices of its triangle, it may be at distance smaller than ε from another vertex of the triangulation. We will check these properties in the final step of the algorithm (Section 6.4).

6.3 Point Location

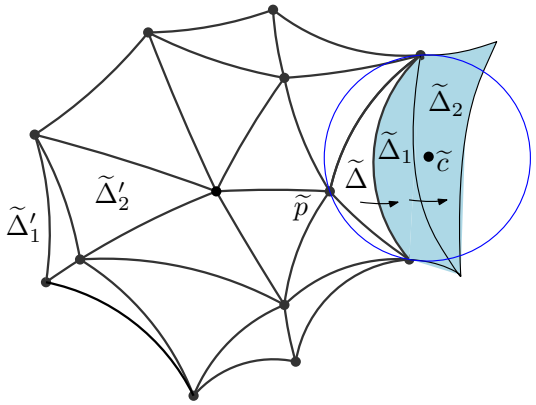

Figure 7 A fundamental domain of the surface is given by the anchors of the triangles (thick black lines). The blue triangles are the lifts constructed by the visibility walk to reach the approximate circumcenter $\widetilde{c}$ of $\widetilde{\Delta}$. Triangles $\widetilde{\Delta}'_1$ and $\widetilde{\Delta}'_2$ are the lifts of Δ_1 and Δ_2 in the domain.

Our implementation maintains a Delaunay triangulation of S using the data structure presented in Section 4. Each point to be inserted is located in this triangulation by locating a lift in the lifted triangulation. We do not store a Dirichlet domain as in the original algorithm (Section 2.3), but instead directly walk in the current triangulation itself.

We tested two walk algorithms: the straight walk and the visibility walk (Figure 7) mentioned in Section 3. In our case, the query point $\widetilde{c}$ is the approximate circumcenter of the lifted triangle $\widetilde{\Delta}$ given by the anchor of the triangle Δ being processed by the algorithm. The walk starts from a vertex $\widetilde{p}$ of the triangle $\widetilde{\Delta}$. Lifts of triangles must be constructed along the walk to find the lifted triangle containing $\widetilde{c}$.

Both walks are based on orientation tests in $\mathbb{H}^2$ with vertices of lifted triangles. The combinatorial map encoding the triangulation provides a direct access to the neighbor Δ' of the triangle Δ adjacent through one of its edges. However, the lift $\widetilde{\Delta}'$ of this triangle given by its anchor may not be adjacent to the lift $\widetilde{\Delta}$. The lift of Δ' that is adjacent to $\widetilde{\Delta}$ is computed from the vertices of $\widetilde{\Delta}$ and the cross-ratio of the common edge as explained in Section 4.

Running the `epsilon_net` method with both walks shows that they perform equivalently (see [16, App B]): the running time of the method remains the same, and they compute a similar number of lifts. The visibility walk does not have to handle the degenerate cases of the straight walk, which may go through a vertex or along an edge; we therefore choose the visibility walk. The bound on the length of the straight walk for the original algorithm, using Dirichlet domains, does not apply to the visibility walk. However we observe in Section 7.2 that the walk has constant length in practice.

6.4 ε-Covering and ε-Packing Checks

As explained in Section 6.2, our algorithm is robust in the sense that the output triangulation is the Delaunay triangulation of a set of points with rational coordinates. On the other hand, the vertices of this triangulation may not be an ε-net, due to approximations of circumcenters. To check the ε-covering property, it is sufficient to check that there is no large triangle. For every triangle Δ, we compute the exact circumcenter $\widetilde{c}_\Delta$ of its anchor, which has coordinates in a degree two algebraic extension, using the number type `CGAL::Sqrt_extension`. We then compute $\lambda(\widetilde{c}_\Delta, \widetilde{v})$ with the same type (see Section 6.2) for a vertex $\widetilde{v}$ of the triangle, and check that it is less than a certified lower bound on $\cosh(\varepsilon) - 1$. To check the ε-packing property, it is sufficient to check that all Delaunay edges are longer than ε. Since all vertices have rational coordinates, the value $\lambda(\widetilde{v}_i, \widetilde{v}_j)$ for two vertices of an edge is rational and it is checked to be larger than the upper bound on $\cosh(\varepsilon) - 1$ computed with the Boost interval library [19]. When these tests succeed, the vertices of the output triangulation are then certified to be an ε-net of the surface. Otherwise, the failure of these tests means that the double precision used for the approximation of circumcenters was not enough.

Our experiments presented in Section 7 show that for surfaces with a long systole, which is the most common case (see Section 7.1), our algorithm is successful. Using a double precision to set the rational coordinates of approximate circumcenters and to compute the bounds on $\cosh(\varepsilon) - 1$ actually constructs valid ε-nets. On the other hand, we also observe in the full version of this article [16, Sec 7.3] that higher precision would be needed to handle a surface with a very small systole.

Our future work will focus on certifying the largeness test for triangles and check the ε-packing property after each insertion. If the ε-packing check fails, this means that the inserted point was not a good enough approximation of the circumcenter and iteratively refining it (which is possible via the CGAL Algebraic Kernel [3]) would eventually recover the ε-packing property. Note that iterative refinement of the rational bounds on $\cosh(\varepsilon) - 1$ must also be computed (which is possible via the Boost library).

7 Experiments

All the experiments of Section 7.2 are performed on 180 random surfaces of genus 2 generated as explained in Section 5 by uniformly choosing, for the Euclidean distance, three points in the upper half of the Poincaré disk. As explained in Section 7.1, these surfaces are expected to have a long systole. Experiments show that 173 of these surfaces have a systole greater than 0.5, while the 7 others have a systole greater than 0.21. See the full version [16, Sec 7.2] for details. Section 7.3 displays and analyzes visualizations of the output.

The source code and complete data of the experiments are available on GitHub [3].

7.1 Distribution of Input Surfaces

To experiment with an algorithm in practice, it is important to sample the space of possible input with some distribution. We discuss this issue below and explain why our random generator of surfaces is likely to produce surfaces with long systole.

Well-Distributed Surfaces?

The situation was nicely described by Mirzakhani [32] (though there are more recent results [33]). We just give a flavor here. The moduli space $\mathcal{M}_g$ is the set of all hyperbolic surfaces of genus g. It can be equipped by two natural metrics: the Teichmüller distance and the Weil-Petersson one. Roughly speaking, they measure the deformation between two hyperbolic metrics: the first one considers the supremum and the second the average. Ideally, we would like to obtain a uniform sampling of $\mathcal{M}_g$, for any of the two metrics. However, today's mathematical literature does not answer this question. The first problem is that there is no known parameterization of $\mathcal{M}_g$, so, we can only work with a parameterization of its universal cover, the Teichmüller space $\mathcal{T}_g$, i.e., the set of so-called marked hyperbolic surfaces. Indeed, in $\mathcal{T}_g$, as opposed to in $\mathcal{M}_g$, applying a non-identity homeomorphism to a hyperbolic surface gives a different element in $\mathcal{T}_g$: the moduli space $\mathcal{M}_g$ is the quotient of $\mathcal{T}_g$ by the mapping class group Mod_g, which is the group of homeomorphisms of the topological surface of genus g. Unfortunately, the known parameterizations of $\mathcal{T}_g$ are not invariant under the action of Mod_g, which is the main reason why sampling $\mathcal{M}_g$ is so intricate. It is not clear how to describe a fundamental domain of $\mathcal{M}_g$ in $\mathcal{T}_g$ in any parameterization of $\mathcal{T}_g$. As of today, the best that can be done is to sample a parameterization of $\mathcal{T}_g$, being aware that this does not lead to a good distribution on $\mathcal{M}_g$.

For completeness, we mention that there are other ways of constructing random surfaces in theory, by randomly gluing hyperbolic ideal triangles together [6, 34]. However, these methods rely on a compactification of the obtained cusped surfaces, which, roughly speaking, boils down to a conformal uniformization of the metric. This process is obviously very far from yielding a practical construction. Additionally, those approaches lead to surfaces with huge genus (typically, several thousands), which cannot be manipulated in practice.

Systole of random surfaces

Remark that $\mathcal{M}_g$ is not a compact set, as a surface can have an arbitrarily small systole: Indeed, in any compact subset of $\mathcal{M}_g$, the systole function $sys(\cdot)$ is bounded. Mirzakhani showed that small systoles are somewhat rare in $\mathcal{M}_g$: the probability to obtain a surface with a systole smaller than some $\sigma_0 > 0$ using a uniform distribution (for the Weil-Petersson point of view) is of the order of σ_0^2. This means that the typical case is a surface with a reasonably long systole. It is the case for the random surfaces that we generated, as explained in Section 5. For completeness, we also specifically design a surface with a small systole and experimentally observe the impact in the full version of this article [16, Sec 7.3].

7.2 Main Results

For each of the 180 random surfaces, an input for the ε-net algorithm is computed as a single vertex Delaunay triangulation of the surface, as explained in Section 5. The `epsilon_net` method is run with 50 values of ε on every input, decreasing from 0.5 to 0.01 with a step of 0.01. Table 1 presents an overview of the results.

We first observe that the number of vertices in the computed ε-nets is close to the theoretical upper bound for an ε-thick surface, which is $16(g-1)/\varepsilon^2 = 16/\varepsilon^2$ ($g = 2$ for all surfaces of the experiments). In proportion, the number of vertices is 54% of the upper bound on average, with a standard deviation of 2%. The minimum is 47% and the maximum is 63% over all tested surfaces and values of ε.

Table 1 Average number of vertices of the ε-nets.

ε	**0.50**	**0.40**	**0.30**	**0.20**	**0.10**	**0.05**	**0.01**
Avg. # of vertices	34	54	96	216	865	3,454	86,314
$\mathbf{16/\varepsilon^2}$	64	100	178	400	1,600	6,400	160,000

Even though, as in the Euclidean case [23], we have no complexity analysis of the visibility walk for the point location, we observe that the walk traverses a (small) constant number of triangles. The walk locates the approximate circumcenter of a triangle in $\mathbb{H}^2$, starting from this triangle. The average number of computed lifted triangles during each walk tends to decrease when ε becomes smaller, while the average proportion of approximate circumcenters located in their own triangle tends to increase, as shown in Figure 8. On average, 68% of the approximate circumcenters lie in their triangle. Over all surfaces and all tested values of ε, the farthest located points were 4 triangles away from the starting triangle of the walk.

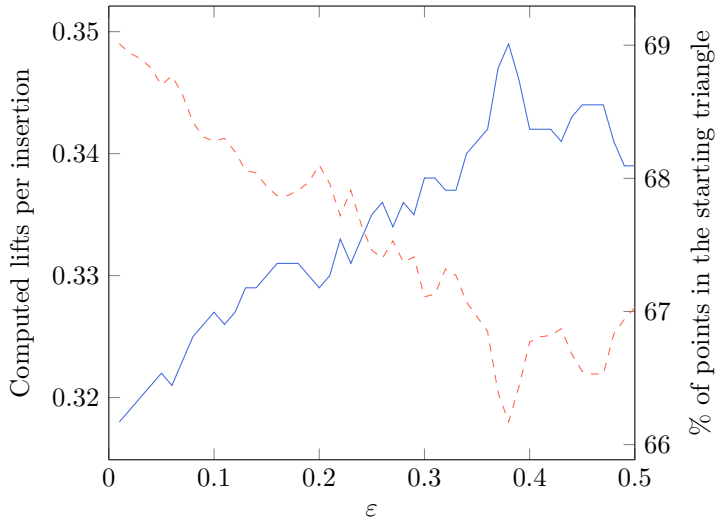

Figure 8 Average number of computed lifted triangles in the walk at each locate query (left, solid), and average percentage of points lying in the initial lifted triangle of the walk (right, dashed).

We counted the number of flips done to restore the Delaunay property of the triangulation after each split. On average, it decreases when ε becomes smaller, going from 3.41 for $\varepsilon = 0.5$ to 2.41 for $\varepsilon = 0.01$, as shown in Figure 9. This shows that the number of flips at each insertion is a small constant in practice. The total number of flips is thus, in practice, linear in the number of points, which is in contrast with the theoretical quadratic bound (see Section 2.3).

In the full version of this article [16, App C], we show an order of magnitude for the running times to give an idea of the practical complexity of our implementation. It appears to be slightly faster than quadratic in $1/\varepsilon$.

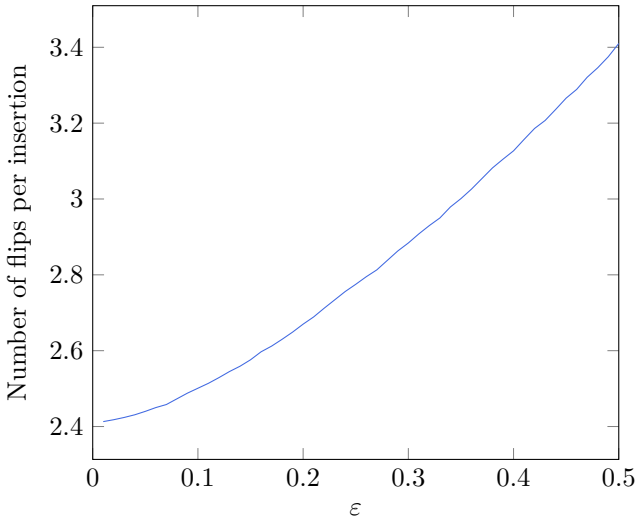

Figure 9 Average number of flips done to recover the Delaunay property after each insertion.

7.3 Visualization of the Output

To visualize an ε-net, we draw a fundamental domain of the surface in the Poincaré disk using its Delaunay triangulation. To do so, it suffices to draw a lift of each triangle in a connected way. We cannot just use the anchors since they would generally not lead to a connected domain. So, we access the anchor of a chosen triangle and build lifts of the other triangles starting from this initial anchor as explained in Section 4. As objects appear smaller near the boundary of the Poincaré disk, we center the drawing at the origin to be able to observe the details. To achieve this, we translate the vertices of the initial anchor such that one of them is 0 before computing the rest of the drawing. If we want similar drawings when running the ε-net algorithm with different values of ε on a given surface, we always use an anchor having a fixed lift $\widetilde{b}$ of b, the unique vertex of the input triangulation (Section 5), as the initial anchor; we then apply the translation that translates $\widetilde{b}$ to 0.

In Figures 10 and 11, the drawings are computed by the lift method of the CGAL package *2D triangulations on hyperbolic surfaces* [13], which uses a weight on edges to order the lifts of triangles of the triangulation T of S. The weight of an edge $(\widetilde{x}, \widetilde{y})$ is defined as $|\widetilde{x}|^2 + |\widetilde{y}|^2$ ($|\cdot|$ being the complex modulus). The drawing is then iteratively computed: given T' the set of triangles that have been lifted, the next triangle to be lifted is the one in $T \setminus T'$ that is incident to the edge of least weight in T'.

Figure 10 shows the obtained Delaunay triangulation of the surface with a small systole studied in the full version of this article [16, Sec 7.3]. Since the systole is very small, there is a very long collar around the shortest non-contractible closed curve.

The drawings of triangulations shown in Figure 11 naturally look like Dirichlet domains since the weights on the edges ensure that the lifts of triangles entirely contained in $\mathcal{D}_{\widetilde{b}}$, the Dirichlet domain of $\widetilde{b}$, are drawn. This becomes clear when $\widetilde{b}$ is translated to the origin (Figure 12). Since the input of the ε-net algorithm is a Delaunay triangulation with the single vertex b, we obtain $\mathcal{D}_{\widetilde{b}}$ by computing the circumcenter of all the lifted triangles incident to $\widetilde{b}$ in the input triangulation, before running the ε-net algorithm.

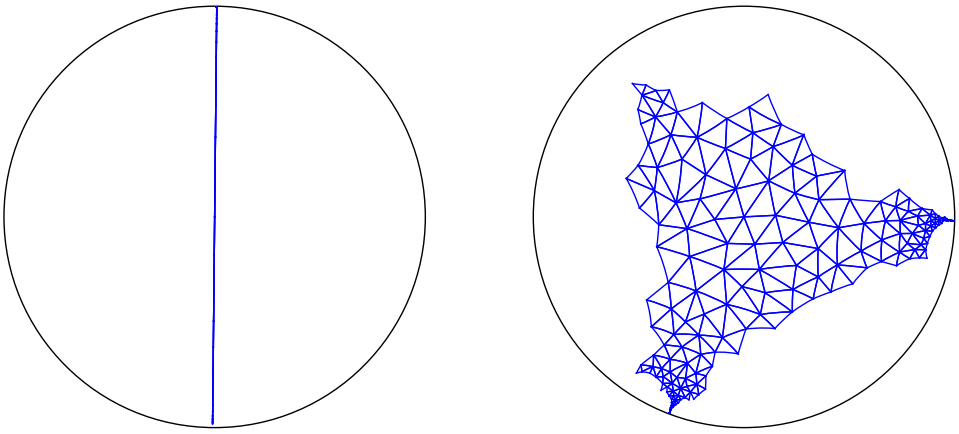

Figure 10 Delaunay triangulation of the computed 0.25-net of the surface with a small systole of [16, Sec 7.3]. Left: Drawing centered at a vertex in the long collar. Right: Drawing centered outside the collar, which appears in the form of "horns" pointing towards the boundary of the Poincaré disk.

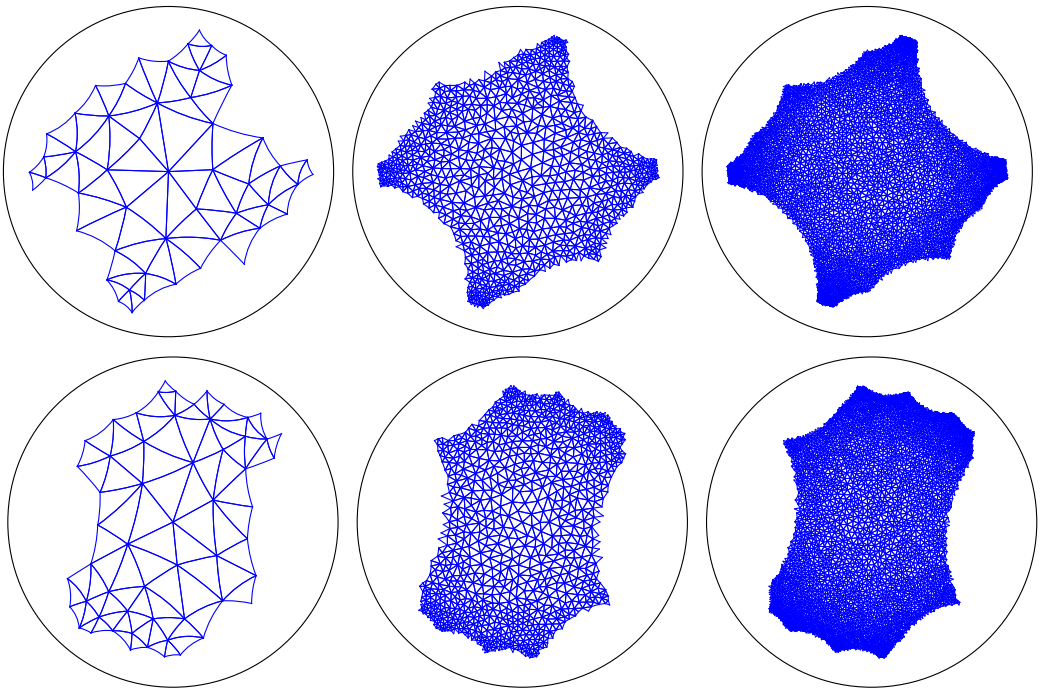

Figure 11 Delaunay triangulations of the computed ε-nets for ε=0.5 (left), ε=0.1 (middle), ε=0.05 (right) on the surfaces of seed 123 (top) and 321 (bottom).

An alternative drawing is obtained by ordering the lifts of the triangles around the initial anchor following a Breadth First Search (BFS) algorithm on the adjacency graph. Such a drawing represents a *combinatorial Dirichlet domain* (see Figure 13). We observe that, when ε decreases, the combinatorial Dirichlet domain fits the Dirichlet domain $\mathcal{D}_{\tilde{b}}$ better. Formalizing this convergence is an interesting open question.

Polynomial-Time Constant-Approximation for Fair Sum-Of-Radii Clustering

Sina Bagheri Nezhad

Sayan Bandyapadhyay
Portland State University, OR, USA

Tianzhi Chen
Portland State University, OR, USA

Abstract

In a seminal work, Chierichetti et al. [20] introduced the (t, k)-fair clustering problem: Given a set of red points and a set of blue points in a metric space, a clustering is called fair if the number of red points in each cluster is at most t times and at least $1/t$ times the number of blue points in that cluster. The goal is to compute a fair clustering with at most k clusters that optimizes certain objective function. Considering this problem, they designed a polynomial-time $O(1)$- and $O(t)$-approximation for the k-center and the k-median objective, respectively. Recently, Carta et al. [15] studied this problem with the sum-of-radii objective and obtained a $(6+\epsilon)$-approximation with running time $O((k \log_{1+\epsilon}(k/\epsilon))^k n^{O(1)})$, i.e., fixed-parameter tractable in k. Here n is the input size. In this work, we design the first polynomial-time $O(1)$-approximation for (t, k)-fair clustering with the sum-of-radii objective, improving the result of Carta et al. Our result places sum-of-radii in the same group of objectives as k-center, that admit polynomial-time $O(1)$-approximations. This result also implies a polynomial-time $O(1)$-approximation for the Euclidean version of the problem, for which an $f(k) \cdot n^{O(1)}$-time $(1+\epsilon)$-approximation was known due to Drexler et al. [24]. Here f is an exponential function of k. We are also able to extend our result to any arbitrary $\ell \geq 2$ number of colors when $t = 1$. This matches known results for the k-center and k-median objectives in this case. The significant disparity of sum-of-radii compared to k-center and k-median presents several complex challenges, all of which we successfully overcome in our work. Our main contribution is a novel cluster-merging-based analysis technique for sum-of-radii that helps us achieve the constant-approximation bounds.

1 Introduction

Given a set of points P in a metric space (Ω, d) and an integer $k > 0$, the task of clustering is to find a partition $X_1, \ldots, X_k$ of P into k groups or clusters such that each group has similar points. The similarity of the clusters is typically modeled using an objective function which is to be minimized. In this work, we focus on the *sum-of-radii* objective, which is defined as the sum of the radii of k balls that contain the points of the respective k clusters. The sum-of-radii objective, while also center-based, has a different flavor from objectives such as k-center, k-median, and k-means, as it directly sums the radii of the clusters rather than measuring distances from each point to its assigned center. In these objectives, k representative points (or cluster centers) are chosen, and the corresponding clusters are

licensed under Creative Commons License CC-BY 4.0

formed by assigning the points of P to their nearest centers. Such a partition is popularly known as the *Voronoi* partition. It is not hard to see that an optimal sum-of-radii clustering is not necessarily a Voronoi partition. The study of sum-of-radii was motivated by the idea that it could reduce the so-called *dissection effect* that is observed in k-center type objectives (see attached full version for details).

Sum-of-radii clustering is known to be NP-hard even in planar metrics and metrics of constant doubling dimension [30]. Consequently, it has received substantial attention from the approximation algorithms community. Charikar and Panigrahy [16] designed a Primal-Dual and Lagrangian-relaxation-based 3.504-approximation algorithm that runs in polynomial time (poly-time). Recently, using similar techniques, Friggstad and Jamshidian [26] improved the approximation factor to 3.389. The best-known approximation factor for sum-of-radii in polynomial time is $3 + \epsilon$ for any $\epsilon > 0$, due to Buchem et al. [14]. In stark contrast to other well-studied center-based objectives such as k-center and k-median, the sum-of-radii objective admits a QPTAS [30], which is based on a randomized metric partitioning scheme. Additionally, the problem can be solved exactly in polynomial time in the Euclidean metric of constant dimension [31]. The problem also admits polynomial time exact algorithms in other restricted settings, such as when singleton clusters are not allowed [9] and the metric is unweighted [33].

In recent years, sum-of-radii clustering has also been studied with additional constraints. One such popular constraint is the capacity constraint, which puts restriction on the number of points that each cluster can contain. In a series of articles [35, 8, 36, 25], $O(1)$-approximation algorithms have been designed for capacitated sum-of-radii with running time fixed-parameter tractable (FPT) in k (i.e., $f(k) \cdot n^{O(1)}$ for a function f of k), culminating in an approximation factor of 3. Inamdar and Varadarajan [35] studied sum-of-radii with a matroid constraint where the set of centers of the balls must be an independent set of a matroid. They obtain an FPT 9-approximation for this problem. The approximation factor has recently been improved to 3 by Chen et al. [18]. Obtaining a poly-time $O(1)$-approximation for any of these constrained versions is an interesting open question. However, poly-time $O(1)$-approximations are known for sum-of-radii with lower bounds and with outliers [3, 14].

Sum-of-radii has also been studied with fairness constraints, which is the main focus of our work. Clustering with fairness constraints or fair clustering stems from the idea that protected groups (defined based on a sensitive feature, e.g., gender) must be well-represented in each cluster. In recent years, fair clustering has received significant attention from researchers across several areas of computer science. In a seminal work, Chierichetti et al. [20] introduced the (t, k)-*fair clustering* problem. In this problem, we are given a set P_1 of red points, a set P_2 of blue points, that together contain n points, and an integer balance parameter $t \geq 1$. A clustering is called (t, k)-*fair* if, for any cluster X, the number of red points in X is at least $1/t$ times and at most t times the number of blue points in X. We say that each cluster in a (t, k)-fair clustering is t-*balanced*.

Chierichetti et al. studied (t, k)-fair clustering with k-center and k-median objectives, and obtained poly-time 4- and $O(t)$-approximation, respectively. Since then obtaining a poly-time $O(1)$-approximation for (t, k)-fair median or means remained an intriguing open question. The main challenge in this case is that the optimal clusterings are no longer Voronoi partitions, as they also need to be (t, k)-fair. Subsequently, (t, k)-fair median/means has been studied in a plethora of works. The only setting where it is known to obtain a poly-time $O(1)$-approximation is when $t = 1$ [12], that is for $(1, k)$-fair median/means. These problems have also been considered in the Euclidean case [46, 5].

The (t, k)-fair median/means problem has also been studied with an arbitrary ℓ number of groups. The algorithm of Böhm et al. [12] for $t = 1$ also yields a poly-time $O(1)$-approximation in this case. Note that for $t = 1$, a cluster contains the same number of points from all groups. Bandyapadhyay et al. [6] obtained a poly-time approximation for (t, k)-fair median with a factor that depends on t, ℓ, and k. Bercea et al. [11] and Bera et al. [10] independently defined a generalization of (t, k)-fair clustering. There we are given balance parameters $\alpha_i, \beta_i \in [0, 1]$ for each group $1 \leq i \leq \ell$. A clustering is called *fair representational* if the fraction of points from group i in every cluster is at least α_i and at most β_i for all $1 \leq i \leq \ell$. They show that it is possible to obtain poly-time bi-criteria type $O(1)$-approximations where we are allowed to violate the fairness constraints by an additive small constant factor. Subsequently, Dai et al. [23] designed a DP-based poly-time $O(\log k)$-approximation for this problem. For ℓ groups, their running time is $n^{O(l)}$.

Carta et al. [15] studied fair versions of sum-of-radii. In particular, they study a more general class of *mergeable* constraints. A clustering constraint is called mergeable if the union of two clusters satisfying the constraint also satisfies the constraint. They show that the fairness constraints defined in (t, k)-fair clustering and fair representational clustering are mergeable. In their work, they obtained a $(6 + \epsilon)$-approximation for sum-of-radii with mergeable constraints. In particular, for the above two fairness constraints, their run time is $O((k \log_{1+\epsilon}(k/\epsilon))^k n^{O(1)})$, so FPT in k. The algorithm iteratively guesses the next cluster based on a *k-center completion problem* leading to the FPT run time. Their approximation factor improves to $3+\epsilon$ when $t = 1$. Drexler et al. [24] obtained an FPT $(1+\epsilon)$-approximation for Euclidean sum-of-radii with mergeable constraints. Chen et al. [18] studied a fair version, which is a special case of matroid sum-of-radii, and hence obtained an FPT 3-approximation. A summary of the results on fair clustering under various objectives is provided in Table 1.

As mentioned before, for fair representational models, only bi-criteria type $O(1)$-approximations are known for k-center/median/means, even with two groups. As we focus on our theoretical quest of designing poly-time $O(1)$-approximations fully satisfying the fairness constraints, we study (t, k)-fair sum-of-radii. In light of the above discussion, we state the following two questions.

Question 1: Does (t, k)-fair sum-of-radii (with two groups) admit a poly-time constant-approximation algorithm?

Question 2: Does $(1, k)$-fair sum-of-radii with an arbitrary $\ell \geq 2$ number of groups admit a poly-time constant-approximation algorithm?

After the work of Chierichetti et al. [20], several other notions of fairness have been considered in the context of clustering problems. The following is a sample of these works grouped by the fairness notions: individual fairness [38, 43, 47, 13, 1], proportional fairness [19, 42], fair center representation [17, 40, 39, 21, 34], colorful [7, 37, 4], and min-max fairness [2, 28, 41, 22, 29, 32].

1.1 Our Contributions and Techniques

In our work, we prove two theorems resolving Questions 1 and 2 in the affirmative. First, we prove the following theorem.

Table 1 Summary of approximation results for fair clustering under various objectives. "Poly" denotes polynomial time; "FPT" denotes fixed-parameter tractable in k; ℓ is the number of groups.

Objective	Fairness Type	Approximation	Time	Reference
k-Center	(t,k) (2 groups)	4	Poly	[20]
k-Median	(t,k) (2 groups)	$O(t)$	Poly	[20]
k-Median	$(1,k)$ (ℓ groups)	$O(1)$	Poly	[12]
k-Median	(t,k) (ℓ groups)	$f(t,\ell,k)$	Poly	[6]
k-Median / Center	Representational (bi-criteria)	$O(1)$	Poly	[10, 11]
Sum-of-Radii	Unconstrained	$3+\varepsilon$	Poly	[14]

Sum-of-Radii	(t,k) (2 groups)	$\mathbf{144}+\varepsilon$	**Poly**	**This work**
Sum-of-Radii	$(1,k)$ (ℓ groups)	$\mathbf{180}+\varepsilon$	**Poly**	**This work**

▶ **Theorem 1.** *There is a polynomial-time* $(144+\epsilon)$*-approximation algorithm for* (t,k)*-fair sum-of-radii (with two groups).*

Our result complements the FPT approximation result of Carta et al. [15] by achieving the first $O(1)$-approximation for the problem in polynomial time. The result also implies a poly-time $O(1)$-approximation for Euclidean (t,k)-fair sum-of-radii, for which only an FPT $(1+\epsilon)$-approximation was known [24]. We note that our result should also be compared with that of (t,k)-fair k-median for which only $O(t)$-approximation is known in polynomial time. In particular, our result places sum-of-radii in the same group of objectives as k-center that admits polynomial-time $O(1)$-approximations. Moreover, our result shows that (t,k)-fair sum-of-radii is in contrast to most of the constrained versions of sum-of-radii, including capacitated clustering, for which only FPT $O(1)$-approximations are known.

Next, we give an overview of our approach. Our approximation algorithm is motivated by the algorithms for (t,k)-fair center and (t,k)-fair median [20]. These algorithms have two major steps. In the first step, a *fairlet decomposition* of the points in $X = P_1 \cup P_2$ is computed, i.e., a partition $\mathcal{Y} = \{Y_1, \ldots, Y_m\}$ such that for each fairlet Y_i, it either has 1 red point and at most t blue points or 1 blue point and at most t red points. Let $\beta : P_1 \cup P_2 \to [m]$ be the function that maps each point x to the index of the fairlet that contains x. From each Y_i, an arbitrary point y_i is designated as its *representative*. In the second step, a clustering of these m representatives is computed with the respective cost function. Also, for each Y_i, all of its points are assigned to the cluster that contains y_i. The new clustering is obviously (t,k)-fair, as each cluster is a merger of fairlets. For the analysis of the cost of the computed clustering, they define a fairlet decomposition cost, which is used to bound the assignment cost of the points in the second step. For k-center, this cost is $\max_{x\in X} d(x, y_{\beta(x)})$, and for k-median, it is $\sum_{x\in X} d(x, y_{\beta(x)})$. Indeed, both of these costs when optimal are comparable to the optimal (t,k)-fair clustering cost. For k-center, it is within a constant factor, and for k-median it is within an $O(t)$ factor. Then, it is sufficient to compute a fairlet decomposition in the first step whose cost is within a small constant-factor of the optimal fairlet decomposition cost.

Coming back to (t,k)-fair sum-of-radii, it is not clear how to define a suitable fairlet decomposition cost that can be compared to the optimal (t,k)-fair sum-of-radii cost. In particular, such a cost needs to be defined independent of the number of clusters k. However, for sum-of-radii, the objective is the sum of radii of k clusters. For example, a natural

candidate, the cost for k-median, i.e., $\sum_{x \in X} d(x, y_{\beta(x)})$, is likely to be much larger than the optimal sum-of-radii cost. In the absence of such a suitable fairlet decomposition cost, it is difficult to argue the increase in the assignment cost, when actual points of Y_i are assigned instead of just the representative y_i.

Our approach. Our algorithm is surprisingly simple to state. We first compute a complete bi-partite graph G with P_1 and P_2 being the two parts. The weight of each edge is set to be the distance between the two corresponding endpoints. Subsequently, a degree-constrained, spanning subgraph of this graph is computed where each vertex has a degree in range $[1, t]$, and the sum of the weights of the edges is minimized. Such an optimal subgraph can be computed in polynomial time using the algorithm of Gabow [27]. Moreover, one can show that such a subgraph is a collection of stars each having at most t edges. Thus, our algorithm up to this point is in a similar spirit to that of k-median. As we argued before, the total weight of such a subgraph can be very large compared to the optimal sum-of-radii cost. Our main contribution is to prove that there is a sum-of-radii clustering of the stars (or representatives of them) computed in this way whose cost is at most a constant times the optimal (t, k)-fair sum-of-radii cost. Then, one can compute an approximate sum-of-radii clustering of these stars and return the corresponding clustering of the points in $P_1 \cup P_2$. The obtained clustering is (t, k)-fair, as the clusters are disjoint union of the vertices of stars, each having at most t edges. The proof of the existence of a clustering of the computed stars whose cost is nicely bounded is based on a novel analysis technique that merges a set of optimal clusters to obtain *superclusters*. We give an overview in the following.

Let H be the degree-constrained subgraph computed with the minimum weight possible. Also, let $\mathcal{C}^* = \{C_1^*, C_2^*, \ldots, C_k^*\}$ be a fixed optimal (t, k)-fair sum-of-radii clustering. We repetitively merge pairs of these clusters if there are edges in H across them. Let $\hat{\mathcal{C}} = \{\hat{C}_1, \hat{C}_2, \ldots, \hat{C}_\kappa\}$ be the resulting clustering. By our construction, each star of H is fully contained in one of these merged clusters or *superclusters*. Thus, it is sufficient to show that the radius of each supercluster $\hat{C}_i$ is at most $O(1)$ times the sum of the radii of the *associated* optimal clusters whose merger is $\hat{C}_i$. To bound such radius, we introduce a notion of *minimum-switch* paths between pairs of clusters. These paths play a central role in our analysis. We prove that it is possible to bound the (weighted) length of any such path by $O(1)$ times the sum of the radii of the associated optimal clusters. Then the diameter (or radius) of the supercluster can also be bounded likewise, as any two cluster vertices are connected by a minimum-switch path. The important distinction is that the length of any arbitrary path might not be bounded in such a nice way.

Next, we prove the following theorem concerning Question 2.

▶ **Theorem 2.** *There is a polynomial-time* $(180 + \epsilon)$*-approximation algorithm for* $(1, k)$*-fair sum-of-radii with* $\ell \geq 2$ *groups of points.*

Again our result directly improves the FPT approximation result of Carta et al. [15] and extends to more than 2 groups. The result matches the known constant-approximation bound for k-center/median/means in this case. The proof of the above theorem is similar to the proof of Theorem 1, and so employs the same supercluster-based analysis framework. However, here we need to handle ℓ colors. The main challenge boils down to bounding the diameter of a certain multi-partite graph G_1^* with $\cup_{i=1}^{\ell} P_i$ being the set of vertices. Intuitively, by the analysis for two groups, the diameter of the graphs induced by only $P_1 \cup P_i$ is nicely bounded. However, we still need to bound the diameter of G_1^*. Consequently, we introduce an additional notion of *minimum-color-switch* paths. We prove that the lengths of these paths can also be bounded nicely, exploiting their special properties.

Organization. We introduce notation in Section 2 and present our algorithms for (t, k)-fair and $(1, k)$-fair sum-of-radii in Sections 3 and 4, respectively. Proofs of statements marked by $(*)$ are available in the full version[1].

2 Preliminaries

In *sum-of-radii clustering*, we are given a set P of n points in a metric space with distance d and an integer $k > 0$. We would like to find: (i) a subset C of P containing k points and a non-negative integer r_q (called the radius) for each $q \in C$, and (ii) a function ϕ assigning each point $p \in P$ to a center $q \in C$ such that $d(p, q) \leq r_q$. The subset $X_q = \phi^{-1}(q)$ for each $q \in C$ is called the *cluster* corresponding to q having *radius* r_q. The goal is to find a clustering $\{X_q \mid q \in C\}$ that minimizes the sum of the radii $\sum_{q \in C} r_q$.

In *(t, k)-fair sum-of-radii clustering*, we are given two disjoint groups P_1 (red) and P_2 (blue) having n points in total in a metric space $(\Omega = P_1 \cup P_2, d)$ and an integer balance parameter $t \geq 1$. A clustering is called *(t, k)-fair* if, for each cluster X, the number of points from P_1 in X is at least $1/t$ times the number of points from P_2 in X and at most t times the number of points from P_2 in X. The goal is to compute a (t, k)-fair clustering minimizing the sum of the radii of the clusters. Each cluster in a (t, k)-fair clustering is called *t-balanced*.

In *Balanced sum-of-radii clustering*, we are given $\ell \geq 2$ disjoint groups $P_1, P_2, \ldots, P_\ell$ having n points in total in a metric space $(\Omega = \cup_{i=1}^{\ell} P_i, d)$ such that $|P_1| = |P_2| = \ldots = |P_\ell|$. A clustering is called *balanced* if, for each cluster X, it holds that $|X \cap P_1| = |X \cap P_2| = \ldots = |X \cap P_\ell|$. The goal is to compute a balanced clustering that minimizes the sum of the radii of the clusters. We say that each cluster in a balanced clustering is *1-balanced*.

Consider any metric space (Ω_1, d_1) and a subset $S_1 \subseteq \Omega_1$. For any cluster Q and a point p, $d_1(p, Q) = \max_{q \in Q} d_1(p, q)$. The center of Q in S_1 is the point, $\arg\min_{p \in S_1} d_1(p, Q)$. The radius of Q w.r.t. S_1 and d_1, denoted by $r_{(S_1, d_1)}(Q)$, is the distance between Q and its center in S_1, i.e., $r_{(S_1, d_1)}(Q) = \min_{p \in S_1} d_1(p, Q)$. We refer to the sum of the radii, w.r.t. S_1 and d_1, of the clusters in any clustering $\mathcal{C}$ as the cost of $\mathcal{C}$ w.r.t. S_1 and d_1 and denote it by $\text{cost}_{(S_1, d_1)}(\mathcal{C})$.

We note that the term "(t, k)-fairness" refers specifically to the two-color case, where each cluster must maintain a red-to-blue ratio within $[1/t, t]$. This notion does not naturally extend to more than two colors. In contrast, in the multi-color setting with $\ell \geq 2$ groups, we adopt the term "balanced clustering" (or "$(1, k)$-fair clustering with ℓ groups") to describe the setting where each cluster must contain an equal number of points from each group. While we use similar notation for consistency, these two notions are structurally different and should be interpreted accordingly.

3 The Algorithm for (t, k)-Fair Sum-of-Radii Clustering

In this section, we prove Theorem 1. To set up the stage, we define the following problem.

Min-cost Degree Constrained Subgraph (Min-cost DCS). A *Degree Constrained Subgraph* (DCS) $H = (V, E')$ of a graph $G = (V, E)$ is a subgraph such that the degree of each vertex v in H is in the range $[l(v), u(v)]$ for given integers $l(v)$ and $u(v)$. Suppose we are also given a weight function $w : E \to \mathbb{R}^+ \cup \{0\}$. A min-cost DCS $H = (V, E')$ of G is a DCS that minimizes the sum of the weights of the edges in E' over all DCS.

[1] https://arxiv.org/pdf/2504.14683

▶ **Proposition 1** ([27]). Min-cost DCS *can be solved in* $O(|V|^4)$ *time.*

The proposition follows from the work of Gabow (Theorem 5.2) [27]. There the stated time complexity is $O((\sum_{i\in V} u_i)\min\{|E|\log|V|, |V|^2\})$, which is $O(|V|^4)$, as each upper-bound u_i can be assumed to be at most the degree of the i-th vertex. One technicality is that they study the maximization version (with real weights), but the minimization version can be solved by the standard method of negating edge-weights in min-cost DCS. Also see [45] that has similar discussions and an $O(|V|^6)$ time algorithm for min-cost DCS, which they call *minimum-cost many-to-many matching with demands and capacities.*

▶ **Observation 1** (∗). *A min-cost DCS with* $l(v) = 1$ *for all* $v \in V$ *does not contain a path of length three, and thus it is a disjoint union of star graphs.*

Our algorithm is as follows.

The Algorithm

1. Construct a graph $G = (V, E)$ where $V = P_1 \cup P_2$ and $E = \{\{p, q\} \mid p \in P_1, q \in P_2\}$. Define the weight function w such that for each edge $e = \{p, q\}$, $w(e) = d(p, q)$. Compute a min-cost DCS $H = (V, E')$ of G with $l(v) = 1$ and $u(v) = t$ for all $v \in V$.
2. Construct an edge-weighted graph G' in the following way: For each $p \in \Omega$, add a vertex to G'; For each star S in H, add a vertex corresponding to S to G', which we also call by S; For each $p, q \in \Omega$, add the edge $\{p, q\}$ to G' with weight $d(p, q)$; For all $p \in \Omega$ and S in H, add the edge $\{p, S\}$ to G' with weight $\max_{q\in S} d(p, q)$. Let d' be the shortest path metric in G'. Construct the metric space (Ω', d') where Ω' is the subset of vertices in G' corresponding to the stars in H.
3. Compute a sum of radii clustering $X = \{X_1, \ldots, X_k\}$ of the points in Ω' using the Algorithm of Buchem et al. [14] (with Ω' also being the candidate set of centers).
4. Compute a clustering X' of the points in $P_1 \cup P_2$ using X in the following way. For each cluster $X_i \in X$, add the cluster $\cup_{p\in S|S\in X_i}\{p\}$ to X'. Return X'.

Next, we analyze the algorithm. First, we have the following observations.

▶ **Observation 2** (∗). X' *is a* (t, k)*-fair clustering of* $P_1 \cup P_2$.

Next, we analyze the approximation factor. Let $\mathcal{C}^* = \{C_1^*, C_2^*, \ldots, C_k^*\}$ be a fixed optimal (t, k)-fair clustering. We will prove the following lemma. Our result follows as a corollary.

▶ **Lemma 1.** *Consider the clustering* X *of* Ω' *constructed in Step 3 of the algorithm. Then* $cost_{(\Omega',d')}(X) \le (\mathbf{48} + \epsilon) \cdot \sum_{i=1}^{k} r_{(\Omega,d)}(C_i^*)$.

▶ **Corollary 1** (∗). *Consider the clustering* X' *of* $P_1 \cup P_2$ *constructed in Step 4 of the algorithm. Then* $cost_{(\Omega,d)}(X') \le (\mathbf{144} + \epsilon) \cdot \sum_{i=1}^{k} r_{(\Omega,d)}(C_i^*)$. *Thus, our algorithm is a* $(\mathbf{144} + \epsilon)$*-approximation algorithm.*

3.1 Proof of Lemma 1

In the following, we are going to prove Lemma 1. Consider the min-cost DCS $H = (V, E')$ computed in Step 1. Also, consider the optimal clusters in $\mathcal{C}^*$. We construct a new clustering $\hat{\mathcal{C}} = \{\hat{C}_1, \hat{C}_2, \ldots, \hat{C}_\kappa\}$ by merging clusters in $\mathcal{C}^*$ in the following way, where $1 \le \kappa \le k$. Initially, we set $\hat{\mathcal{C}}$ to $\mathcal{C}^*$. For each edge $\{p, q\}$ of E' such that $p \in \hat{C}_i, q \in \hat{C}_j$ and $i \ne j$, replace $\hat{C}_i, \hat{C}_j$ in $\hat{\mathcal{C}}$ by their union and denote it by $\hat{C}_i$ as well.

When the above merging procedure ends, by renaming the indexes, let $\hat{\mathcal{C}}=\{\hat{C}_1,\hat{C}_2,\ldots,\hat{C}_\kappa\}$ be the new clustering. Then, we have the following observation.

▶ **Observation 3.** *Consider any star S in H. Then, for some $1\leq i\leq\kappa$, all the points of S are contained in $\hat{C}_i$.*

Consider the clustering $\mathcal{C}'=\{C'_1,\ldots,C'_\kappa\}$ of Ω' defined in the following way. For each star S in H, identify the cluster $\hat{C}_i$ in $\hat{\mathcal{C}}$ that contains all the points in S. By Observation 3, such an index i exists. Assign the point p in Ω' corresponding to S to C'_i.

▶ **Lemma 2** (∗). $cost_{(\Omega',d')}(\mathcal{C}')\leq 2\cdot\ cost_{(\Omega,d)}(\hat{\mathcal{C}})$.

We will prove the following lemma.

▶ **Lemma 3.** $cost_{(\Omega,d)}(\hat{\mathcal{C}})\leq 8\cdot\sum_{i=1}^{k} r_{(\Omega,d)}(C^*_i)$.

Lemma 1 follows by Lemma 2 and 3 noting that the Algorithm of Buchem et al. [14] yields a $(3+\epsilon)$-factor approximation to the optimal clustering (along with an appropriate scaling of ϵ). In the rest of this section, we prove Lemma 3.

3.2 Proof of Lemma 3

For simplicity of notation, we drop (Ω,d) from $r_{(\Omega,d)}(.)$, as henceforth centers are always assumed to be in Ω and the metric to be d. Let us consider any fixed $\hat{C}_i$, and suppose it is constructed by merging the clusters $C^*_{i_1},C^*_{i_2},\ldots,C^*_{i_\tau}$. It is sufficient to prove that $r(\hat{C}_i)\leq 8\cdot\sum_{j=1}^{\tau} r(C^*_{i_j})$. For simplicity of notation, we rename $\hat{C}_i$ by $\hat{C}$, and $C^*_{i_1},C^*_{i_2},\ldots,C^*_{i_\tau}$ by $C^*_1,C^*_2,\ldots,C^*_\tau$.

Let $H_1=(V_1,E_1)$ be the induced subgraph of H such that the vertices of V_1 are in $\hat{C}$. We refer to a point of P_1 (resp. P_2) as a red (resp. blue) point. Note that the edges of H are across red and blue points. In the following, we construct an edge-weighted, directed multi-graph $G^*=(V^*,E^*)$ in the following manner. G^* has a vertex v_j corresponding to each cluster C^*_j, where $1\leq j\leq\tau$. There is an edge $e=(v_i,v_j)$ from v_i to v_j for each $p\in P_1\cap C^*_i$ and $q\in P_2\cap C^*_j$ such that $\{p,q\}$ is in E_1. We refer to such an edge as a 0-edge, i.e., its parity is 0. The weight ω_e of the edge e is $d(p,q)$. Similarly, there is a 1-edge (or parity 1 edge) $e=(v_i,v_j)$ from v_i to v_j for each $p\in P_2\cap C^*_i$ and $q\in P_1\cap C^*_j$ such that $\{p,q\}$ is in E_1. The weight ω_e of the edge e is $d(p,q)$. For each edge $e_i\in E^*$, we denote the corresponding edge in E_1 by $\{r_i,b_i\}$, where r_i is the red point and b_i is the blue point. For simplicity of exposition, we are going to make heavy use of this correspondence.

▶ **Observation 4** (∗). *Suppose there is a 0-edge (resp. 1-edge) (v_i,v_j) in E^*. Then there is also a 1-edge (resp. 0-edge) (v_j,v_i) in E^*.*

A directed path (or simply a path) $\pi=\{u_1,\ldots,u_l\}$ from u_1 to u_l in G^* is a sequence of distinct vertices such that (u_i,u_{i+1}) is in G^* for all $1\leq i\leq l-1$. We say that π contains the edges (u_i,u_{i+1}). If π contains all 0-edges (resp. 1-edges), it is called a 0-path (resp. 1-path). Two consecutive edges $e_1=(u_i,u_{i+1}),e_2=(u_{i+1},u_{i+2})$ on π are said to form a *switch* if they have different parity. We say that the switch happens at u_{i+1} and it is the corresponding switching vertex. The switch is called a b-switch if the parity of e_1 is b for $b\in\{0,1\}$. A directed cycle is formed from π by adding the edge (u_l,u_1) (if any) with it. The *reverse* path of π is the path $\{u_l,\ldots,u_1\}$ that contains the edges (u_{i+1},u_i) for all $1\leq i\leq l-1$. Such edges exist according to Observation 4. A 0-path (resp. 1-path) in a subgraph of G^* starting at v_i and ending at v_j is called *maximal* if v_j does not have any outgoing 0-edges (resp. 1-edges) in the subgraph.

▶ **Observation 5** (∗). *For any two vertices $v_i, v_j \in V^*$, there is a directed path from v_i to v_j in G^*.*

Consider any two vertices v_α and v_β of G^*. Let $\pi^* = \{v_\alpha = u_1, \ldots, u_l = v_\beta\}$ be a directed path from v_α to v_β having the minimum number of switches, i.e., a *minimum-switch path* from v_α to v_β.

We prove the following lemma.

▶ **Lemma 4.** $\sum_{e\in\pi^*} \omega_e \leq 6\cdot\sum_{i=1}^{\tau} r(C_i^*)$. *Moreover, if π^* does not have a switch,* $\sum_{e\in\pi^*} \omega_e \leq 4 \cdot \sum_{i=1}^{\tau} r(C_i^*)$.

Before proving this lemma, we show how to prove Lemma 3. Consider any point p in $\hat{C}_j$. Let $p \in C_g^*$. Now, consider any point q in $\hat{C}_j$ that is the farthest point from p. Let $q \in C_h^*$. By Lemma 4 it follows that, there is a path, say π', from v_g to v_h whose sum of the edge weights is at most $6 \cdot \sum_{i=1}^{\tau} r(C_i^*)$. Then, $r(\hat{C}_j) \leq d(p,q) \leq \sum_{e\in\pi'} \omega_e + \sum_{\text{vertex } v_i\in\pi'} 2 \cdot r(C_i^*) \leq 8 \cdot \sum_{i=1}^{\tau} r(C_i^*)$.

Summing over all clusters $\hat{C}_j$ in $\hat{\mathcal{C}}$, we obtain Lemma 3.

3.3 Proof of Lemma 4

The overall idea is to show the existence of a subset of edges $E_2' \subset E$, such that the set of edges $(E' \setminus \pi^*) \cup E_2'$ form a valid degree-constrained subgraph of G on the set of vertices $P_1 \cup P_2$. Additionally, we need that the total weight of the edges of E_2' is small. Then we can show that the weight of π^* is also small, as $H = (V, E')$ is a min-cost DCS of G. However, it might not be possible to remove only the edges of π^* from E' to show the existence of such a set E_2'. We show that there is a subset $E_1' \subseteq E'$ that contains the edges of π^* and can be removed to obtain such a valid degree-constrained subgraph. In the following, we prove that obtaining two such sets E_1' and E_2' is sufficient to prove Lemma 4. For a set of edges $S \subseteq E$, let $w(S) = \sum_{e\in S} w(e)$.

▶ **Lemma 5.** *Suppose there are $E_1' \subseteq E', E_2' \subset E$, such that the set of edges $(E' \setminus E_1') \cup E_2'$ forms a valid degree-constrained subgraph of G and $w(E_2') \leq 6 \cdot \sum_{i=1}^{\tau} r(C_i^*)$. Then, $w(E_1') \leq 6 \cdot \sum_{i=1}^{\tau} r(C_i^*)$.*

Proof. Note that H is a min-cost DCS of G. Consider the graph H' induced by the set of edges $(E' \setminus E_1') \cup E_2'$. By our assumption, H' is a valid DCS of G. It follows that,

$$w(E') \leq w((E' \setminus E_1') \cup E_2'), \text{or, } w(E_1') \leq w(E_2') \leq 6 \cdot \sum_{i=1}^{\tau} r(C_i^*).$$

The last inequality follows from our assumption. ◀

Assuming that the conditions of the above lemma are true, we finish the proof of Lemma 4.

$$\sum_{e\in\pi^*} \omega_e = \sum_{(v_i,v_j)\in\pi^*} \omega_e$$

$$= \sum_{\{p,q\} \text{ corresponding to } (v_i,v_j)\in\pi^* | p\in C_i^*, q\in C_j^*} w(\{p,q\}) \leq w(E_1') \leq 6 \cdot \sum_{i=1}^{\tau} r(C_i^*).$$

If π^* does not have a switch, then we will show that $w(E_2') \leq 4 \cdot \sum_{i=1}^{\tau} r(C_i^*)$. Hence, the moreover part in Lemma 4 also follows. It is left to show the existence of such E_1' and E_2'.

3.4 Construction of E'_1 and E'_2

Two subgraphs G_1 and G_2 of G^* are called *0-1-edge-disjoint* if for any edge e_{η^1} of G_1 and e_{η^2} of G_2, the corresponding edges in E' are distinct. Thus, if G_1 contains a 0-edge (v_i, v_j), and G_1 and G_2 are 0-1-edge-disjoint, then G_2 cannot contain the 0-edge (v_i, v_j) and the 1-edge (v_j, v_i). Similarly, if G_1 contains a 1-edge (v_i, v_j), and G_1 and G_2 are 0-1-edge-disjoint, then G_2 cannot contain the 1-edge (v_i, v_j) and the 0-edge (v_j, v_i). Let $j^1 < j^2 < \ldots < j^\lambda$ be the indexes of the vertices on $\pi^* = \{u_1, \ldots, u_l\}$ where the switches occur. Note that $j^1 > 1, j^\lambda < l$. Denote the switch that occurs at u_{j^h} by b^h for all $1 \leq h \leq \lambda$ (i.e., b^h is the parity of (u_{j^h-1}, u_{j^h})). Let b^0 be the parity of (u_1, u_2) and $b^{\lambda+1}$ be the parity of (u_{l-1}, u_l).

First, we consider the simple case when the parity of (u_{l-1}, u_l) is 0 (resp. 1) and there is a 0-path (resp. 1-path) from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*. Let us denote the latter path by $\pi(l)$. Note that π^* is a path having the minimum number of switches and the existence of $\pi(l)$ ensures that π^* does not have a switch. Let $U_0 \subseteq E^*$ be the subset of edges that lie on the paths in $\{\pi^*\} \cup \{\pi(l)\}$. Next, we define a subset $E'_1 \subseteq E_1$ that has a one-to-one mapping with U_0. In particular, consider any edge (v_i, v_j) in U_0. Note that if it is a 0-edge, it was added due to an edge $\{p, q\}$ in E_1 such that $p \in P_1 \cap C^*_i$ and $q \in P_2 \cap C^*_j$. We add the edge $\{p, q\}$ to E'_1. Otherwise, if (v_i, v_j) is a 1-edge, it was added due to an edge $\{p, q\}$ in E_1 such that $p \in P_2 \cap C^*_i$ and $q \in P_1 \cap C^*_j$. In this case, we add the edge $\{p, q\}$ to E'_1.

Next, we show the construction of E'_2. Wlog, let us assume that π^* is a 0-path. The other case is symmetric. Note that then $\pi(l)$ is also a 0-path as per our assumption. First, we describe the process of adding the replacement edges for the path π^*. Consider any intermediate vertex (if any) $v_{j'}$ on this path. Then, there are exactly two points in $C^*_{j'}$ corresponding to the edges on π^*, which are of opposite colors. We add an edge between these two points in E'_2 (see Figure 1). Removal of the edges of E'_1 corresponding to π^* and the addition of this edge do not change the degree of the two points in $C^*_{j'}$. Similarly, we add edges to E'_2 corresponding to the intermediate vertices of $\pi(l)$. Next, consider the vertex $u_l = v_i$. There is an incoming 0-edge on π^* and an outgoing 0-edge on $\pi(l)$ that are incident on v_i. Thus, there are exactly two points in C^*_i of opposite colors corresponding to these two edges. We add an edge between these two points in E'_2. Removal of the edges of E'_1 corresponding to those two edges, and the addition of this edge does not change the degree of the two points in C^*_i. Similarly, consider the vertex $u_1 = v'_i$. There is an outgoing 0-edge on π^* and an incoming 0-edge on $\pi(l)$ that are incident on v'_i. Thus, there are exactly two points in $C^*_{i'}$ of opposite colors corresponding to these two edges. We add an edge between these two points in E'_2. Again, the removal of the edges of E'_1 corresponding to those two edges, and the addition of this edge does not change the degree of the two points in $C^*_{i'}$. See Figure 1 for an illustration.

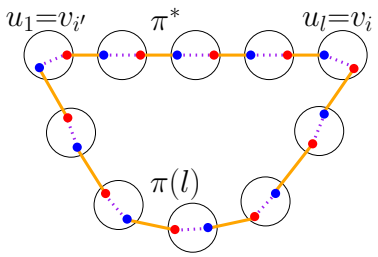

Figure 1 Figure illustrating the construction of E'_2 for $\{\pi^*\} \cup \{\pi(l)\}$. The bold (orange) edges are in E'_1 and the dashed (purple) edges are in E'_2.

By our construction, the set of edges $(E' \setminus E'_1) \cup E'_2$ form a valid degree-constrained subgraph of G on the set of vertices $P_1 \cup P_2$. The way we add the edges to E'_2, both endpoints of each edge lie in a cluster C^*_j such that the vertex v_j corresponding to the cluster lies on a path in $\{\pi^*\} \cup \{\pi(l)\}$. Now, v_j can lie either on one such path or on two paths. Thus, we add at most two edges to E'_2 corresponding to v_j. The sum of the weights of these two edges is at most 2 times the diameter of C^*_j. Hence, by Lemma 5, we obtain $\sum_{e \in \pi^*} \omega_e \leq 4 \cdot \sum_{i=1}^{\tau} r(C^*_i)$.

Next, we consider the remaining case when the parity of (u_{l-1}, u_l) is 0 (resp. 1) and there is no 0-path (resp. 1-path) from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*. Thus, there is no $b^{\lambda+1}$-path from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*.

Consider a path π and let v_i denote its start vertex. Also, consider a cycle O such that π and O have exactly one vertex v_j in common. Note that π might not have an edge, in which case $v_j = v_i$. Let D be the graph formed by the union of π and O, i.e., by gluing them together at v_j. We refer to such a graph D as a *hanging cycle* for v_i with v_j being the *join* vertex. D is called a b-hanging cycle if all the edges of π and O are b-edges. Let p be the point in the cluster C^*_j corresponding to the edge of the cycle O incoming to v_j. Additionally, D is called *special* if the degree of p in H_1 is at least 2, and p is called the *special* point of D (see Figure 2).

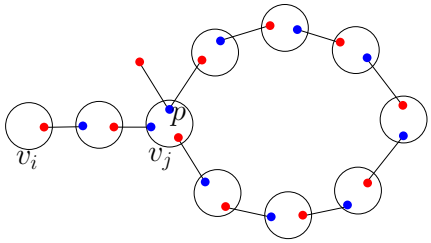

Figure 2 A special hanging cycle with the special point p.

In the current case, we need the following lemmas.

▶ **Lemma 6** (∗). *Suppose the parity of (u_{l-1}, u_l) is 0 (resp. 1), and there is no 0-path (resp. 1-path) from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*. Moreover, suppose there is no special 0-hanging cycle (resp. 1-hanging cycle) in G^* for u_l that is 0-1-edge-disjoint from π^*. Then, there exists a 0-path (resp. 1-path) π_1 in G^* from u_l to a vertex v_j, such that π_1 is 0-1-edge-disjoint from π^* and one of the following is true: (i) the degree of b_η (resp. r_η) in H_1 is at least 2, where e_η is the last edge on π_1 if it has an edge or (u_{l-1}, u_l) otherwise; or (ii) C^*_j has a red (resp. blue) point whose degree in H_1 is at most $t-1$.*

▶ **Lemma 7** (∗). *Suppose the parity of (u_1, u_2) is 1 (resp. 0), and there is no 1-path (resp. 0-path) from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*. Moreover, suppose there is no special 0-hanging cycle (resp. 1-hanging cycle) in G^* for u_1 that is 0-1-edge-disjoint from π^*. Then, there exists a 0-path (resp. 1-path) π_1 from u_1 to a vertex v_j, such that π_1 is 0-1-edge-disjoint from π^* and one of the following is true: (i) the degree of b_η (resp. r_η) in H_1 is at least 2, where e_η is the last edge on π_1 if it has an edge or (u_2, u_1) otherwise, and (ii) C^*_j has a red (resp. blue) point whose degree in H_1 is at most $t-1$.*

Next, we apply the above lemmas to show the construction of E'_1 and E'_2. **Recall that in this case there is no $b^{\lambda+1}$-path from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*.** If π^* has a switch, then there is no 0-path or 1-path from u_l to u_1 in G^* that is

0-1-edge-disjoint from π^*. Otherwise, it must be that $b^0 = b^{\lambda+1}$, and hence by our assumption, there is no b^0-path from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*. We conclude that in this case ($b^0 = b^{\lambda+1}$), there is no b^0-path from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*. Then, by Lemma 7 it follows that, either there is a $(1-b^0)$-hanging cycle for u_1 in G^* 0-1-edge-disjoint from π^*, or a $(1-b^0)$-path starting from u_1 in G^* with special properties. This is true, as the parity of (u_1, u_2) is b^0. We denote this structure by $\pi(0)$. Additionally, if $\pi(0)$ is a path, we call b_η (resp. r_η) an *anchor* point if its degree in H_1 is at least 2. Similarly, by Lemma 6 it follows that, either there is a $b^{\lambda+1}$-hanging cycle for u_l in G^* 0-1-edge-disjoint from π^*, or a $b^{\lambda+1}$-path starting from u_l in G^* with special properties. This is true, as (u_{l-1}, u_l) is a $b^{\lambda+1}$-edge. We denote this structure by $\pi(\lambda+1)$. Additionally, if $\pi(\lambda+1)$ is a path, we call b_η (resp. r_η) an *anchor* point if its degree in H_1 is at least 2.

Now, if $\mathbf{1 - b^0 \neq b^{\lambda+1}}$, then $\pi(0)$ and $\pi(\lambda+1)$ must be vertex-disjoint. If they are not vertex-disjoint, there exists a $b^{\lambda+1}$-path from u_l to u_1 in G^* that is 0-1-edge-disjoint from π^*: take the edges on $\pi(\lambda+1)$ from u_l to a common vertex and the reverse of $\pi(0)$, from the common vertex to u_1. These reverse edges have parity opposite of $1-b^0$, i.e., the same as $b^{\lambda+1}$. But, by our assumption, such a $b^{\lambda+1}$-path does not exist. Hence, $\pi(0)$ and $\pi(\lambda+1)$ are vertex-disjoint.

In the other case, $\mathbf{1 - b^0 = b^{\lambda+1}}$. We note that if π^* has no switch, $b^0 = b^{\lambda+1}$. Thus, if $1 - b^0 = b^{\lambda+1}$, then we can safely assume that π^* has at least one switch. In this case, suppose there are a $(1-b^0)$-hanging cycle for u_1 and a $b^{\lambda+1}$-hanging cycle for u_l in G^*, such that both are 0-1-edge-disjoint, each of the hanging cycles is 0-1-edge-disjoint from π^*, and either the special vertices of both are distinct or the special points are the same and the degree of that point in H_1 is at least 3. Then, we take the hanging cycle for u_1 as $\pi(0)$ and the one for u_l as $\pi(\lambda+1)$. Otherwise, if there is a $(1-b^0)$-hanging cycle for u_1 in G^* 0-1-edge-disjoint from π^* or a $b^{\lambda+1}$-hanging cycle for u_l in G^* 0-1-edge-disjoint from π^*, we consider one of those. Assume that the former holds. The other case is symmetric. We take such a hanging cycle for u_1 as $\pi(0)$. Then, one can prove that there is a $b^{\lambda+1}$-path from u_l in G^* with special properties (Lemma 8 in the full version). We take this $b^{\lambda+1}$-path as $\pi(\lambda+1)$. Otherwise, there is neither a $(1-b^0)$-hanging cycle for u_1 in G^* 0-1-edge-disjoint from π^* nor a $b^{\lambda+1}$-hanging cycle for u_l in G^* 0-1-edge-disjoint from π^*. Then, one can prove that there are two 0-1-edge-disjoint paths with parity $1 - b^0 = b^{\lambda+1}$, from u_1 and u_l, respectively, such that both are also 0-1-edge-disjoint from π^* (Lemma 9 in the full version). In this case, we take the path from u_1 as $\pi(0)$ and the path from u_l as $\pi(\lambda+1)$.

For all $1 \leq h \leq \lambda$, if there are two 0-1-edge-disjoint b^h-hanging cycles for u_{j^h} in G^* that are 0-1-edge-disjoint from π^* and have distinct special points or the same special point of degree at least 3 in H_1, denote them by $\pi_1(h)$ and $\pi_2(h)$. Otherwise, if there is one b^h-hanging cycle for u_{j^h} in G^* that is 0-1-edge-disjoint from π^*, denote it by $\pi_1(h)$. Now, (u_{j^h-1}, u_{j^h}) is a b^h-edge and (u_{j^h}, u_{j^h+1}) is a $(1-b^h)$-edge. Then, one can prove that there is a b^h-path starting from u_{j^h} in G^* with special properties (Lemma 8 in the full version). Denote this path by $\pi_2(h)$. Otherwise, there is no b^h-hanging cycle for u_{j^h} in G^* that is 0-1-edge-disjoint from π^*. In this case, one can prove that there are two b^h-paths starting from u_{j^h} in G^* with special properties. Denote them by $\pi_1(h)$ and $\pi_2(h)$. Note that in all the cases, $\pi()$, $\pi_1()$ or $\pi_2()$ can either be a path or a hanging cycle.

Construction of E'_1. Let $U \subseteq E^*$ be the subset of edges that lie on the structures in $\mathcal{S} = \cup_{i=1}^{\lambda}(\{\pi_1(i)\} \cup \{\pi_2(i)\}) \cup \{\pi(0), \pi(\lambda+1), \pi^*\}$. Next, we define the subset E'_1 of E' that has a one-to-one mapping with U. In particular, consider any edge (v_i, v_j) in U. Note that if it is a 0-edge, it was added due to an edge $\{p, q\}$ in E_1 such that $p \in P_1 \cap C_i^*$ and $q \in P_2 \cap C_j^*$. We add the edge $\{p, q\}$ to E'_1. Otherwise, if (v_i, v_j) is a 1-edge, it was added due to an edge $\{p, q\}$ in E_1 such that $p \in P_2 \cap C_i^*$ and $q \in P_1 \cap C_j^*$. We again add the edge $\{p, q\}$ to E'_1.

Our proof is completed by the following two lemmas.

▶ **Lemma 8** (∗). *There is a subset of edges $E'_2 \subset E$, such that the set of edges $(E' \setminus E'_1) \cup E'_2$ form a valid degree-constrained subgraph of G on the set of vertices $P_1 \cup P_2$.*

4 The Algorithm for Balanced Sum-of-Radii Clustering

In this section, we prove Theorem 2. Recall that we are given ℓ disjoint groups $P_1, \ldots, P_\ell$ having n points in total in a metric space $(\Omega = \cup_{i=1}^{\ell} P_i, d)$, such that $|P_1| = |P_2| = \ldots = |P_\ell|$.

Our algorithm is as follows.

The Algorithm

1. For each $2 \leq i \leq \ell$, construct a graph $G_i = (V_i, E_i)$ where $V_i = P_1 \cup P_i$ and $E_i = \{\{p, q\} \mid p \in P_1, q \in P_i\}$. Define the weight function w_i such that for each edge $e = \{p, q\}$, $w_i(e) = d(p, q)$. Compute a minimum-weight (w.r.t. w_i) perfect matching M_i of G_i. For each $p \in P_1$, let S_p be the union of $\{p\}$ and the points from $P_2, \ldots, P_\ell$ that are matched to p in $M = \cup_{i=2}^{\ell} M_i$.
2. Construct an edge-weighted graph G' in the following way: For each $p \in \Omega$, add a vertex to G'; For each $p \in P_1$, add a vertex corresponding to S_p to G', which we also call by S_p; For each $p, q \in \Omega$, add the edge $\{p, q\}$ to G' with weight $d(p, q)$; For all $p' \in \Omega$ and $p \in P_1$, add the edge $\{p', S_p\}$ to G' with weight $\max_{q \in S_p} d(p', q)$. Let d' be the shortest path metric in G'. Construct the metric space (Ω', d') where Ω' is the subset of vertices $\{S_p \mid p \in P_1\}$ in G'.
3. Compute a sum of radii clustering $X = \{X_1, \ldots, X_k\}$ of the points in Ω' using the Algorithm of Buchem et al. [14] (with Ω' also being the candidate set of centers).
4. Compute a clustering X' of the points in $\cup_{i=1}^{\ell} P_i$ using X in the following way. For each cluster X_i, add the cluster $\cup_{q \in S_p | S_p \in X_i} \{q\}$ to X'. Return X'.

Let $\mathcal{C}^* = \{C_1^*, C_2^*, \ldots, C_k^*\}$ be a fixed optimal balanced clustering.

We have the following lemma. Our main result follows as a corollary.

▶ **Lemma 9** (∗). *Consider the clustering X of Ω' constructed in Step 3 of the algorithm. Then $cost_{(\Omega', d')}(X) \leq (\mathbf{60} + \epsilon) \cdot \sum_{i=1}^{k} r_{(\Omega, d)}(C_i^*)$.*

▶ **Corollary 2** (∗). *Consider the clustering X' of $\cup_{i=1}^{\ell} P_i$ constructed in Step 3 of the algorithm. Then $cost_{(\Omega, d)}(X') \leq (\mathbf{180} + \epsilon) \cdot \sum_{i=1}^{k} r_{(\Omega, d)}(C_i^*)$. Thus, our algorithm is a $(\mathbf{180} + \epsilon)$-approximation algorithm.*

Abstract

The connected k-median problem is a constrained clustering problem that combines distance-based k-clustering with connectivity information. The problem allows to input a metric space and an unweighted undirected connectivity graph that is completely unrelated to the metric space. The goal is to compute k centers and corresponding clusters such that each cluster forms a connected subgraph of G, and such that the k-median cost is minimized.

The problem has applications in very different fields like geodesy (particularly districting), social network analysis (especially community detection), or bioinformatics. We study a version with overlapping clusters where points can be part of multiple clusters which is natural for the use case of community detection. This problem variant is $\Omega(\log n)$-hard to approximate, and our main result is an $\mathcal{O}(k^2 \log n)$-approximation algorithm for the problem. We complement it with an $\Omega(n^{1-\epsilon})$-hardness result for the case of disjoint clusters without overlap with general connectivity graphs, as well as an exact algorithm in this setting if the connectivity graph is a tree.

1 Introduction

Clustering problems, like the k-center and the k-median problem, are classical optimization problems that have been widely studied both in theory and practice. In a typical center-based clustering problem, the input consists of a given set of data points in some metric space and a positive integer k. The goal is to partition the data points into k groups (clusters) and to find a center for each of these groups so as to optimize some objective: In the k-center problem, the goal is to minimize the maximal distance of any point to the center of its cluster; in the k-median problem, the goal is to minimize the sum of the distances of the points to their corresponding cluster centers.

Both the k-center and the k-median problem are NP-hard but various constant-factor approximation algorithms are known. For the k-center problem, there are 2-approximation algorithms [9, 13], and this is best possible [14]. The best known approximation algorithm for the k-median problem achieves a $(2.675 + \epsilon)$-approximation [2], while it is known that no approximation factor better than $1 + 2/e \approx 1.735$ can be achieved, unless P=NP [10].

Beyond these vanilla clustering problems, there has been a lot of interest in variants of clustering problems motivated by specific applications. These variants often introduce additional constraints. For example, in capacitated clustering problems, constraints are added that limit the number of data points that can be assigned to each cluster [17]. There are also models to address outliers in data sets [18], and in the last decade, different variants of fair clustering problems have been studied [4, 20, 21]. These are just a few examples of the numerous variants of clustering problems that have been studied to address diverse challenges in different application domains. Each of these variants requires specialized algorithms, often inspiring novel methodologies and insights in the broader field of clustering and data analysis.

In this paper, we study a *connectivity* constraint. The basic idea of this constraint is that clusters have to correspond to connected subgraphs of a given undirected and unweighted *connectivity graph*. This graph is independent of the metric that defines the distances between the input points.

This model has been studied in different contexts. One line of research, see Ge et al. [8], considers the connected k-center problem to allow for a joint analysis of two type of data: attribute data and relationship data. Attribute data can be used for clustering by finding a suitable metric distance function on the attribute vectors and then applying a popular clustering method like k-means or k-center. Relationship data arises in the context of social networks or other network structures and gives information on pairwise relationships. Clustering on relationship data can be done via methods like correlation clustering. Both types of data thus allow for well studied clustering methods, but the focus by Ge et al. [8] is a joint analysis. Connected clustering gives one option to combine relationship and attribute data by defining a constraint based on the relationships and then optimizing over the attribute vector distances.

More precisely, connected clustering expects as input a set of points in a metric space (stemming from the attribute data) and an unweighted graph G (representing the relationship data), and the goal is to cluster with respect to the metric distance function but under the constraint that clusters are connected in G. We call G the *connectivity graph* in the following.

Ge et al. [8] study the connected k-center problem. For this problem, the goal is to compute k centers $c_1, \ldots, c_k$ and corresponding clusters $C_1, \ldots, C_k$ such that all C_i are connected in the connectivity graph G, and such that the largest radius is minimized (the radius of C_i is $\max_{x \in C_i} d(x, c_i)$). They provide an optimal algorithm via dynamic programming for the special case of a tree connectivity graph which was rediscovered by Drexler et al. [6] in a later publication. Ge et al. also present algorithms for the general case with unknown approximation guarantee[1] and provide an experimental evaluation.

The best-known approximation guarantee for the connected k-center problem is a $O(\log^2 k)$-approximation given by Drexler et al. [6]. For Euclidean metrics with constant dimension and metrics with constant doubling dimension, they provide an $O(1)$-approximation algorithm. Their paper studies the problem from a very different context: Motivated by an application from geodesy and sea level analysis, they use the distance function to model differences in tide gauge measurements and the connectivity graph to model geographic closeness, and their modelling results in the same problem definition as Ge et al. [8].

[1] There is a proof in the paper that claims a guarantee of 6, but [6] gives a counterexample.

In this paper, we study the connected k-*median* problem, i.e., the related problem with the k-median objective instead of the k-center objective. We give a formal definition now.

▶ **Definition 1** (Connected k-Median Problem (disjoint))**.** *In an instance of the (disjoint) connected k-median problem, we are given a set V of points, a metric $d : V \times V \to \mathbb{R}_{\geq 0}$ on V, a positive integer $k \geq 2$, and an unweighted and undirected connectivity graph $G = (V, E)$. A feasible solution is a partition of V into k disjoint clusters $\mathcal{V} = \{V_1, \dots, V_k\}$ with corresponding centers $C = \{c_1, c_2, \dots, c_k\} \subseteq V$ which satisfies that for every $i \in [k] := \{1, \dots, k\}$ the subgraph of G induced by V_i is connected and $c_i \in V_i$. The* connected k-median problem *aims to find a feasible solution $(C, \mathcal{V})$ that minimizes*

$$\Phi_{med}(C, \mathcal{V}) := \sum_{i \in [k]} \sum_{v \in V_i} d(c_i, v).$$

The connected k-median has also appeared in different contexts. For example, Validi et al. [22] study connected k-median for a districting problem. Here the goal is to partition given administrative or geographic units into districts. The clusters should usually correspond to connected areas on the map which can be formulated via introducing centers for each unit and a graph to model which units are neighbors on the map. The k-median objective is one way to model compactness of districts. Validi et al. [22] study various districting methods, and connected k-median is one of them. They solve it via an integer linear programming approach, i.e., to optimality but with exponential worst-case running time. A related variant is the connected k-means problem, which for example has been considered in [19] where a heuristic approach to minimize it is employed.

Gupta et al. [12] study k-median/k-means from the point of view of approximation algorithms. They consider the special case where the number of clusters is $k = 2$ and the connectivity graph is star-like (there exists a point that is connected to all other points). The paper shows that even this case is $\Omega(\log n)$-hard to approximate for both problems and proposed an $O(\log n)$-approximation algorithm for this special case. There is nothing known about the general case, and our work is motivated by the following question:

Can the connected k-median problem be approximated for general connectivity graphs?

Unfortunately, we quickly arrive at the conclusion that no reasonable approximation guarantee is possible if $P \neq NP$ (see Thm 4). We do derive a dynamic programming based exact algorithm for trees that runs in time $O(n^2k^2)$ (see Thm 6), thus extending the landscape for the problem, but the answer to our main question is still negative.

However, our inapproximability proof depends on a subtlety of the problem definition: The clusters V_i have to be disjoint. This is a natural assumption in clustering, and in clustering without constraints, clusters can be assumed to be disjoint (adding a point to multiple clusters will in general only increase the objective). But here, if we allow for overlapping clusters, then satisfying connectivity can become easier because we can add critical vertices like articulation points to multiple clusters. This motivates the definition of *connected k-median with non-disjoint clusters.*

▶ **Definition 2** (Disjoint vs. non-disjoint clusters)**.** *In the* connected k-median problem with disjoint clusters*, we require the clusters $V_1, \dots, V_k$ to be pairwise disjoint. In the* connected k-median problem with non-disjoint clusters*, the clusters are allowed to overlap and we only require $V = \bigcup_{i \in [k]} V_i$.*

One may note that if a vertex appears in multiple clusters it will also contribute to the objective function multiple times. Thus also in the non-disjoint variant, we are incentivized to avoid assigning vertices unnecessarily often.

The non-disjoint version has also been studied previously. For example, Drexler et al. [6] study it for k-center and give a 2-approximation for this case. From the application side, it depends on the interpretation whether disjoint or non-disjoint clusters are preferred. In districting, units should certainly not be in multiple clusters. But for the application of community detection in social networks the modeling is natural since individuals can belong to different groups. We thus study the following question.

Can the connected k-median problem with non-disjoint clusters be approximated for general connectivity graphs?

The proof by Gupta et al. [12] gives a lower bound of $\Omega(\log n)$ for the disjoint case. For the sake of completeness, we provide in the full version of this paper an adapted version that also works if the clusters may overlap [7]. Our main result is a $O(k^2 \log n)$-approximation for the connected k-median problem with non-disjoint clusters.

Before we summarize our results, we need one more definition. For a clustering problem with constraints, the corresponding *assignment* version of the problem asks for assigning points to given centers while respecting the constraints and minimizing the cost. In our case, we get the following problem.

▶ **Definition 3** (Assignment version)**.** *In the* assignment version *of the connected k-median problem, we assume that k centers, denoted as $C \subseteq V$, are given and the goal is to find a feasible assignment of the points in V to the centers C such that the k-median costs are minimized. This version can be defined both for the disjoint and the non-disjoint variant of the connected k-median problem.*

Without a constraint, the assignment version of the k-median problem can be solved optimally by assigning every point to its closest center. For clustering with constraints, assignment problems can be difficult: For example, the assignment problem for fair k-center is NP-hard [1], and the connected k-center with disjoint clusters is also NP-hard [6] (both problems are even hard to approximate better than 3). We will establish an even higher lower bound for the assignment problem in the connected k-median setting.

1.1 Our results

Table 1 Overview of the results presented in this work.

(a) Our results in the non-disjoint setting

	Assignment version	Regular version
Approximation	$O(k \log(n))$ (Theorem 8)	$O(k^2 \log(n))$ (Theorem 9)
Hardness($k = 2$)	$\Omega(\log(n))$ (Theorem 7)	

(b) Our results in the disjoint setting. All results also hold for the assignment version.

	General Graph	Tree graph
Approximation	$O(n \log^2(k))$ (Theorem 5)	1 (Theorem 6)
Hardness($k = 2$)	$\Omega(n^{1-\epsilon})$ (Theorem 4)	–

We prove new approximation and hardness results for the connected k-median problem, both for the disjoint and the non-disjoint variant. Table 1 provides a brief overview of them. First we establish a strong hardness of approximation result for the connected k-median problem with disjoint clusters, which even holds in the special case that $k = 2$.

▶ **Theorem 4.** *For any $\epsilon > 0$, there is no polynomial-time $O(n^{1-\epsilon})$-approximation algorithm for the connected k-median problem with disjoint clusters even if $k = 2$, unless $P = NP$. For the assignment version, this lower bound also holds.*

For completeness we point out that one can almost match this lower bound using the connected k-center algorithm by Drexler et al. [6]:

▶ **Theorem 5.** *For the disjoint connected k-median problem, there is a polynomial-time algorithm with approximation factor $O(n \log^2 k)$.*

Another important special case that has also been studied for the connected k-center problem is the case that the connectivity graph is a tree. For this special case, we obtain a polynomial-time algorithm based on dynamic programming.

▶ **Theorem 6.** *When the connectivity graph G is a tree, then the connected k-median problem with disjoint clusters can be solved optimally in time $O(n^2k^2)$. This is true even if the distances are not a metric or the centers are given.*

Motivated by applications like community detection, in which the clusters do not necessarily have to be disjoint, we also study the connected k-median problem with non-disjoint clusters. This problem is $\Omega(\log n)$-hard to approximate even if $k = 2$.

▶ **Theorem 7.** *There is a constant $c > 0$ such that for all sufficiently large n, the non-disjoint connected k-median problem cannot be approximated within a factor of $c \cdot \log n$ unless P=NP, even when $k = 2$. The same is true for the assignment variant.*

Our main result are approximation algorithms for the clustering and the assignment problem whose approximation factors match this lower bound in terms of n.

▶ **Theorem 8.** *For the assignment version of the non-disjoint connected k-median problem, there is a polynomial-time algorithm with approximation factor $O(k \log n)$. This is true even if the distances are not a metric.*

▶ **Theorem 9.** *For the non-disjoint connected k-median problem, there is a polynomial-time algorithm with approximation factor $O(k^2 \log n)$.*

1.2 Outline

The remainder of this paper focuses on the non-disjoint variant. For the disjoint results we refer to the full version [7]. In Section 2.1 we present our algorithm for the assignment version and in Section 2.2 we give an overview on how the centers can be found. The full description and analysis of the latter algorithm as well as the hardness proof for this setting can again be found in the full version of this work.

2 Non-disjoint Connected k-Median Problem

2.1 Assignment Version

The high-level idea to solve the assignment version of the connected k-median problem is to first define an LP formulation for it and compute an optimum fractional solution for the LP relaxation in polynomial time. Using an observation that the connected clusters are similar to so called node weighted Steiner trees we can use this LP solution to obtain k instances of

the node weighted Steiner tree problem such that every node needs to be contained in at least one Steiner tree and there exist a fractional solution for each of these instances such that the total cost of these solutions is bounded by k times the optimum LP solution. Using a primal-dual algorithm by Klein and Ravi [15] we are able to find integral Steiner trees that cost at most $O(\log n)$ times as much as the respective fractional solutions and which directly form k connected clusters assigning each node to at least one center. In total, this gives us an approximation factor of $O(k \log n)$.

Now we will define the LP formulation. For that, we use the following definition of cuts:

▶ **Definition 10** (Vertex Cuts). *For two arbitrary nodes $v, w \in V$, a (v,w)-*cut *is a subset $S \subseteq V$ such that all paths from v to w in G contain at least one node in S. The set of all (v,w)-cuts is denoted by $\mathcal{S}_{v,w}$.*

Using this, we can reformulate the requirement that a node v must be connected to its assigned center c by ensuring that for any (v,c)-cut $S \in \mathcal{S}_{v,c}$, at least one node in S is also assigned to c. This gives us the following LP-formulation of the non-disjoint connected k-median problem:

$$\begin{aligned}
\min \quad & \sum_{c \in C, v \in V} d(v,c) x_v^c & & \\
\text{s.t.} \quad & \sum_{c \in C} x_v^c \geq 1, & & \forall v \in V, \\
& \sum_{v' \in S} x_{v'}^c \geq x_v^c, & & \forall v \in V, c \in C, S \in \mathcal{S}_{v,c}, \\
& x_v^c \in \{0,1\}, & & \forall c \in C, v \in V,
\end{aligned} \tag{1}$$

where for all $v \in V$, $c \in C$ the variable x_v^c indicates whether v is assigned to c ($x_v^c = 1$) or not ($x_v^c = 0$). While the first constraint ensures, that each point v must belong to at least one cluster, the second constraint ensures that the clusters are connected, i.e., if v is connected to center c, then in each (v,c)-cut, there must be at least one point assigned to c. To relax this problem we drop the integrality constraint and only require that $x_v^c \geq 0$ for all $v \in V$, $c \in C$.

It is worth noting that the linear program may have exponential size, as there can be exponentially many (v,c)-cuts for a given pair v, c. However, since the separation problem can be solved in polynomial time and there also exists an alternative flow-based formulation of the LP with polynomial size [7], it remains possible to find the optimum fractional LP-solution in polynomial time.

Let $\tilde{x}$ be such an optimum fractional solution. By Markov's inequality it is easy to verify that for any $v \in V$ there exists at least one $c \in C$ such that $\tilde{x}_v^c \geq \frac{1}{k}$. By multiplying all values with k, we get a new LP solution x with $x_v^c := k\tilde{x}_v^c$ for all $v \in V, c \in C$ where each node is assigned to at least one center in its entirety. But even if for a $v \in V, c \in C$ it holds that $x_v^c \geq 1$ there may still exist (v,c)-cuts not containing any nodes fully assigned to c. To deal with this problem we need some results shown for node weighted Steiner trees.

▶ **Definition 11** (Node Weighted Steiner Tree Problem). *In an instance of the* node weighted Steiner tree problem *we are given a graph $G = (V,E)$, a set of terminal nodes $T \subseteq V$ and a weight function $w : V \to \mathbb{R}_{\geq 0}$. The goal is to find a subset $S \subseteq V$ such that $T \subseteq S$, the nodes of S form a connected subgraph of G, and the sum $\sum_{v \in S} w(v)$ is minimized.*

Similar as for the connected k-median problem there also exists an LP relaxation for the node weighted Steiner tree problem:

$$\begin{aligned} \min \quad & \sum_{v \in V} w(v) x_v \\ \text{s.t.} \quad & \sum_{v' \in S} x_{v'} \geq 1, \quad \forall u, v \in T, S \in \mathcal{S}_{u,v}, \\ & x_v^c \geq 0, \quad \forall v \in V, \end{aligned} \tag{2}$$

One might note that the assignment version of the connected k-median problem is closely related to the node weighted Steiner tree problem as one could reinterpret the problem as finding k node weighted Steiner trees such that each node is contained in at least one Steiner tree. The distances of the nodes to the respective centers can in this context be interpreted as k different node weight functions for the different trees. Using the solution x we will now define for any center $c \in C$ the set $T_c := \{c\} \cup \{v \mid x_v^c \geq 1\}$. Then the solution x can be subdivided into k solutions for the Steiner tree LP using the respective sets $(T_c)_{c \in C}$ as terminals.

▶ **Lemma 12.** *Let $(x_v^c)_{v \in V, c \in C}$ be a solution for LP (1). Then for any center $c \in C$ the values $(x_v^c)_{v \in V}$ form a solution for LP (2) with $T := T_c$ and $w(v) := d(v, c)$.*

Proof. This lemma is proved by contradiction. Assume that $(x_v^c)_{v \in V, c \in C}$ is a solution for LP (1) that violates some constraint of LP (2). Then there exist two terminals $u, v \in T_c$ and an (u, v)-cut S such that

$$\sum_{v' \in S} x_{v'}^c < 1.$$

Now we distinguish two cases. In the first case let c be one of the nodes $\{u, v\}$, w.l.o.g. $u = c$. Then we can use the definition of LP (1) and T_c to obtain

$$\sum_{v' \in S} x_{v'}^c \geq x_v^c = 1,$$

which contradicts the assumption.

In the second case both $u \neq c$ and $v \neq c$. Then by the previous argument S can neither separate u nor v from c because then its weight would be at least 1. Thus there exists a path from u to c and from c to v not containing any nodes in S. But then there also exists a path from u to v not using any nodes in S and S would not be a (u, v)-cut. ◀

This lemma is crucial because for the node weighted Steiner tree problem there exists an $O(\log n)$-approximation algorithm by Klein and Ravi [15] for which Guha et al. [11] later proved that it is implicitly a primal-dual algorithm and that the cost of the solution is at most $O(\log n)$ times worse than any fractional solution of LP (2). Alternatively Könemann et al provided a more detailed primal-dual algorithm for a generalized version of the node weighted Steiner tree problem ensuring the same guarantees [16]. Using these algorithms and Lemma 12 we are able to subdivide x into k Steiner tree LP solutions that can each be transformed into a feasible cluster.

▶ **Theorem 8.** *For the assignment version of the non-disjoint connected k-median problem, there is a polynomial-time algorithm with approximation factor $O(k \log n)$. This is true even if the distances are not a metric.*

Proof. In the first step of the algorithm we will first calculate an optimum solution $\tilde{x}$ for the relaxed version of LP (1) which as argued above can be done in polynomial time. Since every assignment solution for the connected k-median problem is also an LP solution, the costs of $\tilde{x}$ are upper bounded by the optimum value OPT. After multiplying the values by k, the cost of solution x is then again bounded by $k \cdot \mathrm{OPT}$.

Consider T_c as defined above, by Markov's inequality for every node v there exists a center c such that $\tilde{x}_v^c \geq \frac{1}{k}$ which means that $v \in T_c$. Thus we have $\bigcup_{c \in C} T_c = V$. By Lemma 12 the fractional solution x can be split up into k solutions of the Steiner tree LP (2) with the respective terminal sets $(T_c)_{c \in C}$ such that the total sum of the objective value is exactly the cost of x.

By applying the algorithm by Klein and Ravi [15] with $T = T_c$ and $w(v) = d(v, c)$ for every $c \in C$ separately, one obtains a Steiner tree S_c with $T_c \subseteq S_c$ whose cost is upper bounded by $O(\log n)$ times the cost of the respective LP solution. Thus one obtains in polynomial time k Steiner trees each connecting the respective terminal set T_c and total cost bounded by $O(\log n)$ times the objective value of x which results in an upper bound of $O\left(k \log n\right) \mathrm{OPT}$. Since every node is contained in at least one of these Steiner trees, this directly yields the desired solution for the assignment version of the non-disjoint connected k-median problem.

This proof works even if the distances are not a metric because it does not use any of their properties. ◀

One may note that this approach works with any approximation algorithm for the node weighted Steiner tree problem whose cost is bounded by the optimum LP solution. For some restricted graph classes, including planar graphs, Demaine et al. [5] provided a primal dual algorithm calculating a constant approximation. Thus the approach can also be used to get an $O(k)$-approximation (and $O(k^2)$ if the centers are not given) for these kind of connectivity graphs.

2.2 Finding Centers

In this section we give an overview how suitable centers for the non-disjoint connected k-median problem can be found. For a more detailed description of the procedure and its analysis we refer to the full version of this paper [7]. First we will again provide a suitable ILP formulation:

$$
\begin{aligned}
\min \quad & \sum_{v,c \in V} d(v,c) x_v^c & & \\
\text{s.t.} \quad & \sum_{c \in V} x_v^c \geq 1, & & \forall v \in V, \\
& \sum_{c \in V} x_c^c \leq k, & & \\
& \sum_{v' \in S} x_{v'}^c \geq x_v^c, & & \forall v, c \in V, S \in \mathcal{S}_{v,c}, \\
& x_v^c \in \{0,1\}, & & \forall v, c \in V,
\end{aligned} \tag{3}
$$

where $\mathcal{S}_{v,c}$ denotes the set of vertex cuts, separating v and c, defined as in the previous section.

The main difference to the assignment variant is that we do now allow to assign nodes to any other nodes and not only to some predefined centers. However, by definition of $\mathcal{S}_{v,c}$, it holds that $\{c\} \in \mathcal{S}_{v,c}$ for any $v, c \in V$. Thus x_v^c will automatically be limited by x_c^c. This naturally leads to the property that nodes can only be assigned to c if $x_c^c = 1$. Thus limiting $\sum_{c \in V} x_c^c$ by k directly ensures that any solution of the ILP uses at most k centers.

If we relax the integrality constraint and only require that $x_v^c \geq 0$ for all $v, c \in V$ also LP (3) can be solved in polynomial time despite its exponential size. The drawback of this is that for arbitrarily many nodes $c' \in V$ it can hold that $x_{c'}^{c'} > 0$ if the respective values are sufficiently small. This means that other nodes can at least partially be assigned to them and we will call the value $x_{c'}^{c'}$ the *opening* of c'.

The main focus of this section is to move these openings to a limited set of k centers that will be determined by our algorithm such that reassigning the nodes accordingly is not too expensive. To do this, we follow a similar approach as the LP rounding algorithm for k-median by Charikar et al. [3]. In the first step, we will find a solution in which every node is opened either by at least $\frac{1}{2}$ or not opened at all (limiting the number of centers to $2k$). In the latter steps these openings will then be made integral by first finding possible replacements for some of the centers, which possibly allows us to close the respective centers, and then choosing a subset of the centers of size k such that for every center itself or its replacement is contained in this subset.

We will relax the connectivity constraint during the algorithm. We say for an $\alpha \in [0, 1]$ that an assignment $(x_v^c)_{v,c \in V}$ is an α-connected solution if $\sum_{c \in V} x_c^c \leq k$, $\forall v \in V : \sum_{c \in V} x_v^c \geq 1$ and for all $v, c \in V$ and all cuts $S \in \mathcal{S}_{v,c}$ separating v and c it holds that $\sum_{v' \in S} x_{v'}^c \geq \min(\alpha, x_v^c)$. To simplify notation, we will denote the weight of the minimum cut between two nodes v and c (with respect to the values $(x_{v'}^c)_{v' \in V}$) by $\mathrm{sep}^x(v, c) = \min_{S \in \mathcal{S}_{v,c}} \sum_{v' \in S} x_{v'}^c$. Then the last requirement can be reformulated as $\mathrm{sep}^x(v, c) \geq \min(\alpha, x_v^c)$. It is easy to verify that an assignment corresponds to a fractional solution for LP (3) if and only if it is 1-connected.

Now we give an overview over the different steps of the algorithm. Our main focus will lie on the first step, which ensures that all centers will be half opened afterwards. This is due to the fact that it introduces the largest amount of novel ideas and necessary modifications compared to the existing algorithm by Charikar et al.:

Step 1. To obtain half-opened centers, let an optimal (fractional) LP solution $\tilde{x}$ be given. For each v, let its mass be defined as $m_v = \sum_{c \in V} \tilde{x}_v^c$, its cost (or price) as $p_v = \sum_{c \in V} \tilde{x}_v^c \cdot d(v, c)$ and its (average) radius as $r_v = \frac{p_v}{m_v}$. We say that an assignment of a node v to another node c is *good* if $d(v, c) \leq 4r_v$. Since $m_v \geq 1$ for all nodes $v \in V$, we may observe that because of Markov's inequality at least $\frac{3}{4}$ of v gets assigned via good assignments, i.e., $\sum_{c \in V : d(v,c) \leq 4r_v} \tilde{x}_v^c \geq \frac{3}{4}$.

We will simultaneously maintain two assignments $(x_v^c)_{v,c \in V}$ and $(y_v^c)_{v,c \in V}$ such that for all $v, c \in V$ initially $x_v^c = \tilde{x}_v^c$ and $y_v^c = 0$ and that at the end of the algorithm $x_v^c = 0$. The final values of y_v^c will be the assignment using half opened centers. During the algorithm, the combination of x and y will always be a $\frac{1}{8k}$-connected solution, which means that the following inequalities stay satisfied throughout the entire process:

$$\sum_{c \in V} (x_v^c + y_v^c) \geq 1 \qquad \forall v \in V \tag{4}$$

$$\sum_{c \in V} (x_c^c + y_c^c) \leq k \tag{5}$$

$$\sum_{v' \in S} x_{v'}^c \geq x_v^c \qquad \forall v, c \in V, S \in \mathcal{S}_{v,c} \tag{6}$$

$$\sum_{v' \in S} y_{v'}^c \geq \min\left(\frac{1}{8k}, y_v^c\right) \qquad \forall v, c \in V, S \in \mathcal{S}_{v,c} \tag{7}$$

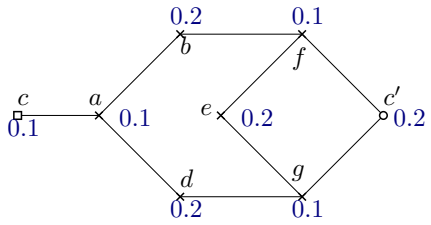

Figure 1 A sketch depicting a situation in which, at least if we require 1-connectivity, the total assignment needs to increase if we apply a shift from c' to c. The blue values denote the assignments of the respective nodes to c' before the shift, i.e., the $x_v^{v'}$-values. We assume that $x_v^c = 0$ for all nodes v. Now if we apply a shift from c' to c by $x_c^{c'} = 0.1$, both c' and c have an opening of 0.1. Thus the nodes b, d, e all need to be assigned to c and c' with value 0.1. If we would try to find assignments of a, f and g such that for each node its total assignment to c and c' is exactly 0.1 we would need to set $x_g^{c'} = x_f^{c'} = 0.1$ to ensure the connectivity of b and d to c'. However this would mean that $y_f^c = y_g^c = 0$ which would separate e from c. Thus to ensure connectivity, for at least one node the total assignment after the shift needs to be larger than the assignment before the shift.

The algorithm will now maintain an initially empty center set C and repeat in an alternating order the following two steps: First it decides for an additional node whether it gets added to the center set or not (in the latter case it will be added to a so called environment of an already existing center). Afterwards it shifts some openings in x (the x_c^c that are greater than 0) to already chosen centers c in C.

To get an intuition regarding the shifts, it can be beneficial to sometimes think about the connectivity constraints not from a cut-perspective but to rather interpret the assignments as flows. Using the max-flow min-cut theorem, it is easy to see that if we interpret the values $(x_{v'}^{c'})_{v' \in V}$ as node capacities then there exists a flow from a node v to a node c' of value f exactly if $\text{sep}^x(v, c') \geq f$. Thus our connectivity constraint implies that there always exists a flow from v to c' of value $x_v^{c'}$. By basically reverting this flow for a center $c \in C$ and a node $c' \in V$ we are able to shift an opening of value $x_c^{c'}$ from c' to c. One important question is now how the nodes that were previously assigned to c' get assigned. If $x_c^{c'}$ was equal to $x_{c'}^{c'}$, the entire opening of c' can be shifted and we can simply reassign all nodes to c by setting $y_v^c = y_v^c + x_v^{c'}$ and $x_v^{c'} = 0$ for any $v \in V$. However, if $x_c^{c'}$ was smaller than $x_{c'}^{c'}$ only a fraction of the opening of c' gets shifted and we basically have to split up the previous assignments to c' between c and c'. As Figure 1 shows this can lead to situations in which the total assignment to c and c' after this shift actually needs to be larger than the assignment before this shift. Since it is actually rather involved to determine the new values in this situation, a formal description will only be provided in the full version of this work. To get an intuition regarding the algorithm it is for now sufficient to only consider the first case.

Since either way also the assignments of nodes assigned to c' have to be shifted in this situation, we have to make sure that the distances of the respective shifts are not too large which the algorithm will ensure by only allowing shifts with a rather small distance between c and c' in the beginning and increasing this distance over time. More details will follow later.

While the shifts depend on the chosen centers C, the choice whether a node v will be added to C in turn depends on the shifts that have already been performed before v gets considered by the algorithm. The algorithm terminates once it has decided for every node whether it gets added to C and all openings in x have been shifted.

To determine which nodes should be added to C, we iterate over all nodes ordered by their radii in increasing order and check whether we can open them by at least $\frac{1}{2}$. To be more precise, a node v will be chosen as a center if the sum of the remaining good assignments $(x_v^{c'})_{c' \in V}$ is at least $\frac{1}{2}$. The construction of the algorithm will ensure that it will shift at least

all remaining openings belonging to good assignments of v to v itself which means that v will be at least half opened. When v is added to the center set we also create its environment $S_v = \{v\}$, which initially only contains v itself.

In the case that v does not get chosen as a center, we know that there were at least $\frac{1}{4}$ of good assignments of v that have already been shifted to other centers in C. Since every center in C gets at least half opened and the entire opening is limited by k, we know that $|C| \leq 2k$ and thus there exists at least one center to which $\frac{1}{8k}$ of the good assignments of v have been shifted. One critical property of the algorithm will be that before v gets considered, the distance between the source c' and target c of any shift will be at most $4r_v$. Thus for any good assignment to a node z whose opening has been shifted to a center c we have that $d(v,c) \leq d(v,z) + d(z,c) \leq 8r_v$. As a result we may conclude that there exists a center $c \in C$ such that $y_v^c \geq \frac{1}{8k}$ while $d(v,c) \leq 8r_v$ and we add v to the environment S_c of the closest center c fulfilling these requirements.

Adding v to this environment allows us to shift some openings of a node c' with $x_v^{c'} > 0$ over the node v to c even if there does not exist a direct flow from c to c' (i.e., c is not assigned to c'). The intuition behind this is that we first revert the flow from v to c' and thus are already shifting the opening to v. Now by combining $y_v^c \geq \frac{1}{8k}$ and Property (7) we know that already before this shift the minimum cut between v and c has value at least $\frac{1}{8k}$. Thus if we are moving the opening (and the assignments to it) to c instead of v itself we know that the solution still stays $\frac{1}{8k}$-connected. Furthermore since v and c are not too far apart, we know that the distances of these shifts does not increase too much compared to a direct shift to v. This will help us ensuring that if the openings of some nodes, to which v got assigned, get shifted to some other centers then the distance added by this shift will not be too large.

Every time after a new node v gets added to either C or to an environment S_c of a center $c \in C$ we will go over all possible shifts ordered by their distances in increasing order, and perform all shifts with distance at most $4r_{\text{next}}$, where r_{next} denotes the radius of the next node that will be considered by the algorithm. Note that any shift with radius $\leq 4_{r_v}$ can only result from the addition of v to S_c or C because any shift not involving v would already have been applied in the last iteration (as r_v is the previous value of r_{next}). As a result all those shifts will be performed before any shift not involving v will be executed. This directly guarantees that if v is added to C then all openings belonging to good assignments will be shifted to v, which ensures that v is half opened.

An important property of the shifts is that if we shift some opening of a node $c' \in V$ over a node $v \in V$ then afterwards $x_v^{c'} = 0$ which ensures that for all $v, c' \in V$ we will only shift some opening of c' over v at most once, limiting the number of shifts by $|V|^2$. Additionally after we have added v to C or a set S_c there always exists a possible shift while $x_v^{c'} > 0$ for a $c' \in V$. Thus, it is possible to execute the described algorithm for a polynomial time until for every $v, c' \in V$, $x_v^{c'} = 0$ and then return $(y_v^c)_{v \in V, c \in C}$. A pseudocode summarizing the structure of the described procedure can be found in Algorithm 1. The cost of the resulting $\frac{1}{8k}$-connected solution is bounded by $O(k)$ times the cost of the LP solution $\tilde{x}$.

Step 2. Now we would like to reduce the number of centers to at most k. However, if we want to reduce the opening of a center $c \in C$ to 0, we will need to find a suitable replacement, i.e., another center $\tilde{c}$ such that reassigning all nodes assigned to c to $\tilde{c}$ neither costs too much nor violates our connectivity constraints (which is further relaxed to $\frac{1}{16k}$-connectivity). To do this we will need two properties of Algorithm 1:

- For any node v we know that if a shift from another node c' to a center c caused v to be (partially) assigned to c then the radius r_c of c can be bounded by the radius r_v of v and the distance from v to c'. To be more precise $r_c \leq d(v,c') + 2r_v$. Intuitively, if this

Algorithm 1 The general structure of the first step.

```
Order v_1, ..., v_n according to their radii (r_v)_{v∈V} in increasing order
for v_1, ..., v_n do
    Decide whether v_i is added to the center set C or to an environment S_c of a
     center c ∈ C
    while A shift from a node v to a center c ∈ C with d(v, c) ≤ r_{v_{i+1}} is possible do
        Apply the cheapest shift
    end
end
```

was not the case, then the algorithm would have shifted some opening of c' either to v itself (if v gets chosen as a center) or over v to another center $\tilde{c} \in C$ with $v \in S_{\tilde{c}}$ before c was even added to the center set which would have prevented v from being assigned to c. The main consequence of this property is that if we can find another center $\tilde{c}$ that is only a constant times r_c away from c then reassigning all nodes that are currently assigned to c, to $\tilde{c}$ instead costs not too much.

- Additionally for any center c it holds that if c got assigned to another center $\tilde{c}$ because some opening got shifted from a node c' to c then it holds that $d(c, \tilde{c})$ is bounded by $d(c, c') + \max(4r_c, d(c, c'))$ because otherwise a shift from c' to c would have happened before the shift to $\tilde{c}$. Since the average length of the original assignments of c was r_c, one can use this to identify a center $\tilde{c}$ that is not too far apart from c.

Using these two properties, we are able to split up C into two sets C_1 and $C_{1/2}$ such that for every center $c \in C_{1/2}$ we have a successor $s(c) \in C$ such that the total cost that occurs if we replace any center in $C_{1/2}$ by its successor would not be too large and $|C_1| + \frac{1}{2}|C_{1/2}| \leq k$. Later we will then open all nodes in C_1 as well as at most half the nodes in $C_{1/2}$ to obtain a integral center set C^* such that for all nodes in $C_{1/2}$ either the node itself or its successor is contained in C^*.

To obtain these sets, we consider an arbitrary center $c \in C$ and define $a_c = 1 - y_c^c$. Then at least a total value of a_c of the openings corresponding to the initial assignments of c (the values $\tilde{x}_c^{c'}$ for any $c' \in V$) were shifted to other centers. If a_c has value at least $\frac{1}{4}$, we are able to use Markov's inequality together with the second property to identify another center $\tilde{c}$ such that $d(c, \tilde{c})$ lies within $O(r_c)$ and c is already sufficiently connected to $\tilde{c}$ (i.e., $y_c^{\tilde{c}} \geq \frac{1}{16k}$). We thus can set $s(c) = \tilde{c}$ and add c to $C_{1/2}$.

However, if a_c is rather small then it can be that all assignments of c to other centers $\tilde{c}$ only resulted from shifts of nodes c' to $\tilde{c}$ that are really far apart from c which means that $\tilde{c}$ can be even further away. Additionally the assignments $y_c^{\tilde{c}}$ might also be quite small which means that we would need to increase some existing assignments to $\tilde{c}$ to ensure $\frac{1}{16k}$-connectivity if we replace c by $\tilde{c}$. However, if there are multiple centers where the respective value a_c is small then we know that since $\sum_{c \in C}(1 - a_c) = \sum_{c \in C} y_c^c \leq k$ that if we add one of these centers to $C_{1/2}$ we can add multiple others to C_1. Since we do not need a replacement for the centers in C_1, we can use a careful potential argument to redistribute parts of the replacement cost of the centers added to $C_{1/2}$ to the centers in C_1 to bound the additional cost among all nodes.

Step 3. To decide which centers in $C_{1/2}$ can be closed we have a look at the directed Graph $G_{1/2} = (C_{1/2}, S)$, where $S = \{(c, s(c)) \mid c, s(c) \in C_{1/2}\}$ contains for any center in $C_{1/2}$ an edge to its successor if the latter is again contained in $C_{1/2}$. If this graph is bipartite we can simply take the smaller half of this partition and add this to the center set C^*. Then for every

edge one of its two endpoints is contained in C^* which ensures that for every center either itself or its successor is contained in C^*. However, the graph might not directly be bipartite because it can contain cycles of uneven length. But we can ensure by being a little bit more careful in step 2 that any of these cycles contains at most one center c with $a_c < \frac{1}{4}$. Using this, we can remove the respective cycles and thus obtain a bipartite graph. For all centers in $C_{1/2}$ not added to C^*, we reassign all nodes assigned to them to the respective successor $s(c)$. Since we bounded the cost of replacing all centers in $C_{1/2}$ and are only replacing a subset of them, the total cost of this is again bounded. The entire cost still stays in $O(k)$ times the cost of the fractional LP solution $\tilde{x}$.

Step 4. After step 3, we have an $\frac{1}{16k}$-connected solution only using integral centers. However the assignments might still be fractional. By multiplying the assignments by $16k$ the solution becomes 1-connected and similarly as for the assignment version in Section 2.1 we obtain that for every node v there exists at least one center c such that $x_v^c \geq 1$. Again applying the primal dual algorithm for node weighted Steiner trees, we obtain an entirely integral solution:

▶ **Theorem 9.** *For the non-disjoint connected k-median problem, there is a polynomial-time algorithm with approximation factor $O(k^2 \log n)$.*

Abstract

Indexing data is a fundamental problem in computer science. The input is a set S of n distinct integers from a universe $\mathcal{U}$. Indexing queries take a value $q \in \mathcal{U}$ and return the `membership`, `predecessor` or `rank` of q in S. A `range` query takes two values $q, r \in \mathcal{U}$ and returns the set $S \cap [q, r]$.

Recently, various papers study a special case where the the input data behaves in an approximately piece-wise linear way. Given the sorted (rank,value) pairs, and given some constant ε, one wants to maintain a small number of axis-disjoint line-segments such that, for each rank, the value is within $\pm\varepsilon$ of the corresponding line-segment. Ferragina and Vinciguerra (VLDB 2020) observe that this geometric problem is useful for solving indexing problems, particularly when the number of line-segments is small compared to the size of the dataset.

We study the dynamic version of this geometric problem. In the dynamic setting, inserting or deleting just one data point may cause up to three line-segments to be merged, or one line-segment to be split at most three-way. To determine and compute this, we use techniques from dynamic maintenance of convex hulls, and provide new algorithms with worst-case guarantees, including an $O(\log n)$ algorithm to compute a separating line between two non-intersecting convex hulls – an operation previously missing from the literature.

We then use our fully-dynamic geometry-based subroutine in an indexing data structure, combining it with a natural hashing technique. The resulting indexing data structure has theoretically efficient worst-case guarantees in expectation. We compare its practical performance to the solution of Ferragina and Vinciguerra, which was shown to perform better in certain structured settings [Sun, Zhou, Li VLDB 2023]. Our empirical analysis shows that our solution supports more efficient range queries in the special case where the update sequence contains many deletions.

1 Introduction

We investigate the use of *learned indices* for the design of *dynamic indexing data structures*.

Indexing data structures. An indexing data structure maintains a set S of n distinct integers from a universe $\mathcal{U}$. Let $\text{RANK} : S \to [n]$ be the function mapping each $s \in S$ to its index in the sorted order of S. The objective is to support the following indexing queries:

- `member(`q`)` returns `true` if $q \in S$.
- `predecessor(`q`)` returns $\max\{t \in S \mid t < q\}$. (We allow $q \notin S$.)
- `rank(`q`)` returns $\text{RANK}(\texttt{predecessor}(q)) + 1$. (We allow $q \notin S$.)

Additionally, we consider *range queries*, where k denotes the output size:

- `range(`q`, `t`)` returns $S \cap [q, t]$. (We allow $q, t \notin S$.)

Static indexing data structures fall into three broad categories: *Tree-based solutions* store S in a sorted array A, requiring no additional space but incurring logarithmic query costs. Tree traversals enable `predecessor`, `rank`, and `member` queries in $O(\log n)$ time and range queries in $O(\log n + k)$ time [1, 3, 32, 37]. *Map-based solutions* store S in sorted order and maintain a hash map $H : S \to [n]$ mapping each element to its rank [4, 23, 31]. This enables constant-time support for `member`, `predecessor`, and `rank` queries if queries are restricted to elements of S, and $O(k)$ time for `range` queries when both endpoints lie in S. The additional space is $O(n)$. A third category use what are called *learned indices*, a recently introduced term [24, 20, 16, 22, 8]. Given an integer parameter ε, a learned index is a function $h_\varepsilon : \mathcal{U} \to [0, n]$ such that

$$h_\varepsilon(q) \in [\texttt{rank}(q) - \varepsilon, \texttt{rank}(q) + \varepsilon].$$

The function h_ε is learned from S and used to guide search in a sorted array A storing S. Ferragina and Vinciguerra [16] interpret h_ε geometrically: each $s \in S$ maps to a point $(\text{RANK}(s), s)$ in the plane, and h_ε is learned as a piecewise-linear approximation to F_S.

A notable instance of learned indices is the *PGM index* [16], where h_ε is a y-monotone piecewise-linear function made of segments, with the property that each point in F_S lies within an ε-wide horizontal strip around some segment. Let $|h_\varepsilon|$ denote the number of segments. The data structure supports indexing queries in $O(\varepsilon + \log |h_\varepsilon|)$ time and range queries in $O(\varepsilon + k + \log |h_\varepsilon|)$ time. They also show how to construct a PGM index in linear time, such that there exists no PGM index h'_ε with $|h_\varepsilon| > 2|h'_\varepsilon|$. Ferragina and Vinciguerra argue that learned indices are the "best of both worlds" since:

- the supported queries are as general as those supported by tree-based solutions,
- the solution uses only $O(|h_\varepsilon|)$ additional space, and
- $O(\varepsilon + \log |h_\varepsilon|)$ is, for an appropriate choice of ε, efficient in practice.

Their performance has been empirically benchmarked in several studies [15, 24, 38, 37].

Dynamic indexing data structures. Due to their fundamental role, dynamic indexing structures have received extensive theoretical and practical attention. When S is dynamic, maintaining a sorted array becomes inefficient. Tree-based structures can be updated in $O(\log n)$ time with tree rotations. Map-based approaches allow constant-time `member` updates but are typically not extended to support other indexing queries. Learned indices offer a promising direction by exploiting structural properties of S, akin to parametrised algorithms. However, just as parametrised algorithms, data structures based on learned indices are not always efficient: if S lacks exploitable structure or access patterns are skewed, traditional

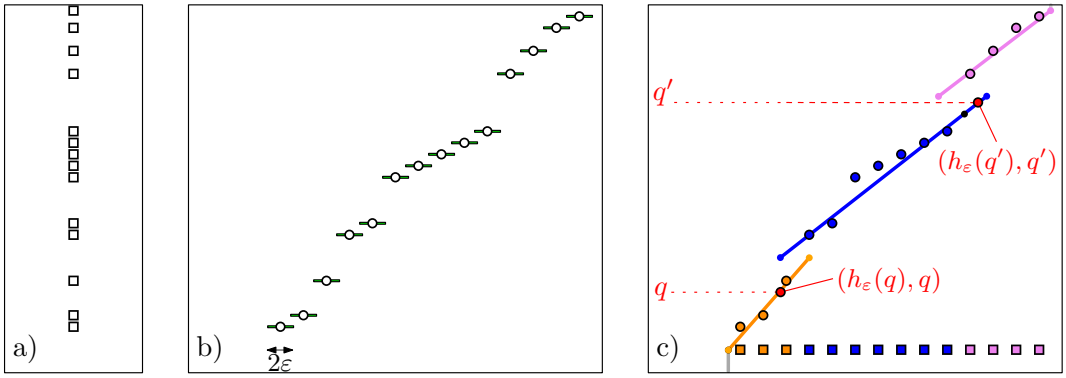

Figure 1 (a) a set of n values S. (b) S corresponds to an xy-monotone point set F_S. (c) The PGM index computes a y-monotone set of segments that starts and ends with a vertical halfline.

indexing data structures are preferred [33, 26]. Experimental studies have examined properties of learned indices [14, 13, 26, 33], in an effort to classify when they are appropriate to use. As a brief summary, learned indices pay a price in updates [26], and traditional indices are preferred if S or the access pattern is complex or skewed, or if concurrency is possible [33]. If there is sufficient structure, both space usage and access times can benefit from learned indices [13, 14], subject to the strategy employed by the learned index.

Dynamic learned indices through the logarithmic method. The logarithmic method of Overmars [29] provides an amortised way to maintain learned indices. S is partitioned into $\lceil \log n \rceil$ buckets B_i, each of size 2^i. Each bucket is either full or empty, and stores its contents in an array A_i in sorted order and maintains a learned index h^i_ε over A_i.

Let the learned index h_ε have a construction time of $T(n)$. This data structure can be maintained insertion-only in amortised $O(T(n) \log n)$ time. An insertion inserts a new value into B_0. Let j be the maximum integer such that all B_i for $i \in [0, j-1]$ are full. This approach empties these buckets, fills B_j in sorted order, and constructs (A_j, h^j_ε) in $O(T(2^j))$ time. Whenever we delete some $s \in S$, this approach instead inserts a *tombstone* s^*, which is a special copy of s. If an insertion fills a new bucket B_j, it first iterates over all elements. If B_j contains both s and s^*, it removes both elements. It then constructs (A_j, h^j_ε) twice. Once on all "normal" values, and once on all tombstones in B_j. This way, deletions take the same time as insertions do. In this paper, we consider the following open question:

"Can a learned index be dynamically be maintained with worst-case guarantees?"

Intermezzo: computing a line cover. The interpretation of learned indices by Ferragina and Vinciguerra [16] translates to a geometric problem where the goal is to (approximately) cover a monotone set of two-dimensional points by a set of line segments. Using the logarithmic method, and the static algorithm of O'Rourke [27] to approximately points, they dynamically maintain an ε-*cover*: a set of lines that are guaranteed to be within an ε horizontal distance from each point. We consider the problem of maintaining dynamic ε-covers to be an interesting geometric problem in its own right.

From learned indices to indexing data structures. Under the logarithmic method, indexing queries decompose naturally across the buckets:

- For `member`(q), $q \in S$ if and only if there exists an $i \in [\lceil \log n \rceil]$ with $q \in B_i$.
- For `predecessor`(q), the output is the maximum predecessor across B_i for $i \in [\lceil \log n \rceil]$.

- For `rank`(q), the rank is the sum of all ranks of q in B_i for $i \in [\lceil \log n \rceil]$.
- For `range`(q, t), the reported range is the union of all ranges in B_i for $i \in [\lceil \log n \rceil]$.

This way, indexing queries require only an additional factor $O(\log n)$ time. Indexing queries can be answered by combining queries to both the normal and tombstone structures. E.g., `rank`(q) is the rank of q in the "normal" data structure minus the rank of q in the tombstone structure. This approach has two downsides:

- First, approach has an amortised update time.
- Second, this approach does not support output-sensitive range queries – as there may be $O(n)$ values s that (together with their tombstones s^*) lie in between a query pair (q, t).

This leads to the following open question:

> "Can a dynamic learned index be converted into an output-sensitive dynamic indexing data structure with worst-case guarantees?"

Contribution and organization. We propose maintaining a dynamic ε-cover (and thereby a dynamic learned index) via dynamic convex hull techniques. Section 3 shows that deciding whether S admits an ε-cover of complexity 1 is equivalent to convex hull intersection testing (Figure 2). Section 4 shows a robust algorithm to compute the intersection between two convex hulls in $O(\log n)$ time. We adapt our algorithm to output a separating line (which is a learned index of complexity 1) in the negative case. Section 5 combines these with dynamic convex hull data structures to yield a dynamic learned index worst-case $O(\log^2 n)$ update time. We empirically compare our learned index to the PGM index from [16].

Section 6 introduces a novel hashing-based approach to convert learned indices into dynamic indexing data structures, using $O(\varepsilon^{-1})$ additional expected overhead. We compare our dynamic indexing structure to the amortised PGM index of [16] in terms of update time and index complexity. We do not benchmark against traditional indexing data structures – since the relation between learned and traditional indices is previously studied [33]. Instead, our goal is to push the theoretical limits and worst-case guarantees of learned indices.

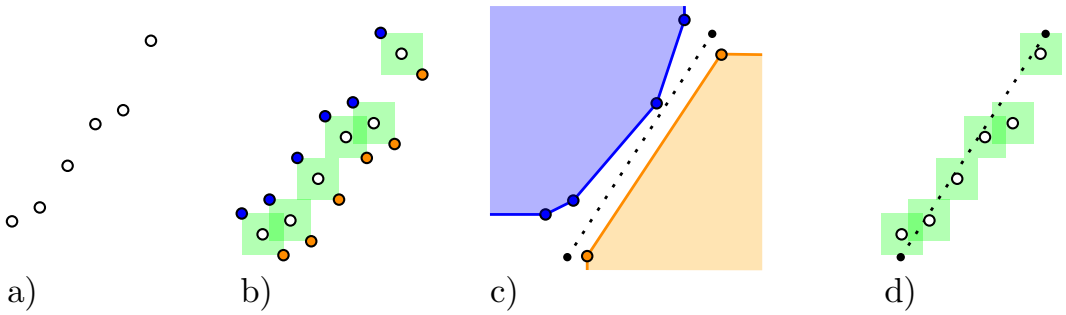

Figure 2 For any set F_S, we construct two convex hulls. We prove that there exists a segment ℓ within L_∞-distance ε of all points in F_S if and only if these hulls do not intersect. We adapt the convex hull intersection testing algorithm to find ℓ whenever these hulls are disjoint.

2 Preliminaries

The input is a dynamic set S of n distinct positive integers from some universe $\mathcal{U}$. For $a, b \in \mathbb{Z}$ with $a \leq b$, we define $S[a, b]$ as the set $S \cap [a, b]$. We denote by F_S the two-dimensional point set obtained by mapping each $s \in S$ to $(\text{RANK}(S), s)$. Throughout this paper, we distinguish between positions and strict positions. E.g., lying above or strictly above a line.

▶ **Definition 1** ([16]). *Let ε be a positive integer. A* PGM index h_ε *of S is defined as a y-monotone set of segments that together cover the y-axis. We regard h_ε as a map from y-coordinates to x-coordinates and require that for all $q \in \mathcal{U}$, $h_\varepsilon(q) \in [\texttt{rank}(q)-\varepsilon, \texttt{rank}(q)+\varepsilon]$.*

Ferragina and Vinciguerra [16, Lemma 1] wrongfully claim an $O(n)$-time algorithm to compute a minimum complexity PGM index h_ε. They invoke a streaming algorithm by O'Rourke [27] for fitting straight lines through data ranges. We show that this algorithm outputs a PGM index h_ε such that there exists no PGM index h'_ε with $|h_\varepsilon| > 2h'_\varepsilon$ (see the full version for details). Their algorithm restricts S to contain no duplicates. We assume the same setting and compute something slightly different as we define an ε-cover instead:

▶ **Definition 2.** *Let ε be a positive integer. We define an ε-cover f of S as a set of vertically separated segments with slope at least 1 where all $(r, s) \in F_S$ are within L_∞-distance ε of f.*

An ε-cover has a functionality and complexity similar to a learned index:

▶ **Observation 3.** *Let f be an ε-cover and Q be a horizontal line with height $q \in [\min S, \max S]$. Let (s, t) be the segment in f closest to q. Then $(line(s, t) \cap Q).x \in [\texttt{rank}(q)-2\varepsilon, \texttt{rank}(q)+2\varepsilon]$.*

▶ **Observation 4.** *For fixed ε, let k denote the minimum complexity of any PGM index of S. If f is an ε-cover of S of minimum complexity, then f contains at most $k-2$ edges.*

▶ **Definition 5.** *For any fixed ε-cover f of S, we define $\Lambda(f)$ as the set of pairwise interior-disjoint one-dimensional intervals that correspond to the y-coordinates of segments in f.*

Dynamic convex hulls. We dynamically maintain an ε-cover f of S of approximately minimum complexity. To this end, we use a result by Overmars and van Leeuwen [30] to dynamically maintain for all $[a, b] \in \Lambda(f)$ the convex hull of $F_{S[a,b]}$. For any point set F, denote by $CH(F)$ their convex hull. The data structure in [30] is a balanced binary tree over F, which at its root maintains a balanced binary tree over the edges $CH(F)$ in their cyclical ordering. It uses $O(n)$ space and has worst-case $O(\log^2 n)$ update time.

Rank-based convex hulls. For any update in S, up to n values in F_S may change their x-coordinate. This complicates the maintenance of a dynamic data structure over F. Gæde, Gørtz, van Der Hoog, Krogh, and Rotenberg [17] observe that all algorithmic logic in [30] requires only the *relative* x-coordinates between points. They adapt [30] to give an efficient and robust implementation of what they call *a rank-based convex hull* data structure $T(S)$ with $O(\log^2 n)$ update time. For ease of exposition, we overly simplify their functionality:

For each $[a, b] \in \Lambda(f)$, we store $S[a, b]$ in $T(S[a, b])$. $T(S[a, b])$ maintains a balanced binary tree $\gamma(S[a, b])$ storing the edges of $\mathrm{CH}(F_{S[a,b]})$ in their cyclical ordering. We use this data structure as a black box, using the following functions that take at most $O(\log^2 n)$ time:

- $T(S[a, b])$.`get_hull()` returns the tree $\gamma(S[a, b])$.
- $T(S[a, b])$.`split(`v`)` returns, for $v \in [a, b]$, $T(S[a, v])$ and $T(S[v, b])$.
- $T(S[a, b])$.`split(`$T([S[b, c])$`)` returns $T(S[a, c])$.
- $T(S[a, b])$.`update(`v`)` updates, for $v \in [a, b]$, the set S (deleting or inserting v).

3 Testing whether a set can be ε-covered by a single segment

We consider the following subproblem: given a parameter ε, a set S of n distinct integers, and the edges of $\mathrm{CH}(F_S)$ stored in a balanced binary tree, can we compute in $O(\log n)$ time whether there exists an ε-cover f of complexity 1? Formally, we seek a line ℓ of slope at least

1 such that all points in F_S lie within L_∞-distance ε of ℓ. Let L (resp. U) denote the set obtained by shifting each $p \in F_S$ downwards and rightwards (resp. upwards and leftwards) by ε, and adding the point $(\infty, -\infty)$ (resp. $(-\infty, \infty)$).

▶ **Lemma 6.** *Let ℓ be a line of slope at least 1. Then all points in F_S lie within L_∞-distance ε of ℓ if and only if ℓ lies below all points in U and above all points in L.*

Proof. Any line with positive slope lies above $(\infty, -\infty)$ and below $(-\infty, \infty)$. Consider a point $p \in F_S$ and the two corresponding points $l \in L$ and $u \in U$ and denote by C an axis-aligned square of radius ε centred at p. If ℓ lies below l then all points on ℓ left of l lie below C. If ℓ lies above u then all points on ℓ right of u lie above C. If ℓ lies above l and below u then because ℓ has positive slope, it must intersect C. The statement follows. ◀

▶ **Corollary 7.** *ℓ is an ε-cover of S iff it has a slope ≥ 1 and separates $CH(L)$ from $CH(U)$.*

Given $\mathrm{CH}(F_S)$, we can extract $\mathrm{CH}(L)$ and $\mathrm{CH}(U)$ in $O(\log n)$ time. Chazelle and Dobkin [6, Section 4.2] remark that, in the negative case, convex hull intersection testing can be modified to produce a separating line. In our setting, the hulls consist of segments with slope at least 1, and any such separator corresponds to an ε-cover. Thus, our problem reduces to the classical convex hull intersection problem and we are seemingly done.

However, the history of convex hull intersection testing is long and intricate. Both Chazelle and Dobkin [6] and Dobkin and Kirkpatrick [10] independently proposed the first $O(\log n)$-time algorithms. In 1987, Chazelle and Dobkin [5] presented a more detailed description of their method. Dobkin and Kirkpatrick revisited their own work in 1990 [11], proposing a unified $O(\log^2 n)$-time algorithm for polyhedron intersection, which O'Rourke later identified as incorrect [28]. He corrected the argument and provided a C-implementation. Further work by Dobkin and Souvaine [9] noted that earlier implementations lacked robustness. More recently, Barba and Langerman [2] observed that the community still lacked a complete, robust algorithm for polyhedral intersection. They proposed an alternative $O(\log n)$ algorithm based on polar transformations. Walther's master's thesis [35], supervised by Afshani and Brodal, implemented both this and earlier methods, but the source code is no longer available.

This 35-year history highlights the complexity and subtlety of convex hull intersection testing. Despite its history, no robust and modern $O(\log n)$-time implementation is available. Moreover, no published algorithm explicitly computes a separating line in the negative case.

Contribution. In the full version, we present a robust $O(\log n)$-time algorithm for convex hull intersection testing. Our algorithm is specialised to convex hulls composed of positively sloped segments and including the points $(\infty, -\infty)$ and $(-\infty, \infty)$. We formally prove its correctness and adapt it to compute a separating line in the negative case, thereby constructing an ε-cover of complexity 1 when it exists. The later adaption and its analysis are nontrivial, and arguably (partly) fill a gap in the existing literature on convex hull intersection testing.

▶ **Theorem 8.** *Let A and B be convex chains of edges with slope at least 1, stored in a balanced binary tree on their left-to-right order. There exists an $O(\log n)$ time to decide whether there exists a line that separates A and B. This algorithm requires only orientation-testing for ordered triangles and can output a separating line whenever it exists.*

4 Robustness

A geometric predicate is a function that takes geometric objects and outputs a Boolean. Our algorithms compute geometric predicates and use their output to branch along a decision tree. In F_S, consecutive points differ in x-coordinate by exactly 1 whilst their y-coordinate

may wildly vary. Consequently, any segment that ε-covers a subsequence of F_S is quite steep. This quickly leads to rounding errors when computing geometric predicates, which in turn creates robustness errors. To illustrate our point, we discuss one of our main algorithms:

Algorithm 1 `intersection_test`(`edge` $\alpha \in CH(A)$, `edge` $\beta \in CH(B)$).

```
1: if α = null OR β = null then
2:     return No
3: end if
4: s(α, β) = line(α) ∩ line(β)
5: if If s ∈ α and s ∈ β then
6:     return Yes
7: end if
8: if α.slope < β.slope then
9:     if α.first.x > s(α, β).x then
10:        return intersection_test(α.left, β)
11:    else if β.first.x > s(α, β).x then
12:        return intersection_test(α, β.left)
13:    else if α.first.x > β.second.x AND α.first.y > β.second.y then
14:        return intersection_test(α.left, β)
15:    else if α.second.x < β.first.x AND α.second.y < β.first.y then
16:        return intersection_test(α, β.left)
17:    else
18:        return yes
19:    end if
20: end if
21: if α.slope > β.slope then
22:    if α.second.x < s(α, β).x then
23:        return intersection_test(α.right, β)
24:    else if β.second.x < s(α, β).x then
25:        return intersection_test(α, β.right)
26:    else if α.first.x > β.second.x AND α.first.y > β.second.y then
27:        return intersection_test(α, β.right)
28:    else if α.second.x < β.first.x AND α.second.y < β.first.y then
29:        return intersection_test(α.right, β)
30:    else
31:        return yes
32:    end if
33: end if
```

`intersection_test` (Algorithm 1) which determines whether an upper quarter convex hull $CH(A)$ and a lower quarter convex hull $CH(B)$ intersect. We receive these hulls as two trees. Our algorithm computes a few geometric predicates given the edges α and β stored at their respective roots. Given (α, β), we either conclude that $CH(A)$ and $CH(B)$ intersect, or, that all edges succeeding (or preceding) α (or β) cannot intersect the other convex hull. Based on the Boolean output, our algorithm then branches into a subtree of α (or β). This way, we verify whether $CH(A)$ and $CH(B)$ intersect in logarithmic time. Rounding causes these predicates to output a wrong conclusion, and our algorithm may branch into a subtree containing edges of $CH(A)$ that are guaranteed to not intersect $CH(B)$. Our algorithm then wrongfully concludes that there exists a line ℓ separating $CH(A)$ and $CH(B)$. Subsequent algorithms then exhibit undefined behaviour when they attempt to compute this line.

Geometric predicates. Our algorithms use on three predicates for their decision making:

- `slope`. Given positive segments (α, β), output whether $\text{slope}(\alpha) < \text{slope}(\beta)$.
- `lies_right`. Given two positive segments α and β with different slopes, output whether the first vertex of β lies right of $line(\alpha) \cap line(\beta)$.
- `wedge`. Consider a pair of positive segments (α, γ) that share a vertex and define W as the cone formed by their supporting halflines containing $(\infty, -\infty)$. Given a positive segment β outside of W, output whether $line(\beta)$ intersects W.

The segments are given by points with integer coordinates. The slopes of these segments (and thereby any representation of their supporting line) are often not integer. A naive way to compute these predicates is to represent slopes using *doubles*. However, this is both computationally slow and prone to rounding errors (and thus, robustness errors).

If we insist on correct output, one can use an *algebraic type* instead. This type represents values using algebraic expressions. E.g., the slope of a positive segment (a, b) is the quotient: $\frac{b.y-a.y}{b.x-a.x}$ and so, in our case, it can be represented as a pair of integers. Algebraic types can subsequently be accurately compared to each other. Indeed, if we want to verify whether $\frac{s}{t} < \frac{q}{r}$ we may robustly verify whether $sr < qt$ using only integers. Exact (algebraic type) comparisons are frequently implemented, and present in the CGAL CORE library [12].

However, exact comparisons are expensive. Our implementation of `slope` requires two integer multiplications, which is still relatively efficient. Evaluating more complex expressions requires too much time. As a rule of thumb, we want to avoid compounding algebraic types to maintain efficiency. Naïvely, `lies_right` compounds two quotients and `wedge` compounds three. We give robust implementations of these functions by invoking three subfunctions. These compare slopes, or whether a point lies above or below a supporting halfplane:

$$\begin{aligned}
&\texttt{slope}((a,b),(c,d)) &&:= (b.y - a.y) \cdot (d.x - c.x) < (d.y - c.y) \cdot (b.x - a.x)\\
&\texttt{above_line}((a,b),c) &&:= (b.x - a.x)(c.y - b.y) - (c.x - b.x)(b.y - a.y) \geq 0\\
&\texttt{below_line}((a,b),c) &&:= (b.x - a.x)(c.y - b.y) - (c.x - b.x)(b.y - a.y) \leq 0
\end{aligned}$$

We can create `lies_right` from our robust predicates (see Figure 3 (a)):

▶ **Lemma 9.** *Let $\alpha = (a, b)$ and $\beta = (c, d)$ be two positive segments of different slope. Then:*

$$\begin{aligned}
\texttt{lies_right}(\alpha,\beta) = &\big(\texttt{slope}((a,b),(c,d)) == \texttt{above_line}((a,b),c)\big)\\
&\vee \big(\texttt{slope}((c,d),(b,c)) == \texttt{below_line}((a,b),c)\big)
\end{aligned}$$

Proof. Suppose that $\text{slope}(\alpha) < \text{slope}(\beta)$. Then c lies right of $line(\alpha) \cap line(\beta)$ if and only if c lies above the halfplane bounded from above by $line((a, b))$. That happens if and only if (a, b, c) are collinear or make a counter-clockwise turn. This in turn occurs if and only if the determinant if the matrix $\begin{vmatrix}(b.x - a.x) & (c.x - b.x)\\ (b.y - a.y) & (c.y - b.y)\end{vmatrix}$ is zero or more. If $slope(\alpha) > slope(\beta)$ the determinant must be negative instead. ◀

Similarly, we can create `wedge` from our robust predicates. We note for the reader that explain our equations in words in the proof of the lemma:

▶ **Lemma 10** (Figure 3 (b))**.** *If $\alpha = (a, b)$, $\gamma = (b, c)$ and $\beta = (d, e)$ be three segments of positive slope where $W = \overleftarrow{\alpha} \cup \overrightarrow{\gamma}$ bounds a convex area containing $(\infty, -\infty)$. Then*

$$\begin{aligned}
&\texttt{wedge}(\alpha,\gamma,\beta) :=\\
&\big(\texttt{below_line}((b,c),d) \wedge \big(\texttt{above_line}((d,e),b) \vee \texttt{slope}((a,b),(d,e))\big)\big) \vee\\
&\big(\texttt{below_line}((a,b),e) \wedge \big(\texttt{above_line}((d,e),b) \vee \texttt{slope}((d,e),(b,c))\big)\big) \vee\\
&\big(\neg\texttt{below_line}((a,b),e) \wedge \neg\texttt{below_line}((b,c),d) \wedge \big(\texttt{slope}((a,b),(d,e)) \vee \texttt{slope}((b,c),(d,e))\big)\big)
\end{aligned}$$

Proof. The predicate is a case distinction of three mutually exclusive cases.

If the first vertex of β lies below the supporting line of γ then $line(\beta)$ intersects W if and only if it intersects $\overleftarrow{\alpha}$. This happens if and only if one of two conditions hold: either b lies below the supporting line of b, or, $\text{slope}(\alpha) < \text{slope}(\beta)$.

If the second vertex of β lies below $line(\alpha)$ then the argument is symmetric.

If neither of those cases apply then both endpoints of β must lie in the open green area. In this case, whenever $\text{slope}(\alpha) < \text{slope}(\beta)$, the supporting line of β always intersects W. Whenever $\text{slope}(\beta) < \text{slope}(\gamma)$, the supporting line of β always intersects W. Whenever $\text{slope}(\alpha) \geq \text{slope}(\beta) \geq \text{slope}(\gamma)$, the supporting line of β cannot intersect W. ◀

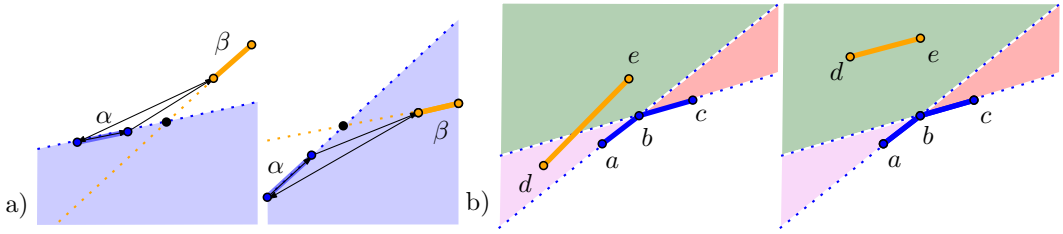

Figure 3 (a) We reduce testing whether the first vertex of β lies right of the intersection point to comparing slopes and the orientation of a triangle. (b) If d lies below the halfplane of $line(b, c)$ then $line((d, e))$ intersects the wedge if and only if b lies below $line((d, e))$.

5 Dynamically maintaining a learned index

We dynamically maintain a learned index h_ε of S by maintaining an ε-cover f of S. We guarantee that there exists no ε-cover f' of S with $|f| > 2|f'|$. By Observation 3, we obtain a learned index h_ε. By Observation 4, there exists no PGM index h_ε where $|f| > 2|h_\varepsilon|$.

To maintain f, we maintain a balanced binary tree $B(f)$ over $\Lambda(f)$. Additionally, for each $[a, b] \in \Lambda(f)$, we maintain a *rank-based convex hull* $T(S[a, b])$ of $S[a, b]$ as described in [17]. We note that we store all segments in f using *relative* x-coordinates. That is, we assume for all $[a, b] \in \Lambda(f)$ that the rank of the first element in $S[a, b]$ is zero. We may then use $B(f)$ to "offset" each line to compute the actual coordinates in rank-space.

▶ **Theorem 11.** *We can dynamically maintain an ε-cover f of S in $O(\log^2 n)$ worst-case time. We guarantee that there exists no ε-cover f' of S where $|f| > 2|f'|$.*

Proof. The proof is illustrated by Figure 4. For any $s, t \in \mathbb{Z}$ with $s \leq t$, we say that $S[s, t]$ is *blocked* if there exists no ε-cover of $S[s, t]$ of size 1. We maintain an ε-cover f where for all consecutive intervals $[a, b], [c, d] \in \Lambda(f)$, $S[a, d]$ is blocked. Thereby, $|f| \leq 2|f'|$ for any ε-cover f' of S (we give a proof of this fact in the full version).

We consider inserting a value s into S; deletions are handled analogously. We query $B(f)$ in $O(\log n)$ time for an interval $[a, b]$ that contains s. If no such interval exists, set $[a, b] = [s, s]$. We search $T(S[a, b])$ and test whether $s \in S$. If so, we reject the update.

Otherwise, we remove $[a, b]$ from $\Lambda(f)$ and insert the intervals $([a, s], [s, s], [s, b])$. We obtain $T(S[a, s])$, $T(S[s, s])$ and $T(S[s, b])$ through the split operation.

Let $([w, x], [y, z], [a, s], [s, s], [s, b], [c, d], [e, f])$ be consecutive intervals in $\Lambda(f)$ and denote $I = ([y, z], [a, s], [s, s], [s, b], [c, d])$ (see Figure 4 (c)). For each $(s, t) \in I$, we have access to $T(S[s, t])$. For any consecutive pair $([s, t], [q, r])$ in I, we may join the trees $T(S[s, t])$ and $T(S[q, r])$ in $O(\log^2 n)$ time to obtain $T([s, r])$. We invoke $T([s, r])$.`get_hull()` and apply

Theorem 8 to test in $O(\log^2 n)$ total time whether $S[s,r]$ is *blocked*. If it is not, we replace $[s,t]$ and $[q,r]$ by $[s,r]$. Otherwise, we keep $T(S[s,r])$ and a complexity-1 ε-cover of $S[s,r]$.

By recursively merging pairs in I, we obtain in $O(\log^2 n)$ time a sequence I' of intervals $([y,\beta],\ldots,[\gamma,d])$ where consecutive intervals are blocked. Since $[y,z] \subseteq [y,\beta]$, $([w,x],[y,\beta])$ is blocked. Similarly, $([\gamma,d],[e,f])$ must be blocked. We remove the line segments corresponding to I from f and replace them with line segments derived from I' in constant time. As a result, we maintain our ε-cover f and our data structure in $O(\log^2 n)$ total time. ◀

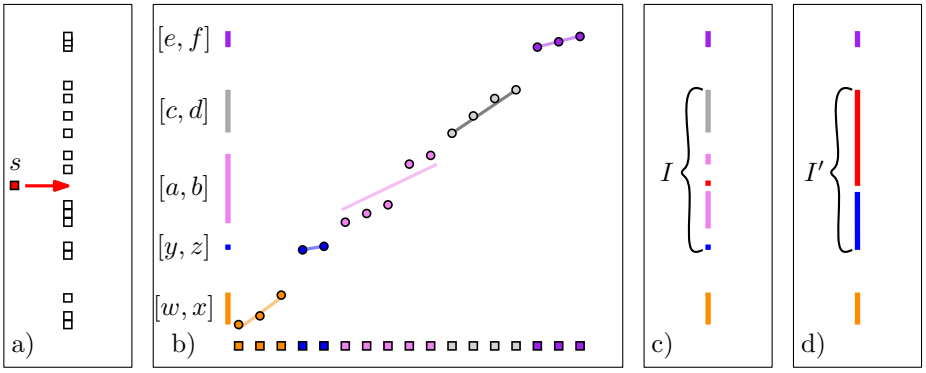

Figure 4 (a) Let S be a set of values and let us insert s. (b) We consider our ε-cover f and five consecutive intervals in $\Lambda(f)$. (c) We create seven intervals by splitting $[a,b]$ on s. (d) By recursively merging intervals in I, we obtain a set of intervals I' where consecutive intervals are blocked.

6 From an ε-cover to an indexing structure

A learned index h_ε does not immediately support indexing and range queries. We obtain an indexing structure by combining h_ε with a hash map H. Combining learned models with hash maps is not new [25, 34, 36] and this technique has even been applied to learned indexing [24]. The core idea is to store S in an unordered vector A and maintain a Hash map $H : \mathbb{Z} \mapsto [n]$. Given some $q \in \mathcal{U}$, the learned function then produces a value v such that $A[h(v)]$ is "close" to q. It is compelling to create H such that $A[H(h(q))]$ is (approximately) the predecessor of q. However, dynamically, this approach fails for the same reason that storing each $s \in S$ at $A[\texttt{rank}(s)]$ fails. Since the ranks of elements in S are constantly changing, we build a hash map using the parts of S that remain constant: the values.

Our data structure. In the full version, we define a data structure independent of the learned index h_ε (we illustrate our approach in Figure 5 (a) + (b)). A *page* p is an integer with a vector that stores all $s \in S$ where $\lfloor \frac{s}{\varepsilon} \rfloor = p$, in order. We store all non-empty pages P in an unordered vector A. We maintain a hash map $H : P \to [|A|]$, where $A[H(p)]$ contains the page p. We additionally maintain a doubly linked list over all pages in P, arranged in sorted order.

Our queries. We restrict our learned index h_ε to a *vertical ε-cover*. I.e., h_ε is a y-monotone collection of line segments such that for all points $p \in F_S$, a vertical line segment of height 2ε centred at p intersects a segment in h_ε. We compute h_ε oblivious of our paging structure.

Given $q \in \mathcal{U}$, we project q onto h_ε (Figure 5 (d)). We project to the x-axis, floor the value, and project back to h_ε. We prove that the resulting y-value corresponds to the page p containing `predecessor`(q). This way, we answer `predecessor` using $O(\varepsilon + \log |h_\varepsilon|)$ time.

As a result, we dynamically maintain a learned index h_ε and a data structure that updates in $O(\varepsilon + \log^2 n)$ and supports indexing queries in $O(\varepsilon + \log |h_\varepsilon|)$ expected time (Theorem 12).

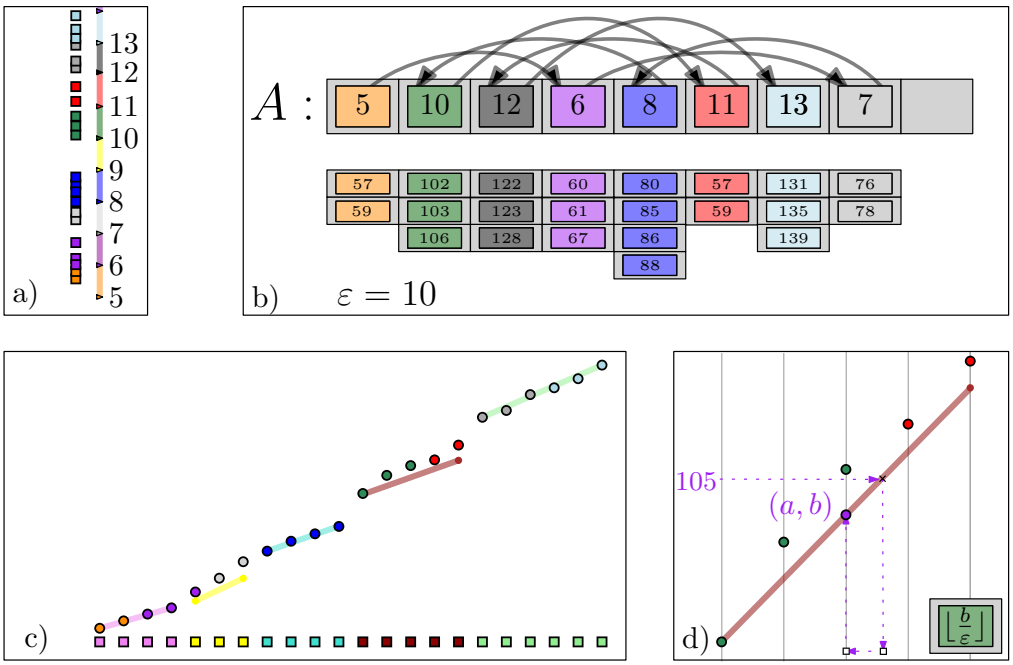

Figure 5 An illustration of our approach in the full version.

▶ **Theorem 12.** *For any ε, there exists a data structure to dynamically maintain a vertical ε-cover F of a dynamic set of distinct integers in $O(\varepsilon + \log^2 n)$ time. We guarantee that there exists no vertical ε-cover F' with $|F| > 2|F'|$. The data structure supports indexing queries in $O(\varepsilon + \log |F|)$ expected time and range queries in additional $O(k)$ time where k is the output size.*

7 Experiments

Our implementation is written in `C++` and made publicly available [18]. We compare to the `C++` implementation in [16], which uses a PGM index under the logarithmic method. The experiments were conducted on a machine with a 4.2GHz AMD Ryzen 7 7800X3D and 128GB memory. Our test bench is available [19], and can replicate experiments, generate synthetic data, and produce plots. As input we consider two synthetic data sets and two real world data sets. Three contain data of geometric nature, with one of random nature to align with precedent. Each set consists of unique 8 byte integers in randomly shuffled order. In the full version, we showcase additional experiments on other datasets.

- **LINES** is a synthetic data set of 5M integers that, in rank space, produces 5 lines of exponentially increasing slope. This set models the ideal scenario for a PGM index.
- **LONGITUDE** is a real world data set that contains the longitudes of roughly 246M points of interest from OpenStreetMap, over the region of Italy. This data is thereby inherently of geometric nature. This data set was used in both [16] and [21]. We follow [16] and convert the data to integers by removing the decimal point from the raw longitudes.

- **UNIF** originates from [16]. It is a synthetic data set, containing a uniform random sample of 50M integers from $(0, 10^{11})$. We adapt this data set to our dynamic setting.
- **DRIFTER** is a real world data set, containing roughly 1.7M steps of accumulated distance travelled by ocean drifters tracked through GPS [7].

Measurements. We compare the quality of the learned indices based the complexity of h_ε, in a dynamic setting. We use the same choice of $\varepsilon = 64$ as in [16] across our experiments. For performance of the indexing structures, we measure their time per operation in a dynamic scenarios with a range of query to update ratios. We note that logarithmic PGM is by default equipped with an optimisation that avoids building a PGM for data below a certain size. In this case, it instead only uses an underlying sorted array without additional search structure. In order to properly compare the performances, this optimisation has been disabled.

7.1 The learned index complexity

Figure 6 presents the complexity of the learned indices, measured by the number of line segments maintained during random-order insertions. The behaviour differs between datasets. For the geometric Lines and Longitude datasets, the dynamic and logarithmic PGMs initially perform similarly. As the data grows, the performance of the logarithmic PGM degrades and its jagged progression reflects its logarithmic partitioning.

On the highly structured synthetic Lines data, the logarithmic method consistently retains more segments than necessary. It misses the optimal line count by a wide margin due to its fragmentation across $O(\log n)$ buckets. A similar pattern appears in the Longitude dataset, where the logarithmic PGM maintains roughly 50 percent more segments than our solution. We note that precisely on these structured data sets, the complexity of the learned indices is $o(n)$. I.e., precisely here one also expects improvements in query time.

For unstructured data such as Unif, both learned indices display similar asymptotic trends, with the logarithmic PGM using approximately 30 percent fewer segments. Here, the complexity appears to scale as $\Omega(n)$ for both methods, suggesting that learned indices offer few to no improvements in the absence of exploitable structure. Surprisingly, the Drifter data – despite its geometric origin – shows similar results to that of Unif. Again, complexity scales linearly, and the logarithmic method outperforms the dynamic one by around 30 percent. This implies that whatever latent geometric structure exists is insufficiently captured by the learned index under either strategy.

An interesting observation is that, on unstructured data, the imposed bucketing of the logarithmic PGM index can introduce a form of regularity that the model benefits from, essentially imposing artificial structure where none exists.

7.2 Running time comparisons

Recall that our indexing structure is composed of a learned index over a vertical ε-cover and a paging structure. We first examine the performance of both the learned index in its own, and then the performance of the full indexing structure.

For the dynamic scenarios, we first follow the precedence set by prior papers [16, 21]. These first construct, insertion-only, the indexing structure. They then perform a batch of 10M operations These batches consist of insertions, deletions, and range queries over ranges such that the output contains approximately $\frac{\sqrt{n}}{10}$ elements. We deviate from the precedent by also deleting from the index before performing a batch of operations, to simulate a scenario in which the structure has existed and transformed prior to processing.

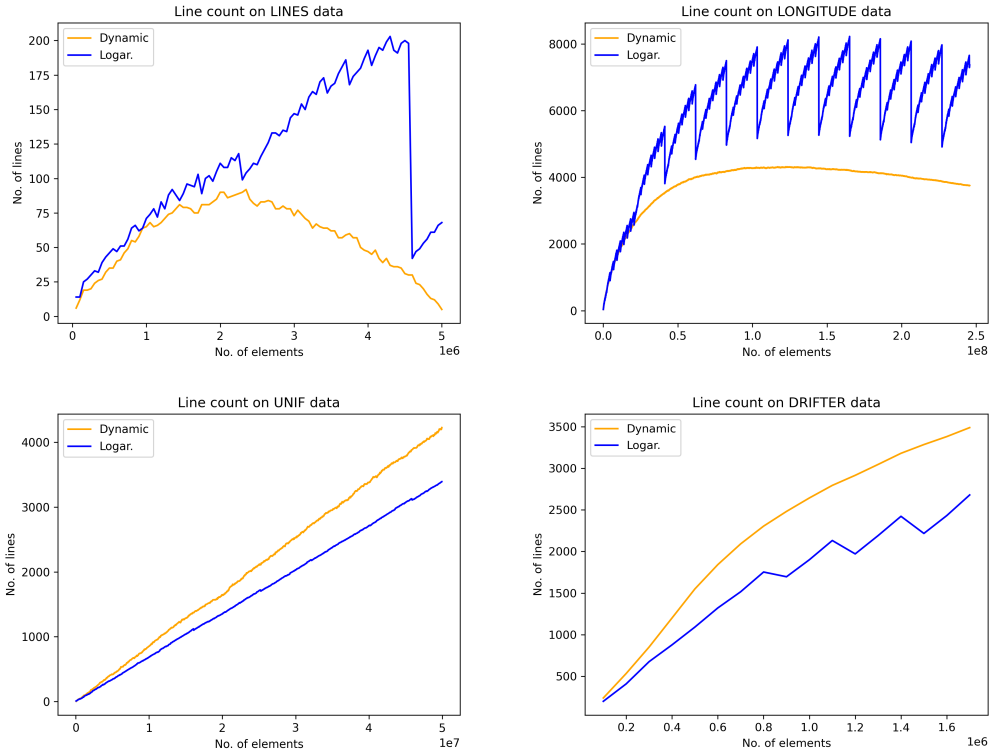

Figure 6 The complexity of the learned indices throughout insertion-only construction. The top graphs represent geometrically structured data. The left graphs represent synthetic data.

7.2.1 Maintaining a learned index

Figure 7 shows the cost of maintaining each learned index under dynamic operations. Our update procedure, which ensures worst-case $O(\log^2 n)$ bounds, performs significantly worse than the amortised $O(\log n)$ updates offered by the logarithmic method – especially on larger datasets such as LONGITUDE and UNIF. On smaller datasets like DRIFTER, the gap narrows, but the logarithmic method generally remains preferable in these update-only scenarios.

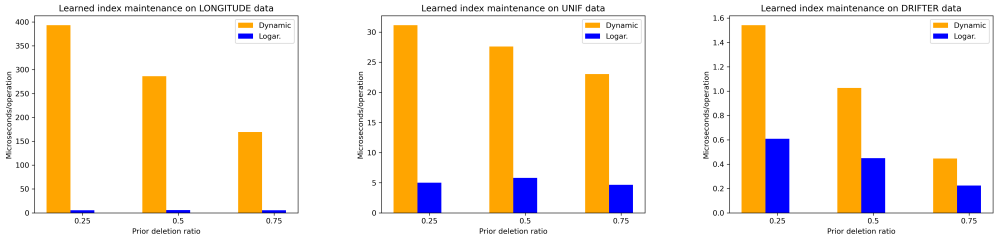

Figure 7 Update times for maintaining the learned index dynamically.

7.2.2 Indexing data structures

We next assess the complete indexing structures under mixed workloads. Batches contain a tunable ratio of queries and updates, where updates are evenly split between insertions and deletions, and operations are randomly ordered. More experiments can be found in the full version. For the LINES dataset, updates are constrained to a single line segment to preserve its idealised structure. For smaller datasets, batch size is limited to 25 percent.

Adversarial workload (ADV). In the above scenario by [16, 21], an update batch of $10M$ operations affects less than ten percent of the data. Therefore, we do not encounter the worst case scenario where range queries take $O(N + \varepsilon + \sum_i^{\lceil \log n \rceil} \log |f_i|)$ time. So, the worst case difference in performance does not come to light. Therefore, we additionally construct an *adversarial scenario* consisting of 10M range queries after deleting all but 1.000 values.

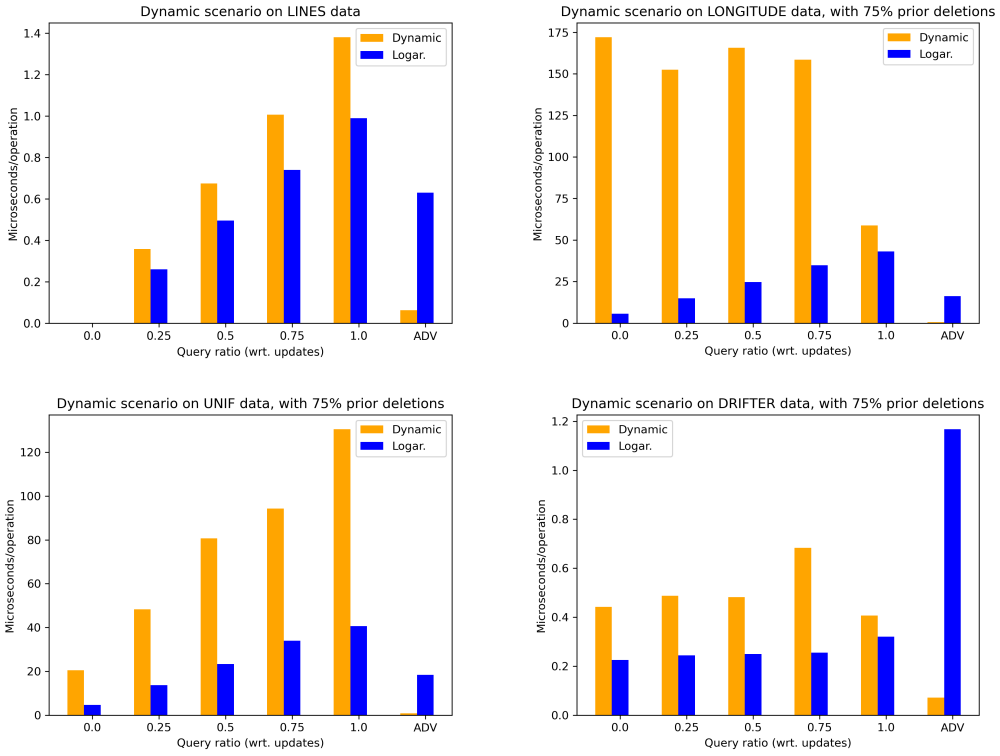

Figure 8 Time per operation in dynamic scenario with varying query ratios. For the LINES data set updates are restricted to points on a single line. The ADV ratio denotes the adversarial case where all but a constant number of elements are deleted before the structure is queried.

Operational performance. Figure 8 summarises the total processing time under varying query-to-update ratios. Structured datasets, particularly LONGITUDE, reveal a trade-off between the fact that we have a lower-complexity learned index and our update time. On one hand, our updates are costly due to our line-merging tests which suffer from the poor cache behaviour from pointer-based trees, and complex rebalancing that is present in the state-of-the-art practical dynamic convex hull data structures. This behaviour is also reflected on our previous analysis of maintaining the learned index itself. On the other hand we see

on geometrically structured data that, as the query ratio increases, performance improves. This trend is absent in the LINES data, where updates are constrained and the structure is small, mitigating cache penalties. Here, running time is largely driven by query processing, which increases as expected with query ratio.

In contrast, the random data from the UNIF dataset shows improved performance with higher query ratios. In our data structure, having smaller segments reduce restructuring costs. Our dynamic implementation suffers greatly from cache inefficiency due to random access during range reporting. The logarithmic PGM, with its lower memory overhead and sequential layout, delivers significantly better performance – particularly as sizes increase.

For the DRIFTER data, one would expect a trend similar to that of the UNIF data, based on the complexity of the ε-cover shown in Figure 6. However, there is little difference in performance for either PGM as the query ratio is varied. This is likely due to the small size of the data set, with both structures performing updates in fractions of microseconds on average. The logarithmic PGM does come out slightly on top, likely due to the machine friendly memory access pattern.

Adversarial impact. Across all datasets, the logarithmic PGM's tombstoning strategy becomes a bottleneck in the adversarial scenario. Its range queries must scan and subtract deleted values before outputting results. Our structure, by contrast, is output-sensitive and avoids such overhead. This illustrates that our data structure, whilst being generally less efficient that the logarithmic PGM, offers worst-case guarantees.

8 Conclusion

We studied dynamic learned indices through a geometric perspective. Following the work of Ferragina and Vinciguerra [16], we maintained a learned index h_ε of a dynamic set S as a piecewise-linear approximation – an ε-cover – of the rank-space point set F_S. We used techniques from computational geometry to answer the following question:

"Can a learned index be dynamically maintained with worst-case guarantees?"

We proposed a new approach to maintain a learned index based on dynamic convex hull data structures. We presented an $O(\log^2 n)$ time algorithm to dynamically maintain a learned index h_ε. To obtain this algorithm, we showed an algorithm to compute a separating line between two non-intersecting convex hulls – an operation previously missing from the literature. The existing logarithmic PGM index has an amortised $O(\log n)$ time update algorithm which is more efficient in practice. Indeed, although close in theory, the memory access pattern associated with dynamically maintaining convex hulls incurs heavy penalties for large datasets. At the same time, the resulting learned index of the logarithmic PGM, h'_ε, can be considerably more complex on geometrically structured data.

From learned indices to indexing. Finally, we considered the following question:

"Can a dynamic learned index be converted into a dynamic indexing data structure?"

To this end, we designed a hybrid technique combining hashing-based fast-access data structures with a doubly linked list to support indexing queries. Our method offers output-sensitive worst-case guarantees, even in the presence of deletions. As it is known that traditional indexing structures currently outperform learned indices in the general dynamic setting [33], we focused our comparisons on improving the theoretical and practical performance within the class of learned approaches.

In practice, the contiguous memory access of the logarithmic PGM index offsets its overhead from querying multiple structures, making it faster in all scenarios, except for an adversarial one. This means that the lower complexity of our learned index does not immediately translate to improved efficiency in the indexing data structure. This raises an interesting open question of whether memory-access efficient fully dynamic approaches to convert a learned index into a dynamic indexing structure can exist.

While we acknowledge that our update-times are slow in comparison with state-of-the art, our approach does illustrate that it brings worst-case guarantees: as it has an advantage when the query-to-update ratio is large and the index has undergone sufficiently many deletions. In adversarial workloads with frequent deletions followed by range queries, we have seen our structure outperform the logarithmic approach – highlighting the value of worst-case guarantees even in specialised settings.

Closing thoughts. We showed what we believe is an interesting connection between the geometric learned index by Ferragina and Vinciguerra, and dynamic convex hulls from computational geometry. We subsequently provided an implementation of a dynamic learned index that relies on the state-of-the-art dynamic convex hull maintenance algorithms. Our empirical analysis shows that the complex tree rebalancing that is used to dynamically maintain a convex hull currently brings considerable operational overhead compared to low-memory techniques under the logarithmic method. Our experiments, though not uniformly favourable, offer interesting insights into the current barriers and adversarial tradeoffs between worst-case dynamic algorithms and memory-efficient amortised rebuilding schemes.

Abstract

Dynamic graph algorithms have seen significant theoretical advancements, but practical evaluations often lag behind. This work bridges the gap between theory and practice by engineering and empirically evaluating recently developed approximation algorithms for dynamically maintaining graph orientations. We comprehensively describe the underlying data structures, including efficient bucketing techniques and round-robin updates. Our implementation has a natural parameter λ, which allows for a trade-off between algorithmic efficiency and the quality of the solution. In the extensive experimental evaluation, we demonstrate that our implementation offers a considerable speedup. Using different quality metrics, we show that our implementations are very competitive and can outperform previous methods. Overall, our approach solves more instances than other methods while being up to 112 times faster on instances that are solvable by all methods compared.

1 Introduction

A (fully) dynamic graph algorithm is a data structure designed to support edge insertions, edge deletions, and answer specific queries. While there has been extensive research on dynamic graph problems, many of these theoretically efficient algorithms have not been implemented or empirically evaluated. In this work, we dynamically maintain an orientation of a graph. Let $G = (V, E)$ be an undirected graph with n vertices and m edges. A *fractional orientation* $\overrightarrow{G}$ of G assigns to each edge $\{u, v\} \in E$ two non-negative weights $d(u \to v)$ and $d(v \to u)$ such that $d(u \to v) + d(v \to u) = 1$. The *fractional out-degree* $d^+(u)$ of a vertex u is the sum over all edges $\{u, v\} \in E$ of $d(u \to v)$. An *integral orientation* is a fractional orientation in which all weights are either 0 or 1. We will denote by $d^*(u)$ the out-degree of a vertex u if the orientation is integral. Graph orientations have a wide range of applications:

Fractional Orientations and Graph Mining. Given a graph G, a *density decomposition* of G is a nested set of subgraphs of G of decreasing density. Finding dense subgraphs lies at the core of graph mining [25]. Density decompositions were first applied in finding clusters in web-data [23, 24, 30, 31] but quickly embedded themselves in pattern mining techniques of other fields such as social graph mining [2, 11, 18, 34, 41], bioinformatics [3, 21, 28, 39, 44], finance [19] and even drawing algorithms for large graphs [1]. Danisch, Chan, and Sozio [14] propose a state-of-the-art density composition of a graph, which they call the *local density*. Due to its applicability, there exist many *static* implementations to efficiently approximate (variants of) this decomposition [29, 35, 42, 43]. There exists a 1:1 correspondence between this density decomposition and fractional orientations. Indeed, consider a fractional orientation $\overrightarrow{G}$ that minimizes the sum-of-squares metric defined by $\texttt{sum}^2(\overrightarrow{G}) := \sum_{v \in V} \left(d^+(v)\right)^2$. The decomposition by Danish, Chan, and Sozio is the partition of vertices by their out-degree.

Integral Orientations and Dynamic Efficiency. A crucial building block for efficient, fully dynamic algorithms is efficient, dynamic edge-orientations. Given an undirected graph G, the *edge orientation problem* asks for an orientation of G in which the maximum out-degree of the vertices is minimized. Many real-world graphs are relatively sparse and allow for edge orientations where the maximum out-degree is considerably smaller than the maximum degree of the graph. Low out-degree integral orientations allow for efficient and low-memory adjacency queries. This, in turn, has many applications, including dynamic map labeling, graph colouring, maximal matchings, and finding k-cliques [16]. Other example applications include Neiman and Solomon [36] who have shown how to maintain a maximal matching in $O(\log n / \log \log n)$ amortized time using a dynamic edge orientation algorithm, dynamic matrix vector multiplication [32], or Kowalik and Kurowski [33] who use dynamic edge orientations to answer shortest-path queries of length at most k in $O(k)$ time in planar graphs. The aforementioned algorithms use time proportional to the maximum out-degree in the orientation. Thus, it becomes important to minimize $\texttt{max}(\overrightarrow{G}) := \max_{v \in V} d^+(v)$.

Minimax versus Least Square Regression. In graph mining, we are interested in orientations $\overrightarrow{G}$ that minimize $\texttt{sum}^2(\overrightarrow{G})$. Minimising this measure optimises for the "average" out-degree which identifies the density of the neighborhood of each vertex. On the other hand, many dynamic algorithmic application domains are interested in orientations $\overrightarrow{G}$ that minimize $\max(\overrightarrow{G})$. Danisch, Chan, and Sozio prove that, in this case, the least square regression is strictly more stringent than the minimax regression as any fractional orientation $\overrightarrow{G}$ minimizing $\texttt{sum}^2(\overrightarrow{G})$ also minimizes $\max(\overrightarrow{G})$ [14]. The value of $\max(\overrightarrow{G})$ equals the pseudoarboricity of

the graph. The (pseudo-)arboricity is defined as the number of (pseudo-)forests that the graph can be partitioned into. The arboricity is either equal to the pseudoarboricity or plus one [37].

Prior Work in Theory. Theoretical dynamic algorithms typically maintain a fractional orientation $\overrightarrow{G}$ over G. A naive rounding scheme then converts each fractional orientation $\overrightarrow{G}$ to an integral orientation $\overrightarrow{G}^*$ where for all $v \in V$, the out-degree $d^*(v)$ is at most $2d^+(v)$. A simple rounding scheme rounds all fractional edges with a value greater than $\frac{1}{2}$ and ones with equal value by a deterministic scheme, like the assigned vertex id. Christiansen and Rotenberg [12] propose a dynamic polylog-time rounding algorithm where for all $v \in V$, $d^*(v) \leq d^+(v) + 1$. The state-of-the-art dynamic theoretical algorithm to maintain a fractional orientation that minimizes $\texttt{max}(\overrightarrow{G})$ is by Chekuri et al. [10]. They dynamically maintain a fractional orientation $\overrightarrow{G}$ where for all $\overrightarrow{G}'$, $\texttt{max}(\overrightarrow{G}) \leq (1+\varepsilon) \cdot \texttt{max}(\overrightarrow{G}')$. Their algorithm uses linear space and has $O(\varepsilon^{-6} \log^4 n)$ update time. Christiansen, van der Hoog, and Rotenberg [13] show that the algorithm from [10], in actuality, maintains a fractional orientation $\overrightarrow{G}$ such that for all $\overrightarrow{G}'$, $\texttt{sum}^2(\overrightarrow{G}) \leq (1+\varepsilon) \cdot \texttt{sum}^2(\overrightarrow{G}')$. Thus, the state-of-the-art theoretical algorithm maintains a fractional orientation that $(1+\varepsilon)$-approximates the optimal solution for both our metrics of interest in $O(\varepsilon^{-6} \log^4 n)$ time per update.

Prior Work in Practice. In contrast to theoretical algorithms, most practical methods for computing edge-orientations on dynamic graphs maintain an integral orientation. We now discuss some experimentally evaluated approaches. Brodal and Fagerberg [9] were the first to consider the problem in the dynamic case. With a bound c on the arboricity of the graph as input, their approach supports adjacency queries in time $O(c)$, edge insertions in amortized time $O(1)$, and edge deletions in amortized time $O(c + \log n)$ time.

Berglin and Brodal [5] allow a *worst-case* user-specific trade-off between out-degree and running time of the operations. Their algorithm maintains an $O(\alpha + \log n)$ orientation in $O(\log n)$ worst-case time or an $O(\alpha \log^2 n)$ orientation in constant worst-case time. Borowitz et al. [6] experimentally evaluated different heuristics and approximation algorithms. This evaluation includes new approaches presented by the authors, which are based on a BFS strategy as well as the algorithm by Brodal and Fagerberg [9] and the K-Flip algorithm introduced by Berglin and Brodal [5]. In this experimental evaluation, the BFS approach performed best. Recently, Großmann et al. [27] presented a dynamic algorithm to solve the problem exactly. The worst-case complexity of this method for insertions is $O(m)$, while for deletion it is amortized $O(m)$. Their experiments show that their exact algorithm achieves up to 32 % lower running times than the inexact BFS approach by Borowitz et al. [6].

Contribution. We engineer an implementation of the recently proposed approximation algorithms by Chekuri et al. [10]. In Section 2.1, we provide crucial details required for an implementation. A straightforward implementation of the algorithms would be quite slow and memory-intensive. This is because [10] defines a large (constant) number of values and pointers to guarantee that all algorithmic operations take theoretically $O(1)$ time. Real-world graphs contain many edges compared to the number of available bits in memory. Storing up to eight integers and pointers per edge is infeasible and a clear bottleneck.

Thus, in Section 3, we present engineering aspects to adapt the algorithm from [10] to reduce space use and considerably improve its efficiency. As a consequence, we obtain two implementations of [10] to maintain a fractional orientation $\overrightarrow{G}$ of a dynamic graph G that simultaneously approximately minimizes both $\texttt{sum}^2(\overrightarrow{G})$ and $\texttt{max}(\overrightarrow{G})$. We note that

these existing algorithms maintain an integral orientation $\overrightarrow{G}^*$ and are designed to minimize $\texttt{max}(\overrightarrow{G}^*)$. To provide a fair comparison between our implementation and the current state-of-the-art, we convert our fractional orientation $\overrightarrow{G}$ to an integral orientation through the naive rounding scheme. Experiments in Section 4 show that our implementations offer a considerable speedup of up to 112.17 times whilst being very competitive on the measure $\texttt{max}(\overrightarrow{G}^*)$. Our algorithm performs considerably better than previous implementations when using $\texttt{sum}^2(\overrightarrow{G}^*)$ as the quality metric. Our implementation has a natural parameter λ, which allows for a trade-off between algorithmic efficiency and the quality of the solution.

2 Preliminaries

Let $G = (V, E)$ be a dynamic, unweighted, undirected graph subject to edge insertion and edge deletion. We say that $|V| = n$ at the time of an update. A *fractional* orientation $\overrightarrow{G}$ of G assigns for every edge $\{u, v\}$ two non-negative weights: $d(u \to v)$ and $d(v \to u)$ such that $d(u \to v) + d(v \to u) = 1$. The *out-degree* of a vertex u is defined as $d^+(u) = \sum_{v \in V} d(u \to v)$. An *integral orientation* is a fractional orientation where for all $\{u, v\} \in E$, $d(u \to v) \in \{0, 1\}$. To distinguish between integral and fractional orientations, we denote by $d^*(u)$ the out-degree of a vertex u if the orientation is integral. In integral orientations, we reference directed edges as $\overrightarrow{uv}$ and $\overrightarrow{vu}$. A naive rounding scheme converts each fractional orientation $\overrightarrow{G}$ into an integral orientation $\overrightarrow{G}^*$ where for all $v \in V$, the out-degree $d^*(v)$ is at most $2d^+(v)$.

Quality Measures. We denote by $\mathbb{O}(G)$ the infinite-size set of all fractional orientations of G. For any orientation $\overrightarrow{G} \in \mathbb{O}(G)$ we define two quality measures:

$$\texttt{max}(\overrightarrow{G}) := \max_{v \in V} d^+(v), \qquad \text{and,} \qquad \texttt{sum}^2(\overrightarrow{G}) := \sum_{v \in V} \left(d^+(v)\right)^2.$$

These measures induce respectively a linear and a convex optimization problem over $\mathbb{O}(G)$:

$$\Delta^{\min}(G) := \min_{\overrightarrow{G} \in \mathbb{O}(G)} \texttt{max}(\overrightarrow{G}), \qquad \text{and,} \qquad \Delta^{local}(G) := \min_{\overrightarrow{G} \in \mathbb{O}(G)} \texttt{sum}^2(\overrightarrow{G}).$$

Problem Statement. State-of-the-art edge orientation implementations use integral orientations. We therefore maintain for a dynamic unweighted graph G either:

- an integral orientation $\overrightarrow{G}^*$ that approximately minimizes $\texttt{max}(\overrightarrow{G}^*)$, or,
- an integral orientation $\overrightarrow{G}^*$ that approximately minimizes $\texttt{sum}^2(\overrightarrow{G}^*)$

To this end, we dynamically maintain a fractional orientation $\overrightarrow{G}$ and apply naive rounding.

Fairness. Sawlani and Wang [40] say that $\overrightarrow{G} \in \mathbb{O}(G)$ is *locally fair* whenever $d(u \to v) > 0$ implies that $d^+(u) \leq d^+(v)$. They prove that if $\overrightarrow{G}$ is locally fair, then $\texttt{max}(\overrightarrow{G}) = \Delta^{\min}(G)$. Christiansen, van der Hoog, and Rotenberg [13] show an even stronger correlation between fair orientations and the sum-of-squares measure as $\overrightarrow{G}$ is locally fair if and only if $\texttt{sum}^2(\overrightarrow{G}) = \Delta^{local}(G)$. A locally fair orientation cannot be maintained without requiring $\Omega(n)$ update time. Hence, several works relax the notion of fairness to approximate the local fairness and thereby $\Delta^{\min}(G)$ and $\Delta^{local}(G)$ [4, 7, 8, 13, 20, 40, 45]. For a fixed $\theta \in \{0, 1\}$ and $\lambda \in [0, 1)$, Chekuri et al. [10] define $\overrightarrow{G}$ as λ-fair if: $d(u \to v) \Rightarrow d^+(u) \leq (1 + \lambda) \cdot d^+(v) + \theta$.
If we subsequently smartly choose $\lambda \in \Theta\left(\frac{\varepsilon^2}{\log n}\right)$ and $\theta = 0$, then any λ-fair fractional orientation $\overrightarrow{G}$ guarantees that $\texttt{max}(\overrightarrow{G})$ is a $(1 + \varepsilon)$-approximation of $\Delta^{\min}(G)$ [10] and that

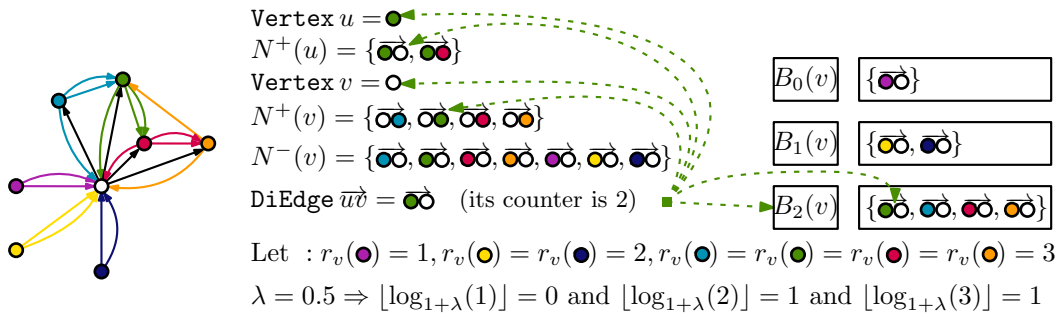

Figure 1 A graph G_b for $b = 2$ and an orientation G_b^*. We illustrate the data structure from [10]. Observe that the `DiEdge` $\overrightarrow{uv}$ stores six pointers in this data structure to allow constant-time updates.

$\texttt{sum}^2(\overrightarrow{G})$ is a $(1+\varepsilon)$-approximation of $\Delta^{local}(G)$ [13]. If $\theta = 1$, the λ-fair orientation may be integral instead, which is considerably easier to maintain. Setting $\theta = 1$ does come at a cost in quality, as the approximation becomes an additive error of $O(\log n)$.

2.1 The Algorithm for Maintaining a λ-fair Orientation by [10]

Let $\lambda \in [0, 1]$ be some quality parameter that the user fixed beforehand. Then, the algorithm by Chekuri et al. [10], on a high level, inserts (or deletes) directed edges in G_b^* (which is an integral orientation over the graph G where each edge is duplicated b times). They orient the edges in such way that they maintain an (integral) λ-fair orientation. After inserting a directed edge $\overrightarrow{uv}$, the out-degree of u increases. So, there may exist some edge $\overrightarrow{ux}$ for which $d^*(u) > (1+\lambda)d^*(x)$. The algorithm then flips this edge, restoring the out-degree of x, and recurses on the edge-insertion $\overrightarrow{xu}$. Instead of spending $O(d^*(u))$ time to inspect all out-edges x of u, the authors show that it suffices to loop over a fraction of the out-edges of u in round-robin fashion. To make all supporting operations in this algorithm run in constant time, the algorithm uses elaborate data structures, data types, and information updates. We explain these first.

For $b \in \mathbb{N}$, denote by G_b the graph G where every edge is duplicated b times. Each edge insertion in G thereby inserts b edges into G_b. We maintain an integral orientation G_b^* over G_b where $d_b^*(v)$ denotes the out-degree. G_b^* induces a fractional orientation over G and we obtain an integral orientation G^* of G from G_b^* by naively rounding each edge.

We denote for all $u \in V$ by $N^+(u)$ all vertices v for which G_b^* has at least one edge $\overrightarrow{uv}$ (see Figure 1). The set $N^-(u)$ are all vertices v where $\overrightarrow{G_b}$ includes at least one edge $\overrightarrow{vu}$. Note that $d_b^*(u)$ is not necessarily equal to $|N^+(u)|$ because G_b is a multigraph.

Information Updates. The update algorithm to G_b^* implements a lazy information update scheme where adding an edge $\overrightarrow{uv}$ to G_b^* increments a counter recording the number of edges $\overrightarrow{uv}$ that G_b^* contains without updating all auxiliary information and data structures.

Formally we define an *information update* (we forward reference Algorithm 3). The algorithm may invoke an information along a directed edge.

▶ **Definition 1.** *Let $d_b^*(w)$ be the out-degree of w at the time of the information update. We define the* log-degree $r_u(w)$ *as the floor of the base $(1+\lambda)$ logarithm of $d_b^*(w)$* at the time of an information update along $\overrightarrow{wu}$. *Or formally: $r_u(w) = \lfloor \log_{1+\lambda} d_b^*(w) \rfloor$.*

This value is recorded such that each directed edge $\overrightarrow{wu}$ in G_b^* has access to the value $r_u(w)$.

Data Structure. Chekuri et al. [10] equip the oriented graph G_b^* with a data structure. They store for each vertex $u \in V$ the following (see also Figure 1):

(a) The *exact value* of $d_b^*(u)$.
(b) The set $N^+(u)$ in a linked list and a pointer some current "position" in the linked list.
(c) The set $N^-(u)$ in a doubly linked list of buckets $B_j(u)$ sorted by j from high to low. Each bucket $B_j(u)$ contains a doubly linked list of all $w \in N^-(u)$ where $r_u(w) = j$.
(d) A pointer to the bucket $B_j(u)$ where j is closest to $\log_{1+\lambda} d^+(u)$.

Data Types. To guarantee that all data structures have $O(1)$ update time, the proofs in [10] reference several pointers stored in their data types. We formalise these here:

`Bucket` $B_i(v)$ stores a doubly linked list with all `DiEdges` $\overrightarrow{uv}$ with $i = r_v(u)$.

`Vertex` u stores:
- a linked list of all `DiEdges` $\overrightarrow{uv}$ (corresponding to vertices $v \in N^+(u)$).
- a doubly linked list of all non-empty `Buckets` $B_i(u)$, ordered by i.
- a pointer to the `DiEdge` *robin* which represents our "current position" in $N^+(u)$.
- a pointer to the *primary bucket* $B_j(u)$ (here j is closest to $\log_{1+\lambda} d^+(u)$).
- the value $d_b^*(u)$.

`DiEdge` $\overrightarrow{uv}$ represents all directed edges $\overrightarrow{uv}$ in G_b^*, simultaneously. It stores:
- two pointers to the `Vertices` u and v, respectively.
- a *counter* counting how many edges $\overrightarrow{uv}$ there are in G_b^*,
- the value $r_v(u)$,
- a pointer to the location of $\overrightarrow{uv}$ in $N^+(u)$.
- a pointer to the bucket $B_i(v)$ of v with $i = r_v(u)$,
- a pointer to the location of $\overrightarrow{uv}$ in the linked list in the bucket $B_i(v)$.
- a pointer to the `DiEdge` $\overrightarrow{vu}$.

2.1.1 Algorithm Definition

The algorithm has three parameters that are used throughout its algorithmic subroutines: $\theta \in \{0, 1\}$, $\lambda \in [0, 1]$ and $b \in \mathbb{N}$. We explain their interplay later in this subsection. Each update operation in G simply invokes b updates to the digraph G_b^* (see Algorithm 1 and 2).

Algorithm 1 Insert(edge $\{u, v\}$ in G).

```
1  for i ∈ [b] do
2    if d*_b(u) ≤ d*_b(v) then
3      Insert(uv→)
4    else
5      Insert(vu→)
```

Algorithm 2 Delete(edge $\{u, v\}$ in G).

```
for i ∈ [b] do
  if u ∈ N⁻(v) then
    Delete(vu→)
  else
    Delete(uv→)
```

Recall that the algorithm does not always immediately update the data structure. Rather, it only exactly maintains the value $d_b^*(u)$ for each vertex u and the set $N^+(u)$. The bucketing data structure is updated only when an *information update* (Algorithm 3) is triggered.

Algorithm 3 InfoUpdate(`DiEdge` $\overrightarrow{xy}$, `Bucket` $B_j(y)$).

```
6  r_y(x) = log_{1+λ} d*_b(x)
7  Starting from B_j(y) find the bucket B_i(y) with i = r_y(x) Inspect at most O(1) buckets
8  Move xy→ into the bucket B_i(y)
```

Suppose that we add a directed edge $\overrightarrow{uv}$ to G_b^*. If there already exists an edge $\overrightarrow{uv}$ in $\overrightarrow{G_b}$ then we implicitly insert the extra copy by identifying the corresponding `DiEdge` $\overrightarrow{uv}$ and incrementing the counter. Otherwise, we need to update $N^+(u)$ and do an information update. The same principle holds when removing a directed edge, where we only do work if we remove the last copy of a directed edge in G_b^* (Algorithm 4 and 5).

Algorithm 4 Add(`DiEdge` $\overrightarrow{uv}$).

```
9   Increment the counter of uv.
10  d*_b(u) = d*_b(u) + 1
11  if uv.counter = 1 then
12    Add uv at the end of N+(u)
13    B_j(v) ← the primary Bucket of v
14    InfoUpdate(uv, B_j(v))
```

Algorithm 5 Remove(`DiEdge` $\overrightarrow{uv}$).

```
    Decrement the counter of uv
    d*_b(u) = d*_b(u) − 1
    if uv.counter = 0 then
      Remove v from N+(u)
      B_i(v) ← the Bucket stored at uv
      InfoUpdate(uv, B_i(v))
```

The true complexity of this algorithm lies in the logic surrounding directed edge insertions and deletions. Intuitively, inserting an edge $\overrightarrow{uv}$ iterates over the out-edges $\overrightarrow{ux}$ of u in a round-robin fashion. If the out-degree of u is considerably larger than the out-degree of x, we flip an edge $\overrightarrow{ux}$ to become an edge $\overrightarrow{xu}$, we terminate the round-robin and recurse on the insertion of $\overrightarrow{xu}$. After this flip, the out-degree of u is unchanged and thus locally, the orientation is still λ-fair. This increased the out-degree of x by one, and we recurse on x (Algorithm 1). Deleting an edge $\overrightarrow{uv}$ only considers a single directed edge, which is an edge $\overrightarrow{xu}$ where the out-degree $d_b^*(x)$ is approximately maximal. If $d_b^*(u)$ is considerably larger than $d_b^*(u)$ then we flip an edge $\overrightarrow{xu}$. After this flip, the out-degree of u is unchanged. Instead, the out-degree of x is decreased by one, and we recurse on x (Algorithm 1).

Finally if, after either an edge insertion or deletion, a vertex u actually changes its out-degree then the algorithm will inform up to $\frac{2}{\lambda}$ out-neighbours of u of its new out-degree.

Algorithm 6 Insert(`DiEdge` $\overrightarrow{uv}$).

```
15  Add(uv)
16  for ⌈2/λ⌉ iterations do: do
17    u.robin = (u.robin + 1) mod |N+(u)|
18    DiEdge ux = *u.robin
19    if d*_b(u) > max{(1 + λ) · d*_b(x) + θ, b/4} then
20      Remove(ux)
21      Insert(xu)
22      Break
23  for all the next ⌈2/λ⌉ uw in N+(u) do
24    InfoUpdate(uw, uw.Bucket)
```

Algorithm 7 Delete(`DiEdge` $\overrightarrow{uv}$).

```
    Remove(uv)
    x ← First( Max( Bucket(N−(u))))
    if d*_b(x) > max{(1 + λ) · d*_b(u) + θ, b/4}
    then
      Add(ux)
      Delete(xu)
    else
      for the next ⌈2/λ⌉ uw in N+(u) do
        InfoUpdate(uw, uw.Bucket)
```

Algorithm Parameters and Asymptotic Complexity. The algorithm has three parameters:

- $\theta \in \{0, 1\}$ is a Boolean that is used in the logic of Algorithms 6 and 7. The Boolean specifies whether we want a slower $(1+\varepsilon)$-approximation (setting $\theta \leftarrow 0$), or, whether we want a faster algorithm that achieves an additive $O(\log n)$-error (setting $\theta \leftarrow 1$).
- $\lambda \in [0, 1]$ is the approximation parameter.
  - If $\theta = 0$, then we may choose $\lambda \in \Theta(\frac{\varepsilon^2}{\log n})$ to obtain a $(1+\varepsilon)$-approximation [10, 13].
  - If $\theta = 1$, then we may choose $\lambda \in \Theta(\frac{1}{\log n})$ to obtain an additive $O(\log n)$ error [10, 13].
- $b \in \mathbb{N}$ records how many edges the multigraph G_b has per edge in G. If $\theta = 1$ then $b = 1$. If $\theta = 0$ then $b > \frac{4}{\lambda}$ in order to make the algorithmic logic work. Indeed, consider an edge $\{u, v\}$ in G. Our algorithm maintains the invariant that if $\overrightarrow{uv}$ is in G_b^* then $d_b^*(u) \leq (1+\lambda)d_b^*$. If both $d_b^*(u)$ and $d_b^*(v)$ are less than $\frac{1}{\lambda}$ then there is no way to orient $\{u, v\}$ in G_b^* such that our invariant is satisfied.

Each update in G triggers at most b updates in G_b. Each update to G_b calls Algorithm 6 or 7. These functions do at most $O(\frac{1}{\lambda})$ constant-time operations before recursing. These functions recurse at most $O(\log_{1+\lambda} n)$ times. It follows that the total runtime is at most:

$$O(b \cdot \frac{1}{\lambda} \cdot \log_{1+\lambda} n) \subset O(b\lambda^{-2} \log n) \Rightarrow \begin{cases} O(\lambda^{-3} \log n) & \text{if } \theta = 0 \\ O(\lambda^{-2} \log n) & \text{if } \theta = 1 \end{cases}$$

In theory, one chooses $\lambda \in \Theta(\varepsilon^2 / \log n)$ where ε is the approximation constant. In practice, we simply choose a smaller λ for a better approximation.

Space Usage. In theory, the data type as we specified in this paper allows each of the operations in Algorithms 1–7 to take constant time. We give three examples: (i) we can flip a directed edge in G_b^* in constant time because the `DiEdge` $\overrightarrow{ux}$ stores a pointer to the `DiEdge` $\overrightarrow{xu}$, (ii) a `DiEdge` $\overrightarrow{uv}$ can remove itself from the linked list $N^+(u)$ in constant time because it stores a pointer to its location, and (iii) a `DiEdge` $\overrightarrow{uv}$ can remove itself from the doubly linked list $B_i(v)$ of $N^-(v)$ in constant time because it stores a pointer to its location.

While theoretically efficient, this solution faces a practical bottleneck due to high space usage. Indeed, it stores six pointers and two integers per edge in the original graph G.

Moreover, the excessive use of pointers makes executing the algorithm less predictable and slowing it down in practice. Additionally, each pointer is not efficient in addressing only a part of the memory, i.e. the out-going edges, since it requires constant (64-bit) memory.

3 Engineering Aspects

We now engineer an efficient implementation of [10]. Our key observation is that there are two data containers where the order of the elements in the container is irrelevant:

- `Vertex` u stores all `DiEdges` $\overrightarrow{uv}$ in arbitrary order, and
- `Bucket` $B_i(v)$ stores all `DiEdges` $\overrightarrow{uv}$ with $i = r_v(u)$ in arbitrary order.

By sorting these sets as arrays, we obtain more control over the size of these objects and the size of pointers to elements in these sets. This in turn allows us to use packing techniques to store the same information in fewer bits.

Arrays. This allows us to use arrays instead of linked list as we give each:

- `Vertex` u an array A_u^+ with all `DiEdges` $\overrightarrow{uv}$ in arbitrary order.
- `Bucket` $B_i(v)$ an array B_i^v with all `DiEdges` $\overrightarrow{uv}$ with $i = r_v(u)$ in arbitrary order.

Adding a `DiEdge` $\overrightarrow{uv}$, given the `Vertex` u and the correct `Bucket` $B_i(v)$, takes amortized constant time. Indeed, we simply increase the sizes of A_u^+ and B_i^v and append $\overrightarrow{uv}$. Removing $\overrightarrow{uv}$ also takes amortized constant time: given its index a in A_u^+ (and b in B_i^v) we may swap $A_u^+[a]$ with the last element of A_u^+ (swap $B_i^v[b]$ with the last element) and decrement the array's size by one. These operations are supported by the `vector` data type in C++.

From Arrays to Packing. Replacing doubly linked lists with vectors naturally reduces algorithmic overhead. It also has a secondary benefit: instead of maintaining, for a `DiEdge` $\overrightarrow{uv}$, pointers to its location in linked lists we store integers maintaining its index in vectors. Recall that we maintain an orientation G_b^* where the maximum out-degree $\texttt{Max}(G_b^*)$ is low. As a consequence, for any vertex v, the array A_u^+ is small. Thus, for a `DiEdge` $\overrightarrow{uv}$ its index in A_u^+ is small. Via the same logic, the integers *robin*, $d_u^*(u)$, $\lfloor \log_{1+\lambda}(r_u(v)) \rfloor$ and the index of the `DiEdge` $\overrightarrow{vu}$ are small. We pack these small values into 32-bit integers.

Indirection. Any `DiEdge` $\overrightarrow{uv}$ contained pointers to: the `Vertex` u, the `Vertex` v, and the `DiEdge` $\overrightarrow{vu}$. If each `DiEdge` only stores a pointer to its target then we can access the `Vertex` u from $\overrightarrow{uv}$ by first accessing the `DiEdge` $\overrightarrow{vu}$ and then reading its target.

Removing Bucket Pointers. Each `Vertex` u maintained a pointer to the primary bucket $B_j(u)$ and each `DiEdge` $\overrightarrow{uv}$ maintained a pointer to the bucket $B_i(v)$ that contains $\overrightarrow{uv}$. These pointers are only used in Algorithm 3. Chekuri et al. [10] prove that to find for a `DiEdge` $\overrightarrow{xy}$ is current bucket, one steps over at most $O(1)$ buckets from the given pointer. We choose to remove these pointers. Instead, we find the correct bucket for $\overrightarrow{xy}$ by looping over all buckets $B_i(y)$. Observe that there are at most $O(\log_{1+\lambda} n) \subseteq O(\lambda^{-1} \log n)$ buckets $B_i(y)$. Moreover, a call to Algorithm 6 or 7 triggers $O(\lambda^{-1})$ information updates *only if* it does not recurse. So, the asymptotic running time remains the same.

Compact Types. By our above analysis, we obtain more compact data types (see Figure 2):

`Bucket` $B_i(u)$ stores a vector B_i^u with `DiEdges` $\overrightarrow{wu}$ with $i = r_u(w)$.

`Vertex` u stores:

- a vector A_u^+ storing all `DiEdges` $\overrightarrow{uv}$ (corresponding to vertices $v \in N^+(u)$).
- a linked list of all non-empty `Buckets` $B_i(u)$, ordered by i.
- a 32-bit integer storing our "current position" *robin* in A_u^+ and the value $d_b^*(u)$.

`DiEdge` $\overrightarrow{uv}$ represents all directed edges $\overrightarrow{uv}$ in G_b^*, simultaneously. It stores:

- A pointer to the `Vertex` v.
- A 32-bit integer storing the *counter*, the value $r_v(u)$, and the index of $\overrightarrow{vu}$ in A_u^+.
- An 32-bit integer storing the index of $\overrightarrow{uv}$ in B_i^v for $i = r_v(u)$.

3.1 A Space-Time Trade-off

Finally, we propose one more modification to the algorithm. The algorithm in [10] and our above implementation store for a vertex v all non-empty buckets $B_i(v)$ in a linked list. The algorithm in [10] accesses these buckets by storing a pointer for each edge in G. In our implementation, we find the bucket $B_i(v)$ where $i = r_v(u)$ in $O(\log_{1+\lambda} n)$ time by iterating over all buckets $B_j(v)$. We showed that that this does not increase the asymptotic running time. However, it does increase the *actual* running time of the program.

Both methods have an inherent downside: [10] uses a lot of memory per edge, and our above implementation is relatively slow. Moreover, doubly linked list inherently bring a lot of overhead and cache misses. We therefore propose a third solution to store the buckets:

We define for a `Vertex` v the *Bucket array* $\mathbb{B}_v$ such that for all i, $\mathbb{B}_v[i] = B_i(v)$. Any `DiEdge` $\overrightarrow{uv}$ can access the bucket $B_i(v)$ where $i = r_v(u)$ by simply indexing $\mathbb{B}_v[r_v(u)]$ in constant time. By storing the array $\mathbb{B}_v$ as a vector, we require only a relatively small amount

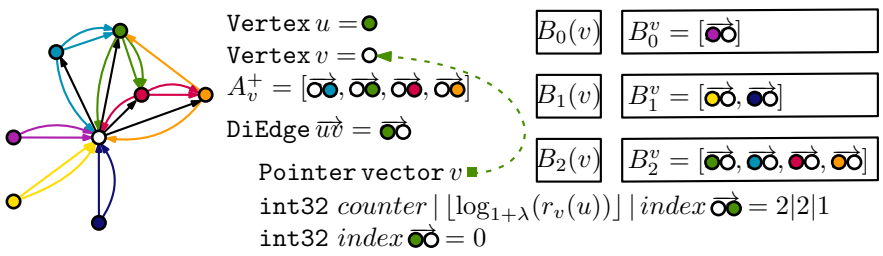

Figure 2 We illustrate our more compact data structure compared to the one from Figure 1.

of memory for every empty bucket. There are $O(\log_{1+\lambda}(n))$ buckets for each vertex v, so this additively increases our space usage by $O(\frac{n}{\lambda}\log n)$. Since the number of edges m is considerably larger than the number of vertices n, this is space-efficient when compared to [10]. This solution does use more space compared to our above implementation, with the benefit of having a significantly faster implementation of Algorithm 3. Thus, we offer two implementations – one using singly linked lists, and one using this array data structure – that together provide a trade-off between time and space used.

4 Experimental Evaluation

In this section we evaluate our algorithm and compare its performance with previous work by Großmann et al. [27] and Borowitz et al. [6]. We compare them on the sparse data set introduced in [6] and present a new dense data set featuring also deletions. The analysis is done in separate sections (sparse, dense) since the performance of the various algorithms highly depend on the density of used inputs.

Methodology. We carried out the implementation of the algorithms in C++ and compiled the programs with g++-11.4. We tested each algorithm on a machine equipped with 768 GB of RAM and an AMD EPYC 9754 128-Core Processor running at 2.25 GHz having a cache of 256 MB. The time loading the graphs is not measured, but instead we measure every operation and sum up the timings. We repeated every experiment 3 times, computations taking longer than a day in total were cancelled and are marked as out of time (OOT) in the result tables. For comparing the results we use performance profiles as introduced by Dolan and Moré [17]. For a factor of $\tau > 1$ we plot the fraction of instances that could be solved within that factor of the best result per instance. Algorithms in the top left corner of the plot (e.g. Figure 3) are considered the best algorithm.

Instances. We use two sets of graphs for the experiments. First, the *sparse set* containing 83 instances collected by Borowitz et al. [6]. Only four of the instances feature deletions. The size of the graphs is small to medium and they have low-density and out-degree. Second, the *dense set*, that contains three, large, denser graphs sourced from the Suite Sparse Matrix collection [15] and four ultra-dense graphs generated with KaGen [22]. See also our supplemental details. The ultra-dense graphs were generated in the Erdos-Renyi model having 8192 vertices and between $\frac{1}{2}$ and $\frac{7}{8}$ of all possible edges. The graphs and their features are listed in the full version. For these instance we generated three different update sequences. The first, building up the graph in lexicographical ordering (Lex). The other two also include deletion of edges afterwards. The edges to be deleted are selected based on an optimal orientation of the final graph, computed with HeiOrient [38]. In the Lex+Top50 configuration all edges outgoing from the upper half of vertices ordered by out-degree are deleted.

The Lex+Out50 configuration is built by maintaining a heap of the vertices by out-degree. Outgoing edges are deleted and the out-degree is updated in the heap until the maximum out-degree is half of the optimal orientation. We select these sequences in order to see how different deletion strategies impact the quality, memory and runtime metrics.

Comparisons and Implementations. We refer to our basic implementation of the algorithm by Chekuri et al. [10] as Fractional and with our engineering improvements as PackedFractional. We provide two implementations of PackedFractional. One with PackedFractional list organizes

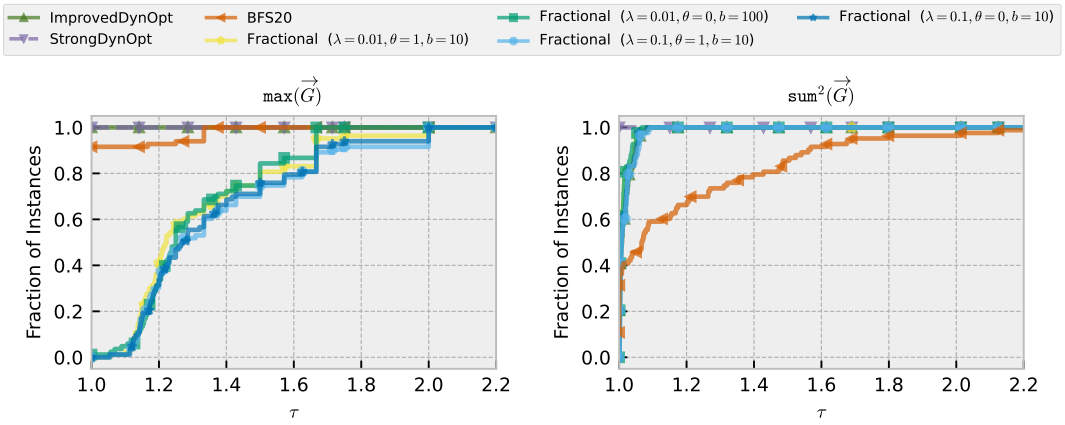

Figure 3 State-of-the-art comparison with different quality measures on the sparse instance set. The PackedF* is omitted due to its similar results as Fractional with a maximum difference of 0.3%.

the in-buckets in a singly linked list, and the one without suffix works with directly addressable, possibly empty, buckets. We compare with BFS20 by Borowitz et al. [6] and StrongDynOpt and ImprovedDynOpt by Großmann et al. [27]. These algorithms are the best performing in the extensive studies in [6] and [27] with regards to the max out-degree metric $\max(\overrightarrow{G})$. The $\text{sum}^2(\overrightarrow{G})$ metric has not been studied in practice. The BFS20 algorithm performs a limited breadth-first-search of length up to 20 to find improving paths upon insertion and removes only the edge on deletion, not optimizing the orientation. The StrongDynOpt runs a breadth-first-search to find improving paths on every insertion and deletion, returning the optimal orientation concerning out-degree and squared-sum of out-degree. The ImprovedDynOpt only searches for improving paths if it is necessary to maintain the optimal out-degree.

Parameters. The algorithms Fractional and PackedFractional derived in Section 2.1 and Section 3 have the three parameters: λ, θ, b. First, $\lambda > 0$ and $\theta \in \{0, 1\}$ control the quality of the approximation by defining its λ-fairness. If $\theta = 0$, b must be larger than $\frac{1}{\lambda}$ so that the fractional orientation inequality can be satisfied. Otherwise ($\theta = 1$), b can be set to 1 making the orientation integral. This comes at costs of quality in the form of an additive error of $O(\log n)$ in the approximation.

4.1 Experiments on Sparse Instances

The following experiments are conducted on the sparse instance set collected by Borowitz et al. [6] and analyse the running times and quality of the orientations. Since some of graphs in this set were too small to consistently measure the maximum resident memory by repeatedly querying the linux internal process stats, we examine the memory consumption only for the dense instances. The maximum peak memory is 23 GB for the Fractional and PackedFractional with $\lambda = 0.01$ and $\theta = 0$ implementations on the LJOURNAL-2008 instance. The PackedFractional list algorithm with $\lambda = 0.1$, $\theta = 1$ only requires 4.4 GB on this instance - only 2.29 times the amount of StrongDynOpt.

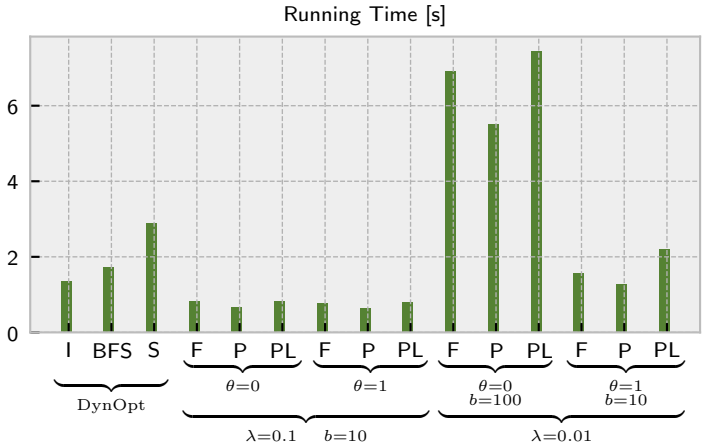

Figure 4 Running times on the sparse set comparing Fractional (F), PackedFractional (P), and PackedFractional, list (PL) with BFS20 (BFS), ImprovedDynOpt (I), and StrongDynOpt (S). Parameters: λ overall fairness of the orientation maintained. θ is a binary variable deciding an additional $O(\log n)$ error, b is the number of fractional edges.

Quality Metrics. In Figure 3 we compare different configurations of Fractional with the state-of-the-art for integral orientations. We evaluate the performance using the two quality measures discussed in Section 2. For better readability, the results for the packed implementations are omitted. They achieve similar to those results of the Fractional configurations with a maximum difference in quality of less than 0.3%. We can observe that smaller values of λ lead to improved solution quality for both metrics.

Maximum Out-Degree. When comparing the algorithms using the metric $\max(\overrightarrow{G})$, we can observe that both exact approaches ImprovedDynOpt and StrongDynOpt always find the optimum solution. Compared to these, Fractional performs worse overall, but maintains a factor of less than two for all parameter choices.

Squared Sum of Out-Degrees. When evaluating with $\text{sum}^2(\overrightarrow{G})$ of the naively rounded fractional orientations, Fractional performs significantly better than the BFS20 algorithm, matching the results of ImprovedDynOpt. The StrongDynOpt algorithm returns the best values on every instance. This is the expected behaviour, because improving all possible paths minimizes both objective functions. Our newly engineered algorithms perform very well in the $\text{sum}^2(\overrightarrow{G})$ metric as they were designed for it. The variation in $\lambda \in \{0.01, 0.1\}$ is not visible in this metric. In exchange, they allow themselves a higher maximum out-degree on some of the vertices which is not accounted for in the definition of λ-fair.

Running Time. Figure 4 shows the geometric mean running time for the approaches on the sparse data set. The normalized running times can be found in the full version. Our fastest algorithm PackedFractional is twice as fast as ImprovedDynOpt, which is the fastest state-of-the-art method on this data set. The running time of our approach is highly dependent on the parameter choices. Setting $\theta = 1$ is faster than $\theta = 0$. Decreasing λ results in longer running times. The smallest value $\lambda = 0.01$ we tested is 8.58 times slower than the fastest configuration with $\lambda = 0.1$. The packed list implementation is up to 35 % slower. The measured difference between ImprovedDynOpt and BFS20 matches the result in [27].

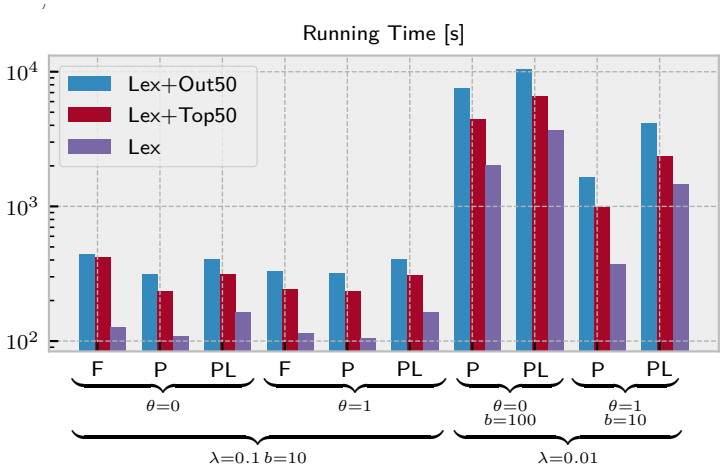

Figure 5 Geometric mean running times on the dense set comparing Fractional (F), PackedFractional (P), and PackedFractional, list (PL). We evaluate them for the different deletion sequences.

4.2 Experiments on Dense Instances

We conduct the following experiments on the new dense instance set, which includes three real-world graphs and four ultra-dense graphs. As in previous sections, we analyze running time and solution quality, and additionally provide an in-depth examination of memory usage.

Quality Metrics. Only three out of the 21 instances were solved optimally by StrongDynOpt on the set of dense instances in the given timeout of 24 hours. Therefore, we show performance profiles for our parameter choices and PackedFractional in the full version on all instances and limited the following discussion about quality on those three instances.

Maximum Out-Degree. Evaluating the performance using $\max(\overrightarrow{G})$ the solutions of Fractional are between 24 % ($\lambda = 0.01$) up to 30 % ($\lambda = 0.1$) worse than the optimal orientations. The method BFS20 also performs worse on these instances with solutions being 26 % worse. Note that this approach does not handle deletions explicitly by running a improving path search, which can explain the observed suboptimal results on our instances featuring deletions. These results match the observations of previous work.

Squared Sum of Out-Degrees. Using $\text{sum}^2(\overrightarrow{G})$, we observe a solution quality for PackedFractional which is less than 0.8 % higher for $\lambda = 0.1$ and only 0.3 % higher when setting $\lambda = 0.01$ than the optimum computed by StrongDynOpt. With this, we achieve better results on these instances compared to ImprovedDynOpt, which in the geometric mean has a solution quality that is 15 % worse. The ImprovedDynOpt is specialised in maintaining the minimum maximum out-degree while requiring fewer operations than StrongDynOpt. Therefore, its $\text{sum}^2(\overrightarrow{G})$ metric is worse than our results. The impact of the λ factor, in the range we tested, on the $\text{sum}^2(\overrightarrow{G})$ metric is small for our new algorithms.

Running Time. The running times on the dense set for our implementations are displayed in Figure 5. We detail these results in the full version. Detailed results per instance are shown in the full version. The choice of lambda greatly impacts the running time. Reducing the value of λ by a factor of 10 from 0.1 to 0.01 (keeping $\theta = 0$) can result in running time that is 20 times slower in the geometric mean. Setting $\theta = 1$ speeds up the algorithm by up to a factor of 5 for small $\lambda = 0.01$ compared to $\theta = 0$. The methods from Borowitz et al. [6]

and Großmann et al. [27] find solutions for considerably fewer number of instances in this data set while requiring more running time. More precisely, BFS20, ImprovedDynOpt, and StrongDynOpt find solutions on 15, 5, and 3 instances while having a geometric mean running time which is 112.17, 29.15, and 25.98 times slower than our fastest algorithm (PackedFractional) on the respective instances.

Memory. As a smaller λ value results in more buckets, we expect the memory consumption to increase with decreasing λ. This behaviour can be observed in Figure 6. Here, we compare the memory consumption of our implementations, which is evaluated separately for the different deletion sequences. Already for $\lambda = 0.1$, we can observe that the PackedFractional is improving over Fractional, where we achieve a geometric mean reduction in memory consumption by a factor of 1.94. In the case of $\lambda = 0.01$, we omit Fractional due to its already high memory consumption for $\lambda = 0.1$ and focus on comparing the implementations PackedFractional and PackedFractional, list. With this configuration, the List implementation can save up to a factor of 2.72 memory ($\lambda = 0.01, \theta = 0, b = 100$). Overall, we can see that the choice for λ has the highest impact regarding memory consumption. However, the parameters θ and b also influence the memory needed. The memory consumption for the competitor algorithms is generally smaller. Compared to our best approach, the competitor methods perform up to a factor of 3.32 better. However, this result is expected since they do not maintain a fractional orientation but an integral one. They store each edge's target on both sides in combination with the position of the reverse edge in the other array. Lastly, we observe that the deletion of edges (Top50, Out50) requires more memory than just the Lex ordering, with the Out50 requiring the most. This is caused by the spreading of indices in the in-bucket, as seen by the smaller difference in the list implementations.

Practitioner Advice: When optimizing the sum of squared out-degrees we recommend using the packed PackedFractional implementation since it is the fastest implementation overall and the difference in quality to the exact method (StrongDynOpt) is minimal. The list implementation should only be used if memory consumption is of utmost importance. The choice of parameters is paramount. Choosing higher values for λ speeds up the computation and reduces the memory needed. Setting $\theta = 1$ can be used to relax the running time further, but is penalized by a quality trade-off. The b parameter should be chosen small to speed up computation, but has to stay above $\frac{1}{\lambda}$ if $\theta = 0$.

5 Conclusion

We have bridged the gap between theoretical results and practical experiments for adaptive edge orientations. We engineered a space efficient implementation of a λ-fair fractional orientation algorithm by Chekuri et al. [10] and presented several effective methods to reduce the memory footprint of the algorithm. In extensive experiments we show the feasibility of our approach in comparison with several competitors from previous work. Our results for the squared sum degree metric are close to optimal, while the running time is considerably lower than competing algorithms. Our algorithm PackedFractional solves more instances than the competitors within one day of compute time per instance while it is up to 112 times faster on the instances that are solvable by all methods compared. Our list-based bucket implementations can decrease the memory consumption by a factor of 2.72. Future avenues of work include reducing the memory costs further and looking at batch updates. These aspects could be combined with efforts to parallelize the algorithms.

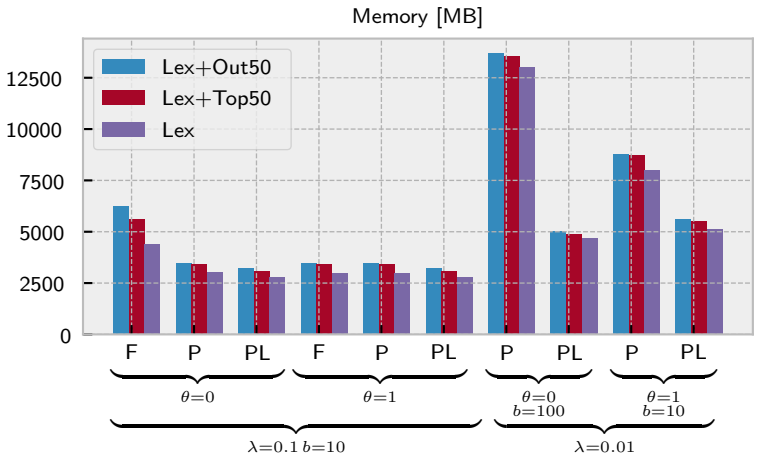

Figure 6 Memory consumption of Fractional (F), PackedFractional (P), and PackedFractional, list (PL) for different configurations evaluated separately for the different deletions sequences.

Abstract

In the k-Edge Connected Spanning Subgraph (k-ECSS) problem we are given a (multi-)graph $G = (V, E)$ with edge costs and an integer k, and seek a min-cost k-edge-connected spanning subgraph of G. The problem admits a 2-approximation algorithm and no better approximation ratio is known. Recently, Hershkowitz, Klein, and Zenklusen [STOC 24] gave a bicriteria $(1, k-10)$-approximation algorithm that computes a $(k-10)$-edge-connected spanning subgraph of cost at most the optimal value of a standard Cut-LP for k-ECSS. We improve the bicriteria approximation to $(1, k-4)$ and also give another non-trivial bicriteria approximation $(3/2, k-2)$.

The k-Edge-Connected Spanning Multi-subgraph (k-ECSM) problem is almost the same as k-ECSS, except that any edge can be selected multiple times at the same cost. A $(1, k-p)$ bicriteria approximation for k-ECSS w.r.t. Cut-LP implies approximation ratio $1+p/k$ for k-ECSM, hence our result also improves the approximation ratio for k-ECSM.

1 Introduction

A graph is **k-edge-connected** if it contains k edge-disjoint paths between any two nodes. We consider the following problem.

k-Edge-Connected Spanning Subgraph (k-ECSS)
Input: A (multi-)graph $G = (V, E)$ with edge costs and an integer k.
Output: A min-cost k-edge-connected spanning subgraph J of G.

The problems admits approximation ratio 2 by a reduction to a bidirected graph (c.f. [17]), and no better approximation ratio is known. Recently, Hershkowitz, Klein, and Zenklusen [14] (henceforth HKZ) gave a bicriteria $(1, k-10)$-approximation algorithm that computes a $(k-10)$-edge-connected spanning subgraph of cost at most the optimal value of a standard Cut-LP for k-ECSS. Our first result improves the connectivity approximation to $k-4$.

▶ **Theorem 1.** *k-ECSS admits a bicriteria approximation ratio $(1, k-4)$ w.r.t. the Cut-LP.*

The k-Edge-Connected Spanning Multi-subgraph (k-ECSM) problem is almost the same as k-ECSS, except that any edge can be selected multiple times at the same cost. For k-ECSM, approximation ratios $3/2$ for k even and $3/2 + O(1/k)$ for k odd were known long time ago [10, 11], and it was conjectured by Pritchard [29] that k-ECSM admits approximation ratio $1 + O(1/k)$. HKZ [14] showed that k-ECSM has an $(1 + \Omega(1/k))$-approximation threshold and that a $(1, k-p)$ bicriteria approximation for k-ECSS w.r.t. the standard Cut-LP implies approximation ratio $1 + p/k$ for k-ECSM. Thus the novel result of HKZ [14] implies an approximation ratio $1 + 10/k$ for k-ECSM (improving the previous ratio $1 + O(1/\sqrt{k})$ of [16]), and we reduce the approximation ratio to $1 + 4/k$.

▶ **Corollary 2.** *k-ECSM admits approximation ratio $1 + 4/k$.*

In addition, we also study bicriteria approximation ratios when the cost approximation is bellow 2, and prove the following.

▶ **Theorem 3.** k-ECSS *admits a bicriteria approximation ratio* $(3/2, k-2)$.

We note that while HKZ presented a novel original approach for attacking the problem and gave the first additive bicriteria approximation, our contribution here is more modest, as follows.

- We present a simpler algorithm that uses the HKZ [14] idea and a much simpler proof, based on new properties of k-ECSS Cut-LP extreme point solutions; see Lemmas 4.
- This enabled us to improve the connectivity approximation from $k-10$ to $k-4$.
- We use the same idea to present another nontrivial bicriteria approximation $(3/2, k-2)$.

We now survey some related work. k-ECSS is an old fundamental problem in combinatorial optimization and network design. The case $k=1$ is the MST problem, while for $k=2$ the problem is MAX-SNP hard even for unit costs [7]. Pritchard [29] showed that there is a constant $\epsilon > 0$ such that for any $k \geq 2$, k-ECSS admits no $(1+\epsilon)$-approximation algorithm, unless P = NP. No such hardness of approximation was known for k-ECSM, and Pritchard [29] conjectured that k-ECSM admits approximation ratio $1 + O(1/k)$. This conjecture was resolved by HKZ [14], who also proved a matching hardness of approximation result.

The k-ECSS problem and its special cases have been extensively studied, c.f [22, 8, 10, 11, 18, 1, 4, 17, 13, 12, 29, 30, 32, 14] for only a small sample of papers in the field. Nevertheless, the current best known approximation ratio for k-ECSS is 2, the same as was four decades ago. The 2-approximation is obtained by bidirecting the edges of G, computing a min-cost directed spanning subgraph that contains k edge-disjoin dipaths to all nodes from some root node (this can be done in polynomial time [5]), and returning its underlying graph. A 2-approximation can also be achieved with the iterative rounding method [15], that gives a 2-approximation also for the more general Steiner Network problem, where we seek a min-cost subgraph that contains r_{uv} edge-disjoint paths for every pair of nodes $u, v \in V$. The directed version of k-ECSS was also studied, c.f. [5, 13, 1, 17], and for this case also no better than 2-approximation is known, except for special cases.

Bicriteria approximation algorithms were widely studied for degree constrained network design problems such as Bounded Degree MST and Bounded Degree Steiner Network, c.f. [31, 21, 20] and the references therein. A particular case of a bicriteria approximation is when only one parameter is relaxed while the cost/size of the solution is bounded by a budget B. For example, the $(1-1/e)$-approximation for the Budgeted Max-Coverage problem can be viewed as a bicriteria approximation $(1, 1-1/e)$ for Set Cover, where only a fraction of $1-1/e$ of the elements is covered by opt sets. Similarly, in the budgeted version Budgeted ECSS of k-ECSS, instead of k we are given a budget B and seek a spanning subgraph of cost at most B that has maximum edge-connectivity k^*.

One can view Theorem 1 as a $k^* - 4$ additive approximation for Budgeted ECSS, where k^* is the maximum edge-connectivity under the budget B. We note that budgeted connectivity problems were studied before for unit costs. Specifically, in the Min-Size k-ECSS and Min-Size k-CSS problems we seek a k-edge-connected and k-node-connected, respectively, spanning subgraph with a minimal number of edges. Nutov [24] showed that the following simple heuristic (previously analyzed by Cheriyan and Thurimella [1]) is a $(1, k-1)$ bicriteria approximation for Min-Size k-CSS: compute a min-size $(k-2)$-edge-cover I_{k-2} (a spanning subgraph of minimal degree $\geq k-2$) and then augment it by an inclusion minimal edge set $F \subseteq E$ such that $I_{k-2} \cup F$ is $(k-1)$-connected. This $(1, k-1)$ bicriteria

approximation implies a $k^* - 1$ approximation for Budgeted Min-Size k-CSS, which is tight, since the problem is NP-hard. A similar result for k-ECSS, for large enough k, can be deduced from the work of Gabow and Gallagher [12].

One can obtain a bicriteria approximation $(2/\theta, \lfloor k/\theta \rfloor)$ for k-ECSS for any $\theta \geq 1$, by just solving the $\lfloor k/\theta \rfloor$-ECSS problem. This is since the 2 approximation is w.r.t. the Cut-LP. Specifically, if x is a k-ECSS Cut-LP solution, then x/θ is a $\lfloor k/\theta \rfloor$-ECSS Cut-LP solution, thus a 2-approximation w.r.t. Cut-LP for $\lfloor k/\theta \rfloor$-ECSS computes a $\lfloor k/\theta \rfloor$-connected subgraph of cost $\leq 2/\theta \cdot \mathsf{opt}_k$. Similar "LP-scaling" gives a bicriteria approximation $(2/\theta, \lfloor r_{uv}/\theta \rfloor)$ for any $\theta \geq 1$ for the Steiner Network problem.

The node connectivity version k-CSS of k-ECSS was also studied extensively [19, 6, 25, 1, 24, 2, 28, 26, 27]; it admits approximation ratio $4 + \epsilon$ when k is bounded by a constant, but for general k only a polylogarithmic approximation is known [6, 25]. The Survivable Network Design Problem (SNDP) is the node-connectivity version of Steiner Network when there should be r_{uv} internally node disjoint path between every $u, v \in V$; k-CSS is a particular case when $r_{uv} = k$ for all $u, v \in V$. The Rooted SNDP is another particular case of SNDP where we require k disjoint paths from a root s to every node in a given set T of terminals, and the k-Out-Connected Spanning Subgraph (k-OCSS) problem is a particular case of Rooted SNDP when $T = V \setminus \{s\}$. Since the best approximation ratios for these problems are w.r.t. to the Cut-LP (a.k.a. "biset LP") they can be used to obtain bicretiria approximations using the method described above. We summarize the best approximation ratios for these problems and the bicriteria approximation ratios that can be derived for them by a simple "LP-scaling" in the following table.

Table 1 LP and bicriteria approximation ratios for node connectivity problems. The third row gives the approximation cost that can achieve connectivity $\lfloor k/\theta \rfloor$ ($\lfloor r_{uv}/\theta \rfloor$ for SNDP) for any $\theta \geq 1$.

problem	SNDP	Rooted SNDP	k-CSS	k-OCSS
approximation	$O(k^3 \log n)$ [3]	$O(k \log k)$ [23]	$4 + \frac{4 \lg k + 1}{\lg n - \lg k}$ [28]	2 [9]
bicriteria appr.	$\frac{1}{\theta} O((k/\theta)^3 \log n)$	$\frac{1}{\theta} O((k/\theta) \log(k/\theta))$	$\frac{1}{\theta}\left(4 + \frac{4 \lg(k/\theta) + 1}{\lg n - \lg(k/\theta)}\right)$	$2/\theta$

This paper is organized as follows. In Sect. 2 we describe our iterative rounding algorithm. In Sect. 3 we prove the connectivity guarantee, and in Sect. 4 we prove a certain property of extreme point solutions that is used in the algorithm. Sect. 5 gives a bicriteria approximation $(3/2, k-2)$.

2 The Algorithm

For an edge set F and disjoint node sets S, T let $\delta_F(S,T)$ denote the set of edges in F with one end in S and the other end in T, and let $d_F(S,T) = |\delta_F(S,T)|$. Let $\delta_F(S) = \delta_F(S, \bar{S})$ and $d_F(S) = |\delta_F(S)|$, where $\bar{S} = V \setminus S$ is the node complement of S. For $x \in \mathbb{R}^E$ let $x(F) = \sum_{e \in F} x(e)$. We will often refer to a proper subset S of V (so $\emptyset \neq S \subset V$) as a **cut**. A standard Cut-LP for k-ECSS is:

$$\begin{array}{lll} \min & c^T \cdot x & \\ \text{s.t.} & x(\delta_E(S)) \geq k & \forall \emptyset \neq S \subset V \\ & 0 \leq x_e \leq 1 & \forall e \in E \end{array}$$

As in HKZ [14], we will use the iterative rounding relaxation method. This means that while $E \neq \emptyset$, we repeatedly compute an extreme point optimal solution x to the Cut-LP above, and do at least one of the following steps:

1. Remove from E an edge e with $x_e = 0$.
2. Add to a partial solution I an edge e with $x_e = 1$, and remove e from E.
3. Relax some cut constraints $x(\delta(S)) \geq k$ to $x(\delta(S)) \geq k - q$ for some integer q.

The relaxation of the cut constraints will be implemented in two different ways.

(i) Relaxing the cut constraint of a single cut S (and also of $\bar{S} = V \setminus S$) and then contracting S into a single node v_S; this also removes the constraint of every cut A such that both $A \cap S$ and $A \cap \bar{S}$ are non-empty. We will store the nodes that correspond to such relaxed contracted cuts S in a set U.

(ii) Relaxing the constraints of all cuts S that separate two nodes $u_1, u_2 \in U$ (that correspond to contracted sets C_1, C_2) to $x(\delta(S)) \geq k - 2$. This is achieved by adding to the partial solution a "ghost edge" u_1u_2 of capacity 2, and considering the "residual" demands of sets w.r.t the ghost edges. We will store the added ghost edges in a set H.

Instead of working with the cut constraints $x(\delta_E(S)) \geq k$ it would be convenient to consider the residual constraints $x(\delta_E(S)) \geq f(S)$ for an appropriately defined set function f. To define this f, suppose that we are already given:

- A partial solution I of already chosen "integral" edges, that were removed from E.
- A set H of "ghost-edges" – these are new virtual edges that are added to the solution.
- A set U of nodes that correspond to contracted cuts whose constraints are relaxed.

Let $f(S)$ be a set function defined on proper node subsets S by

$$f(S) = \begin{cases} k - d_I(S) - 2d_H(S) - 2 & \text{if } S = \{u\} \text{ or } \bar{S} = \{u\} \text{ for some } u \in U \\ k - d_I(S) - 2d_H(S) & \text{otherwise} \end{cases} \tag{1}$$

This function $f(S)$ is a relaxation of the usual residual function $k - d_I(S)$ of k-ECSS. Consider the following LP-relaxation with the function f above:

$$\begin{array}{lll} \min & c^T \cdot x & \\ \text{s.t.} & x(\delta_E(S)) \geq f(S) & \forall \emptyset \neq S \subset V \\ & 0 \leq x_e \leq 1 & \forall e \in E \end{array} \tag{2}$$

A set S is **f-positive** if $f(S) > 0$. Given an LP solution x we say that S is **x-tight** if the LP-inequality of S holds with equality, namely, if $x(\delta(S)) = f(S)$. An **x-core**, or simply a **core** if x is clear from the context, is an inclusion-minimal f-positive x-tight set (note that an x-core must be f-positive and not only x-tight).

To **contract a node subset** C of a graph $G = (V, E)$ means to identify all nodes in C into one node v_C; edges that have an end in C now have v_C as their end and the arising loops (if any) are deleted. During the algorithm, we iteratively contract certain node subsets of G, so we denote the initial graph by $G_0 = (V_0, E_0)$.

Our algorithm is given in Algorithm 1. The main difference between Algorithm 1 and that of HKZ is that we never add parallel ghost edges, namely we must have $d_H(u, v) = 0$ whenever we add a ghost edge uv. This has a chain reaction of simplifying some other parts of the algorithm. For example, we add a ghost edge when $d_I(u, v) \geq \lceil (k-3)/2 \rceil$ (and $d_H(u, v) = 0$) while the analogous condition in HKZ is $d_{I \cup H}(uv) \in [k/2 - 2, k/2)$. The upper bound $d_{I \cup H}(u, v) < k/2$ in HKZ is needed to control the number of parallel ghost edges added, which also complicates the analysis.

In Section 4 we will prove the following lemma about extreme point solutions of LP (2).

Algorithm 1 A bicriteria $(1, k-4)$-approximation.

```
1  initialization: I ← ∅, H ← ∅, U ← ∅, μ ← ⌈(k − 3)/2⌉
2  while E ≠ ∅ do
3      compute an extreme point solution x to LP (2) with f in (1)
4      remove from E every edge e with x_e = 0
5      if there is e ∈ E with x_e = 1 then
6          move from E to I every edge e with x_e = 1 and goto line 2
7      if there is an x-core C with d_E(C) ∈ {2, 3} then
8          contract C into a single node v_C and update U ← (U \ C) ∪ {v_C}
9      else if there are u, v ∈ U with d_I(u, v) ≥ μ and d_H(u, v) = 0 then
10         add to H a ghost-edge uv and update U ← U \ {u, v}
11 return J = I
```

▶ **Lemma 4.** *Let f be defined by (1) and suppose that $d_H(u) \leq 1$ and $d_I(u) + 2d_H(u) \geq k-2$ for all $u \in U$. Let x be an extreme point of the polytope $P = \{x \in [0,1]^E : x(\delta_E(S)) \geq f(S)\}$ such that $0 < x_e < 1$ for all $e \in E$, where $E \neq \emptyset$. Then at least one of the following holds.*

(i) *There is an x-core C with $d_E(C) \in \{2,3\}$; moreover, no edge in E has both ends in C.*

(ii) *There are $u, v \in U$ with $d_H(u,v) = 0$ and $d_I(u,v) \geq \mu$, where $\mu = \lceil (k-3)/2 \rceil$.*

Furthermore, such u, v or such C can be found in polynomial time.

Interestingly, the two cases in Lemma 4 depend on whether there exist a laminar set family $\mathcal{L}$ such that x is the unique solution to the equation system $\{x(\delta_E(S) = f(S) : S \in \mathcal{L}\}$. Specifically, if such $\mathcal{L}$ exists then case (i) in Lemma 4 holds, otherwise case (ii) must hold.

In the next Section 3 we will show that the algorithm terminates after a polynomial number of iterations and prove the connectivity guarantee $k-4$. Since in each iteration the cut constraints are only relaxed (by contractions, or by including nodes in U, or by adding ghost edges), the cost of the produced solution is at most the initial LP-value. In this context note that the -2 relaxation of the nodes $u, v \in U$ is not canceled when u, v are removed from U, it is just replaced by the -2 relaxation caused by the added ghost edge uv.

3 Connectivity guarantee

For every ghost edge $h = uv$ added, let $I(h) = I(uv)$ be the set of (at least $\mu = \lceil (k-3)/2 \rceil$) edges in J that appear in $\delta_I(u, v)$. A key observation is the following.

▶ **Lemma 5.** *For any distinct ghost edges h, h' added during the algorithm, $I(h) \cap I(h') = \emptyset$.*

Proof. This follows from the condition that when a ghost edge $h = uv$ added, there is no other ghost edge between u and v. Specifically, assume w.l.o.g. that $h = uv$ was added after h'. Then all edges in $I(h)$ are uv-edges – go between the sets C_u, C_v that correspond to u, v, while no edge in $I(h')$ is a uv-edge. ◀

▶ **Lemma 6.** *When a core C is found in the algorithm but not yet contracted, $d_H(C) \leq 1$, $x(\delta_E(C)) \in \{1,2\}$, and $d_I(C) = k - 2d_H(C) - x(\delta_E(C))$. Consequently,*

- *$d_I(C) \in \{k-1, k-2\}$ if $d_H(C) = 0$.*
- *$d_I(C) \in \{k-3, k-4\}$ if $d_H(C) = 1$.*

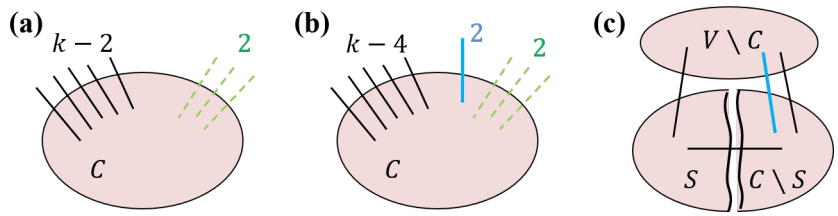

Figure 1 Illustration to the proofs of Lemmas 6 and 8. Edges in I are shown by black lines, edges in E (the fractional edges) by green dashed lines, and the ghost edge is blue.

Proof. If $d_H(C) \geq 2$ then $d_I(C) + 2d_H(C) \geq 2\mu + 4 \geq k$, hence $f(C) \leq 0$, contradicting that C is a core (recall that a core must be an f-positive set). We have $d_E(C) \in \{2, 3\}$, so there are 2 or 3 fractional edges in $\delta_E(C)$. Since C is x-tight, $x(\delta_E(C))$ is a positive integer that is either 1 or 2, so there are $k - 1 - 2d_H(C)$ or $k - 2 - 2d_H(C)$ (integral) edges in $\delta_I(C)$. If $d_H(C) = 0$ then $d_I(C) \in \{k - 1, k - 2\}$ and if $d_H(C) = 1$ then $d_I(C) \in \{k - 3, k - 4\}$; see Fig. 1(a,b) where $\delta_E(x(C)) = 2$ and $d_H(C) = 0$ or $d_H(C) = 1$, respectively. ◀

The following lemma shows that the conditions of Lemma 4 hold during the algorithm, and thus the algorithm terminates.

▶ **Lemma 7.** *During the algorithm $d_H(u) \leq 1$ and $d_I(u) + 2d_H(u) \geq k - 2$ holds for all $u \in U$. Furthermore, $d_H(v) \leq 2$ for all $v \in V \setminus U$.*

Proof. By Lemma 6, when u enters U we have $d_H(u) \leq 1$ and $d_I(u) \geq k - 2d_H(u) - 2$. This implies $f(\{u\}) = k - d_I(u) - 2d_H(u) - 2 \leq 0$. The addition of a ghost edge incident to u excludes u from U but does not increase $f(\{u\})$. Hence $\{u\}$ will never be chosen as a core C and will never enter U again. If we had $d_H(u) = 1$ when u entered U, then u will leave U with $d_H(u) = 2$ and will never enter U again. Thus $d_H(v) \leq 2$ for all $v \in V \setminus U$. ◀

A set family $\mathcal{R}$ is **laminar** if any two sets in the family are either disjoint or one contains the other. Let $\mathcal{R}$ be the family of subsets of V_0 that correspond to the contracted sets during the algorithm (recall that $G_0 = (V_0, E_0)$ denotes the initial graph). It is known and not hard to see that $\mathcal{R}$ is laminar. We will say that a cut S of G_0 is **compatible** with a graph G during the algorithm if $R \subseteq S$ or $R \cap S = \emptyset$ for every $R \in \mathcal{R}$ that was contracted so far to obtain G. As long as S is compatible with G, we can look at the cut of G that corresponds to S, which for simplicity of notation we will also denote by S, and lower bound $d_I(S)$ (the degree of the set that corresponds to S w.r.t to the partial solution I) instead of $d_J(S)$ (the degree of S w.r.t to the final solution J), since $I \subseteq J$ and hence $d_J(S) \geq d_I(S)$.

We would like to establish the bound $d_J(S) \geq k - 4$ for a cut S of G_0 such that $\mathcal{R} \cup \{S\}$ is laminar. For such S, it is easy to determine the last graph G that S is compatible with. For a cut S of G_0 let R_S be the inclusion minimal set in $\mathcal{R} \cup \{V\}$ that properly contains S. If $R_S = V$ then S compatible with G till the end of the algorithm. If $R_S \neq V$ then S (such that $\mathcal{R} \cup \{S\}$ is laminar) is compatible with G as long as R_S is not contracted, hence we will analyze such S as a cut of G right before the core $C = R_S$ is contracted. Due to the fact that at this moment no edge in E has both ends in C and since $d_E(C) \leq 3$ and $x(\delta_E(C)) \leq 2$ (by Lemma 4(i)), the difference between $d_I(S)$ and $d_J(S)$ is small.

▶ **Lemma 8.** *When a core C in the algorithm is found but not yet contracted, the following holds for any proper subset S of C.*

(i) *$d_I(S) \geq d_H(S) \cdot \mu$ and $d_I(S) \geq k - 2d_H(S) - 2$.*

(ii) *$d_I(S, C \setminus S) \geq \mu$.*

Proof. We prove (i). $d_I(S) \geq d_H(S) \cdot \mu$ by Lemma 5. If $S = \{u\}$ for some $u \in U$ then $d_I(u) \geq k - 2d_H(u) - 2$ by Lemma 6. Otherwise, the constraint of S is relaxed by ghost edges only, and since $\delta_E(S) \subseteq \delta_E(C)$ (Lemma 4(i)) and $x(\delta_E(C)) \leq 2$ (Lemma 6), we get

$$d_I(S) \geq k - 2d_H(S) - x(\delta_E(S)) \geq k - 2d_H(S) - 2 \ .$$

We prove (ii). If $d_H(S, C \setminus S) \geq 1$ then $d_I(S, C \setminus S) \geq \mu$ since $d_I(u, v) \geq \mu$ when the ghost edge uv is added. Otherwise, $d_H(S) + d_H(C \setminus S) = d_H(C) \leq 1$ and since $d_J(R) \leq k - 2d_H(C) - 1$ (by Lemma 6) and by part (i) we get

$$\begin{aligned} 2d_I(S, C \setminus S) &= d_I(S) + d_I(C \setminus S) - d_I(C) \\ &\geq [k - 2d_H(S) - 2] + [k - 2d_H(C \setminus S) - 2] - [k - 2d_H(C) - 1] \\ &= k - 3 - 2[d_H(S) + d_H(C \setminus S) - d_H(C)] = k - 3 \ , \end{aligned}$$

concluding the proof. ◀

The notation $\delta_H(S)$ and $d_H(S)$ are well defined for any node subset S at any iteration of the algorithm. We now extend it to any subset S of V. We can view a ghost edge v_1v_2 as a pair $\{C_1, C_2\}$ of sets in $\mathcal{R}$ that correspond to v_1, v_2. We say that such a **ghost-edge covers** S if one of C_1, C_2 is contained in S and the other in $\bar{S}$. Let $\delta_H(S)$ denote the set of ghost edges in H that cover S and let $d_H(S)$ be their number.

▶ **Corollary 9.** *Let S be a cut such that $\mathcal{R} \cup \{S\}$ is laminar. Then $d_J(S) \geq k - 2d_H(S) - 2$ and $d_J(S) \geq d_H(S) \cdot \mu$. Furthermore, if $R_S = V$ and $S \notin R$ then $d_J(S) \geq k - 2d_H(S)$. Consequently, $d_J(S) \geq \max\{k - 2d_H(S) - 2, d_H(S) \cdot \mu\} \geq k - 4$.*

Proof. The bound $d_J(S) \geq d_H(S) \cdot \mu$ follows from Lemma 5, so we prove only the bound $d_J(S) \geq k - 2d_H(S) - 2$. For $S \in \mathcal{R}$ it follows from Lemma 6, so assume that $S \notin \mathcal{R}$. If S is contained in some set in $\mathcal{R}$, then let C be the inclusion minimal set in $\mathcal{R}$ that contains S. The bound then follows from Lemma 8(i). Otherwise, the constraint of S was relaxed by ghost edges only and then $d_J(S) \geq k - 2d_H(S)$. ◀

Before establishing the bound $d_J(S) \geq k - 4$ for sets S such that $\mathcal{R} \cup \{S\}$ is not laminar, we need three additional lemmas. The next lemma considers sets $R \in \mathcal{R}$ and $T \subset \bar{R}$ such that both $\mathcal{R} \cup T, \mathcal{R} \cup (\bar{R} \setminus T)$ are laminar; one can verify that this is equivalent to $\mathcal{R} \cup \{T, \bar{R} \setminus T\}$ being laminar. Moreover, this means that R is an inclusion maximal set in $\mathcal{R}$, and any other set in $\mathcal{R}$, except for maybe $\bar{R}$ (if $\bar{R} \in \mathcal{R}$), is contained in one of $R, T, \bar{R} \setminus T$.

▶ **Lemma 10.** *Let $R \in \mathcal{R}$ and let T be a proper subset of $\bar{R}$ such that the set family $\mathcal{R} \cup \{T, \bar{R} \setminus T\}$ is laminar. Then $d_J(T, \bar{R} \setminus T) \geq \lceil (k-6)/2 \rceil$.*

Proof. If $d_H(T, \bar{R} \setminus T) \geq 1$ then $d_J(T, R \setminus T) \geq \mu > \lceil (k-6)/2 \rceil$ by Lemma 5. Otherwise, $d_H(R) = d_H(T) + d_H(\bar{R} \setminus T)$. Since $d_J(T) \geq k - 2d_H(T) - 2$ and $d_J(\bar{R} \setminus T) \geq k - 2d_H(\bar{R} \setminus T) - 2$ by Corollary 9, and $d_J(R) \leq k - 2d_H(R) + 2$ by Lemma 6, we get (see Fig. 2(a))

$$\begin{aligned} 2d_J(T, \bar{R} \setminus T) &= d_J(T) + d_J(\bar{R} \setminus T) - d_J(R) \\ &\geq [k - 2d_H(T) - 2] + [k - 2d_H(\bar{R} \setminus T) - 2] - [k - 2d_H(R) + 2] \\ &= k - 6 - 2[d_H(T) + d_H(\bar{R} \setminus T) - d_H(R)] = k - 6 \ , \end{aligned}$$

concluding the proof. ◀

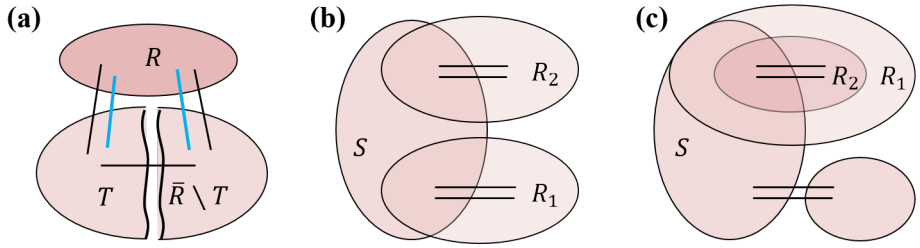

Figure 2 Illustration to the proofs of Lemmas 10 and 13.

We say that a set S **overlaps** a set R, or that R, S **overlap**, if the pair $\{R, S\}$ is not laminar, namely if the sets $R \cap S, R \setminus S, S \setminus R$ are all non-empty. Now we consider sets S that overlap some $R \in \mathcal{R}$. Note however, that it may be that S overlaps some $R \in \mathcal{R}$, but $\bar{S}$ does not, so we can still deduce from Corollary 9 that $d_J(S) = d_J(\bar{S}) \geq k - 4$. To avoid this confusion we will examine among the sets $S, \bar{S}$ one that is more "compatible" with $\mathcal{R}$. More formally, let $\mathcal{R}(S) = \{R \in \mathcal{R} : S \text{ overlaps } R\}$ be the family of sets in $\mathcal{R}$ that S overlaps, and note that so far we examined the case $|\mathcal{R}(S)| = 0$. So now w.l.o.g. we will assume that $1 \leq |\mathcal{R}(S)| \leq |\mathcal{R}(\bar{S})|$. Under this assumption, we have the following.

▶ **Lemma 11.** *If $1 \leq |\mathcal{R}(S)| \leq |\mathcal{R}(\bar{S})|$ then $V \setminus (R \cup S) \neq \emptyset$ for any $R \in \mathcal{R}(S)$.*

Proof. Let $R \in \mathcal{R}(S)$ and suppose that $|\mathcal{R}(S)| \leq |\mathcal{R}(\bar{S})|$. It is known that $\mathcal{R}(R \setminus S) \subset \mathcal{R}(S)$; this is so since every set in $\mathcal{R}$ that overlaps $R \setminus S$ also overlaps S, but R overlaps S but not $R \setminus S$, c.f. [33, Lemma 23.15]. Thus $|\mathcal{R}(R \setminus S)| < |\mathcal{R}(S)|$. If $V \setminus (R \cup S) = \emptyset$ then $R \setminus S = \bar{S}$ and we get $|\mathcal{R}(\bar{S})| < |\mathcal{R}(S)|$ contradicting the assumption $|\mathcal{R}(S)| \leq |\mathcal{R}(\bar{S})|$. ◀

▶ **Lemma 12.** *Suppose that $1 \leq |\mathcal{R}(S)| \leq |\mathcal{R}(\bar{S})|$.*
(i) *If R is a minimal set in $\mathcal{R}(S)$ then $d_J(R \cap S, R \setminus S) \geq \mu$.*
(ii) *If R is a unique maximal set in $\mathcal{R}(S)$ then $d_J(\bar{R} \cap S, \bar{R} \setminus S) \geq \lceil (k-6)/2 \rceil$.*

Proof. We prove (i). The minimality of R implies that if $T \in \{R \cap S, R \setminus S\}$ then $\mathcal{R} \cup \{T\}$ is laminar. Therefore by Lemma 8(ii) $d_J(R \cap S, R \setminus S) \geq \mu$.

We prove (ii). The maximality of R implies that if $T \in \{\bar{R} \cap S, \bar{R} \setminus S\}$ then $\mathcal{R} \cup \{T\}$ is laminar. Therefore by Lemma 10 $d_J(\bar{R} \cap S, \bar{R} \setminus S) \geq \lceil (k-6)/2 \rceil$. ◀

▶ **Lemma 13.** *If $1 \leq |\mathcal{R}(S)| \leq |\mathcal{R}(\bar{S})|$ then $d_J(S) \geq k - 4$.*

Proof. Suppose that there are two disjoint sets in $\mathcal{R}(S)$. Then there are two minimal sets in $\mathcal{R}(S)$ that are disjoint, say R_1, R_2; see Fig. 2(b). Then by Lemma 12(i)

$$d_J(S) \geq d_J(R_1 \cap S, R_1 \setminus S) + d_J(R_2 \cap S, R_2 \setminus S) \geq \mu + \mu > k - 4 \ .$$

Otherwise, $\mathcal{R}(S)$ is a nested family with a unique maximal set R_1 and a unique minimal set R_2; see Fig. 2(c) and note that $R_2 \subseteq R_1$ and possibly $R_1 = R_2$. Then by Lemma 12 we get

$$d_J(S) \geq d_J(\bar{R}_1 \cap S, \bar{R}_1 \setminus S) + d_J(R_2 \cap S, R_2 \setminus S) \geq \lceil (k-6)/2 \rceil + \mu = k - 4 \ ,$$

concluding the proof. ◀

This concludes the proof of the connectivity guarantee of Algorithm 1. Now we show that the algorithm terminates after a polynomial number of iterations.

▶ **Lemma 14.** *The algorithm terminates after $O(n)$ iterations, where $n = |V|$.*

Proof. Let x be an extreme point computed at the first iteration of the algorithm. It is known (c.f. [13]) that $|\{0 < x_e < 1 : e \in E\}| \leq 2n-1$, namely, at most $2n-1$ variables x_e are fractional. This follows from two facts. The first is that after the integral entries are substituted, the fractional entries are determined by a full rank system of constraints $\{x(\delta_E(S)) = k : S \in \mathcal{L}\}$ where $\mathcal{L}$ is laminar, c.f. [15, 13]. The second is that a laminar family on a set of n elements has size at most $2n-1$. The latter fact also implies that $|\mathcal{R}| \leq 2n-1$. By Lemma 7, the ghost edges form a 2-matching on $\mathcal{R}$, thus $|H| \leq |\mathcal{R}| \leq 2n-1$. At each iteration we remove an edge from E, or add a set to $\mathcal{R}$, or add a ghost edge. Hence the number of iterations is bounded by $|\mathcal{L}|+|\mathcal{R}|+|H| \leq (2n-1)+(2n-1)+(2n-1) = 3(2n-1) = O(n)$. ◀

4 Properties of extreme point solutions (Lemma 4)

Here we will prove Lemma 4. Fix an extreme point solution x as in the Lemma. Then there exists a family $\mathcal{L}$ of f-positive x-tight sets such that x is the unique solution to the equation system $\{x(\delta_E(S)) = f(S) : S \in \mathcal{L}\}$; namely, $|\mathcal{L}| = |E|$ and the characteristic vectors of the sets $\{\delta_E(S) : S \in \mathcal{L}\}$ are linearly independent. We will call such a family $\mathcal{L}$ **x-defining**. The following was essentially proved in [14].

▶ **Lemma 15** ([14]). *If there exists a laminar x-defining family $\mathcal{L}$ then there is an x-core C such that $d_E(C) \in \{2,3\}$ and $f(C) \in \{1,2\}$; moreover, no edge in E has both ends in C.*

Proof. Let $\mathcal{C}_{\mathcal{L}}$ be the family of minimal sets in $\mathcal{L}$. It was proved by HKZ [14] that there is $S \in \mathcal{C}_{\mathcal{L}}$ such that $d_E(S) \leq 3$ and no edge in E has both ends in S; we provide a proof sketch for completeness of exposition. Suppose to the contrary that $d_E(S) \geq 4$ for every $S \in \mathcal{C}_{\mathcal{L}}$. Assign 2 tokens to every edge uv, and then reassign these tokens – one to the smallest set in $\mathcal{L}$ that contains u and one to the smallest set in $\mathcal{L}$ that contains v (if such sets exist). The paper of Jain [15] shows that then for any $S \in \mathcal{L}$, the tokens assigned to sets in $\mathcal{L}(S) = \{T \in \mathcal{L} : T \subseteq S\}$ can be redistributed such that S gets at least 4 tokens and every $T \in \mathcal{L}(S)$ gets at least 2 tokens, giving the contradiction $|E| > |\mathcal{L}|$. The proof in [15] is by induction on $|\mathcal{L}(S)|$. If $S \in \mathcal{C}_{\mathcal{L}}$ is a leaf then S already has 4 tokens, since $d_E(S) \geq 4$ for every $S \in \mathcal{C}_{\mathcal{L}}$. Else, S can collect 2 tokens from each child in $\mathcal{L}(S)$, so if S has at least two children then we are done. Else, S has exactly one child, and then [15] shows that by linear independence, there are 2 tokens assigned to S, which together with the extra 2 tokens of the child of S gives the required 4 tokens. This shows that there is $S \in \mathcal{C}_{\mathcal{L}}$ such that $d_E(S) \leq 3$.

Note that for any $T \in \mathcal{C}_{\mathcal{L}}$, no edge in E has both ends in T; this is since for every $e \in E$ there is $S_e \in \mathcal{L}$ such that $e \in \delta_E(S_e)$, since the variable x_e must appear in at least one equation among $\{x(\delta_E(S)) = f(S) : S \in \mathcal{L}\}$. Let $S \in \mathcal{C}_{\mathcal{L}}$ be such that $d_E(S) \leq 3$. If S is an x-core then we are done. Otherwise, let C be an x-core properly contained in S. We claim that $\delta_E(C) \subseteq \delta_E(S)$, and that $d_E(C) \geq 2$. This follows from the following observations.

1. $d_E(C) \geq 2$, since C is f-positive and since we assume that $0 < x_e < 1$ for all $e \in E$.
2. For every $e \in \delta_E(C)$ there is $S_e \in \mathcal{L}$ such that $e \in \delta_E(S_e)$, since the variable x_e must appear in at least one equation among $\{x(\delta(S)) = f(S) : S \in \mathcal{L}\}$.

This gives $d_E(C) \in \{2,3\}$, as required. ◀

In the rest of this section we will prove the following.

▶ **Lemma 16.** *Under the assumptions of Lemma 4, if no laminar x-defining family exists then there are $u, v \in U$ with $d_I(u,v) \geq \mu$ and $d_H(u,v) = 0$.*

In the rest of this section assume that the assumptions of Lemma 4 hold ($d_H(u) \leq 1$ and $d_I(u) + 2d_H(u) \geq k-2$ for all $u \in U$), and that no laminar x-defining family exists.

▶ **Lemma 17.** *There are f-positive x-tight sets A, B that cross (namely, all the four sets $A \cap B, A \setminus B, B \setminus A, \bar{A} \cap \bar{B}$ are non-empty) such that the following holds:*
(i) *$A \cap B = \{u\}$ or $\bar{A} \cap \bar{B} = \{u\}$ for some $u \in U$.*
(ii) *$A \setminus B = \{v\}$ or $B \setminus A = \{v\}$ for some $v \in U$.*

Proof. For a cut S let $\chi_S \in \{0,1\}^E$ be the incidence vector of $\delta_E(S)$. Let $\mathcal{T}$ be the family of f-positive x-tight sets (if S is tight but not f-positive, then $\chi_S \equiv 0$, since $x_e > 0$ for all $e \in E$). Let us say that $A, B \in \mathcal{T}$ are **x-uncrossable** if at least one of the following holds:
(a) $A \cap B, A \cup B$ are both x-tight and $\chi_A + \chi_B = \chi_{A \cap B} + \chi_{A \cup B}$.
(b) $A \setminus B, B \setminus A$ are both x-tight and $\chi_A + \chi_B = \chi_{A \setminus B} + \chi_{B \setminus A}$.
We will prove two claims that will imply the lemma.

▷ Claim. There are $A, B \in \mathcal{T}$ that are not x-uncrossable.

Proof. Let $\mathcal{L}$ be a maximal laminar subfamily of $\mathcal{T}$. Let $\mathsf{span}(\mathcal{T})$ denote the linear space spanned by the incidence vectors of the sets in $\mathcal{T}$ and similarly $\mathsf{span}(\mathcal{L})$ is defined. Since no laminar x-defining family exists and by the maximality of $\mathcal{L}$, there is $A \in \mathcal{T} \setminus \mathcal{L}$ such that $\chi_A \notin \mathsf{span}(\mathcal{L})$; any such A overlaps some set in $\mathcal{L}$. Choose such A that overlaps the minimal number of sets in $\mathcal{L}$, and let $B \in \mathcal{L}$ be a set that A overlaps. We show that (a) cannot hold; the proof that (b) cannot hold is similar. Suppose to the contrary that (a) holds, namely that $\chi_A + \chi_B = \chi_{A \cap B} + \chi_{A \cup B}$ and $A \cap B, A \cup B$ are both x-tight. It is known that each of the sets $A \cap B, A \cup B$ overlaps strictly less sets in $\mathcal{L}$ than A, c.f. [33, Lemma 23.15]. Thus by our choice of A, each of these sets has its incidence vector in $\mathsf{span}(\mathcal{L})$, namely $\chi_{A \cap B}, \chi_{A \cup B} \in \mathsf{span}(\mathcal{L})$. But $\chi_A = \chi_{A \cap B} + \chi_{A \cup B} - \chi_B$, contradicting that $\chi_A \notin \mathsf{span}(\mathcal{L})$. ◁

▷ Claim. If $A, B \in \mathcal{T}$ are not x-uncrossable then A, B cross and both (i) and (ii) hold.

Proof. We show that A, B cross. If A, B do not overlap then $\{A, B\} = \{A \cap B, A \cup B\}$ or $\{A, B\} = \{A \setminus B, B \setminus A\}$ and we are done. We claim that also $\bar{A} \cap \bar{B} \neq \emptyset$. Otherwise, $A \setminus B = \bar{B}$, $B \setminus A = \bar{A}$, and thus $\chi_{A \setminus B} = \chi_{\bar{B}} = \chi_B$ and $\chi_{B \setminus A} = \chi_{\bar{A}} = \chi_A$, implying that $A \setminus B, B \setminus A$ are both x-tight and $\chi_A + \chi_B = \chi_{A \setminus B} + \chi_{B \setminus A}$. Now we prove that (i) holds; a proof that (ii) holds is similar, and in fact can be deduced from (i) by the symmetry of f. Suppose to the contrary that (i) does not hold. Denoting $\Delta = x(\delta_E(A \setminus B, B \setminus A))$ we have:

$$\begin{aligned} f(A) + f(B) &= x(\delta_E(A)) + x(\delta_E(B)) \\ &= x(\delta_E(A \cap B)) + x(\delta_E(A \cup B)) + 2\Delta \\ &\geq f(A \cap B) + f(A \cup B) + 2\Delta \\ &\geq f(A) + f(B) + 2\Delta \ . \end{aligned}$$

The first equality is since A, B are tight, and the second can be verified by counting the contribution of each edge to both sides. The first inequality is since x is a feasible LP-solution. The second inequality is since none of $A, B, A \cap B, A \cup B$ is a singleton from U or its complement, hence f coincides on these sets with the symmetric supermodular function $g(S) = k - d_I(S) - 2d_H(S)$, that satisfies the inequality $g(A \cap B) + g(A \cup B) \geq g(A) + g(B)$. Consequently, equality holds everywhere, hence $A \cap B, A \cup B$ are both tight. Moreover, $\Delta = 0$, and this implies $\chi_A + \chi_B = \chi_{A \cap B} + \chi_{A \cup B}$, contradicting that A, B are not x-uncrossable. ◁

By the first claim there exists $A, B \in \mathcal{T}$ that are not x-uncrossable, while by the second claim such A, B cross and satisfy both (i) and (ii), concluding the proof of the lemma. ◀

By the symmetry of f, assume w.l.o.g. that $A \cap B = \{u\}$ and $A \setminus B = \{v\}$ for $u, v \in U$.

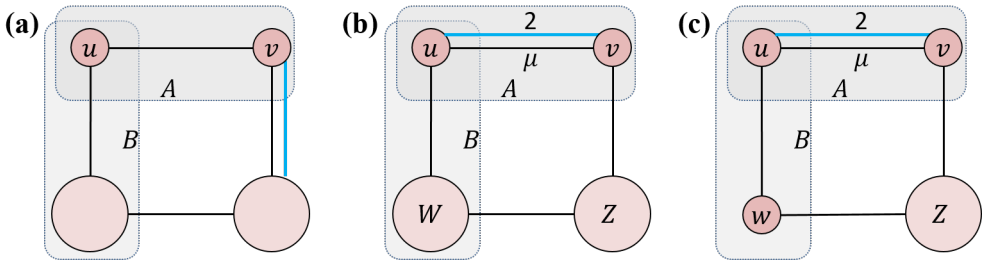

Figure 3 Illustration to the proofs of Lemmas 18 and 19.

▶ **Lemma 18.** *If $d_H(u,v) = 0$ then $d_I(u,v) \geq \mu$.*

Proof. By the assumption of Lemma 4, $d_I(u) + 2d_H(u) \geq k-2$ and $d_I(v) + 2d_H(v) \geq k-2$. Since A is f-positive, $d_I(A) + 2d_H(A) \leq k-1$. Thus we get (see Fig. 3(a))

$$k-1 \geq d_I(A)+2d_H(A) = [d_I(u)+2d_H(u)]+[d_I(v)+2d_H(v)]-2d_I(u,v) \geq 2(k-2)-2d_I(u,v)\ .$$

Consequently, $2d_I(u,v) \geq k-3$, as claimed. ◀

The next lemma shows that if $d_H(u,v) = 1$ then there is an "alternative" node $w \in U$ such that we can add a ghost edge uw or vw.

▶ **Lemma 19.** *If $d_H(u,v) = 1$ then there is $w \in U$ such that one of the following holds:*
(i) *$\bar{A} \cap B = \{w\}$, $d_H(u,w) = 0$, and $d_I(u,w) \geq \mu$.*
(ii) *$\bar{A} \setminus B = \{w\}$, $d_H(v,w) = 0$, and $d_I(v,w) \geq \mu$.*

Proof. For disjoint sets S, T let $\psi(S,T) = d_I(S,T) + 2d_H(S,T) + x(\delta_E(S,T))$, and let $\psi(S) = \psi(S,\bar{S})$ be the "coverage" of S by I, H, and the fractional edges. Note that

$$\psi(S) \geq \begin{cases} k-2 & \text{if } S = \{u\} \text{ or } \bar{S} = \{u\} \text{ for some } u \in U \\ k & \text{otherwise} \end{cases}$$

In particular, $\psi(S) < k$ implies that $S = \{w\}$ or $\bar{S} = \{w\}$ for some $w \in U$.

Let $W = \bar{A} \cap B$ and $Z = \bar{A} \setminus B$, see Fig. 3(b). Note that $\psi(A) = \psi(B) = k$ since A, B are x-tight and that $\psi(u,v) \geq 2d_H(u,v) + \mu = 2 + \mu$. This implies (see Fig. 3(b))

$$\psi(W,Z) \leq \psi(B) - \psi(u,v) \leq k - (2+\mu)\ .$$

Thus we get

$$2k - 2(2+\mu) \geq 2\psi(W,Z) = \psi(W) + \psi(Z) - \psi(A) = \psi(W) + \psi(Z) - k$$

Consequently, $\psi(W) + \psi(Z) \leq 3k - 2(2+\mu) < 2k$, since $2(2+\mu) > k$. Thus $\psi(W) < k$ or $\psi(Z) < k$, and w.l.o.g. assume that $\psi(W) < k$. This implies that $W = \{w\}$ for some $w \in U$; (see Fig. 3(c)). Note that $d_H(u,w) = 0$, since $d_H(u,v) = 1$ and since $d_H(u) \leq 1$ by the assumption of Lemma 4. Also, $d_I(B) + 2d_H(B) \leq k-1$, since B is f-positive. Thus we have

$$\begin{aligned} 2d_I(u,w) &= 2[d_I(u,w) + 2d_H(u,w)] \\ &= [d_I(u) + 2d_H(u)] + [d_I(w) + 2d_H(w)] - [d_I(B) + 2d_H(B)] \\ &\geq (k-2) + (k-2) - (k-1) = k-3\ , \end{aligned}$$

concluding the proof. ◀

To show a polynomial time implementation it is sufficient to prove the following lemma, that was essentially proved in [14]; we provide a proof for completeness of exposition.

▶ **Lemma 20** ([14]). *At any step of the algorithm, an extreme point solution x to LP (2) with f in (1), as well as the x-cores can be computed in polynomial time.*

Proof. An extreme point solution can be found using the Ellipsoid Algorithm. For that, we need the show an existence of a polynomial time separation oracle: given x, determine whether x is a feasible LP solution or find a violated inequality. Checking the inequalities $0 \leq x_e \leq 1$ is trivial. For cut inequalities, assign capacities w_e to the edges in $E \cup I \cup H$ as follows: $w_e = x_e$ if $e \in E$, $w_e = 1$ if $e \in I$, and $w_e = 2$ if $e \in H$. The inequality of a cut S is violated if and only if $w(\delta(S)) < k$ and none of $S, \bar{S}$ is a singleton in U. Thus to find an st-cut with violated inequality do the following. If $s, t \notin U$ then we find a minimum st-cut S; if $w(\delta(S)) < k$ then we found a violated inequality, else no st-cut with violated inequality exists. If $s \in U$ and $t \notin U$, then for every $u \in V \setminus \{s, t\}$ we contract u into s and find a minimum st-cut S_v; if $w(\delta(S_v)) < k$ for some v, then we found a violated inequality, else no st-cut with violated inequality exists. Similarly, If $s, t \in U$ then for every pair $u, v \in V \setminus \{s, t\}$ we contract u into s and v into t and find a minimum st-cut $S_{u,v}$; if $w(\delta(S_{u,v})) < k$ for some u, v then we found a violated inequality, else no st-cut with violated inequality exists.

We show how to find all x-cores. Assume w.l.o.g. that $0 < x_e < 1$ for all $e \in E$. One can see that a cut C is an x-core if and only if C is an inclusion minimal set that has w-capacity k and $\delta_E(C) \neq \emptyset$. For every ordered pair (s, t) with $st \in E$ we check if there exists an st-cut C (so $s \in C$ and $t \notin C$) of capacity exactly k, and if so, then we find the inclusion minimal such cut $C(s, t)$. The x-cores are the inclusion minimal sets among the sets $C(s, t)$. ◀

This concludes the proof of Lemma 4 and thus also of Theorem 1.

5 Proof of Theorem 3

In the algorithm of Theorem 3 we use the following function f:

$$f(S) = \begin{cases} k - d_I(S) - d_H(S) - 1 & \text{if } S = \{u\} \text{ or } \bar{S} = \{u\} \text{ for some } u \in U \\ k - d_I(S) - d_H(S) & \text{otherwise} \end{cases} \tag{3}$$

The main difference between Algorithm 1 and the following Algorithm 2 are:

1. We use a different function f – the one defined in (3).
2. We round to 1 edges e with $x_e \geq 2/3$.
3. Adding a ghost edge uv requires $\mu = \lceil (k-1)/2 \rceil$ integral uv-edges.

Algorithm 2 A bicriteria $(3/2, k-2)$-approximation.

```
1  initialization: I ← ∅, H ← ∅, U ← ∅, μ ← ⌈(k − 1)/2⌉

11 return J = I
```

A counterpart of Lemma 4 is as follows.

▶ **Lemma 21.** *Let f be defined by (3) and suppose that $d_H(u) \leq 1$ and $d_I(u)+d_H(u) \geq k-1$ for all $u \in U$. Let x be an extreme point of the polytope $P = \{x \in [0,1]^E : x(\delta_E(S)) \geq f(S)\}$ with $0 < x_e < 2/3$ for all $e \in E$, where $E \neq \emptyset$. Then at least one of the following holds.*

- **(i)** *There is an x-core C with $d_E(C) \in \{2,3\}$ and $f(C) = 1$; moreover, no edge in E has both ends in C.*
- **(ii)** *There are $u, v \in U$ with $d_H(u,v) = 0$ and $d_I(u,v) \geq \mu$, where $\mu = \lceil (k-1)/2 \rceil$.*

Furthermore, such u, v or such C can be found in polynomial time.

Proof. By Lemma 15, if there exists an x-defining laminar family, then there is an x-core C such that $d_E(C) \in \{2,3\}$, $f(C) \in \{1,2\}$, and no edge in E has both ends in C. But $f(C) = 2$ is not possible, as otherwise there is $e \in \delta_E(C)$ with $x_e \geq 2/3$. Hence in this case (i) holds.

We now show that if no laminar x-defining family exists then (ii) holds. Similarly to Lemma 17 we conclude that there is a pair A, B of x-tight f-positive sets that cross such that $A \cap B = \{u\}$ and $A \setminus B = \{v\}$ for some $u, v \in U$.

We claim that if $d_H(u,v) = 0$ then $d_I(u,v) \geq \mu$. By the assumption of the lemma, $d_I(u)+d_H(u) \geq k-1$ and $d_I(v)+d_H(v) \geq k-1$. Since A is f-positive, $d_I(A)+d_H(A) \leq k-1$. Thus we get (see Fig. 3(a))

$$k-1 \geq d_I(A)+d_H(A) = [d_I(u)+d_H(u)]+[d_I(v)+d_H(v)]-2d_I(u,v) \geq 2(k-1)-2d_I(u,v) \; .$$

Consequently, $2d_I(u,v) \geq k-1$, as claimed.

We prove that if $d_H(u,v) = 1$ then there is $w \in U$ such that one of the following holds:

- $\bar{A} \cap B = \{w\}$, $d_H(u,w) = 0$, and $d_I(u,w) \geq \mu$.
- $\bar{A} \setminus B = \{w\}$, $d_H(v,w) = 0$, and $d_I(v,w) \geq \mu$.

Let $\psi(S,T) = d_I(S,T) + d_H(S,T) + x(\delta_E(S,T))$ and $\psi(S) = \psi(S,\bar{S})$. Note that

$$\psi(S) \geq \begin{cases} k-1 & \text{if } S = \{u\} \text{ or } \bar{S} = \{u\} \text{ for some } u \in U \\ k & \text{otherwise} \end{cases}$$

In particular, $\psi(S) < k$ implies that $S = \{w\}$ or $\bar{S} = \{w\}$ for some $w \in U$.

Let $W = \bar{A} \cap B$ and $Z = \bar{A} \setminus B$. Note that $\psi(A) = \psi(B) = k$ since A, B are x-tight and that $\psi(u,v) \geq d_H(u,v) + \mu = 1 + \mu$. This implies $\psi(W,Z) \leq \psi(B) - \psi(u,v) \leq k - (1+\mu)$, see Fig. 3(b). Thus we get

$$2k - 2(1+\mu) \geq 2\psi(W,Z) = \psi(W) + \psi(Z) - \psi(A) = \psi(W) + \psi(Z) - k$$

Consequently, $\psi(W) + \psi(Z) \leq 3k - 2(1+\mu) < 2k$, since $2(1+\mu) > k$. Thus $\psi(W) < k$ or $\psi(Z) < k$, and w.l.o.g. $\psi(W) < k$. This implies that $W = \{w\}$ for some $w \in U$, see Fig. 3(c). Note that $d_H(u,w) = 0$, since $d_H(u,v) = 1$ and since $d_H(u) \leq 1$ by the assumption of the lemma. Also, $d_I(B) + d_H(B) \leq k-1$, since B is f-positive. Thus we have

$$\begin{aligned} 2d_I(u,w) &= 2[d_I(u,w) + d_H(u,w)] \\ &= [d_I(u) + d_H(u)] + [d_I(w) + d_H(w)] - [d_I(B) + d_H(B)] \\ &\geq (k-1) + (k-1) - (k-1) = k-1 \; . \end{aligned}$$

The polynomial time implementation details are identical to those in Lemma 20. ◀

We now prove the connectivity guarantee. As before, let $\mathcal{R}$ be the family of subsets of V_0 that correspond to the contracted sets during the algorithm. Similarly to the previous case, we have the following sequence of lemmas.

▶ **Lemma 22.** *When a core C is found in the algorithm but not yet contracted, $d_H(C) \leq 1$, $x(\delta_E(C)) = 1$, and $d_I(C) = k - d_H(C) - x(\delta_E(C)) = k - d_H(C) - 1$. Consequently, $d_I(C) = k - 1$ if $d_H(C) = 0$ and $d_I(C) = k - 2$ if $d_H(C) = 1$.*

Proof. If $d_H(C) \geq 2$ then $d_I(C) + 2d_H(C) \geq 2\mu + 2 \geq k$, contradicting that C is a core. Since $d_E(C) \in \{2, 3\}$ and $x(\delta_E(C))$ is a positive integer, we must have $x(\delta_E(C)) = 1$, as otherwise there is $e \in \delta_E(C)$ with $x_e \geq 2/3$. ◀

▶ **Lemma 23.** *During the algorithm $d_H(u) \leq 1$ and $d_I(u) + d_H(u) = k - 1$ holds for all $u \in U$. Furthermore, $d_H(v) \leq 2$ for all $v \in V \setminus U$. Thus the algorithm terminates after $O(m)$ iterations.*

Proof. By Lemma 22, when u enters U we have $d_H(u) \leq 1$ and $d_I(u) = k - d_H(u) - 1$. This implies $f(\{u\}) = k - d_I(u) - d_H(u) - 1 = 0$. The addition of a ghost edge incident to u excludes u from U but does not increase $f(\{u\})$, hence $\{u\}$ will never enter U again. If we had $d_H(u) = 1$ when u entered U, then u will leave U with $d_H(u) = 2$ and will never enter U again. Thus $d_H(v) \leq 2$ for all $v \in V \setminus U$. The proof that the algorithm terminates after $O(m)$ iterations is identical to the proof of Lemma 14. ◀

▶ **Lemma 24.** *When a core C is found in the algorithm but not yet contracted, the following holds for any proper subset S of C.*

(i) *$d_I(S) \geq d_H(S) \cdot \mu$ and $d_I(S) \geq k - d_H(S) - 1$.*

(ii) *$d_I(S, C \setminus S) \geq \mu$.*

Proof. We prove (i). $d_I(S) \geq d_H(S) \cdot \mu$ by Lemma 5. If $S = \{u\}$ for some $u \in U$ then $d_I(u) = k - d_H(u) - 1$ by Lemma 22. Otherwise, the constraint of S is relaxed by ghost edges only, and since $\delta_E(S) \subseteq \delta_E(C)$ (by Lemma 21(i)) and $x(\delta_E(C)) \leq 1$ (by Lemma 22), we get $d_I(S) \geq k - d_H(S) - x(\delta_E(S)) = k - d_H(S) - 1$.

We prove (ii). If $d_H(S, C \setminus S) \geq 1$ then $d_I(S, C \setminus S) \geq \mu$ since $d_I(u, v) \geq \mu$ when the ghost edge uv is added. Otherwise, $d_H(S) + d_H(C \setminus S) = d_H(C) \leq 1$ and since $d_J(C) \leq k - d_H(C) - 1$ (by Lemma 22) and by part (i) we get

$$\begin{aligned} 2d_I(S, C \setminus S) &= d_I(S) + d_I(C \setminus S) - d_I(C) \\ &\geq [k - d_H(S) - 1] + [k - d_H(C \setminus S) - 1] - [k - 2d_H(C) - 1] \\ &= k - 1 - [d_H(S) + d_H(C \setminus S) - d_H(C)] = k - 1 \ , \end{aligned}$$

concluding the proof. ◀

▶ **Corollary 25.** *Let S be a cut such that $\mathcal{R} \cup \{S\}$ is laminar. Then $d_J(S) \geq k - d_H(S) - 1$ and $d_J(S) \geq d_H(S) \cdot \mu$. Furthermore, if $R_S = V$ and $S \notin R$ then $d_J(S) \geq k - d_H(S)$. Consequently, $d_J(S) \geq \max\{k - d_H(S) - 1, d_H(S) \cdot \mu\} \geq k - 2$.*

Proof. The bound $d_J(S) \geq d_H(S) \cdot \mu$ follows from Lemma 5, so we prove only the bound $d_J(S) \geq k - d_H(S) - 1$. For $S \in \mathcal{R}$ it follows from Lemmas 22, so assume that $S \notin \mathcal{R}$. If S is contained in some set in $\mathcal{R}$, then let C be the inclusion minimal set in $\mathcal{R}$ that contains S. The bound then follows from Lemma 24(i). Otherwise, the constraint of S was relaxed by ghost edges only and then $d_J(S) \geq k - d_H(S)$. ◀

▶ **Lemma 26.** *Let $R \in \mathcal{R}$ and let T be a proper subset of $\bar{R}$ such that $\mathcal{R} \cup \{T, \bar{R} \setminus T\}$ is laminar. Then $d_J(T, \bar{R} \setminus T) \geq \lceil (k-4)/2 \rceil$.*

Proof. If $d_H(T, \bar{R} \setminus T) \geq 1$ then by Lemma 5 $d_J(T, R \setminus T) \geq \mu > \lceil (k-4)/2 \rceil$. Otherwise, $d_H(R) = d_H(T) + d_H(\bar{R} \setminus T)$, and since $d_J(R) \leq k - d_H(C) + 2$ (by Lemma 22) we get

$$\begin{aligned} 2d_J(T, \bar{R} \setminus T) &= d_J(T) + d_J(\bar{R} \setminus T) - d_J(R) \\ &\geq [k - d_H(T) - 1] + [k - d_H(\bar{R} \setminus T) - 1] - [k - d_H(R) + 2] \\ &= k - 4 - [d_H(T) + d_H(\bar{R} \setminus T) - d_H(R)] = k - 4 \ , \end{aligned}$$

concluding the proof. ◀

▶ **Lemma 27.** *Suppose that $1 \leq |\mathcal{R}(S)| \leq |\mathcal{R}(\bar{S})|$.*

(i) *If R is a minimal set in $\mathcal{R}(S)$ then $d_J(R \cap S, R \setminus S) \geq \mu$.*

(ii) *If R is a unique maximal set in $\mathcal{R}(S)$ then $d_J(\bar{R} \cap S, \bar{R} \setminus S) \geq \lceil (k-4)/2 \rceil$.*

Proof. We prove (i). The minimality of R implies that if $T \in \{R \cap S, R \setminus S\}$ then $\mathcal{R} \cup \{T\}$ is laminar. Therefore by Lemma 24(ii) $d_J(R \cap S, R \setminus S) \geq \mu$.

We prove (ii). The maximality of R implies that if $T \in \{\bar{R} \cap S, \bar{R} \setminus S\}$ then $\mathcal{R} \cup \{T\}$ is laminar. Therefore by Lemma 26 $d_J(\bar{R} \cap S, \bar{R} \setminus S) \geq \lceil (k-4)/2 \rceil$. ◀

▶ **Lemma 28.** *If $1 \leq |\mathcal{R}(S)| \leq |\mathcal{R}(\bar{S})|$ then $d_J(S) \geq k - 2$.*

Proof. Suppose that there are two disjoint sets in $\mathcal{R}(S)$. Then there are two minimal sets in $\mathcal{R}(S)$ that are disjoint, say R_1, R_2; see Fig. 2(b). Then by Lemma 27(i)

$$d_J(S) \geq d_J(R_1 \cap S, R_1 \setminus S) + d_J(R_2 \cap S, R_2 \setminus S) \geq \mu + \mu > k - 2 \ .$$

Otherwise, $\mathcal{R}(S)$ is a nested family with a unique maximal set R_1 and a unique minimal set R_2; see Fig. 2(c) and note that $R_2 \subseteq R_1$ and possibly $R_1 = R_2$. Then by Lemma 27

$$d_J(S) \geq d_J(\bar{R}_1 \cap S, \bar{R}_1 \setminus S) + d_J(R_2 \cap S, R_2 \setminus S) \geq \lceil (k-4)/2 \rceil + \mu = k - 2 \ ,$$

concluding the proof. ◀

This concludes the proof of the connectivity guarantee of Algorithm 2 and thus also of Theorem 3.

Compact Representation of Semilinear and Terrain-Like Graphs

Jean Cardinal
Université libre de Bruxelles (ULB), Belgium

Yelena Yuditsky
Université libre de Bruxelles (ULB), Belgium

Abstract

We consider the existence and construction of *biclique covers* of graphs, consisting of coverings of their edge sets by complete bipartite graphs. The *size* of such a cover is the sum of the sizes of the bicliques. Small-size biclique covers of graphs are ubiquitous in computational geometry, and have been shown to be useful compact representations of graphs. We give a brief survey of classical and recent results on biclique covers and their applications, and give new families of graphs having biclique covers of near-linear size.

In particular, we show that semilinear graphs, whose edges are defined by linear relations in bounded dimensional space, always have biclique covers of size $O(n \operatorname{polylog} n)$. This generalizes many previously known results on special classes of graphs including interval graphs, permutation graphs, and graphs of bounded boxicity, but also new classes such as intersection graphs of L-shapes in the plane. It also directly implies the bounds for Zarankiewicz's problem derived by Basit, Chernikov, Starchenko, Tao, and Tran (*Forum Math. Sigma*, 2021).

We also consider capped graphs, also known as terrain-like graphs, defined as ordered graphs forbidding a certain ordered pattern on four vertices. Terrain-like graphs contain the induced subgraphs of terrain visibility graphs. We give an elementary proof that these graphs admit biclique partitions of size $O(n \log^3 n)$. This provides a simple combinatorial analogue of a classical result from Agarwal, Alon, Aronov, and Suri on polygon visibility graphs (*Discrete Comput. Geom.* 1994).

Finally, we prove that there exists families of unit disk graphs on n vertices that do not admit biclique coverings of size $o(n^{4/3})$, showing that we are unlikely to improve on Szemerédi-Trotter type incidence bounds for higher-degree semialgebraic graphs.

1 Introduction

Graph covering and partitioning is a well-studied topic in graph theory with numerous connections to real-world problems, see for example the survey of Schwartz [68]. Given a graph G, a *cover* of G is a collection $\mathcal{H}$ of subgraphs of G such that each edge of G is contained in at least one of the subgraphs in $\mathcal{H}$, that is, $E(G) \subseteq \bigcup_{H \in \mathcal{H}} E(H)$. A *partition*

© Jean Cardinal and Yelena Yuditsky;

of G is a collection $\mathcal{H}$ of subgraphs of G such that each edge of G is contained in *exactly* one of the subgraphs in $\mathcal{H}$. Clearly, any partition of a graph is also a cover. The subgraphs in the cover (or partition) can be chosen in different ways, for example, they can be chosen to be cliques, complete bipartite graphs (to which we refer as *bicliques*), cycles, paths, and other graphs (see [68] for a list of results for each of those graph classes).

A natural problem is, for a given graph, to determine the smallest possible number of subgraphs in a cover. We are interested in a related parameter of the cover. Let G be a graph and let $\mathcal{H}$ be a cover of G with any type of subgraphs. The *size* of a cover $\mathcal{H}$ is $\sum_{H\in\mathcal{H}} |V(H)|$. Clearly, those parameters are related. If G has a cover with ℓ subgraphs, then there is also a cover of G of size ℓn where $n = |V(G)|$.

In this work, we focus on the size of covers with bicliques, to which we refer as *biclique covers*. See Figure 1 for an example of biclique cover of a graph.

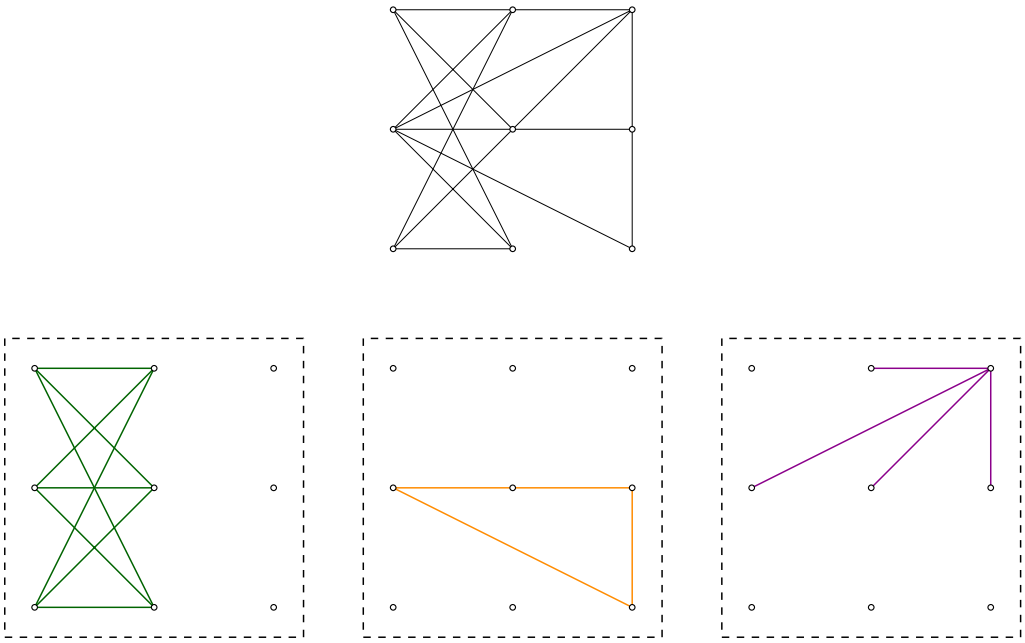

Figure 1 An example of a graph and a biclique cover with three bicliques of total size 15.

Biclique covers have applications to the multicommodity flow problem [47], quantified Boolean formulas [55], and communication complexity of boolean functions [51]. In a seminal paper, Feder and Motwani [41] showed that biclique covers of small sizes can be used as compact representations of graphs, on which many computational problems can be solved more efficiently than on standard representations. The minimum size of a biclique cover of a graph is therefore sometimes referred to as its *representation complexity* [37].

1.1 Our results

We study biclique covers for various classes of graphs defined in geometric terms. We focus on graph classes for which there exist biclique covers of size $O(n \operatorname{polylog} n)$, where n is the number of vertices. Some of the terms used below are defined in the next section 1.2.

Our contribution is threefold. We first consider *semilinear graphs*, defined as semialgebraic graphs for which the defining functions are linear. This class of graphs has first been defined by Basit, Chernikov, Starchenko, Tao, and Tran [13], and further studied by Tomon [73].

We generalize a number of results above by showing that semilinear graphs have biclique partitions of size $O(n \operatorname{polylog} n)$. This in particular gives a simple proof of the bound on Zarankiewicz's problem for semilinear graphs shown by Basit et al. [13]. Semilinear graphs include many previously studied graph classes such as interval graphs, threshold graphs, permutation graphs, bounded-dimension comparability graphs, bounded-boxicity graphs, and intersection graphs of L-shapes and other orthogonal shapes in the plane. For certain restricted classes of semilinear graphs, we establish improved bounds on the size of a biclique cover compared to those obtainable from the general bounds.

We then show that *terrain-like graphs*, also known as *capped graphs* [34] have biclique partitions of size $O(n \log^3 n)$. These graphs contain in particular induced subgraphs of *terrain visibility graphs*. This result can be seen as a combinatorial variant of the influential result of Agarwal, Alon, Aronov, and Sharir [3] on compact representation of visibility graphs of polygons, since terrain-like graphs include terrain visibility graphs. The two results, however, are incomparable, since there exist terrain-like graphs that are not visibility graphs of terrains [11].

Finally, we answer a question asked by Csaba Tóth [74]: Can unit disk graphs have near-linear biclique covers? Note that the existence of such covers is not ruled out by a counting argument, since there are $2^{O(n \log n)}$ unit disk graphs on n vertices [67]. Yet, we answer the question in the negative: There exist unit disk graphs on n vertices, every biclique cover of which has size $\Omega(n^{4/3})$, which is essentially tight. This is proved by considering the standard examples of configurations of points and lines that are tight for the Szemerédi-Trotter Theorem [63], and applying a charging argument. Together with our upper bound for semilinear graphs, this result provides a delineation of what classes of graphs have near-linear biclique covers; as soon as we allow the functions defining a semialgebraic graph to be of degree two, we may obtain strongly superlinear lower bounds on the size of biclique covers.

1.2 Background

Before detailing our results, we first give a brief survey of known results and applications of biclique covers and partitions. We take the opportunity here to gather results that are sometimes considered as folklore, but were never thoroughly compiled.

1.2.1 Covers and partitions in general graphs

The minimal number of bicliques needed to cover a graph has been studied by Tuza [75], Rödl and Ruciński [66], and Jukna and Kulikov [51], among others. As mentioned earlier, we are interested in the size of a biclique cover, which, to recall, is defined as the sum of the number of vertices across all the bicliques in the cover. Let us first note that if G is an n-vertex graph with $O(n)$ edges, then G has a trivial biclique cover of size $O(n)$. Hence the question of bounding the size of a biclique cover is not relevant in classes of graphs with linearly many edges, such as bounded-treewidth graphs or planar graphs.

A cover of size $O(n \log n)$ of the complete graph K_n can be obtained recursively as follows: first split the set of vertices into two disjoint subsets of equal size, and add the corresponding biclique to the cover, then recurse on both subsets. The cover we obtain in this way is also a biclique partition with n bicliques.

A bound on the size of a biclique cover of an arbitrary graph was proved by Chung, Erdős, and Spencer [30], and later by Tuza [75].

▶ **Theorem 1** ([30, 75]). *Let G be a graph on n vertices. Then there exists a biclique cover of G of size $O(n^2/\log n)$, and this bound is tight.*

We observe a connection between the size of a biclique cover and constructions of graphs with many edges and without a complete bipartite graph $K_{t,t}$ as a subgraph, also known as the Zarankiewicz problem. We refer, for example, to Conlon [31] for a construction of such graphs and to Smorodinsky [70] for a survey on the Zarankiewicz problem in geometric graphs. Let G be a graph without a $K_{t,t}$ subgraph and let $\mathcal{H}$ be a biclique cover of G. Let $H \in \mathcal{H}$, then $|E(H)| \leq t|V(H)|$ and therefore $\sum_{H\in\mathcal{H}} |V(H)| \geq \sum_{H\in\mathcal{H}} |E(H)|/t \geq |E(G)|/t$. Hence we can deduce the following observation.

▶ **Observation 2.** *Let G be a graph without a $K_{t,t}$ subgraph, for some $t \in \mathbb{N}$, and with a biclique cover of size s. Then G has at most $t \cdot s$ edges.*

For classes of graphs that have biclique partition of size $O(n \operatorname{polylog} n)$, like the ones studied in this paper, this directly gives an upper bound of $O(n \operatorname{polylog} n)$ on the number of edges of these graphs when $K_{t,t}$ is forbidden, for some constant t.

Let $\mathcal{F}$ be a class of graphs and let $\mathcal{F}_n$ be the graphs in $\mathcal{F}$ with exactly n vertices. If any graph $G \in \mathcal{F}_n$ has a biclique cover of size $s(n)$ then $|\mathcal{F}_n| \leq 2^{s(n)\lceil \log n\rceil + 2s(n)}$. Indeed, every graph can be encoded by a binary string of length at most $s(n)\lceil \log n\rceil + 2s(n)$ where every vertex is encoded by a binary string of length $\lceil \log n\rceil$ and at most $2s(n)$ additional bits separating the bicliques and defining the bipartition inside each biclique. Based on the above, we make the following observation.

▶ **Observation 3.** *Let $\mathcal{F}$ be a family of graphs and let $s(n)$ be the maximum size of a biclique cover of a graph in $\mathcal{F}_n$, then $|\mathcal{F}_n| \leq 2^{O(s(n)\log n)}$.*

Note that for many classes of geometric graphs, the upper bound in the above observation is significantly worse than the best known upper bounds [67].

1.2.2 Algorithms

Feder and Motwani [41] observed that biclique covers can be used to construct compressed representations of graphs, on which several computational problems can be solved efficiently. In a compressed representation, each biclique in the cover is replaced by a subgraph whose number of edges is proportional to the size of the biclique. This can be interpreted as a *sparsification* procedure, that preserves features of the initial graph while reducing the number of edges. A simple application of this idea is to the all-pairs shortest paths problem.

▶ **Lemma 4** ([41])**.** *Given a biclique cover of size s of a graph G on n vertices, then the breadth-first search tree rooted at any vertex of G can be computed in time $O(s)$, hence the (unweighted) all-pairs shortest paths problem can be solved in time $O(n \cdot s)$.*

We refer to Chan and Skrepetos [25] for a discussion on the application of this result to geometric intersection graphs.

Similarly, Feder and Motwani proved that a maximum matching of a bipartite graph given in compressed form as a biclique cover of size s can be found in time $O(\sqrt{n} \cdot s)$ [41, Theorem 4.2]. Using a state-of-the-art maximum flow algorithm [29, 76], Cabello, Cheng, Cheong, and Knauer [18] gave the following improvement.

▶ **Lemma 5** ([18])**.** *Given a biclique cover of size s of a bipartite graph G, the maximum matching problem on G can be solved in time $O(s^{1+\varepsilon})$ for any $\varepsilon > 0$.*

Note that in these results, we assume that a biclique cover is given, and do not take into account the time required to compute it. Ideally, if the graph is given in some kind of implicit form (for instance as a collection of geometric object, of which the graph is the intersection graph), we may hope to be able to compute the biclique cover in time proportional to its size, and then apply the above lemmas.

1.2.3 Spanners

Let $t \in \mathbb{N}$ and let G be a graph. A *t-hop spanner* is a subgraph G' of G such that for any $uv \in E(G)$, there is a path of length at most t in G' between u and v. The following was observed by Conroy and Tóth [33].

▶ **Lemma 6** ([33]). *If G has a biclique cover of size s then there is a subgraph G' of G which is a 3-hop spanner with s edges.*

This is achieved by simply replacing every biclique of the decomposition by two stars, with centers on either side of the bipartition.

Biclique covers of intersection graphs of boxes in constant dimension are also used in a recent preprint by Bhore, Chan, Huang, Smorodinsky and Tóth [14] to obtain 2-hop spanners for fat axis-aligned boxes.

1.2.4 Biclique covers and range searching

Biclique covers and partitions of geometric graphs are natural byproducts of *range searching* algorithms and data structures in computational geometry. The range searching problem can be defined as that of preprocessing a collection of points in $\mathbb{R}^d$ so as to quickly answer queries about the subset of points contained in a given region, called the range. There, bicliques naturally arise as pairs of subsets of points and ranges, such that all points are contained in all ranges. Classical data structures for orthogonal range searching, where ranges are axis-aligned boxes, include segment trees and range trees [35, Chapters 5 and 10]. Halfspace and simplex range queries are typically answered using cuttings and partition trees [58, 59, 26, 60, 23]. More recently, polynomial partitioning techniques, stemming from the seminal paper from Guth and Katz [48], have been used to solve semialgebraic range queries [61, 37, 4, 19, 7]. These structures naturally yield biclique covers of the corresponding incidence graphs. In turn, running times for the offline range searching problem are closely related to incidence bounds [63], an early example of which is the Szemerédi-Trotter theorem bounding the number of incidences between points and lines in the plane. Quoting Agarwal, Ezra, and Sharir [7]: "there is a general belief that the two problems are closely related, and that the running time of (at least off-line) range queries should be almost the same as the number of incidences between points and the corresponding curves/surfaces that bound these regions". It is therefore not surprising that incidence bounds often coincide with representation complexities.

We summarize the known upper bounds stemming from this line of work. Let P be a set of points and let R be a set of geometric objects in $\mathbb{R}^d$. An *incidence graph* $I(P, R)$ is a bipartite graph with the bipartition (P, R) where there is an edge between two elements $p \in P$ and $r \in R$ if and only if $p \in r$. We henceforth assume that every set of points or geometric objects contains at most n elements. The following results are known (the $\tilde{O}$ notation omits polylogarithmic factors):

- Incidence graphs of points and axis-parallel boxes in $\mathbb{R}^d$, for some constant d, have biclique partitions of size $O(n \log^d n)$. This can be deduced from [6, Section 3] and [35, Chapter 5], for instance.
- Incidence graphs of points and halfspaces in $\mathbb{R}^d$, for some constant d, have biclique partitions of size $\tilde{O}(n^{2d/(d+1)})$ [57].
- Incidence graphs of points and hyperplanes in $\mathbb{R}^d$, for some constant d, have biclique partitions of size $\tilde{O}(n^{2d/(d+1)})$ [17].
- Incidence graphs of points and unit disks have biclique partitions of size $\tilde{O}(n^{4/3})$ [54].
- Incidence graphs of points and disks (of arbitrary radii) have biclique partitions of size $\tilde{O}(n^{15/11})$ [7].

In all these cases, the biclique covers can be constructed in time proportional to their size.

Results by Erickson [39] on Hopcroft's problem make the connection between range searching problems and biclique covers explicit. It is shown, among other results, that the running time of a type of a partitioning algorithm for the counting version of Hopcroft's problem with respect to a set of points P and hyperplanes H is bounded from below by the size of the biclique cover of $I(P, H)$.

Biclique covers also have other applications in computational geometry. For instance Agarwal and Varadarajan [8] use them to compute approximations of polygonal chains, and biclique partitions of pairs of points at bounded distance from each other are also at the heart of the expander-based optimization method proposed by Katz and Sharir [54].

A graph G is an *intersection graph* for a class of geometric objects if its vertices can be mapped to objects in the class so that two vertices are adjacent if and only if the corresponding objects have a nonempty intersection. As mentioned by Agarwal et al. [7], *interval graphs*, intersection graph of intervals on the real line, have biclique partitions of size $O(n \log n)$. More generally, it was shown by Chan [21] that intersection graphs of axis-aligned boxes in $\mathbb{R}^d$ have a biclique cover of size $O(n \log^d n)$. The *boxicity* of a graph G is the minimum d such that G is an intersection graph of axis-aligned boxes in $\mathbb{R}^d$. Hence this result shows that bounded-boxicity graphs have near-linear size biclique covers. For intersection graphs of unit disks in the plane, a bound of $\tilde{O}(n^{4/3})$ on the size of a biclique cover can be derived from the bound on the size of a biclique cover in the incidence graph between a set of points and unit disks in the plane. Segment intersection graphs have biclique covers of size $\tilde{O}(n^{4/3})$ [8, 7]. Finally, Chazelle, Edelsbrunner, Guibas, and Sharir [27] proved that the bipartite intersection graph between a set of n disjoint blue segments and a set of n disjoint red segments in the plane has a biclique cover of size $O(n \log^3 n)$.[1]

Many natural classes of geometric graphs are contained in the class of semialgebraic graphs [10, 32, 42, 71]. A graph $G = (V, E)$ is a *semialgebraic graph* of description complexity t and dimension d if the vertices in V can be mapped to points in $\mathbb{R}^d$ so that the presence of an edge is defined by the sign patterns of t polynomial functions of the corresponding pair of points. More precisely, there must exist:

- a map $\varphi : V \mapsto \mathbb{R}^d$,
- t polynomials $f_1, \ldots, f_t \in \mathbb{R}[x_1, \ldots, x_d, y_1, \ldots y_d]$ each of degree at most t in $2d$ variables,
- a boolean function $\Phi : \{\mathrm{T}, \mathrm{F}\}^{3t} \to \{\mathrm{T}, \mathrm{F}\}$,

such that for any $u, v \in V$,

$$uv \in E \Leftrightarrow \Phi\left(\{f_i(\varphi(u), \varphi(v)) < 0, f_i(\varphi(u), \varphi(v)) = 0, f_i(\varphi(u), \varphi(v)) \leq 0\}_{i \in [t]}\right) = T.$$

For example, two closed disks of center respectively (a, b) and (c, d) and radius r and s, for instance, have a nonempty intersection if and only if $f(a, b, r, c, d, s) \leq 0$, where $f(a, b, r, c, d, s) = (a-c)^2+(b-d)^2-(r+s)^2$. Hence disk intersection graphs are semialgebraic graphs of dimension $d = 3$. Note that the union of constantly many semialgebraic graphs is also a semialgebraic graph.

The following result has been proved by Do [37]. A computationally efficient version can be found in Agarwal, Aronov, Ezra, Katz, and Sharir [5, Corollary A.5].

[1] The result is not explicitly stated, but can be deduced from their method for reporting intersections, involving so-called *hereditary segment trees*. See the full version of the paper [20] for details. See also Palazzi and Snoeyink [64].

▶ **Theorem 7** ([37, 5]). *Let G be a semialgebraic graph on n vertices of constant description complexity t and constant dimension d. Then for any $\varepsilon > 0$, G has a biclique cover of size $O(n^{2d/(d+1)+\varepsilon})$, where the constants in the O depend on ε, t, and d.*

Chan, Cheng, and Zheng [24, Final Remarks] showed that the intersection graph of n algebraic arcs in the plane of constant description complexity has a biclique cover of size $O(n^{3/2+\varepsilon})$ and can be found in a similar running time for any $\varepsilon > 0$.

1.2.5 Ordered graphs and visibility graphs

Visibility is a classical theme in computational geometry [35, Chapter 15] [46, 62]. A visibility graph is typically defined on a set of points in the plane, such that two points form an edge if and only if the line segment between them does not hit any obstacle. *Polygon visibility graphs*, for instance, are defined on the set of vertices of a simple closed polygon, and two vertices are adjacent in the graph if and only if the line segment between them is contained in the polygon. A notable result due to Agarwal, Alon, Aronov, and Suri [3] states that polygon visibility graphs have biclique partitions of size $O(n \log^3 n)$. The proof involves an reduction to bichromatic segment intersection graphs [28] and their compact representation based on segment trees by Chazelle et al. [27].

In what follows we consider *ordered graphs*, defined as graphs $G = (V, E)$ where the set of vertices V is totally ordered. For simplicity, we will often assume that $V = [n] =: \{1, 2, \ldots, n\}$ with the natural ordering on $\mathbb{N}$. An ordered graph $([n], E)$ is a *capped graph* if for any four vertices $i < j < k < \ell$, if $ik \in E$ and $j\ell \in E$, then $i\ell \in E$ [34]. See Figure 2 for an illustration.

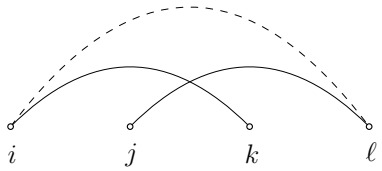

Figure 2 The forbidden ordered subgraph in a capped graph. The dashed curve represents a non-edge: If ik and $j\ell$ are edges, then $i\ell$ must be an edge.

This property is also sometimes referred to as the *X-property*, and capped graphs are also referred to as *terrain-like graphs* [43, 12, 45].

A *terrain visibility graph* is defined on the set of vertices of an x-monotone polygonal line in the plane, also called a terrain, where two vertices are adjacent in the graph if and only if the open line segment between them lies completely above the terrain [1, 40, 11, 52]. Terrain visibility graphs have applications to time series analysis [56], and have been used for instance in medical contexts [9, 72].

It is not difficult to realize that terrain visibility graphs are capped graphs. Indeed, if we are given four points in the order $i < j < k < \ell$ along the terrain such that there is a line of sight between i and k and between j and ℓ, then there must be one between i and ℓ. In fact, capped graphs also contain induced subgraphs of terrain visibility graphs, as well as visibility graphs involving points on an arbitrary, not necessary polygonal, x-monotone curve. See Figure 3 for an example.

Persistent graphs are capped graphs that also satisfy the so-called *bar property*: for any edge of the form ik such that $k \geq i + 2$, there exists j such that $i < j < k$ and both ij and jk are also edges [11, 44]. It is known that terrain visibility graphs are also persistent, and it was once conjectured that they form the same class. This conjecture was disproved by Ameer, Gibson-Lopez, Krohn, Soderman, and Wang [11].

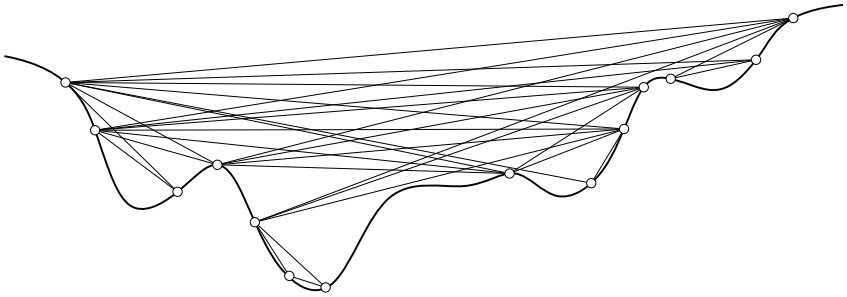

Figure 3 The visibility graph of a set of points on an x-monotone curve. When vertices are ordered from left to right, this is an example of capped graph.

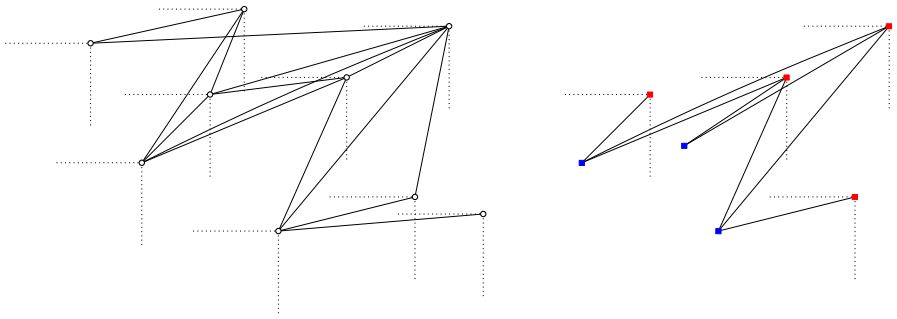
Algorithms on terrain visibility graphs and terrain-like graphs have been studied by Katz, Saban, and Sharir [53], Froese and Renken [43], and De Berg, Van Beusekom, Van Mulken, Verbeek, and Wulms [36]. The Zarankiewicz problem for polygon visibility graphs was recently studied by Ackerman and Keszegh [2].



1.3 Plan of the paper

In Section 2, we construct near-linear biclique partitions for comparability graphs and bigraphs of bounded dimension. This will be used as a building block for many of the subsequent results. In Section 3, we state and prove our main result on the existence and construction of near-linear biclique partitions for any semilinear graphs. In Section 4, we give our main result on terrain-like graphs. In Section 5 we consider lower bounds on the size of biclique covers.

2 d-dimensional comparability graphs

A graph $G = (V, E)$ is a *comparability graph* if there exists a partial ordering $P(G)$ of V such that two vertices are adjacent if and only if they are comparable in $P(G)$. One may wonder if comparability graph could have small biclique covers. A simple counting argument rules this out: all bipartite graphs are comparability graphs, and there are $2^{\Omega(n^2)}$ bipartite graphs on n vertices. From Observation 3, there must exist comparability graphs all biclique covers of which have size $\Omega(n^2/\log n)$, which from Theorem 1 is not better than for general graphs.

We therefore restrict our attention to *d-dimensional comparability* graphs. A partial ordering P has dimension d if there is a collection $\mathcal{L} = \{L_1, L_2, \ldots, L_d\}$ of linear extensions of P such $P = \bigcap_{i=1}^{d} L_i$. A comparability graph G has dimension d if there is a partial ordering $P(G)$ of V of dimension d. Equivalently, a d-dimensional comparability graph is a graph $G = (V, E)$ for which there exists a map $\varphi : V \mapsto \mathbb{R}^d$ such that any two vertices $v, u \in V$ are adjacent if and only if they are comparable with respect to φ, that is either $\varphi(v) \prec \varphi(u)$ or $\varphi(v) \succ \varphi(u)$, where $a \prec b$ if and only if $a_i < b_i$ for all $i \in [d]$. We can assume without loss of generality that no pair of points in $\varphi(V)$ share a coordinate. See Figure 4 for an example of a two-dimensional comparability graph. Note that two-dimensional comparability graphs are also known as *permutation graphs* [16]. We also define a bipartite version of a d-dimensional comparability graph. A *d-dimensional comparability bigraph* is a bipartite graph $G = (L \cup R, E)$ for which there exists a map $\varphi : L \cup R \mapsto \mathbb{R}^d$ such that no pair of points in $\varphi(L) \times \varphi(R)$ share a coordinate, and such that for any pair $(\ell, r) \in L \times R$, $\ell r \in E$

(a) A two-dimensional comparability graph. **(b)** A two-dimensional comparability bigraph.

Figure 4 Comparability graphs and bigraphs.

if and only if $\varphi(\ell) \prec \varphi(r)$. We also adopt the convention that 0-dimensional comparability bigraphs are complete bipartite graphs, where $E = L \times R$. See Figure 4 for an example of a two-dimensional comparability graph. For both graph classes, we refer to the function φ as the *embedding map* of G.

We proceed by showing two key theorems concerning the size of a biclique cover of d-dimensional comparability bigraphs and graphs. The proofs rely on a simple induction for the *dominating pairs* problem [65, 22].

▶ **Theorem 8.** *Any d-dimensional comparability bigraph on n vertices has a biclique partition of size $O(n \log^d n)$.*

Proof. We prove the theorem by induction on d. For $d = 0$, the bigraph is a biclique, hence has a trivial partition of size $O(n)$.

Now let $d \geq 1$ and assume that the theorem holds for any $d' < d$. Let G be a d-dimensional comparability bigraph and let φ be its embedding map in $\mathbb{R}^d$. Let $p \in \mathbb{R}$ be a point on the dth axis such that the orthogonal hyperplane H through p divides the points in $L \cup R$ into two parts of size at most $\lceil n/2 \rceil$. Let φ_d be the restriction of φ to the dth coordinate and let $\varphi_{1,\dots,d-1}$ be the restriction of φ to the first $(d-1)$ coordinates. Let $L' \subseteq L$ be the set of vertices $\ell \in L$ for which $\varphi_d(\ell) < p$ and let $R' \subseteq R$ be the of vertices $r \in R$ for which $\varphi_d(r) > p$. Observe that $\ell r \in E$, for $\ell \in L'$ and $r \in R'$, if and only if $\varphi_{1,\dots,d-1}(\ell) \prec \varphi_{1,\dots,d-1}(r)$. Let G' be a $(d-1)$-dimensional comparability bipartite subgraph of G induced on $L' \cup R'$ with the embedding map $\varphi_{1,\dots,d-1}$ obtained by projecting those points on H. By induction, G' has a biclique partition of size $O(n \log^{d-1} n)$. It remains to recurse twice on each side of H with half the points. Let $S(n)$ be the size of a biclique partition of G. The total size $S(n)$ therefore obeys the recurrence

$$S(n) \leq 2S(\lceil n/2 \rceil) + O(n \log^{d-1} n) = O(n \log^d n).$$ ◀

The same method gives an upper bound on the size of a biclique partition of d-dimensional comparability graphs. We omit the proof here.

▶ **Theorem 9.** *Any d-dimensional comparability graph on n vertices has a biclique partition of size $O(n \log^d n)$.*

3 Semilinear graphs

Semilinear graphs were recently introduced by Basit, Chernikov, Starchenko, Tao and Tran [13], and form a subclass of semialgebraic graphs. A graph $G = (V, E)$ is a *semilinear graph of complexity t* if the vertices in V can be mapped to points in $\mathbb{R}^d$ and there exist t *linear* functions $f_1, \dots, f_t : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$ such that the edges of G are defined by the sign patterns of those functions. More precisely, let F and T denote false and true respectively. Then G is semilinear if there exist:

- a map $\varphi : V \mapsto \mathbb{R}^d$,
- t linear functions $f_1, \dots, f_t \in \mathbb{R}[x_1, \dots, x_d, y_1, \dots y_d]$ in $2d$ variables,
- a boolean function $\Phi : \{\mathrm{T}, \mathrm{F}\}^{3t} \to \{\mathrm{T}, \mathrm{F}\}$,

such that for any $u, v \in V$,

$$uv \in E \Leftrightarrow \Phi\left(\{f_i(\varphi(u), \varphi(v)) < 0, f_i(\varphi(u), \varphi(v)) = 0, f_i(\varphi(u), \varphi(v)) \leq 0\}_{i \in [t]}\right) = T.$$

The bounded-dimensional comparability graphs of the previous section are simple examples of semilinear graphs. Interval graphs are another. Indeed, two intervals $[a, b]$ and $[c, d]$ intersect if and only if $a \leq d$ and $b \geq c$. A similar condition can be written for the intersection of two boxes in $\mathbb{R}^d$. Furthermore the union of constantly many such graphs is also a semilinear graph.

Tomon [73] observed that we can restrict the definition above to boolean formulas in disjunctive normal form, and involving only strict inequalities. A graph $G = (V, E)$ is *dnf-semilinear of complexity (t, ℓ)* if there exist a map $\varphi : V \mapsto \mathbb{R}^d$ and $t \cdot \ell$ *linear* functions $f_{i,j} : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}$, $(i, j) \in [\ell] \times [t]$, such that for any $u, v \in V$,

$$uv \in E \Leftrightarrow \bigvee_{i \in [\ell]} \left(\bigwedge_{j \in [t]} f_{i,j}(\varphi(u), \varphi(v)) < 0 \right) = T. \tag{1}$$

As shown in [73], any semilinear graph of complexity t is a dnf-semilinear graph of complexity (t', ℓ) where t' and ℓ depend only on t, and therefore the two definitions are essentially equivalent. The second definition will be useful in our proofs.

▶ **Theorem 10.** *Let $G = (V, E)$ be a semilinear graph of constant complexity on n vertices. Then G has a biclique cover of size $O(n \operatorname{polylog} n)$.*

Proof. From the above discussion, we can assume that G is dnf-semilinear of complexity (t, ℓ), for some constants t and ℓ. Consider a function $f_{i,j}$ appearing in this definition, for some $(i, j) \in [\ell] \times [t]$. Since $f_{i,j}$ is linear, we can rewrite it as $f_{i,j}(x, y) = g_{i,j}(x) + h_{i,j}(y)$ with suitable functions $g_{i,j}, h_{i,j} : \mathbb{R}^d \to \mathbb{R}$. Let $g_i(x) = (g_{i,1}(x), \dots, g_{i,t}(x))$ and $h_i(x) = (h_{i,1}(x), \dots, h_{i,t}(x))$. Now the condition $f_{i,j}(x, y) < 0$ can be rewritten $g_{i,j}(x) < -h_{i,j}(x)$, and

$$\bigwedge_{j \in [t]} f_{i,j}(x, y) < 0 \Leftrightarrow g_i(x) \prec -h_i(y).$$

This condition defines a subgraph G_i of G whose edges are the pairs $u, v \in V$ such that either $g_i(\varphi(u)) \prec -h_i(\varphi(v))$ or $g_i(\varphi(v)) \prec -h_i(\varphi(u))$.

We now show that G_i has a biclique partition of size $O(n \log^{t+1} n)$. Let us split the set V of vertices into two subsets L and R of size at most $\lceil n/2 \rceil$. The graph whose edges are the pairs $(u, v) \in L \times R$ such that $g_i(\varphi(u)) \prec -h_i(\varphi(v))$ is a t-dimensional comparability bigraph.

Similarly, the graph whose edges are the pairs $(u, v) \in L \times R$ such that $-h_i(\varphi(u)) \succ g_i(\varphi(v))$ is also a t-dimensional comparability bigraph. These two graphs cover the edges of G_i that are in the cut (L, R). From Theorem 9, they each have a biclique cover of size $O(n \log^t n)$. It remains to cover the edges contained in L and R recursively. This yields a biclique cover of size $O(n \log^{t+1} n)$, proving our claim.

G is the union of the ℓ graphs G_i for $i \in [\ell]$. Taking the union of the biclique covers for each of the G_i yields a biclique cover of size $O(n \log^{t+1} n)$ for G, as required. ◀

Combined with Observation 2, this directly implies the result from Basit, Chernikov, Starchenko, Tao, and Tran [13].

▶ **Corollary 11** ([13]). *Let G be a semilinear graph without a $K_{t,t}$ subgraph, for some $t \in \mathbb{N}$. Then G has at most $O(n \operatorname{polylog} n)$ edges.*

Also note that the proof of Theorem 10 provides a construction algorithm running in time proportional to the output size. This holds provided that the d-dimensional comparability bigraph in Theorem 8 and the semilinear graph in Theorem 10 are given in the following implicit form: Every vertex is encoded as a point in $\mathbb{R}^d$, and the functions determining the presence of an edge are encoded in constant space.

▶ **Lemma 12.** *Given a semilinear graph G of constant complexity, we can compute a biclique partition of G of size $O(n \operatorname{polylog} n)$ in time $O(n \operatorname{polylog} n)$.*

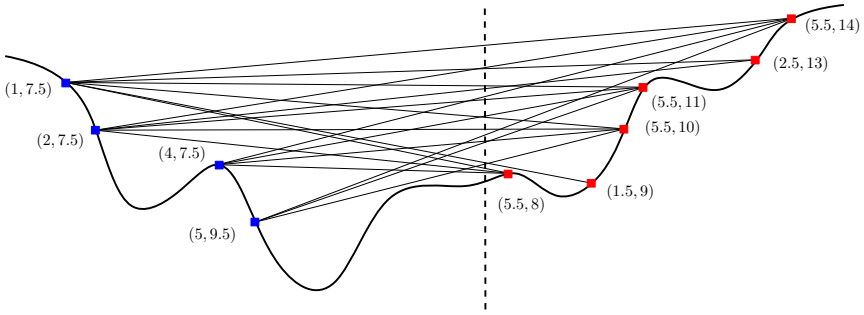
Combining Lemma 12 with the known computational results of Lemmas 4 and 5, we obtain the following.

▶ **Theorem 13.** *Given a semilinear graph G of constant complexity on n vertices, we can compute a maximum matching of G in time $O(n^{1+\varepsilon})$, and solve the all-pairs shortest path problem on G in time $O(n^2 \operatorname{polylog} n)$.*

4 Terrain-like graphs

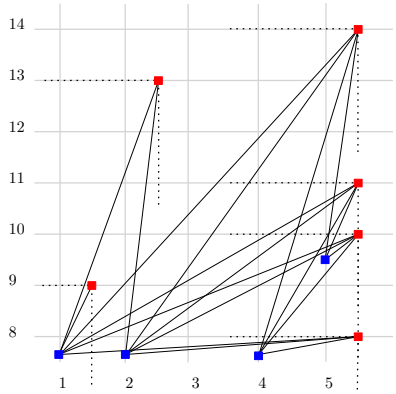
Recall that capped graphs, also known as terrain-like graphs, are ordered graphs such that for any four vertices $i < j < k < \ell$, if both ik and $j\ell$ are edges, then so is $i\ell$. We first define the bipartite counterpart of capped graphs, that we call *capped bigraphs*, as ordered bipartite graphs $G = (L \cup R, E)$, where the elements in L appear before the elements in R in the order, and that satisfy the same property, that is for all $i < j \in L$ and $k < \ell \in R$, we have that if $ik \in E$ and $j\ell \in E$, then $i\ell \in E$.

▶ **Lemma 14.** *Every capped bigraph is a two-dimensional comparability bigraph.*



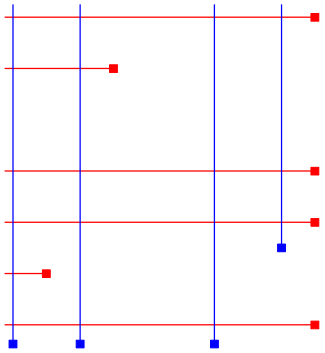
Proof. Let $G = (L \cup R, E)$ be a capped bigraph. We assume for now that G does not have any isolated vertex. Let us suppose, without loss of generality, that $L, R \subset \mathbb{N}$. Consider the map $\varphi : L \cup R \mapsto \mathbb{R}^2$ defined as

$$\varphi(\ell) = (\ell, \min\{r' \in R : \ell r' \in E\} - 1/2)$$



for any $\ell \in L$, and

$$\varphi(r) = (\max\{\ell' \in L : \ell' r \in E\} + 1/2, r),$$



for any $r \in R$. We claim that $\ell r \in E$ if and only if $\varphi(\ell) \prec \varphi(r)$.

(a) A capped bigraph obtained from the example of Figure 3, together with the values of $\varphi(u)$ for each vertex u.

(b) A representation of the capped bigraph as a two-dimensional comparability bigraph.

(c) A representation of the capped bigraph as a two-directional orthogonal ray graph.

Figure 5 Illustration of the proof of Lemma 14.

We first show that if $\ell r \in E$, then $\varphi(\ell) \prec \varphi(r)$. Indeed, if $\ell r \in E$, it must be the case that $\ell < \max\{\ell' : \ell' r \in E\} + 1/2$. Similarly, it must be the case that $\min\{r' : \ell r' \in E\} - 1/2 < r$. Hence the point $\varphi(\ell)$ is dominated by $\varphi(r)$.

Conversely, suppose that $\varphi(\ell) \prec \varphi(r)$. Let $\ell^* = \max\{\ell' : \ell' r \in E\}$ and $r^* = \min\{r' : \ell r' \in E\}$. If either $\ell^* = \ell$ or $r^* = r$, then we have $\ell r \in E$ by definition. Let us therefore suppose that $\ell^* \neq \ell$ and $r^* \neq r$. Then, since $\varphi(\ell) \prec \varphi(r)$, we have $\ell < \ell^*$ and $r^* < r$. By definition, $\ell r^* \in E$ and $\ell^* r \in E$, hence from the X-property of capped bigraphs, it must be the case that $\ell r \in E$ as well.

Finally, note that isolated vertices can easily be added, by assigning them either a very large vertical or horizontal coordinate. ◀

The proof is illustrated in Figure 5. Note that conversely, any two-dimensional comparability bigraph $(L \cup R, E)$, as witnessed by a map φ, is a capped bigraph, where the order of the vertices in L and R is given respectively by the x and y-coordinates of the points in the image of the map φ. It suffices to observe that the X-property is satisfied. One can observe that this class of bigraphs is in fact the same as that of *interval containment bigraphs* in Huang [50] and Hell, Huang, Lin, and McConnell [49], and *two-directional orthogonal ray graphs* studied by Shrestha, Tayu, and Ueno [69]. Therefore, capped bigraphs, two-dimensional comparability bigraphs, interval containment bigraphs, and two-directional orthogonal ray graphs are one and the same class. The equivalence with two-directional

orthogonal ray graphs is immediate: Suppose that the vertical rays extend upwards and the horizontal rays extend to the left, and observe that a vertical ray v intersects a horizontal ray h if and only if the origin of v is dominated by the origin of h.

▶ **Theorem 15.** *Every capped graph on n vertices admits a biclique cover of size $O(n \log^3 n)$.*

Proof. Consider a capped graph $G = ([n], E)$ and let $L := [\lfloor n/2 \rfloor]$ and $R = [n] \setminus L$. Let $F = \{ij \in E : i \in L, j \in R\}$. By definition, $H := (L \cup R, F)$ is a capped bigraph. From Lemma 14 and Theorem 8, H admits a biclique cover of size $O(n \log^2 n)$. It remains to cover the edges of the two subgraphs $G[L]$ and $G[R]$, which are also capped graphs. This can be done recursively, yielding a total size of $S(n) \leq 2S(\lceil n/2 \rceil) + O(n \log^2 n) = O(n \log^3 n)$, as claimed. ◀

We now consider the computational problem of constructing a biclique cover of size $O(n \log^3 n)$ of a capped graph given as input. The natural encoding of the input graph can be of size proportional to the number of edges. Remember that capped graphs are ordered graphs. We can suppose that a capped graph is given in *sorted adjacency list* representation, in which not only the order of the vertices is given, but we are also given the neighbors of each vertex in sorted order. Note that sorting adjacency lists requires an additional cost of $O(|E| \log \log n)$, since the numbers to sort lie in the range $[n]$ [77].

▶ **Lemma 16.** *Given a capped graph $G = (V, E)$ in sorted adjacency list representation, we can compute a biclique partition of G of size $O(n \log^3 n)$ in time $O(\max\{|E|, n \log^3 n\})$.*

Proof. We follow the proof of Theorem 15. Given a bipartition of the vertices of G into the sets L and R, we need to efficiently compute the implicit representation of the corresponding comparability bigraph, as described in the proof of Lemma 14. This requires finding, for each vertex ℓ in L, the smallest index $r \in R$ such that $\ell r \in E$, and conversely for every vertex in R. This can be achieved by storing adjacency lists in binary search trees, for instance, which can be done in linear time if they are sorted. ◀

We can then for instance combine Lemma 16 with Lemma 4.

▶ **Theorem 17.** *Given a capped graph G on n vertices in sorted adjacency list representation, we can solve the all-pairs shortest path problem on G in time $O(n^2 \operatorname{polylog} n)$. Furthermore, after a $O(\max\{|E|, n \log^3 n\})$-time preprocessing, one can construct the breadth-first search tree rooted at any vertex in time $O(n \log^3 n)$.*

5 Lower bounds

It is known that there exist configurations of n points and n lines with $\Theta(n^{4/3})$ point-line incidences, hence that are tight examples for the Szemerédi-Trotter incidence bound; see for instance the construction from Erdős described in Edelsbrunner [38]. From Observation 2, we have that the size s of a biclique cover for a graph $G = (V, E)$ without $K_{t,t}$ for some constant t must satisfy $s \geq |E|/t$. Clearly, point-line incidence graphs do not have $K_{2,2}$ subgraphs, hence there exist such graphs on n vertices for which $s \geq \Omega(n^{4/3})$. We first prove a similar statement for incidence graphs of points and *halfplanes* in $\mathbb{R}^2$. The proof is essentially the same as that of Erickson [39, Theorem 3.4].

▶ **Lemma 18.** *There exist incidence graphs between n points and n closed lower halfplanes, any biclique cover of which has size $\Omega(n^{4/3})$.*

Proof. We consider a configuration (P, L) of n points and n lines with $\Theta(n^{4/3})$ point-line incidences. Let H be the set of closed lower halfplanes bounded by the lines of L. We denote by $I(P, H)$ the incidence graph between the points of P and the halfplanes of H.

Let $P_i \subseteq P$ and $H_i \subseteq H$ be the two sets of vertices in the ith biclique of a biclique cover of $I(P, H)$. Let $L_i \subseteq L$ be the lines bounding the halfspaces of H_i, and let us denote by $\iota(P_i, L_i)$ the number of pairs $(p, \ell) \in P_i \times L_i$ such that $p \in \ell$.

▷ Claim 19.

$$|P_i| + |H_i| \geq \iota(P_i, L_i).$$

Proof of claim. Let R_i denote the intersection of the lower halfplanes in H_i. By definition, R_i is a downward closed convex polygonal region, and $P_i \subset R_i$.

Consider the leftmost incidence (p, ℓ) in (P_i, L_i), involving the leftmost point with the leftmost line. Suppose that p is incident to more than one line. It must then be the case that ℓ does not contain any other point than p. Hence either p is incident to only one line, or ℓ contains only one point. We can therefore always remove either a point or a line and remove one incidence. The number of incidences is then at most $|P_i| + |L_i| = |P_i| + |H_i|$, as claimed. ◁

We now obtain a lower bound on the size of the biclique cover as follows:

$$\sum_i |P_i| + |H_i| \geq \sum_i \iota(P_i, L_i) \geq \iota(P, L) \geq \Omega(n^{4/3}).$$

where the second inequality is from the fact that every incidence in (P, L) is an edge of $I(P, H)$, hence must be covered by at least one of the biclique. ◀

We now turn our attention to unit disk graphs, which are perhaps among the simplest non-semilinear geometric intersection graphs.

▶ **Lemma 20.** *There exist unit disk graphs on n vertices, any biclique cover of which has size $\Omega(n^{4/3})$.*

Proof. It is enough to show that the incidence graph $I(P, H)$ in the proof of Lemma 18 can be realized with unit disks. Indeed, take the configuration (P, L) and shift every line of L upwards by a small vertical offset, so that the points involved in the incidences lie now slightly below their lines. We can now safely replace these lines by circles of the same very large radius, keeping the points of P in the same relative positions with respect to each of the lines. Let Q denote the set of centers of the circles. By a proper scaling, we can assume without loss of generality that those circles have radius two.

Observe that if a graph G has a biclique cover of size s, then any bipartite graph obtained from G by coloring the vertices in two colors and removing all monochromatic edges also has a biclique cover of size s. It is therefore sufficient to prove a lower bound on the size of a biclique cover of the bipartite intersection graph of the unit disks of centers respectively in P and Q. By construction, this is exactly the point-halfplane incidence graph $I(P, H)$, and we can now apply the result of Lemma 18. ◀

Note that a similar statement should hold for intersection graphs of translates of any smooth strictly convex body.

One may also wonder if there exists superlinear lower bounds on the size of biclique covers for families of semilinear graphs. We can easily deduce such a lower bound from a recent result from Bhore et al. [14].

▶ **Lemma 21.** *There exist graphs on n vertices and boxicity at most d, any biclique cover of which has size $\Omega(n(\log n/\log\log n)^{d-2})$.*

Proof. A construction from Bhore et al. [14] shows that there exist intersection graphs of n boxes in dimension d such that any 3-hop spanners requires $\Omega(n(\log n/\log\log n)^{d-2})$ edges. From Lemma 6, it implies the same lower bound on the size of their biclique covers. ◀

6 Open questions

Many open questions remain. We showed a few upper bounds on the size of the biclique cover for restricted families of semilinear graphs, such as intersection graphs of axis-aligned boxes and grounded L-shapes (see the full version of the paper for the definition and the bound on intersection graphs of grounded L-shapes [20]). These bounds improve upon those that can be derived from the general upper bound for semilinear graphs. A first natural question is whether any of those bounds can be improved or, alternatively, what are the achievable lower bounds on the size of a biclique cover for these graphs. The question of improving the upper bound also remains for capped graphs; do capped graphs admit $O(n\log^2 n)$-size biclique covers?

For both capped and non-jumping graphs we showed an upper bound of $O(n\log^3 n)$ on the size of their biclique cover. Recall that capped and non-jumping graphs are graphs equipped with an ordering on their vertices such that for any four vertices $i<j<k<\ell$, if ik and $j\ell$ are edges, then the edge $i\ell$ must also be present in a capped graph, and the edge jk must be present in a non-jumping graph. There is an interesting superclass of both capped and non-jumping graphs, in which given four vertices $i<j<k<\ell$ such that ik and $j\ell$ are edges, *either* the edge $i\ell$ *or* jk must be present. In particular, they contain the terrain visibility graphs considered by Katz, Saban, and Sharir [53], in which points lying strictly above the terrain are also allowed as vertices. Do these ordered graphs admit biclique covers of small size?

More generally, it would be interesting to characterize the forbidden patterns which give rise to families of (ordered) graphs for which the size of a biclique cover is $O(n\operatorname{poly}\log n)$. Note that there are forbidden patterns of size 3 for which the family of graphs which forbids them does not have such a bound. For example, 3 vertices which induce a triangle.

Finally, in this work we mostly focused on graph classes that are either arising in a geometric setting or forbid some ordered patterns. It would be interesting to understand how the size of a clique cover correlates with other width parameters of graphs, for example, the *twin-width* of a graph [15].

Abstract

Let G be a directed graph on n vertices and m edges. In this article, we study (s,t)-cuts of second minimum capacity and present the following algorithmic and graph-theoretic results.

1. **Second (s,t)-mincut:** Vazirani and Yannakakis [ICALP 1992] designed the first algorithm for computing an (s,t)-cut of second minimum capacity using $\mathcal{O}(n^2)$ maximum (s,t)-flow computations. We present the following algorithm that improves the running time significantly. For directed integer-weighted graphs, there is an algorithm that can compute an (s,t)-cut of second minimum capacity using $\tilde{\mathcal{O}}(\sqrt{n})$ maximum (s,t)-flow computations with high probability.[1] To achieve this result, a close relationship of independent interest is established between (s,t)-cuts of second minimum capacity and global mincuts in directed weighted graphs.
2. **Minimum+1 (s,t)-cuts:** Minimum+1 (s,t)-cuts have been studied quite well recently [Baswana, Bhanja, and Pandey, ICALP 2022 & TALG 2023], which is a special case of second (s,t)-mincut. We present the following structural result and the first nontrivial algorithm for minimum+1 (s,t)-cuts.
   a. Algorithm: For directed multi-graphs, we design an algorithm that, given any maximum (s,t)-flow, computes a minimum+1 (s,t)-cut, if it exists, in $\mathcal{O}(m)$ time.
   b. Structure: The existing structures for storing and characterizing all minimum+1 (s,t)-cuts occupy $\mathcal{O}(mn)$ space [Baswana, Bhanja, and Pandey, TALG 2023]. For undirected multi-graphs, we design a directed acyclic graph (DAG) occupying only $\mathcal{O}(m)$ space that stores and characterizes all minimum+1 (s,t)-cuts. This matches the space bound of the widely-known DAG structure for all (s,t)-mincuts [Picard and Queyranne, Math. Prog. Studies 1980].
3. **Dual Edge Sensitivity Oracle:** The study of minimum+1 (s,t)-cuts often turns out to be useful in designing dual edge sensitivity oracles – a compact data structure for efficiently reporting an (s,t)-mincut after insertion/failure of any given pair of query edges. It has been shown recently [Bhanja, ICALP 2025] that any dual edge sensitivity oracle for (s,t)-mincut in undirected multi-graphs must occupy $\Omega(n^2)$ space in the worst-case irrespective of the query time. Interestingly, for undirected unweighted simple graphs, we break this quadratic barrier while achieving a non-trivial query time as follows. There is an $\mathcal{O}(n\sqrt{n})$ space data structure that can report an (s,t)-mincut in $\mathcal{O}(\min\{m, n\sqrt{n}\})$ time after the insertion/failure of any given pair of query edges.

To arrive at our results, as one of our key techniques, we establish interesting relationships between (s,t)-cuts of capacity (minimum+Δ), $\Delta \geq 0$, and maximum (s,t)-flow. We believe that these techniques and the graph-theoretic result in 2.(b) are of independent interest.

1 Introduction

The concept of cut is fundamental in graph theory and has numerous real-world applications [1]. Let $G = (V, E)$ be a directed weighted graph on $n = |V|$ vertices and $m = |E|$ edges with a designated source vertex s and a designated sink vertex t. Every edge e of G is assigned with a non-negative real value as the capacity of the edge, denoted by $w(e)$. There are mainly two types of well-studied cuts in a graph – global cuts and (s,t)-cuts. A *global cut*, or simply a *cut*, of G is defined as a nonempty proper subset of V. A cut C is said to be an (s,t)-*cut* if $s \in C$ and $t \in \overline{C}(= V \setminus C)$. Every cut of G is associated with a capacity defined as follows. The *capacity* of a cut C, denoted by $c(C)$, is the sum of the capacities of every edge (x, y) satisfying $x \in C$ and $y \in \overline{C}$. A global cut (likewise (s,t)-cut) of the least capacity is called a *global mincut* (likewise (s,t)-*mincut*). Henceforth λ denotes the capacity of (s,t)-mincut.

The study of cuts from both structural and algorithmic perspectives has been an important field of research for the past six decades [21, 19, 14, 25, 36]. In this article, we provide the following two main results for (s,t)-cuts. (1) We present efficient algorithms for computing an (s,t)-cut of second minimum capacity in directed weighted graphs. After more than 30 years, our algorithms provide the first improvement by a polynomial factor over the existing result of Vazirani and Yannakakis [37]. To arrive at this result, we establish that computing an (s,t)-cut of second minimum capacity has the same time complexity as computing a global mincut. (2) We present a dual edge sensitivity oracle for (s,t)-mincut – a compact data structure that efficiently reports an (s,t)-mincut after the insertion or failure of any pair of edges. This is the first dual edge sensitivity oracle for (s,t)-mincut that occupies subquadratic space while achieving nontrivial query time in undirected unweighted simple graphs[1]. This breaks the existing quadratic lower bounds [3, 6] on the space for any dual edge sensitivity oracle for (s,t)-mincut in undirected multi-graphs[2]. We arrive at this result by designing a compact structure for storing and characterizing all *minimum+1* (s,t)-*cuts* (a special case of second minimum (s,t)-cut). This structure improves the space occupied by the existing best-known structure [3] by a linear factor.

We now present the problems addressed in this article, their state-of-the-art, and our results.

[1] A simple graph refers to a graph having no parallel edges.
[2] A multi-graph refers to an unweighted graph having parallel edges.

1.1 Faster Algorithm for Second Minimum (s,t)-cuts

An algorithmic graph problem aims at computing a structure that optimizes a given function. Examples of such classical problems are Minimum Spanning Tree, Shortest Path, Minimum Cut. Having designed (near) optimal algorithm for such problems, the next immediate objective is the following. Design an efficient algorithm that, given a structure S achieving optimal function value, computes a structure S' that differs from S and achieves the optimal or *next* optimal function value. There has been an extensive study on computing the second minimum spanning tree [8, 26, 29], the second shortest path [38, 18, 34], and second (s,t)-mincut [37]. The algorithms for these problems are so fundamental that they appear in textbooks on algorithms [13, 1]. In addition, they act as the foundation for generalizing the problem to compute k^{th} optimal structure, such as computing k^{th} minimum spanning tree, k^{th} shortest path, k^{th} (s,t)-mincut.

The problem of designing efficient algorithms for computing (s,t)-mincut (or equivalently, maximum (s,t)-flow) has been studied for more than six decades. This problem is now almost settled with the recent breakthrough result on almost linear time algorithm for maximum (s,t)-flow by Van et al. [36]. Interestingly, given an algorithm for maximum (s,t)-flow, we can compute all (s,t)-mincuts implicitly with an additional $\mathcal{O}(m)$ time, as shown by Picard and Queyranne [33]. It is, therefore, natural to redefine the second (s,t)-mincut problem as follows. Design an algorithm that computes an (s,t)-cut of second minimum capacity. For brevity, henceforth we call (s,t)-cut of second minimum capacity by second (s,t)-mincut.

Vazirani and Yannakakis [37] addressed the problem of computing an (s,t)-cut having k^{th} minimum capacity in 1992. For computing any k^{th} minimum capacity (s,t)-cut, they gave an algorithm that uses $\mathcal{O}(n^{2(k-1)})$ maximum (s,t)-flow computations. Conversely, they also argued, using NP-hardness of computing a maximum cut, that exponential dependence on k is unavoidable assuming $P \neq NP$. To arrive at their result, the key problem they addressed is the design of an algorithm that computes a second (s,t)-mincut using $\mathcal{O}(n^2)$ maximum (s,t)-flow computations. They further improve the running time by designing a faster algorithm that computes a second (s,t)-mincut using only $\mathcal{O}(n)$ maximum (s,t)-flow computations. We show that this faster algorithm is incorrect due to a serious error in its analysis. As a result, the existing best-known algorithm for computing a second (s,t)-mincut uses $\mathcal{O}(n^2)$ maximum (s,t)-flow computations [37]. We design an algorithm for the second (s,t)-mincut with a significantly improved running time as shown in the following theorem.

▶ **Theorem 1** (Second (s,t)-mincut algorithm). *For any directed graph G on n vertices with integer edge capacities, there is an algorithm that computes a second (s,t)-mincut in G using $\tilde{\mathcal{O}}(\sqrt{n})$ maximum (s,t)-flow computations with high probability.*

The two well-known minimum cuts in a graph are (s,t)-mincut and global mincut. Recently, there has been a growing interest in understanding the difference in the complexity of computing an (s,t)-mincut and computing a global mincut. For undirected weighted graphs, Li and Panigrahi [28] established that the running time of computing a global mincut differs by only poly-logarithmic factors from the running time of computing an (s,t)-mincut. In particular, the authors showed that there is an algorithm that can compute a global mincut using $\tilde{\mathcal{O}}(1)$ maximum (s,t)-flow computations with additional $\tilde{\mathcal{O}}(m)$ time. However, for directed weighted graphs, there is a *large* gap between the running time of computing an (s,t)-mincut and computing a global mincut as follows. Cen et al. [9] designed an algorithm that can compute a global mincut using $\tilde{\mathcal{O}}(\sqrt{n})$ maximum (s,t)-flow computations with additional $\tilde{\mathcal{O}}(m\sqrt{n})$ time. Interestingly, to arrive at our result in Theorem 1, we show that the complexity of computing a global mincut is the same as the complexity of computing a second (s,t)-mincut *modulo* a single maximum (s,t)-flow computation as follows, which might find many other important applications.

▶ **Theorem 2** (Equivalence between global mincut and second (s,t)-mincut)**.** *For any directed weighted graph G on n vertices and m edges, the following two assertions hold.*

1. *The problem of computing a second (s,t)-mincut is reducible to the problem of computing a global mincut in $\mathcal{O}(MF(m,n))$ time, where $MF(m,n)$ denotes the time complexity for computing a maximum (s,t)-flow in G.*
2. *The problem of computing a global mincut is reducible to the problem of computing a second (s,t)-mincut in $\mathcal{O}(m)$ time.*

▶ Remark 3. Our algorithm for computing a second (s,t)-mincut in Theorem 1 is Monte Carlo and works for graphs with integer edge capacities. However, the equivalence between second (s,t)-mincut and global mincut in Theorem 2 is deterministic and holds even for graphs with real edge capacities.

1.2 Minimum+1 (s,t)-cuts: Efficient Algorithm & Compact Structure

The cuts of capacity minimum+1, known as minimum+1 cuts, have been studied quite extensively in the past [3, 15, 6]. For (un)directed multi-graphs, a minimum+1 (s,t)-cut is a special case of second (s,t)-mincut. We present the following structural result and the first nontrivial algorithm for minimum+1 (s,t)-cuts.

Algorithm. For both minimum+1 global cuts [15] and minimum+1 (s,t)-cuts [3], there exist compact data structures. These data structures have important applications in maintaining minimum+2 edge connected components [15] and designing dual edge sensitivity oracle for (s,t)-mincut [3]. Moreover, there exist efficient algorithms [24, 4, 30] that can compute a global cut of capacity minimum+1. Unfortunately, the existing best-known algorithm for computing an (s,t)-cut of capacity minimum+1 is nothing but the algorithm for computing a second (s,t)-mincut by [37], which uses $\mathcal{O}(n^2)$ maximum (s,t)-flow computations. We present the following result as the first efficient algorithm for computing an (s,t)-cut of capacity minimum+1.

▶ **Theorem 4** (Minimum+1 (s,t)-cut algorithm)**.** *For any directed multi-graph G on n vertices and m edges, there is an algorithm that, given any maximum (s,t)-flow, computes a minimum+1 (s,t)-cut, if exists in G, in $\mathcal{O}(m)$ time.*

▶ Remark 5. The best-known algorithm for computing an (s,t)-mincut uses one maximum (s,t)-flow computation. It follows from Theorem 4 that the running time of computing a minimum+1 (s,t)-cut differs from the running time of computing an (s,t)-mincut only by additional $\mathcal{O}(m)$ time.

Structure. There are several algorithmic applications on cuts, namely, fault-tolerance [33, 14], dynamic algorithms [22, 23], edge-connectivity augmentation [31, 10] that require an efficient way to distinguish a set of cuts, say minimum cuts or minimum+1 cuts, from the rest of the cuts. A trivial way to accomplish this objective is to store each cut of the required set explicitly. However, this is totally impractical since the set of these cuts is usually quite huge. For example, the number of (s,t)-mincuts are exponential [33], and the number of global mincuts are $\Omega(n^2)$ [14]. This has led the researchers to invent the following concept. A structure H is said to *characterize* a set of cuts $\mathcal{C}$ using a property P if the following condition holds. A cut $C \in \mathcal{C}$ if and only if C satisfies property P in H. It is desirable that H is as compact as possible. Moreover, verifying if a given cut C satisfies P in H has to be as time-efficient as possible.

The design of compact structures for characterizing minimum cuts started with the seminal work of Dinitz, Karzanov, and Lomonosov [14] in 1976. In this work, the well-known cactus graph occupying $\mathcal{O}(n)$ space was invented for storing and characterizing all global mincuts. Several compact structures have been designed subsequently for storing and characterizing cuts of capacity both minimum and near minimum [33, 4, 15, 16, 3]. Quite expectedly, they are playing crucial roles in establishing many important algorithmic results [37, 4, 15, 23, 27, 3]. In particular, compact structures for storing and characterizing all minimum+1 cuts of a graph have been well-studied. For all minimum+1 global cuts in undirected multi-graphs, Dinitz and Nutov [15] constructed an $\mathcal{O}(n)$ space 2-level cactus model that stores and characterizes them. For all minimum+1 (s,t)-cuts in directed multi-graphs, the existing structure that provides a characterization occupies $\mathcal{O}(mn)$ space [3]. Unfortunately, the space occupied by this structure of [3] is significantly inferior to the following widely-known structure designed by Picard and Queyranne [33] for (s,t)-mincut. There is an $\mathcal{O}(m)$ space directed acyclic graph (DAG) that stores and characterizes all (s,t)-mincuts of any graph using 1-*transversal* cuts of this DAG. An (s,t)-cut is said to be 1-transversal if its edge-set[3] intersects any path at most once. Interestingly, we are able to achieve the $\mathcal{O}(m)$ bound on space for storing and characterizing all minimum+1 (s,t)-cuts.

An edge (u,v) is said to *contribute* to a cut C if $u \in C$ and $v \in \overline{C}$. We first establish that for any maximum (s,t)-flow f, there exists a set containing at most $n-2$ edges, called the *anchor* edges, such that for any minimum+1 (s,t)-cut C, exactly one anchor edge contributes to C. By exploiting this result, we design the following structure for storing and characterizing all minimum+1 (s,t)-cuts.

▶ **Theorem 6** (Structure for minimum+1 (s,t)-cuts). *Let G be an undirected multi-graph on n vertices and m edges with a maximum (s,t)-flow f. There is an $\mathcal{O}(\min\{m, n\sqrt{\lambda}\})$ space structure, consisting of a directed acyclic graph $\mathcal{D}$ and the set of $n-2$ anchor edges, that stores and characterizes all (s,t)-mincuts and all minimum+1 (s,t)-cuts of G as follows.*

1. *An (s,t)-cut C is an (s,t)-mincut in G if and only if C is a 1-transversal cut in $\mathcal{D}$ and no anchor edge corresponding to f contributes to C.*
2. *An (s,t)-cut C is a minimum+1 (s,t)-cut in G if and only if C is a 1-transversal cut in $\mathcal{D}$ and exactly one anchor edge corresponding to f contributes.*

For undirected graphs, the best-known structure for storing and characterizing all (s,t)-mincuts is the DAG of Picard and Queyranne [33] that occupies $\mathcal{O}(\min\{m, n\sqrt{\lambda}\})$ space, which is tight as well (refer to [20] and Lemma 12 in [22]). Interestingly, not only our structure in Theorem 6 matches the bound on space with the DAG for (s,t)-mincuts [33] but also it stores and characterizes both (s,t)-mincuts and minimum+1 (s,t)-cuts.

1.3 Dual Edge Sensitivity Oracle: Breaking the Quadratic Barrier

The study of minimum+1 (s,t)-cuts often turns out to be useful in designing elegant *dual edge sensitivity oracles* [3, 15, 6], which is defined as follows.

▶ **Definition 7** (Dual edge sensitivity oracle). *A dual edge sensitivity oracle for minimum cuts is a compact data structure that can efficiently report a minimum cut in the graph after the insertion or failure of any given pair of query edges.*

Designing sensitivity oracles for various minimum cuts of a graph has been an emerging field of research [33, 15, 16, 3, 2]. For (s,t)-mincut in multi-graphs, the DAG structure of Picard and Queyranne [33], as shown in [3], can be used to design an $\mathcal{O}(n)$ space sensitivity oracle

[3] The *edge-set* of a cut C is the set of edges with exactly one endpoint in C.

that can report an (s,t)-mincut in $\mathcal{O}(n)$ time after the failure/insertion of any single edge. It is now interesting to design a sensitivity oracle that can handle multiple failures/insertions of edges. To solve this generic problem, as argued in [3], the natural approach is to first design a dual edge sensitivity oracle for (s,t)-mincut. This approach has also been taken for various other classical graph problems, including distance and connectivity [17], traversals [32], reachability [12, 11]. Moreover, it has been observed that handling two edge failures/insertions is significantly more nontrivial than handling a single one. It also provides important insights that either expose the hardness or help in generalizing the problem for multiple failures. To extend the result of [33] from single to multiple edge failures/insertions, Baswana, Bhanja, and Pandey [3] designed the first dual edge sensitivity oracle for (s,t)-mincut occupying $\mathcal{O}(n^2)$ space in directed multi-graphs. It can report a resulting (s,t)-mincut in $\mathcal{O}(n)$ time.

Note that quadratic space data structures often pose practical challenges as n can be quite *large* for the real world networks/graphs. It thus raises the need to design sensitivity oracles for various fundamental graph problems that occupy subquadratic space [7, 35, 5]. Unfortunately, it has been shown [3, 6] that any dual edge sensitivity oracle for (s,t)-mincut in undirected multi-graphs must occupy $\Omega(n^2)$ bits of space in the worst case, irrespective of the query time. However, for undirected unweighted simple graphs, we break this quadratic barrier on the space of any dual edge sensitivity oracle while achieving nontrivial query time as follows.

▶ **Theorem 8** (Dual edge sensitivity oracle for (s,t)-mincut)**.** *Let G be an undirected unweighted simple graph on n vertices and m edges. There exists a data structure occupying $\mathcal{O}(\min\{m, n^{1.5}\})$ space that can report an (s,t)-mincut C (including the contributing edges of C) in $\mathcal{O}(\min\{m, n^{1.5}\})$ time after failure/insertion of any given pair of query edges in G.*

For the existing dual edge sensitivity oracles for (s,t)-mincut [3, 6], no nontrivial preprocessing time is known till date. We establish the following almost linear preprocessing time for our dual edge sensitivity oracle stated in Theorem 8.

▶ **Theorem 9** (Preprocessing time)**.** *For undirected unweighted simple graphs on n vertices and m edges, there is an algorithm that, given any maximum (s,t)-flow, can construct the dual edge sensitivity oracle in Theorem 8 in $\mathcal{O}(m)$ time.*

2 Organization of this article

This article is organized as follows. Basic preliminaries and notations are stated in Section 3. A limitation of an existing algorithm in [37] for computing second (s,t)-mincut is provided in Section 4. In Section 5, we design two algorithms for computing a second (s,t)-mincut in directed weighted graphs. For undirected multi-graphs, in Section 6, we establish close relationships between maximum (s,t)-flow and (s,t)-cuts of capacity beyond (s,t)-mincut, which are used as tools to arrive at the results in the following sections. For undirected multi-graphs, Section 7 contains the design of our linear space structure for storing and characterizing all $(\lambda+1)$ (s,t)-cuts. In Section 8, we design the subquadratic space dual edge sensitivity oracle for (s,t)-mincut in undirected unweighted simple graphs. Finally, we conclude in Section 9. All the omitted proofs are provided in the full version.

3 Preliminaries

By integrality of maximum (s,t)-flow [19], for integer-weighted graphs, we consider any given maximum (s,t)-flow to be integral. The following notations to be used throughout the article.

- $G \cup A$ (likewise $G \setminus A$): Graph obtained after adding (likewise removing) a set of edges A in G.
- $(\lambda + \Delta)$ (s,t)-cut: An (s,t)-cut of capacity $\lambda + \Delta$ where $\Delta \geq 0$.
- (u,v)-path : A simple directed path from vertex u to vertex v.
- f denotes a maximum (s,t)-flow in graph G.
- $c(C,H)$: Capacity of a cut C in a graph H.
- A cut C *subdivides* a set of vertices X if $C \cap X \neq \emptyset$ and $\overline{C} \cap X \neq \emptyset$.
- A cut C *separates* a pair of vertices u, v if $u \in C$ and $v \in \overline{C}$ or vice-versa.
- The *edge-set* of a cut C, denoted by $E(C)$, is the set of all edges whose endpoints are separated by C.

Let f' be any (s,t)-flow in G.

- $H^{f'}$ denotes the residual graph for any graph H corresponding to an (s,t)-flow f'.
- $f'(e)$ denotes the value of flow f' assigned to an edge e.
- $f'_{out}(C)$ and $f'_{in}(C)$: For any (s,t)-cut C, $f'_{out}(C)$ (likewise $f'_{in}(C)$) is the sum of flow assigned to all edges $e = (u,v) \in E(C)$ with $u \in C, v \in \overline{C}$ (likewise $v \in C, u \in \overline{C}$).

▶ **Lemma 10** (Conservation of flow). *For any (s,t)-cut C, $f'_{out}(C) - f'_{in}(C) = value(f')$*

▶ **Definition 11** (Quotient Graph). *A graph H is said to be a quotient graph of G if H is obtained from G by contracting disjoint subsets of vertices into single nodes.*

▶ **Definition 12** (Quotient Path). *A path P_q is said to be a quotient path of a path P if P_q is obtained from P by contracting a set of edges in P.*

Residual graph for undirected multi-graphs. Although the residual graph is defined for directed graphs [19], for undirected graphs, we define the residual graph in the following way. Let $e = (x,y)$ be any edge in an undirected multi-graph H with an (s,t)-flow f'. There exist two edges (y,x) (likewise (x,y)) in $H^{f'}$ if e carries flow in the direction x to y (likewise y to x); otherwise, there is a pair of edges (x,y) and (y,x) in $H^{f'}$.

3.1 A DAG structure for storing and characterizing all (s,t)-mincuts

In a seminal work, Picard and Queyranne [33] designed a DAG, denoted by $\mathcal{D}_{PQ}(G)$, that stores all (s,t)-mincuts in G and characterizes them as 1-transversal cuts. We now briefly describe the construction of $\mathcal{D}_{PQ}(G)$.

Construction of $\mathcal{D}_{PQ}(G)$. Let G' be the graph obtained by contracting each Strongly Connected Component (SCC) of G^f into a single node. Let $\mathbb{T}$ denote the node containing t and $\mathbb{S}$ denote the node containing s in G'. If G is an undirected graph, $\mathcal{D}_{PQ}(G)$ is the graph G'. For directed graphs, $\mathcal{D}_{PQ}(G)$ is obtained by suitably modifying G' as follows. For each node μ reachable from $\mathbb{S}$ in G', μ is contracted into node $\mathbb{S}$. Likewise, each node μ that has a path to $\mathbb{T}$, is contracted into the node $\mathbb{T}$. Given any maximum (s,t)-flow f, $\mathcal{D}_{PQ}(G)$ can be obtained in $\mathcal{O}(m)$ time and has the following property. Without causing ambiguity, we refer to $(\mathbb{S},\mathbb{T})$-cut in $\mathcal{D}_{PQ}(G)$ by (s,t)-cut.

▶ **Theorem 13** ([33]). *Let G be any directed weighted graph on m edges with a designated source vertex s and designated sink vertex t. There is an $\mathcal{O}(m)$ space DAG $\mathcal{D}_{PQ}(G)$ that stores and characterizes each (s,t)-mincut in G as follows. An (s,t)-cut C is an (s,t)-mincut in G if and only if C is a 1-transversal cut in $\mathcal{D}_{PQ}(G)$.*

4 Limitation of the Existing Algorithm for Second (s,t)-mincut

We state here a limitation of the existing algorithm given by Vazirani and Yannakakis [37] to compute a second (s,t)-mincut. The algorithm for computing an (s,t)-cut of k^{th} minimum capacity by [37] uses $\mathcal{O}(n^{2(k-1)})$ maximum (s,t)-flows. So, for $k=2$, the algorithm uses $\mathcal{O}(n^2)$ maximum (s,t)-flow computations. In the same article [37], they stated the following property.

▶ **Lemma 14** (Lemma 3.2(1) in [37]). *Let G^f be the residual graph corresponding to a maximum (s,t)-flow f in G. Let H be an SCC in G^f and u,v be a pair of vertices in H. If the capacity of the least capacity cut separating $\{u\}$ and $\{v\}$ is k in H, then the least capacity cut separating $\{s,u\}$ and $\{v,t\}$ has capacity $\lambda+k$ in G.*

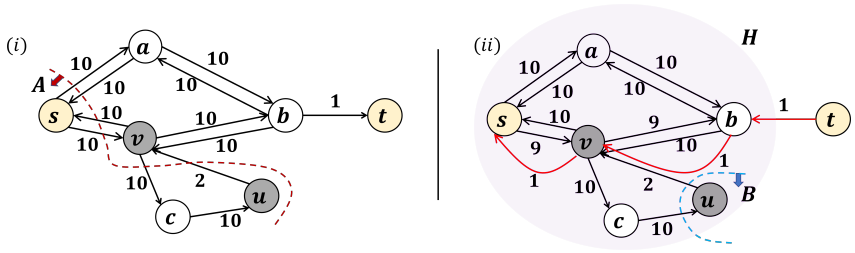

Figure 1 A counter example for Lemma 3.2(1) in [37] (i) A graph G. $V\setminus\{t\}$ is the (s,t)-mincut in G with capacity 1 and $c(A)$=22. (ii) H is an SCC in G^f and $c(B,H)=2$.

Vazirani and Yannakakis [37] used Lemma 14 to design an algorithm that computes second (s,t)-mincut using $\mathcal{O}(n)$ maximum (s,t)-flow computations (the algorithm preceding Theorem 3.3 in [37]). Unfortunately, Lemma 14 (or Lemma 3.2(1) in [37]) is not correct as shown in Figure 1(ii). H is the SCC in G^f containing vertices u and v. The least capacity cut B separating $\{u\}$ and $\{v\}$ has capacity 2 in H. By Lemma 14, the least capacity cut separating $\{s,u\}$ and $\{v,t\}$ must have capacity $2+1=3$ in G. However, as it can be verified easily using Figure 1(i), A is a least capacity cut separating $\{s,u\}$ and $\{v,t\}$ in G and its capacity is 22. Therefore, the algorithm stated above Theorem 3.3 in [37], fails to correctly output a second (s,t)-mincut.

5 Faster Algorithm for Second (s,t)-mincut

We design two efficient algorithms for computing a second (s,t)-mincut. Our first algorithm computes a second (s,t)-mincut for directed weighted graphs using $\mathcal{O}(n)$ maximum (s,t)-flow computations, which achieves the aim of Vazirani and Yannakakis [37]. This algorithm can be seen as an immediate application of the recently invented covering technique of [3]. We refer to the full version for the details of this algorithm. Our second algorithm takes a totally different approach. This approach is based on a relationship between the second (s,t)-mincuts and the global mincuts in directed weighted graphs. So, as our main result, we design an algorithm for computing a second (s,t)-mincut that uses $\tilde{\mathcal{O}}(\sqrt{n})$ maximum (s,t)-flow computations and works for directed graphs with integer edge capacities. We now provide an overview of this result.

Observe that a global mincut is not necessarily an (s,t)-cut in G. On the other hand, any second (s,t)-mincut can never be a global mincut in G. So apparently there does not seem to be any relationship between the global mincuts and the second (s,t)-mincuts of G.

Let us first work with a special case when graph G has exactly two (s,t)-mincuts – $\{s\}$ and $V \setminus \{t\}$. Suppose there exists a second (s,t)-mincut C in graph G such that C separates all the neighbors of s from all the neighbors of t. It is easy to compute a second (s,t)-mincut in this graph as follows. Compute a maximum (s,t)-flow after contracting all neighbors of s with s and all neighbors of t with t. The challenge arises when every second (s,t)-mincut has at least one contributing edge that is incident on s and/or t. We now show that the residual graph G^f plays a crucial role in overcoming this hurdle. Moreover, G^f turns out to establish the bridge between second (s,t)-mincuts and global mincuts.

In a seminal work in 1956, Ford and Fulkerson [19] established a strong duality between (s,t)-mincut and maximum (s,t)-flow, which is widely known as the *Maxflow-Mincut Theorem*. We begin by stating the following property, which is immediate from Maxflow-Mincut Theorem.

▶ **Fact 15.** *For any graph G with maximum (s,t)-flow f', every (s,t)-mincut in G is an (s,t)-cut of capacity zero in $G^{f'}$.*

It follows from Fact 15 that there is a bijective mapping between the set of all (s,t)-mincuts in G and the set of global mincuts containing s and not t in G^f. However, Fact 15 does not reveal any information on how a second (s,t)-mincut in G appears in residual graph G^f. To explore the structure of second (s,t)-mincuts in G^f, using only the conservation of flow and the construction of the residual graph, we provide a generalization of Fact 15 as follows.

▶ **Theorem 16** (Maxflow (Min+Δ)-cut Theorem)**.** *Let $G = (V,E)$ be a directed weighted graph with a designated source vertex s and a designated sink vertex t. Let f be any maximum (s,t)-flow in G and G^f be the corresponding residual graph. Let C be an (s,t)-cut in G. The capacity of C in G is $(\lambda + \Delta)$ if and only if the capacity of C in G^f is Δ, where $\Delta \geq 0$.*

Proof. Let $E_{out}(A,H)$ (likewise $E_{in}(A,H)$) denote the set of outgoing edges (likewise the set of incoming edges) of a cut A in a graph H. For any edge e in G, let $r(e)$ be the residual capacity, that is, $r(e) = w(e) - f(e)$. For any edge e in graph G^f, let $w'(e)$ denote the capacity of edge e. By construction of G^f, for each edge $e = (u,v) \in E_{out}(C,G)$ with $r(e) \neq 0$, there exists a forward edge $(u,v) \in E_{out}(C,G^f)$ with $w'(u,v) = r(e)$. Similarly, for each edge $e = (u,v) \in E_{in}(C,G)$ with $f(e) \neq 0$, there exists a backward edge $(v,u) \in E_{out}(C,G^f)$ with $w'(v,u) = f(e)$. This provides us with the following equality.

$$\begin{aligned}
\sum_{e' \in E_{out}(C,G^f)} w'(e') &= \sum_{e \in E_{out}(C,G)} r(e) + \sum_{e \in E_{in}(C,G)} f(e) \\
&= \sum_{e \in E_{out}(C,G)} (w(e) - f(e)) + \sum_{e \in E_{in}(C,G)} f(e) \\
&= \sum_{e \in E_{out}(C,G)} w(e) - \sum_{e \in E_{out}(C,G)} f(e) + \sum_{e \in E_{in}(C,G)} f(e) \\
&= c(C) - (f_{out}(C) - f_{in}(C)) = c(C) - \lambda \qquad \text{Using Lemma 10} \qquad (1)
\end{aligned}$$

Equation 1 completes the proof. ◀

It follows from Theorem 16 that every second (s,t)-mincut in G is a second (s,t)-mincut in G^f. Let the capacity of second (s,t)-mincut in G be $\lambda + \Delta_2$, where $\Delta_2 > 0$. Recall that our aim is to establish a relationship between second (s,t)-mincuts and global mincuts using G^f. So, by Theorem 16, we need to focus on global cuts of capacity exactly Δ_2 in G^f. However, observe that a global cut of capacity Δ_2 can never be a global mincut in G^f since $\Delta_2 > 0$. Moreover, there may exist *many* global cuts of capacity Δ_2 that cannot be a second (s,t)-mincut in G.

It is observed that a directed graph has global mincut capacity strictly greater than zero if it is an SCC. It turns out that there is exactly one nontrivial SCC, say H, in the residual graph G^f since G has exactly two trivial (s,t)-mincuts. Let us consider any global mincut A in H. Observe that A is not a second (s,t)-mincut in G^f since $s,t \in \overline{A}$. In fact, the capacity of any global cut A in H might be strictly less than the capacity of A in G^f. This is because of the existence of edges that are incident on s and/or t, which may contribute to A in G^f. Interestingly, exploiting the structure of G^f, the properties of SCC H, and Fact 15, we establish the following bijective mapping between the set of all second (s,t)-mincuts in G^f and the set of all global mincuts in H.

▶ **Lemma 17.** *Let C_1 be a global mincut in H and C_2 be a second (s,t)-mincut in G^f. Then,*
1. $c(C_2, G^f) = c(C_1, H)$,
2. $C_1 \cup \{s\}$ *is a second (s,t)-mincut in G^f and $C_2 \setminus \{s\}$ is a global mincut in H.*

Proof. Let us consider global mincut C_1 in graph H, and let $c(C_1, H) = \lambda_1$. Since H is an SCC, it is easy to show that $\lambda_1 > 0$. It follows from the construction of G^f that $C_1 \cup \{s\}$ is an (s,t)-cut in G^f. Observe that the edge-set of $C_1 \cup \{s\}$ in G^f and the edge-set of C_1 in H differ only on the set of edges, say E', that are incident on s and t in G^f. Since f is maximum (s,t)-flow, by Fact 15, s has outdegree zero; likewise, t has indegree zero in G^f. So, every edge in E' is an incoming edge to (s,t)-cut $C_1 \cup \{s\}$ in G^f. This implies that the contributing edges of (s,t)-cut $C_1 \cup \{s\}$ in G^f are the same as the contributing edges of cut C_1 in H. Hence, we arrive at the following equation.

$$c(C_1 \cup \{s\}, G^f) = c(C_1, H) = \lambda_1 \tag{2}$$

It is given that C_2 is a second (s,t)-mincut in G^f. Let $c(C_2, G^f) = \lambda_2$, where $\lambda_2 > 0$. It follows from Fact 15 that $\{s\}$ and $V \setminus \{t\}$ are the only (s,t)-mincuts in G^f. So, any (s,t)-cut in G^f except $\{s\}$ and $V \setminus \{t\}$ has capacity at least λ_2. Since C_1 is a cut in H, $C_1 \cup \{s\}$ is neither $\{s\}$ nor $V \setminus \{t\}$. Moreover, since $C_1 \cup \{s\}$ is an (s,t)-cut in G^f, we get $c(C_2, G^f) \leq c(C_1 \cup \{s\}, G^f)$. So, it follows from Equation 2 that $c(C_2, G^f) \leq \lambda_1$. Therefore, we arrive at the following inequality.

$$\lambda_2 \leq \lambda_1 \tag{3}$$

Observe that second (s,t)-mincut C_2 must separate a pair of vertices in H since $\{s\}$ and $V \setminus \{t\}$ are (s,t)-mincuts in G^f. Thus, the cut $C_2 \setminus \{s\}$ appears as a global cut in graph H. Thus, we can arrive at the following equation using similar arguments as in the case of Equation 2.

$$c(C_2 \setminus \{s\}, H) = c(C_2, G^f) = \lambda_2 \tag{4}$$

Since C_1 is a global mincut in H and $C_2 \setminus \{s\}$ is a global cut in H, $c(C_1, H) \leq c(C_2 \setminus \{s\}, H)$. Therefore, by Equation 4, we get the following inequality.

$$\lambda_1 \leq \lambda_2 \tag{5}$$

It follows from Equations 3 and 5 that $\lambda_2 = \lambda_1$. Evidently, $c(C_2, G^f) = c(C_1, H)$ and it completes the proof of (1). Now, by Equation 2, $c(C_1 \cup \{s\}, G^f) = \lambda_2$ and by Equation 4, $c(C_2 \setminus \{s\}, H) = \lambda_1$. Therefore, (s,t)-cut $C_1 \cup \{s\}$ is a second (s,t)-mincut in G^f and $C_2 \setminus \{s\}$ is a global mincut in H. This completes the proof of (2). ◀

The following lemma is immediate from Lemma 17 and Theorem 16.

▶ **Lemma 18.** *Suppose G has exactly two (s,t)-mincuts – $\{s\}$ and $V \setminus \{t\}$. There is an algorithm that, given any maximum (s,t)-flow in G, can compute a second (s,t)-mincut in G using one global mincut computation.*

It turns out that Lemma 18 does not immediately hold for graphs with one or more than two (s,t)-mincuts. For graphs with exactly one (s,t)-mincut, we suitably modify the SCC H in G^f. Finally, to extend our result for graphs having more than two (s,t)-mincuts, we partition the graph into a set of *roughly* disjoint subgraphs, each having at most two (s,t)-mincuts. This is obtained by applying a graph decomposition technique using DAG $\mathcal{D}_{PQ}(G)$ (Theorem 13), which was originally introduced in [3] for (s,t)-cuts of capacity $(\lambda+1)$ (Section 5.4 in [3]). This leads to Theorem 2(1). The proof of Theorem 2(2) is straightforward using standard techniques.

Cen et al. [9] recently designed an efficient algorithm for computing a global mincut in directed graphs with integer edge capacities. Their algorithm uses $\tilde{\mathcal{O}}(\sqrt{n})$ maximum (s,t)-flow computations to compute a global mincut. This result of Cen et al. [9], along with Theorem 2(1), immediately leads to Theorem 1.

6 Characterization of Minimum+1 (s,t)-cuts using Maximum flow

The widely known Maxflow-Mincut Theorem [19] provides a characterization of all (s,t)-mincuts using a maximum (s,t)-flow. However, it seems that any extension of this result might not exist for characterizing (s,t)-cuts of capacity $\lambda+1$. This is because no equivalent (s,t)-flow is known corresponding to a $(\lambda+1)$ (s,t)-cut, as stated in [3]. Interestingly, we show that, in fact, there exist close relationships between maximum (s,t)-flow and $(\lambda+1)$ (s,t)-cuts as follows.

For undirected multi-graphs, we first establish the following property for $(\lambda+k)$ (s,t)-cuts, where $k \geq 0$ is an integer, based on a maximum (s,t)-flow.

▶ **Lemma 19.** *Let C be a $(\lambda+k)$ (s,t)-cut in G, where $k \geq 0$ is an integer. Let f be any maximum (s,t)-flow in G and let $\mathcal{E} \subseteq E(C)$ be the set of edges such that $f(e) = 0$ for every edge $e \in \mathcal{E}$. Then, (**1**) $|\mathcal{E}| \leq k$ and (**2**) $|\mathcal{E}|$ is odd if and only if k is odd.*

Proof. Suppose C is a $(\lambda+k)$ (s,t)-cut in G. It follows from conservation of flow (Lemma 10), $f_{out}(C) \geq \lambda$, since f is a maximum (s,t)-flow and $f_{in}(C) \geq 0$. Let $f_{out}(C) = \lambda + j$, for any integer $j \geq 0$. Again by Lemma 10, $f_{in}(C) = j$. Therefore, $f_{out}(C) + f_{in}(C) = \lambda + 2j$. It follows that there are exactly $\lambda + 2j$ edges belonging to $E(C)$ that are carrying flow. Let $\mathcal{E} \subseteq E(C)$ be the set of remaining edges such that, for every edge $e \in \mathcal{E}$, $f(e) = 0$. In undirected graphs, every edge belonging to the edge-set of a cut is a contributing edge of the cut. Therefore, using $f_{out}(C) + f_{in}(C) = \lambda + 2j$, we arrive at the following equality.

$$|\mathcal{E}| = c(C) - (f_{out}(C) + f_{in}(C)) = \lambda + k - (\lambda + 2j) = k - 2j \tag{6}$$

It follows from Equation 6 that $|\mathcal{E}| \leq k$. In addition, since $2j$ is always an even number, this implies that $|\mathcal{E}|$ is odd if k is odd; otherwise $|\mathcal{E}|$ is even. ◀

By crucially exploiting Lemma 19, we now establish an interesting *flow-based characterization* of all the $(\lambda+1)$ (s,t)-cuts, which is of independent interest.

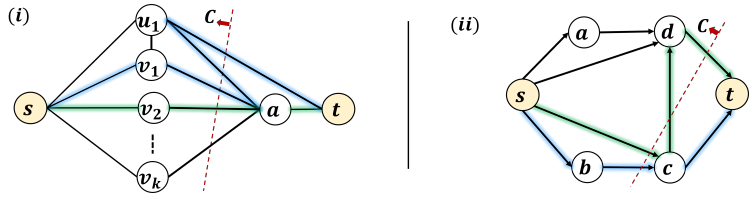

Figure 2 A colored edge represents that the edge carries flow and $\lambda = 2$. (i) Example showing that Theorem 20 cannot be generalized for $k \geq 2$ (ii) Cut C is a $(\lambda+1)$ (s,t)-cut with $k = 1$ where each edge belonging to $E(C)$ carries flow. So, $|\mathcal{E}|$ is even although k is odd.

▶ **Theorem 20** (Maxflow (Min+1)-cut Theorem)**.** *Let G be an undirected multi-graph with a designated source s and a designated sink t. Let f be any maximum (s,t)-flow in G. Then, an (s,t)-cut C in G is a $(\lambda+1)$ (s,t)-cut if and only if there exists exactly one edge $e \in E(C)$ such that*

1. *$f(e) = 0$ and*
2. *for every edge $e' \in E(C) \setminus \{e\}$, $f(e') = 1$ and e' carries flow in the direction C to $\overline{C}$.*

Proof. Suppose C is a $(\lambda+1)$ (s,t)-cut. Let $\mathcal{E} \subseteq E(C)$ be the set of edges such that $f(e) = 0$ for each edge $e \in \mathcal{E}$. By assigning the value of $k = 1$ in Lemma 19, we have $|\mathcal{E}| \leq 1$ and $|\mathcal{E}|$ is odd. Since $|\mathcal{E}|$ is odd, therefore, $|\mathcal{E}| = 1$. Since f is a maximum (s,t)-flow, by Lemma 10, $f_{out}(C) \geq \lambda$. Moreover, we have $|E(C)| = \lambda + 1$. Therefore, for every edge $e' \in E(C) \setminus \{e\}$, $f(e') = 1$ and e' carries flow in the direction C to $\overline{C}$.

We now prove the converse part. Suppose C is an (s,t)-cut satisfying properties (1) and (2). It follows that there is no edge $e' \in E(C)$ such that $f(e') = 1$ and carries flow in the direction $\overline{C}$ to C. So, $f_{in}(C) = 0$. By using Lemma 10, we have $f_{out}(C) = \lambda$. So, in $E(C)$, there are exactly λ edges that are carrying flow and exactly one edge that is carrying no flow. Therefore, $|E(C)| = \lambda + 1$. ◀

We are thankful to an anonymous reviewer for pointing out that the forward direction of Theorem 20 can also be established using the concept of edge-disjoint paths instead of using conservation of flow.

▶ Remark 21. An immediate generalization of Theorem 20 would be the following. An (s,t)-cut C is a $(\lambda + k)$ (s,t)-cut if and only if there are exactly k edges in $E(C)$ that carry zero flow and every other edge carries flow in the direction C to $\overline{C}$. However, Figure 2(i) shows that for $\lambda = 2$, (s,t)-cut C has capacity $k+2$ but there are $k-2$ edges in $E(C)$ carrying zero flow. Hence, this generalization of Theorem 20 is not possible for any $k \geq 2$.

7 Compact Structure for All Minimum+1 (s,t)-cuts

We address the following problem for undirected multi-graphs in this section.

▶ **Problem 22.** *Design a compact structure for storing and characterizing all $(\lambda+1)$ (s,t)-cuts.*

The problem of designing a compact structure for storing and characterizing all (s,t)-mincuts immediately reduces to Problem 22 by modifying the given graph as follows. Add a dummy source s' (likewise a dummy sink t') with $\lambda-1$ edges from s' to s (likewise t to t'). Interestingly, for directed multi-graphs, Baswana, Bhanja, and Pandey [3] provide a solution to Problem 22 by essentially reducing it to the problem of designing a compact structure for storing and characterizing all (s,t)-mincuts. However, their structure occupies $\mathcal{O}(mn)$ space. For undirected multi-graphs, we present a structure for storing and characterizing all $(\lambda+1)$ (s,t)-cuts that occupies $\mathcal{O}(\min\{m, n\sqrt{\lambda}\})$ space as follows.

We construct a graph G' such that every $(\lambda+1)$ (s,t)-cut of G appears as an (s,t)-mincut in G'. This will help us store and characterize all $(\lambda+1)$ (s,t)-cuts of G using a structure that stores and characterizes all (s,t)-mincuts in G'. To achieve this objective, we pursue the following simple idea – remove one edge from every $(\lambda+1)$ (s,t)-cut. A naive implementation of this idea might not work as follows. There may be a pair of edges e, e' contributing to the cut $C_1 \cap C_2$ defined by the intersection of two $(\lambda+1)$ (s,t)-cuts C_1, C_2. Even if none of the edges e, e' contribute to both C_1 and C_2, their removal will reduce the (s,t)-mincut capacity if $c(C_1 \cap C_2)$ is λ or $\lambda+1$ (refer to Figure 3(i)). In order to materialize the idea, we exploit Theorem 20, which motivates us to define a set of edges with respect to $(\lambda+1)$ (s,t)-cuts in the following way.

▶ **Definition 23** (Anchor edge). *For any given maximum (s,t)-flow f, an edge e is said to be an anchor edge if e contributes to a $(\lambda+1)$ (s,t)-cut and $f(e)=0$.*

By Maxflow-Mincut Theorem, the removal of a set of edges carrying no flow in f does not reduce the capacity of (s,t)-mincut. Moreover, by Theorem 20, for every $(\lambda+1)$ (s,t)-cut C in G, exactly one anchor edge contributes to C. Hence, every $(\lambda+1)$ (s,t)-cut, as well as (s,t)-mincut in G, appears as an (s,t)-mincut of capacity λ in $G \setminus \mathcal{A}$. It is also easy to observe that there may exist (s,t)-cuts with capacity more than $\lambda+1$ appearing as (s,t)-mincuts in $G \setminus \mathcal{A}$. However, using anchor edges $\mathcal{A}$, we can distinguish the $(\lambda+1)$ (s,t)-cuts as follows.

▶ **Lemma 24.** *An (s,t)-cut C is a $(\lambda+1)$ (s,t)-cut in G if and only if C is an (s,t)-mincut in $G \setminus \mathcal{A}$ and exactly one edge from $\mathcal{A}$ contributes to C.*

By Lemma 24, our compact structure consists of set of edges $\mathcal{A}$ and a structure that stores and characterizes all (s,t)-mincuts in $G \setminus \mathcal{A}$. It follows that the space occupied by our structure exceeds that of any structure for storing and characterizing all (s,t)-mincuts only by the size of $\mathcal{A}$. Therefore, we need to show that the set $\mathcal{A}$ is *small*.

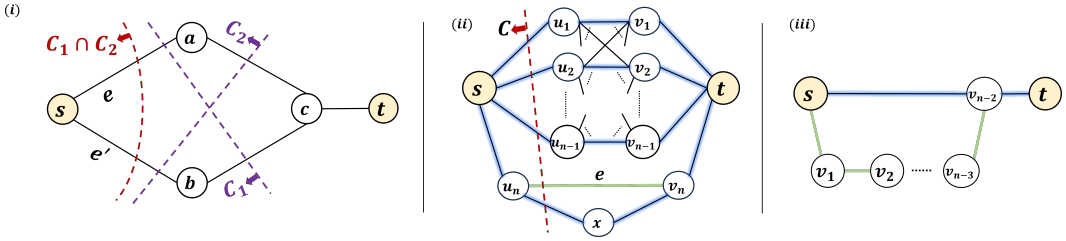

Figure 3 A blue edge carries flow and a green edge is an anchor edge. (i) $C_1 \cap C_2$ has capacity less than that of (s,t)-mincut in $G \setminus \{e, e'\}$. (ii) A graph with a given maximum (s,t)-flow satisfying $|\textsc{NoFlow}| = \Omega(n^2)$ but exactly one anchor edge e. (iii) Graph with exactly $(n-2)$ anchor edges.

7.1 Bounding the Cardinality of The Set of Anchor Edges

We now provide a tight bound on the cardinality of the set of all anchor edges $\mathcal{A}$. We present an efficient algorithm that, exploiting the properties of anchor edges, computes a set of edges $\mathcal{F}$ such that the following two properties hold.

1. The set of all anchor edges is a subset of $\mathcal{F}$.
2. The number of edges belonging to $\mathcal{F}$ is at most $n-2$.

By Definition 23, every anchor edge belongs to the set, say NoFlow, of all edges carrying zero flow in f. However, there exist graphs H such that, for any maximum (s,t)-flow in H, the cardinality of set NoFlow can be $\Omega(n^2)$, yet the number of anchor edges is only $\mathcal{O}(1)$ (refer to Figure 3(ii)). So, NoFlow provides a *loose* upper bound on the number of anchor

edges. Naturally, the question arises whether it is possible to eliminate a large number of edges from NoFlow while still keeping the set of all anchor edges intact. We answer this question in the affirmative by exploiting the following lemma.

▶ **Lemma 25.** *Let $\mathbb{H}$ be a cycle formed using a subset of edges in NoFlow. Then, no edge in $\mathbb{H}$ can be an anchor edge.*

Proof. Consider any edge $e \in \mathbb{H}$ and C be any (s,t)-cut in G such that $e \in E(C)$. Since C is a cut, C must intersect cycle $\mathbb{H}$ at least twice. Hence, C contains at least two edges that carry no flow. Therefore, it follows from Theorem 20 that C cannot be a $(\lambda+1)$ (s,t)-cut. Hence, by Definition 23, e cannot be an anchor edge. ◀

We now use Lemma 25 to construct a spanning forest $G_{\mathcal{F}}$ to provide an upper bound on the cardinality of set $\mathcal{A}$.

Construction of Spanning Forest $G_{\mathcal{F}} = (V, \mathcal{F})$. The vertex set of $G_{\mathcal{F}}$ is the same as G. Initially, there is no edge in $G_{\mathcal{F}}$. We construct graph $G_{\mathcal{F}}$ incrementally by executing the following step for each edge e in NoFlow. If a cycle is formed in $G_{\mathcal{F}} \cup \{e\}$, then by Lemma 25, e cannot be an anchor edge. Hence, we ignore edge e. Otherwise, if there is no cycle in $G_{\mathcal{F}} \cup \{e\}$, then insert edge e to $G_{\mathcal{F}}$.

It follows from the construction of $G_{\mathcal{F}}$ that $\mathcal{A} \subseteq \mathcal{F}$. Moreover, $|\mathcal{F}|$ is at most $n-1$ since $G_{\mathcal{F}}$ is a spanning forest. We now show a tight bound on $|\mathcal{A}|$, as well as $|\mathcal{F}|$, in the following lemma.

▶ **Lemma 26.** *Set $\mathcal{A}$, as well as set $\mathcal{F}$, contains at most $(n-2)$ edges.*

Proof. Let us assume to the contrary that $\mathcal{F}$ contains exactly $n-1$ edges. It follows that $G_{\mathcal{F}}$ is a spanning tree. Hence, $\mathcal{F}$ contains at least one edge from the edge-set of every (s,t)-cut in G. It implies that there exists an (s,t)-mincut C in G such that $\mathcal{F}$ contains at least one edge from the edge-set of C. By Maxflow-Mincut Theorem, for every edge $e \in E(C)$, $f(e) = 1$. Thus, $\mathcal{F}$ contains an edge e such that $f(e) = 1$, which is a contradiction since $\mathcal{F} \subseteq$ NoFlow. Since $\mathcal{A} \subseteq \mathcal{F}$, it follows that the cardinality of $\mathcal{A}$ is at most $n-2$. ◀

We show that there also exist graphs where $\mathcal{A}$ contains exactly $n-2$ edges (refer to Figure 3(*iii*)). Therefore, the bound on the set $\mathcal{A}$ given in Lemma 26 is tight.

We also show that set $\mathcal{A}$ can be obtained in $\mathcal{O}(m)$ time. Finally, using the best-known structure $\mathcal{D}_{PQ}$ for storing and characterizing all (s,t)-mincuts [33], we show that $\mathcal{D}_{PQ}(G \setminus \mathcal{A})$ occupies $\mathcal{O}(\min\{m, n\sqrt{\lambda}\})$ space, which leads to Theorem 6.

8 Dual Edge Sensitivity Oracle: Breaking the Quadratic Barrier

In this section, for undirected unweighted simple graphs, we design a subquadratic space data structure that can efficiently answer the query: report an (s,t)-mincut after the failure/insertion of any pair of edges. We assume G to be an undirected unweighted simple graph in this section. We provide an overview for handling the failure of edges in G. Note that handling the insertion of a pair of edges is along a similar line and is provided in the full version. Henceforth, let $e_1 = (x_1, y_1)$ and $e_2 = (x_2, y_2)$ be the two failed edges in G.

There is a folklore result that the residual graph G^f acts as an $\mathcal{O}(m)$ space dual edge sensitivity oracle for (s,t)-mincut that achieves $\mathcal{O}(m)$ query time. The query algorithm is derived from the *augmenting path* based algorithm for computing maximum (s,t)-flow by Ford and Fulkerson [19] (briefly explained as a warm-up below). However, it is known that

the residual graph occupies quadratic space if $m = \Omega(n^2)$. To design a subquadratic space dual edge sensitivity oracle for undirected unweighted simple graphs, instead of the residual graph G^f, we work with our compact structure, consisting of $\mathcal{D}$ and the set $\mathcal{A}$ of anchor edges, from Theorem 6. Recall that $\mathcal{D}$ is the graph $\mathcal{D}_{PQ}(G \setminus \mathcal{A})$, which is just a quotient graph of G^f. Hence, $\mathcal{D} \cup \mathcal{A}$ may fail to preserve the complete information of every path in G^f. However, we show that $\mathcal{D} \cup \mathcal{A}$ is still sufficient to answer dual edge failure queries using the same algorithm used for the folklore result using residual graph G^f.

Warm-up with residual graph. Observe that if none of the failed edges e_1, e_2 carry flow in maximum (s,t)-flow f, then the capacity of (s,t)-mincut remains unchanged in $G \setminus \{e_1, e_2\}$. Henceforth, we assume that edge e_1 always carries flow in the direction from x_1 to y_1. It follows from the construction of residual graph that there must exist a (t,s)-path P in G^f containing edge (y_1, x_1). We first reduce the flow in G using P in G^f, and then remove the edges (x_1, y_1) and (y_1, x_1) from G^f. Finally, using the concept of *augmenting paths* [19] in residual graph, we can verify in $\mathcal{O}(m)$ time whether the value of maximum (s,t)-flow becomes $\lambda - 1$ or remains λ in $G \setminus \{e_1\}$. In the residual graph corresponding to the obtained maximum (s,t)-flow in $G \setminus \{e_1\}$, repeat the same procedure for edge e_2 to verify whether failure of edge e_2 reduces the capacity of (s,t)-mincut in $G \setminus \{e_1\}$. This helps in reporting an (s,t)-mincut in the graph $G \setminus \{e_1, e_2\}$ in $\mathcal{O}(m)$ time.

Our solution using $\mathcal{D} \cup \mathcal{A}$. We now use the structure $\mathcal{D} \cup \mathcal{A}$ from Theorem 6 as a subquadratic space dual edge sensitivity oracle. $\mathcal{D}_{PQ}(G)$ (Theorem 13) can be used to design a single edge sensitivity oracle that occupies $\mathcal{O}(n)$ space [33, 3]. As observed by Baswana, Bhanja, and Pandey [3], $\mathcal{D}_{PQ}(G)$ can also handle dual edge failures for the special case when both failed edges contribute to only (s,t)-mincuts, using its reachability information. However, for handling any dual edge failures, the main difficulty arises when endpoints of both edges are mapped to the same node in $\mathcal{D}_{PQ}(G)$ [3]. Our structure $\mathcal{D} \cup \mathcal{A}$ addresses this difficulty seamlessly by first ensuring the following condition. The capacity of (s,t)-mincut changes only if the endpoints of at least one failed edge appear in different nodes of $\mathcal{D}$. This is achieved using the following property of $\mathcal{D}$.

▶ **Lemma 27.** *Any (s,t)-cut separating a pair of vertices mapped to the same node in $\mathcal{D}$ must have capacity at least $\lambda + 2$.*

Henceforth, we assume without loss of generality that endpoints of edge e_1 appear in different nodes in $\mathcal{D}$. Let us first handle the failure of edge e_1. It turns out that $\mathcal{D} \cup \mathcal{A}$ can easily report an (s,t)-mincut in $G \setminus \{e_1\}$. This exploits the following mapping of paths between G^f and $\mathcal{D} \cup \mathcal{A}$.

▶ **Lemma 28.** *Let u, v be any pair of vertices mapped to different nodes μ and ν in $\mathcal{D}$. There exists an (u,v)-path P in G^f if and only if there exists a (μ,ν)-path P_q in $\mathcal{D} \cup \mathcal{A}$. Moreover, path P_q is a quotient path of P.*

We establish Lemma 28 by using the fact that graph $\mathcal{D} \cup \mathcal{A}$ is a quotient graph of G^f by construction. Let D_1 be the graph obtained from $\mathcal{D} \cup \mathcal{A}$ after applying the query algorithm (described above) on $\mathcal{D} \cup \mathcal{A}$ for the failure of edge e_1. By following the mapping of paths in Lemma 28, let f_1 be the corresponding maximum (s,t)-flow in $G \setminus \{e_1\}$ and G^{f_1} denote the corresponding residual graph. On a high level, our technical contribution lies in showing that even after handling failure of e_1, D_1 still preserves enough information about augmenting paths in G^{f_1} that facilitates the handling of the failure of edge e_2 in $G \setminus \{e_1\}$. We now provide the overview.

To handle the failure of edge e_2, the obtained graph D_1 must satisfy the following property, which actually holds between graphs $\mathcal{D} \cup \mathcal{A}$ and G^f (refer to Lemma 27).

▶ **Lemma 29.** *D_1 is a quotient graph of G^{f_1} and for every path P in D_1, there is a path P_1 in G^{f_1} such that P is a quotient path of P_1.*

In order to establish Lemma 29, the challenging case appears when the (s,t)-mincut remains unchanged after the failure of e_1. In this case, let us first observe the change in the residual graph after reducing the flow that was passing through edge e_1. In the resulting residual graph, the query algorithm finds a path P from s to t, and flips the direction of every edge belonging to it. A similar update is executed by the query algorithm using a path P_1 in graph $\mathcal{D} \cup \mathcal{A}$, where P_1 is a quotient path of P. This could lead to the following scenario for the resulting graph D_1. There is a path P_{uv} in D_1, but there is no path P^r_{uv} in G^{f_1} such that P_{uv} is a quotient path of P^r_{uv}. In other words, Lemma 29 may fail to hold. So, we might report an incorrect (s,t)-mincut in $G \setminus \{e_1, e_2\}$. Interestingly, exploiting the SCC structure of G^{f_1}, the structure of $\mathcal{D}$, and Lemma 27, we ensure that such a scenario never occurs. This allows us to handle the failure of e_2 using D_1 exactly in the same way as handling the failure of e_1 using $\mathcal{D} \cup \mathcal{A}$. This leads to Theorem 8.

9 Conclusion

In this article, we have mainly solved the following two problems, achieving significant improvements over the existing bounds.

Firstly, we have addressed the problem of designing an efficient algorithm for computing a second (s,t)-mincut in directed integer-weighted graphs. Our algorithm achieves a running time that is $\tilde{\Omega}(n\sqrt{n})$ times faster than the existing best-known algorithm [37]. Most importantly, to arrive at the solution, a close relationship between global mincut and second (s,t)-mincut is exposed for the first time here. We believe that this connection between global cuts and (s,t)-cuts (via residual graph) should be quite useful for addressing future research problems, including the problem of designing an algorithm for computing an (s,t)-cut of k^{th} minimum capacity, for any $k > 2$, that breaks the existing bound [37].

Finally, we have addressed the problem of designing a dual edge sensitivity oracle for (s,t)-mincut in undirected unweighted simple graphs. This problem is shown to be closely related to the study of (s,t)-cuts of capacity minimum+1, which is a special case of the second (s,t)-mincut in unweighted graphs. Our dual edge sensitivity oracle breaks the recently established quadratic lower bound on space in multi-graphs [6] by a factor of $\Omega(\sqrt{n})$. The foundation of this result lies in our newly designed structure for storing and characterizing all minimum+1 (s,t)-cuts, which also improves the existing best-known structure [3] by $\Omega(n)$ factor. Now, it is interesting to see whether the query time of our dual edge sensitivity oracle can be improved and whether our approach can help us in designing a sensitivity oracle for handling more than two edge insertions/failures.

Abstract

We provide the first approximation quality guarantees for the Cuthull-McKee heuristic for reordering symmetric matrices to have low bandwidth, and we provide an algorithm for reconstructing bounded-bandwidth graphs from distance oracles with near-linear query complexity. To prove these results we introduce a new width parameter, BFS width, and we prove polylogarithmic upper and lower bounds on the BFS width of graphs of bounded bandwidth. Unlike other width parameters, such as bandwidth, pathwidth, and treewidth, BFS width can easily be computed in polynomial time. Bounded BFS width implies bounded bandwidth, pathwidth, and treewidth, which in turn imply fixed-parameter tractable algorithms for many problems that are NP-hard for general graphs. In addition to their applications to matrix ordering, we also provide applications of BFS width to graph reconstruction, to reconstruct graphs from distance queries, and graph drawing, to construct arc diagrams of small height.

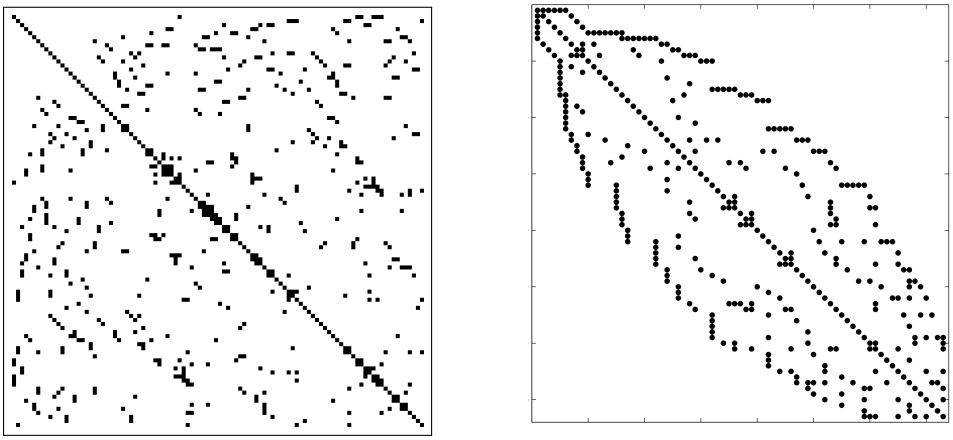
1 Introduction

When a graph has a linear layout of low bandwidth, it is natural to guess that breadth-first search produces a low-width layout. This is the underlying principle of the widely used Cuthill–McKee algorithm [13] for reordering symmetric matrices into band matrices with low bandwidth. In this paper, we quantify this principle, for the first time, by providing the first worst-case analysis of the Cuthill–McKee algorithm, proving polylogarithmic upper and lower bounds for its performance on bounded-bandwidth graphs. Using the same techniques, we also study the problem of reconstructing an unknown graph, given access to a distance oracle. We use a method based on breadth-first search to reconstruct graphs of bounded bandwidth in near-linear query complexity. Additionally, we apply our results in graph drawing, by constructing arc diagrams of low height for any graph of bounded bandwidth.



The key to our results is a natural but previously-unstudied graph width parameter, the **breadth-first-search width** or **BFS width** of a graph, which we define algorithmically in terms of the size of the layers in a breadth-first search tree. To develop our results, we prove that bandwidth and BFS width are polylogarithmically tied: the graphs of bandwidth $\leq b$, for any constant b, have BFS width that is both upper bounded (for all graphs of bandwidth $\leq b$) and lower bounded (for infinitely many graphs of bandwidth b) by functions of the form $\log^{f(b)} n$. To provide context for our contributions, we review the background of our three application areas below and then describe our new results in more detail for each.

Sparse Numerical Linear Algebra

A symmetric matrix, A, is called a **band matrix** if its nonzeros are confined to a **band** of consecutive diagonals centered on the main diagonal; the **bandwidth** is the number of these nonzero diagonals on either side of the main diagonal. That is, it is the maximum value of $|i - j|$ for the indexes of a nonzero matrix entry $A_{i,j}$. Any symmetric matrix corresponds to an undirected graph, with n numbered vertices, and with an edge $\{i, j\}$ for each off-diagonal nonzero entry $A_{i,j}$; the numbering of vertices describes a **linear layout** of this graph and the bandwidth of this layout is the largest difference between the positions of any two adjacent vertices in this linear layout. The bandwidth of the graph itself is the minimum bandwidth of any of its linear layouts; the goal of the Cuthill–McKee algorithm is to permute the vertices of the graph into a layout with bandwidth close to this minimum, and correspondingly to permute the rows and columns of the given matrix to produce an equivalent symmetric band matrix of low bandwidth. See Figure 1. Such a reordering, for instance, can be used in sparse numerical linear algebra to reduce fill-in (zero matrix elements that become nonzero) when applying Gaussian elimination to the matrix.

Graph bandwidth is NP-complete [20] and hard to approximate to within any constant factor, even for trees of a very special form [15]. For any fixed b, testing whether bandwidth $\leq b$ is polynomial, but with b in the exponent of the polynomial [25]. Therefore, practitioners have resorted to heuristics for bandwidth, rather than exact optimization algorithms. Notable among these are the Cuthill–McKee algorithm [13], and the closely related reverse Cuthill–McKee algorithm [21]; both are heavily cited and widely used for this task. More sophisticated methods have also been used and tested experimentally [34].

The best known polynomial time algorithm provides a $O(\log^3 n\sqrt{\log \log n})$-approximation factor for bandwidth on general graphs with high probability using a semi-definite relaxation [16]. A randomized polynomial time $O(\log^{2.5} n)$-approximation algorithm is known for the special cases of trees and chordal graphs using caterpillar decomposition [24]. In contrast, the Cuthill–McKee and reverse Cuthill–McKee algorithms are much simpler since they only rely on BFS and are deterministic. Despite their simplicity, we are unaware of any

past work providing worst-case performance guarantees for the Cuthill–McKee and reverse Cuthill–McKee algorithms. The only theoretical upper bound we are aware of regarding these algorithms concerns random matrices whose optimal bandwidth is sufficiently large, for which this algorithm will produce a constant factor approximation. The same work also provides a logarithmic lower bound on the approximation factor for matrices with optimal bandwidth 2, weaker than our result [35]. Instead, we are interested in deterministic guarantees for these algorithms for matrices of low optimal bandwidth. We prove the following results:

- For $n \times n$ matrices of bounded optimal bandwidth $\leq b$, we show that the Cuthill–McKee algorithm and the reverse Cuthill–McKee algorithm will find a reordering of bandwidth upper bounded by a function of the form $\log^{f(b)} n$. Equivalently, for n-vertex graphs of bandwidth $\leq b$, these algorithms will find a linear layout of bandwidth $\leq \log^{f(b)} n$.
- We show that there exist matrices for which this polylogarithmic dependence is necessary. For every polylogarithmic bound $\log^k n$ on the bandwidth, there is a constant bandwidth bound b such that, for infinitely many n, there exist matrices of optimal bandwidth $\leq b$ that cause both the Cuthill–McKee algorithm and the reverse Cuthill–McKee algorithm to produce reordered matrices of bandwidth $\Omega(\log^k n)$.

We remark that, for any graph,

$$O(1) \text{ BFS width} \implies O(1) \text{ bandwidth} \implies O(1) \text{ pathwidth} \implies O(1) \text{ treewidth [28]},$$

and graphs of bandwidth b have tree-depth $O(b \log n/b)$ [23]. Thus, many algorithmic results based on width parameters such as pathwidth, treewidth, and tree-depth are also available for BFS-width. However, both pathwidth and tree-depth have approximation algorithms with fixed polylogarithmic approximation ratios [6, 19], better than the polylogarithmic ratio with a variable exponent depending on the optimal bandwidth that we prove for the Cuthill–McKee algorithm.

Graph Reconstruction

We also provide new results for **graph reconstruction**, a well-motivated problem with numerous applications, such as learning road networks [2] and communication network mapping [1]. Suppose we are given the vertex set but not the edge set of a graph G. The **graph reconstruction** problem is to determine all the edges of G, by asking queries about G from an oracle, with the goal of minimizing the **query complexity**, the number of queries to the oracle [27, 32]. Various oracles can be used. In particular, we consider the **distance oracle** from several previous works [27, 32]. This oracle takes a pair of vertices and returns the number of edges on a shortest path between the two given vertices. Following previous work [27, 32], the graph is assumed to be connected, undirected, and unweighted. It is also generally assumed to have bounded degree, because distinguishing an n-vertex star from a graph with one additional edge between the leaves of the star would have a trivial quadratic lower bound. For reconstruction from distance oracles, the following results are known:

- For graphs of maximum degree Δ, there is a randomized algorithm with query complexity $O(\Delta^3 \cdot n^{3/2} \cdot \log^2 n \cdot \log\log n)$, which is $\tilde{O}(n^{3/2})$ when $\Delta = O\big(\text{polylog}(n)\big)$ [27].[1]
- Chordal graphs can be reconstructed in randomized query complexity $\tilde{O}(n)$ when $\Delta = O(\log\log n)$ [27]. The k-chordal graphs can be reconstructed in randomized query complexity $O_{\Delta,k}(n \log n)$ when $\Delta = O(1)$ [4].

[1] We use $\tilde{O}(*)$ to denote asymptotic bounds that ignore polylogarithmic factors.

- Outerplanar graphs can be reconstructed in randomized query complexity $\tilde{O}(n)$ when Δ is polylogarithmic [27].
- For reconstructing uniformly random Δ-regular graphs with maximum degree $\Delta = O(1)$, there is a randomized algorithm using $\tilde{O}(n)$ queries in expectation [32].

Our new results in this area are that the graphs of bounded bandwidth can be reconstructed deterministically in query complexity $\tilde{O}(n)$, by a very simple algorithm. More generally, the graphs of BFS width B can be reconstructed deterministically in query complexity $O(nB)$. No additional assumption on Δ is needed here because bounded bandwidth and bounded BFS width both automatically imply bounded degree.

Graph Drawing

Graph drawing is the study of methods for visualizing graphs; see, e.g., [5,30]. One type of graph visualization tool that has received considerable attention is the **arc diagram** of a graph, $G = (V, E)$, where the vertices of G are laid out as points on a straight line and edges are drawn as semicircular arcs or straight-line segments (for consecutive points) joining pairs of such points. See Figure 2.

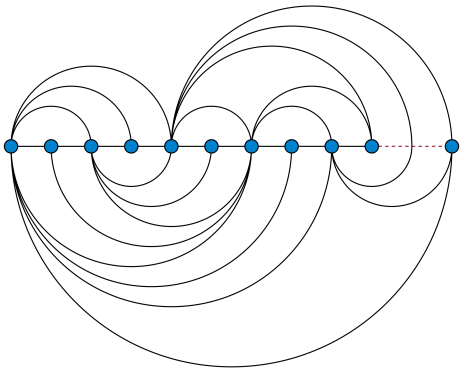

Figure 2 An example arc diagram. Public-domain image by David Eppstein.

Arc diagrams have received considerable attention, both as a visualization tool and as a topic of study in discrete mathematics; see, e.g., [9,11,14,30,31,36]. As a direct consequence of Theorem 14, when an n-vertex graph has an arc diagram of bounded height, we can find a drawing with polylogarithmic height. Here, the height of an arc diagram, with vertices placed at integer positions along the x-axis, is just half the bandwidth of the linear layout describing the vertex placement.

2 Preliminaries

We define BFS width as follows. From a given undirected graph, $G = (V, E)$, choose arbitrarily a starting vertex v in G and perform a breadth-first search of G from v. The edges traversed during this search define a breadth-first search tree T such that the depth of each vertex in T equals its unweighted distance from v, the number of edges in a shortest path from v. We define the **layer** $L_i(v)$ to consist of all vertices at distance i from v; if $u \in L_i(v)$, we say that u has **layer number** i. The maximum size of any $L_i(v)$ set is the BFS width of G from v and the BFS width of G is the maximum BFS width taken over all choices of the starting vertex v in G. That is, we have the following formal definition of BFS width building upon the definition of width in layered graph drawing [5].

▶ **Definition 1** (BFS Width). *Let $G = (V, E)$ be a graph. A **layering** of G is a partition of V into subsets $L_0, L_1, \ldots$, and the **width** of G for this layering is $\max_{i \in \mathbb{Z}_{\geq 0}} |L_i|$. Any vertex, $v \in V$, defines a layering by letting $L_i(v) = \{u \in V : d(v, u) = i\}$. The **BFS width of G from v**, denoted $\mathbf{bfsw}(G, v)$, is defined as $\mathbf{bfsw}(G, v) = \max_{i \in \mathbb{Z}_{\geq 0}} |L_i(v)|$. The **BFS width of G**, denoted $\mathbf{bfsw}(G)$, is defined as $\mathbf{bfsw}(G) = \max_{v \in V} \mathbf{bfsw}(G, v) = \max_{v \in V} \max_{i \in \mathbb{Z}_{\geq 0}} |L_i(v)|$.*

We also define the **minimum BFS width**, $\mathbf{bfsw}_{\min}(G) = \min_{v \in V} \mathbf{bfsw}(G, v)$. These two BFS width parameters can differ significantly, and we will show that there exist graphs such that $\mathbf{bfsw}(G)/\mathbf{bfsw}_{\min}(G) = \Omega(\log n)$. Clearly, $\mathbf{bfsw}(G)$ and $\mathbf{bfsw}_{\min}(G)$ can both easily be computed in $O\big(n(n+m)\big)$ time for any graph, G, with n vertices and m edges by performing n breadth-first searches; see, e.g., [12, 22]. In contrast, it is NP-hard to compute other well-known width parameters for a graph, including bandwidth [18], pathwidth, and treewidth [7]. Nevertheless, we prove that bounded BFS width implies bounded bandwidth for the graph, which, in turn, implies bounded pathwidth and treewidth for the graph.

Some Preliminary Facts About Bandwidth and BFS Width

Bandwidth

Two lower bounds on bandwidth are as follows:

▷ Claim 2 (Degree lower bound [10]). $\mathbf{bw}(G) \geq \lceil \Delta/2 \rceil$, where Δ is the graph's maximum degree.

▷ Claim 3 (Local density lower bound [24]). $\mathbf{bw}(G) \geq D(G) \coloneqq \max_{v \in V, d} \left\lceil \frac{|N(v,d)|}{2d} \right\rceil$, where $D(G)$ is the local density of G, and $N(v, d)$ is vertices at distance at most d from v (excluding v).

When v is a maximum degree vertex and $d = 1$, this implies the degree lower bound.

BFS Width

Recall that a **caterpillar tree** is a tree in which every vertex is within distance 1 of a central path; i.e., the central path contains every vertex of degree 2 or more; see, e.g., [26]. Caterpillar trees have applications in chemistry and physics [17], and they are the graphs of pathwidth one [33]. A simple, but useful, fact regarding BFS width is the following:

▶ **Theorem 4.** *If G is a caterpillar tree with maximum degree, $\Delta \geq 2$, then $\mathbf{bfsw}(G) \leq 2(\Delta - 1)$.*

Proof. To upper bound $\mathbf{bfsw}(G)$, we want to find a root vertex v that can maximize the BFS width of G from v. Choose a vertex, v, that is not one of the end points on the central path as the root for a BFS tree, T. Then layer 1 will have size at most Δ and each vertex of degree Δ in G that is not v will correspond to an interior vertex in T with at most $\Delta - 1$ children. All degree Δ vertices are on the central path. The maximum layer size occurs in T when two such vertices are in the same layer. The layer below it has $2(\Delta - 1)$ children. ◀

We also have the following.

▶ **Theorem 5.** *For any graph, G, its bandwidth $\mathbf{bw}(G) \leq 2\big(\mathbf{bfsw}_{\min}(G)\big) - 1$.*

Proof. Let T be the BFS tree for G rooted at a vertex, v, that achieves the minimum BFS width, $\mathbf{bfsw}_{\min}(G) = \mathbf{bfsw}(G, v)$. By definition, every layer in T has at most $\mathbf{bfsw}_{\min}(G)$ vertices. It is well-known that in a graph, G, with a BFS tree, T, every non-tree edge, (u, v),

connects two vertices whose layer numbers differ by at most 1; see, e.g., [12,22]. Thus, we can number the vertices of T as $1, 2, \ldots, n$ so as to have nondecreasing layer numbers. The BFS ordering is one way to achieve this. This numbering defines a linear layout of the vertices. The maximum distance on the x-axis between two endpoints of an edge, therefore, will be at most that determined by the first vertex in a layer i and the last vertex in a layer $i+1$, which can be at most $2\big(\mathbf{bfsw}_{\min}(G)\big) - 1$. ◀

This immediately implies the following.

▶ **Corollary 6.** *For any graph, G,* $\mathbf{bw}(G) \leq 2\big(\mathbf{bfsw}(G)\big) - 1$.

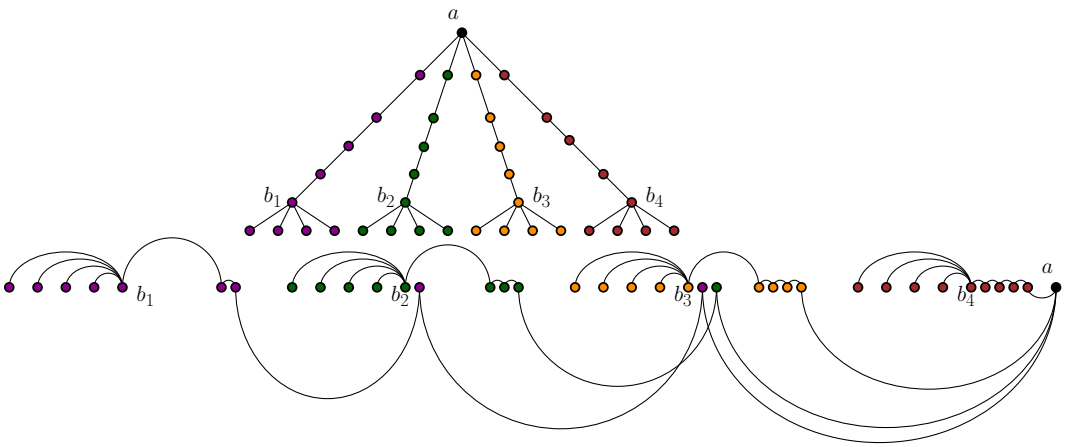

Figure 3 An example graph with $\mathbf{bfsw}(G) = \Theta(n)$ and $\mathbf{bfsw}_{\min}(G) = \Theta(n)$ and a linear layout that achieves its optimal bandwidth $\mathbf{bw}(G) = \Theta(\sqrt{n})$.

Given a linear layout of the vertices of a graph with respect to bandwidth, we say that the **length** of an edge, $\{u, v\}$, is one plus the number of vertices between u and v.

▶ **Theorem 7.** *There is a graph, G, with n vertices such that its bandwidth* $\mathbf{bw}(G) = \Theta(\sqrt{n})$ *but* $\mathbf{bfsw}(G) = \Theta(n)$ *and* $\mathbf{bfsw}_{\min}(G) = \Theta(n)$.

Proof. The example is illustrated in Figure 3. Take a star with $\sqrt{n}$ leaves and subdivide each edge $\sqrt{n}$ times. Then add a star with $\sqrt{n}$ leaves at the end of each path. This example first appeared in [24] but they only gave a lower bound on bandwidth and did not compute the bandwidth. By the degree lower bound, $\mathbf{bw}(G) = \Omega(\sqrt{n})$. Regardless of which vertex is chosen as the root for BFS, BFS will produce a layout with bandwidth $\Theta(n)$. Now it remains to show a linear layout with bandwidth $O(\sqrt{n})$.

The path from a to vertex b_i and the star at b_i are considered as one block and we call this block B_i. Suppose we have already placed $B_{\sqrt{n}-1}, B_{\sqrt{n}-2}, \ldots, B_{i+1}$. Now we describe how to place B_i. All $\sqrt{n}$ leaves of b_i are placed on its left. Next we place the path from a to b_i. Starting from a, we place one vertex to the right of $b_{\sqrt{n}-1}, b_{\sqrt{n}-2}, \ldots, b_{i+1}$. This step uses $\sqrt{n} - i - 1$ vertices. The remaining path segment with $i+1$ vertices are placed to the right of b_i.

Next we analyze the bandwidth. The edge between b_i and its leftmost leaf has length $\sqrt{n}$. Any vertex b_i introduces a path vertex to the right of $b_{\sqrt{n}-1}$. In total there are $\sqrt{n} - 2$ vertices between $b_{\sqrt{n}-1}$ and its parent in the tree. Block $B_{\sqrt{n}}$ has $2\sqrt{n} + 1$ vertices. Thus, the length of the first edge on path ab_1 is at most $4\sqrt{n}$. The linear layout has bandwidth $O(\sqrt{n})$. ◀

This shows that there are graphs for which the linear layout produced by BFS is off by a factor of $\Theta(\sqrt{n})$.

As noted above, there are many algorithmic applications with respect to graphs with bounded bandwidth, which, in turn, implies bounded pathwidth and treewidth. Theorem 5 implies that a graph with bounded minimum BFS width has bounded bandwidth. Thus, any polynomial-time algorithm for graphs with bounded bandwidth, pathwidth, or treewidth (e.g., see [3,8]) also applies to any graph with bounded BFS width for one of its vertices, with the added benefit that we can determine the minimum BFS width for a graph in polynomial time. Unfortunately, as the following theorem shows, bounded treewidth does not imply bounded BFS width.

▶ **Theorem 8.** *There is a graph, G, with n vertices such that its treewidth* $\mathbf{tw}(G) = 1$ *but* $\mathbf{bfsw}(G) = n - 1$ *and* $\mathbf{bfsw}_{\min}(G) = n - 2$.

Proof. Let G be the star graph with internal vertex v. The BFS tree, T, from the vertex v will have $n - 1$ vertices on its layer 1. For any vertex $w \neq v$, the BFS tree, T, from w will have v on its layer 1, and the remaining $n - 2$ vertices of G on its layer 2. ◀

In these subsequent sections, we sometimes drop the graph, G, in width notations when the context is clear. When the graph is a tree with root v, a natural layering is defined by distances to the root and we use the term width to denote the BFS width of G from v.

3 Graphs of Bounded Bandwidth and Polylogarithmic BFS Width

In this section, we show how to construct a graph to prove that when bandwidth is bounded, BFS width can be as large as polylogarithmic in the number of vertices. This graph also proves that BFS width and minimum BFS width can differ by a logarithmic factor. The graph that we use to establish this lower bound is an arbitrarily large binary tree. Our construction is an induction based on defining trees in terms of a level parameter, k, which is the primary inductive term, plus an independent height parameter, h, which determines the size, n, of the tree.

Level 1. A level 1 tree, $T_{1,i}$, is simply a path, which defines a tree when viewed as being rooted at one of the ends of this path. Thus, $\mathbf{bw}(T_{1,i}) = 1$ and $\mathbf{bfsw}(T_{1,i}) = 2$. Before next jumping to the general case, for $k > 1$, let us first describe the level 2 trees, which introduce a constructive pattern we repeat for the general case.

Level 2. A level 2 tree $T_{2,j}$ is defined for height, $h = 2^j$, for any integer, $j > 1$. We start with $j + 1$ level 1 trees, where $T_{1,i}$ has height $h_i = 2^i - 1$, for $i = 0, 1, \ldots, j$. We also define another level 1 tree of height $h = 2^j$, which we call the **spine**. We connect each tree, $T_{1,i}$, with an edge to a vertex v_i on the spine so that every leaf in the resulting tree has the same depth. See Figure 4.

Thus, each subtree "hanging off" the spine is a path with height $h_i = 2^i - 1$, where $i = 0, 1, \ldots, j$. The height of the level 2 tree is $h = 2^j$, where j is independent of the level number 2. As mentioned above, all leaves in a level 2 tree have the same depth; hence, the number of edges on the spine between two consecutive roots must be the height difference between the corresponding subtrees: $d(v_{i+1}, v_i) = h_{i+1} - h_i = 2^i = h_i + 1$, where d is the shortest path distance. Therefore, when we interleave a subtree, $T_{1,i}$, and the spine edges between v_{i+1} and v_i in the linear layout, we can alternately take one vertex from each. This is illustrated in Figure 4. This layout has bandwidth 2, which is the minimum possible.

Let us now consider the width (BFS width from the root) of a level 2 tree, $T_{2,j}$. This width lower bounds BFS width. Since $h = 2^j$, $j = \log h$ where log is base 2. The total number of subtrees is $j + 1$, each contributing one vertex to the widest layer. The spine also

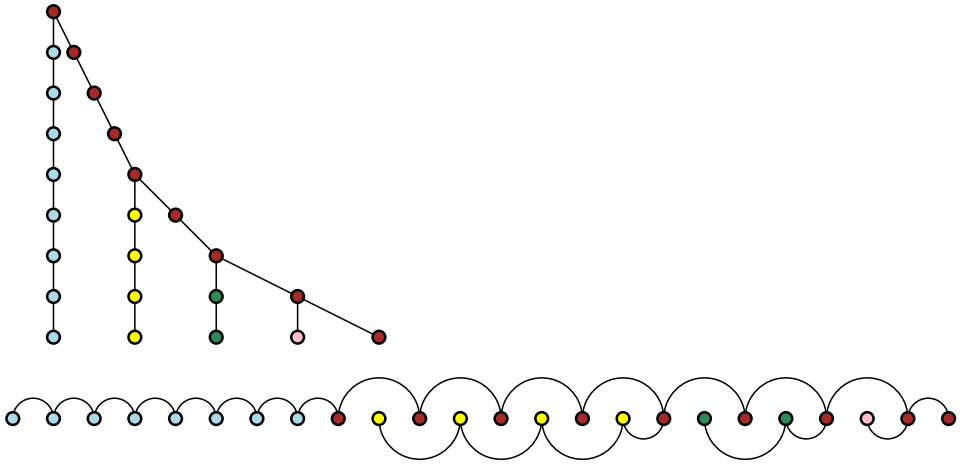

Figure 4 Top: the level 2 tree is constructed by attaching level 1 trees on a spine. The heights of these level 1 subtrees approximately follow a geometric sequence. Bottom: an arc diagram illustrating the linear layout of the level 2 tree. Each edge is a semicircle. The maximum diameter of these semicircles equals the bandwidth of the linear layout. This linear layout achieves the minimum bandwidth 2.

has one vertex at the widest layer. Therefore, the width of $T_{2,j}$ is $w = j + 1 + 1 = \log h + 2$. We want to express this width in terms of the number of vertices, n. Any vertex of this tree is either in a subtree or on the spine. The spine has height h and $h + 1$ vertices. Subtrees have $n_s = \sum_{i=0}^{j}(h_i + 1) = \sum_{i=0}^{j} 2^i = 2h - 1$ vertices. Thus, $n = h + 1 + 2h - 1 = 3h$; hence, we can define a level 2 tree $T_{2,j}$ to have an arbitrarily large number, n, of vertices. Therefore, $T_{2,j}$ has bandwidth $\mathbf{bw}(T_{2,j}) = 2$, and width, $w = j+2$, which implies $\mathbf{bfsw}(T_{2,j}) = \Omega(\log n)$, where $n = 3h = 3 \cdot 2^j$ can be arbitrarily large.

Following the structural pattern we used to build a level 2 tree, to construct a tree at level k, we take trees from level $(k - 1)$ whose heights approximately follow a geometric sequence and attach them to a path, which we again call the **spine**. These level $(k-1)$ trees are called **subtrees**. Their placement on the spine is such that the leaves of these trees have the same depth in the level k tree, thus achieving their width in a single (last) level of a breadth-first layering. To get a bounded bandwidth layout of the level k tree, we interleave vertices from the spine and level $(k - 1)$ subtrees. These constructions are illustrated in Figure 5.

Let us, therefore, consider the bandwidth and BFS width of a level k tree. Suppose the subtree below vertex v_i (excluding v_i) is $T_{k-1,i}$. Given this notational background, let us prove the following theorem, which is one of the two main technical theorems in this paper:

▶ **Theorem 9** (Lower bound on BFS width)**.** *For each non-negative integer, k, and for arbitrarily large values of n, there exists a (level k) tree, T, with n vertices that satisfies:*

$$\mathbf{bw}(T) = O_k(1),$$
$$\mathbf{bfsw}(T) = \Omega(\log^k n),$$

where $O_k(1)$ denotes a number that depends on k but is bounded when k is bounded.

Proof. We construct the level k tree to have an arbitrarily large integer, n, of vertices, by induction, from level $(k - 1)$ trees. To keep track of the tree and subtree sizes, we let $n_{k,j}$ denote the size of the tree, $T_{k,j}$, we are constructing (to roughly have height that is arbitrarily large as a power of j). The base case is the construction given above, which in this notation,

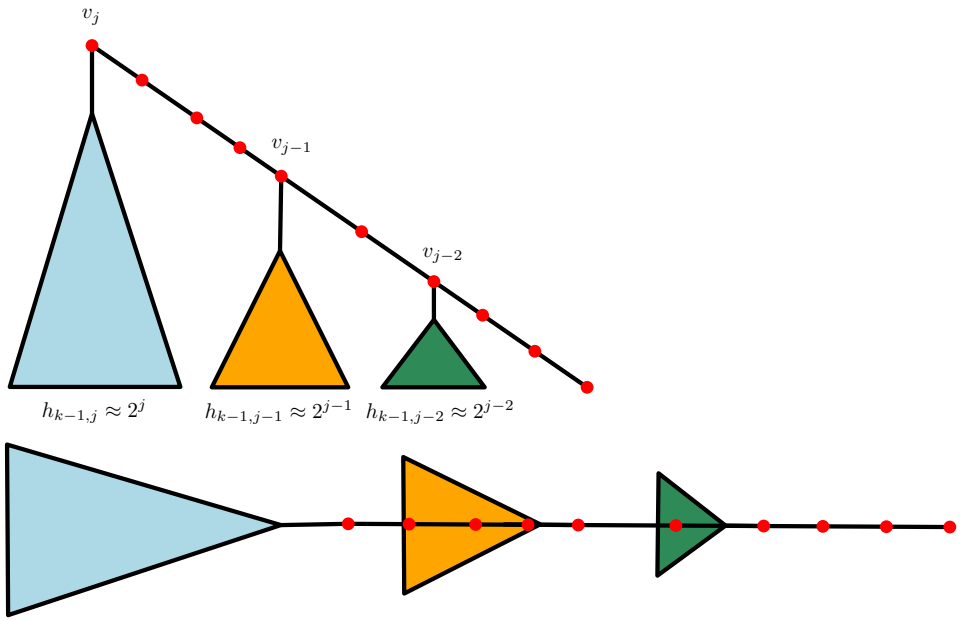

Figure 5 Top: the level k tree is constructed by attaching level $(k-1)$ trees on a spine. The heights of these level $(k-1)$ subtrees approximately follow a geometric sequence. The leaves of these subtrees have the same depth in the level k tree. Bottom: a diagram illustrating the linear layout of the level k tree. This does not necessarily achieve the minimum possible bandwidth. Intuitively, this is the level k tree rooted at the rightmost vertex of the spine. We interleave vertices from the spine and level $(k-1)$ subtrees. Vertices from a level $(k-1)$ subtree are arranged according to their linear layout from the previous level.

gives a level 2 tree with $n_{2,j} = 3h_{2,j}$ vertices and height $h_{2,j} = 2^j$ and to have bandwidth 2 and BFS width at least $d_2 j + 2$, for the constant, $d_2 = 1$. Accordingly, in our analysis below, we focus on the dominant components sufficient for our asymptotic analysis.

Inductive step. Suppose, for $i = 0, 1, 2, \ldots, j$, we have a level $(k-1)$ tree, $T_{k-1,i}$, with height $h_{k-1,i} = 2^i + k - 3$ having width $w_{k-1,i}$ and $n_{k-1,i}$ vertices such that

$$n_{k-1,i} = c_{k-1} \cdot 2^i + p_{k-1}(i), \qquad w_{k-1,i} = d_{k-1} i^{k-2} + q_{k-1}(i), \qquad \mathbf{bw}'(T_{k-1,i}) = O_{k-1}(1),$$

where $\mathbf{bw}'$ is the bandwidth of the linear layout we construct, c_{k-1} and d_{k-1} are constants, and p_{k-1} and q_{k-1} are polynomial functions with degree $k-3$. Let us now construct a level k tree where the height of the leftmost subtree is $h_{k-1,j} = 2^j + k - 3$, so this level k tree has height $h_{k,j} = 2^j + k - 2$. Using Faulhaber's formula (e.g., see Knuth [29]), we can characterize the total number of vertices in all the subtrees as

$$n_s = \sum_{i=0}^{j} (c_{k-1} \cdot 2^i + p_{k-1}(i)) = c_{k-1} \cdot (2^{j+1} - 1) + p_k(j),$$

where p_k is a polynomial function with degree $k-2$. The spine has $h_{k,j} + 1$ vertices. The total number of vertices in this level k tree, therefore, is

$$\begin{aligned} n_{k,j} &= n_s + h_{k,j} + 1 = c_{k-1} \cdot (2^{j+1} - 1) + p_k(j) + 2^j + k - 2 + 1 \\ &= (2c_{k-1} + 1) \cdot 2^j + p'_k(j) = c_k \cdot 2^j + p'_k(j), \end{aligned}$$

where p'_k is a polynomial function with degree $k-2$, and $c_k \coloneqq 2c_{k-1} + 1$. Since $c_2 = 3$, we can solve this recurrence relation to yield $c_k = 2^k - 1$.

Bandwidth. Let us next upper bound the bandwidth, $\mathbf{bw}(T_{k,j})$, of the tree, $T_{k,j}$. We interleave each subtree $T_{k-1,i}$ and the spine path between v_{i+1} and v_i in the linear layout. $T_{k-1,i}$ has height $h_{k-1,i}$ and $n_{k-1,i}$ vertices. The spine path $v_{i+1}v_i$ has length $d(v_{i+1}, v_i) = h_{k-1,i+1} - h_{k-1,i} = 2^i$. We use the linear layout of subtree $T_{k-1,i}$ obtained from the previous level and insert vertices from the spine path. Let $r_i \coloneqq n_{k-1,i}/2^i = c_{k-1} + p_{k-1}(i)/2^i$. We alternately place $\lceil r_i \rceil$ vertices from $T_{k-1,i}$ and one vertex from the spine path $v_{i+1}v_i$, until all vertices from $T_{k-1,i}$ have been placed, in which case we place the remaining vertices from $v_{i+1}v_i$ consecutively. Any edge connecting two vertices from $T_{k-1,i}$ with length equal to $\mathbf{bw}'(T_{k-1,i})$ may have at most $\left\lceil \frac{\mathbf{bw}'(T_{k-1,i})}{\lceil r_i \rceil + 1} \right\rceil$ spine vertices inside it. Any edge connecting two vertices from the spine path $v_{i+1}v_i$ has at most $\lceil r_i \rceil$ vertices from $T_{k-1,i}$ inside it. These are the only two factors that cause the bandwidth to increase from level $(k-1)$ to level k, so the recurrence relation is

$$\mathbf{bw}'(T_{k,j}) \leq \max_{i=0}^{j} \max \left(\mathbf{bw}'(T_{k-1,i}) + \left\lceil \frac{\mathbf{bw}'(T_{k-1,i})}{\lceil r_i \rceil + 1} \right\rceil, \lceil r_i \rceil + 1 \right).$$

Since $\lim_{i \to \infty} r_i = c_{k-1}$, for large values of i, $r_i < c_{k-1} + 1$, and for small values of i, r_i can be upper bounded by another constant. Thus, this level k linear layout has bandwidth $O_k(1)$.

BFS width. BFS width is lower bounded by width, which can be computed using Faulhaber's formula (e.g., see Knuth [29]):

$$w_{k,j} = \sum_{i=0}^{j} (d_{k-1} \cdot i^{k-2} + q_{k-1}(i)) = \frac{d_{k-1}}{k-1} j^{k-1} + q_k(j) = d_k j^{k-1} + q_k(j),$$

where $d_k \coloneqq \frac{d_{k-1}}{k-1}$ and q_k is a polynomial function with degree $k-2$. Since $d_2 = 1$, we can solve this recurrence relation to yield $d_k = \frac{1}{(k-1)!}$.

We have therefore shown that the tree $T_{k,j}$ has height $h_{k,j} = 2^j + k - 3$ and $n_{k,j}$ vertices, with

$$\begin{aligned} n_{k,j} &= c_k \cdot 2^j + p'_k(j), \\ \mathbf{bw}(T_{k,j}) &= O_k(1), \quad \text{and} \\ \mathbf{bfsw}(T_{k,j}) &\geq w_{k,j} = d_k j^{k-1} + q_k(j) = \Omega(\log^{k-1} n_{k,j}). \end{aligned}$$

◀

Thus, a graph with bounded bandwidth can have polylogarithmic BFS width. Also:

▶ **Theorem 10** (Lower bound on minimum BFS width). *For each non-negative integer, k, and for arbitrarily large values of n, there exists a (level k) tree, T, with n vertices that satisfies:*

$$\begin{aligned} \mathbf{bw}(T) &= O_k(1), \\ \mathbf{bfsw}_{\min}(T) &= \Omega(\log^k n), \end{aligned}$$

where $O_k(1)$ denotes a number that depends on k but is bounded when k is bounded.

Proof. A construction similar to Figure 5 can be used to place the root at one end of the linear layout. Taking two reflected copies of the resulting tree, connected at the root, gives a lower bound for minimum BFS width (with different constants than Theorem 9). ◀

▶ **Theorem 11.** *For arbitrarily large values of n, there exists a binary tree, T, with n vertices that satisfies* $\mathbf{bfsw}(T)/\mathbf{bfsw}_{\min}(T) = \Omega(\log n)$.

Proof. The level 2 tree, $T = T_{2,j}$, is originally rooted at the leftmost spine vertex v_j. Consider rooting T at the rightmost spine vertex v_s, as in the bottom of Figure 4. The width of the new tree is 2. Thus,

$$\begin{aligned}
&\mathbf{bfsw}(T, v_j) = j + 2,\\
&\mathbf{bfsw}(T, v_s) = 2,\\
&\frac{\mathbf{bfsw}(T)}{\mathbf{bfsw}_{\min}(T)} \geq \frac{\mathbf{bfsw}(T, v_j)}{\mathbf{bfsw}(T, v_s)} = \frac{j+2}{2} = \frac{\log\left(\frac{n}{3}\right) + 2}{2}, \quad \text{and}\\
&\frac{\mathbf{bfsw}(T)}{\mathbf{bfsw}_{\min}(T)} = \Omega(\log n).
\end{aligned}$$

◀

4 Polylogarithmic BFS Width for Graphs of Bounded Bandwidth

In this section, we show that if bandwidth is bounded, then BFS width is at most polylogarithmic in the number of vertices. The construction in Section 3 shows that this upper bound is tight. The proof follows a structure similar to our lower-bound construction. First, we make several simplifying assumptions with respect to the graph, which we make without loss of generality (wlog). Next, we identify spines and subtrees as in our construction above. Then we use strong induction to prove our bound.

The inductive hypothesis is as follows: for arbitrarily large values of n, any graph on n vertices with bandwidth $\mathbf{bw} \leq k$, for a fixed constant, $k \geq 1$, has BFS width $\mathbf{bfsw} = O\big(\log^{k-1}(n)\big)$. The base case, $k = 1$, is clearly true, since a connected graph with bandwidth 1 is a path. For the induction step, suppose that if any graph, G, on n vertices has bandwidth $\mathbf{bw}(G) \leq k$, for a fixed constant, $k \geq 1$, then $\mathbf{bfsw}(G) = O\big(\log^{k-1}(n)\big)$. To show the induction hypothesis holds for $k+1$, we consider a widest BFS tree of G, and show that there are at most a logarithmic number of subtrees in T and each subtree has width $O\big(\log^{k-1}(n)\big)$. Consequently, when these subtrees are combined, the overall width remains polylogarithmic, with a higher (constant) exponent.

Suppose we have a linear layout of an n-vertex graph, G, that achieves minimum bandwidth, let T be a widest BFS tree of G, and let r be the root of T. We want to show that T has width $O\big(\log^{k}(n)\big)$. Thus, without changing the BFS width, we can delete non-tree edges from G as well as all vertices and edges below the first widest layer of T. This may reduce the number of vertices, but, wlog, let us nevertheless refer to the reduced number of vertices as n and the reduced tree as T, since we are interested in an upper bound in terms of the number of vertices in the original graph. Thus, let us focus our attention on the reduced tree, T, instead of the original graph.

Furthermore, we can make extreme points of the linear layout leaves of T. Suppose this is not the case. Wlog, we consider two scenarios:

1. The leftmost vertex v of the linear layout is the root. If the root only has one child, then we can remove it and make its child the new root. After repeating this step, either the new leftmost vertex is not the root, or it is the root with at least two children. In the latter case, we can take the subtree rooted at one child and flip its linear layout around the root. Thus, extreme points of the linear layout will not be the root.
2. The rightmost vertex v of the linear layout is neither the root nor a leaf. All leaves of the subtree T_v rooted at v are to the left of v in the linear layout. We can flip this subtree around v to move non-root vertices of T_v to the right side of v. After this, we check the new rightmost vertex $w \in T_v$. If it is not a leaf, then $T_w \subset T_v$ and $v \notin T_w$. Since the subtree T_w contains fewer vertices than T_v, each iteration of this process reduces the size of the subtree rooted at the rightmost vertex. Therefore, after repeating this process finitely many times, the rightmost vertex will be a leaf.

After these operations, extreme points of the linear layout are now leaves of T. Note that the width of the tree does not change and the bandwidth of this new ordering cannot be greater than before. The **left spine** is defined as the path from the root to the leftmost vertex, and the **right spine** is defined similarly. All non-spine vertices belong to a **subtree** "hanging off" the spine. In this section, it is more convenient to treat the root vertices of these subtrees as the intersection of subtrees and the spine. Now we upper bound the number of subtrees that contribute to the width of T.

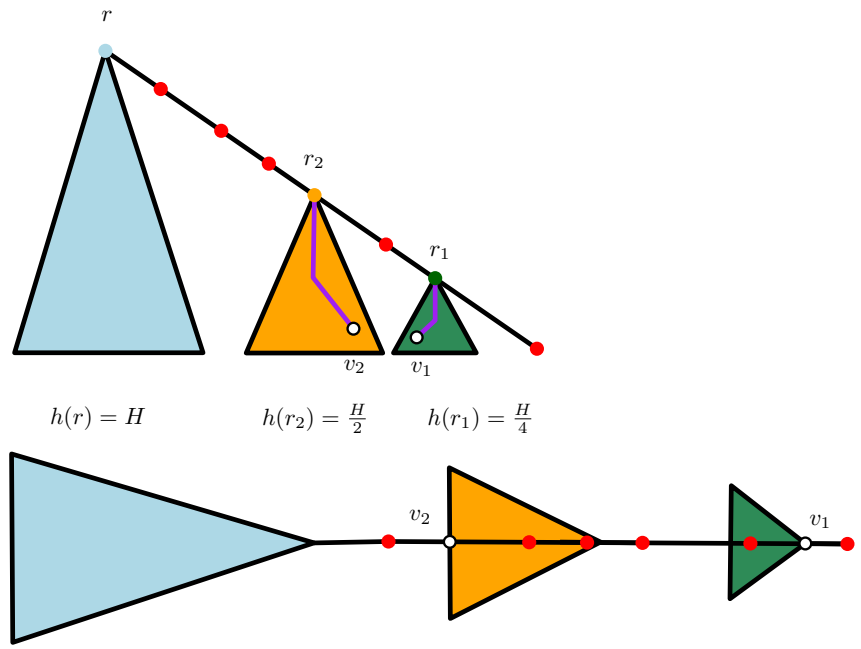

Figure 6 Proof of Lemma 12 illustrated. When $i = 1$, S_1 is the set of all subtrees with height $h(r_s) \in I := [\frac{H}{4}, \frac{H}{2}]$. In this figure, it contains the two subtrees on the right. We want to upper bound the total number of vertices in these subtrees.

▶ **Lemma 12.** *The number of subtrees that have at least one leaf at the widest layer of the tree T is $O(\log n)$.*

Proof. Because of symmetry, we only bound the number of subtrees whose root is on the right spine. Suppose the tree T rooted at r has height H. For integer $i = 0, 1, \ldots, \lfloor \log H \rfloor$, let S_i be the set of all subtrees with height $h(r_s) \in I := [\frac{H}{2^{i+1}}, \frac{H}{2^i}]$ where r_s is the root of a subtree. See Figure 6. We do not need to consider subtrees with height 0.

Now we upper bound the total number of vertices in all subtrees in S_i. Consider the position of these subtrees in the linear layout. Suppose the rightmost vertex is v_1 and it belongs to the subtree rooted at r_1, and the leftmost vertex v_2 belongs to the subtree rooted at r_2. Recall that d denotes the shortest path distance in the graph. For any root r_s of a subtree in S_i, $d(r, r_s) = H - h(r_s) \in H - I := [H - \frac{H}{2^i}, H - \frac{H}{2^{i+1}}]$. The shortest paths from r to all such root vertices are part of the right spine. Thus,

$$
\begin{aligned}
&d(r_1, r_2) \le |H - I| = |I| \\
&d(v_1, v_2) \le d(v_1, r_1) + d(r_1, r_2) + d(r_2, v_2) \le h(v_1) + |I| + h(v_2) \\
&\qquad \le \frac{H}{2^i} + \left(\frac{H}{2^i} - \frac{H}{2^{i+1}}\right) + \frac{H}{2^i} = \frac{3H}{2^i} - \frac{H}{2^{i+1}} = \frac{5H}{2^{i+1}}.
\end{aligned}
$$

Because of the bounded bandwidth, the number of vertices between v_1 and v_2 in the linear layout is at most $\frac{5H}{2^{i+1}}(\mathbf{bw})$.

Each subtree with height in I must have at least $\frac{H}{2^{i+1}}$ vertices to reach the minimum height. Consequently, the total number of subtrees with height in any given interval I is at most a constant and this completes the proof. ◀

Next, we prove that removing spine vertices from the linear layout reduces the bandwidth of subtrees. Since the roots of these subtrees also belong to the spine, each subtree may decompose into a forest. Given that bounded bandwidth implies bounded maximum degree, the number of trees in each resulting forest is bounded. If these trees have smaller bandwidth, we can apply the inductive hypothesis to show that they have width $O\big(\log^{k-1}(n)\big)$. Thus, the original subtree also has width $O\big(\log^{k-1}(n)\big)$. Thus, the following lemma is essential to the induction:

▶ **Lemma 13.** *If the tree T has bandwidth* **bw***, then each tree in the forests obtained after removing the spine has bandwidth at most* $\mathbf{bw} - 1$.

Proof. The proof outline is as follows. By definition, the extreme points of the original linear layout are spine vertices and thus subtrees with one vertex. We denote them as v_l and v_r respectively. Consider any subtree T_v rooted at $v \neq v_l, v_r$. After removing the spine vertices, the linear layout for T naturally defines a linear layout for $T_v \setminus v$ by preserving the relative position of its vertices. We show that the maximum length of any edge of $T_v \setminus v$ will become less than **bw**.

In the linear layout for T, the length of any edge is at most **bw**. If an edge has length equal to **bw**, we say that this edge is saturated. Let S be the set of all saturated edges of $T_v \setminus v$. If this is an empty set, the proof is complete. Otherwise, suppose there is one edge $e \in S$ with no spine vertex inside it. v_l and v_r are connected through edges of the spine and one of these edges must enclose the two endpoints of e. The length of e is **bw**, so the length of this edge is greater than **bw**, and this is a contradiction. Thus, there is a spine vertex inside every saturated edge of $T_v \setminus v$. After removing the spine vertices, all edges of $T_v \setminus v$ have length at most $\mathbf{bw} - 1$. $T_v \setminus v$ may be a forest, so this upper bounds the bandwidth of each connected component. ◀

With these lemmas, we can apply strong induction on bandwidth, which gives us:

▶ **Theorem 14** (Upper bound on BFS width)**.** *For any constant, $k \geq 1$, and n-vertex graph, G, if* $\mathbf{bw}(G) = k$*, then* $\mathbf{bfsw}(G) = O\big(\log^{k-1}(n)\big)$.

5 Applications

In this section, we prove the application results claimed in the introduction.

5.1 Numerical Linear Algebra

For the purposes of this section, the only facts we need about the Cuthill–McKee and reverse Cuthill–McKee algorithms are:

- The bandwidth of a reordered matrix PAP^T, where A is any symmetric matrix and P is any permutation matrix, is the same as the bandwidth of the linear layout of the graph of nonzeros of A obtained by laying out the vertices of this graph in the order given by permutation P.
- Both the Cuthill–McKee and reverse Cuthill–McKee algorithms, applied to a matrix A choose their orderings (interpreted as linear layouts of graphs) by the breadth-first layer of the graph of nonzeros of A, and then carefully permute the vertices within each layer.

We can directly relate the performance of these algorithms to BFS width:

▶ **Theorem 15.** *Let G be the graph of nonzeros of a symmetric matrix A, and let v be an arbitrary vertex of G. Then the Cuthill–McKee and reverse Cuthill–McKee algorithms, using a breadth-first layering rooted at v, produce layouts of bandwidth $\Theta\big(\mathbf{bfsw}(G,v)\big)$.*

Proof. Let u be a vertex in the widest layer of the breadth-first layering of G, chosen among the vertices of this layer to be the one that the Cuthill–McKee or reverse Cuthill–McKee algorithm places farthest from the previous layer. Then the positions of u and its BFS ancestor differ by at least $\mathbf{bfsw}(G,v)$, so the bandwidth of the layout is at least $\mathbf{bfsw}(G,v)$. Every edge in G extends over at most two consecutive layers, and has endpoints whose positions differ by at most $2\mathbf{bfsw}(G,v)-1$, so the bandwidth of the layout is at most $2\mathbf{bfsw}(G,v)-1$. ◀

By combining Theorem 15 with Theorem 14, we have:

▶ **Theorem 16.** *If a symmetric matrix A can be reordered to have bounded bandwidth, the Cuthill–McKee and reverse Cuthill–McKee algorithms will produce a reordered matrix PAP^T of at most polylogarithmic bandwidth.*

Note that this theorem holds even if we do not know the optimal bandwidth of the matrix A. Moreover, the bound of Theorem 16 is is tight, up to the dependence of the polylogarithmic bound on the bandwidth; by combining Theorem 15 with Theorem 10, we have:

▶ **Theorem 17.** *For any k, there exist $n \times n$ symmetric matrices A of bounded bandwidth (for arbitrarily large n) for which the Cuthill–McKee and reverse Cuthill–McKee algorithms produce reordered matrices PAP^T of bandwidth $\Omega(\log^k n)$.*

Theorems 16 and 17 provide the first non-trivial deterministic analyses for the Cuthill-McKee algorithm and its reversal.

5.2 Graph Reconstruction

To reconstruct graphs of low bandwidth or low BFS width, we apply Algorithm 1.

Algorithm 1 Reconstructing graphs with low BFS width.

```
v ← an arbitrary vertex in V                          ▷ this is the root of the BFS tree
for u ∈ V \ {v} do
    Query(v, u)                                       ▷ this is a distance query
Ê ← {{a, b} : {a, b} ⊆ V \ {v} ∧ |d(v, a) − d(v, b)| ≤ 1}
for {a, b} ∈ Ê do
    Query(a, b)
return {{u, v} : u ∈ V ∧ d(v, u) = 1} ∪ {{a, b} : {a, b} ∈ Ê ∧ d(a, b) = 1}
```

Less formally, Algorithm 1 first picks a vertex v as the root of the BFS tree. Then, it obtains distances from this root to every other vertex to determine their layer number. It constructs the set of all vertex pairs from the same layer or in two consecutive layers, and queries each such pair. Recall that in the proof of Theorem 5, non-tree edges connect two vertices whose layer numbers differ by at most one, so each pair of adjacent vertices in G must belong to the set of queried pairs. The algorithm then returns the set of all pairs for which a

query found two vertices to be at distance one. [4] used a similar approach to reconstruct trees and k-chordal graphs. They divided the graph into BFS layers and reconstructed edges in the same layer and in two consecutive layers, but querying each pair would incur a high query complexity for those graph classes.

▶ **Theorem 18.** *For any graph G with n vertices and BFS width B, Algorithm 1 reconstructs G with deterministic query complexity $O(nB)$.*

Proof. It takes $n-1$ queries to find the distances from the chosen root v and partition the vertices into layers. Then, the algorithm makes at most $3B-1$ queries involving each remaining vertex, between it and at most $3B-1$ other vertices in its layer and the two adjacent layers. This double-counts the queries, so the total number of queries is at most $n-1+(n-1)(3B-1)/2 = O(nB)$. ◀

▶ **Corollary 19.** *For any constant bound b on the bandwidth of graphs, Algorithm 1 reconstructs n-vertex graphs of bandwidth $\leq b$ with deterministic query complexity $\tilde{O}(n)$.*

Proof. This follows immediately from Theorem 18 and from the relation between bandwidth and BFS width of Theorem 14. ◀

5.3 Graph Drawing

In our graph drawing application, we specifically focus on arc diagrams, which were used to study the crossing number problem [31] and visualize structure in strings [36]. In an arc diagram, vertices of a graph are positioned along a straight (e.g., horizontal) line, and edges are semicircles drawn on either side of the line [31], joining pairs of points (possibly using straight-line segments for consecutive points). Examples are shown above in Figures 2 and 4.

To analyze such diagrams, we constrain the vertices to be placed at consecutive integer coordinates. Thus, the horizontal line is a linear layout of the vertices. The drawing fits within a bounding box $n-1$ units wide and $b/2$ units tall, where n is the number of vertices in the graph and b is the bandwidth of the given layout.

We immediately obtain the following result:

▶ **Theorem 20.** *Suppose that a given graph G has n vertices and has an arc diagram of bounded height h. Construct an arc diagram for G by ordering the vertices by their breadth-first layer numbers, starting from an arbitrary root vertex. Then if h is bounded by a constant, the height of the arc diagram that we construct will be bounded by $O\big(\text{polylog}(n)\big)$.*

Improved Parallel Derandomization via Finite Automata with Applications

Jeff Giliberti
University of Maryland, College Park, MD, USA

David G. Harris
University of Maryland, College Park, MD, USA

Abstract

A central approach to algorithmic derandomization is the construction of small-support probability distributions that "fool" randomized algorithms, often enabling efficient parallel (NC) implementations. An abstraction of this idea is fooling polynomial-space statistical tests computed via finite automata [Sivakumar STOC'02]; this encompasses a wide range of properties including k-wise independence and sums of random variables.

We present new parallel algorithms to fool finite-state automata, with significantly reduced processor complexity. Briefly, our approach is to iteratively sparsify distributions using a work-efficient lattice rounding routine and maintain accuracy by tracking an aggregate weighted error that is determined by the Lipschitz value of the statistical tests being fooled.

We illustrate with improved applications to the Gale-Berlekamp Switching Game and to approximate MAX-CUT via SDP rounding. These involve further several optimizations, such as the truncation of the state space of the automata and FFT-based convolutions to compute transition probabilities efficiently.

1 Introduction

A fundamental problem in the theory of computation is to *derandomize* existing randomized algorithms. Such randomized algorithms typically use a large number of independent random bits. One main genre of derandomization is the construction of a probability distribution which is much smaller (of polynomial instead of exponential size), to "fool" the randomized algorithm. That is, the behavior of relevant statistics should be similar when presented with fully-independent random bits vs. bits drawn from a small, carefully-constructed correlated distribution. This probability space can be searched exhaustively, and in parallel, to find a specific input with desired properties.

A simple and popular example of this technique comes from a probability space with k-wise independence, for constant k [2, 30, 32, 35]. This preserves basic statistical properties such as means and variances [7, 42]. There are many other constructions for more-advanced properties, e.g., near-k-wise independence [3, 5, 14, 17, 38], probability spaces fooling halfspaces or polytopes [33, 41, 23, 22], ordered branching programs [12, 15, 37, 27, 40] etc.

A significant abstraction of these methods is the construction of probability spaces that fool statistical properties (also called "tests") computed by finite automata [10, 24, 31, 36, 39, 40, 43]. Such tests are ubiquitous in randomized algorithm analysis, encompassing k-wise independence, sums of random variables, and many other properties. For example, they are used in deterministic parallel algorithms for finding balanced independent sets in graphs [26], for applications of the Lovász Local Lemma in combinatorics [25], for covering and packing integer programs [6, 44], for undirected connectivity problems [40], and more.

1.1 Our contribution

We describe new parallel algorithms to fool automata, with significantly reduced processor complexity. The analysis is also simplified because we can cleanly separate out problem-specific optimizations from the general lattice discrepancy problems that are at the core of the algorithm. A summary of our algorithm performance is as follows:

▶ **Theorem 1** (Simplified). *Consider a probability space Ω on n binary random variables and a collection of ℓ statistical tests over Ω, each with η possible states and Lipschitz value λ.*

There is a deterministic algorithm to generate a distribution D of size $\varepsilon^{-2}\operatorname{polylog}(n, \eta, \ell, 1/\varepsilon)$ to simultaneously "fool" all statistical tests to absolute weighted error $\lambda\varepsilon$. *It uses $\tilde{O}(n\ell\eta\varepsilon^{-2} + n\ell\eta^{\omega})$ processors and polylogarithmic time, where ω is the exponent of matrix multiplication.*

By way of comparison, the algorithm of [24] would require roughly $O(n^3\ell^2\eta^4\varepsilon^{-2})$ processors to construct a distribution of size $O(\ell\eta^2\epsilon^{-2})$. Our full results are more general, easily allowing for non-binary alphabets, or more complex automata types; see Theorem 5 for details. We emphasize that the algorithm is still typically more efficient even for applications with no particular Lipschitz bounds.

We illustrate this framework through two prototypical applications: the Gale-Berlekamp Switching Game and SDP rounding for approximate MAX-CUT.

▶ **Theorem 2** (Gale-Berlekamp Switching Game). *Given an $n \times n$ matrix A, there is a deterministic parallel algorithm using $\tilde{O}(n^{3.5})$ processors and polylogarithmic time to find $x, y \in \{-1, +1\}^n$ satisfying $\sum_{i,j} A_{i,j}x_iy_j \geq (\sqrt{2/\pi} - o(1))n^{3/2}$.*

It is interesting that the Gale-Berlekamp analysis revolves around *anti-concentration* bounds, which are precisely the opposite of discrepancy-minimization. Our algorithm for this problem beats the $n^{5+o(1)}$ complexity of the optimized algorithm of [24].

▶ **Theorem 3** (MAX-CUT Approximation). *Let $\varepsilon > 0$ be an arbitrary constant. Given an n-vertex m-edge graph $G(V, E)$, there is a deterministic parallel algorithm using $\tilde{O}(mn^3)$ processors and polylogarithmic time to find an $\alpha(1 - \varepsilon)$ approximate MAX-CUT of G, where $\alpha \approx 0.878$ is the Goemans-Williamson approximation constant [21].*

The SDP relaxation of MAX-CUT can be approximated in polylogarithmic time and near-linear work by [1], so we will be concerned with rounding the SDP solution. A rounding procedure was presented in [43], which however required a very large number of processors. We drastically improve it, getting closer to the *sequential* $\tilde{O}(n^3)$ runtime of [9].

The complexity bounds in Theorems 2 and 3 do not depend on fast matrix multiplication; the runtimes are valid even using naive multiplication ($\omega = 3$). Although thy are still not fully work-efficient, this makes progress toward practical deterministic parallel algorithms.

In a broader perspective, our construction differ in various aspects from classical derandomization via (sequential) PRGs. While our automata framework does not provide a PRG, it seems better suited to efficient parallel derandomization. It is known that, by connections to Boolean circuits [11], a PRG for log space-bounded computation can be simulated in PRAM in polylog time with a polynomial number of processors. However, relying on the equivalence between PRAM and Boolean circuits leads to very high processors complexities (e.g., Nisan's log space-bounded PRG uses at least $\Omega(n^{45})$ processors [39]). Therefore, using known PRGs constructions would either require high polynomials (if logspace bounded) or not parallelize well. In addition to providing fast parallelization, our construction returns a distribution with seed length $O(\log 1/\varepsilon + \log\log(n, \eta, \ell)$, which is line with known PRGs.

1.2 Technical approach

Our work follows the same general outline as previous algorithms for fooling automata, built from two main subroutines Reduce and Fool. The Fool algorithm (Section 5) recursively invokes Reduce (Section 4) to construct a fooling distribution, beginning with single-step automaton transitions and progressively scaling up to multi-step distributions. After $\log_2 n$ levels, the final distribution effectively fools n-step walks in the automata.

We introduce several novelties such as a work efficient Reduce subroutine and an analysis of Fool based on a different measure of error. Here, we attempt here to provide some high-level intuition on the technical content of this paper.

Distribution error tracking. Prior work on automata fooling [24, 36] considered a notion of unweighted absolute error, where the goal was to fool all pairs of (start, end) states. We replace this with an *aggregated* notion: the weight of a final state corresponds to the value of the associated final outcome (e.g., the final count for a counter automaton). The value of an intermediate state is then the expected weight of the final state under a random suffix. This is similar to a scheme used in the context of pseudorandom generators and branching programs [12, 15], where it is taken advantage of sub-maximal influence on the final expected value. The processor complexity is determined by the *Lipschitz value* of each state: how much the expected final weight changes with a single step of the automaton.

REDUCE subroutine. This subroutine takes as input a distribution $E = D^1 \times D^2$ over automata walks (drivestreams) with a weight function w; it outputs a refined distribution D with significantly smaller support while maintaining a weighted measure of closeness to E. This leverages the connection between automata fooling and lattice approximation noted by [36] and applies the work-efficient lattice approximation of [19]. Our key approach to reduce the processor complexity is to sparsify E – without materializing it – in $\log_2 |E|$ steps.

In each step, we model the problem of rounding the i^{th} bit of the elements in D as a lattice-discrepancy problem, which is then solved by invoking [19]. This step resembles the PRG of INW [28]; there, one replaces the concatenation of two independent random walks with correlated random walks, using the derandomized square instead of the algorithm of [19].

Further optimizations. In both of these applications, and many others, the relevant automata are counters which track the running sum of certain statistics. Instead of keeping track of these exactly, we truncate the counters to within a few standard deviations of their means.

This reduces the state space of the automata by roughly a square-root factor. Doing this while also preserving relevant Lipschitz properties of the automata is technically challenging and requires significant analysis. This optimization will be discussed in Section 6.

The approximate MAX-CUT application (Section 7.2) requires a few additional problem-specific optimizations and arguments. In particular, to simulate the SDP rounding procedure efficiently, we (i) work with discretized truncated Gaussians and quantized counters, (ii) use a pessimistic estimator with a better Lipschitz constant, and (iii) we compute the transition matrices via FFT's to exploit their convolution structure. We believe that these optimizations may generalize to other (SDP) rounding procedures and other settings as well.

2 Preliminaries

For an input of size N, our goal is to develop deterministic PRAM algorithms with $\text{poly}(N)$ processor complexity and $\text{polylog}(N)$ runtime. Unless stated otherwise, we assume that all relevant algorithms run in *deterministic polylogarithmic time* as a function of their processor and input complexities. For processor complexity and other parameters, we use $\tilde{O}$ notation: we say that $f(x) \leq \tilde{O}(g(x))$ if $f(x) \leq g(x) \cdot \text{polylog}(N, g(x))$ processors, where N is the size of all algorithm inputs. Throughout, we use log for logarithm in base e and lg for base 2. We write $\lceil x \rfloor$ for rounding to the nearest integer.

Throughout, proofs that are omitted (or sketched) appear in the full version.

2.1 Basic definitions for automata

The underlying probability space Ω is defined by drawing a sequence $\vec{r} = (r_0, \ldots, r_{n-1})$, where each r_t is independently drawn from a distribution Ω_t over an arbitrary alphabet. We consider an automaton F with a state space S. At each timestep $t = 0, 1, \ldots, n-1$, the automaton in state $s \in S$ receives an input r_t and transitions to state $F(r_t, s)$.

For times t, t', we define $\Omega_{t,t'} = \Omega_t \times \Omega_{t+1} \times \cdots \times \Omega_{t'-1}$. In this context, we call $h = t' - t$ the *horizon* and the pair (t, h) as the *window*. We refer to a vector $\vec{r} = (r_t, r_{t+1}, \ldots, r_{t'-1}) \in \Omega_{t,t'}$ as a *drivestream*. We define $F(\vec{r}, s)$ to be the result of transiting from time t to t' under $\vec{r}$. We write $\vec{r} \in \Omega_{t,t'}$ to indicate that each $r_j : j = t, \ldots, t'-1$ has non-zero probability in Ω_j.

For a distribution D on drivestreams, we denote the *transition matrix* as T_D, i.e. $T(s, s')$ is the probability of transiting from state s to s' for a drivestream $\vec{r} \sim D$. For brevity, we also write $T_{t,t'} := T_{\Omega_{t,t'}}$ and, for any weight function $w : S \to \mathbb{R}$, we also define

$$T_D(s, w) = \sum_{s' \in S} T_D(s, s') w(s').$$

Throughout, we define $\eta = |S|$ and $\sigma = \sum_{t=0}^{n-1} |\Omega_t|$ where $|\Omega_t|$ is the size of Ω_t.

Our goal is to find a polynomial-size distribution D on drivestreams that "fools" the automaton. That is, the behavior of the automaton given a drivestream $r \sim D$ should be similar to its behavior when given a drivestream $r \sim \Omega$. We will follow a strategy of [12] and measure error via a weight function $W : S \to \mathbb{R}$ over final states. It will be necessary to measure the "smoothness" of W as a function of the drivestream values. Formally, we consider two, closely related, notions:

▶ **Definition 4** (Lipschitz value/confusion of a weight functions). *Let $W : S \to \mathbb{R}$ be a weight function for automaton F.*

- *The* Lipschitz value *at state s and time t is defined by*

$$\mathfrak{L}(s, t) = \max_{\vec{r}_1, \vec{r}_2} \left| W(F(\vec{r}^1, s)) - W(F(\vec{r}^2, s)) \right|$$

where the maximum is over $\vec{r}^1, \vec{r}^2 \in \Omega_{t,n}$ which differ in only the t^{th} coordinate.

- *The* confusion *at state s and time t is defined by*

$$\mathfrak{C}(s,t) = \max_{r_1,r_2\in\Omega_t} \left|T_{t,n}(F(r_1,s),W) - T_{t,n}(F(r_2,s),W)\right|.$$

Colloquially, these are the maximum change to *actual weight* or the *expected weight* of the final state due to changing drivestream entry t. Note that $\mathfrak{C}(s,t) \le \mathfrak{L}(s,t)$.

We define the *total variability* $\mathfrak{V}(s)$ of a starting state $s \in S$ as:

$$\mathfrak{V}(s) := \sum_{t=0}^{n-1} \max_{\vec{r}\in\Omega_{0,t}} \mathfrak{C}(F(\vec{r},s),t)$$

With this rather technical definition, we can state our algorithm concretely:

▶ **Theorem 5.** *The algorithm* Fool *takes as input a parameter $\varepsilon > 0$, and produces a distribution D with*

$$|T_D(s,W) - T_\Omega(s,W)| \le \varepsilon\mathfrak{V}(s) \qquad \text{for all states } s.$$

The distribution D has size $\varepsilon^{-2}\operatorname{polylog}(n,\eta,\sigma,1/\varepsilon)$. The cost of Fool *is $\tilde{O}\big(n\eta/\varepsilon^2 + \eta\sigma\big)$ processors, plus the cost of computing the expectations $T_{t,n}(s,W)$ for states $s \in S$ and times $t = 0,\dots,n$ (more details on this step later.)*

2.2 Lattice approximation

The problem of automata fooling is closely linked to lattice approximation, defined as follows:

▶ **Definition 6** (Lattice Approximation Problem (LAP))**.** *Given an $m \times n$ matrix A and fractional vector $\vec{u} \in [0,1]^n$, the objective is to compute an integral vector $\vec{v} \in \{0,1\}^n$ to minimize the discrepancies $D_k = |\sum_{j=1}^n A_{kj}(u_j - v_j)|$.*

Intuitively, this models the process of "rounding" each random bit (represented by u_j) to a static zero or one (represented by v_j). The work [19] provides a parallel algorithm with near-optimal discrepancy as well as complexity; we summarize it as follows:

▶ **Theorem 7** (Theorem 1.3 of [19])**.** *Suppose that $A_{kj} \in [0,1]$ for all k,j. There is a deterministic parallel algorithm for the LAP with $D_k \le O(\sqrt{\mu_k \log m} + \log m)$ for all k, where $\mu_k = \sum_{j=1}^n A_{kj}u_j$. The algorithm uses $\tilde{O}(n+m+nnz(A))$ processors, where $nnz(A)$ denotes the number of non-zero entries in the matrix A.*

It will be convenient to allow for the discrepancy matrix A to take arbitrary real values.

▶ **Proposition 8.** *Let $\Delta_k = \max_j |A_{kj}|$ for each row k. There is a deterministic parallel algorithm for the LAP where $D_k \le O(\sqrt{\Delta_k\tilde{\mu}_k \log m} + \Delta_k \log m) \le O(\Delta_k(\sqrt{n\log m} + \log m))$ for all k, where $\tilde{\mu}_k = \sum_{j=1}^n |A_{kj}|u_j$. The algorithm uses $\tilde{O}(n+m+nnz(A))$ processors.*

Proof. Construct a $2m \times n$ matrix $\tilde{A}$, where for each row $k = 0,\dots,m-1$ of A, the matrix $\tilde{A}$ has $\tilde{A}_{2k,j} = \max\{0, \frac{A_{kj}}{\Delta_k}\}$ and $\tilde{A}_{2k+1,j} = \max\{0, \frac{-A_{kj}}{\Delta_k}\}$. Then apply Theorem 7 to $\tilde{A}$. ◀

3 Overview of algorithms and data structures

The subroutine REDUCE (Section 4) is the technical core of the automata-fooling construction: given an input distribution E over drivestreams and a weight function w, it returns a distribution D which is close to E (measured in terms of w), but which has much smaller support. Importantly, through the use of appropriate data structures, the cost of REDUCE may be significantly less than the total size of E itself. Later, the final algorithm FOOL (Section 5) will be defined by repeated calls to REDUCE over successively larger time-horizons.

Concretely, we store each distribution D over window (t, h) as an array of drivestreams $D[0], \ldots, D[\ell - 1] \in \Omega_{t,t+h}$ with associated probabilities $p_D(0), \ldots, p_D(\ell - 1)$. Here $\ell = |D|$ is the *size* of D. By adding dummy zero entries, we can assume that $|D|$ is a power of two.

For a bitstring b of length at most $\lg |D|$, we denote by $D[b*]$ the induced distribution consisting of all the drivestreams in D whose indices start with b. So $D[b*] = D[b0*] \cup D[b1*]$, where $b0$ and $b1$ refer to concatenating a 1 or 0 bit to b. Similarly, $p_D(b*) = \sum_{a \in D[b*]} p_D(a)$.

We define the *Prediction Problem* for a distribution D and a weight function $w : S \to \mathbb{R}$ as follows: we need to produce a data structure $\mathcal{Q}(D, w)$, which can answer the following two types of queries: (i) given any bitstring b, return the value $p_D(b*)$; (ii) given (b, s) where b is a bitstring and s is a state, return the value $T_{D[b*]}(s, w)$. Each query should take polylogarithmic time and processors. In either case, b can take on any length $\ell \leq \lg |D|$.

▶ **Observation 9.** *Let D be a distribution on window (t, h). The Prediction Problem for D and a weight function w can be solved with $\tilde{O}(|D|h\eta)$ processors.*

The most important case is for a Cartesian product, which will be used in Section 5. Critically, we can use the structure within a distribution to avoid materializing it explicitly.

▶ **Proposition 10.** *Given distributions D^1, D^2 on windows (t_1, h) and $(t_1 + h, h)$ respectively, the Prediction Problem for distribution $E = D^1 \times D^2$ and any weight function w can be solved with $\tilde{O}(\eta h(|D^1| + |D^2|))$ processors.*

4 The REDUCE Algorithm

To reiterate, the goal of REDUCE (Algorithm 1) is to take an input distribution E and weight function w, and produce a smaller distribution D which is close to it. Note that here w will not be the given weight function over final states W.

For intuition, consider the following process. Draw m elements $D[0], \ldots, D[m - 1]$ randomly and independently with replacement from the support of the distribution E, wherein $D[i] = v$ is selected with probability proportional to $p_E(v)$. Then set $p_D[i] = 1/m$, so the process is unbiased. Via standard concentration bounds, appropriate choices of m ensure that $T_D(s, w) \approx T_E(s, w)$. The algorithm REDUCE is based on derandomizing this process via a slowed-down simulation: to compute D, we iteratively compute distributions $D_0, D_1, \ldots, D_\ell = D$ by fixing the i^{th} bit level of each entry in D_{i-1}.

Algorithm 1 REDUCE(E, ε, w).

Set $\ell = \lg |E|$ and $m = \frac{C\ell^2 \log \eta}{\varepsilon^2}$ for a constant C.
Solve Prediction Problem for distribution E
Initialize the multiset $H_0 := \{m \text{ empty bitstrings}\}$
for $i = 0, \ldots, \ell - 1$ **do** ▷ Fix i^{th} bit
    Formulate LAP $\mathcal{L}$ for H_i.
    $\vec{v} \leftarrow$ solve $\mathcal{L}$ via Proposition 8 with sampling rate $u_b = \frac{p_E(b1*)}{p_E(b*)}$ for each $b \in H_i$
    $H_{i+1} \leftarrow \{bv_b : b \in H_i\}$ ▷ Concatenate vector $\vec{v}$ as i^{th} bit level
parfor $j \in \{0, \ldots, m-1\}$ **do** ▷ Convert bitstring (index) to drivestream (value)
    Set $D[j] = E[H_\ell[j]]$ and set probability $p_D[j] = 1/m$.
return D

In order to measure distribution error, we introduce the following key definition:

▶ **Definition 11** (Sensitivity). *For a function $w : S \to \mathbb{R}$ and state s, the* sensitivity $\alpha(s, w, E)$ *is:*

$$\alpha(s, w, E) := \max_{\vec{r} \in E} w(F(\vec{r}, s)) - \min_{\vec{r} \in E} w(F(\vec{r}, s))$$

The following is our main result analyzing the algorithm:

▶ **Theorem 12.** *The algorithm* REDUCE *runs in $\tilde{O}((h + \eta)/\varepsilon^2)$ processors, plus the cost of solving the Prediction Problem for E. The final distribution D is uniform with size $O(\frac{\log \eta \log^2 |E|}{\varepsilon^2})$. For large enough constant C, the distribution D satisfies*

$$|T_D(s, w) - T_E(s, w)| \le \varepsilon \alpha(s, w, E) \qquad \text{for each state } s$$

Proof. Let us fix E, w; for brevity, we write $\alpha_s := \alpha(s, w, E)$ for each state s.

Each multiset H_i contains m bitstrings $H_i[0], \ldots, H_i[m-1]$ of length i. Consider the distributions D_i obtained by drawing a bitstring $b \in H_i$ uniformly at random and then drawing drivestream from $E[b*]$. In particular, $D_0 = E$ and the distribution returned by REDUCE is precisely $D_\ell = D$. We have the following equation for every state s:

$$T_{D_i}(s, w) = \frac{1}{m} \sum_{b \in H_i} T_{E[b*]}(s, w).$$

Now, to analyze a given step i, observe that H_{i+1} is obtained by appending a bit v_b to each bitstring $b \in H_i$. We expose the choice of the next bit in D_i and D_{i+1} as follows

$$T_{D_i}(s, w) = \frac{1}{m} \sum_{b \in H_i} \left[\frac{p_E(b1*)}{p_E(b*)} \cdot T_{E[b1*]}(s, w) + \frac{p_E(b0*)}{p_E(b*)} \cdot T_{E[b0*]}(s, w) \right]$$

$$T_{D_{i+1}}(s, w) = \frac{1}{m} \sum_{b \in H_i} \left[v_b \cdot T_{E[b1*]}(s, w) + (1 - v_b) \cdot T_{E[b0*]}(s, w) \right].$$

Thus we can calculate the difference between probabilities for D_i and D_{i+1} as:

$$T_{D_{i+1}}(s, w) - T_{D_i}(s, w) = \frac{1}{m} \sum_{b \in H_i} \left(\frac{p_E(b1*)}{p_E(b*)} - v_b \right) \left(T_{E[b1*]}(s, w) - T_{E[b0*]}(s, w) \right). \tag{1}$$

In light of Eq. (1), we apply Proposition 8 where each state s corresponds to a constraint row k with entries $A_{kb} = T_{E[b1*]}(s,w) - T_{E[b0*]}(s,w)$, and with $u_b = \frac{p_E(b1*)}{p_E(b*)}$ for all b. It is evident that, after solving the Prediction Problem for E, the values $T_{E[bx*]}, p_E(bx*)$ for the Lattice Approximation Problem at Line 6 can be generated using $O(\eta m)$ processors. Furthermore, the maximum spread of the values $w(F(\vec{r},s))$ over $\vec{r}$ is at most α_s, so $\Delta_k = \max_k |A_{kb}| \le \alpha_s$. Since the matrix has η rows and m columns, Proposition 8 gives:

$$\left|T_{D_{i+1}}(s,w) - T_{D_i}(s,w)\right| \le O(\frac{\alpha_s\sqrt{m\log\eta} + \alpha_s\log\eta}{m})$$

By our choice of m, this is at most $\varepsilon\alpha_s/\ell$. Over all iterations, this gives the desired bound

$$\left|T_D(s,w) - T_E(s,w)\right| = \sum_{i=0}^{\ell-1}\left|T_{D_{i+1}}(s,w) - T_{D_i}(s,w)\right| \le \varepsilon\alpha_s. \qquad \blacktriangleleft$$

5 The FOOL Algorithm

We build the automata-fooling distribution via the algorithm Fool (Algorithm 2).

Algorithm 2 Fool(ε) (Assume n is a power of two).

1: Set $D_{0,t} = \Omega_t$ for each $t = 0,\dots,n-1$
2: Determine approximate transition vectors $\hat{V}_t(s) \approx T_{t,n}(s,W) : s \in S$ for all $t = 0,\dots,n$.
3: **for** $i = 0,\dots,\lg n - 1$ **do**
4: **parfor** $t \in \{0, 2h, 4h, 8h, n-2h\}$ where $h = 2^i$ **do**
5: $D_{i+1,t} \leftarrow$ Reduce$(D_{i,t} \times D_{i,t+h}, \delta, \hat{V}_{t+2h})$ for $\delta = \frac{\varepsilon}{20(1+\lg n)}$
return final distribution $D = D_{\lg n,0}$

The algorithm first finds the "expected value" vectors V_t for each distribution $\Omega_{t,n}$. This may take advantage of problem-specific automaton properties, and it may have some small error. We will also describe a few "generic" methods to calculate these probabilities exactly.

The main loop fools distributions on time horizons $h = 1, 2, 4, 8, \dots$ in a bottom-up fashion, and merges them together using the Reduce procedure from the previous section. Specifically, at each level i, it executes Reduce in parallel to combine $D_{i,t}$ and $D_{i,t+h}$ to obtain $D_{i+1,t}$. Note that we never materialize the Cartesian product of $D_{i,t}$ and $D_{i,t+h}$.

▶ **Theorem 13.** *The cost of Fool is $\tilde{O}(n\eta/\varepsilon^2 + \eta\sigma)$ processors, plus the cost of computing the vectors $\hat{V}_t : t = 0,\dots,n$. The final distribution $D_{\lg n,0}$ has size $O(\frac{\log^5(n\eta\sigma/\varepsilon)}{\varepsilon^2})$.*

Let us now proceed to analyze the error of the final distribution D. For purposes of analysis, we define the *exact* transition vector $V_t = T_{t,n}(s,W)$ and its approximation error by $\beta = \max_{s,t}|V_t(s) - \hat{V}_t(s)|$.

▶ **Theorem 14.** *For any state $s \in S$, the final distribution D returned by Fool(ε, W) satisfies*

$$|T_D(s,W) - T_\Omega(s,W)| \le \varepsilon\mathfrak{V}(s) + 3\beta n$$

Proof Sketch. For any state s and times $k \ge t$, let $a_{s,t,k}$ be the maximum value of $\alpha(s', V_{k+1}, \Omega_k)$ over $s' = F(\vec{r},s) : \vec{r} \in \Omega_{t,k}$. We show by induction on i that each $D_{i,t}$ for any s satisfies

$$|T_{D_{i,t}}(s, V_{t+2^i}) - T_{t,t+2^i}(s,W)| \le 3(2^i-1)\beta + 2i\delta \sum_{k=t}^{t+2^i-1} a_{s,t,k} \qquad (2)$$

The base case $i = 0$ is vacuous since $D_{0,t} = \Omega_t$. The final case $i = \lg n, t = 0$ establishes the claimed result, since $\delta = \frac{\varepsilon}{20(1+\lg n)}$ and $\mathfrak{V}(s) = \sum_{t=0}^{n-1} a_{s,0,t}$. $\blacktriangleleft$

As we have mentioned, there can be problem-specific shortcuts to compute (or approximate) the transition matrices T and resulting expected-value vectors V_t. There is the following generic method to compute them via matrix multiplication.

▶ **Proposition 15.** *All vectors $V_t = T_{t,n}(s, W)$, can be computed with $\tilde{O}(n\eta^\omega)$ processors, where ω is the exponent of any efficiently-parallelizable matrix-multiplication algorithm.*

In particular, for the Coppersmith-Winograd algorithm [16], we have $\omega \le 2.38$. (See [29] for further details on parallel implementation.)

Moreover, if we can compute all transition matrices $T_{t,t+h} : h = 2^i, t = j2^i$, then we can compute all vectors $V_t = T_{t,n}(\cdot, W)$ exactly (for any W) with $\tilde{O}(n\eta^2)$ processors.

Therefore, when dealing with multiple statistical tests, we have the following result.

▶ **Corollary 16.** *Consider statistical tests $i = 1, \dots, \ell$, each computed by its own automaton F_i on a state space S_i of size $|S_i| = \eta_i$, with its own weight function W_i. When combined into a single automaton, the resulting automaton F has the following properties:*

1. *The total statespace is $\eta = \sum_i \eta_i$.*
2. *Each starting state s for automaton i has $\mathfrak{V}(s) = \mathfrak{V}_i(s)$, where $\mathfrak{V}_i$ denotes the value of $\mathfrak{V}$ for weight function W_i and automaton F_i.*
3. *The exact vectors V_t can be calculated in $\tilde{O}(n \sum_i \eta_i^\omega)$ processors.*

In particular, the FOOL algorithm has processor complexity $\tilde{O}\big(n\eta/\varepsilon^2 + \sigma\eta + n\sum_i \eta_i^\omega\big)$, and the resulting distribution D has $|T_D(s, W) - T_\Omega(s, W)| \le \varepsilon \mathfrak{V}_i(s)$ for each state s of automaton i.

6 Reducing the state space for counter automata

Given a weight function W, let us consider a statistic of the form

$$W\big(\sum_t f_t(r_t)\big) \qquad \text{for functions } f_t : \Omega_t \to \mathbb{Z}$$

We refer to such statistics as *counters*. They are ubiquitous in randomized algorithm; they are often used directly, and can also be combined together into higher-order statistics.

In the automata-fooling setting, it is easy to compute $\sum_t f_t(r_t)$ by tracking all possible values for the running sum. However, this is often overkill: typically, the running sum is confined to a much smaller window, roughly the standard deviation around the mean. We can take advantage of this by constructing an automaton which only maintains the running sum within "typical" values close to the mean, along with a "reject" state for some exponentially-rare deviations. Let us define some relevant parameters for the counter.

$$\mu_t = \mathbb{E}_{r\sim\Omega_t}[f_t(r)], \quad M_t = \max_{r\in\Omega_t} |f_t(r) - \mu_t|, \quad \kappa = \sum_{t=0}^{n-1} \mathbb{V}\mathrm{ar}_{r\sim\Omega_t}[f_t(r)], \quad M = \max_{t\in[n]} M_t$$

Given some error parameter $\delta > 0$, we choose a value B with $B \ge \lceil 100(1 + M + \sqrt{\kappa}) \log(n/\delta) \rceil$. In this context, we refer to B as the *span* of the automaton.

▶ **Observation 17.** *For a drivestream $\vec{r}$ drawn randomly from Ω, it holds with probability at least $1 - \delta$ that $\left|\sum_{i=t}^{t'} (f(r_i) - \mu_i)\right| < 0.15B$ for all times t, t'.*

Proof. Apply Bernstein's inequality and take a union bound over t, t'. ◀

In light of Observation 17, our strategy will be to construct a truncated automaton $\tilde{F}$, which only stores the running sum within a window of $\pm B$ from the running mean. Define $a_t = \lceil \sum_{i=0}^{t} \mu_i \rfloor$ for each value t. The truncated automaton has state space $\tilde{S} = \{-B, -B+1, \ldots, B-1, B\} \cup \{\perp\}$; given input r_t, it updates its state c to a new state c' as:

$$c' = \begin{cases} c + f(r_t) - a_t + a_{t-1} & \text{if } c \neq \perp \text{ and } |c + f(r_t) - a_t + a_{t-1}| \leq B \\ \perp & \text{if } c = \perp \text{ or } |c + f(r_t) - a_t + a_{t-1}| > B \end{cases}$$

Each integer state c at time t corresponds to a running sum $c + a_t$. The state $\perp$ represents a "reject" or "rare" state where the running sum has deviated too far from its mean. We define a related potential function $\phi : \tilde{S} \to [0, 1]$ as

$$\phi(c) = \begin{cases} 1 & \text{if } |c| \leq B/3 \\ (2B/3 - |c|)/(B/3) & \text{if } B/3 < |c| < 2B/3 \\ 0 & \text{if } |c| > 2B/3 \text{ or } c = \perp \end{cases}$$

Intuitively, ϕ measures how close the current state c is to a reject state. It can be used to "damp" the weight function W and make a gradual transition to the reject state.

For purposes of analysis, it is useful to compare $\tilde{F}$ with the "truthful" automaton F. The potential function ϕ can also be applied on the original state space S, where we use the convention that any states $|s| > B$ corresponds to the reject state $\perp$ of $\tilde{S}$.

Relevant properties of $\tilde{F}$ such as computing its transition matrix or its weight variability can be derived from F up to a small error. Indeed, our application to Gale-Berlekamp Switching Game will use precisely this approach. For the MAX-CUT application, we will need to combine multiple truncated automata; this will require a slightly different damping function and analysis.

▶ **Proposition 18.** *Let W be a weight function for automaton F and define*

$$\tilde{W}(c) = \begin{cases} 0 & \text{if } c = \perp \\ \phi(c)W(c) & \text{if } c \neq \perp, \end{cases} \qquad \Delta = \max_{c \in S} |W(c)|, \qquad \tilde{\Delta} = \max_{\substack{c \in S: \\ |c - \mu_t| \leq 2B}} |W(c)|.$$

Let $T, \tilde{T}$ denote the transition matrices for automata $F, \tilde{F}$ respectively.

1. *For any time t and state $c \in S$, there holds $|\tilde{T}_{t,n}(c, \tilde{W}) - T_{t,n}(c, \tilde{W})| \leq \delta\Delta$.*
2. *For the starting state $c = 0$ and time $t = 0$, there holds $|\tilde{T}_{t,n}(c, \tilde{W}) - T_{t,n}(c, W)| \leq \delta\Delta$.*
3. *For any time t and state c, there holds*

$$\tilde{\mathfrak{C}}(c, t) \leq \mathfrak{L}(c, t) + 2\Delta\delta + 6\tilde{\Delta}M_t/B,$$

where $\tilde{\mathfrak{C}}$ denotes the confusion with respect to automata $\tilde{F}$ and weight function $\tilde{W}$, while $\mathfrak{L}$ denotes the Lipschitz value with respect to automaton F and weight function W.

Note that, in both these cases, we use the convention that if $|c| > B$, then c corresponds to the reject state of automaton $\tilde{F}$.

7 Applications

We present the derandomization of two basic problems: the Gale-Berlekamp Switching Game (Section 7.1) and approximate MAX-CUT via SDP rounding (Section 7.2). Through our new construction, we improve the deterministic processor complexity for both problems.

7.1 Gale-Berlekamp Switching Game

The Gale-Berlekamp Switching Game is a classic combinatorial problem: given an $n \times n$ matrix A with entries $A_{ij} = \pm 1$, we want to find vectors $x, y \in \{-1, +1\}^n$ to maximize the imbalance $I = \sum_{i,j} A_{i,j} x_i y_j$. An elegant randomized algorithm of [4], based on the Central Limit Theorem, gives imbalance of $I \geq (\sqrt{2/\pi} - o(1))n^{3/2}$. This was derandomized in [24], using automata-fooling with a processor complexity of $n^{5+o(1)}$.

▶ **Theorem 19.** *There is a parallel deterministic algorithm to find $\vec{x}, \vec{y} \in \{-1, +1\}^n$ with imbalance $I \geq (\sqrt{2/\pi} - o(1))n^{3/2}$ using $\tilde{O}(n^{3.5})$ processors.*

In order to show Theorem 19, following [8] and [4], we set $x_i = 1$ if $\sum_j A_{ij} y_j > 0$, and $x_i = -1$ otherwise. This gives

$$\sum_{i,j} A_{i,j} x_i y_j = \sum_i x_i \sum_j A_{i,j} y_j = \sum_i \Big| \sum_j A_{i,j} y_j \Big|.$$

As shown in [13], for $\vec{y}$ uniformly drawn from $\Omega = \{-1, +1\}^n$, we have $\mathbb{E}[|\sum_j A_{i,j} y_j|] \geq \sqrt{2n/\pi} - o(\sqrt{n})$ for each i. This is the statistical test we want to fool.

We will choose our drivestream values to be $r_t = y_t$, with Ω_t the uniform distrubition on $\{-1, 1\}$ For each value i, we have a truncated counter automaton $\tilde{F}_i$ to track $\sum_j A_{ij} r_j$. This uses the construction of Section 6 with $\delta = n^{-10}$, where $M = 1$ and $\kappa = \sum_j A_{ij}^2 = n$ and $B = \tilde{O}(\sqrt{n})$. This automaton uses the weight function

$$\tilde{W}(c) = \begin{cases} 0 & \text{if } c = \perp \\ \phi(c)|c| & \text{if } c \neq \perp \end{cases}$$

▶ **Proposition 20.** *Fix a row i and automaton $\tilde{F} = \tilde{F}_i$, and correspondingly let F be the full "truthful" automaton. Let $T, \tilde{T}$ be the transition matrices for $F, \tilde{F}$ respectively.*

1. *For any time t and state s of F, we have $|T_{t,n}(s, \tilde{W}) - \tilde{T}_{t,n}(s, \tilde{W})| \leq 2\delta n$.*
2. *The final state $\tilde{z} = \tilde{F}(\vec{y}, 0)$ for $\vec{r} \sim \Omega$ satisfies $\mathbb{E}[\tilde{W}(\tilde{z})] \geq \sqrt{2n/\pi} - o(\sqrt{n})$.*
3. *The weight function $\tilde{W}$ for automaton $\tilde{F}$ has total variability $O(n)$.*

Proof. We apply here Proposition 18 with $W = |c|$. Clearly here $\mathfrak{L}(c, t) = 2$ and $M_t \leq 1$ for all c, t. Also, we calculate $\Delta = n, \tilde{\Delta} \leq \tilde{O}(\sqrt{n})$. With Proposition 18(a), this proves (a). Similarly, by Proposition 18(b), we have

$$\mathbb{E}[\tilde{W}(\tilde{z})] \leq \delta n + \mathbb{E}_\Omega[W(z)] \leq o(\sqrt{n}) + (\sqrt{2/\pi} - o(1)) \cdot \sqrt{n}$$

where z is the final state for the automaton F.

Finally, for (c), we use the definition of total variability and Proposition 18(c) to get:

$$\mathfrak{V}(c) = \sum_{t=0}^{n-1} \max_{\vec{r} \in \Omega_{0,t}} \tilde{\mathfrak{C}}(\tilde{F}(\vec{r}, c), t) \leq \sum_{t=0}^{n-1} (\mathfrak{L}(c, t) + 2\Delta\delta + 6\tilde{\Delta} M_t / B) = \tilde{O}(n). \qquad \blacktriangleleft$$

The complexity now follows from Corollary 16 with $\varepsilon = 1/\sqrt{n \log n}$, where we have n automata each of state space $\hat{\eta}_i = \tilde{O}(\sqrt{n})$. By applying Proposition 20, we get that for any sequence $\vec{y}$ drawn from the resulting distribution D and automaton $\tilde{F}_i$,

$$\begin{aligned} |\tilde{T}_D(0, \tilde{W}) - T_\Omega(0, W)| &\leq |\tilde{T}_D(0, \tilde{W}) - \tilde{T}_\Omega(0, \tilde{W})| + |\tilde{T}_\Omega(0, \tilde{W}) - T_\Omega(0, W)| \\ &\leq \varepsilon \mathfrak{V}(0) + o(\sqrt{n}) = o(\sqrt{n}) \end{aligned}$$

Therefore, for any row i, the final state $\tilde{z}$ satisfies

$$\mathbb{E}_D\Big[\big|\sum_j A_{ij}y_j\big|\Big] \geq \mathbb{E}_\Omega[W_i(\tilde{z})] - o(\sqrt{n}) \geq (\sqrt{2/\pi} - O(\epsilon))\sqrt{n}$$

By searching the space exhaustively, we can find a specific sequence $\vec{y}$ satisfying the desired imbalance bounds. This concludes the proof of Theorem 19.

7.2 Approximate MAX-CUT

The MAX-CUT problem for a graph $G = (V, E)$ is to find a vertex set $S \subseteq V$ to maximize the total weight of edges with exactly one endpoint in S. The seminal work of Goemans & Williamson [21] showed that MAX-CUT can be approximated to a factor of $\alpha \approx 0.878$ by rounding its semi-definite programming (SDP) formulation. Moreover, the integrality gap of the SDP is precisely α [18], and assuming the Unique Games Conjecture no better approximation ratio is possible for polynomial-time algorithms [34].

A sequential deterministic α-approximation with $\tilde{O}(n^3)$ runtime was shown in [9]. This relies on the method of conditional expectation, which is hard to parallelize. The work of [43] used the automata derandomization framework to get a parallel deterministic $\alpha(1-\varepsilon)$-approximation algorithm. The main downside of this approach is the huge polynomial processor complexity (on the order of n^{100}). We give an improved analysis with our new automata-fooling construction and some other optimizations.

To review, note that MAX-CUT can be formulated as the following integer program:

$$\max \quad \frac{1}{2}\sum_{(i,j)=e\in E} w_e(1 - v_i \cdot v_j) \quad \text{s.t.} \quad v_i \in \{-1, 1\}, i \in [n].$$

This can be relaxed to the following SDP:

$$\max \quad \frac{1}{2}\sum_{(i,j)=e\in E} w_e(1 - v_i \bullet v_j) \quad \text{s.t.} \quad v_i \in [-1, 1]^n, ||v_i||_2 = 1, i \in [n],$$

where $\bullet$ denotes the inner product in $\mathbb{R}^n$.

We can round a given SDP solution v by drawing independent standard Gaussian random variables $X_0, \ldots, X_{n-1}$ and constructing the cut $S = \{i \mid v_i \bullet X \geq 0\}$, which gives cutsize W

$$\begin{aligned}\mathbb{E}[W] &= \sum_{(i,j)=e\in E} w_e \Pr[(i,j) \text{ is cut}] = \sum_{(i,j)=e\in E} w_e \Pr[\operatorname{sgn}(v_i \bullet X) \neq \operatorname{sgn}(v_j \bullet X)] \\ &= \sum_{(i,j)=e\in E} w_e \frac{\arccos(v_i \bullet v_j)}{\pi} \geq \alpha \cdot \mathrm{OPT},\end{aligned}$$

where OPT denotes the size of the maximum cut. Following [43], we will derandomize this by fooling each statistical test $\Pr[\operatorname{sgn}(v_i \bullet X) \neq \operatorname{sgn}(v_j \bullet X)]$.

▶ **Theorem 21.** *There is a deterministic parallel algorithm to find an $\alpha(1-\varepsilon)$-approximate rounding of a MAX-CUT SDP solution with $\tilde{O}(\frac{mn^3}{\varepsilon^4})$ processors.*

Via the algorithm of [1] to solve the SDP, this gives the following main result:

▶ **Corollary 22.** *For arbitrary constant $\varepsilon > 0$, we can find an $\alpha(1-\varepsilon)$-approximate MAX-CUT solution using $\tilde{O}(mn^3)$ processors and polylogarithmic time.*

The remainder of the section is devoted to showing Theorem 21. To avoid cumbersome calculations, we will show an algorithm for a $(1 - O(\varepsilon))$-approximation, assuming ε is smaller than any needed constants. For readability, $\tilde{O}()$ suppresses any polylog(n/ε) terms.

As a starting point, consider the following process. We draw n independent standard Gaussian variables $X_0, \dots, X_{n-1}$. For each edge (i, j), we have a statistical test to read these values in order and compute $c_i = v_i \bullet X$ and $c_j = v_j \bullet X$. We then apply the weight function $W_{ij}(c_i, c_j)$ as the indicator variable that $\operatorname{sgn}(c_i) = \operatorname{sgn}(c_j)$.

In order to apply our derandomization framework efficiently, we make a number of changes to this basic strategy: (i) we define the drivestream value r_t to be a discretized truncated Gaussian; (ii) we further quantize each term $v_{ik}r_k$ in the computation of the sum $c_i = \sum_k v_{ik}r_k$; (iii) we apply the optimization of Section 6 to reduce the state space for each counter automaton; and (iv) we modify the weight function to a pessimistic estimator with better Lipschitz properties.Let us fix two quantization parameters for some constant $C > 0$

$$\gamma = \frac{\varepsilon}{C\sqrt{n \log(n/\varepsilon)}}, \qquad R = C \log(n/\varepsilon)$$

Concretely, each drivestream value r_k is derived by truncating a standard Gaussian to within $\pm R$, and rounding to the nearest multiple of γ. Then, each term in the product $v_{ik}r_k$ is rounded to the nearest multiple of γ. Since this comes up frequently in the analysis, let us denote this "rounded" inner product by: $v \star r = \gamma \sum_k \lceil \frac{1}{\gamma} v_k r_k \rfloor$. Given this definition, we will form our cut set by setting $S = \{i : v_i \star r \geq 0\}$.

▶ **Lemma 23.** *For appropriately chosen C, there is a coupling between random variables X and Y such that, for any unit vector $u \in \mathbb{R}^n$, there holds $\Pr\big(|u \bullet X - u \star r| > \varepsilon\big) \leq (\varepsilon/n)^{10}$.*

Observe that the scaled sum $\frac{1}{\gamma}(v_i \star r)$ is an integer-valued counter. We can apply the method of Section 6 to construct a "vertex" automaton $\tilde{F}_i$ that tracks the running sum within a window. We record a few parameters and observations about this automaton.

▶ **Proposition 24.** *The automaton $\tilde{F}_i$ can be implemented with the following parameters:*

$$M_t \leq \tilde{O}(|v_{it}|/\gamma), \quad M \leq \tilde{O}(1/\gamma), \quad \kappa \leq \tilde{O}(1/\gamma^2), \quad \delta = (\varepsilon/n)^{10}, \quad B = \tilde{\Theta}(1/\gamma).$$

From these vertex-automata, we construct an edge-automaton $\tilde{F}_{ij}$ for each edge $(i, j) \in E$. Automaton $\tilde{F}_{ij}$ keeps track of the joint states of $\tilde{F}_i, \tilde{F}_j$, i.e. the truncated running sums $v_i \star r$ and $v_j \star r$. It uses the following weight function for the state $s = (c_i, c_j)$:

$$\tilde{W}_{ij}(s) = \begin{cases} 0 & \text{if } c_i = \perp \text{ or } c_j = \perp \\ 0 & \text{if } \operatorname{sgn}(c_i) = \operatorname{sgn}(c_j) \\ \min\{1, \frac{|c_i - c_j|}{\varepsilon}\}\phi_i(c_i)\phi_j(c_j) & \text{otherwise} \end{cases}$$

Note that whenever $\tilde{W}_{ij}(s) > 0$, we have $\operatorname{sgn}(v_i \star r) \neq \operatorname{sgn}(v_j \star r)$, i.e. edge ij is cut.

▶ **Proposition 25.** *For an edge ij, let $\tilde{F} = \tilde{F}_{ij}$, and consider the "truthful" automaton $F = F_{ij}$ (which uses the full untruncated automata for vertices i and j). Let $T, \tilde{T}$ denote the transition matrices for $F, \tilde{F}$ respectively.*

1. *For any time t and state s of F, there holds $|T_{t,n}(s, \tilde{W}) - \tilde{T}_{t,n}(s, \tilde{W})| \leq 2\delta$.*
2. *The final automaton state $\tilde{z} = \tilde{F}(\vec{r}, 0)$ for $\vec{r} \sim \Omega$ satisfies $\mathbb{E}[\tilde{W}(\tilde{z})] \geq \frac{\arccos(v_i \bullet v_j)}{\pi} - O(\varepsilon)$.*
3. *For drivestreams $\vec{r}^1, \vec{r}^2$ differing in coordinate t, the final states $z^1 = F(\vec{r}^1, 0), z^2 = F(\vec{r}^2, 0)$ of automaton F have $|\tilde{W}(z^1) - \tilde{W}(z^2)| \leq \tilde{O}(\varepsilon^{-1}(|v_{it}| + |v_{jt}|))$.*
4. *The weight function $\tilde{W}$ has total variability $\tilde{O}(\sqrt{n}/\varepsilon)$ for automaton $\tilde{F}$.*

Proof. The proof is very similar to Proposition 18; see full version. ◀

Next, we discuss how to approximate the transition matrices for the automata. In light of Proposition 25(a), we will compute vectors $\hat{V}_t(s) = T_{t,n}(s, W)$ for the full automaton F_{ij}. This is much easier than computing the transition matrices for $\tilde{F}_{ij}$, since we do not need to track reject states. In particular, this achieves error $\beta = 2\delta$ compared to $V_t = \tilde{T}_{t,n}(s, W)$.

▶ **Proposition 26.** *For each automaton F_{ij}, the vectors $T_{t,n}(s, W) : t = 0, \dots, n$, can be computed with $\tilde{O}(n^3\varepsilon^{-4})$ processors.*

Proof Sketch. We will recursively compute transition matrices $T_{t,h}$ for $h = 1, 2, 4 \dots$, and t divisible by h. The critical observation here is that since F_{ij} is a pair of counters, we only need to keep track of the probability distribution on the difference pairs

$$\Big(\sum_{k=t}^{t+h-1} \lceil v_{ik} r_k / \gamma \rfloor, \sum_{k=t}^{t+h-1} \lceil v_{jk} r_k / \gamma \rfloor \Big).$$

This is effectively a convolution, computable via an FFT. ◀

We are now ready to compute the total complexity. Each probability distribution Ω_t has size $\tilde{O}(\gamma^{-1}) = \tilde{O}(\sqrt{n}/\varepsilon)$, thus $\sigma = \tilde{O}(n^{1.5}/\varepsilon)$. The reduced total number of states of an edge-automaton F_{ij} is $\tilde{O}(1/\gamma^2) = \tilde{O}(n/\varepsilon^2)$ and the weight function W_{ij} has total variability $\tilde{O}(\sqrt{n}/\varepsilon)$. So we run Fool with parameter $\varepsilon' = \varepsilon/\sqrt{n}$, and the fooling process has cost $\tilde{O}(m\frac{n^3}{\varepsilon^4} + m\frac{n^{2.5}}{\varepsilon^3})$. Consider the resulting distribution D. The edge i, j is only cut if $\tilde{W}_{ij}(s) > 0$. For each F_{ij}, by Theorem 14, the resulting final state z satisfies

$$\Pr_{\vec{r} \sim D}(\text{edge } ij \text{ cut}) \geq \mathbb{E}_{\vec{r} \sim D}[W_{ij}] \geq \mathbb{E}_{\vec{r} \sim \Omega}[W_{ij}] - O(\varepsilon) - O(\beta n)$$

Here Proposition 25(a) gives $\beta \leq 2\delta \ll \varepsilon/n$, and Proposition 25(b) gives $\mathbb{E}_{\vec{r} \sim \Omega} \geq \frac{\arccos(v_i \bullet v_j)}{\pi} - O(\varepsilon)$. Thus, overall, the edge i, j is cut with prob. at least $\frac{\arccos(v_i \bullet v_j)}{\pi} - O(\varepsilon)$. Summing over all edges, the total expected weight of the cut edges is

$$\sum_{ij \in E} w_e \frac{\arccos(v_i \bullet v_j)}{\pi} - \sum_{ij \in E} w_e O(\varepsilon)$$

The first term is at least $\alpha \cdot \text{OPT}$. The second term is at most $O(\varepsilon \cdot \text{OPT})$ since $\text{OPT} \geq \sum_e w_e/2$. By searching D exhaustively, we can find a cut satisfying these bounds.

Abstract

Let G be a weighted (directed) graph with n vertices and m edges. Given a source vertex s, Dijkstra's algorithm computes the shortest path lengths from s to all other vertices in $O(m + n \log n)$ time. This bound is known to be worst-case optimal via a reduction to sorting. Theoretical computer science has developed numerous fine-grained frameworks for analyzing algorithmic performance beyond standard worst-case analysis, such as instance optimality and output sensitivity. Haeupler, Hladík, Rozhoň, Tarjan, and Tětek [FOCS '24] consider the notion of universal optimality, a refined complexity measure that accounts for both the graph topology and the edge weights. For a fixed graph topology, the universal running time of a weighted graph algorithm is defined as its worst-case running time over all possible edge weightings of G. An algorithm is universally optimal if no other algorithm achieves a better asymptotic universal running time on any particular graph topology.

Haeupler, Hladík, Rozhoň, Tarjan, and Tětek show that Dijkstra's algorithm can be made universally optimal by replacing the heap with a custom data structure. Their approach builds on Iacono's [SWAT '00] working-set bound $\phi(x)$. This is a technical definition that, intuitively, for a heap element x, counts the maximum number of simultaneously-present elements y that were pushed onto the heap whilst x was in the heap. They design a new heap data structure that can pop an element x in $O(1 + \log \phi(x))$ time. They show that Dijkstra's algorithm with their heap data structure is universally optimal.

In this work, we revisit their result. We use a simpler heap property that we will call timestamp optimality, where the cost of popping an element x is logarithmic in the number of elements inserted between pushing and popping x. We show that timestamp optimal heaps are not only easier to define but also easier to implement. Using these time stamps, we provide a significantly simpler proof that Dijkstra's algorithm, with the right kind of heap, is universally optimal.

1 Introduction

Let $G = (V, E)$ be a (di)graph with edge weights w, n vertices, and m edges. Let s be a designated source vertex. In the *single-source shortest path* problem, the goal is to sort all the vertices in V by the length of the shortest path from s to v. Dijkstra's algorithm with a Fibonacci heap solves this problem in $O(m + n \log n)$ time, which is worst-case optimal.

However, worst-case optimality can be overly coarse as a performance measure. A stronger notion, called *universal optimality*, requires an algorithm to run as fast as possible on *every* graph topology. Recently, Haeupler, Hladík, Rozhoň, Tarjan, and Tětek [6] proved that Dijkstra's algorithm, when paired with a suitably designed heap, achieves universal optimality. The paper was well-received, as it won the best paper award at FOCS'24. Their contribution is threefold: First, they observe that Dijkstra's efficiency relies on a heap supporting Push and DecreaseKey in amortized constant time, and Pop in $O(\log n)$ time. They refine this analysis using the *working-set bound* by Iacono [9] (we forward reference Definition 1). Intuitively, for a heap element x, the working set size $\phi(x)$ is the maximum number of elements y that are simultaneously present in the heap while x resides in it (excluding all y' that already were in the heap). Haeupler et al. [6] design a new heap data structure for in the word-RAM model in which the Pop operation for element x takes $O(1 + \log \phi(x))$ time.

Secondly, they show, for any fixed graph topology $G = (V, E)$ and designated source s, a universal lower bound of $\Omega(m + n + \sum_{x_i \in V \setminus \{s\}} \log \phi(x_i))$. This lower bound matches the running time of Dijkstra's algorithm, when it is equipped with their heap. They thereby prove that Dijkstra's algorithm is universally optimal.

Third, they refine their analysis by distinguishing between edge weight comparisons and all other operations. This argument is technical, and we only refer to it on a high level. For completeness, we explain this result in great detail in the full version. Imagine $m_G \leq m$ to be some technical parameter that only depends on G. Note that, for any fixed weighted graph, Dijkstra's algorithm always performs the same sequence of push and pop operations on the heap. Therefore, the weighted graph uniquely determines the working set size of each element. For a fixed graph topology G, for any weighting w of G with corresponding working set sizes $\phi(x_i)$, they prove a universal lower bound of $\Omega(m_G + \sum_{x_i \in V \setminus \{s\}} (1 + \log(\phi(x_i))))$ on the number of weight comparisons used to solve the single shortest path problem. They adapt Dijkstra's algorithm so that the number of edge weight comparisons performed is also asymptotically universally optimal. A recent paper by Haeupler et al. [7] shows a simple instance optimal result for the bidirectional problem: Compute, given G and two vertices (s, t), the shortest st-path. Although the problems are related, the techniques and bounds are different, and thus, we do not consider the st-path problem in the paper at hand.

Contribution. We offer a significantly more concise proof of Dijkstra's universal optimality. Our main insight is to replace the working-set bound with a conceptually simpler measure called *timestamps*.[1] We maintain a heap H and global time counter that increments after H.Push. For each heap element x_i, let a_i and b_i denote the time it was pushed and popped, respectively. We define H to be *timestamp optimal* if popping x_i takes $O(1 + \log(b_i - a_i))$ time. Timestamps are not only conceptually simpler than working-set sizes, timestamp optimality is also considerably simpler to implement.

[1] We note that the original work by Iacono [10] included several notions of working-set bounds. One of these notions, not present in [6, 9], but used in [5], matches our notion of timestamp optimality. By working set, we explicitly refer to the definition used in [6, 9]. We use the more distinct term timestamps to properly distinguish between the concepts in this work and [6]. This also highlights that our notion yields a family of intervals $[a_i, b_i]$, which is more convenient than having just the working set sizes $\phi(x_i)$.

We design a heap data structure that supports Push and DecreaseKey in amortized constant time, and Pop in amortized $O(1 + \log(b_i - a_i))$ time. Using timestamps, we show a universal lower bound of $\Omega(m + \sum_{x_i \in V \setminus \{s\}}(1 + \log(b_i - a_i)))$ for any fixed graph topology $G = (V, E)$ and source s. We consider this to be our main contribution, as it offers a significantly simpler proof that Dijkstra's algorithm can be made universally optimal. Finally, our formulation of timestamps allow us to apply recent techniques for universally optimal sorting [5, 11] to show that Dijkstra's algorithm, with our timestamp optimal heap, matches our universal lower bound. Additionally, we show in the full version that our algorithm is equally general to that of [6], as it can be made universally optimal with respect to edge weight comparisons. While this proof is indeed new, different, and perhaps simpler, it is not self-contained; therefore, we relegate it to the full version for the sake of completeness.

2 Preliminaries

Let $G = (V, E)$ be a (directed) graph and let w assign to each edge a positive weight. For ease of notation, we say that G has $n + 1$ vertices and m edges. In the *single-source shortest path* problem (SSSP), the input consists of G, w, and a designated source vertex s. The goal is to order all n vertices in $V \setminus \{s\}$ by the length of the shortest path from s to each vertex $v \in V$. We follow [6] and assume that the designated source s can reach every vertex in $V \setminus \{s\}$ and that no two vertices are equidistant from s.

For weighted graph algorithms A that solves SSSP, the running time $\text{Runtime}(A, G, s, w)$ depends on the graph topology $G = (V, E)$, the designated source vertex s, and the edge weights w. Let $\mathbb{G}_n$ denote the set of all (directed) graph topologies $G = (V, E)$ with $|V| = n + 1$. For a fixed graph topology G, let $\mathbb{W}(G)$ denote the (infinite) set of all possible edge weightings of G. Then, for a fixed input size n, the worst-case running time of an algorithm A that solves the single-source-shortest path problem is a triple maximum:

$$\text{Worst-case}(A, n) := \max_{G \in \mathbb{G}_n} \max_{s \in V(G)} \max_{w \in \mathbb{W}(G)} \text{Runtime}(A, G, s, w).$$

An algorithm A is worst-case optimal if there exists a constant c such that, for sufficiently large n, there exists no algorithm A' with $\text{Worst-case}(A, n) > c \cdot \text{Worst-case}(A', n)$.

Haeupler, Wajc, and Zuzic [8] introduce a more fine-grained notion of algorithmic optimality for weighted graphs called *universal optimality*. Universal optimality requires an algorithm to perform optimally for every fixed graph topology. Formally, in the single-source-shortest path problem, it removes the outer two maximizations: For a fixed algorithm A, graph topology $G = (V, E)$, and source s, the universal running time is

$$\text{Universal}(A, G, s) := \max_{w \in \mathbb{W}(G)} \text{Runtime}(A, G, s, w).$$

An algorithm A is *universally optimal* if there exists a constant c such that for every fixed topology G and every $s \in V$, no algorithm A' satisfies $\text{Universal}(A, G, s) > c \cdot \text{Universal}(A', G, s)$.

2.1 Dijkstra's algorithm

Dijkstra [2] presented an algorithm for the single-source shortest paths problem in 1959. Since the invention of Fibonnacci heaps [3], Dijkstra's algorithm can be implemented in a way that is worst-case optimal, by utilising these heaps in the implementation of Dijkstra's algorithm. A heap H maintains a set of elements where each $x \in H$ is associated with a unique *key* $\gamma(x)$. A heap H typically supports the following five operations:

Algorithm 1 Dijkstra's algorithm with a black-box heap H.

Require: (Di)graph $G = (V, E)$, weighting w, designated source $s \in V$
  `distance` $\leftarrow$ array with n entries equal to ∞
  H $\leftarrow$ empty min-heap
  `distance`$[s] = 0$
  H.PUSH$(s, 0)$
  while H is not empty **do**
    u $\leftarrow$ H.POP()
    OUTPUT.append(u)
    for Each edge $(u, v) \in E$ **do**
      if `distance`$[v]$ is ∞ **then**
        `distance`$[v] \leftarrow$ `distance`$[u] + w((u, v))$
        H.PUSH$(v,$ `distance`$[v])$
      else if v is in H and `distance`$[v] >$ `distance`$[u] + w((u, v))$ **then**
        `distance`$[v] \leftarrow$ `distance`$[u] + w((u, v))$
        H.DECREASEKEY$(v,$ `distance`$[v])$
      end if
    end for
  end while

- PUSH(x, y): Insert x into H where the key $\gamma(x)$ is y.
- DECREASEKEY(x, y): For $x \in H$ and $y \leq \gamma(x)$, update $\gamma(x)$ to y.
- POP(): Remove and return the element $x \in H$ with the smallest key.
- PEAK(): Return an element $x \in H$ with the smallest key.
- MELD(H'): Return a heap H'' on the elements in $H \cup H'$.

Fibonacci heaps support PUSH and DECREASEKEY in $O(1)$ amortized time, POP in amortized $O(\log n)$ time, and PEAK and MELD in worst-case $O(1)$ time [3]. Dijkstra's algorithm only uses the first three heap operations. Using Fibonacci heaps, it runs in $O(m + n \log n)$ time which is worst-case optimal. Dijkstra's algorithm (Algorithm 1) is conceptually simple: it initializes the heap with all vertices v that s can directly reach, where the key $\gamma(v)$ is the edge weight of (s, v). Then, it repeatedly pops the vertex u with the smallest key and it appends u to the output. Each time a vertex u is popped, its neighbors v are examined. For each neighbor v, the tentative distance d_v is computed as the distance from s to u plus the edge weight $w(u, v)$. If v is not in the heap, it is pushed with key $\gamma(v) = d_v$. If v is already in the heap and $\gamma(v) > d_v$ then the key $\gamma(v)$ is decreased to d_v.

2.2 Universally optimal Dijkstra

Iacono [9] introduced a refined measure for the running time of heap operations via the concept of *working-set size*:

▶ **Definition 1** ([9]). *Consider a heap supporting* PUSH *and* POP *and let x_i be an element in the heap. For each time step t between pushing x_i and popping x_i, we define the working set of x_i at time t as the set of elements $W(x_i, t)$ inserted after x_i and still present at time t. We include x_i itself in $W(x_i, t)$. Fix any time t_0 that maximizes the value of $|W(x_i, t)|$; we call the set $W(x_i, t_0)$* working-set *of x_i and $\phi(x_i) := |W(x_i, t_0)|$ the* working-set size.

Haeupler, Hladík, Rozhoň, Tarjan, and Tětek [6] design a heap H that supports Push and DecreaseKey in amortized $O(1)$ time, and supports Pop for an element $x \in H$ in $O(1 + \log \phi(x))$ time. The basis of their data structure are Fibonacci heaps F which support Push and DecreaseKey in amortized constant time and Pop in amortized $O(\log N)$ time where N is the number of elements in the heap.

The core idea of their data structure is to partition elements into buckets B_j of doubly exponentially increasing size. Each bucket B_j contains a Fibonacci heap F_j. Denote by m_j the minimum key of F_j. The set of $O(\log \log n)$ values m_j is stored in a fusion tree [4]. Fusion trees of size at most $O(\log \log n)$ have constant update time in the word-RAM model. By carefully merging and managing buckets, they ensure that each element x_i is stored in a Fibonacci heap F_j whose size is proportional to $\phi(x_i)$. We refer to [6] for full details; we only note here that ensuring that Push and DecreaseKey take amortized constant time whilst Pop takes $O(1 + \log \phi(x_i))$ time requires non-trivial maintenance and analysis.

Using this heap, Dijkstra's algorithm takes $O(m + \sum_{x_i \in V \setminus \{s\}} (1 + \log \phi(x_i)))$ time. They [6] also prove a universal lower bound: for any fixed (directed) graph topology $G = (V, E)$ and source $s \in V$, no algorithm A' achieves runtime $o(m + n + \sum_{x_i \in V \setminus \{s\}} \log \phi(x_i))$ for all edge weightings $w \in \mathbb{W}(G)$. Dijkstra's algorithm with this heap is therefore universally optimal.

3 Timestamp optimal heaps

Instead of designing heaps with a running time proportional to the working-set size of a heap element, we use a simple timestamp approach:

▶ **Definition 2.** *For any heap H, we define* time t *as a counter that increments after each H.Push(x, y). For any element $x_i \in H$, we denote by a_i the time when x_i was pushed onto the heap, and by b_i the time when x_i was popped from the heap. Observe that $b_i > a_i$.*

▶ **Definition 3.** *A heap H is* timestamp optimal *if it supports Push and DecreaseKey in amortized constant time, and Pop with output x_i in amortized $O(1 + \log(b_i - a_i))$ time.*

Our Data Structure. Let H denote our abstract heap data structure, supporting operations H.Push(x, y), H.DecreaseKey(x, y), and H.Pop$()$. We implement H as follows:

▶ **Invariant 1** (Figure 1). *We partition the elements of H into an array of buckets B. Each bucket $B[j]$ contains one or two Fibonacci heaps. Every element of H lies in exactly one Fibonacci heap. Along with each Fibonacci heap F we store a half-open interval $I_F \subset \mathbb{R}$. We maintain the following invariants; for all times t:*

(a) *An element $x_i \in H$ is in F if and only if $a_i \in I_F$,*
(b) *The interval I_F for $F \in B[j]$ has size 2^j,*
(c) *All intervals of $B[j-1]$ lie to the right of the intervals in $B[j]$,*
(d) *All intervals collectively partition $[0, t)$.*

By Invariant 1, for all elements $x_i \in B[j]$, $(t - a_i)$ is at least 2^{j-1}, but less than 2^{j+2}. We define M as an array of size $\lceil \log n \rceil$, where $M[j]$ stores the minimum key in $B[j]$. Furthermore, we maintain a bitstring S_M where $S_M[j] = 1$ if for all $k > j$, we have $M[j] \leq M[k]$.

▶ **Lemma 4.** *For any element $x_i \in H$ we can, given a_i and t, compute the bucket containing x_i and the Fibonacci heap that contains x_i in constant time.*

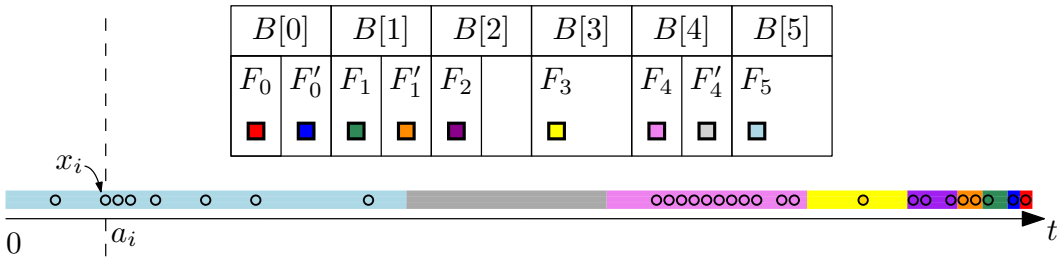

Figure 1 We illustrate our invariant. Each bucket $B[j]$ contains one or two Fibonacci heaps. Each heap F is associated with an interval on the number line in $[0, t)$. The elements x_i stored in a Fibonacci heap F are visualised by placing them at positions a_i along the number line. Importantly, when the buckets in B are indexed from left to right (i.e., from low to high indices), the corresponding intervals of the Fibonacci heaps appear in the reverse order along the number line.

Proof. Let a_i be the insertion time of x_i. We now want to determine the possible values j such that $B[j]$ contains x_i. From invariant 1.b we get: $t - a_i \geq 2^{j-1}$, or equivalently, $j \leq \log(t-a_i)+1$; and $t-a_i < 2^{j+2}$, or equivalently, $j > \log(t-a_i)-2$. In particular, for $\ell = \lfloor \log(t-a_i) \rfloor$, the Fibonacci heap containing x_i lies in one of the buckets $B[\ell-1], B[\ell], B[\ell+1]$. For each of these at most 6 corresponding intervals of the at most 6 heaps contained in those 3 buckets, we test, in constant time, whether a_i is contained in the interval. This procedure returns us the interval containing a_i, and thus, the heap (and bucket) containing x_i. ◀

▶ **Theorem 5.** *The above data structure is a timestamp optimal heap H.*

Proof. We prove that the data structure supports all three heap operations within the specified time bounds while maintaining Invariant 1.

Push(x_i, y). To push x_i onto H, we set $a_i = t$ and increment t. We then add a new Fibonacci heap F to $B[0]$ with $I_F = [a_i, a_i+1)$. Whilst a bucket $B[j]$ contains three Fibonacci heaps, we select its oldest two Fibonacci heaps F_1, F_2. We MELD F_1 and F_2 into a new Fibonacci heap F' in worst-case constant time, and we move F' to $B[j+1]$. We define the corresponding interval $I_{F'}$ as the union of the consecutive intervals I_{F_1} and I_{F_2}. Since Property (a) held for both F_1 and F_2, it now holds for F'. Moreover, $|I_{F'}| = 2^{j+1}$ and so Property (b) is maintained. Since, before the update, all intervals collectively partitioned $[0, t)$ and we only added the interval $[t, t+1)$ we maintain Properties (c) and (d). Every MELD operation decreases the number of Fibonacci heaps and every push operation creates only one heap. Hence, each push operation performs amortized $O(1)$ MELD operations.

Finally, we update M and the string S_M. After we have merged two heaps in a bucket $B[j]$, only $M[j]$ and $M[j+1]$ change. Moreover, $M[j]$ can only increase in value and $M[j+1]$ can only decrease to at least the original value of $M[j]$. Therefore, all bits $S_M[k]$ for $k \notin \{j, j+1\}$ remain unchanged and we update S_M in amortized constant time. Thus, a push operation takes amortized constant time.

DecreaseKey(x_i, y). By Lemma 4, we find the Fibonacci heap F and the bucket $B[j]$ that contain x_i in constant time. We perform F.DECREASEKEY(x_i, y) in amortized constant time. We update $M[j]$ and identify the index k of the leftmost 1-bit in S_M after index j in constant time using bitstring operations [4]. Note that $S_M[j] = 1$ if and only if $M[j] \leq M[k]$.

If $S_M[j] = 1$, then we recursively find the next $j' < j$ for which $S_M[j'] = 1$ using the same bitstring operation. If $M[j] < M[j']$, then we set $S_M[j'] = 0$ and we recurse. If $M[j] \geq M[j']$ then for all $j'' < j'$ with $S_M[j''] = 1$, $M[j] \geq M[j'']$ and our update terminates. The recursive call takes amortized constant time since it can only decrease the number of 1-bits in S_M.
